ISBN-13: 978-1-9752-2126-3

Cataloging in Publication data available on request from publisher.

This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals’ examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and

dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

shop.lww.com

To our patients, whose courage, suffering, and triumphs have instructed us;

To our teachers, from whom we learned that true wisdom is found at the intersection of knowledge and values;

To our trainees, who will demonstrate that the best way to predict the future of cancer care is to invent it;

To the universities where we have worked and continue to work—institutions that are committed to generation, conservation, and dissemination of knowledge about the causes, prevention, and treatment of human disease and disability; and

To our families, who unselfishly supported our work on this book.

*Deceased.

Preface: The Past and Future of *Principles and Practice of Radiation Oncology*

It was probably 2002 when I flew from the Raleigh-Durham airport in North Carolina to the Philadelphia airport. I took a taxi cab (remember those?) to the neighborhood of Independence Hall. It was where the Declaration of Independence was crafted and adopted and the Liberty Bell then resided. I walked south of the national historic landmark into a conference room at the Independence Square home offices of the venerable medical publishing house, J.B. Lippincott. I was being brought on-board to join Carlos Perez and Luther Brady as one of the senior editors of *Principles and Practice of Radiation Oncology*. Our task was to create the fourth edition.

I was seated at a table with Drs Perez and Brady. We were joined by Stuart Freeman, managing editor and representing J.B. Lippincott. As "the new kid on the block" I thought it best to sit quietly and "learn the ropes."

"Do you want to know how I came to create this book in 1987?," Luther Brady asked me earnestly. By his expression, it seemed clear that he had a story to tell and intended to tell it.

"Yes, sir, certainly," I replied.

Carlos Perez cut him off. "Oh no, Luther," he said. "Edward does NOT want to hear THAT story."

Luther Brady sat back in his chair, looking somewhat deflated. I learned several key lessons: (1) There was only one person I would ever meet who had the authority to tell Luther Brady "no." (2) That person was the courtly and dignified Carlos Perez. (3) If Luther Brady wanted to tell a story, there was no one, including Dr Perez, who was, in the long run, going to stop him.

The meeting to prepare the fourth edition continued for about another hour and it was time for a break. Mr Freeman and Dr Perez left the room. A

nanosecond after they left, Luther Brady turned to me.

"Let me tell you the story of how I came to create this book," he said.

"Yes, sir, certainly," I once again replied.

"Years ago," he began, "I sat down with Phil Rubin [the Chair of Radiation Oncology at the University of Rochester] to discuss the need for a definitive textbook to succeed Gilbert Fletcher's *Textbook of Radiotherapy*. I had asked Fletcher if he planned on a new edition and he told me the current edition of his book had no need for improvement. We also discussed the need for a definitive dedicated radiation oncology scholarly journal. We agreed that both needed to be created. What we couldn't agree upon was who would take charge of which project."

I had the feeling that Dr Brady had wanted to be the founding editor-in-chief of the radiation oncology journal. I knew that, in fact, he had been the founding editor-in-chief of the *American Journal of Clinical Oncology*, but I said nothing and urged him to continue his tale.

"Well," he resumed, "we flipped a coin and Phil got the journal and I got the book. That's why Phil was the founding editor of the *International Journal of Radiation Oncology Biology Physics*, generally called the red journal, and I created this book!"

As a part-time historian, I would like to have independent verification of this coin flip story from an objective third party, but I don't have it. Whether it is the founding story of this textbook or the founding myth, I am unable to say. Whichever it is, the book you hold in your hands, which emerged from that coin flip, may be rightly referred to as "The Bible of Radiation Oncology," "The *New York Times* of Radiation Oncology," or, as I often hear, "The Book." I have come to be one of the stewards of the edifice created by Drs Perez and Brady. I have taken that responsibility seriously.

Drs Perez and Brady asked Rupert Schmidt-Ullrich to join the team of senior editors for the fourth edition. Unfortunately, Rupert passed away before we could prepare the fifth edition. David Wazer joined as an associate editor for the fifth edition in 2008 and moved up to join me as a senior editor for the sixth and subsequent editions. Drs Perez and Brady continued to actively work on the book until Dr Brady's death as the seventh edition was being prepared for publication in 2018 and Dr Perez's death as we were collecting chapters for the eight edition. Since it takes

about 2 years to prepare each edition, Dr Perez devoted 39 years to this book; Dr Brady devoted 33 years; I have devoted 22 years to four editions so far; and David Wazer has devoted 18 years to three editions so far. Those are big numbers.

From the first edition of the *Principles and Practice of Radiation Oncology* in 1987 to this eighth edition being published in 2025, we have clocked 38 years, approximately 13,300 pages of printed text, many tens of thousands of pages of typed and computer printed text, and an immeasurable number of meetings, phone calls, letters, e-mails, faxes, and text messages to produce these eight editions. Many things have changed and others have stayed the same.

What has stayed the same? For 38 years, radiation therapy has remained a major component of the curative and palliative therapy of cancer and plays a major role in the management of many benign diseases. Patients with cancer are generally best managed by a combined modality approach that requires the participation of a well-informed, well-trained, and well-equipped radiation oncologist and medical physicist collaborating with a radiation oncology team. The radiation oncologist must be capable of taking a detailed medical history; performing a thorough and accurate physical examination of the patient; assessing and integrating the information from diagnostic imaging, from gross and microscopic pathology—incorporating a growing list of chemical and molecular markers that guide therapy and predict outcome—and from clinical chemistry; and formulating and implementing a treatment plan that is cognizant of the wishes of the patient and realistic in its goals.

For this book, in particular, what has also stayed the same since 1987 is the vision and participation of the editorial team. Having such stability in the editorial team is exceptional in the history of textbook publishing. As we note in our acknowledgments, we remember and mourn those who contributed to previous editions of this book but are no longer with us: Ruth Aultman, Jonathan Pine, Rupert Schmidt-Ullrich, Carlos Perez, and Luther Brady.

What has changed? There has been an explosion of knowledge concerning the molecular biology of cancer and tumor physiology. Concepts that were unknown in the 1980s are now considered fundamental building blocks of knowledge concerning cancer. As it concerns the

technology of this specialty, when the first edition of this book was published, some radiation oncology residents were training, in part, on orthovoltage units; cobalt-60 machines remained in widespread use; simulation using diagnostic radiographs still vied with clinical setups of treatment fields using surface anatomy; and many radiation oncologists carried slide rules, protractors, right angle drafting triangles, and rulers to calculate and map radiation dose distributions. Now, elaborate linear accelerators with multileaf collimators, particle machines, intensity-modulated and/or image-guided radiation therapy, complex brachytherapy devices, dose painting, image fusion, metabolic imaging, and increasingly powerful computers that support the preceding list of technologies have become the norm in the developed world. (And, unfortunately, the paucity of even the most minimal radiation therapy services remains the norm in many parts of the economically less-developed world, and economic and racial disparities persist in cancer care and outcomes in the economically developed world.) In some diseases, the diagnostic and staging workup has changed profoundly in the past quarter of a century—for example, the role of staging laparotomy in Hodgkin disease. In other diseases, the role of radiotherapy in treatment has shifted dramatically, as demonstrated by the decline in the role or frequency of use of radiation therapy in the management of retinoblastoma, Burkitt lymphoma, and Wilms tumor, following balloon angioplasty and stenting for coronary artery disease, and AIDS-associated malignancies. There have been significant changes in the patterns of use of radiation therapy for breast and prostate cancer, brain metastases, and non–central nervous system oligometastases.

The editors have striven to be cognizant of change by constantly adding and pruning chapters to document the current state of knowledge of cancer biology, medical radiation physics, dosimetry, cancer epidemiology, clinical radiation oncology, and radiation oncology economics, education, ethics, and policy. Particular attention has been devoted to an attractive and usable design of the printed version of this book and the new electronic versions. We have taken care to have this book evolve with the times. We have simultaneously striven to be true to the core mission of being “the book of record” for clinical care, providing the data that justify treatment recommendations as well as comprehensive illustrations and references in radiation oncology. We take this responsibility very seriously.

We have been gratified by the public reception of this book. Sales of the fifth edition rose dramatically compared to the fourth edition—an atypical pattern in the medical book business. Sales of the sixth and seventh editions remain high. It is, we like to believe, evidence that the pact wordlessly exchanged between the editors, the chapter authors, and our readers is being honored by all parties.

The editors sincerely hope that this eighth edition of *Principles and Practice of Radiation Oncology* will continue to advance the understanding of the causes, prevention, and treatment of human cancer. We pray that this new edition will contribute to the cure of some malignancies, the amelioration of suffering for many patients and their families, the relief of pain, and the ultimate triumph of human knowledge over cancer.

I began this preface with stories that included the fact that Drs Perez and Brady worked on this book until they died. Dr Wazer and I hope to have many fruitful years to continue working on the ninth edition and its successors. We have both decided, however, that prudent responsibility for this international treasure of a book includes both having a long-term succession plan for its leadership and increasing the diversity of the editorial team. We have, therefore, invited Drs Baumann, Blitzblau, and Esiashvili to join the team as associate editors for the eighth edition and begin "learning the ropes," as I did back in that Philadelphia conference room over 20 years ago.

Immediately following this preface, the reader will find a page of acknowledgments from all five senior and associate editors. I will, however, take the prerogative as the author of this preface to particularly acknowledge David Wazer. David has negotiated the personalities and politics of editorship and publishing with a calm hand, a steady gaze, and a mission-driven focus. He has done all of this while being a busy clinician, journal editor, and academic leader. He has also done all of this while dealing with the curve balls that life often throws you. Both David and I can testify that "Getting old isn't for sissies." I have been blessed to have him as a partner in creating this book for the last 18 years.

Acknowledgments

When I joined the editorial leadership team of *Principles and Practice of Radiation Oncology*, for the preparation of the fourth edition, which was published in 2003, my secretary was Ms Ruth Aultman. Ms Aultman was a quiet, hardworking, church-going woman who suffered much hardship in her life. She and I worked side-by-side when I was on the faculty at Duke University, department chair and vice dean at Duke, and dean of the School of Medicine at the University of Louisville—about 25 years in all. She was responsible for a great deal of the work on this book up through 2012 when she passed away. I remain grateful for her loyalty and kind, reliable presence.

Since 2012, when I became chancellor/CEO of New York Medical College, I have benefited from the assistance in my office of the college's chief-of-staff Vilma Bordonaro and executive assistant Ashley McCarrick. The director of the college's library, Marie Ascher, and her staff have fulfilled endless requests for references and intra-library loans. I express my appreciation to all three.

The publisher's representatives over the years have included Stuart Freeman, Joseph Cho, Anne Malcom, Ariel S. Winter, and Sean Hanrahan. I am grateful for their hard work. Jonathan Pine served as our publisher's supervising editor for the fifth and sixth editions of this book. Jonathan was an endearing person: kind and possessed of a gentle sense of humor. The editors did not know of his long-standing diagnosis of lymphoma until what was perceived by us as his unexpected death in 2013. An obituary in *The Baltimore Sun* quoted one of Mr Pine's friends, who called him the "perfect gentleman. He had manners you don't see anymore, and he also had his first job. He was a rarity for this generation."

I was taught that in the decalogue "Honor thy father and thy mother" encompassed honoring one's teachers. In that spirit, I acknowledge my teachers of radiation oncology: James J. Fisher at Yale; Leonard Prosnitz at

Yale and Duke; Rita M. Linggood and Noah C. Choi at the Massachusetts General Hospital; J. Robert Cassady at Boston Children's Hospital; C. Norman Coleman at Stanford; and, most importantly, Herman D. Suit at the Massachusetts General Hospital.

My wife, Sharon Halperin, and our three daughters, three sons-in-law, and six grandchildren have patiently endured the house being filled with piles of references and manuscripts and my consumption of reams of printer paper and ink cartridges. Without their love and support, neither the eighth edition nor the previous four editions would have been produced.

We are grateful for the scholarly, meticulous, and thorough work of the contributors to this volume. Through eight editions, this book has become the "book of record" for the specialty of radiation oncology. It has achieved that distinction through the hard work of the individual chapter authors.

The staff of Wolters Kluwer have professionally seen this work through from planning to distribution. We are in their debt.

We express our gratitude to our patients and their families for trusting us to be part of their cancer care team and inspiring our research. Our fellow faculty members, residents, medical students, and interdisciplinary cancer care teams have supported our work, providing consistent intellectual stimulation, valuable suggestions, and materials that have contributed to our knowledge and, consequently, to this book. We are grateful to the many librarians of our respective institutions who have come to our aid in finding the necessary books and articles to support the preparation of this book.

We thank our mentors throughout our training and careers, generously giving of their time and wisdom to help us grow as people, physicians, and radiation oncologists.

Dr Esiashvili thanks her two daughters, who have always had a deep appreciation for her work. "I firmly believe it helped them become empathetic and kind human beings."

Dr Blitzblau thanks her wonderful family for their unwavering support and encouragement throughout her career and in the making of this book. "I could not do it without you."

Dr Baumann expresses his "gratitude to my patients who place their trust in me, to my partners for their support, and to my mentors and trainees who have helped me to learn and improve as a clinician and human being. I want

to express my sincere love and gratitude to my wife and children who are such a wonderful blessing in my life, and to my parents who gave me the gift of opportunity and the support and love I needed to pursue my dreams. I am very lucky to have such wonderful family, friends, and colleagues. I am eternally grateful."

Contents

Volume I
The Scientific, Technological, Economic, and Ethical Basis of Radiation Oncology

Contributors
Preface: The Past and Future of Principles and Practice of Radiation Oncology
Acknowledgments

SECTION I Overview and Basic Science of Radiation Oncology

1. **The Discipline of Radiation Oncology**
   Edward C. Halperin

PART A: Cancer Biology

2. **Molecular Cancer and Radiation Biology**
   Michael Baumann, Ina Kurth, Nils Cordes, Cristina Conde Lopez, Mechthild Krause, and Annett Linge
3. **Biologic Basics of Radiation Oncology**
   Gopika SenthilKumar, Buck E. Rogers, Francisco Reynoso, Julie Schwarz, and Carmen Bergom
4. **Molecular Pathophysiology of Tumors**
   John D. Martin, Dan G. Duda, and Rakesh K. Jain
5. **Precision Medicine as Applied to Radiation Oncology**
   Jeffrey C. Buchsbaum and Pataje G. S. Prasanna

PART B: Medical Radiation Physics and Dosimetry

6. **Principles of Radiation Physics and Dosimetry**
   James A. Purdy, Geoffrey D. Hugo, and Hania A. Al-Hallaq
7. **Patient Positioning Methods: Immobilization, Stabilization, and Monitoring**

Tianjun Ma, Kujtim Latifi, Bruce Libby, Joshua Evans, and Stanley H. Benedict

8. **Photon External-Beam Dosimetry and Two-Dimensional Radiation Treatment Planning**
James A. Purdy, Geoffrey D. Hugo, and Hania A. Al-Hallaq

9. **Electron-Beam Therapy Dosimetry, Treatment Planning, and Techniques**
Angélica Pérez-Andújar and Eric E. Klein

10. **Conformal and Intensity-Modulated Radiation Therapy Physics: Treatment Planning and Techniques, and Clinical Applications**
James A. Purdy, Geoffrey D. Hugo, and Hania A. Al-Hallaq

11. **Physics and Dosimetry of Proton Therapy**
Brian Winey

SECTION II **Techniques, Modalities, and Modifiers in Radiation Oncology**

12. **Late Effects, QUANTEC, and HyTEC**
John P. Kirkpatrick, Michael T. Milano, Jimm Grimm, Louis S. Constine, Zeljko Vujaskovic, and Lawrence B. Marks

13. **Quality Assurance and Error Avoidance in Radiation Therapy**
Wesley J. Talcott, Kelly Paradis, Eric Ford, and Suzanne Evans

14. **Methodology of Clinical Trials**
Ethan B. Ludmir, Ruitao Lin, Abigail T. Berman, Clifton D. Fuller, and Charles R. Thomas, Jr

15. **Stem Cell Transplantation and Radiation Therapy Techniques**
Christopher R. Kelsey, Jeffrey W.C. Wong, Pranalee Patel, Mitchell E. Horwitz, Qiuwen Wu, and Sarah Jo Stephens

16. **Stereotactic Irradiation of Tumors of the Central Nervous System**
Trey C. Mullikin, John C. Flickinger, and Paul W. Sperduto

17. **Stereotactic Irradiation of Tumors Outside the Central Nervous System and Oligometastases**
Ambrosia J. Simmons, Brian D. Kavanagh, and Robert D. Timmerman

18. **High-Dose, Ultra-High Dose Rate (FLASH), and Spatially Fractionated Radiotherapy**
Robert J. Griffin, Yolanda Prezado, and Nina A. Mayr

19. **Intraoperative Radiotherapy**
William Sperduto, Jonathan B. Ashman, and Safia K. Ahmed

20. **Particle Therapy: Protons, Heavy Ions, and Neutrons**
Nancy P. Mendenhall and Perry B. Johnson

21. **Physics and Radiobiology of Brachytherapy**
Zhe (Jay) Chen, Jeffrey F. Williamson, David J. Brenner, Emily Draeger, and Mark J. Rivard

22. **Clinical Applications of Brachytherapy: Low Dose Rate and Pulsed Dose Rate**
Aspazia Spyrou, Sophie Otter, Caroline Holloway, Phillip M. Devlin, and Alexandra J. Stewart

23. **The Physics and Dosimetry of High-Dose Rate Brachytherapy**
Bruce Thomadsen, Eric N. Carver, and Mark J. Rivard

24. **Clinical Aspects and Applications of High-Dose-Rate Brachytherapy**
Mustafa Al-Balushi, Ivan Buzurovic, Phillip M. Devlin, Peter Orio, and Martin T. King

25. **Beyond the Beam: Radiopharmaceutical Therapy**
Freddy E. Escorcia, Ravi B. Patel, Teresa Fisher, and Katherine A. Vallis

26. **Radiation Therapy and the Immune System**
Ahsen Ahmed, Charles X. Wang, Michael Gough, and Arta M. Monjazeb

27. **Hyperthermia**
Mark Hurwitz, Mark Dewhirst, and Johannes Crezee

28. **Reirradiation**
Carsten Nieder and Anthony E. Dragun

29. **Chemical Modifiers of Radiation Response**
Yvonne Marie Mowery, Ashlyn G. Rickard, and David M. Brizel

30. **Oncologic Imaging and Oncologic Anatomy**
Edina Wang, Pooja Karukonda, Christopher R. Kelsey, Bryan O'Sullivan-Murphy, Travis Henry, and Junzo P. Chino

31. **Basic Concepts of Chemotherapy and Irradiation Interaction**
Sean C. All, D. Nathan Kim, and Christopher D. Willey

32. **Artificial Intelligence and Data Science as Applied to Radiation Oncology**
Tafadzwa L. Chaunzwa, Danielle S. Bitterman, Christian Guthier, Carl F. Haugg, Benjamin H. Kann, and Raymond H. Mak

SECTION III Policy, Economics, Education, Ethics, and Technology Assessment

33. **Technology Assessment, Outcome Analysis Research, Comparative Effectiveness, and Evidence-Based Radiation Oncology**
James B. Yu and Ronald C. Chen

34. **Global Radiation Oncology**
Timothy P. Hanna, Melinda Mushonga, Fabio Ynoe de Moraes, and C. Norman Coleman

35. **Radiation Oncology Undergraduate, Graduate, and Continuing Medical Education**
Eulanca Y. Liu and Ann C. Raldow

36. **Ethics, Professional Values, and Legal Considerations in Radiation Oncology**
Austin J. Sim and Brian D. Kavanagh

37. **Health Economics and Health Policy**
P. Travis Courtney, Ann C. Raldow, Eric M. Chang, and Michael L. Steinberg

38. **Economic, Gender, and Racial Disparity in Radiation Oncology**
Erica Fleming-Hall and Shearwood McClelland III

Volume II
The Clinical Practice of Radiation Oncology

SECTION IV Clinical Radiation Oncology

PART A: Skin

39. **Skin**
William M. Mendenhall, Anthony A. Mancuso, Peter T. Dziegielewski, and Christiana Shaw

PART B: Central Nervous System

40. **Primary Intracranial Neoplasms**
Vinai Gondi, Qian S. Zhang, Michael A. Vogelbaum, Yazmin Odia, and Minesh P. Mehta

41. **Fractionated Radiation Therapy and Stereotactic Radiosurgery for Pituitary Adenomas**
Chloe Dumot, Georgios Mantziaris, Salem M. Tos, and Jason P. Sheehan

42. **Primary Base of Skull Tumors**
Mark W. McDonald

43. **Spinal Canal Tumors**
Nikhil Rammohan, Clifford G. Robinson, Jeff M. Michalski, and Jiayi Huang

PART C: Head and Neck

44. **Adult Tumors of the Eye and Orbit**
Shervin Tabrizi and Helen A. Shih

45. **Ear**
Geoffrey Sedor, Luqman Dad, and Tony J. C. Wang

46. **Locally Advanced Squamous Carcinoma of the Head and Neck**
Jessica W. Lee, Jessica L. Geiger, and David M. Brizel

47. **Nasopharynx**
Fan Yang, Benjamin H. Lok, Jonathan E. Leeman, and Nancy Y. Lee

48. **Cancer of the Nasal Cavity and Paranasal Sinuses**
Steven J. Frank, Anesa Ahamad, and Carlos A. Perez

49. **Salivary Glands**
Neil Panjwani, Pattana Wangaryattawanich, Brittany Barber, Lauren Shih, Christina P. Rodriguez, and Upendra Parvathaneni

50. **Oral Cavity**
Irini Yacoub and Nancy Y. Lee

51. **Oropharynx**
Pooja Karukonda, Joseph K. Salama, and Yvonne Marie Mowery

52. **Hypopharynx**
Matthew E. Witek, Jonathan P. Giurintano, Nitika Tripathi, and Paul M. Harari

53. **Laryngeal Cancer**
William M. Mendenhall, Anthony A. Mancuso, Rui P. Fernandes, and Peter T. Dziegielewski

54. **Unusual Nonepithelial Tumors of the Head and Neck**
Adam L. Holtzman and Daniel M. Trifiletti

55. **Neck Cancer, Including Carcinoma of Unknown Primary**
William M. Mendenhall, Anthony A. Mancuso, Robert J. Amdur, Rui P. Fernandes, and Peter T. Dziegielewski

56. **Thyroid Cancer**
Robert J. Amdur and Roi Dagan

PART D: **Thorax**

57. **Lung Cancer**
John Kang, Michael T. Milano, Marco Schwarz, Rafael Santana-Davila, Ramesh Rengan, and Jing Zeng

58. **Mediastinum and Trachea**
Florence K. Keane, Annemarie Shepherd, Christopher S. Nabel, Ravi A. Chandra, Anneyuko Saito, Gregory A. Russo, Clifton D. Fuller, and Charles R. Thomas, Jr

59. **Esophageal Cancer**
Brian G. Czito and Christopher G. Willett

60. **Tumors of the Heart, Pericardium, and Great Vessels**
Aviva Berkowitz

PART E: Breast

61. **Breast Cancer: Stage Tis**
Alfredo I. Urdaneta, Todd Adams, David E. Wazer, and Douglas W. Arthur

62. **Breast Cancer: Early Stage**
Nisha Ohri, Sharad Goyal, Thomas Buchholz, and Bruce G. Haffty

63. **Breast Cancer: Locally Advanced and Locally Recurrent**
Christin A. Knowlton, Nancy Chan, Serena Wong, Meena S. Moran, and Jennifer R. Bellon

PART F: Gastrointestinal

64. **Stomach Cancer**
Brian G. Czito and Christopher G. Willett

65. **Pancreatic Cancer**
Christopher G. Willett and Brian G. Czito

66. **Cancer of the Liver and Hepatobiliary Tract**
Jia-Shing Wu, Huei-Chuang Yeh, and Andrew T. Huang

67. **Cancer of the Colon and Rectum**
Christine E. Eyler, Manisha Palta, Brian G. Czito, and Christopher G. Willett

68. **Anal Cancer**
Paul Riviere and James D. Murphy

PART G: Urinary Tract

69. **Cancer of the Kidney, Renal Pelvis, and Ureter**
Hiram A. Gay and Jeff M. Michalski

70. **Adjuvant and Neoadjuvant Radiation Therapy for Locally Advanced Bladder Cancer**
Brian C. Baumann and Mohamed S. Zaghloul

71. **Bladder Cancer**
Sophia C. Kamran, Brian C. Baumann, and Jason A. Efstathiou

PART H: Male Genitourinary

72. **Low-Risk Prostate Cancer**
Hiram A. Gay and Bridget F. Koontz

73. **Management of Intermediate- and High-Risk Prostate Cancer**
Quaovi H. Sodji and Mack Roach III

74. **Testicular Cancer**
Gerard C. Morton

75. **Cancer of the Penis and Male Urethra**
Vivek Verma and Hiram A. Gay

PART I: **Gynecologic**

76. **Cancer of the Uterine Cervix**
Yosef Landman-Gigi, Darien Colson-Fearon, Akila N. Viswanathan

77. **Endometrial Cancer**
Benjamin W. Fischer-Valuck and Yuan James Rao

78. **Ovarian and Fallopian Tube Cancer**
Christopher Weil

79. **Vaginal Cancer**
Joanne W. Jang and Akila N. Viswanathan

80. **Female Urethral**
Benjamin D. Hopkins and Tony Y. Eng

81. **Carcinoma of the Vulva**
Diandra N. Ayala-Peacock, Mary Katherine Anastasio, and Junzo P. Chino

PART J: **Adrenal and Retroperitoneal Tumors**

82. **Retroperitoneum**
Meng Xu-Welliver, Eric D. Miller, Joel L. Mayerson, Brian A. Van Tine, and Jeffrey C. Buchsbaum

83. **Adrenal Cancer**
Filip T. Troicki

PART K: **Lymphoma and Hematologic Tumors**

84. **Hodgkin Lymphoma**
Bradford S. Hoppe, Omran Saifi, and Richard T. Hoppe

85. **Non-Hodgkin Lymphomas**
Christopher R. Kelsey, Edina Wang, Alex J. Gooding, and Leonard R. Prosnitz

86. **Primary Cutaneous Lymphomas**
Tarsheen K. Sethi, Youn H. Kim, Lynn D. Wilson, and Richard T. Hoppe

87. **Leukemia**
Timothy J. Robinson, Kenneth B. Roberts, Scott Huntington, Jessica M. Stempel, and Nikolai Podoltsev

88. **Plasma Cell Neoplasms: Multiple Myeloma and Solitary Plasmacytomas**
Belinda A. Campbell, Sarah A. Milgrom, Andrea Lo, Amit Khot, Richard Bakst, and Joseph Mikhael

PART L: **Soft Tissue**

89. **Soft Tissue Sarcoma (Excluding Retroperitoneum)**
Kilian E. Salerno and Elizabeth H. Baldini

PART M: **Pediatric**

90. **Central Nervous System Tumors in Children**
Kevin X. Liu, Hesham Elhalawani, and Daphne A. Haas-Kogan

91. **Wilms Tumor**
John A. Kalapurakal and Arnold C. Paulino

92. **Neuroblastoma**
Christine E. Hill-Kayser and Mark Gaze

93. **Rhabdomyosarcoma**
Michael D. Young and Dana L. Casey

94. **Nonrhabdomyosarcoma Soft Tissue Sarcoma in Children**
Leslie Chang, Erin McCammack, Dana L. Casey, Susan Hiniker, Colette J. Shen, and Stephanie A. Terezakis

95. **Osteosarcoma and Other Primary Tumors of Bone**
Safia K. Ahmed and Nadia N. I. Laack

96. **Ewing Sarcoma**
Line Claude, Akmal Safwat, Raquel Davila Fajardo, Marija Kacar, Matthew Krasin, and Daniel Indelicato

97. **Lymphomas in Children, Adolescents, and Young Adults**
Sarah A. Milgrom, James E. Bates, Matthew D. Hall, Jamie E. Flerlage, Sharon M. Castellino, and Louis S. Constine

98. **Retinoblastoma**
Beate Timmermann and John T. Lucas, Jr

99. Rare Tumors in Children
Cheng-Chia Wu and Matthew Krasin

PART N: **Benign Diseases**

100. Nonmalignant Diseases
Simon A. Brown, Jerry J. Jaboin, Tony Y. Eng, Jose Bazan, and Charles R. Thomas, Jr

SECTION V **Palliative and Supportive Care**

101. Palliation of Brain Metastases
Hua-Ren R. Cherng, Mark Mishra, Roy A. Patchell, William F. Regine, and Young Kwok

102. Palliation of Vertebral and Spinal Cord Metastases
Emily MacDuffie and Joshua Jones

103. Palliation of Bone Metastases
Alexander A. Harris, Michael Kharouta, Chirag Modi, and William F. Hartsell

104. Palliation of Visceral Recurrences and Metastases and Treatment of Oligometastatic Disease
Alexander A. Harris, Michael Kharouta, Chirag Modi, and William F. Hartsell

105. Cancer Pain: Assessment and Management
Ellen Kim and Tracy A. Balboni

106. Palliative and Supportive Care
Ellen Kim and Tracy A. Balboni

107. Management of Radiation Side Effects
Shirin Sioshansi, Gavin Jones, and Paul Rava

Index I-1

SECTION I

Overview and Basic Science of Radiation Oncology

CHAPTER 1

The Discipline of Radiation Oncology

Edward C. Halperin

WHAT IS RADIATION ONCOLOGY?

Radiation oncology is a discipline of human medicine concerned with the generation, conservation, and dissemination of knowledge concerning the causes, prevention, and treatment of cancer and other diseases. The discipline requires special expertise in the therapeutic applications of ionizing radiation (Box 1.1). As a discipline that exists at the juncture of physics and biology, radiation oncology addresses the therapeutic uses of either ionizing radiation alone or in combination with other treatment modalities, such as cytotoxic chemotherapy and biologic and immunologic and cellular therapies, surgery, radiosensitizing and radioprotective drugs, oxygen, and heat. Furthermore, radiation oncology is concerned with the investigation of the fundamental principles of cancer biology; the physical, chemical, and biologic interaction of radiation with normal and malignant tissue; and the physical basis of therapeutic radiation. As a learned profession, radiation oncology is concerned with clinical care, scientific research, and the education of professionals within the discipline.

Box 1.1

The Etymology of *Radiate*

The defining verb of the discipline of radiation oncology, *radiate*, is derived from the Latin verb *radiatus. Radiatus* is the participial stem. Some dictionaries cite the origin of the word *radiate* as being from other tenses of the verb such as the present infinitive *radiarae* or the first-person singular present indicative *radio*. Radiate is defined as “to spread from the common center” or “to diverge or spread from the common point” or “to issue and raise.” Radiate shares a common root and related meanings with other English words, such as *ray*, *radius*, and *radial*. The verb *radiate* is more distantly related to other words. For example, if one proceeds along the ray from the political center to the extreme, then one is called *radical*.

The verb *irradiate* means “to direct rays upon” or “to cause rays to fall upon something.” In Latin, the prefix *in* conveys the meaning of in, within, on, upon, or against. When the prefix *in* is used with the word that begins with the letter *r*, the letter *r* is substituted for the letter *n* in the prefix to assimilate the initial sound of the verb. Thus, the verb that indicates the placement of water within or on the ground changed from *inrigate* to *irrigate*. Similarly, *inradiate* was changed to *irradiate*.

An object may be said to radiate something or to emit a ray. For example, “The block of cobalt 60 radiates gamma rays.” The verb that indicates directing rays on or into an object is *irradiate*. An example of proper usage would be “I recommend that we irradiate the tumor to a total dose of 45 Gy.” Incorrect usage would be “I think the primary tumor should be radiated to a dose of 45 Gy.”[1]

Radiation therapy is a clinical modality dealing with the use of ionizing radiation in the treatment of patients with malignant neoplasias (and occasionally benign diseases). The aim of radiation therapy is to deliver a precisely measured radiation dose to a defined tumor volume with as minimal damage as possible to surrounding healthy tissue, resulting in the eradication of the tumor, high quality of life, and prolongation of survival or palliation of symptoms at a reasonable cost. In addition to curative efforts, radiation therapy plays a major role in cancer management in the effective palliation or prevention of symptoms of the disease: Pain can be alleviated, luminal patency can be restored, skeletal integrity can be preserved, and organ function can be reestablished with minimal morbidity.[2]

WHAT IS A RADIATION ONCOLOGIST?

Franz J. Buschke (1902-1983) posed and answered the question “What is a radiotherapist?”

> When the patient is under our care we take full and exclusive responsibility, exactly as does the surgeon who takes care of a patient with cancer . . . . During the course of treatment, we ourselves direct any additional medication that may be necessary . . . and are ready to be called in an emergency at any time.[3] (Reproduced with permission from Buschke F. Editorial: what is a radiotherapist? *Radiology*. 1962;79(2):319-321. Copyright © 1962 Radiological Society of North America.)

Eli Glatstein (1938-2019) and Leonard Prosnitz rank ordered the priorities of a radiation oncologist as follows: “You are a general physician first, a general oncologist second, and a radiation oncologist third - and you need to keep them in that order” (Figure 1.1).

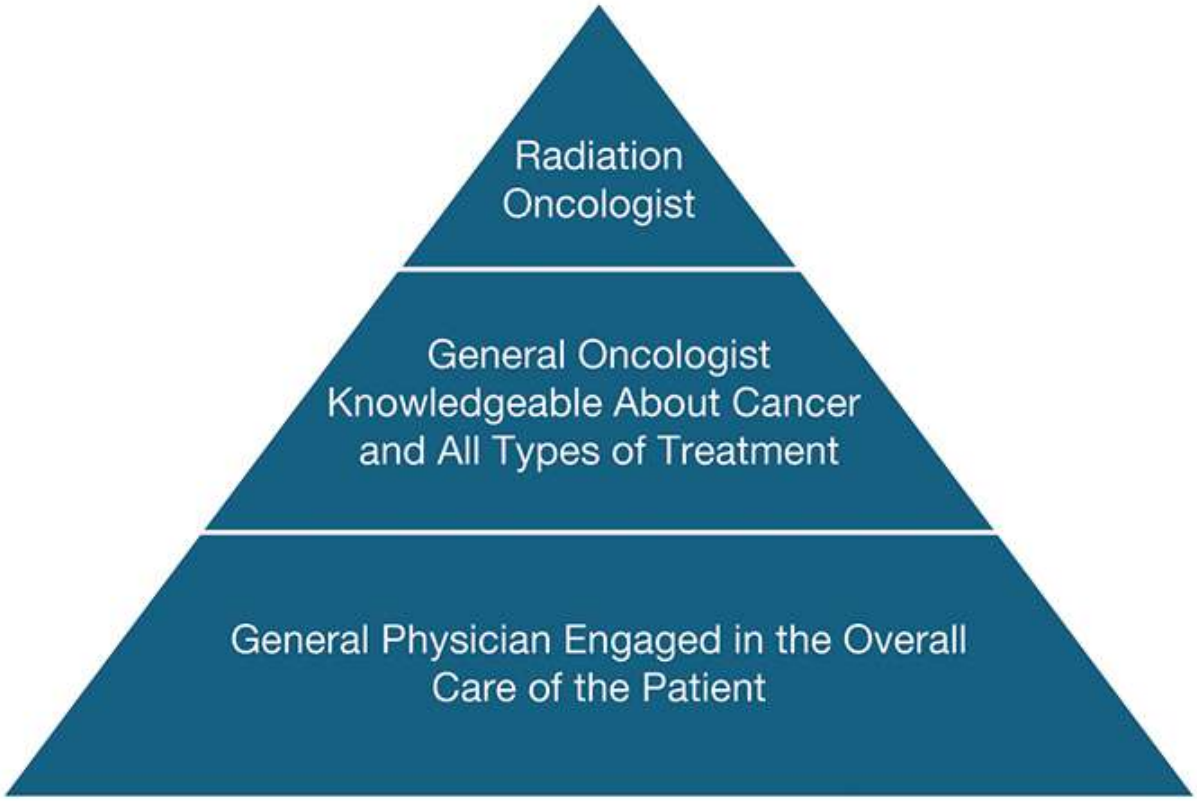

FIGURE 1.1 Eli Glatstein and Leonard Prosnitz have proposed a pyramidal definition of a radiation oncologist. Built upon the solid base of general medical knowledge resides a broad knowledge of oncology. The specialized knowledge of radiation oncology, in turn, sits upon that second base.

Morton Kligerman (1917-2006) tackled the topic in his 1982 American Society for Radiation Oncology (ASTRO) Gold Medal Address. Kligerman criticized the departure of the specialty from the ideals articulated by Buschke, Glatstein, and Prosnitz.

> I would like to suggest that the radiotherapy community bears the major responsibility for the loss of [respect for] our traditional role, largely because we have given up the general medical care of patients under our management, There is a growing unwillingness on our part to participate in many of the activities normally associated with primary care physicians . . . it is on the [hospital] floor where the radiation therapist meets medical students, interns, and other house officers . . . . The failure to admit patients on our own services . . . is the self-recognition that the radiation therapist has not kept up with primary patient care. Secondly . . . [it is often because] the radiation therapist is unwilling to spend the time and be inconvenienced by the requirements of in-patient care.[4] (Used with permission of Elsevier Science & Technology Journals from Kligerman MM. Gold medal acceptance speech: comprehensive patient care in radiation therapy practice. *Int J Radiat Oncol Biol Phys*. 1983;9(7):1091-1092; permission conveyed through Copyright Clearance Center.)

Buschke, Glatstein, Prosnitz, and Kligerman are all making the same fundamental points: A radiation oncologist is a physician who strives to understand the causes, prevention, and treatment of human cancer with special expertise in the use of

ionizing radiation. Most importantly, the radiation oncologist is a physician who cares for the whole patient and provides that care in the clinic and on the hospital wards. The radiation oncologist performs a complete medical history and physical examination, reviews the pertinent laboratory and imaging data relevant to the patient, and offers an opinion on the optimum treatment plan with special expertise in the use of radiation therapy.

If this IS what a radiation oncologist is, then what IS NOT a radiation oncologist? The radiation oncologist is not the button pusher in the basement. They are not a physician who says, "If the patient can't come downstairs from their hospital bed to my clinic, then I can't treat them - so I don't made inpatient rounds." They are not the type of doctor who says, "I don't need to do a medical history and physical, I can tell what I need to do by looking at the CT and/or MRI." They are most emphatically not the type of doctor who refuses to deal with the complications of radiation therapy, refuses to see patients on nights and weekends, refuses to evaluate patients in the emergency department, and refuses to provide inpatient care.[5]

In Galatians 6:7, we read: "For whatsoever a man soweth, that shall he also reap." If a radiation oncologist acts like a technician in the basement and declines to act like a full-fledged member of the medical team, then their fellow physicians will treat them that way and the radiation oncologist will only have themselves to blame.

It is the goal of the eighth edition of this textbook to provide radiation oncologists with the tools they need to practice their specialty commensurate with the ideals described earlier. It is the goal of this chapter to provide an overview of this branch of medicine. In particular, the author hopes that this overview will be of value to medical students and residents experiencing their first significant contact with radiation oncology.

A CANCER BIOLOGY PRIMER

What Is Cancer?

If the medical discipline of radiation oncology primarily concerns itself with the causes, prevention, and treatment of human cancer, then it seems logical that we must begin an introduction to this discipline by answering the fundamental question, "What is cancer?"

For many years, it has been the habit of the author to ask medical students beginning a clinical elective on the radiation oncology service or new radiation oncology residents beginning their training, "How do you define the word *cancer*?" For someone beginning the study of cancer, this would seem to be the most fundamental question to answer at the outset. The question is most often met by a blank stare. Faced with the likelihood that, like these trainees, many of my readers

have not grappled with this question, it seems worthy of some consideration in these pages.

James Ewing, early in his magisterial 1919 textbook *Neoplastic Diseases*, grapples with this question. He begins with the statement, "A tumor is an autonomous growth of tissue." He then succinctly reviews the views of his era.

> v. Rindfleisch says briefly, "A tumor is a localized degenerative excess of growth." Ziegler defines a tumor as a new growth of tissue, which apparently originates and grows spontaneously, possesses an atypical structure, does not subserve the uses of the organism, and reaches no definite termination of its growth. According to Birch-Hirschfeld, tumors are progressive new growths of tissue arising spontaneously from cells of its own, and separated from normal tissue both in morphology and in function. Ribbert states that tumors are new growth of tissue, self-centered, largely or wholly uncontrolled by the organism which supplies their nutrition, and a structure never entirely normal, and reaching no definite termination of growth.[6]

Ewing, who is profiled elsewhere in this chapter, spends many pages in the four editions of *Neoplastic Diseases* trying to present a succinct definition. He settles on "a tumor is an autonomous new growth of tissue" while citing the attempts of others. He writes, " Adami accepts White's descriptive definition: 'A tumor proper is a mass of cells, tissues or organs resembling those normally present, but arranged atypically. It grows at the expense of the organism without at the same time subservient any useful function.'"[7]

The National Cancer Institute (NCI) Dictionary of Cancer Terms offers the following definition: Cancer is "a term for diseases in which abnormal cells divide without control and can invade nearby tissues. Cancer cells can also spread to other parts of the body through the blood and lymph systems."[8]

If you were to line up a series of dictionaries and pathology textbooks on your desk, and open each to the proffered definition of cancer, you will find phrases such as "an uncontrolled division of abnormal cells . . .," "a malignant tumor of potentially unlimited growth that expands locally by invasion and systemically by metastasis . . .," and "an abnormal growth of cells which tend to proliferate in an uncontrolled way and, in some cases, to metastasize (spread)."

No matter what definition one chooses, there will always be exceptions. The best is the enemy of good, as Voltaire reminded us, and the lack of a perfect definition should not dissuade us from finding a good, working, reasonable definition.

A modern definition of cancer is "a disease of cell proliferation, it is heritable in that it is conveyed by a cell to its daughter cells; in which cells do not respect the usual constraints on their growth of space and time. It is characterized by invasion and metastases" (Figure 1.2).

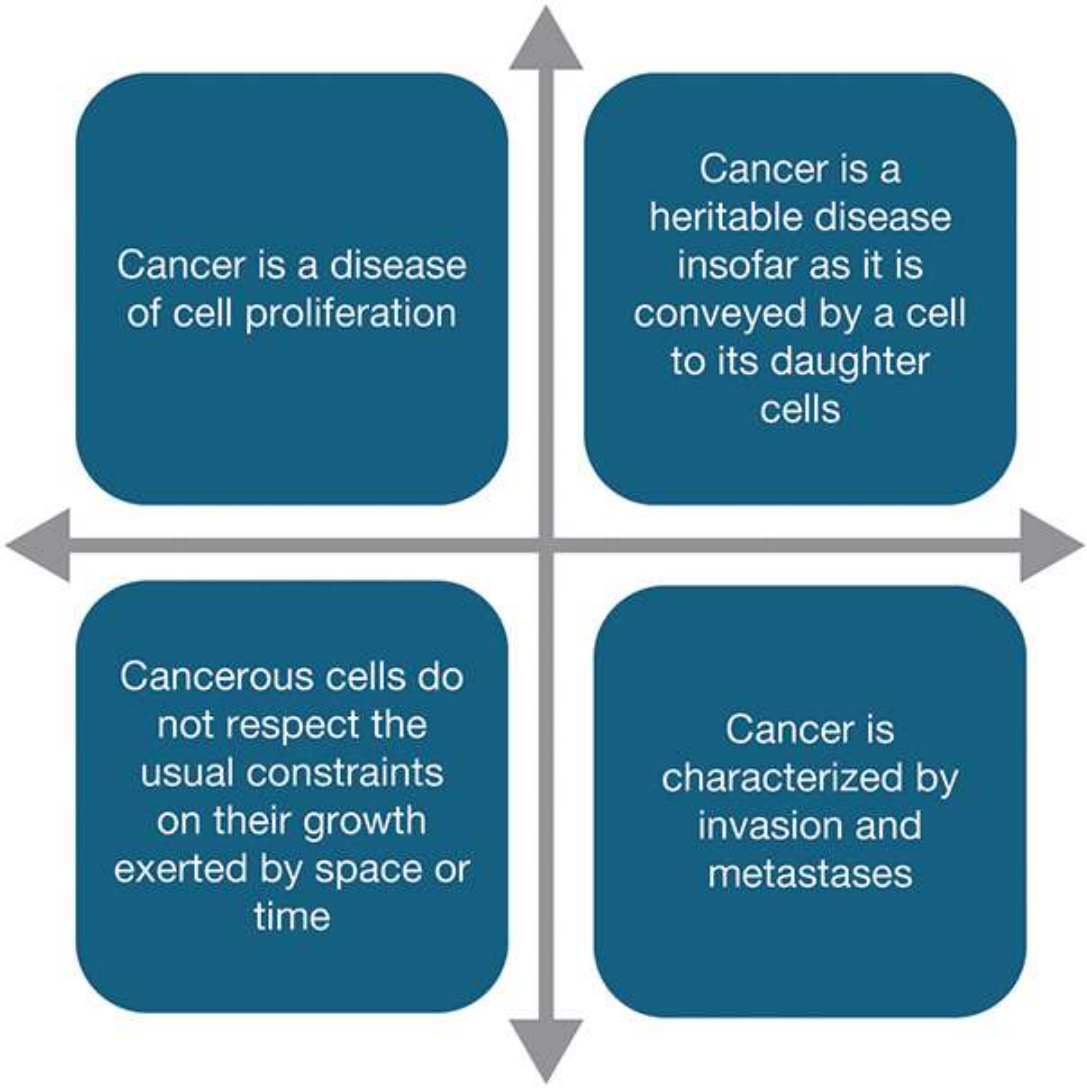

FIGURE 1.2 The four components of the definition of cancer.

Let us unpack this definition and strive to understand its full meaning.

- "a disease of cell proliferation"

  The fundamental essence of cancer is that it is a problem of cell multiplication.

- "conveyed by a cell to its daughter cells"

  When a cancerous cell divides, both of its daughter cells are also cancerous. The cancerous nature of a cell is passed with the parent genetic material to the daughter cells.

- "cells do not respect the usual constraints on their growth of space and time"

  Normal cell growth is constrained. If you cut yourself, then fibroblasts begin to proliferate to heal the wound. They grow and grow and then a cellular switch

turns the growth off (except in keloid formation). Similarly, in embryonic development, our cells proliferate to grow organs; at some point, however, the growth stops. Cancer cells do not stop growing when they bump up against adjacent cells (contact inhibition) or according to some internal time clock. Their growth is not constrained. Contact inhibition is not a characteristic of cancer cells. Furthermore, cancer cells generally have cell cycle times faster than normal tissue.

- "characterized by invasion and metastases"

  As Ewing wrote, "Growth is infiltrative, single cells or cell groups pushing their way through and destroying adjacent tissues". Cancers tend to invade surrounding tissue. Most have the ability to disseminate cells into the blood, lymph, cerebrospinal fluid, and/or pleural and peritoneal cavities where they will eventually come to rest, invade, and proliferate in different tissues from whence they began.

In contrast to cancerous tumors, benign tumors do not invade adjacent tissues. When benign tumors are fully removed, they usually do not grow back nor do metastases appear elsewhere in the body, in contrast to cancerous tumors. Nonetheless, in certain situations, benign tumors can be life-threatening—such as in the brain.

In what ways are cancer cells different from normal cells? Here is a partial list, stated in very broad strokes:

- Normal cells typically rely on the receipt of growth signals to proliferate. A typical signal of this type would be hormonal. In contrast, cancerous cells grow due to intrinsic properties possessed within; such as growth-promoting genes.
- Cancer cells have the ability to ignore growth-inhibiting messages.
- Cancer cells are able to avoid programmed cell death (apoptosis).
- Normal cells stop growing when they abut other cells (contact inhibition), cancer cells generally do not.
- Cancer cells invade surrounding tissues, normal cells do not.
- Cancer cells can produce chemical signals to draw blood vessels toward themselves. Creating a ready supply of nutrients and oxygen promotes further growth. Indeed, some cancer cells have alternative pathways for nutrition, and they derive energy in ways normal cells cannot.
- In contrast to normal cells, cancer cells can detach, travel via the blood or lymph or cerebrospinal fluid or in the pleural or peritoneal cavities, reattach, and develop as a new colony, called a metastasis.

- While the immune system patrols the body and destroys damaged or abnormal cells, cancer cells often have the ability to avoid the assault of the immune system and, sometimes, even manipulate the immune system to aid cellular proliferation.
- Cancer cells often have multiple copies of chromosomes and/or duplications and deletions of chromosomes. It is common for cancer cells to have a very high nuclear to cytoplasm ratio, compared to normal cells. This makes sense for a cell that devotes itself so profoundly to proliferating.

Genes and the Biology of Cancer

The infectious nature of some cancers was demonstrated by Francis Peyton Rous (1879-1970) in a 1910 experiment showing that defined, submicroscopic, filterable agents (viruses) isolated from a chicken sarcoma could induce new sarcomas in healthy chickens. Rous and his work languished in obscurity before being rediscovered and recognized with the Nobel Prize in Physiology or Medicine in 1966 (Figure 1.3).[9] In his Nobel Lecture, "The Challenge to Man of the Neoplastic Cell," Rous considered the possible existence of growth-promoting genes—what he called oncogens and what are now called oncogenes.

FIGURE 1.3 Peyton Rous won the Nobel Prize in 1966 for experiments he began in 1910. He demonstrated that a sarcoma could be transmitted from one chicken to another via a very small carcinogenic agent—a virus. A. Rous as a young investigator. B. Tumors destroy man in a unique and appalling way, as the flesh of his own flesh that has somehow been rendered proliferative, rampant, predatory, and ungovernable. They are the most concrete and formidable of human maladies, yet despite more than 70 years of experimental study, they remain the least understood. This is the more remarkable because they can be evoked at will for scrutiny by any one of a myriad chemical and physical means, which are left behind as tumors grow. These had acted merely as initiation. Few situations are more exasperating to the inquirer than to watch a tiny nodule form on a rabbit's skin at a spot from which the chemical agent inducing it has long since been gone and to follow the nodule as it grows, and only too often becomes a destructive epidermal cancer. What can be the reason for these happenings?

> Every tumor is made up of cells that have been so singularly changed as to no longer obey the fundamental law whereby the cellular constituents of an organism exist in harmony and act together to maintain it. Instead the changed cells multiply at its expense and inflict damage that can be mortal. We term the lawless cells neoplastic because they form new tissue, and the growth itself is a neoplasm; but on looking into medical dictionaries, hoping for more information, we are told, in effect, that *neoplastic*

means “of or pertaining to a neoplasm,” and turning to *neoplasm* learn that it is “a growth which consists of neoplastic cells.” Ignorance could scarcely be more stark.

The chemical and physical initiators ordinarily are called *carcinogens*; but this is a misleading term because they induce not only the malignant epithelial growths known as carcinomas but also other neoplasms of widely various kinds.... the less often used term oncogenes will be used, meaning “thereby capable of producing a tumor.” It hews precisely to the fact. . . .

What can be the nature of the generality of neoplastic changes, the reason for their persistence; for their irreversibility; and for the discontinuous, steplike alterations that they frequently undergo? A favorite explanation has been that oncogenes cause alterations in the genes of the body—somatic mutations as these are termed. But numerous facts, when taken together, decisively exclude this supposition.[10] (Peyton Rous—Nobel Lecture. The Challenge to Man of the Neoplastic Cell. NobelPrize.org. From Nobel Lectures, Physiology or Medicine 1963-1970, Elsevier Publishing Company, Amsterdam, 1972. Copyright © The Nobel Foundation 1966.)

Rous, it turned out, was wrong about oncogenes. Theodor Boveri[256] was right. In 1914, he used his studies of normal mitosis in sea urchins and worms as a platform for suggesting that cancer might be caused by the abnormal gain or loss of chromosomes and their function. In a 1929 English translation of his 1926 book, *The Origin of Malignant Tumors*, Boveri wrote:

The unlimited tendency to rapid proliferation in malignant tumor cells [could result] from a permanent predominance of the chromosomes that promote division. . . . Another possibility [to explain cancer] is the presence of definite chromosomes which inhibit division. . . . Cells of tumors with unlimited growth would arise if those “inhibiting chromosomes” were eliminated . . . [since] each kind of chromosome is represented twice in the normal cell, the depression of only one of these two might pass unnoticed.[11]

Boveri predicted that the genetic abnormalities leading to the development of cancer are of two sorts: growth-promoting genes and growth-suppressing genes. If the growth-promoting genes are excessive in number or activity, they lead to cell proliferation. If, however, the growth-suppressing genes are defective in amount or activity, they fail to halt cell proliferation and lead to unbridled cell replication (Figure 1.4). These growth-promoting genes are called *oncogenes*. The growth-suppressing genes are called *tumor suppressor genes*.

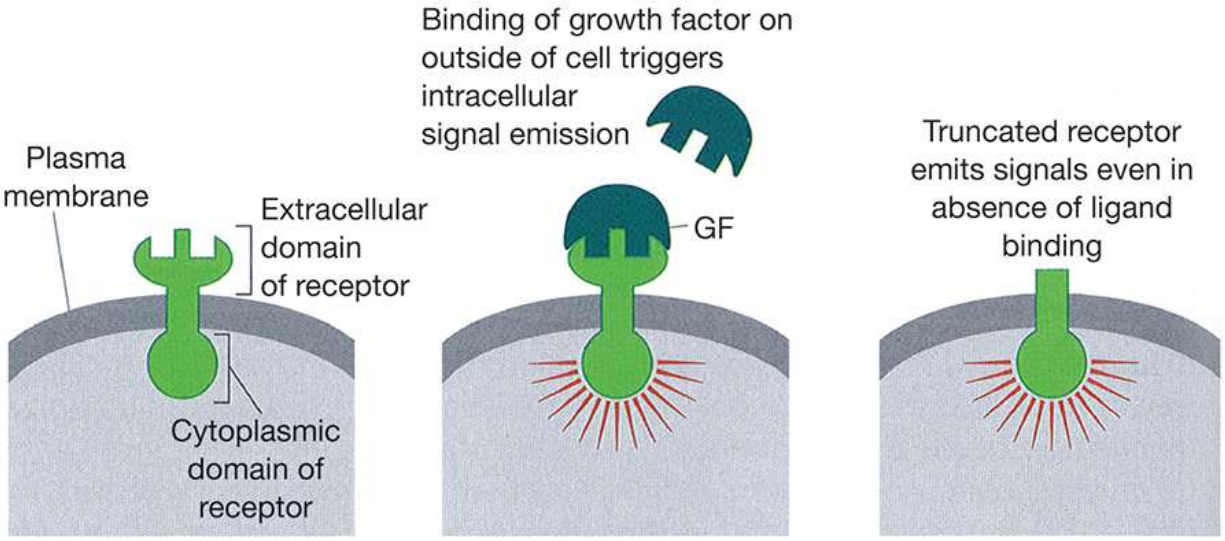

FIGURE 1.4 Oncogenes can act in multiple ways. One method is for a growth factor receptor, which ordinarily is only active when it binds to a ligand, to become active all the time, even in the absence of a growth factor binding to it. This is called "being constitutively active" and is the result of an oncogenic mutation. (From Weinberg RA. *The Biology of Cancer*. Garland Science; 2007. Copyright © 2007 by Garland Science, Taylor & Francis Group. Used by permission of W. W. Norton & Company.)

We may think of oncogenes and tumor suppressor genes as analogous to the accelerator pedal and the brake pedal of an automobile. The car can move forward when it is idling with the transmission in drive either by pushing on the accelerator pedal, by taking pressure off the brake pedal, or by doing both simultaneously. Similarly, cell growth and proliferation, leading to cancer, can occur either by the activity of the oncogenes or by the inactivity of the suppressor genes.

There are clearly a wide variety of physiologic conditions that call for the effective use of growth-promoting and growth-suppressing genes. There must be a mechanism to cause the fetus to grow and then, at the appropriate time, to restrain growth. There must be a way of causing fibroblasts to proliferate to heal a wound and then, at the appropriate time, halt the fibroblasts (except in the case of keloid formation). Uncontrolled cell growth, or cancer, may be thought of as a set of physiologic controls of cell growth gone awry.

Oncogenes

The experiments that initially identified oncogenes were based largely on transformed retroviruses in transplantable tumors in chickens, mice, and rats.[12] Oncogenes were described as the genetic material carried by RNA tumor viruses that resulted in rapid malignant transformation of target cells.[13,14] The name oncogene was given to virus-encoded single genes that either alone or in combination with other genes induced a transformed phenotype in affected cells.[15,16]

The word oncogene derives from the Greek *onkos*, a “mass” or “tumor.” Many oncogenes are those found in retroviruses. However, not all cellular genes capable of transforming cells have been identified within the genome of known retroviruses. It is accepted that an oncogene is a gene capable of contributing directly to the conversion of a normal cell to a tumorigenic one and that a proto-oncogene is a cellular gene convertible to an oncogene by various molecular mechanisms: sequence mutations, gene amplification, chromosomal translocation, viral transduction, and insertional mutagenesis. In general, these perturbations result in two net effects: altered regulation or augmented expression of an oncogene through mutation or rearrangement of the nucleotide sequences that constitute signals for control of transcription, messenger RNA processing, and stability via insertion of a strong foreign promoter or by increased gene dosage and altered biochemical function or ectopic expression of a protein product as a result of a mutation or translocation within the protein-coding region of the oncogene. Proto-oncogene products are involved in the regulation of normal cellular growth and differentiation.

A large number of viral oncogenes have been identified. In addition, oncogenes have been identified that are not associated with RNA tumor viruses but are recognized either by their activity in transformation or by their association with chromosome translocations.[17] In a study of tumors in chickens using DNA probing techniques, it was found that sequences homologous to the oncogene region of the virus were present in the DNA of all tissues of virus-free chickens. The normal cellular sequences are proto-oncogenes. The oncogene carried by a virus is referred to as *v-onc*, whereas the proto-oncogene is referred to as *c-onc*. In the normal cell, the expression of proto-oncogene is well controlled and appears to play a role in the growth and development of the organism. The function of some of these genes has been determined, whereas for others, a close association between cell proliferation and gene expression has been established.

Stimulation of a nonmalignant cell into a proliferative state often depends on an external signal, which is received by a receptor on the cell membrane and transferred through the membrane into the cytoplasm and ultimately to the nucleus where DNA synthesis is initiated. Proto-oncogenes have been found to function at each step of this pathway. The *erb*-B oncogene is homologous to the gene encoding for the cell membrane receptor of epidermal growth factor (EGF). The interaction of EGF with this receptor reduces the proliferation of epidermal cells, such as breast epithelium.

Strong evidence suggests that malignancy induction may be associated with genetic changes in the cell. Examples of this are the finding of specific chromosomal abnormalities in malignant cells, association of tumor development with DNA-damaging agents such as ionizing irradiation and chemical carcinogens, and increasing incidence of cancer in hereditary diseases such as xeroderma pigmentosum. It is recognized that oncogenes are normal cellular genes that may

contribute to the development of the malignant cell if their expression is altered through mutation, translocation, amplification, or some other mechanism. Evidence suggests that several genetic changes are needed to produce a cancer cell, and oncogene studies support this concept.

Chromosome translocations occur at a high frequency in some types of tumors, suggesting that they may play a role in their development. Examples of translocations are the t(9;22) Philadelphia chromosome in chronic myelogenous leukemia (CML), the t(15;17) in promyelocytic leukemia, and several translocations involving chromosome 8 seen in lymphatic malignancies. Common sites of translocations in malignant cells are frequently near an oncogene. Those translocations such as the t(9;22) in CML can result in the formation of a new protein that is intimately involved in the tumorigenic transformation of the cell. In the CML example, the *ber*-gene is translocated next to the *abl*-oncogene, forming the new *bcr-abl* gene. The proteinaceous product of this newly formed gene is a hyperactive protein kinase that provides permanent growth signals to the cell.

Role of Proto-Oncogenes in Normal and Transformed Cells

Proto-oncogenes are genes with oncogenic potential, and because they are apparently present in all animals, some kind of activation of proto-oncogenes is likely to be associated with the initiation and progression of neoplasia. Activated oncogenes are detected in a large percentage of human tumors, suggesting a prominent role of these genes in their development; the association between activated oncogenes and neoplastic diseases must have some kind of specificity for both the oncogene and the tumor.

Proto-oncogenes can be activated by genetic changes that affect either protein expression or structure. As succinctly stated by Weinberg:

> The somatic mutations that caused proto-oncogene activation could be divided into two categories—those that caused changes in the structure of encoded proteins and those that led to elevated, deregulated expression of these proteins. Mutations affecting structure included the point mutations affecting *ras* proto-oncogenes and the chromosomal translocations that yielded hybrid genes such as bcr–abl. Elevated expression could be achieved in human tumors through gene amplification or chromosomal translocations, such as those that place the *myc* gene under the control of immunoglobulin enhancer sequences. . . .
>
> Gene amplification occurs through preferential replication of a segment (the amplicon) of chromosomal DNA. The result may be repeating end-to-end linear arrays of the segment, which appear as homogeneously staining regions (HSRs) of a chromosome when viewed under the light microscope. Alternatively, the region carrying the amplified segment may break away from the chromosome and can be seen as small, independently replicating, extra-chromosomal particles (double minutes). Gene amplification does not always result in overexpression of the gene. . . .[18] (From Weinberg RA. *The Biology of Cancer*. Garland Science; 2007. Copyright © 2007 by Garland Science, Taylor & Francis Group. Used by permission of W. W. Norton & Company.)

A variety of structural changes in proteins can also lead to oncogene activation. Examples include alterations in the structure of growth factor receptors (such as the EGF receptor [EGFR]) and translocations that fuse two distinct reading frames to yield a hybrid protein (such as *bcr-abl*). Both types of alterations deregulate the proteins, causing them to emit growth-promoting signals in a strong, unremitting manner.

Oncogene protein products can be grouped into several classes depending on their location and reactivity: nuclear, cytoplasmic, and membrane protein kinases; cytoplasmic guanosine triphosphate–binding proteins; growth factors; and others. The protein products of the proto-oncogenes *src*, *abl*, and *ras* are cytoplasmic in location. The proto-oncogene products of *myc*, *fos*, *ski*, and *myb* are nuclear in location and are believed to play an important role in the control of cell division. The expression of these genes may be responsible for the entry of the cell into DNA synthesis. Growth factors are proteins that act at the cell surface to stimulate cell growth.

Current evidence suggests that *ras* oncogenes contribute to both initiation and progression of human neoplasia. The incidence of proto-oncogene amplifications in biopsy specimens from tumors, although highly variable, is usually low. However, there may be a tendency toward association of amplification of specific proto-oncogenes and particular types of tumors. Amplifications of the c-*erb*-B-2/*neu* proto-oncogene (also referred to as *her*-2) may be involved in the etiology of human breast, salivary gland, and ovarian cancers and might serve as a useful prognostic marker for these malignancies.[19] The *erb*-B-2/*neu* locus is amplified in 30% of primary breast carcinomas and that amplification is associated with a worse prognosis.[20-21]

Amplification of another proto-oncogene, C-*myc*, occurs mainly in adenocarcinomas, squamous cell carcinomas, and sarcomas, but not in hematologic malignancies, whereas N-*myc* amplification occurs most frequently in neuroblastomas and occasionally in retinoblastomas and a few small cell lung carcinomas.

Tumor Suppressor Genes

The concept that a gene product could inhibit or suppress the proliferation of cells in a tumor was derived from experiments using somatic cell genetics.[22] Different chromosomes from normal human cells carry tumor suppression genes that are able to block tumor formation by the cancer cell. The cancer cells must sustain mutation in both alleles of these genes to develop the ability to produce tumors.[23,24]

These somatic cell genetic experiments relied on cell fusion. In the first type of experiment, a cancerous cell that was able to form a tumor in an animal was fused

with a normal cell. The hybrid cell no longer produced tumors in animals. One could conclude that there was an element in the normal cell that was able to suppress the tumorigenic potential of the cancerous cell. It was found that, on occasion, one of the hybrid cell lines produced by the fusion of cancerous and normal cells was tumorigenic. Why? These malignant cell lines were missing genetic material supplied by the normal parent cells. Further investigation identified the presence of tumor-suppressing genes from the normal parent. Eventually, several specific tumor suppressor genes were identified and named.[383,384]

The next important part of the story of tumor suppressor genes comes from studies of the ocular tumor of infancy—retinoblastoma. Retinoblastoma can be either unilateral and unifocal or bilateral and multifocal. The disease also can be heritable or nonheritable based on the presence of a positive family history. Alfred Knudson[25] (1922-2016) noted that heritable retinoblastoma was more often bilateral and multifocal and occurred in younger children rather than nonheritable unilateral retinoblastoma, which occurred in older children (Figures 1.5 and 1.6). Knudson postulated that there was a gene that renders children susceptible to retinoblastoma. Patients with early-onset bilateral, multifocal disease inherit one defective copy of this gene and one normal allele. With a very high frequency, mutations develop in the normal allele, and children develop the tumor. However, patients with nonheritable retinoblastoma inherit two normal alleles. Only if two independent mutations develop in the same gene, completely obliterating the function of that gene, will a cancer arise.

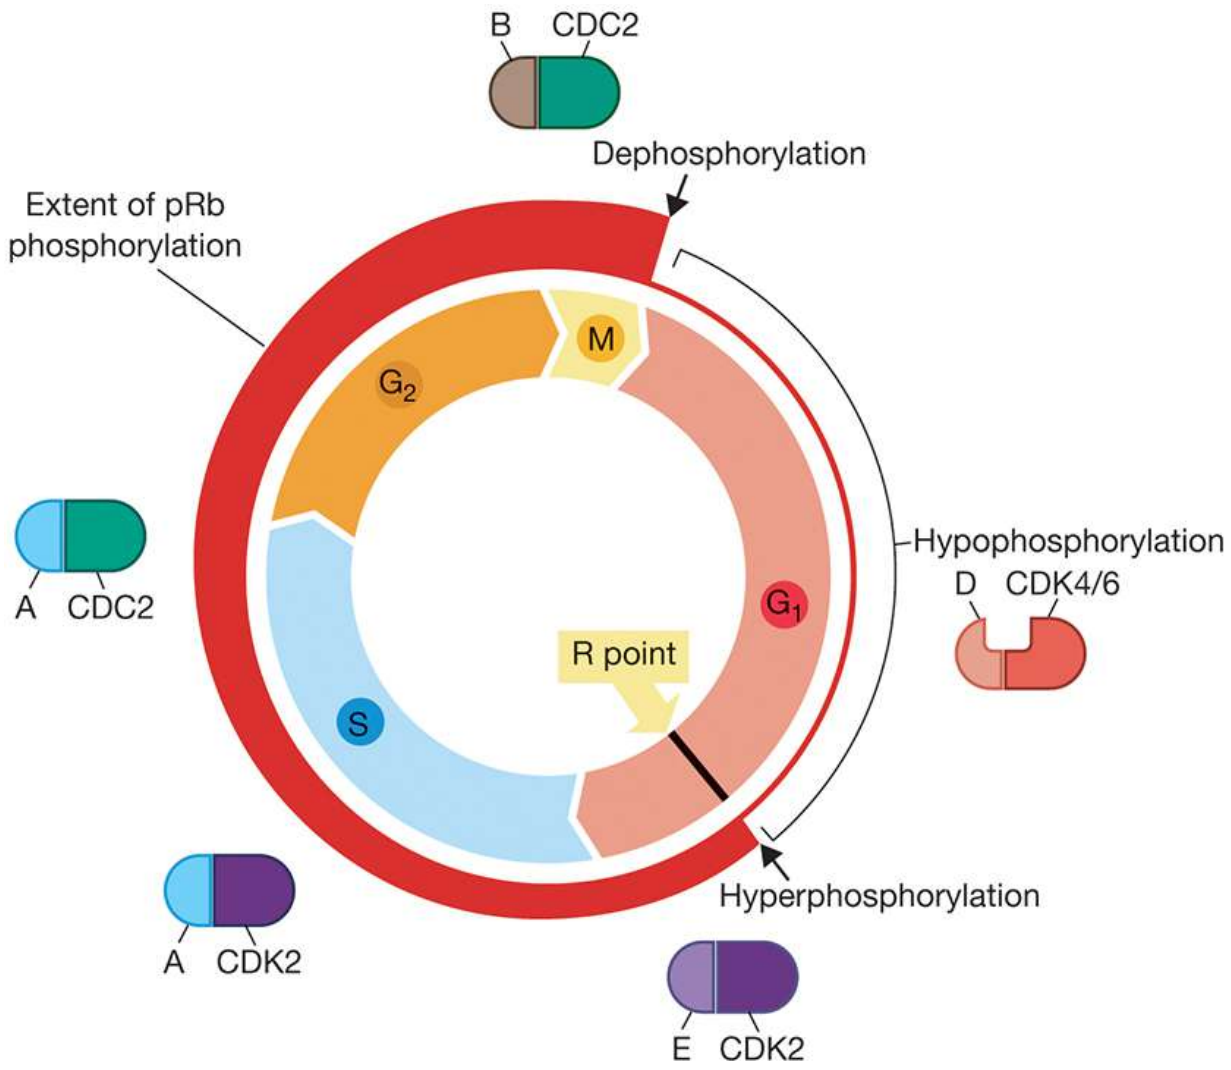

FIGURE 1.5 The phosphorylation of the retinoblastoma gene product protein, depicted as the red circle, helps to control the cell cycle. As the cell moves from M to G1, the protein is unphosphorylated; as the cell progresses through G1, the protein is hypophosphorylated; and after passing the R point (the restriction point), it is hyperphosphorylated. This process of phosphorylation is controlled by cyclins. (From Weinberg RA. *The Biology of Cancer*. Garland Science; 2007. Copyright © 2007 by Garland Science, Taylor & Francis Group. Used by permission of W. W. Norton & Company.)

FIGURE 1.6 Alfred Knudson (1922-2016) received a BS degree from the California Institute of Technology (Caltech) in 1944, an MD from Columbia in 1947, and a PhD from the California Institute of Technology in 1956. He served in the Navy during World War II and in the Army during the Korean War. In 1971, he published his "two-hit" hypothesis for the etiology of some forms of cancer. We now know this to be the result of the disabling of a tumor suppressor gene.[26] (Photo courtesy of Fox Chase Cancer Center Archives, Philadelphia, PA.)

Knudson concluded that it requires two genetic injuries in two alleles to produce retinoblastoma. This is called the "Knudson two-hit" hypothesis. The hypothesis predicts that if only one of the two gene copies remains active, there is sufficient growth suppression activity to keep the cell normal. Only if both copies are inactivated is there sufficient loss of genetic activity to allow unbridled cell proliferation. The retinoblastoma gene, *Rb*, was isolated on the long arm of chromosome 13. Because the short arm of chromosomes is abbreviated as p and the long arm as q, the deletion of the *Rb* gene is abbreviated as 13q-.[26]

How could one find tumor suppressor genes when their existence was most apparent by their absence? Robert Weinberg explains:

The dominantly acting oncogenes, in stark contrast, could be detected far more readily through their presence in a retrovirus genome, through the transfection-focus assay, or through their presence in a chromosomal segment that repeatedly undergoes gene amplification in a number of independently arising tumors. . . .

A more general strategy was required that did not depend on the chance observation of interstitial chromosomal deletions or the presence of a known gene . . . that, through good fortune, lay near a tumor suppressor gene on a chromosome. Both of these conditions greatly facilitated the isolation of the Rb gene. In general, however, the searches for most tumor suppressor genes were not favored by such strokes of good luck.[27] (From Weinberg RA. *The Biology of Cancer*. Garland Science; 2007. Copyright © 2007 by Garland Science, Taylor & Francis Group. Used by permission of W. W. Norton & Company.)

The tendency of tumor suppressor genes to undergo loss of heterozygosity (LOH) during tumor development provided cancer researchers with a novel genetic strategy for tracking them down. Because the chromosomal region flanking a tumor suppressor gene seemed to undergo LOH together with the tumor suppressor gene itself, one might be able to detect the existence of a still-uncloned tumor suppressor gene simply from the fact that an anonymous genetic marker lying nearby on the chromosome repeatedly undergoes LOH during the development of a specific type of human tumor.

The use of more powerful mapping techniques allowed geneticists to plant polymorphic markers more densely along the genetic maps of each chromosomal arm. Within a given chromosomal arm, some markers were found to undergo LOH far more frequently than others. Clearly, the closer these markers were to a sought-after tumor gene (ie, the tighter the genetic linkage), the higher the probability that such markers would undergo LOH together with the tumor suppressor gene. Conversely, markers located further away on a chromosomal arm were less likely to undergo LOH together with the tumor suppressor gene. Genetic analyses of DNAs prepared from various types of human tumors have revealed a large number of chromosomal regions that frequently suffer LOH. A subset of these regions have yielded to the attacks of the gene cloners, resulting in the isolation of many tumor suppressor genes.[28]

A number of distinctions separate the oncogenes from the tumor suppressor genes. It is almost certain that, in most human cancers, there is a multistep pathway to tumor development, which involves the accumulation of mutations in a series of oncogenes and suppressor genes.[29]

Many tumor suppressor genes have been cloned. The suppressor p53 gene resides in 20 kb of DNA located in chromosome 17p13.1. The gene is a nuclear phosphoprotein composed of 393 amino acid residues in humans.[30] p53 mutations have been detected in a wide variety of malignant human tumors. The *p53* gene

encompasses 16 to 20 kb of DNA on the short arm of human chromosome 17. Loss of normal p53 function is associated with cell transformation in vitro and the development of neoplasms in vivo. Abrogation of the normal p53 pathway is a common feature in human cancers, and it appears to be critical in the pathogenesis and progression of these tumors.[31] In some cases, candidate tumor suppressor genes have been identified based on an association between loss or inactivation and tumor development, with the causal connection being only inferred.

Cell Cycle Control

The cell cycle, which consists of four phases (G1, S, G2, and M), regulates the duplication of genetic information and the distribution of duplicated chromosomes to daughter cells. The phrases "cell cycle control" and "cell cycle clock" are used to describe the cell's molecular circuits operating in the nucleus that process and integrate afferent signals and decide if the cell will actively proliferate or remain quiescent. If the "go/no-go" decision is to "go" into proliferation, the circuitry is engaged to launch the biochemical changes necessary to allow the cell to double its contents and divide into two daughter cells. Key providers of the afferent information are tyrosine kinase receptors, G-protein coupled receptors, transforming growth factor-β (TGF-β) receptors, integrins, and the cell's nutritional status.

The Nobel Prize in Physiology or Medicine for 2001 was awarded to Leland H. Hartwell, R. Timothy Hunt, and Sir Paul M. Nurse for their discoveries regarding the control of the cell cycle. The Nobel presentation speech by Professor Anders Zetterberg succinctly describes the important controls of cell replication elucidated by these three scientists:

Cell division is a fundamental process of life. All living organisms on earth are descended from an ancestral cell that appeared about 3 billion years ago, and which has undergone an unbroken series of cell divisions since then. Each human being also began life as one single cell—a cell that divided repeatedly to give rise to all one hundred thousand billion cells that we consist of. . . . Every second millions of cells divide in our body.

The cycle of events that a cell completes from one division to the next is called the cell cycle. During the cell cycle the cell grows in size, duplicates its hereditary material—that is, it copies the DNA molecules in the chromosomes—and divides into two daughter cells.

This year's Nobel Laureates have discovered the key regulators of the cell cycle—cyclin dependent kinase (CDK) and cyclin. Together these two components form an enzyme, in which CDK is comparable to a "molecular engine" that drives the cell through the cell cycle by altering the structure and function of other proteins in the cell. Cyclin is the main switch that turns the "CDK engine" on and off. This cell-

cycle engine operates in the same way in such widely disparate organisms as yeast cells, plants, animals, and humans.

How were the key regulators CDK and cyclin discovered? Lee Hartwell realized the great potential of genetic methods for cell cycle studies. He chose baker's yeast as a model organism. In the microscope, he could identify genetically altered cells—mutated cells—that stopped in the cell cycle when they were cultured at an elevated temperature. Using this method Hartwell discovered, in the early 1970s, dozens of genes specific to the cell division cycle, which he named *CDC* genes. One of these genes, *CDC28*, controls the initiation of each cell cycle, the "start" function. Hartwell also formulated the concept of "checkpoints," which ensure that cell cycle events occur in the correct order. Checkpoints are comparable to the program in a washing machine that checks if one step has been properly completed before the next can start. Checkpoint defects are considered to be one of the reasons behind the transformation of normal cells into cancer cells.

Paul Nurse also used the genetic approach in his cell-cycle studies but in a different kind of yeast. In the late 1970s and early 1980s he discovered the gene *CDC2*, which could be mutated in two different ways. Either the cells did not divide, or they divided too early. From this he correctly concluded that *CDC2* controls cell division. He later discovered that *CDC2* not only controls cell division, the final event of the cell cycle; it also has a key regulatory function for the whole cell cycle, including that described for *CDC28* in baker's yeast. This key function was shown to be that of CDK in the cell-cycle engine. By moving human genes into yeast cells, in 1987 Nurse isolated a human *CDC2* gene. This human *CDC2* gene functioned perfectly in yeast cells. Thus, the CDK function in the cell-cycle engine had been conserved through more than 1 billion years of evolution—from yeast to man.

Tim Hunt discovered the other key component of the cell-cycle engine, the protein cyclin, which regulates the function of the CDK molecule. Working with sea urchin eggs as a model organism, in 1982 he discovered a specific protein that increased in amount before cell division but disappeared abruptly when the cells divided. Because of these cyclic variations, he named the protein cyclin. These experiments not only led to the discovery of cyclin, but also demonstrated the existence of periodic protein degradation in the cell cycle—a fundamental control mechanism. Hunt also showed the existence of cyclins in other, unrelated species. Thus cyclins, like CDK, had been conserved during evolution.[32] (Zetterberg A. Award ceremony speech. The Nobel Prize in Physiology or Medicine 2001. NobelPrize.org. https://www.nobelprize.org/prizes/medicine/2001/ceremony-speech/. Copyright © The Nobel Foundation 2001.)

Since the structure of the DNA molecule—the double helix—was discovered, we have a molecular explanation of how a gene can make a copy of itself. With the

discoveries of CDK and cyclin, we are now beginning to understand, at the molecular level, how the cell can make a copy of itself.

To ensure that the daughter cells possess a full complement of genetic information, checkpoints exist to ensure fidelity of DNA duplication and accuracy of chromosome segregation.[48] Checkpoint pauses permit editing and repair of genetic information so that each daughter cell receives a full complement of genetic information identical to the parent cell. In some cells, there are checkpoints for initiation of mitosis. Mutation of the checkpoint genes allows the cell to enter mitosis after x-irradiation.[33] For example, the *rad-9* is a G2/M checkpoint gene which responds to two different types of signals.[34] Experimental observations suggest that the *p53* gene, shown to be a transcriptional activator,[35] may be critical for G1 checkpoint control. *p53* has been shown to induce transcription of *p21*, which, in turn, inhibits the association of CDK 4,6 with proliferating cell nuclear antigen and cyclin D. As a consequence, the retinoblastoma protein cannot be phosphorylated and stays in complex with the transcription factor E2F, effectively blocking the transcription of cell cycle–promoting proteins and causing a cell cycle arrest.

Checkpoints are signal transduction systems that must receive a signal, amplify it, and transmit it to other components that regulate the cell cycle. Double-strand DNA breaks, unexcised ultraviolet light–induced dimers in DNA, and centromeres not engaged by the spindle are potential signals.[36,37] Checkpoints ensure the fidelity of genomic replication and segregation. Biologically significant levels of spontaneous damage require checkpoint control for cells to maintain a high fidelity of chromosome transmission. Therefore, restoration of compromised checkpoints could slow cancer cell evolution even in the absence of exogenous sources of DNA damage.[266] Many signal transduction systems, including checkpoint controls, exhibit adaptation; that is, in the presence of a constant stimulus, the response diminishes with time. As a consequence, the cell may proceed through the cell cycle, although the original perturbation has not been removed or cannot be repaired. Checkpoint activation may induce a variety of cell responses, including cell death. The checkpoint controlling entry into S phase in mammalian cells includes *p53*. One function under the control of this pathway is apoptosis. Restoration of defective checkpoints could restore the apoptotic response of cancer cells and increase their sensitivity to DNA-damaging agents. It may be possible to achieve specificity for certain types of cancer cells because not all cells respond to the same apoptotic signals.[38-44]

Growth Factors and Signal Transduction

Transmission of biochemical signals to the cellular nucleus leads to altered expression of a wide variety of genes involved in microgenic and differentiation responses. A number of growth factors exert their effects through receptors possessing intrinsic protein tyrosine kinase activity. On activation, these receptors phosphorylate both themselves and other intracellular proteins on the amino acid tyrosine. Among the receptors for growth factors are EGF, platelet-derived growth factor, insulin, nerve growth factor, and macrophage colony–stimulatory factor. The mitogenic signaling pathway activated by protein tyrosine kinase receptors involves the activation of *ras* proteins. *Ras* undergoes conformational change and interacts with additional downstream targets. A protein kinase cascade is activated, which conveys the growth factor–initiated signal to the nucleus via the *raf*, *mek*, *map* kinase, and other proteins.

Telomeres

Human chromosomes are linear. At each end of the chromosome are structures known as telomeres, from the Greek *telo* for "end" and *mere* for "structure." Telomeres are composed of specialized DNA and DNA-binding proteins. As chromosomes are replicated, telomeres shorten each time during the process of cell division. Continued cycles of cell division result in shortened telomeres. The telomeres, for example, in the fibroblasts of older adults are shorter than those in children. Normal human cells senesce when the telomeres shorten to a critical length.

Stem cells and cancer cells must maintain their telomere lengths to prevent senescence. Two mechanisms of telomere maintenance have been identified: expression of the telomerase enzyme and the recombination of telomeres.

The telomere hypothesis states that critical telomere shortening prevents somatic cells from dividing. In contrast, the maintenance of telomere length allows cancer cells to continue to divide. An increasing body of experimental evidence supports the telomere hypothesis and its association with cancer.

The capacity of cells to respond to ionizing radiation is determined by multiple factors. There are a variety of syndromes associated with molecular defects that are characterized by clinical radiosensitivity, including ataxia, telangiectasia, Nijmegen breakage syndrome, and ataxia telangiectasia–like disorder. These syndromes all have defective telomere maintenance in common. It has been hypothesized, therefore, that the radiosensitivity phenotype and the telomere dysfunction phenotype may be linked. A variety of experimental models suggest that telomere maintenance and radiosensitivity are associated and that this may offer the opportunity for a therapeutic target.

Apoptosis

Apoptosis or programmed cell death, a phenomenon distinct from necrosis, was described in 1972 by Kerr et al.[45] Apoptosis is programmed by specific signals in the cell that cause an endonuclease to cleave DNA at internucleosomal sites.

Apoptosis is detected by histologic evaluation of membrane blebbing and chromatin condensation, by flow cytometry using fluorescent nucleotides and terminal transferase to detect fragmented DNA, by detecting apoptotic cells that are usually very small with characteristic profiles of right-angle and forward light scattering, or by using DNA fluorochrome to detect a decrease in fluorescence as small DNA fragments diffuse from the cell that is undergoing apoptosis. An early change in apoptosis, the flip-flop of the phospholipid phosphatidylserine (PS) from the inner to the outer leaflet of the bilayer membrane, also can be detected using a fluorescently labeled annexin V protein that has a high binding affinity to PS. Several oncogenes, cytokines, and growth factors have been reported to play a role in promoting or reducing radiation-induced apoptosis.[46,47]

Most radiation-induced cell lethality (loss of reproductive integrity) for dividing cells appears to be caused by mitotic-linked death, resulting in the loss of genetic information as cells with chromosomal aberrations divide. Apoptosis, frequently seen within 4 to 6 hours after irradiation, occurs spontaneously and is enhanced by radiation as observed in vivo in the intestinal crypt and salivary and lacrimal glands with nondividing cells and nondividing lymphocytes. Apoptotic cells are eliminated rapidly in vivo, making it difficult to quantify. In contrast, this cell death mechanism is easy to quantify in vitro because apoptotic cells persist in culture for many hours. However, cell division of nonapoptotic cells complicates quantification. In cell lines susceptible to apoptosis, this process sometimes occurs early before cells enter mitosis or later after the cells divide. Late apoptosis may be associated with mitotically linked death and, in fact, may be triggered by chromosomal aberrations. Apoptosis may be quite important for clinically relevant doses of fractionated irradiation, even if it causes a relatively small reduction in clonogenic survival. However, this requires that cells be recruited into the apoptotic susceptible fraction after each dose fraction.

It appears that with the progression of certain tumors, spontaneous and therapy-related apoptosis occurs less frequently. The apoptotic response to irradiation can be modified by cytokines to protect normal tissues or to induce tumor cell killing.[48,49] Tumor necrosis factor increases apoptosis after irradiation in some tumors while protecting the hematopoietic compartment, possibly by blocking apoptosis. Irradiation prevents extensive cellular proliferation by increasing differentiation in both tumors and normal tissues. Also, irradiation appears to increase the aging of normal cells. Another mechanism of reversible loss of proliferative capacity induced

by irradiation is necrosis, which occurs with high doses of radiation and is a major mechanism seen with large-dose fractions such as in stereotactic irradiation.

The Biology of Metastasis

The prefix *meta* is of Greek origin and is defined as "after," "beyond," or "over." It is used to denote change or transformation. The word *stasis* means "stand" or "stationary." Thus, when the two words are combined to form *metastasis*, the new word is used to represent a change in the location of a disease or its manifestations. It also means the transfer of a disease from one organ or body part to another organ or body part not directly connected. The oncologist uses the term *metastasis* to refer to the manifestation of malignancy that arises from the primary growth but is now in a secondary site.

It is clear that the pattern of metastatic spread of cancer is not random.[50] The distribution of some secondary tumor deposits can be explained on mechanistic grounds (ie, that the tumor cells are shed into the bloodstream and lodge in the first narrow capillary network that they encounter downstream). This would explain, for example, why the liver is the most common site for secondary tumors in patients with primary cancer within the catchment area of the hepatic portal vein, such as gastrointestinal malignancies. Similarly, the lung would be a favored site in patients with primary tumor spilling into the systemic veins. There can be no doubt that vascular drainage patterns influence the distribution of secondary tumor deposits from some types of primary cancer.

It is also clear, however, that the distribution of some metastatic tumors cannot be explained solely by patterns of encountering and lodging in the nearest narrow capillary bed. This is called "metastatic tropism": Carcinomas form detectable metastases in only a limited subset of possible distant organ sites. The seminal paper addressing the problem of metastatic tropism was by Stephen Paget (1855-1926) (Figure 1.7). Paget was the fourth and youngest son of the famous British physician Sir James Paget (1814-1899). James Paget was one of the founders of modern pathology and is the namesake of Paget disease. Stephen Paget worked as an assistant surgeon at the West London and Metropolitan Hospitals in England. Later in life, he devoted himself to public health issues and became a highly regarded biographer and essayist.[51] Writing in *The Lancet* on March 23, 1889, on "The distribution of secondary growth in cancer of the breast," Paget wondered:

FIGURE 1.7 Stephen Paget (1855-1926) (Image courtesy of the U.S. National Library of Medicine.).

> The question ought to be asked, and if possible answered: "What is it that decides what organs shall suffer in a case of disseminated cancer?" If the remote organs in such a case are all alike passive and, so to speak, helpless—all equally ready to receive and nourish any particle of the primary growth which may "slip through the lungs," and so be brought to them—then the distribution of cancer throughout the body must be a matter of chance. But if we can trace any sort of rule or sequence in the distribution of cancer, any relation between the character of the primary growth and the situation of the secondary growths derived from it, then the remote organs cannot be altogether passive or indifferent as regards embolism. . . . Every single cancer cell must be regarded as an organism, alive and capable of development. When a plant goes to seed, its seeds are carried in all directions; but they can only live and grow if they fall on congenial soil.[52]

Paget observed, in a large number of autopsies of women with breast cancer, that the lymph nodes, liver, lung, bone, and brain commonly were involved. However, he found that the kidney and spleen rarely were involved despite receiving a significant amount of blood flow. He was struck by the discrepancy between the relative blood supplies and the relative frequencies of metastatic tumors in various organs. From his data, Paget expounded his "seed and soil hypothesis." He argued that metastasis required both a willing seed (intrinsic cellular factors) and hospitable soil (host organ). There must be intrinsic cellular factors that lead to a satisfactory interaction between the tumor cell and the host organ, resulting in successful metastasis. In contemporary terms, we understand this to mean that the tumor cell must have favorable adhesion molecules, and the host organ must be accepting receptors on its endothelial cells, which results in appropriate sites for the circulating tumor cells to bind, migrate into the organ, and subsequently grow, or, perhaps, that tumor cells promote upregulation of adhesion receptors in specific stromal cells.

As they grow, tumors almost certainly release large numbers of malignant cells into the blood and lymphatics continuously. It is clear, however, that the mere presence of tumor cells in the bloodstream does not always lead to the formation of distant metastases. A. J. Salisbury of the Brompton Hospital in London is credited as being one of the first to emphasize that the metastatic process is highly inefficient. The overwhelming majority of malignant cells released in the blood die.[282] They are battered in the circulation, assaulted by the immune system, and fail to reproduce. Metastasis formation is an inefficient process. Fidler and colleagues[53-56] injected melanoma cells into the peripheral vein of a mouse whose DNA had been labeled with radioactive iodine. They found that, shortly after the injection, most of the injected cells rested in the lung (ie, the nearest narrow capillary bed). Most of the tumor cells, however, went on to die in the lung. Only a few live cells continued to circulate. Within a day, only 1% of the injected cells were alive, and after 2 weeks, no known metastasis could be seen in the lungs. Only 0.1% of the cells originally

injected were still alive.[57] Blood-borne metastasis must be a highly selective process. Only a very small proportion of malignant cells that enter into the bloodstream are able to survive and grow.

The fact that only a small fraction of a tumor's cells can successfully form metastatic colonies implies that the survivors are, indeed, specially adapted cells. One might think of them in evolutionary terms. These successfully metastasizing cells must represent the survival of the fittest: the most hardy, most resilient, and most able to fend off the body's attempt to kill them. Isaiah J. Fidler performed an experiment with B16 melanoma cells in mice wherein he injected them into a peripheral vein, harvested the ones that grew in the lungs, grew them in a tissue culture environment, and repeated the process over and over and showed that he could create increasingly efficient cancers, which became better and better of metastasizing to the lung. He showed that they truly were "the fittest" when they came to metastatic potential.

A long period of tumor growth leads to progressive changes in a tumor's structure, blood supply, oxygenation status, antigenic characteristics, doubling rate, growth properties, and metastatic potential. Several investigators have performed variations of the following experiment: Unselected tumor cell suspensions were divided into two parts. One part was injected intravenously into a group of mice. The other part was subdivided into separate cultures. From each culture, a single tumor cell was isolated and grown to produce a large number of different clones, that is, cells with identical genetic composition. Then, these clones were injected into groups of mice.[58]

If the metastatic potential of tumor cells was homogeneous, then you would expect that the number and location of tumor colonies in the injected mice would be similar in the mice receiving the unselected tumor cell suspensions and the mice receiving the cloned lines. If different cloned subpopulations gave rise to widely different numbers of colonies compared to the uncloned cells, it would indicate that the tumor was heterogeneous—that the tumor contained cells with a variety of metastatic potential. The result was that there were widely different numbers of metastatic colonies. This implies the intrinsic heterogeneity of metastatic potential in a growing tumor.

As Stephen Paget suggested, there really is a tendency for particular types of primary tumors to preferentially metastasize to particular organs. Can we show, experimentally, that this is true and that it really is not about "the nearest, narrowest capillary bed trapping the tumor cells"? Garth L. Nicholson and Isaiah J. Fidler took highly metastatic melanoma cells, serially passed so that they were quite efficient at metastasizing to the lungs, and injected some into the tail vein of mice where the first narrow capillary bed they would encounter was the lung and, in other animals, they injected the cells into the left ventricle, just beyond the lungs, where they would

be more likely to be disseminated throughout the body. Initially, the animals who had cells injected into the tail vein had far more tumor cells in the lungs. One day after injection, there was no difference in the number of cells in the lungs, irrespective of the site injection. After 2 weeks, the same number of lung tumors were found for the two sites of injection. Tumor cells destined to form metastases in a particular organ appear capable of detaching from their first home and recirculating until they come to rest at their preferred site of ultimate metastases.[59]

The three major pathways of metastasis are as follows:

- Across body cavities such as the peritoneal cavity or within the cerebrospinal fluid. This is the way, for example, that medulloblastoma disseminates via the leptomeninges or that ovarian tumors form on the peritoneal surface of the intestine.
- Via the lymphatic system. Axillary masses following breast cancer, which are easily palpable, would be a common example of lymphatic metastases.
- Hematogenously, usually via veins rather than arteries. The spread of a limb sarcoma to the lungs would be an example.

The molecular mechanism of tumor metastasis is a multistep process involving many tumor cells—host-cell interactions as well as cell-matrix associations.[60,61] This process is sometimes called the invasion-metastasis cascade. The crucial processes are as follows:

- Tumor cell adhesion to other tumor cells at the site of the primary malignancy, host cells, or components of the extracellular matrix
- Proteolysis of the extracellular matrix during invasion
- Tumor cell motility through the extracellular matrix to reach the vascular or lymphatic endothelium
- Intravasation into the lumina of blood vessels or lymphatics— this is facilitated by molecular changes that promote the ability of carcinoma cells to cross the pericytes and endothelial cell barriers
- Embolism into the lymphatic system and/or the blood circulation
- Tumor cell survival despite both the mechanical trauma endured by the cell in transit in the vascular system and the body's immunologic assault directed against the circulating tumor cell (insofar as most tumor cells have a diameter of 20-30 μm and capillaries have a diameter of ~8 μm; most tumor cells in circulation are probably quickly trapped in capillary beds)
- Adherence to the endothelium when the tumor cell comes to rest at the metastatic site in the secondary organ

- Dissolution of the cell-cell junction and the basement membrane of the blood vessel or lymphatic into the organ parenchyma
- Survival in the new host organ microenvironment and interaction with that new microenvironment in the host organ to permit growth of the tumor deposit
- Tumor cell proliferation in the new organ and angiogenesis to achieve metastatic colonization

Only if all of these steps can be negotiated successfully can the tumor cell ultimately "set up shop" as a metastatic focus (Figure 1.8). The fact that only a small fraction of tumor cells survive and successfully establish a metastasis would suggest that the ultimately successful cells must be quite unusual. It would be reasonable to believe that they represent a subpopulation of tumor cells that are endowed with particular characteristics that make for successful metastasis. As the population of tumor cells evolves, it is likely that aggressive subpopulations, having diverse properties, will arise and that their frequency in the population will increase under selective pressure of the host immune defenses. This will lead, ultimately, to the emergence of cells with enhanced malignancy.[62] Many people believe that tumor cells evolve via a Darwinian selection—a concept we referred to earlier in this section of the chapter as "survival of the fittest." Genetic variation continuously occurs in the tumor population and clones with a survival advantage become overrepresented. These cells have "metastasis virulence genes" enabling their spread. The successful metastatic cells will possess characteristics of neoplastic transformation—the ability to turn on an angiogenic switch, an invasive phenotype, and the capacity to evade the immune response—as well as favorable cell adhesion and motility characteristics.[63,64]

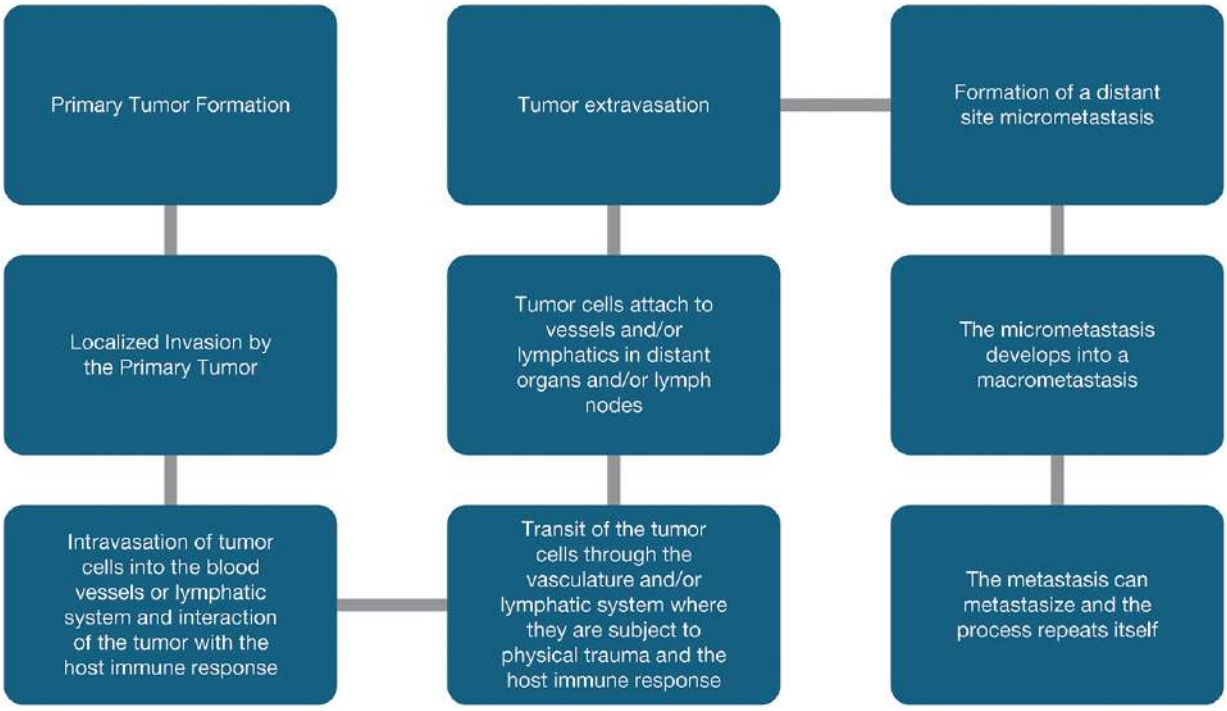

FIGURE 1.8 The development of metastasis is a multistep process that is highly inefficient. In order to form a metastasis, the tumor must breach the basement membrane and enter either a blood vessel or a lymphatic, travel through the bloodstream or the lymphatics, and not be destroyed either by attack of the immune system or mechanical trauma, adhere to the endothelium at a distant anatomic site, invade the organ parenchyma, draw a blood supply into the metastatic deposit, and colonize the new organ.

Metastatic progress involves not only the tumor's cells but also those cells' ability to recruit the aid of stromal cells. As tumors progress, the stroma becomes increasingly "reactive"—akin to the tissue of wound healing or chronic inflammation.

The Molecular Biology of the Metastatic Phenotype and Angiogenesis

Tumor progression is the acquisition of permanent, irreversible, qualitative changes in one or more characteristics of neoplasm that ultimately will lead to the tumor becoming more autonomous and malignant.[65] A genetic analysis of the stages of tumor progression has led to the formulation of the multistep theory of tumorigenesis. The multistep theory involves activation of oncogenes, inactivation of tumor suppression genes, and identification of many tumor-associated molecules. The metastatic phenotype appears to require cells to have the additive effect of positive modulators (oncogenes) as well as the loss of negative effectors (tumor suppressor genes, invasion and metastasis suppressor genes). Thus, the molecular biology of a metastatic cell is clearly a multistep process of diversification and clonal selection for aggressive cells.

The mutated *ras* oncogene sequences, when transfected into mouse embryo–derived fibroblasts (NIH 3T3 cells), cause those transfected cells to produce numerous metastases. This finding has been confirmed in both fibroblasts and epithelial cells of human and rodent origin. A number of other metastasis-associated genes have been described. These include NM23-1 and stomelysm-3 (ST-3). NM23-1 has features similar to a transcription factor and may play a role not only in *c-myc* expression but also in the response of cells to TGF-β. ST-3 is a member of the matrix proteinase family.[66]

It would be far too simplistic to conclude that the metastatic phenotype arises only from genetic alterations associated with the acquisition of aggressive tumorigenicity. Cells clearly can be transformed by oncogene transfection, but not all cells acquire a metastatic phenotype after this oncogene transfection. Simply stated, we must bear in mind that there is a separation between the genetic changes that drive tumorigenicity and the metastatic phenotype. Invasion and metastasis will require the activation of additional effector genes or loss of suppressor local inhibitors above those genetic changes required for uncontrolled growth alone.

The successful development of a metastatic focus requires new blood vessel growth. There are angiogenesis promoters and inhibitors that may be modified or removed during the tumor- induced angiogenic response. Tumor angiogenesis in the nascent metastasis is a tightly regulated process in a delicate balance between the proangiogenic and antiangiogenic factors.[66]

Angiogenesis and Tumor Cell Invasion into Blood Vessels

The success of the growth of a tumor is, in part, governed by a complex interplay between the tumor cells and the surrounding normal tissue. A dramatic example of this interplay is the process of tumor angiogenesis (also called tumor neovascularization).

The growth of the tumor depends on the tumor's access to nutrients and oxygen as well as its ability to eliminate metabolic waste and carbon dioxide. In very small tumors, these requirements are addressed by diffusion. As the tumor enlarges, however, diffusion is inadequate. The growing tumor requires direct access to the circulatory system.

Tumor access to the circulatory system is secured through angiogenesis, through which the tumor cells encourage the ingrowth of capillaries and larger vessels from the adjacent normal tissue. The tumor cells recruit these vessels through the release of angiogenic factors. These cause the proliferation of endothelial growth factor and, almost certainly, tissue growth factor-β. The generation of tumor vessels is the result of a delicate balance between angiogenesis-promoting factors and angiogenesis-

inhibiting factors. These factors have now provided a growing body of therapeutic targets in the treatment of cancer.

Some authorities encourage us to think about the tumor as a structure composed of varied compartments, including the actual clonogenic cells, a connective structure, and the blood vessels. Utilizing this way of thinking about tumors, we envision cancer treatment as striking at different components of the tumor (ie, antiangiogenesis agents directed against the vasculature and anticlonogenic agents directed against proliferating cells). Experimental evidence suggests that, in certain tumor systems, the combination of radiation and antiangiogenic agents is a fruitful way of treating cancer. We may expect to see an increasing body of evidence for the use of combinations of radiation, chemotherapy, hormonal therapy, and antiangiogenesis agents in the coming years.

The "father of angiogenesis" was a pediatric surgeon, Judah Folkman (1933-2008) (Figure 1.9). While he was not the first person to notice that tumors needed blood vessels to grow, his detailed investigation into why tumors draw blood vessels to themselves and how to inhibit that process was groundbreaking. Folkman published a controversial theory that is now widely accepted: Targeting angiogenesis may potentially arrest cancer. The author of this chapter distinctly recalls Dr Folkman presenting his research, when the author was a resident, at the invitation of the chair of radiation oncology at the Massachusetts General Hospital, Dr Herman Suit, in 1980 to 1983. Folkman's work created a frenzy in 1998 when a front-page article in *The New York Times* reported how two drugs he had developed had eradicated tumors in mice. The article quoted Dr James Watson, a Nobel laureate who shared the prize with Francis Crick for the discovery of the structure of DNA, as saying, "Judah is going to cure cancer in two years (Box 1.2)."[67]

FIGURE 1.9 Judah Folkman (1933-2008).

Box 1.2

Antiangiogenesis Therapy of Cancer

Tumor vessels are fundamentally different from normal blood vessels insofar as they are usually irregular and disorganized. In vessels that are leaky, hemorrhagic, or torturous or in those containing poorly oxygenated blood that may flow backward and forward in the same vessel, tumor vasculature may provide an interesting therapeutic target. The general public and the scientific community have recently experienced a wave of considerable excitement associated with the possibility that antiangiogenesis agents may be employed clinically to disrupt tumor angiogenesis. This form of therapy may complement existing cancer treatments. Vascular endothelial growth factor (VEGF) is a key element in the stimulation of angiogenesis. VEGF binds to a receptor on endothelial cells (VEGFR), which stimulates tyrosine kinase activity, which, in turn, stimulates downstream signaling and activation of endothelial cells. The drugs in the therapeutic pipeline may be categorized as follows:

- Anti-VEGF agents: Some drugs prevent the binding of VEGF to its receptors. *Bevacizumab (Avastin)* is a monoclonal antibody that binds to VEGF, prevents it binding to VEGFR, and

inhibits VEGFR activation. It is being utilized in the therapy of a variety of human malignancies.

- Anti-VEGFR agents: Several receptors bind to VEGF: VEGFR1, VEGFR2, NRP-1, and NRP-2. VEGR2 is thought to mediate most of the angiogenic properties of VEGF and is expressed at high levels on the endothelial cells of tumor vasculature. Several monoclonal antibodies are under investigation in animal models to target the VEGFR.
- Receptor tyrosine kinase inhibitors: An antiangiogenesis strategy is to target the downstream activity of the binding of the VEGFR by inhibition of tyrosine kinase activity. The following drugs, now in human clinical trials, fall into this category: cediranib or recentin (AZD2171), pazopanib, BIBF 1120, sorafenib, and sunitinib (SU11248).

The hallmark of an invasive cancer is its ability to disrupt the epithelial basement membrane and the presence of cancer cells in the stromal compartment. It makes sense, therefore, that two broad classes of molecules have been implicated repeatedly in contributing to the metastatic ability: Cell-cell adhesion molecules and motility molecules play a crucial role in the development of metastatic potential.[68] The ability of tumor cells to adhere to other tumor cells, cells of the host, or components of the extracellular matrix affects multiple components of the metastatic cascade. These interactions depend on several classes of molecules expressed on the cell surface. Cadherins are calcium-dependent molecules that mediate homophilic cell-cell adherence. Integrins are heterodimeric transmemory proteins that are formed by the noncovalent association of α- and β-subunits. The binding of the extracellular matrix ligands to integrins is known to initiate similar transduction pathways. These pathways lead to cell proliferation, differentiation, migration, or cell death. Selectins act through a terminal calcium-dependent lexon domain. They are prominently involved in heterotypic cell-cell adhesion between blood cells and endothelial cells.[69]

Tumor adherence to the extracellular matrix and cell motility is the next crucial component of the metastatic cascade. Tumor cells are able to attach to a specific lipoprotein of the extracellular matrix, such as fibronectin, collagen, and laminin. These adherences are formed either through integrin or through nonintegrin cell surface receptors. CD44 is a crucial transmembrane glycoprotein with a large echo domain and a single cytoplasm domain. CD44 is involved in cell adhesion to hyaluronan[70].

The potentially metastatic cell must overcome a series of tissue barriers. These include the basement membrane and connective tissue. These must be traversed by the tumor cells during the metastatic process. Five classes of naturally occurring proteinases have been associated with aggressive tumor cells and implicated in metastases. These include members of the gene family of matrix metalloproteinases. These enzymes, each of which is secreted by a proenzyme that subsequently requires activation, may be divided into three general subclasses: interstitial collagenase, type

4 collagenase (gelatinases), and stromelysins. Once having dissolved barriers, active tumor cell motility is required for the penetration of the basement membrane and the interstitial stoma. Successful migration of metastatic cells requires the transition of propulsive force from the extracellular matrix to the cytoskeleton. Tumor cells exhibit amoeboid movement, which is characterized by pseudopod extension. For the protrusion and retraction of pseudopods, the network of intracellular polymerized cross-linked filaments must be disassembled and then reassembled.[71,72]

THE COMMON FORMS OF ADULT AND PEDIATRIC CANCER

We have now defined the word cancer, discussed its characteristics and pathophysiology, and been introduced to the biology of cancer metastases. Now we are ready to review the most common forms of cancer in adults and children.

Our first problem to resolve is that there is more than one way to define "common" in the context of "common forms of cancer." We could list the most common forms of cancer by counting the "incidence" during a year. "Incidence" means the number of newly diagnosed cases in a year. We could list the most common forms of cancer by counting the number of deaths from each type of cancer during the year. We could also list the most common forms of cancer by counting the "prevalence" during a year. "Prevalence" means the number of people alive with a particular form of cancer (Box 1.3).

Box 1.3

A Call to Arms

An Institute on Cancer meeting was conducted at the University of Wisconsin in Madison in 1936. Among the prominent scientists in attendance were James Ewing, professor of oncology at Cornell University Medical College, after whom Ewing sarcoma is named; Gioacchino Failla, the famous radiation physicist of the Memorial Hospital for Cancer and Allied Diseases of New York; and Henri Coutard, pioneer radiation therapist of the Curie Institute of Paris. Glenn Frank, president of the University of Wisconsin, addressed the scientists on the first day of the meeting. Seventy-five years later, Frank's opening address remains a moving call to arms for basic science, translational, and clinical researchers, physicists, and clinicians.

> "Down the ages, cancer has been the most hideously persistent and the most persistently hideous enemy of mankind, the suffering it lays upon men intolerably horrible, its toll of life progressively devastating, its blows falling so often just when men have reached the years of ripest usefulness to family and state. But not all these tragic consequences together are the worse evil wrought by cancer. For every *body* that is *killed* by the *fact* of cancer, multiplied thousands of *minds* are *unnerved* by the *fear* of cancer. What cancer, as an unsolved mystery, does to the morale of millions who may never know its ravages is incalculable. This is an incidence of cancer that cannot be reached by the physician's medicaments, the surgeon's knife, or any organized advice

against panic. Nothing but the actual conquest of cancer itself will remove this sword that today hangs over every head. I can remember, as a boy in rural Missouri, that death from cancer was rarely mentioned and then only with bated breath. I realize now that this reaction was born of a feeling of utter helplessness and awe in the presence of a mysterious enemy. That almost primitive reaction to cancer has happily vanished. We have not penetrated the mystery, but, thanks to you and your colleagues the world over, we have made notable rents in the veil surrounding the mystery. The world is determined to conquer this thing that steals upon men like a thief in the night and without warning strikes down the strong and weak alike. By one thing alone can this conquest come, and that is by the tireless, painstaking, and self-sacrificing genius of scientists who, like yourselves, go to their laboratory tables as to an altar and sink their lives in the great adventure of emancipating mankind from the fact and fear of this plague. Surely, if anywhere in the secular activities of men, there is a spark of divinity in lives so dedicated!"[73]

These three ways of counting the number of cancer cases will give varying answers to the question, "What are the most common forms of cancer?" For example, the mortality rate of lung cancer in adults is very high. The mortality rate of prostate cancer in adults is very low. If you measure mortality from cancer, lung cancer will rank higher than prostate cancer. If you measure prevalence, the reverse is the case. Some will argue that this fact manifests itself politically. There are a great many prostate and breast cancer survivors in the United States who vote and express their wishes to their elected representatives to fund research for these diseases. Most patients with lung cancer die and do not, therefore, constitute a voting bloc to advocate for research in lung cancer.

Basal and squamous cell carcinomas of the skin are so common, so often curable, and so often treated in the offices of dermatologists and surgeons that they are not reported in the lists of common adult cancers. The most common forms of adult cancer are listed by incidence and mortality, for the United States, in Table 1.1. Trends in cancer incidence and mortality are shown in Figure 1.10. The most common forms of childhood cancer are listed by incidence in Table 1.2.

TABLE 1.1 ESTIMATED NEW CANCER CASES AND DEATHS, UNITED STATES, 2024

	Estimated New Cases	Estimated Deaths
All sites	2,001,140	611,720
Oral cavity and pharynx	54,450	12,230
Digestive system	353,820	174,320
Respiratory system	252,950	130,450
Bones and joints	3,970	2,050
Soft tissue (including the heart)	13,590	5,200

	Estimated New Cases	Estimated Deaths
Skin (excluding	108,270	13,120
Breast	313,510	42,780
Genital system	427,800	70,100
Urinary system	169,360	32,350
Eye and orbit	3,320	560
Brain and other nervous system	25,400	18,760
Endocrine system	48,010	3,300
Lymphoma	89,190	21,050
Myeloma	35,780	12,540
Leukemia	62,770	23,670
Other and unspecified primary sites	34,950	49,240

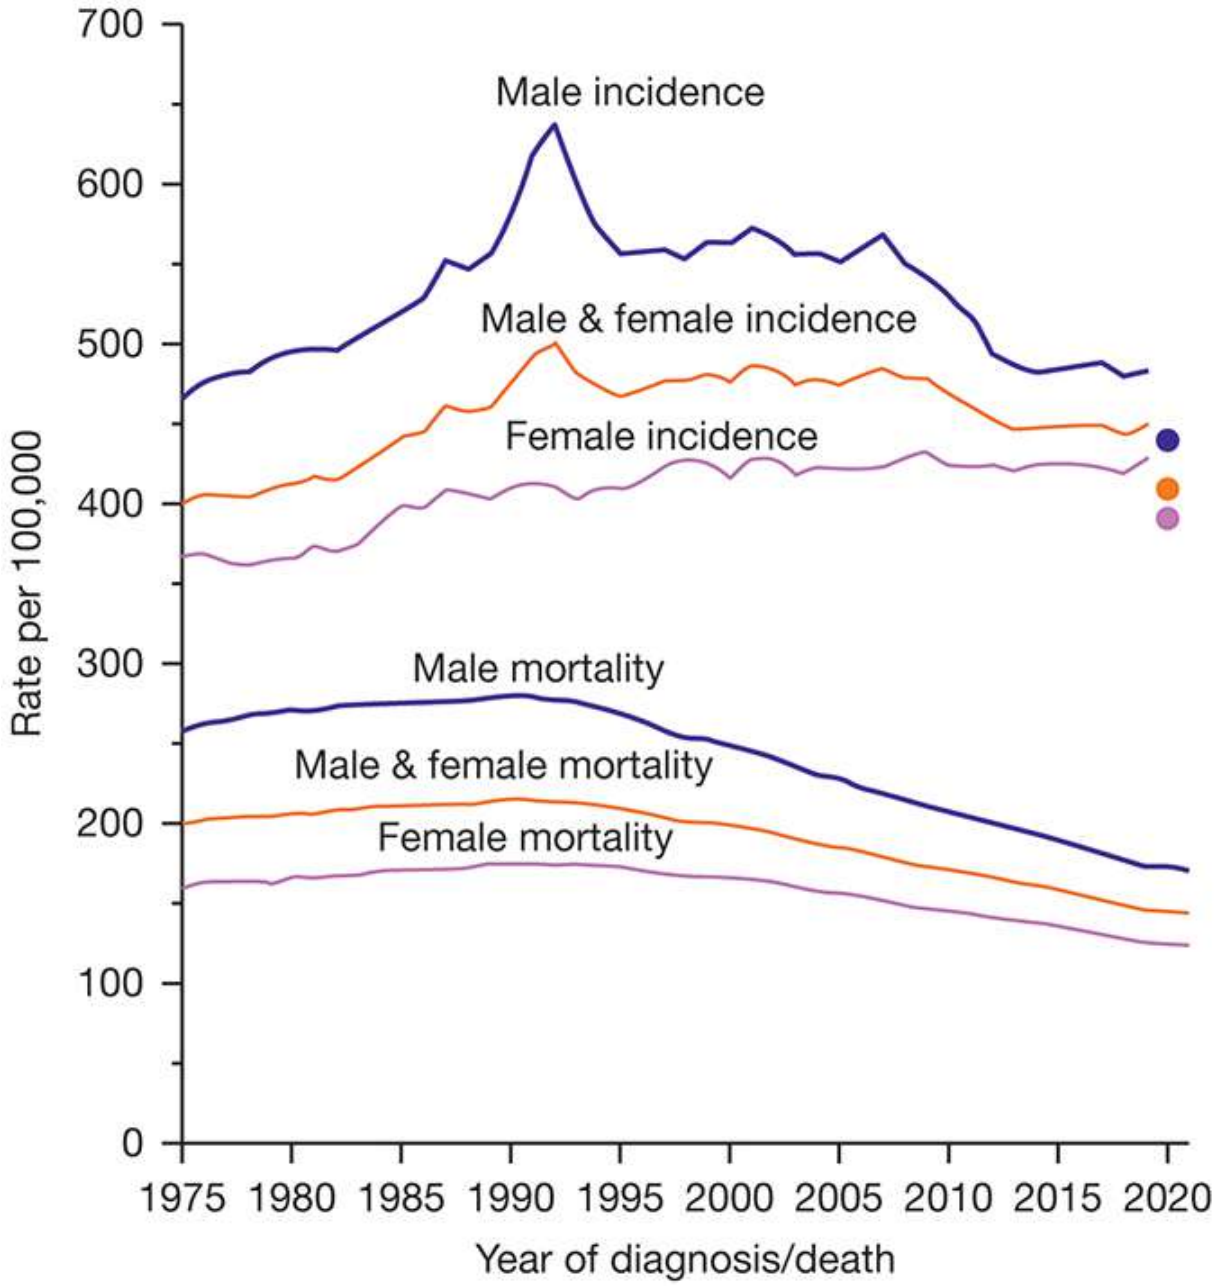

FIGURE 1.10 Trends in cancer incidence (1975-2020) and mortality (1975-2021) rates for selected cancers by sex, United States. Rates are age adjusted to the 2000 U.S. standard population and adjusted for delays in reporting. (From Siegel RL, Giaquinto AN, Jemal A. Cancer statistics, 2024. *CA Cancer J Clin*. 2024;74[1]:12-49. Reprinted by permission of John Wiley & Sons.)

As you examine Tables 1.1 and 1.2, you will note that there is almost nothing in common. The major problems of adult cancer are cancers of the lung, breast, gastrointestinal tract, head and neck, prostate, bladder, cervix, and uterus. In contrast, the major forms of childhood cancer are brain tumors, leukemias, lymphomas, and a series of interesting but rare tumors: Wilms tumor, rhabdomyosarcoma and nonrhabdomyosarcoma, soft tissue sarcomas, Ewing sarcoma, neuroblastoma, and retinoblastoma. Why?

The short answer is that adults get cancer in places where their bodies meet the environment. Children do not. Adults douse their bodies with carcinogens via excessive sun exposure, tobacco use, chewing betel nuts, drinking alcohol, having a diet with too little fiber and too much fat, sexual practices that transmit carcinogenic viruses, and occupational exposures. These repetitive carcinogenic insults produce an array of activated oncogenes and failed tumor suppressor genes, which result in malignancies. Children, in contrast, do not smoke too much, drink too much alcohol, or engage in unsafe sex. They get cancers because of intrinsic genetic problems leading to malignancies rather than inducing genetic changes by exogenous carcinogens.

In adults, therefore, cancer is a largely preventable disease. Epidemiologic studies have identified the causative agents for a significant proportion of adult cancers. Approximately 30% to 35% of cases of cancer in the United States are associated with tobacco use.[74] Another 30% to 35% of cases are associated with excessive dietary fat and obesity. Approximately 5% of cancer is related to alcohol use. Another 5% is associated with exposure to viral agents.[75] Among the other causative factors of cancer, each responsible for a small percentage of malignancies, are occupational exposures, a family history of cancer, environmental pollution, ionizing and ultraviolet irradiation, prescription drugs, and medical procedures (Tables 1.3 and 1.4).[76-81]

TABLE 1.3 QUANTITATIVE ESTIMATES OF AVOIDABLE RISKS OF CANCER IN THE UNITED STATES, 1981: THE CLASSIC STUDY BY DOLL AND PETO

Diet	35%
Tobacco	30%
Infection	7%
Reproductive and sexual behavior	4%
Occupation	4%
Alcohol	3%
UV light	3%
Pollution	2%

CANCER PREVENTION

There are two general approaches to cancer prevention. They are referred to as *primary prevention strategies* and *secondary prevention strategies*. A primary preventive strategy may be invoked when there is an explicit and indisputable behavior that should be avoided or adopted because of its association with a predictable and certain reduction in cancer risk for an individual. A secondary prevention is distinguished from primary prevention in that it is an intervention focused on altering the natural history of a disease and thus avoiding disease-related adverse outcomes.[82] The most commonly used secondary prevention strategy is broad based or targeted population screening.

The principal primary prevention strategies are directed against cancers that have been associated with certain behaviors. They begin with the avoidance of tobacco. Tobacco is the single largest preventable cause of death in the Western world today. Tobacco use, either in the form of cigarette, pipe, or cigar smoking or the use of snuff or chewing tobacco, is strongly associated with carcinoma of the lung, larynx, pharynx, oral cavity, and esophagus. Tobacco also appears to be an important

contributing factor in cancer of the pancreas, bladder, kidney, stomach, colon, and uterine cervix. In addition to its role in the etiology of cancer, tobacco also is associated with coronary heart disease, chronic lung disease, stroke, and other maladies.[83]

Chewing betel nuts has long been known to be a cause of head and neck cancer in the less economically developed world. With immigration to the economically developed world, cancers associated with betel nut chewing are increasingly being seen in these counties as well. The combination of tobacco use, betel nut chewing, and alcohol consumption creates a lethal Ven diagram where all three intersect to produce a very high incidence of head and neck cancer.

We have come to understand the role of diet, excessive fat consumption, and obesity in the etiology of cancer.[84] Studies suggest a direct correlation between average dietary fat intake in various countries and the incidence of breast cancer. Classic studies have shown that the incidence of stomach cancer among the Japanese decreases when Japanese individuals migrate to Hawaii. Second-generation Japanese residents of Hawaii have an incidence of stomach cancer equivalent to that of the White population.[85] Clearly, a healthier diet could reduce the incidence of cancer.[86]

Excessive alcohol consumption also is associated with cancer. Alcohol consumption is particularly harmful among cigarette smokers. It appears that smoking acts as an initiator, producing injurious mutations, and alcohol acts as a promoter of cancers of the oral cavity, oropharynx, pharynx, larynx, and esophagus.

A variety of occupational exposures also are associated with specific cancers, including cancer in asbestos miners and workers, various forms of cancer in workers in the chemical industry, and radiation-associated cancers in uranium miners. An obvious preventive strategy is to minimize or eliminate such harmful exposures in the workplace.

In recent years, scientists have become increasingly aware of various genetic syndromes associated with the etiology of cancer, including the multiple endocrine neoplasia syndromes and their association with medullary cancer of the thyroid, susceptibility genes that increase the risk of colon cancer, and the association of the *BRCA1* and *BRCA2* genes with carcinoma of the breast and ovary. For some of these genetic susceptibility traits, the best that the physician can offer is close follow-up. There are certain situations where the avoidance of a potentially lethal cancer may lead an individual to consider prophylactic surgery.

An exciting development in cancer prevention is the development of a vaccine capable of reducing, by about 70%, the incidence of human papillomavirus–associated cervical cancer. The U.S. Food and Drug Administration (FDA) approved this vaccine for clinical use in 2006. This vaccine, along with the use of routine Pap testing, has the potential to make invasive cervical cancer a rare event, although

adoption of the vaccine has been hindered by the false claim that it is associated with the encouragement of sexual relations in the young.

Cancer screening is the most frequently considered secondary preventive strategy. A cancer screening procedure should lead to the early detection of an asymptomatic or unrecognized disease by the application of simple, inexpensive tests or examinations in a targeted population. For cancer screening to be appropriate and successful, several criteria should be met, including:

1. The cancer for which one is screening should have a substantial morbidity and/or mortality rate that warrants the screening procedure.
2. The cancer for which one is screening should have a sufficiently high prevalence in a detectable, preclinical state to warrant screening.
3. Once the cancer is detected by a screening procedure, there should be an effective treatment related to early detection. This criterion is quite important because there is little value in screening for an untreatable malignancy.
4. The screening test should have a high sensitivity and specificity.
5. The screening test should be of low cost such that the expense of screening a large population would be more than offset by the reduced cost to society of treating early rather than advanced malignancy.
6. Individuals screened should suffer little inconvenience and discomfort.

There is no perfect screening test. Those tests currently used generally meet most, but not all, of the aforementioned criteria.

There are several examples of currently used screening tests. For breast cancer, these include self-examination, examination by a trained health practitioner, and mammography, augmented, when appropriate, by ultrasound and magnetic resonance imaging (MRI). The value of these tests in various populations of women is a long-standing debate. Every few years, in the United States, organizations issue new, and sometimes conflicting, advice on which women need routine screening mammography, when they need it, and how often they need it.

In screening for colorectal cancer, the tools available to the clinician include testing for fecal occult blood, sigmoidoscopy, colonoscopy, barium enema studies, the developing field of virtual colonoscopy, stool DNA testing, and fecal immunochemical testing. There is a general consensus that in the appropriate aged population screening colonoscopy is worthwhile.

Among the most controversial areas for cancer screening is the role of screening in the detection of early prostate cancer. There was rapid general acceptance of the use of physical examination and prostate-specific antigen (PSA) testing to ascertain the presence of early prostate cancer. On further consideration, however, many investigators fear that we have, as a society, successfully identified large numbers of

men who would never have been diagnosed with symptomatic prostate cancer in their remaining lifetime or required treatment. The appropriate role of screening for prostate cancer has generated as much controversy as the debate over mammography in breast cancer. A considerable amount of anxiety has been generated in asymptomatic men compulsively watching their PSA levels. The U.S. oncology community has engaged in a very public debate over a 2012 recommendation of the U.S. Preventive Services Task Force ("USPSTF") to rescind a recommendation in favor of the widespread use of PSA for screening. The task force report in 2012 advised that healthy men should no longer receive the PSA blood test to screen for prostate cancer because the test does not save lives overall and often leads to more tests and treatments that needlessly cause pain, impotence, and incontinence in many.

The draft recommendation was based on the results of five clinical trials and had the potential to substantially change the care given to men aged 50 years and above. There are 44 million such men in the United States, and 33 million of them have already had a PSA test—sometimes without their knowledge—during routine physicals. As further evidence became available, the USPSTF revised its recommendations and, in 2018, recommended that men between 55 and 69 years discuss with the doctor the risks and benefits of PSA screening and make a decision based on personal values and risk factors. The USPTF does not recommend screening for men aged 70 years and above. Recent studies suggest that the use of PSA, Kallikrein panel, and MRI may be better at detecting high-grade prostate cancer.[87]

It is likely that, in the future, efforts will be expended to identify that subset of men with biologic markers suggesting that they might benefit from PSA screening and, if diagnosed, treatment compared to those who are "best left alone."

Far less controversial, however, has been the use of the Pap test for early detection of carcinoma of the cervix. Where properly used, the test appears to have resulted in a decrease in mortality from this malignancy.

Cancer chemoprevention is defined as a pharmacologic intervention with specific nutrients or other chemicals intended to suppress or reverse carcinogenesis and to prevent the development of invasive cancer. Trials involving chemopreventive therapy require large numbers of individuals who are at high risk for malignancy because of family history, carcinogenic exposure, or the presence of a mutated gene. The ideal chemopreventive agent would have minimal side effects because it would be given to a considerable number of people, none of whom have cancer. Chemoprevention trials differ from other types of cancer prevention studies and from therapeutic studies in important ways. The participants are healthy volunteers, and one seeks to measure a reduction in morbidity and mortality in the long run. Chemoprevention trials are, by definition, large. There are strict enrollment criteria

that reflect the group of interest. These studies are often long term and expensive. To date, the best studied agents in human preventive trials are retinoids (the natural derivatives and synthetic analogs of vitamin A) and one member of the carotenoid class, β-carotene. The results are mixed.[88]

INTRODUCTORY RADIOBIOLOGY

The Concept of Dose in Radiation Therapy

The concept of "dose" is fundamental to medical therapeutics. The dictionary definitions of "dose" include "a quantity of a medicine or drug taken or recommended to be taken at a particular time" ("Johnny took his dose of cough medicine."); "an amount of ionizing radiation received or absorbed either at one time or over a specified period of time" ("Johnny received a dose of 50 Gray of radiation in five weeks."); or "a quantity of something analogous to medicine", ("Let's give Johnny a dose of his own medicine. That will teach him not to misbehave.")

Radiation therapy was administered to human patients well before there were any standardized concepts of radiation dose. The early radiation oncologists learned that the production of a skin reaction to ionizing radiation depended on four physical factors:

- The **voltage** of the x-ray tube, which was originally measured by the number of inches of spark gap
- The **current** flowing through the x-ray tube, which was measured in milliamperes
- The **focal skin distance** measured in the distance to the patient's skin
- The **time** duration for the administration of the radiation therapy

It was recognized that the first, second, and fourth factors increased the amount of radiation administered but that the third factor reduced the dose because the dose fell off as the square of the distance.

While the relative importance of the four factors was not well understood for many years, the general formula employed was

$$\text{Dosage} = \frac{(\text{milliamperes}) \times (\text{spark gap})^2 \times \text{time}}{(\text{focal skin distance})}$$

Chemical reactions began to be used to estimate the dose in radiation therapy around 1900. Holzknecht developed a "chemoradiometer." Reported in 1902, this device consisted of small discs of KCl and Na_2CO_3, which became discolored when irradiated. The degree of discoloration was associated with dose[89] (Figure 1.11). In 1904, Sabourand and Noire described a "radiometer" where small pastilles of compressed barium plastinocyanide varied in color from bright green to deep orange based on the dose of radiotherapy.[90] By correlating the dose with the effects on the patient, one could infer a "minimum skin erythema dose," for example.

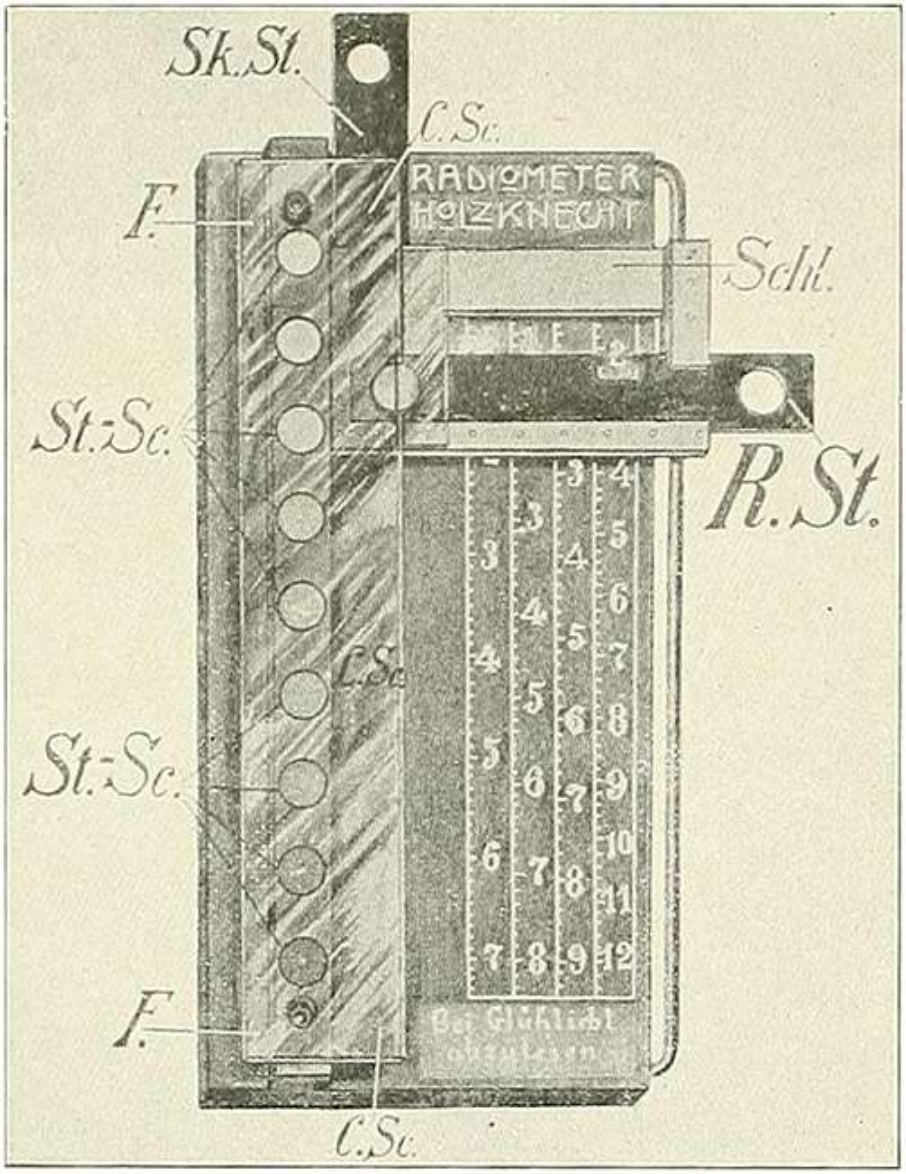

FIGURE 1.11 This is a Holznecht Radiometer as illustrated in I. Seth Hirsch's 1920 textbook *The Principles and Practice of Roentegenological Technique*. The pastille exposed to an unknown dose of radiation exposure is matched to the tint of a standard tint of a known radiation dose exposure (C. Sc. = reddish brown color band, under which was a semicircular piece of screen, carried on Sk.St. is placed; R.St. holds the exposed pastille with the unknown dose exposure; R.St. slides on Schl. until both semicircles form a circle of the same color.) The scale is read on the notch of R.St. The other scales are for pastille pieces, which have slightly different initial tints. (Reading Room 2020/Alamy Stock Photo.)

Over time, radiation therapy came to be reported in a unit called a "Roentgen" or "R." It was defined as "the amount of radiation producing one electrostatic unit of positive or negative ionic charge in one cubic centimeter under standardized conditions." This was replaced by a "rad" or "radiation absorbed dose" or "r." It was defined as *a unit of absorbed dose of ionizing radiation equal to an energy of 100*

ergs per gram of irradiated material. The rad was succeeded by the centigray or cGy. A centigray is 0.01 of a Gray (Gy), and the Gray is defined as the absorption of 1 J of energy from ionizing radiation by 1 kg of matter. A Roentgen, obviously, was named in honor of the discoverer of the x-ray: Wilhelm Conrad Roentgen. The Gray was named in honor of Louis Henry Gray, a pioneer in the measurement of radiation and its effects on living tissue.

In modern practice, a typical description of external beam radiation therapy (EBRT) dose might be "the patient received 2 Gy per day, five days per week, to a total dose of 60 Gy in six weeks." An example of a description of brachytherapy dose is that "the patient received a dose of 4 Gy to a depth 2 millimeters below the vaginal surface, five days per week via a radioactive implant, for a total dose of 28 Gy in seven brachytherapy sessions."

DNA Damage by Ionizing Radiation

The biologic effects of ionizing radiation are largely the result of DNA damage, which is caused directly by ionization within the DNA molecule or indirectly from the action of chemical radicals formed as a result of local ionization in water. The general forms of DNA damage are base damage, DNA-protein cross-links, single-strand breaks, double-strand breaks, and complex combinations of all of these.[91]

Normal mammalian cells repair a significant proportion of radiation-induced DNA damage. Long-term biologic consequences are the result of those injuries, which are irreparable or misrepaired. The cell will attempt to repair DNA injury induced by radiation via several pathways. Key genes are involved in repair of double-strand DNA breaks.

There is some evidence that clustered local damage to DNA, such as a double-strand break accompanied by additional breaks, base damage, or DNA-protein cross-links, is especially difficult for cells to repair. Even lesions that are potentially repairable may be repaired incorrectly (misrepaired) if lesions are accumulating very rapidly because of high-dose rate (HDR) radiation or if the cell enters M phase and attempts DNA synthesis while repair is in progress. Conversely, radiation, which is given at a low-dose rate (LDR) or is highly fractionated, provides an opportunity for repair of radiation-induced lesions and recovery from injury. DNA damage that is not repaired may cause cell death, prevent cell division, or permanently give rise to heritable lesions, such as point mutations, small and large deletions and translocations of DNA sequences, and a wide variety of DNA aberrations.[92],[93]

Effects of Irradiation on Cells

The radiation-induced lesion most detrimental to cell survival involves damage to the DNA. This may result in either mitotic cell death or apoptosis. If the cell

survives and repairs the damage, it may achieve a normal status. If there is misrepair, it may be associated with permanent mutations and induction of carcinogenesis. The physical interaction of ionizing radiation with the molecular infrastructure of the cell results in chemical reactions that occur within 10^{-18} to 10^{-3} seconds[94] (Figure 1.12). Absorption of the photon energy destabilizes the target molecule, resulting in molecular breaks or release of energetic electrons and secondary energy-attenuated photons, which may interact with other cellular molecules, leading to a chain reaction that produces a variety of short-lived ions and chemically unstable free radicals. The most common radicals are produced from the radiolysis of cellular water and include hydroxyl radicals (•OH), hydrated electrons (e_{aq}), hydrogen atoms ($H^{\bullet}$), and hydrogen peroxide (H_2O_2). Free radicals are extremely unstable and interact nearly instantaneously with neighboring molecules to produce chemically stable lesions. This process can be modified by free radical scavengers or by oxygen, which has opposing effects on the number of stable lesions and the level of cellular radiosensitivity. However, if all factors remain constant, the permanent damage is linear with dose. Experiments in which the cell nucleus and the cytoplasm were selectively irradiated show that the dose required in the cytoplasm to kill a cell is larger than doses required in the nucleus.[95],[96] It is generally accepted that most target molecules for radiation-induced cell killing are located in the nucleus and involve damage to the DNA.[97] However, other targets such as the cell membrane and the membrane of mitochondria have been proposed as the origin of apoptotic cascades that follow irradiation also contributing to cell death (Figure 1.13).

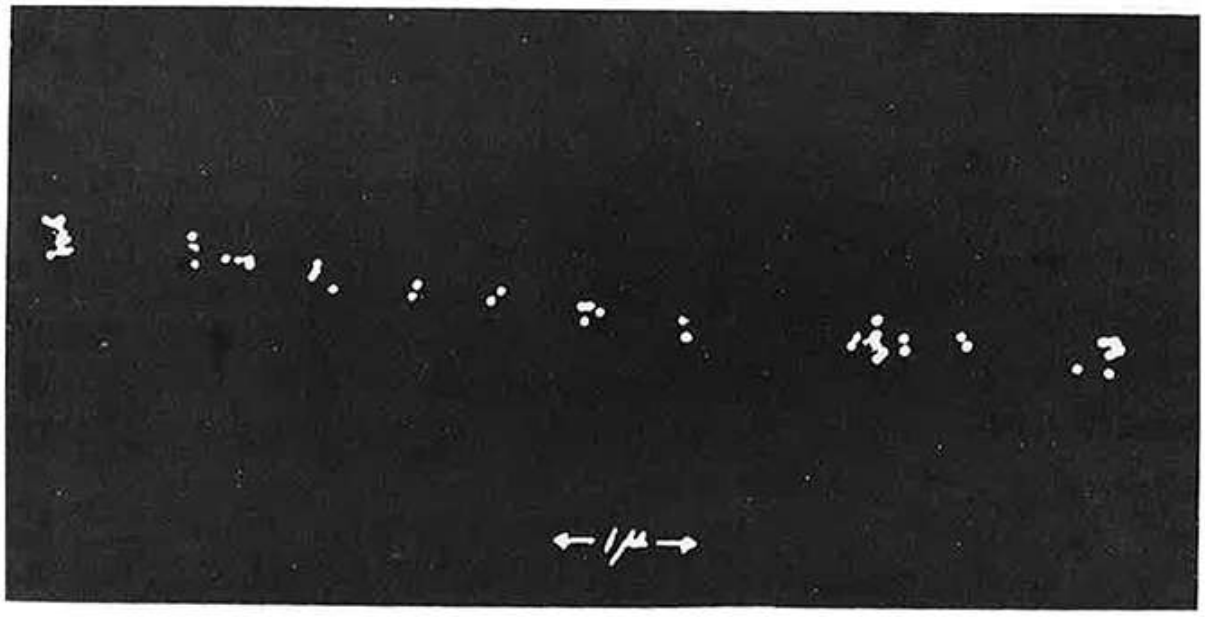

FIGURE 1.12 This cloud chamber photograph of a fast electron illustrates that ionization occurs in clusters. (Reprinted from Bacq ZM, Alexander P. *Fundamentals of Radiobiology*. 2nd ed. Pergamon Press; 1961. Copyright © 1961 Elsevier. With permission.)

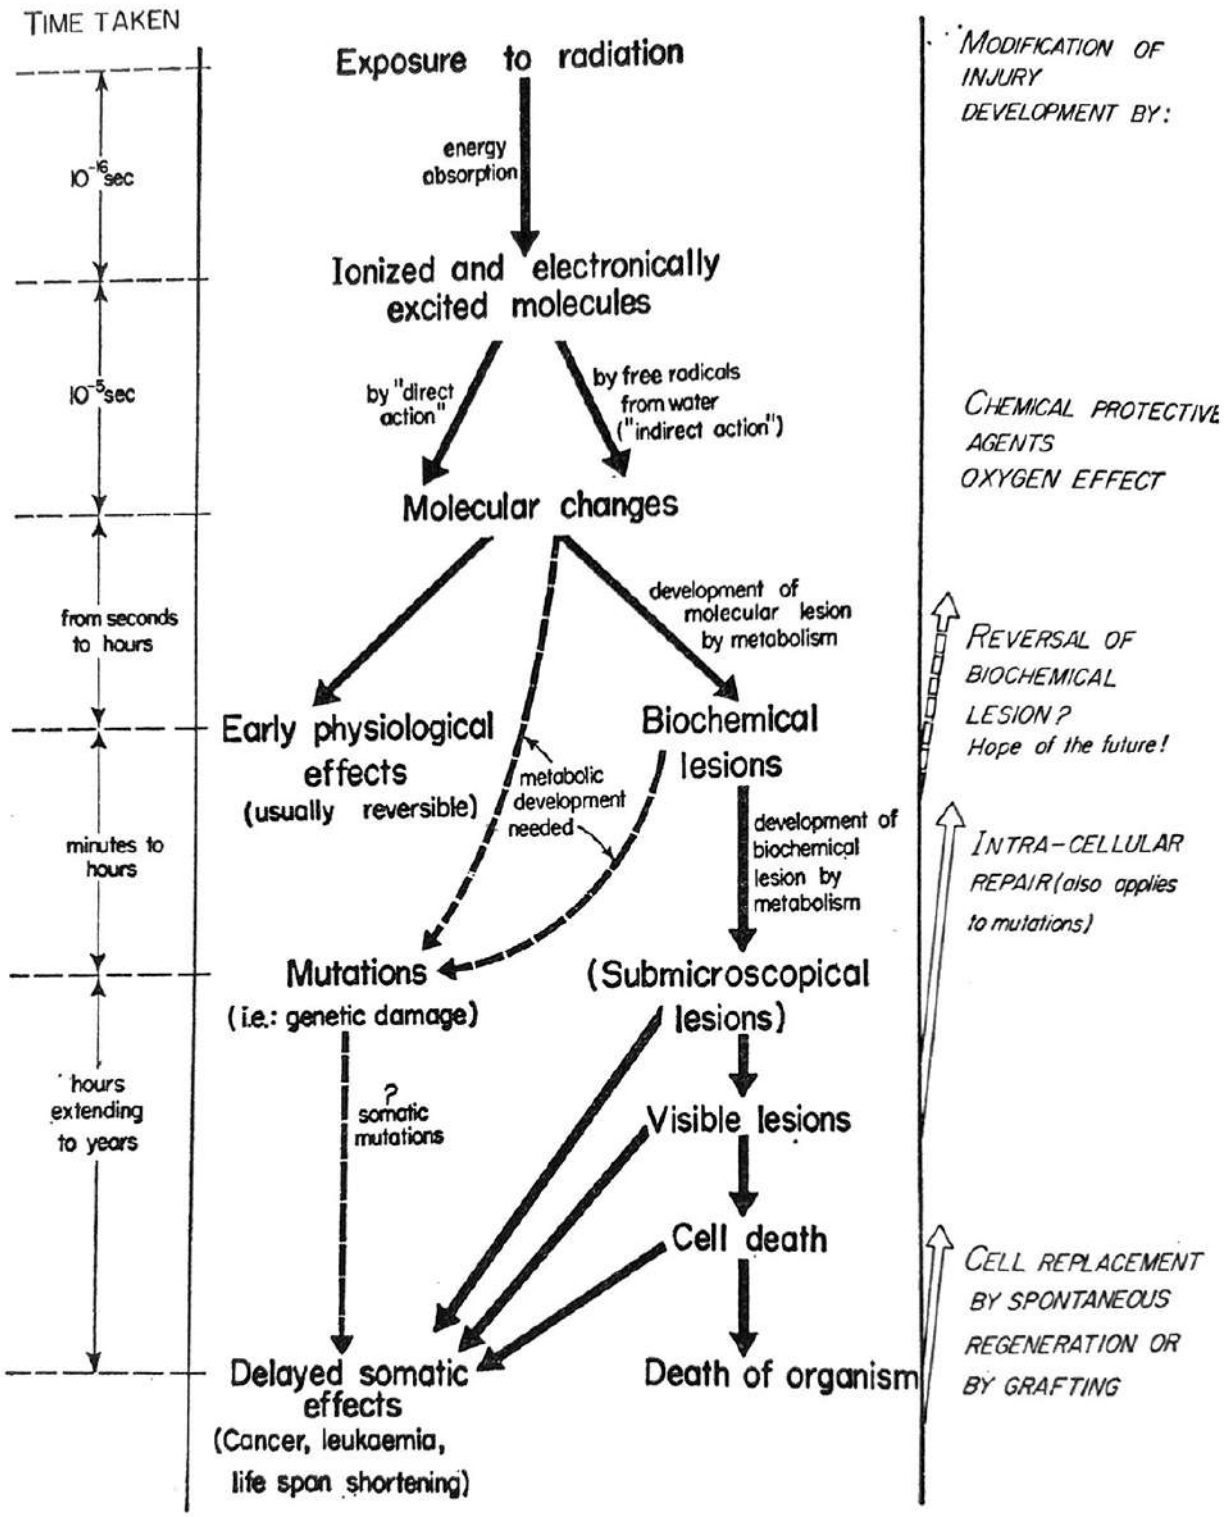

FIGURE 1.13 In their 1961 *Fundamentals of Radiobiology*, second edition, Z. M. Bacq and Peter Alexander managed, in a single diagram, to describe the stepwise development of ionizing radiation's injury to a cell and an organism. Our knowledge has grown, but the principles described by Bacq and Alexander over 60 years ago remains the same. (Reprinted from Bacq ZM, Alexander P. *Fundamentals of Radiobiology*. 2nd ed. Pergamon Press; 1961. Copyright © 1961 Elsevier. With permission.)

In many cells, radiation-induced lethality is not instantaneous because cells continue to function and even undergo several divisions before final mitotic death occurs. Noncycling lymphocytes, thymocytes, and hematopoietic cells were shown to undergo an interphase cell death without progressing through the mitotic phase of the cell cycle.[98] Two patterns of morphologic changes are associated with cell death in mammalian cells. Cell necrosis, which is degenerative, is the most usual type of cell damage. Necrotic cell death results from collapse of cellular metabolism and depletion of its adenosine triphosphate storage. The final events of necrosis involve membrane rupture, loss of lysosomal enzymes, degradation of nuclear chromatin, and karyolysis. The other process of radiation-induced cell death is apoptosis. Programmed cell death, or apoptosis, is a physiologic process that involves a series of characteristic, genetically controlled steps. These include chromatin condensation and segmentation, fragmentation of the nucleus into apoptotic bodies, cell shrinkage, and loss of cellular contact with neighboring cells. Apoptosis culminates in the engulfment of the cell by neighboring cells, such as macrophages, without a concomitant inflammatory response. Apoptosis occurs spontaneously in various solid tumors and contributes to the balance between tumor cell gain and cell loss.[99]

Within minutes after irradiation, signal transduction pathways mediated by protein kinase C and tyrosine kinase are stimulated. Genes and enzymes involved in genetic control of radiation damage repair are activated, stress genes are induced, and growth factors and cytokines that modulate response of mammalian cells to ionizing radiation are activated. Radiation-induced stimulation is probably critical to induction of many genes and proteins, including early response genes, which, in turn, activate other genes, including those for tumor necrosis factor, fibroblast growth factor, and TGF. In addition, new proteins, such as tissue plasminogen activator, are synthesized. This cascade of gene activation and transcription and protein synthesis is related to key cellular functions that the cell invokes in an attempt to survive a dose of radiation.[100-109]

Modifiers of Radiation Response

Several approaches have been used to enhance the therapeutic ratio in radiation therapy:

1. *Physical modifiers of low linear energy transfer (LET) radiations*. Intensity-modulated proton therapy (IMPT), photon therapy, EBRT, intensity-modulated radiation therapy (IMRT), three-dimensional (3D) treatment planning, respiratory-gated radiation therapy, improvements in anatomic and functional imaging, the increasing power of computer hardware and software, and treatment machine improvements have led to better photon, electron, and proton dose distributions; less side scatter; less differential absorption in the bone and

normal tissues; and, with charged heavy particles, selective energy deposition at specific depths.

2. *High LET radiations*. Tumor hypoxia and cells residing in relatively resistant phases of the mitotic cycle are less likely to cause unsatisfactory clinical results with neutrons, pi mesons, and heavy ions than with standard radiation doses delivered with low LET beams. The risk of adverse normal tissue reactions with high LET radiation, however, is significant.[110]
3. *Hyperbaric oxygen or tourniquet techniques*. These techniques involve the use of increased oxygen tension to improve the effects of irradiation on the tumor or the use of a tourniquet to produce severe hypoxia in the surrounding normal tissues so that higher irradiation doses can be delivered.[104] Theoretically, these approaches yield better tumor control without damaging normal tissues. Interest in the tourniquet technique waned years ago. Some investigators continue to evaluate hyperbaric oxygen. The logistics are formidable, and clinical trials have been inconclusive.[111-114]
4. *Hypoxic and other radiosensitizers*. Compounds with electron affinity, from the nitroimidazole group, theoretically produce free radicals in a manner similar to that of oxygen, selectively sensitizing hypoxic cells to radiation. Misonidazole (RO-07–0582) was evaluated in numerous clinical trials by the RTOG, with no evidence of clinical efficacy; however, in the Danish Head and Neck Cancer trial, there was a highly significant survival benefit in the subgroup of patients with pharynx tumors.[108,109] There are other radiosensitizers under study.[115-117]
5. *Perfluorocarbons*. These agents are administered in emulsion (they are insoluble in water) in sufficient concentrations coupled with inhalation of 95% to 100% oxygen to enhance oxygen transport and release in the presence of low oxygen tension. Their potential application in the treatment of patients with cancer was evaluated.[118,119] Interest in the technique waned.
6. *Cytotoxic agents*. Actinomycin D, doxorubicin, 5-fluorouracil, cyclophosphamide, taxanes, cisplatin, methotrexate, bleomycin, and others have been shown to interact with radiation in several forms to maximize tumor cell killing.[120-126]
7. *EGFR*. EGFR, a member of the ErbB family of receptor tyrosine kinases, is activated in several epithelial cancers. Radiotherapy increases the expression of EGRF in cancer cells, and blockade of EGFR signaling can sensitize cells to radiation. Cetuximab is a chimeric monoclonal antibody that targets EGFR. The drug appears to improve locoregional tumor control and survival in locally advanced squamous cell carcinoma of the head and neck.[127,128]

8. *Radioprotectors*. Sulfhydryl-containing compounds, such as cystine and cysteamine, have been used in animals to protect normal tissues against irradiation. Amifostine (WR-2721), a thiophosphate derivative of cysteamine, has been shown to selectively protect normal tissues, including the bone marrow, salivary glands, and intestinal mucosa, in animals, with little effect on tumor response to irradiation. Amifostine undergoes dephosphorylation by cellular-bound alkaline phosphatase to an active metabolite, WR-1065. This alkaline phosphatase–dependent activation is thought to contribute to selective normal tissue protection because of a higher concentration of alkaline phosphatase in normal tissue. Cytoprotection is believed to be the result of the elimination of free radicals. The compound was widely investigated in phase II and III clinical trials. It is used to reduce the incidence of neutropenia-related fever and infection from drugs like cyclophosphamide and cisplatin and for the reduction of xerostomia in patients with head and neck cancer undergoing radiotherapy. A meta-analysis has shown that amifostine does not reduce overall or progression-free survival in patients treated with radiotherapy or chemoradiotherapy—arguing against amifostine protecting tumor tissue.[129-132]
9. *Hyperthermia*. Heat at temperatures of more than 42.5 °C kills cells by itself or enhances the effects of irradiation and numerous cytotoxic agents. Heat selectively kills cells that are chronically hypoxic, acidotic, and nutritionally deficient—characteristics shared by tumor cells in comparison with the better oxygenated and better nourished normal cells. Furthermore, heat preferentially kills cells in the S phase of the proliferative cycle, which are known to be relatively resistant to irradiation.[133] This topic is addressed in Chapter 27.
10. *FLASH*. Ultra HDR radiation therapy appears to create a favorable therapeutic ratio for sparing normal tissue. The mechanism of action is unclear but may involve tissue depletion of oxygen, vascular effects, immune effects, and/or microdosimetric effects.[134]

Radiosensitivity and Radiocurability

In 1906, Bergonié and Tribondeau[135] formulated a law relating radiosensitivity to reproductive capacity of cells, based on their experiments on rat testis in which they were able to destroy the germinal cells while the interstitial tissue and Sertoli syncytium remained unimpaired. They wrote that "x-rays are more effective on cells which have a greater reproductive activity; the effectiveness is greater on those cells which have a longer dividing future ahead. . . . From this law, it is easy to understand that roentgen radiation destroys tumors without destroying healthy tissues." Fletcher[136] and del Regato[137] felt that this observation, which was interpreted to indicate that radiosensitivity of tumors was linked to that of the mother

organ, did much harm to clinical radiation therapy, leading to the erroneous concept that undifferentiated tumors with mitotic activity were radiosensitive and that more differentiated tumors were radioresistant.

In 1914, Schwarz[138,139] introduced the concept of fractionation by postulating that it was inefficient to deliver the total radiation dose in one treatment because cells were in different states of radiosensitivity and because there was a better chance that multiple exposures could hit the cells in a radiosensitive phase (eg, mitosis). Fractionation was assumed to create a favorable therapeutic ratio because the tolerance of normal tissues increased relative to that of tumors and because malignant cells had a greater reproductive capacity and were, therefore, more likely to be in a radiosensitive phase.

Based on these and other observations, the term *radiocurability* was coined. It refers to the eradication of tumor at the primary or regional site and reflects a direct effect of the irradiation producing logarithmic cell killing; this does not necessarily equate with the patient's cure from cancer. In contrast, *radiosensitivity* is a measure of tumor-radiation response, thus describing the degree and speed of regression during and immediately after radiotherapy. However, for some malignant tumors, no significant correlation exists between the responsiveness of a tumor to irradiation and its radiocurability.

At least four explanations have been considered that could either alone or in combination account for the different radiosensitivities of tumors[140-142]:

1. *Hypoxia*. To explain the spectrum of clinical radioresponsiveness on this basis, it is likely that the less responsive tumors either have a high hypoxic fraction, have failed to reoxygenate during fractionated treatment, or both.[143] Direct oxygen electrode measurements have shown that human cervical cancer, breast cancer, and squamous cell cancers have mean oxygen pressures below those of the surrounding tissue.[144,145] Despite a wide range of values, the oxygen pressure in tumors tends to decrease with increasing tumor size.[146] Although it is not possible to prove that hypoxia is unimportant in conventional radiation therapy, some doubts about its importance have been expressed based on the limited success of neutron therapy or hypoxic cell radiosensitizers.[147-149] Hypoxia can act as an important determinant of selecting tumor cells of a more malignant phenotype that is likely to adversely affect treatment outcome.
2. *Proportion of clonogenic cells*. Proliferating cells are more radiosensitive and have a greater turnover (cell loss) rate. Tumor regression during irradiation may be proportional to the total number of proliferating cells (growth fraction) or the proliferative rate, which may accelerate for certain tumor cells as a result of adaptive processes (accelerated repopulation) during fractionated irradiation.

3. *Inherent radiosensitivity of tumor cells*. Fertil and Malaise[150] and Deacon et al[151] established a positive correlation between the steepness of the initial slope of the oxic cell survival curve for human tumor cells and their response to radiation. The magnitude of differences between cell lines at low doses is sufficient to explain the range of curability observed clinically. Steel and Peacock[152] analyzed human tumor radiosensitivity in light of existing concepts of cell killing based on the linear quadratic (LQ) equation. However, despite encouraging correlations in some studies, these radiobiologic parameters have not been accepted for routine clinical use.
4. *Repair of radiation damage*. Repair of sublethal damage (SLD; split-dose effect) is observed in almost all tumor cell lines.[153-157] Potentially lethal damage (PLD) repair after a single dose varies considerably from one cell line to another and has been reported by Weichselbaum and Little[158] to correlate with clinical radiocurability, with less curable tumors showing the greatest degree of PLD recovery. These repair parameters have not been confirmed in larger clinical experiences to justify their use as predictors of radiotherapy outcomes.

By the 1970s to 1980s, it was observed that there was a correlation between the clinical or pathologic response of a tumor after the completion of irradiation with the ultimate probability of local tumor control.[159] For this analysis to be valid, it was necessary to compare patients with the same initial stage because, in general, more advanced lesions have a greater probability of tumor persistence at the completion of radiation therapy and local recurrence may be more frequent. Barkley and Fletcher[160] reported 82% tumor control in 88 patients with tumors of the oropharynx that had regressed completely at the end of therapy, in contrast to 41% in 237 patients with persistent tumors at the completion of therapy. Sobel et al[161] concluded that local tumor control in head and neck carcinomas could be predicted with the greatest accuracy and consistency 1 to 3 months after the completion of radiotherapy. They noted that the prediction was 80% accurate in favorable tumors (T1 and T2) but decreased to 50% to 60% in more advanced primary lesions; complete tumor clearance was a more accurate predictor of tumor control. This was confirmed for the radiotherapeutic management of N2 (>3 cm) neck disease, where complete clinical resolution of tumor within 8 weeks of completion of irradiation correlated with a less than 90% freedom from neck failures.[162] Modern studies are based on pathologic confirmation of complete tumor response or positron emission tomography (PET) scan response. They show similar results. Depending upon the type of tumor and its stage, there is a debate as to when to get the post-radiotherapy PET scan.

Tumor Radiosensitivity and Predictive Assays

Since the inception of the use of ionizing radiation, many investigators have categorized the response of tumors according to their sensitivity to irradiation. Wetterer[163] in 1913 characterized tumor radiosensitivity based on histologic types, and Paterson[164] divided tumors into three groups: radiosensitive, intermediate, and radioresistant. The first category included germ cell tumors and what were called reticuloses (leukemia and lymphoma); the second included squamous cell and adenocarcinomas; and the third group included soft tissue and bone sarcomas and melanomas. However, depending on the variation in proliferative rates and cell loss, end points for response assessment may vary substantially, as has been pointed out for malignant melanoma.[165]

Attempts have been made to predict the response of tumors to radiation depending on several parameters, such as the assay proposed by Glucksmann[166] consisting of differential cell counts of mitotic, resting, and degenerating cells in biopsy samples from the growing edge of the tumor before and after initiation of radiotherapy. It is generally accepted that tumors contain mixed cell populations of stem cells with differing sensitivity to antineoplastic agents and that therapy can be selected for resistant cell populations or, in the case of certain cytotoxic agents, to induce cellular resistance.[167] Peters et al[168,169] described a predictive assay to assess tumor response in vitro and the difficulties in predicting the probability of tumor control by irradiation in a given patient.

Unfortunately, despite promising correlations between radiosensitivity in vitro and radioresponsiveness of normal tissues and tumors,[170] sufficiently powered predictive assays have not been identified. Given the inherent intertumor variability of predictive parameters, such as SF_2[171,172] or T_{pot},[173,174] and the genetic profile of tumor cells, a single predictive assay is unlikely to carry sufficient predictive power. The incorporation of multiple radiobiologic tumor cell parameters (eg, markers for radiosensitivity and proliferation potential) into tumor control probability (TCP) (see later in this chapter) models appears more promising but awaits broader validation in clinical trials.[175]

Probability of Tumor Control

For many histologic types of cancer, higher radiation doses produce better tumor control. Numerous dose-response curves for a variety of tumors have been published. The first dose-response data were reported for skin cancer by Miescher[176] in 1934; 10 years later, Strandqvist[177] published a dose-response curve for skin cancer. The Strandqvist plots were refined by von Essen,[178,179] who demonstrated from a large skin carcinoma experience that the slopes for 97% tumor control and 3% skin necrosis differed and permitted, through appropriate fractionation schedules also considering the volume of disease, a dissociation of the two endpoints. As

Fletcher[170] pointed out, meaningful dose-response curves can be generated only when a group of homogeneous tumors is given a range of radiation doses, indicating that tumor control is a probabilistic event. For every increment of radiation dose, a certain fraction of cells will be killed; therefore, the total number of surviving clonogenic cells will be proportional to the initial number present and the fraction killed with each dose[180,181] (Table 1.5). Thus, various levels of irradiation will yield different probabilities of tumor control, depending on the extent of the lesion (number of clonogenic cells present) (Box 1.4). For subclinical disease in squamous cell carcinoma of the upper respiratory tract, doses of 45 to 50 Gy will result in disease control in more than 90% of patients.[182,183] Subclinical disease has been referred to as deposits of tumor cells that are too small to be detected clinically and even microscopically but, if left untreated, subsequently may evolve to clinically apparent tumor.[184,185] It must be emphasized that microscopic evidence of tumor, such as at the surgical margin, should not be regarded as a subclinical disease; cell aggregates $10^5/cm^3$ or larger are required for the pathologist to detect them. Therefore, these volumes must receive higher doses of irradiation, in the range of 60 to 65 Gy, in 6 to 7 weeks for epithelial tumors (Figure 1.14). This distinction of disease extent is reemphasized by clinical results, demonstrating the need for irradiating patients with likely subclinical carcinoma to postoperative doses near 60 Gy[186] (Figure 1.15).

TABLE 1.5 VARIOUS LEVELS OF IRRADIATION WILL YIELD DIFFERENT PROBABILITIES OF TUMOR CONTROL, DEPENDING ON THE SIZE OF THE LESION

Cumulative Dose (Gy)	Initial Cell Number	Probability of Survival	Remaining Cell Number
2	1,000,000,000	×0.5 =	500,000,000
4	500,000,000	×0.5 =	250,000,000
6	250,000,000	×0.5 =	125,000,000
8	125,000,000	×0.5 =	62,500,000
10	67,500,000	×0.5 =	31,250,000

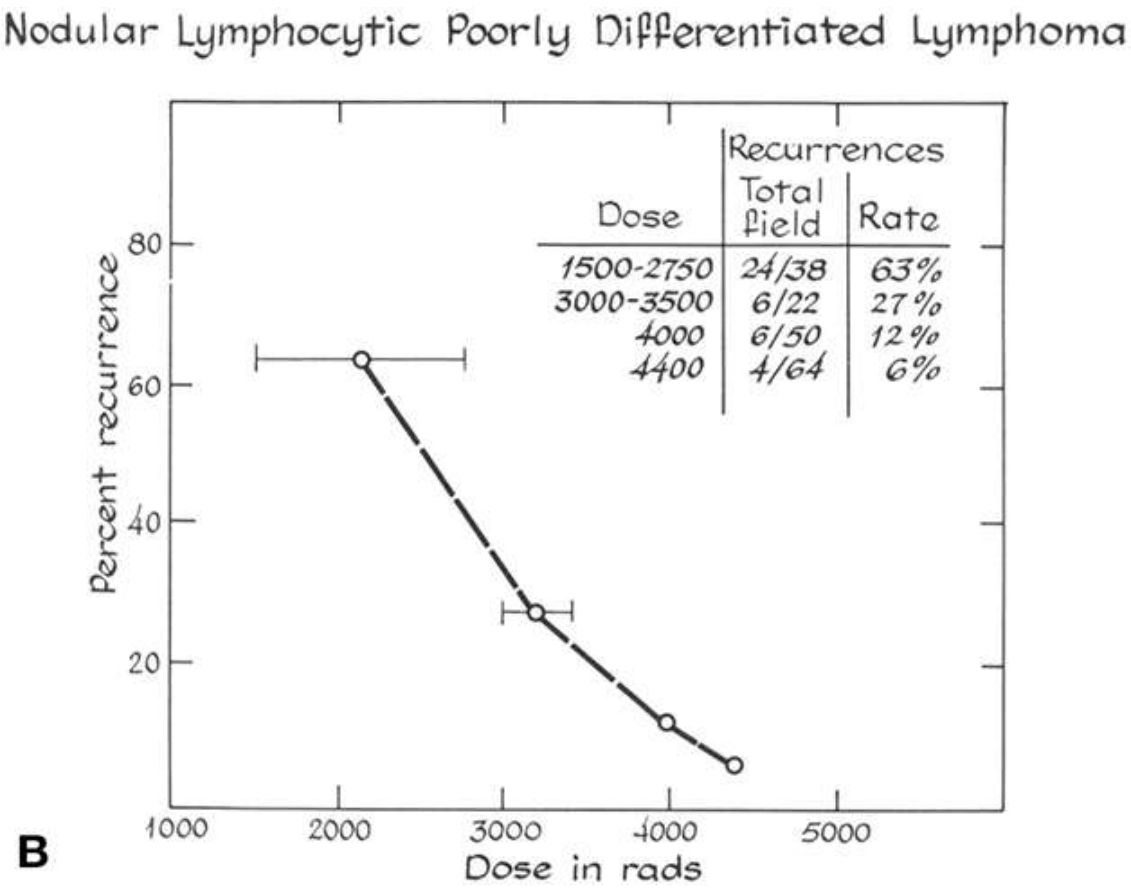

FIGURE 1.14 As a physical, rather than a chemical, modality of cancer treatment, radiation therapy is in a unique position to correlate *dose* with treatment outcomes. If a radiation oncologist says they administered 40 Gy to a tumor, they actually did. The dose of radiation administered is not affected by factors that influence chemotherapy dose to a tumor cell: blood flow, interstitial tumor pressure, membrane transport, and/or speed of the body's excretion or metabolism of the drug. Here are two examples of radiation dose-response relationships: A. The dose that yields a local control in 50% of irradiated tumors (TCD_{50}) in 16 experimental animal dose-response curve studies shows tumor control as a function of dose and tumor volume. (Reprinted with permission from HD Suit. Radiation biology: a basis for radiotherapy. In: Fletcher GH, ed. *Textbook of Radiotherapy*. Lea & Febiger; 1966:77.) B. This is an example of a classic clinical radiation dose-response relationship for local control of a solid tumor. Zvi Fuks and Henry Kaplan, in 1973, analyzed the local recurrence rate after initial radiotherapy in 198 patients with nodular and diffuse non-Hodgkin lymphoma. In this example, Figure 2 from their paper, they plot the probability of tumor recurrence on the y-axis for nodular poorly differentiated non-Hodgkin lymphoma. On the *x*-axis, they show the dose of external beam radiotherapy. This is an example of an attempt to correlate tumor histology, radiation dose, and local control for the purpose of identifying the recommended treatment dose. (Used with permission of Radiological Society of North America from Fuks Z, Kaplan HS. Recurrence rates following radiation therapy of nodular and diffuse malignant lymphomas. *Radiology*. 1973;108(3):675-684; permission conveyed through Copyright Clearance Center.)

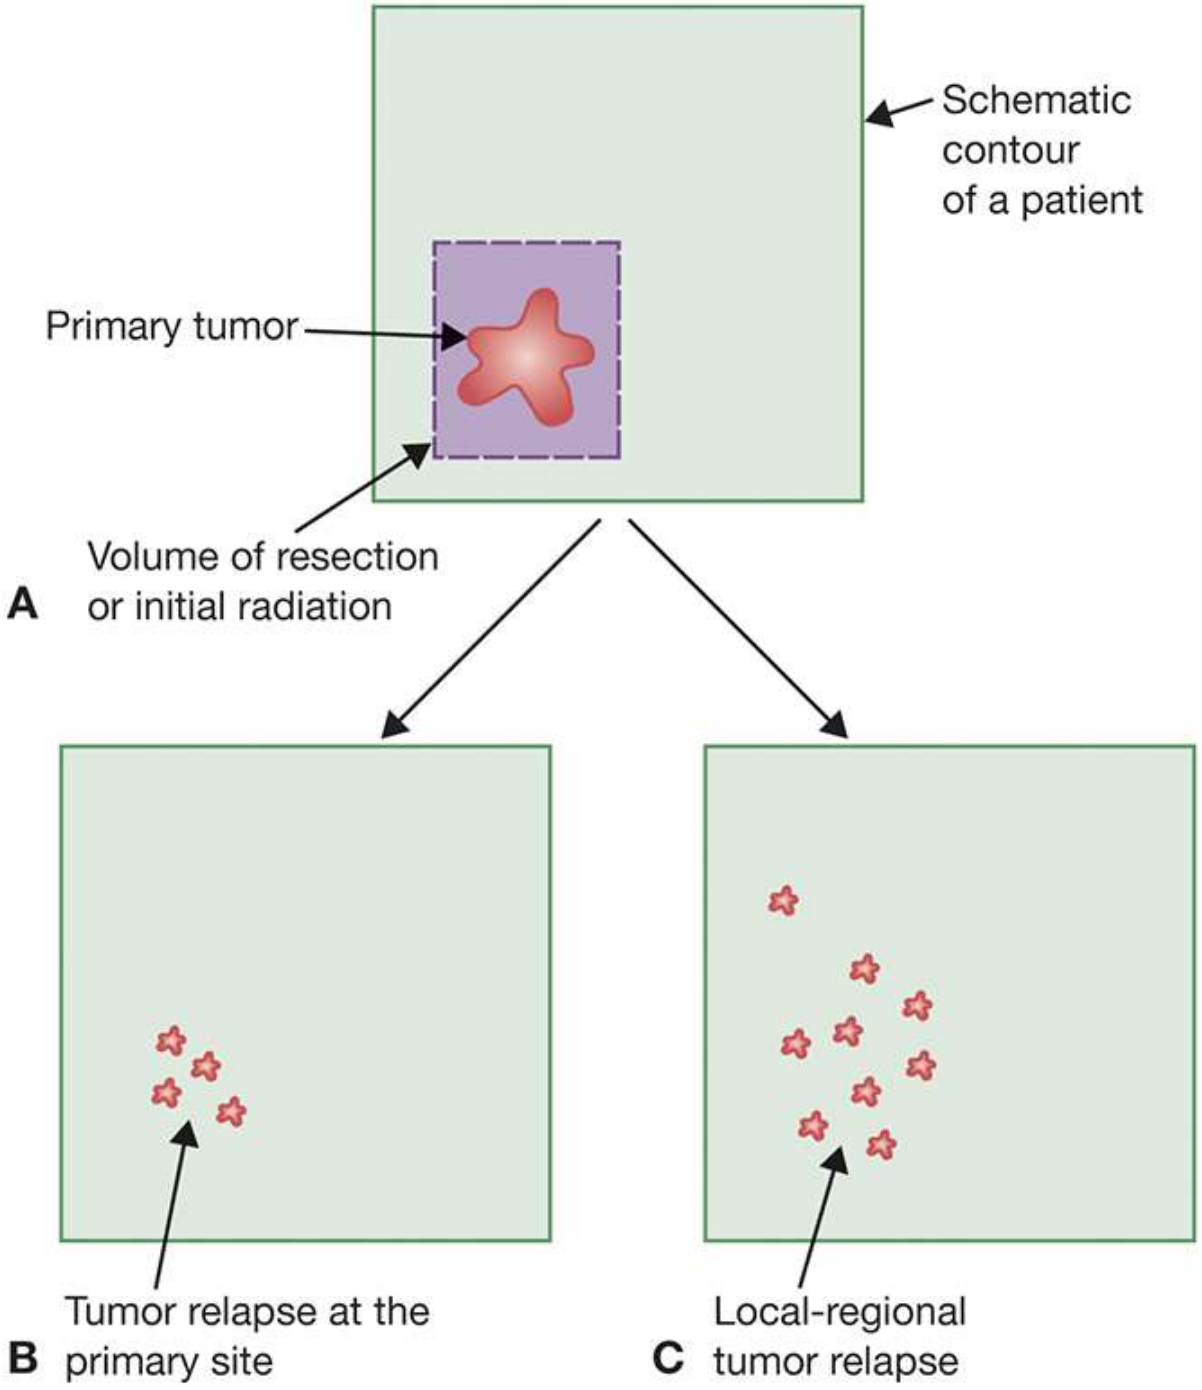

FIGURE 1.15 A. A pattern of failure analysis is useful to improve the treatment of malignancies. B. If the tumor after surgery and/or radiotherapy tends to relapse at the primary site within the volume treated, it would suggest that the local therapy is insufficiently intense. C. If, however, there is a locoregional tumor relapse, it would suggest that the initial surgery or radiotherapy field size is insufficient to cover the microscopic extension of disease that has the potential to be controlled. A pattern of failure as shown in panel C is not, by itself, sufficient to make the case for extended-field radiation. One must have a pattern of failure such as that which is seen in panel C and also be able to show that intervention with large field irradiation can alter that pattern in a favorable manner.

Box 1.4

Logarithmic Cell Kill

Among the simplest exercises a radiation oncologist–in-training can undertake is the creation of a table of logarithmic cell kill. At first, such an exercise seems trivial. The effort expended on this somewhat tedious exercise will, however, be repaid many times over.

Let us assume that we have a tumor that follows a typical cell survival curve. These tumor cells have a 50% probability of cell survival after a radiation dose of 2 Gy. If we assume, for the purpose of this exercise, that there are no changes in the probability of cell kill wrought by changes in tumor oxygenation, pH, or other factors during the course of treatment; that there is no accelerated repopulation; and that only the simplest conditions apply (ie, that there is 50% kill for each dose), then we can create a table showing the number of cells killed and the number of cells remaining after each dose (Table 1.5).

Let us assume that we begin with a relatively small tumor (ie, a spherical tumor a bit >1 cm in diameter containing, say, 10^9 cells). At each dose of 2 Gy, 50% of the cells are killed. Thus, after the first dose, 500 million cells are killed and 500 million cells remain. At each successive dose, 50% of the cells are killed. Therefore, by the end of the course of radiation, very few cells are killed with each individual dose.

One can see, from going through the exercise, that even for a very small tumor, the number of initial cells is very large and the marginal killing of the absolute number of cells, with the last few doses, is small. It is not surprising, therefore, that for a tumor of average radiation sensitivity, quite a high dose of radiation is required.

Obviously, the exercise would change if we were to use a different radiation dose per fraction, producing a different probability of survival, or if the intrinsic radiosensitivity of the tumor cell line were different and the probability of survival were different.

Based on Suit HD. Radiation biology: a basis for radiotherapy. In: Fletcher GH, ed. *Textbook of Radiotherapy*. Lea & Febiger; 1966.

For clinically palpable head and neck tumors, doses of 65 (for T1) to 75 to 80 Gy or higher (for T4 tumors) are required at 2 Gy/day using five fractions weekly. This dose range and probability of tumor control have been documented for squamous cell carcinoma and adenocarcinoma.[187-189] Even with preoperative irradiation, the dose effect on the probability of tumor control can be documented.

Baclesse[190] introduced the concept of different doses of irradiation for various portions of the tumor. The higher dose administered through small portals to residual disease is called a *boost*, which is delivered in an effort to achieve the same probability of tumor control as for subclinical aggregates.[191] One consequence of the concepts discussed earlier is the use of portals that are progressively reduced in size. This *shrinking-field* technique administers higher radiation doses to the entire gross tumor where more clonogenic cells (including hypoxic cells) reside, relative to lower doses to tissues in the immediate proximity of the clinically apparent (gross)

tumor. The tissues making up the "tumor margin" contain a lower number of tumor clonogens that are better oxygenated (see Figure 1.16).

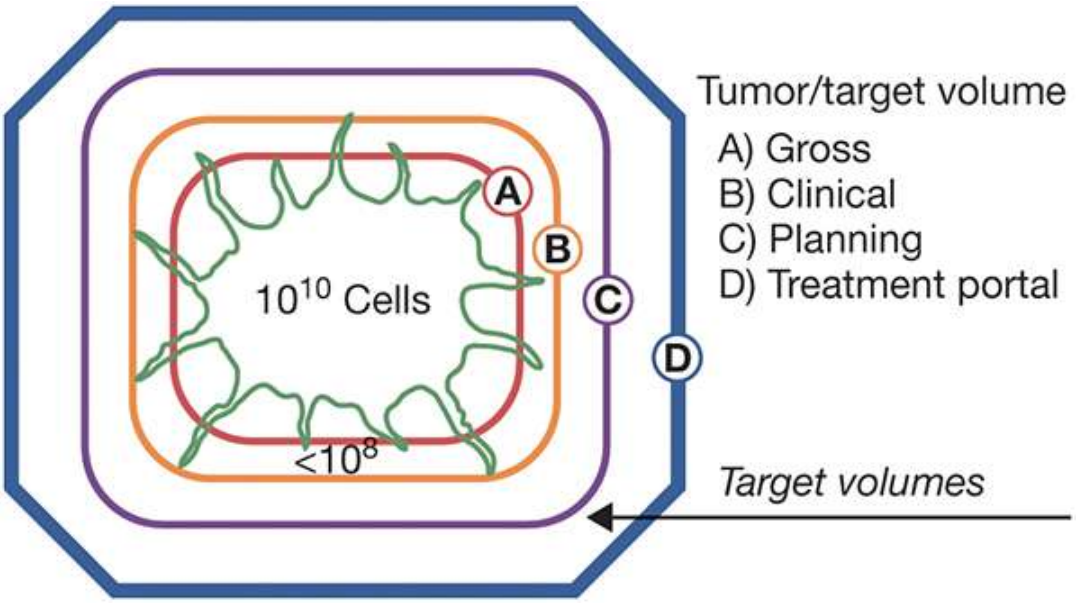

FIGURE 1.16 Schematic representation of "volumes" in radiation therapy. The treatment portal volume includes the tumor volume, potential areas of local and regional microscopic disease around the tumor, and a margin of surrounding normal tissue. (Modified with permission from Perez CA, Purdy JA. Rationale for treatment planning in radiation therapy. In: Levitt SH, Khan FM, Potish RA, eds. *Levitt and Tapley's Technological Basis of Radiation Therapy: Practical Clinical Applications*. 2nd ed. Lea & Febiger; 1992.)

The Impact of Local Tumor Control on Survival

Systemic chemotherapy, immunotherapy, and molecularly targeted therapy have been emphasized as therapies that could improve survival of cancer through control of systemic metastatic disease. The effect of locoregional tumor control on patient survival has also been emphasized repeatedly.[192] Clinical experiences and randomized trials demonstrate for cancers with high metastatic potential, such as breast, prostate, and lung, that improved locoregional control by radiotherapy with or without chemotherapy enhances overall survival. This has revived the interest in locoregional radiotherapy as a survival-prolonging treatment modality, also confirming earlier clinical experiences in patients with carcinoma of the lung, prostate, and uterine cervix.

Because of the emphasis on control of systemic disease, assessment of the importance of locoregional tumor control in patients with malignant tumors has been relatively underemphasized. In a large proportion of patients with cancer seen in the United States, locoregional recurrence is just as prevalent (69% of patients dying

with locoregional disease) as distant metastases. A large proportion of patients (50%) have both locoregional recurrence and distant metastases.

Clinical data demonstrate that tumor persistence after initial therapy does, because of tumor progression, carry as poor a prognosis as treatment of a more advanced cancer. In addition, radiotherapy has been shown, for tumors with high metastatic potential such as breast, prostate, and lung, to prolong overall survival if higher radiation doses are delivered and achieve improved local control rates.[193]

RADIATION THERAPY AND THE RISK OF INJURY TO NORMAL TISSUE

In 1936, Herman Holthusen (Figure 1.17) published a landmark paper in *Strahlentherapie*.[194] He described uncomplicated tumor control on the one hand and normal tissue injury on the other hand. Holthusen observed that the dose-response relationship for both tumor control and normal tissue injury had a sigmoidal shape. At very low doses, there was little or no effect. At very high doses, both tumor control and normal tissue injury probabilities plateau. At intermediate doses, the slope of the curve is steep, and there is a marked dose-response relationship (Figure 1.18).

FIGURE 1.17 Hermann Holthusen (1886-1971).

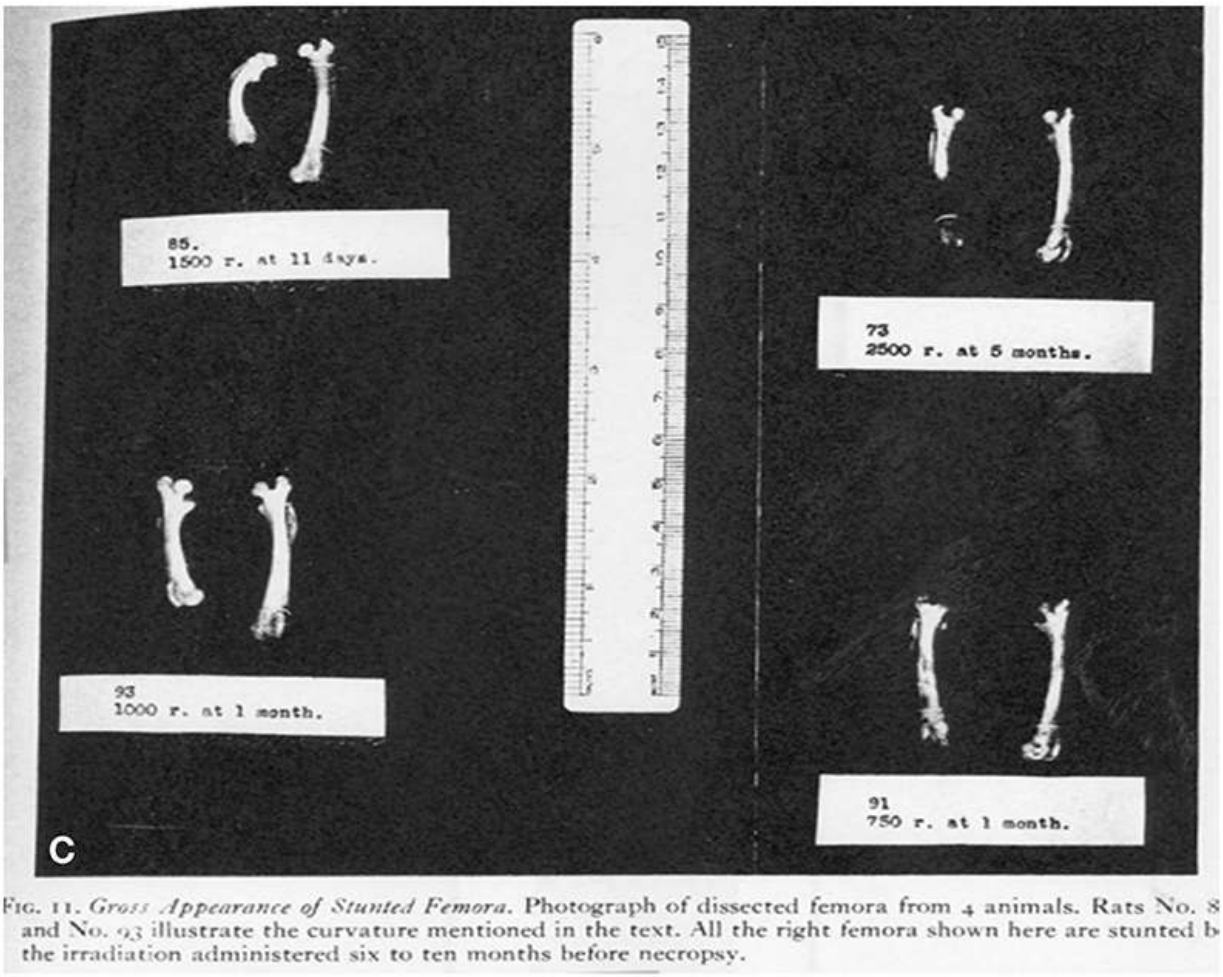

FIG. 11. *Gross Appearance of Stunted Femora.* Photograph of dissected femora from 4 animals. Rats No. 8 and No. 93 illustrate the curvature mentioned in the text. All the right femora shown here are stunted b the irradiation administered six to ten months before necropsy.

FIGURE 1.18 Radiation oncologists quickly ascertained that radiation could cause normal tissue injury. If there ever were examples of "one picture is worth a thousand words," they would include this demonstration by (A) Georg Perthes. B. In 1903, Perthes published this dramatic picture showing the ability of radiation to arrest tissue growth. He observed stunting of the growth of a chicken's wing exposed to radiation while a chick. (A, B. From Perthes G. Über den Einfluss der Röntgenstrahlen auf epitheliale Gebilde. *Arch Kiln Chir*. 1903.). (C) A graphic demonstration of femoral bone growth arrest in albino rats following a single dose of 750, 1,000, 1,500, or 2,500 Roentgen at 1 month of age by Charles Hinkel, MD, Med Sc D, and reported in 1942. (C. From Hinkel CL. The effect of roentgen rays upon the growing long bones of albino rats. I. Quantitative studies of the growth limitation following irradiation. *Am J Roentgenol Radium Ther Nucl Med*. 1942;47:439-457, Figure 11. Reprinted with permission from the *American Journal of Roentgenology*.)

The radiation oncologist seeks to find a "sweet spot" where there is a high probability of tumor control and a low risk of normal tissue injury (Figures 1.19-1.23). This "sweet spot" only exists if there is a separation between the two sigmoidal-shaped curves.

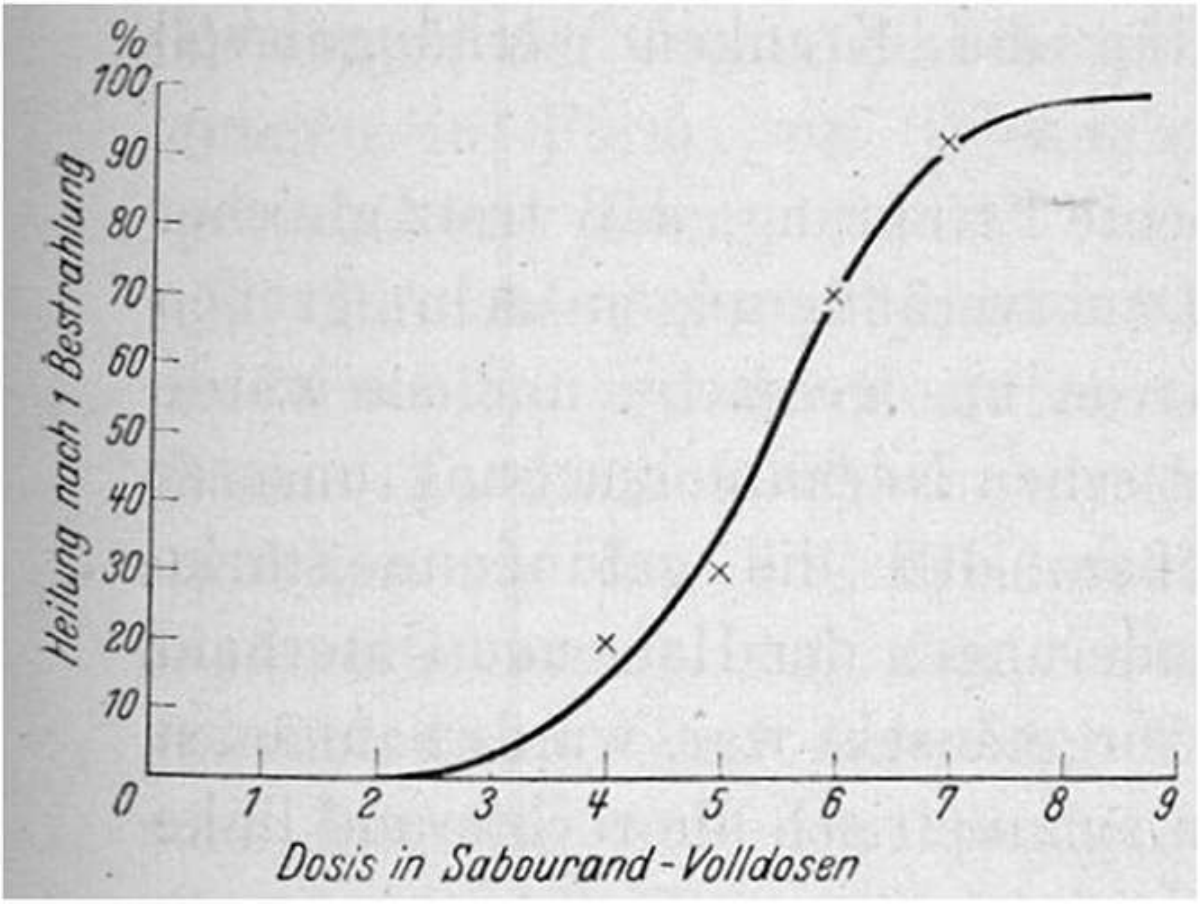

FIGURE 1.19 This is figure 1 from Holthusen's 1936 paper. The dose of radiation is indicated on the *x*-axis in Sabourand units. The concept of Sabourand units was described earlier in this chapter in the section on the origin of the concept of dose in radiation therapy. The *y*-axis shows the percentage cure rate of a tumor with a single fraction of radiation therapy. The curve is sigmoidally shaped. (Used with permission of Springer Nature BV from Holthusen H. Erfahrungen über die Vertraglichkeitsgrenze fur Röntgenstrahlen und deren Nutzanwendung zur Verhütung von Schäden. *Strahlentherapie*. 1936;57:254-269, Figure 1; permission conveyed through Copyright Clearance Center.)

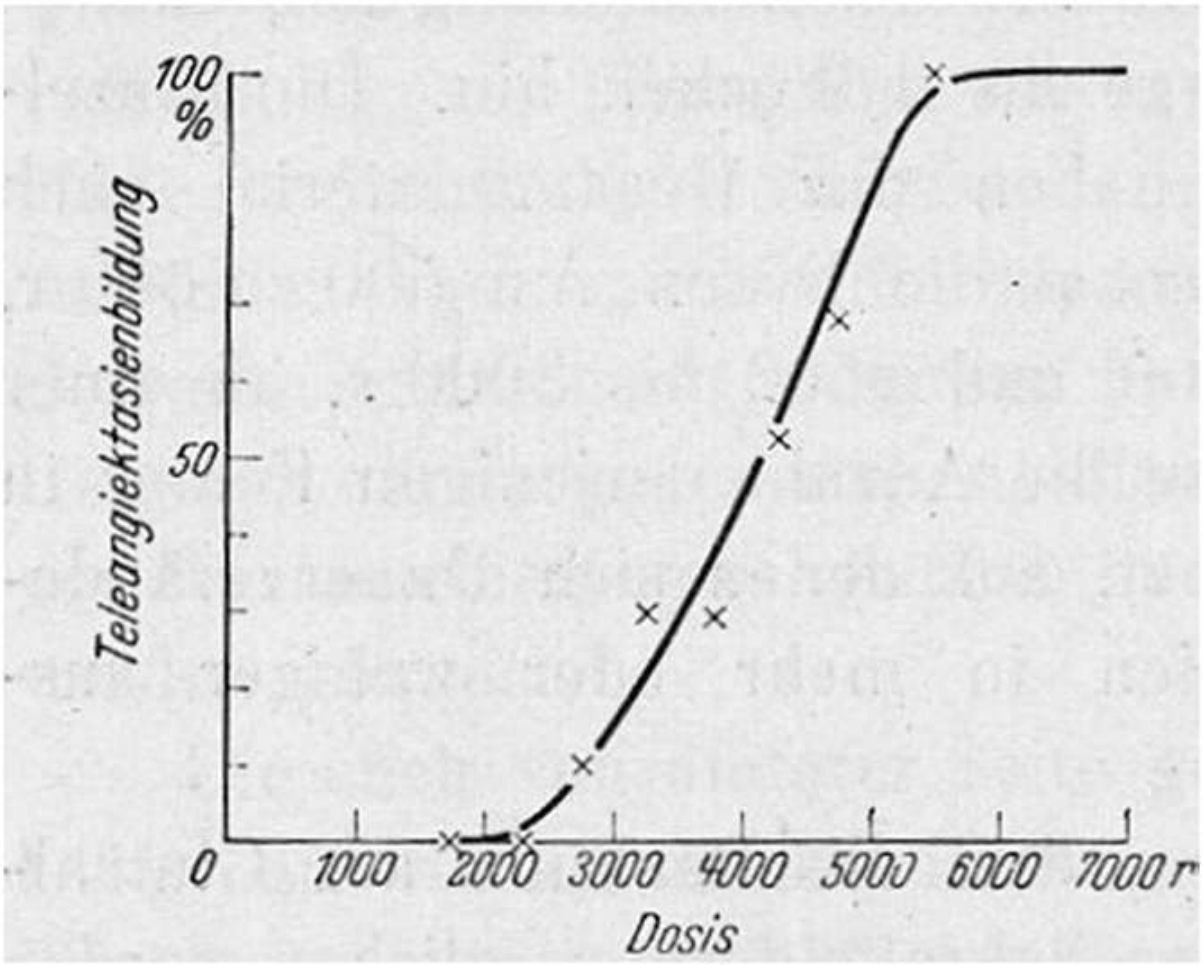

FIGURE 1.20 This is figure 3 from Holthusen's 1936 paper. The dose of radiation is shown on the *x*-axis. The probability of telangiectasis on the y-axis. Once again we see a sigmoidal-shaped curve. (Used with permission of Springer Nature BV from Holthusen H. Erfahrungen über die Vertraglichkeitsgrenze fur Röntgenstrahlen und deren Nutzanwendung zur Verhütung von Schäden. *Strahlentherapie*. 1936;57:254-269, Figure 3; permission conveyed through Copyright Clearance Center.)

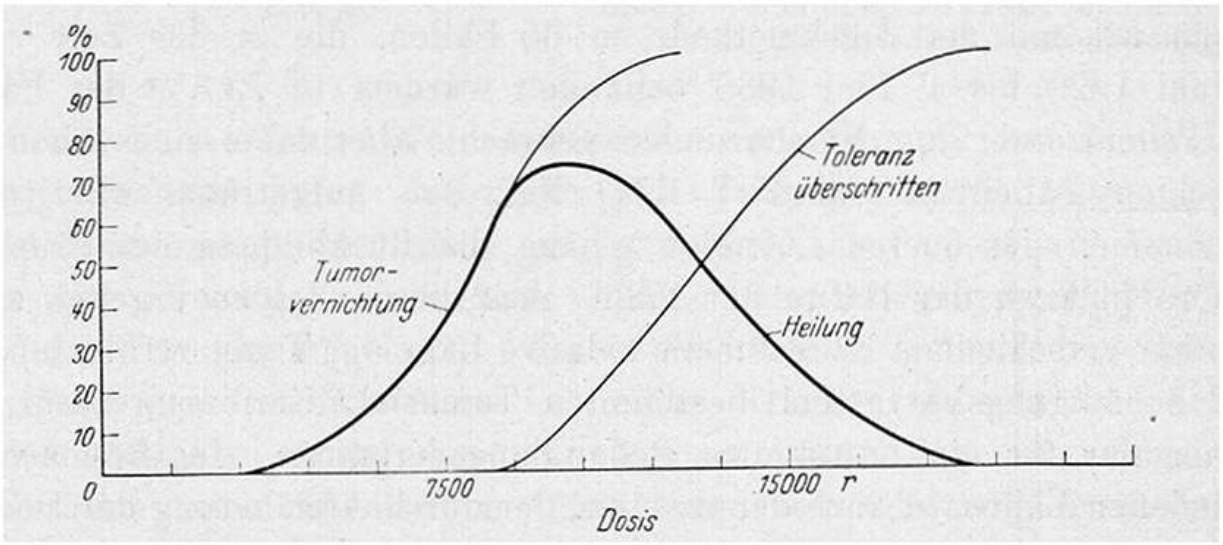

FIGURE 1.21 This is figure 6 from Holthusen's 1936 paper. The *x*-axis represents dose of radiation. The *y*-axis represents efficacy. The sigmoidal curve on the left depicts tumor destruction. The sigmoidal curve on the right shows the probably of normal tissue injury (he labeled it "tolerance exceeded"). The bell-shaped curve with the dark line is "cure rate" by which he meant tumor control in the absence of complications. If the treating radiation oncologist can find the right dose, then they will maximize the chance of cure while avoiding undesired effects on normal tissue. (Used with permission of Springer Nature BV from Holthusen H. Erfahrungen über die Vertraglichkeitsgrenze fur Röntgenstrahlen und deren Nutzanwendung zur Verhütung von Schäden. *Strahlentherapie*. 1936;57:254-269, Figure 6; permission conveyed through Copyright Clearance Center.)

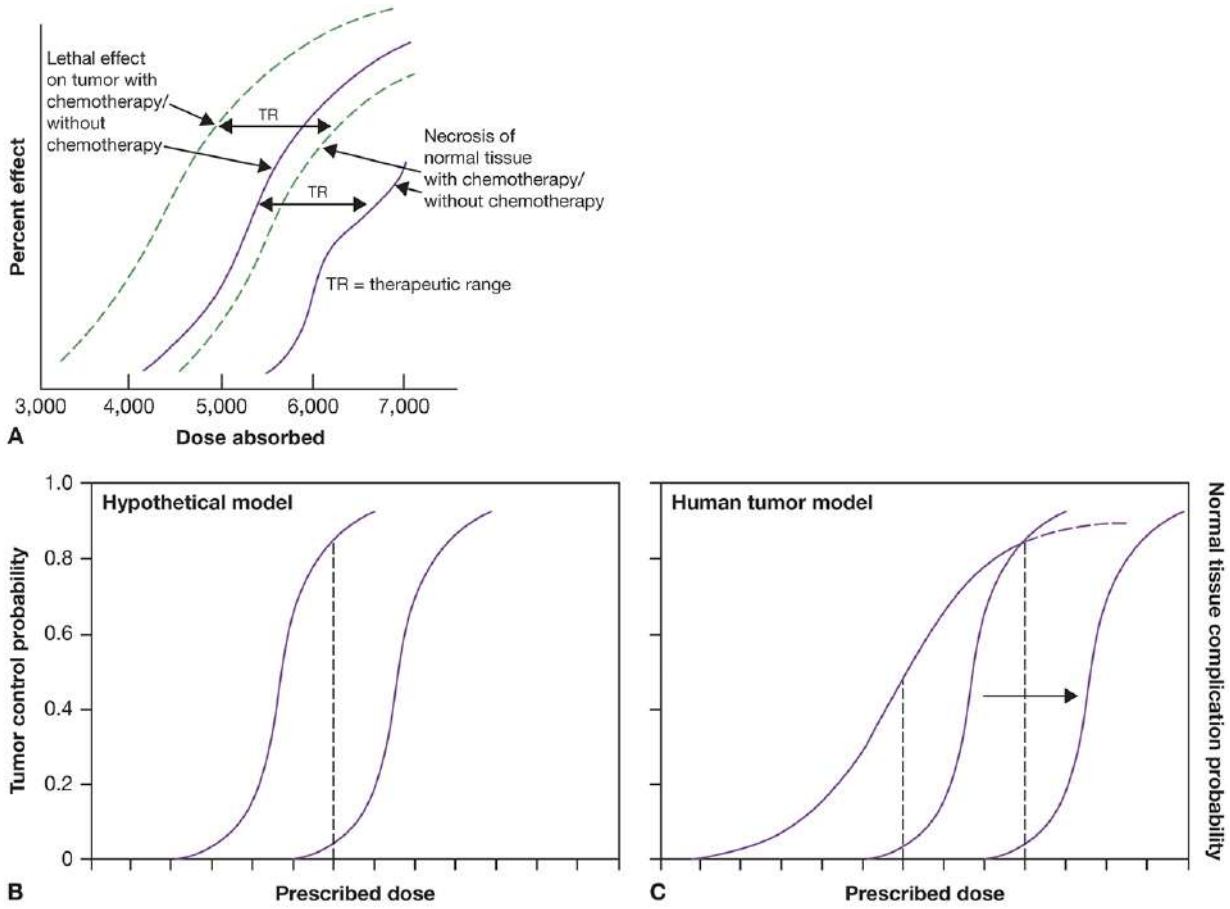

FIGURE 1.22 A. Building upon the work of Holthusen theoretical curves are shown for tumor control and complications as a function of radiation dose with and without chemotherapy. *TR* is the therapeutic ratio, or the difference between tumor control and complication frequency. (Reprinted from Perez CA, Thomas PRM. Radiation therapy: basic concepts and clinical implications. In: Sutow WW, Fernbach DJ, Vietti TJ, eds. *Clinical Pediatric Oncology*. 3rd ed. CV Mosby; 1984:167-209. Copyright © 1984 Elsevier. With permission.) B. Hypothetical dose-response curves for tumor control and normal tissue injury. Because the tumor control and the normal tissue complication curves are approximately parallel in shape and are sufficiently separated, the dose levels necessary to cure a high percentage of patients can be administered without producing excessive normal tissue damage (indicated by the vertical dotted line). C. Human tumor model. The slope of the tumor control curve is less steep than the normal tissue-complication curve; thus, for an acceptable level of normal tissue injury, the probability of tumor control is decreased compared to the hypothetical model. Because of the volume effect, reducing the volume of normal tissues shifts the curve to the higher dose region, thereby effectively increasing the separation of the dose-response curves. Consequently, a higher dose can be given to the tumor, improving the probability of tumor control without increasing the probability of normal tissue injury. (B, C. Reprinted with permission from Leibel SA, Fuks Z, Zelefsky MJ, et al. Intensity-modulated radiotherapy. *Cancer J*. 2002;8[2]:164-176.)

FIGURE 1.23 In the absence of the knowledge of the late adverse effects of radiation and of the principles of radiation protection, many pioneering radiologists and radiation oncologists suffered injuries. These are the hands of Dr Mihran Krikor Kassabian (1870-1910) of Philadelphia, photographed in 1903 and showing severe late radiation dermatitis from exposures that began in 1899. Kassabian developed skin cancer that metastasized. He died at age 39. (From Kassabian MK. *Röntgen Rays and Electro-Therapeutics, with Chapters on Radium and Phototherapy*. J.B. Lippincott; 1907.)

Holthusen's curves are among the most famous in radiation oncology. They have been recreated innumerable times by investigators in the approximately 90 years since they were first published—often without giving credit to Holthusen. They repay careful study today.

Improved definitions of TCP and normal tissue complication probability (NTCP)[195] imply that there is an optimal radiation dose that produces a maximum tumor control with a minimum (reasonably acceptable) frequency of complications, also called treatment sequelae. The farther the TCP and NTCP curves diverge, the

more favorable the therapeutic ratio. The therapeutic ratio or therapeutic gain factor (TGF) of a given regimen could be expressed as a ratio: The higher the TGF, the more efficient a particular therapy. Such a quantitative expression could be used to compare different therapeutic strategies. Mendelsohn[196] expressed this concept in terms of "uncomplicated tumor ablation."

The selection of a dose must weigh the probability of major complications for any potential enhancement of tumor control. Models for decision-making, using Bayesian theory, incorporate values assigned to positive or negative outcomes. Positive outcome is considered tumor cure without complication, whereas negative outcomes include tumor cure with significant complications or tumor recurrence with or without complications (Figures 1.24 and 1.25).

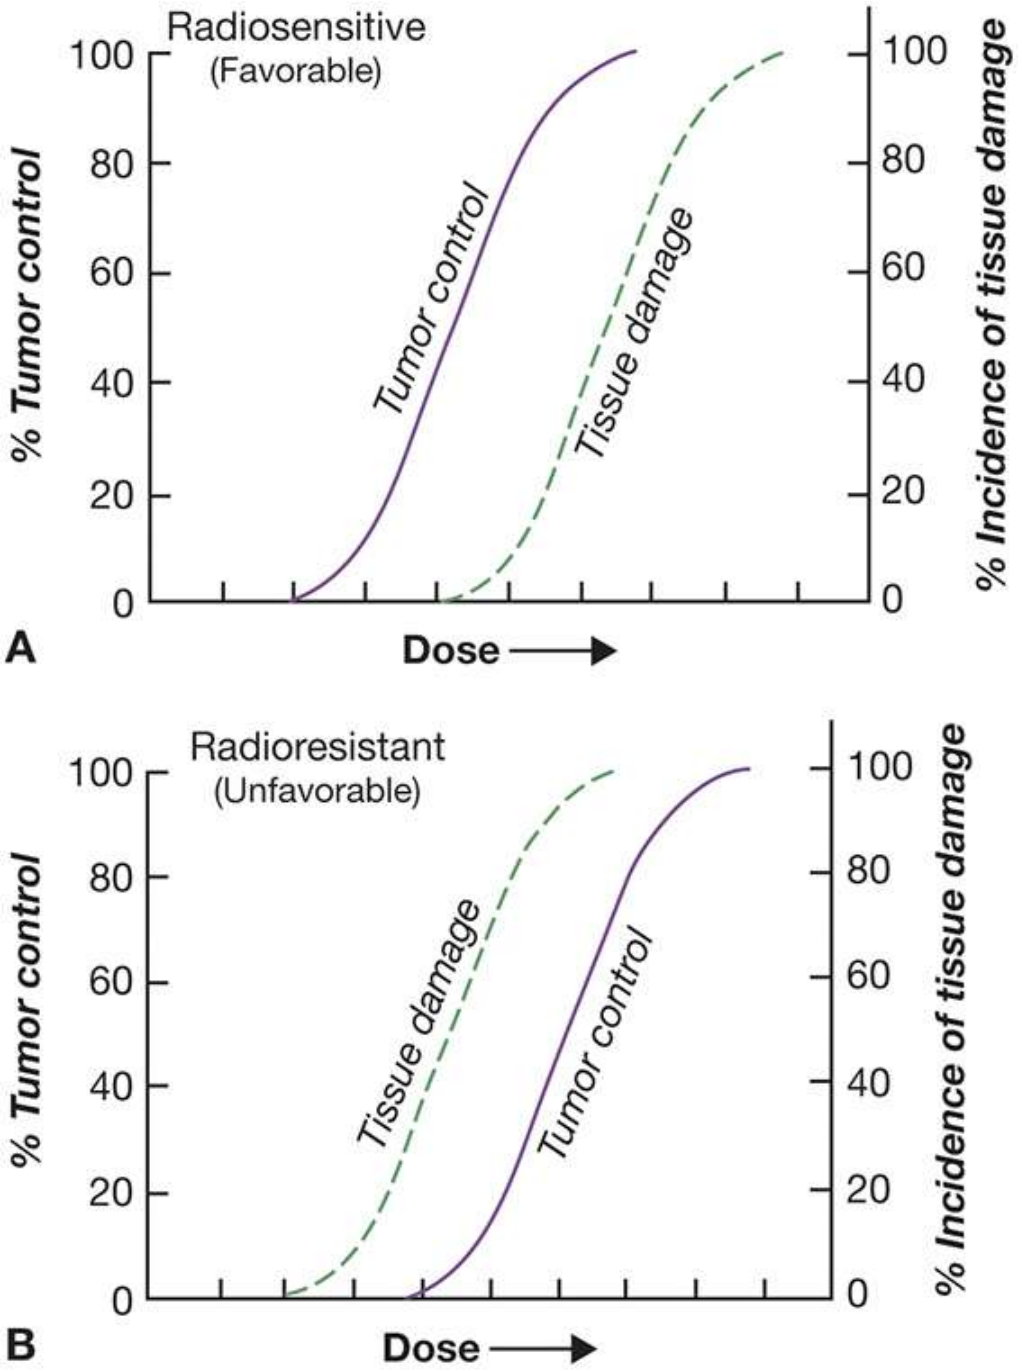

FIGURE 1.24 Different therapeutic ratios exist in different clinical circumstances depending on the radiosensitivity (dose-response curves) for the tumor versus critical normal tissue in the treatment field. A. Favorable. B. Unfavorable. (Reprinted from Rubin P. *Clinical Oncology: A Multidisciplinary Approach for Physicians and Students*. 7th ed. W.B. Saunders; 1993. Copyright © 1993 Elsevier. FIGURE 1.25 Treatment outcomes. Uncomplicated curves (dashed line) are the desired results of treatment. This is illustrated as a function of the therapeutic ratio; that is, the greater the separation of the tumor control curve and the normal tissue-complication curve, the greater the number of uncomplicated cures that will result. The letters *A*, *B*, and *C* represent three different dose levels, which, if chosen, would lead to three different outcomes: *A* would result in few tumor cures but no complications; *C* would lead to complete cure in many cases, but virtually all patients would suffer complications. The optimal choice in this group of dose levels is *B*, which would result in the greatest number of cured patients without complications. (From Mendelsohn ML. The biology of dose-limiting tissues. In: *Time and Dose Relationships in Radiation Biology as Applied to Radiotherapy*. Brookhaven National Laboratory; 1969:154-173. Brookhaven National Laboratory (BNL) Report 5023 (C-57). Courtesy of Brookhaven National Laboratory.)

THE ORIGINS OF CLINICAL RADIATION THERAPY

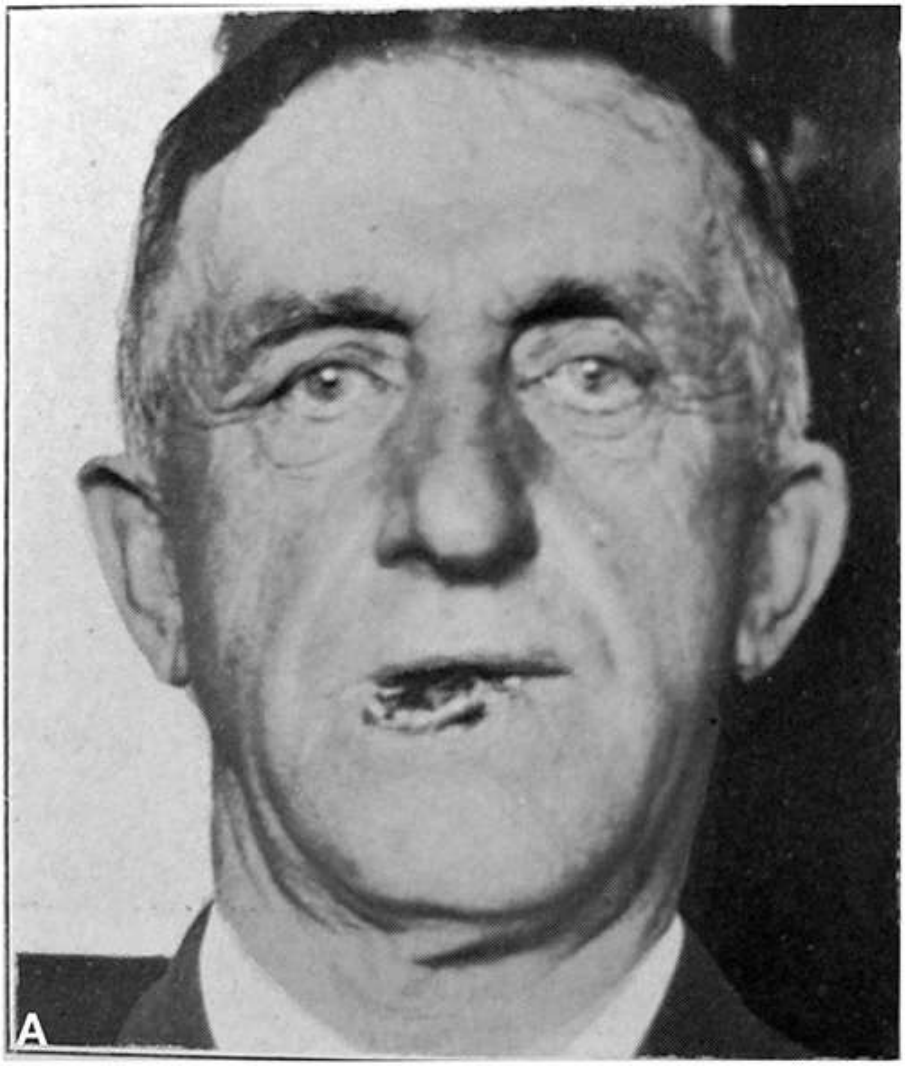
EBRT quickly showed itself to be a useful form of cancer treatment. Only 8 years after Röntgen's discovery, Dr Charles L. Leonard, in 1903, observed that:

> in spite of the most diligent study, there is nothing known of the etiology and histology of malignant disease that aids its treatment. Its development and fatal termination cannot be retarded, if the diseased tissue be permitted to remain in the body. Total extirpation by surgical intervention has been the only chance of cure.[197]

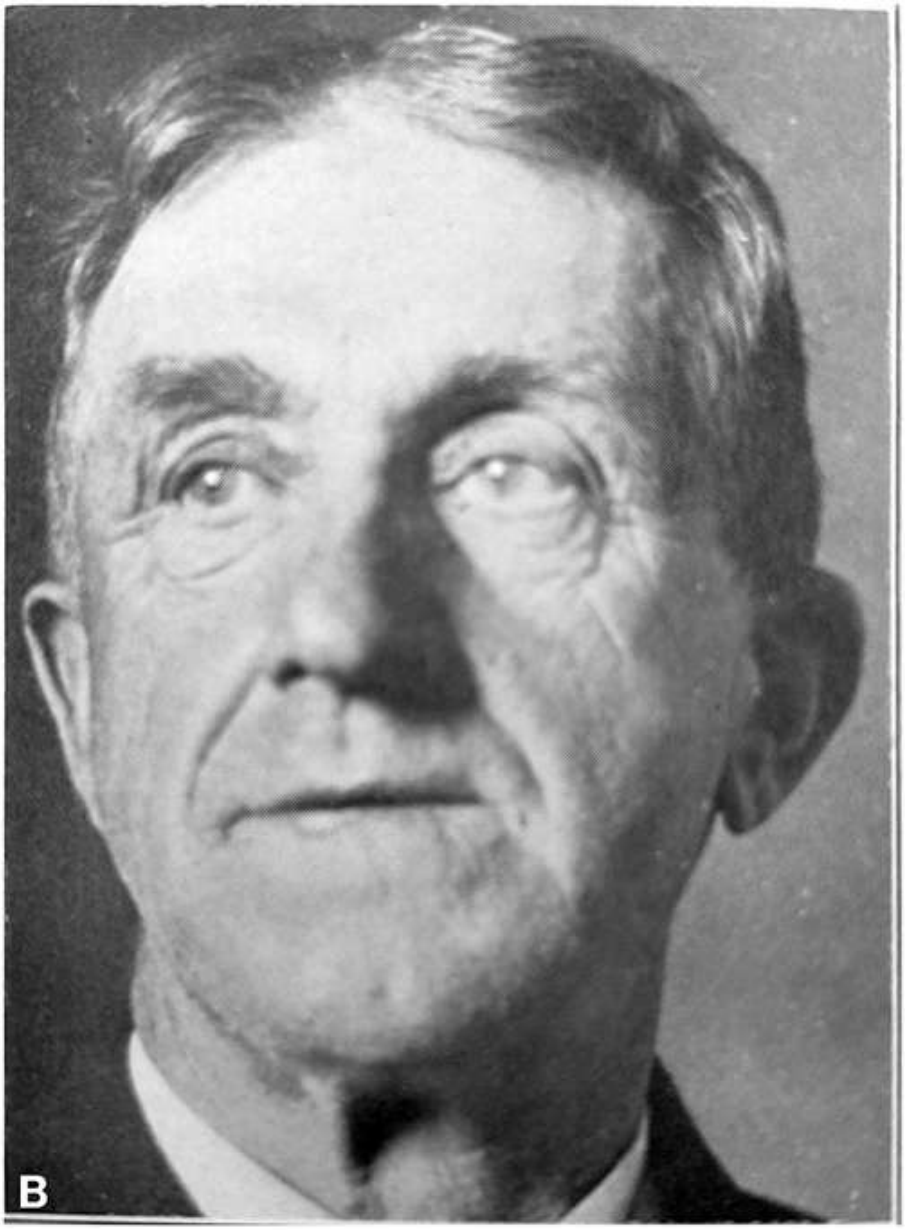
Leonard, however, discerned some promise in a new form of treatment.

> The results obtained by the use of the Röntgen rays seems to . . . have demonstrated their power to alter the character of malignant cells, to prevent their spread and development, and to produce retrograde changes that result in fatty and cystic degeneration or absorption, and often terminate in a restoration of the affected part to a nearly normal state. . . . The Röntgen treatment applied as a palliative in many hopeless, operatively impossible cases, has resulted frequently in cures that, if not permanent, have at least restored the patient to health and given months and even years of usefulness. . . . The results so far obtained are, therefore, very encouraging. An agent has been found which has a greater influence in retarding the growth of malignant tumors than any heretofore known. Many remarkable and apparently permanent cures have been obtained.[198]

Although it is controversial, most likely Leopold Freund was the first to report, in 1897, the use of ionizing radiation to "cure" a large nevus pigmentosus on the back of a young girl. Unfortunately, she later developed skin ulceration and scars.[199] Another pioneer in the therapeutic use of x-rays was Victor Despeignes who, in 1896, published on the treatment of a 52-year-old man who had an advanced stomach tumor (likely a lymphoma), with "considerable improvement in the condition of the patient"[200] (Figure 1.26).



A



B

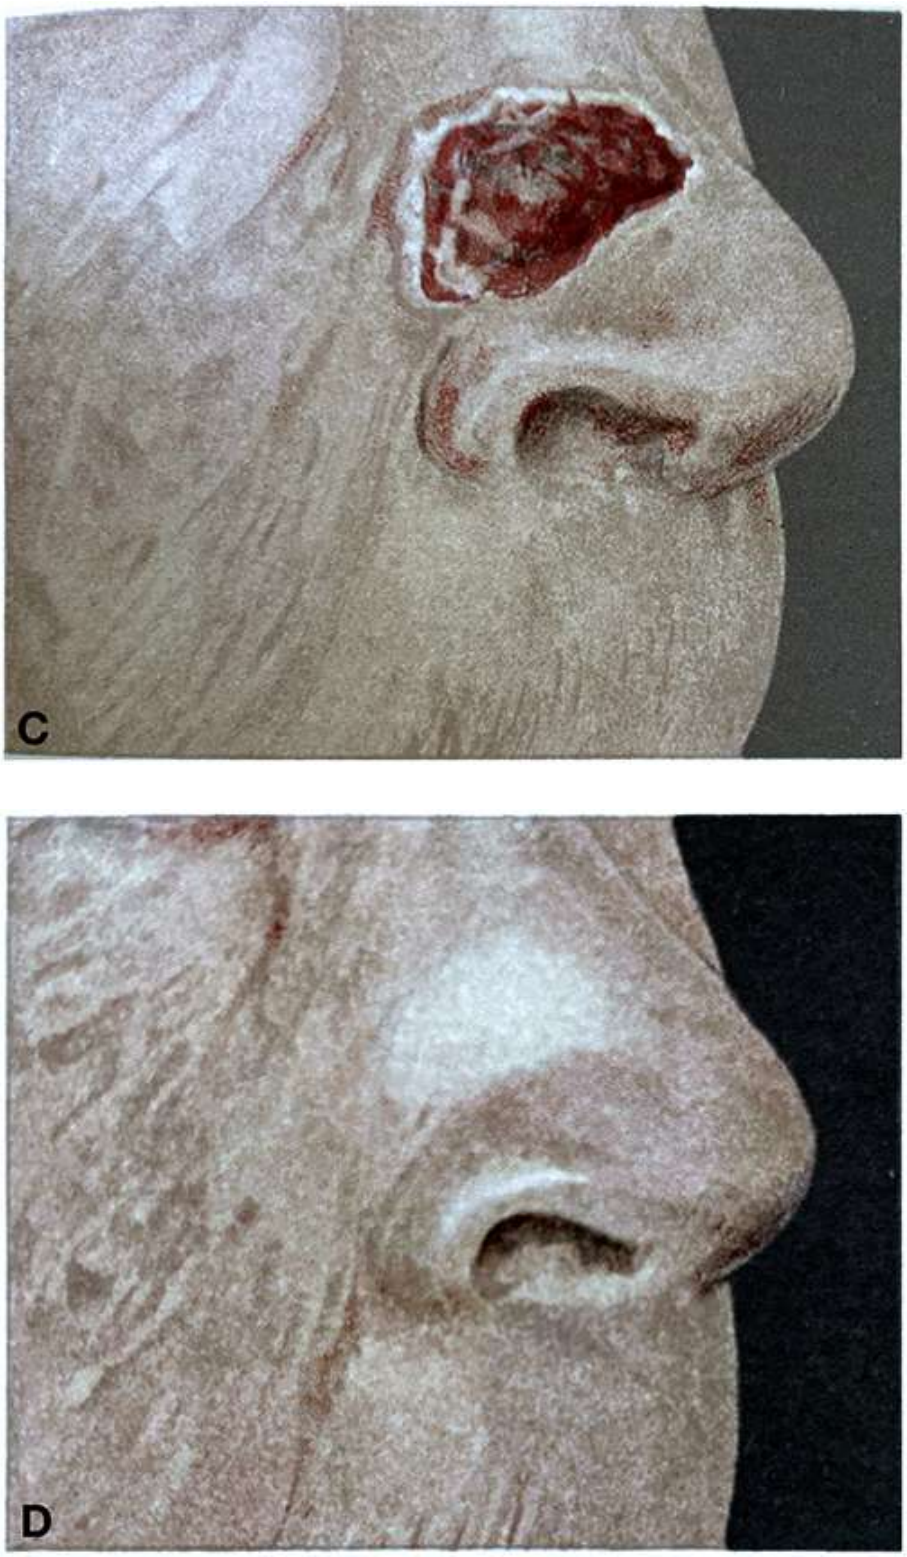


FIGURE 1.26 A and B. The pioneers of radiation therapy reported promising results. In 1918, Dr Albert F. Tyler of Nebraska reported the case of a 42-year-old male with carcinoma of the lower lip, recurrent after treatment with a caustic paste and surgery. After 19 fractions of radiotherapy administered over a 4-month period, he was alive and well 3.5 years after therapy, and “the lip is as pliable as it was before

the growth occurred" (A, B. Reproduced from Tyler AF. *Roentgenotherapy*. CV Mosby Company; 1918.) C and D. Similar dramatic results were demonstrated in 1910 with radiation therapy for a skin cancer of the nose by Dr Wickham and Degrais of Paris (C,D. Reproduced from Wickham L, Degrais P. *Radiumtherapie*. Verlag von Julius Springer; 1910.)

At the International Congress of Oncology in Paris in 1922, Coutard[201] and Hautant presented evidence that advanced laryngeal cancer could be cured without disastrous, treatment-induced sequelae. By 1934, Coutard[202] had developed a protracted, fractionated scheme that remains the basis for current radiation therapy, and, in 1933, Paterson[203] published results on the classification of tumors in relation to radiosensitivity.

The use of brachytherapy, starting with radium-226 (^{226}Ra) needles and tubes, is useful in the treatment of malignant tumors in many anatomic locations. Isotopes such as cesium, iridium-192 (^{192}Ir), iodine-125 (^{125}I), and palladium-103 (^{103}Pd) were generated from nuclear reactors, and the use of afterloading techniques, including remote afterloading devices and high dose rate (HDR) brachytherapy, has contributed to this important treatment modality. With time, ionizing radiation became more precise; high energy photons, electrons, protons, neutrons, and carbon ions became available for treatment; and treatment planning and delivery became more accurate and reproducible. Advances in computer and electronic technology fostered the development of more sophisticated treatment planning and delivery techniques, leading to the development and eventually broad implementation of 3D conformal radiation therapy (3DCRT) and IMRT.

The Planning and Conduct of a Course of Radiation Therapy

When a physician proposes administering radiation therapy to a patient, six fundamental questions must be answered. Once these questions have been answered, an appropriate first step has been taken toward the development of a comprehensive justification and plan for the conduct of a course of radiation therapy. The six questions are as follows:

1. What is the *indication* for radiation therapy?
2. What is the *goal* of radiation therapy?
3. What is the treatment *volume*?
4. What is the treatment *technique*?
5. What is the treatment *dose* and *fractionation*?
6. What is the radiation *tolerance* of surrounding normal tissues?

The *indication* for radiation therapy is that body of data that can be brought to bear showing that radiation therapy would be efficacious for the patient's condition.

Such data might exist in the form of retrospective single-institution reviews of the specific malignancy, which provide evidence favoring the role of radiotherapy. Phase I and II studies demonstrating safety and possible efficacy could be invoked to justify a course of radiation therapy. For many physicians, the gold standard, however, is a prospective, randomized, phase III trial that demonstrates the value of radiation therapy and a meta-analysis of multiple trials confirming its benefit. There remains a role for sound personal clinical experience. Although there is increasing reliance on published trials, and special deference is given to double-blind, prospective, randomized phase III trials, it is still appropriate for a physician to rely firmly on their clinical experience in the context of an intimate knowledge of the patient's problems. A sound scientific basis and an extensive knowledge of clinical research augment the essential nature of the physician-patient relationship, but they do not substitute for it.

Radiation therapy can be justified either because it improves local tumor control, ameliorates a specific symptom, improves the quality of life, or increases the probability of cure. Any data used to justify a course of radiation therapy must have a clearly defined end point, appropriate data analysis, and accepted statistical methodology. It is incumbent on the radiation oncologist to know how to critically evaluate the scientific literature and synthesize it in the best interest of the patient.

There are two possible *goals* of radiation therapy. *Curative* radiation therapy is used for the purpose of curing the patient where one is willing to engender a small risk of significant side effects in return for the possibility of cure. An example is the use of radiation therapy for the treatment of early-stage breast cancer. In return for a high probability of cure, one is willing to engender a very small risk of pneumonitis. *Palliative* radiation therapy is designed to ameliorate a specific symptom such as pain, obstruction, or bleeding (Figure 1.27). When palliative radiation therapy is used in the context of an incurable malignancy, one is not willing to engender a significant risk of side effects to achieve a palliative goal. Thus, if one wishes to relieve pain from lung cancer metastatic to a bone, one would pick a dose and technique of radiation therapy sufficient to relieve pain but not enough to run a risk of radiation osteonecrosis.

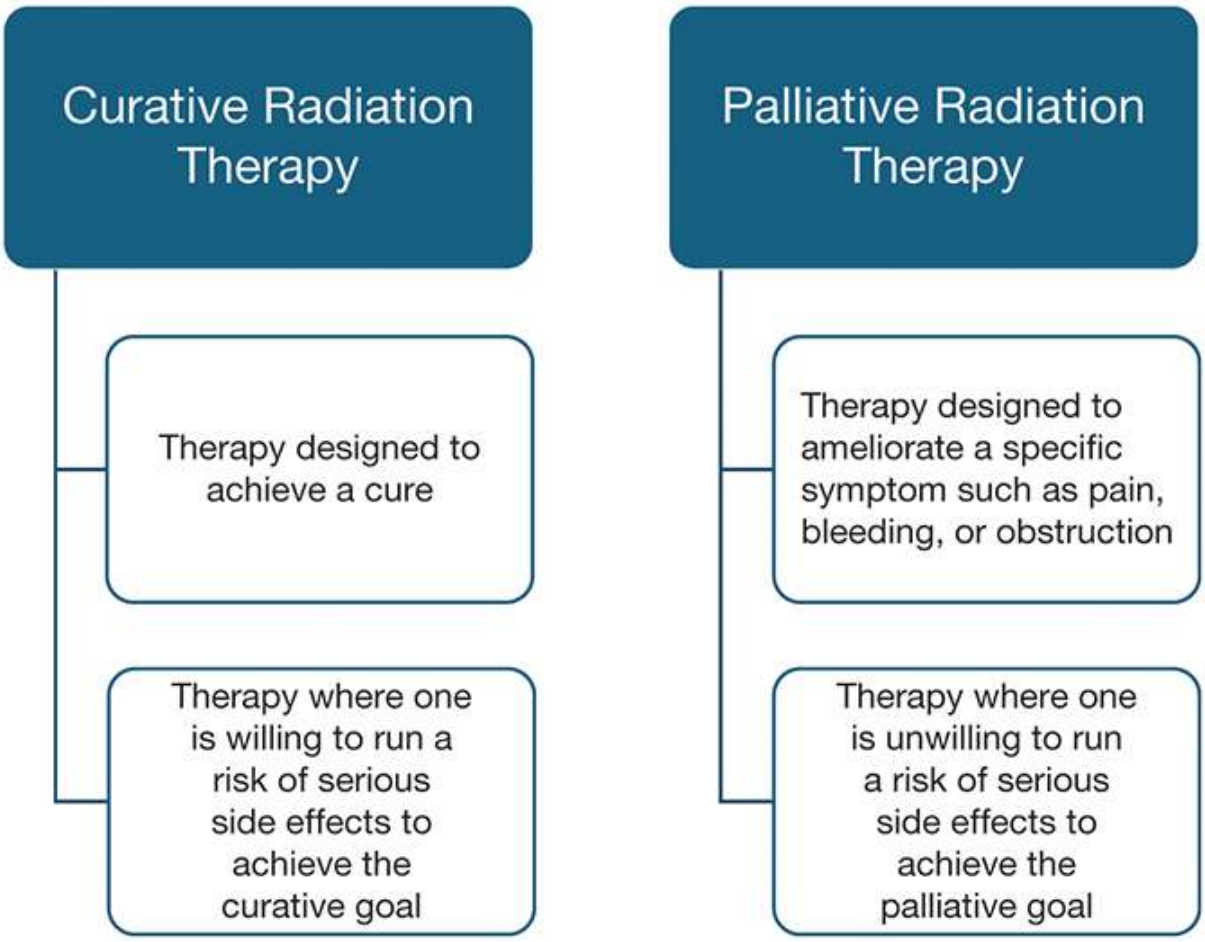

FIGURE 1.27 The *goal* of a course of radiation therapy may be *curative* or *palliative*.

The questions of *indication* and *goal* are generic. They should be answered irrespective of the modality of therapy being used for the treatment of malignancy. It is reasonable to ask for indications and goal if one is planning on using chemotherapy, surgery, cellular therapy, immunotherapy, hyperthermia, biologic therapy, or radiation therapy.

Oncologists are often better at formulating indications for curative than for palliative therapy. It is not good palliative medicine to make the patient ill from therapy in order to make asymptomatic metastatic masses smaller. In palliative cancer treatment, one must treat the patient and their symptoms and not treat the mass devoid of its context.

The next three of the six major questions, *volume*, *dose*, and *technique*, are not generic—they are specific to the discipline of radiation oncology. First, the radiation oncologist must consider *volume*. What is the appropriate volume of tissue that needs to be irradiated for the purpose of achieving the desired curative or palliative goal in the context of the justification? Does one need to treat strictly the visualized

or palpable tumor mass? Is it also appropriate to treat the mass and surrounding lymphatic drainage? Does one have to worry about the routes of spread of microscopic disease? All of these are crucial questions in formulating a plan for a course of radiation therapy. If radiation oncologists only needed to treat visible or palpable masses, then radiation oncology would be more of a physics exercise than the practice of human medicine. Understanding a cancer's routes of spread and the radiation tolerance of organs surrounding the cancer requires honed clinical judgment.

An example of the problem of volume in the radiation therapy of cancer is medulloblastoma, a tumor that arises in the posterior fossa of the human brain. If, however, one is treated with resection alone, patients almost uniformly relapse both locally and by leptomeningeal dissemination via the cerebrospinal fluid. Thus, the treatment volume for radiation therapy of medulloblastoma, in children older than 3 years, is the area within the posterior fossa wherein the tumor arises and the entire craniospinal axis. Another example of the problem of treatment volume would be in head and neck cancer. Many of these tumors, by physical examination and by diagnostic imaging, appear to be localized at their site of origin. For many of these squamous cell cancers, there is, however, a high incidence of dissemination to the lymph nodes of the neck. Thus, the appropriate radiation therapy treatment volume would include both the primary tumor site and the neck.

The next question that the radiation oncologist must face is what is the appropriate *technique*.

Radiation oncologists, in general, have two techniques at their disposal. The first, *teletherapy*, has a similar etymology to telephone, telegraph, and telepathy. It refers to the projection of radiation through space. Teletherapy is administered with external beam sources such as a cobalt-60 (^{60}Co) machine or a linear accelerator. If one elects to treat a patient with teletherapy, one must derive appropriate external beam treatment plans. These plans include considerations such as whether the patient should be treated with photons, electrons, neutrons, carbon ions, or protons; with parallel-opposed fields, four fields, or multiple oblique fields; with IMRT or IMPT; with or without respiratory gating; with or without compensators; and the like. There has been an explosion of interest in techniques of teletherapy related to improvements in sophisticated diagnostic imaging and the rapidly increasing power of computers to allow manipulation of vast amounts of data.

Brachytherapy is the other important technique of radiation therapy. The word brachytherapy shares an etymology with words such as brachycephaly and brachydactyly. It refers to short or slow therapy (ie, a radioactive implant). There are several broad categories of brachytherapy: *interstitial* brachytherapy, *intracavitary* brachytherapy, and *mold* therapy. Interstitial brachytherapy refers to the placement of radioactive sources directly into tissue. An example might be the implantation of

the tumor bed for breast cancer or soft tissue sarcoma. Intracavitary radiotherapy refers to the placement of a radioactive source in a body cavity such as sources placed within the nasopharynx or against and through the cervical os. Mold brachytherapy refers to the placement of radioactive sources on the skin surface, such as treatment utilized for a superficial malignancy on the back of the hand. If brachytherapy is used, the radiation oncologist must determine the appropriate isotope and whether that isotope is to be delivered by an afterloading technique or by a direct radioactive application (a hot implant).

Once the radiation oncologist has determined the appropriate treatment volume and the treatment technique(s), they must determine the appropriate radiation *dose*. Radiation dose selection is a complex issue. One must determine the correct number of *fractions* of radiation per day, the correct dose per fraction, and the proposed total dose of irradiation. Furthermore, in certain situations, the dose rate (ie, the number of cGy per minute) matters, such as in total-body irradiation (TBI) for bone marrow transplantation and in brachytherapy. FLASH radiotherapy (FLASHRT) uses ultra HDRs. Decisions concerning dose will, in part, be driven by decisions concerning treatment volume and technique. Paramount in the physician's mind will be the goal of treatment. The physician must determine what the correct dose is to achieve the proposed curative or palliative goal. In broad terms, the radiation oncologist must consider what is known about the dose-response relationship for tumor control in a particular clinical situation. This subject, addressed in detail earlier in this chapter, concerns the probability of tumor control within a radiation therapy field as a function of the dose administered.

Finally, the radiation oncologist must consider normal tissue *tolerance*. In general terms, the probability of acute and late ill effects of radiation is a function of total dose and dose per fraction. Ultimately, the prescription of a dose requires the radiation oncologist to engage in a balancing act between a sufficient dose of radiation to achieve the desired treatment goal and not giving so much dose as to engender an unacceptable risk of side effects.

The fundamental questions of radiation therapy are not for the physician alone. A patient has the right to be apprised of the physician's views on these questions, probability of tumor control (and cure, if possible), and sequelae. This information should be presented to the patient in an appropriate intellectual, social, and cultural context (ie, in a manner in which the patient can understand) and translated skillfully into the patient's preferred language if necessary so that the patient becomes a full partner in their care. The signing of an informed consent document by the patient is the norm, but a signed document does not substitute for a proper doctor-patient conversation.

TREATMENT PLANNING IN RADIATION THERAPY

Treatment Volume

Tumor cell killing by ionizing radiation is an exponential function of dose. The dose required for a certain level of TCP (or local control) is proportional to the logarithm of the number of clonogenic cells in the tumor. Subclinical extensions of tumor (also called microscopic disease or disease below the level of ready clinical detection) should be controlled, in general, by a lower dose of radiation than is required for a palpable tumor mass. Microscopic tumor extensions may be less likely than bulky tumors to contain hypoxic cells. This also means that they may be more readily controlled by radiation.

Insofar as the dose tolerated by normal tissue is inversely related to the volume of normal tissue irradiated, delivering a uniform physical dose of radiation requires that one choose between the risks of marginal recurrence around small volumes of high dose, central recurrences in large volumes of low dose, or excessive normal tissue damage and large volumes of high dose. We may conclude that different doses of radiation are required for a given probability of tumor control, depending on the type and initial number of clonogenic cells present.

A shrinking-field technique is a rational approach to the problem of heterogeneous tumor distribution (Figure 1.28). Withers and Taylor[204] have argued that "in the ideal case, the doses would be graded to provide a homogeneous TCP throughout the treatment volume rather than a homogeneous physical dose distribution." We are entering an era of "dose painting" where a heterogeneous dose will be layered on a tumor as determined by sophisticated imaging tools.[205] The radiation oncologist delivers varying radiation doses to certain portions of the tumor (periphery vs central portion or metabolically active vs inactive on computed tomography [CT]/PET) or may vary the dose in cases in which gross tumor has been surgically removed.

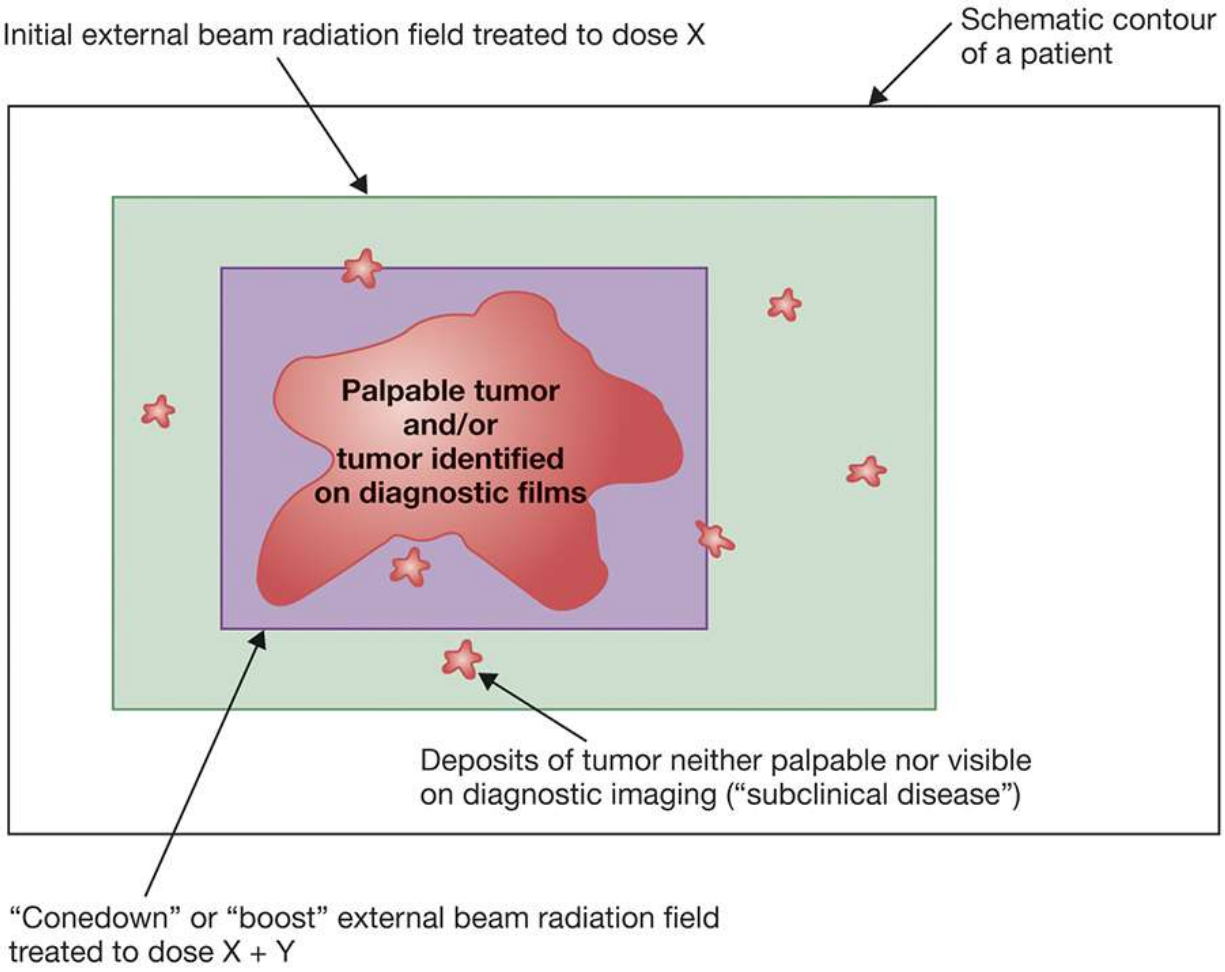

FIGURE 1.28 Cell killing by ionizing radiation is an exponential function of dose. It follows that the dose required for a certain level of tumor control probability (TCP) is directly proportional to the logarithm of the number of clonogenic cells in the tumor deposit. It would be reasonable to expect that subclinical extensions of disease could be controlled by a lower dose of irradiation than what is required for a bulky palpable tumor mass. It has been argued by some researchers that microscopic tumor extensions are less likely to contain hypoxic foci that will minimize the requirement for reoxygenation for their control—but this is controversial. Insofar as the dose tolerated by a tissue is inversely related to the volume of tissue irradiated, delivering a uniform physical dose requires that one choose between the risk of marginal recurrences around small volumes of high dose, central occurrences in large volumes of low dose, or excessive normal tissue damage in large volumes of high dose. A reasonable approach is to use a shrinking-field technique in which one delivers an initial external beam field that is treated to dose X and then "cones down" to a smaller field to treat to dose X + Y. In the ideal case, doses are graded to provide a homogeneous TCP throughout the treatment volume rather than a homogeneous physical dose distribution. (Based on a concept articulated by Withers HR, Peters LJ. Biologic aspects of radiotherapy. In: Fletcher GH, ed. *Textbook of Radiotherapy*. 3rd ed. Lea & Febiger; 1980:142.)

The International Commission on Radiation Units and Measurements (ICRU) Report 50 has recommended definitions of terms and concepts for radiation therapy treatment volumes and margins[206]:

- The gross tumor volume (GTV) denotes demonstrable tumor. It includes all known gross disease including abnormally enlarged regional lymph nodes. In the determination of GTV, it is important to use the appropriate imaging modality and physical examination to give the maximum dimension of what is considered potential gross disease.
- The clinical target volume (CTV) denotes the GTV and subclinical disease (ie, volumes of tissue with suspected tumor).
- The planning target volume (PTV) denotes the CTV and includes margins for geometric uncertainties. One also should account for variation in treatment setup and other anatomic motion during treatment, such as respiration.

Because the PTV does not account for treatment machine characteristics, the actual treated volume is that volume enclosed by an isodose surface that is selected and specified by the radiation oncologist as being appropriate to achieve the goal of treatment. It is impossible to design a radiation therapy treatment plan that limits the prescribed dose to the PTV only. Some tissues en route to the target or near the target also will be irradiated to the same dose as the target. The treated volume is, therefore, almost always larger than the PTV and usually has a somewhat simpler shape.

- The irradiated volume is that volume of tissue that receives a dose considered significant in relationship to tissue tolerance. This would include tissues in the exit region of unopposed photon, electron, or neutron beams or in the penumbra region of a beam.
- The planning organ at risk (OAR) volume refers to the definition of margins around OARs for injury by radiation. For example, one might define a 0.5-cm margin around the optic chiasm to avoid the risk of blindness.

Uncertainties

There are, inevitably, uncertainties in the planning and delivery of a course of radiation therapy. These were well characterized by the esteemed dosimetrist Gunilla Bentel[207,208] (1936-2000), to whom I am grateful for the following discussion. Ms. Bentel's biography will be found near the end of the chapter.

Uncertainties are divided into two general categories. First, there are uncertainties related to the delivery of dose, such as inhomogeneities in the beam, problems related to dose calculations, variables in the output of treatment machines, instability of the beam monitoring technique, and problems related to beam flatness. Spatial uncertainties in the delivery of radiation therapy may be divided into those related to mechanical inaccuracies in the equipment and those related to the patient.

Mechanical Uncertainties

- *Field-size settings*. There can be errors related either to mechanical dials or to digital settings in which the field-size set on the machine is not precisely the same as that delivered.
- *Rotational settings*. Mechanical or digital settings that display the degree of angulation of the gantry or the collimator may be in error.
- *Cross hairs*. Wires in the linear accelerator designed to show the central axis or the field edges may become displaced.
- *Isocenter*. Deviations in the position of the isocenter may occur as a result of sagging of the gantry head.
- *Light beam congruence*. The light beam within the treatment machine may be in error. These misalignments may be caused by small shifts in the mirror or the light bulb.
- *Alignment systems*. The laser beam systems used for alignment may be in error.[209] They may not intersect exactly at the isocenter, they may not be perpendicular, and some systems may display relatively thick lines allowing for errors in judgment.
- *Couch top*. There can be differences in sag between radiation treatment couches. In addition, there may be differences in sag between the simulator couch, the CT couch used for 3D or IMRT planning, and the accelerator couch. Sometimes, in the treatment room, a tennis racket–type insert is used. Over time, couch tops can become tilted from side to side or from end to end.
- *Beam-shaping blocks or collimators*. At institutions that are still using blocks rather than a multileaf collimator (MLC), there may be errors in constructing the blocks related to user error or because the cutting wire becomes too hot or is moved too fast around a corner when the Styrofoam mold is cut. If MLCs are used, there may be errors in alignment.

Patient-Related Uncertainties

- *Target delineation*. No matter how sophisticated the computerized treatment planning system, it will be to no avail if the physician is uncertain about where the tumor is located. The inherent problems related to PET, MRI, CT, and our ability to make correlations between anatomic and functional imaging and the location of tumor may result in difficulty determining the extent of tumor as well as in transferring anatomic information from imaging studies to the 3D or IMRT treatment planning system.

- *Organ motion*. Organ motion can occur from respiration, heartbeat, or changes in the size or shape of an organ as a function of digestive or excretory function (ie, changes in the size and position of the stomach, intestines, bladder, and rectum and, in the last case, its influence on prostate position).
- *Skin marks or marks on a stabilization device*. Skin marks can shift relative to deeper tissues. This can change as a result of alterations in patient weight, patient positioning, or the use of steroids during a course of radiation therapy. A particular problem is related to the width of setup lines drawn by therapists on the patient's skin. The thickness of the point of the marking pen used can produce variation in the width of the lines drawn. When this is accompanied by variation in the position of the light fields in relationship to the lines, it can cause uncertainty in treatment delivery. Marks drawn on a stabilization device may cease to match deeper tissues.
- *Repositioning*. Day-to-day problems in reproducing the position may occur.
- *Patient motion*. Some patients simply will not hold still during radiation therapy. Whether this is related to the patient being anxious, in pain, demented, or subject to a neurologic disorder, it can lead to uncertainties in radiation therapy treatment delivery.

Immobilization and Spacing

The magnitude of uncertainties in radiation therapy treatment delivery varies. Furthermore, some uncertainties may be additive and some may cancel each other out. The net effect, on any given day, can be quite variable.

To irradiate a tumor while minimizing the radiation dose to uninvolved normal tissue, control of patient movement must be precise and absolute. Sophisticated tumor localization, 3D treatment planning, radiosurgery, and/or IMRT or IMPT will be of no use if the patient is not holding still. Often, positioning and mobilization can be the weakest link in the chain of treatment planning.[210] Quality radiotherapy demands that a daily setup accuracy of a few millimeters be ensured.

Mechanical immobilization of the awake radiotherapy patient is an adjunct to patient education and psychological preparation of the patient. Although not a substitute for education and psychological preparation, mechanical aids can greatly facilitate accurate treatment. The ideal mechanical aid for patient positioning will achieve the following goals[211]:

1. The patient must be comfortable and secure. There must be no danger of falling. The patient should not become claustrophobic.
2. The device must satisfy the radiotherapy treatment plan regarding patient position for correct geographic irradiation.

3. The setup should be quick and easy for the radiation therapist.
4. The body part treated should be rendered immobile.
5. Position of the body part should be reproducible for daily treatment.
6. Construction of the device should be reasonably quick. It should not be difficult to train therapists, dosimetrists, and physicians in the construction procedure.
7. The stabilization device should not adversely affect beam buildup and backscatter characteristics.
8. This system should be economical.
9. If anesthesia is being used, the device must not interfere with the establishment of a secure airway, intravenous access, or the use of monitoring equipment.

A variety of immobilization devices meet these stated criteria to varying degrees. There is no perfect system. Techniques will vary among institutions. It is reasonable to expect, however, that the radiation oncologist should be knowledgeable in several techniques that can be brought to bear as the situation demands.

There are a variety of stabilization devices. These include commercially available accessories such as plastic headholders and sponges; bite blocks; thermoplastics; plaster of Paris; vacuum-molded thermoplastics; polyurethane foams; vacuum bags; intrarectal balloons to stabilize the prostate and rectal wall during prostate radiotherapy or injectable absorbable material, respiratory-gated radiotherapy, and therapy while breath holding to minimize respiratory excursion; and mechanical devices to compensate for patient movement by compensatory couch movement, collimator leaf movement, or robotic arms to move the linear accelerator.

Accuracy of external beam placement was typically assessed periodically with portal (localization) films. It is now far more common to use online imaging verification (electronic portal imaging) devices or online CT, fluoroscopy CT/PET, MRI, or ultrasound.[212,213] Portal localization errors may be systematic or occur at random. Online electronic portal imaging has been used to document inter- or intratreatment portal displacement.

Clinical evidence supports the benefit of stabilization devices in reducing patient motion. Marks et al[214,215] demonstrated, by systematic use of verification films, a high frequency of localization errors in patients irradiated for head and neck cancer or malignant lymphomas. These errors were corrected with improved patient immobilization; with the use of a bite block in patients with head and neck tumors, localization errors were reduced from 16% to 1%[49] (Table 1.6). The use of 3DCRT and IMRT, as well as the emphasis on stereotactic body radiosurgery, has led to several excellent contributions to the literature assessing the value of stabilization devices. Such devices are particularly important in the treatment of lung, liver, and paraspinal tumors. Often, these devices include a combination of a thermoplastic

body cast, vacuum pillow, arm and leg support, wooden backing and/or sides, or a carbon plate. It has been demonstrated that such devices can achieve setup errors and deviations in the 1- to 3-mm range.[216,217] Some institutions rely on vacuum-molded plastic shells. These devices, similarly, will achieve displacements on the order of 1 to 3 mm.[218]

TABLE 1.6 THE IMPACT OF STABILIZATION DEVICES ON EXTERNAL BEAM SETUP REPRODUCIBILITY

	Number of Position Adjustments per Number of Times Tested (%)	*P*
Hodgkin disease (*n* = 56)[a]		
Short cradle stabilization device	48/237 (20)	.009
Whole-torso cradle stabilization device	21/213 (10)	—
Head and neck cancer (*n* = 71)[b]		
Three casting strip stabilization device	55/307 (18)	.23
Customized mask device	40/291 (14)	—
Lung cancer (*n* = 60)[c]		
No stabilization device	17/119 (14)	.139
Cradle	14/171 (8)	—

[c]Bentel GC, Marks LB, Krishnamurthy R. Impact of cradle immobilization on setup reproducibility during external beam radiation therapy for lung cancer. *Int J Radiat Oncol Biol Phys*. 1997;38(4):527-531.

In a randomized trial from the Karolinska University Hospital in Stockholm, Sweden, patients with head and neck cancer were randomly assigned to be stabilized with a thermoplastic head mask or a thermoplastic head and shoulder mask. Reproducibility was assessed by comparing port films in these 3D planned patients with simulator films. This was done twice during treatment and by comparing the actual treatment table positions weekly. Patient tolerance and skin reactions were also assessed. A total of 241 patients were evaluated. There were no statistically significant differences between the head mask stabilization device or the head and shoulder mask stabilization device in terms of reproducibility. It was of note, however, that patients with the thermoplastic mask extending over the head and

shoulders experienced significantly more claustrophobic reactions and greater skin reactions. This study has been criticized for its reliance on thermoplastic devices rather than the vacuum-formed clear polyethylene masks.[219]

Because different stabilization devices are utilized in different clinical situations, there is no simple way to know which is the best stabilization device. An excellent comparative study done at the Northeast Proton Therapy Center analyzed the length for which there is a 95% probability that the total displacement will be smaller as a result of intrafractional patient motion. It is reasonable to expect that customized closely fitting molds should achieve intrafractional stabilization of 2 to 7 mm, with the best stabilization being obtained in precision treatment of the brain utilizing a rigid halo and bite block (Table 1.7).[220]

TABLE 1.7 INTRAFRACTIONAL PATIENT MOTION AS A FUNCTION OF THE IMMOBILIZATION DEVICE

Immobilization Device	Patient Motion (mm)
Alpha cradle	5.0
Beanbag	6.8
Head Aquaplast	3.6
Duncan headrest	7.0
Modified Gill-Thomas-Cosman frame	1.8
Prone craniospinal head support	3.0
Head Aquaplast with bite block	2.9
Wing board	5.9

Based on an analysis of >10,000 fields, there is a 95% chance that the change in patient position between the initial patient setup and the position before the next treatment field setup will be less than the measurement shown.

Modified from Engelsman M, Rosenthal SJ, Michaud SL, et al. Intra and interfractional patient motion for a variety of immobilization devices. *Med Phys*. 2005;32(11):3468-3474. Copyright © 2005 American Association of Physicists in Medicine. Reprinted by permission of John Wiley & Sons, Inc.

We may expect further benefits from research on stabilization. For example, injectable material in the rectal wall has been shown to decrease reduce the risk of rectal injury during prostate radiotherapy.

The best radio protector of normal tissue is not to irradiate it. An intraoral bite block can be fabricated by a dentist with dental mold material, or with mold material or a bottle cork and tongue depressors in the radiation oncology department. However, it is made, the goal is to push the tongue away from a prepared radiation beam above it. During intraoperative radiotherapy in the abdomen, packing may be used to push normal tissue away from the radiotherapy beam.

Respiratory-Dampened, Respiratory-Gated, and Respiration-Synchronized Radiotherapy

The movement associated with respiration affects the position of multiple organs. If the radiation oncologist wishes to administer highly conformal fractionated or single-fraction treatment(s) to tumors of the liver, lung, pancreas, kidney, retroperitoneum, thoracic wall, mediastinal region, and adjacent structures, it will be necessary to either account for respiration-induced movement by putting a larger margin around the tumor or use an intervention to reduce this movement (Table 1.8).

TABLE 1.8 AVERAGE DIAPHRAGM MOTION DURING ACTIVE BREATHING CONTROL (ABC) (MEAN, RANGE)

By Fluoroscopy at Simulation	By Fluoroscopy During Treatment	Beam's-Eye View During Treatment
1.4 mm (0-3.4 mm)	1.2 mm (0.4-2.5 mm)	0.5 mm (0-4.2 mm)

From Dawson LA, Brock KK, Kazanjian S, et al. The reproducibility of organ position using active breathing control (ABC) during liver radiotherapy. *Int J Rad Oncol Biol Phys*. 2001;51:1410-1421; Eccles C, Brock KK, Bissonnette JP, Hawkins M, Dawson LA. Reproducibility of liver position using active breathing coordinates for liver cancer radiotherapy. *Int J Rad Oncol Biol Phys*. 2006; 64(3):751-759; and Wang JW, Sharpe MB, Jaffray DA, et al. The use of active breathing control (ABC) to reduce margin for breathing motion. *Int J Rad Oncol Biol Phys*. 1999;44:911-919.

One method for limiting respiratory motion during radiotherapy is the *abdominal compression method*. This involves placing a plate or some other restrictive device above or around the abdomen and chest, sometimes in association with supplemental oxygen, in an effort to minimize the amount of diaphragmatic motion during radiotherapy.[221,222] This is also referred to as *respiratory-dampened radiotherapy*.[223] Many patients can be trained to modify their respiratory excursion by use of feedback by showing their respiration graphed on a video screen. Another technique involves general anesthesia and high-frequency jet ventilation to minimize diaphragm motion during liver radiosurgery.[224]

Respiratory-gated radiotherapy involves turning the beam on only during portions of the respiratory cycle. Some techniques call for the patient to hold their breath during the irradiation.[225]

THE QUANTITATION OF TREATMENT TOXICITY

Normal Tissue Effects

A variety of normal tissue changes are induced by ionizing radiation, depending on the total dose, fractionation schedule (daily dose and overall treatment time), and volume treated. These factors are closely interrelated. We discussed the work of Hermann Holthusen (1886-1971) earlier in this chapter. He created a diagram, which

represented the hoped-for relationship between radiation dose and tumor control and radiation dose and normal tissue injury. Holthusen "maintained that the margin of safety between effective tumor dose and safe tissue tolerance was dependent on volume of tissue irradiated and fractionation of the total dose . . . tolerance could be increased by fractionation."[226,227]

It has been postulated that for many normal tissues, the radiation dose necessary to produce a particular sequela increases as the irradiated fraction of volume of the organ decreases. This concept was demonstrated for skin by Paterson,[228] who plotted doses delivered with orthovoltage x-rays that would produce moist desquamation (Figure 1.29). The same phenomenon later was reported for supervoltage irradiation of other organs[229] and for brachytherapy (Figure 1.30).

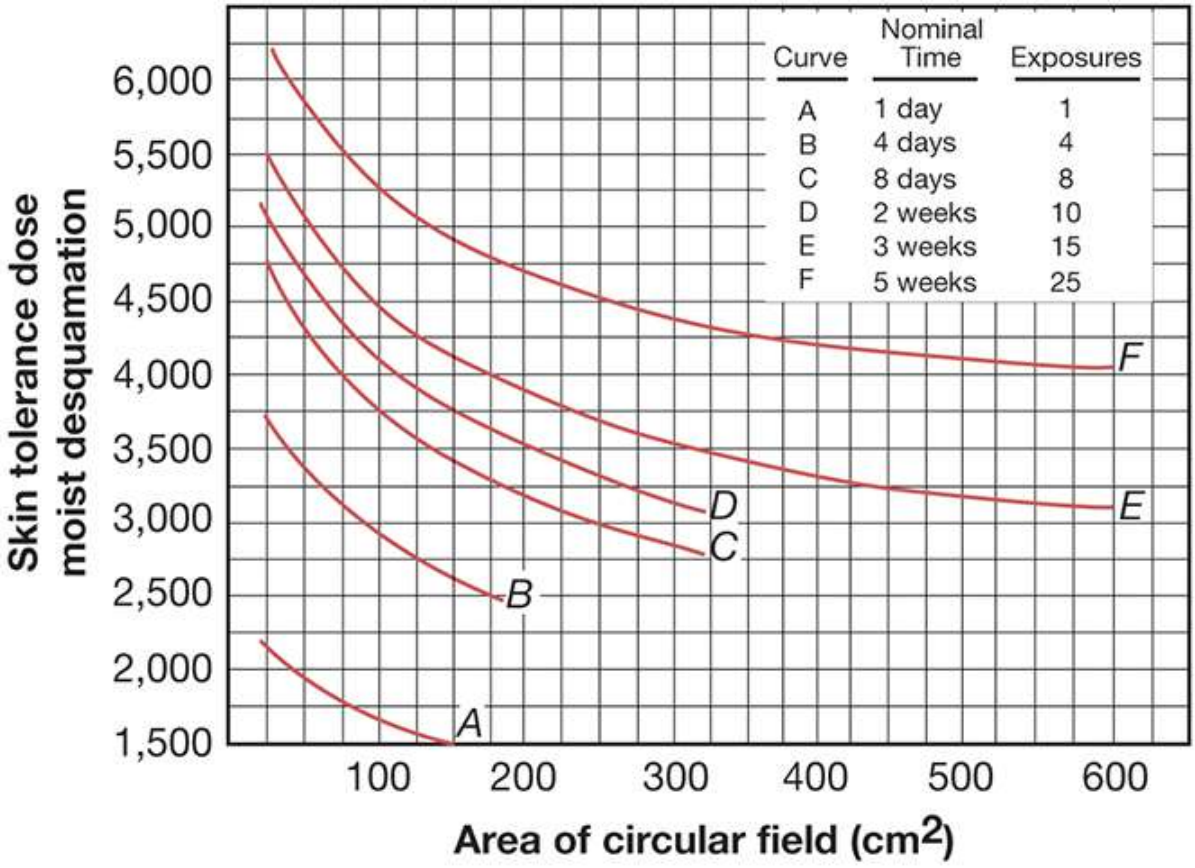

FIGURE 1.29 Graph showing the relationship between dose and size of area irradiated (healthy skin in an "average" site) to produce moist desquamation for various overall treatment times (daily irradiation at about 50 R/min for each exposure with radiation of half-value layer 1.5 mm Cu). (Reprinted with permission from Paterson R. *The Treatment of Malignant Disease by Radium and X-rays*. Williams & Wilkins; 1949:39.)

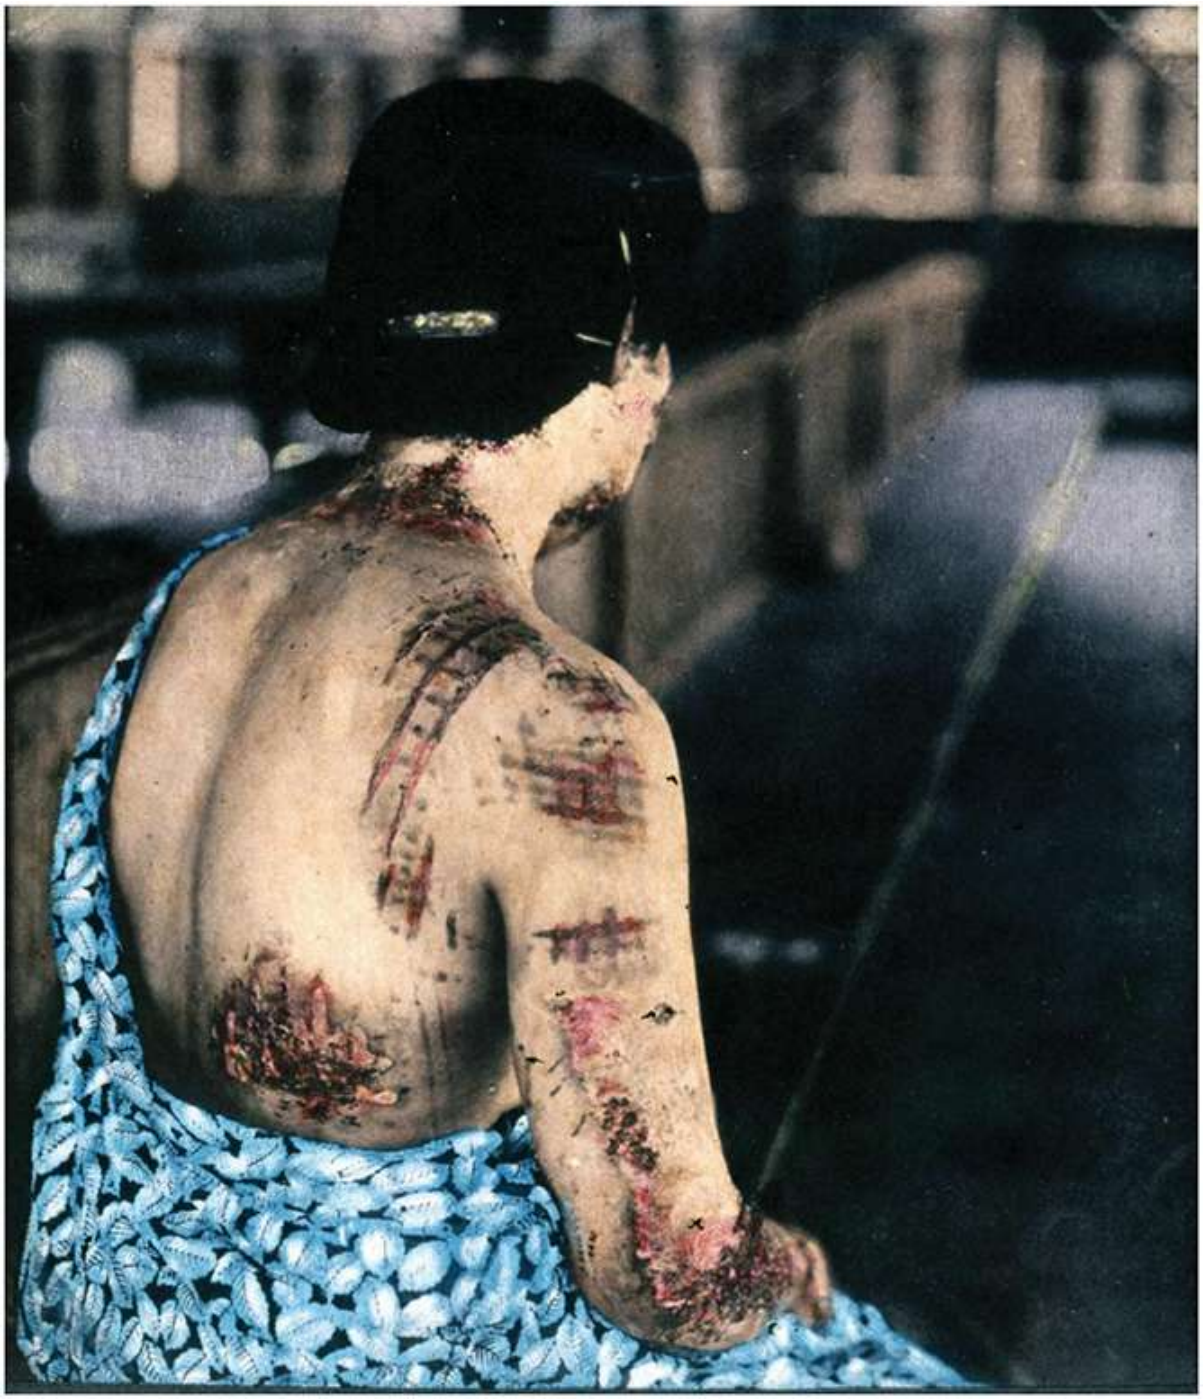

FIGURE 1.30 The Joint Commission for the Investigation of Effects of the Atomic Bomb in Japan issued detailed reports of their findings. This illustration demonstrates acute injury from the thermal effects of the blast. The victim's skin was burned in a pattern produced by the colors in her kimono. The darker colors more readily absorbed the heat of the thermal blast and burned the skin more than the lighter colors. The photograph was taken about nine days after the bombing of Hiroshima. (National Archives and Records Administration.)

Higher tolerance doses (TDs) than initially reported have been observed for a variety of organs,[230-234] as a result of conformal irradiation. This stresses the importance of updating tolerance information in light of more precise treatment planning and delivery of irradiation and more accurate evaluation and recording of sequelae. Examples are radiation dose escalation studies using CRT delivery techniques.

In studying late radiation effects, it is useful to think of organs, which are made up of multiple functional subunits (FSUs) that are arranged serially or in parallel.[235,236] For serially structured organs, such as gastrointestinal tract or spinal cord, damage to one portion of the organ may render the entire organ dysfunctional. In contrast, in organs with parallel structure, like a kidney, FSU damage may not impair the entire organ function because the remaining FSUs operate independently from the damaged group, and clinical injury occurs only when a critical volume of the organ (or proportion of FSUs) is damaged and the surviving FSUs are unable to maintain organ function. Therefore, the sensitivity of an organ depends on the number of FSUs. Marks and others[237,238] have discussed the importance of organ structure in determining late radiation effects and pointed out that conventional dose-volume histograms (DVHs) and NTCP models are frequently inadequate because they ignore functional and structural heterogeneities. Such considerations will be particularly important for partial irradiation of the lung, liver, and kidney to doses that approach the tolerance of the organs' functional units. Variations in FSUs and functional reserve in a patient population may produce NTCP dose-response curves, the widths of which are comparable with those observed clinically.[239,240]

Structural alterations without anatomic or functional impairment may be noted, whereas in other instances, substantial injuries with tissue destruction, severe dysfunction, or even death may occur. Normal tissues have a substantial capacity to recover from sublethal or PLD induced by radiation (at tolerable dose levels). Injury to normal tissues may be caused by the radiation effect on the microvasculature or the support tissues (stromal or parenchymal cells).

Rubin et al[241-243] indicated the usefulness of assigning a certain percentage of risk of complication, depending on the dose of the radiation. The minimal TD is defined as $TD_{5/5}$, which represents the dose of radiation that could cause no more than a 5% severe complication rate within 5 years after treatment. (Some authors use the equivalent terms "tissue tolerance dose," or $TTD_{5/5}$. Both the $TD_{5/5}$ and the $TTD_{5/5}$ are based on treatment at 2 Gy per fraction, five fractions per week.) A complication risk rate for severe injury of 5% in most curative clinical situations is generally viewed as acceptable. Moderate sequelae are noted in varying proportions (10%-25% of patients), depending on the dose of irradiation given and the OARs.

Chronologically, the effects of irradiation are subdivided into acute (first 3 months) and late effects (>3 months after irradiation), according to the NCI Common Toxicity Criteria. The gross manifestations depend on the kinetic properties of the cells (slow or rapid renewal) and the total radiation dose given.[244]

Early applications of time-dose considerations were applied by Baclesse[245,246] based on observations by Coutard[247] that various degrees of mucositis and moist desquamation were repaired by reepithelialization of the mucosa and skin from the periphery of the irradiated field and from cells surviving in the center of the field. Protracted fractionation schedules for carcinoma of the breast with lower daily doses over 10 to 12 weeks were successful in avoiding acute moist desquamation,[248] but the higher radiation doses caused severe tissue damage in a large number of patients.[249]

No correlation has been established between the incidence and severity of acute reactions and the occurrence of late effects. Withers et al[250] compiled data depicting isoeffect lines for acute or late effects in several organs. The slopes for late reactions were steeper than for acute effects, and there was a lack of correlation between the doses producing similar severities of acute or late effects.[251,252] This may result from the difference in the slopes of cell survival curves for acute or late-reacting.[253]

Combining irradiation with surgery or cytotoxic drugs frequently modifies the tolerance of normal tissues to a given dose of irradiation, which may necessitate adjustments in treatment planning and dose prescription. The lack of correlation between acute and late-reacting tissues represents one rationale for combining radiotherapy with chemotherapy.

There is a critical need to accurately assess and record the morbidity of treatment because this, in addition to therapeutic efficacy, is a crucial parameter in the evaluation of new regimens and the selection of therapy for an individual patient. Multiple schemata have been developed, although a complete consensus has not been reached as to ideal grading scores. Toxicity grading systems for various organs were developed by RTOG and the European Organisation for Research and Treatment of Cancer (EORTC). Overgaard and Bartelink[254] stressed the importance of proper recording of morbidity in clinical radiation oncology, with quantification of the normal tissue effects and description of the treatment-related factors correlating with morbidity.

The evolution of radiation treatment planning and delivery, with innovative techniques (3DCRT, IMRT, IMPT image-guided radiation therapy, image-guided brachytherapy) allowing for better definition of target and sensitive structure volumes and more precise quantitation of dose, has introduced more complexity into the evaluation of radiation effects on OARs.[255] Journal articles and books have been devoted to the “Quantitative Analysis of Normal Tissue Effects in the Clinic” (QUANTEC), which provided an updated review of knowledge in this area and

practical guidance on toxicity risks and attempted to identify future research to elucidate radiation effects in normal tissues and organs. The QUANTEC program has continued its efforts and is reviewed in Chapter 12.

ADVERSE NORMAL TISSUE EFFECTS OF RADIATION THERAPY

The Pathology and Pathophysiology of Radiation Fibrosis in Normal Tissue Uninvolved With Tumor

We are in debt to the pathologist Shields Warren (1898-1980) of the New England Deaconess Hospital and New England Baptist Hospital for meticulous and detailed descriptions of the pathology of ionizing radiation, particularly from the atomic bombings of Japan (Figures 1.30-1.32). He described the light microscopic appearance of late radiation fibrosis of the subcutaneous tissues. In heavily irradiated tissues the fibrocytes become functionally and structurally abnormal. The elastic tissue may increase while losing its fine lamellar arrangements. Sometimes irradiated elastic tissue degenerates. Collagen increases "and loses its fibrillar structure, becoming hyalinized." With high doses of radiation "necrosis of collagen will occur. A number of fibrocytes become large and irregular with giant and distorted nuclei resembling those seen in tumor giant cells, although not in themselves neoplastic."[256]

FIGURE 1.31 Total-body irradiation from a nuclear explosion will cause injuries, which have been categorized as the CNS syndrome, GI syndrome, and bone marrow syndrome. The physical manifestations of total-body irradiation exposure on the hair, gastrointestinal tract, and bone marrow are illustrated in this photograph. This 21-year-old soldier was in a wooden house within 1 kilometer of the hypocenter of the Hiroshima explosion. He suffered lacerations on his back and abdomen from the explosion. Twelve days after the blast his hair fell out. Twenty-three days after the blast his gums bled. Purple subcutaneous hemorrhage spots appeared and 25 days after the blast he developed a fever. This was followed by throat pain, which prevented him from drinking. Continuous gum bleeding began. Purple spots spread over the face and upper body. He lost consciousness 27 days after the blast and died on the 28th day after the blast. (National Archives and Records Administration.)

A

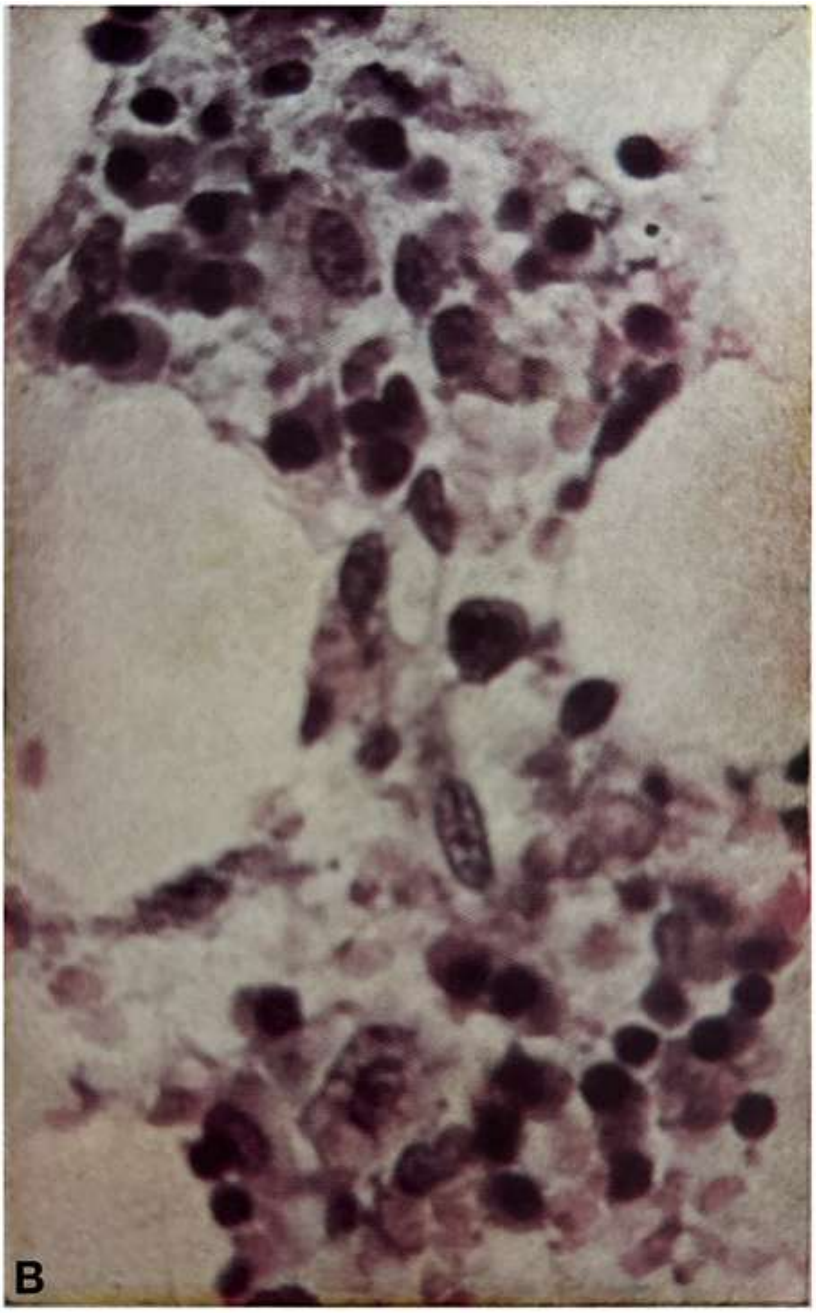

FIGURE 1.32 A 39-year-old male died 6 days after the atomic bombing. He was about 1,000 years from the hypocenter. A. The femur has red gelatinous and gray-red cellular marrow in the upper portion of the shaft but only gelatinous and yellow fatly marrow distally. B. In the microscopic image, there is no normal hematopoietic tissue. There are reticulum cells, plasmacytoid elements, and some large intermediate cells between the two. There is reticulum cell erythrophagocytosis (650×). (Reproduced, with permission from Oughterson AW, Warren S. *Medical Effects of the Atomic in Japan*. McGraw-Hill; 1956.)

With our modern understanding of molecular and cellular biology, we may characterize the development of late radiation injury to normal tissue as a process

launched by the direct and indirect damage of DNA through the generation of reactive oxygen species and free radicals. In normal tissue, what follows is a cascade of chemical signals and cellular responses that produce radiation fibrosis[257], including:

- Radiation induces inflammatory, epithelial, and mesenchymal cells to secrete TGF-β. In response to TGF-β, fibroblasts convert into matrix-synthesizing myofibroblasts. The myofibroblasts secrete collagen, proteoglycans, and fibronectin. This results in avascularity of tissues and their thickening, stiffness, scarring, atrophy, and loss of function. The effects of TGF-β are widespread. Matrix metalloproteinases 2 and 9 are downregulated, while fibroblast growth factor, tumor necrosis factor, EGF, and interleukin-1 are upregulated.
- Radiation damages the vascular endothelium. Platelet aggregation and coagulation occur, and vessels are narrowed or obliterated. Normal tissue hypoxia ensues.
- Radiation causes activation of the Janus kinase and signal transducer and transcription proteins along with nuclear factor κ light-chain enhancer of activated B-cell pathways. As a result, pro-inflammatory cytokines and growth factors are released.[258]

Radiation-Induced Second Primary Malignant Tumors

Patients cured of cancer have a significant probability of developing other cancers. Many publications have documented the frequency of second malignant neoplasms, associated with radiation therapy, in cancer survivors.[250] Several principles characterize radiation-induced cancers:

1. A wide variety of histologic types of cancers can be induced by radiation therapy. The current state of knowledge does not allow us to distinguish these tumors, morphologically, from "naturally" occurring cancers. In the future, it may be possible to identify specific genetic changes associated with radiation-induced malignancy. This future technology, termed *molecular forensics*, may, ultimately, affect our understanding of attributable risk of radiation-induced malignancies.[259,260]
2. The dose incidence curve for carcinogenesis generally rises more steeply with high LET radiation doses than with low LET doses, especially at LDRs (Figure 1.33).[253] In a liver cancer model in mice, neutron irradiation produces a greater incidence of hepatomas than γ irradiation.[261] Low LET radiation becomes less effective at carcinogenesis per cGy as the dose falls. High LET radiation, however, does not.[262,263]

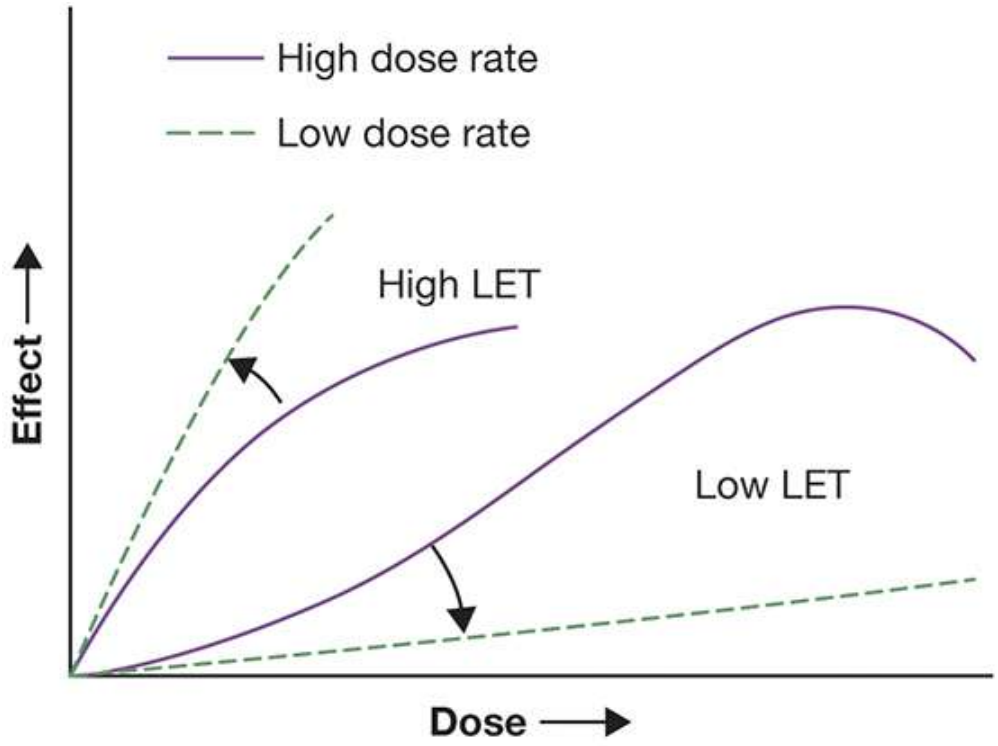

FIGURE 1.33 Dose-response curves for incidence of tumors in relation to dose and dose rate of high linear energy transfer (LET) and low LET irradiation. (Reprinted with permission from Upton AC. Biological aspects of radiation carcinogenesis. In: Boice JD, Fraumeni JF, eds. *Radiation Carcinogenesis: Epidemiology and Biological Significance*. Raven Press; 1984:9.)

3. Earlier in the history of radiation oncology, when one compared the frequency of second malignant neoplasms over time, it appeared that orthovoltage radiation therapy was more likely to be carcinogenic than megavoltage therapy. This may have been a dose-related phenomenon insofar as orthovoltage irradiation gave a higher dose to bone. It was also possible that the longer term follow-up available for survivors of orthovoltage irradiation, somewhat artifactually, leads to a higher reported incidence of tumors.
4. The sensitivity of tissues to radiation-induced malignancies is not uniform. Current evidence indicates that the thyroid gland and the breast are sensitive to cancer induction at relatively low doses of radiation; lymphoid tissue, lung, and liver require moderate doses; and bone requires the highest dose. It also seems likely that the relationship between dose and response may vary according to the type of induced tumor. One can estimate the cancer risk from radiation either per unit dose measured in Gy or per unit dose equivalent measured in sievert. When one measures in sieverts, a quality factor (Q) is used to take account of the varying biologic effectiveness of the different forms of radiation. For example, for a conventional γ-ray or x-ray, $Q = 1$. For neutron irradiation, $Q = 20$. A review of the available literature indicates that the lifetime cancer mortality risk

for a working population of both sexes is 0.008 per Sv for high doses and 0.004 per Sv for low doses.[264] The cancer mortality risk for the general population after whole-body exposure is 0.0001 to 0.0004 per cGy per person.

5. One of the most puzzling aspects of radiation-induced cancer concerns the issue of the relation of low radiation dose to carcinogenesis. Most of the data we have concern relatively high doses. Much of the public debate, however, concerns exposure to relatively low doses. Because we have few exact data regarding low doses, extrapolation is, for the most part, used to predict risk at low doses. This can be a particularly vexing problem in litigation where a plaintiff sues for an alleged radiation-induced malignancy following relatively low-dose exposure to radiation.
6. Any assessment of the radiation dose-response curve for the production of second malignant neoplasms has to take into account the fact that neoplasms also can be induced by agents other than radiation. These include chemotherapy, environmental exposures, and hereditary disposition.
7. Because the risk of radiation-induced carcinogenesis is very small, a large denominator of irradiated patients followed for a long period with thorough follow-up would be necessary to calculate risk with any reliability.
8. Latent periods for the production of a radiation-induced tumor vary according to the type of induced tumor. One type of latency is exemplified by the risk of leukemia in survivors of the atomic bombing. This consisted of an early pulse of increased risk followed by a gradual decline to baseline levels. The second pattern of occurrence, more typical of solid tumors, is an increase in the relative risk of second malignant neoplasms over many years that remains constant over time thereafter. It is important to remember, therefore, that the duration of follow-up for any study population is very likely to influence the frequency of tumors seen.
9. Age is a critical factor in determining radiation risk. In children, second cancers would be more likely to occur in tissues undergoing rapid proliferation, such as the bone and thyroid tissue.[265,266]

There are several classically cited episodes of human radiation carcinogenesis, including:

1. Individuals who were treated with radiation for ankylosing spondylitis suffered from an increase in leukemia. Mortality from colon cancer, which is associated with spondylitis through a common association with ulcerative colitis, was increased in irradiated patients. Mortality for patients with cancers other than leukemia or colon cancer also rose.[267]

2. Diagnostic x-rays of the abdomen and pelvis taken of a pregnant woman to ascertain the size of the pelvic outlet before delivery were associated with an increased risk of malignancy in the offspring.
3. Thomas Edison's assistant died of radiation-induced cancer from experiments conducted shortly after the discovery of the x-ray (Figure 1.52).
4. A large number of immigrants entered the State of Israel following its founding in 1948. X-ray epilation was used to treat tinea capitis. There was an increased incidence of brain and nervous system tumors (1.8 excess risk per 10,000 persons per year) in 10,834 children irradiated for tinea capitis compared with the same number of nonirradiated matched controls and 5,392 siblings. There were 12 malignant brain tumors in the irradiated patients versus five and one suspected in nonirradiated people. The average dose received was 4 Gy in 5 consecutive days. Irradiation doses of 1 to 2 Gy significantly increased the risk of neurologic tumors.[268]
5. The United States dropped atomic bombs on Hiroshima and Nagasaki in Japan in August 1945. Radiation-related risks among bomb survivors show that the incidence of leukemia rose. The increased risk appeared 1 to 3 years after the bombing and peaked at 6 to 7 years. In solid tumors, excess tumor risk was manifest only after exposed individuals reached the age at which the cancer was normally prone to develop.
6. Uranium miners suffered an increase in lung cancer as a result of inhalation of radon gas. Workers who painted luminous radium dials on watch faces developed bone sarcomas because of the habit of shaping the paintbrush in the mouth and ingesting bone-seeking radium.[269]
7. In the past, thorotrast was used as a contrast medium in diagnostic radiology. This material is a colloidal suspension of the α-emitter thorium dioxide. The compound was associated with the late development of angiosarcoma.
8. Canadian studies of women with tuberculosis who were fluoroscoped repeatedly for monitoring of an induced pneumothorax demonstrated an increased incidence of breast cancer.
9. The Chernobyl Nuclear Power Plant accident of April 26, 1986, is associated with an increased risk of thyroid cancer in Belarus and Ukraine.

An important review of radiation-induced sarcomas was published by Cahan et al[270] in 1948. Cahan et al's criteria, which were used to define a radiation-induced sarcoma, have wide applicability and are used, by some investigators, as the standard for demonstration of any alleged radiation-induced malignancy. The Cahan criteria are as follows:

a. A radiation-induced malignancy must have arisen in an irradiated field.
b. A sufficient latent period, preferably longer than 4 years, must have elapsed between the initial irradiation and the alleged induced malignancy.
c. The treated tumor must have been biopsied. The alleged induced tumor must have been biopsied. The two tumors must be of different histologies.
d. The tissue in which the alleged induced tumor arose must have been normal (ie, metabolically and genetically normal) prior to radiation exposure.

THE BASIC CONCEPTS OF CLINICAL RADIATION THERAPY

Dose-Time Factors

Dose-time considerations constitute complex relationships that express the interdependence of total dose, time, and number of fractions in the production of a biologic effect within a given tissue volume. This phenomenon, from a radiobiologic viewpoint, is closely related to the four Rs of ionizing radiation:

1. *Repair* of sublethal damage (SLD), repaired within hours under normal circumstances, and potentially lethal damage (PLD), which can be modified by post-irradiation conditions.
2. *Repopulation* of cells between fractions
3. *Redistribution* of cells throughout the cell cycle (partially, the result of radiation-induced synchrony secondary to transient arrest at cell cycle checkpoints and cell cycle–dependent cell killing)
4. *Reoxygenation* occurring during repeated radiation exposures

The advantages of dose fractionation include the following:

1. Reduction in the number of hypoxic cells occurs through cell killing and reoxygenation. There is increased oxygenation in the tumor after irradiation, whereas changes in normal tissue oxygen are slight or nonexistent.[271]
2. Reduction in the absolute number of clonogenic tumor cells by the preceding fractions with the killing of the better oxygenated cells. Assuming a constant supply of oxygen, fewer cancer cells will have access to an increased amount of oxygen.
3. Blood vessels compressed by a growing cancer are decompressed secondary to tumor regression, thus permitting better oxygenation despite the constant diffusion distance of oxygen in tissue near 200 μm.
4. Fractionation exploits the difference in recovery rate between normal, acute, and late-reacting tissues and tumors. Radiation-induced redistribution of cells within

the cell cycle tends to sensitize rapidly proliferating cells as they move into the more sensitive phases of the cell cycle.

5. The acute normal tissue toxicity of single radiation doses can be decreased with fractionation. Thus, patients' tolerance of radiotherapy will improve with fractionated irradiation.

In general, fractionated irradiation will spare acute reactions because of compensatory proliferation in the epithelium of the skin or the mucosa, acceleration of which can be measured experimentally 2 or 3 weeks after initiation of therapy, but most likely starts with initiation of irradiation.[272-275] However, a prolonged course of therapy with small daily fractions will decrease early acute reactions, but not necessarily prevent serious late damage to normal tissues. This approach also promotes accelerated repopulation and permits the growth of rapidly proliferating tumors. A major research effort in clinical radiobiology is and will be devoted to the optimization of dose-time fractionation schedules for various tumors that are individualized depending on cell kinetic characteristics, molecular biology, and clinical observations.[276,277] Fowler[278] published theoretic considerations based on a series of assumptions of the values used in the LQ equation with a time factor in which he attempted to predict the optimal dose fractionation schedules for tumors with various cell doubling times. He concluded that optimal overall times depend primarily on the doubling time of the tumor cells and intrinsic radiosensitivity, α (assumed to be proportional to α/β). Short overall treatment times are required for tumors with a low α/β ratio or fast proliferation. For median potential doubling times of 5 days and intermediate radiosensitivity, overall times of 2.5 to 4 weeks would be optimal. More slowly proliferating tumors, he argued, should be treated with longer overall times (Figure 1.34). Clinical studies, however, support relatively short overall treatment times in several common solid malignancies, in contrast to Fowler's conclusions. In vitro techniques to assess tumor radiosensitivity in biopsy specimens ultimately may be helpful as predictive assays.

Altered Fractionation

Without a solid biologic basis and out of empiricism and convenience, the "standard fractionation" for radiation therapy has evolved into five fractions weekly. Other fractionation schedules have been proposed that deliver a single fraction, multiple fractions daily, fractions 3 days a week, six fractions weekly, or use a hyperfractionation split-course regimen (Figure 1.35). Based on the narrow window between improvements in tumor control and enhanced normal tissue toxicities,[279] any altered fractionation schedule is potentially harmful and must be approached with caution. However, the improved quality of clinical trials by national study groups and by individual institutions has generated a growing body of clinical outcome data that, together with improved biologic modeling, allows relatively accurate predictions of clinical outcomes based on relative biologic effectiveness (RBE) calculations[280] (Table 1.9).

TABLE 1.9 COMPARISON OF VARIOUS FRACTIONATION SCHEDULES

	Conventional	Split-Course	Accelerated Fractionation	Hyperfractionation
Indication, in tumors, of	Average	Average or slow	Rapid	Slow (with large cell loss factors)

	Conventional	Split-Course	Accelerated Fractionation	Hyperfractionation
growth rate				
Normal tissue effects, acute	Standard	Standard or greater	Greater	Standard or greater
Normal tissue effects, late	Standard	Greater	Standard (if complete repair of sublethal damage occurs) or greater	Lower
Advantages	—	Shorter actual treatment time (fewer fractions)	Destroys more tumor cells; prevents tumor cell repopulation; less overall treatment time	Lower OER with small doses; spares late damage; allows reoxygenation; allows stem cell repopulation
Disadvantages	—	May permit tumor repopulation	—	More fractions

OER, oxygen enhancement ratio.

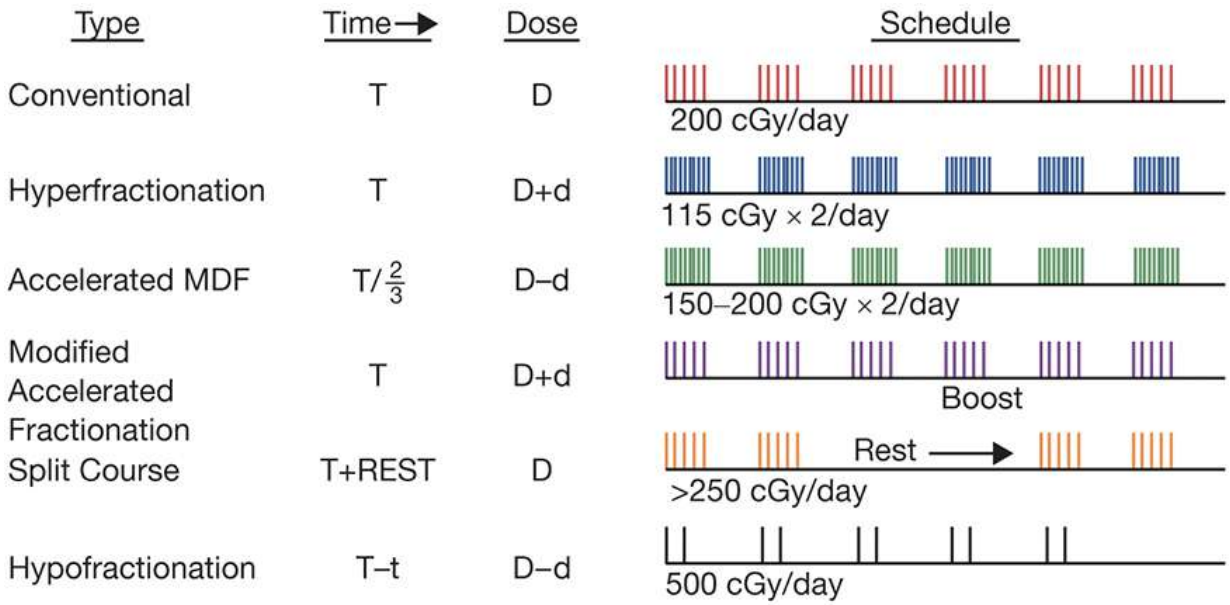

FIGURE 1.35 Various types of fractionation used in radiation therapy.

Multiple daily fractions are likely to be more effective in rapidly growing tumors with a high growth fraction. Normal tissues behave as actively proliferating cells for expression of acute reactions but as slowly proliferating cells in the manifestation of late injury.[281,282] As suggested by several biologic studies,[283] clinical trial results conducted by EORTC and RTOG demonstrated that a minimum of 6 hours of

interfraction interval should be allowed when multiple daily fractions are used to allow maximum repair of normal tissues. This is supported by reduced complication rates in patients irradiated for carcinoma of the lung and a highly uniform cohort of patients with tonsillar squamous cell carcinomas.[284]

Accelerated fractionation aims at shortening the overall treatment time. Schedules may use larger than standard size fractions 5 times weekly or more than five fractions per week of 2 Gy. In addition, multiple fractions of radiation may be given daily exclusively or in combination with standard fractions of 2 Gy. Some reduction in the total dose delivered may have to be used for fractions greater than 2 Gy for normal tissue sparing. These schedules may be preferable with hypoxic cell sensitizers or other chemical modifiers of radiation response that require the presence of a high concentration of the compound in the tumor at the time of the radiation exposure.

With hyperfractionation, a larger number of smaller than conventional dose fractions are given daily; the total daily dose is usually 10% to 20% greater than with standard fractionation; the total period of time is minimally changed; and the total dose needs to be escalated to achieve tumor toxicity similar to that of standard fractionation. The aim of hyperfractionation is to achieve the same incidence of late effects on normal tissue as observed with a comparable conventional regimen while increasing the probability of tumor control through dose escalation.[285]

Accelerated Repopulation

Withers and Taylor[286] described experimental observations documenting accelerated repopulation of tumor cells during fractionated radiotherapy and provided convincing evidence that this phenomenon occurs in clinical situations. Although Withers and Taylor's analyses suggested that accelerated repopulation occurs preferentially after the fourth week of radiotherapy, reanalysis of the same data by Bentzen[287] and Thames et al[288] and independent derivations by Fowler[289] suggested that repopulation starts early during fractionated irradiation. The latter is supported by experimental data of Schmidt-Ullrich et al,[290] showing that molecular processes of accelerated repopulation, mediated through radiation-induced receptor activation and cellular growth stimulation, occur after a single radiation exposure of 2 Gy. The effectiveness of a course of fractionated irradiation depends in part on the killing by individual fractions as well as on the rate of proliferation of surviving cells between irradiation fractions (Figures 1.36-1.38). Neoadjuvant chemotherapy also may lead to increased proliferation of surviving tumor cells after partial regression of the lesion, which could result in decreased cell killing by subsequent fractionated irradiation.

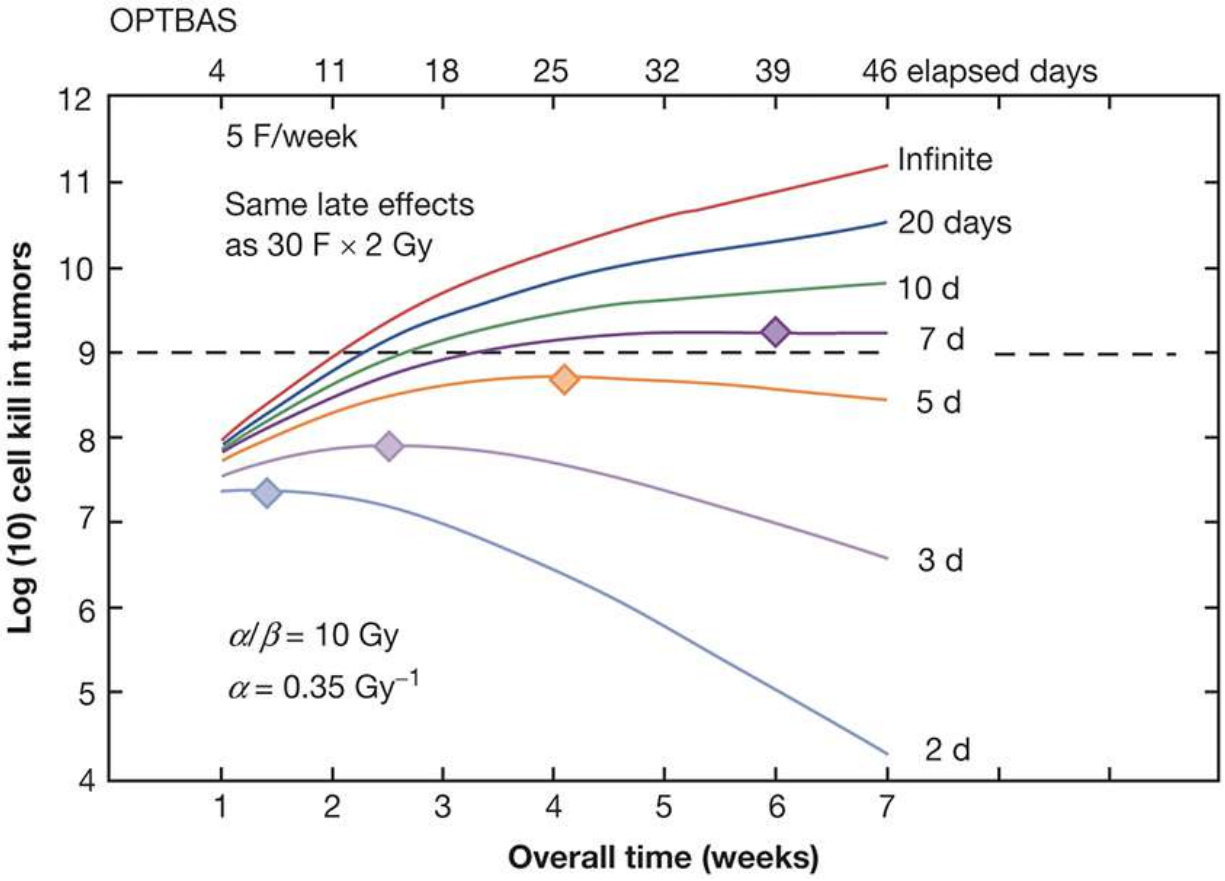

FIGURE 1.36 Log cell kill in tumors as a function of overall time, for schedules using five fractions per week to a total dose that gives the same late effects as 30 fractions of 2 Gy (assuming α/β = 3 Gy for late effects). Each curve is for the stated proliferation doubling time (average over the overall time). The diamond-shaped symbols show the maximum cell kill for that doubling time, at the optimum overall time for that number of fractions per week. If there is no diamond, the optimum overall time is >7 weeks. The dotted line is drawn arbitrarily at 9 logs of cell kill. (Reprinted from Fowler JF. How worthwhile are short schedules in radiotherapy? A series of exploratory calculations. *Radiother Oncol*. 1990;18[2]:165-181. Copyright © 1990 Elsevier Ireland Ltd. With permission.)

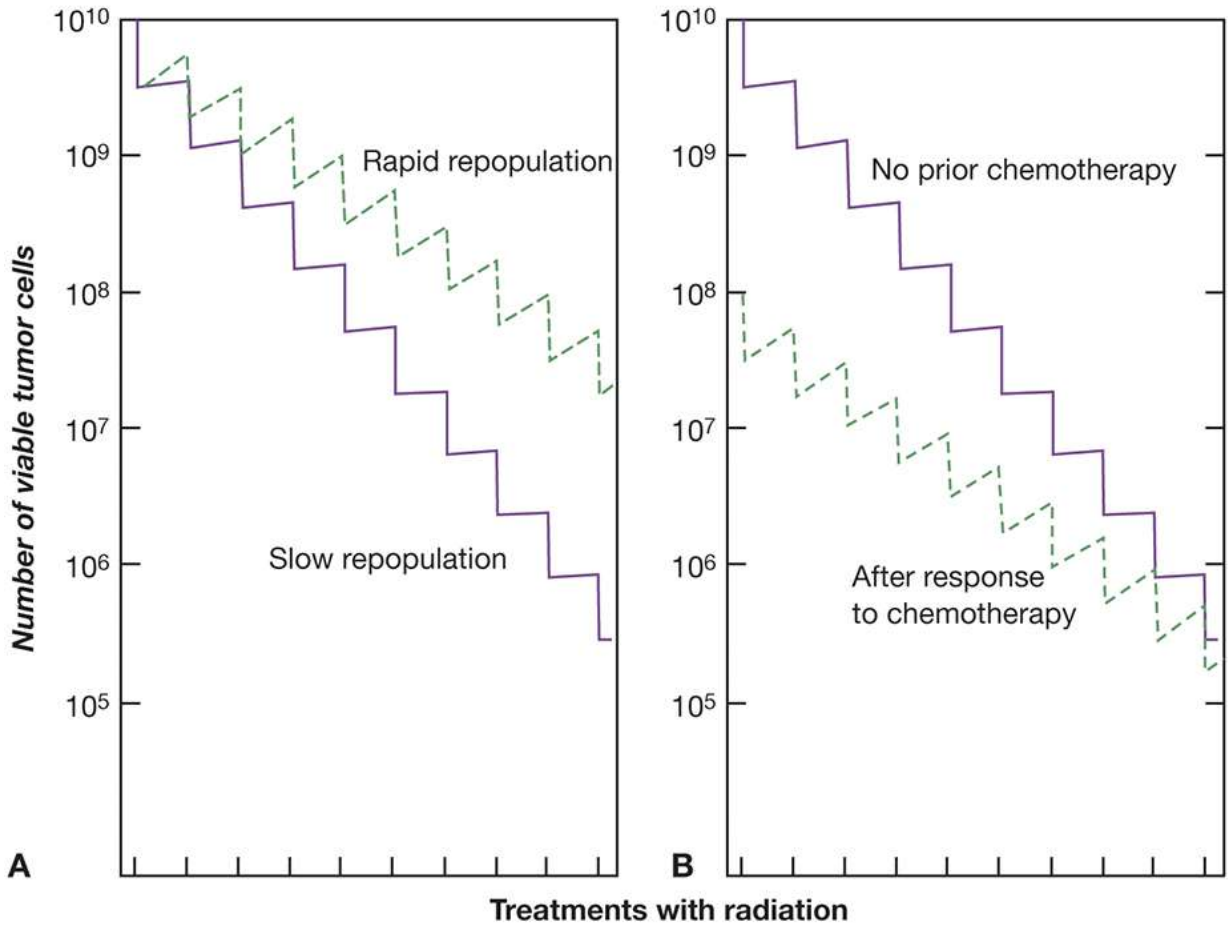

FIGURE 1.37 A. Schematic diagram indicating that cell survival during a course of fractionated irradiation depends not only on the proportion of cells killed with each dose (equal for the two curves shown) but also on the rate of proliferation of surviving cells between dose fractions, which differs for the two curves. (Reprinted from Tannock IF. Combined modality treatment with radiotherapy and chemotherapy. *Radiother Oncol*. 1989;16[2]:83-101. Copyright © 1989 Elsevier Ireland Ltd. With permission.) B. Hypothetical diagram to illustrate the number of surviving cells in a tumor during treatment with irradiation alone (solid line) or during radiation therapy delivered to a tumor that has responded to chemotherapy (ie, cell number reduced to 1% at the start of irradiation) but where proliferation has been stimulated (dashed line). Note that cell survival is similar after fractionated irradiation, despite the initial response to drugs. (Reprinted from Tannock IF. Combined modality treatment with radiotherapy and chemotherapy. *Radiother Oncol*. 1989;16[2]:83-101. Copyright © 1989 Elsevier Ireland Ltd. With permission.)

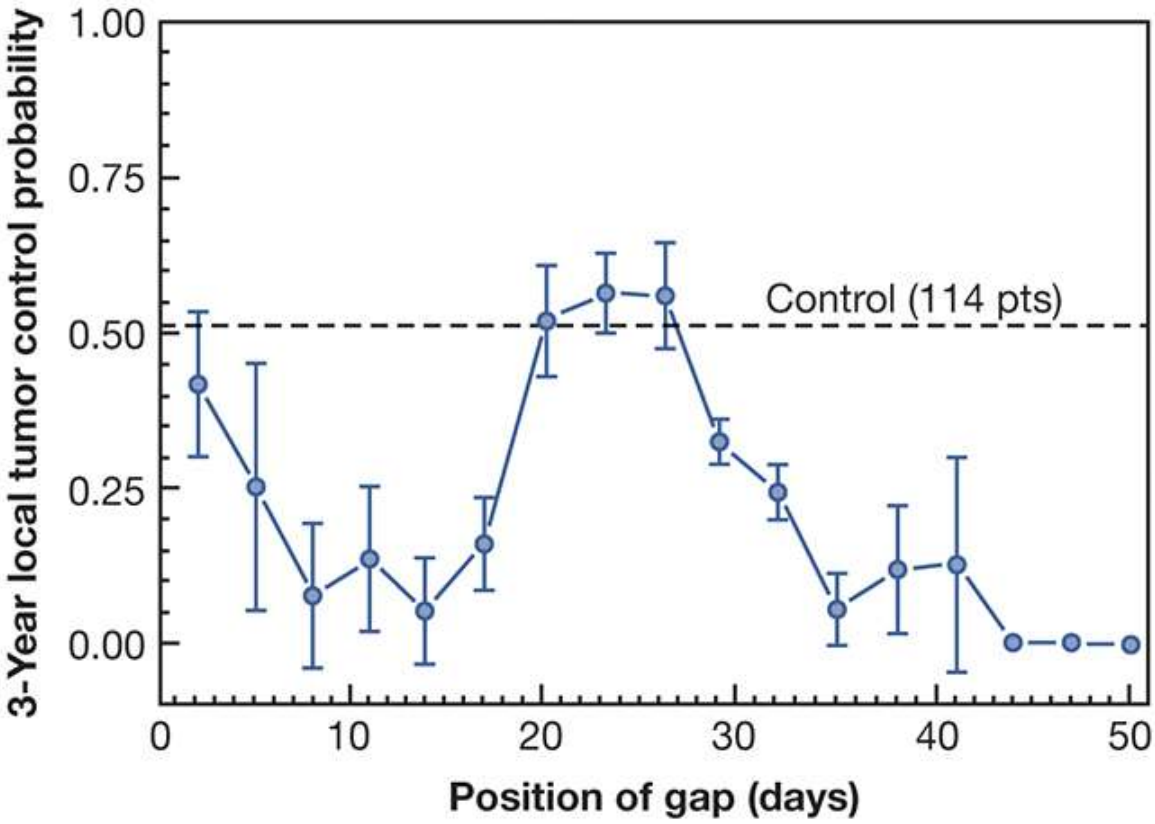

FIGURE 1.38 Dependence of tumor control probability (TCP) on the position of a single-treatment gap in 533 patients. Gap duration ranged from 3 to 20 days. Position of a gap is defined by its starting point. Each point shows the TCP averaged over 3 consecutive days (±SD). (Reprinted from Skladowski K, Law MG, Maciejewski B, Steel GG. Planned and unplanned gaps in radiotherapy: the importance of gap position and gap duration. *Radiother Oncol*. 1994;30[2]:109-120. Copyright © 1994 Elsevier Ireland Ltd. With permission.)

Isoeffect Graphs

To express an equal biologic effect produced by various fractionation schedules, isoeffect lines have been generated. Kronig and Friedrich[291] first published the observation that a specific physical dose of irradiation is less biologically effective if given in multiple fractions, which embodies the original concept of recovery between fractions. Later, MacComb and Quimby[292] and Reisner[293] established the rate of recovery in experimentally produced skin reactions in patients.

In 1944, Strandqvist[294] published a monograph describing the results of treatment of 280 patients with skin cancer (squamous cell and basal cell carcinoma); most tumors were treated within 14 and 29 days, and only one was treated within 45 days. An isoeffect line was drawn, with a slope of 0.22. He fitted the recovery factors of MacComb and Quimby and Reisner using an extrapolated value of 0.35 per day as the time for a single dose. He also produced a graph for various degrees of radiation reaction on the skin, ranging from erythema to necrosis (Figure 1.39). It should be

emphasized that in these curves, the vertical coordinate represents the total dose given, and the abscissa represents the total duration in days after the first irradiation. However, some authors have plotted similar graphs representing the number of fractions in the horizontal coordinate. It is critical to identify these two parameters because one could deliver 60 Gy in 6 weeks in 30 fractions given 5 times weekly or the same dose delivered in 18 fractions given 3 times weekly. The effects on normal tissues certainly would be different. von Essen,[295] using the Strandqvist data as well as his own, pointed out the importance of the volume irradiated when isoeffect parameters are studied and generated a 3D display of these data.

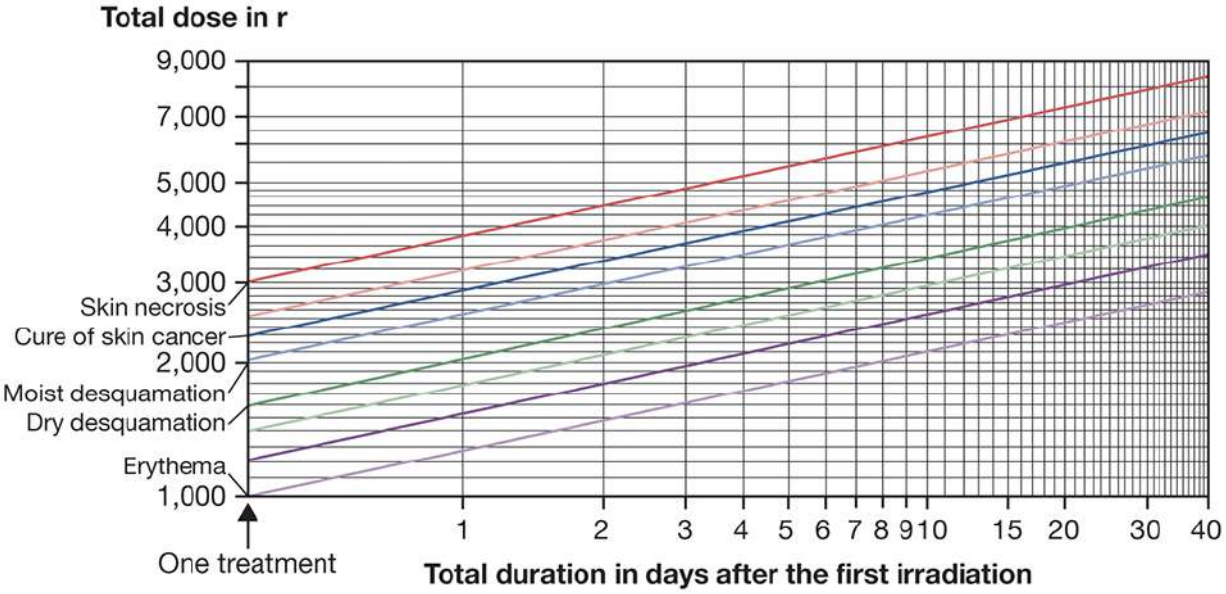

FIGURE 1.39 Strandqvist's curves on log paper.[177] The slope of the curves (0.22) is the same for the tumoricidal dose for squamous cell carcinoma for various degrees of skin reactions. (From Strandqvist M. Studien iiber die kumulative Wirkung der Rontgenstrahlen bei Fraktionierung. Erfahrungen aus dem Radiumhemmet an 280 Haut- und Lippenkarzinomen. *Acta Radiol*. 1944;55[suppl]:1-300. Copyright © 1944 SAGE Publications. Reprinted by permission of SAGE Publications.)

Dutreix et al[296] published observations on the influence of fraction size in patients with cancer of the lung, on whom one of the supraclavicular areas received a single exposure and the other area received two exposures separated by 6 hours. They noticed that two fractions of 1 Gy produced the same skin reaction as one fraction of 2 Gy. As the fraction size increased, however, it took a higher dose in the two-fraction schedule to produce the same reaction as with the single-fraction schedule. With mucositis of the faucial arch used as an end point, researchers at MD Anderson Cancer Center observed that 10 Gy per week given in five fractions of 2 Gy is equivalent to 11 Gy given in 10 fractions, twice a day, separated by 3 hours.[297]

The slopes for reactions for various normal tissues differ, as do slopes of tumor curability and normal tissue late effects. In general, the slope for tumor curability is less steep than that for normal tissue reactions. Isoeffect lines for various squamous cell carcinomas of the head and neck, different stages, have slopes varying from 0.33 to 0.38.[298,299] Furthermore, as stated earlier, tolerance of normal tissues is strongly related to the volume irradiated. Whereas 60 Gy could be given safely in 5 weeks for a small glottic tumor with a 5-cm by 4-cm portal, the same dose delivered in the same period for a supraglottic carcinoma, with a larger portal covering the entire larynx, would result in more severe acute and late sequelae[300] (Box 1.5).

Box 1.5

Nominal Standard Dose and Time-Dose Factor

The nominal standard dose (NSD) concept is of historic interest. For 20 years, NSD was used frequently to express equivalency of clinical doses of irradiation based on human skin tolerance and curability of squamous cell carcinoma. Cohen[374] pointed out that the regression coefficient for squamous cell carcinoma was different from that of normal skin (0.24). In 1969, Ellis[375] suggested that if one number could be used to represent the dose of irradiation that reached normal tissue tolerance, this would be advantageous in comparing different techniques. This figure should represent the normal connective tissue tolerance because this was, in his thinking, the limiting factor in most tumor therapies.

The unit for NSD expression was the *ret*. It could never be assumed that the NSD value represented a “single equivalent dose” because the isoeffect time calculated by Ellis used data from 4 to 30 fractions. Another flaw of the NSD calculation was that it did not allow for the effect of variations in volume treated or for interruptions of therapy (split-course therapy). Orton[380] estimated that NSD calculations were misused about 50% of the time by unaware clinicians comparing different radiation therapy regimens. The NSD formula did not predict isoeffect in pig skin irradiation using two to five fractions per week. Moreover, early reactions did not predict the magnitude of late damage when dose fractionation was altered from conventional daily schedules.

In 1973, Orton and Ellis[376] (*Br J Radiol*. 1973;46:529-537) published a simplification of the NSD concept more applicable to clinical radiation therapy, stating that when a treatment did not result in normal connective tissue tolerance, treatment effectiveness should be described in terms of partial tolerance. Although there was no definite basis for the application of the time-dose factor (TDF) concept to clinical radiation therapy, equivalency of various dose schedules is sought constantly. For split-course regimens, the TDF values (in units of ret) were used by adding the TDF value for each of the partial tolerance factors corresponding to each component of the treatment and correcting for the decay of the first part of the treatment TDF.

In 1974, Orton[377] (*Radiology*. 1975;46:526-537) defined TDF values for continuous irradiation that could be used with temporary or permanent brachytherapy implants, using various isotopes. A standard radium therapy regimen of 60 Gy in 168 hours was used for comparison with other equivalent techniques. This was equivalent to 1,800 ret of fractionated external irradiation.

Linear Quadratic Equation (α/β Ratio)

Formulations based on dose survival models have been proposed to evaluate the biologic equivalence of various doses and fractionation schedules. These assumptions are based on an LQ survival curve represented by the following equation:

$$\log_e S = \alpha D + \beta D^2,$$

in which α represents the *linear* (ie, first-order dose-dependent) component of cell killing and β represents the *quadratic* (ie, second-order dose-dependent) component of cell killing. Thus, β represents the more reparable (over a few hours) component of cell damage. The dose at which the two components of cell killing are equal constitutes the α/β ratio (Table 1.10).

TABLE 1.10 RATIO OF LINEAR (*A*) TO QUADRATIC (*B*) TERMS FROM MULTIFRACTION EXPERIMENTS AND CLINICAL DATA

	α/β Ratio (Gy)	
Tissue	**Experimental**	**Clinical**
Early Reactions		
Skin/subcutaneous tissues	9-12	5-10
Jejunum	6-10	2.2-8
Colon	10-11	—
Testis	12-13	—
Callus	9-10	—
Late Reactions		
Spinal cord	1.0-4.9	3.3
Kidney	1.5-2.4	—
Lung	2.4-6.3	4.2-4.7
Bladder	3.1-7.0	3.4-4.5

Modified with permission of Elsevier Science & Technology Journals from Fowler JF. Fractionation and therapeutic gain. In: Steel GG, Adams GE, Peckham MJ, eds. *The Biological Basis of Radiotherapy*. 2nd ed. Elsevier Science; 1983:181-194; permission conveyed through Copyright Clearance Center.

In a study of 17 human tumor cell lines, Steel and Peacock[301] observed that the average surviving fraction at 2 Gy is 0.44 from the α component and 0.88 from the β component. The β effect at that dose level appears to be similar in radiosensitive and radioresistant tumors; thus, among radiosensitive tumors in which the survival from the α component is below 0.3, the β effect makes a very small contribution to overall

radiosensitivity in the lower dose region. The overall effect of many small fractions is to amplify the dominance of the α component. The β effect is unimportant because repair will be almost complete. In the more radiocurable tumors, cell killing by the α component represents the predominant fraction of tumor cell killing (Figure 1.40).

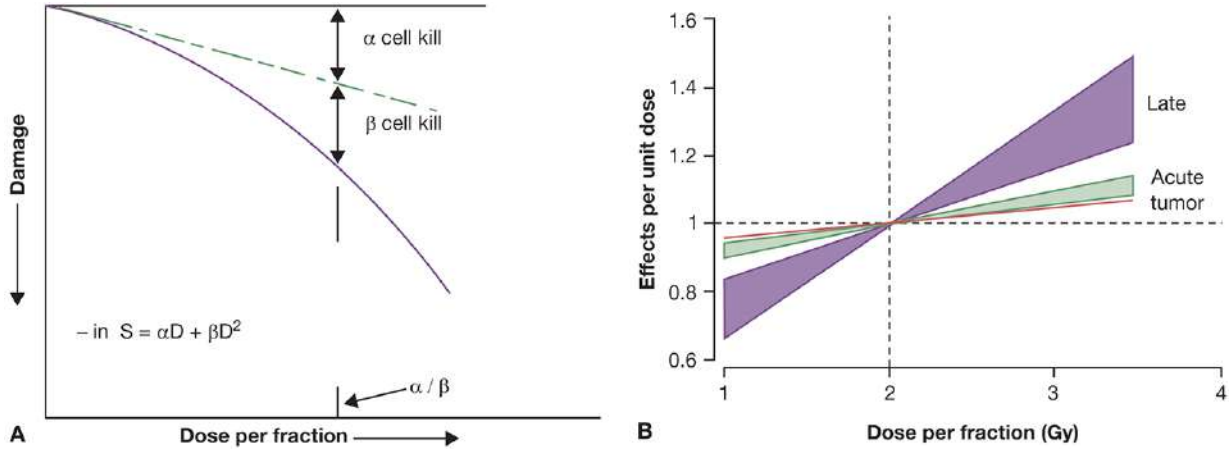

FIGURE 1.40 A: At a dose equal to the *α/β* ratio, the log cell kill because of the α-process (nonreparable) is equal to that because of the β-process (reparable injury); *α/β* is thus a measure of how soon the survival curve begins to bend over significantly. The *α/β* ratio for late effects on normal tissue generates a "curvier curve" than the *α/β* ratio for radiation's effects on acutely reacting normal tissue and tumor cells. Thus, the relative effect of dose per fraction is higher for late-responding tissues than for acutely responding tissues. In particular, for the central nervous system, high dose per fraction radiation therapy is associated with an increased risk of late effects. An *α/β* ratio of 2 to 3 commonly is used in calculations of radiation effects on late-reacting tissue, whereas a ratio of 10 is used more commonly for acute-responding tissues or tumor. (Used with permission of Elsevier Science & Technology Journals from Fowler JF. Fractionation and therapeutic gain. In: Steel GG, Adams GE, Peckham MJ, eds. *The Biological Basis of Radiotherapy*. 2nd ed. Elsevier Science; 1983:181-194; permission conveyed through Copyright Clearance Center.) B. A schematic representation of biologic data relating dose per fraction to effect on tumors, early-reacting, and late-reacting normal tissues. (Reprinted from Saunders MI. Programming of radiotherapy in the treatment of non-small-cell lung cancer—a way to advance care. *Lancet Oncol*. 2001;2[7]:401-408. Copyright © 2001 Elsevier. With permission.)

The shape of the dose survival curve with photons differs for acutely and slowly responding normal tissues. This difference in shape is not observed with neutrons. The severity of late effects changes more rapidly with a variation in the size of dose per fraction when a total dose is selected to yield equivalent acute effects. With a decreasing size of dose per fraction, the total dose required to achieve a certain isoeffect increases more for late-responding tissues than for acutely responding tissues. Thus, in hyperfractionated regimens, the tolerable dose would be increased more for late effects than for acute effects. Conversely, if large doses per fraction are used, the total dose required to achieve isoeffects in late-responding tissues would be reduced more for late effects than for acute effects. In general, tumors and acutely

reacting tissues have a high α/β ratio (8-15 Gy), whereas tissues involved in late effects have a low α/β ratio (1-5 Gy).

The values for α and β can be obtained from graphs in which the reciprocal of the total dose (Gy^{-1}) and the dose per fraction (Gy) are plotted. A straight line is obtained. The intercept of this line with the zero dose-per-fraction axis is proportional to α and equal to $\alpha/\ln S$, wherein S is the natural logarithm of survival. The slope is proportional to β and equal to $\beta/\ln S$.

The algebraic functions to derive the straight line from the reciprocal total dose per fraction plot are as follows: Tumor cell survival following n fractions, each of dose d:

$$S = (e^{-\alpha d} - \beta d^2)n$$
$$-\ln S = n\,(\alpha d + \beta d^2)$$
$$-\ln S = \alpha\, nd + \beta n d^2$$
$$-\ln S = nd\,(\alpha + \beta d)$$

Dividing both sides by total dose nd, we have

$$\frac{-\ln S}{nd} = \alpha + \beta d$$

Intercept Slope

Withers et al[302] proposed a method for using these survival curve parameters for calculating the change in total dose necessary to achieve an equal response in tissue when the dose per fraction is varied, using the α/β ratios. This calculation accounts only for the effect of repair of cellular injury. The isoeffect curves vary for different tissues. A biologically equivalent dose (BED) can be obtained using following formula:

$$\text{BED} = \frac{\ln S}{\alpha}$$
$$\text{BED} = nd\left[1 + d/(\alpha/\beta)\right]$$

If one wishes to compare two treatment regimens, the following formula can be used:

$$\frac{Dr}{Dx} = \frac{\alpha/\beta + dx}{\alpha/\beta + dr}$$

in which Dr is the known total dose (reference dose), Dx is the new total dose (with different fractionation schedule), dr is the known fractionation (reference), and dx is the new fractionation schedule.

Let us consider an example of the use of this formula (with some reservations). Suppose 50 Gy in 25 fractions is delivered to yield a given biologic effect. If one assumes that the subcutaneous tissue is the limiting parameter (late reaction), it is desirable to know what the total dose to be administered will be using 4-Gy fractions. Assume α/β for late fibrosis equals 2 Gy.

Using the above formula:

$$Dx = \frac{Dr\ (\alpha\ /\ \beta + dr)}{\alpha/\beta + dr}$$

Thus,

$$Dx = 50\ Gy \left(\frac{5 + 2}{5 + 4}\right) = 39\ Gy$$

The basic LQ equation addresses the inactivation of a homogeneous population of cells. One should be wary, however, of accepting the basic equation as being complete. Because it is likely that accelerated repopulation of tumor clonogens occurs during the course of radiotherapy, and that cell cycle redistribution and reoxygenation also occur, we should consider how these factors can be accounted for in the formula.[303,304]

Repopulation may be accounted for, in broad approximation, by describing the number of clonogens (N) at time t as being related to the initial number of clonogens (No).

Then,

$N = \mathrm{No}^{e\lambda t}$

The parameter λ determines the speed of cell repopulation and is given by

$$\lambda = \frac{\log e^2}{T_{\text{pot}}} = \frac{0.693}{T_{\text{pot}}}$$

where T_{pot} is the effective doubling time of cells in the tumor. If we ignore spontaneous cell loss, then T_{pot} is approximately the same as the measurable in vitro doubling time of tumor cells. Reported values of T_{pot} are 2 to 25 days with a median value of approximately 5 days. For late-responding tissues, T_{pot} is so large that λ is effectively zero.

Incorporating the allowance for tumor proliferation, with t representing time, the LQ equation becomes

$$\text{BED} = nd\left(1 + \frac{d}{\alpha/\beta}\right) - \frac{0.693t}{\alpha T_{\text{pot}}}$$

Let us assume an α/β for an acutely reacting tissue, such as a tumor, of 10, and an α of 0.3 with a T_{pot} of 5. The BED of 70 Gy of 2 Gy/fraction, five fractions per week, in 46 days, is

$\text{BED} = 70(1 + 0.2) = 84\ \text{Gy}_{10}$.

Now let us add the correction for tumor repopulation during the course of treatment:

$$\text{BED} = 70\left(1 + \frac{2}{10}\right) - \frac{0.693t}{0.3} \times \frac{46}{5}$$

$$\text{BED} = 84 - 21 = 63\ \text{Gy}_{10}.$$

The decrease in clonogens by radiotherapy is attenuated, in part, by the repopulation of the surviving clonogens (Figures 1.41 and 1.42).

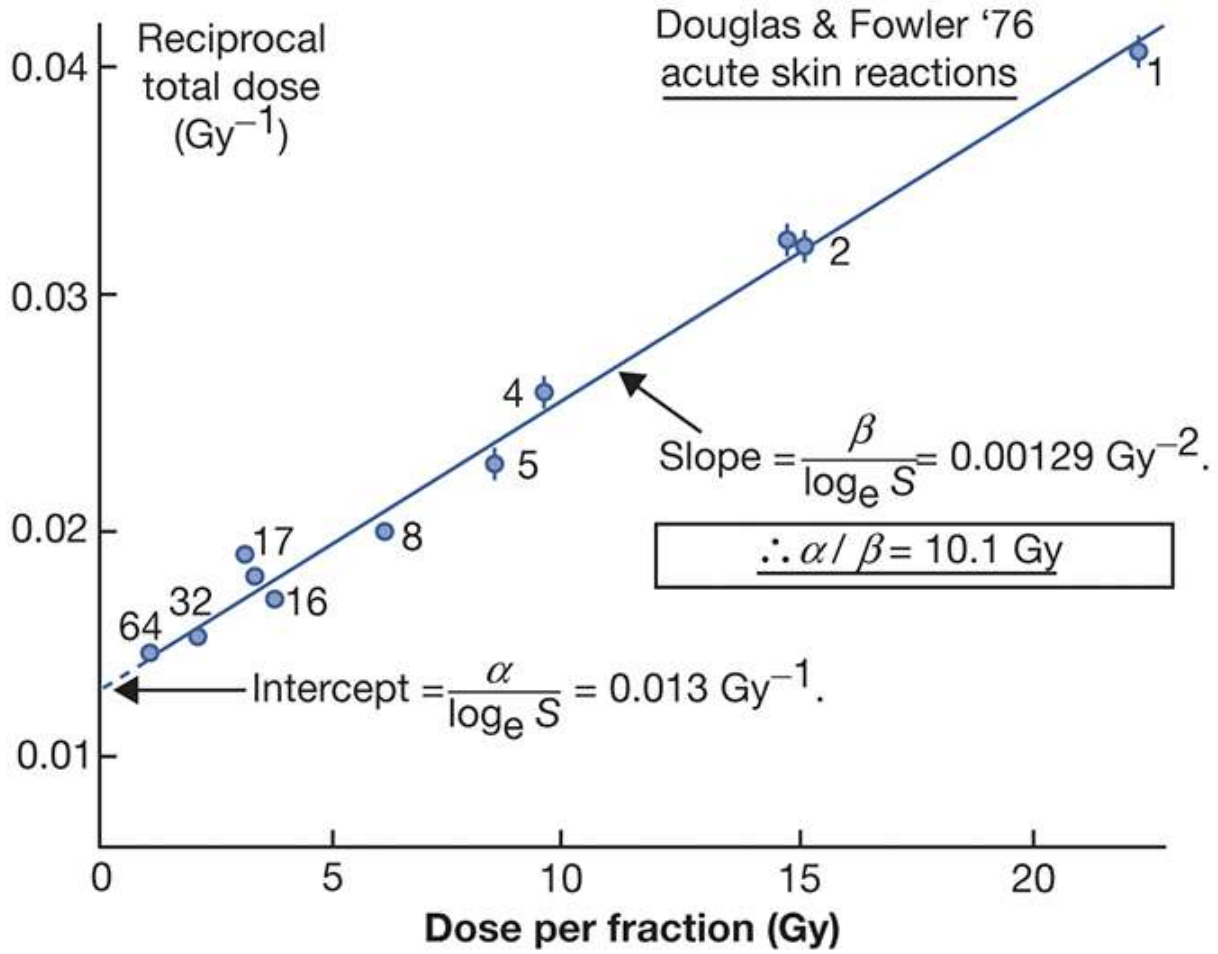

FIGURE 1.41 Values of α and β. If the reciprocal of the total dose (for several multifraction schedules) is plotted against dose per fraction, a straight line will be obtained. The intercept of this line with the zero dose-per-fraction axis is proportional to α (α/ln S). The slope is proportional to β (β/ln S). The α/β ratio is readily determined. For absolute values of α and β, the clonogenic assay is necessary for the end point. (Used with permission of Elsevier Science & Technology Journals from Fowler JF. Fractionation and therapeutic gain. In: Steel GG, Adams GE, Peckham MJ, eds. *The Biological Basis of Radiotherapy*. 2nd ed. Elsevier Science; 1983:181-194; permission conveyed through Copyright Clearance Center.)

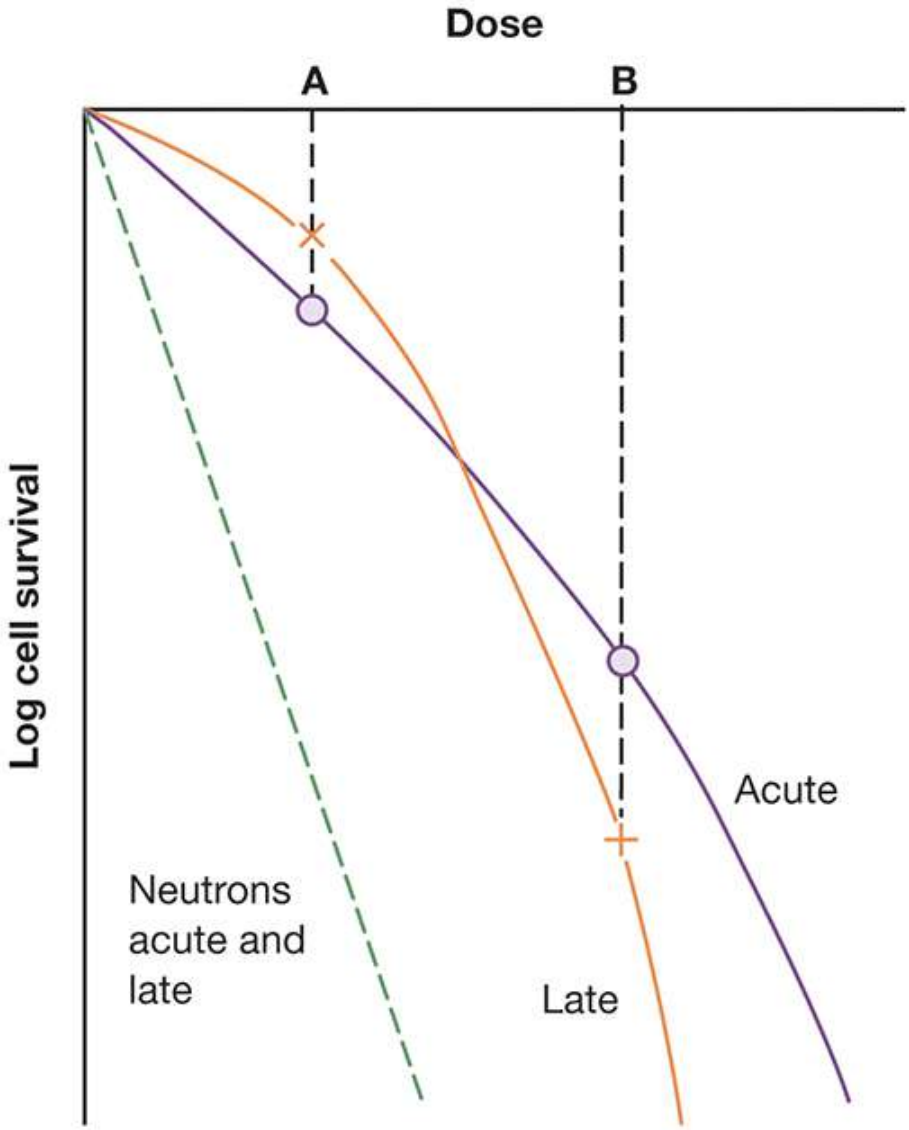

FIGURE 1.42 Hypothetical survival curves for the target cells for acute and late effects in normal tissues exposed to x-rays or neutrons. The α/β ratio in the equation for surviving fractions (SF = $e^{-\alpha D+\beta D_2}$) is higher for late effects than for acute effects in x-irradiated tissues, resulting in a greater rate of change in effect in late-responding tissues with a change in dose. At dose A, survival of target cells is higher in late effects than in acute effect tissues, whereas at dose B, the reverse is true. Therefore, increasing the dose per fraction from A to B results in a relatively greater increase in late rather than acute injury. In the case of neutrons, the α/β ratio is low, with no detectable influence on the quadratic function ($e\beta D \pm D_2$) over the first two decades of reduction in cell survival, implying that accumulation of sublethal injury plays a negligible role in cell killing by doses of neutrons of clinical interest. At these doses, the relative biologic effectiveness is higher for late effects than it is for acute effects. (Reprinted from Withers HR, Thames HD Jr, Peters LJ. Biological bases for high RBE values for late effects of neutron irradiation. *Int J Radiat Oncol Biol Phys*. 1982;8[12]:2071-2076. Copyright © 1982 Elsevier. With permission.)

In the LQ equation, redistribution in the cell cycle and reoxygenation may be modeled by a single term called *resensitization*. Immediately after a dose of

radiation, the average radiosensitivity of the cell population falls and then gradually returns to greater sensitivity. In contrast to tumor proliferation, resensitization probably increases as overall treatment time increases. Not enough is known about resensitization's clinical importance to make it useful to incorporate a numeric value for it in the LQ formula.

The LQ model can be used to construct a biologically oriented dose distribution algorithm for clinical radiation therapy.[305,306] A physical dose distribution can be translated to a BED using published biologic parameters. It may help clinicians to optimize treatment plans, and the technique may be used for outcome analysis in clinical research when the biologic parameters and the assumptions can be validated.

Brachytherapy and the Radiobiologic Dose Rate Effect

An interesting letter to the editor appeared in *Nature* on August 6, 1903.[307,308] The author, Alexander Graham Bell (1847-1922), is best known for his role in the invention of the telephone (Figure 1.43).

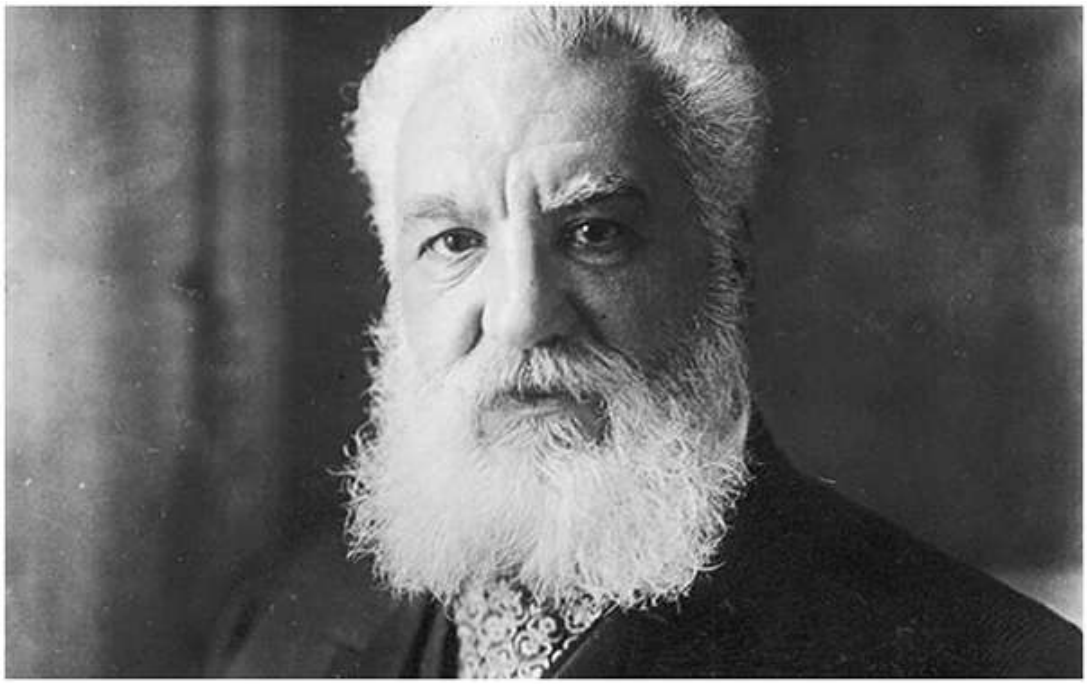

FIGURE 1.43 Alexander Graham Bell (1847-1922).

It has occurred to me that perhaps you would care to publish the enclosed letters, and thus start some one experimenting with the radium rays in the manner suggested. Dr. Sowers is a distinguished physician of Washington, D.C., now spending a portion of his summer vacation in Baddeck, Nova Scotia.

Alexander Graham Bell.

Beddeck, N.S., July 21

Dr. Z.T. Sowers,

1707 Massachusetts Avenue,

Washington, D.C.

Dear Dr. Sowers,

I understand from you that the Röntgen x-rays, and the rays emitted by radium, have been found to have a marked curative effect upon external cancers, but that the effects upon deep seated cancers have not thus far proved satisfactory.

It has occurred to me that one reason for the unsatisfactory nature of these latter experiments arises from the fact that the rays have been applied externally, thus having to pass through healthy tissues of various depths in order to reach the cancerous matter.

The Crooke's tube from which the Röntgen rays are emitted is, of course, too bulky to be admitted into the middle of a mass of cancer, but there is no reason why a tiny fragment of radium sealed up in a fine glass tube should not be inserted into the very heart of the cancer, thus acting directly upon the diseased material. Would it not be worth while making experiments along this line?

Yours sincerely,

(Signed) Alexander Graham Bell

Baddeck, N. S., July 21.

Dr. A. Graham Bell,

Baddeck, N. S.

Dear Dr. Bell,

> The suggestion which you make in regard to the application of the radium rays to the substance of deep seated cancer I regard as very valuable. If such experiments should be made, I have no doubt they would prove successful in many cases where we now have failures.
>
> Yours sincerely,
>
> (Signed) Z. T. Sowers, MD
>
> Baddeck, N. S., July 21.

The recipient of Bell's letter was the distinguished Washington D.C. physician, Zachariah Turner Sowers, MD (1845-1919), vacationing in Nova Scotia.

This form of radiotherapy is referred to as *brachytherapy* or *endocurietherapy*. The prefix *brachy*, from the Greek, means short, slow, or short range. The suffix therapy is derived from *therapeaia*, also Greek, meaning care or service to the sick. Some physicians use the alternative term *endocurietherapy*. The prefix *endo*, also from the Greek, means "within."

There are several ways we can describe the forms of brachytherapy. First, we can subdivide brachytherapy into a classification system based upon the physical placement of the radioactive sources. Thus, (1) *interstitial brachytherapy* is the placement of the radioactive sources directly into the tumor of the tumor bed. Implanting radioactive seeds into the prostate would be an example of this form of treatment. (2) *Intracavitary brachytherapy* is the placement of the radioactive sources inside a body cavity and up against a tumor-bearing structure. The placement of tandem and ovoids for the treatment of carcinoma of the cervix or of a radioactive source–bearing catheter inside the nasopharynx are examples of this form of brachytherapy. Finally, (3) *mold brachytherapy* is the placement of radioactive sources upon the skin surface bearing a tumor. The use, for example, of radioactive sources embedded in a glove worn upon the hand for a period of time to treat a tumor of the dorsum of the hand, while preserving the function of the ligaments controlling the fingers, is an example of this form of treatment.

Another way we can subdivide the forms of brachytherapy is by the duration of the treatment. A (1) *temporary brachytherapy* application resides in the tumor, body cavity, or adjacent to the tumor for a finite period of time before it is removed. Tandem and ovoid placement for carcinoma of the cervix is typically a temporary brachytherapy application. A (2) *permanent brachytherapy* application is placed permanently and, over time, the radioactive source decays. Injecting radioactive Au-198 seeds into a bronchogenic carcinoma for palliation of bronchial obstruction by tumor is an example of a permanent implant.

Yet, a third way we can think about the forms of brachytherapy is by the speed with which the radiation is administered in cGy/min. Three types are generally described. (1) *low dose rate (LDR) brachytherapy* typically administers its dose over a period of days. For example, administering 1,000 cGy/day to point A in a Cs-137 tandem and ovoid application would be a classic example of LDR brachytherapy. (2) *high dose rate (HDR) brachytherapy* delivers the dose in a few minutes. The use of a robot referred to as a remote HDR remote afterloader to pump high-activity Ir-192 into and out of a series of Teflon catheters in the tumor bed for the postoperative treatment of a high-risk soft tissue sarcoma is an illustration of HDR brachytherapy. Finally, there is a so-called (3) *intermittent HDR brachytherapy* or *pulsed-dose rate brachytherapy*. This usually refers to fractionating the HDR brachytherapy several times during the day, but the term is used by some physicians to refer to once per day or once every other day insertion of the HDR sources in the Teflon catheters. In either situation, an HDR remote afterloader machine is used.

When LDR brachytherapy is used for cancer treatment, we must give due consideration to its particular radiobiologic effects. We can think of LDR brachytherapy as the ultimate form of fractionation, being equivalent to an infinite number of small fractions with no interfraction intervals devoid of irradiation. What are the implications of this infinite fractionation on tumor cell killing and normal tissue tolerance?

The first point to consider is that much of the value of brachytherapy has less to do with biology than it has to do with physics. Brachytherapy is typically highly localized irradiation. The radiation beam in EBRT comes “from the outside in” and passes through normal tissue on its way to the tumor volume and, in the case of uncharged beams like photons and neutrons, passes through normal tissue on its way back out of the body after passing through the tumor. In contrast, the radiation beams in brachytherapy come “from the inside out” and are generally within or directly upon the tumor with the dose falling off rapidly as the square of the distance as one moves away from the radioactive source(s). Long before computer modeling of external beam irradiation and MLCs for external beam treatment, brachytherapy was, to some extent, the first form of “dose painting” or “IMRT.” The ability to confine the radiation dose to a small area with brachytherapy, with the avoidance of exposing large areas of normal tissue, allows the treating clinician to safely give doses sometimes unimaginable with external beam treatment.

Perhaps, the ultimate clinical example of the volume effect of brachytherapy is the treatment of choroidal melanoma or retinoblastoma with a I-125 or Ir-192 or Co-60 or Ruthenium plaque sewn to the choroid and overlaying the tumor bed. In some cases, 40,000 to 70,000 cGy will be administered to a small area of the outer surface of the choroid with an acceptable long-term ill effect on normal tissue profile. This is only possible by the use of highly localized brachytherapy. This had led some

wags to observe that “this isn’t really radiotherapy as we know it. It is nuclear warfare.”

It is also worth remembering that the dose in the tumor volume created by brachytherapy is often highly heterogeneous. In the treatment of carcinoma of the cervix, for example, generations of radiation oncologists have prescribed and described the dose administered to “point A” and “point B,” both located lateral to the cervix. Radiation dose, however, falls off as the square of the distance. Therefore, the dose at the surface of the tumor-containing cervix from a Cs-137 tandem and ovoid application is much higher and more tumoricidal than the dose at point A.

I have treated vaginal embryonal rhabdomyosarcoma in very young girls with intracavitary pulsed HDR brachytherapy and custom-built lead shields to both push uninvolved normal tissue away from the brachytherapy catheters and partially shield this tissue with lead. It is difficult to imagine achieving more exquisitely conformal radiation dose distributions by any means other than brachytherapy.

The second point to consider is the fundamental series of effects of LDR on cell death. We can think of the radiation damage to mammalian cells as divisible into (1) lethal, irreversible, and irreparable lethal damage; (2) PLD whose injurious effects can be either exacerbated or ameliorated by the postirradiation environmental conditions of the irradiated cells; and (3) SLD, which, under normal circumstances, can be repaired unless additional SLD is heaped upon existing damage and converts it to lethal damage. Here is a simple way to think about SLD mathematically. Assume that A% of cells are killed by dose X of external beam irradiation. If you take dose X and split it into two equal fractions, then each fraction is $X/2$. Now, instead of giving all of the radiotherapy dose X at once, give $X/2$ today and the remaining $X/2$ tomorrow. What will happen? Instead of A% of cells dying as a result of radiation, $A\% - B\%$ will die. The improvement in the probability of cell survival, represented by B, is repaired SLD.

Let us turn our attention to PLD. By definition, PLD is influenced by the conditions the cells find themselves in after being irradiated. Let us assume we do something to the cells, which prevents them from moving forward in the cell cycle. We might achieve this by lowering the ambient temperature or allowing the cells to be packed in closely so that density inhibition of growth occurs or by using a culture media, which starves the cells of nutrients. If we keep the cells from moving forward in the cell cycle, then we will inhibit the ability of radiation-induced DNA injury to manifest itself by causing cell death when the cells try to divide. Cell survival will rise compared to allowing the cells to vigorously march through the cell cycle into M phase. This diminution in cell mortality represents PLD.[309]

With LDR, several things happen simultaneously, which influence cell killing. The relative importance of these factors will vary based on the specifics of whether

you are thinking about normal tissue tolerance to radiotherapy or the tumor type, the tumor's growth environment, and, for normal or tumor tissue, the dose rate (Figure 1.44). The factors are as follows:

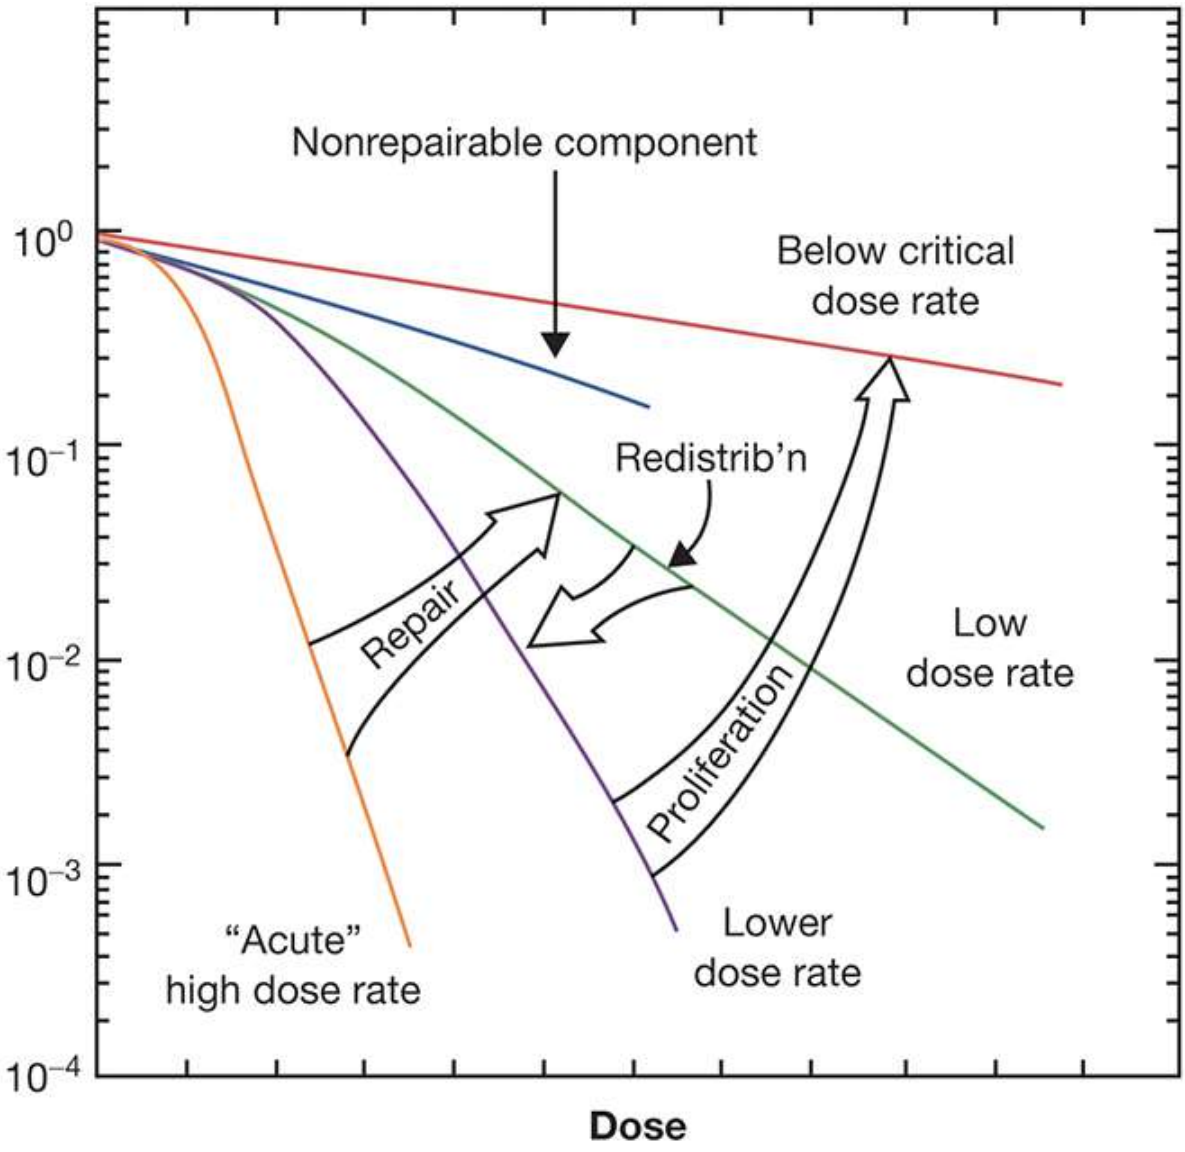

FIGURE 1.44 The dose rate effect as a result of repair of sublethal damage, redistribution in the cycle, and cell proliferation. The dose-response curve for acute exposures is characterized by a broad initial shoulder. As the dose rate is reduced, the survival curve becomes progressively shallower as more and more sublethal damage is repaired, but cells are "frozen" in their positions in the cycle and do not progress. As the dose rate is lowered further and for a limited range of dose rates, the survival curve steepens again because cells can progress through the cycle to pile up at a block in G2, a radiosensitive phase, but still cannot divide. A further lowering of dose rate allows cells to escape the G2 block and divide; cell proliferation then may occur during the protracted exposure, and survival curves become shallower as cell birth from mitosis offsets cell killing from the irradiation. (Based on the ideas of Dr. Joel Bedford, and from Hall EJ. *Radiobiology for the Radiologist*. 4th ed. J.B. Lippincott; 1994.)

(a) *Repair*: As the dose rate slows, some cells will endeavor to repair the radiation injury as it occurs. The cell's ability to survive may gain the upper hand if the dose rate is low enough, and the cell's intrinsic radiation repair functions can handle the injury as it occurs. Imagine you are sitting in a rowboat in the middle of a lake and the boat springs a pinhole-sized leak. If the rate of the water entering your boat is slow enough, you can bail the boat fast enough to get yourself back to shore. If the rate of the water entering the boat becomes too fast, you and your boat are going to find yourselves seated on the bottom of the lake. The size of the hole in your boat is analogous to the rate of induction of radiation injury by brachytherapy.

(b) *Repopulation*: Some cells will be killed by the radiation. For those that survive, they no longer have to compete with their adjacent newly dead neighbor for oxygen and other nutrients. They will start to grow faster and, to varying extents depending upon the type of tissue or tumor, repopulate the neighborhood with new cells.

(c) *Reoxygenation*: Oxygen is the most powerful radiosensitizer. To the extent that LDR kills cells, the "neighborhood effect" as described in (b) also applies to oxygen. The continuous reoxygenation will render the remaining cells, which have survived the initial onslaught of radiation more sensitive to subsequent radiation injury.

(d) *Reassortment*: As a general principle, reassortment refers to the progression of cells through the cell cycle during the interval between split doses. To the extent that cells move into the more radiosensitive phases of the cell cycle, they are more likely to be killed by radiotherapy. To the extent that they move into less radiosensitive phases of the cell cycle, they are more likely to be spared. There is a paradoxical form of reassortment, which occurs in some cell lines during LDR. It is called the "inverse dose rate effect." When the inverse dose rate effect occurs, cells march through the cell cycle but become arrested in G2. G2 is a highly radiosensitive phase of the cell cycle, and the cells are more likely to be mowed down by radiation.[310]

Let us put all these factors together and think about what the net effect will be of LDR.

To the extent that cells repair SLD more effectively, then the lower the dose rate, the better the cell survival. The magnitude of the effect will be dependent upon the efficacy and speed of SLD repair in an individual cell line.

To the extent that cells are redistributed into a more sensitive phase of the cell cycle, then the lower the dose rate, the worse the survival unless the dose rate is so low that the cells progress right on through into more resistant phases of the cell cycle. Then, their survival will rise.

To the extent that cells become better oxygenated as a result of LDR, then the worse the cell survival.

On net, from most mammalian cell lines, LDR produces a decrease in cell killing via a "flattening" of the cell survival curve and a "loss of the survival curve shoulder."[311]

Brachytherapy is often a highly effective treatment for solid tumors as a result of its conformal dose distribution and radiobiologic effects on killing tumor cells and sparing normal tissue (Figure 1.45). Brachytherapy requires technical expertise, patience, access to a procedure room or operating room, and due attention to radiation safety and radiation protection. Catheters and seeds can be misplaced, and there are risks of bleeding and infection. Practice makes perfect, and, unfortunately, many radiation therapy treatment centers do not do brachytherapy procedures frequently enough to develop local expertise and confidence with the techniques. It is not surprising that in the United States, inadequate brachytherapy experience is a common citation against radiation oncology residency programs. I am reminded of the words of wisdom of one of my beloved professors at the Massachusetts General Hospital in the early 1980s, Leonidas Harisiadis: "Brachytherapy is a highly effective form of treatment, but doing it can be a pain in the neck."

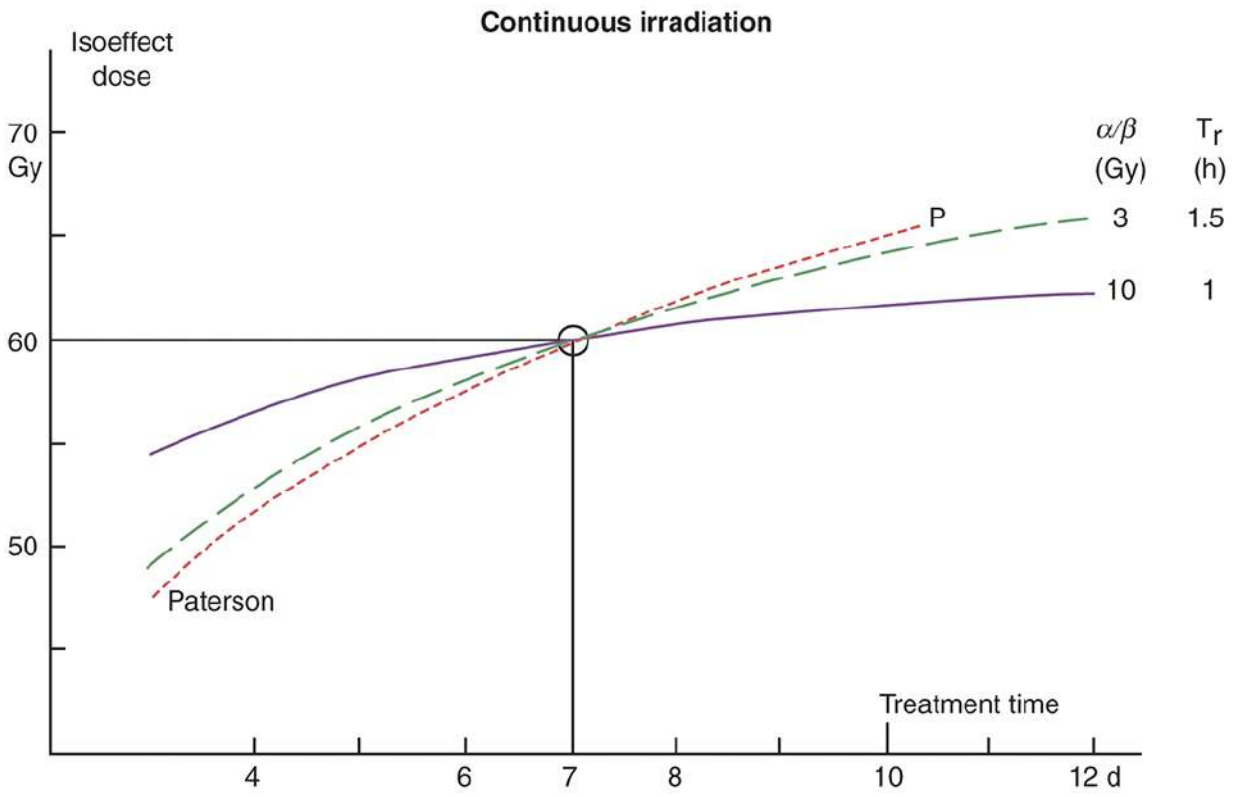

FIGURE 1.45 Low-dose rate irradiation. Isoeffect dose equivalent to 60 Gy in 7 days. Two sets of parameters have been considered for the computation, which would presumably correspond to skin and mucosa early reactions and to the effect on the epithelioma (α/β = 10 Gy, T_r = 1 hour) and to late reactions (α/β = 3 Gy, T_r = 1.5 hour). (Reprinted from Dutreix J. Expression of the dose rate effect in clinical curietherapy. *Radiother Oncol*. 1989;15[1]:25-37. Copyright © 1989 Elsevier Ireland Ltd. With permission.)

With the advent of moderate-dose rate and HDR remote control afterloading devices, increased emphasis has been placed on the biologic effects of dose rate. Many in vitro and in vivo experimental observations indicate variations in cell killing and repair of SLD or PLD with varying dose rates. The so-called dose rate effect is most dramatic between 1 cGy/min and 1 Gy/min.[312] The biologic effect achieved by a given irradiation dose decreases as the dose rate diminishes, chiefly as a result of the increase in cell repair that occurs during continuous prolonged irradiation, because cell proliferation is virtually negligible in the range of treatment times used in LDR brachytherapy.[313]

In some experiments, a bending of the cell survival curve at very LDRs has been noted, instead of the expected exponential result, possibly because of cell redistribution or a decline in the repair capacity with large doses.[314] At a very LDR, because the cell killing is caused only by direct lethal events that are considered independent of the dose rate, cell repair is also negligible. The induction of sublethal injury is relatively slow compared with the rate of repair, and cell killing, by

accumulation of sublethal injury, remains minimal. Variation of the isoeffect dose occurs mainly in the range of medium-dose rates (1-10 Gy/hour), and it vanishes at very HDRs because the cell repair is negligible during the short treatment time.[315]

The dose rate effect in clinical brachytherapy was described initially by Paterson and reiterated by Ellis and Orton.[315-321] The historic isoeffect curve showed a significant increase in dose when time was increased from 2 to 7 days. However, the validity of Paterson's curve was questioned by Pierquin et al,[322] who used the same dose of 70 Gy with treatment times ranging from 3 to 8 days for the treatment of head and neck tumors with Ir-192 implants and did not observe any difference in the control rate or incidence of necrosis. The agreement with Paterson's curve is acceptable when the α/β value equals 3 Gy and repair half-time (T_r) equals 1.5 hours, but the curve is shallower when α/β equals 10 Gy and T_r equals 1 hour. One should expect Paterson's curve to correspond to late reactions and to overestimate the variation for early reactions and control of squamous cell carcinoma.

Several important concepts should be considered regarding the clinical relevance of brachytherapy dose rate:

1. At ultra-high doses and instantaneous dose rates (ie, 10 Gy pulsed in nanoseconds), the rapid deposition of energy consumes oxygen too quickly for diffusion to maintain an adequate level of oxygenation, and dose-response curves are characteristic of hypoxia. The disparate effect of radiation on tumor versus normal tissue lessens. It is thought by some that FLASHRT exploits this phenomenon to achieve relative sparing of normal tissue. Others question this mechanism of action.
2. Based on laboratory data, it may be possible to design schedules with a pulse width of several minutes and a pulse interval of about 1 hour to achieve cell killing equivalent to that obtained with a continuous 30 Gy in 60 hours (0.5 Gy/hour).
3. Using the LQ equation, it is possible to estimate the equivalency of HDR and LDR exposures with a variety of fractionation schedules (remembering that a lower number of fractions may result in enhanced late effects).

Special consideration should be given to the effect of HDR brachytherapy on normal tissues. The tumor dose must be decreased 30% to 50% in comparison with that delivered with conventional LDR brachytherapy.[323,324] (For further discussion, see Chapters 22-24.)

In the past, there was some interest in continuous LDR irradiation with external cobalt units.[203] Pierquin et al[325] used a modified cobalt unit with a small industrial source (activity 45 Ci). Radiation was delivered at 1 to 1.39 Gy/hour to administer

daily tumor doses of 8 to 10 Gy in 7 to 8 hours. A minimum of five treatments was given per week, although occasionally weekends and holidays caused schedule modifications. Patients were given short rest periods every 1 or 2 hours. Tumor doses of approximately 63 Gy were delivered in 8 to 11 fractions, with the volume reduced to 8 by 10 cm^2 after 45 Gy. Nineteen patients with advanced tumors of the mouth and pharynx were treated; 15 had no evidence of tumor 3 months after treatment. Only three patients developed recurrences. Of the 19 patients, 2 developed moist desquamation and 6 developed dry desquamation; the others had only erythema. No significant late effects on the skin or the subcutaneous tissues were noted; 16 of 19 patients developed severe mucositis. Seven patients developed necrosis, six in large areas of the oral cavity and pharynx and, in several instances, at the tumor site.

The Target Theory of Radiobiology and How It Has Shaped Our Understanding of the Cell Survival Curve

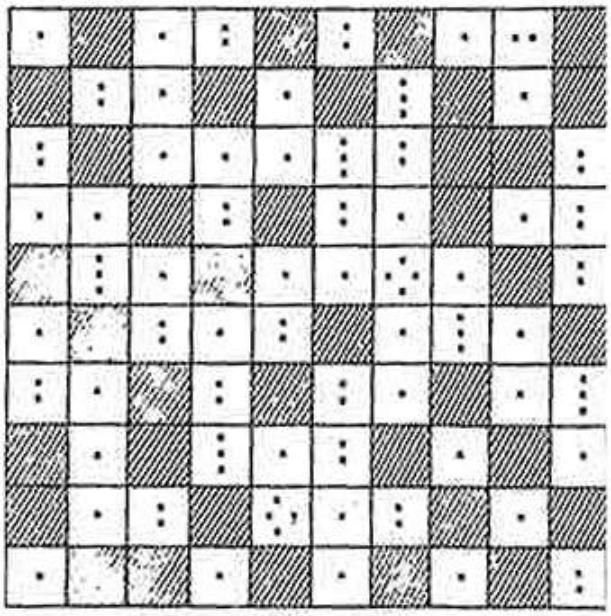
We hold a dart in our hand and toss it at the dart board. What is our goal? To hit the target; to make a "bull's eye." We go to a pistol range and, similarly, aim at the target. We try to "hit the target," whether it is a series of concentric circles or a paper outline of a man. A hunter stalks their prey in the woods with a rifle or a bow and arrow. They, similarly, want to cause a lethal injury and "bag the game."

A dart, a bullet, and an arrow are all physical modalities, not chemical, either used to inflict injury or death or show a person's ability to shoot straight and true. It is not much of a leap to envision how the early students of ionizing radiation's ability to kill cells envisioned that the physical modality of radiation would kill cells by hitting a target. Because many of these original investigators came from the world of physics, they sought to reduce the description of radiation's killing effect on viruses, bacteria, and cells to a series of mathematical equations, which described the cell survival curve. Furthermore, the empirical data, which were derived from radiation survival curves from the exposure of viruses and bacteria, could be fit to these equations.

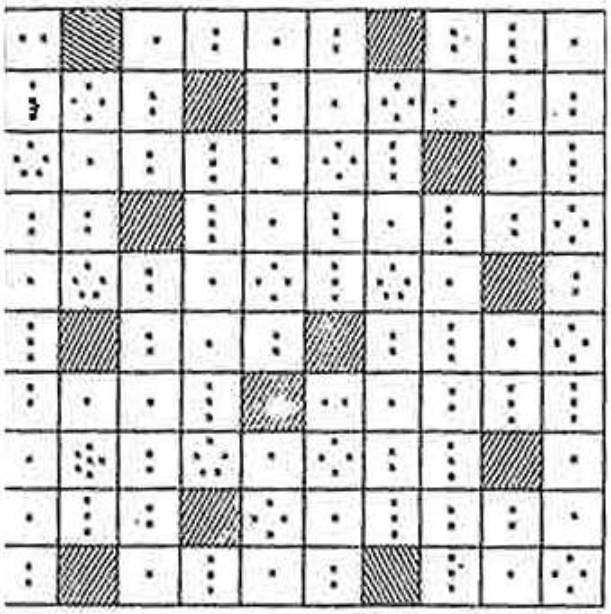
The target theory is based on the concept that the biologic end product of cell death is related to the initial physical events, which occur upon irradiation. The fundamental principle of target theory is that inactivation of the target inside a cell or a bacteria or a virus results in its death.[326] The target is considered a unit of biologic function. The theory implies that the exact site where an ionizing event occurs, such as a double-strand DNA break, is the place where the primary ionizations responsible for that event occurred. Radiation-induced cell death can occur, in simplest terms, when there is a single hit of sufficient power to inactivate a single target and that target is sufficiently important that, when inactivated, the cell dies.

This is called the single-hit/single-target model. One can also envision that some cells might not die unless multiple targets are inactivated. This is called the multiple-hit/multiple-target model. All manner of variations might be imagined, such as a stubborn single target that required repetitive assaults to be inactivated (multiple hit/single target).[327,328]

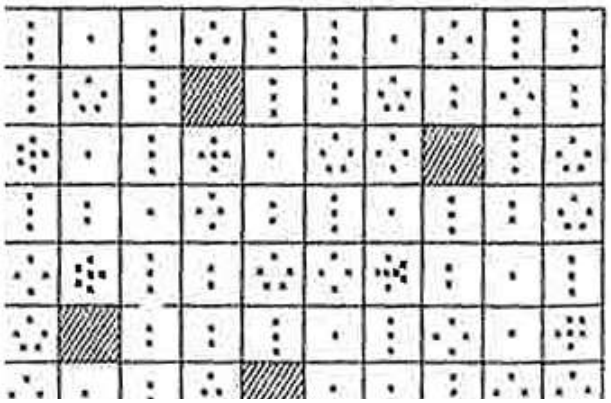
With low LET radiation, ionizations occur in clusters and sporadically along the path traveled by the particle. The radiation survival of most bacteria and viruses is a constant exponential function of dose. To kill them, it would seem to require inactivation of at least one target per bacteria or virus. At this point, however, we need to rethink our metaphor of the dart, the bullet, or the arrow. Darts, bullets, or arrows are very consciously and with great intent aimed at a specific target. Radiation beams, however, while they are aimed at tumors, are not aimed at individual cells, and they certainly are not aimed with any knowledge of where, at any moment, the important target is located. The target, the DNA, is moving within the cell. This brings us to a crucial point: The deposition of ionizations from radiation and the production of radiochemical injury to the cell are random events[329,330] (Figure 1.46).



$\lambda = 1$



$\lambda = 2$



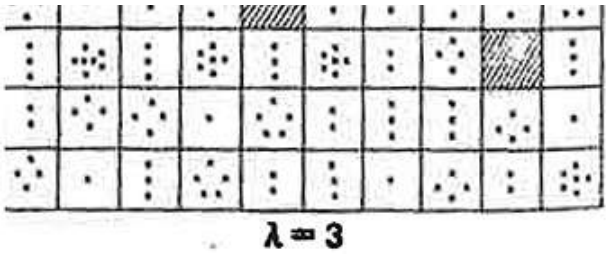


FIGURE 1.46 Let us assume that there are 100 equally sized tumor cells. Any individual cell will be killed if a crucial single target is hit at least once. This is a single-hit/single-target model. Assume we fire a radiation beam capable of producing 100 lethal hits/ionizations at the 100 cells in the upper panel, and the deposition of ionizations occurs along the beam bath in clusters and randomly. Any individual cell's target is struck 0 to 4 times with lethal ionizations. Any cell's target, which is struck at least once, is killed. Sixty-three cells die. Thirty-seven survive. The probability of any one cell surviving the onslaught is 37%, which is e^{-1}. In the next panel, in the middle, we fire a radiation beam capable of producing 200 lethal hits/ionizations at the same 100 cells. The targets of some cells are completely missed. Others are hit up to 6 times. Eighty seven cells die. Thirteen survive. Thirteen is 37% × 37% or e^{-2}. In the lowest panel, we fire a radiation beam capable of producing 300 lethal hits/ionizations at the same 100 cells. How many cells survive? 37% × 37% × 37% or e^{-3} = 5 cells or 5% of the 100. The mathematical result of this random deposition of ionizing energy, which is part of target theory, helps us understand the derivation of the equations, which gives mathematical representation to the cell survival curve, and helps define the concept of D_0. (Reprinted with permission from Withers HR, Peters LJ. Biological aspects of radiotherapy. In: Fletcher GH, ed. *Textbook of Radiotherapy*. 3rd ed. Lea & Febiger; 1980:103-180.)

Unlike the straight-line survival curves of many bacteria and viruses, when you plot the cell survival curve of most mammalian cells on a semilog plot, you see a "shoulder" in the low-dose region indicative of a decreased efficiency of cell killing and then a straight or "exponential" component of the curve.

If we think about a strand of DNA as containing some regions that are essential to maintain the reproductive ability of the cell, then these regions are the specific targets for radiation damage. As we have pointed out, straight survival curves are usually found for the inactivation of bacteria and viruses and some very sensitive normal and malignant human cells, for the radiation response to low LET radiation at very LDRs and the response to high LET radiation.

We described how the dose D_0 is that dose of radiation, which gives an average of one hit per target and reduces the probability of cell survival from 1 to 0.37 or e^{-1}. Using Poisson statistics, and understanding that the probability of the next hit occurring in any given cell is small, then the probability of a given cell surviving is the same as the probability that a cell suffers zero hits = $\exp(-D/D_0)$. (For a brief description of the Poisson distribution, see Box 1.6.) We could also look at the situation, mathematically, this way[330,331]:

Box 1.6

How the Poisson Distribution Helps Us Understand the Equations for the Radiation Cell Survival Curve

The Poisson distribution is named after the French mathematician Siméon Denis Poisson (1781-1840). A Poisson distribution expresses the probability of a given number of events occurring in a fixed interval of time and/or space if these events occur with a known average rate and independently of the time since the last event.

Let us think of some examples in order to understand this concept. Assume that a person receives an average of 50 text messages on their personal electronic device (cell phone or pad) every day from a very wide variety of sources. If the receipt of any particular email message does not affect the probability of getting the next email message, then some days the person will get 49 emails, some days they will get 51, some days they will get 100, and if enough time elapses, then there will be a day when they get zero. While the average number of emails that arrive per day is 50, on any particular day, the number of emails received will vary. Most days, the number of emails will cluster close to the number 50, but there will be a wide variation.

We can think of the deposition of ionizing events in cells and inactivating targets as following a Poisson distribution. If you look back at the panel at the top of Figure 1.46, the average number of hits per cells is 1, but the actual number of hits per cell varies from 0 to 4. If you plot the number of hits per cell, they will follow a Poisson distribution. Most cells will have one hit, but they will be a wide variation.

A Poisson distribution is not the same as a normal distribution (sometimes called a “bell-shaped curve”), although, at first glance, they look somewhat similar. These two statistical concepts come from two different principles. A Poisson distribution is one example for discrete probability distribution, whereas normal belongs to the idea of a continuous probability distribution.

If there is one target per cell, then the probability of that cell surviving (S) an average of one hit per cell for a large number of cells is

$$P(1) = S = e^{-1}$$

If we gave a dose, which caused an average of two hits per cell, for a large number of cells, then the probability of any individual cell surviving is

$$P(2) = S = e^{-2}$$

If we gave a dose, which caused an average of X hits per cell, for a large number of cells, then the probability of any individual cell surviving is

$$P(X) = S = e^{-X}$$

Because the typical radiation cell survival curve for normal and malignant mammalian cells has a "shoulder" and then an exponential component, it can be fit to a multitarget model. The initial slope of the curve, D_1, is the result of single-hit killing and has a slope, which represents the dose that is required to reduce the number of surviving cells from 100% to 37%. The final slope of the curve is the dose that is required to reduce survival from 0.1 to 0.037 or from 0.01 to 0.0037.

We can represent this "two-sloped" curve in the multitarget model by

$$P(\mathrm{X}) = S = 1 - (1 - \mathrm{e}^{-xD})^n$$

S is the probability of survival, D is the dose that causes a mean of hit per cell, X is the number of hits per cells, and N is the number of targets that must be hit in an individual cell to cause cell death.

If we use the term D_0 for the slope of the exponential part of the curve, then

$$S = [1 - (1 - \mathrm{e}^{-D/D_0})^n]^m$$

In this equation, S is the probability of survival; D is the dose of radiation administered; D_0 is the dose that causes a mean of one hit per cell; N is the heterodiploid number so that 1 is haploid, 2 is diploid, and 3 is triploid; and m is the number of targets that must be hit in an individual cell to cause cell death.

For a diploid cell with an average of one target per cell, the equation becomes

$$S = 1 - (1 - \mathrm{e}^{-D/D_0})^2$$

Although there may or may not be discrete and identifiable target areas within DNA, the multitarget model does a pretty good job of predicting many cell survival curves, and the concepts of DQ, D_0, and n are understandable tools in describing radiation sensitivity. There are radiation cell survival curves, which are not well represented by the target model, and the LQ theory was developed to be a more general concept.

RELEVANCE OF RADIOBIOLOGIC CONCEPTS IN CLINICAL RADIATION THERAPY

Radiation and Cancer Biology's Contributions to the Clinical Practice of Radiation Oncology

Generations of radiation oncologists have grappled with the question of radiation and cancer biology's contribution to the clinical practice of radiation oncology. The question was posed and addressed in two classic lectures: first by Stanford's Henry

S. Kaplan[332] in his 1970 Failla Lecture to the Radiation Research Society and then by Harvard's Herman D. Suit[333-335] in his 1983 Failla Lecture. (There are brief biographies of Suit and Kaplan at the end of this chapter.) Treading on the ground prepared for us by Kaplan and Suit, we will reconsider the question in the context of the explosion of knowledge concerning the molecular and cellular basis of cancer.

One can look at the history of cancer biology's contribution to the clinical practice of radiation oncology in terms of two debates: *empiricism versus research-based radiation oncology* and *biology versus physics*.

Empiricism Versus Research-Based Radiation Oncology

Empiricism harkens to the views of David Hume (1711-1776) and other British philosophers of the 17th and 18th centuries and their distrust of the power of unaided reason. In the philosopher's view of empiricism, the best contact between one's understanding of knowledge and the world is not the point at which a mathematical proof crystallizes, but the point at which you see and touch a familiar object. Their paradigm was knowledge by sensory experience rather than by reason alone.[336-338]

Empirical radiation oncologists rely on accumulated clinical experience, also known as "what has worked in the past." They are suspicious of therapies based on theories and laboratory research and feel safest when treading the pathway of tested experience. One can find very strong signs of empiricism in the radiation oncology literature: case reports, single-institution retrospective clinical series, and a marked concern with retrospective clinical analyses of radiation therapy that mine clinical experience to aid the selection of radiation treatment volume, dose, and treatment techniques.

There can be no doubt that the development of radiation oncology has been extensively based on empiricism. We must note, however, that radiation biologists worked closely with the early radiation oncologists. It would be erroneous to suggest that the early history of radiation oncology was completely devoid of reliance on radiation biology.

The theme of hostility to empiricism and support for finding a firm basis for clinical radiation oncology in radiation and cancer biology research is easily identified in the development of the specialty. "Some people do the same thing wrong for 30 years and then call it accumulated clinical experience," said one critic; or it has been said, "If radiation oncologists were put in charge of the war against polio in 1945, they certainly would have perfected the iron lung by now." Our growing knowledge of the genome, proteomics, secondary messengers, and solid tumor biology and the identification of new molecular targets for drugs, immunotherapies, cellular therapies, angiogenesis, oxygenation, and cell cycle

control are changing the present and future of medicine. If clinical radiation oncologists have a future, these individuals say, then they must actively participate in the investigation of the molecular and cellular basis of cancer and in translational research.

Physics Versus Biology

One may also formulate the debate over the role of basic biology in clinical radiation oncology as a pull and tug between physics and biology. Medical radiation physics has dominated the thinking of clinical radiation oncologists. Among the major achievements of this discipline are the following:

- The identification and characterization of physical units of radiation dose
- Significant changes in photon and electron radiation therapy apparatus (initially, kilovoltage and later 60Co, high-energy linear accelerators, the Gamma Knife [Elekta Corp.], and the CyberKnife [Accuray])
- The development of 3D treatment planning for the identification of tumor volume and characterization of irradiated normal tissue
- IMRT and IMPT for improved conformality of treatment beams
- Particle therapy, including neutrons, protons, pions, and stripped nuclei
- Improved stabilization devices to aid the reproducibility of treatment
- Advances in brachytherapy technology, including new isotopes, the afterloading technique, and remote HDR machines
- The apparatus for intraoperative radiation therapy (IORT)
- Equipment for heat deposition in tumors leading to the clinical applications of hyperthermia

At present, a considerable effort in clinical radiation oncology is focused on the tools and techniques provided to the physician by the physicist. Radiation oncology meetings are dominated by discussions of proton therapy, IMRT, radiosurgery/conformal radiation FLASH, and innovations in equipment. Many of these techniques offer better radiation dose distributions, which, one hopes, will lead to an increase in local control of tumors and a decrease in normal tissue toxicity. At present, a better dose distribution is the solution physics offers to the problems of oxygenation, monitoring of tumor blood flow, tumor pH, secondary messengers, tumor suppressor genes, oncogenes, the biology of metastasis, normal tissue radioprotectors, and tumor radiosensitizers. Could it be that “if all you have is a hammer, then everything looks like a nail”?

What has cancer biology ever done for the clinical radiation oncologist? It is, we think, a generally fair question, although it might be characterized as somewhat

narcissistic, along the lines of "what have you done for me lately?" Among the areas one should consider on the list of laboratory contributions to the clinic are the following:

- As early as 1906, Bergonié and Tribondeau[339] enunciated a series of famous laws of radiosensitivity. This was followed by the work of the French investigators Regaud and Ferroux,[340] who demonstrated that whereas a single dose of radiation to the testes always produced maximal damage to the scrotal skin, fractionated exposure spared the skin but destroyed spermatogenesis. They speculated that this same technique of fractionation might be differentially advantageous in the treatment of tumors. This led to Coutard's[341] studies that culminated in the fractionated EBRT techniques of today.
- The identification of the relationship between radiation dose and cell kill led to the characterization of the radiation cell survival curve. This contributed to our understanding of radiation therapy dose and fractionation and, consequently, to our knowledge of radiation repair. This development placed our grasp of radiation fractionation on sound footing and led to investigations of alternative fractionation schemes. This has contributed to improved tumor control as well as the limitation of normal tissue toxicity. Ultimately, the radiation cell survival curve also provided the underpinnings for our views of elements of the dose-response relationship for tumor control and normal tissue toxicity.
- In 1909, Schwarz[342] demonstrated that compression of the skin to diminish capillary blood flow reduces the severity of cutaneous radiation reactions. This may have been the first demonstration of the "oxygen effect." L. H. Gray[343] pointed out the relevance of the "oxygen effect" to radiation oncology by identifying the fact that human neoplasms contain a significant subpopulation of hypoxic cells.[344] A series of important developments have driven home the centrality of hypoxia to our understanding of radiation's effects on tumors. Histopathologic studies and invasive measurements of intratumoral partial oxygen pressure have shown that many human tumors contain regions with low oxygen tension.[345] We now believe that there are at least two different mechanisms, called *diffusion-limited* and *perfusion-limited* hypoxia, behind this observation. Some have called these *permanent* and *transient* hypoxia.[346] Diffusion-limited hypoxia results from inadequate angiogenesis, whereas perfusion-limited hypoxia is associated with intermittent closure of tumor vessels, leading to acute hypoxic conditions for tumor cells downstream from the obstruction. In addition, we now understand how hypoxia activates genes and may produce tumor differentiation and increase a tumor's metastatic potential. Clinical studies have associated the prognostic value of hemoglobin level with tumor local control.[347] The characterization of the hypoxia problem has led to a

variety of largely unsuccessful strategies to overcome it. One has been to have the patient breathe high oxygen content gas mixtures or to irradiate patients in hyperbaric oxygen chambers. Another option involves the use of oxygen-mimetic chemicals. Other treatment strategies include blood transfusions or the specific use of hypoxic-specific cytotoxins, such as mitomycin C.

- There has been considerable growth in our understanding of cell proliferation, the cell cycle, and cell repair mechanisms. We now understand that cells are more sensitive to radiation in M phase and more sensitive to hyperthermia in S phase. Our understanding of the differential sensitivity of cells to radiation during the cell cycle helps provide a rational basis for the use of radiation and chemotherapy.
- As an extension of the knowledge associated with the radiation cell survival curve, clinicians obviously need to have a good understanding of the radiation dose and response for both normal and malignant tissues. The development of research involving the lethal dose of 50% (LD50), local control rates, and normal tissue toxicity in animal models has led to an improved understanding of the radiation dose-response relationship. Correlates of this understanding have included the use of the progressive shrinking-field technique, IORT, and brachytherapy as a "boost" and the use of increasingly conformal beams associated with our improved understanding of how radiation dose should be associated with tumor volume and dose painting. One expects, in the future, to see increasing work in intentional dose heterogeneity as a technique for improving local control.

In his 1983 Failla Lecture, Herman Suit[348] considered the evolution of the principles of clinical radiation therapy. He prepared a table in which he attempted to articulate the principles of radiation therapy invoked in the United States in 1956 and 1982. This is reproduced in the first two columns of Table 1.11. The author of this chapter has added a third column identifying the appropriate principles for 2026. One can see, by scanning across the table, the significant changes that have taken place in our discipline. It is clear that the future holds a role both for empiricism and for research-based radiation oncology as well as a role for improvements in physics and biology. Through cooperation and constructive dialogue, all may contribute to the future of cancer care.

TABLE 1.11 PRINCIPLES OF RADIATION ONCOLOGY DERIVED FROM THE INITIAL WORK OF SUIT

1956	1982	2026
1. Aim for uniform dose throughout	1. Use shrinking-field technique (ie, a	1. Moderate, conform, and "paint" the external beam or brachytherapy dose distribution in

1956	1982	2026
the treatment volume. Treatment volume is constant for entire treatment (ie, no shrinking field).	nonuniform dose distribution related to number of tumor cells).	accordance with the viable tumor cell distribution and minimize injury to normal tissue.
2. Initial large treatment volume is carried to tolerance.	2. Dose to the initial volume is usually less than tolerance. Only the final treatment volume is carried to tolerance dose level.	2. Dose to the initial volume is less than tolerance and may be moderated because of the specific host and treatment factors affecting tolerance.
3. No special emphasis to push dose to higher levels for larger tumors	3. Dose aim is planned on the basis of tumor size or estimated tumor cell number. a. Maximum doses (with higher risk of morbidity) for large tumors b. Modest well-tolerated dose levels for subclinical disease c. For combination of radiation and surgery, use less than radical dose level.	3. Dose aim is planned on the basis of tumor size, estimated tumor cell number, extent and completeness of surgical resection, biologic and genetic and imaging predictors of tumor aggressiveness, and response to induction chemotherapy. a. Maximum doses (with higher risk of morbidity) for large and more aggressive tumors b. Modest well-tolerated dose levels for subclinical disease c. For combinations of radiation and surgery, chemotherapy, and/or biologic therapy, one might use less than radical dose level in certain situations. d. For combinations of external beam radiation therapy and brachytherapy or radiation therapy and hyperthermia, the dose of each modality is modified as a function of the other modalities used.
4. Little priority given to planned combinations of radiation and surgery.	4. Major emphasis on planned combinations of radiation and surgery	4. Major emphasis on planned combinations of radiation, surgery, chemotherapy, hormonal therapy, and biologic therapy
5. Treatment fields are square or rectangular.	5. Secondary collimation is utilized on virtually all fields to reduce irradiation of tissues not suspected of involvement by tumor.	5. Multileaf collimators and intensity modulation and/or use of electrons, protons, or charged nuclei are used in an attempt to improve conformality of the radiation and reduce irradiation of tissue not suspected of being involved with tumor. Radiation dose distribution is based on sophisticated imaging technologies.

1956	1982	2026
6. Radiation alone is the general rule.	6. Multidisciplinary approach accepted as most effective for most tumor problems	6. The radiation oncologist is expected to be trained in and make use of genetics, biomarkers, and conventional pathology for tumor subtyping and grading; anatomic and molecular staging; diagnostic imaging; and the therapeutic role of chemotherapy, hormonal therapy, biologic therapy, and surgical therapy.
7. Results of treatment described almost exclusively in terms of absolute survival at a fixed period (eg, 5 y).	7. Results analyzed on the basis of detailed assessment of causes of failure (eg, local persistence or regrowth, local complication, marginal miss, regional spread, distant metastases, intercurrent disease)	7. The phase III randomized prospective trial the gold standards for clinical decision-making. Decisions based on properly planned and conducted cancer trials concerning radiation therapy dose, volume, and technique are most appropriate. It is expected that evidence-based medicine will guide clinical decision-making. If such trials are not available or are inadequate, then phase II trials or retrospective reviews involving survival, local control, patterns of failure, and multivariate analysis of outcome are often useful. The future will depend on and meta-analyses are research in cancer biology and medical physics being brought to the clinic.

It is essential that radiation oncologists remain current with scientific findings that will be critical in the development of improved therapeutic strategies. Approaches that alter the cell's surface membrane, receptors, secondary messengers, or nuclear contents may overcome cellular radiation resistance. By exploiting cellular mechanisms related to apoptosis, it may be possible to kill cells with irradiation by inducing changes other than unrepaired DNA damage. With an understanding of the tumor microenvironment and techniques such as complementary DNA microarrays, as well as an understanding of how growth factors may alter cellular processes, innovative bioinformatics and improved combined modality strategies may emerge. The ability to genetically sequence tumors will provide information beyond the era when biologic effects were attributed to a single gene. A better understanding of hypoxia may improve clinical outcome with antihypoxia strategies, including hypoxic cell radiosensitizers and hypoxic cytotoxic agents. Cyclins and growth factors may be useful as clinical radiation modifiers. Pharmacogenomics may inform how we prescribe drugs.

There is a critical need to balance the investment in technical aspects of radiation therapy with concepts and innovative approaches derived from a better understanding of cancer biology. These scientific developments will greatly alter the way in which we practice our discipline

IMPORTANCE OF TREATMENT PLANNING IN RADIATION THERAPY

The predicted consequences of radiation therapy are based on the precision with which the dose and the irradiated volume are defined. An imprecise treatment system could lead to a high incidence of normal tissue injury with a low probability of tumor control.[349] Decreasing irradiation doses to avoid complications will further reduce the probability of achieving tumor control if such action is based on the wrong assumption that the tumor control/complication ratio is related only to radiation dose levels. The ICRU recommends a ±5% accuracy for dose delivery computations.[350,351] However, every effort should be made to develop accurate dose calculation algorithms, including methods to correct for inhomogeneities in tissue density and the shape of the patient's body, and to develop practical treatment planning capabilities to obtain the highest possible dose optimization in the irradiated volume (tumor and normal tissues). There are benefits of reducing the treatment volume in an effort to deliver higher doses of irradiation. This may improve the quality of tumor control without excessively irradiating surrounding normal tissues, thereby decreasing treatment-related morbidity.

Various steps can be taken to decrease toxicity in normal tissues, including precise treatment planning and irradiation techniques, selectively decreased volume receiving higher doses dictated by estimated cell burden, and maneuvers to exclude sensitive organs from the irradiated volume. With the emphasis on organ preservation, treatment planning is critical to achieve maximum TCP and satisfactory cosmetic results.

Optimal dose distribution in EBRT may be achieved by a combination of multiple stationary beams or by moving beam therapy, such as in arc or full rotational techniques or IMRT or IMPT. In addition, the optimal dose distribution in many tumors requires access to more than one modality or beam energy particle type. A combination of external beams and brachytherapy may also be required, depending on the location of the tumor.

Three-Dimensional Treatment Planning

Computer technology creates accurate and timely computation, display of 3D radiation dose distributions, and dose-volume histograms (DVHs).[352,353] These developments have stimulated sophisticated 3D treatment planning systems, which yield relevant information in the evaluation of tumor extent, definition of target volume, delineation of normal tissues, virtual simulation of therapy, generation of digitally reconstructed radiographs, design of treatment portals including the use of MLCs and aids (eg, compensators, blocks), calculation of 3D dose distributions and dose optimization, and critical evaluation of the treatment plan.[354,355]

With advanced computerized and display technologies, contiguous CT and/or MRI and/or PET slices are used to define anatomic structures and target volumes. External radiation beams of any possible orientation are simulated. A significant feature of these systems is the so-called beam's-eye view, in which patient contours are viewed as if the observer's eye is placed at the source of radiation looking out along the axis of the radiation beam.[356] These systems allow simulation of the geometric setup; evaluation of the plan for dose optimization still is made on the merits of volumetric dose distributions.

Quantitative treatment planning evaluation is crucial in the selection of the best portals and radiation beams to deliver an optimal dose to the tumor with relative sparing of normal tissues. The ICRU Report 50 and its supplement G2 define 3D volumes for the prescription and reporting of EBRT.[357] The concepts of PTV and CTV were defined earlier in this chapter.

The DVH is useful as a means of dose display, particularly in assessing several treatment plan dose distributions.[358] A DVH provides a complete summary of the entire 3D dose matrix, showing the amount of target volume or critical structure receiving more than a specified dose level. Because a DVH does not provide spatial dose information, it cannot replace the other methods of dose display; it can only complement them.

Models for optimization of 3D dose distribution using biologic models of tumor and normal tissue responses correlated with physical radiation doses have been described.[359,360]

Intensity-Modulated Radiation Therapy and Intensity-Modulated Proton Therapy

An approach to 3D treatment planning and conformal therapy optimizes the delivery of irradiation to irregularly shaped volumes through a process of complex inverse (or forward) treatment planning and dynamic delivery of irradiation that results in modulated fluence of photon or proton beam profiles and a more conformal dose to the target volume(s), with enhanced sparing of surrounding normal tissues.[361,362]

Treatment planning begins with the determination of the GTV and the CTV, and an estimate of where the tumor may spread. CT, MRI, and fluorodeoxyglucose PET imaging along with image fusion have enhanced the possibilities for determining the target more accurately. The PTV accounts for inaccuracies in positioning patients and organ motion.

In "forward" planning, software calculates the dose distribution, displays it with a 3D anatomic model, and provides analytical and graphical metrics for assessing the adequacy of tumor treatment and normal tissue avoidance. The physician decides if

the plan is acceptable. If not, an alteration is made in the beam arrangement, and the process is repeated.[363]

Computerized optimization techniques have led to "inverse" planning. Goals of an acceptable treatment plan are delineated, and the inverse planning algorithm searches through many thousands of possibilities to find a plan that best satisfies the goals. In IMRT, the beams are broken up into "beamlets" (on the order of 0.5 by 0.5 or 1 by 1 cm^2) that can each have a different intensity. IMRT or IMPT may improve the ability to treat with a high radiation dose while minimizing dose to nearby critical structures.

There are a variety of forms in which IMRT can be administered:

1. A linear accelerator and MLC, with a variety of beam configurations at various angles, may be used; the MLC determines the portal shape of each of the portals. Photon-modulated fluency may be obtained (a step-and-shoot method). Analogous techniques may be used with protons.
2. Dynamic computer-controlled IMRT is delivered when the configuration of the beams outlined with the MLC is changing at the same time that the gantry or the accelerator is changing positions around the patient.
3. In helical TomoTherapy, the photon fan beam continually rotates around the patient as the couch transports the patient longitudinally through the ring gantry. The verification processes for helical TomoTherapy are enabled by the use of the ring gantry; the geometry of a CT scanner allows tomographic processes to be reliably performed. Dose reconstruction is a key process of tomography; the treatment detector sinogram computes the actual dose deposited in the patient. The length of the beam is 40 cm at the central axis and has a width that can vary between 0.5 and 5 cm. The lengths of the MLC in helical tomography are temporarily modulated or binary in the sense that they are rapidly driven either in or out by air system actuators rather than beam slowly pushed by motors driving lead screws as in the conventional MLC.
4. The robotic IMRT system consists of a miniaturized 6-MV photon linear accelerator mounted on a highly mobile arm and a set of ceiling-mounted x-ray cameras to provide near real-time information on patient position and target exposure during treatment.

The majority of the IMRT systems use 6-MV x-rays, but energies of 8 to 10 MV may be more desirable in some anatomic sites (to decrease skin and superficial subcutaneous tissue dose). Higher energies will increase neutron contamination of the therapeutic beam(s). The dose distribution and field-shaping parameters are based on inverse 3D planning using a specially defined minimal dose to target and dose constraints for surrounding normal tissues.[364,365] Inverse planning starts with an

ideal dose distribution and finds through trial and error or multiple iterations (simulated annealing) the beam characteristics (fluence profiles) and then produces the best approximation to the ideal dose defined in a 3D array of dose voxels organized in a stack of 2D arrays.[366]

A back-projection technique through careful choice of filters, beam placement, and shaping of the portals conforms the irradiation dose to the shape of the tumor, minimizing dose to critical adjacent structures. When this technique is used, it is critical to adhere to basic concepts of treatment planning and evaluation of the pathobiology of malignant disease. Well-designed treatment plans based on radiographic imaging (CT, MRI, or PET), which, in most instances demonstrates gross disease, are necessary to minimize the risk of missing or underirradiating adjacent microscopic or subclinical tumor.

Given the added time and labor involved in IMRT, numerous issues require study:

1. Can the tumor be localized with sufficient accuracy to take advantage of the improved dose localization?
2. Treatment plans that produce a rapid drop in dose between the edge of the tumor and the normal tissue require more exact patient positioning; otherwise, there is a high risk of underdosing the tumor or overdosing normal tissue.
3. Some IMRT plans treat the center of the tumor with a very high dose to achieve an acceptable dose at the edge. This may not be optimal.
4. Many IMRT techniques spread a low dose over a larger volume or normal tissue. This may increase the risk of secondary malignancies years later.

Four Truisms Regarding Radiation Oncology or Four Debatable Points of View?

Herman Suit asserted the existence of four truisms related to randomized trials and proton beam radiation therapy.[367,368] The definition of "truism" is "a statement that is obviously true" or, perhaps, a statement which is self-evident. Suit's truisms, while derived regarding whether randomized prospective clinical trials are necessary for proton beam therapy, might be reviewed as having general applicability to the specialty. Suit argued that randomized prospective clinical trials to ascertain the alleged benefits of highly conformal proton beam therapy were unnecessary. Protons, he felt, were intuitively obviously better.

The four truisms are:

(1) There is no benefit to any patient for any radiation of normal tissue not suspected of involvement by tumor.

(2) Complications of radiation therapy never occur in unirradiated tissues.

(3) Ascertaining whether a smaller treatment volume of normal tissue being exposed to radiation is superior is not a medical research question.

(4) Experimentation only investigates the magnitude of gain for a superior radiation therapy dose distribution or its cost—it does not ascertain the necessity of seeking that gain.

Following Suit's logic, we can claim two benefits attributed to proton beam radiation therapy for some forms of childhood cancer: (a) either the ability to reduce radiation dose to tissues uninvolved with tumor in some cases and/or (b) the potential to escalate the dose to the tumor in some cases.

Suit's truisms are articulate, but are they all self-evident, particularly for adult tumors? Each alleged truism may be critiqued.

> "There is no benefit to any patient for any radiation of normal tissue not suspected of involvement by tumor."

"Suspected" is an imprecise term in this context. In many patients, we make a probabilistic assessment of whether tissue is involved by tumor. Then, based on that assessment, we decide if the risks of irradiating that tissue warrant the potential benefit. Should the patient's neck be irradiated, when we can neither palpate any involved cervical lymph nodes or image any, in squamous cell carcinoma of the oral cavity, oropharynx, hypopharynx, nasopharynx, or larynx? Should the internal mammary or paraclavicular lymph nodes be irradiated in a patient with infiltrating ductal carcinoma of the breast? How much "suspicion" or normal tissue involvement by tumor is required to derive a potential benefit by subjecting it to radiation therapy?

"Complications of radiation therapy never occur in unirradiated tissues."

We know that we can find evidence of cells reacting to pulmonary radiation therapy in the unirradiated lung. Infections promoted by the immunosuppression produced by radiation therapy can occur in tissues distant from those irradiated.

> "Ascertaining whether a smaller treatment volume of normal tissue being exposed to radiation is superior is not a medical research question. Experimentation only investigates the magnitude of gain for a superior radiation therapy dose distribution or its cost—it does not ascertain the necessity of seeking that gain."

These are the most controversial of the alleged truisms. First of all, in many cases, we do not have the clinical tools to ascertain the presence of any benefit to a smaller radiation therapy treatment volume. Yes, highly conformal radiation therapy to a 65-year-old with glioblastoma multiforme (GBM) will expose less normal tissue to radiation than less conformal treatment. We have no ability to measure any alleged benefit of a 20-Gy isodose line administered over 6 weeks to the nondominant

hemisphere of the brain in this GBM patient with less conformal treatment compared to, say, a 10-Gy isodose line over 6 weeks with more conformal treatment. Second of all, and most importantly, the world of medicine is full of examples of concepts that did not warrant randomized prospective studies because the answer was self-evident. Then someone did the randomized study and showed that the self-evidently true answer was wrong.

HEAVY PARTICLE BEAMS

One can imagine two possible mechanisms by which one could improve on therapeutic x-rays with an alternative particle. First, the alternative particle could have energy deposition characteristics that lead to a superior dose distribution. A beam, conceivably, could have more skin sparing than x-rays, better stopping characteristics, and/or less side scatter. This might allow a more conformal therapy. Second, the alternative particle could have advantageous radiobiologic properties. It might be more toxic than x-rays to hypoxic cells or cells in the late S phase of the mitotic cell cycle. Such a particle would have, perhaps, a lower oxygen enhancement ratio (OER) and a higher RBE than x-rays. These two possible mechanisms of improving on x-rays are not mutually exclusive. A particle could have both superior physical dose distribution and radiobiologic properties.

The effort to identify improved alternatives to x-rays has focused on the group of particles called hadrons. These are particles constituted of strongly interacting particles called quarks and gluons. The hadrons include the mesons and the baryons. The latter include protons, neutrons, negative pions, and the nuclei of heavier atoms, such as He^{2} (helium), C^{6} (carbon), O^{8} (oxygen), Ne^{10} (neon), and Ar^{18} (argon). All of these forms of radiation are distinguished from x-rays and electrons by their greater masses. These alternative radiation modalities are relatively difficult to produce, are expensive, and are considerably more difficult to control.

Proton, heavy ion, and hadron beams have attracted radiation oncologists because they offer interesting and potentially beneficial dose distribution characteristics. Radiobiologically, their properties are not significantly different from x-rays. When a heavy particle beam traverses tissue, the dose is deposited in an approximately constant rate. The rate of energy loss (also called the “stopping power”) of a heavy charged particle is proportional to the square of the particle charge and inversely proportional to the square of its velocity. As a proton or heavy ion slows down, its rate of energy loss increases and so does the ionization or absorbed dose to the tissue. Near the end of the proton’s range, the deposition of energy rises very sharply before dropping to almost zero. This peaking of dose near the end of the particle range is called the Bragg peak. As a result of the Bragg peak effect and minimal scattering, the proton offers the potential advantage and the ability to concentrate

dose inside and immediately adjacent to the tumor volume and minimize dose to surrounding normal tissues. There are multiple proton treatment facilities operational and under construction throughout the world.

For a thorough discussion of proton and neutron radiation, as well as a consideration of pi meson therapy and charged nuclei therapy such as helium ions and neon ions, the reader is referred to Chapters 11 and 20 of this volume.

BORON NEUTRON CAPTURE THERAPY: AN IDEA WHOSE TIME HAS NOT YET COME

The fundamental concept of boron neutron capture therapy (BNCT) is the production of high LET particles ($^{7}Li^{3+}$ and $^{4}He^{2+}$) when one "tags" or "labels" a tumor cell with a compound having a large cross section capable of capturing a "slow" (thermal) neutron. After the compound captures the neutron, it goes into an excited state. The excited fission of the ^{9}B nucleus will release energy, which drives the heavy ion products over short distances comparable to the dimensions of one cell. A 0.48-MeV photon is also produced in 94% of the fission events. This is useful for monitoring the reaction but is of little consequence for cell killing.

The neutron has a mass of 0.782 MeV, more than that of the proton. Neutrons were identified in 1932 by Chadwick[369] at Cambridge University's Cavendish Laboratory. Subsequently, Fermi[370] discovered that neutrons react most efficiently with a number of elements after they are slowed by passage through a hydrogen-rich substance such as paraffin. Chadwick and Goldhaber,[371] Taylor and Goldhaber,[372] and Burcham and Goldhaber[373] showed that slow neutron bombardment of specific stable isotopes of boron, lithium, and nitrogen yields charged particle tracts in photographic plates. The tracts from boron's interaction with neutrons were short and straight and were consistent with the formation of two particles traveling in opposite trajectories. In photographic gelatin, their average travel distance was 7.6 μm. The boron neutron capture process is highly localized. In principle, one could kill a tumor cell containing boron while sparing an adjacent normal cell that does not contain boron (Box 1.7).

Box 1.7

Terms Pertinent to Neutron Capture Therapy

Epithermal neutrons: Energetic neutrons pass through an intermediate energy range on the way to becoming slow or thermal neutrons. This intermediate energy range is called epithermal.
Fast neutrons: Fast neutrons are highly energetic and travel quickly.

Moderation: Neutrons generated from the fission process or from particle bombardment of materials have significant energy. They lose that energy by colliding with atoms in their environment and create energetic recoil atoms. After a sufficient number of collisions, the neutrons lose essentially all of their energy and become thermal. This process of energy loss is called moderation. The material that provides the atoms the fast neutrons collide with is called a moderator. Water is the usual moderator.

Slow neutrons: Slow neutrons have little energy. They also are referred to as thermal neutrons because they have the same average kinetic energy as gas molecules in their environment.

Thermalize: Epithermal neutron beams, as they penetrate tissue, become additionally moderated. This is called becoming thermalized.

Based upon Yanch JC, Shefer RE, Busse PM. Boron neutron capture therapy. In: Fletcher GH, ed. *Sci Med.* 1999;January/February:18-27.

The complete chemical reaction is as follows:

$^{10}B + {}^{1}n \rightarrow {}^{7}Li + {}^{4}He + \gamma + 2.4$ MeV.

The attraction of BNCT, for many clinicians, was the notion of the "magic bullet." The idea that one could specifically label tumor cells with a compound with an enlarged cross-sectional area, not label surrounding normal tissue, and therefore, deposit radiation only in the tumor is most attractive. Unfortunately, reality is far different from the ideal.

Fast neutrons differ from x-rays in the mode of their interaction with tissue. Whereas x-ray photons interact with the orbital electrons of atoms via the Compton or photoelectric process and set fast electrons in motion, neutrons interact with the nuclei of the atoms of the absorbing tissue. Neutrons put fast recoil protons, α-particles, and heavier nuclear fragments in motion. At energies above about 6 MeV, inelastic scattering by neutrons takes place.[374] A neutron may interact, for example, with a carbon or an oxygen nucleus to produce α-particles. These led to nuclear fragments called spallation products.

The LET is considerably higher for neutrons than for x-rays. Because the LET of neutron radiation is higher, the slope of the cell survival curve becomes steeper and the size of the initial shoulder gets smaller. This produces a beam with a lower OER than x-rays—neutrons are considerably more toxic to hypoxic cells than x-rays. Also, neutrons are more toxic to cells in phases of the cell cycle that are relatively radioresistant to x-rays. Thus, the RBE of neutrons is higher than x-rays.[378]

In 1936, Locher[379] published a theoretical account of the possible biologic effects and therapeutic possibilities of boron neutron capture.

> The possibility of destroying or weakening cancerous cells is by the general or selective absorption of neutrons by themselves, and particularly there is the possibility of introducing small quantities of neutron absorbers into the regions where it is desired to liberate ionizing energy. A simple illustration

> would be the injection of a soluble nontoxic compound of boron, lithium, or gold into a superficial cancer followed by bombardment with slow neutrons. (Locher GL. Biologic effects and therapeutic possibilities of neutrons. *Am J Roentgenol*. 1936;36:1-13.)

In 1950, Conger and Giles[380] from Oakridge National Laboratories reported that the trace amounts of boron normally present in lily bulbs were responsible for most of the radiation changes in the plants following exposure to slow neutrons. This demonstrated the biologic fact clearly and led William H. Sweet[381] and others to see if the normal brain could exclude enough boron and if tumor tissue could take up enough boron to produce an appropriate therapeutic ratio.

Sweet began work at the Brookhaven National Laboratory in New York with a 20-MW nuclear reactor in 1950.[382] He initially treated 10 patients with glioblastoma multiforme who had undergone gross total resection of their tumors at the Massachusetts General Hospital in Boston. Sweet described the initial clinical work:

> A portion of the shielding atop the reactor was removed to permit placing the lateral aspect of the patient's intact scalp and skull at the specially designed portal. To prevent scalp damage, we tied off the external carotid arteries and covered the entire scalp with tight elastic bandages in an attempt to prevent boron-containing blood from entering the scalp. These tactics, however, did not prevent the development of several large radiation erosions of the scalp. Five patients received a single radiation dose and the remaining 5 were given the treatment in 2 to 4 fractions. Although there were no life threatening complications of therapy, all of the patients died from 6 to 21 weeks after the first session of neutron capture therapy, which was usually the case in the 1950s for glioblastoma patients treated by any means. Postmortem studies done in 6 of the patients showed abundant viable tumor. Their painful scalp lesions together with the inadequacy of the radiation dose lead us to attempt to deliver the thermal neutron beam directly to the grossly normal but microscopically tumor-infiltrated brain. The Rockefeller Foundation made this approach possible with a $500,000 gift to the Massachusetts Institute of Technology to provide additional features to a nuclear reactor that was then being constructed. Included was a surgical operating room immediately beneath the reactor core. This permitted us to turn down the scalp, bone, and dural flap used in the prior removal of gross tumor. At reopening the cerebrospinal fluid replacing tumor was also drained away to give maximally unimpeded access of the thermal neutrons through sterile air to the tumor-infiltrated brain.[383] (Reprinted by permission from Springer: Sweet WH. Early history of development of boron neutron capture therapy of tumors. *J Neurooncol*. 1997;33(1-2):19-26. Copyright © 1997 Kluwer Academic Publishers.)

Sweet treated 18 patients at the Massachusetts Institute of Technology. They died from 10 days to 11.5 months after radiation. In every patient, the cause of death was cerebral, and extensive irradiation necrosis of the brain was induced in nine cases. In two cases, only recurrent tumor was seen, and in one patient, there was extensive radiation necrosis and tumor.

Some of the initial work with BNCT was highly controversial and, decades later, led to investigations concerning the nature of informed consent for these human experiments. President William J. Clinton created, by executive order, a commission to study the ethics of Cold War–era medical experimentation using radiation. One of the collateral effects of this commission's report was that Sweet and his colleagues

were sued for malpractice 40 years after the BNCT experiments. Although the plaintiffs were awarded substantial damages at trial, the decision was eventually overturned on appeal.[384]

Lack of progress in BNCT may be attributed to two factors: inadequate tumor specificity of the boron compounds used to localize in the tumor and poor penetration into tissue of the thermal neutrons. In addition, the thermal and antithermal neutron beams produced by nuclear reactors have considerable contamination with γ-rays and fast neutrons. These can cause normal tissue damage even in the absence of boron concentration in tissues. In addition, there are a number of compounds in normal tissue that can interact with thermal neutrons and have capture events of their own, producing biologic damage even to non–boron-containing tissue.

The development of suitable boron-carrying agents remains a stumbling block to clinical programs. The ideal agent will be nontoxic, will have a high tumor-to-normal tissue ratio, and will have a high absolute boron concentration.

Investigations of improved ways of delivering thermal neutrons have centered on two areas: the use of nuclear reactors and useful alternatives to reactors.

The most intense way to generate a neutron beam is with a nuclear reactor. Despite the high neutron intensities available from these reactors, it is widely recognized that alternative neutron sources will be necessary for BNCT to be performed. First of all, there are few suitable nuclear reactors in operation. A patient would have to travel a long distance for treatment. Second, nuclear reactors, for political and social reasons, are not likely to be sited near major population centers in the future. A major reactor facility located far from a population center would have to be provided with its own clinical infrastructure The target patient population would not be large enough to support the operation of more than a few medical reactors. Therefore, some investigators have been pursuing nonreactive sources of thermal and epithermal neutrons with a sufficiently high flux to be used for BNCT.[385-387]

An alternative to the reactor would be a neutron source from radioactive decay such as californium-252 (^{252}Cf). However, the production of a neutron beam with sufficient intensity for BNCT would require more than the entire present annual supply of ^{252}Cf. Another alternative source is a particle accelerator. Accelerator-based neutron beams are created when light ions such as protons or deuterons are accelerated in an electric field and are made to bombard target materials.

GRID THERAPY, BYSTANDER EFFECTS, ABSCOPAL EFFECTS, RADIATION-ENHANCED ANTIGEN PRESENTATION, AND DANGER-ASSOCIATED MOLECULAR PATTERNS

Early in radiotherapy's history, some clinicians tried to improve normal tissue sparing, particularly the skin, by creating a shielding block that resembled a checkerboard. Imagine a radiation beam striking a checkerboard in which the black squares are lead and the white squares are open. This would permit radiation to travel through the open squares, while the black squares would shield the patient, the patient's normal tissue, and the tumor from radiation. If a single-photon field was used to deliver the grid pattern of radiation, there would be a dose distribution of peaks and valleys across the normal tissue and the tumor because of penumbra and side scatter. A radiation dose, which is delivered to a contiguous region, induces greater damage than the same dose fractionated in space. This concept is generally called *GRID radiation therapy*. It can now be performed with TomoTherapy, MLCs, and/or a proton beam. In three dimensions, the GRID or "checkerboard" is probably better thought of as a honeycomb.

Spatially fractionated radiotherapy causes irradiated tumor cells to engage in cell-to-cell signaling. Neighboring unirradiated cancer cells are clearly affected. One observes cells undergoing a stress response, activation of repair enzymes, and antioxidant gene expression. It is as if the irradiated cells are sending a "mayday . . . mayday . . . I am under attack" message to neighboring cells. Furthermore, in some experimental models, the irradiated cells provoke an immune response, which can kill irradiated and unirradiated cells. It appears that the radiation causes the emission of antigens and cell signals, which activate an immune reaction. The phenomena of the irradiated cells have an effect upon neighboring unirradiated calls, called "the bystander effect."[388]

The *abscopal effect* is a phenomenon where the localized treatment of a tumor causes not only a shrinking of the treated tumor but also a shrinking of tumors outside the scope of the localized treatment. Imagine, for example, an experimental mouse with a tumor implanted in the left thigh and a tumor of the same histology implanted in the right thigh. If a highly localized external radiation beam were directed against the tumor of the left thigh and it regressed and, in addition, the unirradiated tumor of the right thigh regressed, then the behavior of the tumor of the right thigh is called an abscopal effect. In a 1953 paper in the *British Journal of Radiology*, R.H. Mole proposed the term "abscopal" ("ab," away from; "scopus," target) to refer to radiation's effects "at a distance from the irradiated volume but within the same organism."[389]

A current active area of research addresses the idea that irradiation may augment the immunogenicity of tumors and accentuate the cytotoxic effects of radiotherapy both on the irradiated tumor and on distant tumors—a form of the abscopal effect. In combination with immunotherapeutic agents, an irradiated tumor might be able to act as an autologous in situ tumor vaccine. The mechanism of action might involve radiation-enhanced antigen presentation, damage-associated molecular patterns, or

danger-associated molecular patterns, by which host molecules initiate and perpetuate a noninfectious inflammatory response, immunomodulation of tumor cell surface molecules, and the modulation of cellular infiltrates in the tumor microenvironment.[390,391]

FLASH THERAPY

FLASH radiotherapy (FLASHRT) is defined as the ultrafast delivery of therapeutic radiation at dose rates several orders of magnitude greater than those used in conventional radiation therapy. If a typical linear accelerator delivers its dose at 0.5 to 5 Gy/min, FLASHRT treats at a rate on the order of 40 Gy/s.

Why? The leading theory is that ultrafast delivery of radiation therapy depletes tissue of oxygen and causes transient hypoxia. (There is far from uniform acceptance of this theory.) This exerts a protective effect on oxic normal tissue by rendering it hypoxic. In contrast, tumors have significant anoxic and hypoxic components, FLASHRT eliminates the differential oxygen effect between normal tissue and tumor and, therefore, allows the delivery of high doses of radiation therapy with a relatively protective effect on normal tissue.

If this story sounds vaguely familiar to older radiation oncologists, it is because it is familiar and almost 60 years old. In 1968, Herman Suit and Robert Lindberg described this idea succinctly. A possible explanation of the radioresistance of sarcomas of bone and soft tissue is the presence of hypoxic and radioresistant cells. If one could eliminate the pO_2 differential between tumor and normal tissue, then it might be possible to achieve increased effectiveness of radiation therapy without increasing the risk of normal tissue injury. "A simple, direct, and relatively effective way of essentially eliminating tissue pO_2 differentials between and tumor of an extremity and the surrounding normal tissue would be to apply a tourniquet to the upper thigh or arm and thereby prevent accession of oxygen-containing blood to the part."[392]

The clinical results of the tourniquet technique of radiotherapy were unsatisfactory, but the principle articulated is the same biologic explanation offered for the normal tissue–sparing effect of FLASHRT: eliminating the discrepancy between the oxygen status of normal tissue and tumor.

In 1959, Dewey and Boag found that the radiosensitization achieved by irradiating bacteria in 1% oxygen compared to 100% nitrogen was eliminated by using ultra HDRs compared to conventional dose rates.[393] Beginning with these experiments, the oxygen depletion hypothesis of FLASHRT was developed.

There are alternative theories regarding the mechanism of action of FLASHRT, including induction of an immune response, vascular changes, and/or microdosimetric effects.

FLASHRT and its early clinical results are addressed in Chapter 18.

THE CARE AND PROTECTION OF THE RADIATION ONCOLOGY PATIENT

The Process of Care in Radiation Oncology

The "process of care" in radiation oncology refers to a conceptual framework for ensuring the appropriateness, quality, and safety of all patients treated with radiation for therapy. Each of the aspects of the process of care in radiation oncology requires knowledge and training in the natural history of cancer and certain benign diseases, radiobiology, medical physics, and radiation safety that can only be achieved by board certification in radiation oncology (or equivalent training) to synthesize and integrate the necessary knowledge base to safely and completely deliver care. This high level of training and board certification applies as a recommendation for all of the specialists on the radiation oncology team. The medical therapeutic application of ionizing radiation is irreversible, may cause significant morbidity, and is potentially lethal. The use of ionizing radiation in medical treatment, therefore, requires direct or personal physician management, as the leader of the clinical team, as well as input from various other essential coworkers.

The radiation oncology process of care can be separated into categories:

- Patient evaluation
- Preparing for treatment
- Therapeutic simulation
- Treatment planning
- Pretreatment quality assurance (QA) and plan verification
- Radiation treatment delivery
- Radiation treatment management
- Follow-up care management

A course of radiation therapy is composed of a series of distinct activities of varying complexity and is a function of the individual patient situation. All components of care involve intense cognitive medical evaluation, interpretation, management, and decision-making by the radiation oncologist and other members of the clinical team. Each time a procedure is approved and reported, its level of effort/complexity should be appropriately documented in the patient record.

The clinical team, led by the radiation oncologist, provides the medical services associated with the process of care. Other team members involved in the patient's planning and treatment regimen include the medical physicist, dosimetrist, radiation therapist, and nursing staff. Many of the procedures within each phase of care will

be carried to completion before the patient's care is taken to the next phase. Others will occur and recur during the course of treatment, and they are by necessity repeated during treatment because of patient tolerance, changes in tumor size, need for boost fields or port size changes, or protection of normal tissue, or as required by other clinical circumstances (ie, certain procedures may need to occur multiple times during the treatment course). Each phase of care involves medical evaluation, interpretation, management, and decision-making by the radiation oncologist as well as other team members.

Patient Evaluation

Patient evaluation is a service provided by a physician to either recommend care for a specific condition or problem or determine whether to accept responsibility for the ongoing management of the patient's entire care or for the care of a specific condition or problem. The physician as part of this process will review the pertinent imaging and pathologic studies, the patient's complaints, and physical findings. Nowadays far too many radiation oncologists seem to act as if the patient evaluation starts and ends with a review of the CT, CT/PET, or MRI. "The good physician treats the disease"; Sir William Osler said, "The great physician treats the patient who has the disease."[394] Cancer occurs in the context of the patient's general medical condition, family, culture, means of employment, home, and aspirations. All of these must be considered along with the anatomic location of the tumor and normal tissue. This initial visit can also be used for patient counseling, coordinating care, and making recommendations about other aspects of oncologic management or staging.

Preparing for Treatment

The selection of a comfortable and appropriate patient position for treatment is an important part of the simulation process. The selected position should consider the location of the target and the anticipated orientation of the treatment beams. Appropriate immobilization devices provide comfort, support, and reproducibility. Immobilization of the patient in a comfortable position for treatment might involve the construction or selection of certain treatment devices for helping the patient remain in position during treatment. This step must consider the potential treatment planning considerations so that the treatment aids do not restrict the treatment techniques.

Simulation is the process of determining critical information about the patient's geometry, to permit safe and reproducible treatments on a megavoltage machine. Simulation for external beam radiation treatment is always image based. Simulation procedures have shifted away from the direct use of the treatment beam to using diagnostic x-rays, CT, PET/CT, or MRI. In general, this part of the overall process of

care determines the relationship between the position of the target or targets and the surrounding critical structures. When a simulator of conventional design is used that mimics the geometry of the treatment unit, when direct simulation is performed on the treatment machine, or if a CT or MRI simulator is used, this relationship is sometimes determined indirectly through observation of skeletal anatomy that can act as a surrogate for the target position. A CT or MRI simulator can include the ability to produce volumetric data in addition to 2D images.

The preparation for external beam treatment can also depend on other imaging modalities that are directly or indirectly introduced in the simulation process. MRI, ultrasound, and/or PET are frequently used, and treatment planning systems that include image registration capabilities allow combining of information from other imaging modalities with the standard CT data set obtained during simulation in appropriate situations. It is now possible to produce image data sets that quantify the motion of structures and targets because of respiration, cardiac motion, and physiologic changes in the body.

For most brachytherapy, treatment preparation is similar to the procedure described earlier for EBRT. The simulation process is also image based. Multiple imaging modalities may be important for some brachytherapy procedures, and these studies can be obtained as part of the preplanning imaging process. For clinical situations where therapy is delivered by unencapsulated radionuclides, a separate and distinct treatment planning process is necessary because of its multidisciplinary execution.[395]

Clinical treatment planning is a comprehensive, cognitive team effort performed under the direction of the radiation oncologist for each patient undergoing radiation treatment. The radiation oncologist is responsible for understanding the natural history of the patient's disease, knowing the extent of the disease relative to the adjacent normal anatomic structure, and integrating the patient's overall medical condition and associated comorbidities. A detailed understanding of the integration of chemotherapeutic and surgical treatment modalities with radiation therapy is also essential.

The skills of the trained and appropriately credentialed dosimetrist relate to the efficient and effective use of the complex treatment planning system hardware and software. This individual must also understand the clinical aspects of radiation oncology in order to interact with the radiation oncologist during the planning process. The role of the medical physicist is to guarantee proper functioning of the hardware and software used for the planning process, consult with the radiation oncologist and dosimetrist, check the accuracy of the selected treatment plan, and perform measurements and other checks aimed at ensuring accurate delivery of the plan.

For either EBRT or brachytherapy, treatment planning starts with a complete, formally documented, and approved directive. Details including total dose to all targets and OARs, fractionation, treatment modality, energy, time constraints, normal tissue constraints, and all other aspects of the radiation prescription in a written or electronic format must be provided by the radiation oncologist prior to the start of treatment planning. In some cases, this prescription can require modification based on the results of the treatment planning process.

Clinical treatment planning for either EBRT or brachytherapy is an important step in preparing for radiation oncology treatment. This planning includes the following components: determining the disease-bearing areas based on the imaging studies and pathology information, identifying the type (brachytherapy, external photon, or electron or proton beam) and method of radiation treatment delivery, specifying areas to be treated, and specifying the dose and dose fractionation. In developing the clinical treatment plan, the radiation oncologist may use information obtained from the patient's clinical evaluation as well as any additional tests, studies, and procedures that are necessary to complete treatment planning. Studies ordered as part of clinical treatment planning may or may not be associated with studies necessary for staging the cancer and may be needed to obtain specific information to accomplish the clinical treatment plan. Review of imaging studies and laboratory tests must be performed to determine treatment volume and critical structures in close proximity to the treatment area.

At various steps in the treatment planning process, the radiation oncologist is presented with one or more treatment plans for review and selection. This process is often iterative and requires additional treatment planning. The radiation oncologist is responsible for selecting and formally approving the plan to be used for treatment.

The QA steps taken after the completion of treatment planning and before the start of treatment are critical for guaranteeing patient safety. In the past, treatment verification consisted of field aperture imaging using radiographic film. These images were referred to as portal images or port films. With the introduction of IMRT or IMPT, imaging of individual apertures is no longer practical. However, the traditional method of verifying the plan isocenter position using "beam's-eye" imaging is often used for 3DCRT, IMRT, and IMPT. For IMRT, this important QA technique is not considered to be sufficient to guarantee patient safety. In addition to this isocenter check procedure, for IMRT and other complex delivery techniques that use inverse treatment planning, patient-specific QA measurements are also required.

Radiation Treatment Delivery

The physician is responsible for verification and documentation of the accuracy of treatment delivery as related to treatment planning and setup procedures. Image

guidance radiation therapy (IGRT) may be performed to ensure accurate targeting of precise radiation beams. IGRT requires a target that is expected to move from day to day and can be reliably identified by the selected imaging modality. The physician is responsible for the supervision and review of these images and prescribing necessary positional shifts to ensure the therapy delivered conforms to the originally planned dosimetric constraints. Similarly, the management of organ motion during treatment delivery is the responsibility of the treating physician.

Radiation Treatment Management

Radiation treatment management encompasses the radiation oncologist's overall management of the course of treatment and care for the patient as well as checks and approvals provided by other members of the radiation therapy team that are necessary at various points in the process. For the radiation oncologist, radiation treatment management requires and includes a minimum of one examination per week of the patient for medical evaluation and management. The professional services furnished during treatment management typically include the following:

- Review of portal images in a format appropriate to the technique of radiotherapy delivery
- Review of dosimetry, dose delivery, and treatment parameters
- Review of patient treatment setup
- Patient evaluation visit

Not all of these elements of treatment management are required for all patients for each week of management (except for the patient evaluation visit) because the clinical course of care may differ due to variations in treatment modality and individual patient requirements. Examinations and evaluations may be required more often than once weekly.

Follow-Up Care

Continued follow-up care of patients who have completed radiation therapy is necessary to manage acute and chronic morbidity resulting from treatment as well as to monitor the patient for tumor recurrence.

In the team approach to cancer care, the role of the radiation oncologist in follow-up is debatable. Traditionalists will say that "you irradiated the patient. You know more about radiotherapy effects than any other member of the team. You must follow the patient for the rest of their lives." Others say that "see the patient once or twice for follow-up and then return them to the care of their primary care physician, or surgeon, or medical oncologist" or "see the patient once per year." Unfortunately,

one also hears “you make money treating patients, not doing follow-up visits. Minimize them.”—a despicable point of view. Patients with cancer require follow-up. If the radiation oncologist does not do it themselves, then they must ensure that it is done by a competent health care provider.

Telemedicine and Remote Practice

With the worldwide shutdown that occurred in 2020 to 2022 due to the COVID-19 pandemic, many medical practices adopted telemedicine visits. Using readily available computer video technology, the patient and the physician can see each other and speak. Even some elements of a physical examination can be done via telemedicine including remote auscultation of the heart and lungs using an electronic stethoscope plugged into the computer or an electrocardiogram. One cannot, of course, palpate and measure the size and feel the consistency of a lymph node by telemedicine, do a pelvic examination for carcinoma of the cervix, or examine a patient’s prostate for the presence or absence of a nodule.

Radiation oncologists adopted telemedicine for follow-up visits during the pandemic. They were far from perfect, but they served a purpose in reducing the risk of the spread of COVID-19. Multidisciplinary tumor boards are relatively easy to conduct using online meeting software—pathologists can show their slides, and diagnostic radiologists can show their images. Professional meetings can be conducted online. Scientific papers can be presented and discussed. Indeed, some physicians found that they prefer online scientific and professional meetings: no drives to the airport, no delayed flights, no checking into and out of hotels, and minimizing time away from the family.

We now here widespread vaccination. Recognizing the convenience of telemedicine (The patient does not have to leave the house. The doctor can work from home.), there will continue to be a role for this technique postpandemic.

Radiation oncologists have observed that some medical specialties have adopted a work-from-home ethos. To various levels, some of the subspecialties among diagnostic radiologists, psychiatrists, and dermatologists are practicing medicine from workstations at home. Indeed, in some parts of the United States, employers are hard-pressed to find diagnostic radiologists who are willing to set foot in the hospital anymore.

What about radiation oncologists? Is it possible to use telemedicine to replicate the treating radiation oncologist walking in and out of the treatment room, checking the position of the stabilization device, looking at the alignment of the laser beams for patient positioning, looking at the projection of the light field on the patient, giving the patient a comforting word or pat on the arm, and looking at the QA portal images on the screen remotely? Is it possible to use telemedicine to stage most forms

of human cancer using a physical examination to assess the size, location, and mobility of the primary tumor and the presence or absence of involved lymph nodes; to check the function of the cranial nerves, sensation in response to tuning forks or pinpricks, or reflex response to a reflex hammer; or to look at the eye grounds, the tympanic membranes, or palpate internal organs or view them with a fiberoptic scope remotely? Even if it is possible, is it equivalent? At present, it is neither possible nor equivalent.

Furthermore, medicine is fundamentally a social activity that takes place between two people. Any seasoned clinician will tell you that there is therapeutic value to touching your patients and showing them that you care.

At the time the author is writing these words, he thinks that "remote, practice-from-home" radiation oncology has a limited role. First, there are some patients who live so far away from a radiation oncology facility that telemedicine serves a very real benefit by providing initial consultative services to the on-site physician that otherwise could not be delivered. Similarly, telemedicine may be of benefit to incarcerated patients at a distance from the radiation oncologist. Initial advice may be given without the risks attendant to moving a prisoner out of prison and transporting them great distances. Second, multidisciplinary tumor conferences seem to work well using computer technology and spare doctors from long hours on the highway driving in order to attend an 8 am conference at a distance from their home or their primary practice site. Third, some departmental conferences can be conducted by use of group meeting computer video technology. Finally, as long as the department is properly staffed on site, allowing some staff members to have a "hybrid model" of work (ie, 1 or 2 days out of 5 at home, 3 or 4 days out of 5 in the clinic), where the days at home are devoted to sitting at the computer or desk making sure all clinical charting is up to date, insurance forms are completed, protocol paperwork is done, and manuscripts are being written will have a role in the modern radiation oncology department.

Artificial Intelligence

If you take a long view of the history of medicine, there is always something that "is going to transform medicine." A partial list of these "transforming inventions / technologies / discoveries" over the past 200 years might include "the invention of the stethoscope is going to transform medicine (1816) . . . the discovery of anesthesia is going to transform medicine (1842-1846) . . . the discovery of antisepsis is going to transform medicine (1865-1867) . . . the discovery of penicillin is going to transform medicine (1928) . . . heart transplantation is going to transform medicine (1967) . . . the invention of commercially viable CT scan is going to transform medicine (1967-1971). . . ." To be added to the list, it is being widely

asserted as this book is being written, that "artificial intelligence is going to transform medicine."

Artificial intelligence (AI) is a branch of computer science that concerns itself with the development of computer software and computers that mimic human cognitive functions such as learning and problem-solving (Box 1.8).

Box 1.8

The Language of Artificial Intelligence

Artificial Intelligence is a term used to describe computer systems that are able to perform tasks that normally require human intelligence. Examples include visual perception, speech recognition, decision-making, translation between languages, and writing. Machine learning is a form of artificial intelligence.

Machine learning enables computers to learn from a dataset without being programmed with explicit rules. There are three general forms of machine learning: supervised, unsupervised, and reinforcement.

Supervised machine learning uses algorithms which are trained to learn from accurate, ground truth data.

Unsupervised machine learning does not require algorithms to rely on labeled input data. Instead the computer examines datasets independently and identifies patterns passed upon similarities and differences.

Reinforcement machine learning uses algorithms that are not explicitly trained but, instead, learn from the consequences of interactions with their environment. On an assembly line, for example, this technique is used to train a robot to navigate from picking up a part in a bin, carrying it to the assembly line, and placing it in the correct location while not bumping into anything and performing the task with speed and accuracy.

Machine learning can be performed with *artificial neural networks*. Artificial neural networks are a type of machine learning which uses computational platforms modeled on neuronal circuitry. It makes use of interconnected elements called artificial neurons, also called nodes, to process information. The two general types of artificial neural networks are convolutional and generative adversarial.

Convolutional neural networks provide local connectivity between neurons of adjacent layers. These connections exploit spatially local correlations to allow the network to learn features on a global and local scale. This should make the network more robust to subtle variations in inputs.

General adversarial networks use two trained networks simultaneously, serving different purposes to train algorithms.

Chapter 32 of this book is devoted to AI in radiation oncology. We will, therefore, only briefly mention a few of its potential applications.

- Compilation of a large number of patient variables, such as physical findings, laboratory tests, and imaging findings to suggest a diagnosis, predicts a clinical

outcome or prioritizes a clinical work list to decrease the time to diagnosis and treatment.

- Reviewing diagnostic images or pathology slides, identifying abnormalities, and suggesting diagnoses
- Decreasing the levels of required radiation, contrast dosage, and scanning time in diagnostic radiology
- Generation of medical reports, patient communications, patient appointment schedules, staffing assignments, clinical bills, assigning *ICD-10* codes to patient charts, and addressing payment claim denials
- Search Engines to explore databases to aid research

While the promise of AI in radiation oncology is enormous, so are its dangers. These dangers in part include leakage or misuse of medical data, biases built into AI models, erroneous algorithms, invention of nonexistent but plausible-sounding references for publications, exam-taking and term-paper-writing for medical students, and black box treatment models wherein the underlying reasoning is opaque. While AI is capable of doing many things well and quickly, we do not know if AI actually improves patient outcomes. It is for these reasons that many thought leaders in the field think AI should be subject to the same level of regulatory scrutiny and approval that are currently in place for drug and medical devices.

The Radiation Oncology Team

The radiation oncology team ensures every patient undergoing radiation treatment receives the appropriate level of medical, emotional, and psychological care before, during, and after treatment, through a collaborative multidisciplinary approach.

The radiation oncology team consists of, but is not limited to, radiation oncologists, physicists, dosimetrists, oncology nurses, and radiation therapists. The process of care in radiation oncology involves close collaboration of a team of qualified professionals. On-site or consultation services can be provided by nonphysician providers, including nurse practitioners, clinical nurse specialists, advanced practice nurses and physician assistants (PAs), dentists, clinical social workers, psychologists/psychiatrists, nutritionists, speech pathologists, physical therapists, occupational therapists, genetic counselors, integrative medicine specialists, and pastoral care providers.

Board certification is the primary consideration for establishing proper qualifications and training for any professional working in radiation oncology. The relevant professional societies will establish the eligibility requirements to sit for a board exam. This may include education and training requirements, such as a

clinical residency. In addition, in some jurisdictions, professionals must meet additional requirements for obtaining appropriate licensure.

The applications, technologies, and methods of radiation oncology continue to expand and develop. Lifelong learning is vital to ensure incorporation of new knowledge into clinical practice. Therefore, each member of the interdisciplinary radiation oncology team should participate in available Continuing Education and Maintenance of Certification programs. Each facility should have a policy regarding orientation, competency, credentialing, and periodic competency evaluations of all team members.

Staffing Requirements

Starting in 1986, the Intersociety Council for Radiation Oncology published a set of guidelines in a small pamphlet titled "Radiation Oncology in Integrated Cancer Management," often referred to as the "Blue Book."[396] This was updated several times.[397] The document offered guidelines for staffing requirements and equipment utilization.

The American College of Radiology (ACR) provides data on average staffing levels.[398] The staffing needs of each facility are unique based on the patient mix and complexity of the services offered. The patient load, number of machines, and satellite clinics and affiliated treatment centers will influence the demand on management and clinical staff. The minimum personnel requirements for a radiation oncology facility specify the need for one medical director (radiation oncologist), chief medical physicist, and department manager per program[399] (Table 1.12).

TABLE 1.12 AVERAGE STAFFING LEVELS FOR RADIATION ONCOLOGIST, MEDICAL PHYSICIST, DOSIMETRIST, AND RADIATION THERAPY TECHNOLOGIST

Clinical FTE[a]	Approximate Maximum # of Patients Treated per FTE per Year
Radiation oncologist	212
Physicist	258
Dosimetrist	254
Therapist	85
Treatment machine	300[b]
Therapists/treatment machine	3.1

These data vary by the type of practice, assignment of staff duties, complexity of patients seen, and the age and pathologies of the patients seen.

FTE, full-time equivalent.

[a]It is recommended that a minimum of two qualified individuals be present for any external beam patient treatment.

[b]Each treatment machine is assumed to be operational for 9 hours a day.

QUALITY AND SAFETY

Quality and safety are important topics in radiotherapy.[400] The issue of patient safety for radiation therapy and diagnostic imaging has been pulled to the forefront by press reports and associated congressional hearings. A number of misadministrations described in a series of *New York Times* articles triggered increased interest in improved patient safety in radiation oncology.[401,402] These articles highlighted some of the risks inherent to advanced radiation therapy treatment planning and delivery systems and techniques. Many new patient safety initiatives, meetings, and other efforts have been organized to address the need to continue to enhance the safety of patients undergoing radiation therapy.

Safety and quality are different but related concepts. Safety generally relates to preventing errors that can have major therapeutic implications (eg, treatment of the wrong patient, treatment with the wrong plan, incorrect placement of a block or wedge, failure to correctly transfer electronic data between the various computer systems). In contrast, quality often relates more to somewhat subjective issues such as ensuring that the defined volumes, doses, beams, and so forth are clinically appropriate and that the treatment is delivered as prescribed within acceptable clinical tolerance limits. To reconcile these concepts, beginning in 2011, the ASTRO sponsored the Intersociety Council to review and update previously published guidelines concerning the role of radiation oncology in integrated cancer management. Every facet of patient evaluation, treatment planning, and treatment delivery was described with the specific goal of maximizing patient safety.[403-406] The process of care, the roles and responsibilities of staff, staff training and maintenance of competency, requirements for facilities and equipment, and the management of QA were formally recognized as inextricably linked to the provision of safe, efficient, and effective radiation therapy. These ASTRO initiatives have involved cooperation with other organizations, including the American Association of Physicists in Medicine, the American Brachytherapy Society, the ACR, the American College of Radiation Oncology, the American Board of Radiology, the American Society of Radiation Technologists, and the Society of Radiation Oncology Administrators.

Modern radiation therapy is complex and rapidly evolving. The safe delivery of radiation therapy requires the concerted and coordinated efforts of many individuals with varied responsibilities. Thus, all team members need to work together to create a *safe*, *high-quality*, and *efficient* clinical environment and workflow.

QA in radiation oncology is a set of processes and procedures designed to improve the practice of radiation therapy by confirming that radiation therapy will be or was administered appropriately and safely and documented properly. The overall goal of a QA process is the delivery of high-quality radiation oncology treatment to all patients. Note that QA is an all-encompassing term that is often used to describe some or all of the different elements involved in quality management (QM) and a culture of safety. Cost and value are important in determining the quality of care. To prove that technology adds value to patients, patient-reported outcomes should be included.

A radiation oncology facility must satisfy numerous requirements:

- A department must provide adequate clinic space, exam rooms and equipment, patient waiting and changing space, convenient patient parking, treatment rooms, simulation and imaging space, brachytherapy source preparation and storage space, dosimetry/treatment planning rooms, office space for professional staff, and medical physics laboratory and equipment storage space. The extent of facilities should be appropriate for the volume of patients seen and treated.
- Treatment rooms must be carefully designed for radiation shielding, environmental conditions, adequate storage space for spare parts, testing and dosimetry equipment, and patient access and safety (Figure 1.47).

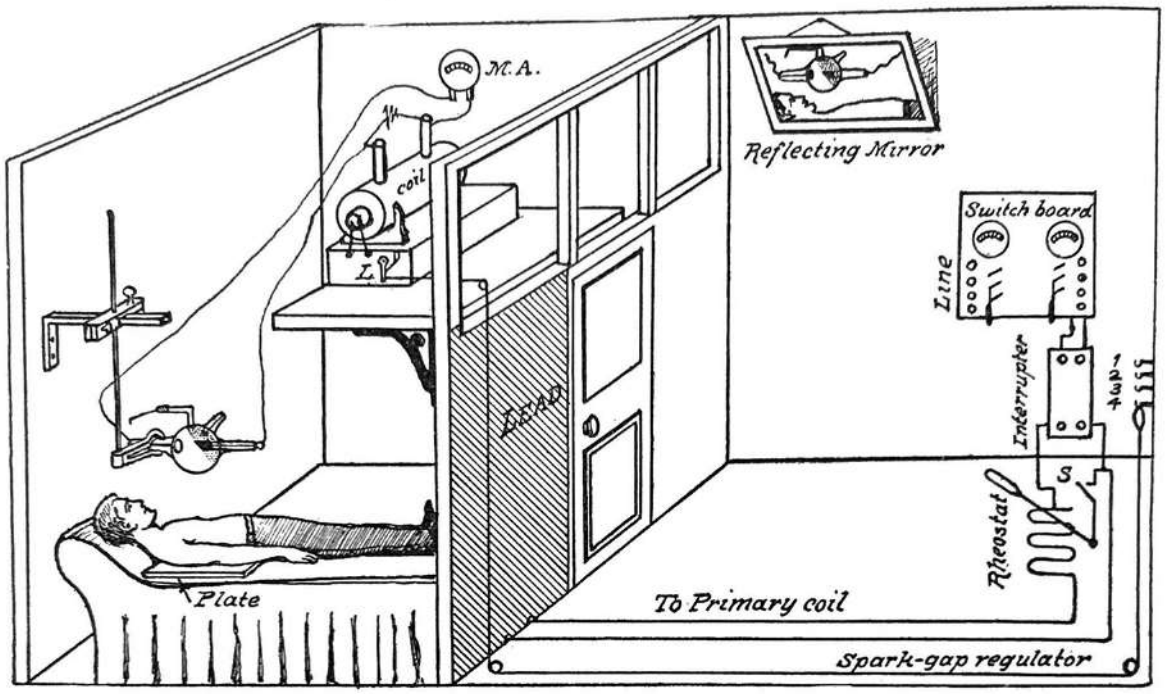

FIGURE 1.47 This diagnostic radiology and radiation therapy treatment room, designed by Dr M.K. Kassabian of Philadelphia and published in his 1907 textbook, exhibits several elements still familiar to a modern radiation oncologists: lead shielding, remote operation of the radiation equipment and a mirror to observe the patient around a barrier. (From Kassabian MK. *Röntgen Rays and Electro-Therapeutics, with Chapters on Radium and Phototherapy*. J.B. Lippincott; 1907.)

- There must be access to CT, MRI, and PET imaging for treatment planning.
- Rooms used for brachytherapy procedures require special attention to the specific radiation protection requirements associated with the particular brachytherapy modalities to be used. If the brachytherapy procedures warrant it, a brachytherapy suite should be available, including patient waiting space, procedure rooms, recovery rooms, and brachytherapy source preparation and storage areas.
- Each department must have electronic access to the hospital or clinic information system for medical records and picture archiving and communication.

The following specific capabilities and methods for various aspects of the radiotherapy process are considered essential:

- Calibration of treatment machines, CT and MRI scanners, treatment planning systems, and brachytherapy sources is to be carefully accomplished according to the appropriate protocols described by scientific/professional organizations.
- A safety program designed to monitor patient safety, avoid radiation incidents, and prevent errors in the treatment process should be in place and subject to periodic review and update.

- A system for documenting radiotherapy treatment and other aspects of the patient's medical care should be rigorous and be subject to periodic review and update.
- High-quality and comprehensive treatment planning, using 3D computerized treatment planning for dose calculations, imaging, and other aspects of the planning process
- A comprehensive QA program
- Radiation monitoring of simulators and treatment machines. A system to carefully control and monitor all radioactive sources in accordance with the requirements of regulatory agencies
- A program for maintenance and repair of equipment
- Staff training that is comprehensive, ongoing, and well documented
- A well-developed process for continuous peer review. This should include a mechanism for peer review of the entire department and its procedures as well as for individual clinical care decisions.
- Access to pathology, diagnostic radiology, medical oncology, surgical oncology, and other physician and nonphysician specialists involved in the multidisciplinary care and follow-up of the patient
- Each department must implement careful and well-described policies and procedures for every aspect of patient care, for QA of the patient care process, for staff behavior, and for any issues that may impact the safety of patients and/or staff. Each specific treatment modality (eg, IMRT, IGRT, IMPT, stereotactic body radiation therapy [SBRT]) should have detailed documentation of its treatment planning and delivery process including a description of the roles and responsibilities of each team member in that procedure, QA checklists, and a plan for continuous quality improvement and safety.

One of the most crucial activities in a quality radiation oncology department is the organized review and monitoring of all aspects of safety, errors, and outcome. Creating a "culture of safety" depends on guidance, direction, and financial support from the leadership of the institution and of the radiotherapy department, on individual effort by every member of the department, and on organized support for quality and safety at every level in the institution.

Each department should have a department-wide review committee that monitors specific quality metrics, including near misses and errors in treatment, diagnosis, patient care, or other procedural problems that might lead to errors. This committee should organize the collection and analysis of such events, work to identify potential problems in devices or processes, and then try to mitigate these problems by

modifying processes or adding new checks or actions to minimize the likelihood of further problems. Radiation oncology departments should hold regularly scheduled rounds to review patient morbidity and mortality, dose discrepancies, and any incident reports that involved an accident or injury to a patient. Morbidity and mortality monitoring includes unusual or severe complications of treatment, unexpected deaths, or unplanned interruptions of treatment. Staff included should represent all the team members, including radiation oncologists, nurses, physicists, dosimetrists, therapists, and administrators.

Equipment and Device Quality Management

Radiation therapy is employed for the treatment of a broad spectrum of diseases. The delivery of radiation therapy relies on computer-controlled treatment machines, interconnected imaging, delivery and planning systems, and complex ancillary devices. Any new radiotherapy system should go through the following processes as it is prepared for clinical use:

- Each system should be carefully specified before acquisition, purchase, or development, including design, expectations, capabilities, tolerances, hazards, necessary training, usability, and technical specifications.
- To prevent data communication errors and clinical efficiency issues, each system must be interoperable and connectable with other systems in the clinic.
- Acceptance testing must be performed to document that the new system satisfies the specifications. Often, the acceptance criteria and/or testing methods should be documented as part of the specification for the system.
- Clinical commissioning includes all the activities that must be performed to understand, document, characterize, and prove that a given system is ready to be used clinically. Standard operating procedures, training, and hazard analysis should be part of the commissioning process.
- Each new system, device, and process must be formally released for clinical use after clinical commissioning has been completed.

Clinical use of a device, system, or process must involve the creation and application of a safety- and quality-oriented program designed to ensure that the machine or device is functioning in accordance with accepted standards:

- QM is defined as the overall program to organize the oversight of the use of any system or process in radiation oncology. The QM program should include hazard analysis, quality control (QC), QA, training and documentation, and ongoing quality improvement efforts.

- Hazard analysis is the active evaluation of the potential for failures that will cause incorrect results or harm to the patient and should be performed for any new system.
- QC checks on the data that are input into a decision or process and is designed to prevent the propagation of error.
- QA is the typical shorthand term for the entire QM program and addresses quality checks that confirm that a given process is reasonable and generates appropriate results. QA checks, along with QC, are essential parts of the QM process for most devices and systems, as they can check the output of potentially very complicated decisions or actions performed by the system.
- Training of staff in goals, methods, results, operation, and evaluation of the quality of the output is important for the proper use of any system.

Patient-Related Quality Management

Within the complex and many-step process with which radiotherapy patients are treated, patient-specific issues must be carefully and comprehensively analyzed, documented, and verified. Each radiation oncology facility, regardless of its location or size, must appropriately manage and adhere to high-quality standards of practice for general medical issues, including:

- Drug allergies
- Medication reconciliation
- Do-not-resuscitate codes
- Cleanliness and efforts to reduce infection
- Patient confidentiality and security of protected health information

Modern oncology patient care very often involves multiple modalities and requires the review and discussion of experts in various oncology-related disciplines. It is critical that the management of most cancers be addressed by the appropriate mix of disciplines. Regular presentation of these cases to a multidisciplinary tumor board is the standard of care and should be performed for most cancer cases to determine the appropriate combination (and coordination) of therapies for each individual case.

The details of the patient care process in radiation oncology vary from institution to institution. However, maintenance of the safety and quality of the radiotherapy process for most patients requires that a number of procedures be performed, including:

- A new patient conference that consists of a brief presentation of the details of each patient's history and physical examination, disease status, and plan for therapy to the other departmental physicians and staff involved in patient care is used as an initial peer review for the basic treatment decisions and plan.
- The physician must obtain a clear, accurate, and detailed description of the patient's chief complaint and pertinent history in conjunction with an appropriate physical examination as part of the decision process for radiation therapy.
- Most patients who receive radiation therapy should receive a CT, PET/CT, or MRI-based simulation.
- After treatment planning is complete, the physician and members of the planning team should review the plan at a conference and verify that it satisfies the clinical requirements and prescription(s) from the physician and that it can be carried out accurately.
- On-treatment visits of the patient by the physician are essential for continuity of care and monitoring of tumor response and normal tissue toxicity. Typically, this occurs every five daily fractions, but some situations may require more frequent visits.
- Patient chart rounds are an important peer-review procedure used involving weekly review of all patients under treatment by the radiotherapy team, including physicians, therapists, nurses, dosimetrists, and physicists.
- Follow-up visits are a critical component of care for the radiotherapy patient. The frequency of follow-up visits and if they are done by the radiation oncologist or another physician will vary in accordance with the type of cancer, stage, degree of tumor response, normal tissue reactions, and other factors.
- Documentation is required of all the relevant details of patient care. Maintenance and continuous improvement of the quality and accessibility of the treatment record are essential.

The overall performance status of the patient prior to treatment should be recorded. Assessment of tumor response and normal tissue toxicity should occur both during and after treatment. Clinical assessment of patient response is a valuable independent check on the success of the overall QM system as unexpected outcomes may identify issues related to technique or equipment performance.

External Beam Quality Assurance

Nearly all external beam treatment requires the following steps, each of which must be carefully confirmed as part of the patient-specific QA process: determination of patient setup position and immobilization; cross-sectional imaging (CT, PET/CT, or

MRI simulation); creation of the anatomic model (contouring); specification of the treatment intent; creation of the planning directive and treatment prescription by the physician; computerized treatment planning and dose calculation; monitor unit calculation and/or IMRT or IMPT leaf sequencing; plan and (electronic chart) preparation; plan evaluation; download to treatment management system; patient-specific QA as typically performed for IMRT, IMPT, stereotactic radiosurgery (SRS), or SBRT; patient setup and delivery; plan verification checks; plan adaptation and modifications; chart checks; and more.[388]

Brachytherapy Quality Assurance

The QA process for brachytherapy is similar to that of external beam and involves several components that must be confirmed as part of the patient-specific QA management: treatment planning; treatment delivery systems; applicator commissioning and periodic checks; cross-sectional imaging (often with CT simulation); specification of the treatment intent, planning directive, and treatment prescription by the physician; plan preparation; plan evaluation; download to the electrical medical record; plan verification checks; plan modifications; and chart checks.[407-413]

COMBINATION OF THERAPEUTIC MODALITIES

Management of the Patient With Cancer

The optimal care of patients with cancer is a multidisciplinary effort that may combine multiple disciplines: surgery, radiation therapy, chemotherapy, and biologic or immunotherapy. Many professionals, including physicians, physicists, laboratory scientists, nurses, rehabilitation staff, sociologists, and social workers, are intimately involved. Pathologists, radiologists, clinical laboratory physicians, and immunologists are integral members of the team. Biology, biochemistry, and pharmacology have contributed greatly to the advancement of methods used to evaluate and treat patients with cancer (eg, biomarkers, cell kinetic indicators, oncogenes).

The radiation oncologist, must assess all conditions relative to the patient and the tumor under consideration for treatment and systematically review the need for diagnostic and staging procedures as well as the best therapeutic strategy. This is well illustrated by treatment algorithms or "decision trees."[414] In several instances, a clear relationship existed between compliance with guidelines for diagnostic or therapeutic procedures (best current management consensus) and therapy outcome, as defined by survival, recurrence patterns, or complications of treatment.

Emphasis on screening and early diagnosis of cancer, as well as improvements in therapeutic strategies, has had a significant positive impact on the survival of patients with cancer. In the United States, results of the Surveillance, Epidemiology, and End Results program have shown a small but steady improvement in survival for a variety of tumor sites. The relative survival of patients with cancer at various times after diagnosis has improved substantially since 1960.

How Radiation Therapy Was Perceived to Be Different From Surgery in the Treatment of Cancer

At the beginning of his 1929 textbook *Radium Treatment of Cancer*, the legendary British surgeon and pioneering radiation oncologist Sir Stanford Cade carefully lays out the evolution of oncologic thinking.[415] Changing from "to cut is to cure," Cade developed a more holistic view of the roles of surgery and radiation therapy in cancer treatment. (For a biographical note on Sir Stanford Cade, the reader is referred to the last section of this chapter.)

> Until recently the principle underlying the treatment of cancer was the elimination of the growth by excision with knife or diathermy. The vital question for each case was: "Is it removable?" The answer varied with the site of the growth, the skill and courage of the surgeon, the general condition of the patient, and the presence of recognizable metastasis. Even in its widest sense the measure of operability depended on the question: "Is the lesion removable?" and not on the question: "Is the removal of the lesion going to cure the patient?" In the last ten years rapid progress of radium therapy has changed the concept of operability, and for the disappearance of the cancerous lesion it is no longer imperative to rely entirely upon the scalpel . . . no patient, however "inoperable," should remain untreated . . . . The combination of the biological factor of selectivity with the power of penetration of gamma rays gives the possibility of treating lesions which are irremovable either because of their situation or because of the involvement of important structures. Further, radium therapy abolishes or at least minimizes, operative mortality and mutilation. It enlarges the field of "treatable" cases beyond the limits imposed on purely operative surgery.[416]

We now practice medicine in an age in which the concepts articulated by Cade almost 100 years ago have been extended to the use of preoperative, intraoperative, and postoperative radiation therapy and, in some cases, definitive irradiation in lieu of definitive surgery. What has not changed is the principle articulated by Cade: The core issue is what provides the patient with the best chance of cure or palliation of cancer with the preservation, where possible, of organ function.

Irradiation and Surgery

The rationale for *preoperative radiation therapy* relates to its potential ability to eradicate subclinical or microscopic disease beyond the margins of the surgical resection, to diminish tumor implantation by decreasing the number of viable cells within the operative field, to sterilize lymph node metastases outside the operative

field, to decrease the potential for dissemination of clonogenic tumor cells that might produce distant metastases, and to increase the possibility of resectability. The disadvantages of preoperative irradiation are that it may interfere with normal healing of the tissues affected by the radiation, it delays surgery, and it may disrupt surgical staging of the tumor and/or the expression of histologic or immunohistochemical prognostic factors.

The rationale for *postoperative irradiation* is based on the fact that it is possible to eliminate subclinical foci of tumor cells in the tumor bed (including lymph node metastases). By delivering higher doses to the volume of high-risk or known residual disease than can be achieved with preoperative irradiation, a greater tumor control may be obtained. The potential disadvantages of postoperative irradiation are related to the delay in the initiation of radiation therapy until wound healing is completed. Theoretic and experimental evidence suggests that the radiation effect may be impaired by vascular changes produced in the tumor bed by surgery.

Irradiation and Drug Therapy

Tumor or *normal tissue enhancement* describes any increase in effect greater than that observed with either cytotoxic chemotherapy, biologic therapy, immunotherapy, or irradiation alone.[399] Agents used in chemoirradiation include those with cytotoxic activity against the tumor, which may show additive, subadditive, or supra-additive effects, such as 5-fluorouracil or mitomycin C in anal carcinoma; agents with minimal or no significant activity against a specific tumor, which may, however, enhance the irradiation effect; radiation hypoxic cell cytotoxins or bioreductive agents; and radioprotectors.

Chemotherapy alone or combined with irradiation may be used in many settings.[417,418] *Primary chemotherapy* is used as part of the primary lesion treatment (even if later followed by other local therapy) and when the primary tumor response to the initial treatment is the key identifier of systemic effects. *Adjuvant chemotherapy* is used as an adjunct to other local modalities as part of the initial curative treatment. The term *neoadjuvant chemotherapy* is used when this modality is used in the initial treatment of patients with localized tumors, before surgery or irradiation.

The effects of combined radiation therapy-chemotherapy can be independent, additive, or interactive. Chemotherapy and irradiation can be administered sequentially or concomitantly. Sequencing of treatment at the appropriate time is significantly related to the residual tumor cell burden at the point of introduction of each new treatment program.

Administration of chemotherapy before irradiation may produce cell killing and reduce the number of cells to be eliminated by irradiation. The use of chemotherapy

concurrently with radiation therapy has a strong rationale because it could interact with the local treatment (additive and even supra-additive action) and also could affect subclinical disease early in treatment. However, the combination of modalities may enhance normal tissue toxicity. When agents with added toxicity are used, lower tumor control may result because the added morbidity requires lowering the doses of the effective agents or prolonging overall irradiation treatment time. When fatal toxicity from chemotherapy occurs, it is possible that in some patients the clinical researcher will fail to record a tumor response that could have been observed had they survived.

Biologic Considerations in Combinations of Drug Therapy and Radiation

Many experimental animal studies have shown therapeutic benefits from a combination of irradiation and drugs, but most are phenomenologic. Therapeutic benefit requires differential properties on tumor and normal tissues, which may be exploited for therapeutic gain, including genetic instability of tumors compared with normal tissues, differences in cell proliferation (particularly cell repopulation during fractionated radiation therapy), and environmental factors such as hypoxia and acidity (which are usually confined to tumors). There are variations in sensitivity or resistance to irradiation or drugs. The mechanisms for resistance to these agents may be shared in some tumors and different in other tumors. Resistance to anticancer drugs may have implications for resistance to radiation therapy; many drug mechanisms for resistance are multifactorial, such as in cisplatin, in which this phenomenon may be the result of decreased drug uptake, increased repair of DNA, increased expression of sulfhydryl compounds such as glutathione and metallothionein, and increased expression of glutathione-*S*-transferase. Combined treatment with radiation and drugs might result in an improved therapeutic index if mechanisms of resistance are independent.

Oxygen, pH, and nutrient supply can play an important role in the combined effects of chemotherapy and irradiation on tumor cells.[419] Hypoxic cells are less radiosensitive and chemosensitive to many drugs, and chronic hypoxia can alter cell cycle age distribution and proliferation rate—both important modifiers of cellular response to ionizing radiation and drugs. In addition, chronic hypoxia can affect cellular ability to repair radiation- and drug-induced DNA damage. Bioreductive drugs such as mitomycin C are activated to toxic species under hypoxic conditions. DNA repair, cell cycle age distribution, and the activity and stability of some chemotherapeutic drugs may be pH dependent; thus, this factor plays a role in the sensitivity of cells to irradiation and cytotoxic agents.

Hypoxic conditions may lead to the amplification of genes. Under hypoxic conditions, hypoxia-inducible factor-1 (HIF-1) occurs, levels rise, and functional HIF-1 transcription factor complexes induce angiogenesis, erythrocytopoiesis, glycolysis, and glucose transport into cells—all techniques to allow the cell to survive hypoxia. HIF-1 induces the genes encoding vascular endothelial growth factor (VEGF), platelet-derived growth factor, and TGF.[420] Some cytokines such as tumor necrosis factor-α or interleukin[421] and growth factors such as platelet-derived and fibroblast growth factors are seen in malignant and normal human cells after irradiation.[422] These cytokines and growth factors enhance the cytotoxic effects of irradiation and chemotherapy in tumor cells or offer radioprotection in normal cells.[423]

Possible molecular or cellular mechanisms of interaction of chemotherapy and irradiation include the following:

1. Modification of the slope of the dose-response curves, as has been shown with actinomycin D, cisplatin, doxorubicin, mitomycin C, 5-fluorouracil, and other agents
2. Decreased accumulation or inhibition of repair of SLD, as induced by actinomycin D, cisplatin, bleomycin, hydroxyurea, and nitrosoureas.[424,425] Doxorubicin and other DNA intercalators decrease the shoulder widths but do not decrease the slope or suppress the repair of lethal damage in in vitro studies.[426]
3. Inhibition of repair of PLD, as has been shown with actinomycin D, doxorubicin, and cisplatin[427]
4. Perturbation of cell kinetics, for example, after treatment with hydroxyurea, which kills cells in the S phase, when cells may become partially synchronized and blocked at the G1/S phase of the cell cycle. If irradiation is delivered during this sensitive phase, as the cells subsequently emerge from the block, an enhanced cytotoxic effect may be expected.
5. Selective cytotoxicity and radiosensitization of hypoxic cells, which have been reported with mitomycin C and cisplatin[428]
6. Inhibition of cell repopulation
7. Decrease in tumor bulk leading to improved blood supply, reoxygenation, and cell cycle recruitment, resulting in increased radiosensitivity and chemosensitivity

A possible danger in the administration of cytotoxic drugs before radiation therapy is accelerated cell proliferation or repopulation. Because some tumor regression is induced by the cytotoxic agent (drugs or irradiation), the distance

between the tumor cells, and decreases in adjacent functional capillaries, this may induce tumor cell proliferation so that higher doses of irradiation would be required to produce a given tumor control. This may occur because, during radiation therapy, tumor cells surviving neoadjuvant chemotherapy may be stimulated to repopulate at a faster rate. Because of this effect, the initial advantage in cell killing by drugs is lost, and the survival curves for fractionated radiation therapy may come together or even cross over. Although this mechanism is hypothetical, it suggests caution in the use of induction chemotherapy and explains why an initial tumor response may not necessarily translate to a therapeutic advantage with combined modality treatment given in this manner. For example, three courses of induction chemotherapy might reduce tumor cell numbers from 10^{10} to 10^{8} (from 10 to about 0.1 g), which is considered a complete clinical tumor regression. Even a pathologic complete response has limited long-term implications; a complete pathologic regression is consistent with the presence of about 10^{6} tumor cells per gram, a substantial biologic cell burden (Figure 1.48).

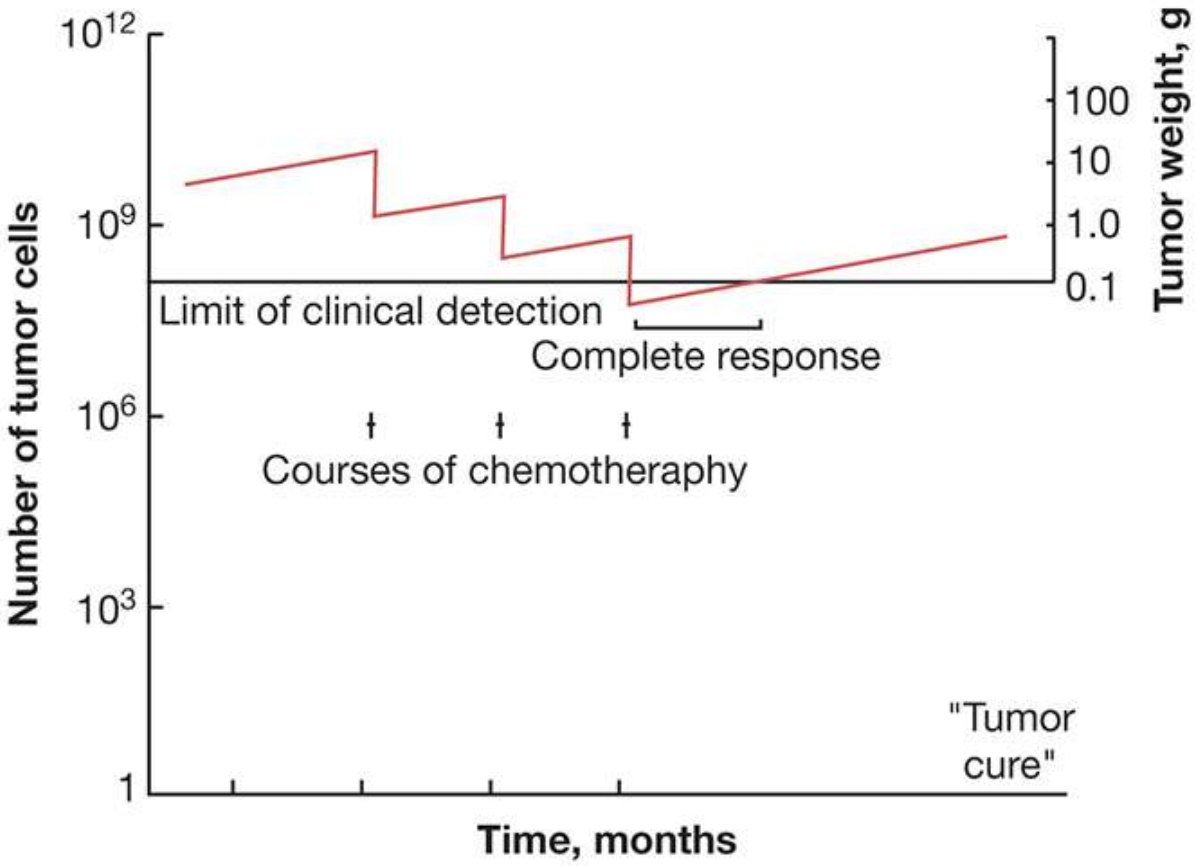

FIGURE 1.48 Relationship between clinical remission and cure. A 10-g tumor containing 10^{10} cells is treated with three courses of chemotherapy, each of which kills 90% of the tumor cells present. After three courses, the number of viable tumor cells is $<10^{8}$ (<0.1 g), and the patient is judged to be in clinical and radiologic complete remission. Note that this is a small step toward tumor cure. Moreover, additional chemotherapy may not be helpful if drug-resistant cells have been selected after three courses of chemotherapy. Integrated Multimodality Cancer Management and Organ Preservation

Combined treatment modalities are frequently used to improve tumor control and patient survival. Steel and Peckham[429] postulated the biologic basis of cancer therapy as spatial cooperation, in which an agent is active against tumor cells spatially missed by another agent, addition of antitumor effects by two or more agents, and nonoverlapping toxicity and protection of normal tissues. Large primary tumors or metastatic lymph nodes must be removed surgically or treated with definitive radiation therapy. Regional microextensions are eliminated effectively by irradiation without the anatomic and at times physiologic deficit produced by equivalent medical surgery. Chemotherapy is applied mainly to control disseminated subclinical disease, although in some diseases in clearly has an effect on primary tumors.

Organ preservation is being vigorously promoted because it enhances the quality of life and psychoemotional feelings of patients if it can be combined with excellent tumor control and survival. In some types and stages of head and neck tumors, breast cancer, gastrointestinal malignancies, genitourinary tumors, soft tissue sarcomas, and pediatric tumors, studies have shown that less radical surgical procedures combined with chemotherapy and radiation therapy yield the same local tumor control at the primary site and survival as did radical procedures. Advances in reconstructive surgery have greatly improved our ability to repair defects of radical surgery.

Clinical Trials

These studies have been classified as phase I (toxicity), phase II (dose/efficacy), and phase III (efficacy and toxicity of a new drug compared with an established standard). Randomized phase III clinical trials and meta-analyses of those trials are the two most accepted sources of scientific information in evidence-based medicine. These randomized clinical studies, with sometimes complicated treatment schemas, large numbers of patients, defined end points, and rigorous statistical testing, which are increasingly required by the U.S. FDA to document the efficacy and safety of new drugs (and, I believe I should add, should be required for medical devices), are logistically difficult and expensive to conduct. Cooperative clinical trial groups have been a major contributor, to clinical investigation centered on the application of ionizing radiations, either alone or combined with other treatment modalities to improve the management of patients with cancer. It is the responsibility of practicing radiation oncologists in academic and community centers to be active contributors, with both scientific input and encouragement of their patients to participate in many of these trials.

THE PRACTICE OF RADIATION ONCOLOGY

The Three A's of Being a Successful Consulting Radiation Oncologist

For the most part, radiation oncologists are consulting physicians. Patients do not enter the front door of the health care system via the radiation oncologist's office. Instead, they first see their primary care physician, pulmonologist, surgeon, obstetrician-gynecologist, adult or pediatric medical oncologist, urologist, or neurosurgeon. A diagnosis is made. A referral request brings the radiation oncologist into the management of the patient.

Many years ago, the author of this chapter was given sound advice as to how to succeed as a consulting physician. It was to follow "the three A's": *availability*,

affability, and *ability*. It was not enough to follow "the three A's," it was important to remember that they need to be observed precisely in the stated order.

Availability: Come when the referring physician calls. When taking care of a patient with cancer, the referring physician does not want to be told that it is hard to get an appointment, that the radiation oncologist is "very busy," or that there will be a delay in seeing the patient. The referring physician wants the patient checked-off of their "to do" list and moved onto the radiation oncologist's "to do" list. If you want to succeed as a radiation oncologist, be readily available.

Affability: No referring physician wants to deal with a grumpy radiation oncologist. They do not want to hear how busy you are, how behind you are in your tasks, or why you would rather not be bothered with yet another "uninteresting" referral. They want to have a radiation oncologist on the team who is a cheerful, cooperative, and businesslike professional.

Ability: After you make yourself available and are affable, then you need to know, clinically, what you are doing. But you will never get to show your clinical ability if you are not available and affable.

Go to Their Office

Eugene Anson Stead Jr., MD (1908-2005) was Dean of the Emory University School of Medicine and later Chair of the Department of Medicine at Duke University School of Medicine. A master clinician, teacher, and cardiovascular researcher, he is perhaps best known today as the founder of the profession of physical assistant (PA). He taught the author a valuable lesson that has proven its worth during a career in clinical radiation oncology.

Stead taught that one should avoid requesting meetings in your own office. When you go to someone else's workspace, he would say, you are sending the nonverbal message that they are very important and, therefore, you have chosen to stop what you are doing to go seek them out. In contrast, when you ask people to come see you or if you interrupt them with a phone call, you are sending the nonverbal message that you are important and the other person must arrange their day to suit your needs.

Some radiation oncologists read diagnostic imaging reports on the electronic medical record and/or look at the images on their computer. They read pathology reports on the computer. What they should do, whenever possible, is walk over to the diagnostic radiology reading room to review the images with the radiologist and walk to the pathology department to review the slides with the pathologist. A great deal more information about the case can be gleaned in this manner, questions may be posed, and new insights obtained. In addition, the radiation oncologist is demonstrating, to the pathologist and radiologist, their importance in the oncology

team and the respect in which they are held. Similar behavior is appropriate when discussing the case with the referring physician or doctors you elect to consult.

Rosen's Rules Applied to Radiation Oncology

When the author of this chapter was a rising second-year medical student, he was assigned to a summer clinical rotation at the Berkshire Medical Center in Pittsfield, Massachusetts. At that hospital, he was, for part of the summer, under the supervision of internal medicine resident Clifford Rosen, MD. Rosen would go on to have a distinguished career and become the director of clinical and translational research and a senior scientist at Maine Medical Center's Research Institute. He is a professor of medicine at Tufts University School of Medicine. Rosen is the founder and former director of the Maine Center for Osteoporosis Research and Education. He was the first Editor-in-Chief of the *Journal of Clinical Densitometry*, is the current Editor-in-Chief of *The Primer in Metabolic Bone Diseases*, and is an associate editor for *New England Journal of Medicine*. He has close to 400 peer-reviewed publications.

Clifford Rosen taught me "Rosen's Rules of Clinical Medicine." I have used them to advantage in my career, such as:

1. Clinically, if what you are doing is working, keep doing it.
2. Clinically, if what you are doing is not working, stop doing it.
3. If you are not sure what to do clinically, do not do anything lest you make the patient worse.

When I was a medical student, I did not fully appreciate both the wisdom and the errors intrinsic to these three rules. It may seen obvious, as indicated by rules 1 and 2, that a course of treatment that is producing a favorable response should be continued and one that is not ought to be abandoned. One must remember the dictum, however, that "some doctors do the same thing wrong for 40 years and call that 'decades of clinical experience.'" As Hippocrates taught, clinical experience is, sometimes, delusive. As a profession, radiation oncologists certainly cured small children with retinoblastoma with EBRT. Orbital malformations and second malignant neoplasms occurring decades later taught us, however, that we could do a better job for these children.

In my experience as a radiation oncologist, the most valuable rule has been number 3. An inability to figure out what else to try for a patient's treatment is not an indication for radiation therapy.

MALPRACTICE AND RADIATION ONCOLOGY

A plaintiff initiates a radiation oncology malpractice lawsuit by filing papers with the court claiming that they were harmed by the radiation oncologist and is entitled to legal redress. The claim of malpractice must be set out in the plaintiff's prima facie case. This will include a statement of the facts and legal theories that establish that the plaintiff believes they are legally entitled to enforceable claims against the physician.

There are four essential elements to a prima facie case of medical malpractice: *establishment of duty*, *breach*, *causation*, and *damages*. To demonstrate medical malpractice, a plaintiff-patient must show that the radiation oncologist had a duty to provide nonnegligent care to the patient, that the provider breached that duty by providing negligent care, and that this breech caused the patient injury or damage.[430-433]

To establish a *duty*, the plaintiff must have facts that demonstrate a legal relationship between the radiation oncologist and the patient. It is a basic rule of Anglo American law that there is no duty to another person unless there is a legally recognized relationship with that person. The plaintiff-patient must demonstrate the existence of a physician-patient relationship.[434]

To establish a *breach*, the patient-plaintiff must demonstrate facts that illustrate the radiation oncologist breached the legal duties implied in the physician-patient relationship or duties that would be generally imposed on members of society. The plaintiff must establish that the appropriate standard of care was violated. Although, in theory, the establishment of the standard of care and the breach of that standard are legally separate, in reality, unless there is a factual question about what the radiation oncologist actually did, the proof of the standard of care would also demonstrate the defendant's breach. Most commonly, in law, the definition of *standard of care* is how similarly qualified radiation oncologists would have managed the patient's care under the same or similar circumstances. In 2024, the American Law Institute proposed a new standard for medical malpractice, where "reasonable medical care is the care, skill, and knowledge regarded as competent among similar medical providers in the same or similar circumstances."[435] In most medical malpractice cases, both the standard of care and the breach are established through the testimony of expert witnesses.

Negligence is "the omission to do something which a reasonable man guided by those ordinary considerations which ordinarily regulate human affairs would do, or the doing of something which a reasonable and prudent man would not do." The person claiming malpractice is asserting that they are owed a duty by the defendant physician and that violation of that duty by the physician caused injury. The court will make a determination concerning the propriety or impropriety of the defendant physician's performance on the basis of "the reasonable man" had they been in the same situation as the individual being judged. Negligence may derive from the

physician's lack of training or experience or from their carelessness or inadvertence[436] (Box 1.9).

Box 1.9

The New York Times Investigates Radiation Therapy

Radiation therapy practice was severely shaken when *The New York Times* published an article on June 21, 2009, titled "At V.A. Hospital, a Rogue Cancer Unit" and a second article on January 23, 2010, titled "Radiation Offers New Cures, and Ways to Do Harm." Both were authored by Walt Bogdanich.[401,402]

The first article described allegations that the prostate brachytherapy program at the Philadelphia V.A. Medical Center was "a rogue cancer unit at the hospital, one that operated with virtually no outside scrutiny and botched 92 of 116 cancer treatments over a span of more than six years—and then kept quiet about it. . . ." There were allegations of repetitive misplacement of prostate brachytherapy seeds, changing of treatment plans to cover up alleged errors, lack of peer review and quality assurance procedures, and the development of severe complications in patients.

The second article focused on the death of a 43-year-old man who had been irradiated at St Vincent's Hospital in Manhattan for a tongue carcinoma and a 32-year-old female with breast cancer treated at the State University of New York Downstate Medical Center. In the former case, the multileaf collimator was left fully open during IMRT. In the latter case, a wedge was left out of the linear accelerator. Both patients were overdosed, and the patient with tongue cancer died of radiation injuries. Bogdanich explores the causes of the errors: possible software malfunctions, human error, and lack of QA and safety check procedures. Furthermore, the reporter raised the question of whether governmental oversight was sufficient to ensure the safety of clinical radiation therapy.

The articles made the safety of radiation therapy a national concern and produced considerable soul searching in the medical physics and clinical radiation therapy communities. Error-reduction programs seek to understand what can go wrong in radiation therapy, what can be done to prevent errors, how much can be done to engineer procedures to prevent machine and human error, and what types of oversight are necessary to minimize error. We must never forget the Hippocratic admonishment *primum non nocere:* "First do no harm."

To understand the concept of an expert witness, we must consider the legal doctrines of the *school of practice*, the *locality rule*, and the concept of the *qualifications of an expert*.[441],[442] The legal doctrine of the school of practice is designed to deal with the historic problem of the competing interests of physicians. Physicians generally do not want to testify against their colleagues, but they are often tempted to try to run their competitors out of business. Allopathic physicians were happy to label homeopathic physicians as quacks, and many medical doctors would be happy to dispute the competence of a chiropractor. To deal with the problem, the courts use the legal doctrine of the *school of practice* in which they refuse to allow physician experts to question a different school based on philosophic

or psychological beliefs.[443] The school of practice rule is now generally used to differentiate physicians in the self-designated specialties. (We use the term *self-designated* because few state licensing boards recognize specialties or limit physicians' rights to practice the specialties in which they have been trained.)

The *locality rule* refers to the concept that a physician's competence should be determined by comparison with other physicians in the community or in similar neighboring communities.[444] However, with the development of national standards for the practice of radiation oncology, there is no justification for rules that shelter substandard medical decision-making by using an excuse that it is the norm for a given community. A radiation oncologist, for example, could not be held at fault for failing to treat a patient with an unusual or exotic technology if that technology were not available in their local community. However, physicians are required to inform the patients of the limitations of the available facilities and recommend prompt transfer if indicated. Failure to refer patients when a provider lacks the experience to appropriately treat may create malpractice liability. Furthermore, if a radiation oncologist does not give a patient information about the potential result associated with not seeing a subspecialist able to use a specific technology, then the initial radiation oncologist may be held liable. Physicians must recognize when a particular medical problem is beyond their capacity for diagnosis or treatment. They are responsible for obtaining timely and adequate consultations when indicated and for referring the patient to an appropriate specialist or facility whenever the requirements for the appropriate or specialized care cannot be satisfied at the available facilities. The continued expansion of knowledge in radiation oncology and the increasingly specialized training of physicians make it essential that the radiation oncologist be able to recognize any limitations in their capabilities or ability to treat a given patient with what is perceived to be standard of care. Failure to obtain an appropriate consultation or make an appropriate referral may denote negligence.[445-447]

Qualified experts sometimes disagree as to the standard of care. When alternative schools of thought exist, the physician defendant is entitled to be judged by the tenants of the school they follow. In such states, this is called the *minority practice doctrine*. With this doctrine, also called the *respectable minority rule*, the physician may show that although the course of therapy followed was not the same as other practitioners would have followed, it was one that was accepted by a respectable minority group of practitioners.[448]

A problem that is increasingly facing physicians in the United States has been the pressure radiation oncologists face from their employers or from insurance companies to conform their proposed care to a predetermined regimen. Despite legislative initiatives to hold such organizations accountable, the radiation oncologist will, for the most part, carry a significant portion of the risk of liability in cases

where the patient asserts that they were unable to obtain the most accurate and appropriate diagnostic and therapeutic measures. It is essential that the radiation oncologist come to their own conclusions about the standard of care, irrespective of any pressures applied by an employer or an insurance company. In litigation, the radiation oncologist's best defense against a claim of malpractice is if they can demonstrate action only in the interest of the patient, regardless of any financial consideration or bureaucratic restraint imposed by an insurance company, a health maintenance organization (HMO), a health care system or any other financial consideration. If a conflict arises between the radiation oncologist's recommendations for the best course of treatment and the level of care authorized by their employer, or insurance company, or an HMO, the physician must give the best care to the patient even if it means they will not ultimately be compensated.[449]

Radiation oncologists will, on occasion, be called on to serve as expert witnesses in malpractice cases. Physicians, trained to give opinions, may find the give and take of the courtroom off-putting. For an expert witness, the foremost qualifications are effective presentation and teaching ability. The radiation oncologist, serving as an expert witness, must educate the attorneys, judge, and jury. Once there is a perception of understanding, the radiation oncologist may be able to convince the judge and jury that they can make an independent decision that their testimony is correct.

Both the plaintiff's attorney and the defense attorney will retain expert witnesses who will be persuaded to "take sides." The expert witness will be asked to swear, under oath, what influence the radiation dose, volume, or technique had on the risk of an ill effect of radiation therapy on normal tissue or alleged failure to control the tumor. This expert witness system troubles many physicians who feel that they can bring a dispassionate and scientific view to such cases and come to a reasonable conclusion about whether malpractice occurred outside the process of litigation.[450] Whatever the wishes of the physician, a trial is an adversarial process. The physician as an expert witness is advised, therefore, to state their opinion about the case frankly and not attempt to predict or handicap how a trial will turn out. They should do their best to provide an opinion and then step aside to let a system, in which they have little expertise, run its course in the hands of the attorneys and judge. Although often frustrating and distressing, the physicians will find themselves out of their league if they attempt to act as attorney or judge.

Each physician must make a determination as to whether they feel comfortable participating as an expert witness. Some radiation oncologists accept employment as expert witnesses in both plaintiffs' actions and in defense. Some only choose to participate as expert witnesses for the defendant physicians or simply wash their hands of the matter and will have nothing to do with the process. The lure of money is strong and serving as an expert witness can be lucrative. There are physicians who

became well-paid professional expert witnesses and companies that broker their services. Each physician must, however, determine for themself whether the financial compensation for serving as an expert witness outweighs the considerable effort and troubling aspects of the process.

It is important that radiation oncologists understand that the concept in malpractice law of *res ipsa loquitur*,[451] roughly translated as "the thing speaks for itself," is used to deal with cases in which the actual negligent act may not be proved, but it is clear that the injury was caused by negligence. In law, this doctrine was first recognized in the case of a man who was injured when a barrel rolled out of a second-story window of a warehouse. The defense attorney argued that the plaintiff did not know what events preceded the barrel rolling out of the window, and, therefore, it could not be proven that an employee of the warehouse was negligent. The plaintiff, however, countered that barrels do not normally fall out of second-story warehouse windows. The simple fact that the barrel fell from the window and caused an injury "spoke for itself" and demonstrated that someone must have been negligent.

In medical malpractice law, *res ipsa loquitur* is used to shift the burden of proof to the defendant's position regarding causation. *Res ipsa loquitur* can be invoked if the patient suffers an injury that is not an expected complication of medical care, the injury does not normally occur unless someone has been negligent, and the defendant was responsible for the patient's well-being at the time of the injury. Examples in which this concept has been invoked include the dislocation of a patient's shoulder while aligning it for a chest x-ray, knocking out a patient's tooth while the patient was under anesthesia for a tonsillectomy, nerve injury because of a hypodermic injection, leaving a sponge in the abdomen during an operation, or fracturing a patient's jaw while extracting a tooth.[452]

An *intentional tort* is an action that can result in harm to the plaintiff. The classic intentional tort in medical malpractice law is forcing unwanted medical care on a patient. Even if care clearly would benefit a patient, if that care were refused and the radiation oncologist had no state mandate to force care on the patient, but did so anyway, the patient might sue for intentional tort. The most common intentional tort is *battery*. The legal standard for a battery is "an intentional unconsented touching."[453]

Battery is not the same, in law, as *assault*. Assault is the act of putting a person in fear of bodily harm. Most battery claims against physicians are based on real attacks. However, battery claims can also be created by the circumstances of the medical treatment. The legal standard of care is that male health care providers do not examine female patients without a female attendant present. Although the standard frequently is ignored, it should not be. An attorney representing a plaintiff-patient may attempt to demonstrate that allowing an unattended examination of a female

patient by a male radiation oncologist is concrete evidence that, at the very least, the physician has very poor judgment.

Of particular concern to radiation oncologists, in the realm of malpractice, is the concept of *loss of chance*. This is usually evoked in circumstances where physicians failed to diagnose a terminal illness. The loss of chance stems from the failure to diagnose in time for the patient to have a chance of cure. Not all states recognize this standard. In those states that do, however, the patient must show that the loss of chance is statistically significant.[454]

It is generally viewed that any patient injured by exposure to a defective x-ray machine will be compensated as a matter of law.[455] If, however, the radiation oncologist did not know or could not have reasonably been expected to know that a machine was defective, they will generally not be held liable if they used the machine properly.[456] Radiation oncologists are bound by the usual standards of skill, knowledge, and appropriate diligence that apply to the specialists within the field.

If a patient is hypersensitive to radiation therapy, and in the absence of any reasonable way to predict this, the radiation oncologist will not be expected to predict or prevent it.[457-459] There is, however, the possibility that the plaintiff's attorney will invoke *res ipsa loquitur* in certain circumstances.[460] For example, in a patient who received radiation therapy for a benign condition and suffered a severe radiation cutaneous reaction that required bilateral amputation, the radiation oncologist was found to be negligent.[461] In the employment of diagnostic radiation, minimal exposure is involved, and it is not expected that a skin reaction will be produced. Thus, if a skin reaction does ensue, many courts would infer negligence.[462] If a part of the body is unintentionally irradiated and injured, liability will generally follow. For example, a patient who is undergoing radiation therapy to the head and neck was compensated when he suffered severe injury to the arms.[463] A patient given radiation therapy to the ear suffered reaction of the head, face, and neck. Liability was also imposed.[464] It is reasonable to expect that patients give informed consent for radiation therapy and will accept a certain risk of ill effects. This does not mean that the patient assumes a risk of negligent care.[465,466]

In a case where a patient with carcinoma of the rectum was given radiation therapy at a dose above that recognized as proper and suffered severe ill effects, the radiation oncologist offered a defense that such dosage had been given in accordance with the recommendation of a recently delivered scientific paper. The court rejected this claim. In the court's view, this was not a generally accepted course or program of therapy, and the patient's specific consent to the variance in therapy had not been obtained.[467]

One must be particularly cautious in dealing with a woman of childbearing age concerning the possibility of pregnancy before exposing her to radiation therapy. Because the fetus might be injured, producing birth defects or necessitating an

abortion, the patient has a right to refuse or at least should be given the full chance of providing informed consent.[468] Some departments require a negative pregnancy test on the chart before irradiating any woman of childbearing age.

One must also be wary of injury through other forms of negligence involving radiation therapy. Injuries of this type include allowing the patient to fall, unstrapped, off the couch of a treatment machine as it is being moved into the correct position, being struck by equipment from a treatment machine or a simulator, being shocked or burned, or being permitted to come in contact with high tension electrical wires.

There are some data concerning the types of malpractice claims brought in radiation oncology. From 1975 through 1994, a total of 18,860 malpractice suits were brought in Cook County, Illinois, naming at least one codefendant physician; 8% named a radiation oncologist as one of the defendants. The number of suits directed against radiation oncologists fell sharply in Cook County after 1982. At that time, allegations that thyroid cancer in adults developed from tonsillar irradiation administered in childhood for benign disease halted when such suits proved unsuccessful. The most common complaints initiating radiation oncology suits in recent years relate to:

(a) Alleged complications of radiation therapy
(b) Alleged administration of radiation therapy for inappropriate indications
(c) Alleged inappropriate withholding of radiation therapy[469]

An interesting survey of 107 radiation oncology lawsuits conducted by the Fletcher Society found that 59% of the plaintiff patients were female. The four most common organ sites involved in the suits were gynecologic (17%), breast (16%), head and neck (14%), and urologic (12%). The actuarial probability of a radiation oncologist remaining free of a lawsuit after 30 years in practice was 35%.[470]

From 1985 to 2007, I reviewed 20 cases of alleged malpractice involving radiation oncology in the capacity of an expert reviewer employed by an attorney—almost always for the defense. When there was sufficient information to determine the intent of treatment, it was always curative rather than palliative. A few themes emerged from an analysis of the primary complaints of the plaintiffs. In 6 of the 20 cases, the plaintiff alleged that a delay in diagnosis by someone other than the radiation oncologist adversely affected the prognosis and/or increased the risk of adverse late effects of radiotherapy. In 4 of the 20 cases, the plaintiff alleged a breach of the standard of care caused radionecrosis, cognitive injury, or second malignant neoplasm induction. In two cases, the plaintiff alleged that the treating radiation oncologist should have obtained a second surgical pathology or cytology opinion and that failure to do so resulted in unnecessary ill effects of treatment.[471]

The National Association for Insurance Commissioners conducted an extensive study of medical liability claims and insurance indemnity. It was published yearly between 1977 and 1980. The final report was based on data collected from over 70,000 medical liability claims arising from over 62,000 alleged injuries or incidences that were closed with payments to the plaintiffs by insurers. These data show that 4% of paid claims were related to EBRT.[472]

Marshall et al reviewed 362 closed malpractice claims filed against radiation oncologists collected by a U.S. liability trade association from 2003 to 2012. Of the 362 claims, 102 (28%) were paid, totaling $38 million or an average of $372,468/paid claim. The most common alleged error leading to a paid claim was improper performance of radiation therapy (18%). Examples include misplaced prostate brachytherapy seeds causing rectal toxicity, or forgetting a spinal cord block and causing radiation myelitis. Errors in diagnosis accounted for 12% of paid claims. Examples include failure to diagnose a new tumor on a follow-up imaging study, stimulating a patient for prostate radiotherapy and not recognizing the presence of a colon cancer, or failure to diagnose appendicitis or an aortic aneurysm.

Death-related claims had a lower average payment and lower percentage of paid claims than claims for radiation injury. Why? It may be more difficult to blame a radiation oncologist for the death of a patient with cancer than for radiation toxicity in a living patient.[473]

Prabhu et al used an online legal database to retrospectively study radiation oncology medical malpractice cases from 1985 to 2015. Thirty-two cases were analyzed. In only 23% was the radiation oncologist the sole defendant. In the remainder of the cases, two or more specialists were named as defendants. The most common reasons for litigation were allegations of excessive radiation (34%), failure to refer or order appropriate tests (28%), death of the patient (22%), failure to treat (19%), and failure to diagnose in a timely manner (16%). The jury verdicts were for the doctor(s) 53% of the time, the plaintiff(s) 34% of the time, and 13% of the cases were settled without a verdict. The mean settlement was $1.5 million. The mean award for the plaintiff, if they won the case, was $4.7 million.[474]

Marshall et al performed a retrospective analysis of 1,517 closed malpractice claims filed between 1985 and 2012 by a nationwide medical liability trade association involving radiation oncology. Only 22.5% of closed claims resulted in indemnity payments ranking radiation oncology as 18 out of 22 specialties in the percentage of closed claims paid. The highest was obstetrics-gynecology at 34.2%, and the lowest was gastroenterology at 18.1%. The average indemnity payment per claim is $276,972, the fifth highest of the 22 specialties. The highest were neurology and neurosurgery; the lowest was dermatology. About 2.4% of U.S. radiation oncologists had a closed claim and 0.68% a paid claim.[475]

Brachytherapy as the origin of a malpractice action poses particular problems for the radiation oncologist. Brachytherapy procedures are relatively rare. Therefore, expertise is often limited and the individual experience of the practicing radiation oncologist may be minimal. The existence of postimplant films, which document the location of the radioactive material, can be used to challenge the quality of the implant procedure. Brachytherapy complications can take years to occur and, because brachytherapy is often employed in the treatment of carcinoma of the prostate, cervix, and uterus, the development of fistulas in long-term survivors can be the cause of a malpractice action.

Radiation oncologists conduct their practice with the assistance of others: physicists, dosimetrists, nurses, and therapists. It is necessary, therefore, for radiation oncologists to understand *vicarious liability*. In general, employers are responsible for the actions of their employees. This is called *respondent superior*—also called the master-servant relationship.[476] The fundamental issue that determines whether a person is legally treated as an employee is the extent to which the person hiring the worker may control the details of that work. Nurses, PAs, radiation therapists, and other physician extenders are professionals, but in most states in which they are licensed, they generally have a limited license. The extent to which they make medical decisions is determined by state law, but they usually must work under the supervision of a practicing physician. The physician's license, however, is unlimited. The physician, for example, may perform nursing tasks without violating nursing practice laws. Injury caused by extenders may, ultimately, lead to a malpractice claim against the physician. Physician liability for the actions of hospital employees is particularly problematic for radiation oncologists. Many radiation oncologists practice in hospital-based clinics. In general, the *doctrine of the borrowed-servant* or the *captain of the ship doctrine* states that all actions of hospital employees are attributable to the patient's attending physician. Under such a doctrine, the radiation oncologist may be found liable for the actions of a nurse, dosimetrist, or radiation therapist who the physician can neither hire, fire, nor otherwise directly control.[477]

When radiation oncologists are directors of clinical services, they also should be aware of the fact that they may be vicariously liable for the behavior of employees if they tolerate inappropriate activity or do not properly screen employees for dangerous tendencies. If, for example, a therapist has assaulted persons in the past and the radiation oncologist was negligent in discovering this, the radiation oncologist could be held liable under the theory of negligent hiring. The radiation oncologist also could be held liable for negligent retention if there were complaints about the behavior of the therapist and the physician failed to act on them.[478]

The captain of the ship doctrine means that physicians may have responsibility for the mistakes of their radiation therapy technologists, dosimetrists, physicists, nurses,

and fellow practicing physicians allegedly under their supervision or control. It is, therefore, incumbent upon the responsible radiation oncologist to take care in staff selection, training, and supervision. There is a risk in delegating such matters to an office manager. Ultimately, the physician must maintain an active role in ascertaining that they can fully trust the person selected to assist in all aspects of patient care. This means that the radiation oncologist must protect against allegations of sexual misconduct or abuse, alcohol or drug impairment, or mental illness potentially affecting patient care; because the physician is ultimately liable for the care given to a patient, the radiation oncologist must play an active role in ongoing training and professional development of their staff.

If an accident or allegation of misconduct occurs, the radiation oncologist must have a thorough, efficient, and adequate means of investigation of the matter and, if necessary, discipline or dismissal. Adequate employment records must be maintained (Box 1.10).

Box 1.10

Systematic Radiation Therapy Overdose and Underdose: Events in the United Kingdom

In the United Kingdom, it was discovered in 1998 at Exeter that 207 patients were given a radiation dose >25% than that generally deemed appropriate for the treatment of breast cancer. Some patients had more marked radiation reactions than appropriate. When this became known, adverse publicity appeared in the press. At Stafford, ~1,000 patients received ~25% underdosing over a 20-year period. An investigation concluded that in ~500 patients, there was a real possibility that underdosage may have affected the outcome of treatment and, in a small number of patients, produced a cancer recurrence higher rate than that expected.[479-481]

The causes of these two incidents were analyzed in great detail and may have been related to inadequate medical physics staffing. A Royal College of Radiologists survey showed that radiation oncologists in many UK radiotherapy departments were seeing ≥600 new patients per year as compared to the usual 250 to 300 patients seen in France, Germany, and the United States.

One of the most vexing problems now facing the practicing radiation oncologist is the matter of substance and alcohol abuse in the workplace and the potential criminal records of employees. Some practices are instituting mandatory preemployment screening for alcohol and drug abuse and criminal background checks. These issues, however, are extremely complicated. There is a growing list of which drugs should be tested for, no consensus for when the testing should occur, who should be evaluated for a potential criminal background, which positive

criminal background checks merit a decision not to employ an individual or to dismiss the person, under what circumstances a person can be felt to have paid their debt to society in a way that allows the individual to practice in a health care environment, and to what extent a radiation oncologist can be held liable for failure to exercise due caution in this process. Obtaining sound advice from experts in personnel relations and legal counsel is advisable.[482]

It is well recognized that no radiation oncologist can be available at all times and in all circumstances. A physician may arrange, during their absence for vacation or ill health, for practice coverage by another physician. When one radiation oncologist "covers" for another, there are risks to patient safety, and possible susceptibility to malpractice claims, if clinical care "falls through the cracks."[483] To minimize the risk of malpractice claims, the following guidelines should be followed:

- When you are away from your practice, you should select a covering radiation oncologist who possesses knowledge and skill at least equal to yours.
- Inform and obtain consent from those patients who will be affected.
- Apprise your covering physician of any important clinical information pertaining to patients that they will see in your absence.
- The covering physician is expected to do more than just "fill in." They must apply the same degree of medical skill and care as the regular radiation oncologist.
- When the regular radiation oncologist returns, they should receive a report of any noteworthy patient care events, laboratory tests or diagnostic imaging results that deserve follow-up, and any other "loose ends."[484]

It cannot be overemphasized that well-maintained, either electronic or paper and ink, medical records are crucial to a satisfactory legal defense in malpractice claims in radiation oncology. In law, the concept of *spoliation* refers to the destruction of evidence of significance or a meaningful alteration of a document. In medical malpractice cases, this would refer to the absence or disappearance of medical records. One radiation oncologist wisely counseled: Now and then look over an old chart, see if you can trace all of your steps in making decisions and executing treatments. Would this chart be sufficient to defend yourself against a malpractice claim?[485]

The Nature of Grievances, Malpractice Claims, and Insurance Disputes in Radiation Oncology

Dissatisfied patients might ignore their physician's advice or seek a new physician. Assertive patients may confront their physician. It is also commonplace for patients

to discuss their complaints about physicians with friends and relatives.

Patients whose dissatisfaction prompts formal action have several options. These include bringing a malpractice claim and seeking redress in courts. Other options include filing a complaint with a government medical board; filing a complaint with the "patient relations office" of a hospital or group practice; directing a complaint to a hospital's chief of medical staff or credentials office; or submitting a grievance to the local, state, district, or national medical society. Why do some dissatisfied patients do nothing and others take formal action?[486] The general nature of patient grievances against physicians, has been evaluated by several authors.[487,488] Complaints fall into several broad categories:

- Alleged failure of physicians to fulfill the patient's expectations for examination and treatment (ie, inadequate therapy, failure to obtain informed consent prior to a procedure, inadequate physical examination, or lack of prompt attention following hospitalization)
- Alleged failure to make a prompt diagnosis
- Alleged rude or discourteous behavior
- Alleged unacceptable practice behavior, such as producing excessive pain or practicing outside an area of expertise
- Alleged inappropriate behavior related to billings and collections
- Alleged physician's use of alcohol or drugs
- Alleged sexual misconduct
- Alleged errors in prescribing
- Alleged insurance fraud

Formal complaints, including malpractice suits, represent only the tip of the iceberg of patient dissatisfaction. Patients far more often deal with their dissatisfaction by complaining to family and friends or switching doctors than by submitting a written complaint. A study by the Harvard Medical Practice Study Group, for example, found that less than 2% of patients who had adverse events because of medical malpractice ever filed malpractice claims.[489]

Few complaints turn into malpractice claims, a fraction of these claims go to trial, and a fraction of those end up in a finding for the plaintiff. Patients pursue medical malpractice claims for a variety of reasons. The four most common include an attempt to hold the offending caregiver accountable, to seek a more complete or satisfying explanation for the adverse event, to stop similar events from occurring to other patients, and to obtain financial compensation[490,491] (Box 1.11).

Box 1.11

The RAGE Campaign

In 1991, a group of women formed an organization in the United Kingdom called RAGE (Radiation in Action Group Exposure). A patient developed brachial plexus damage following surgery and radiotherapy for breast cancer. The patient wrote a letter to several newspapers describing these events and criticizing the medical and legal processes. This produced an outpouring of concern from other patients who claimed to have suffered from the same side effects. RAGE called for significant changes in the use of radiotherapy for the treatment of breast cancer.[374] The group successfully applied to the legal aid board for funds to undertake research toward a group legal action and, in 1995, constituted a group of plaintiffs in a malpractice case. Publicity associated with the litigation prompted the Royal College of Radiology to establish a multidisciplinary working party that made recommendations to ensure that patients with symptoms that might be due to radiation-associated brachial plexus injury had access to a network of health care professionals and cancer centers with the necessary skills for diagnosis, functional assessment, and treatment. The case highlighted the risks of high dose per fraction radiation therapy used in the 1970s and 1980s. When the case eventually came to judgment, Justice Ebsworth concluded that there was no negligence and costs were directed against the plaintiffs. The justice commented that "it was unfortunate that litigation in terms of medical negligence was felt to be the only mechanism available," particularly in view of the fact that the cost of litigation exceeded £4 million. The case is instructive on several grounds:

1. The ill effects of radiation therapy may take a long time to become manifest.
2. Communication with patients concerning the causes and treatment of an injury is crucial.
3. The cost of litigation is high, would hope that in the future society can derive alternative mechanisms to costly malpractice actions to allow patients to understand how and why injuries occur and prevent future occurrences.[437-440]

A disagreement between a patient and their radiation oncologist may cause the patient to have diminished trust in the physician, to be dissatisfied with the clinical results, to change physicians or health plans, to file a complaint, or to undertake litigation. For physicians, however, disagreements with patients may result in frustration, anger, a feeling of loss of control, and career dissatisfaction.

In 2010, California law required that radiation oncologists disclose wrong site of treatment, treatment of the wrong patient, and dose variance of 20% or more of the total prescribed dose to the patient and the Department of Public Health.[492] Mandatory disclosure of medical errors, either by law or institutional policy, is becoming increasingly popular. There is, of course, considerable judgment involved in what kind of error warrants disclosure. Few would argue that a major discrepancy in the dose administered versus the one prescribed would warrant disclosure. Not placing the bolus for 1 fraction out of 30, for example, probably has no significant influence on patient outcome.

When a medical error is discovered, prompt action needs to be taken in regard to disclosure. This topic is eloquently addressed by Evans and Decker.[493] We articulate some basic principles of the response.

- Your first obligation is to be certain that the care of the patient is receiving full attention, including any medical care that may be necessary as a result of the medical error.
- Notify your institution's office of risk management about the error. This will set in motion the implementation of the appropriate institutional policies and procedures. (And if your institution does not have an office of risk management with written policies, it should.)
- After carefully preparing, in advance, what you want to tell the patient and their family and how you want to present the information, do so in a quiet place, without distractions, in an unhurried fashion, with clear and understandable explanations and plenty of time to hear and answer questions. Do follow-up meetings as indicated.
- Make sure that all documentation of what happened and what was reported to the patient is meticulously prepared and recorded.
- Complete any required reports to government agencies.
- Learn from medical errors. A departmental conference designed to understand "What happened? Why it happened? How it can be prevented from happening again?" is an important part of a radiation oncology department's QA process.

The Vanderbilt University Medical Center's Center for Patient and Professional Advocacy database was used to ascertain the number and types of unsolicited patient complaints that were leveled by patients against radiation, medical, and surgical oncologists up until 2018.[494] Radiation oncologists engendered fewer complaints per doctor (1.28) than medical oncologists (3.81) or surgical oncologists (6.89). In an ordinal regression model, academic radiation oncologists and radiation oncologists who graduated from a medical school outside the United States seemed to provoke more complaints. For radiation oncologists, the most common source of the complaint was dissatisfaction with the quality of care and treatment, complaints about communication, complaints about the doctor's accessibility, and concern for the patient's welfare.

It is important to document your explanation of the risks and benefits of radiation therapy and to obtain the patient's written authorization to proceed, with a full understanding of those risks. In discussing any procedure or treatment with the patient or their guardian, the radiation oncologist should endeavor to explain all of the risks in sufficient detail to permit the patient to make a well-educated decision. Written informed consent should be obtained. But simply having the patient sign a

standard form is not the end of the matter. The forms need to be easily understood and written in clear language. It is unwise for a physician to adopt standard printed forms without giving them proper scrutiny. Radiation oncologists must also be sure that the consent form is properly filled out. If, for example, there are blanks for explanations of particular risks involved for the procedure, they should be properly filled in.[495]

It is essential that radiation oncologists use fundamental communication skills to avoid grievances and malpractice claims, understand the patient's worries and concerns, express empathy, actively discuss care options, negotiate differences of opinion, and allow time for adequate conversation. The challenge for radiation oncologists is to recognize patients' unfulfilled expectations and to engage patients in a discussion with the goal of identifying and avoiding dissatisfaction while building a trusting therapeutic relationship.[496]

Insurance disputes involving radiation oncology typically centered on one or more of the following questions: Is the recommended course of radiotherapy covered under the patient's insurance contract? Is the proposed treatment standard of care or experimental? Is the proposed course of treatment likely to be more beneficial than alternatives? What are the supporting references from the medical literature underpinning the doctor or the insurance company's decisions?

I was asked, between 1995 and 2007, to review 69 radiation oncology insurance disputes. Overwhelmingly, these disputes were about a radiation oncologist's desire to employ and bill for the use of an expensive technique of external beam radiotherapy and the insurance company's response that the technology was not standard of care. Examples include Gamma Knife or Cyber Knife treatment of metastatic corner or proton therapy for prostate cancer or vestibular schwannoma or IMRT for localized breast cancer.[497]

Health Insurance Portability and Accountability Act

The Health Insurance Portability and Accountability Act of 1996 (HIPAA) resulted in changes in the area of health care fraud and abuse. HIPAA created new criminal offenses and brought civil remedies while strengthening existing ones. More important for the practicing radiation oncologist, however, HIPAA is part of a larger political initiative in which health care fraud and abuse became a top law enforcement priority. Large numbers of civil investigations have been brought regarding alleged abuses of Medicare and Medicaid. Many physicians and organizations have been excluded from federally funded health care programs, and there have been criminal convictions and the collection of large criminal fines.

Risk Management in Radiation Oncology

In an era of increasing litigation and, unfortunately, a growth in adversarial situations between physicians and patients, it is critical for the radiation oncologist and staff to make every effort to decrease professional liability risks.

The origins of medical malpractice suits include[498]:

- Medical accidents that may not be adequately understood by the patient or explained by the treating physician
- Less than successful or unexpected adverse results of treatment
- Poor results from previous treatment elsewhere and ill-advised comments by other physicians or health care personnel
- Rejection of a plan of therapy without appropriate documentation that the physician has advised the patient of the consequences of declining treatment. Some physicians document this discussion in the chart and send a certified letter advising the patient of the consequences of rejection of treatment.
- Complaint of experimentation when the patient has not been appropriately informed of the nature of the therapy to be administered
- An angry patient who may find this a way to vent anger or frustration about any events surrounding treatment, including lack of communication, discourteous treatment by the physician or staff, or the amount of the medical bill

The best prevention against a lawsuit is good rapport with the patient and relatives, effective communication and QA programs, and clear and accurate documentation of all procedures, discussions, and events that take place before, during, and after treatment.

After appropriate clinical assessment, the histologic diagnosis of the patient must be confirmed at the treating institution; this often includes a review of outside pathologic slides. The rationale of therapy and any changes in the treatment plan should be duly explained and documented in the record. All procedures performed on the patient should be recorded in the chart, including details of daily treatments, such as the use of special treatment aids (ie, bight blocks, testicular shields, eye shields, immobilization devices), and any problems related to equipment operation. All treatment parameters and calculations should be accurately recorded and verified by a physicist or dosimetrist, in addition to the radiation oncologist. We should remember that, as liability attorneys say, “If it is not recorded on the chart, we may assume it never happened.”

The physician and staff may help in their own professional liability defense in case a lawsuit occurs. It is extremely important for the physician to understand and, at an appropriate time, identify early warning signs of an impending malpractice suit. The physician should promptly contact their attorney, risk management office, and insurance carrier.

The physician should prepare an incident report in anticipation of potential litigation, describing the potential liability, including dates when events took place and actors and witnesses to be identified by name, affiliation, and status. Incident reports are confidential information between the physician and the attorney, risk manager, or insurance carrier. The report should be prepared while the facts are still fresh so that documentation will be optimal.

Clear and well-kept records with notes documenting every discussion and procedure that is performed on the patient should help in case of a lawsuit. A full discussion with the patient and relatives regarding planned therapy, particularly side effects of irradiation, and a well-documented informed consent form are valuable in risk management.

Informed Consent

The need to obtain informed consent for treatment is based on the patient's right to self-determination and the fiduciary relationship between the patient and physician.[499] The law requires that the treating physician adequately apprise every patient of the nature of the disease requiring treatment, recommended course of therapy and details regarding it, alternative treatments available, benefits of recommended treatment, and all minor and major risks (acute and late effects) associated with the recommended therapy (Table 1.13). If the plan of therapy is modified, this should be discussed with the patient, and, if warranted, a second informed consent may be required. It is advisable to discuss the informed consent contents in the presence of a witness and have that person sign an informed consent form or the chart verifying that the information was discussed with the patient.

TABLE 1.13 POSSIBLE SPECIFIC SEQUELAE OF THERAPY DISCUSSED IN INFORMED CONSENT

Anatomic Site	Acute Sequelae	Late Sequelae
Brain	Earache, headache, dizziness, hair loss, erythema	Hearing loss Damage to middle or inner ear Pituitary gland dysfunction Cataract formation Brain necrosis
Head and neck	Odynophagia, dysphagia, hoarseness, xerostomia, dysgeusia, weight loss	Subcutaneous fibrosis, skin ulceration, necrosis Thyroid dysfunction Persistent hoarseness, dysphonia, xerostomia, dysgeusia Cartilage necrosis Osteoradionecrosis of mandible Delayed wound healing, fistulae Dental decay

Anatomic Site	Acute Sequelae	Late Sequelae
		Damage to middle and inner ear Apical pulmonary fibrosis Rare: myelopathy
Lung and mediastinum or esophagus	Odynophagia, dysphagia, hoarseness, cough Pneumonitis Carditis	Progressive fibrosis of lung, dyspnea, chronic cough Esophageal stricture Rare: chronic pericarditis, myelopathy
Breast or chest wall	Odynophagia, dysphagia, hoarseness, cough Pneumonitis (asymptomatic) Carditis Cytopenia	Fibrosis, retraction of breast Lung fibrosis Arm edema Chronic endocarditis, myocardial infarction Rare: osteonecrosis of ribs
Abdomen or pelvis	Nausea, vomiting Abdominal pain, diarrhea Urinary frequency, dysuria, nocturia Cytopenia	Proctitis, sigmoiditis Rectal or sigmoid stricture Colonic perforation or obstruction Contracted bladder, urinary incontinence, hematuria (chronic cystitis) Vesicovaginal fistula Rectovaginal fistula Leg edema Scrotal edema, sexual impotency Vaginal retraction or scarring Sterilization Sexual impotence Damage to liver or kidneys
Extremities	Erythema, dry/moist desquamation	Subcutaneous fibrosis Ankylosis, edema Bone/soft tissue necrosis

Informed consent is a process, *not a form*. A consent form documents and codifies the process but does not substitute for clear and appropriate provision of information to the patient with adequate time for questions, answers, and free discussion and exchange. Ultimately, the competent adult patient or a legal representative must agree to the treatment and give approval. For unemancipated minors or legally incompetent adults, informed consent must be signed by the parents, adult brothers or sisters, or a responsible near relative or legal guardian. For incompetent adults, spouses may be allowed by the state to sign. Emancipated minors may provide their own consent. It is extremely important for the radiation oncologist and the staff to spend as much time as is needed to ensure that the patient and, if necessary, relatives understand all aspects of the radiation therapy, particularly the specific description of the various potential deleterious effects of this modality.[500] Many physicians indicate which situations may require surgery to treat a complication and, specifically, when

a gastrostomy, colostomy, ileal bladder, or other organ-substituting operation may be necessary to correct sequelae of therapy.

The radiation oncologist is always balancing a full disclosure of risks and options without overwhelming the patient with data and causing distress. It is reasonable to expect the patient to come away from a meeting with the treating radiation oncologist with a general realistic hope regarding the proposed course of treatment and honest understanding of the side effects and a sense of trust for the physician and the organization. Good documentation is crucial, and, if a malpractice action were to occur, liability may hinge on who said what to whom at what point of the treatment process. Absent, incomplete, or lost records will reflect extremely poorly on the radiation oncologist.[501]

It must be stressed that in dealing with children or mentally incompetent adults, a thorough discussion of the plan of therapy and sequelae should be held with the parents, relatives, or legal guardian of the patient. Also, they must sign the informed consent.

Although, in case of a lawsuit, having a properly executed informed consent form in the record is helpful, more important is the incontrovertible documentation in the chart of the pertinent discussion held with the patient. Radiation oncologists should also be aware of court decisions that place a greater burden on the physician to disclose statistical life expectancy information to critically ill patients as part of the informed consent and as an affirmation of patient-centered decision-making (regarding treatment) in the context of a physician-patient relationship based on trust.[502]

BIOGRAPHICAL SKETCHES OF SOME IMPORTANT EUROPEAN AND NORTH AMERICAN FIGURES IN THE HISTORY OF RADIATION ONCOLOGY

Radiation oncologists of the modern era stand upon the shoulders of their predecessors. The following biographical sketches, presented in order of their subject's year of birth, is a partial representation of the European and North American giants of the specialty. The author has taken the liberty of adding some personal recollections of those individuals he had met.

Wilhelm Conrad Röntgen (1845-1923)

On March 27, 1845, in Lennep, Germany, a son, Wilhelm Conrad, was born to Friedrich Conrad Röntgen and his wife, Charlotte Constanze (Figure 1.49). Röntgen's father was a textile merchant. When Wilhelm was 3, the family moved from Prussia to Apeldoorn in the Netherlands, about 100 miles to the northwest, where Wilhelm's maternal grandparents lived. Wilhelm enrolled in the Utrecht

Technical School in 1862. A fellow student caricatured a teacher on the fire screen of the schoolroom. The schoolmaster demanded the name of the unflattering artist, but Wilhelm refused to betray his classmate and was expelled. There was a risk that his education would come to an end after this episode. Fortunately, the Polytechnical School in Zurich, Switzerland, accepted students based on stiff entrance examinations. The black mark of expulsion was no impediment. Röntgen began classes in 1865 and received his diploma in mechanical engineering in 1868.[503-505]

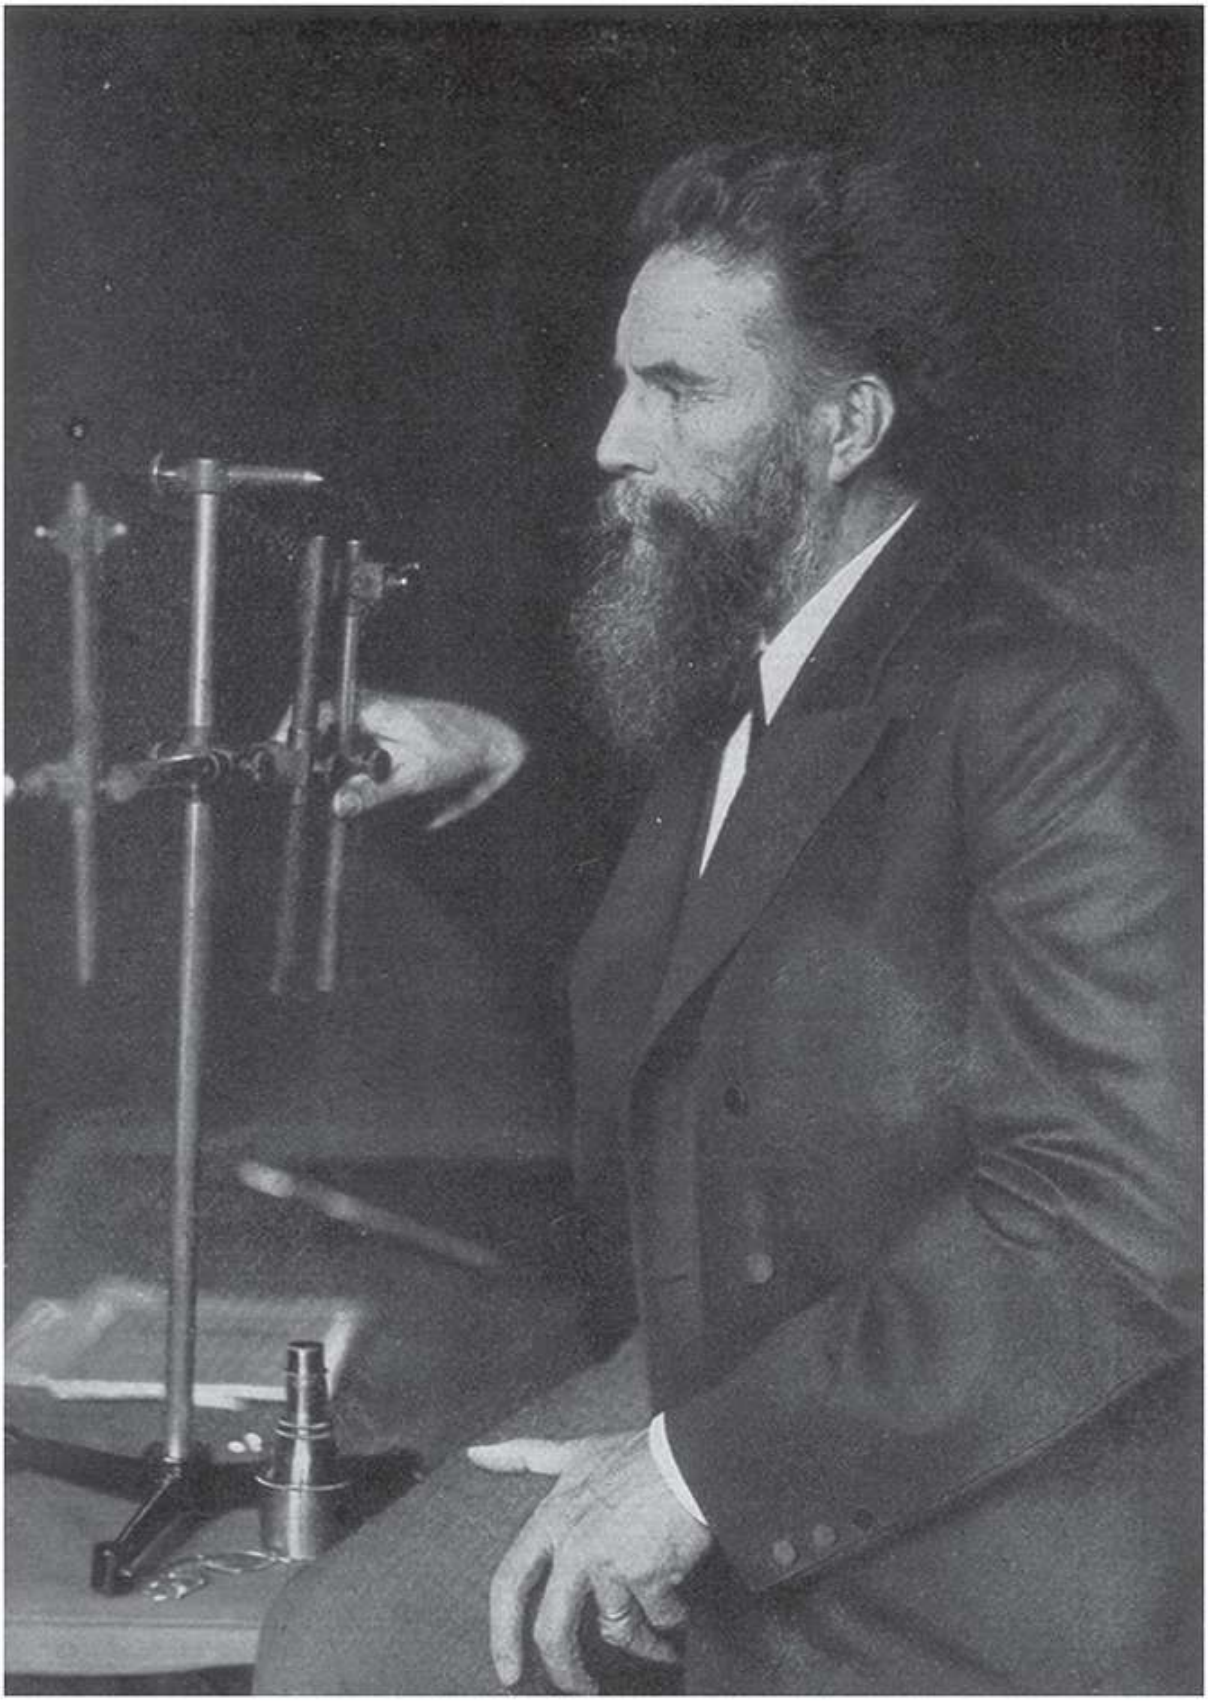

FIGURE 1.49 Wilhelm Conrad von Röntgen. He is shown in this photograph with physics instruments. (From Glasser O. *Wilhelm Conrad Röntgen and the Early History of the Roentgen Rays*. Charles C. Thomas; 1934.From Glasser O. *Wilhelm Conrad Röntgen and the Early History of the Roentgen Rays*. Charles C. Thomas; 1934.)

Röntgen's considerable skill in designing and constructing precision instruments for measuring physical phenomena attracted the attention of Dr August Kundt, a theoretical physicist. Röntgen became Kundt's assistant at the University of Zurich. When Kundt moved, in turn, to the University of Würzburg and then to the University of Strasbourg, Röntgen followed. In 1879, Röntgen struck out on his own as a professor at the University of Giessen.

In 1888, Röntgen accepted a professorship of theoretical physics at the University of Würzburg (Figure 1.50). On November 8, 1895, Röntgen saw the effects of an unusual phenomenon while doing laboratory experiments. He presented his results to the president of the Physical Society at Würzburg on December 28, 1895[506,507] (Figure 1.51).

FIGURE 1.50 Photograph of the Physical Institute of the University of Würzburg from 1896. Professor Röntgen and his wife lived on the top floor. On the left side of the upper story can be seen the conservatory, of which Röntgen and his wife were particularly fond. (Photograph by G. Glock, Würzburg, 1896.)

FIGURE 1.51 A print of one of the first of Rontgen's x-ray images. It shows the left hand of Rontgen's wife, Anna Bertha Ludwig. The wedding ring can be clearly seen. The image was presented to Professor Ludwig Zehnder of the Physik Institut, University of Freiburg, on January 1, 1896. (A similar image exists which is said to have been made on December 22, 1895 and was sent by Rontgen to the Vienne physicist F. Exner. The original plate of that image is in what was called the Deutsche Museum, Munich, and is now the Deutsches Rontgen Museum, Munich.)

There are many accounts of Röntgen's discovery. Among the multitude of reporters who rushed to interview Röntgen was H. J. W. Dam, an Englishman who

was a correspondent for the Canadian *McClure's Magazine*. Dam had a letter of introduction but, like all other reporters, when he arrived in Würzburg, he was turned away. Dam, however, was persistent and wrote a letter in French to Röntgen insisting upon an interview. "You are very difficult, much more difficult than Berthelot, Pasteur, Dewar, and other men of science about whose discoveries I have written." Apparently taken by Dam's audacity and, perhaps, willing to have a sensible article written by a knowledgeable reporter, Röntgen granted Dam an exclusive interview.

Dam's lead story in the April 1896 *McClure*'s is generally regarded as an accurate depiction.[508] Dam told his readers that "in all the history of scientific discovery there has never been, perhaps, so general, rapid, and dramatic an effect wrought on the scientific centers of Europe as has followed, in the past four weeks, upon an announcement made to the Wurzburg Physio-Medical Society, at their December meeting, by Professor William Konrad Röntgen, professor of physics at the Royal University of Würzburg . . . . Röntgen's own report arrived, so cool, so business-like, and so truly scientific in character, that it left no doubt either of the truth or of the great importance of the preceding [newspaper] reports."[509]

Dam, who was able to converse with Röntgen in English, French, and German, conducted an on-site interview in Röntgen's laboratories and had him describe the circumstances related to the discovery. Dam's charming description, excerpted here, gives an excellent insight into Röntgen the man and the nature of his scientific inquiry.

> "Now, Professor," said I, "will you tell me the history of the discovery?"
>
> "There is no history," he said. "I have been for a long time interested in the problems of the cathode rays from a vacuum tube as studied by Hertz and Lenard. I had followed theirs and other researches with great interest, and determined as soon as I had time to make some researches of my own. This time I found at the close of last October. I had been at work for some days when I discovered something new."
>
> "What was the date?"
>
> "The eighth of November."
>
> "And what was the discovery?"
>
> "I was working with a Crookes' tube covered with a shield of black cardboard. A piece of barium platino- cyanide paper lay on the bench there. I had been passing a current through the tube and I noticed a peculiar black line across the paper."
>
> "What of that?"
>
> "The effect was one which could only be produced, in ordinary parlance, by the passage of light. No light could come from the tube, because the shield which covered it was impervious to any light known, even that of the electric arc."
>
> "And what did you think?"
>
> "I did not think; I investigated. I assumed that the effect must have come from the tube, since its character indicated that it could come from nowhere else. I tested it. In a few minutes there was no doubt about it. Rays were coming from the tube which had a luminescent effect on the paper. I tried it successfully at greater and greater distances, even at two metres. It seemed at first a new kind of invisible light. It was clearly something new, something unrecorded."
>
> "Is it light?"

"No."

"Is it electricity?"

"Not in any known form."

"What is it?"

"I don't know. Having discovered the existence of a new kind of rays, I of course began to investigate what they would do. It soon appeared from the tests that the rays had penetrative power to a degree hitherto unknown. They penetrated paper, wood and cloth with ease, and the thickness of the substance made no perceptible difference within reasonable limits. The rays passed through all the metals tested with the facility varying, roughly speaking, with the density of the metal. These phenomena I have discussed carefully in my report to the Würzburg Society and you will find all the technical results therein stated. Since the rays had this great penetrative power, it seemed natural that they should penetrate flesh, and so it proved in photographing the hand I showed you."

A detailed discussion of the characteristics of his rays the professor considered unprofitable and unnecessary. He believes, though, that these mysterious radiations are not light, because their behavior is essentially different from that of light ways, even those light rays that are themselves invisible. The Röntgen rays cannot be reflected by reflecting surfaces, concentrated by lenses, or refracted or diffracted. They produce photographic action on a sensitive film, but their action is weak as yet, and herein lies the first important field of their development. The professor's exposures were comparatively long—an average of 15 minutes in easily penetrable media, and half an hour or more in photographing the bones of the hand. Concerning vacuum tubes, he said that he preferred the Hittorf, because it had the most perfect vacuum, the highest degree of air exhaustion being the consummation most desirable. In answer to the question, "What of the future?" he said:

"I am not a prophet, and I am opposed to prophesying. I am pursuing my investigations, and as fast as my results are verified I shall make them public."

"Do you think the rays can be so modified as to photograph the organs of the human body?"

In answer he took up the photograph of the box of weights. "Here are already modifications," he said, indicating the various degrees of shadow produced by the aluminum, platinum, and brass weights, the brass hinges, and even the metallic stamped lettering on the cover of the box, which was faintly perceptible.

"But, Professor Neusser has already announced that the photographing of the various organs is possible."

"We shall see what we shall see," he said; "we have the start now; the developments will follow in time."

"You know the apparatus for introducing the electric light into the stomach?

"Yes."

"Do you think that this electric light will become a vacuum tube for photographing, from the stomach, any part of the abdomen or thorax?"

The idea of swallowing a Crookes tube, and sending a high frequency current down into one's stomach, seemed to him exceedingly funny. "When I have done it, I will tell you," he said, smiling, resolute in abiding by results.

"There is much to do, and I am busy, very busy," he said in conclusion. He extended his hand in farewell, his eye already wandering toward his work in the inside room. And his visitor promptly left him; the words, "I am busy," said in all sincerity, seeming to describe in a single phrase the essence of his character and the watchword of a very unusual man.[510]

Kaiser Wilhelm II invited Röntgen to the imperial court at Potsdam in January 1896, shortly after the scientist had mailed out reprints to prominent physicists. Röntgen demonstrated his findings and was decorated with the Prussian Order of the Crown, Second Class. On January 23, he gave a lecture to the Würzburg Physical-Medical Society and was startled and overwhelmed by the cheers of the audience. At

the end of the talk, Röntgen invited Albert von Kölliker, one of Germany's most distinguished anatomists, to come to the podium and have his hand x-rayed. When the audience saw the bones of his hand, it erupted in thunderous applause. This was one of Röntgen's last formal lectures on x-rays. He became flustered before large groups and, when lecturing to small groups of students, was generally regarded as lusterless and dull.

Röntgen received the Nobel Prize in Physics in 1901 from the Swedish king. He thanked him but gave no speech. He willed the prize money to the University of Würzburg.[511] In the presentation speech, the president of the Royal Swedish Academy of Sciences, C. T. Odhner, commented on the enormous potential of Röntgen's discovery for diagnosis and therapy:

> The Academy awarded the Nobel Prize in Physics to Wilhelm Conrad Röntgen, Professor in the University of Wurzburg, for the discovery with which his name is linked for all time: the discovery of the so-called Röntgen rays, or, as he himself called them, x-rays. These are, as we know, a new form of energy and have received the name "rays" on account of their property of propagating themselves in straight lines as light does. The actual constitution of this radiation of energy is still unknown. Several of its characteristic properties, however, have been discovered first by Röntgen himself and then by other physicists who have directed their research into this field. And there is no doubt that much success will be gained in physical science when this strange energy form is sufficiently investigated and its wide field has been thoroughly explored. Let us remind ourselves of one of the properties that has been found in Röntgen rays—the basis of the extensive use of x-rays in medical practice. Many bodies, just as they allow light to pass through them in varying degrees, behave likewise with x-rays but with the difference that some that are totally impenetrable to light can be penetrated easily by x-rays, whereas other bodies stop them. Thus, for example, metals are impenetrable to them; wood, leather, cardboard, and other materials are penetrable as are the muscular tissues of animal organisms. Now, when a foreign body impenetrable to x-rays (eg, a bullet or a needle) has entered these tissues, its location can be determined by illuminating the appropriate part of the body with x-rays and taking a shadowgraph of it on a photographic plate, whereupon the impenetrable body is detected immediately. The importance of this for practical surgery and how many operations have been made possible and facilitated by it is well known to all. If we add that in many cases severe skin diseases (eg, lupus) have been treated successfully with Röntgen rays, we can say at once that Röntgen's discovery already has brought so much benefit to mankind that to reward it with the Nobel Prize fulfills the intention of the testator to a very high degree[512] (Figures 1.52 and 1.53).

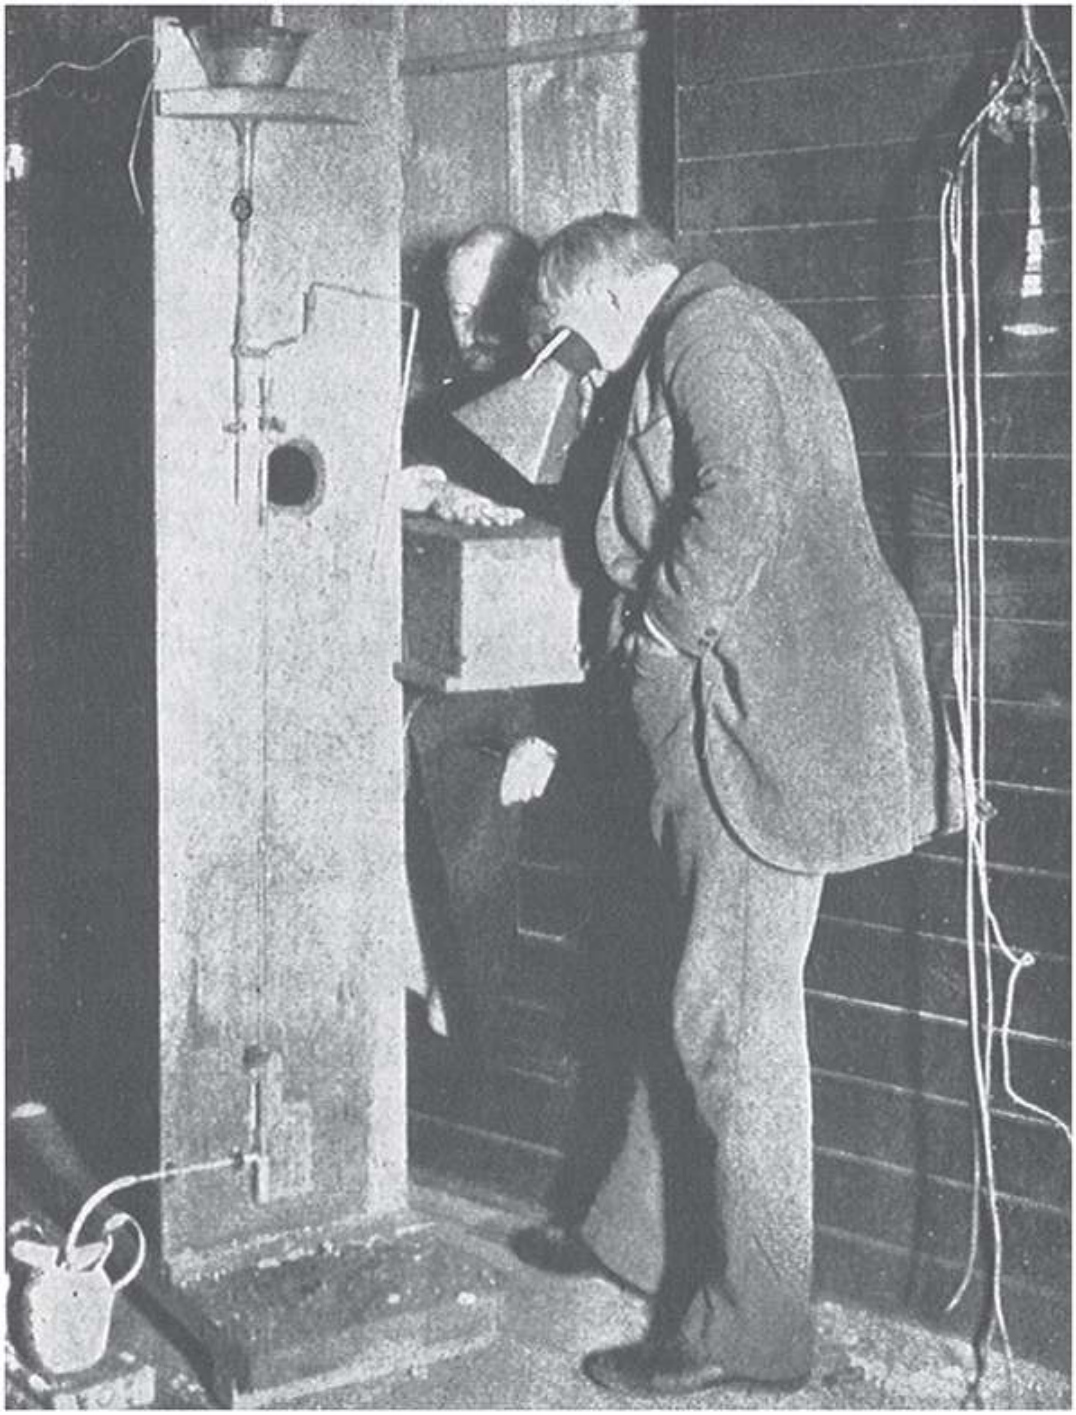

FIGURE 1.52 Thomas A. Edison experimenting with x-rays with no radiation protection. Edison's assistant, Clarence Dally, died of radiation-induced cancer. By 1903, Edison told a reporter for the *New York World*, "Don't talk to me about x-rays. I am afraid of them. I am afraid of radium and polonium too and I don't want to monkey with them." (Thomas Edison National Historical Park, U.S. National Park Service, 1896.)

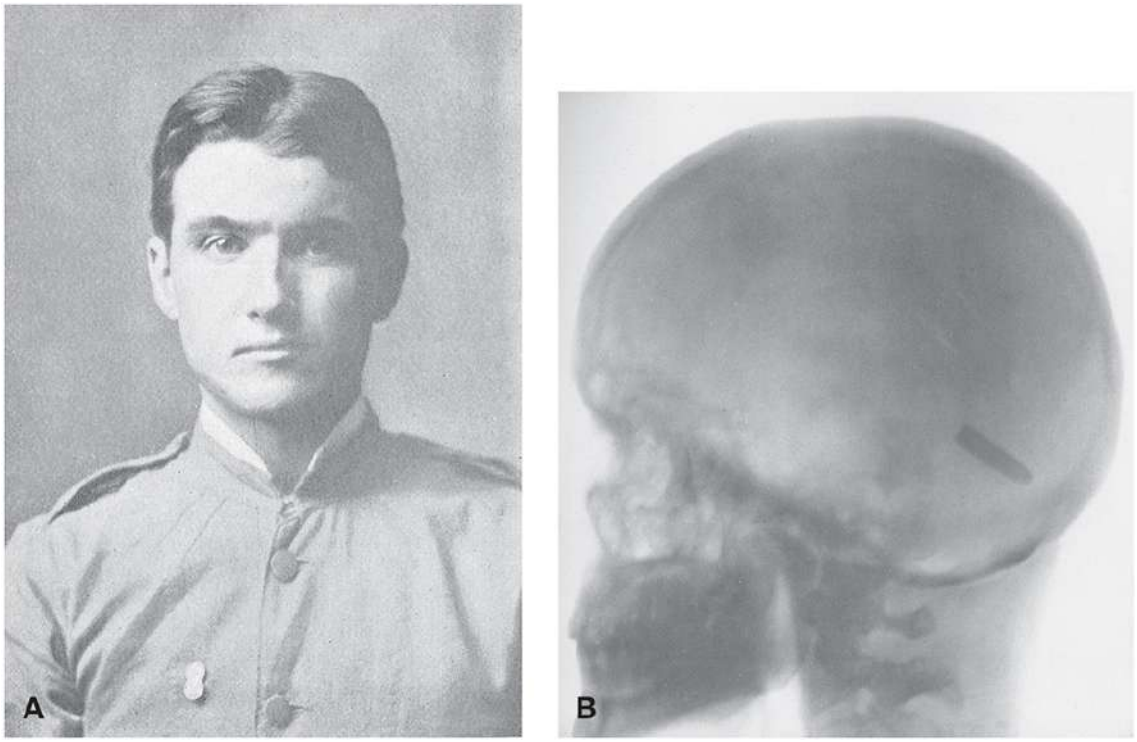

FIGURE 1.53 A and B. Private John Gretzer, Jr, Company D, First Nebraska Volunteers, U.S. Army injury, wounded above his left eye at long range in combat at Mariboa, Philippines. Five months after the injury, he returned to duty in the military mail service. Diagnostic x-ray units were utilized by the U.S. Army Medical Department in the 1898 war with Spain and the Philippine insurrection—within 4 years of the discovery of the x-ray. (From Borden WC, Sternberg GM. *The Use of the Röntgen Ray by the Medical Department of the United States Army in the War with Spain (1898)*. Government Printing Office; 1900.)

Antoine Henri Becquerel (1852-1908)

Antoine Henri Becquerel was born in Paris in 1852 into a family of scientists (Figure 1.54). His father was a professor of applied physics who had conducted research on solar radiation and phosphorescence. His grandfather was the inventor of an electrolytic method of extracting metals from ores.

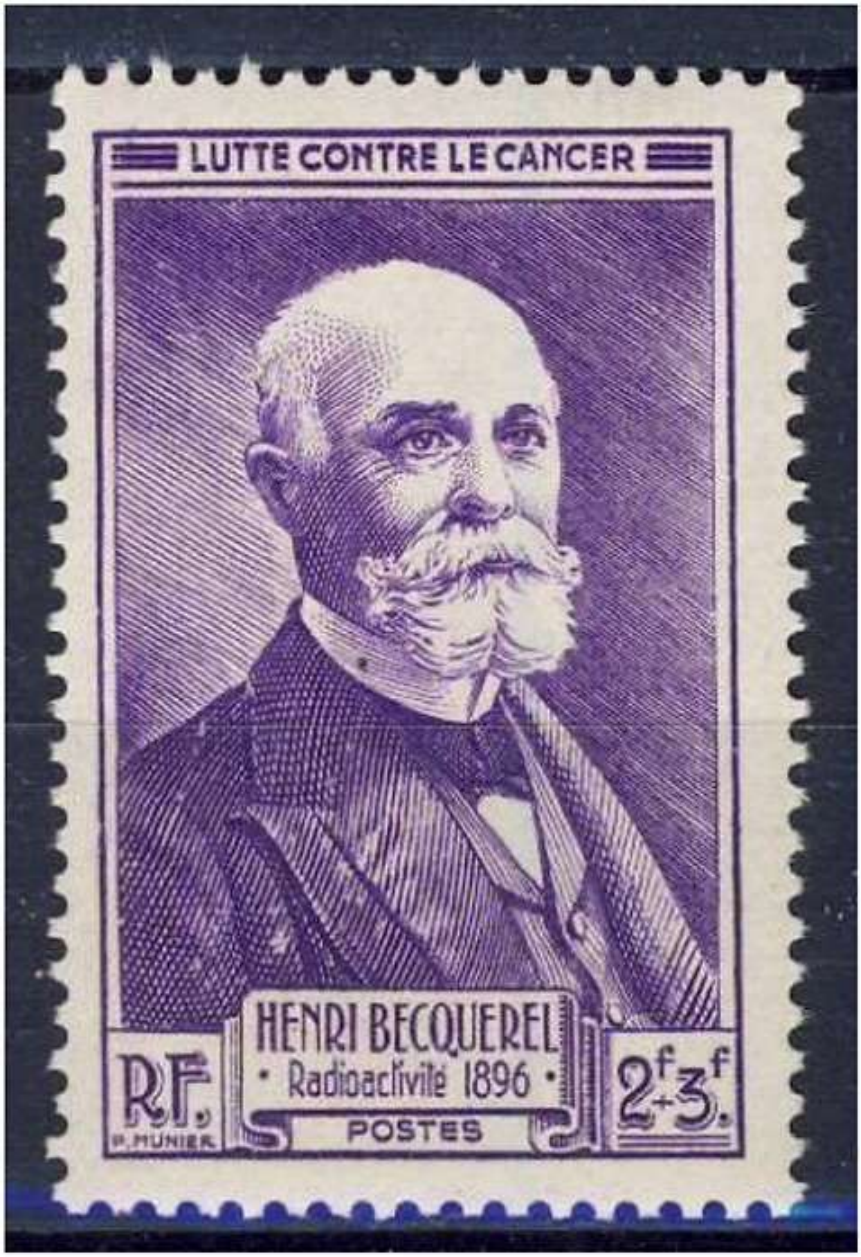

FIGURE 1.54 Henri Becquevel (1852-1908) honored on a French postage stamp.

Becquerel's early scientific work concerned the plane polarization of light, phosphorescence, terrestrial magnetism, and the absorption of light by crystals. Becquerel first heard of Röntgen's discovery in January 1896 at a meeting of the French Academy of Science. He wondered if there was a connection between phosphorescence and x-rays. He had inherited, from his father, a supply of uranium salts, which phosphoresced upon exposure to light.

Becquerel thought that the phosphorescent uranium salts might absorb sunlight and, in turn, reemit the energy as x-rays. He placed crystals of the uranium salts on

top of photographic plates wrapped in opaque black paper. After placing the experimental setup in the sun, he developed the plates and saw an outline of the crystals. When he placed coins and other metal objects between the crystals and the plates, he could produce outlines of the shapes of the metal objects. These initial experiments seemed to confirm his suspicions.

When he encountered several overcast days in February 1896, Becquerel put his uranium crystals and photographic plates in a drawer. On March 1, he opened the drawer and developed the plates. It is not clear why he did this. Nonetheless, he saw a clear image of the crystals on the plates. He had demonstrated that the uranium crystals were emitting x-rays on their own and had discovered spontaneous radioactivity (Figure 1.55).

FIGURE 1.55 In 1915, Dr Sinclair Tousey of New York City, after describing how Henri Becquerel, Marie Curie, and Pierre Curie, suffered painless skin ulcers after carrying a radium tube in a shirt pocket, reported that he reproduced the event by self-experimentation. He exposed his own forearm to contact with radium in a sealed glass tube and caused radiation dermatitis. (From Tousey S. *Medical Electricity: Rontgen Rays and Radium with a Practical Chapter on Phototherapy*. 2nd ed. W.B. Saunders; 1915.)

Becquerel subsequently showed that the radioactive emissions from uranium could ionize gases and be deflected by electric or magnetic fields.[513-515]

Half of the 1903 Nobel Prize in Physics was awarded to Becquerel. The other half was given to Pierre and Marie Curie.[516]

Pierre Curie (1859-1906) and Marie Sklodowska Curie (1867-1934)

Marya Sklodowska was born in Warsaw on November 7, 1867. The youngest of four sisters and a brother, she lived under Russian rule in partitioned Poland. At 17, she left home to work as a governess to the daughters of the supervisor of a large sugar beet factory northeast of Warsaw in order to save enough money to attend university. In 1891, Sklodowska enrolled at the Faculte des Sciences at the Sorbonne in Paris—one of just 23 women in a student body of about 1800. She completed degrees in mathematics and physics and in 1893 was hired by the Society for the Encouragement of National Industry to study the magnetic properties of steel. While in the process of securing additional laboratory space, she was introduced to Pierre Curie.

Curie was the son of a physician who had worked in the laboratory of Louis Pierre Gratiolet (1815-1865), who described the occipital visual pathways. Pierre Curie's doctoral thesis, "Magnetic Properties of Bodies at Diverse Temperatures," evaluated changes in magnetic properties of materials heated to high temperatures. He found that the magnetic properties of a substance change at a very specific temperature. This temperature is called the "Curie point" and is of great importance in studying plate tectonics, understanding extraterrestrial magnetic fields, and measuring the chemical contents of liquids. Curie also found that when crystals were pressed along their axis of symmetry, they produced an electric charge. This phenomenon is called "piezoelectricity," from the Greek word *piezin*, meaning "to squeeze," and is of importance in the operation of quartz watches, ink-jet printers, autofocus cameras, and medical ultrasound.

Marya Sklodowska (now using the French form of her first name, "Marie") and Pierre Curie wed on July 26, 1895 (Figure 1.56).

FIGURE 1.56 Marie Curie honored on a Swedish postage stamp.

For her doctoral thesis, Marie chose to investigate Becquerel's rays. She found that the intensity of the rays was affected neither by external conditions nor by any chemical process—they were an atomic property of the element. Marie observed that "it was obvious that a new science was in the course of development . . . . I coined the word *radioactivity*."[517]

After confirming Becquerel's observations, Marie and Pierre Curie in 1898 published a paper entitled "Sur une substance fortement nouvelle radio-active, continue dans la pechblende" ("On a new, strongly radio-active substance contained in pitchblende"). The new radioactive substance was called polonium (named in honor of Poland). In late 1898, while working on polonium, they noticed another substance, chemically akin to barium and more radioactive than polonium. Demarçay found specific spectral characteristics of this new element, which was called radium (from the Latin word for "ray"). The Curies declined to patent their

findings because, in Pierre's words, "it would be contrary to the scientific spirit." In 1903-1904, radium-226 began to be used in the treatment of patients with skin and uterine cancer.[518] On June 25, 1903, Marie defended her thesis "Researches on Radioactive Substances" and became the first woman in France to receive a doctorate. Later that year, the Curies and Becquerel shared the Nobel Prize in Physics.

On April 19, 1905, Pierre Curie was killed while crossing the Rue Dauphine near the Seine—run down by a horse-drawn carriage carrying 13,000 pounds of military equipment. Marie returned to work and described the radioactive decay series of polonium. In 1911, she became the first person to win the Nobel Prize twice, this time in chemistry.

When France entered World War I, Marie Curie assembled hospital and mobile x-ray units for the care of the wounded. The mobile units were dubbed "petites Curies."[519] In March 1912, a glass tube containing 20 mg of radium was declared the international radium standard after comparison with a similar standard prepared in Vienna. The radioactivity unit was called Curie and defined as the emanation in equilibrium with 1 g of radium. In 1975, the International Commission on Radiation Units and Measurements replaced the Curie with the Becquerel (1 Curie = 3.7×10^{10} Bq). Marie Curie died on July 4, 1934, from the consequences of radiation exposure.

James Ewing (1866-1943)

For much of the 20th century, if a person was selected by the editors of *Time* magazine to appear on the weekly newsmagazine's cover, it was a mark of distinction. Individuals on the cover of the magazine were "newsmakers": important, notable, and worthy of your attention. The January 12, 1931, issue of *Time* portrayed a dignified pathologist in a drawing. "Cancer Man Ewing": The "weapons" referred to in the caption were dedicated cancer institutions. "He wants six $10,000,000 weapons" (Figure 1.57).

FIGURE 1.57 James Ewing (1866-1943).

James Ewing, born in Pittsburgh in 1866, was the son of Thomas Ewing who began his career as a teacher and began the study of law at age 36. He became a judge in the Court of Common Pleas in Pittsburgh, an elder of the Presbyterian

Church, and was viewed as a leading local citizen. Ewing's mother, Julia, graduated in the first class of Mt. Holyoke College and was a teacher.[520,521]

Ewing's personal life was marked by a series of illnesses and tragedies. He developed osteomyelitis of the femur when he was 14 and was bedridden for 2 years, his wife died after less than 3 years of marriage from toxemia of pregnancy, he suffered from tic douloureux and was operated on by Harvey Cushing, a urinary calculus developed later in life, and he ultimately died of bladder cancer. It was said of him that adversity, suffering, disappointment, and sorrow left their mark on him not in the form of bitterness or disillusionment but in increasing sensibleness for the misfortune of others. "His sympathy and kindliness became almost legendary during his lifetime and the very legend of his benignity impressed itself on his character. . . . That this benignity was not of the mere sentimental variety was shown by his intolerance of sham, hypocrisy, and mental laziness, which led him to be an unsparing critic."[522]

Ewing received his undergraduate education at Amherst College and was in the first class of the College of Physicians and Surgeons of New York that graduated after the institution had become affiliated with Columbia University.[523]

In 1899, Ewing was appointed the first professor of pathology at Cornell Medical College and held that position for 33 years. Ewing began to focus his interest on cancer when Mrs Collis P. Huntington (c.1851-1924) established the C.P. Huntington Fund for Cancer Research in 1902. The thrice-married Mrs Huntington was the heiress to a railway and industrial fortune and was said, by some, to be "the richest woman in America." Income from the fund was expended for cancer research at Cornell Medical College under Ewing's direction. Ewing's early studies focused on lymphosarcoma of dogs. (Many other U.S. institutions benefited from the philanthropic support of C.P. Huntington and his wife including the Collis P. Huntington Memorial Hospital in Boston, the site of important early work in radiation therapy. After the closure of this hospital, some of its radiation therapy equipment was moved to the Massachusetts General Hospital.)

In 1919, after a decade of work, Ewing published the first of four editions of *Neoplastic Diseases*, the definitive reference of its time on tumor pathology. Unlike the multiauthored oncology books of today, including the one you are holding in your hands, *Neoplastic Diseases* was solely Ewing's work with greater than 450 illustrations and 49 chapters (Figure 1.58). He wrote in the preface to the first edition:

NEOPLASTIC DISEASES

A TEXT-BOOK ON TUMORS

By

JAMES EWING, A. M., M. D., Sc. D.

Professor of Pathology at Cornell University Medical College
New York City

WITH 479 ILLUSTRATIONS

PHILADELPHIA AND LONDON

W. B. SAUNDERS COMPANY

1919

FIGURE 1.58 The title page of the first edition of Ewing's outstanding textbook.

> Up to a very recent time it has been the prevailing impression that tumors fall into a limited number of grand classes in which the forms occurring in the several organs are so nearly related as to be virtually identical. Hence the practical physician or surgeon has been content without regard to the organ involved, and on this theory to treat the members of each class alike . . . . I believe that this point of view has greatly retarded the progress of the knowledge of tumors, and it has been the writer's effort to combat such a conception, so far as present knowledge permits.[524]

In 1920, Ewing reported to the New York Pathological Society that he had observed a malignant tumor of the bone, most frequently arising in teenagers, and "composed of broad sheets of small polyhedral cells with pale cytoplasm, small hyperchromatic nuclei, well-defined cell borders, and complete absence of intercellular material." He considered the tumor to be an "endothelioma of bone" arising from blood vessels. In a second report, he called the tumor an "endothelial myeloma." Ewing commented on the tumor's marked radiosensitivity, its tendency to invade soft tissues, and its ability to metastasize to lymph nodes.[525,526]

Ewing was quick to recognize the potential of radiation therapy for cancer treatment. He called it "the first rational treatment of cancer ever devised."[527] Ewing revisited radiation therapy many times in his publications:

"From the most unexpected source, experimental physics, a new and powerful weapon has been brought into play."[528,529]

"Radiation therapy, by demanding a detailed knowledge of the symptoms, clinical course and pathology of tumors, has introduced a new era in the study of cancer."[530]

"Cancer research has entered a . . . fruitful era of therapeutics and more intelligent descriptive study . . . . The developments of radiotherapy have opened a new biology of tumors, have stimulated new lines of research and suggested new concepts . . . many new facts and principles of tumor growth have been brought to light."[531,532]

Ewing conducted experimental work on cancer, vigorously worked to secure the funding for the establishment of New York's Memorial Hospital for Cancer and Allied Diseases (now called Memorial Sloan Kettering Cancer Center), investigated the role of radium in the treatment of cancer and worked to establish the production of radium in the United States, wrote four editions of the *Neoplastic Diseases*, and helped found the American Society for the Control of Cancer (now called the American Cancer Society) in 1913 and served on the organization's governing board for more than 30 years.[533]

Ewing viewed an organized war on cancer as a societal imperative and that success would be slow and incremental:

> It is a growing conviction that to know cancer in man, one must study the disease most carefully in the human subject. Personally, I do not look for any startling advances or sensational discoveries, since it is much more likely that a steady reduction in the mortality from cancer will come chiefly from a large number of separate factors, of which the most significant appear to be increased control of the conditions leading to cancer, more general recognition of the preliminary stages of the disease, early diagnosis, and treatment of the established disease. From the consideration of these various functions of the modern cancer research hospital, I think that it must be evident that such an institution not only can justify its existence, but fill a very urgent need without which progress of cancer research would be handicapped and much relief that might early be extended to cancer victims would be unavailable. Nor is there any doubt that the function of supporting such an institution is properly exercised by the State, which support should be continuous and liberal.[534] (Reprinted from del Regato JA. James Ewing. *Int J Radiat Oncol Biol Phys*. 1977;2(1-2):185-198. Copyright © 1977 Elsevier. With permission.)

At the age of 76, Ewing fractured his right femur. The fracture site showed metastatic bladder carcinoma. He died of bladder cancer in 1943.

Claudius Regaud (1870-1940)

Claudius Regaud attended medical school at the University of Lyon, France. His research demonstrated that the formation of new blood vessels in malignant tumors was not accompanied by a proliferation of lymphatics, but rather their progressive obliteration.

In 1904, Jean Bergonié (1857-1925) and Louis Tribondeau began studies on the irradiation of mouse testis. They verified the production of azoospermia after a latent period. Histologic studies showed seminal tubules with preserved Sertoli cells and mature sperm cells in the epididymis. Regaud also began studying the effects of radiation on the testis. Regaud and his collaborators identified the increased radiosensitivity of cells in mitosis. It also appeared that the less differentiated the cells, the more radiosensitive they were. Bergonié and Tribondeau had articulated a "law" of radiosensitivity: "The effects of irradiation on the cells are more intense the greater their reproductive activity, the longer their mitotic phases, and the less their morphology and functions are established."[535]

Regaud's work on the development of brachytherapy and radiobiology was interrupted by his service as a French military physician during World War I. After the war, he resumed his work and found that fractionated radiation therapy was better able to sterilize the testes of an experimental animal, with acceptable normal tissue tolerance, than single fractions. He became convinced that fractionated radiotherapy was the superior way to treat human malignant tumors and popularized the principles of fractionated treatment that continue to this day.[536]

Ernest Rutherford (1871-1937)

Many essential aspects of our understanding of atomic structure can be directly or indirectly attributed to the work of Ernest Rutherford (Figure 1.59). Rutherford's supervisor discovered the electron, Rutherford discovered the proton, and Rutherford predicted the existence of the neutron and his student discovered it. In the words of one of his biographers, the radiation oncologist Juan A. del Regato, "He became the outstanding atomic physicist of his time: amid a constellation of brilliant protagonists, he was second to none; in an era of rapidly developing, new revolutionary concepts, his own prevailed."[537]

Courtesy of New Zealand Post). B. Ernest Rutherford (AIP Emilio Segrè Visual Archives, W. F. Meggers Gallery of Nobel Laureates Collection).

Born in New Zealand, Ernest Rutherford received his BA and MS degrees at Canterbury College, Christchurch, New Zealand, received a scholarship to continue his studies at Cambridge University in England, and began work in the Cavendish Laboratories under the supervision of Professor Sir J. J. Thomson (1856-1940), discoverer of the electron and recipient of the 1906 Nobel Prize in Physics for his work on the conduction of electricity in gases. Within a few weeks of Rutherford's

arrival in England, Röntgen's discovery of the x-ray became known. Thomson and Rutherford soon demonstrated the ability of x-rays to produce ionization in gases.

In 1898, Rutherford accepted the professorship of physics at Montreal's McGill University. It was at McGill that he identified and named α- and β-radiation and also described the concept of radioactive half-life. In collaboration with the chemist Frederick Soddy (1877-1956), he developed a disintegration theory of radioactivity in which chemically different elements undergo a series of changes with decreasing radioactivity at each step. Most radioactive elements, they concluded, are the product of this successive decay.[538]

In his 1904 Bakerian Lecture, he laid out a broad and prescient view of radioactivity. In 1907, Rutherford became professor of physics at Victorian University of Manchester, England. He demonstrated that α-particles were helium atoms. The next year, he was awarded the Nobel Prize in Chemistry for "investigations into the disintegration of elements and the chemistry of radioactive substances."

Rutherford collaborated with Hans Wilhelm Geiger (1882-1945) and invented what is generally called the Geiger counter or scintillation counter to identify radioactivity. Working in Rutherford's laboratory, Geiger and Sir Ernest Marsden (1889-1970) observed that α-particles that were streamed into a thin metal foil were sometimes scattered at very wide angles. Rutherford reasoned that this was the result of the α-particles encountering an atomic particle of large size. The atom, he concluded, had a central, large, positively charged portion surrounded by negatively charged electrons.

After World War I ended, Rutherford returned to Cambridge University to succeed Thomson as professor and director of the Cavendish Laboratory. Rutherford proved that the hydrogen nucleus is present in other nuclei. He could show that hydrogen nuclei were produced as a product of the impact of α-particles on nitrogen gas. The majority of air consists of nitrogen. When α-particles passed through air, scintillation detectors showed the signatures of typical hydrogen nuclei as a product. When alphas were fired into pure nitrogen gas, the effect was larger. Rutherford determined that hydrogen could have come only from nitrogen, and therefore, nitrogen must contain hydrogen nuclei. One hydrogen nucleus was being knocked off by the impact of the α-particle, producing oxygen-17. $^{14}N + \alpha \rightarrow {}^{17}O + p$.

Insofar as the hydrogen nucleus is present in all other nuclei as an elementary particle, Rutherford decided to give the hydrogen nucleus a special name as a particle, since he suspected that hydrogen, the lightest element, contained only one of these particles. He named this new fundamental building block of the nucleus the *proton*, after the neuter singular of the Greek word for "first."

After the experiments of Walther Wilhelm Georg Franz Bothe (1891-1957) and Herbert Becker who, when they bombarded boron and beryllium with α-particles,

found that they produced a beam more penetrating than γ rays, and in the work of the Joliot-Curies (described in the next section) and Sir James Chadwick (1891-1974), the neutron was identified. Rutherford had predicted its existence in 1923. Chadwick was the 1935 Nobel Laureate in Physics. Bothe shared the 1954 Nobel Prize in Physics for his role in the description of wave-particle duality.

Irene (1897-1956) and Frederic Joliot-Curie (1900-1958)

In 1924, Marie Curie interviewed Frederic Joliot for a position in her laboratory. Joliot had a recommendation from the famed physicist Paul Langevin (1872-1946). Marie Curie's daughter Irene also worked in the laboratory. Romance blossomed and Frederic and Irene were married in 1926 (Figure 1.60). The two worked together in the laboratory.[539] A reporter for *Time* magazine wrote:

FIGURE 1.60 Irene and Frederic Joliot-Curie honored on a French postage stamp.

> Husband and wife work like one person with two heads, four hands, 20 fingers. "We compare notes," says M. Joliot, "and exchange our thoughts so constantly that we honestly don't know which of us is the first to have an original idea. Don't you agree, ma chere?"[540]

Toward the end of 1931, the Joliot-Curies were studying the effects of α-particle irradiation of elements such as boron and beryllium. These metals gave off

secondary radiations more penetrating than the γ rays of radium. Interposing substances containing hydrogen in the beam, such as paraffin or cellophane, increased the intensity of secondary radiation. The couple considered these secondary radiations to be high-energy x-rays that knocked out protons from the atomic nucleus of hydrogenated substances. In England, James Chadwick conducted similar experiments with superior equipment. Remembering that Ernest Rutherford had predicted the probable existence of a nuclear chargeless particle, Chadwick correctly deduced that the secondary radiations were this chargeless particle, the neutron. Frederic Joliot-Curie admitted that he had not read Rutherford's Bakerian Lecture where he had predicted the existence of this particle and said the credit for the discovery ought go to Chadwick.

In 1934, Irene and Frederic Joliot-Curie, by bombarding aluminum targets with α-particles, transformed a naturally stable element into radioactive phosphorus. Additional radioactive isotopes were produced by the irradiation of fluorine, sodium, and other metals. The induction of "artificial radioactivity" created the field of nuclear medicine—but Frederic always insisted that the so-called artificial radioactivity was identical with natural radioactivity. In 1935, they learned that they had been awarded the Nobel Prize in Physics for their work. Husband and wife divided the Nobel Lecture between them. Frederic predicted that researchers would find ways of exploiting progressive transmutations of elements by irradiation such that "veritable chemical chain reactions" would be produced—intimating the creation of self-sustaining nuclear fission chain reactions. In 1936, Irene Joliot-Curie was appointed by the Socialist President of France Léon Blum as under-secretary of state for scientific research.

Frederic Joliot realized the possibility of atomic release of large amounts of energy and the potential of this for warfare. He pursued experiments designed to establish that a sustained chain reaction could be produced through nuclear fission leading to the production of vast amounts of energy.

Joliot might have been the first to achieve a sustained nuclear chain reaction had not the German invasion of France and the capture of Paris intervened. Frederic Joliot-Curie and his scientific collaborators spirited their stock of heavy water and uranium out of France just ahead of the Germans. The Joliot-Curies hid their scientific papers on nuclear fission in a vault. Frederic joined the French Resistance, whereas Irene, her health in decline, moved to the French Alps with the couple's daughter. Eventually, mother and daughter crossed over to Switzerland in 1944. One wonders what would have been different in the history of science if the couple had taken the opportunity to escape to England in 1940 and continue their work. They would, perhaps, have played an even greater role in the development of nuclear weapons and atomic energy.

The work of Joliot-Curie was invoked in the famous letter Albert Einstein signed sent to President Franklin D. Roosevelt on August 2, 1939. The letter, written by the Hungarian American physicist Leo Szilard, was designed to spur American action to assure that the United States would acquire nuclear weapons before Nazi Germany.

> Some recent work by E. Fermi and L. Szilard, which has been communicated to me in manuscript, leads me to expect that the element uranium may be turned into a new and important source of energy in the immediate future. Certain aspects of the situation which has arisen seem to call for watchfulness and if necessary, quick action on the part of the Administration. I believe therefore that it is my duty to bring to your attention the following facts and recommendations.
>
> In the course of the last four months it has been made probable through the work of Joliot in France as well as Fermi and Szilard in America—that it may be possible to set up a nuclear chain reaction in a large mass of uranium, by which vast amounts of power and large quantities of new radium-like elements would be generated. Now it appears almost certain that this could be achieved in the immediate future.
>
> This new phenomenon would also lead to the construction of bombs, and it is conceivable—though much less certain—that extremely powerful bombs of this type may thus be constructed. A single bomb of this type, carried by boat and exploded in a port, might very well destroy the whole port together with some of the surrounding territory.
>
> In view of this situation you may think it desirable to have some permanent contact maintained between the Administration and the group of physicists working on chain reactions in America.
>
> I understand that Germany has actually stopped the sale of uranium from the Czechoslovakian mines which she has taken over. That she should have taken such early action might perhaps be understood on the ground that the son of the German Under-Secretary of State, von Weizsacker, is attached to the Kaiser Wilhelm Institute in Berlin, where some of the American work on uranium is now being repeated.[541]

After the war, France created a civilian atomic energy authority. Frederic was appointed head of the Commisariate de l”Energie Atomique, the French Atomic Energy Commission. In 1946, he was promoted to Commandeur de la Legion d’Honneur and was awarded the Croix de Guerre for heroism during the Nazi occupation of France. A member of the French Communist Party, Joliot was dismissed as high commissioner for atomic energy in 1950 because of his political views.

Irene Joliot-Curie died of acute leukemia in 1956. Frederic Joliot-Curie died in 1958.

Edith Hinkley Quimby (1891-1982)

Edith Smaw Hinkley Quimby graduated from Whitman College in Washington with a bachelor's degree in mathematics and physics. After a brief period teaching high school in Oregon, she received an MS degree from the University of California. In 1919, she became an assistant physicist under Gioacchino Failla at the Memorial Hospital for Cancer and Allied Diseases in New York. In 1942, she moved, with Failla, to the Center for Radiological Research at Columbia University where she remained for the rest of her career (Figure 1.61).

A

FIGURE 1.61 A. Edith Quimby (1891-1982) (From the Center for the American History of Radiology, courtesy of American Institute of Physics (AIP) Emilio Segrè Visual Archives). B. Edith Quimby with equipment at the Presbyterian Hospital at Columbia-Presbyterian Medical Center, 1955 (AIP Emilio Segrè Visual Archives, Physics Today Collection).

When Quimby began work as a medical radiation physicist in 1919, the field was in a primitive state. "Major engineering developments were required to attain reproducibility, reliability, and safety in the operation of [radiation-emitting] sources, physical quantities and their units had to be defined to permit measurement, instruments to perform these measurement needed to be invented . . . Quimby was principally responsible for confronting the . . . problems that arose when patients were exposed to ionizing radiation . . . [including devising] means to achieve optimal irradiation conditions, including the use of multiple fields [for external beam irradiation and for radioactive implants] . . . the most effective placement of sources . . . [For external beam irradiation she helped develop the use] "of filters, bolus, wedges."[542] She trained more than 1,000 physicians in the fundamentals of radiation physics. She also made fundamental contributions to the physics of nuclear medicine.

Generations of radiation oncologists, including the author of this chapter, learned the distinction between the Patterson- Parker (Manchester) system for a radioactive implant and the Quimby System. The Patterson-Parker system was designed to deliver a uniform dose within the target volume by the nonuniform distribution of the radioactive sources. Sources with more source strength were concentrated in the periphery of the tumor target volume. In contrast, the Quimby system is based upon the uniform distribution of source strength, with the radiation dose in the target center being higher than the dose in the periphery. Radiation doses at specific points were obtained by consulting "Quimby Tables." For points equidistant from the implant plane of a single-plane implant, the dose rate is higher near the center.

Quimby was the recipient of the Janeway Medal of the American Radium Society and Gold Medals of the ACR and the Radiological Society of North America.[543,544]

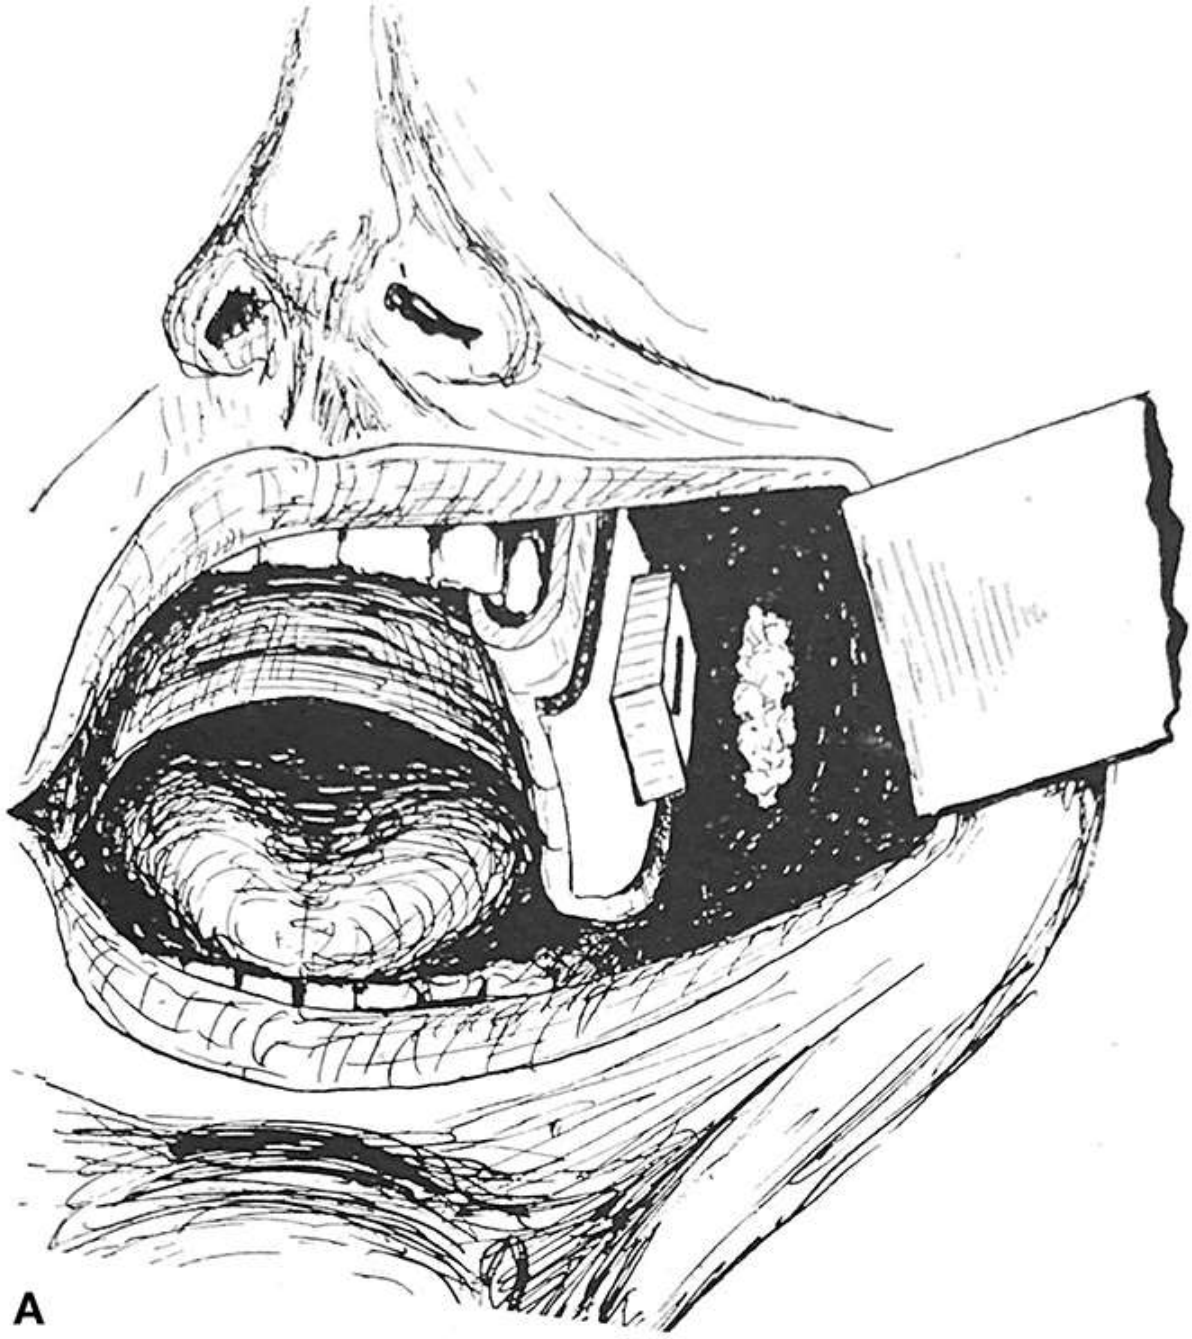
Quimby's husband, Shirley Leon Quimby (1893-1986), was also a professor of physics at Columbia University. He pioneered the use of quartz crystals to make precise measurement of the elastic qualities of solids. He was also an accomplished amateur magician.

Stanford Cade (1895-1973)

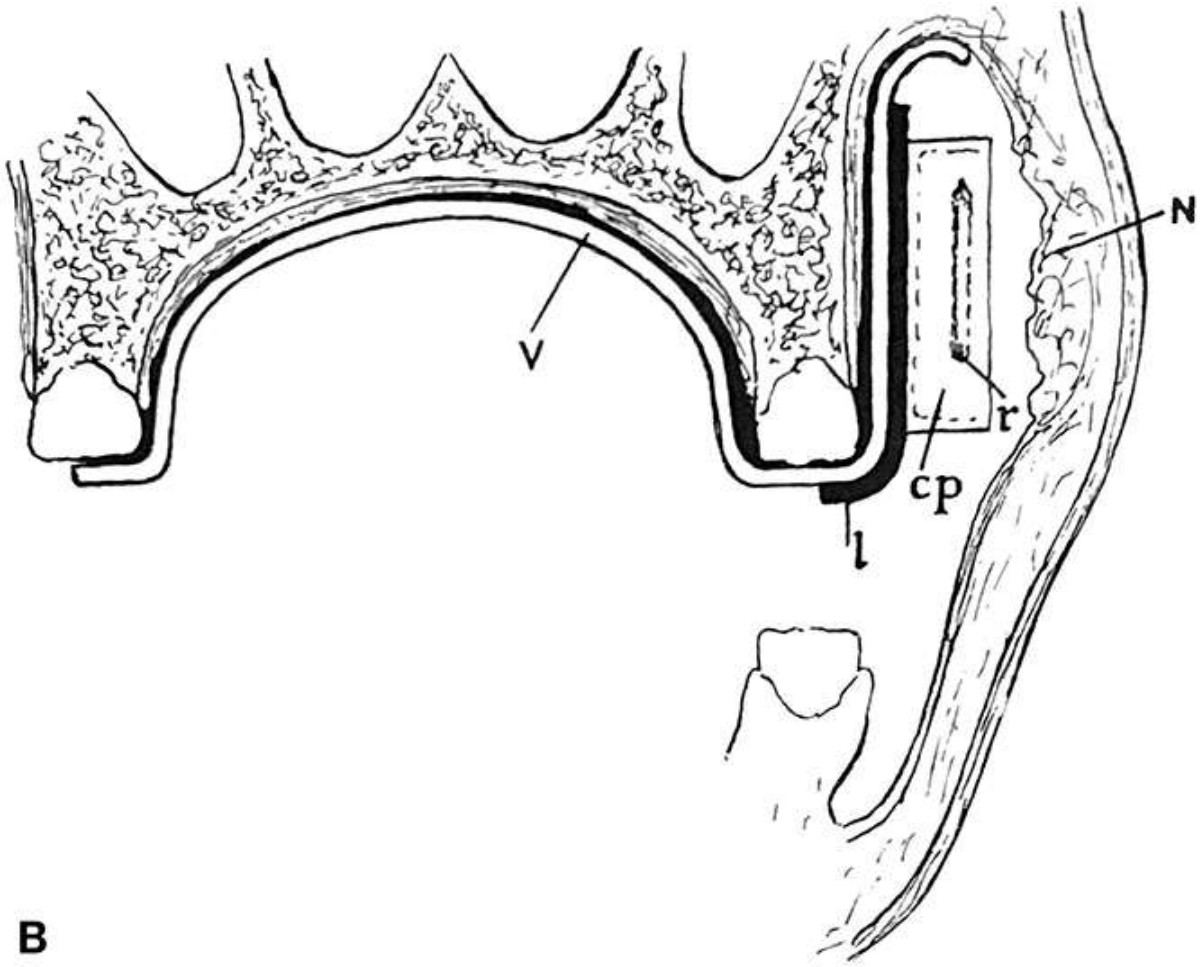
Saloman Kadinsky was born in a part of the Czar's Russian Empire, which is now part of Latvia. His father was Jewish and a diamond dealer. Salomon was sent to school in Antwerp, Belgium, in 1903. In 1913, he began medical school at the University of Brussels. With the onset of World War I, he served in the Belgian army in the doomed attempt to thwart the German invasion. Evacuated to Great Britain, he was unable to enlist in the British army because of an insufficient knowledge of English. He was permitted to sit for his admissions examinations in French and was admitted to King's College, London, to begin medical school. He completed his clinical studies at Westminster Medical School. He qualified with MRCS LRCP in 1917.[545]

He became a British citizen in 1920 and legally changed his name to Stanford Cade in 1924. After training as a surgeon, he spent his career at the Westminster Hospital, the Mount Vernon Hospital, and The Radium Institute.

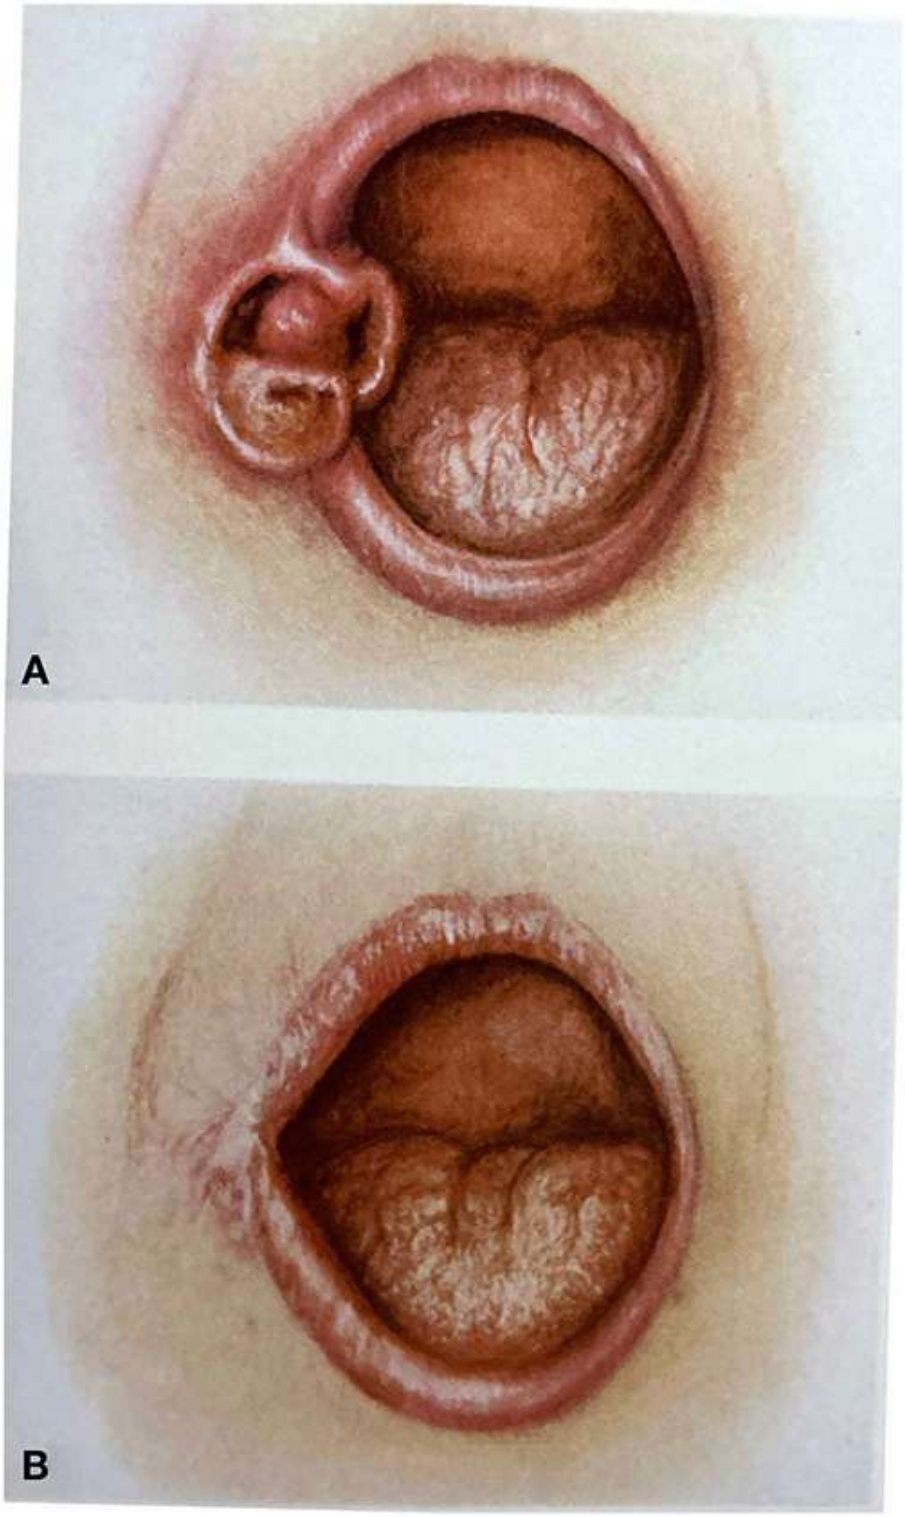
Cade obtained a supply of radium in Paris in 1924 and became an expert in medical radiation physics, radiation biology, and brachytherapy. He generated a vast clinical experience, kept careful records of his results, was an early proponent of multidisciplinary cancer management, and published the important text *Malignant Disease and Its Treatment by Radium*. His creativity in the brachytherapy treatment of a wide variety of malignancies is astonishing (Figure 1.62). He was also an early proponent of supervoltage EBRT over orthovoltage.[546]



A



B



C

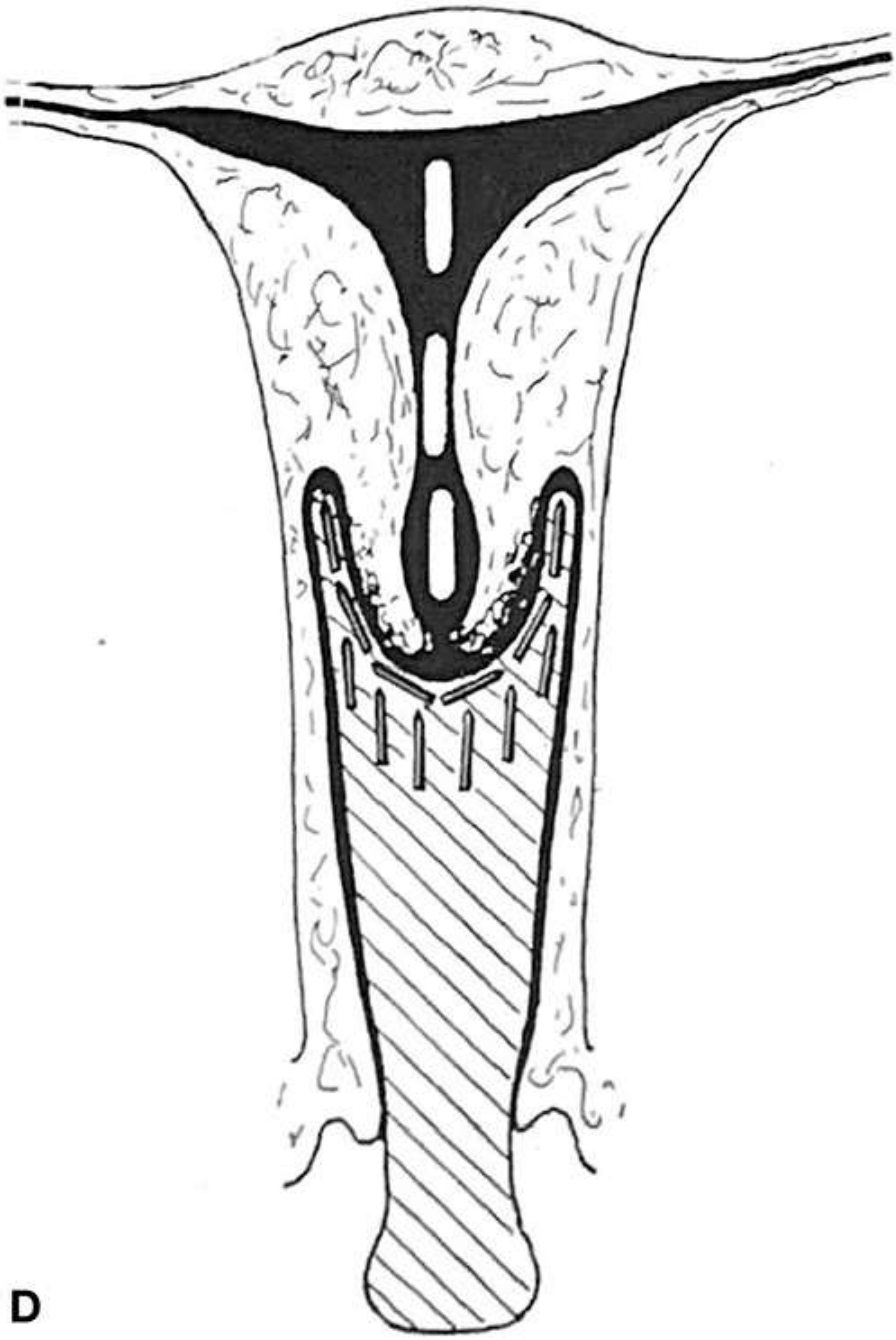


FIGURE 1.62 The erudition of Sir Stanford Cade and his extensive knowledge of oncology and medical radiation physics are demonstrable in these examples from his 1929 textbook *Radium Treatment of Cancer.* (This work is in the public domain.) A. An intrabuccal apparatus was used to treat squamous cell carcinoma of the buccal mucosa. The apparatus is lined with lead and carries a small box containing radium. The box keeps the tumor, and the alveolar margins a proper distance from the radium. B. The same device shown in A is illustrated in cross section wherein v represents vulcanite, l is lead, cp is Columbia paste, and N is the neoplasm. (Reproduced from Cade S. *Radium Treatment of Cancer*. J. & A. Churchill; 1929.) C. This colored plate shows an excellent response to the radium treatment of squamous cell carcinoma of the lip. A is before treatment and B is after. D. This is a highly creative design for the use of brachytherapy in the treatment of carcinoma of the cervix. There are three tubes of radium in the cervical canal and uterus inside a rubber tube. (For clarity, the rubber tube

is not shown in the drawing.) A wax mold containing radium is in the vaginal canal and the radium is placed to irradiate the cervix and the fornices. One can well imagine how this would create what we know would consider a desirable “pear-shaped dose distribution” from modern-day cesium-137 brachytherapy or the use of a remote high-dose rate afterloading machine.

Cade served with distinction in the medical corps of the Royal Air Force in World War II. His modifications of airplane cockpit design substantially reduced pilot death and injury. For his service, he was knighted and named an Honorary Air Commodore, a distinction he shared at that time with only one other person, Sir Winston Churchill.[547]

Among Cade’s many contributions to cancer therapy and radiation therapy, a particular interesting one was his 1955 clinical review of his experience with osteosarcoma.[548] This paper contains a well-known and oft-misquoted description of the high mortality rate of this childhood tumor in the era prior to chemotherapy.

> [The] relentlessness of the disease, its lack of control by accepted therapeutic measures . . . has led to a sense of despondency among surgeons and occasionally cynicism amongst radiotherapists. Thirty years ago a celebrated surgeon of international repute summarised a scientific meeting on “Bone Sarcoma” with the sentence: “If you do not operate they die, if you operate they die just the same – gentleman, this meeting should be concluded with prayers.” And 20 years later a radiotherapist in a discussion on the same topic suggested that for all the good radiotherapy does in bone sarcoma, the surgeon might just as well send the amputated limbs to be irradiated.[549]

Cade concluded that if high-dose supravoltage irradiation was given, that in many cases the tumor would respond locally. One could then wait for 6 to 12 months and see if distant metastases appeared. If they did not, then one would have reason to think that local control alone might lead to cure and consider definitive surgery. This plan of therapy was called “The Cade Technique.”

James Ralston Kennedy Paterson (1897-1981)

After service as an officer in the British army in World War I, Ralston Paterson received an MD, ChB from the Royal Infirmary of Edinburgh in 1923, a DMRE (Diploma in Medical Radiology and Electrology) from Cambridge in 1925, and a MD from Edinburgh in 1927. He did brief stints at the Mayo Clinic and the University of Chicago in the United States, and in private practice in Toronto.

He was appointed radiotherapy director of the Holt Radium Institute and Christie Hospital in Manchester in 1931 where he would remain for the rest of his career.

In collaboration with the medical physicist Herbert Myers Parker (1910-1984), Patterson developed a series of rules for the homogeneous irradiation of a given surface area and, later, by a similar system for interstitial radioactive implants. (See the note on Edith Hinkley Quimby earlier in this section of the chapter to compare the Patterson-Parker system with the Quimby system.)

Under Patterson's leadership, the Holt Radium Institute became a leading center for radiation therapy where generations of physicians trained. Treatments were standardized, and most courses of external beam radiation therapy took 3 weeks. Patients were stabilized for the treatment in plaster casts. The use of points A and B for brachytherapy for carcinoma of the cervix was developed. In 1947, he published a widely used and admired textbook *The Treatment of Malignant Disease by Radium and X-Rays: Being a Practice of Radiotherapy*. Medical textbooks rarely employ the phrase "being a practice of" nowadays. It referred to a text that "told you how to do it" rather than reviewing and commenting upon the array of medical literature from multiple authors and institutions.[550]

Ralston Patterson was married to Dr Edith Isabel Patterson (1900-1995), a radiation biologist and pediatric radiation oncologist.

Shields Warren (1898-1980)

Shields Warren was an outstanding pathologist of radiation injury. Born in Cambridge, Massachusetts, he received an AB from Boston University, MD from Harvard University, and spent his academic career at Harvard Medical School's affiliates the New England Deaconess Hospital, New England Baptist Hospital, and Pondville State Hospital.[551] His book *Medical Effects of the Atomic Bomb in Japan* (1956)[552] and his small monograph *The Pathology of Ionizing Radiation* (1961)[553] can both still be read today, with profit, by the interested student to learn about the acute and late effects of ionizing radiation.

Gilbert H. Fletcher (1911-1982)

As I sit at my desk writing, I can turn to my right and see, on my bookshelf, Gilbert Fletcher's *Textbook of Radiotherapy*. During my residency in the 1980s, this textbook, along with Moss and Brand's *Therapeutic Radiology*, and Ralston Paterson's text (described in the biographical note about Paterson), were the most widely used English-language textbooks—but unquestionably Fletcher's book was the most often relied upon. Fletcher's chapter authors were largely drawn from his home institution, the MD Anderson Cancer Center of Houston, Texas. The book was peppered with photographs illustrating specific cases. It was long on practical advice and short on theory, but it was indispensable.

Fletcher was among the first to develop practical cobalt-60 teletherapy units and high-voltage linear accelerators. He had particular interests in the treatment of head and neck and gynecologic cancers and coauthored a large number of papers related to determining the proper radiation dose, volume of treatment, and technique.[554]

Fletcher was raised in France and Belgium, the son of an American father and a French mother. His undergraduate and medical degrees were from the University of

Brussels. As World War II raged in Europe, his American passport, because of his father's citizenship, got him out of harm's way and into the United States. His postgraduate training was at New York Hospital, and he served in the Army Medical Corps. By 1949, he was the first full-time radiologist at the newly founded MD Anderson Cancer Center. He chaired the radiation oncology department until 1981.[555]

He was a short, bald, energetic man with a thick French accent and strongly held and often strongly expressed opinions (Figure 1.63).

FIGURE 1.63 Gilbert H. Fletcher (1911-1982), far left and the first cobalt-60 unit; the design and installation owed much to Drs Leonard Grimmett, Robert Shalck, and R. Lee Clark.

M. Vera Peters (1911-1993)

Mildred Vera Peters (known throughout her career as Vera) was born and raised on a farm in Ontario, Canada, and received her elementary education in a one-room schoolhouse. After high school, she enrolled in the Faculty of Medicine of the University of Toronto and graduated in the class of 1934. During medical school, she met her future husband. Peters' mother had been treated at the Radiotherapy

Institute of the Toronto General Hospital by Dr Gordon Richards but died while her daughter was still in medical school.

Dr Peters, after a 1-year internship at St John's Hospital, a women's surgical hospital in Toronto, joined Richards as a trainee—although there was no formal residency program in radiotherapy. A 400-kV treatment unit was installed at Toronto General Hospital in 1937, the same year Dr Peters was appointed to the hospital's full-time staff as a junior assistant radiotherapist. She became one of the first female physicians to have a clinical appointment at a Toronto teaching hospital.

Peters can be justly credited for two major contributions to modern radiotherapy. We will consider, first, her role in the development of curative treatment for Hodgkin disease. In 1947, Richards stopped Peters in the hallway at the Toronto Radiotherapy Institute and in his characteristically formal way said, "Dr. Peters, how would you like to review our experience with Hodgkin's disease? All the textbooks say it is a fatal disease, but we seem to be seeing patients who are cured." In response, Peters carefully reviewed the Toronto clinical experience, working at night at home on records and files at her kitchen table while balancing her career, her marriage, and the care of her children.[556]

Richards died in 1949 before Peters completed her study. By 1950, Peters published the first of a series of landmark papers in which she described a three-level staging system for Hodgkin disease and observed the prognostic importance of constitutional symptoms.[521] The current staging system of Hodgkin disease is based on the foundation laid by Peters. She also reported superior survival rates to those previously described and observed that irradiation of involved lymph nodes along with the inclusion of adjacent nodal groups in the radiotherapy fields improved survival in early-stage disease. Peters also identified factors which predicted findings in staging laparotomy and the value of lymphangiography. She persisted in reporting her findings and advocating for the curability of Hodgkin disease in spite of denigrating treatment by prominent male radiation oncologists.

Peters was also one of the pioneers in the development of techniques for the conservative management of early-stage breast cancer. She began to study a cohort of women who were treated with lumpectomy and radiation therapy in contrast to the prevailing wisdom favoring modified radical mastectomy. The patients Peters studied had received limited surgery and radiation because of advanced age, poor general medical condition, the patients' refusal to accept their surgeon's advice to have radical surgery and, instead, insisting upon breast conservation, or the views of a limited number of surgeons favoring more conservative treatment. Peters observed that cancer-specific survival rates in these women seemed no different than those treated with radical surgery.[557] In 1967, Peters published a paper in *Journal of the American Medical Association* titled "Wedge resection and irradiation: an effective treatment in early breast cancer."[558] She also began giving lectures arguing that for

patients with stage I and early-stage II breast cancer, lumpectomy and radiotherapy were as effective as radical surgery. She continued to publish and lecture on the topic until her retirement in the mid-1970s. The rise of the women's movement and its associated contribution to the insistence of women to have a say in their treatment, and not be subservient to the dictates of a largely male-dominated medical profession, helped promote Peters' views. Large-scale randomized prospective clinical trials ultimately validated her initial observations (Figure 1.64).

FIGURE 1.64 Vera Peters (1911-1993) honored on a Canadian postage stamp and first day cover.

N. Harold E. Johns (1915-1998) and Sylvia Ferchuck (1927-2012)

When the author of this chapter was a resident in radiation oncology at the Massachusetts General Hospital in the early 1980s, Professor Harold E. Johns of the University of Saskatchewan was invited to serve as visiting professor by the chief of medical physics, Professor Edward R. Epp. Epp and Johns had coauthored one of the seminal papers in medical radiation physics of the 20th century in 1951: the report of the development of a cobalt-60 machine for external beam radiation therapy.[559]

A fellow resident asked Johns what he thought was the greatest discovery in the therapy of cancer in the 20th century up to that point. "Cobalt 60," he replied. "Think about the amount of press that is devoted to the use of MOPP chemotherapy for Hodgkin disease. Hodgkin disease is a rare disease. In contrast, Cobalt 60 machines are used to treat a large variety of malignancies including deep seated

common tumors like, for example, carcinoma of the cervix. Cobalt 60 has impacted far more patients than chemotherapy."

With cobalt-60 supplied by the Canadian nuclear reactor at Chalk River, Ontario, Johns designed an elegant, simple, reliable machine that contained a block of cobalt-60 surrounded by a lead box. A rotating wheel inside the box moved the cobalt-60 so that it was over a hole in the box and allowed the escape of 1.17- and 1.33-MeV γ-ray beams. By this means, the machine was "on." When the wheel continued to rotate so that the cobalt-60 was encased by the lead box, the beam was "off." Meticulous depth dose measurements were performed on the machine by Sylvia Ferchuck[560] (Figure 1.65).

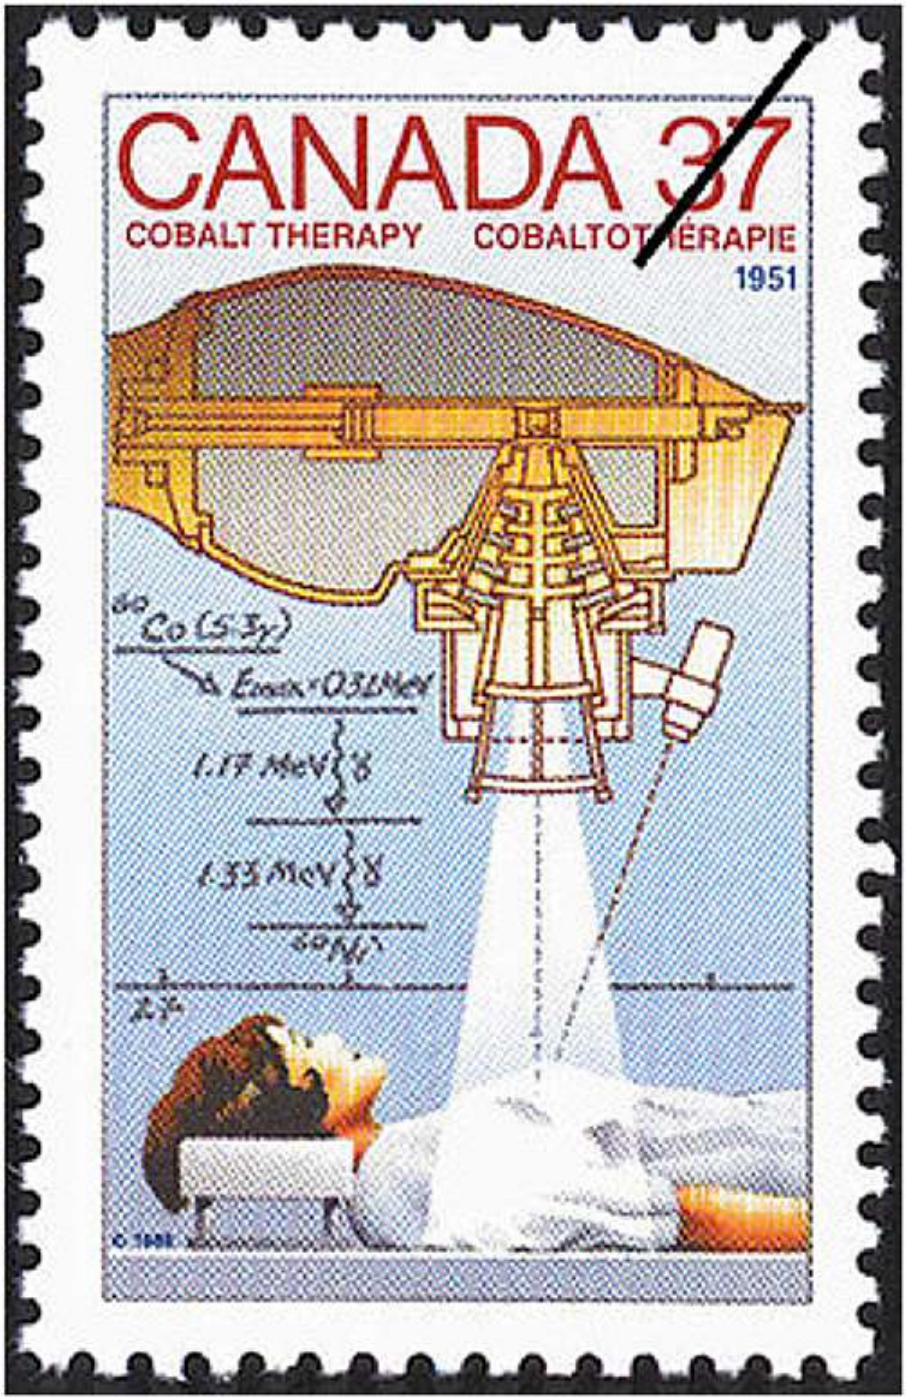

FIGURE 1.65 A 1988 series of Canadian postage stamps honors scientific and technological achievements by Canadians. The stamp portrayed honors the 1951 invention of the cobalt-60 teletherapy machine.

Henry S. Kaplan (1918-1984)

Henry S. Kaplan received a BS from the University of Chicago, MD from Rush Medical College, and an MS in radiology from the University of Minnesota. After 2

years as an instructor at Yale, he became the chair of radiology at Stanford University in 1948 where he remained for the rest of his career.

Kaplan's major contributions to radiation oncology include his role in the development of a medical linear accelerator with Ginzton and Hansen. It was put into use in 1954 and changed the nature of radiation oncology profoundly; he identified the viral causation of murine leukemia; and with his collaborator and medical oncologist Saul Rosenberg, he conducted a series of important clinical trials to improve the treatment of Hodgkin disease. Therapy adapted to the stage of the disease, where staging including lymphangiography and staging laparotomy, became the norm and remained so for several decades.[561,562]

Kaplan has been described as sometimes difficult to work with, combative, and acerbic. I never experienced such behavior. I first met Dr Kaplan in 1978 when I was a fourth-year medical student interviewing for a radiation oncology residency. He had me sit next to him while he reviewed port films for the patients with Hodgkin disease receiving radiotherapy and explained the reason behind a junction block over the spinal cord. When I was in his office for the formal residency interview, I commented on the large number of honors and awards on the wall.

"What's the one over there?," I asked.

"The French Legion of Honor (Ordre national de la Legion d'honneur)," he replied. There was, of course, no follow-up to a statement like that!

I was an internal medicine intern at Stanford from 1979 to 1980 where we saw many cases of acute myelocytic leukemia after curative therapy for Hodgkin disease. In 1983, as a chief resident of the Massachusetts General Hospital, I presented my data on the use of total lymphoid irradiation (TLI) as an immunosuppressive agent for solid organ transplantation in monkeys. Because there were other speakers on the program discussing TLI for the treatment of multiple sclerosis, rheumatoid arthritis, and for bone marrow transplantation, Dr Kaplan was in attendance. During a break in the meeting, I went to sit near the conference center pool and found myself next to Dr Kaplan. We discovered that we were both lifetime readers of *The New Yorker* and spent hours discussing which articles he liked and which I liked.

Maurice Tubiana (1920-2013)

Born and raised in French Algeria, Tubiana left for Paris to study medicine. When his studies were interrupted by World War II and the anti-Semitic policies of the Vichy government, he fought with the Free French Forces in North Africa, Italy, and France. He was named *Chevalier de la Legion d'Honneur* and received the *Croix de Guerre*.

Tubiana received doctoral degrees in medicine in 1945 and physics in 1947. In 1952, he joined the Institut Gustave Roussy in Villejuif. Author and coauthor of

more than 350 publications, he is remembered for pioneering the use of megavoltage units in radiotherapy, development of standards for the treatment of lymphoma and thyroid cancer, QA standards, and the development of computerized dosimetry and computerized medical records. He played a major role in public health reform in France and smoking prevention laws.[563]

I recall having dinner with Dr Tubiana in the early 1980s. My memories are of a dignified gentleman with a philosophical bent of mind.

Luther W. Brady (1925-2018)

At his death, an obituary referred to Luther W. Brady as a "venerable Philadelphia physician . . . recognized as one of the world's foremost experts on radiation oncology and who has served as chairman of the Department of Radiation and Nuclear Medicine at Hahnemann Medical College of Pennsylvania and Graduate Hospital."[564] At the time of his death, he was in his 55th year on the staff of Hahnemann University Hospital. His name is attached to a cancer center in Philadelphia, an endowed professorship at George Washington University where he was a triple graduate (AA, BA, MD), an art gallery at that university, a curatorship at the Philadelphia Museum of Art, and endowed professorships at the Wills Eye Hospital and Hahnemann Medical College before it transitioned to be part of Drexel University. His name, of course, also sits on the masthead of this textbook.

Brady was born in Rocky Mount, North Carolina. After graduating from medical school, he served as an intern at the Thomas Jefferson Medical College Hospital in Philadelphia and during the Korean War trained in nuclear medicine at the U.S. Naval Hospital in Bethesda, Maryland. After leaving the Navy, he resumed his training in radiology and radiation oncology at Thomas Jefferson and the Hospital of the University of Pennsylvania. After a stint at Columbia University in New York, he returned to Philadelphia where he became a medical and cultural institution as a physician and patron of the visual arts and music. He served on the board of directors of the Opera Company of Philadelphia, the Philadelphia Museum of Art, Philadelphia's Settlement Music School, the Curtis Institute of Music, and the Santa Fe, New Mexico, opera.[565,567]

Brady's medical contributions included the development of iodine-125 plaque therapy for choroidal melanoma, multiple publications regarding tumors of the eye and orbit, and a long list of publications concerning radioimmunotherapy, and cancers of the breast, lung, cervix, and lymphatics. Later in life, he developed an interest in radiosurgery.

Luther Brady was a master of organized radiation oncology. He served as president of at least eight different national radiation oncology organizations, founded and edited journals, and chaired multiple committees. Generations of

radiation oncologists went through their oral certification board examinations under his supervision.

Brady had exceptional diction, an eye for fine art and home furnishings, and a taste for fine food and wine. He could be withering in dissecting the foibles of others and could trade stories and gossip with the best. In working on this textbook, one only argued with him about the quality of the paper and the depiction of the illustrations at one's peril.

Seymour H. Levitt MD (1928-2017)

Born in Chicago, Levitt received a BA and MD degrees from the University of Colorado. After an internship at the Philadelphia General Hospital and service in the U.S. Army, he did his residency in radiology at the University of California, San Francisco. After stops at several institutions, he became chair of the Department of Therapeutic Radiology at the University of Minnesota where he remained for the rest of his career.[568]

Levitt made significant contributions to the treatment of Hodgkin disease and breast cancer. A textbook he co-edited with Tapley, Kahn, Perez, Purdy, Vijayakumar, and Poortman, *The Technological Basis of Radiation Therapy* went through four editions. It was an important contribution to improvements in the technical administration of radiation therapy.

Levitt was responsible for training a large number of radiation oncologists and served as a leader of multiple radiation oncology organizations.

Carl Mansfield (1918-2018)

Born in Philadelphia and a graduate of Howard University School of Medicine, Carl Mansfield successively served as professor and chair of radiation oncology at the University of Kansas, Thomas Jefferson University, and the University of Maryland. His research focused on the treatment of breast cancer. He was very active in multiple professional societies, and he has the distinction of being the first Black person to be president of a major U.S. radiation oncology organization, the American Radium Society.[569]

He was a dignified presence at national professional meetings.

Herman D. Suit (1929-2022)

Herman D. Suit was born in Waco, Texas, and attended the University of Houston and the Baylor College of Medicine in Houston.

As a young man, he directly observed racial discrimination, found he was not in agreement with the prevailing Texas attitudes favoring bigotry, and became and

remained a staunch advocate for inclusiveness throughout his life. He also showed no interest in religion and its ritualistic trappings. Regarding these two topics, he would write as an adult, "All humans are one species and are near identical genetically. . . . Time is absolutely equalitarian. There is not and has not been an unnatural event in this universe. Luck is the dominant factor in an individual's success in life. At birth, the infant has zero choice of genes, parents, siblings, relatives, era, and site of birth."[570]

After medical school, he trained under Dr Frank Ellis at the University of Oxford where he received a DPhil for his studies on the effects of radiation on the cellularity of human bone marrow. Upon his return to the United States, after a brief period at the NCI, he returned to Houston for a position at the MD Anderson Cancer Center where the radiation oncology department was chaired by Gilbert Fletcher, MD, whose life and career was described earlier in this chapter.

Suit worked at the MD Anderson Cancer Center from 1959 to 1970 when he was named professor and chair of radiation medicine at the Harvard Medical School at the Massachusetts General Hospital. He had chosen the name "radiation medicine" rather than "radiation therapy" or "radiation oncology" to be more inclusive and to recognize the myriad roles of ionizing radiation in diagnosis and therapy.

Suit's contributions to the field of radiation oncology were extensive. At their core, they were based in a profound belief in laboratory science, the application of scientific principles to clinical medicine, rigorous experimentation, thoughtfulness, and a belief in identifying talented individuals wherever in the world he encountered them and bringing them to the Massachusetts General Hospital to work, study, and do science.

A partial list of his major accomplishments, in approximate chronological order, would include a fuller understanding of the role of hypoxia in tumor resistance to radiation therapy, authoring the chapter on radiobiology in the early editions of Fletcher's *Textbook of Radiotherapy*, which gave generations of radiation oncologist their first taste of the biologic basis of their medical specialty, creating a world-class mouse colony for the conduct of research, invention of what would be called the Fletcher-Suit Apparatus for the afterloading brachytherapy treatment of carcinoma of the cervix, establishing the ability to obtain local tumor control with improved functional results of nonrhabdomyosarcoma soft tissue sarcoma through the skillful combined used of surgery and radiotherapy, developing techniques of 3D tumor and normal tissue radiation treatment planning with the physicist Michael Goitein, and the development of proton beam external beam radiation therapy as an established treatment modality.[571,572]

Suit was the president of the Radiation Research Society and the American Society for Therapeutic Radiology and Oncology (ASTRO). He was the recipient of multiple awards and medals. His wife, Joan Suit, was a noted bacterial geneticist.

Suit was a tall, thin man. He was careful-of-speech, extraordinarily polite, and with a fondness for garish neckties. He had exacting standards, and it was hard, when one was one of his subordinates, to ever "measure up." He also inspired fierce loyalty among his trainees—including me (Figure 1.66).

FIGURE 1.66 Herman D. Suit (1929-2022) and the author of this chapter, Edward C. Halperin. The picture was taken circa 2006.

Gunilla Bentel (1936-2000)

Gunilla Bentel was an international leader in the application of practical innovations to improve the accuracy of the planning and delivery of radiation therapy. Born in Sweden, Gunilla was formally trained as a nurse/radiation therapist, but spent most of her career functioning as a dosimetrist and physicist at Duke University in Durham North Carolina. She was a superb clinician who had a knack to develop practical solutions to real clinical problems. Her major contributions were in the areas of treatment planning, dose calculation, patient setup, and immobilization, and she authored three textbooks on these topics (packed with helpful illustrations), which were the mainstay for students in our field for decades. She was active in the clinic, often working closely with her physician colleagues, assessing patients, and their technical challenges, together. She was a founding member of the American Association of Medical Dosimetrists (in 1975) and served as editor of *Medical Dosimetry*. Through her books, her leadership, and other activities, Gunilla helped to

improve the quality of care for patients around the world. Lawrence B. Marks, MD, University of North Carolina—Chapel Hill (Figure 1.67).

FIGURE 1.67 Gunilla Bentel.

James J. Fischer (1936-2012)

I knew him as a tall, owlish-looking man with a droll sense of humor and a penchant for sports cars and dining out. I also heard Herman Suit refer to him as "the smartest radiation oncologist" he knew. Now, a decade after his death, few radiation oncologists have heard of J. J. Fischer. This is because, in part, he had little interest in organizational radiation oncology or publishing textbooks. To my knowledge, he never held any office in national professional organizations.

Fisher received a BS in biophysics from Yale and an MD and PhD from Harvard. He used nuclear magnetic resonance to study enzyme complexes and published important findings in *Nature* in 1963. He returned to Yale for residency training and served as professor and chair of the department for a remarkable 30 years: 1972-2002. His best known published papers focused on targeting hypoxic tumor cells with hypoxia-activated prodrugs and improved oxygen-carrying drugs like Fluosol. He also wrote prescient papers, 50 years ago, on the potential for computers in radiation oncology and mathematical modeling of the benefits of combined chemoradiotherapy.[573]

Fischer authored a murder mystery titled *Runner's Blood*, which centers around long-distance running, oxygen transport, and partially takes place in a thinly disguised fictional version of Yale's Department of Radiation Oncology. He was an avid cyclist and runner.

As an example of Dr Fischer's dry sense of humor, when I was a fourth-year Yale medical student, I requested a letter of reference for my applications for radiation

oncology residency training. Everywhere I went for an interview, I observed distinguished department chairs chuckling as they read the letter. Eventually, I got to see it. Dr Fischer advised that I had played softball while at medical school, was a weak hitter, not aggressive on the basepaths, and had a weak throwing arm but, perhaps, with coaching I might improve. When I discovered what he had done, I asked him why.

"You were cute," he replied. "You asked for a letter-of- reference with solemnity, as if you were applying for a residency in internal medicine with large numbers of entering residents in each program. You asked for a letter so I gave you one. This is a small field, young man, and everyone knows everyone. Now that you are back from your interviews tell me where you want to go and I'll make a phone call."

Carlos Perez (1934-2023)

Carlos A. Perez was born in Pereira, Columbia. He earned his medical degree from the University of Antioquia School of Medicine in Medellin, Columbia, in 1960. After residency training in Colombia, he came to Washington University School of Medicine for a residency in radiation oncology at that institution's Mallinckrodt Institute of Radiology (MIR). He completed his fellowship at what was them known as MD Anderson Hospital and Tumor Institute in Houston, before returning to St Louis to join the Washington University faculty in 1964. He became director of MIR in 1976. When radiation oncology became a separate academic department at Washington University in 2001, he was the inaugural department chair.

Perez's contributions to radiation oncology were primarily in gynecologic cancers and tumors of the breast, prostate, and lung. Along with Luther Brady, whose profile appears in this chapter, he founded the textbook you are now reading. Perez received the ASTRO's Gold Medal Award in 1992; the ACR's Gold Medal Award in 1997; the Society's Janeway Gold Medal in 2003; and the Marie Curie Medal from the Groupe Europèen de Curiethèrapie—European Society for Therapeutic Radiology and Oncology Brachytherapy Society in 2012. He was the president of ASTRO, a trustee of the American Board of Radiology, a member of the National Board of the American Cancer Society. His name appears as an author/coauthor on more than 370 scientific articles and more than 40 book chapters.[574,575]

Dr Perez was a courtly, dignified, and gracious gentleman with an extraordinary work ethic. He was always impeccably dressed and groomed. He continued to work on chapters for the edition of the book you are now reading up until the time of his death (Figure 1.68).

FIGURE 1.68 The team responsible for the fourth edition of this textbook from left to right. Jonathan W. Pine, Carlos M. Piecz, Luther W. Brady, Edward C. Halperin, Rupert Schmidt-Ullrich. This photograph was taken in approximately 2003. Jonathan Pine was a kind and gentle individual who represented the publishing company in the preparation of several editions of this textbook. Drs Brady, Schmidt-Ullrich, and Perez were very different in temperament. Brady could alternate between withering criticism and effusive charm. Schmidt-Ullrich was serious and strong-willed. Perez was unfailingly gracious and able to defuse editorial meetings becoming tense because of Dr Brady's temper. All of the senior editors of the first to seventh editions of this book are the subjects of biographical sketches in this chapter except for Dr David Wazer and the author of this chapter who are carrying on the duties of our predecessors and mindful of our roles as stewards of this book.

Rupert Schmidt-Ullrich (1943-2004)

Rupert Schmidt-Ullrich completed his medical studies at the University of Heidelberg in 1970. He then became a research fellow at the Max Planck Institute for Immunobiology in Freiburg, Germany. This was followed by an appointment as a research fellow and a subsequent appointment to the faculty in the Division of Cancer and Radiation Biology at Tufts-New England Medical Center. From 1978 to 1981, he completed his radiation oncology residency at Tufts. According to my co-senior editor of this textbook, Dr Schmidt-Ullrich "remains, to my knowledge, the first and only resident ever to complete his residency while simultaneously being awarded two RO-1 research grants and earning the rank of associate professor in the

same department. He achieved the rank of full professor within 3 years of completing his residency."

In 1988, Schmidt-Ullrich moved to the Virginia Commonwealth University in Richmond where he became professor and chairman of the Department of Radiation Oncology. He was an authority in the molecular mechanisms that underpin radiotherapy. He investigated altered fractionation for the treatment of head and neck cancer. He was instrumental in the development of IMRT. He discovered the molecular mechanisms by which tumor cells adapt to radiotherapy through accelerated repopulation and helped establish the discipline of "genetic radiation therapy."[576]

He was a cultured man, an exacting scientist, and very brave. He carried on with his work in the face of colorectal cancer and never disclosed his illness to me. I only learned of it when he died.

C. Norman Coleman (1945-2024)

C. Norman Coleman received his undergraduate degree from the University of Vermont and an MD from Yale. He trained in internal medicine at the University of California San Francisco, medical oncology at the NCI, and in radiation oncology under the direction of Henry S. Kaplan at Stanford University. After a period of time on the Stanford faculty, he was named the Alvin T. and Viola D. Fuller American Cancer Society Professor and Chair of the Harvard Joint Center for Radiation Therapy. He then moved to the National Institutes of Health (NIH) and NCI as the director of the Radiation Oncology Sciences Program, chief of the Radiation Oncology Branch in the NIH Clinical Center, and associate director of the Radiation Research Program, which administered NCI's grants in radiation research. He was the was the founder of the International Cancer Expert Corps, a nonprofit he created to provide mentorship to cancer professionals in low- and middle-income countries and in regions with indigenous populations in upper income countries. He became an expert in dealing with nuclear catastrophes and participated in the response to the Fukushima Daiichi disaster in 2011 (Figure 1.69).

FIGURE 1.69 C. Norman Coleman, MD (1945-2024). (Bill Branson/National Cancer Institute.)

Former NCI director Richard Klausner wrote of Coleman.

Norm had four characteristics that made him outstanding:

First was his dedications to patients, both his and those around the world who could not access places like NCI and doctors like Norm

Second, he was a curious, generous, and dedicated scientist who wanted to push the boundaries of our understanding about how radiation interacted with biology.

Third, he was the ultimate mensch, a delight to work with, to be with and a selfless colleague where the outcome of work vastly superseded the credit he sought or expected—always crediting instead the colleagues he felt lucky to be among.

Fourth, he was an engaged citizen and physician of the world, from international partnerships such as the All-Ireland Cancer Consortium to the King Hussein Medical Center to his work post 9/11 and after Fukushima.

Finally, Norm was just a delight to spend time with—fun, funny, a valuable thought partner who always brightened a conversation with generosity, listening, and humor.[577]

The author of this chapter first met Dr Coleman when he was an attending radiation oncologist at Stanford and the author was an internal medicine intern. They kept in touch over the subsequent decades, and I can confirm Dr Klausner's impressions. He was a remarkable individual.

Jay S. Loeffler (1955-2023)

Jay S. Loeffler attend Williams College and medical school at Brown University. He completed his radiation oncology training at the Harvard Joint Center for Radiation Therapy, where he served as chief resident. He began his academic career at the Brigham and Women's Hospital and Dana-Farber Cancer Institute, where he focused on neuro-oncology and became the founding director of the Brain Tumor Center.

In 1996, he was recruited to the Massachusetts General Hospital to be the director of the Francis Burr Proton Therapy Center. He later was the Herman and Joan Suit Professor of Radiation Oncology and Professor of Neurosurgery at Harvard Medical School. For 20 years, he served as Chairperson of Radiation Oncology at Massachusetts General Hospital.

The author and coauthor of more than 400 publications and co-editor of nine cancer textbooks, Dr Loeffler helped develop stereotactic radiosurgery for central nervous system tumors and stereotactic body radiation therapy for malignancies throughout the body. He was elected to the National Academy of Medicine[578-580] (Figure 1.70).

FIGURE 1.70 Jay Loeffler, MD (1955-2023).

A. William Blackstock Jr (1963-2023)

Blackstock was born in Eden, North Carolina; received a scholarship to attend Wake Forest University and then went on to medical school at East Carolina University School of Medicine. He completed a radiation oncology residency at the University of North Carolina Chapel Hill.

His initial work focused on gemcitabine radiation sensitization for pancreatic cancer.

He eventually returned to Wake Forest University School of Medicine where he rose through the ranks to become professor and then chair of the Department of Radiation Oncology. His clinical focus was on the treatment of gastrointestinal and thoracic malignancies. He helped establish a role for PET in the prognostic assessment of the treatment response of esophageal cancer.

Dr Blackstock played an active role in clinical cooperative group studies, and, along with Dr Mansfield who was profiled early in this chapter, he was among the

first Black physicians to chair an academic radiation oncology department[581,582] (Figure 1.71).

PART A

Cancer Biology

CHAPTER 2

Molecular Cancer and Radiation Biology

Michael Baumann, Ina Kurth, Nils Cordes, Cristina Conde Lopez, Mechthild Krause, and Annett Linge

Over the past several decades, molecular cancer research has become a rapidly growing branch of the biomedical sciences. Many advances in our understanding of cancer are closely related to innovations in biotechnology, such as gene editing techniques to modify the specific gene of interest, experimental maneuvers to manipulate temporal and spatial gene expression, the utilization of high-throughput methods to study the entire genome and proteome of cancer cells, and a vastly growing methodology to specifically interfere with signal transduction. Due to the rapidly expanding knowledge in molecular cancer and radiation biology, this chapter can only provide an introductory overview on selected topics.

Cell biology approaches contribute to modern radiobiology and help to better understand the effects of ionizing radiation on cells, tumors, and normal tissues. Knowledge in molecular cancer biology is important for clinical decision-making in oncology and the development of novel biology-driven strategies in the multidisciplinary clinical environment.[1-4] *Molecular pathology* of tumors increasingly supplements classic histopathology and immunohistochemistry, thereby providing the basis for improved treatment stratification in oncology.[5-7] *Molecular pathophysiology* describes mechanisms leading to a characteristic microenvironment of tumors or that eventually manifest radiation sequelae in normal tissues.[8] *Molecular imaging* has become important not only for staging but also for

biologic characterization of tumors and for determination of target volumes in radiation oncology, including approaches such as dose painting.[9-12] *Molecular targeting* in radiotherapy may either increase the tumor response or protect normal tissues, thereby enhancing the therapeutic gain of the treatment.[13-17]

Radiotherapy appears to be particularly promising to integrate molecular targeting approaches.[15,17] First, the radiobiologic mechanisms of the response of tumors and normal tissues to radiotherapy are well characterized, and the molecular pathways involved in these responses are increasingly known. Second, similar to conventional chemotherapeutic drugs, the novel drugs developed are not necessarily curative by themselves. In contrast, radiotherapy in itself is extremely efficient in eradicating cancer stem cells (CSCs), and recurrences often occur from only one or a few surviving CSCs.[18-20] Thus, even if novel drugs have only the potential to kill a limited number of CSCs, this might be sufficient to increase local control when combined with radiotherapy. The same argument applies when these drugs increase the radiosensitivity of tumor cells or when normal tissues are specifically protected. Third, in contrast to systemic chemotherapy, radiotherapy can be modulated in dose, time, and space. This allows individual tailoring of the effects of combined treatments in consideration of the spatial distribution of CSC burden as well as with consideration of normal tissues. Preclinical data and early clinical results corroborate these arguments[18,19,21-26] and support further translational research on biologically enhanced radiotherapy.

THE HALLMARKS OF CANCER

During carcinogenesis, neoplastic cells are gaining several biologic capabilities, which enable tumor growth and metastatic dissemination. Molecular biology of cancer can be summarized by a simplified concept based on a small number of underlying principles. In their seminal articles, Hanahan and Weinberg described these principles, which are being shared by most human tumor types, as the eight core *hallmarks of cancer*, as well as four *emerging hallmarks* and two *enabling characteristics* facilitating tumor promotion.[27-29] The hallmarks describe molecular and cellular characteristics such as specific genetic and epigenetic alterations as well as

modifications in key oncogenes and tumor suppressor genes that elicit neoplastic malignant transformation and tumor evolution, whereas the enabling characteristics (genome instability and tumor-promoting inflammation) are rather consequences of the aberrant tumor state that provide the tumor with functional means for further development.[29]

Sustaining Proliferative Signaling

Mitogenic signals from growth factors, cytokines, extracellular matrix, and cell-cell adhesion molecules are transferred into the cell by different classes of transmembrane receptors.[27,28] Malignant cells acquire the capability to escape from the tightly regulated dependence on extracellular growth signals. The molecular mechanisms include overexpression of growth factors as well as growth factor receptors (autocrine and paracrine stimulation), receptor mutations leading to constitutive receptor activation without ligand binding, and molecular aberrations in the intracellular signal transduction pathways.[27,28]

Evading Growth Suppressors

Normal cell division is tightly regulated by stimulatory and inhibitory growth signals. Growth signaling involves interaction of diffusible growth factors or cytokines with transmembrane receptors, as well as regulation of growth by components of the extracellular matrix and by cell-cell interactions. Once a resting cell receives a sufficient growth stimulus, it enters the cell cycle by passing the restriction point and four distinct phases of cytokinesis and mitogenesis: gap-1 (G1), DNA synthesis (S), gap-2 (G2), and mitosis (M).[30] The passage through the restriction point and the entry into S and M (G1/S and G2/M checkpoints) are governed by several proto-oncogenes and tumor suppressor genes such as *TP53* and *RB1* encoding for p53 and the retinoblastoma protein (pRb), respectively (Figure 2.1).[27,28,31,32] Inactivation of tumor suppressor genes by genetic mutations or epigenetic mechanisms will ultimately lead to sustained cell proliferation.[27,33-35]

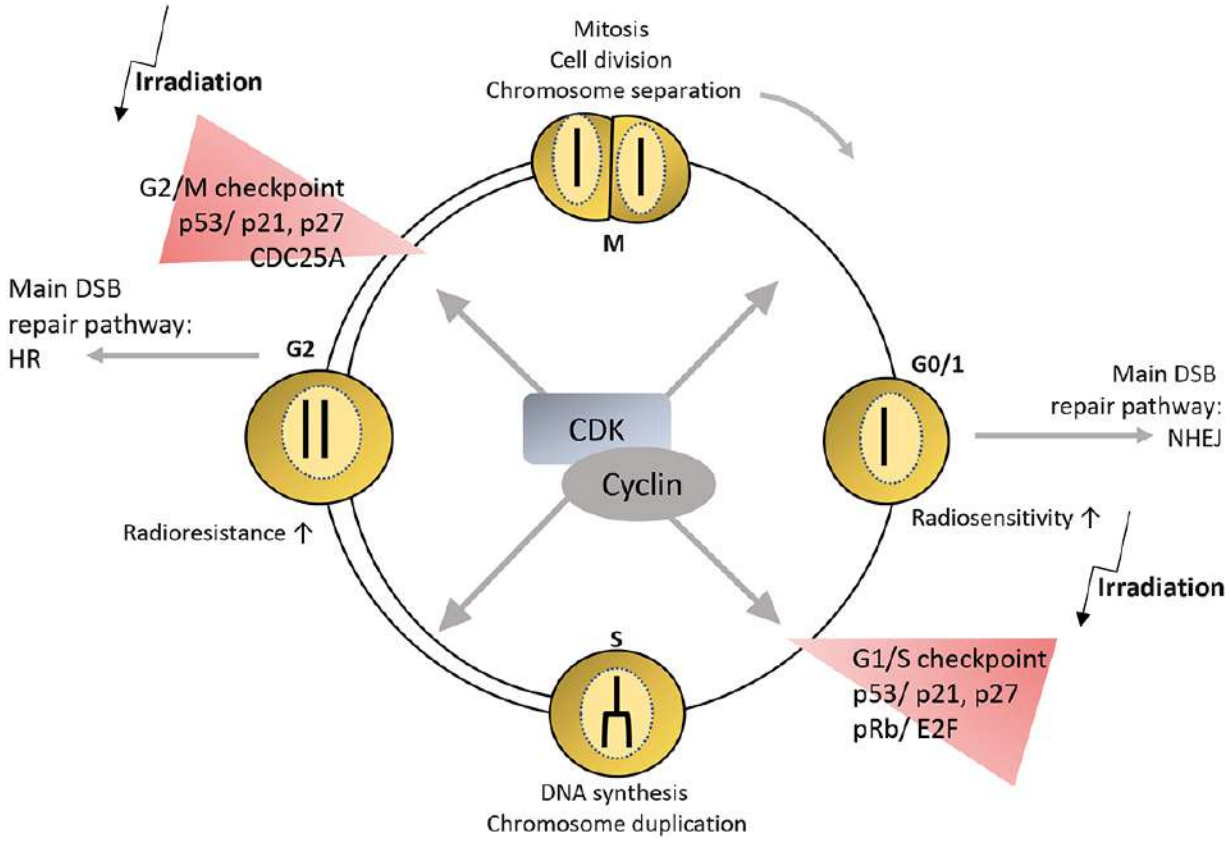

FIGURE 2.1 Cell cycle and checkpoints. The cell cycle is the backbone process that facilitates duplication of the DNA and cell division in order to generate two daughter cells. The distinct phases of the cell cycle are differently susceptible to irradiation damage. The highest radiation sensitivity is in early S and late G2/M phase. The cell cycle checkpoints in gap 1 (G1) and gap 2 phase ensure that the cell is ready for DNA synthesis (S phase) or mitosis (M). If the DNA is damaged the cell stops cycling and either the damage will get repaired and the cell continues with the cycle or the cell undergoes apoptosis and dies. Many types of cancer arise from mutations that lead to checkpoint misregulation or skipping of those. Cell cycle progression is governed by various cyclins and cyclin-dependent kinase (CDK). Different cyclin-CDK complexes determine targeted downstream proteins that, for example, promote DNA replication and degrade S-phase inhibitors.

Activating Invasion and Metastasis

Locoregional and distant spread of tumor cells requires detachment from the primary tumor, invasion into surrounding tissues, intravasation into blood or lymphatic vessels, anoikis resistance, adhesion to endothelial cells at distant sites, extravasation, and eventually colonization in distant organs.[28,36] The acquired capability of cancer cells to grow invasively and to metastasize is associated with multiple genetic and biochemical alterations of the cell-cell and cell-matrix interactions.[27,28] Tissue invasion and

metastasis require, at different steps, contrary capabilities—for example, detachment from the primary tumor versus adhesion at the metastatic site—suggesting that rapid adaptations, genetic instability, and clonal selection play an important role.[36] Primary tumors, by, for example, releasing membrane vesicles containing signaling molecules into the bloodstream, are also capable of remodeling the vasculature in distant organs, thereby creating organotropic pre-metastatic niches that enhance the ability of circulating metastatic cells to colonize these organs.[37,38] Also the intratumoral microenvironment of the primary tumor plays a key role; for example, hypoxia is described as one possible activator of metastasis.[39] To effectively metastasize, several critical steps are necessary, which involve epithelial to mesenchymal transition, extracellular matrix modulation, intravasation, circulation, extravasation, homing, forming the pre-metastatic niche for organotropic colonization, and mesenchymal to epithelial transition.[40,41]

Enabling Replicative Immortality

Loss of growth control and resistance to cell death are not sufficient for the development of macroscopic tumors. Normal cells have the capacity for a finite number of cell divisions, which results in a limited replicative potential. Thereafter cells either stop proliferating and enter the process of senescence, which is a viable but nonproliferative state, or they die.[28,42] During tumorigenesis, some premalignant cells become immortal by circumventing senescence, that is, by acquiring a capability of limitless replicative potential.[27,28] Of importance, malignant tumors consist of heterogeneous populations differing in their replicative potential. While most cancer cells have a limited replicative potential, a small subpopulation (ie, CSCs) have an infinite replicative capacity and the capability to reconstitute the tumor.[43] Thus, this subpopulation represents the target for curative cancer therapy, that is, all of these stem cells have to be inactivated by therapy or by host-related mechanisms to achieve cure.[18] It remains to be clarified whether CSCs represent distinct tumor cell subpopulations or whether they can switch between different stages in response to stress or environmental conditions.[44-46]

The molecular mechanisms underlying the escape from senescence and other modes of cell death include loss of tumor suppressor proteins such as p53 and pRb as well as telomere maintenance.[28] Telomeres are chromatin segments located at the ends of the chromosomes that protect these regions from recombination and degradation.[47] As telomeres are incompletely replicated, they become progressively shorter during cell divisions, subsequently resulting in loss of chromosomal protection, which in turn triggers senescence. Cancer cells generally have shorter telomeres than normal cells but are able to perpetuate their replicative potential by expressing telomerase, a complex including DNA polymerase, which reconstitutes the telomeres.[47]

Inducing or Accessing Vasculature

To grow beyond microscopically sized cell aggregates of around 1 mm, tumors depend on angiogenesis. Proliferating cells require appropriate oxygen and nutrient supply, which is physiologically limited to a distance of 100 to 200 μm from the next blood vessel. Therefore, malignant cells must induce and sustain their own vascular system to form tumors and metastases.[48] The process of the *angiogenic switch* during tumorigenesis (ie, the transition from the avascular phase to the vascular stage) is governed by different molecular changes in tumor cells and in cells of the surrounding stroma.[27,28,49] The major event of the angiogenic switch is that proangiogenic factors—mostly growth factors such as vascular endothelial growth factors (VEGFs), fibroblast growth factors, and platelet-derived growth factors (PDGFs)—outbalance antiangiogenic factors, such as thrombospondin (*TSP-1*), *angiostatin*, and *endostatin*. Hypoxia promotes tumor angiogenesis via the hypoxia-inducible factor 1, which transcriptionally regulates many angiogenic molecules.[50,51]

Resisting Cell Death

Under physiologic conditions, tissue homeostasis results from the balance of cell division and cell loss. This balance is disturbed in most tumors by an increased cell division rate due to the molecular mechanisms previously described and by a reduced rate of cell death, such as by apoptosis and senescence[27,28,52,53] (Table 2.1).

TABLE 2.1 TYPES OF RADIATION-INDUCED CELL DEATH AND THEIR CHARACTERISTICS

Type of Cell Death	Important Morphologic Characteristics	Important Molecular Mechanisms
Mitotic catastrophe	During or after mitosis, missegregation of chromosomes, cell fusion, micronuclei, giant cell formation	Lethal chromosome damage, caspase independent
Apoptosis	Chromatin condensation, nuclear fragmentation, blebbing of cell membrane	Damage to DNA, and/or membranes, and/or alterations of intracellular signaling, caspase dependent (intrinsic pathway via caspase 9)
Senescence	Metabolically active but nondividing, functionally differentiated cells	Damage to DNA and/or alterations of intracellular signaling, generally p53-dependent terminal growth arrest, increased senescence-associated β-galactosidase
Autophagy	Partial chromatin condensation, cell membrane blebbing, increased number of autophagic vesicles	Protein degradation characterized by double-membrane vesicles in the cytoplasm, possibly related to DNA protein kinase activity
Necroptosis	Early plasma membrane permeabilization, translucent cytosol, swollen mitochondria	Damage to DNA, and/or membranes, and/or alterations of intracellular signaling, caspase independent
Necrosis	Increased vacuolation, swelling of organelles and cells, rupture of cell membranes, formation of necrotic mass	Unregulated traumatic cell destruction; after irradiation as consequence of, for example, mitotic catastrophe or vascular damage

Deregulating and Reprogramming Cellular Metabolism

The sustained cell proliferation of cancer cells requires modifications and adjustments to and reprogramming of their energy metabolism.[28] Because deciphering the metabolome of cancer cells is still in its infancy, it is generally understood that all known metabolic pathways are altered and reprogrammed to provide a survival advantage.[54,55] Across the entire metabolome, cellular functions related to oxygen, pH, and glycolysis are the most intensively studied. Under aerobic conditions, normal cells use oxygen and pyruvate, which are split into carbon dioxide and water inside the

mitochondria to produce energy in the form of adenosine triphosphate. Under anaerobic conditions, cells rely solely on glycolysis—the breakdown of glucose into pyruvate. Cancer cells were shown to favor enhanced glycolysis for energy production, also under aerobic conditions, and this has been termed *aerobic glycolysis* or *Warburg effect*.[28,56-58] Glutamine and lactate have also been shown to serve as metabolic fuel in cancer cells.[59-61]

Avoiding Immune Destruction

During the development of cancer, antitumor responses represent a barrier that must be overcome. It has been shown that many types of tumors use different strategies to evade immune destruction. Tumor cells change such that surface expression of antigens renders them invisible to cytotoxic T cells or secrete immune inhibitory proteins.[62]

Tumor-Promoting Inflammation

Immune cell infiltration can be seen in most neoplastic tissues, but to a varying extent.[63] Inflammation has been shown to be involved in a number of hallmark capabilities by supplying growth and survival factors, proangiogenic factors, and extracellular matrix-modifying enzymes.[28,64-66] Furthermore, inflammation can drive the progression of cancers from incipient neoplasias.[28,66] The release of reactive oxygen species (ROS) by cells of the immune system can also have a mutagenic effect on surrounding cells.[28,65] However, the immune system is also capable of evoking an antitumor response.[67]

Genome Instability and Mutation

Genomic alterations or modifications of neoplastic cells are largely necessary to acquire the hallmarks outlined earlier. During tumor progression, not only mutations and epigenetic modifications but also nonmutational gene expression changes are leading to the accumulation of more favorable genotypes and clonal expansion of cells.[28] The identification of driver mutations leading to malignant progression is important also in terms of therapeutic targeting. For the detection of epigenomic changes,

more comprehensive analyses such as histone modifications and DNA methylation are necessary.[28,68]

Upcoming Hallmarks and Enabling Characteristics

Unlocking phenotypic plasticity can be achieved through several processes: (1) Through dedifferentiation, cancer cells can acquire the capability to revert to cellular states that are similar to that of progenitor cells. This has already been described for different entities such as colon cancer and malignant melanoma.[29,69-72] (2) Cells that are following the differentiation process may escape on the way, that is, maintaining in a not fully differentiated state, and thus serve as progenitors, leading to tumor progression as discovered in acute promyelocytic leukemia, melanoma, and others.[29,73,74] Thereby, cancer cells can also go into dormancy and escape into protective niches before eventually proliferating.[29] (3) Transdifferentiation may occur, during which cells switch between different development pathways, which may help to gain additional hallmark capabilities. An example is the development of adenosquamous esophageal cancer instead of squamous cell cancer that would be expected when cells arise from its original squamous epithelium.[29,70]

Nonmutational epigenetic reprogramming has been understood to be independent from changes in gene expression that are solely epigenetically regulated.[29] This form of epigenetic reprogramming is well known and needed in embryonic development, differentiation, and organogenesis.[29,75-77] However, during tumor development and progression, also microenvironmental mechanisms such as hypoxia-induced changes in the methylome are leading to reprogramming. Also, the deprivation of nutrients has been shown to cause inflammatory responses at transcriptional and translational level in tumor cells.[29,78] Epithelial to mesenchymal transition is another well-known example for microenvironmental-induced changes thus enhancing tumor growth in solid tumors.[29,79] Moreover, epigenetic heterogeneity has been linked with heterogeneous phenotypic states, as discovered through modern technologies.[29,80,81] Finally, the tumor microenvironment (TME) is also capable of recruiting and epigenetically modifying endothelial cells, cancer-associated fibroblasts, innate immune cells, and others through physical and soluble factors.[29,82]

Polymorphic microbiomes were shown to have an impact in cancer phenotypes. Especially bacteria have been identified that can positively or negatively affect the whole process of malignant transformation including development of cancer, malignant progression, and therapy response.[29,83,84] To date, the most important and best investigated microbiome is the gut microbiome, also because of its impact on the development of colon cancer. Studies have shown that the microbiome can have cancer-protective or cancer-promoting effects, which is due to a particular subset of bacteria.[29,85] Bacterial toxins and other secreted molecules can negatively impact the colon cells by promoting mutagenesis, by causing DNA damage with insufficient DNA repair, and others.[29,86] In addition, bacteria have been shown to enhance epithelial cell proliferation, which in turn may lead to an increasing number of neoplastic cells. In addition, bacteria are also capable of producing so-called immunomodulatory factors that lead to the activation of various chemokines and cytokines, which in turn affect both the number and characteristics of immune cells within the colonic epithelium, its associated stroma, and the draining lymphatic tissue,[29] but they may also be able to cross the epithelia and their connecting tight junctions and make their way into the stroma, which in turn activates the innate and adaptive immune systems, potentially leading to tumor-promoting inflammation and also determining response or nonresponse to various types of immunotherapy.[29,83,87-89] Interestingly, some (solid) tumor entities were also shown to be populated by a distinct microbiome that together with the gut microbiome affects the immune phenotype and, more importantly, also survival.[29,90]

Cellular senescence, more specifically the activation of a senescence-associated phenotype, may lead to the stimulation of tumor progression by affecting several processes such as proliferative signaling, induction of angiogenesis, and invasion and metastases.[29,91,92] Especially transitory senescence, where senescent cells can resume with cell proliferation and become a full tumor cell again, has been shown to be an important issue in the development of resistance to anticancer therapy.[29,93] Besides the senescence-associated phenotype, cancer-associated fibroblasts in the TME can also undergo senescence and thereby enhance malignant progression.[29,94,95]

PRINCIPLES OF MOLECULAR CANCER BIOLOGY

Carcinogenesis describes the transformation of normal cells into cancer cells and the subsequent development of a tumor. This is a multistep process that includes accumulating changes on the cellular, genetic, and epigenetic level and is characterized by abnormal cellular proliferation. However, these changes can differ between tumor cells within the same tumor leading to intratumoral heterogeneity but also between patients causing intertumoral heterogeneity.

Genetic cancer factors include somatic mutation, deletion, insertion, gene amplification, chromosomal instability and rearrangements, chromothripsis, loss of heterozygosity, and translocation. More than 700 cancer driver genes have been described up to date[96] that contribute to the above-described hallmark traits in cancer evolution and therapy resistance. A curated list of evidence-based driver genes can be found within the Cancer Gene Census of the Catalogue of Somatic Mutations in Cancer.[97]

Chromothripsis is a massive catastrophic single mutational event that is thought to occur at the onset of tumorigenesis and results in massive chromosomal rearrangements leading to loss of tumor suppressor function and activation of oncogenes, loss of cell cycle checkpoint regulation, and impaired DNA repair.[98] Recent pan-cancer studies revealed an average prevalence of 30% across all cancer types with a frequency above 50% in certain cancer entities.[99,100]

Epigenetic regulation of cancer, that is, a genomic mechanism that reversibly modifies gene expression without altering DNA sequences,[101] is less well defined, yet, and includes, for example, silencing of tumor suppressor genes by promoter hypermethylation, histone modifications, transcription of these modifications, chromatin remodeling, and the effects of transcription.[102] Chromatin remodeling and the effects of noncoding RNA such as microRNA expression are important epigenetic mechanisms in tumorigenesis.[33,35,103]

Environmental factors such as chemical agents, radiation and errors in DNA replication, infection with oncogenic viruses, as well as chronic inflammation caused by other infectious agents can also contribute to the development of human cancer (eg, human papillomaviruses in cervical or head and neck cancer, hepatitis B viruses in hepatocellular carcinoma, and

human immunodeficiency viruses in Kaposi sarcoma, bovine meat and milk factors, small episomal DNA molecules).[104-106] The hostile micromilieu in solid tumors, particularly hypoxia, further promotes progressive genomic alterations and clonal selection.[107,108] The potential role of the microbiome in cancer development, metastasis, and treatment response via secreted or modulated metabolites is increasingly recognized. Consequently, cells gain advantage in proliferation and survival, which eventually results in malignant transformation, a prerequisite for the development of cancer and metastatic spread.

Conceptually, three classes of cancer genes can be distinguished. First, *oncogenes* are activated in cancer cells by genomic alterations (vide supra) resulting in a gain of function. Typical oncogene functions are stimulation of cell proliferation (eg, by activation of Ras) and increase in cell survival (eg, by activation of phosphoinositide 3-kinase [PI3K]/Akt signaling). Disorders in the second class of cancer genes, *tumor suppressor genes*, which normally slow down cell division and instruct cells to die at the right time, cause loss of function and allow cells to grow out of control, leading to cancer. The third class of cancer genes are *DNA repair genes*, which help to repair DNA damage or trigger cell death if they can't repair the damage. While some cancers can be attributed to single genetic alterations, most sporadic solid tumors exhibit a wide range of disorders in numerous cancer genes. Simplified mathematical modeling of the increasing incidence of common cancers as a function of age suggests that four to seven somatic gene alterations are required for carcinogenesis.[109,110] A typical example for multistep tumorigenesis is the adenoma-carcinoma sequence in colorectal cancer.[111]

Inherited cancer predisposition can be divided into the rare group of inherited cancer syndromes and familial cancers (strong predisposition) and the more frequent group of predisposition without evident family clustering (weak predisposition).[112] The first group includes syndromes caused by germline mutations affecting DNA repair, genomic stability, and cell cycle control, for example, the tumor suppressor gene *TP53* (Li-Fraumeni syndrome), nucleotide excision repair genes (xeroderma pigmentosum), *ATM* (ataxia telangiectasia mutated), DNA mismatch repair genes (hereditary nonpolyposis colorectal cancer), and *BRCA 1/2* (familial breast cancer). An example of a familial cancer syndrome related to oncogene

activation is neurofibromatosis type 1, in which the mutated *NF1* gene results in activation of the Ras oncogene.[112] Germline mutations causing inactivation of the cell-cell adhesion molecule E-cadherin can be found, for example, in familial diffuse gastric carcinoma.[113] An ongoing debate is the question of how close the risk of cancer depends on the number of normal stem cell divisions in contrast to the influence of environmental factors.[114,115] Approximately 70% to 90% of cancers are believed to be related to environmental exposures.[116] This issue is highly relevant for public health considerations as it points to the "bad luck" hypothesis versus a cancer risk importantly effected by external influences. As a general note, more investigations into early precancerous lesions are key for a better understanding of tumorigenesis, the relative importance of intrinsic or external risk factors, as well as the rationale behind the development of potential interventions and preventive strategies. Current molecular knowledge of these processes is often extrapolated from observations made at much later stages of tumor progression, which may obscure and bias our understanding of the initial events.[117-119]

MOLECULAR RADIATION BIOLOGY

Biologic Consequences of Irradiation

The effects of ionizing radiation on cellular target molecules may lead to various functional consequences. These functional effects can be broadly categorized into cell death, repair, cell cycle effects, altered gene expression, modification of signal transduction, mutagenesis, and genomic instability (Figure 2.2). These categories are not exclusive.

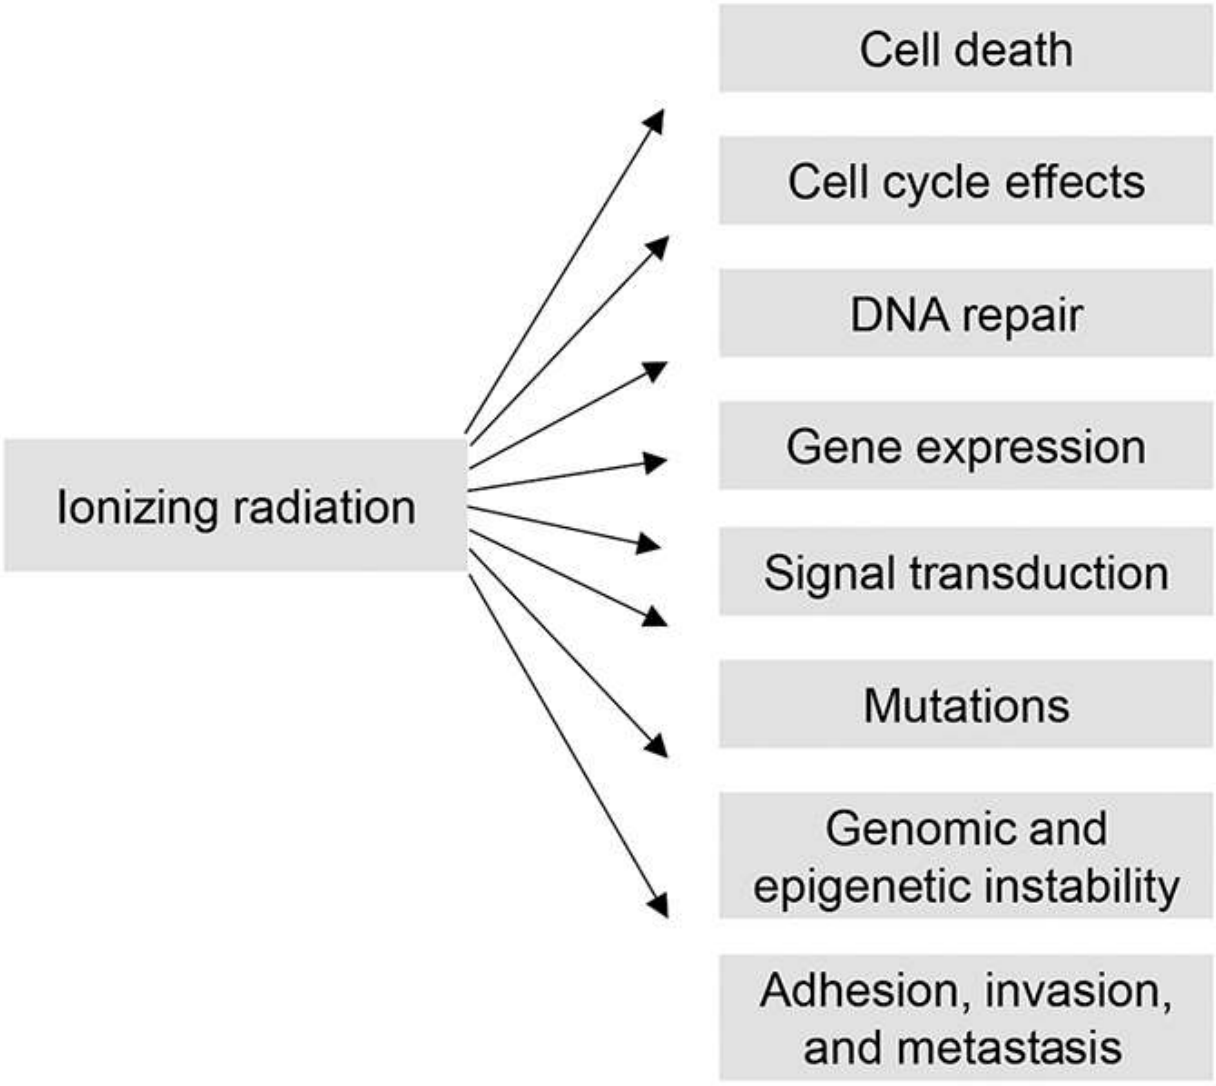

FIGURE 2.2 Illustration of cellular effects on ionizing radiation.

Cell Death

Among the functional consequences of ionizing radiation, cell death is the most important one for radiation oncology. Cells can die in several ways[120] —by apoptosis, mitotic catastrophe, senescence, necrosis, necroptosis, ferroptosis, disulfidptosis, pyroptosis, and autophagy (Figure 2.3 and Table 2.1). Most important for the cell killing effect of radiotherapy of solid tumors is the *mitotic catastrophe*, which is caused by lethal chromosome damage.[121] After irradiation, cells can pass through one or few mitotic cycles before missegregation of chromosomes or cell fusion leads to the loss of their replicative potential (or clonogenicity). Often micronuclei,

containing nonrepaired chromosome fragments, can be detected. Those micronuclei, and hence essential genetic information, will be lost during the following cell cycle, which results in cell death. Frequent multinucleate giant cells reflect a radiation-induced failure of cytoplasmatic separation on cell division.

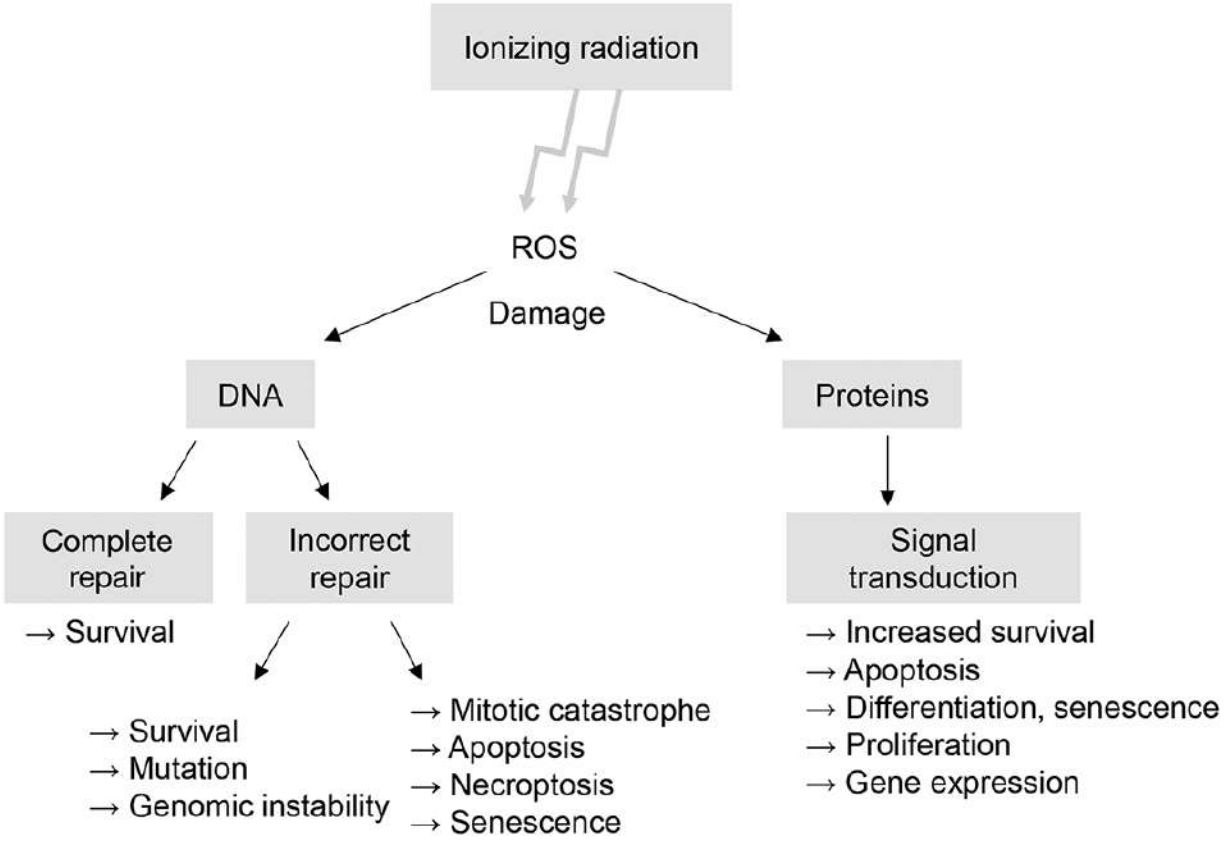

FIGURE 2.3 Simplified illustration of cellular reactive oxygen species (ROS) effects. The generation of ROS causes DNA and non-DNA damage and results in different cellular effects.

Neoplastic hematopoietic or lymphatic cells often die from radiation-induced *apoptosis* via the intrinsic, caspase 9-dependent pathway or pyroptosis.[122] Two different forms of radiation-induced apoptosis can be distinguished—early or premitotic versus late or postmitotic apoptosis.[123] Early apoptosis is p53 dependent, occurs within a few hours after irradiation before the cells enter mitosis, and is primarily a consequence of DNA damage. Early apoptosis represents a distinct mode of radiation-induced cell death. In contrast, secondary apoptosis occurs after mitosis and

is one of several possible manifestations of radiation-induced lethal chromosome aberrations and DNA damage. In most cancers, apoptosis appears not to be the main mechanism of radiation-induced cell death.[124]

Radiation-induced *senescence* plays an important role in the development of normal tissue damage—for example, fibrosis[125]—but occurs also in response to nonlethal stress in tumor cells.[126] Cells survive and are metabolically active but lose their replicative potential. *Necrosis* is an unregulated process of cell destruction by the release of intracellular components. This is usually the consequence of pathophysiologic conditions such as ischemia and inflammation.[120] It is well known that tumors often show massive necrosis after neoadjuvant radiotherapy or radiochemotherapy, which in some tumors correlates with improved prognosis.[127,128] It is likely that this radiation-induced necrosis is explained by several factors, including mitotic catastrophe of tumor cells and the effects of irradiation on tumor vessels leading to changes in the TME, which consequently cause cell death.

Necroptosis, the prototype of regulated necrosis, is a caspase-independent form of programmed cell death (PD) and kills apoptosis-deficient cells. It is stimulated by death receptor ligands of the tumor necrosis factor (TNF) receptor subfamily such as TNF-α, CD95 ligand, or tumor necrosis factor–related apoptosis-inducing ligand, but also by other receptors such as ectodermal dysplasia receptor.[129] Necroptosis can also be induced by other stress-inducing factors such as ionizing radiation, DNA-damaging agents as well as ROS.[130] Experimental data show that knockout of necroptotic genes leads to significantly enhanced radiosensitivity and reduces tumor formation in mice.[131] Other reported forms of regulated necrosis are ferroptosis, oxytosis, ETosis, NETosis, cyclophilin D–mediated regulated necrosis, parthanatos, pyroptosis, and pyronecrosis.[130]

Ferroptosis is a form of iron-dependent regulated cell death/necroptosis caused by ROS-induced lipid peroxidation by radiotherapy. Increased ferroptosis after radiotherapy correlates with improved patient survival.[132] Increased expression of cellular inhibitors of ferroptosis, such as SLC7A11 that protects cancer cells from oxidative stress, may contribute to radioresistance and provides a promising target for inhibitors.

Disulfidptosis is caused by extensive toxic levels of intracellular cystine and other disulfide molecules.[133] Moderate expression of SLC7A11, the

cystine transporter, seems to protect tumor cells from oxidative stress leading to therapy resistance, whereas overexpression leads to increased amounts of cystine in the tumor cell that cannot be reduced to cysteine via nicotinamide adenine dinucleotide phosphate.

Autophagy is a form of nonapoptotic and nonnecrotic cell death that is related to lysosomal degradation of proteins and cell organelles that are then utilized for the production of new cells.[120] This mode of PD is triggered by growth factor withdrawal, differentiation, and developmental stimuli. Although the molecular regulation is not completely understood, data suggest an ambiguous role of autophagy in radiotherapy response with evidence for cytoprotective and cytotoxic effects.[134] A high rate of autophagy contributes to radiation resistance, and autophagy is regulated through different hypoxia-dependent pathways, thereby cellular homeostasis and survival during metabolic stress.[134-136]

Target Molecules of Radiation Damage

Nuclear DNA, lipids, and proteins are considered as the three main target molecules of radiation-induced cell death or damage. Radiation effects may occur as direct ionizations in an organic molecule or indirectly via free radical processes. As cells consist mostly of water, most ionizations produced by irradiation occur in water molecules. Within only 10^{-10} seconds, radiolysis of water leads to, among other entities, e^{-}_{aq}, $H^{\cdot}$, and $OH^{\cdot}$. About 60% to 70% of cellular DNA damage produced by ionizing radiation is caused by OH.[137] The radiation-induced ROS undergo further reactions—for example, production of H_2O_2 from two hydroxyl radicals. Aerobes have evolved antioxidant defenses to protect themselves against the oxygen-derived species generated in vivo or from external sources. These defenses include enzymes (eg, superoxide dismutases, catalase, and glutathione peroxidase [GPX]), low-molecular-mass agents (eg, α-tocopherol and ascorbic acid), and proteins that bind metal ions in forms unable to catalyze the generation of free radicals. The oxygen molecule has a high affinity to free radicals, which may give rise to further cascades of radical production and thereby to the fixation of free radical damage to important macromolecules of the cell (eg, DNA). This is one explanation of the

oxygen effect of radiation damage, that is, the fact that well-oxygenated cells are more radiosensitive than hypoxic cells.[138,139]

By far the most important target for the biologic effects of ionizing radiation is the DNA (Figure 2.3). For example, irradiation of the cytoplasm of cells with short-range α-particles only leads to cell kill at very high doses, whereas 1,000-fold lower doses to the nucleus are sufficient to kill the cell.[140] Radioactive isotopes with short-range emission effectively kill cells when incorporated into the DNA but not when predominantly incorporated in cell membranes.[141] Modification of radiation-induced cell kill by different measures, including hypoxia, high linear energy transfer radiation, or hyperthermia is linked closely with a change in the induction and repair of DNA double-strand breaks (DSBs). Exposure of cells to about 1 Gy causes approximately 3,500 DNA injuries, 1,500 to 2,500 of which are damaged bases, 1,000 single-strand breaks (SSBs), 40 DSBs, and an estimated 100 to 200 local multiple-damaged sites, where one or several DSBs occur in close proximity to SSBs and base damage.[142] Most radiation-induced DNA damage is recognized and very efficiently repaired by the cell (*vide infra*). Importantly, it also has to be considered that different types of radiation treatment can cause different extent of damage to the DNA in a tumor cell. In contrast to photon therapy, particle therapy causes more severe DNA damage.[143,144]

Besides effects on DNA, ionizing radiation also evokes biologically important responses on proteins (eg, transmembrane receptors) and on lipids (eg, ceramides) (Figure 2.3). Radiation-induced activation of receptors will be discussed later in this chapter. Lipids are a critical buffer against ROS, maintaining lipid redox homeostasis and thereby ensuring cell survival.[145] The susceptibility of tumor cells to radiation-induced damage via lipid peroxidation depends on the ROS scavenging system involving glutathione and GPX4.[146] Radiation-induced lipid peroxidation triggers ferroptosis (*vide supra*).[147] Interestingly, FLASH irradiation, that is, ultra-high-dose-rate radiation, inhibits lipid peroxidation in liposomes and micelles, which may partly explain the FLASH effect of preserving normal tissue.[148]

Recognition of Radiation-Induced DNA Damage

The DNA damage response (DDR) to DNA DSBs and replication stress is orchestrated by the kinases ATM[149] and ataxia telangiectasia and Rad3-related (ATR)[127] signaling cascades (Figure 2.4).[150,151] In response to DNA damage ATM and ATR phosphorylate thousands of downstream effectors. ATM activation requires the highly conserved Mre11-Rad50-Nbs1 (MRN) complex and other factors at sites of DNA breaks.[152] Oxidation of ATM activates the kinase independently of the MRN complex.[153] In addition to proper activation of downstream DNA repair proteins, histone H2AX molecules need to be phosphorylated in the vicinity of the DSB. Phosphorylated H2AX, termed γH2AX, is therefore frequently used as surrogate marker for DSBs. All of these proteins assemble at the site of the breaks and presumably control the choice of one of several repair pathways. ATM is involved in the regulation of multiple cell cycle checkpoints (G1/S, S, G2/M) following DNA damage, thereby slowing cell cycle progression to allow for proper repair.[154] ATM, ATR, and DNA-dependent protein kinase catalytic subunit (DNA-PK_{CS}) phosphorylate p53 and a number of proteins involved in cell cycle delay, apoptosis, and induction of DNA repair. ATR appears to be important for sensing ultraviolet-related and other types of bulky lesions, as well as damage that induces a replication block, while ATM seems to be the sensor for DSB induced by ionizing radiation.[150]

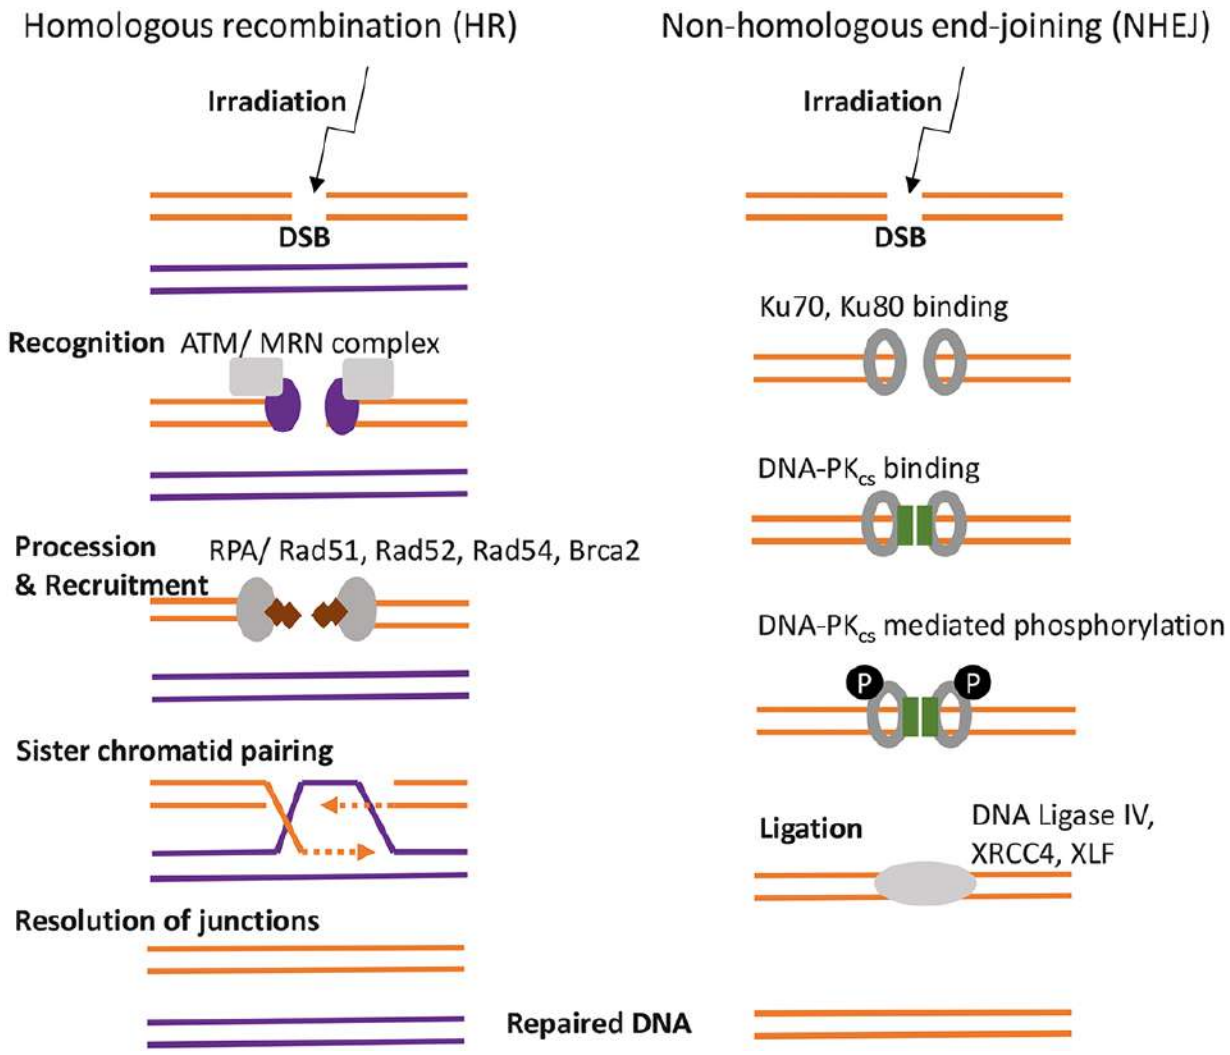

FIGURE 2.4 Main DNA double-strand break damage repair mechanisms. The more error-prone nonhomologous end-joining (NHEJ) is active throughout the whole cell cycle. For homologous recombination (HR) an identical DNA strand is necessary and used as template for precise repair.

DNA Repair

Genome integrity is essential to the survival of cells and organisms. It is estimated that about 10^4 DNA lesions occur in a single human cell every day.[155] Most of the damage is caused by endogenous sources such as oxygen free radicals, replicative errors, and spontaneous deaminations. To cope with the plethora of continuous damage, a repair system was developed during evolution that also acts on external challenges such as radiation or chemical DNA damage. To enable repair of massive DNA damage, the cells stop proliferation. This may prevent replication or segregation of damaged

genetic material. If repair is not possible, the cells either die or, in case of survival, may propagate mutated DNA (see Figure 2.4). When the DNA replication machinery meets damaged DNA, replication may continue despite the damage by translesion synthesis, which requires DNA polymerase with low fidelity. Different mechanisms are involved in DNA repair.[150,156]

Base Excision Repair

Base damages and SSB are the most frequent types of DNA damage after irradiation.[157,158] The mechanism of base excision repair (BER) is responsible for the repair of various kinds of base damage (abasic sites, oxidized bases, deaminated bases, and alkylated bases) and SSB. The major BER pathway is the short-patch pathway, which involves excision of only one base. SSBs are primarily recognized by the enzymes poly(ADP-ribose) polymerase (PARP)1 and PARP2.[151]

DSB Repair

Radiation-induced DSBs are, despite their relatively low induction frequency (40 Gy per cell), biologically much more important as they pose a higher threat to genome integrity than base damage and SSB and are far more difficult to repair.[151] There are two major pathways—homologous recombination (HR) and nonhomologous end-joining (NHEJ)—to repair DSB (Figure 2.5).[159,160]

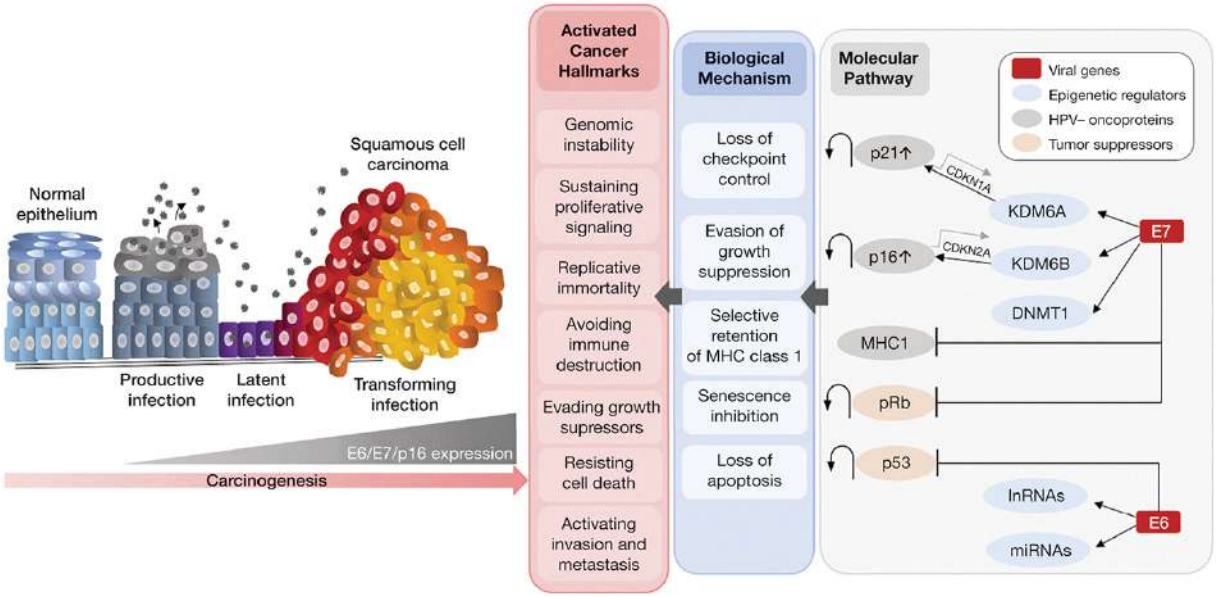

FIGURE 2.5 Human papillomavirus (HPV) infection and activation. Left: Microtraumas allow the entrance of HPVs to the epithelial basal cell layer. This is followed by the coordinate expression of different viral genes. E6/E7 causes viral genome amplification and shedding of the newly produced viral particles. Persistent expression can lead to malignant dysplasia once the HPV infection has established and evaded from immune recognition. Malignant transformation is characterized by loss of differentiation, high E6/E7 level, and no viral replication. Right: Mechanism of E6/E7-mediated addiction: The expression of the viral genes E6 and E7 inhibits the expression of the tumor suppressor genes p53 and pRP, respectively. E6-triggered inhibition of the tumor suppressor p53 leads to loss of apoptosis control and with this to uncontrolled growth of squamous carcinoma cells. The E7 oncoprotein inactivates pRb, which prevents oncogene-induced senescence. The epigenetic reprogramming via the E7-KDM6A/B axis leads to induction of p16 (used as histologic biomarker for HPV infection) and p21, resulting in loss of cell cycle control and avoidance of lethal replication stress. The intracellular mechanisms driven by HPV oncogenes are cancer hallmark–enabling processes.[299] E6 induces additional epigenetic regulators such as long noncoding RNAs and microRNAs that further contribute to HPV-driven tumor evolution and maintenance.

HR is a slow, high-fidelity repair pathway. Regions of DNA homology—usually the sister chromatid—are used as the template. During HR, activated ATM recruits endonucleases that process broken ends, which ultimately creates single-stranded 3′ ends. For the processing, the MRN complex is required. In concert with BRCA1, BRCA2, and Rad51 paralogues (XRCC-2, XRCC-3, Rad51B, Rad51C, Rad51D, Rad52, Rad54), the Rad51 protein binds to single-stranded DNA with the aid of replication protein A and searches for a homologous sequence on the sister

chromatid template. On strand invasion, Rad51 enables the formation of a temporary triple helix. Once the complementary strands have paired, the 3′ end of the damaged DNA will be elongated by DNA polymerase beyond the position of the former DSB. When the 3′ single strand of the second end of the DSB also invades the structure, a quadruple helix is formed called a *Holliday junction*, which can be extended in both directions. After the gap has been safely bridged (usually about 50 base pairs will be copied), the Holliday junction is resolved, and the remaining nicks are sealed by a DNA ligase.[161,162]

NHEJ is a fast pathway often referred to as error-prone repair pathway that rejoins DNA ends without needing a repair template, usually after removal of a limited number of base pairs.[163] Most (~80%) radiation-induced DSBs outside of S phase are repaired by NHEJ independently of ATM. NHEJ is initiated by the Ku70/Ku80 heterodimer, which binds to DNA ends and recruits the DNA-PK_{CS}. DNA-PK_{CS} can phosphorylate a variety of repair proteins such as Ku, x-ray cross-complementation protein 4 (XRCC-4), Artemis, p53, or replication protein A. However, only the autophosphorylation has been identified as being essential for repair. Artemis, in concert with DNA-PK_{CS}, trims the DSB ends for subsequent processing. After release of DNA-PK_{CS} from the DNA, the end will be bridged by the complex of ligase IV/XRCC-4/XRCC-4-like factor (XLF), which also performs the final ligation step. It has been observed that NHEJ can, to some extent, occur in the absence of several core proteins. This gave rise to the idea of a backup pathway that only operates when the DNA-PK-dependent NHEJ fails.[164] Besides the genuine repair proteins, the tumor suppressor p53 is involved in controlling the repair. p53 appears to suppress both HR and NHEJ in case an error-free repair is not possible and thereby reduces the mutagenic effect of radiation.[165]

Chromatin organization has also been shown to impact DSB induction and repair.[166-169] Chromatin is organized as euchromatin and heterochromatin, representing loose and condensed DNA areas, respectively. While DSBs in euchromatin are easily accessible for repair proteins, DSBs in heterochromatic DNA regions need to be moved to less condensed areas for efficient repair.[167,169]

Radiation-Induced Cell Cycle Delay

It has long been recognized that radiation-induced DNA damage is associated with delay in the cell cycle, which has been interpreted as allowing additional time for the cells to repair. Radiation-induced DSBs are key signals leading to arrest in the cell cycle at various stages in G1, S, and G2/M phase. Spindle assembly checkpoints arrest in the mitotic phase upon damage. Furthermore, DSBs can be found in all cell cycle phases, suggesting incomplete repair before entering the next phase. For example, tracking of radiation-induced γ H2AX foci, representing DSBs, revealed transfer of DSBs induced in the G1 cell cycle phase to daughter cells.[170]

G1 Phase

The G1 cell cycle checkpoint prevents damaged DNA from being replicated and is the best understood checkpoint in mammalian cells.[171] Radiation-induced G1 phase cell cycle arrest is regulated by p53 (see Figure 2.1). Loss of p53 function, which is found in most tumors, leads to a lack of G1-phase arrest. These cells only exert a dose-dependent block in the G2 and M phases of the cell cycle. Central to the G1 checkpoint is the accumulation and activation of the p53 protein, which is controlled by the ATM and ATR kinases. These kinases, together with DNA-PK, are activated by and recruited to radiation-induced DNA lesions. Physiologically, p53 expression levels are low due to interaction with its negative regulator MDM2, which targets p53 for nuclear export and proteasome- mediated degradation in the cytoplasm.[172] Following radiation-induced DNA damage, ATM activates the downstream cell cycle checkpoint kinase Chk2 by phosphorylation, leading to p53 phosphorylation and finally resulting in p53 accumulation. Moreover, ATM exerts p53 stability and thereby prevents p53 nuclear export to the cytoplasm for degradation. p53 target genes include several genes that are involved in the DDR (eg, *MDM2, GADD45A, CDKN1*). Accumulation of the cyclin-dependent kinase inhibitor $p21^{Cip1}$ blocks G1/S-phase progression by binding to the cyclin E/cdk2 complex, reducing cdk2 activity, which has an important function in the phosphorylation of retinoblastoma protein pRb.[173] Loss of pRb function is often found in malignant cells and leads to an uncontrolled G1/S transition, genomic instability, and loss of differentiation.

S Phase

After irradiation, the rate of DNA synthesis is decreased via ATM- and NBS1-dependent pathways.[174] Radiation-induced DNA damage activates ATM for Thr68 phosphorylation of Chk2.[175] Activated Chk2 targets CDC25A phosphatase for ubiquitination. As a result, Cdk2/cyclin E and Cdk2/cyclin A complexes remain inactive, which prevents completion of DNA synthesis and G2 entry. Alternatively, radiation-activated ATM phosphorylates several downstream substrates, including BRCA1, NBS1, and SMC1.[175,176] ATR phosphorylates the cell cycle checkpoint kinase Chk1. Subsequently, Chk1 phosphorylates CDC25A, which results in cytoplasmic sequestration and thereby inhibition of S-G2 transition.[177]

G2/M Phase

In contrast to the G1 checkpoint, all mammalian cells, normal or transformed, undergo cell cycle arrest in G2 after radiation-induced damage.[178] The G2 cell cycle checkpoint is the essential final determinant allowing cells to divide. The entry into mitosis is regulated by the activity of the cyclin- dependent kinase Cdk1[179] (see Figure 2.1). Phosphorylation of Cdk1 blocks cell entry into G2. These phosphorylations are removed by the phosphatase CDC25C. After irradiation, ATR and ATM activate the downstream checkpoint kinases Chk1 and Chk2, which phosphorylate CDC25C.[180] This results in binding of 14-3-3 proteins. The CDC25C/14-3-3 protein complex is translocated into the cytoplasm for sequestration. As a consequence of this CDC25C degradation, Cdk1 remains phosphorylated, thereby preventing entry into mitosis. ATM appears to be more dominant at the early stage of G2/M checkpoint activation, whereas ATR seems to contribute mainly to sustained checkpoint events.[181] G2/M arrest prevents cells from entering mitosis in the presence of DSBs.[182]

Molecular Targets for Radiotherapy

Molecularly targeted anticancer drugs specifically interfere with signaling pathways that keep tumor cells alive, thereby affecting the “hallmarks of cancer” mechanisms inside a tumor cell. Most clinically used anticancer agents are not developed for use in radiotherapy. A major challenge is to define the optimal dose, timing, and drug distribution for combination

therapies and to evaluate and utilize synergistic potentials between the drugs and irradiation. Therapeutic success is highly dependent on proper patient stratification and the ability to predict the response potential of a given combination.[4] Tumor cells respond to radiation by altering the expression or downstream signaling of the desired target molecule. The effect of a targeted drug in combination with radiotherapy is highly dependent not only on the expression but also on the alterations of the target molecule under irradiation. Different radiation qualities, such as photons versus particles, may trigger different molecular signaling pathways. With increasing molecular investigations and novel sequencing techniques, many putative targets have emerged. However, druggability is not always given, and some other considerations have to be taken into account. Not all differentially expressed genes, pathways, and mutations are necessarily critical for cancer progression and maintenance but instead represent so-called passenger mutations and only coincide within the particular cancer; they do not reflect the actual driving force of malignancy, which, as described above, is often due to three driver mutations.[183] This does not facilitate the selection of potential targets and patient stratification. Cell surface–associated proteins such as serine/threonine/tyrosine kinases, growth factor receptors, G protein–coupled receptors, and receptor ligands are classical druggable targets. Intracellular molecular targets that do not function as an enzyme, but are loss-of-function targets, such as tumor suppressors, are not directly druggable. Transcription factors are also considered undruggable, but recent advances in understanding the regulation of transcription factors such as c-Myc, YAP/TAZ, and β-catenin are emerging and may lead to useful drug approaches.[184]

RTK

Receptor tyrosine kinases (RTKs) represent a group of transmembrane receptors consisting, if complete, of an extracellular ligand-binding domain, a transmembrane part, and an intracellular catalytic domain with tyrosine kinase activity.[185] RTKs are central to cell growth and survival, hence most cancers rely on their activity.[186] Upon ligand binding and receptor homo- or heterodimerization, the protein kinase is subsequently activated, resulting in phosphorylation of tyrosine residues of the receptor itself

(autophosphorylation) or target proteins. Depending on the cellular context, this triggers an intracellular signaling cascade that eventually leads to proliferation, survival, differentiation, and migration. Among the known human RTKs are the epidermal growth factor receptors (EGFRs), the PDGF receptors, the VEGF receptors (VEGFRs), the fibroblast growth factor receptors, the ephrin receptors, and tyrosine kinase receptor. RTK dysregulation is implicated in many cancers, driven by their overexpression, activating mutations, oncogenic fusions, and ligand dysregulation, making them attractive targets for molecular drugs.[186]

EGFRs

The *EGFR family* consists of four distinct members (EGFR/ErbB-1, HER2/ErbB-2, HER3/ErbB-3, and HER4/ErbB-4) that are dimerized after ligand binding to the extracellular domain.[187,188] The receptor ligands, such as epidermal growth factor (EGF), tumor growth factor alpha (TGF-α), and neuregulin-1, as well as their cognate receptors, are abundantly expressed in a large variety of human cancers, including lung, breast, head and neck, and gliomas, and have been related to poor prognosis. The EGFR is being activated through its natural ligands such as EGF, TGF-α, or amphiregulin and can be transactivated by cell adhesion molecules such as integrins or immunoglobulin-like receptors.[189] In addition, ionizing radiation is able to stimulate EGFR.[190] Radiation doses of 1 to 2 Gy activate the EGFR and its downstream signaling cascades with similar efficiency as physiologic EGF concentrations of 0.1 to 1 nM. EGFR signaling via Ras-Raf-MAPK after irradiation has been implicated in increased proliferation,[191] which corresponds to observations that EGFR overexpression is associated with repopulation during fractionated irradiation.[192-194] In addition, EGFR-dependent signaling via PI3K/Akt has been associated with increased cellular survival and cell cycle progression.[195,196] Monoclonal antibodies and tyrosine kinase inhibitors against the EGFR have been investigated in the past 20 years without showing clinical superiority over cisplatin-based combined radiotherapy (summarized by Krishnamurthy et al[197]). A direct comparison in unselected patients with head and neck squamous cell carcinoma (HNSCC) even revealed a lower locoregional control rate after cetuximab versus cisplatinum.[198] Preclinically, EGFR amplification status in

combination with gene expression profiling has been shown to have predictive potential, suggesting that appropriate patient stratification is necessary to guide anti-EGFR therapy.[199] In addition, a combined approach of molecularly radiolabeled anti-EGFR antibodies plus radiotherapy may have the potential to improve curative outcomes.[200] As also shown preclinically, EGFR tyrosine kinase inhibitors may be able to offset the negative impact of KRAS mutations on local tumor control after radiotherapy.[201] The heterogeneity of the results suggests the need to improve patient selection and preclinical testing of combined modality drugs.

PI3K/AKT/mTOR and the Ras-Raf-MEK-ERK Pathway

Inhibitors of the PI3K/AKT/mTOR and the Ras-Raf-MEK-ERK pathways aim to target important signal transduction routes within RTK signaling. Constitutive activation of the mammalian target of rapamycin (mTOR) is a key PI3K/AKT signaling molecule that contributes to radioresistance. Dual PI3K/AKT/mTOR inhibitors are currently under investigation and have shown promising therapy improvement for patients with non–small cell lung cancer (NSCLC) with Ras mutations.[202]

The *Ras proteins* (H-Ras, K-Ras4A, K-Ras4B, and N-Ras) are GTPases and are attached in their active state (GTP bound) to the inner surface of the cell membrane. The Ras proto- oncogene, predominantly K-Ras, is mutated in about one-third of human cancers. Activating mutations are frequent in adenocarcinomas of the pancreas (up to 90%), colorectum (about 50%), and the lung (about 30%).[203] The processing and membrane attachment of the functional Ras are governed by farnesyltransferases, which are the molecular target for specific pharmaceutical inhibitors of activated Ras.[204] Activated Ras has an effect on various downstream molecules, including *PI3K*.[205] Signaling mediator molecules of PI3K include phosphoinositide-dependent kinase 1, Akt, protein kinase C, and subsequently the nuclear transcription factor nuclear factor kappa B (NF-κB). The cellular responses on activation of the PI3K pathway are cell type specific and include changes in gene expression, cell cycle progression, survival, and apoptosis. The tumor suppressor protein *PTEN* negatively regulates the PI3K/Akt pathway. Akt overexpression or hyperactivity and PTEN mutations are

found in numerous human malignancies.[206] Therefore, Ras proteins and their signaling pathways represent attractive targets for combined radiotherapy treatment. To date, most Ras-Raf-MEK-ERK inhibitors have only been tested as monotherapies and warrant further investigation in combination with radiotherapy.

VEGFR-Mediated Signaling

For neoangiogenesis the VEGF plays an important role in cancer therapy as there is almost no angiogenesis in adults except in growing tumors. Transmembrane receptors for VEGF and related ligands include VEGFR-1 (Flt-1), VEGFR-2 (KDR/Flk-1), VEGFR-3 (Flt-4), neuropilin-1, and neuropilin-2.[207] Upregulated VEGFR expression has been found after ionizing irradiation.[208,209] Besides normalizing the tumor micromilieu,[210] inhibition of radiation-induced VEGF/VEGFR signaling represents the rationale for combining anti-VEGF strategies with radiotherapy. First clinical trials combining anti- angiogenic drugs with radiotherapy are awaiting randomized phase III results. A summary of the clinical progress can be found in Hamming et al and Goedegebuure et al.[211,212]

Immune Checkpoints

Immune therapy today uses predominantly checkpoint blockade, targeting the PD protein 1 (PD-1)/PD ligand 1 (PD-L1) and cytotoxic T-lymphocyte–associated protein 4 (CTLA-4). This immune checkpoint blockade (ICB) relies on the abundance and activity of immune effector cells within the TME.[149] For tumor infiltration, immune cells require a normal vasculature (see earlier). Radiotherapy has the potential to reprogram non-immune "cold" TMEs into immunoreactive "hot" tumors, thereby facilitating ICB and in parallel promoting neoantigen expression on the tumor cell surface.[213] Radiotherapy- induced DNA damage can induce the cytoplasmic DNA–sensing cyclic guanosine monophosphate–adenosine monophosphate synthase (cGAS)-stimulator of interferon genes (STING) pathway, which induces type I interferon production and inflammatory cytokine secretion necessary for T-cell infiltration into the TME.[214,215] Radiotherapy combined with ICB has been shown to enhance so-called abscopal effects (ie, response of tumor deposits not directly exposed to radiation) in numerous

clinical and preclinical studies.[216] The immunologic effects of different types of radiation are currently poorly understood. ICB concentrations, fractionation schemes, and radiotherapy doses as well as the optimal sequence of ICB and fractionated radiotherapy are currently being investigated for combined ICB-radiotherapy optimization.

Wnt Signaling

Wnt proteins are diffusible growth factors that bind to specific surface receptors (Frizzled) and trigger distinct intracellular pathways leading to cell growth.[217] Wnt signaling involves the tumor suppressor protein adenomatous polyposis coli (APC) and regulates by phosphorylation the steady-state levels of cytosolic β-catenin. An increased level of β-catenin facilitates its transit into the nucleus, activation of transcription factors, and subsequently transcription of β-catenin target genes, including *MYC*, *JUN*, *CCND1*, and *ALDH1A1*.[218,219] The aberrant activation of Wnt signaling caused by mutations in the β-catenin and *APC* genes are typical findings in colon cancer and melanoma but also have been identified in a large variety of other human cancers. Wnt/β-catenin signaling has been shown to play an important role in tumorigenesis, CSC self-renewal and differentiation, and radioresistance, making it a promising target for cancer therapy.[220]

Integrin-Mediated Signaling

Crosstalk between tumor cells and tumor stroma has emerged as an important determinant for tumor response to radiation and as a potential target for novel therapeutic combinations. Interactions between cells and extracellular matrix proteins are facilitated mainly by the integrin family of cell adhesion molecules.[221] Resistance-promoting effects by integrin-mediated adhesion to extracellular matrix were found in cell lines from solid tumors of the lung,[222,223] breast,[224] liver,[225] colon,[226] pancreas,[227-229] ovary,[230] prostate,[231] brain,[232] and leukemia cells.[233] Certain integrins seem to communicate increased radiation and drug resistance, which is cooperatively influenced by RTKs like EGFR.[234,235] For example, α5β1 integrin, the “classic” fibronectin receptor, acts as a major antagonist of cell death induced by doxorubicin or melphalan in multiple myeloma,[236] by paclitaxel in breast cancer or small cell cancer and NSCLC,[237,238] or by

cisplatin or mitomycin C in NSCLC.[237] Additional studies underscored the important role of β1 integrins in promoting resistance against ionizing radiation.[239,240] In addition to regulating cell survival, cell-matrix interactions affect radiation-induced cell cycle arrest, that is, adhesion of cells to matrix proteins prolongs the G1 and G2 cell cycle blockage in parallel with enhanced activation of DNA repair pathways involving the checkpoint kinases Chk1, Chk2, Cdk1, p53, and diverse cyclins.[237,241-243] Following radiation exposure, the expression of several integrin subunits, including β1, β3, α5, and αv, is upregulated in human skin and lung fibroblasts,[227] endothelial cells, and keratinocytes,[244] as well as in tumor cells of the colon,[226] hematopoietic cells,[245] prostate,[246] lung,[247] brain,[248] and melanomas.[227] Generally, integrin-mediated adhesion to matrix proteins confers chemoresistance and radioresistance.[233,234,249,250] Integrin antagonists and monoclonal antibodies are currently under clinical investigation (summarized by Li et al).[251]

Transcription Factors

Transcription factors bind to the DNA and activate the expression of specific genes. Oncogenic transcription factors are overactive in most human cancers and contribute to the autonomy of growth signaling. Key dysregulated transcriptional programs in cancer cells and how they are altered upon radiotherapy provide opportunities for therapeutic intervention.[252] Transcription factors as such are not druggable at present (see earlier).

Cancer Stem Cells

Malignant tumors are composed of genetically and phenotypically heterogeneous cells in various differentiation states. Within this pool, CSCs are considered the major cell population responsible for tumor initiation, growth, and relapse as well as for metastasis formation and therapy resistance.[253] Evidence shows that CSCs, which constitute a rather small fraction of the tumor mass, are often stunningly resistant to cytotoxic therapies as compared to the bulk tumor cells.[254] This is one of the reasons why the reduction of tumor mass is not an adequate measure of therapy success.[18] The identification of CSC populations within a tumor represents a

promising strategy for prognosis, prediction, and also targeting of aggressive tumors (also see section “Molecular Stratification Toward Personalized Radiotherapy”). However, identification and targeting of CSC is challenged by the high inter- and intratumoral diversity of different putative stem cell populations and CSC plasticity during cancer evolution and treatment. The CSC phenotype does not describe a static subpopulation but rather a highly dynamic intrinsic property of a tumor cell. This means that the CSC pool might be reestablished by non-CSC tumor mass cells and cancer therapy can only be effective when eradicating both tumor mass and CSC simultaneously.[255]

Targeting the signaling axes of CSC alone and in combination with cytotoxic drugs and/or radiotherapy is one approach. For example, simultaneous application of radiotherapy and putatively targeting the CSCs using a monoclonal antibody to the CSC marker CD44 (specifically targeting CD44v6) showed significant higher tumor control rates compared to radiotherapy alone in vitro.[256] CSC signaling pathways often shared with normal stem cells include Notch, Hedgehog, and Wnt/β-catenin signaling.[257] Activated Wnt/β-catenin signaling, for instance, is one of the key pathways during embryonic development and is described for carcinogenesis, epithelial to mesenchymal transition, and radiation resistance, such as summarized by Yang et al.[220] The first clinical phase I trial in patients with previously treated metastatic or untreated tumors applying the Wnt signaling inhibitor ipafricept (FZD8-Fc, *OMP-54F28*) showed safety and resulted in stable disease in some of the patients analyzed but could not lead to partial or complete remission.[258] Another phase I trial investigated the combination of ipafricept with cytotoxic drugs (gemcitabine and nab-paclitaxel) in patients with previously untreated advanced pancreatic cancer, which improved therapy outcome. However, this combined therapy approach was also associated with increased toxicity.[259] In both trials, the expression of Wnt signaling genes as well as CSC genes was downregulated after therapy in comparison to their pretreatment expression.[258,259] Another promising example for CSC signaling pathway targeting is the monoclonal antibody demcizumab, which inhibits the Notch signaling pathway by preventing DLL4-mediated Notch signaling, and has been tested in combination with carboplatin and pemetrexed in metastatic nonsquamous NSCLC.[260] While again, at least grade 3 toxicity was

observed in the majority of patients because of the combined treatment approach, a high response rate was observed.[260] Many other combinations are being tested in early clinical trials, for example, as recently summarized by Philchenkov and Dubrovska.[261] Both preclinical and clinical trials studying combined treatment of these novel agents with radiotherapy are awaited.

Metastatic spread is caused by disseminated tumor cells with CSC characteristics that leave the primary tumor and settle and grow at distant hostile places in the body. The transport phase of those cells, then called circulating tumor cells (CTCs), through the blood system represents another attractive diagnostic and therapeutic target. However, there is still no standard definition of those CTCs. To date, the magnetic bead–mediated CellSearch system is the only U.S. Food and Drug Administration (FDA)-approved method for the enrichment of epithelial cell adhesion molecule (EpCAM) expressing CTCs. Within the context of clinical studies, but with no FDA approval yet, the RareCyte liquid biopsy platform is being used, which is based on the identification of nucleated cells, which express EpCAM and cytokeratin, but lack CD45.[262] Counts of EpCAM-positive cells show significant prognostic relevance for patients with breast and prostate cancer.[263-265] Further biomarkers for the identification of CTCs are under investigation in different tumor entities. Also, methods for CTC enrichment are evolving, such as patient-derived CSC/3D cultures, that are being accumulated from the patient's tumor cell culture. This method also formed the basis for a randomized clinical trial in patients with recurrent glioblastoma, where successful enrichment was based on increased positivity in CD44, CD24, and CD133 cells.[266] Patients receiving a selected chemotherapy based on the CSC assay showed very promising results, with a prolonged overall survival.[266]

Several CSC-directed therapies are being tested in phase I/II clinical trials. For the implementation in the clinics, this requires not only the development of appropriate, standardized methods for CSC-specific analyses for screening and to measure CSC response, but also selection of appropriate CSC-based clinical endpoints such as locoregional tumor control.[261]

The CSC niche as a tumor-supporting microenvironment resembles another potential target for anti-CSC therapies. The niche maintains and

sustains CSCs and orchestrates their fate decisions via extracellular matrix molecules, cell-to-cell contacts, pH value, vascularization, hypoxia, etc, that may induce, for instance, stem cell–related signaling cascades.[39] Thereby the niche also provides a protective microenvironment for CSCs, for example, hypoxia can induce quiescence of the cells.[45] Thus, the cells escape chemotherapy, which mainly attacks rapidly proliferating cells. However, the extracellular matrix molecules and their cognate receptors on the CSC surface represent further potential druggable targets. One example is the c-Met protein, which can be targeted by the multitargeted inhibitors cabozantinib or crizotinib.[267,268] The CSC metabolism, in part intrinsically regulated, also depends on the microenvironment and the given nutrition supply, comprising a targetable CSC feature. One example is a hypoxic microenvironment. Preclinical studies showed that application of the hypoxic cell sensitizer nimorazole prior to radiotherapy can lead to higher local control rates in a subset of HNSCC compared to radiotherapy alone,[269,270] but selection of patients requires further biomarkers.[269,271] Safety of nimorazole has been shown in the clinical setting.[272]

Epigenetics

A variety of epigenetic mechanisms contribute to tumor heterogeneity and to the initiation and maintenance of CSC traits. Per definition, epigenetics defines stable heritable changes in gene expression that are not caused by changes in the underlying DNA sequence.[35] Chromatin and histone modifications and DNA methylation are epigenetic key mechanisms that are influenced by cancer risk factors such as chronic inflammation, aging, and environmental changes including radiation. Replication of DNA methylation is highly error prone, and it is contemplated that not only genomic but also epigenetic instability drives tumorigenesis and heterogeneity.[68,273,274] Epigenetic alterations can silence or activate genes and thereby offer tumor cells two possible choices to rapidly evolve under therapy pressure, which can lead to therapy resistance and tumor relapse.[35] Epigenetic therapeutics can reverse those epigenetic changes and resensitize tumor cells. Epigenetic drugs such as enhancer of zeste homolog 2 (EZH2), isocitrate dehydrogenase (IDH), and bromodomain and extra-terminal inhibitors are currently under investigation in clinical trials.[275,276] IDH1

mutations lead to DNA and histone hypermethylation. The IDH1 R132 mutation is of particular interest because it can also act as a so-called neoantigen (*vide infra*). Peptide vaccines that capture this mutated region are currently under development and testing.[277] Epigenetic changes such as the IDH1 R132 mutation can directly affect tumor immune evasion because DNA hypermethylation and promoter methylation can regulate the expression of cancer antigens and foster the evolvement of neoantigens. Therefore, epigenetic inhibitors also play an important role in immunotargeting. How the epigenetic machinery is affected by radiotherapy is not yet fully understood, so few clinical trials are currently being conducted that combine epigenetic targeting with radiotherapy. (Note: The histone phosphorylation γH2AX mentioned earlier is the best-known epigenetic modification following radiotherapy, which is rapidly reversed within a few days.) Another well-known epigenetic example is promoter methylation of the O6-methylguanine DNA methyltransferase (MGMT) gene, a DNA mismatch repair gene, which results in suppressed MGMT enzyme activity and increased sensitivity of glioblastoma to temozolomide.[278]

Antitumor Immunity

Mutagenesis as well as genomic and epigenomic instability in the tumor can lead to the expression of tumor-specific mutant proteins (neoantigens) that are not present on normal cells.[279] Neoantigens are short peptides presented by major histocompatibility complexes on the tumor cell surface and thereby become recognizable to T cells as foreign antigen. Those neoantigens resemble attractive immune targets with minimal risk of autoimmunity and immune tolerance, because of their exclusive presentation on the surface of tumor cells. Also, virus antigens can be released by tumors with a viral etiology (eg, human papillomavirus [HPV]-caused cancers of the cervix and the oropharynx). However, neoantigens arise in most cases from unique mutations, which complicates identification and needs individualized targeted immunotherapy. Current advancements in proteomics, genomics, and sequencing coupled with epitope prediction algorithms are speeding up the future development of such therapy approaches. Immune checkpoint inhibitors targeting CTLA-4 and PD-1

were shown to provide clinical benefit in melanoma,[280] NSCLC, and others.[281] In recent years, clinical studies have been investigating them not only in second-line therapy or later but also—often in combination with cytotoxic drugs—in first-line therapy such as in patients with recurrent or metastatic cervical cancer[282] or HNSCC.[283] Recently, a randomized, double-blind, phase III clinical trial in patients with locally advanced cervical cancer has shown, that the addition of pembrolizumab to primary radiochemotherapy leads to significantly improved progression-free survival (*clinicaltrials.gov*, NCT04221945).[284] However, this combined therapy is associated with an increasing severity of therapy-related side effects and thus requires optimal patient selection in the future.

Also, cell-based therapies, including engineered bispecific T cells and chimeric antigen receptor T cells have been shown to be therapeutically active in several cancers, including leukemia.[285,286]

Radiation therapy has been increasingly shown to cause systemic activation and local expansion of CD8+ T cells in preclinical as well as clinical studies, which is due to the cell surface localization of many tumor-associated antigens as well as presentation of neoantigens.[287] The combination of radiotherapy and immune checkpoint inhibitors has not only been shown to be tolerable in clinical studies but may also suggest a radiotherapy-enhanced response rate to immunotherapy in some but not all tumor entities.[288-290] More clinical studies assessing the combinational effect of radiotherapy plus immunotherapy and biomarkers for appropriate patient selection are needed.

Human Papillomavirus

Oncogenic viruses such as HPV are contributing to carcinogenesis and are driving malignant progression. Papillomaviruses are small, nonenveloped, double-stranded circular DNA viruses. More than 200 HPV genotypes have been identified, including low-risk and high-risk subtypes.[291] Especially the high-risk subtypes HPV16 and HPV18 are known to cause a variety of carcinomas such as cervical cancer, oropharyngeal cancer, and anal cancer. While traditional risk factors like tobacco use have been declining in recent years, a noteworthy upward trend in the incidence of HPV-driven cancers has emerged. The most effective approach to address this rising trend is to

prevent HPV infection. Vaccination programs for youth are being implemented worldwide to address this pressing issue.[292,293]

In contrast to most viral infections, where virions are produced directly in the target cell, the syntheses of new HPV virions occurs only after the target cell has undergone mitosis, followed by differentiation of one of its daughter cell.[294] HPV infects proliferating cells in the basal layer of stratified squamous epithelia following microtrauma, and leads to the establishment of the HPV genome as extrachromosomal elements or episomes. Since HPV genomes lack the necessary replication machinery, they rely on the host's DNA replication machinery to replicate viral DNA.[295] During early infection, the virus remains relatively inactive but prevents the cell from entering a resting phase (G0). After undergoing differentiation, virus-infected cells remain active in the cell cycle. In the suprabasal layers, some cells are still able to reenter the S phase in order to replicate HPV genomes and synthesize virions. When the epithelial cells reach the outer layer, the HPV virions are released.[294]

HPV infection triggers an immune response, but the virus has evolved sophisticated mechanisms to evade immune clearance, including interference with antigen processing and presentation. Despite these evasion mechanisms, HPV-specific immune responses can occur in HPV-driven cancers, which suggests that the immune system can still recognize and respond to HPV infection.[296] The presence of an HPV-specific immune response is a strong prognostic marker for patients with HPV-driven cancer, with significantly improved disease-specific survival in those with detectable HPV-specific T cells.[297,298] This highlights the role of the immune system in controlling HPV-driven cancer growth and metastasis.

HPV carcinogenesis is driven by two key viral oncoproteins, E6 and E7, which inactivate two important cellular tumor suppressor proteins—p53 and pRb, respectively. This inactivation is a fundamental step in the development of HPV-associated cancers, since it disrupts the normal control of cell cycle progression, leading to uncontrolled proliferation and malignant transformation of the affected tissue.[299,300] While increased E6 and E7 expression is associated with viral DNA integration into the host genome, carcinogenesis has also been observed in cases lacking integration, where the presence of viral episomes was identified.[301]

The E6 oncoprotein targets and degrades p53, a critical regulator of cell cycle arrest and apoptosis. The loss of the tumor suppressor gene *p53* leads to defective control at the G1/S and G2/M checkpoints and subsequently to uncontrolled cell cycle progression.[302] The HPV E7 oncoprotein binds to proteins of the pRb and targets them for degradation. The degradation of Rb proteins removes the inhibitory effect of Rb on E2 transcription factors inducing the expression of genes involved in S-phase progression, initiating the cell cycle.[303] The inactivation of the pRb pathway by E7 also disrupts the normal negative feedback loop that controls the expression of the tumor suppressor protein p16. Normally, the Rb-E2F pathway suppresses the transcription of the *CDKN2A* gene, which encodes for p16. However, when the pRb pathway is inactivated, p16 expression is no longer suppressed, leading to its overexpression, which is then detected histologically by p16-positive staining of the tumor cells[304] (see Figure 2.5).

In addition to its direct interaction with Rb, HPV infection can also trigger epigenetic changes that further contribute to Rb inactivation.[305] For instance, HPV can induce the expression of lysine demethylases, such as KDM6A and KDM6B, which remove repressive methyl groups from histone H3K9. This histone modification, known as H3K9 demethylation, can promote the recruitment of transcription factors to Rb-controlled promoters, leading to the activation of E2F-dependent genes and Rb inactivation.[306,307] HPV infection also affects the expression of microRNAs and other noncoding RNAs, which can further alter gene expression and contribute to carcinogenesis.[308]

The heterogeneity of HPV-driven cancers, resulting from a wide range of factors such as the level of HPV protein transcripts, the integration or episomal state of HPV DNA, the anatomic location of the cancer, or the immune response, can have a significant impact on both the prognosis and treatment of patients with HPV-driven cancer.[300] HPV-driven HNSCC is more radiosensitive than non–HPV-driven carcinoma, which is due to their cell cycle dysregulation (*vide supra*) including impaired DNA DSB repair capacity.[309]

This heterogeneity highlights the complexity of HPV-driven cancers and the importance of considering these factors when determining treatment options for patients.

Radiation-Induced Gene Expression

Radiation may significantly modify gene expression.[310] Many of the transcriptionally activated proteins have been shown to be centrally involved in the pathogenesis of radiation damage or to modulate the effect of radiation on tumor cells. Early responses may occur within hours after irradiation and involve mostly transcription factors such as the proto-oncogenes *JUN*, *FOS*, *JUNB*, and early growth response gene 1 (*EGR1*).[149] Sustained activation of early radiation response genes such as NF-κB may contribute to late radiation damage.[311] Other examples of radiation-induced genes that may occur early and/or late after irradiation include TGF-β, TNF-α, basic fibroblast growth factor, PDGF, interleukin 1 (IL-1), and EGFR.[312-314]

Gene expression and DNA-binding activity of *NF-κ B* are induced soon after ionizing radiation.[315] NF-κB is a sequence-specific DNA-binding protein complex that binds to DNA as a dimer. According to its multiple functions, NF-κB can also be activated by a variety of agents, for example, membrane receptors such as TNF receptor or Toll-like receptors and oxidative stress. Radiation-induced activation of NF-κB is mediated by IκB kinase (IKK).[316] This response does not depend on a nuclear signal, as it also occurs in enucleated cells.[317] However, it has been shown that ATM is required for chronic activation of the transcription factor NF-κB.[318] NF-κB acts in an antiapoptotic way and mediates radioresistance.[319]

Radiation exposure induces immediate and sustained *TGF-β1* gene expression, as well as activation of this cytokine.[320] On transcriptional activation TGF-β is produced as an inactive latent form and secreted. Latent TGF-β is stored in the extracellular matrix and proteolytically activated in irradiated tissues.[321] Active TGF-β1 binds and activates the TGF-β1 type I receptor, resulting in TGF-β1-dependent gene expression, inducing, for example, p21, p27, collagen, and tissue inhibitor of metalloproteinase (TIMP).[15,322] This is most likely responsible for the cellular effects of TGF-β, such as modulation of proliferation, differentiation, and radiation sensitivity of fibroblasts, and for the biochemical events (eg, collagen deposition, characteristic of radiation-induced fibrosis). In addition, TGF-β secreted by tumor cells on irradiation contributes to the development of radiation-induced fibrosis.[323] Intervention of TGF-β-mediated effects (eg, by

TGF-β1-neutralizing antibodies and superoxide dismutase) offers a promising strategy to prevent radiation-induced fibrosis. Moreover, a recent preclinical study showed that combined inhibition of TGF-β and PDGF with small molecules is a promising approach in diminishing radiation-induced lung toxicity.[324] Aside from fibrosis, TGF-β has been demonstrated to reduce latency, promote aggressive tumor growth, and increase estrogen receptor–negative breast cancers.[325] Moreover, the radiosensitivity of cancer cells can be enhanced by TGF-β-directed treatments.[326,327]

TNF-α belongs to the group of proinflammatory cytokines involved in radiation-induced normal tissue damage, such as pneumonitis and lung fibrosis. Immediately after irradiation, TNF-α is transcriptionally upregulated and released by the bronchiolar epithelium. TNF-α enhances phagocytosis and cytotoxicity by neutrophilic granulocytes and modulates the expression of other cytokines such as IL-1 and IL-6.[328] Experimental data show that also tumor lines, particularly pediatric sarcomas, may produce large quantities of bioactive TNF-α after irradiation, which is of potential importance for tumor response and for normal tissue reactions after radiotherapy.[329]

Tracking of genetic changes during and after ionizing radiation will further elucidate the molecular and basic impact of how cancer and normal cells respond to radiation and may serve as predictors for therapy response.

Genome Instability and Mutation

Cells may survive radiation despite unrepaired or misrepaired DNA damage, that is, with mutations or chromosomal aberrations. These may remain silent or result in radiation-related secondary primary cancers or, as germline mutations, cause hereditary disease.[330-332] In addition to directly induced mutations, radiation may induce a heritable, genome-wide process of instability (ie, genomic instability) that leads to an enhanced frequency of genetic changes occurring among the progeny of the original irradiated cell, which is transmissible over many generations of cell replication.[333] Whereas most mutations induced directly by radiation involve loss of large parts of the tested gene, leading to a loss of heterozygosity, most mutations resulting from radiation-induced genomic instability involve point mutations and small deletions.[333,334] While some studies, particularly on

thyroid cancer in children after the Chernobyl fallout, suggest a nonrandom pattern of chromosomal damage, generally no fingerprint alterations have been identified that would unequivocally indicate radiation-induced cancer.[332]

Molecular Stratification Toward Personalized Radiotherapy

The treatment decision for patients with malignant tumors is clinically based on anatomic location and histopathologic features. To verify the anatomic extent of the disease, the tumor, node, metastases classification has been introduced, which considers the size of the primary tumor, the regional lymphatic spread (lymph node metastases) as well as distant metastases. The cell type and histopathologic features are being assessed based on the World Health Organization classification. With recent advances in molecular pathology, implementation of DNA or RNA sequencing of cancer and normal tissue genomes, single-cell analysis, and biologic imaging techniques, a better understanding of the tumor and radiation biology is being gained and is leading toward molecular subclassification of tumors and, thus, to molecular stratification of patients along with clinically established biomarkers.

In patients with HNSCC and specifically in those with oropharyngeal carcinomas, the HPV infection status has been found to be associated with improved therapy response and prognosis. Preclinical studies showed that HPV infection leads to increased radiosensitivity in HNSCC cell lines.[309,335] Retrospective and prospective clinical studies including patients with HNSCC who received radio(chemo)therapy revealed that the HPV status is a strong independent parameter for locoregional tumor control, disease-specific survival, and overall survival.[336,337] After postoperative radiochemotherapy, patients with HPV-positive HNSCC showed an excellent locoregional control of nearly 100%,[338] suggesting that these patients may benefit from de-escalation therapy, such as by reducing the radiation dose. A number of clinical studies on radiation dose de-escalation in the postoperative treatment of HPV-driven oropharyngeal squamous cell carcinoma (OPSCC) has been set up in the past (*clinicaltrials.gov*, NCT03396718).[339-341] The first of the abovementioned clinical studies, conducted in patients with HPV-driven OPSCC who are undergoing

surgery, have been finished and showed that this is safe and reduces radiation-induced side effects while achieving high tumor control probability.[339,341]

Patients with HPV-negative tumors who received postoperative radio(chemo)therapy could be further stratified by CSC marker expression as well as tumor hypoxia, which is in line with radiobiologic knowledge. Patients with HPV-negative, low-hypoxic, and low CSC marker–expressing tumors also showed a superior locoregional control, while patients with hypoxic, CSC marker–overexpressing tumors showed a poor locoregional control and might benefit from intensified therapy regimes.[342] In contrast to the patients receiving postoperative radiochemotherapy, where only a few remaining tumor cells may have been left, the tumor volume is an important parameter for patients who are undergoing primary radiochemotherapy. The tumor volume is associated with the CSC number and is therefore important for local control. CSC marker expression reflecting CSC density varies widely between different tumors and can further enhance the powerful predictor tumor volume. Also patients receiving primary radiochemotherapy could be stratified for their risk of locoregional failure based on their HPV status, tumor hypoxia, and CSC marker expression levels within the tumors.[343] DNA methylome–based analyses of tumor hypoxia further improved the identification of patients with HPV-negative HNSCC who are on high risk for developing locoregional recurrences after postoperative or primary radiochemotherapy.[344,345] Also, several biomarker panels have been developed that may help to identify patients with radiosensitive and/or radioresistant HNSCC, such as that of the Radiation Oncology Group of the German Cancer Consortium (DKTK-ROG).[346-351] Overall, these studies highlight the potential for refined patient stratification for specific treatment intensification or de-escalation based on molecular biology. For the application of biomarkers for patient stratification in the clinics, the selection of the “most suitable” biomarker panel still remains a challenge.

An important issue in research on biomarkers for radiotherapy is that parameters reflecting tumor response may change during treatment. For example, hypoxic tumors may reoxygenate during treatment, and it has been demonstrated that this is associated with improved local control compared to tumors with residual hypoxia.[352,353] Therefore, more extensive

investigations into biomarker dynamics, by imaging, repeat tumor biopsies, or liquid biopsies, are underway in several (pre-)clinical studies to further improve their predictive value.

The identification of predictive biomarkers for the development of normal tissue toxicity in the individual patient is also a relevant issue in terms of personalized radiotherapy. It is well recognized that the degree of radiation-related toxicity varies between patients, which may be partly due to genotypic variation. The study of germline genotypic variations and the large clinical variability associated with the response to radiotherapy is termed *radiogenomics*.[354] The overall aim of radiogenomics is to identify patients with common genetic variants who are particularly likely to develop normal tissue toxicity following radiotherapy. A meta-analysis of genome-wide association studies in prostate cancer identified two single-nucleotide polymorphisms (SNPs), which are associated with late toxicity following radiotherapy in patients with prostate cancer: rs17599026 on 5q31.2 with urinary frequency and rs7720298 on 5p15.2 with decreased urine stream.[355] Also for patients with breast cancer, a recent multicenter study identified several SNPs that are associated with radiation-induced late toxicity such as induration, breast lymph edema as well as arm lymph edema, underlining the evidence of the association of SNPs with respective toxicity endpoints.[356]

CHAPTER 3

Biologic Basics of Radiation Oncology

Gopika SenthilKumar, Buck E. Rogers, Francisco Reynoso, Julie Schwarz, and Carmen Bergom

Ionizing radiation therapy (RT) involves the utilization of high-energy electromagnetic waves or particles that interact with tissue atoms or molecules with enough energy to eject one or more orbital electrons. This ionization can generate reactive oxygen species (ROS) and overall contribute to damage to a wide array of cellular compartments and membranes. DNA is the primary cellular target of ionizing radiation. Radiation can cause direct damage to DNA or indirectly damage DNA and other structures by the radiolysis of water molecules and subsequent formation of ROS. The effect and type of damage inflicted depend on factors such as radiation quality, dosage, and time available for repair. Additionally, radiation exposure can detrimentally affect both DNA repair mechanisms and antioxidant defense mechanisms such as glutathione, superoxide dismutase, and catalase. DNA damage accumulation can impair cell cycle progression, and oxidative stress can contribute to organelle damage. These collectively lead to the activation of cell death mechanisms. Beyond the cellular level, the overall tumor microenvironment (ie, blood vessels, immune landscape) is also altered by radiation exposure. This chapter details the biologic basics of RT and sheds light on how the physics of RT influences both tumor and normal tissue damage versus repair.

BIOPHYSICS OF TISSUE DAMAGE FROM RADIATION

The interaction between radiation and tissues varies significantly between uncharged particle radiation (eg, x-rays, γ-rays, neutrons) and charged particle radiation (eg, α and β particles, protons, carbon ions). Uncharged particles may go through tissue with no interactions at all or may deposit their energy in a few large interactions. For massive uncharged particles

like neutrons, these interactions are directly with the nuclei via neutron capture (thermal neutrons) or elastic and inelastic scattering (intermediate and fast neutrons). For massless uncharged particles like x-rays and γ-rays, these interactions are with outer electrons (the Compton effect) or less commonly with inner electrons (the photoelectric effect), producing secondary electrons that damage DNA. In comparison, charged particles interact with electrons and the nucleus of almost every atom it passes due to Coulombic forces.

The mechanistic differences in how radiation interacts with matter influence tissue penetration and the density of energy deposition in radiation tracks of any given RT. Linear energy transfer (LET) describes the rate of energy deposition of charged particles released during radiation exposure and has deep implications for the type of DNA damage produced. The secondary electrons produced by x-rays and γ-rays have low-LET values (0.3-2 keV/μm).[1,2] LET is inversely proportional to the square of the particle's energy; therefore, as charged particles lose energy penetrating tissues, LET increases and the particle deposits a large portion of its energy at the end of its track, producing a peak of dose deposition (ie, Bragg peak). This explains why protons have high-LET values (10 keV/μm)[1,2] at the end of their tracks when compared to that of secondary electrons produced by x-rays and γ-rays, but have relatively low LET at high energies (>100 MeV) upon entry. LET is also proportional to the particle's mass, so heavier charged particles like carbon ions (10-100 keV/μm) and α particles (114 keV/μm) have the highest LET at the end of their tracks of any particles used clinically. These differences in LET are important given that they impact the extent and mechanism of tissue damage.[3] Low-LET radiation requires about 1,000 ionization tracks to deposit 1 Gy in a hypothetical 8 μm cell, while high LET requires only about four tracks. The density of ionization events in each of these tracks is much lower with low-LET radiation, and thus less energy is deposited over the distance of a track, which limits the complexity of tissue damage. High-LET radiation creates more dense energy deposition sites along its tracks, concentrating the damage to a smaller volume of tissue.

The principal contributor to cellular damage and death following radiation is DNA damage. High-LET RTs cause more direct and complex DNA strand breaks that contribute to cell death. Low-LET radiation causes

damage primarily (>70%) through indirect, oxidative stress that stems from the ionization of water within cells. These interactions result in the formation of highly reactive species such as hydroxyl radicals (·OH), through a process known as radiolysis. Hydroxyl radicals are extremely potent ROS and can cause significant cellular damage by modifying DNA, proteins, and lipids. Radiation also disrupts mitochondrial integrity and increases ROS production via leakage of electrons from the electron transport chain; these electrons react with molecular oxygen to produce superoxide ions ($O_2 \cdot^-$). Superoxide ions are highly reactive and contribute to DNA damage and are also broken down into other damaging ROS species such as hydrogen peroxide (H_2O_2) by superoxide dismutase enzymes. ROS not only contributes to direct cellular damage but also can damage the tumor parenchyma, especially the blood vessels,[4,5] and increase immune cell recruitment into the tumor microenvironment.[5] Catalase breaks down H_2O_2 into water and oxygen to help mitigate the harmful effects of radiation-induced ROS generation. Another key antioxidant defense mechanism includes the glutathione peroxidase/reductase system.[5] However, radiation itself can damage antioxidant enzymes, and damaged DNA prevents the replenishment of antioxidant enzyme levels; these effects amplify ROS-induced DNA damage. Of note, ROS induce base modifications, including 8-oxoguanine, that are typically repaired by alternate DNA repair pathways (ie, base excision repair) instead of repair pathways classically utilized to repair DNA double-stranded breaks (non-homologous end joining [NHEJ] and homologous recombination [HR]; see next section as well as Chapters 2 for further details on DNA repair pathways).[3,6,7]

Complex or Clustered DNA Damage and Repair Mechanisms

Differences in the type and severity of DNA damage determine the DNA repair pathways activated within cells (Figure 3.1). It is estimated that low-LET radiation results in about 50% to 70% single-strand, base, or isolated double-strand damage and 30% to 50% complex or clustered double-strand breaks (DSBs; termed “multiply damaged sites”).[8,9] Single-base, non-DNA helix–distorting lesions are resolved through base excision repair while bulky helix-distorting damages are repaired through nucleotide excision

repair. Single-strand breaks (SSBs) are repaired through base repair pathways, as well as through single-strand base repair. DSBs can be repaired using either the more accurate, but slower, S/G2-phase-restricted HR, which uses sister chromatids as a template, or the error-prone, non-cell cycle–restricted, more rapid NHEJ (see DNA repair mechanisms detailed in Chapters 2). Importantly, nearly 50,000 to 100,000 spontaneous DNA lesions per day (most commonly single strand or base damage) are generated within cells from naturally occurring oxidative stress or DNA replication errors within the body, and approximately 50 DSBs are said to occur per cell cycle within mammalian cells. As such, these DNA repair mechanisms are well conserved within cells, although they are most optimized for resolving *isolated* lesions. These mechanisms are less efficient in resolving locally multiply damaged sites in DNA, which are defined as having two or more damage sites within 1 to 2 turns of the DNA helix (ie, within 10-20 base pairs). These clustered DNA lesions are comprised of not only double-stranded DNA breaks but also oxidative stress–induced base damage.[8,10]

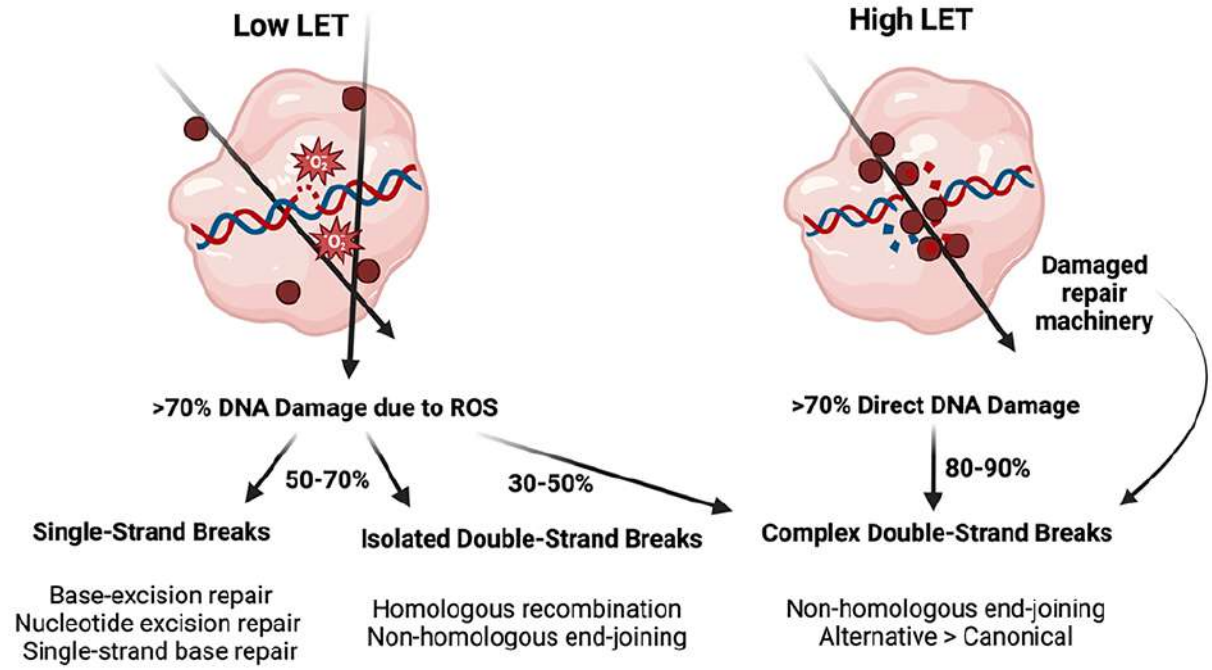

FIGURE 3.1 Differences in DNA strand damage and repair mechanisms activated by low versus high linear energy transfer radiation. (Created in BioRender: Bergom C. BioRender. 2025. https://BioRender.com/e74k396.)

As LET increases so does the percent of complex DNA damage created. It is estimated that proton beams can induce nearly 80% clustered lesions while α particles generate >90%.[11] Unlike the previously described repair mechanisms for isolated single-stranded, double-stranded, and base damage, it is well established that the efficiency of repair is reduced for complex lesions.[12,13] Numerous studies show a persistence of complex DNA damage for days to weeks following radiation exposure,[14-16] while low-LET-induced DSBs are commonly resolved in less than 24 hours.[3] Damage to DNA repair machinery is also reported with high-LET radiation, which contributes to the persistence of DNA damage that ultimately leads to chromatin fragmentation[17] and catastrophic genetic rearrangement.[3] It should be noted that the generation of complex lesions is thought to reflect the mechanism of DNA damage and repair induced by high versus low LET rather than the amount of energy deposited, since the extent of complex damage is greater with low-energy high-LET proton exposure compared to high-energy low-LET x-rays.[18] In line with these findings, a combination of low- and high-LET radiation has synergistic effects on cellular damage, likely due to the impaired repair machinery from high-LET radiation that sensitizes cells to further DNA damage from low-LET radiation.[19]

The DNA repair pathways are detailed in Chapters 2. In essence, DNA damage is detected by specialized “sensor” molecules that upon recognizing the damage initiate the activation of “transducer” protein kinase cascades. These stimulate the downstream effectors involved in the DNA damage response (DDR). One of these key kinase cascades is initiated by the ataxia telangiectasia mutated (ATM) protein, the deficiency of which results in heightened radiosensitivity and manifests as a complex human syndrome (ataxia telangiectasia). Another important kinase pathway is initiated by ATR (ataxia telangiectasia and Rad3-related), which identifies and rectifies stalled DNA replication complexes at the sites of DNA damage. The ATR pathway is primarily activated in response to SSBs. The third important kinase cascade involves DNA-dependent protein kinase (DNA-PK), which is a crucial component in the NHEJ pathway, which facilitates the repair of DSBs in DNA.

Early phases of DNA repair are marked by ionizing radiation–induced foci (IRIF), which congregate at DNA DSBs to signal the initiation of the DDR. The complexity and quantity of IRIF are sophisticated, varyingly

dependent upon factors such as the chromatin state where the DSB has occurred (ie, euchromatin is more easily accessed by DDR compared to heterochromatin) and the specific phase of the cell cycle during irradiation. In early stages of the IRIF event, the histone 2A subtype H2AX is phosphorylated by one of several phosphatidylinositol 3-kinase–related protein kinases, which include ATM, DNA-PK, and ATR. This phosphorylation results in the formation of γ-H2AX molecules that latch onto DSBs spanning several megabases along the neighboring chromatin, a phenomenon that can be conveniently identified via antibody tagging. This methodology, owing to its high sensitivity, has gained popularity as a go-to method for tracking DSB formation and repair processes.[20,21] The phosphorylated histone establishes interaction platforms for IRIF, facilitating the recruitment of repair and checkpoint molecules, subsequently activating further kinase-dependent pathways that pave the way for a coordinated downstream DDR response.

The exact cellular machinery that can contribute to repair of *clustered* DNA damage has yet to be fully elucidated; however, studies highlight complex activation of numerous DNA repair pathways—mainly alternative NHEJ. Alternative NHEJ, also called microhomology-mediated end joining, is the process by which short homologous sequences at the breakpoints of DNA are used to align DNA strands for ligation; this process is even more error-prone than NHEJ. Inhibition of poly(ADP-ribose) polymerase-1 (PARP-1), a protein that is critical for shifting cells from canonical to alternative NHEJ, further radiosensitizes cells to high-LET radiation.[22] Of note, these inhibitors are known to sensitize tissues to RT in general. However, it is postulated that its effects on alternative NHEJ may allow PARP inhibitors to more effectively sensitize cells to high-LET RT. Studies also suggest that the short fragments of DNA overhangs generated from complex lesions result in the inhibition of enzymes responsible for canonical, but not alternative, NHEJ, an effect that can also push cells toward HR during the G2 phase.[23] The presence of SSBs activates ATR pathways.[24] Interestingly, the DNA-PK catalytic subunit, a key complex involved in canonical NHEJ (see Chapters 2), is also thought to more specifically regulate the delayed repair of complex DNA damage compared to isolated SSBs.[19,25] Although the mechanisms contributing to DNA repair

are complex and influenced by the type of DNA damage, inhibition of DDR machinery has emerged as a key radiosensitization strategy.[26]

Oxygen and the Severity of DNA Damage

The presence of oxygen has critical effects on the severity of DNA damage. Oxygen interacts with damaged DNA free radicals to form DNA peroxides, which are stable and difficult for cells to repair. As such, these DNA peroxides effectively "fix" the cellular DNA damage. On the contrary, cells can more effectively repair DNA damage in hypoxic conditions through the interaction between DNA free radicals and H^+ ions from nonprotein sulfhydryl compounds; this contributes to tumor radioresistance.[27]

Figure 3.2 highlights the relationship between the partial pressure of oxygen and the relative radiosensitivity of tumors. The ratio of radiation dose needed in hypoxic conditions to oxic conditions is defined as the oxygen enhancement ratio, which ranges from 2 to 3 in normal tissues and with low-LET radiation treatment of tumors.[28] With high-LET radiation, this ratio is closer to 1, which signifies that a similar dose is needed in both conditions and the effectiveness of radiation treatment is less affected by oxygen presence. This makes high-LET radiation more suitable, in theory, for treating hypoxic tumors.

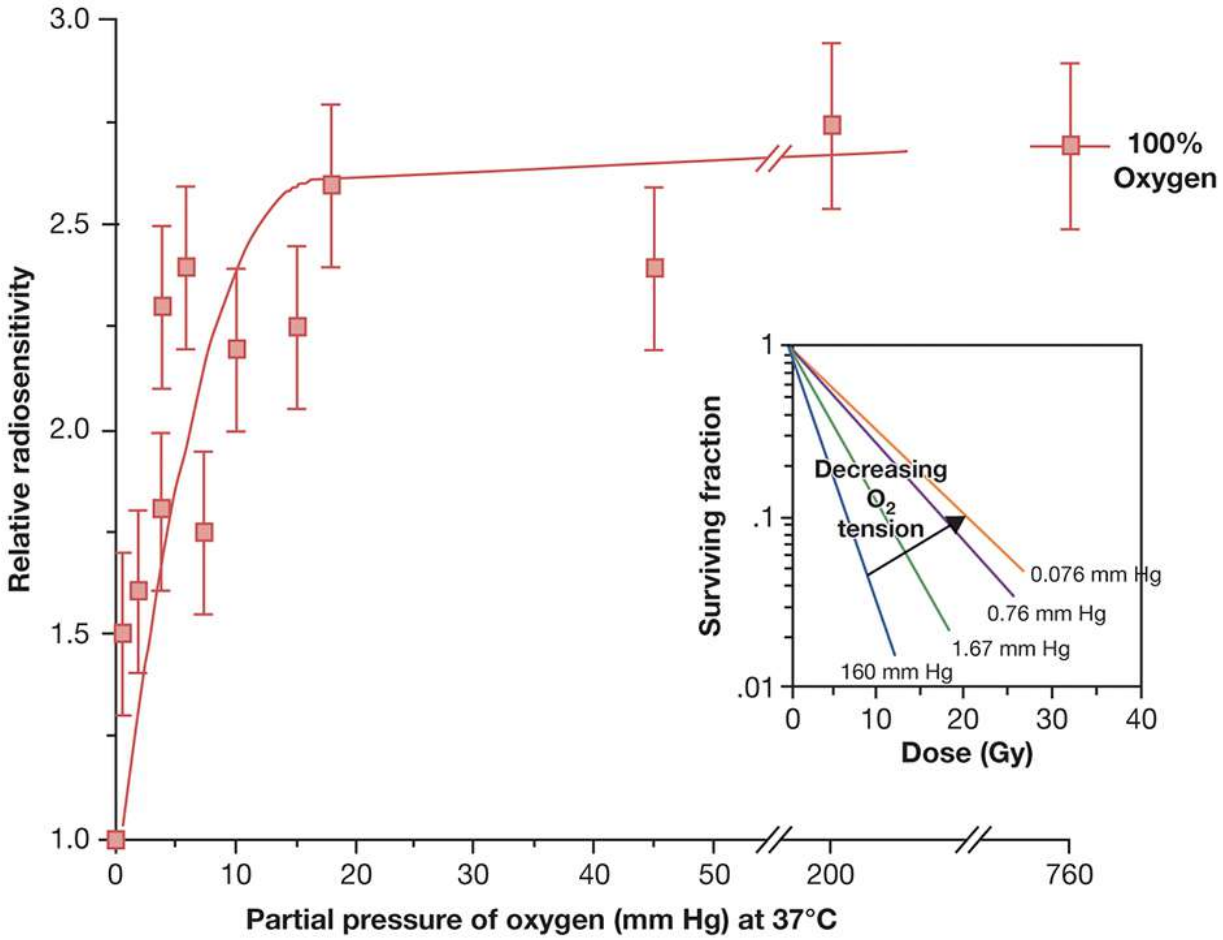

FIGURE 3.2 Curve relating cellular radiation sensitivity to partial pressure of oxygen at the time of irradiation. Data were obtained by scoring anaphase aberrations in Ehrlich ascites tumor cells, although similar curves have been obtained for killing of bacteria. About 50% of the total sensitization by oxygen is seen at a partial pressure of approximately 4 mm Hg at 37 °C. The inset shows survival curves for different levels of oxygenation.

This phenomenon extends beyond tumor control, as studies report a more severe reduction in coronary arterial radiosensitivity to low-LET radiation compared to high-LET radiation with hypoxic conditions,[29] which has critical implications for radiation-induced heart disease as well as brachytherapy for preventing restenosis after percutaneous coronary stent implantation.[30]

Cell Death Mechanisms

The ultimate goal of RT for cancer is to induce tumor cell death. The primary cell death pathway that is activated can differ based on radiation

type (eg, high vs low LET), the dose and fractionation scheme utilized, coadministration of chemo- or immune therapies, the tumor microenvironment, and cellular mutation profiles.

Apoptosis is a form of programmed cell death that can be activated through an intrinsic cellular pathway or extrinsic signaling. This form of cell death involves the shrinking of cells, chromatin condensation and DNA fragmentation, and subsequent formation of apoptotic bodies that are cleared by neighboring and immune cells. Importantly, apoptotic bodies maintain plasma membrane integrity that limits inflammation. Intrinsic apoptosis is driven by the activation of proapoptotic Bcl-2 family proteins (Bax and Bak) as a result of unrepairable DNA damage and/or endoplasmic/mitochondrial damage. Bax and Bak then trigger mitochondrial membrane permeabilization, which releases cytochrome C. Cytochrome C then activates caspase-9, which activates the effector caspases 3 and 7. These caspases cleave critical cellular proteins, including those in the cytoskeleton, nuclear lamin, and DNA repair pathways, leading to programmed cell death. Extrinsic apoptosis is primarily driven by extracellular activation of death receptors (eg, Fas and tumor necrosis factor receptor 1), which then activate caspase-8. Caspase-8 then activates the effector caspases 3 and 7.[31,32] Certain solid cancers such as colon, glioblastomas, and pancreatic tumors are known to often be more resistant to apoptosis due to overexpression of antiapoptotic proteins (Bcl-2 and Bcl-xl) or mutations in the p53 tumor suppressor protein, a key regulator of the intrinsic apoptosis pathway.[33] On the contrary, lymphomas and leukemias are often much more sensitive to apoptosis.

Mitotic catastrophe is the most common contributor to cell death following radiation exposure, and it occurs due to severe DNA damage that interferes with proper mitosis. Morphologically, these cells show multi- and macro-nucleation due to chromosomal mis-segregation, as well as areas of micronucleation due to acentric chromosomes.[34] Cells can die following mitotic catastrophe (ie, mitotic cell death) through activation of intrinsic apoptosis or entering a state of non-replication called cellular senescence (described further). Notably, these catastrophes are key players in initiating neoplastic changes and progression and as such are important mechanistically in driving secondary cancers. It is suspected that high-LET radiation increases susceptibility to mitotic catastrophe compared to low-

LET radiation given the extent of unrepairable clustered DNA damage that occurs with high-LET radiation.

Necrosis is a form of disorganized, unregulated cell death that results from severe tissue injury, and it is characterized by cell swelling, release of lysosomal enzymes, and loss of membrane integrity. The cells eventually rupture and trigger an inflammatory response. This form of cell death is more prominent with high-LET radiation, although can be seen with both low- and high-LET radiation. Necrosis is seen after a number of types of pathologic tissue injuries. After radiation, necrosis can occur from direct damage or by secondary immune responses triggered after radiation. Necrosis can be triggered by the opening of mitochondrial permeability transition pores (MPTs) following oxidative stress–dependent destabilization of mitochondrial membranes (ie, MPT-driven necrosis).

Necroptosis is a form of regulated cell death triggered by death receptor activation (eg, tumor necrosis factor family, interferon, and toll-like receptors) in response to both intra- and extracellular perturbations. These receptors initiate the formation of a necrosome complex comprised of receptor-interacting protein kinase 1 and 3 (RIPK1, 3).[34] This subsequently activates mixed-lineage kinase domain–like pseudokinase (MLKL), which is primarily responsible for the disruption of the plasma membrane and eventual cellular rupture. Notably, cells with increased caspase-8 are able to cleave and inactivate RIPK1 and 3, which prioritizes apoptotic cell death and prevents necroptosis.[35] Higher doses of radiation can decrease caspase-8 to push cells toward necroptosis-dependent cell death.[31] This pathway in general is thought to be highly immunogenic and increases the recruitment of immune cells that can promote antitumor responses (discussed in more detail in later sections).

Parthanatos is a form of cell death driven by the prolonged hyperactivation of PARP-1, which as previously described plays a key role in alternative NHEJ and is seen in cells with high levels of clustered DNA damage, severe alkylation of DNA, excess oxidative stress, and/or hypoxia.[31] Overactivation of PARP-1 consumes cellular NAD^+ stores to produce PARPs. Not only does this trigger a bioenergetic crisis from the loss of adenosine triphosphate (ATP) formation, but these polymers activate apoptosis-inducing factor (AIF) that translocates to the nucleus to trigger DNA fragmentation and chromatin condensation.[34]

Ferroptosis is a form of regulated cell death initiated by iron- and ROS-dependent lipid peroxidation. It is characterized by mitochondrial contraction and reduction in or loss of mitochondrial cristae. Specifically, radiation-induced oxidative stress consumes the antioxidant glutathione and increases expression of ACSL4, an enzyme that metabolizes lipids and plays a key role in upregulating membrane lipid peroxidation.[36,37] Radiation-induced ferroptosis has important implications not only in cancer cell death and the development of antitumor immunity, but also in normal tissue damage, including injury of the skin, lungs, and intestine.[37]

Autophagy is a regulated cellular recycling machinery defined by the engulfment of damaged cellular material by autophagosomes that then fuse with lysosomes to degrade the material.[38] This process is upregulated in response to radiation, and studies show that excessive upregulation in autophagy can lead to cell death and enhance radiosensitivity.[39] Notably, basal levels of autophagy can help maintain cellular homeostasis by clearing damaged proteins and organelles in response to radiation.[40] As such, the interplay between radiation and autophagic cell death is complex and dependent on both the extent of radiation-induced damage and level of cellular autophagic activation.

Lysoptosis is a highly evolutionarily conserved form of cell death, and the hallmark of lysoptosis is the leakage of cathepsin proteases from lysosomes triggered by increased permeabilization of lysosomal membranes.[41] This pathway is inhibited by cysteine protease inhibitors that are known to be upregulated in cancers (eg, cervical cancer), and inhibition of these proteases has been shown to radiosensitize cancer cells by upregulating lysoptosis.[42]

Methuosis is a cell death pathway that primarily occurs in cancers with activating H-Ras or K-Ras mutations, although there is some level of methuosis that can be triggered in response to radiation in cancers that do not contain H- or K-Ras mutations.[43] Morphologically, the dying cells exhibit large, fused, fluid-filled vacuoles formed through macropinocytosis. These vacuoles displace the cytoplasm, and eventually cells lose plasma membrane integrity and the resulting phenotype resembles necrotic cell death.[44]

Senescence is a state of irreversible, non-replicative cell cycle arrest that can be upregulated due to both aging- and stress-related pathways, such as

radiation-induced DNA damage and subsequent cell cycle dysregulation. Cellular senescence is commonly triggered from sublethal, sustained radiation exposure while higher doses/high-LET radiation triggers more apoptosis compared to senescence.[43,45] Morphologically, senescent cells are enlarged, resistant to apoptosis, and secrete proinflammatory molecules (commonly defined as the senescent-associated secretory phenotype [SASP]). This SASP can trigger neighboring cell damage and recruit immune cells, further augmenting antitumor effects in the initial stages.[46,47] However, the presence of senescence cells chronically can break down extracellular matrices to promote tumor invasion and metastasis, suppress immune cells, and become resistant to future therapies. As such, newer evidence suggests that the use of senolytics to remove senescent cells may allow for the beneficial antitumor initial stages of post-RT effects, while preventing the chronic detrimental effects.[46,47] Importantly, the SASP-related processes also contribute to damage and senescence activation within the surrounding tissues that increase the risk for cardiovascular disease,[48] pulmonary fibrosis,[49] bone damage,[50] and other chronic pathologies. Whether senolytic strategies can prevent these effects is currently unclear.

Inflammation and Radiation

Inflammation following RT has been linked to DNA damage and oxidative stress, as well as activation of nonapoptotic cell damage/death pathways—mainly necrosis, senescence, and mitotic catastrophe. Evidence shows that mitotic catastrophe following DNA DSBs can activate the cytoplasmic nucleic acid sensors: stimulator of interferon genes cyclic GMP-AMP synthase (STING-cGAS).[51] STING-cGAS pathway subsequently activates nuclear factor-κB and upregulates interferon gamma (IFNγ) signaling as well as other cytokine cascades to promote inflammation[52-54]; importantly, these pathways are seen in many cell types within the tumor microenvironment.[26] In addition to the release of cytokines, radiation increases major histocompatibility complex I expression, which allows for neoantigen presentation and subsequent recruitment of $CD8^+$ T cells. Following RT, tumor cells also release damage- associated molecular patterns (DAMPs) (eg, ATP, calreticulin, high mobility group box 1), which

allow for cross-presentation by dendritic cells in the tumor microenvironment and activation of phagocytic tumor clearance.[26,55] Recent studies critically link the persistence of DNA damage with the extent of inflammation, as inhibition of DDR machinery further enhances IFNγ signaling, release of cytokines, and neoantigen presentation by tumor cells. This is commonly described as turning a tumor "hot" and allows for tumor cell killing by immune cells such as natural killer cells and $CD8^+$ T cells.[26]

Interestingly, local tumor radiation has rarely been associated with shrinkage of metastatic tumors, outside of the treatment field an effect termed the "abscopal effect." This effect is linked to the migration of antigen-presenting dendritic cells from the tumor microenvironment to lymph nodes, where they can activate tumor-specific $CD8^+$ T cells.[56] These activated T cells then target metastatic tumors. The abscopal effect can be exacerbated in models that combine RT with immune checkpoint inhibitors,[57] and enhancing this effect robustly in patients with cancer with combined radiation and immunotherapy is a focus of a number of investigations.

The effect of radiation on antitumor immunity can be complex. Studies show that ablative RT can promote antitumor inflammatory responses; however, paradoxically some studies also report increases in immunosuppressive myeloid-derived suppressor cells and regulatory T cells in the tumor microenvironment following RT.[58,59] The balance between antitumor immunogenicity versus immunosuppression is likely influenced by the varying sensitivities of immune cells as well as the vasculature to radiation damage, which greatly influences the tumor microenvironment.[58] Activated and regulatory T cells are more radioresistant, while B cells are highly radiosensitive. Macrophages and dendritic cells are relatively radioresistant; however, following high-dose radiation, dendritic cells have impaired ability to activate T cells.[58,60] Fractionated dosing is less cytotoxic to the vasculature, and low-dose fractionations (0.5-2 Gy) of radiation in fact may normalize dysfunctional vessels within the tumor stroma.[61] On the contrary, ablative doses can severely damage the vasculature and promote killing of tumors. Despite these benefits, areas of hypoxia promote radioresistance.[58] As such, when selecting appropriate RT doses and regimens, one needs to consider the complex impact they have on the inflammatory milieu and tumor microenvironment.

NORMAL TISSUE RESPONSES TO RADIATION INJURY

Kinetics of Tissue Injury versus Regeneration

The rate of cell cycle turnover greatly influences normal tissue responses to RT, as well as damage from RT. In general, tissues with high turnover, such as the small intestine, hair follicles, and lymphoid tissues, have more early damage from RT given the importance of DNA integrity for cell cycle progression. This principle is one of the primary drivers of tumor death from radiation, but this effect in normal tissues can lead to many radiation-induced side effects.

The ability of a tissue to regenerate also influences the extent and prolongation of damage from RT. In homeostatic states, the rate of cell production and loss are balanced, and the cell loss factor ϕ, which is the fraction of newly produced cells that die or stop dividing, is equal to 1. During tissue regeneration and in solid tumors, ϕ is typically less than 1. Tumors with a low ϕ are more radioresistant. ϕ can also change with tumor size, with increasing values with increasing tumor size. After radiation therapy, some rapidly regenerating normal tissues have ϕ closer to 0, while additional tissues—such as skin—may have reduced ϕ to approximately 0.5 and regenerate more slowly, and other tissues such as seminiferous epithelium have little change in ϕ. As such, cell counts (eg, sperm) remain reduced for months to years following RT, and this is in direct proportion to the number of cells depleted during therapy.

The rate of cellular turnover influences the temporal changes in tissues after radiation. Platelet and white blood cell counts decrease most quickly after radiation to the bone marrow, which is related to their rapid turnover rate and in comparison to later and more minimal decreases in red blood cells due to their long turnover rate (~115 days).[62]

Functional Subunits and Radiation Tolerance

The ability of any given tissue to regenerate is influenced by the availability of surviving clonogenic cells that can divide and repopulate into mature cells capable of maintaining normal organ function. Unlike tumors where a few surviving cells can regrow into a tumor, many organs are organized into functional subunits (FSUs) that can be linked in series or parallel. These units can sometimes be defined anatomically (eg, nephrons in kidney or

lobules in the liver); however, this is not always the case (eg, the spinal cord).

In series organs (eg, spinal cord, esophagus), the FSUs are arranged end to end, and each subunit critically influences the broader organ function. As such, damage to one FSU can contribute to whole organ dysfunction. In addition, in series organs, each FSU is limited to the availability of surviving cells within that FSU to repopulate and regenerate that FSU; thus, if the FSUs are smaller and contain lower number of clonogens, then a lower dose of radiation can sufficiently kill all the cells. For example, if radiation damages a segment of the spinal cord, it disrupts signal transmission across the whole cord. This greatly limits how much radiation organs can tolerate. This principle also affects tumors as they act as one FSU. Larger tumors require greater doses of radiation than many small tumors to avoid any surviving clonogen at each tumor location that can repopulate the tissue.

On the contrary, parallel tissues such as the kidneys, lungs, and the liver have independent FSUs that can continue maintaining organ function even if a portion of the FSUs is damaged. Other tissues such as the skin/mucosa and gut epithelium have poorly defined/no defined FSUs and as such there are no physical barriers that prevent cell migration. Thus, if one area of these tissues is greatly impacted, clonogens from other FSUs can migrate and repopulate that area. Even within these tissues, the number of available clonogenic cells influences the radiation dose tolerance and subsequent tissue effects. For instance, hair follicles contain a smaller number of melanocytes than the epidermis, thus hair follicles get depigmented from lower radiation doses compared to the epidermis.

Volume Effect

The tolerance dose of any given tissue can be defined as the dose necessary to produce a complication beyond an acceptable threshold of symptomology. This dose depends on the volume of tissue irradiated (ie, volume effect). The tolerance dose is influenced by the number of FSUs irradiated (n) and the probability of the loss of one FSU (p). As such, the probability (P) of complications can be quantified using:

$$P = 1 - (1 - p)n$$

This equation is illustrated in Figure 3.3, which shows that radiation exposure of a greater number of FSUs (left curves) shifts the probability curve to the left and makes it steeper; that is, complications are more likely to be seen with lower radiation doses, and with each subsequent dose increase a greater likelihood of complication rates is seen. In serial tissues, this produces a binary phenotype whereby above a certain tolerance dose threshold, significant loss of organ function is seen. Below this threshold, the organ functions normally. On the contrary, in parallel tissue or in serial tissues with only one FSU irradiated, the probability of a complication rises relatively slowly with higher dose (the rightmost curve in Figure 3.3). As such, these tissues exhibit a graded response to increasing doses of radiation, rather than a binary response, after reaching a threshold of tissue volume radiation. This threshold is dependent on the functional reserve capacity of a given organ. The lungs and kidney only need approximately 30% of their total organ volume for adequate, physiologic functioning. As such, they are tolerant to higher doses of radiation administered to smaller areas, despite being highly sensitive to radiation-induced damage with whole organ irradiation.

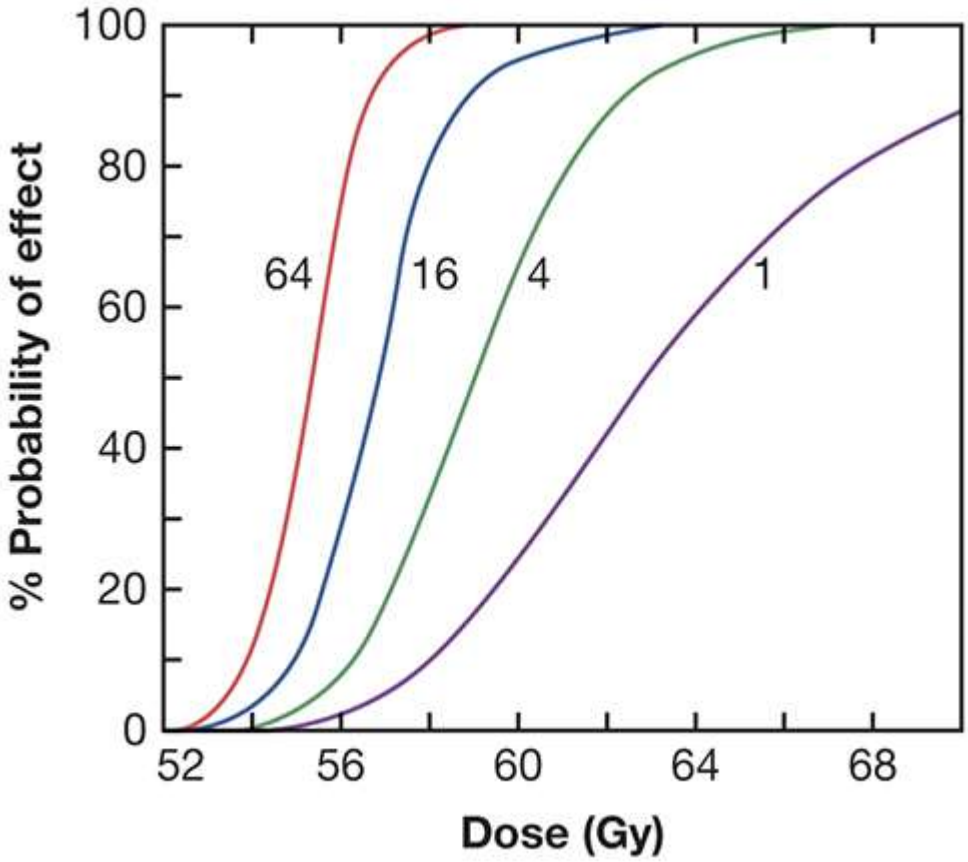

FIGURE 3.3 Curves illustrating how the probability of producing a complication increases with increases in the number of serially arranged FSUs included in the treatment volume. The curves were positioned by assuming that 58 Gy in 2-Gy fractions sterilized 10% of FSUs and that for a series of 2-Gy fractions, the effective D_0 for the target cells was 4 Gy. The curves are shifted to the left and are steeper with increase in number of FSUs exposed; however, this effect becomes less obvious once large numbers of subunits are involved. FSU, functional subunit. (Reprinted from Withers HR, Taylor JM, Maciejewski B. Treatment volume and tissue tolerance. *Int J Radiat Oncol Biol Phys*. 1988;14[4]:751-759. Copyright © 1988 Elsevier. With permission.)

The skin/mucosa shows an interesting phenomenon clinically, whereby at low levels of injury, they can heal from migrating clonogens throughout the volume of irradiation and thus do not exhibit the same volume effect described earlier. However, symptomatically, a smaller area of injury (eg, ulceration) is better tolerated by patients than a larger area, and the latter can also have longer healing times and increased risk for infection. As such, in these tissues the volume effect clinically is based on the tolerability of injury rather than the probability or severity of injury.

Latency of Tissue Effects from Radiation

The time taken for normal tissues to express radiation-induced injury is termed "latency," and based on acute, subacute, or late response to radiation, the symptomology from radiation can vary.[63] An acute response to radiation is defined as occurring during treatment or within days to weeks after treatment and is seen in tissue with a rapid turnover of cells: mucosa of oropharynx and esophagus, bone marrow, gastrointestinal epithelium, and skin. These tissues commonly have a well-defined stem cell population; however, the acute effect symptoms develop when the stem cell population is damaged and cannot replace the cells that are lost from fast turnover/radiation damage.[63] Eventually the remaining stem cells proliferate, allowing for repair of the tissue. A subacute response, sometimes called a consequential effect, is seen in the period of months from RT. These effects can be due to the persistence of acute effects,[63] often stemming from not having enough undamaged stem cells available for tissue restoration. Examples include spinal cord demyelination (Lhermitte syndrome) and pneumonitis. The severity of both acute and subacute effects worsens with increasing doses. A late response to radiation commonly occurs months to years after treatment and is seen in tissues with the slowest turnover rate: heart, lungs, kidneys, liver, and central nervous system organs. Notably, despite being late response tissues, acute inflammatory or edematous changes can result in the presentation of acute timelines as well. The pathophysiology of late effects has many overlapping mechanisms to wound healing: radiation-induced inflammation and vascular damage promote leakage of cytokines, fibrin, and subsequent collagen deposition and tissue scarring (ie, fibrosis).[64] Late effects are also more sensitive to fractionated treatments compared to acute/subacute effects. Secondary malignancies are also considered late effects of RT.

The latency of tissues also influences how long it takes for cells to regenerate and repair radiation-induced damage. Figure 3.4 shows the days after the initial dose of radiation when the repopulation of cells can be seen. This figure highlights that in acute-responding tissues, repopulation of cells can be seen even within 24 hours due to the rapid loss of cells. On the contrary, this effect is not seen for months in late-responding tissues. There are also major differences in the tissue turnover kinetics between mice and

humans, with humans having slower kinetics. These need to be accounted for when translating findings across species.

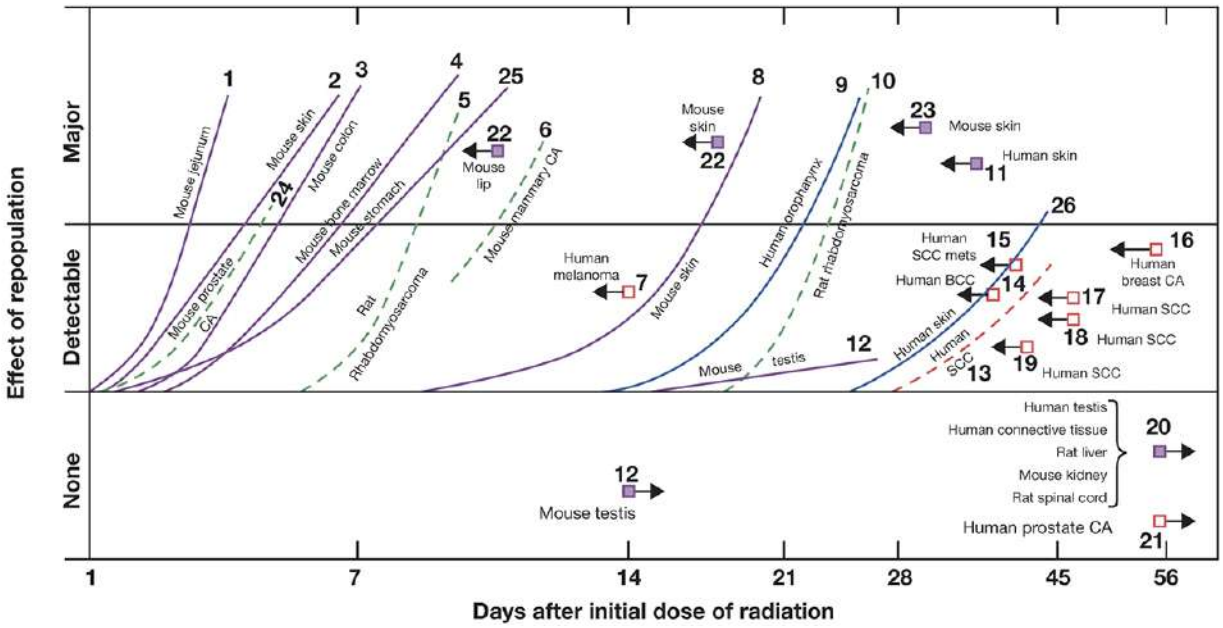

FIGURE 3.4 Representation of the approximate kinetics of regeneration of irradiated normal tissues (solid lines, solid symbols) and tumors (dashed lines, open symbols). Curves are based on measurements or estimates of regeneration; symbols denote times at which an effect of regeneration has already appeared (left-pointing arrow) or has not yet appeared (right-pointing arrow). The logarithmic abscissa is for convenience of presentation only and has no biologic rationale. In general, the human data are displaced to the right of experimental animal data, reflecting a slower initiation of repopulation. Because human tissues proliferate more slowly than do their rodent counterparts, they were exposed to protracted dose regimens, and less-sensitive end points were used to detect onset of repopulation in humans. Numbers on the curve and symbols refer to different sources of data. These come from many sources. (Further details are in the previous editions of this book.)

Skin and Connective Tissue

Erythema/dermatitis, desquamation (eg, scaling or peeling), pruritus, and hypersensitivity are common acute manifestations of radiation effects in the skin/connective tissue. While these commonly resolve throughout the course of the treatment, some patients can present with painful moist desquamation following high doses of radiation; this is due to the complete loss of basal stem cell populations and any healing requires migration of cells. These changes, especially dermatitis, can persistent over weeks to months (subacute) or show discoloration during the healing process (eg,

hypo- or hyperpigmentation). Late effects on the skin include pigmentation changes, telangiectasias, fibrosis, and/or atrophy. Connective tissue fibrosis can cause pain and affect mobility, and if it impairs lymphatic drainage, it can lead to lymphedema as well. The most concerning late skin effects include skin necrosis and chronic nonhealing wounds.[65]

Head and Neck

Acute manifestations after head and neck radiation commonly present as skin/soft tissue reactions like those noted earlier, as well as mucosal ulceration or infection. Fibrotic changes during the healing process as well as persistent mucositis are subacute manifestations within the mucosa. Such symptoms, when severe, might necessitate a feeding tube. Chronically, patients can have dental infections/caries and xerostomia (from salivary gland radiation) and osteoradionecrosis of the jaw, which can worsen quality of life and dental health.[66,67] These late effects are one of the primary reasons for recommending removal of damaged or unhealthy teeth prior to treatment in areas of high radiation exposure and emphasizing oral hygiene throughout treatment.

Central Nervous System

Acute symptoms from central nervous system radiation stem from local edema. Symptoms include fatigue, nausea, vomiting, loss of appetite, headaches, and rarely acute encephalopathy. Subacute effects include the persistence of fatigue, neurocognitive defects, and acute transient myelopathy of the spinal cord (Lhermitte syndrome) resulting from demyelination. Late effects can range from cavernous hemangioma formation[68] and cognitive/memory impairment[69] to progressive myelopathy, which can result in complete paraplegia when severe.[70]

Cardiovascular System

Acute cardiac symptoms include pericarditis, pericardial effusion, and vascular dysfunction. Late effects include the development of coronary artery disease from vascular damage and heart failure/cardiomyopathy from fibrotic and inflammatory changes,[71,72] which can contribute to morbidity and mortality in patients with breast cancer, lung cancer, and lymphomas

undergoing thoracic radiation with incidental heart exposure. Within the broader vascular system, acute radiation-induced damage can lead to thrombus. Chronically, the veins are less radiosensitive than arteries, and radiation can contribute to arteriolar senescence and atherosclerosis development chronically.[73] Notably, lung damage from radiation can greatly influence cardiovascular function, and vice versa. As such, studies aimed at differentiating the damage in the two organ systems need to be designed carefully to isolate lung radiation versus cardiac radiation.[74]

Lungs

Subacute effects include pneumonitis and fibrosis, which can progress into chronic fibrotic changes leading to restrictive lung disease that can limit respiratory function (late effects).[75] The persistence of inflammatory cascades within the lungs as well as general wound healing processes contribute to the late fibrotic changes in the lung.[76] Given that the lung FSUs (lobules) are organized in parallel, the volume of lung irradiated greatly influences the extent of functional limitations.

Gastrointestinal System

The acute effects of gastrointestinal system irradiation result from damage to the rapidly dividing cells throughout the system.[77] These effects include difficulty swallowing due to damage to the mucosal layer of the esophagus, nausea/vomiting from damage to the columnar epithelium of the stomach (which contains mucin-containing cells), as well as damage to the precursor cells that replenish the epithelium, diarrhea from damage to the intestinal epithelium, stem cells located in the crypts of Lieberkuhn, and the villus structures. Ulcerations can also be seen throughout the system. Late effects in the esophagus are driven by muscular layer necrosis and thickening of the epithelial layers, which impair swallowing. Within the stomach and intestine, late effects include fibrosis and ischemia resulting from atrophy of the supplying vasculature and potentially bowel obstruction.[78-80]

Tissue Tolerance to Retreatment

Tissue tolerance to retreatment is higher in early-responding tissues (eg, intestinal crypt cells, epithelial cells, hemopoietic cells) since they usually

recover well from the initial treatment. On the contrary, late-responding tissues can tolerate lower doses (eg, spinal cord) during retreatment since they do not recover well from the initial treatment. As such, the limiting factor in the decision for retreatment is late effects.[81] Additionally, whether the initial treatment was below or above the tolerance level of a given organ also influences the safety of retreatment. In tissues where the tolerance was not exceeded during the initial treatment, retreatment may be safe, while this is not typically the case if the tolerance was exceeded— especially in serially organized tissues. For example, Figure 3.5 shows how initial doses of radiation (priming dose) to the spinal cord in a variety of animal models influence the remembered dose of the tissue. The higher the remembered dose, the lower the tissue tolerance to re-irradiation.[82-84] The tissue tolerance to retreatment also decreases with decreasing times between treatment, likely due to the lower recovery of tissue from the initial damage.

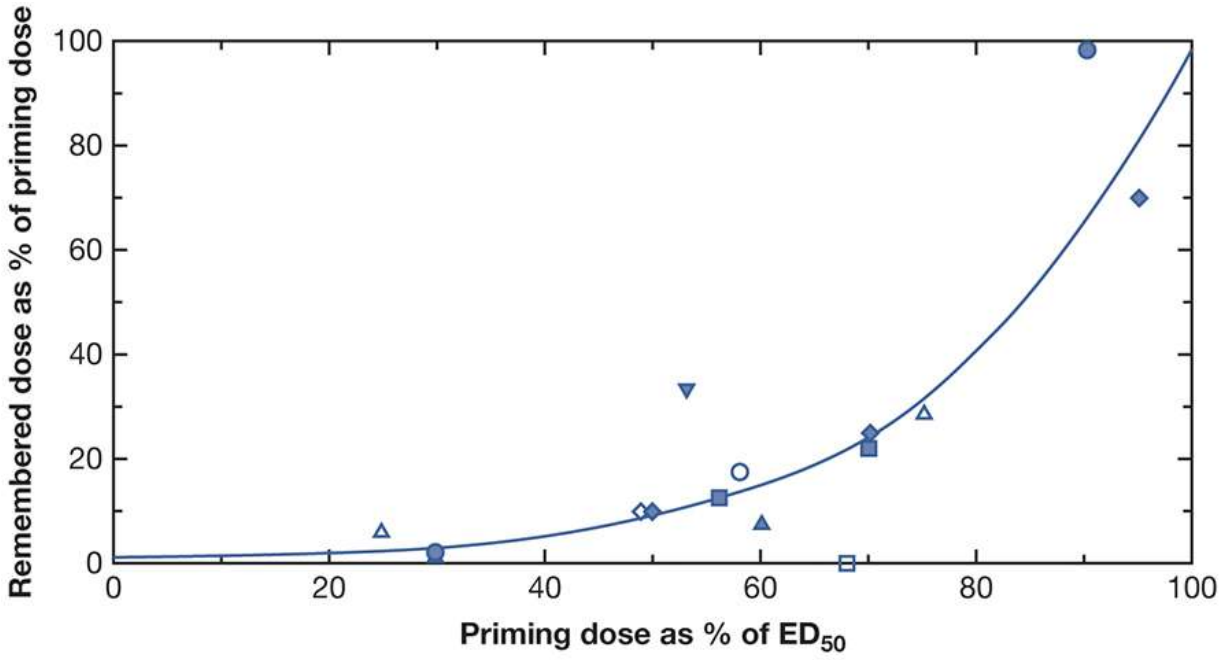

FIGURE 3.5 The dependence of remembered dose on size of priming dose (as a percentage of ED_{50}) is shown for a variety of animal species at long periods (6 months to 2 years) after the initial radiation treatment: O, adult rhesus monkey; Δ, 12-week-old rat([49]); ◊, 1-day-old guinea pig; •, young adult mouse; filled ▲, 8-week-old guinea pig; filled ▼, 8-week-old guinea pig; filled ■, 3-week-old weanling rat; ♦, young adult rat. (Reprinted from Mason KA, Withers HR, Chiang CS. Late effects of radiation on the lumbar spinal cord of guinea pigs: re-treatment tolerance. *Int J Radiat Oncol Biol Phys*. 1993;26[4]:643-648. Copyright © 1993 Elsevier. With permission.)

The injury from further damage in tissues where its tolerance for recovery has been exceeded is not only specific to re-irradiation but also to other trauma or stressors. For example, in patients with a high level of spinal cord dysfunction and late effects, hyperthermia can induce myelitis. In patients with significant chronic effects from head and neck radiation, the trauma of dental procedures can be enough to induce necrosis of the mandible.

Prediction of Normal Tissue Toxicities

The high level of patient-to-patient variation in normal tissue toxicity from RT has been extensively documented, and it is suggested that up to 90% of this variation can be explained by patient-specific factors such as genetics, lifestyle, comorbidities, and other factors beyond dose and fractionation.[85] For instance, numerous studies show that patients with cardiovascular disease risk factors are at higher risk for adverse cardiac events following thoracic RT.[72,86]

Recent advances in genomic sequencing can allow for the development of more precise risk prediction strategies that assess patient-specific genetic variations to (1) predict those who will be at high risk for specific normal tissue toxicities and (2) predict which therapies may be beneficial in preventing toxicities in specific populations.[87] For example, studies show that small nucleotide polymorphisms (SNPs) in the follicle-stimulating hormone gene can increase the risk for erectile dysfunction in patients receiving RT for prostate cancer.[88,89] Another study showed that SNPs within genes that regulate DDRs can predict the risk for acute toxicity following head and neck RT.[90] The large prospective REQUITE cohort study, which included more than 1,600 patients with breast cancer in the United States and Europe, identified eight specific SNPs associated with chronic late effects on breast tissue (eg, lymphedema, nipple retraction).[91] For the various late effects that the researchers measured, the top genomic risk loci ranged from those encoding adhesion proteins to transcription factors that have crucial roles in embryonic development.[91] The variability in genes associated with different toxicities suggests that unique genetic predispositions determine risk for various toxicities. Notably, analysis of the REQUITE study also showed that polygenic predisposition to cancers

(breast, prostate, or lung) did not increase the risk for late normal tissue effects, highlighting that SNPs associated with cancer risk may be distinct from those associated with RT-induced toxicity,[92] that is, those at high risk for normal tissue toxicity may not necessarily also be at high risk for secondary malignancies.

Therapeutic Use of Normal Tissue Radiation

While RT is commonly associated with cancer treatment, it has a broader range of therapeutic applications. For instance, RT, specifically high-dose stereotactic body RT, is currently being evaluated for noninvasive treatment of refractory ventricular tachycardia.[93,94] While radiation of the vasculature and heart can be associated with dysfunction, radiation can cause changes in inflammatory pathways, and the ROS produced by radiation has been shown to upregulate stress protection pathways in some preclinical models. This protection can trigger a "preconditioning" effect that has been shown to protect kidney,[95] brain,[96] and heart[97] tissue from ischemic injury. Radiation can also cause changes in other pathways that in some situations may be favorable to reduce symptoms, such as alterations in cell surface proteins that may contribute to reductions in ventricular tachycardiac events.[98] Additionally, by altering different pathways, intravascular brachytherapy has been used after angioplasties to reduce the risk of vascular restenosis.[99]

Outside the cardiovascular system, RT can decrease the recurrence of keloids[100] following surgical removal and can prevent the formation of heterotopic ossification (abnormal bone growth in soft tissues) following surgeries such as joint replacements.[101] RT has also been examined to minimize symptoms in osteoarthritis.[102] These varied therapeutic uses of RT take advantage of advances in technology that allow for targeted and more precise delivery of radiation.

TUMOR RESPONSE TO RADIATION THERAPY

The tumor response to radiation is influenced by the heterogeneity of cell populations, the capacity for DNA repair, the extent of apoptosis/senescence upregulation, the organization and oxygenation of the tumors, and the intrinsic turnover rate of the cancer cells. Similar to normal tissue, tumors

with higher turnover rates exhibit greater cell death from radiation, analogous to acute effects. The tumors with lower turnover rates are more radioresistant and have slower regression rates, analogous to late effects.

Tumor growth rate is also influenced by growth fraction (GF), tumor doubling time, and the tumor's cell loss factor (ϕ). GF represents the proportion of proliferating tumor cells (P) to quiescent tumor cells (Q), and can be represented as:

$$\mathrm{GF} = P/(P + Q)$$

The level of quiescent cells is determined by the proportion of stem cells (generally quiescent) as well as the extent of hypoxia in the tumor. For most solid tumors, the GF is approximated to be 30% to 50% in animals, highlighting the heterogeneity of cell proliferation within a tumor. The doubling time (T_D) of a tumor is determined by the GF and the time required to go through one cell cycle (T_C) and can be defined as:

$$T_D = T_C / \mathrm{GF}$$

Tumor doubling times can range from 4 to 34 days for a wide range of tumors, and the doubling time is mainly influenced by the fraction of cells that are in the S phase (labeling index [LI]) at any given time. This can be modeled as:

$$T_D = \lambda T_s / \mathrm{LI}$$

T_S represents the time spent in the S phase with a cell distribution correction factor λ to account for the uneven distribution of cells throughout the cell cycle; this value is usually between 0.67 and 1.00. T_S is thought to be relatively similar across most cells, and as such increased proportion of cells in the S phase primarily results in a lower doubling time. The tumor's cell loss factors, with $\phi < 1$ representing tumor growth and $\phi > 1$ representing tumor regression, can be defined based on the predicted doubling time (T_D) and actual doubling time (T_{Da}) calculated based on measurements of tumor diameter:

$$\phi = 1 - T_D / T_{Da}$$

This, in essence, estimates the level of cell loss while accounting for the rate of new cell production/doubling and the growth rate of the tumor.

In general, tumors that have a high ϕ regress quickly following RT and this is independent of their pretreatment tumor growth rate or fraction. In tumors with a low ϕ, rapid postradiation tumor regression can also be seen if the tumor has a high GF and rate of new cell production (ie, doubling time).

Mammalian Survival Curves and the Random Nature of Cell Killing

Survival curves for tumor cells are usually plotted as dose (x-axis, linear scale) versus surviving tumor fraction (y-axis, log scale), and this curve differs based on the LET. Low-LET radiation is characterized by sparse ionization events and at lower doses the surviving fraction shows an exponential relationship with increasing doses; this is represented as a straight line on this log-linear plot. The curve then bends for a range of doses and turns into a straight line at higher doses as these sparse ionization events compound with multiple hits creating more damage. On the contrary, the curve remains a straight line across dose ranges with high-LET radiation due to more dense ionization events generating more complex DNA damage and is steeper compared to low-LET radiation curves, suggesting that cell survival decreases exponentially with increasing doses of high-LET radiation.[103,104]

This survival relationship can be described using numerous mathematical models. The initial model proposed was the multitarget model, which models the surviving fraction in relation to dose based on an initial slope (D_1) that represents a single-hit killing event while the final slope (D_0) represents damage from multiple hits. The width of the initial shoulder (D_q) is the dose range of single-hit killing events. This dose-response relationship is modeled in Figure 3.6 and is based on the dose required to decrease the fraction of surviving cells to 37% of the previous value. Given the linear nature of the second component of the curve on a logarithmic scale, the dose required to decrease cell survival to 37% of the prior value

remains the same across all survival levels (ie, to kill 63% of existing cells $\rightarrow 1 - e^{-1}$).

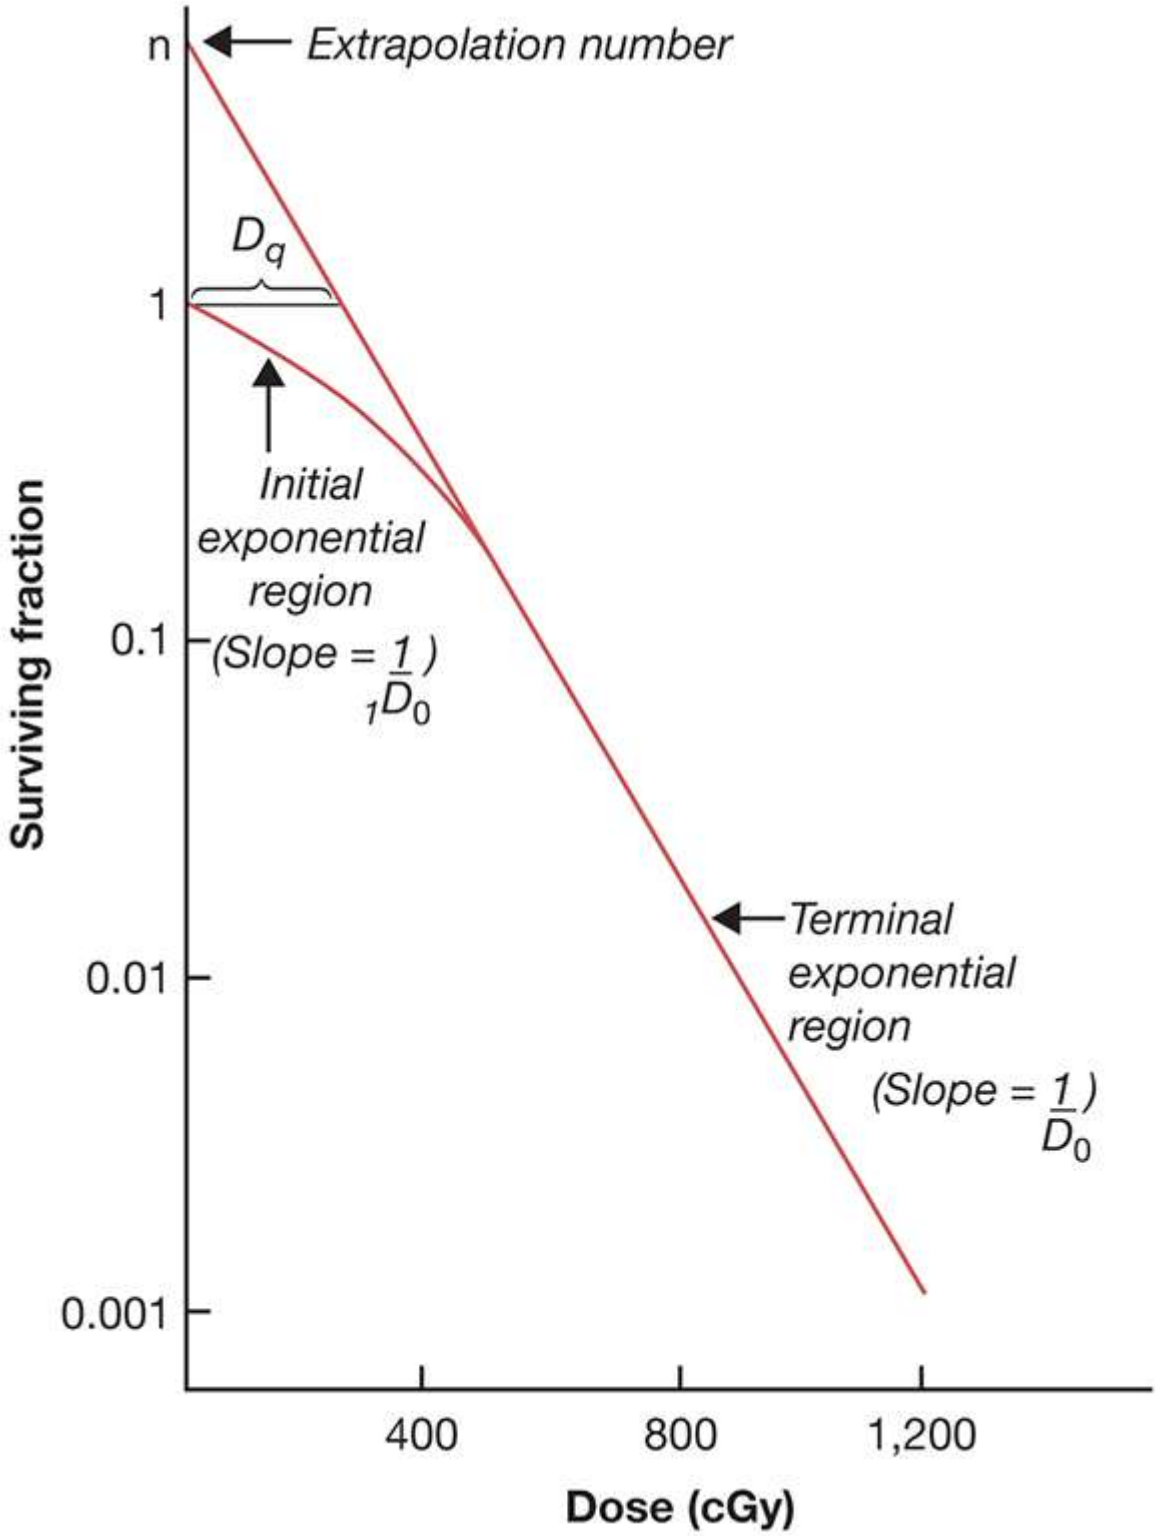

FIGURE 3.6 A TC survival curve for mammalian cells is characterized by a "shoulder" followed by a terminal exponential region, the slope of which is defined by a D_0 value (slope = $1/D_0$). The position of the curve on the radiation dose axis can be fixed by the intercepts of the terminal exponential region extrapolated back to the zero-dose axis (n) or to the

100% survival level (D_q): *n* is termed the extrapolation number, and D_q the quasi-threshold dose. Although *n* and D_q are parameters that define the width of the shoulder on the survival curve, they do not indicate its shape, which is of prime importance in RT. The survival curve shoulder can be considered to consist of an initial exponential region (the slope of which is defined by JDQ), followed by a downward-bending segment that merges asymptotically into the final exponential region of the survival curve. (Reprinted with permission from Withers HR, Peters LJ. Biological aspects of radiotherapy. In: Fletcher GH, ed. *Textbook of Radiotherapy*. 3rd ed. Lea & Febiger; 1980:103-180.)

The basis of this relationship is shown in Figure 3.7, which in essence shows that if 100 cells are irradiated, there is approximately a 37% (ie, e^{-1}) probability that any one of the cells will not be hit when 100 hits are delivered randomly. An additional 100 hits (200 total) would result in a 13.7% ($e^{-2} = 0.37 \times 0.37$) likelihood of survival (no hits).

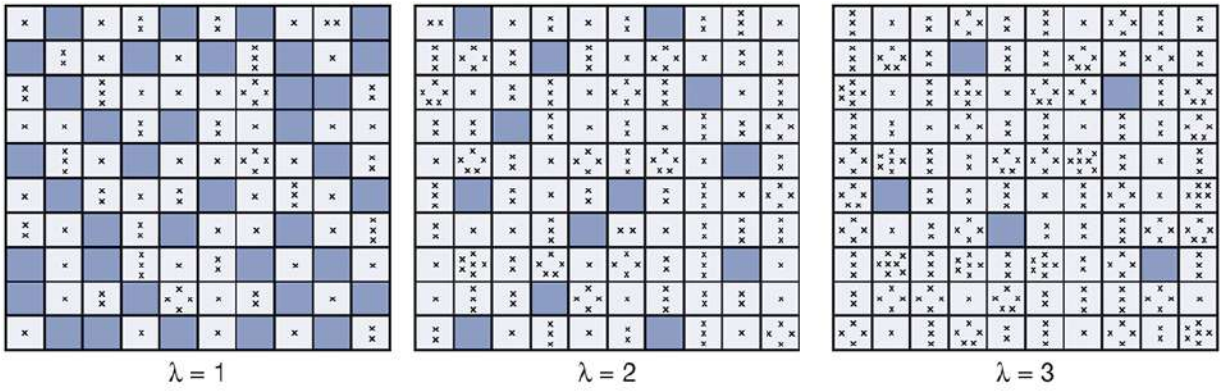

FIGURE 3.7 Random distribution in 100 equal-sized "targets" of 100, 200, or 300 "hits." The probability that any one of the 100 targets will not be struck when 100 hits are delivered randomly is e^{-1}, or 37%. The same probability of survival applies for each equal increment in the number of hits: 200 hits would result in a probability of survival of e^{-2}, or 0.37 × 0.37. Even after 300 hits are delivered, there is still a chance of e^{-3} = 5% that any one target will survive. This proportionate, or geometric, decrement in survival rate may be plotted as a straight line on semilogarithmic coordinates. (Reprinted with permission from Withers HR, Peters LJ. Biological aspects of radiotherapy. In: Fletcher GH, ed. *Textbook of Radiotherapy*. 3rd ed. Lea & Febiger; 1980:103-180.)

The most widely accepted mathematical model for describing cell survival curves is the linear quadratic (LQ) model, which assumes there are two components of damage that result in cell killing. The first is linearly associated with radiation dose (*D*) and modeled using the coefficient α and the second is proportional to the square of radiation dose modeled using the

coefficient β. Using these coefficients, the fraction of cells surviving (S) a dose of D is modeled as:

$$S = e^{-\alpha D - \beta D2}$$

The first component, $e^{-\alpha D}$, describes the injury from a single radiation hit and thus has a linear effect on cell survival in a log-linear plot. The $e^{-\beta D2}$ describes injury from multiple or cumulative hits and shows a continuously bending relationship between dose and cell survival (Figure 3.8).

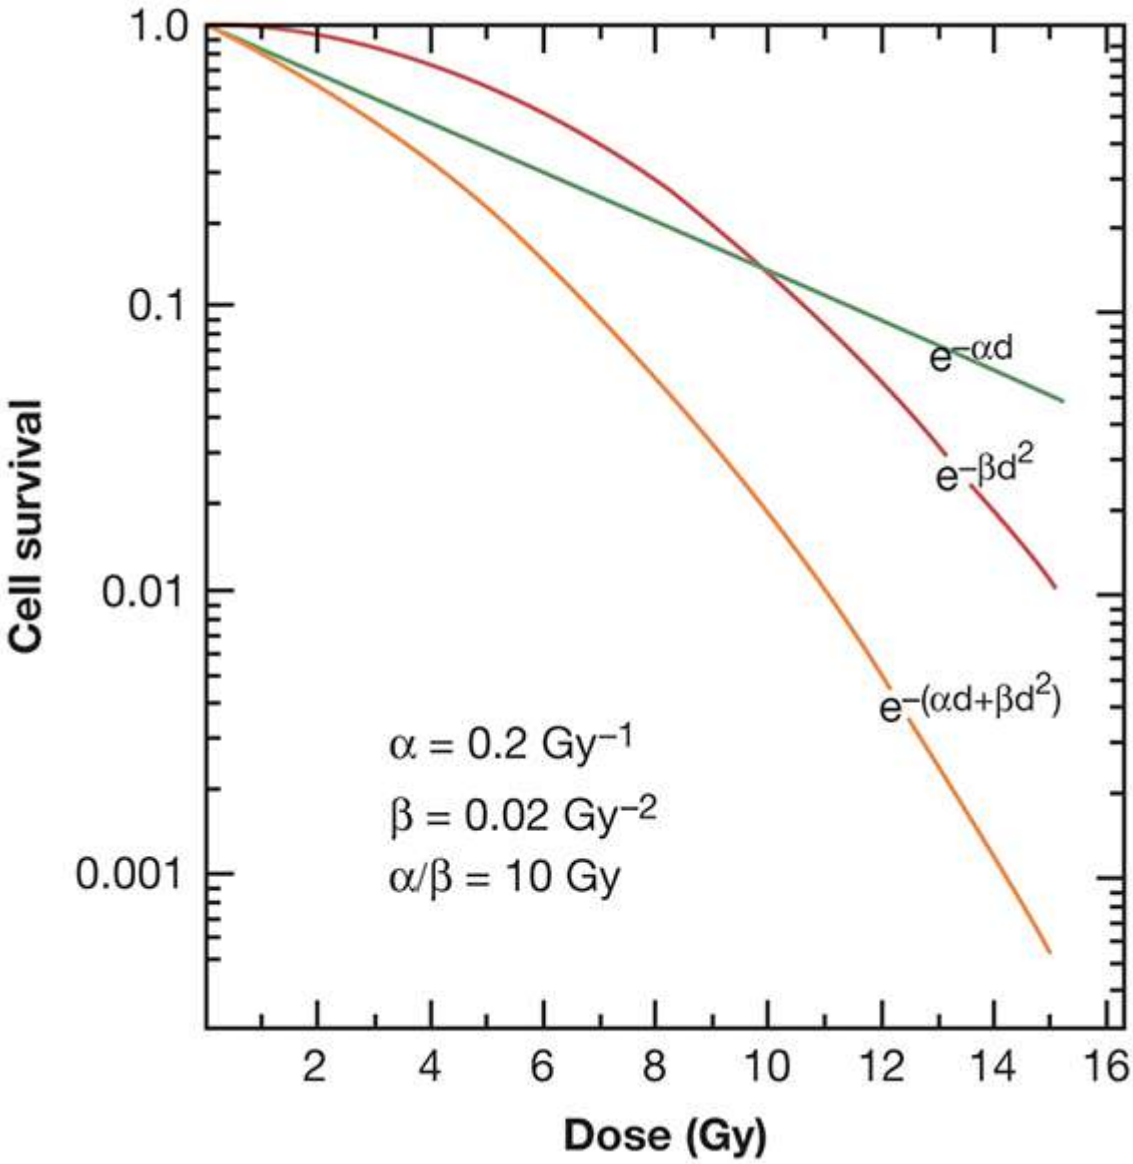

FIGURE 3.8 Model dose-survival curves for mammalian cells showing that the experimentally determined curve for acute exposures (lowest curve) is the product of two mechanisms: single-hit injury described by an exponential curve ($e^{-\alpha d}$), and multihit, or cumulative, injury described by a continuously bending curve related by a coefficient, β, to the square of the dose. At doses of clinical relevance, cell death from the single-hit mechanism predominates. The rate at which the survival curve bends from an initial, essentially exponential region depends on the ratio (α/β) of the coefficients for single-hit and multihit killing: the lower the value, the sooner and more steeply the curve bends. The value of α/β is the dose at which single- and multihit mechanisms contribute equally to cell killing. In these curves, α/β = 10 Gy, which is a value characteristic of acutely responding tissues. Target cells in late-responding normal tissues are characterized by low α/β values; hence their survival curves are curvier. The flexure dose, D_f, is the dose at which deviation from the initial exponential part of the curve is difficult to detect and, for available biologic assay systems, is about one-tenth of α/β. When doses in a multifraction regimen are less than D_f,

further dose fractionation does not produce detectable "sparing" (because cell killing is essentially all the result of single-hit events, the lesions potentially contributing to multievent killing being completely repaired during the fractionation intervals). The lower the α/β value, the lower the dose at which multihit mechanisms cause cell death, the lower the value of D_f, and the lower the dose per fraction below which a sparing effect of dose fractionation is lost. The curve for single-hit killing ($e^{-\alpha d}$) can be measured experimentally using very small dose fractions or a continuous low-dose-rate exposure; however, the curves for multihit killing ($e^{-\beta D2}$) can be determined only indirectly from a knowledge of the other two curves.

The dose range when the curve stays linear as well as the extent of bending beyond the initial linear component can be described by the ratio of the two coefficients α/β, known as the α/β ratio. Mathematically, the actual value of α/β describes the dose at which both mechanisms (single hit and cumulative/multihit) contribute equally to cell death. As such, a lower value is interpreted as needing a lower dose to induce a multihit mechanism of cell killing.

Biologically, the ratio of these coefficients is linked to the acute versus late response of tissues. The tissues with higher α/β are usually more acute-responding, and most tumors fall within this category as well. However, some tumors such as melanomas, liposarcomas, prostate tumors, soft tissue sarcomas, and breast tumors can have lower α/β ratios. The α/β ratio is lower in late-responding tissues and thus their survival curves start bending at lower doses and are steeper; at low doses, this results in lower cell killing compared to acute effects as shown in Figure 3.9. At higher doses, however, a greater level of cell death compared to acute tissues is seen with each subsequent dose escalation. Table 3.1 shows the α/β values for various early- and late-responding tissues. It illustrates that the α/β values for early-responding tissues are close to 10 Gy, while they are closer to 2 Gy for late-responding tissues.

TABLE 3.1 *A/B* VALUES

Early-Responding Tissues	α/β (Gy)	Late-Responding Tissues	α/β (Gy)
Skin (desquamation)	9.4-21.0	Spinal cord (paresis)	1.6-5
Skin—pig (desquamation)		Cervical	2-3.4
Time ≤16 d	8.7	Lumbar	4-5
Time >16 d	0.9	Brain (LD_{50}/10 mo)	2.1

Early-Responding Tissues	α/β (Gy)	Late-Responding Tissues	α/β (Gy)
Lip mucosa (desquamation)	7.9	Kidney (multiple endpoints)	0.4-5
Jejunal mucosa (clones)	7-13	Lung (pneumonitis)	1.6-4.5
Tongue mucosa (ulceration)	11.6	Lung (fibrosis)	2.3
Colonic mucosa (clones)	7-8.5	Heart failure	3.7
Hair follicles (epilation)		Liver (clones)	2.5
Anagen	7.5	Bladder (frequency)	7.2
Telogen	5.5	Bladder (contraction)	5.8-11.0
Testis (clones)	13.9	Bowel (stricture/perforation)	3.5-5
Spleen (clones)	8.9	Bowel (fistula/obstruction)	10.7
Bone marrow (clones)	9.0	Bowel (rectal stenosis, <5 d)	6.2
Melanocytes (depigmentation)	6.5	Bowel (rectal stenosis, >5 d)	1.1
Tumors (cure)		Dermal contraction	1.5-3.5
Experimental tumors	10-35	Dermal wound healing	2.5
Most human tumors	6-25	Eye cataracts	1.2
Human prostate cancer	1.5	Bone (human fracture)	2.2
		Cartilage and submucosa	1-4.9
		Total body irradiation (LD_{50}/1 y)	5.1

These values represent a synthesis from many sources. Individual values are means from one study. Where a range is given, it represents mean values from multiple studies.

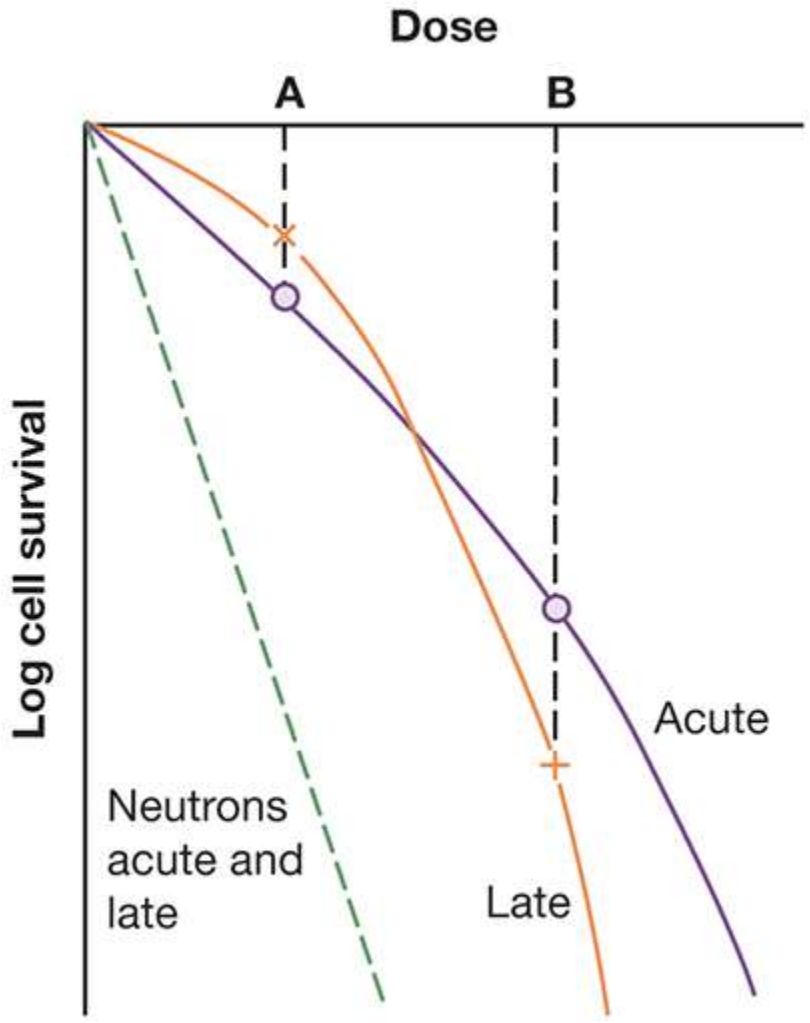

FIGURE 3.9 Hypothetical survival curves for the target cells for acute and late effects in normal tissues exposed to x-rays or neutrons. The α/β ratio is lower for late effects than for acute effects in x-irradiated tissues, resulting in a greater change in effect in late-responding tissues with change in dose. At dose A, survival of target cells is higher in late-effect than in acute-effect tissues; at dose B, the reverse is true. Increasing the dose per fraction from A to B results in a relatively greater increase in late than acute injury. For neutrons, the α/β ratio is high, with no detectable influence of the quadratic function (βd^2) over the first two decades of reduction in cell survival, implying that accumulation of sublethal injury plays a negligible role in cell killing by doses of neutrons of clinical interest. (Reprinted from Withers HR, Thames HD Jr, Peters LJ. Biological bases for high RBE values for late effects of neutron irradiation. *Int J Radiat Oncol Biol Phys*. 1982;8[12]:2071-2076. Copyright © 1982 Elsevier. With permission.)

The LQ model also explains differences in response to fractionated treatment of early- versus late-responding tissues. With each treatment fraction, the shoulder of the dose-response curve gets repeated. Acute-

responding tissues, with higher α/β values and a steeper dose-response relationship, are less sensitive to dose fractionation. On the contrary, the late-responding tissues with more curved relationships and lower α/β values are greatly influenced by changes in the fractionation pattern. Figure 3.10 illustrates this by showing the isoeffect of various tissues. This graph portrays the relationship between the total dose of radiation and the dose per fraction needed to achieve the same biologic effect. The curve typically slopes down since increasing the dose per fraction reduces the total dose needed to achieve the same effect. This is due to the greater cumulative cell-killing effect with larger individual doses per fraction. This curve for late effects in normal tissue is steeper compared to acute effects, due to lower tolerance to large individual doses within late-responding tissues. Figure 3.11 shows the relationship between dose per fraction and the total dose represented as the ratio of 2 Gy fractions. This graph shows that with a reduction in the dose per fraction, the isoeffect dose increases more rapidly in late-responding tissues. The biologic effective dose (BED) can be calculated accounting for the fractionation using the equation:

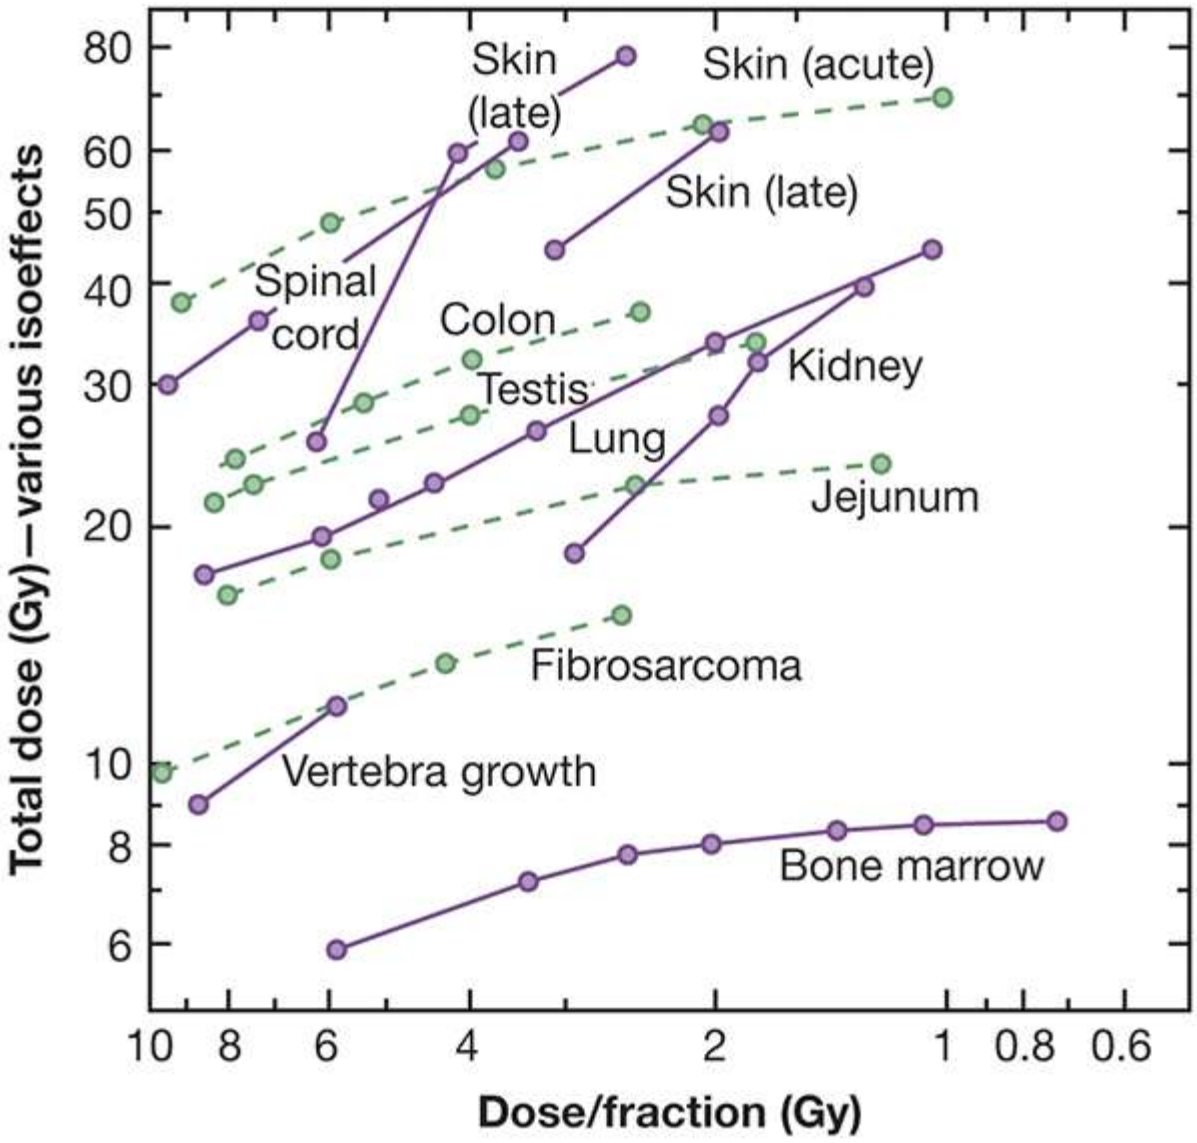

FIGURE 3.10 Isoeffect curves in which the total dose necessary for a certain effect in various tissues is plotted as a function of dose per fraction (late effects, solid lines; acute effects, broken lines). Data were selected to exclude an influence on the total dose of regeneration during the multifraction experiments. The isodoses for late effects increase more rapidly with decrease in dose per fraction than is the case for acute effects. (From Withers HR. Biologic basis for altered fractionation schemes. *Cancer*. 1985;55[9 suppl]:2086-2095. Copyright © 1985 American Cancer Society. Reprinted by permission of John Wiley & Sons, Inc.)

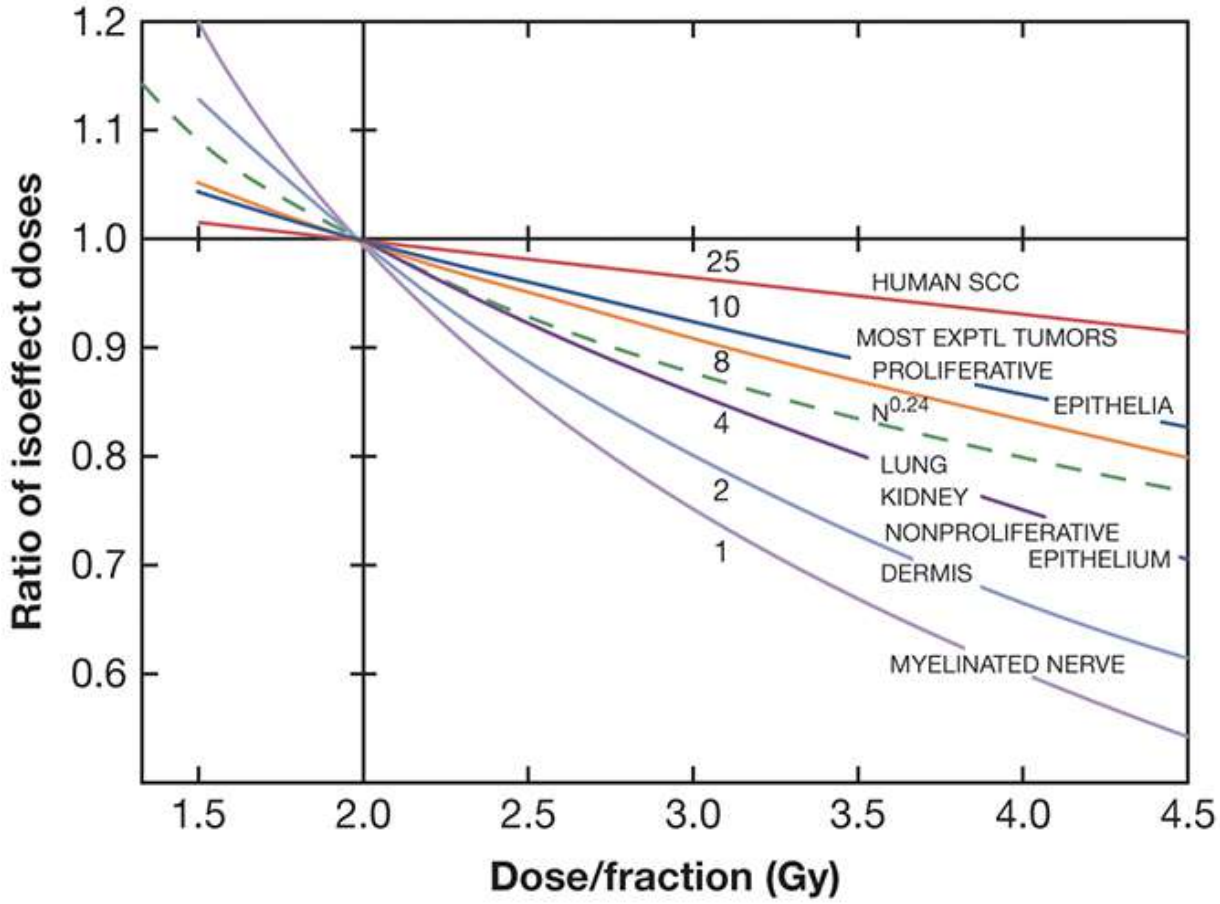

FIGURE 3.11 Isoeffect curves relating total dose to dose per fraction, with total dose being expressed as a ratio of that necessary in 2-Gy fractions (ie, the $LQED_{2Gy}$). α/β ratios (in Gy) are shown on the curves. Although the α/β ratios are not yet established accurately or even precisely for most normal tissues, especially late-responding ones (Table 2.2), the likely order of fractionation sensitivities is as shown. The broken line traces the change in dose, as it would have been predicted by a factor $N^{0.24}$ in the NSD formula. Phenomena other than repair of sublethal injury, specifically repopulation, are not accounted for by these curves. (From Withers HR. Failla memorial lecture. Contrarian concepts in the progress of radiotherapy. *Radiat Res*. 1989;119[3]:395-412. Copyright ©2024 Radiation Research Society.)

$$\mathrm{BED} = \frac{nd}{1 + \dfrac{d}{\alpha/\beta}}$$

This equation is based on the LQ model, and the n represents the number of fractions of dose d.[105]

Tumor Control Probability

The likelihood of successfully controlling a tumor is directly linked to the increasing amounts of radiation administered and subsequently the higher proportion of tumor cells that do not survive. This hinges on the ability to eliminate the final clonogen, which could be the cell capable of regenerating the entire tumor. Hence, the achievement of tumor control happens quite suddenly. When visualizing the relationship between tumor control probability (TCP) and the dosage of radiation, a unique pattern emerges. For a certain range of dosages, there appears to be no noticeable response. However, once a specific threshold is crossed, there's a swift rise in the TCP, culminating in a hypothetical 100% control rate when all tumor cells are killed. This progression closely follows a sigmoidal pattern with a low initial slope, increasing the slope to an inflection point, and leveling off as it approaches 100%. Furthermore, if the radiation treatment manages to diminish cell survival to the point where there is just one clonogen left in each tumor on average, the cure rate would be 37%. This probability of tumor control can be modeled using the equation:

$$\mathrm{TCP} = e^{-Sn}{}_0$$

In this equation, n_0 is the initial number of tumor cells and S is the surviving fraction of clonogens per tumor. Thus, if the average number of surviving clonogens is 1, the TCP is 37%.

It is often advantageous to use the dose required to kill 90% of the population, D_{10}, to calculate TCP where D_{10} is defined as:

$$D_{10} = \ln 10 \times D_0 = 2.3 \times D_0$$

Therefore, if a tumor has 10^{10} initial clonogens, and on average there is 1 clonogen remaining (ie, TCP = 37%), the tumor will have been treated with $10 \times D_0$. If the D_0 in this example is 3 Gy, then D_{10} is 6.9 Gy and the total dose required to achieve 37% TCP is 69 Gy. If one additional D_{10} is given with a total dose of 75.9 Gy, then there is only 0.1 clonogen surviving on average and TCP increases to 90%. This sensitive behavior of TCP is due to the sigmoidal shape of the function requiring careful consideration of

radiation dose. This relationship is modeled in Figure 3.12, which further shows that as the tumor size increases, the dose needed for tumor control also increases.

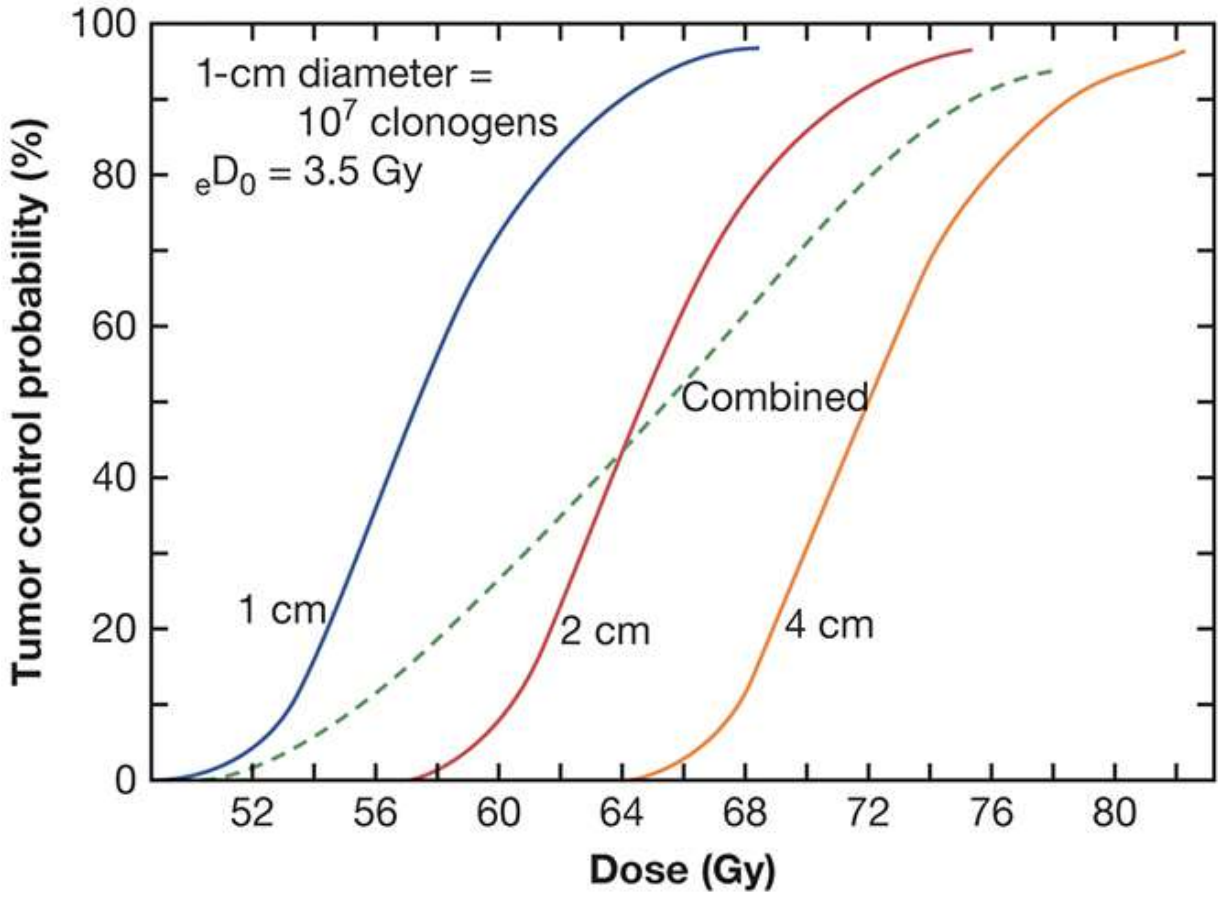

FIGURE 3.12 Theoretic tumor control probability (TCP) curves for three sizes of spherical tumors (solid lines) and one that would result from a study incorporating into the dose-response analysis all three tumor sizes in equal proportions (broken line). They were calculated on the assumptions that the dose was given in 2-Gy fractions, that the $_eD_0$ value for 2 Gy/fraction was 3.5 Gy, and that a 1-cm diameter spherical tumor contained 10 clonogens. As tumor volume increases, so does the dose required for a certain probability of control. The cell number increases by 8 times and 64 times as the spherical tumor increases from 1 cm diameter to 2 and 4 cm, respectively. An exponential increase in clonogen number is related to a linear increase in dose for an isoeffect. Heterogeneity of even one factor, initial clonogen number, causes the TCP curve to be shallower (broken line). Retrospective clinical studies incorporate a large number of causes for heterogeneity of response.

This same relationship can be applied to normal tissues as well, generating a dose-response relationship curve for tumors versus normal

tissues. If the tumor is more sensitive to radiation than the normal tissue, then the tumor's dose-response curve will be shifted more to the left than the tissue's curve (Figure 3.13); this would be clinically favorable. On the contrary, if the likelihood of controlling the tumor falls to the right of the risk of damaging normal tissue, it implies a high risk of complications. In such cases, other treatments, like surgery or chemotherapy, might need to be considered if possible.

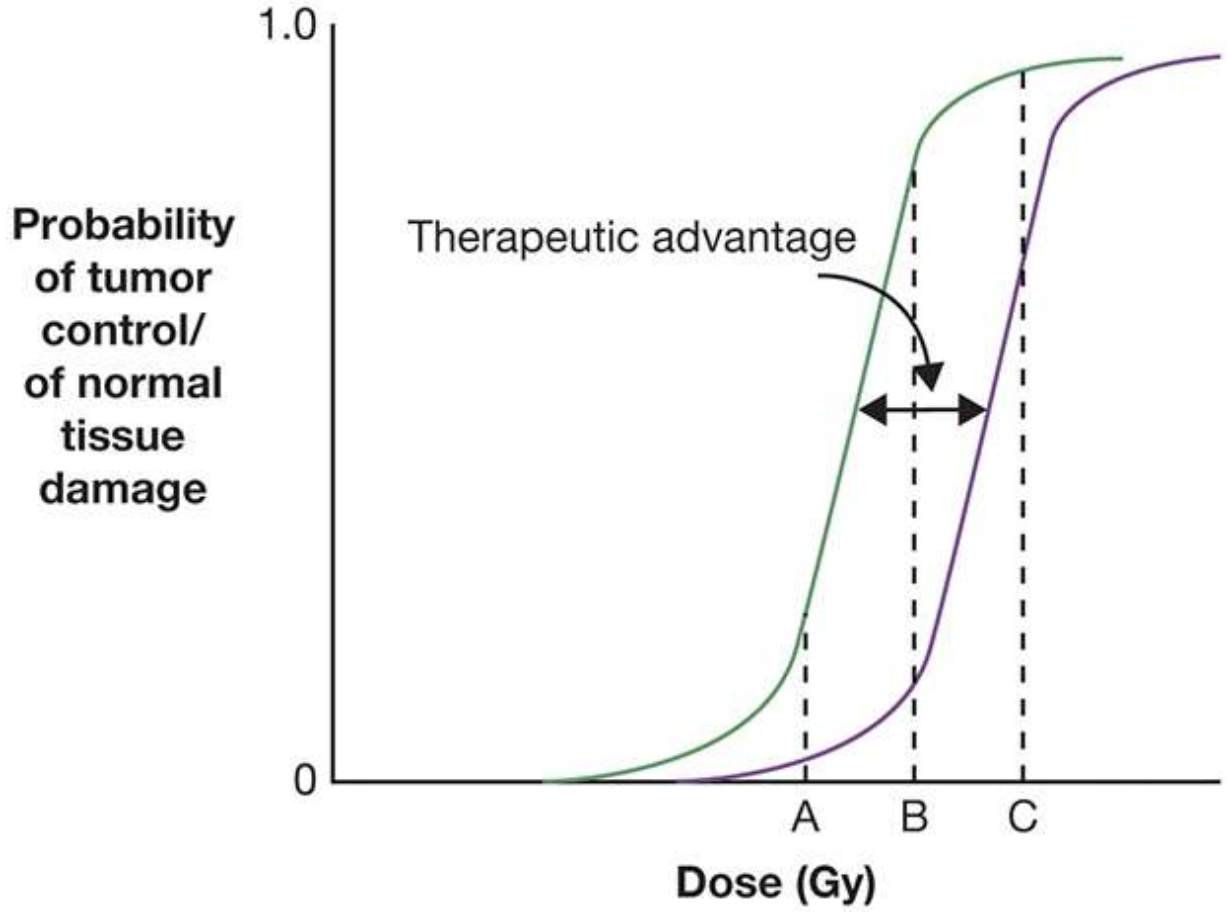

FIGURE 3.13 Theoretical curves showing the probability of tumor control and normal tissue complications. Both curves have a threshold and are log sigmoid in nature. The art of radiotherapy is to increase the distance between these two curves, that is, to derive a therapeutic benefit. If the normal tissue damage curve is to the left of that for tumor control probability (TCP), tumor control is unlikely without unacceptable normal tissue complications.

The Rs of Radiobiology

The *four classical Rs of radiobiology* are repair, reoxygenation, repopulation, and redistribution. These Rs are fundamental principles that explain why fractionated radiotherapy (dividing the total dose of radiation into multiple smaller doses over time) is effective in killing cancer cells. In recent years, two new Rs have been introduced: radiosensitivity and reactivation of antitumor immune responses.

Repair

Repair refers to the ability of cells to repair DNA damage following radiation exposure. The rate and degree to which normal tissue and tumor cells repair their DNA damage influence the effectiveness of RT. The ideal treatment regimen will allow for normal tissues to repair their DNA, while impairing repair mechanisms within cancer cells. Tumors frequently have defects or mutations in their DNA repair machinery. As such, fractionation of radiation treatment can allow for DNA repair within normal tissue, with more limited efficacy of repair in tumor cells. The accumulation of DNA damage within tumor cells with repeated radiation doses ultimately promotes cell death.

The extent of repair is influenced by whether the damage from radiation treatment is lethal or sublethal. Lethal damage is unrepairable and irreversible, while sublethal damage can be repaired unless additional doses are administered to collectively cause lethal damage. This phenomenon is illustrated in Figure 3.14, which shows that a same dose split over time will allow for greater cell survival compared to administering the total dose at one time; this is due to the ability of cells to repair between treatments. In line with this principle, increasing the time between each dose allows for more time for repair and thus increases the surviving fraction. The LET of the radiation administered can alter this relationship due to the higher complexity of DNA damage of high-LET radiation (ie, complex DSB vs isolated DSB and SSB). Damage from low-LET radiation is therefore easier to repair, and increasing the time between fractions can help promote tissue repair. On the contrary, the damage from RT is more pronounced for high-LET radiation given the complexity of DNA damage as well as known damage to the DNA repair machinery (see previous sections of this

chapter). This leads to more irreversible lethal damage, and greater time between doses might be needed to repair the sublethal damage.

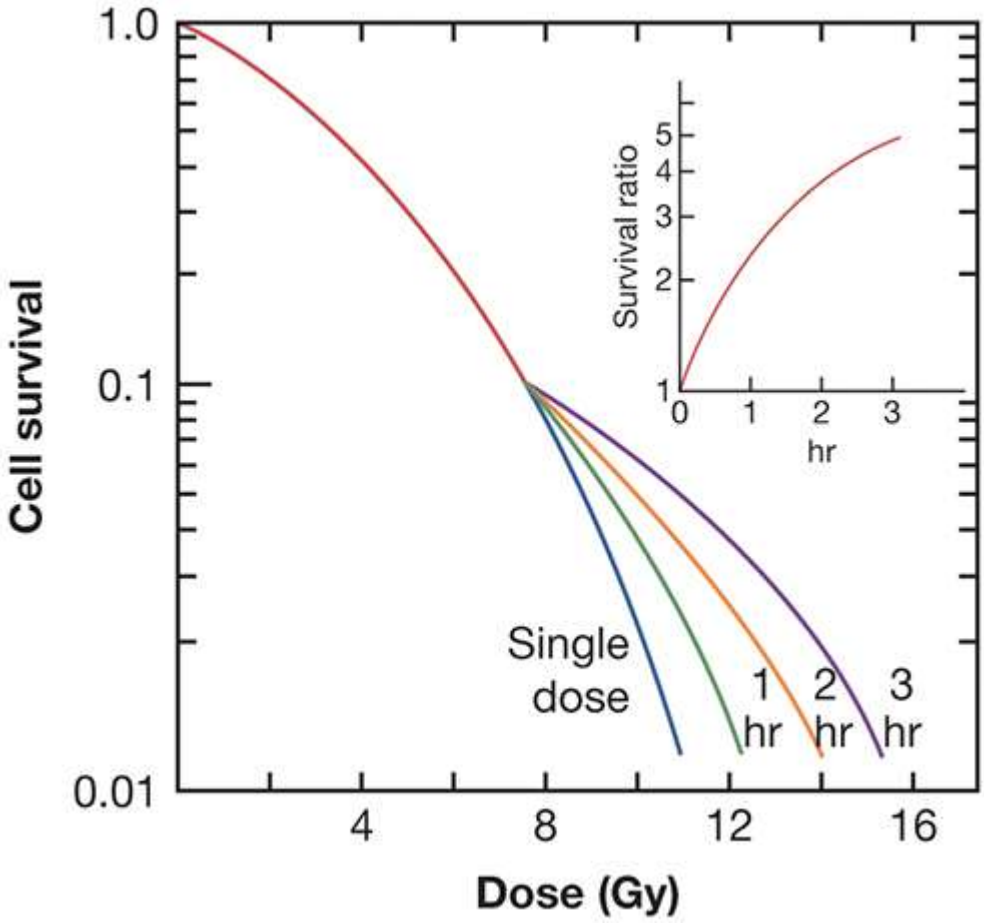

FIGURE 3.14 Recovery curves of the type first described by Elkind and Sutton.[77] The repair of sublethal injury begins immediately and can be measured in terms of survival ratio (inset) *or* the increment in dose to achieve isosurvival. (Reprinted by permission from *Nature:* Elkind MM, Sutton H. X-ray damage and recovery in mammalian cells in culture. *Nature*. 1959;184:1293-1295. Copyright © 1959 Springer Nature.)

The dose-rate effect is another principle of radiobiology primarily influenced by the extent of sublethal damage repair. Dose rate is the amount of radiation delivered per unit time, and a low-dose-rate (LDR) regimen is delivered throughout a more extended period. One example of this is with LDR brachytherapy. LDR treatments enhance the ability of normal tissues to repair sublethal damage. On the contrary, high-dose-rate (HDR) radiation regimens may limit the time available for repairing sublethal damage. As

shown in Figure 3.15, fractionated delivery repeats the “shoulder” of the LQ survival curve, illustrating the ability to repair sublethal damage due to the time between radiation fractions. LDR irradiation achieves the same effect and can be considered as infinitesimally small fractions yielding a shallower cell survival curve with no visible shoulder. Conversely, HDRs lead to less time available to repair sublethal damage, resulting in a steeper curve than LDR. As the dose rate is reduced, the curve shows a shallower relationship due to the higher repair of sublethal damage.

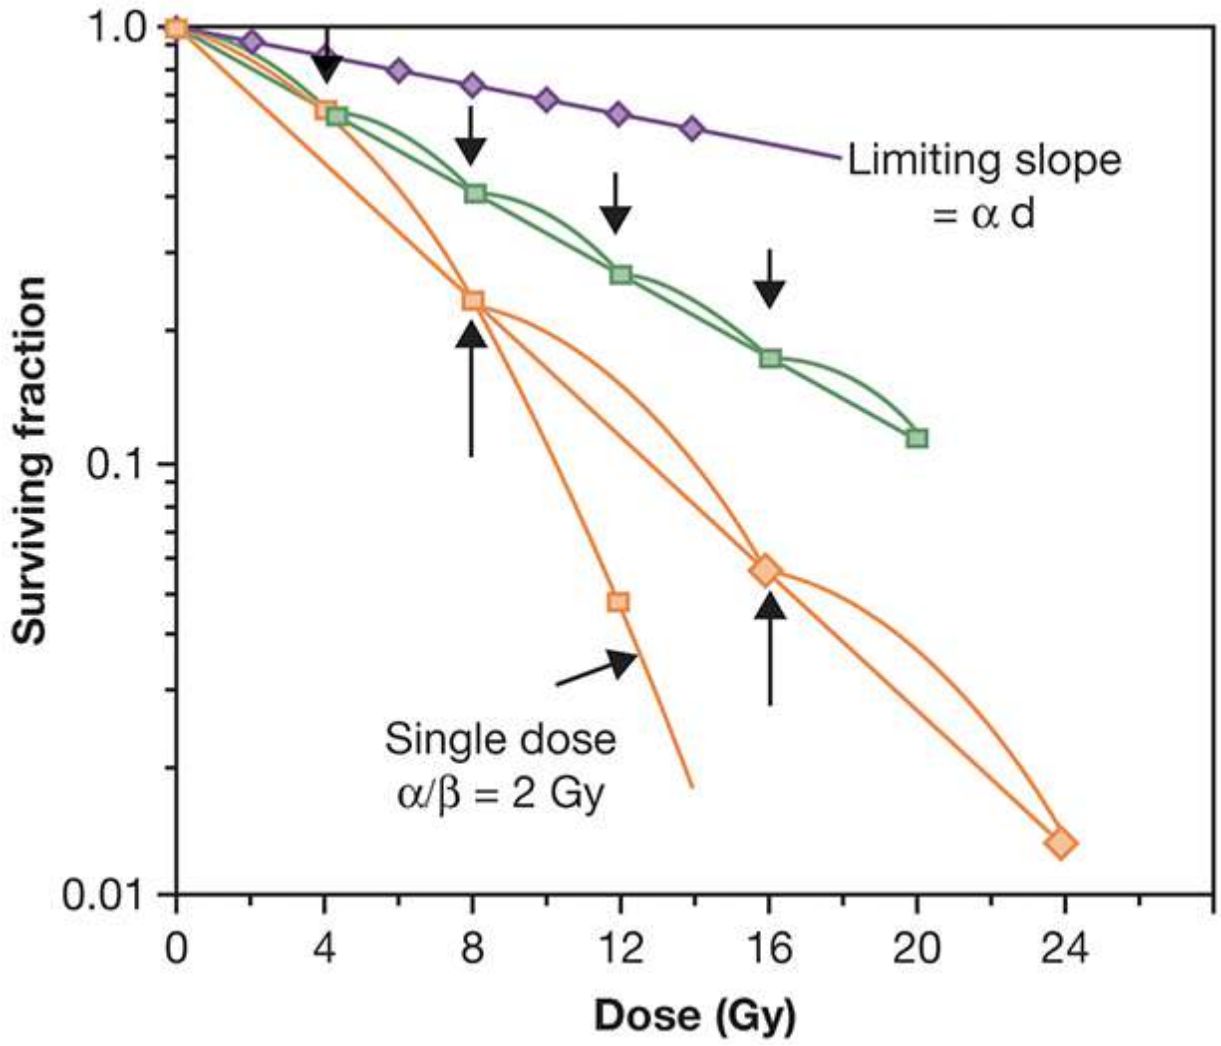

FIGURE 3.15 Multifraction dose-survival curves compared with a single-dose curve. Effective survival curves for multifraction regimens that produce an equal (proportionate) decrement in survival from each dose are linear, with shallower slopes than the single-dose curve at the same dose. Slopes of the multifraction curves become less steep with a decrease in fraction size until the dose per fraction is so low that multihit killing contributes negligibly and the slope is the limiting one determined by single-hit killing (and ${}_eD_0$ = 1/cr). The dose per fraction below which the effective survival curve becomes no shallower is a function of the curviness of the single-dose survival curve and is lower than the α/β value.

Reoxygenation

There is great heterogeneity in the level of oxygenation within solid tumors, given the abnormal and aberrant blood supply commonly seen within tumors. As previously discussed, oxygen helps stabilize DNA damage and limits the cell's ability to repair DNA. As such, during each radiation treatment, the well-oxygenated radiosensitive tumor cells are preferentially

killed. The clearance of these cells allows for more oxygen to become available to other previously hypoxic areas of the tumor. This process of making the formerly hypoxic cells more susceptible to radiation-induced DNA damage is termed "reoxygenation." Importantly, "reoxygenation" commonly occurs between doses of radiation treatment and is one of the primary reasons for delivering radiation treatment in small, fractionated doses. The importance of oxygen in RT-induced cell killing has sparked interest in strategies that help increase tumor oxygenation. These include hyperbaric oxygen therapy,[106] as well as treatment with nanoparticles carrying oxygen-producing molecules.[107,108]

Redistribution

The cell cycle is broken down into multiple phases: G1 (post- mitotic), S (DNA synthesis), G2 (pre-mitotic), and M (mitosis). Cells in the G2 and M phases are more radiosensitive while those in the late S phase are most resistant to radiation (Figure 3.16). As such, during radiation treatment, the cells in the M and G2 phases are preferentially killed. Fractionating the doses allows for multiple opportunities for cells to "redistribute" to the more radiosensitive cell cycle phases during treatment. This phenomenon also is another important reason for fractionating treatment. Of note, certain tumor cells can be slow-cycling or enter a senescent stage where they do not progress through the cell cycle phases; this can promote radioresistance.

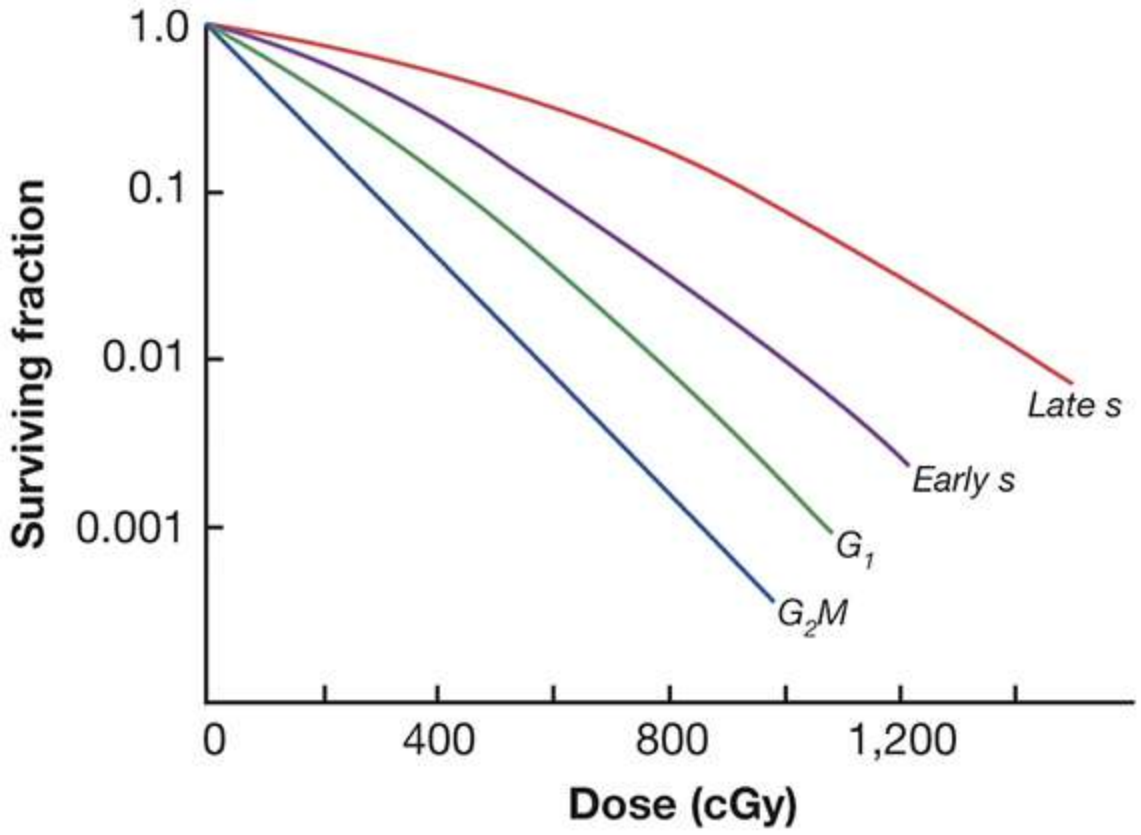

FIGURE 3.16 Radiation dose-survival curves for one line of mammalian cells (V79 Chinese hamster) synchronized in four positions in the division cycle. Significant differences occur in the survival of cells at different ages, with the differences relative to absolute survival being greatest at lower doses. The survival ratio between late S and G_2M cells after 2 Gy is approximately 5. (Reprinted with permission from Withers HR, Peters LJ. Biological aspects of radiotherapy. In: Fletcher GH, ed. *Textbook of Radiotherapy*. 3rd ed. Lea & Febiger; 1980:103-180.)

Cell cycle redistribution is one of the primary influencers of the "reverse dose-rate effect," whereby reducing the dose rate can allow for cells to more efficiently cycle through the cell cycle and thus increase the likelihood that they are in the more radiosensitive phase during radiation administration. On the contrary, with HDRs, cells can enter a senescent state or have sufficient damage to the DNA to prevent quick progression through the cell cycle.

Repopulation

Following radiation exposure, cellular repopulation can occur in normal tissues and tumors. Most cancer cells have a higher rate of cell division and

act similarly to acute-responding tissues. In cancer cells after cytotoxic therapy, the surviving cells (clonogens) can increase their rate of division to repopulate the tumor, termed “accelerated repopulation.” Figure 3.17 shows an example of a rat rhabdomyosarcoma’s exponential repopulation of the surviving clonogens within days after radiation treatment.[109] In this figure, the repopulation of surviving clonogens can be appreciated even when the overall tumor seems to be regressing. This phenomenon is known as accelerated repopulation, and if the surviving tumor cells are able to divide faster than the speed of radiation-induced cell killing, the tumor grows back over time. This is especially relevant during long treatment regimens (eg, over several weeks).

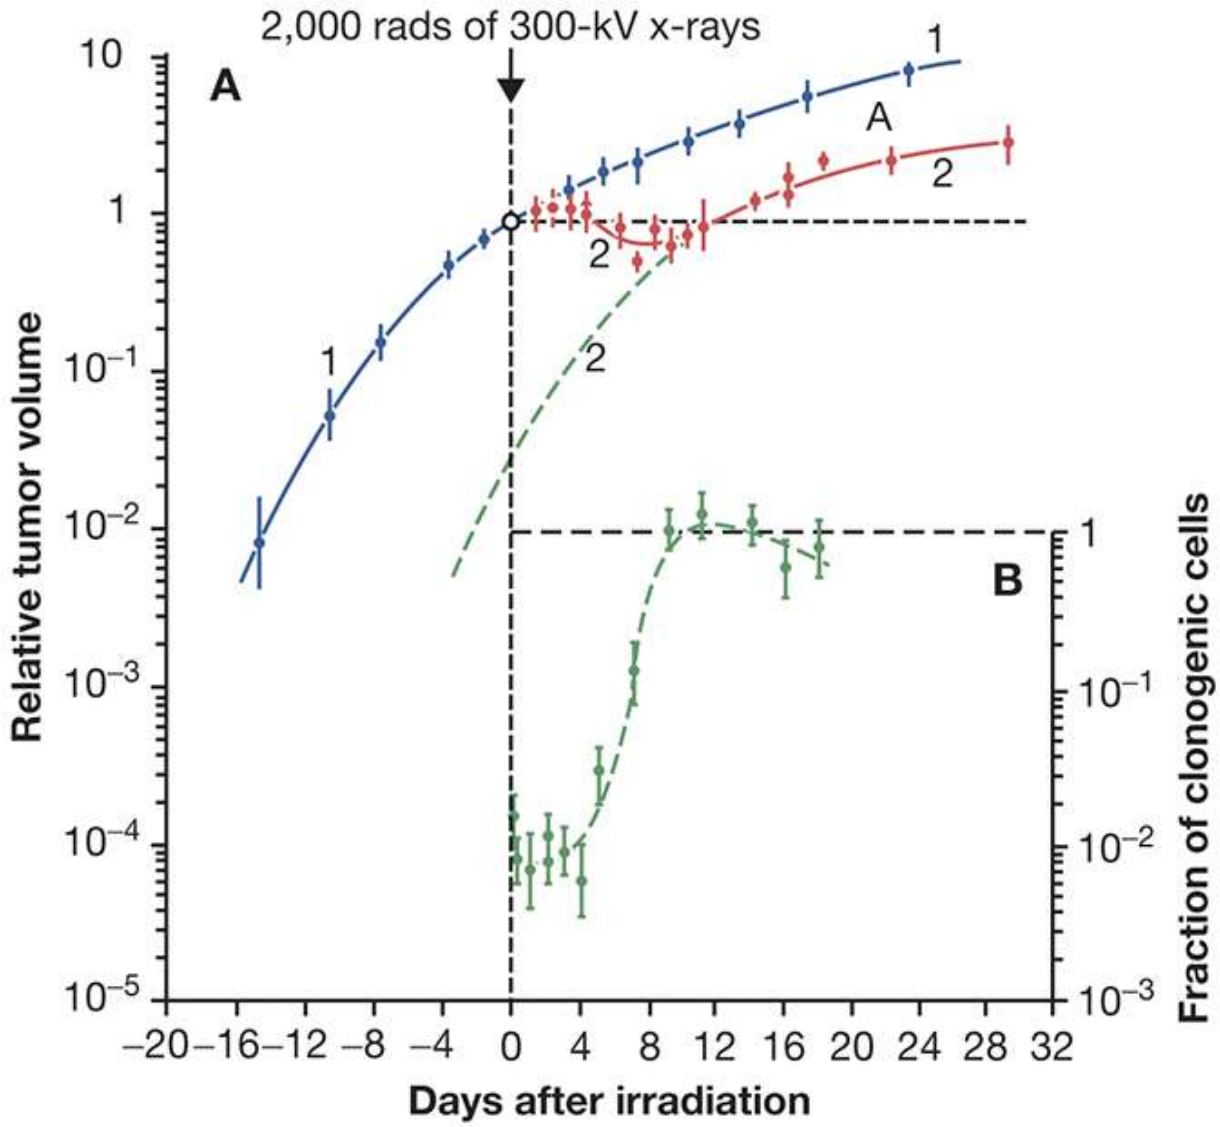

FIGURE 3.17 A. Growth curves for a rat rhabdomyosarcoma and its constituent clonogenic cells after a dose that reduced survival to 1%. The upper curve (1) shows unperturbed growth of tumors; the middle curve (2) shows regression and regrowth of tumors irradiated on day 0 with a dose that reduced cell survival to 1%; the lower curve (B) traces the repopulation of the tumor by surviving clonogens. Exponential regrowth of the surviving clonogenic cells occurs, whereas the gross tumor is regressing. (Reprinted from Hermens AF, Barendsen GW. Changes of cell proliferation characteristics in a rat rhabdomyosarcoma before and after x-irradiation. *Eur J Cancer*. 1969;5[2]:173-189. Copyright © 1969 Elsevier. With permission.)

To conceptualize the significance of accelerated repopulation during treatment, consider this: a 2- to 3-fold increase in the number of surviving clonogenic cells can enhance the tumor burden to an amount comparable to advancing the tumor's T-stage by one level.

One potential strategy to counteract repopulation is to use a technique called accelerated fractionation. This involves delivering the same total dose of radiation over a shorter time period, and sometimes delivering more than one fraction per day. While this strategy aims to complete radiation treatment before substantial repopulation can occur, it's important to balance this effect against the other Rs of radiobiology—which require time between treatments. Shortening the overall treatment time may limit the opportunity for healthy cells to repair, and for tumor cells to redistribute and reoxygenate. Notably, late-responding tissues are not affected by such treatment time changes given that they are not influenced by the extent of repopulation.

Radiosensitivity

The susceptibility to RT-induced DNA damage varies across tumor types, and it is based on the dose and fractionation regimen used; this understanding led to the proposal of "radiosensitivity" as the fifth R of radiobiology.[110] Relative radiosensitivity can be defined generally based on tumor types. For instance, hematologic-origin cancers and lymphomas are more radiosensitive while melanomas and sarcomas are more radioresistant. In addition, cellular-level genetic changes, alterations in signaling pathways, and availability of cancer stem cells within the tumor can all influence the relative radiosensitivity of a tumor. These cellular-level factors have led to the study of more targeted radiosensitization pathways for various cancers—for example, targeting the fibroblast growth factor receptor pathway to radiosensitize head and neck cancer and lung cancer,[20,111] suppressing autophagy to radiosensitize breast cancers,[112] and impairing DNA repair to radiosensitize prostate cancer.[113]

Reactivation of Antitumor Immune Response

As described in earlier sections, radiation significantly alters the immune cell milieu of the tumor microenvironment, and these changes can either promote or impair tumor cell killing. Importantly, the dose and fractionation regimen utilized greatly influence whether RT has a pro- or antitumor promoting effect; preclinical studies show that there is a threshold of dose/fractionation that increases antitumor immune responses while higher

doses can actually decrease tumor immunogenicity.[51] These thresholds have yet to be evaluated and established in humans with various cancers. Immunomodulators also show great promise as combination therapies with RT have been suggested to improve patient survival.[114] These observations have led to the recent proposal of reactivation of antitumor immune response as the sixth R of radiobiology.[115]

MODIFICATION OF DOSE FRACTIONATION PATTERNS

Conventional fractionated RT routines delivering around 2 Gy/day for 5 days a week were developed more than 50 years ago with the aim of limiting late effects by exploiting the differential response of tumors and normal tissues. The typically high α/β ratios of rapidly proliferating tissues like tumors make them more susceptible to radiation damage than tissues with lower α/β ratios like most normal tissues. This difference in α/β ratios is mostly evident in the initial shoulder of cell survival curves with low α/β ratio cells showing a large shoulder and high α/β ratio cells showing a much steeper curve. At a low dose of 2 Gy, the difference in cell survival is not as evident, but by repeating these 2 Gy fractions there is a large difference in cell survival at larger cumulative doses.

Early clinical data that supported conventional fractionation have been obtained with 2D radiotherapy techniques that irradiated the tumor volume along with larger volumes of normal tissues in close proximity. Modern RT techniques can deliver much more conformal dose distributions that limit the dose and volume of normal tissues receiving radiation, thereby decreasing late effects. Therefore, while conventional fractionation has proven effective for many situations, this delivery strategy is not universally ideal at maximizing the therapeutic ratio in all clinical scenarios.

In particular, this regimen might not be suitable for all medical scenarios, especially when dealing with extremely fast-growing tumors, and in tumors with heterogeneous α/β ratios that result in the accumulation of radioresistant cells with low α/β ratios.[116,117] The development of radioresistance following delivery of standard fractionated radiation regimens has been linked to improved DNA damage repair mechanisms in surviving clonogens, the high prevalence of radioresistant cancer stem cells within the tumor, and a higher redistribution of cells into the radioresistant

cell cycle phase.[118-120] These changes represent mechanisms that overcome the classical 4Rs of radiobiology that assist in tumor radiosensitization. Alternate fractionation regimens can help overcome radioresistance, improve targeting of tumors with low α/β ratios, and alter the delivered BED to tumors and normal tissues in order to maximize the therapeutic ratio.

Hypofractionation

Conventional dose fractionation might not be the best approach for low α/β ratio tumors that are late responding like most normal tissues. In fact, a low α/β ratio nulls the benefits of multifractionated, low-dose conventional fractionation regimens. Instead, hypofractionation could offer more therapeutic benefits administering larger doses of radiation in fewer sessions, which allows for the delivery of more substantial doses in each fraction while reducing the overall number of treatments. This strategy capitalizes on the fact that tumors with a lower α/β ratio are more sensitive to larger doses given in fewer fractions delivering a higher BED. However, clinicians often approach high-dose fractions with caution given that these large doses have historically been linked to vascular injuries, prolonged inflammation, and severe delayed side effects that could significantly impair a patient's quality of life and life span. However, technological and methodologic advancements allow for high-accuracy dose delivery to smaller well-defined targets that can tackle some of these biologic drawbacks. The safe delivery of large radiation doses and resulting high BED characteristic of hypofractionation and stereotactic body radiotherapy (SBRT) requires a high level of confidence in the accuracy of the entire treatment delivery process. This is accomplished by integrating modern imaging, simulation, treatment planning, and delivery techniques into all phases of the treatment process.

High single-dose RT regimens typical in stereotactic radiosurgery (SRS) or SBRT were pioneered in the late 1960s to target deep-seated brain lesions using single-dose treatments. These lesions required the use of stereotactic techniques to precisely locate lesions by using a well-defined three-dimensional coordinate system without the availability of modern image-guided techniques. This innovative approach paved the way for

Gamma Knife, a radiation tool designed for precise targeting of small brain lesions using 192 radiation beams emitted by radioactive Co-60 and collimated to deliver a single heavily focused dose of radiation.

The success of SRS pioneered by Leksell forms the basis of hypofractionation. SBRT has evolved into a highly effective treatment in controlling early-stage primary and oligometastatic cancer at locations throughout the abdominopelvic and thoracic cavities, as well as spinal and paraspinal sites; these treatments can now be delivered on linear accelerators. SBRT is used for select patients with primary or metastatic disease, with excellent local recurrence outcomes. The majority of patients treated with SBRT suffer from lung, liver, and/or spinal tumors, which also are common sites of oligometastatic disease. Eligibility for SBRT is typically limited to well-circumscribed tumors with a maximum cross-sectional diameter of up to 5 to 7 cm in order to limit the total volume of normal tissues receiving high doses.

Mounting evidence suggests that SBRT has remarkable efficacy in early-stage non–small cell lung cancer patients who are not candidates for surgery and its potential utility against limited metastatic disease.[121,122] The doses administered through stereotactic ablative radiotherapy are often adjusted based on the tumor's position, especially for tumors centrally located in the lung due to the presence of critical mediastinal structures. While the lung can tolerate the loss of function in small areas because of its ample residual functionality, not all tissues offer such flexibility. Therefore, the location and size of the treatment area are primary considerations in SBRT.

An illustrative example of hypofractionation comes from a study on SBRT for low- to intermediate-risk prostate cancer. This study revealed that delivering 36.25 Gy over four to five sessions led to prostate-specific antigen relapse-free survival rates on par with other standard treatments. Fraction sizes close to 8 Gy are particularly interesting, not just because they align well with the LQ model's parameters, but also due to their potential therapeutic advantages.[123] By optimizing dose distributions with intensity-modulated radiation therapy, fewer normal tissues are exposed to high radiation doses. Even if the total dose to the body might be higher, the rapid high-dose falloff outside the tumor can create a beneficial environment. In addition, it can result in gradients of immune mediators like cytokines and chemokines, which may boost the body's immune

response against the tumor.[124] Such doses might also send stronger "danger" signals, boosting tumor immunity and having a positive distant effect, which helps target smaller metastatic tumors (see the discussion about the abscopal effect in the prior section).

Hyperfractionation

Hyperfractionation involves delivering smaller radiation doses than the standard dose per fraction. The foundational principle behind this technique is to take advantage of the differential responses between the late-responding normal tissues and the acute-responding tumors when exposed to certain doses. By utilizing this difference, the treatment seeks to maximize tumor control while minimizing damage to the surrounding healthy tissues. The scheduling for hyperfractionation is also unique. While it can be performed by treating patients once a day for 6 or 7 days a week, the more common approach is to deliver two fractions per day for 5 days a week, with an intrafraction interval of no less than 6 hours.

Tumors that proliferate slowly and have a low α/β ratio might not benefit as significantly from hyperfractionation, making the approach more suited for acute-responding tumors. For late-responding tissues such as fibrovascular tissues, a 2 Gy/day fraction can be substituted with two fractions of about 1.2 Gy each. On the other hand, acute-responding tissues and tumors respond better to a fraction of about 1.05 Gy. This results in a therapeutic differential of 1.2/1.05, which translates to a 14% therapeutic benefit. Despite the tumor control benefits, it is important to note that there is a trade-off in the form of increased acute toxicity.

Several studies have been conducted to understand the benefits of hyperfractionation over conventional RT. A meta-analysis of randomized trials, mostly centered on cancers of the oropharynx and larynx, demonstrated the advantages of hyperfractionated RT. Even when some trials included a reduction in the total radiation dose, the hyperfractionated approach resulted in an 8% 5-year survival benefit.[125] It should be noted that clinically, hyperfractionation has not gained much use. This may in part be due to challenges in scheduling the twice-daily treatments.

LDR continuous irradiation, often seen in LDR brachytherapy, shares the biologic benefits of hyperfractionation. LDR brachytherapy involves

implantation of radioactive material into or close to the tumor. This method can delay proliferative cells in their cell cycle, especially in the late G2 phase, which can sensitize proliferative tissues and tumors without harming late-responding normal tissues. It ensures a high likelihood of sterilizing areas close to the radioactive sources and minimizes the volume of normal tissue exposed to high doses due to the rapid falloff of dose outside the treated area, providing what is known as a double advantage. However, the misplacement of seeds can create "cold spots" within the target volume, potentially reducing tumor control. Prolonged implantation of certain radioisotopes may expose normal tissues to high doses. Comparatively, HDR brachytherapy offers logistic benefits and increased safety for medical staff, along with the possibility of moving some normal tissues away from the high-dose field.

CHAPTER 4

Molecular Pathophysiology of Tumors

John D. Martin, Dan G. Duda, and Rakesh K. Jain

Radiotherapy (RT) is widely used for treating various cancer types. While RT has long been used, incorporating it in regimens involving the newest therapies remains a challenge. RT kills individual cancer cells by interfering with the biology of their proliferation. However, the efficacy of and resistance to RT are dependent on the pathophysiology of the tumor microenvironment (TME; Figure 4.1), which is made up of nonmalignant components. In addition, the efficacy of and resistance to the most commonly used cancer medicines, including chemotherapy, targeted therapy, and immunotherapy, depend on how RT alters the pathophysiology of the TME.

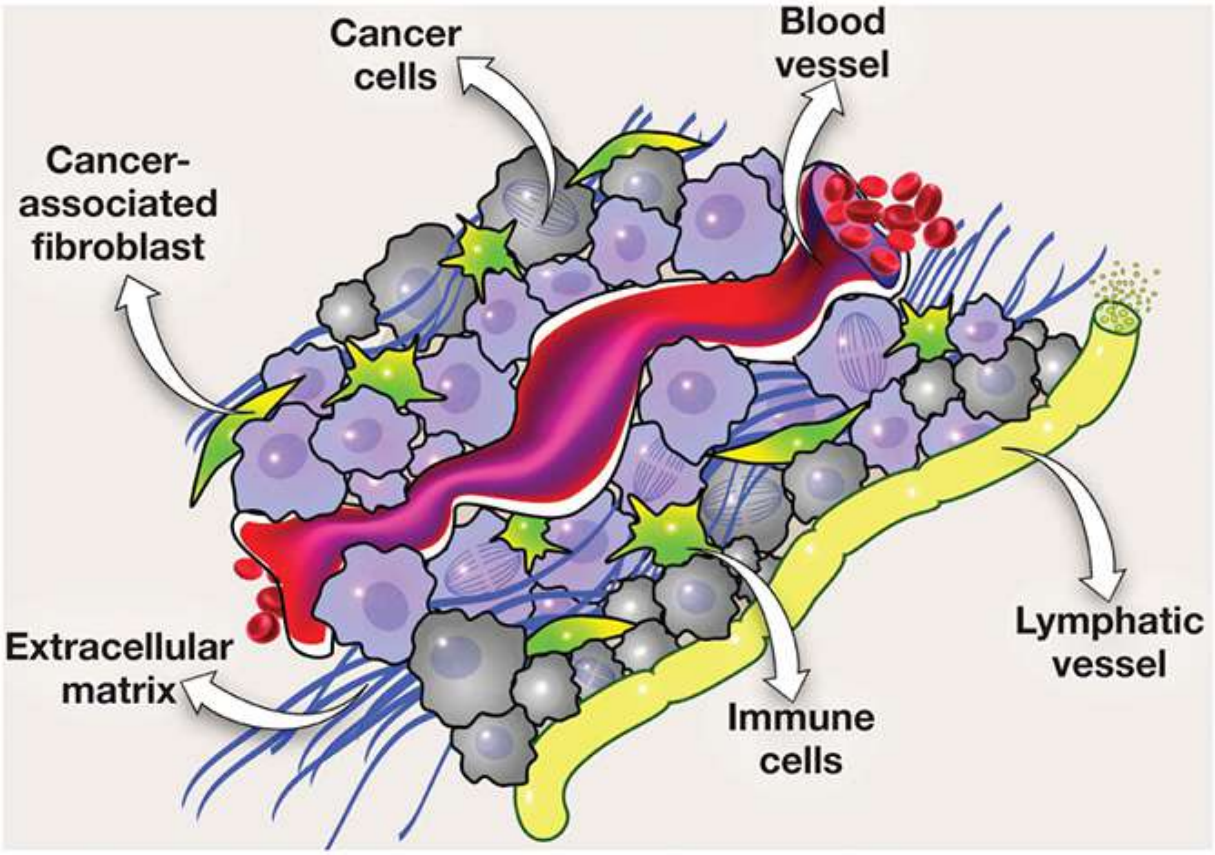

FIGURE 4.1 Solid tumors comprise cancer cells and stroma, produced abnormally through dysregulated angiogenesis, desmoplasia, and inflammation. Cancer cells recruit nonmalignant stromal cells, including fibroblasts, immune cells, blood, and lymphatic vascular cells, and promote extracellular matrix deposition. The result is a pathologic molecular, metabolic, and physical microenvironment that promotes tumor progression while resisting therapy and host immune response. (Used with permission of Annual Reviews: from Martin JD, Seano G, Jain RK. Normalizing function of tumor vessels: progress, opportunities and challenges. *Annu Rev Physiol*. 2019;81:505-534; permission conveyed through Copyright Clearance Center.)

Researchers have long appreciated that resistance to RT is fueled by subphysiologic oxygen concentration—hypoxia— within tumors.[1] However, we and others have worked to test the hypothesis that hypoxia is both a cause and effect of the molecular pathophysiology of tumors. Furthermore, we propose that RT be employed to reduce hypoxia toward sensitizing tumors to other therapies. In addition, alleviation of hypoxia can effectively sensitize a tumor for RT alone and with other treatments.

To increase the efficacy and overcome resistance to RT in patients, radiation oncology researchers must strive to understand the interplay

between RT, TME, and other therapies. This chapter describes how RT works and how the TME mediates its efficacy. It explains how RT affects other cancer therapies and how the TME inhibits these actions, as well as how RT can affect TME. How to modulate the TME to increase RT efficacy and overcome resistance and how to optimally combine these therapies are also explored.

HYPOXIA

Hypoxia is a hallmark of the TME. Several processes cause hypoxia in the TME. First, the abnormal growth (angiogenesis) and structure of vessels[2,3] make tumor vessels leaky and tortuous. Second, fibrosis (desmoplasia)[4] contributes to the compression of tumor blood vessels, which makes blood flow slower or not at all. Finally, immune cells (inflammation)[5-7] make vessels even leakier than angiogenic factors alone. Biomarkers related to these processes and hypoxia are negative prognostic biomarkers in many types of cancer, thereby underscoring their importance.[1] Thus, strategies that reverse these processes make TME more like a "normal" organ and prevent hypoxia have demonstrated benefits in some cancers when combined with RT or other cytotoxic therapies.[1,2,4,8-15]

Several strategies exist to "normalize" the TME toward alleviating hypoxia and increasing cytotoxic treatment efficacy. Tumor blood vessel leakiness and tortuosity are normalized with antiangiogenic therapies (AATs). Compression of tumor blood vessels is reversed by cancer-associated fibroblast (CAF)/extracellular matrix (ECM) normalization through CAF reprogramming by the administration of mechanotherapeutics.[16] Besides alleviating hypoxia, immunosuppression is reversed by administering immunotherapeutics, particularly immune checkpoint blockade (ICB), to normalize the activity of immune cells and blood vessel leakiness.[1] In this chapter, we describe these normalization strategies in the context of RT. We explore how RT primes the TME for other therapies and vice versa. We consider the various combinations of these therapies one by one. Finally, we survey some of the challenges of translating the results of preclinical studies of these drug combinations into clinical practice.

Hypoxia Mediates Treatment Response and Resistance

Blood vessels supply nutrients for cancer cells to expand. Paradoxically, cancer cells make blood flow inefficient by making vessel walls leaky through signaling and physically compressing the vessels.[17] Cancer cells produce angiogenic factors that produce vessels that never become mature.[2] Cell proliferation generates forces applied throughout the TME as compressive solid stresses. Cancer cell signaling stimulates CAF-mediated production and maintenance of ECM, which stores and transmits solid stresses.[4] Immature vessels are hyperpermeable with irregular morphology.[18] Solid stresses compress vessels, resulting in a reduced area through which blood flows. While in normal organs blood vessel permeability is consistent, and there is no compression, in tumors, these characteristics are heterogeneous and can differ between tumor types, stages, and locations within a tumor and between primary tumors and metastases in the same host.[1,19,20]

Healthy cells depend on nutrients to survive and proliferate, while cancer cells can survive in nutrient-sparse situations. Therefore, low oxygen concentrations (hypoxia) resulting from the dysfunctional tumor vasculature are a survival advantage for malignant cells. In addition, hypoxia in the TME reduces immune surveillance. Also, hypoxia promotes resistance to radiation, chemotherapy, and immunotherapy through various mechanisms. These factors provide a physiologic basis for findings demonstrating that the oxygen level in the TME is a validated prognostic biomarker and an emerging candidate biomarker of response.[1]

Hypoxia Promotes Malignant Disease Progression

Hypoxia makes cancer progress faster through several mechanisms. First, hypoxia exerts selection pressure because only particular cancer cells can survive the apoptotic cues induced by low oxygen.[21,22] Second, hypoxia inhibits tumor-suppressive genes, thereby permitting the proliferation of cancer cells.[23] Third, hypoxia promotes the production of immune-suppressive cytokines.[4] Fourth, hypoxia promotes invasive cancer cell phenotypes. Specifically, it stimulates cancer stem cells[24] and epithelial-to-mesenchymal transition phenotypes.[25] Fifth, hypoxia promotes some steps of the metastatic cascade, which is the process of cancer cells spreading

from the primary tumor throughout the host. For example, hypoxia promotes the production of promigratory and ECM-degrading factors that facilitate cancer cells to invade out of the primary tumor, intravasate into tumor blood vessels, and, from there, circulate throughout the host toward colonizing distant organs.[26,27]

Hypoxia Promotes Anticancer Treatment Resistance

Hypoxia is a cause of resistance to RT, most types of chemotherapy, and immunotherapy reducing these drugs' efficacy through multiple mechanisms. Here, we describe how hypoxia affects the efficacy of anticancer treatment modalities.

Radiotherapy

Ionizing radiation causes damage to mitochondria. The damage produces reactive oxygen species (ROS), which damage DNA, resulting in cell death. Unfortunately, RT induces less DNA damage in hypoxia.[28] Hypoxia stabilizes hypoxia-inducible factor 1 (HIF1). HIF1 induces glycolysis and accumulation of NADPH. Glycolysis induces lactate accumulation, which upregulates HIF1 to complete a feedback cycle.[29] Meanwhile, NADPH scavenges ROS, which are required for cell damage.[30]

Chemotherapy

Oxygen relies on functional tumor blood vessels to reach cancer cells; so does chemotherapy, both small molecules and nanoforumlations.[31] Unfortunately, these vessels are immature and inefficient. The drug concentration in a tumor lesion correlates with the lesion's volume reduction in patients.[32,33] If the delivery of oxygen is limited to a tumor, then it is likely that chemotherapy delivery is similarly restricted and that the efficacy of chemotherapy is weakened. So, hypoxia is likely correlated to chemotherapy resistance. Also, many chemotherapies are less potent in hypoxia. Along these lines, weak-base chemotherapies are neutralized by acidity, another metabolic characteristic of a hypoxic TME.[1] Therefore, hypoxia indicates that chemotherapy cannot reach tumors in sufficient concentrations and its presence reduces most chemotherapies' efficacy.

Immunotherapy

ICBs have revolutionized the treatment of many solid tumors. However, they are effective in less than 20% of patients with cancer,[34] and many develop severe immune-related adverse events.[35] Hypoxia mediates resistance to ICBs through several mechanisms.[6,36,37]

First, hypoxia recruits immunosuppressive cells. For example, hypoxia promotes the expression of chemokines that recruit regulatory T (Treg) cells.[38] These cells are immunosuppressive because they induce the immune system to tolerate cancer cells, which enables survival and proliferation.[38-40] Second, hypoxia stimulates proangiogenic and immunosuppressive signaling. Specifically, hypoxia promotes the expression of the angiogenic and immunosuppressive factor vascular endothelial growth factor (VEGF). Besides promoting the growth of immature tumor vessels, which leads to hypoxia, VEGF has immunosuppressive functions. For example, VEGF reduces the recognition of cancer cells by the immune system by inhibiting dendritic cell (DC) maturation.[41] With VEGF signaling, DCs do not present cancer cell antigens to other immune cells so that they can recognize cancer cells for elimination. Also, angiogenic signaling reduces the ability of leukocytes to attach to the tumor vessel wall toward migrating into the tumor parenchyma.[37],[42] Beyond angiogenic signaling, hypoxia affects the activities of leukocytes, which migrate slower in hypoxic tissues.[43,44] Hypoxia also reduces the functions of leukocytes. Specifically, hypoxia recruits immunosuppressive cells that block antitumor immune cells from recognizing and killing cancer cells.[38,45] Third, hypoxia signaling induces immunosuppression. Hypoxia and its signaling upregulate immune checkpoints on antitumor immune cells and checkpoint ligands on cells throughout the TME to halt the activities of T cells.[46-50] Similarly, acidity impairs antitumor immune cells' ability to kill cancer cells.[51] Fourth, hypoxia and immunosuppression are both related to low blood perfusion. Trafficking immune cells must enter lymph nodes and subsequently traverse tumor blood vessels to reach cancer cells.[52,53] In hypoxic areas of tumors where perfusion is low, immune cell infiltration also is low.[54] Accordingly, increase in perfusion is correlated with response to ICB in preclinical murine models.[55] Therefore, hypoxia affects the efficacy of immunotherapy through multiple mechanisms.

Hypoxia as a Prognostic Biomarker

Beyond affecting response to treatment, hypoxia plays a role in tumor progression. Many clinical studies have supported and validated the notion that hypoxia causes tumor progression and treatment resistance because hypoxia is an independent prognostic biomarker of poor outcome in many cancer types.[1,14,21] In an apparent contradiction with hypoxia as a negative prognostic biomarker, for decades, researchers observed that angiogenesis and a high degree of tissue vascularization are required for tumor growth.[2] Specifically, the density of blood vessels in tumor regions of intense new vessel formation[56] is validated broadly as an independent and prognostic biomarker of worse response.[1] Thus, neovascularization is required for tumor growth, while the lack of oxygen, which depends on blood vessels, also predicts faster disease progression.

Key Determinants of Hypoxia

Hypoxia is a biomarker of worse outcomes for patients with cancer, as is high vascularity.[1] This is paradoxical because oxygen is delivered to tumors through blood vessels, so assuming that higher vascularity results in more oxygen is reasonable but incorrect. To address this conundrum, in 2001, we proposed that the judicious use of angiogenesis inhibitors, which block new vessel formation, could improve vascular function and thus improve oxygenation.[8,9] In other words, the normalization hypothesis posits that an excess of immature blood vessels reduces oxygen delivery. In this section, we describe the vascular abnormalities caused by TME and how angiogenesis, desmoplasia, and inflammation cause them (Figure 4.2).

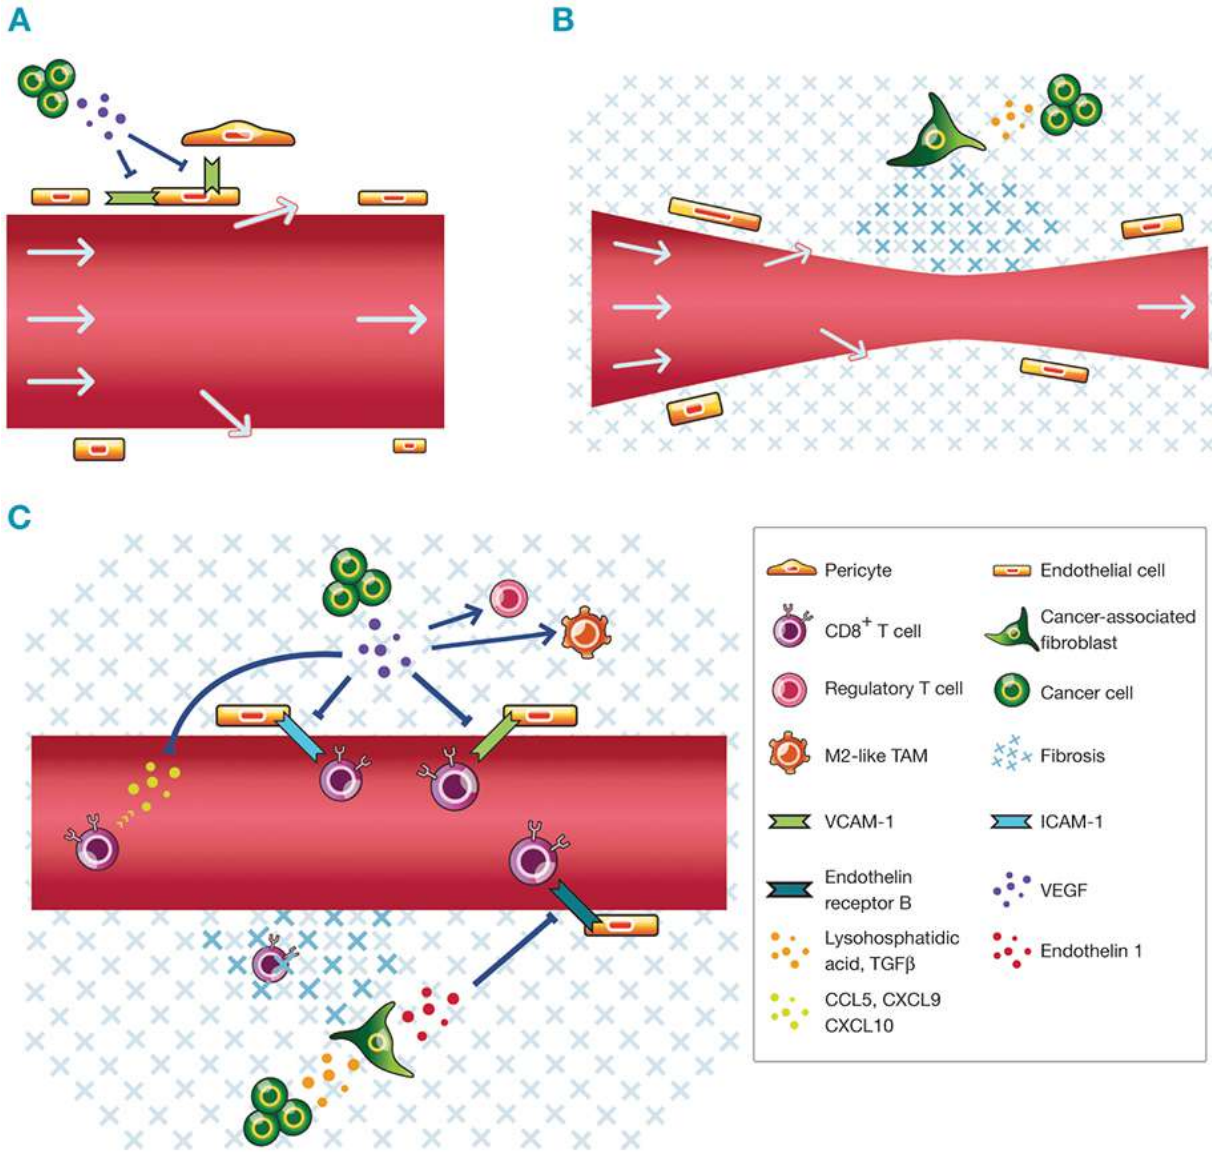

FIGURE 4.2 Tumors promote angiogenesis, desmoplasia, and immunosuppression, thereby inhibiting blood flow, oxygen delivery, and immune cell infiltration. A. Simplified depiction of leaky tumor blood vessels and relevant cells. Cancer cells secrete angiogenic factors, including vascular endothelial growth factor (VEGF), that reduce the expression of vascular stabilizing molecules, such as vascular adhesion molecule 1 (VCAM-1), which mediates the interaction of endothelial cells with themselves and perivascular cells in mature vessels. Plasma and blood-borne molecules (arrows) flow out of pores in the vessel wall, impairing blood flow. B. Simplified depiction of a compressed tumor blood vessel and pertinent cells. Cancer cells activate cancer-associated fibroblasts through various signals, including transforming growth factor-β (TGF-β). This activation leads to more fibrosis, which mediates the transfer of compressive physical force from the rapidly expanding cancer cell population onto blood vessels. Blood flow is reduced with compression. C. Simplified depiction of immunosuppression and pertinent cells. Cancer cells secrete VEGF and TGF-β among other factors that affect angiogenesis and fibrosis. VEGF recruits regulatory T cells and polarizes tumor-associated macrophages (TAMs) toward M2-like immunosuppressive

phenotypes. Further, VEGF blocks the recruitment and transmigration of $CD8^+$ T cells by interfering with VCAM-1 and intercellular adhesion molecule 1 (ICAM-1). In addition, TGF-β signaling increases fibrosis, physically impedes the migration of $CD8^+$ T cells, and inhibits their vascular transmigration through endothelin 1 signaling through the endothelin receptor type B. Vascular Abnormalities

Structure

Tumor endothelial cells (ECs), which line the vessel wall, have an abnormal phenotype. In blood vessels of healthy organs, ECs are aligned with blood flow and attached tightly. Tumor ECs are misaligned with the flow. They are loosely connected and often protrude from either side of the vessel wall.[3,57] Similar to ECs in normal organs, tumor ECs have vesiculo-vacuolar organelles (VVOs), which connect the intravascular and extravascular areas. Their presence is increased with VEGF.[2,58,59] Perivascular cells provide structural support, filling gaps between ECs.[3] These cells send quiescence signals to ECs and separate from ECs during angiogenesis.[60] Tumor perivascular cells are less contractile, compromising their influence over vessel function.[61] In vessels in healthy organs, there is a vascular basement membrane (BM) that provides structural support for both ECs and pericytes. In tumor vessels, the BM is heterogeneous, thick in some sections, and absent in others.[62] Therefore, tumor vessels' components and structure are abnormal.[2,11,18]

Pathologic angiogenesis dictates that the blood vessels within a single tumor are more heterogeneous in their characteristics than in normal organs.[63] Vessels branch in an ordered hierarchy of arteries, arterioles, capillaries, venules, and veins in normal organs. In tumors, blood vessels do not display these phenotypes. They are often saccular with irregular branching.[64] The characteristics of single vessels can even vary substantially over their length.[64-66] Some tumor vessels have a large, dilated diameter. Others are tortuous rather than straight.[67,68] Solid stress leads to vessels collapsing shut with buckling.[69-71] As a result of angiogenesis and solid stress, only some tumor regions have perfusion while others have low or

none. In certain cases, tissue volumes on the order of cubic millimeters lack perfusion, while in normal tissues, vessels are only 100 to 200 μm apart.[66]

Function

As tumor vessels undergo angiogenesis and ECs detach from each other and pericytes, they become leaky[3] (Figure 4.2A). In addition, VVOs may cause leakiness.[58,59] As plasma leaks from vessels, the fluid pressure difference across the vessel wall is reduced, and fluid transport into tumors slows.[67,72] After plasma leaks, the red blood cell density increases so viscosity increases.[73] Also, leaky vessels upstream have lesser pressure such that the intravascular pressure gradient, which is the driving force of intravascular blood flow, is reduced.[74] Tumor ECs and pericytes cannot control flow, which is transient in speed and direction. Tumor vessels that collapsed lack blood flow.[75] Compressed vessels have reduced flow rates because of smaller luminal cross-sectional area.[65,74] One upstream collapsed vessel could eliminate flow to several downstream vessels.[64,71,75] Thus, the function of tumor blood vessels is characterized by spatial and temporal variations in flow.[76,77]

Causes of Vascular Abnormalities

Angiogenesis. One century ago, scientists noted that the vasculature is associated with tumor growth.[78] Afterward, the development of transparent window techniques enabled more insights.[79-82] In 1968, scientists suggested that tumors produce an "angiogenic" substance that initiates neovascularization.[83,84] In 1971, Folkman hypothesized that blocking angiogenesis reduces tumor growth and metastasis.[85] In 1978, researchers observed that angiogenesis occurs during neoplastic transformation—and, thus, the hypothesis that antiangiogenesis could be used to prevent cancer was put forth.[86] Decades later, in 2004, bevacizumab was the first antiangiogenic agent (AAT) approved for cancer treatment. An antibody specific to VEGF increased survival when added to standard chemotherapy in patients with metastatic colorectal cancer.[87] Today, more than a dozen AAT are approved for various types of cancer in combination with various treatments, including seven with ICBs.[1]

Angiogenesis is regulated by the balance of proangiogenic and antiangiogenic factors.[9] In normal physiology, this balance is in equilibrium spatially and the "angiogenic switch" is "off." A transient increase in proangiogenic molecules turns the "angiogenic switch" "on" during physiologic angiogenesis (eg, during embryonic development, wound healing, and formation of the corpus luteum). During tumor initiation and progression, the increase in tumor-derived proangiogenic molecules tips this balance permanently, and blood vessels form haphazardly to support the growing tumor mass. In "sprouting" angiogenesis, BM and other ECM are digested; ECs divest of pericytes, migrate and proliferate into a sprout; a lumen forms through canalization; branches form through confluence and anastomoses of sprouts enabling perfusion; and the newly formed vessels invest in BM and pericytes.[3] Tumor vessels remain immature, without typical differentiation into arterioles, capillaries, and venules.[3,18,82,88]

Besides sprouting angiogenesis, there are at least five mechanisms of neovascularization described in tumors: vessel co-option,[89,90] intussusception,[91] vasculogenesis,[3,92] vascular mimicry,[93] and cancer cell to EC transdifferentiation.[2] During vessel co-option, tumor cells migrate and proliferate surrounding vessels, forming "perivascular" cuffs. These cuffs grow past the diffusion distance limit of oxygen and other nutrients. Furthermore, they can collapse vessels as they generate solid stresses.[90] During intussusception, a vessel enlarges in response to angiogenic factors from cancer cells, and a tissue column grows in the expanded vessel lumen to separate the lumen into a vessel branch point.[91,94-96] During tumor vasculogenesis, endothelial precursor cells (EPCs)—originating from bone marrow niches and circulating in the peripheral blood circulation—can also promote neovascularization.[92,97,98] EPCs of non–bone marrow origin are recruited from adjacent tissues and/or circulation.[99,100] During vascular mimicry, the luminal surface of vessels may be lined by cancer cells.[93] Finally, trans-differentiated cancer cells[101] or cancer stem-like cells[3,102-104] can compose a fraction of ECs in tumor vessels. Thus, "vasculogenesis" describes neovascularization induced by cancer stem cell integration into the vasculature.[105] Parsing the relative contribution of these processes to tumor neovascularization could lead to better drugs to ameliorate pathologic angiogenesis.[105],[106]

Desmoplasia. Other components of the TME include CAFs and the ECM, which CAFs produce and maintain, giving a physical structure to tumors. Cancer cells stimulate desmoplasia, the growth of fibrotic tissue and ECM, through fibroblasts. Depending on the tumor type and its differentiation stage, malignant cells may be distributed throughout the ECM as individual cells (eg, lymphomas, melanomas) or clumps or nests (eg, carcinomas). In poorly differentiated carcinoma, the cancer cells are loosely packed in clumps, whereas in well-differentiated carcinoma, the cells are connected with intercellular junctions and tightly packed in a nest enveloped by a BM. Nearby host cells such as fibroblasts migrate from the adjacent connective tissue or the primary tumor to the metastatic site.[107]

Desmoplasia also is dysregulated in tumors. Cancer cells signal to fibroblasts through proteins (eg, transforming growth factor-β or TGF-β), transcriptional factors, interleukins, matrix metalloproteinases, and ROS.[108] Hypoxia induces fibroblasts to produce and maintain ECM through connective tissue growth factor, TGF-β, and Sonic hedgehog signaling.[109,110] Once activated by cancer cells or hypoxia, CAFs greatly differentiate, contract, proliferate, and generate ECM components. The proliferation and contraction of CAFs generate physical forces stored in and transmitted by the dense ECM. As a result, solid stress levels are elevated, and blood and lymphatic vessels are compressed[71,74] (Figure 4.2B). In turn, tumors' interstitial fluid pressure (IFP) is elevated because fluid drainage is reduced through the collapsed lymphatics.[71] Fluid is also trapped in dense ECM, thereby raising IFP.[20] Thus, therapies modulating desmoplasia reduce both solid stress and IFP. Given the effects on the mechanical TME, these therapies are called mechanotherapeutics.[16] Nonetheless, agents altering fibrotic pathways such as TGF-β also affect other components of TME, including immune cells and ECs.[111]

Desmoplasia exacerbates reduced blood flow in tumors by increasing solid stress and IFP. Reduced blood flow leads to hypoxia-induced disease progression. Independent of the effects on blood vessels, solid stress promotes disease progression by making cancer cells more invasive[112] and tumor-adjacent tissue more malignant.[113] Desmoplasia promotes angiogenesis and immunosuppression through signaling, as certain CAFs produce angiogenic molecules[114] and inflammatory cytokines[115,116] (Figure 4.2C). Thus, desmoplasia promotes disease progression.[117]

Microenvironment Normalization Alleviates Hypoxia and Overcomes Resistance to Various Treatments

Vascular Normalization

Microvascular density (MVD) in vascularized areas within tumors[56] and hypoxia[14,21] are independent biomarkers predictive of worse treatment response in most cancer types.[1] While vessels deliver oxygen, dense vessels and low oxygen concentrations predict shorter survival. In 2001, to resolve this paradox, we postulated that the judicious use of AAT, which usually reduces MVD, increases vascular function, and reduces hypoxia.[8] Results from subsequent clinical studies have demonstrated that vascular normalization does occur with judicious use of AAT.[2],[4,11,12] Furthermore, patients with tumors having increased vessel function and reduced hypoxia after AAT have better outcomes.[1,4,12,14] These clinical results confirm that reduced hypoxia post-AAT slows disease progression and overcomes treatment resistance. Changes in hypoxia should be investigated as a predictive biomarker of response.

Passive vessel normalization is the pruning of immature vessels (their leakiness shown in Figure 4.3A), resulting in the remaining vessels being mature. The remaining vessels are more efficient, but the MVD might not be sufficient to supply the entire tumor volume. Active vessel normalization is the fortification of immature vessels with perivascular cells, which makes them more mature (Figure 4.3B). The vessels are on average more efficient, and the MVD is more likely to be sufficient to supply the entire tumor volume. Data from clinical trials, in agreement with preclinical data,[118-120] demonstrate that vascular normalization occurs after administration of an appropriate dose of AAT that avoids too much vessel pruning.[1,2,4,11,12] Along these lines, there is clinical evidence that active rather than passive normalization is associated with improved response to chemotherapy.[121]

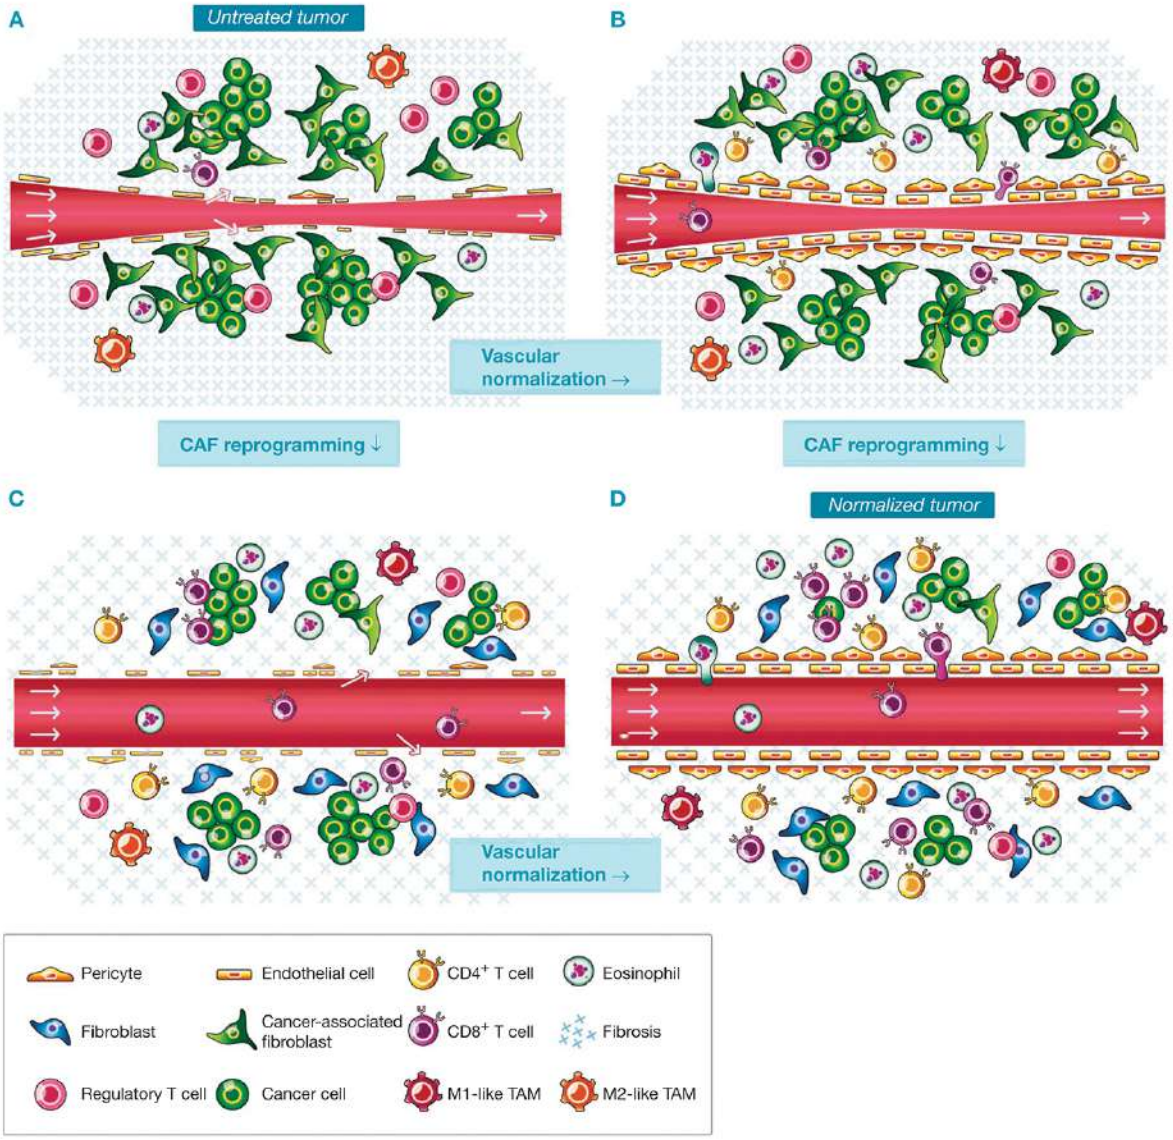

FIGURE 4.3 Vascular normalization and cancer-associated fibroblast reprogramming alleviate hypoxia toward promoting antitumor immunity. A. Depiction of a cross-sectional view of a single blood vessel in an untreated tumor. A pinch point in the blood vessel (red tube) and the inconsistent fortification of the endothelial cell layer with pericytes impair blood flow (gray arrows). The tumor has excessive immunosuppressive cancer-associated fibroblasts (CAFs), fibrosis, and $CD4^+CD25^+FOXP3^+$ regulatory T cells (T_{regs}), and reduced infiltration by $CD8^+$ and other subsets of $CD4^+$ T cells. B. Depiction of a cross-sectional view of a single blood vessel in a tumor treated with vascular-normalizing therapy. With treatment, the balance of pro- and antiangiogenic factors shifts such that endothelial cells are aligned and fortified with pericytes. Still, blood vessels remain compressed by mechanical stress. Immune trafficking and transmigration occur more efficiently. In addition, the immunosuppressive cells are reduced because of inhibited angiogenic and hypoxia signaling. Normalization by immune checkpoint inhibitors could depend on the accumulation of activated eosinophils. C. Depiction of a cross-sectional view of a single blood vessel in a

tumor treated with therapy that induces CAF reprogramming. With treatment, CAFs shift to quiescent fibroblasts and produce and maintain lower levels of fibrosis. These effects reverse vessel compression. Trafficking immune cells flow through tumors and migrate the interstitial space efficiently with less immunosuppressive CAF and hypoxia signaling. Also, the lack of fibrosis, particularly collagen, results in less physical migration restriction. D. A depiction of a cross-sectional view of a single blood vessel in a tumor treated with a combination of vascular-normalizing and CAF reprogramming therapy. Immune cells efficiently traffic to tumors, transmigrate, and migrate to clusters of cancer cells. (Reprinted from Melo V, Bremer E, Martin JD. Hypoxia as a Potential Biomarker of Response to Vascular Normalization

Data from hypothesis-generating clinical trials indicate that patients with tumors that after AAT have increased tumor vessel function (eg, improved perfusion, increased vessel maturity, and less hypoxia) derive the most benefit.[1,4,12,14] For example, cediranib, an oral pan-VEGFR tyrosine kinase inhibitor (TKI), normalizes tumor vessel structure and reduces leakiness in patients with recurrent glioblastoma (GBM), as seen in preclinical studies.[122,123] More so, progression-free survival and overall survival (OS) were associated with the relative degree of normalization as quantified by a set of biomarkers characterizing vessel structure and function.[124] This correlation was confirmed subsequently, as cediranib-increased perfusion and oxygenation correlate with survival of patients with GBM.[125-127] Similarly, in patients with breast cancer, correlations between normalization and outcome have been observed using nintedanib,[128] eribulin,[129] and bevacizumab.[129-132] In addition, patients with non–small-cell lung cancer (NSCLC) treated with bevacizumab who had increased tumor blood perfusion had improved OS.[133] These findings indicated that normalization is a potential predictive physiologic biomarker of response that must be validated prospectively.

Stromal Normalization

Reducing fibrosis through “stromal” or “CAF/ECM normalization” can complement vessel normalization and is best embodied by reprogramming CAFs to a quiescent phenotype[75,134-137] (shown in transition from Figure 4.3A to C). Although vessel normalization enhances the function of

immature tumor vessels, it cannot affect collapsed vessels. Reprogramming of CAFs normalizes their phenotype and function, thereby reducing their production and maintenance of ECM.[75,134-136] Accordingly, ECM levels are lower after reprogramming CAFs. Either by "normalizing" CAFs and ECM through CAF reprogramming or by destroying CAFs/ECM, the fluid and solid stress is reduced toward normal levels.[71,74,138] Unfortunately, therapeutically killing CAFs and/or digesting ECM induces tumor progression and immunosuppression.[1] Therapies that reprogram CAFs are called mechanotherapeutics,[16] even though, in some cases, they might have effects on stromal cells besides CAFs, as well. CAF reprogramming decompresses vessels, thereby increasing perfusion and delivering oxygen and drugs.

Combined Vascular and Stromal Normalization

Normalizing vessels and reprogramming CAFs, either independently or in combination, are TME normalization and improve vascular function, thereby alleviating hypoxia and treatment resistance[1] (Figure 4.3D). Still, the best way of combining AAT with mechanotherapies is unclear and likely will depend on the context.[139-141] First, the state of the vessels matters. In tumors with leaky and compressed vessels, the combination of AAT and mechanotherapeutics will be most effective.[139] Second, in tumors with a lesser density of perfused vessels, mechanotherapeutics should precede AAT. Large doses of AAT can excessively prune vessels, causing hypoxia and resistance.[4,12] In contrast, preclinical data indicate that mechanotherapeutics restore blood flow to small, immature vessels.[120] As a result, there are more immature vessels on which subsequent AAT could act. Clinical data from hypothesis-generating trials support this notion as tumors with more vessels with open-lumen pre-AAT are associated with improved response to AAT and chemoradiation.[121] In patients with GBM, imaging studies revealed that angiotensin system inhibitors (ASIs), which decompress tumor blood vessels[75] and have unrelated effects on other stromal cells,[111] increased the amount of perfused vessels.[142] Retrospective studies indicate that ASIs alone or combined with other therapies increase the survival of patients.[36,143-146] By increasing perfusion, mechanotherapeutics counteract AAT-induced pruning. Third, AAT

preceding mechanotherapeutics is beneficial in certain cases. AAT can induce CAF activation and ECM deposition. So, administering mechanotherapies after AAT could reduce this AAT-induced treatment resistance.[147-149] Thus, combination normalization strategies are better suited for tumors with certain vascular characteristics, and the order could matter.

Tumor Microenvironment Normalization for Immunotherapy

TME normalization improves immunotherapy.[6,58,58,58] Immunotherapy can be radiosensitizing,[150] and RT primes tumors for immunotherapy. One example of this interaction is the abscopal effect.[151] Given the role immunotherapy could play in RT regimens, understanding how to combine TME normalization and immunotherapy is necessary to develop radiosensitizing strategies. For immunotherapy to be effective, the steps of cancer-immunity cycle must continue (Figure 4.4, outer ring). The characteristics of the TME determine where in the cycle is the "set point" or the current step of resistance to immunotherapies.[152] We hypothesized that TME normalization overcomes the resistance of each set point (Figure 4.4, inner ring).[36] These seven set points can be classified into three TME phenotypes.

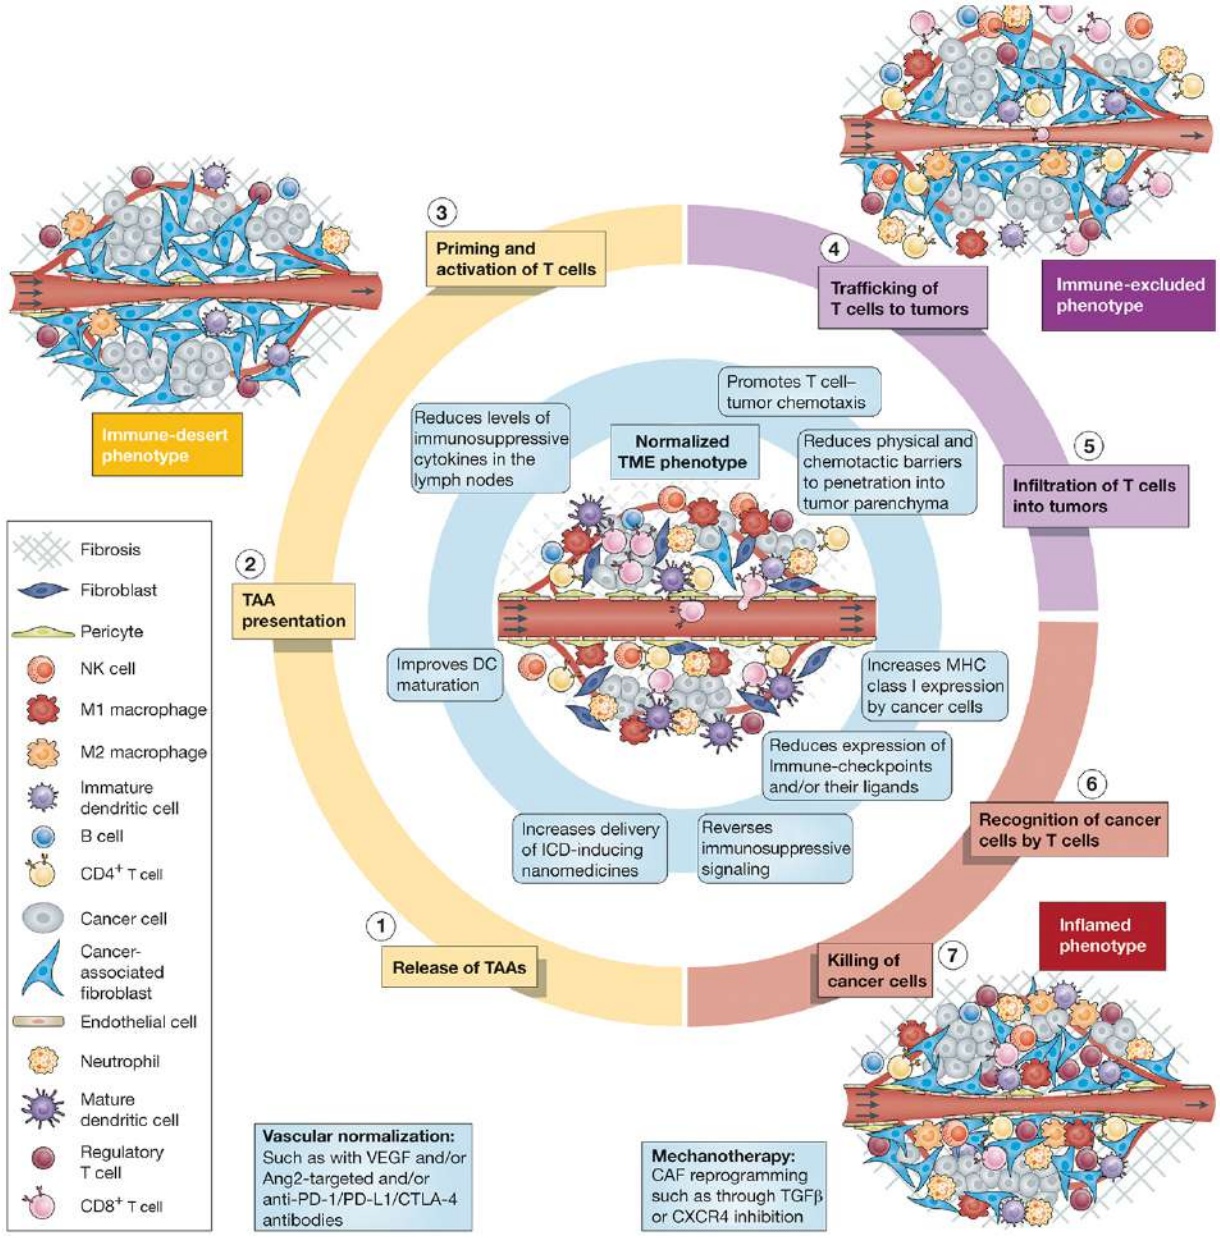

FIGURE 4.4 Cancer-immune TME phenotypes define the set points that predict sensitivity to immunotherapy,[152] while TME normalization perpetuates the cancer-immunity cycle.[36] TME normalization (blue inner circle) pushes the cycle through the various set points. In the immune-desert phenotype (yellow), the TME with sparse immune cells is immunosuppressed. The immune system allows malignant cell expansion because often it does not recognize antigens, tolerates the antigens if it does recognize them, and/or eventually fails to prime cytotoxic T cells. Hypoxia affects these steps in the cycle. In the immune-excluded phenotype (purple), the stroma restricts immune cell infiltration such that immune cells are retained in the tumor periphery and/or stroma. The TME characteristics that distinguish immune exclusion also reduce the delivery of various radiosensitizers and/or oxygen. In the inflamed phenotype (red), pro-inflammatory cytokines stimulate the relatively large amounts of immune cells migrating through the parenchyma. However,

inhibitory factors often induced by hypoxia reduce antitumor immunity. The structure and function of vessels may be normalized by inhibiting angiogenic factors and/or immune checkpoint molecules. Meanwhile, normalization of CAFs and/or the ECM could decompress vessels collapsed by solid stress. These two strategies work independently or as a combination to improve perfusion, oxygen delivery, and drug distribution. Strategies that cause excessive vessel, CAF, and/or ECM depletion could induce disease progression. Immune checkpoint blockade therapies such as anti-programmed cell death protein 1 (PD-1) or PD ligand 1 (PD-L1) antibodies induce blood vessel maturation in some tumor types, thereby protecting them from excessive pruning by antiangiogenic agents, which affect immature vessels. Blocking TME-normalizing signaling pathways such as those activated by vascular endothelial growth factor, angiopoietin 2, CXCL12/CXCR4, and TGF-β can also alleviate immunosuppression through additional mechanisms. Thus, combining these therapies that inhibit some of these pathways with radiosensitizers and immunotherapies could synergize. In conclusion, TME normalization strategies tailored to the immune TME phenotype of a tumor could enhance response rates and duration of responses to radiosensitizing immunotherapies. CTLA-4, cytotoxic T-lymphocyte protein 4; MHC, major histocompatibility complex; PD-1, programmed cell death protein 1; PD-L1, programmed cell death 1 ligand 1; TAA, tumor-associated antigen; TME, tumor microenvironment. Cancer-Immune Tumor Microenvironment Phenotypes

Of the three cancer-immune TME phenotypes, the immune desert is most resistant to immunotherapies.[153] This phenotype lacks antitumor immune cells, antigen presentation, and T-cell priming (Figure 4.4, light orange). Because angiogenesis and hypoxia promote the immune-desert phenotype, TME normalization could progress the tumor through the cycle (Figure 4.4, blue) into the immune-excluded phenotype (Figure 4.4, purple). One way that angiogenesis promotes the immune-desert phenotype is through VEGF expression, which reduces DC maturation, thereby interfering with antigen presentation.[41] Hypoxia enables immune tolerance by inducing chemokine expression that recruits protumor Treg cells.[38,39]

Less resistant than the immune-desert, immune-excluded tumors (Figure 4.4, purple) feature immune cells in the tumor periphery and/or stroma, but in not parenchyma.[152] The transition of these excluded immune cells is reduced by abnormal vessels and excessive fibrosis. Indeed, excessive levels of TGF-β, ECM, and CAFs characterize this phenotype.[135,136,154] Cancers resistant to ICBs tend to have a TME defined as “an immune desert” (Figure 4.4, red) because of the absence of intratumoral T cells.[153,154]

Besides the physiologic effects, the signaling that causes desmoplasia, solid stress, and vessel compression could also directly impair immune cells' cancer cell killing. CAFs secrete chemokines including TGF-β and stromal cell–derived factor 1α (SDF-1α), which hamper the transit of cytotoxic T lymphocytes (CTLs) to the tumor parenchyma.[135,136,154] Also, TGF-β promotes the maturation of naïve T cells into cells with a Treg phenotype.[39] Furthermore, excessive desmoplasia physically obstructs CTL migration.[155] Angiogenesis signaling also causes immune exclusion by reducing the expression of adhesion factors on vessel walls, thereby limiting CTL adhesion.[37,42,156] T-cell migration is reduced in hypoxic tumor regions.[43,44] Dysregulated angiogenesis and excessive desmoplasia cause hypoxia, and both the signaling and physiologic consequences of these processes limit the transit of CTLs.

The inflamed phenotype (Figure 4.4, red) is most sensitive to treatment, as it features T cells in the parenchyma and pro- inflammatory cytokines. Their presence indicates there was a previous antitumor immune response.[152] Accordingly, the densely accumulated T cells have T-cell receptors (TCRs) against tumor-associated antigens. As a result, stimulating these cells with ICB is likely to produce an antitumor effect.[154] Nonetheless, this phenotype also has immunosuppression mediated by angiogenesis, desmoplasia, and hypoxia such that TME normalization could further stimulate antitumor immunity. For example, VEGF signaling recruits immunosuppressive cells, such as Treg cells, myeloid-derived suppressor cells (MDSCs), and M2-like tumor-associated macrophages (TAMs).[45] In addition, hypoxia and CAFs increase the recruitment of Treg cells.[38,116] As there was already an immune response in inflamed tumors, immune checkpoints are expressed, reducing immune cell activity. Furthermore, VEGF upregulates various immune checkpoints on T cells.[46-48] Along these lines, hypoxia through HIF-1α does the same on MDSCs, TAMs, DCs, and cancer cells.[49,50] Acidity,[51] CAFs,[116] and collagen density[157] impair the cytotoxic activity of CTLs, even if they are already in the parenchyma.

While angiogenesis restricts cancer-immunity cycle, inflamed immune cells promote pathologic angiogenesis.[7,55,158,159] Thus, there is a vicious cycle of abnormal vasculature and protumor immunosuppression. To stop this cycle, we propose normalization of the TME to alleviate hypoxia[1,14] and increase immune cell density and antitumor function.[1,4,6] Given its role

throughout the entire cycle, this approach could be useful in the many patients with primary tumors and metastases with heterogeneous cancer-immunity phenotypes.[32,33,160,161]

Tumor Microenvironment Normalization Through Inhibition of Immunosuppressive Signaling Pathways

Normal, physiologic levels of tumor perfusion and oxygenation facilitate progression through the cancer-immunity cycle (Figure 4.4, inner ring).[55] Besides physiologic effects, blocking vascular "abnormalizing" pathways such as VEGF and ANG-2 and fibrosis pathways such as TGF-β and SDF-1α/CXCR4 promote antitumor immunity by blocking immunosuppressive signaling.[36,37,162] Preclinical studies show that vascular normalization enhances the antitumor efficacy of ICB,[156,163,164] whole cancer cell vaccines,[118] and adoptive cell therapy.[165,166] These studies are consistent with the success of combined AAT with ICB in patients. Indeed, phase III trials demonstrated the combination of the anti-VEGF antibody bevacizumab with the ICB atezolizumab and the chemotherapy paclitaxel in patients with metastatic nonsquamous NSCLC.[167] Similarly, the small-molecule VEGFR1-3 inhibitor axitinib with either ICB of avelumab[168] or pembrolizumab[169] succeeded in patients with advanced-stage renal cell carcinoma. In reverse, ICBs induce immune cells to normalize vessels in preclinical models.[55,159,164] Thus, combining vascular normalization with ICB could promote a cycle of efficient vasculature, alleviating hypoxia toward stimulating antitumor immunity.[1,58,58,58,58]

Mechanotherapeutics are in clinical trials with ICB. Mechanotherapeutics, such as angiotensin receptor blockers (ARBs) like losartan, that interfere with certain pathways, such as TGF-β signaling, in CAFs[75,135,144,170] could increase the efficacy of immunotherapies through various mechanisms including alleviating stresses in the TME.[171] TGF-β signaling affects many aspects of cancer immunosuppression.[154,171,172] TGF-β signaling inhibition increases the expression of adhesion molecules (such as intercellular adhesion molecule 1 [ICAM-1] or vascular cell adhesion molecule 1 [VCAM-1]) on tumor blood vessels so that leukocytes may better bind tumor vessels and penetrate into tumors.[6] In addition, TGF-β signaling inhibition promotes abscopal effects induced by RT.[173]

TGF-β associates with poor responses to ICB in patients with cancer.[154] Data from hypothesis-generating clinical trials support the notion that ARBs may improve outcomes with immunotherapeutics. In patients with pancreatic ductal adenocarcinoma (PDAC), gene expression associated with T-cell activation was enhanced with losartan treatment.[174] Retrospective analyses largely indicate that patients fare better when taking ARBs long-term versus those without long-term ARB use.[36,144] Adding losartan to chemoradiation reduces proinvasion and immunosuppression-related genes.[175] These various mechanisms provided a rationale for the clinical trial in patients with locally advanced PDAC receiving losartan in combination with nivolumab, FOLFIRINOX, and stereotactic body RT (NCT03563248). Unfortunately, losartan alone or without nivolumab did not show a benefit in increasing resection rates.[176] This failure could be related to variability in decisions to resect. Whether and how the clinical investigation of losartan will continue as PDAC therapy is currently unclear, but it is noteworthy to mention that losartan has shown the potential to improve ICB response and morbidity in preclinical GBM models.[177]

Immunotherapy-Induced Vascular Normalization

ICBs are part of the standard of care for most types of solid tumors, but they benefit a much smaller proportion of patients with cancer.[34] Even in responding cancer types, most patients do not experience a response to ICB-based therapies. To address this inherent resistance, which is mediated by immunosuppression, hypoxia, angiogenesis, and fibrosis in the TME, translational oncology researchers are investigating ICB therapy–based combination strategies with other immunotherapies and vascular-normalizing therapies,[37] CAF reprogramming, and nanomedicine.[36,178] Besides the role of antiangiogenic and CAF reprogramming therapies in TME normalization, researchers recently worked to understand the role of ICB in TME normalization.[140,179] These findings indicate that elucidating how immunotherapies normalize the TME could result in more effective combination regimens.

Recent studies produced data indicating that ICB alone can normalize blood vessels, particularly in tumors that responded to the treatment.[55] In

ICB-responsive murine models, immunotherapy led to vascular normalization and enhanced perfusion.[55] These effects were dependent on $CD8^+$ T cells and IFNγ production reversed.[55] As effective ICB therapy is thought to depend on $CD8^+$ T-cell accumulation and interferon γ (IFNγ) production, these findings support the notion that ICB-induced increased perfusion could be a potential biomarker of response to ICB treatment.[55]

Mechanisms of Immunotherapy-Induced Vascular Normalization

IFNγ and $CD8^+$ T cells are required for antitumor immunity.[180] High level of IFNγ induces apoptosis of cancer cells.[181] Lower levels of IFNγ induce cancer cell stemness, which facilitates metastatic progression.[181] In addition, IFNγ has non–immune-mediated antiangiogenic properties[182] that are IFNγ level dependent.[158] Specifically, high levels of IFNγ, independently of cancer cells, induce vascular regression and eliminate blood flow to tumors.[183] This effect is similar to that of AAT at high doses and distinct to vascular normalization.[4,14] Lower levels of IFNγ could induce vascular normalization. Indeed, IFNγ upregulates ICAM-1,[184] which mediates adhesion between ECs and leukocytes, and VCAM-1,[185] which promotes adhesion between pairs of ECs and ECs and leukocytes or mural cells. IFNγ might also normalize vessels through TAMs. Specifically, through IFNγ, $CD8^+$ T cells polarize TAMs to an antiangiogenic, antitumor M1-like phenotype.[186] ICB treatment, TAM polarization, adoptive cell transfer, and experimental models of inducible IFNγ all induce antiangiogenic effects to a different extent, which could result from the varying concentrations of IFNγ.[158] Thus, the extent of vascular normalization is mediated by IFNγ and must be elucidated in various tumor types and immunotherapies.

Studies from patients with various types of tumors underscore the host and tumor type dependence of the effect of IFNγ on vascular normalization. Patients with ICB-responding GBM had reduced vascular permeability, indicative of vascular normalization.[187] Interestingly, this effect occurred 6 months after ICB treatment initiation. In mice, the effect is induced more rapidly. Also, this effect occurred after a short period of increased vascular permeability, which has been observed in murine models.[177] These results reveal discrepancies between the kinetics of these ICB-induced vascular permeability changes between murine breast and brain tumors and between

patients and mice. To better determine the kinetics of a potential vascular normalization window, vascular permeability must be studied longitudinally before and shortly after ICB treatment initiation.[188] Further discrepancies exist. For example, in patients, vascular regression associated with ischemic tumor necrosis after vaccination or ICB immunotherapies was observed in responding melanoma and ovarian tumors.[189] These conflicting results highlight areas of future study.

The type of cells that produce IFNγ depends on the context. When interventions are administered before tumors grow, the experiment models the clinical "preventive" setting before cancer diagnosis. In such studies, knockout models indicated that T-cell subsets induce opposing angiogenic effects. Specifically, $CD8^+$ T cells promoted angiogenesis through EC proliferation. In contrast, $CD4^+$ T cells promoted vascular normalization through pericyte recruitment, reducing hypoxia.[159] Consistent with previous angiogenesis studies in early tumor development,[190] these studies suggest that in early stages, $CD4^+$ T cells and IFNγ promote vessel fortification through pericyte recruitment.[159,188]

ICB administered in the "interventional" setting normalized the breast tumor vasculature in an IFNγ-dependent manner. This conclusion was reached based on studies of abrogated ICB-induced normalization through IFNγ receptor knockout and IFNγ neutralization studies.[55] T-cell depletion studies in wild-type mice revealed that ICB-induced normalization and increased perfusion revealed a dependence on $CD8^+$, but not $CD4^+$, T cells.[55] Thus, $CD4^+$ T cells promote vessel maturation early in tumor development, while in the treatment setting with ICBs, $CD8^+$ T cells normalize blood vessels. The latter conclusion is supported by observations that adoptive transfer therapy of T cells contributes to normalized vascular morphology.[191]

Besides $CD8^+$ T cells and IFNγ, ICB-induced normalization also depends on the cross talk between eosinophils and $CD8^+$ T cells. The cross talk initiates a positive feedback loop of vascular normalization and antitumor immunity.[192] In addition, activated eosinophils in the TME, through IFNγ, skew TAMs to an antiangiogenic M1-like phenotype and an increased expression of VCAM-1. As a result, there is increased adhesion of eosinophils and T lymphocytes (among other cells) to the endothelium, transmigration, and infiltration. Accumulated T cells can then further

promote vascular normalization and TAM polarization. Another factor promoting tumor-specific effector T-cell trafficking are interferon-induced chemoattractants produced by activated eosinophils.[192] Supporting these preclinical findings, increased eosinophil and lymphocyte counts after ICB correlated with increased survival of patients.[193] Thus, ICB promotes a positive feedback loop of $CD8^+$ T cells and activated eosinophils, which normalizes vessels through IFNγ and TAM polarization and results in increased eosinophil and lymphocyte adhesion and accumulation (Figure 4.5A).

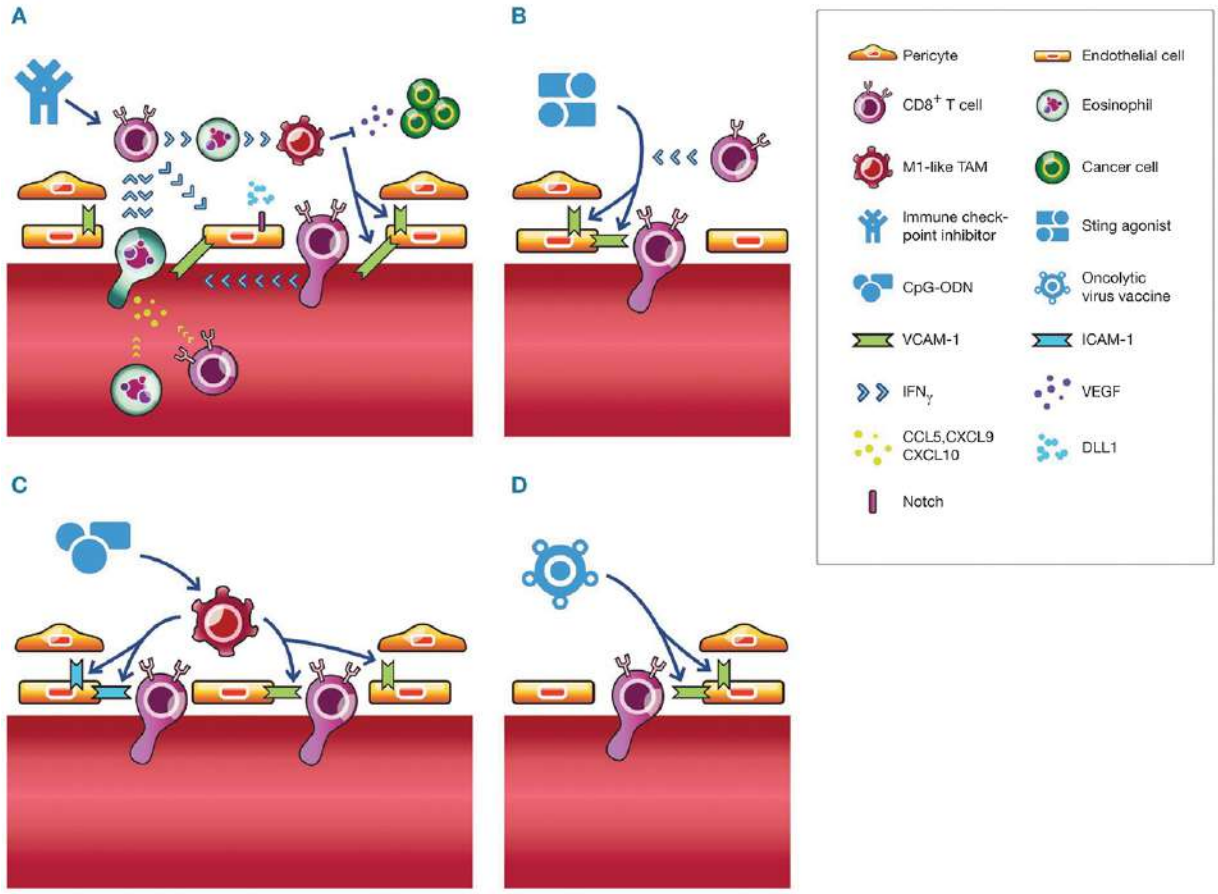

FIGURE 4.5 Vascular normalization induced by various immunotherapies through distinct mechanisms. A. Immune checkpoint blockers (ICBs) activate $CD8^+$ T cells, which secrete IFNγ and interact with activated eosinophils to induce M1-like tumor-associated macrophage (TAM) phenotypes. The TAM polarization reduces vascular endothelial growth factor signaling and increases vascular cell adhesion molecule 1 (VCAM-1) expression, leading to infiltration of $CD8^+$ T cells and activated eosinophils. The latter secretes chemokines (ie, CCL5, CXCL9, and CXCL10) that promote lymphocyte trafficking. For this mechanism, activated eosinophil accumulation precedes and is required for enhanced $CD8^+$ T-cell homing to normalized tumors. This process is a positive feedback loop of vascular normalization and antitumor immunity. In addition, DLL1-Notch signaling promotes $CD8^+$ T-cell activation and IFNγ production, further reinforcing this positive feedback loop for long-term vascular normalization. B. STING agonists increase levels of antiangiogenic factors, thereby increasing pericyte coverage and T-cell infiltration through increased VCAM-1 expression. C. CpG-ODN acts on TAMs and promotes an M1-like phenotype, leading to upregulation of intercellular adhesion molecule 1 (ICAM-1) and VCAM-1. In some but not all cases, depletion of regulatory T cells similarly increases ICAM-1 and VCAM-1 expression. D. Oncolytic vaccines prune vessels and increase VCAM-1 expression through poorly understood mechanisms. (Reprinted from Melo V, Bremer E, Martin JD. Towards immunotherapy-induced normalization of the tumor microenvironment. *Front Cell Dev Biol*. 2022;10:908389. http://creativecommons.org/licenses/by/4.0/)

The role of the ligand Delta-like canonical Notch ligand 1 (DLL1) in vascular normalization mediated by activated $CD8^+$ T cells[194] supports this positive feedback cycle hypothesis.[195] DLL1 levels are inversely correlated with circulating VEGF. The latter occurs in hosts bearing tumors with high levels of angiogenesis.[194] Circulating VEGF, through reduction of DLL1-Notch signaling in bone marrow precursors, reduces T-cell activation and antitumor immunity.[194] Overexpressing DLL1 in cancer cells induced long-term vascular normalization by overcoming circulating VEGF-induced DLL1-Notch signaling inhibition.[195] As in other studies, normalization occurred in ICB responders and required IFNγ production and $CD8^+$ T-cell accumulation.[195] These results support the notion that immune cells induce long-term vascular normalization by interfering with angiogenic and immunosuppressive signaling, thereby increasing the antitumor effect of ICB (Figure 4.5A).

Immunotherapy-Induced Vascular Normalization Beyond Immune Checkpoint Blockade

The findings that immunotherapies beyond ICB have normalizing effects support the observations of the role of immune cells in vascular normalization. STING agonist offers one example. In mice bearing melanoma, low-dose local administration led to the expression of antiangiogenic factors, leading to EC pericyte coverage and expression of VCAM-1.[196] This effect was mediated by STING activation of DCs rather than cancer cells.[196] STING agonism promoted the formation of normalized vessels and tertiary lymphoid structures, leading to increased T-cell infiltration.[196] Beyond melanoma, researchers explored STING agonism in breast, lung, and colorectal cancer models.[197] While confirming the findings in melanoma, these studies clarified several additional findings of STING agonist–induced vascular normalization. First, STING agonism of nonhematopoietic stromal cells, particularly ECs, mediates normalization.[197] Second, normalization depends on $CD8^+$ T cells and IFNγ, not TAMs.[197] Thus, similar to ICBs, STING agonists induce vascular normalization through $CD8^+$ T cells and IFNγ (Figure 4.5B).

Oligodeoxynucleotides with cytosine-guanine (CpG-ODN) motifs normalize vessels. CpG-ODN stimulates TAMs, which upregulate ICAM-1

and VCAM-1 in ECs.[198] After treatment, adoptively transferred immune cells extravasate and infiltrate tumors more efficiently (Figure 4.5C). CpG-ODN has not succeeded in the clinic, likely due to its local administration. Another potential cause of resistance could be the TME of distant metastatic lesions, which could present barriers to administration even if local treatment in the primary tumor induces a systemic abscopal effect.[36] The effects of depletion of T_{regs} can be similar to those of CpG-ODN treatment, as they both upregulate ICAM-1 and VCAM-1.[199] Other observed markers of normalization induced by the depletion of T_{regs} are reduced vessel diameter and increased perfusion.[199] In most cases, depletion of T_{regs} induces antitumor immunity. In PDACs, T_{regs} deplete fibroblasts, which promotes tumor growth and immunosuppression.[200] Thus, the effect of T_{reg} depletion varies by tumor type.

Oncolytic viruses also promote markers of normalization. Indeed, they reduce vascular density transiently while increasing VCAM-1 gene expression.[201] However, the mechanism and whether hypoxia is alleviated is unclear (Figure 4.5D). Considering the results when testing therapies other than ICB, we can generate hypotheses. Whereas ICB and STING agonists act through T cells and IFNγ, oligonucleotide therapies act through TAMs, increasing the expression of adhesion molecules. How to combine these immunotherapies for enhanced vascular normalization and antitumor efficacy remains untested.

Combined Antiangiogenic Therapy and Immunotherapy

AATs and ICB have disparate effects on vascular regression and normalization, so there could be potential to combine them. One observed mechanism of synergy involves passive vessel normalization, in which immature blood vessels are destroyed while the mature vessels remain. The other observations involved active vessel normalization, where pericytes are recruited to existing vessels. In the former, AAT recruits $CD8^+$ T cells, resulting in increased IFNγ, which upregulates immune checkpoints that can be neutralized by ICB.[156] This case involved passive normalization, as the combined AAT of VEGF and angiopoietin 2 inhibition induced vascular regression and necrosis, yet the vessels remained covered with pericytes.[156] In contrast, another study found evidence of active vessel normalization.

The researchers found that VEGF inhibition and ICB were complimentary in forming high endothelial venules, which are blood vessels supporting the interaction of T cells with antigen-presenting cells in tertiary lymphoid structures or lymph nodes.[163] While the researchers overserved regression of half of the vasculature, they also found the distinct contributions of AAT and ICB to vessel pruning and fortification.[163] Blocking VEGF induced vascular regression and fortification, but its combination with ICB led to increased pericyte coverage without additional regression.[163] Therefore, ICB induced active normalization through myeloid cells in the TME.[163] In the setting of tumor relapse from AAT monotherapy, the combination of AAT and ICB was necessary to reduce vessel density, which underscores the lack of redundancy of these therapies in their antiangiogenic properties.[163] A key takeaway of these studies is that ICB has stronger effects on vessel fortification than regression. A key challenge will be to determine whether the vascular regression induced by the combination is necessary for the efficacy, and if not, then to determine how best to combine AAT and ICB to alleviate hypoxia and promote antitumor immunity.

The findings in a series of reports on hepatocellular carcinoma (HCC) demonstrate the role of the organ environment and type of TME when combining AAT and ICB with respect to vascular normalization. The AAT sorafenib causes vascular regression, hypoxia, and resistance through activating SDF-1α/CXCR4 pathway.[149] In many tumor types, blocking CXCR4 reduces immunosuppression and fibrosis and increases T-cell infiltration.[136] In HCC, blocking CXCR4 alleviates immunosuppressive cell recruitment and angiogenesis after sorafenib treatment.[149] Then, combining ICB with AAT and CXCR4 inhibition ameliorates these resistance mechanisms further by increasing the amount of IFNγ and $CD8^+$ T cells in the tumor center, indicating further normalization of the TME.[149] A follow-up study in HCC investigated further, as ICB enhanced vessel normalization when combined with an anti-VEGFR2 antibody compared to AAT using multitargeted TKIs.[164] In HCC, the contribution of AAT and ICB to vascular normalization was mediated by $CD4^+$ T cells. AAT induced EC expression of immune checkpoints (programmed cell death 1 ligand 1 and programmed cell death protein 1) in an IFNγ-dependent manner and in $CD4^+$ T cells, which could be neutralized by ICB.[164] With further fortification by ICB treatment (Figure 4.6A), vessels resisted vascular

regression, even at higher doses of anti-VEGFR2 antibody.[164] Given the sensitivity of vascular normalization to AAT dose, ICB-induced resistance to regression makes finding an acceptable dose of AAT easier.[4] Indeed, when the AAT sorafenib follows ICB in HCC, the density of fortified blood vessels increases in a $CD8^+$ T-cell–dependent manner (Figure 4.6B), while sorafenib alone induces vascular regression.[202] Thus, ICB fortifies vessels, thereby preventing regression induced by AAT. In a study that supports these findings but with a differing order of treatment, administering vessel-fortifying AAT before oncolytic vaccine therapy avoided vascular regression and improved efficacy.[203] Nonetheless, the combination of ICB and AAT often induces vascular regression caused by high levels of IFNγ or high doses of AAT. In one case, high doses of the small-molecule tyrosine kinase anti-VEGFR inhibitor regorafenib combined with ICB induced vascular regression in HCC.[204,205] In conclusion, combinations of AAT and ICB or other immunotherapies should be tested in an agent- and tumor-specific manner to identify schedules that maximize vessel fortification while minimizing vascular regression to promote antitumor immunity optimally.

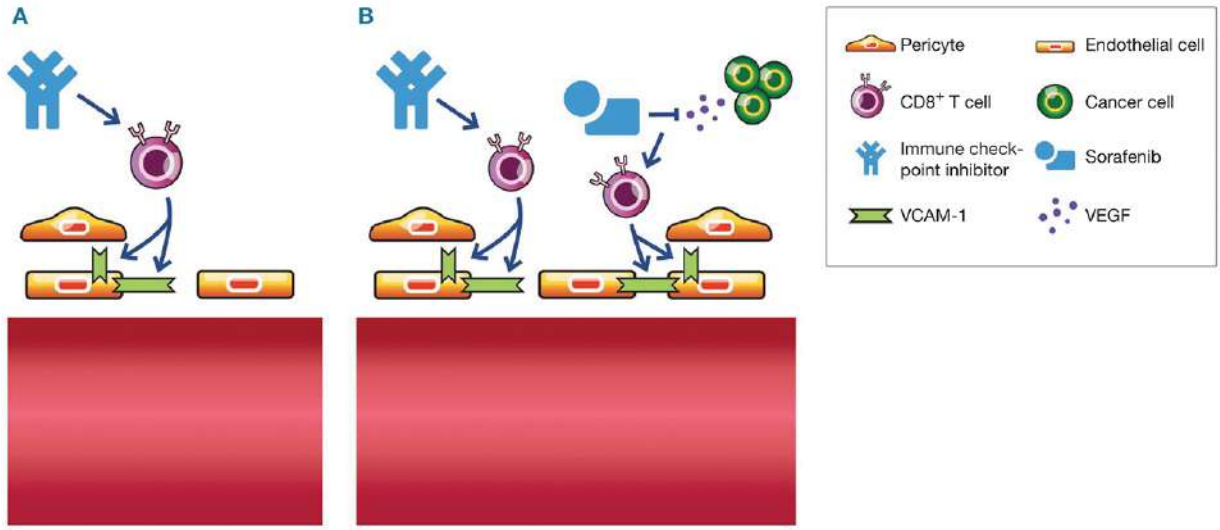

FIGURE 4.6 Immune checkpoint blockade (ICB) preceding antiangiogenic therapies (eg, sorafenib) promotes vascular normalization by protecting against vessel pruning in hepatocellular carcinoma. A. ICB monotherapy fortifies vessels by increasing the interaction between endothelial cells and perivascular cells through vascular cell adhesion molecule 1 (VCAM-1) upregulation in a $CD8^+$ T-cell–dependent manner. B. Sorafenib following ICB increases the density of tumor blood vessels fortified by pericytes and the antitumor efficacy in a $CD8^+$ T-cell–dependent manner. In contrast, sorafenib monotherapy causes vascular pruning and does not slow tumor growth. Thus, vascular-fortifying ICB alters the effect of subsequent antiangiogenic therapy from vessel regression to vascular normalization. (Reprinted from Melo V, Bremer E, Martin JD. Towards immunotherapy-induced normalization of the tumor microenvironment. *Front Cell Dev Biol*. 2022;10:908389. http://creativecommons.org/licenses/by/4.0/)

The studies in HCC support the notion of a positive feedback loop of vascular normalization and antitumor immunity induced by AAT and immunotherapy. Moreover, when dosed judiciously, the AAT regorafenib induces vascular normalization and the expression of CXCL10 in HCC cells. This chemokine binds to its receptor CXCR3 on infiltrating T lymphocytes, thereby resulting in increased trafficking into these tumors.[204] As more T cells enter the tumor, vascular normalization is further promoted.

Other immunotherapies besides ICB, when combined with AAT, can support vascular normalization and induce CAF reprogramming. An anti-CD40 antibody is one such immunotherapy. Interfering with CD40 promotes DC maturation, antigen presentation, and priming of T cells. Administration of the antibody to genetically engineered mouse models of colorectal cancer in combination with anti-VEGF and anti-angiopoietin 2

therapy fortified blood vessels.[206] This combination of AATs induced CAF reprogramming effects, which were increased by treatment with an anti-CD40 antibody.[206] While the antitumor efficacy depended on angiogenic (ie, angiopoietin 2) signaling and on T-cell infiltration, vascular normalization and CAF reprogramming were T-cell independent.[206] In this study, the tumors were well perfused before treatment. This raises the hypothesis that the increased antitumor activity results from increased T-cell trafficking and infiltration because of increased vessel maturity as well as increased T-cell migration resulting from reduced fibrosis.[206] These studies demonstrate that immunotherapies can promote vascular normalization and CAF reprogramming in combination with AAT, and the resulting increase in antitumor efficacy can occur through mechanisms independent of alleviated hypoxia.

NORMALIZING THE MOLECULAR PATHOLOGY OF TUMORS FOR RADIATION WITH COMBINATION THERAPY REGIMENS

RT is a local treatment. In certain cases, patients with fewer metastases in spatially defined sites may also have these oligometastases directly treated by RT, which may prolong OS. By treating oligometastases, which are limited in number and susceptible to local treatment, the fraction of patients who can benefit from RT can be expanded.[207-209] Unfortunately, even in this relatively easy-to-treat setting, the TME impairs the efficacy of RT. Priming tumors for RT could benefit patients with oligometastases, thereby increasing the fraction of patients with localized cancer that can be cured therapies to prime tumors likely must be systemically administered so that they can also induce antitumor efficacy against nonirradiated lesions. We put forth the following rationale. First, these systemically administered priming agents will act on nonirradiated lesions. Second, these priming agents can act on distant lesions to render them amenable to abscopal effects initially induced by RT treatment against the accessible lesion. This could occur by enabling antitumor immune cells to infiltrate distant lesions better. Third, these systemic priming agents can increase the abscopal effects by sensitizing the accessible lesion to RT by aiding immunogenic cell death (ICD) and antigen presentation. Here we describe strategies for

RT priming by nanomedicine-, TME normalization-, chemotherapy-, and/or immunotherapy-based radiosensitizers.

Combination With Nano-Radiosensitizers

High atomic number metals are radiosensitizers. Irradiation causes the atoms in high atomic number metals to undergo inner shell ionization and emit electrons, which damage cancer cells directly or indirectly by ROS production.[210] Researchers developed nanomedicines containing high atomic number metals that enhance the efficacy of RT at lower doses.[210] Nanomedicines administered systemically accumulate in tumors through the enhanced permeability and retention effect.[36,67,211-213] Nanomedicines with more toxicity are administered with an intratumoral injection in superficially located tumors. Given their inability to diffuse in the dense ECM of tumors, intratumorally injected nanomedicines are retained more than locally administered small molecules.[210] The European Medicines Agency (EMA) approved intratumoral injections of NBTXR3 hafnium oxide nanoparticles. These particles increase the RT abscopal effect in locally advanced soft tissue sarcomas.[214] Particles like these are especially important for immunotherapy regimens because they can increase the RT dose with the tumor while limiting the dose applied to healthy immune cells systemically. This is important because the efficacy of RT combined with immunotherapy is inversely correlated to the RT dose to healthy immune cells.[215]

Other nanomedicines that could prime tumors for RT include those encapsulating chemotherapies and/or TME-normalizing drugs.[36,137,216] Nano-based chemotherapy can prime tumors for RT more effectively than small-molecule chemotherapy for several reasons.[36] First, nanomedicines lessen and/or alter toxicity profiles compared to small molecules.[217,218] Second, nano-based chemotherapy normalizes the TME, similarly to metronomic chemotherapy, because nanocarriers have long blood circulation.[219,220] The presence of chemotherapy in the circulation either with metronomic small-molecule chemotherapy or with long circulating nanomedicine limits the proliferation of ECs, resulting in an antiangiogenic effect. Similarly, the constant supply of chemotherapy alleviates solid stress by steadily eliminating proliferating cancer cells, thereby decompressing vessels. Thus,

nano-based chemotherapy can act as an AAT, a mechanotherapeutic and a cytotoxic chemotherapy that induces ICD.

Mechanotherapeutic strategies often rely on drugs repurposed from other diseases to cancer, reprograming CAFs to a quiescent phenotype. The resulting lack of desmoplasia alleviates stresses, decompresses vessels, restores perfusion, and reduces hypoxia. Some mechanotherapeutic drugs also directly shift immune cells toward antitumor immunity.[111] These small-molecule repurposed drugs can benefit from a reformulation as a nanomedicine because the nanoformulation alters the pharmacokinetics, thereby reducing the normal systemic effects of these drugs while increasing their tumor accumulation.[36] For example, ARBs, used to treat hypertension, did not reduce blood pressure but had increased TME-normalizing effects when formulated as nanomedicine.[135] Still, it is unclear if these nanoformulations will be more effective in the clinic than the relatively inexpensive, generic, and repurposed TME-normalizing drugs.

Combination With Tumor Microenvironment Normalization

RT requires oxygen to kill cancer cells efficiently, and TME normalization increases oxygen levels in tumors. Accordingly, TME-normalizing therapies may prime tumors for RT by alleviating hypoxia.[4,125,221] In preclinical tumor models, AAT transiently normalizes vessels, providing a window of reduced hypoxia during which RT is effective.[221] In patients, AAT is administered with radiation increased tumor oxygenation after AAT is associated with survival.[125] In locally advanced PDAC, losartan potentiated tumor shrinkage by chemoradiation in some patients, thereby enabling more tumor resections.[222] Separately, TME normalization could enhance RT-induced abscopal effects on distant lesions by stimulating the distribution and phenotype of antitumor immune cells. Specifically, VEGF and TGF-β signaling pathways are immunosuppressive and pose barriers to immune cell transit to and within the TME.[173] Thus, TME normalization could enhance progression through the cancer-immunity cycle initiated by RT, which induces ICD, causing the release of tumor-associated antigens (see Figure 4.4).

Combination With Chemotherapy

Certain cytotoxic nanomedicines induce vascular and stromal normalization.[216] There are hypothesized mechanisms for additive and synergistic benefits when combining systemic chemotherapy and RT. For additive benefits, systemic chemotherapy can act against distant metastases that local RT cannot affect apart from inducing a systemic antitumor immune response. In addition, chemotherapy and RT might cooperate synergistically through at least five potential mechanisms.[223] First, certain chemotherapies that incorporate themselves into the structure of DNA enhance radiation damage. These drugs include halogenated pyrimidines and cisplatin, which, through different mechanisms, interact with DNA to enhance RT.[224] Second, although some cancer cells repair themselves after sublethal doses of RT, certain chemotherapies (eg, halogenated pyrimidines, nucleoside analogs, and cisplatin) inhibit this self-repair capacity. This effect of certain chemotherapies could be most important in fractionated RT, because lower sublethal doses are used.[225,226] Third, certain chemotherapies pause cancer cells into a proliferative, radiosensitive phase, while other chemotherapies can be combined to eliminate radioresistant cells that are in a nonproliferative phase. Taxanes arrest cells in proliferation,[227-229] while nucleoside analogs kill nonproliferative cancer cells.[226] Fourth, chemotherapies can reduce hypoxia. For example, paclitaxel increases tumor oxygenation through two mechanisms.[228] It decompresses vessels, thereby increasing blood flow. It also kills cancer cells, thereby reducing oxygen consumption. Alternatively, certain chemotherapies activate in hypoxia, thereby selectively killing hypoxic cells, so that RT can act on normoxic cancer cells.[226] Fifth, chemotherapies combined with fractionated RT stop the repopulation of cancer cells, which improves the efficacy of the subsequent fraction of RT.[223] The main downside of this combination is that chemotherapy could increase the toxicity of RT to normal tissues.

While the mechanisms of combination for small-molecule chemotherapy we described involve the chemotherapy priming the tumor for RT, cytotoxic nanomedicines might be best used after RT. Preclinical studies indicate that RT increases the penetration of nanomedicines by normalizing the TME and modulating immune cells.[230,231] TME normalization by RT depends on the dose and varies across tumor type.[232] Another approach involves developing nanomedicines with ligands targeting P-selectin, which better accumulate in

the tumor after RT-induced expression of P-selectin.[233] Whether these approaches will translate to patients remains unanswered.

Combination With Immunotherapy

Immunotherapy normalizes the TME and ameliorates hypoxia in certain cases.[6] Thus, in settings where immunotherapy enhances oxygen delivery, it could prime tumors for RT.[150] Alternatively, RT can prime the TME to improve the efficacy of subsequent immunotherapy through several mechanisms. First, RT normalizes the TME and ameliorates hypoxia in certain cases.[230,232,234] RT affects hypoxia through conflicting mechanisms. Radiation kills normoxic cancer cells, thereby increasing the fraction of hypoxic cells. In contrast, the killing of cancer cells, whether normoxic or hypoxic, reduces solid stress,[71] thereby ameliorating hypoxia by increasing supply and reducing consumption.[235] Also, fewer cells mean lesser levels of proangiogenic factors. Furthermore, RT directly kills proliferating ECs, so RT could have a large antiangiogenic effect that excessively prunes tumor vessels and ultimately results in regrowth of the vasculature.[105] In this case, testing that RT is not inducing hypoxia through excessive pruning is necessary. Reduced solid stress caused by cancer cell killing by RT decompresses lymphatic vessels.[71] As a result, RT alleviates IFP transiently. This can increase the accumulation of macromolecules and nanomedicines if administered during this window.[230,234]

The abscopal effect is the induction of ICD in one or more lesions, which can induce a systemic immune response against distant metastases[236-240] in part by expanding the circulating effector T cells.[241] ICD expands the diversity of the TCR repertoire.[242] Radiation dose and fractionation affect the abscopal effects. Fractionated RT induces ICD.[243,244] High-dose RT may limit immunogenicity because of the enzymatic digestion of cytosolic DNA, which eliminates one mechanism of immune recognition.[245] More research is needed to determine the dose dependency in various tumor types. EMA-approved NBTXR3 with RT stimulates an antitumor immune response in patients,[246] underscoring the applicability of this approach.

Treatment With Three or Four Modalities

There is potential to combine these various agents that prime tumors for RT treatment. Nano-based high atomic number metal radiosensitizers administered systemically or locally could have increased intratumor distribution if administered after TME normalization.[36,211] Vascular normalization increases the systemic delivery of smaller nanomedicines.[119,217,247] Mechanotherapeutics increase the penetration of systemically administered[75,220,248] and locally administered nanomedicines of all sizes.[170,249] Increased RT and/or chemotherapy payload delivery to cancer cells could increase ICD. Antitumor T cells sometimes normalize the vasculature, so immunotherapy and TME normalization combinations could better alleviate hypoxia toward potentiating RT. Through multiple mechanisms and combinations, TME normalization could increase the tumor infiltration of antitumor T cells, further reducing hypoxia.

Various immunotherapies benefit from TME normalization,[6,37] which can overcome each barrier posed by the cancer-immunity cycle.[36] TME normalization could increase chemotherapy and/or RT induction of ICD for subsequent immunotherapy. Also, TME normalization could reduce immunosuppressive cytokines in the tumor and the draining lymph nodes. T cells traffic through the circulatory system, infiltrate tumors, and migrate into the parenchyma. Although tumor signals reduce chemotaxis of T cells,[250] vascular normalization polarizes TAMs into an M1-like antitumor phenotype secreting chemokines-binding T cells[251] and induces T cells to express receptors to further enable chemotaxis.[48] T cells then must penetrate from tumor blood vessels to cancer cells. Vascular normalization could increase T-cell infiltration and activity[118] by increasing the number of perfused vessels, thereby reducing the distance T cells must migrate to cancer cells.[118,135,136] T cells[252] and natural killer cells[253] both are inhibited by low levels of adhesion molecules on the vessel wall. By inducing maturation, vascular normalization can increase T-cell adhesion and penetration.[48,165,254] Finally, vascular normalization improves T-cell recognition of cancer cells through at least two mechanisms. First, it reduces the hypoxia-induced shedding of major histocompatibility complex type I (MHC-I) molecules.[255] Second, it increases the expression of MHC-I molecules by limiting nitric oxide[255] and VEGF levels.[48] Indeed, vascular normalization improves antigen-specific T-cell migration.[48]

CHALLENGES

Rigorous Preclinical Models

Genetically engineered mouse models (GEMMs) reflect the natural occurrence of cancer as they form tumors without implantation and have mutations related to clinical disease. In many cases, GEMMs better recapitulate the physiology of the TME, such as hypoperfusion in PDAC.[256] Cell lines isolated from GEMMs, grown in mice by inoculating as a cell suspension or transplanting as a solid chunk into recipient mice, can recapitulate hypoperfusion.[75] A significant advantage of solid passage is that cancer cells are introduced along with their co-opted TME. During cancer initiation, mutations occur in single cells gradually and affect the physiology of the TME in the earliest stages of malignant transformation.[17] In contrast, the modifications in GEMMs are present before the TME is co-opted. There is a similar benefit when implanting tumor spheroids.[257]

Orthotopic models also recapitulate the TME.[258] Unfortunately, ectopic subcutaneous models have different TME properties than orthotopic ones of the same cell line.[19,20,256] Another critical decision is the selection of murine syngeneic versus human xenograft models for testing. The latter models form tumors with human cancer cells, and murine host cells are co-opted in the TME. Thus, investigating TME modulation is suboptimal in these models, especially given the importance of the immune system in current standard-of-care therapeutic regimens.[207] Still, there are experimental uses for mixing human and murine cells in a tumor model. For example, there is a model used with human stromal cells and murine cancer cells implanted into immunocompromised mice, and the human cells can be depleted selectively with diphtheria toxin to isolate the effects of specific cells in the TME.[70,71,107]

Using standard operating procedures when employing preclinical models for testing would better help determine the optimal combinations of drugs. Comparing data across studies is confounded by suboptimal experimental design, execution, and reporting.[259] TME-normalizing therapies should be tested with the standard of care, often chemoradiation.[260] Appropriate primary end points should be selected before initiating the study.[260]

Treatment Time Windows

TME normalization might lose its effectiveness with extended treatment. Tumors develop resistance through alternative signaling pathways.[2] Excessive doses and/or durations of TME normalization treatment deplete the stroma-inducing treatment resistance.[118,221] One main problem is the depletion by AAT of too many immature vessels, which exacerbates rather than alleviates hypoxia. AAT does not deplete mature vessels. Prioritizing AAT strategies that fortify vessels by reinvesting them of pericytes and reprograming CAFs toward quiescence addresses the problem of a limited time window of TME normalization.[1]

Identifying the TME normalization window would enable the optimal administration timing of RT and/or chemotherapy toward inducing ICD. However, the optimal timing of immunotherapy after ICD-inducing chemotherapy and/or RT is still being determined. Furthermore, whether these cytotoxic therapies should be continued during ICB treatment is still being determined. The answers to these questions differ for nano- and macromolecule-based therapies, which have long circulation times.

Imaging Biomarkers

Imaging predictive biomarkers of response to RT[261] and TME-normalizing strategies would help identify patients with susceptible tumors and aid in optimizing the timing of combination treatments. We hypothesize that hypoxia is a critical biomarker of treatment resistance and response. High oxygen levels result in better responses to RT. Thus, periods of high oxygenation in tumors could predict patient response to RT and optimal treatment windows.

Many therapies that can be combined with RT are nanomedicines or macromolecules. These drugs could have heterogeneous distribution in various metastases within patients and spatially within a single tumor.[36] Imaging of probes similar in size to nanomedicines and macromolecules that emit positron emission tomography or magnetic resonance imaging signals has heterogeneous distribution in solid tumors in patients.[32,33] Advances in imaging with such probes could help investigate the TME,[262] including the effects of immunotherapies.[263] These probes enable the evaluation of the ability of TME-normalizing strategies to reduce the heterogeneity of drug distribution, which could serve as a predictive marker

of delivery and response. Current predictive biomarker strategies include state-of-the-art tumor histology techniques, flow cytometry/CyTOF, and RNA and DNA sequencing. These biomarkers provide limited information about the pathophysiology of the TME. Imaging of drug distribution would visualize dynamic events to complement or replace other biomarker methods. TME normalization and nanomedicine development could advance symbiotically with the information gleaned from such biomarkers.

PERSPECTIVES

More research is needed to effectively combine RT with various forms and combinations of TME normalization and immunotherapy. Such research includes identifying and validating predictive biomarkers and biomarkers of response. In addition, understanding the temporal windows of the various treatments will enable effective drug combinations with fewer toxicities. We hypothesize that alleviating hypoxia is the critical biomarker for TME normalization and RT.

Hypoxia is a validated negative prognostic biomarker, induces disease progression through multiple mechanisms, and promotes resistance to most treatment modalities. Inefficient tumor blood vessel function causes hypoxia. Pathologic angiogenesis and desmoplasia cause hypoperfusion, resulting in hypoxia, acidity, and immunosuppression. Here, we described how to normalize the TME by reversing these pathologies to potentiate RT efficacy. Furthermore, we describe how TME-normalizing strategies benefit ICB, which has revolutionized cancer treatment but is estimated to benefit only a minority of patients with cancer.[34] There is an urgent need for novel combination strategies for ICB to expand its use, so we highlighted the mutually beneficial combinations of RT with ICB. TME normalization can improve the efficacy of this combination. Nanotechnologies and chemotherapies can be integrated rationally to enhance effectiveness further and limit the toxicity of RT, immunotherapy, and TME-normalizing combination strategies.

Given the potential mechanisms of synergies of these cancer therapies, future research should elucidate how to optimally combine these drugs. Unfortunately, the benefit of preclinical studies can be limited by suboptimal model choices, inconsistent reporting and protocols, and a need

for proper controls and study endpoints. These errors limit researchers' ability to determine optimal treatment windows for each therapy, as has been done for TME normalization. One solution involves the use of imaging biomarkers. Recent improvements in the imaging of perfusion, oxygen, and drug delivery in tumors have enabled data collection, supporting the notion that these biomarkers are central to determining how to best combine RT with chemotherapy, immunotherapy, AATs, and mechanotherapeutics.

DISCLOSURES

R.K.J. received consultant fees from Cur, DynamiCure, Elpis, SPARC, and SynDevRx; owns equity in Accurius, Enlight, and SynDevRx; served on the Board of Trustees of Tekla Healthcare Investors, Tekla Life Sciences Investors, Tekla Healthcare Opportunities Fund, and Tekla World Healthcare Fund; and received research grants from Boehringer Ingelheim and Sanofi. D.G.D. received research grants from Bayer, Surface Oncology, Exelixis, and BMS.

CHAPTER 5

Precision Medicine as Applied to Radiation Oncology

Jeffrey C. Buchsbaum and Pataje G. S. Prasanna

When we were asked to write this chapter, reflecting on our previous contributions to the SMART radiotherapy chapter in the seventh edition of this textbook, we chose to make our intentions clear, that is, to link biology and physics. As stated in the previous versions, we anticipate that the radiobiology chapters will cover the essential aspects of molecular radiation therapy and the tumor microenvironment, the physics chapters will include critical elements of particle therapy, and the clinical chapters will cover the molecular characterization of tumors, the use of molecular and functional imaging, and the current studies with molecularly targeted agents for various diseases. This chapter presents a new view of precision radiation oncology that is dynamic and critical to the field with some futurist thinking. "Precision" generally means matching the treatment to the patient in more than a generic way as done in the past—be it biomarker-driven, location-driven, genetics-driven, or some combination of those. Precision has historically focused on the choices at the start of the treatment course—getting drug A or drug B. We will address and expand this in this chapter, a text that has undergone transformative change in this edition.

The goal of this chapter is to take a broad view of some of the emerging innovative concepts in the practice of oncology that are relevant to radiation therapy researchers and practitioners in the optimization of selection and treatment choice—starting with what is called "precision" or, to be more precise, perhaps solid estimation. However, multiple areas covered previously in this chapter in previous editions are now further developed elsewhere in the textbook: artificial intelligence (AI; Chapters 32), radiotherapy in underdeveloped countries (Chapters 34 and 37), radiopharmaceutical therapy (Chapters 25), radiation and the immune

system (Chapters 26), hadron therapy and boron neutron capture therapy (Chapters 20), training and education (Chapters 35), and normal tissue radiobiology (Chapters 107).

A first major point that remains unchanged and needs to be stated early and firmly is that perhaps now more than ever, radiation oncology needs to be at the center of the science of cancer care. Our clinical expertise transcends all diseases; our technology impacts the most expensive, high-technology, upper-income-country care but can also reach people in dire need of cancer care in lower- and middle-income countries (as noted, it is discussed in another chapter). While not always recognized as such, in the evolving era of "precision medicine," radiation is both "precision and accurate medicine" when one looks at radiation as a "drug" compared to other drugs. We can control the pharmacokinetics and pharmacodynamics of radiation by hitting specific physical targets and using doses and schedules designed to activate molecular, cellular, and tissue pathways.[1] The term "focused biology" was coined about 20 years ago,[2,3] and it is now becoming increasingly relevant in image-guided radiation therapy, particle therapy, immune modulation, hypofractionation, and molecular-targeted drug treatment. We will focus on this aspect of radiation oncology in this textbook edition and finish with some thoughts on optimizing the patient's path, not just selecting which path to start.

PRECISION REQUIRES SCIENCE-FOCUSED CLINICAL CARE BASED ON CANCER, MOLECULAR, CELLULAR, AND TISSUE BIOLOGY

Radiation as a Drug

A concept introduced in previous editions of this chapter is radiation as a drug and immune modifier. Luo et al[4] modified the "hallmarks of cancer" model of Hanahan and Weinberg[5] by targeting non-oncogene addiction in addition to oncogene addiction. Logically, the biochemical and metabolic machinery of the cell carries out the functions of the genes, be they normal or abnormal, so that the target of cancer therapy is to disrupt the turning on and off of genes directly and also to disrupt the metabolic and biochemical pathways that they activate. Non-oncogene pathways include the stress responses: metabolic, proteotoxic, mitotic, oxidative, deoxyribonucleic acid

(DNA) damage, and evading immune surveillance. Notably, all these pathways can be modulated by radiation. Appreciating this aspect of radiation biology is critical to understanding precision medicine in our field, and we are developing this further here.

The initial work by Tsai et al[6] showed that multi-fraction adaptive responses used ribonucleic acid (RNA) microarrays to study the effects of 10 Gy as a single dose or as multi-fractionated radiation, 2 Gy × 5, in three tumor cell lines—breast, prostate, and brain—in vitro and in vivo. Fractionation results in a substantially different gene expression pattern compared to a single dose, with immune response genes being significantly upregulated. Fractionated radiation made the cell lines somewhat more alike (one of the hypotheses tested), with a substantial difference between tumors treated in vivo and in vitro, which might reflect the effects of radiation and the presence of various cell types within a tumor.

Aryankalayil et al[7] studied the molecular changes in prostate cancer cells exposed to 10 Gy as a single dose or multiple fractions using 2 Gy × 5 (multiple fraction 2) and 1 Gy × 10 (multiple fraction 1). The gene profiles are markedly different between single dose and multiple fractions, and multiple fraction1 induces more changes than multiple fraction 2. Summarizing substantial work in this regard,[3,7-9] it has been observed that: (a) an inflection point occurs after six to seven 1 Gy doses, with immune response genes being a major pathway so that this multi-fraction adaptive response may be missed in schedules using only three to five fractions; (b) changes occur in microRNA, metabolomics, and protein expression, which are now being correlated; (c) 0.5 Gy × 10 will induce changes so that many tissues know they've been hit; (d) similar changes are seen in endothelial cells, including immune response genes; and (e) as a proof of principle, drugs targeting the AKT-mTOR pathway were effective after multiple fractions but not before, demonstrating that radiation could stimulate drug susceptibility. These studies indicate the potential unique use of radiation in the "focused biology" concept for molecular-targeted therapy and emphasize the importance of investigating the molecular phenotype in cells that survive radiation.

The Tumor Microenvironment

The efficacy of radiotherapy is in part determined by tumor microenvironmental factors, including, but not limited to, the extent of tumor oxygenation, the tumor pH, and the interaction of tumor cells with host stroma and inflammatory cells. Tumors contain areas of poor vascular perfusion, low pH, and oxygen, which may provide regions in which both the delivery and activity of cytotoxic therapies are attenuated and in which cancer stem–like cells (CSC) reside.[10,11] In addition, certain tumor environments may select far more aggressive or resistant tumor clonogens.[12] One factor that has received little clinical attention but may provide an avenue for future advances is the impact of mechanical force on the transformation, progression, and treatment response of cancer cells.[13] Similarly, signaling originating from the interaction of stromal components with integrins on cancer cells can influence tumor survival and provide targets for intervention.[14,15]

The tumor microenvironment changes during radiotherapy.[16] Fractionated radiotherapy results in reoxygenation of the tumor due to the elimination of well-oxygenated cells, thus increasing oxygen delivery to the previously hypoxic areas. Conversely, high-dose single fractions (over 13 Gy) have been shown to result in the destruction of both tumor cells and vascular endothelium.[17] How and under what circumstances radiation-induced vascular injury impacts tumor responses continues to be a topic of investigation and is relevant to the current use of large-fraction stereotactic radiosurgery or therapy.[18-21] Radiation also results in the release of tumor antigens, and this release is qualitatively and quantitatively modulated by fractionation schedules, as discussed in the immunotherapy chapter.

Tumor Hypoxia

The longest-studied example of tumor microenvironment effects on cancer cell radiation survival remains the impact of tumor oxygenation. Radiation under atmospheric oxygen conditions enhances killing by a factor of 2 to 3 compared to irradiation under anoxic conditions, which has been termed the oxygen enhancement ratio[22] (as reviewed by Horsman et al[16]). In the clinical setting, hypoxia affects outcomes after radiotherapy.[23,24] However, hypoxia has also been shown to be a poor prognostic factor after chemotherapy[25] and surgery.[26,27] These findings were attributed to chronic hypoxia, which was

studied under controlled oxygen concentrations in vitro or using electrodes or immunohistochemical staining to measure tissue oxygenation in vivo. Overcoming hypoxia by biochemical targeting of hypoxic regions in tumors has proven difficult to translate to the clinic.[28] Going forward, molecular targeting of hypoxic cells may prove more practicable and effective.[29] The approach of reducing tumor oxygen consumption may also be more effective than either targeting hypoxic cells or trying to increase tumor oxygen.[30] Recent advances in noninvasive tumor hypoxia imaging may also play a role in the future, allowing precise definition of hypoxic tumors and tumor subregions through imaging with positron emission tomography,[31] magnetic resonance imaging (MRI),[32-34] or electron paramagnetic resonance imaging (reviewed in Colliez et al[35]). The resolution of these imaging modalities will be critical.[36]

More recent studies have shown that acute fluctuations in tumor oxygenation ("transient" or "cycling" hypoxia) interspersed with periods of reoxygenation may be even more effective in promoting tumor survival and progression than chronic hypoxia.[37] A third type of hypoxia, termed "longitudinal hypoxia," has also been proposed, which occurs as a gradient along the length of tumor vessels.[38] Defining the relative contributions of these hypoxia mechanisms to radiobiologic responses is ongoing; however, all could likely contribute to resistance. Cycling hypoxia may complicate efforts to identify and target radiobiologically important hypoxic regions within tumors using approaches such as radiation dose painting to hypoxic tumor subregions.[39] Cycling hypoxia is more difficult to image using current methods, such as nitroimidazole markers, which are better suited to detecting chronic hypoxia. Developments in imaging hypoxia with MRI and electron paramagnetic resonance may facilitate real-time detection of transient hypoxia in the future.

Hypoxic Cell Sensitizers and Cytotoxins

Targeting hypoxic cells should improve outcomes in frequently hypoxic tumors. Nimorazole, a nitroimidazole hypoxic cell sensitizer, has shown promising results when used with radiotherapy in patients with hypoxic tumors.[40,41] However, testing and adoption of this drug in countries other than Denmark have been limited. The alternative approach of using hypoxic

cell cytotoxins has also been tested. Tirapazamine (TPZ, 3-amino-1,2,4-benzotriazine-1,4-dioxide) undergoes reduction under hypoxia to form a highly reactive radical that causes DNA damage, leading to cell killing.[42] Under normoxic conditions, the reduction of nitroimidazoles and TPZ is reversed, thus providing the specificity for hypoxic tissues.[43,44] Despite promising early results, phase III testing of TPZ in combination with chemoradiotherapy failed to demonstrate improvement in failure-free survival, time to locoregional failure, or quality of life among patients with head and neck cancers.[45] However, patients in this trial were not selected for tumor hypoxia, and other treatment concerns were subsequently raised.[46] Developing new-generation hypoxic cell cytotoxins with greater preclinical efficacy than TPZ is underway.[47] In future tests of hypoxia-targeting agents, selecting or stratifying patients based on their tumor oxygenation status will be crucial.[48]

The identification and selective treatment of hypoxic tumors may enhance the results of radiotherapy in the future. This approach will benefit from novel imaging methods to identify hypoxia and new-generation hypoxic cytotoxins and sensitizers. In addition, hypoxia has been recently shown to impart susceptibility to DNA damage response inhibitors, as it downregulates components of the homologous recombination (HR) DNA damage repair machinery.[49,50] Exploiting this finding in radiotherapy with poly ADP ribose polymerase or other HR inhibitors could effectively eliminate otherwise resistant hypoxic tumor cells. The history and possible paths forward in exploiting hypoxia as a clinical target with a focus on lung cancer were recently reviewed.[51]

Tumor Angiogenesis and Antiangiogenic Approaches

Normal angiogenesis is a highly regulated process involving endothelial cells with differing functions (tip, stalk, and phalanx cells) under tight regulation of oxygen sensors (prolyl- hydroxylase-2 [PHD-2]), growth and maturation factors (vascular endothelial growth factor [VEGF], angiopoietins), and transmembrane receptors (Notch family) (reviewed in Carmeliet et al[52]). Small changes or imbalances in the expression of these regulators can significantly impact vascular development and lead to the formation of abnormal tumor vessels that are inefficient in transporting

nutrients, oxygen, and metabolic wastes. Limited perfusion and convection also reduce the efficacy of chemotherapeutic delivery. Unlike tumor cells, vascular endothelial cells are genetically stable and thus an attractive target. Antiangiogenic agents reduce or cut off tumor vascular flow by selectively targeting tumor vessel growth by blocking VEGF signaling. Targeting the tumor vasculature was initially proposed by Judah Folkman.[53] It is now clear, however, that this approach is complicated because development, structure, and the potential for recovery of tumor vasculature after treatment are influenced by bone marrow–derived progenitor cells in addition to the tumor and other stromal elements.[54] In addition, where tumor cell–derived vascular channeling (vasculogenic mimicry) plays a role in tumor circulation, the effects of antiangiogenic strategies that target host vascular endothelial cells may be less effective.[55]

VEGF can be induced in response to radiation, and inhibition of VEGF can increase tumor control after radiation in preclinical models.[56] VEGF receptor inhibition reduces endothelial cell proliferation in vitro after irradiation and reduces microvessel density in irradiated tumors.[57] Clinical trials have suggested a potential benefit of combining radiation and antiangiogenic therapy in rectal cancer and sarcoma.[58,59] However, the toxicity of bevacizumab in combination with radiotherapy has been of concern in some tumors.[60]

Vascular normalization is a term coined to denote transient changes observed in tumor vessels after VEGF inhibition with a VEGF receptor-2 antibody.[60] Other antiangiogenic approaches have shown similar morphologic effects on tumor vasculature. Methylselenocysteine, which has antiangiogenic activity, has been shown to induce a more mature morphology in FaDu xenograft tumor vessels, accompanied by enhanced perfusion and a 4-fold increase in doxorubicin delivery to treated tumors.[61] Normalization is characterized by a reduction in the chaotic branching and tortuosity of tumor vessels and is accompanied by a decrease in tumor hypoxia and enhanced radiosensitivity. The effects of vascular normalization may also involve a reduction of tumor interstitial fluid pressure. High tumor interstitial fluid pressure has been shown to impact survival after irradiation and may also be influenced by the tumor stroma.[62] Tong et al[63] demonstrated that blocking VEGF signaling decreases interstitial fluid pressure in mouse tumor xenografts. Although the

normalization period offers an opportunity for improved response to radiation and chemotherapy, the period of normalization obtained with direct targeting of VEGF signaling in preclinical studies lasts less than a week, followed by vascular insufficiency. In addition, vascular normalization may not occur in all tumors and has not been observed in all studies (reviewed in Horsman and Siemann[64]). In the clinical setting, vascular normalization has been proposed as a predictive marker in patients undergoing cediranib (VEGF inhibitor) treatment for recurrent glioblastoma.[65] Elevated blood perfusion after cediranib treatment has recently been associated with increased survival in these patients.[66]

More durable normalization of tumor vasculature might be clinically achievable through growth factor or oncogenic signaling inhibition. Studies have shown changes in vascular morphology, function, and maturation accompanied by decreased tumor hypoxia after inhibition targeting epidermal growth factor (EGF) receptor, RAS, phosphoinositide (PI) 3-kinase, or AKT in human tumor xenografts and spontaneous mouse tumors that last up to 2 weeks.[67] Others have shown that blocking EGF signaling increased tumor uptake of cisplatin while enhancing vascular function and oxygenation seen in tumor xenografts.[68] Signaling inhibition in these studies decreased, but did not eliminate, VEGF production by tumors, which might account for the effects seen and their duration.

Other approaches to altering tumor vasculature are being investigated. Inhibition of $\alpha(v)\beta(3)/\alpha(v)\beta(5)$ integrin has been reported to cause effects similar to signaling inhibition on tumor vascular morphology.[69] Using another approach, investigators showed that shutting off NOS1 production in U87 glioblastoma tumors restored a nitric oxide gradient around the tumor vessels. This was accompanied by a normalized phenotype with less tortuous and more abundant vessels that had increased perivascular cell coverage.[70] Hypoxia in these tumors was reduced, and their response to radiation increased, as measured by relative tumor volume and survival endpoints. Modulation of host PHD-2 can affect tumor vascular structure and maturity.[71] Inhibitors of PHD-2, such as dimethyloxalyl glycine, might be developed for clinical application. More recently, the interaction between T cells and tumor vasculature has been studied in the context of immunotherapy. Interferon (IFN) β produced by T-helper type 1 cells has

been shown to promote vascular normalization, facilitating T-effector functions.[72]

Inhibition of Vasculogenesis

Vasculogenesis, unlike angiogenesis, recruits cells from distant sites, including the bone marrow, to participate in the formation of new blood vessels (reviewed in Patenaude et al[73]). The process is considered an essential contributor to the tumor vasculature, but the precise contribution of the different recruited cell types is still debatable.[54] The CD11b-positive, matrix metalloproteinase-9-expressing myeloid cells appear central to this process.[74] A neutralizing antibody to CD11b inhibited the recruitment of myeloid cells to tumors and prolonged radiation-induced regrowth delay. Additionally, mice with reduced CD11b expression showed enhanced xenograft radiosensitivity.[75] Stromal-derived factor-1 (SDF-1) and the chemokine receptor CXCR4 also contribute to the recruitment of endothelial cell precursors and could be targeted. Inhibition of the interaction of CXCR4/SDF-1 reduced bone marrow– derived progenitor cell recruitment into irradiated glioblastoma orthotopic xenografts and slowed tumor regrowth.[76] An inhibitor of CXCR4 activation by SDF-1, AMD3100 (plerixafor), is in clinical use for stem cell mobilization and could be quickly adopted. This drug has been shown to have promising effects in chemoradiotherapy for cervical cancer.[77]

Antivascular Therapy

Selectively destroying tumor vasculature with vascular disrupting agents (VDA) is an approach that seeks to kill tumors by shutting off their blood supplies (reviewed in McKeage and Baguley[78]). This approach, however, acts primarily on the tumor core and does not eradicate host vessels that border the tumor and are in proximity to normal host vasculature. Tumor cells at the host-tumor interface can remain viable after this treatment to repopulate the tumor. Furthermore, vascular disruption could generate areas of hypoxia that still contain viable tumor cells, thereby selecting for more resistant clones.[12] Combining VDA treatment with a cytotoxic modality could overcome this problem. The effects of VDAs, both alone and in combination with antiangiogenics, chemotherapy, radiation, or other

modalities, have been examined in several preclinical studies (reviewed by Horsman and Siemann[64]). VDAs are currently in phase II to III clinical trials alone or in combination with cytotoxic chemotherapies.[79]

Tumor Stroma and Extracellular Matrix

The tumor stromal compartment, including the extracellular matrix, host fibroblasts, and immune cells, contributes to tumor progression and survival.[80,81] In certain tumors, like pancreatic cancers, activation of quiescent stromal cells, known as stellate cells, to myofibroblast-like cells involved in extracellular matrix production contributes significantly to tumor progression.[82] Activated fibroblasts deposit collagens, leading to changes in stromal rigidity, which can impact both transformation and progression.[83] This mechanism of stromal-induced tumor promotion includes intercellular signaling initiation via integrins to pro-survival pathways, including PI 3-kinase.[84]

There are multiple points at which stromal changes can be inhibited, including inhibition of fibroblast or stellate cell activation by angiotensin-converting enzyme (ACE) inhibitors or other antifibrogenic compounds such as halofuginone.[85] This class of agents can also protect from normal tissue fibrosis and inhibit tumor growth factor (TGF)-β.[86,87] Signaling by the cytokine TGF-β strongly promotes fibrosis, both in response to tumor growth and in normal tissues in response to treatment with radiation. Direct inhibition of TGF-β in tumors can interrupt or mitigate desmoplasia and reduce tumor growth.[88] Angiotensin-II (Ang II) can promote stellate cell growth under pathologic conditions, and ACE inhibitors partially act by blocking Ang II.[89] Angiotensin-(1-7), an endogenous amino acid peptide antagonist of Ang II, has been shown to reduce TGF-β expression, block the proliferation of cancer-associated fibroblasts, and inhibit tumor growth.[90] Inhibition of Hedgehog pathway signaling is another approach tested in pancreatic cancer mouse models.[91] However, there is controversy surrounding the role of Hedgehog signaling in pancreatic and other cancers.[92]

Integrin binding and signaling have been identified as potential targets for cancer treatment, as these receptors are involved in tumor growth, angiogenesis, and therapy resistance.[93] Cilengitide is a pentapeptide mimic

of the RGD binding site that blocks $\alpha(v)\beta(3)$ and $\alpha(v)\beta(5)$ integrin binding to extracellular matrix components.[94] In addition to its antiangiogenic activity, it inhibits focal adhesion kinase signaling.[95] Cilengitide is well tolerated and has some antitumor activity as a single agent.[96] It has been shown to be active in combination with radiation in several, but not all, reports.[97-99] However, questions remain about potential normal tissue toxicity in combined modality treatment because integrin signaling is required for normal cell function and survival.[97] A phase III trial of cilengitide with temozolomide-radiotherapy for glioblastoma multiforme saw no unanticipated toxicities but failed to meet its endpoints.[100]

Targeting Stem Cells

The CSC model is currently used as a framework for understanding cancer proliferation, growth, and treatment resistance (reviewed in Bednar and Simeone[101]). CSCs are considered a subset of cells at the peak of a developmental chain within a tumor with the capacity for unlimited self-renewal and lineage plasticity.[102] These cells give rise to more differentiated daughter cells with less replicative and tumorigenic potential that comprise the bulk of the tumor cell population. The CSC may be more quiescent than the general population of cells in a tumor and relatively resistant to cytotoxic therapy.[103,104] Some studies have identified perivascular niches for these cells[105,106] and the conditions that promote their colonization and survival. Still, identifying both the stem cells and their niches in a disorganized and dynamic tumor environment remains challenging.[107] The perivascular niche, particularly the endothelial cells, may aid in tissue repair and promote tumor growth by secreting "angiocrine factors."[108] Targeting these factors could be an approach to cancer treatment. Disruption of the perivascular niche with VDAs or antiangiogenics might also reduce CSC numbers. The potential for CSCs as targets and biomarkers for radiotherapy has recently been reviewed by Krause et al.[109]

Recent work indicates a novel potential target within the tumor stroma, fibroblast activation protein, which has the potential to enhance innate antitumor immune responses. In a transgenic mouse model, the elimination (through genetic manipulation) of fibroblasts and pericytes expressing fibroblast activation protein enhanced antitumor immune responses.

Activation of tumor-infiltrating T cells and the resulting increase in IFN-γ and tumor necrosis factor-α (TNF-α) promoted the antitumor immune response in a transgenic mouse model.[110] A possible pharmacologic approach to eliminating these activated fibroblasts is inhibiting the matrix enzyme lysyl oxidase–like 2 (LOXL2). Inhibition of this enzyme using a monoclonal antibody decreased desmoplasia and both primary and metastatic tumor growth[111]; small-molecule inhibitors of this enzyme also exist. Targeting LOX, which has been shown to promote tumor growth in orthotopic and spontaneous mouse tumor models, might also inhibit tumor growth.[84]

FLASH Radiotherapy

Since the publication of the last edition, the most significant emerging area in the field has been the exploration of ultrahigh dose rate, or FLASH, radiotherapy, where a dose of 6 to 15 Gy is given at an ultrahigh dose rate of above 40 Gy/s (these parameters are not formally set and are considered variable based on context).[112-115] It has enormous promise in that it seems to offer the possibility of equal tumor control in the proper dose regime (rate, total dose, field number) and a likely significant sparing of normal tissue, seeming to range from moderate to 50% with an average based on a review of the literature and perhaps of 30% dose reduction to normal tissue. Many questions exist in the FLASH domain: dose rate that is needed, mechanism, interaction with other agents (drugs, etc), quality assurance and measurement, feasibility of use with more than one field per day, whether planning systems can optimize it, how variable the effect is from person to person and tissue to tissue in the same individual, whether a FLASH effect on day one can still happen on day *N* over fractionated therapy, whether tumors can survive, whether they are more or less resistant to further treatment than standard treatment, and whether there are any odd side effects with normal tissue.[116-118] This incomplete list goes beyond the scope of this chapter, but we'll approach just a few of these issues from the precision radiation therapy perspective with full knowledge that these are very early days in this emerging field and patient data really do not exist yet in this space, so our short commentary should be considered just some open

thoughts and discussion pending more data in the coming years in preclinical and ultimately clinical trials.[119,120]

In the context of precision medicine, the primary question for the field is whether the FLASH effect is observed in all patients, and if not in all patients, whether it can be modified to personalize to benefit from the flash effect, and whether there is a way to tell immediately if the normal tissue sparing is occurring so that potential injuries can be avoided.[121] This is crucial because the plan may require the FLASH effect to keep an organ at risk (OAR) under a tolerance constraint value. In a similar vein, some people are more likely to have serious late effects from FLASH radiotherapy that may not appear until months or years after treatment. This is of particular concern in patients where treatment with standard therapy is very much able to deliver quality care with minimal risk in the context of expected long survivorship, such as in a pediatric patient with Hodgkin disease. Finally, whether people adapt to FLASH therapy differently is a critical question and completely unknown at this point. To be fair, it is also not very well known for standard radiation therapy. In case they adapt differently and in a significant fashion, the interpretation of a FLASH plan, even if done with the most robust methods and fewest assumptions, may only reflect the first fraction or two of treatment as adaptation may make FLASH an invalid approach over multiple fractions.[118]

The major current potential limitation of FLASH is that the window where it is useful may be different from a clinically viable window for most patients. We avoid using large fraction size radiotherapy in many situations because it can cause increased toxicity to normal tissue. While FLASH promises to reduce that, it may not or only partially do that. Large fraction sizes are generally used palliatively or for stereotactic cases where we know exactly (we think) where the tumor is. When there is an unknown tumor margin involved, we have mostly normal tissue but some tumor tissue. If the FLASH effect works without question, this might be a very sensible approach for this sort of margin, but if it does not, large areas of normal tissue may be damaged, and this is just one example of a situation where large fractions may not work.[122,123] If we accept that not all situations are best managed by hypofractionated therapy, not knowing if FLASH can be used for 10- or 20-fraction courses matters a lot. Finally, we need to understand the mechanism of FLASH better to understand how to take

maximal advantage of it by setting up the patient to have the best FLASH outcome and how to potentially mitigate it in cases where it appears to be sparing tumor unexpectedly.[124,125] We have not even started to discuss if other agents work as expected with FLASH, such as traditional chemotherapy. Given these and other issues, what is certain about FLASH is that there is much to learn, and we are not close to calling it a standard-of-care therapy in 2024. Yet, it has enormous promise and must be studied carefully via clinical trials.[126] More tools are needed, but we are slowly moving toward randomized trials in this space, given the published road maps for doing so.[117,127]

Summary of Microenvironment

It is impossible to predict how radiotherapy will evolve in its utilization of knowledge regarding the tumor microenvironment and host-tumor interactions. What appears clear is that increasing emphasis will be placed on these factors. Targeting changes specific to the microenvironment has the advantage of being largely tumor-specific and potentially less toxic than cytocidal therapies. Future developments may allow for hypoxic tumor region dose painting. Alternatively, hypoxia-targeting drugs may finally reach clinical maturity. Inhibition of hypoxia in tumors may also arise from strategies that revert tumor vasculature to more normal morphology and function. This strategy has the added advantage of reducing hypoxia selection for aggressive tumor clones and enhancing chemotherapy delivery. The impact of the immune response on tumors and, in turn, the effects of different radiotherapeutic interventions on immunity are now being exploited with the explosion of trials combining checkpoint inhibitors and radiation (see the next section). Findings relating to the impact of host stromal elements on tumor cell radiation survival through direct intercellular signaling, autocrine stimulation, or mechanical force may also soon reveal new targets and interventions applicable to radiotherapy.

In addition to the host and tumor microenvironment, external environmental factors may also play a role in response to therapy. These have yet to be thoroughly evaluated or exploited. Temperature (hyperthermia) is well known to impact radiation response,[128-130] but its evaluation and clinical application, at least in the United States, have

continued to lag. Conversely, preclinical studies have shown that lower ambient temperatures can induce resistance to cytotoxic therapies[131] and influence tumor growth and immune responses.[132] The impact of time of day of treatment and the role of circadian clock proteins are other understudied areas that could be exploited.[133] Preclinical work points to the possibility that the clock proteins influence tumor radiosensitivity.[134] There are indications from clinical studies that both toxicity and treatment failure could be impacted by the time of irradiation, but the data are not yet conclusive.[135] At a minimum, further study of these factors could inform preclinical study conditions and perhaps enhance the translation and reproducibility of results. And, as pointed out, we don't yet have enough data on FLASH therapy to really know much about when and how to best use it with actual patients with real tumors in the context of current standard-of-care therapy regimens.

Combining agents that alter the tumor environment with radiotherapy requires robust preclinical data demonstrating at least additive effect and acceptable toxicities. Careful preclinical testing, including normal tissue response evaluation, may avoid subsequent problems in many instances. Having markers and imaging that detect the targets of interventions, such as hypoxia, cancer-associated fibroblasts, or immune infiltrating cells, which can be used to assess intervention-mediated changes in the environment, will be critical to fully exploiting this approach. Recent developments in the analysis of circulating tumor cells and cell-free DNA (cfDNA) may revolutionize treatment monitoring, as discussed later in this chapter.

Chapters 26 addresses the unique role of the immune system, a critical part of the tumor microenvironment, and is closely connected to the abovementioned topics.[3]

PRECISION MEDICINE REQUIRES A MULTIDIMENSIONAL APPROACH FOR MAXIMUM IMPACT

Dimension 1: Normal Tissue Injury Science

Radiation risk to humans stems from a variety of complex radiation exposure scenarios, which include therapeutic and diagnostic medical exposures, occupational exposures, radiation accidents, nuclear weapons detonation, and terrorist events. Radiation exposure can cause acute,

intermediate, late, and/or chronic injury. The severity of the injury is dependent on radiation type, dose and dose rate, and volume of the tissue irradiated in addition to an individual's inherent sensitivity to radiation. In addition, different normal organs and normal tissues respond to radiation exposure in differing ways, influenced by, among other factors, intrinsic sensitivity to radiation, functional architecture, cellular turnover rate, and differences in damage response.

Acute exposure to total-body ionizing radiation in the dose range of 0.5 to 30 Gy can result in acute radiation syndrome (ARS), which is divided into organ syndromes based on the dose and cause of mortality.[136] The sequence of manifestation of ARS from lower to higher doses is as follows: hematopoietic, gastrointestinal, dermatologic, cardiovascular, and neurologic. However, syndromes overlap. For example, damage to the gastrointestinal or dermatologic systems can impact the outcome of hematologic syndrome at sublethal doses. Bioindicators or biomarkers of radiation exposure, even in the lower dose range, can reflect a response by multiple organs, all of which sense and respond to the radiation.[137]

At radiation doses below 0.5 Gy, acute effects are not observed, but there is the probability of late effects such as cancer and hereditary effects.[138] The possibility of exposure of a large number of people to radiation following a nuclear incident has raised the public's concerns about the increase in the chances of developing radiation-induced cancers.[139] However, public perception and "fear of radiation" appear well beyond the actual risk. This fear was elevated due to the Fukushima disaster despite the lack of evidence for acute radiologic injury in the general population.[140] Quantifying the risk associated with low-level radiation exposures is problematic and uncertain because of the unresolved shape of the dose-response curve for radiation-induced cancer in the low-dose region.[141] For the purposes of radiation protection, it is assumed that there is a linear relationship between exposure and future cancer risk. A linear no-threshold model is used to assess risk at doses below 100 mSv, recognizing that epidemiologic information in this dose region cannot unambiguously support or refute the model assumptions.[142] However, data from the Radiation Effects Research Foundation in Japan seem to align more with a linear relationship between radiation dose and cancer risk.[143] Evidence is emerging on the possibility of additional late-developing effects on health following somewhat higher

doses, such as cardiovascular[144] and respiratory disease,[145] premature senescence,[146] and damage to endothelial cells.[147,148]

A multidimensional approach is necessary to address the complexity of the radiobiologic issues facing society across a wide range of energies, types, and doses. Various agencies of the U.S. government conduct and fund studies on radiation-induced normal tissue injury and develop medical countermeasures (MCMs) to mitigate many risks to individuals or populations associated with radiation exposures, addressing different dose ranges relevant to an agency's mission. Successful development of risk mitigation strategies requires a multidimensional approach with mechanistic scientific underpinnings to address the complex biologic variables. Ongoing research efforts among various government agencies related to radiation-induced normal tissue injury are summarized in Figure 5.1.

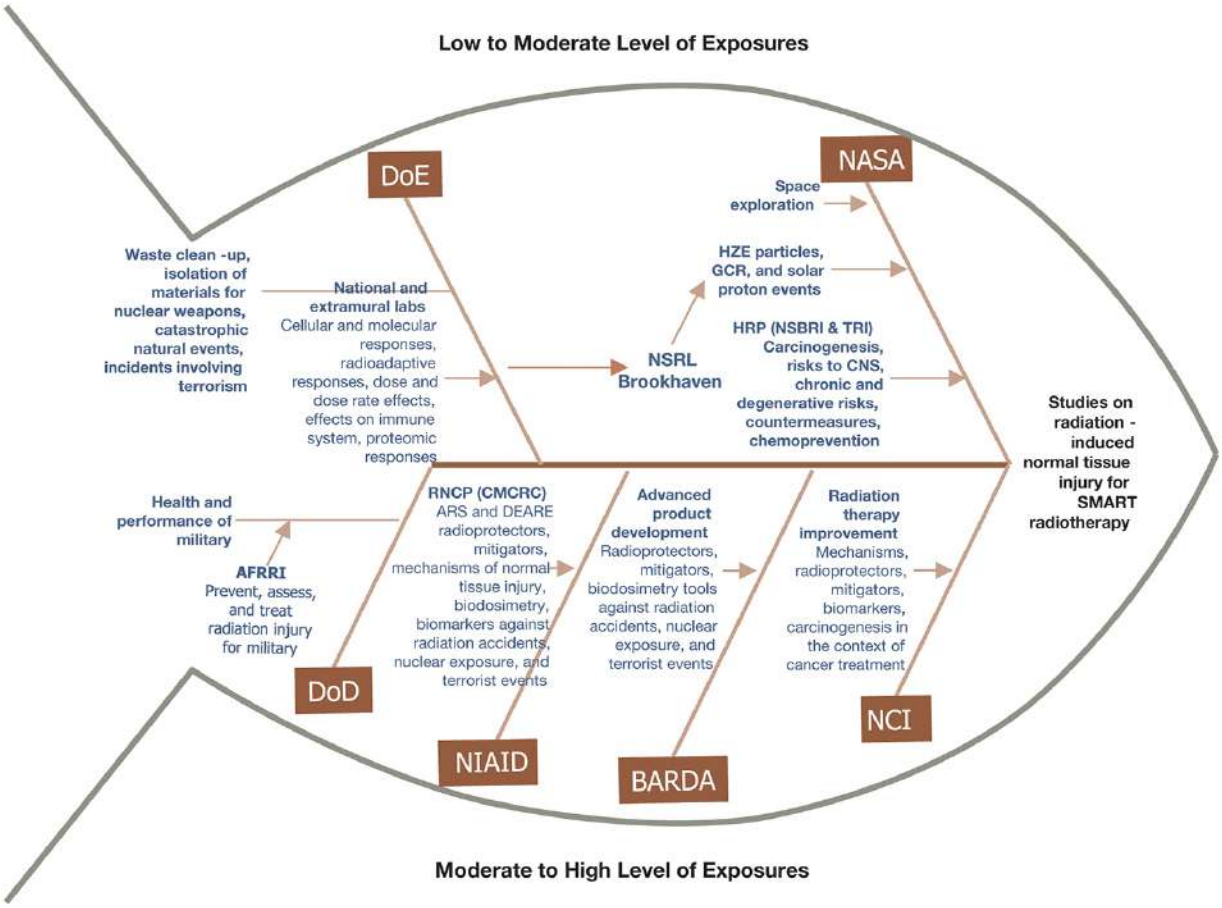

FIGURE 5.1 U.S. government research efforts among various government agencies related to radiation-induced normal tissue injury. AFRRI, Armed Forces Radiobiology Research Institute; ARS, acute radiation syndrome; BARDA, Biomedical Advanced Research and Development Authority; CMCRC, Center for Medical Countermeasures against Radiation Consortium; CNS, central nervous system; DEARE, delayed effects of acute radiation exposure; DoD, Department of Defense; DoE, Department of Energy; GCR, galactic cosmic rays; HRP, Human Research Program; HZE, High (H) Atomic number (Z) and Energy (E); NASA, National Aeronautics and Space Administration; NCI, National Cancer Institute; NIAID, National Institute of Allergy and Infectious Diseases; NSBRI, National Space Biomedical Research Institute; NSRL, National Space Radiation Laboratory; RNCP, Radiation and Nuclear Countermeasures Program; SMART, Societal focused, Molecularly aware, Altruistic, Research supportive, and wary of Technological solutions to biologic problems; TRI, Translational Research Institute (also known as the Translational Research Institute for Space Health [TRISH]).

The Department of Energy (DoE) under the Biological Systems Science Division studies radiation-related health risks from exposures to low levels of radiation. Exposures to low doses can occur in several scenarios, including (a) around nuclear power plants, (b) during isolation of materials for nuclear weapons and nuclear power production and waste cleanup, (c)

during medical diagnostic exposures, (d) during radiation terrorism incidents, etc.[149] The DoE's Low Dose radiation research program (poised to reopen with a promise of significant funding over a decade planned) is focused on cellular and molecular responses to doses relevant to workplace exposure limits, radio-adaptive responses, genetics of interindividual variation, low-dose and dose-rate effects, effects on the immune system, and epigenetic regulations.

The National Aeronautics and Space Administration (NASA)'s interest in radiation research focuses on space exploration, including earth orbits and, more recently, potential manned missions to Mars and beyond. The duration of the Mars mission necessitates understanding immediate health risks in the space radiation environment and long-term post-mission quality of life. The Human Research Program (HRP) was developed to refocus the space program in early 2004. NASA identified major risk categories attributable to space radiation, including carcinogenesis, risks to the central nervous system (CNS),[150] and chronic and degenerative tissue risks.[151] High-charge and high-energy ion components of galactic cosmic radiation can cause genetic mutations,[152] inflammation, and CNS structural damage and dysfunction.[153] The HRP is focused on understanding the possibility of reducing these health risks by developing countermeasures for acute exposures of greater than 1 Gy associated with large solar particle events and mitigators for lower-level exposures, particularly iron ions that will be encountered in the Mars mission. NASA's National Space Biomedical Research Institute conducts integrated biomedical research to support long-term human presence during space exploration and the enhancement of life on earth by applying these advances. The NASA Translational Research Institute was founded in 2016 to work in partnership with the HRP to translate cutting-edge terrestrial research into applications for space flight, focusing on human risk mitigation strategies for exploratory missions. Teaming up with the DoE's Office of Science, NASA has established the Space Radiation Laboratory (NSRL) at the Brookhaven National Laboratory. NSRL uses the Brookhaven ion beam facilities to enhance understanding of the link between radiation and cellular damage and also seeks approaches to limit the damage to healthy tissues by cosmic radiation in a simulated space radiation environment. NSRL uses beams of heavy ions extracted from Brookhaven's Booster accelerator to simulate cosmic

rays found in the space environment. NSRL has a beam line dedicated to radiobiology research. These studies are also relevant in particle therapy research for cancer treatment. Different but related is the International Space Station National Laboratory, which funds numerous studies on radiation effects in both human biology and manufacturing.

The Armed Forces Radiobiology Research Institute (AFRRI), within the Department of Defense, conducts basic and applied research to identify and develop measures to prevent, assess, and treat radiation injury to preserve and protect the health and performance of U.S. military personnel. The biodosimetry program has been developing rapid and precise methods to assess the severity of radiation injury as early as possible after the event to guide treatment decisions and aid in monitoring recovery from and the effectiveness of treatments for radiation injury.[154] AFRRI continues an intensive program on the identification and development of radiation countermeasures to be used by military and also civilian personnel.

The Department of Health and Human Services has two programs relating to normal tissue injury: (a) Medical Countermeasures against Radiological and Nuclear Threats at the National Institute of Allergy and Infectious Diseases and (b) the Public Health Emergency Medical Countermeasures Enterprise, which includes research and advanced development efforts in MCMs and biodosimetry including the Biomedical Advanced Research and Development Authority that deals with the full range of national security threats.[155] A key underlying principle of the entire radiologic or nuclear medical response program is that it is built on solid scientific underpinnings.[155] Research in normal tissue radiation biology received a substantial boost as the radiation biology community proactively responded to bringing the best science to help address the threat of radiologic and nuclear terrorism that became apparent following the September 11, 2001, terrorist attacks. Scientists from the academia and the government conceptualized a research plan that distinguished modifiers of normal tissue injury into three time phases: (a) protectors that are administered before radiation, (b) mitigators that are used following radiation exposure but before the damage has been fully manifest, and (c) treatment that is given for established radiation injury.[156] Some agents may function in more than one role. The radiologic or nuclear incident research plan includes the broad categories of (a) MCMs, which are drugs or

biologics developed as radiation mitigators, (b) biomarkers that can quantify an individual's radiation dose as a guide to treatment, and (c) agents that serve to reduce the exposure to internalized radionuclides by blocking uptake or enhancing excretion. The medical consequences of interest are those that result from a total-body exposure (or significant partial-body exposure) of a dose that can produce ARS.[137] A radiologic or nuclear incident will be a "no-notice" event, and for a large-scale nuclear incident, the requirement for an MCM is that it should be effective if started up to 24 hours after radiation.[157,158] A longer window of opportunity would be better given the chaos of the situation and that is part of the MCM development effort. What is not often appreciated is the concept of latency between exposure and clinical manifestation of radiation injury. To that end, there are two terms used to convey the concept: ARS and delayed effects of acute radiation exposure (DEARE). The development of the next generation of MCMs will exploit the evolving understanding of mechanisms by which radiation induces injury in normal tissue and its manifestation over time, from acute effects to DEARE to long-term late effects. The challenges in employing radioprotectors to reduce normal tissue injury during the course of radiotherapy are different. Here, a significant concern is the protection of the tumor itself, which would result in a compromised therapeutic benefit.

The National Cancer Institute (NCI)'s Radiation Research Program (RRP) has supported studies of normal tissue injury in radiation therapy for several decades. In the clinical context, a radioprotective drug might allow dose escalation to the tumor, leading to better tumor control or the same local control with less toxicity. Although many novel approaches of dose delivery to the tumor volume significantly reduce collateral normal tissue injury and improve the therapeutic ratio, the tumor's location within an organ of an inherent sensitivity to radiation and the dose needed to cure the tumor can still result in normal tissue injury.[156] Many patients still suffer adverse effects from radiotherapy, largely due to the biologic variables influencing treatment outcomes.[159,160] Improved survival results in increases in treatment-related adverse late effects, such as pulmonary fibrosis,[161] cognitive damage,[162] and secondary cancers, especially among children.[163] Prevention of these late occurring adverse effects warrants the development of countermeasures for enhancing posttreatment health-related quality of life (HRQOL) for cancer survivors.

Synergy among government agencies in supporting drugs to reduce radiation injury ensures our investments are rational, viable, sustainable, and cost-effective across a broad, multidimensional space so that precision can be applied to varied, critical situations. Academic and government research efforts can be leveraged by the NCI Small Business Innovation Research (SBIR) program through RRP initiatives to test promising radiologic countermeasures for clinical applicability so that such products gain "dual utility"—use in cancer treatment and also use for accidental or intentional civilian exposure. The development of dual utility agents will greatly reduce costs and risks of failure while enhancing the value of research.[164] The RRP-SBIR effort for advanced development of radiation-effect modulators serves as a model to reduce the risk for small businesses by providing government support.[165] Repurposed MCMs in the cancer treatment setting may help improve the treatment outcome by protecting normal tissue during treatment, reducing the acute adverse effects, or mitigating late effects, including therapy-induced secondary cancers, thus improving the HRQOL of patients.

A nuclear accident or terrorist incident could potentially expose a large number of people to low- to moderate doses of ionizing radiation and increase their lifetime cancer risk. There is an urgent need to develop low or nontoxic mitigators for this purpose. Current status, issues, and challenges regarding developing mitigators against radiation-induced cancers have been published.[166] These challenges include the long latency between exposure and cancer manifestation, limitations of animal models, potential side effects of the mitigator itself, the potential need for long-term use, the complexity of human trials to demonstrate its effectiveness, and statistical power constraints for measuring health risks (and reduction of health risks after mitigation) following relatively low radiation doses (<0.75 Gy). Nevertheless, progress in the understanding of the molecular mechanisms resulting in radiation injury, along with parallel progress in dose assessment technologies, makes this an opportune, if not critical, time to invest in research strategies that result in the development of agents to lower the risk of radiation-induced cancers for populations that survive a significant radiation exposure incident. Such mitigators will also be of immense value to counter late effects, including secondary cancers, after radiation therapy among cancer survivors.

Products that target the tumor promotion stage of a multistep carcinogenesis model, which involves initiation, promotion, and progression,[167] have primarily come from the field of chemoprevention. Modifiers of radiation-induced transformation in vitro systems include the following classes of compounds: (a) vitamins (or vitamin-like compounds), their precursors (eg, vitamin A, its precursor carotene and other carotenoids), and derivatives (eg, retinoids); (b) protease inhibitors (eg, the soybean-derived protease inhibitor, Bowman-Birk inhibitor); (c) hormones (eg, glucocorticoid hormones, testosterone, dihydrotestosterone); (d) modifiers of arachidonic acid metabolism (eicosanoids); (e) inhibitors of protein kinase C; and (f) antioxidants, including numerous products that scavenge free radicals.[166] Many cancer prevention products recognized by the Division of Cancer Prevention (DCP, NCI) also may be useful as mitigators of carcinogenesis after exposure to carcinogens, implying their potential to intervene in radiation-induced carcinogenesis at the promotion stage as exemplified by a curcumin study in which dietary administration significantly reduced the incidence of mammary tumors in rats.[168]

However, testing MCM drugs for use after radiation accidents for effectiveness, as well as mitigators to counter radiation-induced cancers, is challenging. The U.S. Food and Drug Administration (FDA)'s Animal Rule provides a regulatory framework for obtaining regulatory approval for MCMs. Previously, the FDA approved Neupogen (filgrastim), a granulocyte colony-stimulating factor, and Neulasta to counter radiation-induced neutropenia in a radiation emergency. The FDA recently approved a granulocyte-macrophage colony-stimulating factor growth factor supporting white blood cell production (Leukine) and a synthetic thrombopoietin receptor agonist, Nplate. Given the uncertain relationship between low-dose exposures and late effects, lack of suitable models, and early predictive biomarkers, regulatory challenges regarding mitigators have been even more significant.[166]

Dimension 2: Biomarkers

Clinical Application of Circulating Cell-Free Deoxyribonucleic Acid and Circulating Tumor Cell Deoxyribonucleic Acid to Assess Tumor Response and Evolution Under Treatment

One of the limiting factors slowing the integration of molecular therapies in the context of radiotherapy has been the relative lack of radiation biomarkers to monitor and predict clinical responses of both tumor and normal tissues, but this is changing rapidly. For monitoring tumor responses, the capacity to rapidly analyze cfDNA and circulating tumor DNA (ctDNA) promises to overcome this limitation. Analysis of free circulating DNA in plasma by droplet digital polymerase chain reaction (ddPCR) can reveal the presence of cancer in as little as 3 days compared to 4 weeks to obtain next-generation sequencing (NGS) results. In ddPCR, the purified plasma DNA is emulsified with oil into thousands of droplets containing at most one target DNA molecule that is PCR amplified, fluorescently labeled, and then read in an automated droplet flow cytometer. Each droplet is individually scored based on fluorescent intensity for the mutant or wild-type allele of a target locus.[169] This technology's high sensitivity and specificity have been demonstrated in a prospective study of non–small cell lung cancer.[170] The limitations of this test are that it is applicable only when the tumor sheds DNA into the bloodstream, it detects only known genotypes, it cannot detect rearrangements, and it is difficult to multiplex.

NGS can detect a broad range of targetable genomic alterations with 100% specificity. The sensitivity of this technique is equivalent to that of ddPCR.[171] When assessing for the presence of a driver or resistance-associated mutation, this technique applied to circulating DNA could avoid biopsy when results are positive. Still, sensitivity limitations mean that it cannot rule out mutation with a negative result. ctDNA analysis can also be used to monitor the evolution of a tumor under treatment. Novel methods have been and continue to be developed to use ctDNA analysis as a longitudinal diagnostic tool for patients with localized and metastatic cancers.[172-174] The mutation levels in patient plasma samples reflect the clonal hierarchy inferred from the sequencing of tumor biopsies. Serial changes in circulating levels of subclone-specific mutations correlate with different treatment responses between metastatic sites. A comparison of biopsy and plasma samples in individual patients with metastatic breast cancer demonstrates that ctDNA provides a dynamic sampling of somatic alterations that reflect the size and activity of distinct tumor subclones. Analysis of ctDNA also mirrors the clonal hierarchy determined by

multiregional tumor sequencing and tracks the variability of treatment responses by different metastases.

Identifying actionable somatic mutations, or alterations known to confer resistance to specific therapies and their relative circulating levels in pretreatment plasma samples, could inform an individualized choice of targeted treatments and represent a breakthrough for precision radiotherapy and cancer treatment.

The NGS-based approach of Cancer Personalized Profiling by Deep Sequencing (CAPP-Seq) for analysis of ctDNA enhances both the sensitivity and specificity of ctDNA detection and mutation analysis.[175] This method uses labeled DNA oligonucleotides (selectors) that target known DNA sequences mutated in the cancer of interest. The selector is applied to a tumor or circulating DNA to identify, by hybrid affinity capture, a patient's cancer-specific genetic aberrations (including driver mutations and rearrangements) and then used to quantitate their presence and change over time in circulating DNA. When combined with integrated digital error suppression, which eliminates most technical artifacts observed in cfDNA sequencing data,[176] CAPP-Seq can achieve the same sensitivity as the ddPCR technique. CAPP-Seq can achieve the equivalent or better sensitivity to ddPCR techniques (down to 4 in 10^5 cfDNA molecules) but can test a much wider number of sites on the genome. Epigenetic research has had a high impact in the radiation oncology space, with, for example, work in the prostate being of high impact and ongoing.[177,178]

These new minimally invasive genomic analysis techniques can monitor response, minimal residual disease, and give advanced warning of recurrence allowing for early changes in therapy. In the future, they may be adapted to early detection, allowing for early-stage radiotherapy treatment of currently intractable diseases such as pancreatic and CNS malignancies. An example of this is the demonstration of the sensitivity of ctDNA in cases of new melanoma brain metastases.[179] Biomarkers are not just blood-borne. Imaging tools and AI have made rapid strides in this space and will continue to accelerate.[180-182] These will be addressed in the AI chapter.

Dimension 3: Predictive Oncology Methods

The application of predictive biomarkers of radiation injury is another rapidly evolving area of research, with the potential to integrate with precision radiotherapy by (1) predicting individual differences in radiation sensitivity,[183] (2) predicting the severity of normal tissue injury among patients,[184] and (3) assessing and monitoring tumor response to radiation therapy.[185] A biomarker-based test that can predict the risks of developing severe radiotherapy-related complications will not only allow the delivery of alternative treatment modalities and the use of mitigators and protectors, but may also allow dose escalation to the tumor in less sensitive patients. This might improve the overall therapeutic benefit and outcomes among all patient cohorts. Various radiation biomarkers have already been explored or are currently under development at different technology readiness levels in the context of their potential application for individual dose assessment in accidental exposures to radiation or malevolent use of radiation.[186] However, the discovery, development, and validation of predictive biomarkers of radiation hypersensitivity are as challenging, if not more challenging, as radiation-effect modulators. This is due to the low prevalence of normal tissue complications in the clinic, a need for long-term studies for predicting late effects (eg, radiation-induced cognitive damage),[162] and the complexity related to the combination of chemotherapy with radiation as the standard of care for most tumors.

Mitigating the risk of radiation-induced cancers will require the use of three categories of biomarkers: (1) radiation dose assessment biomarkers (biodosimeters), (2) genomic health predictors, and (3) cancer surveillance biomarkers.[166] Diagnostic biomarkers for determining the radiation dose of individuals following accidental exposures or therapeutic exposures may also be useful in assigning risk to the exposed population for developing delayed health risks, including cancer. This would help identify “at-risk” individuals who may benefit from mitigators of late and/or enhanced cancer screening. In this context, well-established/validated cytogenetic assays, such as cytokinesis-block micronucleus assay[187] performed using peripheral blood lymphocytes for assessing “total genomic health risk,”[188] will be useful. There is also a need for using an enhanced cancer surveillance program for selected high-risk radiation-exposed cohorts, especially following a radiologic mass casualty. The Early Detection Research Network of the DCP at NCI, a laboratory consortium, focuses on

identifying, testing, and validating methods to noninvasively and accurately detect cancers at their earliest stages. Biomarker-based treatment decisions may eventually drive personalized medicine. Issues related to designing clinical trials with biomarkers have been discussed elsewhere.[189]

Several biomarker technologies are currently under development across government agencies and have been reviewed.[186] The biomarker and MCM development efforts complement one another. Concurrently, predictive biomarkers for radiation dose and genomic health will benefit commercial development and use of radiation risk mitigators, helping to understand the impact of nutrition, repurposed drugs, or other interventions.

In summary, Figure 5.1 provides a glimpse of ongoing multidimensional efforts in radiobiology related to radiation-induced normal tissue injury at various government agencies. These efforts over the past decades have significantly advanced our understanding of mechanisms of radiation injury to normal tissue and its manifestation in different cell renewal and organ systems, allowing the discovery and development of next-generation radiation countermeasures and biomarkers with foundational mechanistic radiobiology, which could be used to enhance precision radiotherapy. These issues and many others were addressed in a workshop on predictive oncology in radiation oncology held with NCI and DoE in 2021,[190] with the field exploding since then with a new focus on the digital twin, an area of research that has been of use in aerospace and engineering for decades but is only now being explored in the biomedical arena.[191] Radiation oncology lends itself to the use of digital twins in some ways because we are, as a field, comfortable with electronic models of our patients (eg, treatment plans). Adaptive radiotherapy is, in some ways, a digital twin approach as changes are incorporated during therapy to optimize dose delivery—with precision approaches ultimately allowing us to make better treatment plans for adapting and optimizing treatment courses.[192] The induction of targets via radiation delivery and what happens during the treatment course is being addressed with the NCI's U54 Radiation Oncology-Biology Integration Network consortium being established to collect the baseline data on what happens multidimensionally before, during, and after radiation therapy so that we can begin to create models and "twins" as a field to ultimately help our patients get the best therapy course as they evolve over the treatment course.[193,194]

Dimension 4: Different Types of Energy Delivery (Radiation and Other Things) Are Different Drugs

Particles Versus Photons: Two Different Drugs?

Particle therapy is, in many ways, a paradox in terms of precision radiotherapy. It is both very precise and not precise at all. It has the most complex infrastructure of the external beam modalities in terms of physics support and costs. As such, it is relatively uncommon in most countries and is often considered the most specialized form of radiation. It has been touted as having fewer side effects and is often considered the first choice when treating pediatric tumors.[195] It also may be the most problematic on multiple levels. It is, in some sectors, the most promoted form of radiation therapy, and yet it is the most immature form of radiotherapy.[196]

Particle therapy can be divided into two major categories: protons and the so-called "heavy ions," which typically include helium, carbon, and oxygen, among others (although these are often termed "light ions" in the physics literature because of their position on the periodic table), and neutrons are a separate subject that is addressed in other chapters. Unlike photons that are generated from electrons hitting a target or from radioactive decay from isotopes such as cobalt-60, charged particles must be accelerated to near the range of the speed of light to be effective. To achieve this, large machines employing large magnetic fields are used to accelerate particles. Typical devices to accomplish this include cyclotrons, synchrotrons, and other devices—areas of discussion in other chapters, so we only briefly mention them here. This section applies to both of these subgroups unless otherwise stated explicitly.

To explore the concept of precision particle radiotherapy, several interrelated domains that will likely change simultaneously will be presented in this section. While not exhaustive of all the possible changes to this type of radiation therapy, they are meant to reflect the overall trends in particle therapy broadly. What they have in common is that they are likely to reflect the decreasing cost of the devices and a crucial, newfound willingness to treat particles as imperfect and in need of rigorous study. These changes are all based on financial change and increasing translational knowledge.

Hopefully, the field will conduct and complete prospective randomized trials to better define and develop where particle therapy has clear advantages and is not only "less good" but perhaps "uniquely bad." This is something we have needed in the field for a long time—with published articles at one point debating if trials were needed, in this case, to evaluate protons because protons' superiority was supposedly obvious and not up for debate.[197] Many things have conspired to make that supposedly obvious truth less and less evident in the current space of using physical doses to prescribe proton therapy treatment. We really don't know if particles have unique long-term problems based on their biology compared to normal tissue.[198] We think they are likely better if used carefully by those with experience, but with relative biologic effectiveness higher than 1.1, how will 75 to 100 Gy equivalent doses affect normal tissues over time?[199] Conversely, if used poorly, they are, at best, likely to be far worse because it is far easier to dosimetrically miss a tumor with particles. Plans with photons and standard planning target volumes are generally more robust, making widespread use of particles without extensive expertise in the subtleties of their use a somewhat risky prospect moving forward for the field unless methods can be developed to make their use more robust and to contain the complexity in manageable planning interfaces.[200]

Trials and the development of new tools are needed to address these issues and will generate a host of data to be incorporated prospectively into the field. An honest evaluation of planning skills and time spent with the outcome will need to be performed. The risks particle therapy presents to the field due to biologically incomplete planning will be one of the forces that may drive the inclusion of AI into the planning process—to introduce more expertise into the treatment process. This goes beyond the rapid normalizing of auto-contouring. Over time, proper particle therapy will require advanced dose and robustness optimization tools that are accessible and easy to use as the number of users increases. Still, patients who benefit remain about the same. Beam selection will need to optimize (a) not only Bragg peak location but also (b) all areas of high linear energy transfer dose deposition, such as the penumbra of each field, perhaps of each spot, (c) inherent geometric motion statistics for site in three and four dimensions, and (d) specific tissue data based on voxel by voxel beam data and

situational awareness of other medical issues such as oxygenation of tissue, concurrent agent concentration, and prior tissue injury status.[199,201]

These changes in the domain of particle therapy are a component of the precision radiation therapy concept of radiation as a drug. Each particle will finally be seen and considered as a different drug. Trials will be designed in this way.[202] To date, we have allowed a mixture of photon and proton patients, use of two agents that may have vastly different activity based on the radiation type used, and looking at the results only after the fact will no longer be a viable trial design. Trials will need to be powered for each "drug" used. What each particle does to DNA and even the normal components of cells like the membranes, organelles, and proteins are vastly different and may yield opportunities for therapeutic index gain or cause just the opposite.[202] Each particle will be thought of as a new agent rather than just radiation therapy.[203] As such, agent mixes and even new agents designed to work specifically with our newly appreciated war chest of radiation "drugs" will allow further optimization of treatment and perhaps even cost savings. It might turn out that mixtures of particles of different types in specific sequences in time and space will be far superior to any monotherapy of particles or photons in use today, improving the precision of radiation therapy.

These new data are likely to shed light on the reality of particle therapy and allow it to reach the level of promise many have envisioned for it from the beginning. To do this, the resulting new set of biologic data will be the basis of a significant, global change in radiation oncology driven by particle therapy that affects all modalities: biologic treatment planning. The software methodologies discussed earlier will collapse to classical photons as the control state, like classical mechanics, is the default state of special relativity when one's velocity is far slower than the speed of light.[204] Plans for patients will move from physical energy dose prescription to this integrative form of a biologic dose prescription and OAR risk tolerance mapping model. Computer models incorporating libraries of biologic data will be invoked to do this work, adding situational precision. Imaging-based biomarkers will be used in real time to monitor biologic response to fit the models to an actual host response, adding path of treatment optimization—precision path radiation oncology. This new paradigm could be called adaptive biologic treatment planning.[205] Building the models in ways that

allow for real-time adjustment by incorporating biomarker data will be very labor-intensive. However, once built, what we do now with physical dose will seem extremely crude in comparison. This is perhaps the most accurate form of precision radiation therapy that is to come in the future. It will involve and allow for the use of all sorts of new agents and combinations of agents, their dynamic change, and the idea that radiation is very much biologically driven by the point in space and time it is being used, and rather than "a Gy is a Gy," it will be the new paradigm. Potentially critical to this new domain will be advancements in multiscalar, dynamic modeling —exemplified by the digital twin.[191,206]

Inexorably linked in time with more trials being performed will be a combination of decreasing cost of the devices, increasing availability of computing resources that can scale to these issues affordably, increasing numbers of particle treatment machines, more narrowly defined uses for radiation in general based on concurrent research expanding our biologic understanding, and likely decreased reimbursement. This is a metastable situation at best on several levels. The most profound level is the reality that everyone who wants one of these centers might be unable to support it with sufficient patient numbers where it is indicated to keep staff experts and bills paid. Financial uncertainty in radiation oncology is increasing, and these particle centers are likely to be the most uncertain financial component of any given center unless they are run with a "break-even at best" long-term business plan somehow supported by institutional commitment to the science involved despite risk of losses, the rare disease capacity, or development support.[207]

Light as a Drug

Photodynamic therapy (PDT), in which light interacts with chemical agents to deliver energy to tissue, is currently one of many prospective trials sponsored by several program project grants from the NCI and other support mechanisms. Areas of interest involve tumors of many regions, both from a definitive perspective in a postoperative and preventive setting. Additionally, some studies evaluate the interplay between the immune system and PDT usage.[208-210] PDT is under intense investigation, and its use may become more widespread if these trials define areas of significant

therapeutic benefit. This active milieu of trials will be the contemporary environment of PDT for the reader of this text during the active period of this edition.

Much of the work described in the last two editions[211] has progressed in terms of both molecular mechanistic understanding of how PDT works and of new light plus photo-agents that expand the use of the technology spatially.[212] These data will likely both inform the use of rationalized drug combinations with PDT, including checkpoint inhibitors,[209,213,214] and expand the spatial and temporal use of the methodology to new clinical indications.

Beyond this natural evolution of PDT, there have been exciting, promising developments in creating agents that interact with traditional ionizing radiation much like light does in PDT to make the range of action not just millimeters as in the case of light but centimeters.[215,216] This area may allow yet another way to use ionizing radiation with chemotherapy but with the agents being inert until radiated—that is, to be triggered with the radiation therapy like a mousetrap. This will move the scope of radiation therapy into a more diverse set of clinical situations as it further opens up the ability to spatially constrain side effects. Obviously, care will be needed to optimize this approach, given that radiation entry and exit doses may limit the ability to prevent damage to normal tissue in, at a minimum, entry dose regions. One could envision a mixture of old and new radiation modalities harnessing these new agents' potential.

The implications here are broad for radiation therapy departments globally. Orthovoltage optimization may become useful in this context again, as could the use of heavy ions at low doses. Suppose the agents can be designed to require a dosimetric threshold for action of, say, 0.25 Gy. In that case, one can imagine simple plans being able to address this with three-dimensional conformal radiotherapy at relatively low doses, opening up the possibility of routinely avoiding treating to normal tissue tolerance in the future. This would better enable retreatment and would lower costs to society overall. Given radiation's unique capacity to be spatially delivered, this approach has promise. The biodistribution of these agents, like any chemical, will impact the success of these methods radically.

Combinatory Therapies

Systemic administration of therapeutic agents for cancer treatment is a common practice. However, their presence in normal tissue is generally unfavorable as it could lead to adverse toxicities. The undue toxicity might be avoided if the therapeutic agents remained encapsulated or inactive until exposed to an extremal stimulus within the well-defiled volume. In addition, the time of activation could be adjusted so that the concentration of the therapeutic agents in the target volume reaches levels necessary for an effective treatment. The key criteria for achieving effective and safe treatment include minimal invasiveness of the external stimuli and quantitative control of localized therapeutic agent release or activation. Remote triggering mechanisms may include photodynamic, photothermal, photo-triggered chemotherapeutic release, ultrasound, electrothermal, magnetothermal, x-ray, particle beam, and radiofrequency. Examples of three combinatory strategies using nanoparticles are shown in Figure 5.2.

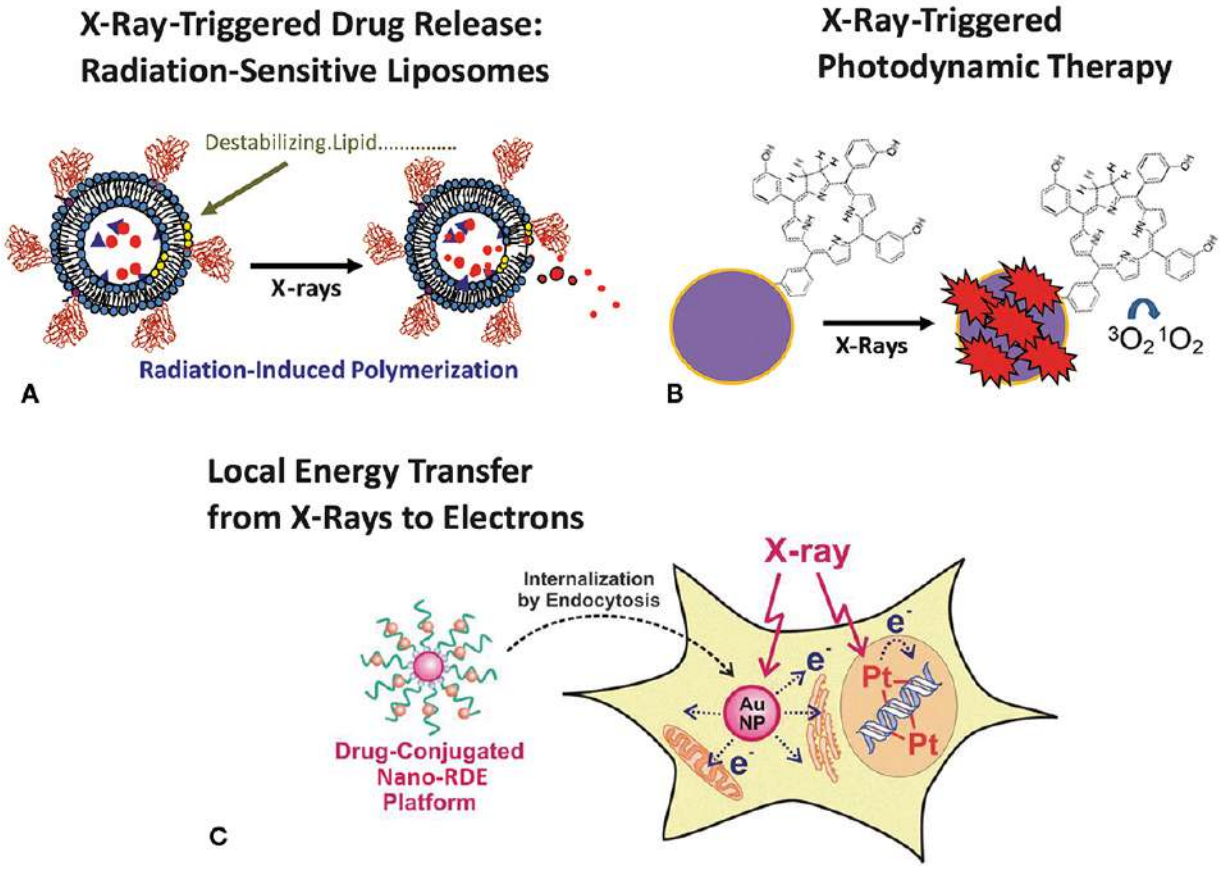

FIGURE 5.2 Examples of three combinatory strategies using nanoparticles. A and B. Radiation used to trigger liposomes and photodynamic therapy. C. Nanoparticles used to internalize drugs/molecules that enhance the effects of x-rays.

The use of radiation or ultrasound to activate or release therapeutic agents is an active research topic in many academic centers, and it has yielded fruitful results. The thermal release of drugs from liposomes has been a clinical practice for years. Other "smart" systems that might release drugs or induce a toxic effect in response to an externally controlled stimulus promise unique clinical benefits over conventional systems that release their cargo passively or are activated internally. In combination with radiotherapy, x-rays might be used to stimulate the local release of encapsulated drugs in tumor volume, or the combination of x-rays with nano scintillators producing light used in PDT would allow its extension to deep-seated tumors.

Even more novel, perhaps, is the use of combinations of radiation types, coined "blending," to take advantage of different biologies. The concept is not new, given combinations of brachytherapy with external beam therapy, but the differences may be more biologically advantageous in the case of photons mixed with protons, helium, carbons, and/or neutrons. Other combinations of energy delivery need to be tested perhaps further and seem to show promise, with radiation types including magnetic and electrical fields, different types of ultrasound including histotripsy, and new methods to deliver heat.[217]

Nanotechnology

Multifunctional nanoparticles allow simultaneous targeted delivery of diagnostic and therapeutic agents to the tumor tissue, giving rise to a new, fast-growing field of theranostics that combines the modalities of diagnosis and therapy.[218]

Gold Nanoparticles

Over the last two decades, radiation dose enhancement by high atomic number elements such as iodine has been explored for cancer radiotherapy.[219] As a small-molecule radiation dose enhancer (smRDE), iododeoxyuridine (IUdR) has been used due to its facile incorporation into cellular DNA.[219,220] The subsequent external irradiation of high-energy photons on the IUdR-containing target cells can trigger the secondary emission of photoelectric radiation (ie, Auger/secondary electron emission

or x-ray fluorescence).[221] The resulting triggered emission from smRDE can cleave the nuclear DNA double strands that can induce radio-sensitized cell death.[222] In this smRDE-mediated radiotherapy, several advantages have been demonstrated. The triggered emission from smRDEs generally decays in several millimeters, a typical length scale of a cell, so the resulting cytotoxicity is highly dependent on the cellular location of smRDEs. Therefore, only the smRDEs inside the target cells can deliver high toxicity upon radiation, but their off-target toxicity can be reduced to healthy cells.[223]

Although such smRDEs can improve radiotherapeutic efficacy with reduced side effects, safe and effective delivery of smRDE to target tissue remains one of the major drawbacks to clinical applications.[223] As iodine-attached tumor-targeting antibodies were used to improve their biodistribution, their targeting and therapeutic efficacies were not satisfied due to the rapid dehalogenation mechanism in DNA and the heterogeneity and limited expression of target receptors on cancer cells.[224] Furthermore, prolonged treatments with high dosages of iodine compounds should be avoided due to their toxic side effects on the host organs.

These limitations might be circumvented by developing a nano-encased RDE (nano-RDE) platform based on functionalizable polymer-modified nanoparticles. Nano-RDE platforms can demonstrate several advantages: First, the biodistribution of nano-RDE can be highly improved by the "enhanced permeation and retention" effect in solid tumor tissue, which allows for the selective accumulation of nano-RDE at diseased sites (passive targeting).[225,226] Second, a high amount of nano-RDE can be readily internalized in target cells by endocytic pathways, known as a completely different cellular internalization mechanism from small molecules.[227] In addition, the subsequent acidic endosomal environments can be used as a trigger for the pH-sensitive release of additional chemotherapeutic agents.[228]

In conventional chemotherapy, the rapid developments of multidrug-resistant characteristics in cancer cells cause a critical problem in clinical cancer treatments.[229] As such, it is evident that a combinational therapy is more effective than a single modality treatment. To this end, anticancer drug– conjugated nano-RDE could be a novel approach to achieve "precision combined modality therapy" as a multimodal delivery platform for both radio- and chemotherapy if susceptibility via biomarkers or other

means was evaluable. Gold nanoparticles (AuNPs) are one example of nanoparticles in this potential space.

AuNPs have been tested for improving chemotherapy[230] and radiotherapy.[231] The TNF-α-polyethylene glycol-colloidal AuNP, CYT-6091 (Citimmune, Gaithersburg, MD), has been shown to selectively traffic to tumor tissue. This agent was evaluated in a phase I trial and shown to selectively deliver TNF-α to tumors with reduced toxicity compared to recombinant human TNF-α alone.[232]

In addition to its properties as a nano-carrier, colloidal gold, being a high-*Z* element, may also increase the radiation dose explicitly delivered to the target cells. This system uses AuNPs as inorganic nanoRDEs for radiotherapy and as a delivery platform for chemotherapeutic agents. Due to the K-edge of gold at 80.7 keV, x-ray radiation with the energy level of Au K-edge can trigger the secondary emission of photoelectric radiation from AuNPs.[233,234] The resulting radiation can induce the degradation of target molecules by ionization and interact with surrounding water molecules to produce reactive oxygen species that can damage the target molecules.[235] As such, AuNP-sensitized degradations of plasmid DNA[236] and human proteins[237] upon x-ray radiation have been demonstrated in in vitro model systems. Additionally, when AuNP-containing tumor cells were irradiated, increased apoptotic cell death was detected due to the continuous stress on cytosolic organelles.[238] Furthermore, enhanced in vivo efficacy of AuNPs upon radiotherapy was also observed in human cancer-bearing mouse models.[231] However, these AuNPs have shown inferior pharmacokinetic results due partly to their limited surface functionality as bare colloidal particles.

AuNPs have been used in various biologic applications due to their biocompatibility and well-known surface chemistry. Using the known reactions, AuNPs can be readily modified with thiol-end-capped polymers[239] that can significantly alter the pharmacokinetics.[240,241] This functional polymer can be prepared by reversible addition-fragmentation chain-transfer radical polymerization, allowing for copolymerization of a wide range of monomers.[242]

As the gold K-edge is at 80.7 keV and the enhancement is optimal in the photoelectric-dominated x-ray spectrum, irradiation conditions could be optimized using monoenergetic x-rays. However, a significant enhancement

of the treatment efficacy might also be obtained in standard megavoltage x-ray beams.[243] To track the biodistribution of AuNPs, these can be easily activated with thermal neutrons prior to administration to emit 411 keV γ-rays, which can be detected by single-photon emission computed tomography. Recent work has confirmed that the enhancement of radiation dose is real from AuNPs.[244]

Liposomes

Another alternative approach would be using radiation as a trigger, releasing or activating drugs delivered to the tumor before irradiation. One option could provide radiosensitive liposomes. For decades, liposomes have been explored as viable carriers for targeting, imaging, and delivery of payloads of drugs.[245] Various triggering modalities such as local hyperthermia, pH-triggered, tissue-associated enzyme- and light-triggered drug release have been developed to date.[246] Among these, the electromagnetic radiation–triggered release of liposomal drugs appears promising and includes strategically designed phospholipid molecules to initiate a light- induced trigger. These liposomes are based on the principle of photo-polymerization of lipids,[247] photo-sensitization by membrane-anchored hydrophobic probes,[248,249] and/or photo-isomerization[250] of photo-reactive lipids. However, one major challenge to date has been the lack of adequate photon energy produced by the radiation source(s) and/or the inability of radiation to penetrate biologic tissues. However, this seems to be changing with the deployment of radiopharmaceuticals directly via liposomes.[251,252]

Radiation-Activated Photodynamic Therapy

PDT is increasingly recognized as an attractive and valuable tool in treating many diverse human diseases, including macular degeneration, dermatologic disorders, and oncology.[253] PDT utilizes photosensitizers that can be preferentially localized in malignant tissues. The interaction of the photosensitizer and light generates cytotoxic species, including singlet oxygen ($^1O_2$), free radicals, and peroxides, that attack key structural entities within the targeted cells. Those very toxic species are characterized by a short lifetime (<0.04 μs) and a short radius of action. Therefore, the

damaged area is essentially confined to tissue containing the photosensitizer and exposed to light.

Relative to current treatments, such as surgery, radiation therapy, and chemotherapy, PDT is also comparatively noninvasive, can be more accurately targeted, and is not subject to the total dose limitations associated with radiotherapy. In addition, the healing process typically results in little or no scarring.[254] Despite these advantages, PDT has yet to gain general clinical acceptance. The photosensitizers approved for routine PDT treatment absorb light in the visible spectral regions below 700 nm, thus preventing access to deeper residing tumors. As a result, even with the advent of more sophisticated light delivery systems, the clinical application of PDT is mostly limited to superficial solid tumors, endoscopically accessible regions, or skin lesions. Multiple new approaches in the photodynamic space are under investigation, with one example of a newer approach being akin to brachytherapy with the catheters delivering light at depth volumetrically.[255]

The combination of radiotherapy with PDT, exploiting the tissue penetration of ionizing x-ray radiation and the cell-level targeting of PDT, might provide a novel approach to overcome the problems with penetration depth and might help with the delivery and targeting of photosensitizing agents. It has been observed that some photosensitizers act as radiosensitizers under certain conditions. The combination of Photofrin, an FDA-approved photosensitizer, with radiation therapy significantly enhanced the cytotoxic and apoptotic death of cancer cells.[256,257] However, the molecular mechanism for this effect is still unknown.

There has been interest in developing a nanoparticle-based photosensitizer delivery system for a combination of PDT with radiation therapy. Chen and Zhang[258] used scintillating nanoparticles conjugated to photosensitizers; in response to irradiation with deeply penetrating x-rays, these nano scintillators would produce light capable of activating the attached photosensitizers, thereby producing toxic amounts of free radicals in any desired location of the body. These nanoparticles would overcome the limitations imposed on current PDT and expand its application to deeply located tumors. Multiple complex delivery methods are under investigation and may promise more active use of PDT for solid tumors.[255]

Several doped nanoparticles ($LaF_3:Ce^{3+}$, $LuF_3:Ce^{3+}$, $CaF_2:Mn^{2+}$, $CaF_2:Eu^{2+}$, $BaFBr:Eu^{2+}$) and semiconductor nanoparticles (ZnO, ZnS, and TiO_2) are potential light sources for use in a nanoparticle-PDT system. The emission spectra of these nanoparticles can be matched perfectly to the absorption spectra of Photofrin, fullerenes, and TiO_2 nanoparticles. For example, $BaFBr:Eu^{2+}:Mn^{2+}$ nanoparticles excited by x-ray have three emission bands, one peaking at approximately 400, 500, and 640 nm, respectively. The emission spectrum of these nanoparticles is well-matched to the absorption spectrum of hematoporphyrin. Another example is the x-ray luminescence spectrum of $LaF_3:Ce^{3+}$ nanoparticles with maximum emission at 350 nm, tailing to 500 nm. This emission spectrum matches the absorption spectra of most photosensitizers as well. The rationale for this approach is to combine the effects of PDT and radiation therapy while reducing toxicity.

A DYNAMIC, BIOLOGIC PRECISION MEDICINE FUTURE: FINAL THOUGHTS

This chapter focused on the complexity of integrating opportunities in biology with radiation oncology with the caveat that the only way forward, past where we are now, is a position of precision brought about by technology and physics, which is likely via biology.[116,201] Perhaps the crucial path forward for radiation oncology is the further development of the linkage between biology and physics that is elegant, robust, and based on kindness and trust to achieve the next accurate level of precision medical practice (along with other fields, we are not alone by any means)—via pragmatic trials, newly focused molecular small trials, and traditional trials where their design allows vast collection of data to later analyze in terms of dynamic biology. We are in the process phase where, in many ways, we need to pause and redefine the normal course of treatment from a granular biologic perspective because a lot is happening to patients during treatment that we have only recently been able to appreciate.[194] This pause and future similar biologic ground state reviews are setting up the field for a future of precision medicine that is far more robust and promising than that of today.[193]

The integration and interpretation of the presented data will allow accurate "precision." In this regard, we are in the infancy of the path toward a biologically optimized dose. Dynamic, multiscale modeling will be a core component of our processes to manage the added complexity. We have just begun to understand when to use imaging-focused adaptive radiation. Still, we need to incorporate the ever-changing tumor and host (normal tissue) biology with imaging. To do this, the digital twin approach is likely necessary to allow new "precision medicine" approaches for our patients.[191,206] If used as envisioned, the digital twin of a patient would be able to be developed to assess their risk of cancer, the response to therapy and likely toxicities, what agents to use for the best results both in the short term and the long term, how and when to modify their treatments as they move along a treatment course, how to follow them after therapy, and ultimately how their case can impact and help others in a FAIR (regarding data that is Findable, Accessible, Interoperable, and Reusable)[259] and equitable manner.[190]

We are approaching peak technology in terms of delivery of physical dose, where we achieve benefits via summations of marginal gains, and where our primary global challenge is not the advancement of technology but access to it. Improvements continue due to brilliant engineering and physics, but the improvements are often moderate, with the toughest of tumors showing little benefit from the technology (eg, glioblastoma). In some cases, machines can now cost, with custom building and additional staff, upward of half a billion dollars, and the results of trials have shown that a lack of insight into biology may have made such machines produce results that are inferior to standard, inexpensive therapy.[195,202]

That there is so much new material to discuss in this edition of this chapter is encouraging (resulting in the addition of multiple whole new chapters, too). There are improvements in the existing technology, including amalgamation of imaging and therapy to target the desired anatomic sites better. Particle therapy is understood to be much more than better dose distribution. Indeed, we must think of radiation in terms of the biologic changes it produces and how future inverse planning will include biologic events rather than just physical doses. The era of precision medicine is firmly upon us. It has already changed how cancer is diagnosed and classified and elucidated the remarkable heterogeneity in the cancer cells

before, during, and after treatment that makes targeting ever more challenging and exciting. As a result, trials are evolving to address the profound heterogeneity of precision medicine unearths, making for new challenges.[260] We are finally approaching a point in time where, just perhaps, the focal stress response induced by radiation and/or the other new technologies described in this chapter can help force tumor cells (or the normal tissue, or both) onto desired biologic paths where we have better agents and methods to then treat the tumor optimally—moving toward precision in terms of biologically forcing tumor treatment down a chosen, optimal path for the patient—dynamic, biologic precision medicine.[193,201]

ACKNOWLEDGMENTS AND DISCLOSURES

This chapter in the seventh edition was a work led by the late Dr C. Norman Coleman. The current authors miss Dr Coleman dearly and dedicate this chapter to him. He was a friend, colleague, and mentor who practiced kindness always. The authors also acknowledge the contributions of Jacek Capala, Mansoor Ahmed, Bhadrasain Vikram, and Eric Bernhard to the previous version of this chapter.

This work was supported by the NCI's Radiation Research Program, Division of Cancer Treatment and Diagnosis, NIH, Bethesda, MD. The views expressed are those of the authors and do not represent the views of the agency(ies) in which they are employed.

PART B

Medical Radiation Physics and Dosimetry

CHAPTER 6

Principles of Radiation Physics and Dosimetry

James A. Purdy, Geoffrey D. Hugo, and Hania A. Al-Hallaq

A solid foundation in the principles of radiation physics, dosimetry, and treatment planning is essential for the practice of modern-day radiation oncology. This chapter discusses the basic concepts in radiation physics, radiation therapy treatment machines, and the dosimetry parameters used for photon external beam treatment planning and dose/monitor unit calculation methods. As this textbook is aimed at practicing radiation oncologists and physician residents, these topics are not treated in the detail required for medical physicists. More details on these topics can be found in the medical physics textbooks listed in the references.[1-3]

ATOMIC AND NUCLEAR STRUCTURE

The *atom* may be thought of as consisting of a centrally located core, the *nucleus*, surrounded by small orbiting particles called *electrons*. The overall dimension of an atom is about 10^{-10} m, and the nucleus is about 10^{-14} m. An electron has a rest mass (m_e) of 9.109×10^{-31} kg and has a negative electrical charge equal to 1.602×10^{-19} coulomb (C). Most of the mass of the atom is contained in the nucleus, making it extremely dense (10^{15} kg/m^3). The nucleus is composed of two kinds of particles—*protons* and *neutrons*, known collectively as *nucleons*. A proton has a rest mass (m_p) of 1.673×10^{-27} kg and has a positive electrical charge equal in magnitude to the charge of the electron (1.602×10^{-19} C). Collectively, the protons

constitute the electrical charge of the nucleus. A neutron is slightly more massive than a proton ($m_n = 1.675 \times 10^{-27}$ kg) and has no electrical charge.

Units used to describe atomic processes include the *atomic mass unit* (amu) for mass, *nanometer* (nm) for distance, *electron volt* (eV) for energy, and *electronic charge* (*e*) for electrical charge. The amu is defined as one-twelfth the mass of a neutral carbon-12 atom. Thus, 1 amu = 1.660×10^{-27} kg. In terms of amu, a proton's rest mass is equal to 1.00727 amu, a neutron's rest mass is equal to 1.00866 amu, and an electron's rest mass is equal to 0.000548 amu. The electron volt (eV) is defined as the kinetic energy acquired by an electron accelerated through a potential difference (voltage) of 1 volt (V). One electron volt is equal to 1.6×10^{-19} joule (J) of energy. One writes 1,000 electron volts (keV) as 10^3 eV, and 1 million electron volts (MeV) as 10^6 eV. The nanometer is defined as equal to 10^{-9} m, and the electronic unit of charge is defined as equal to 1.602×10^{-19} C.

The planetary model of the atom is credited to Niels Bohr who embraced the revolutionary quantum concepts postulated by Max Planck and Albert Einstein.[4,5] Departing from classical physics, Bohr's model incorporated the newly emerging theory of quantized energy levels. He proposed that electrons orbit the nucleus in discrete, quantized energy states, or "shells," rather than in continuous paths as shown in Figure 6.1. This concept not only explained the stability of atoms but also elucidated the spectral lines observed in atomic spectra. Energy is released when an electron moves to an orbit closer to the nucleus, and energy is required to move an electron into a higher orbit. Historically, the shells are labeled, from innermost outward, by the letters *K*, *L*, *M*, and so forth. There are a maximum number of electrons that can be accommodated in each shell: 2 in the first shell, 8 in the second, 18 in the third, and so on. The maximum number of electrons allowed in each shell is given by $2n^2$, where *n* is an integer specific to each shell and is called the principal quantum number. By integrating the quantum theory with the planetary model, Bohr laid the foundation for a deeper understanding of the intricate nature of atoms and their behavior, marking a significant leap forward in the field of atomic physics.

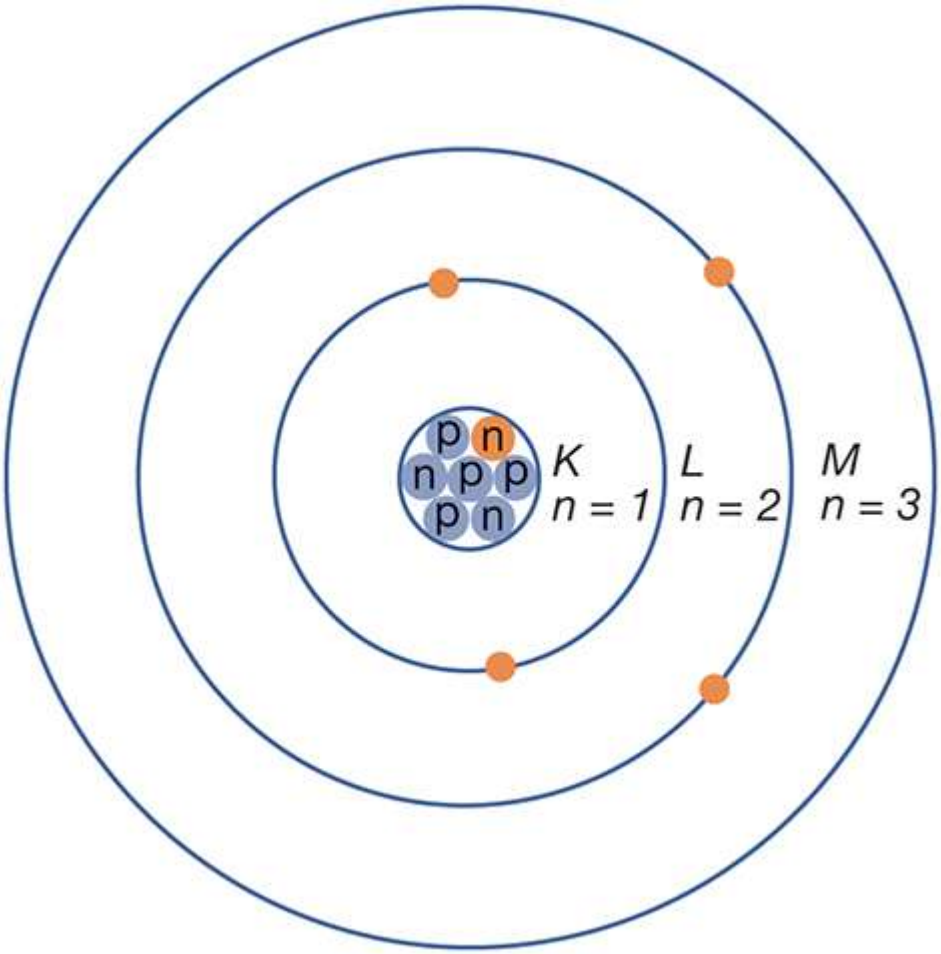

FIGURE 6.1 Schematic drawing of the Bohr model of the atom. The nucleus contains protons (p) and neutrons (n). Electrons revolve around the nucleus in specific orbits having discrete energy levels. By convention, the orbits (energy levels) are assigned either quantum numbers (n = 1, 2, 3, …) or letters (K, L, M,…).

Several other properties of the electron were also found to have discrete values specified by quantum numbers. These include the electron's angular momentum as it orbits the nucleus, denoted by quantum number l (l = 0, 1,…, n − 1); its spin about its axis, denoted by s ($s = \pm 1/2$); and its magnetic moment, denoted by m_l (m_l = 0, ±1,…, ±l). Thus, each electron in an atom has an associated set of quantum numbers (n, l, s, m_l). This is the basis of the Pauli exclusion principle, which states that no two electrons can have the same set of quantum numbers within a particular atom. As quantum theory continued to evolve, atomic physics replaced the early quantized orbiting electron model of Bohr with a more complex quantum mechanical

model of diffuse electron clouds that represent probability functions of the electron's position.[6]

In addition, modern physics research has discovered that protons and neutrons are not elementary particles and a new theory of matter (the Standard Model) is now in place (Figure 6.2).[7,8] As defined by the Standard Model, an *elementary particle* or *fundamental particle* is a subatomic particle that is not composed of other particles. Currently, the Standard Model recognizes 17 distinct particles. As a consequence of allowed characteristic combinations and antimatter, 61 elementary particles are embraced by the Standard Model. Note that in the earlier atom models consisting of electrons and nuclei containing protons and neutrons, only the electron is now considered an elementary particle, whereas a proton and a neutron contains three *quarks* each.[9] The experimental confirmations of the existence of quarks (1995) and the Higgs boson (2012) have provided strong credibility to the Standard Model. Physical properties of the particles most relevant to radiation therapy are listed in Table 6.1.

TABLE 6.1 PARTICLES OF INTEREST IN RADIATION THERAPY

Particle	Symbol	Charge	Mass
Photon	hν, γ	0	0
Electron	e, e^-, β^-	−1	0.000549 amu
Positron	e+, β+	+1	0.000549 amu
Proton	p, $^1_1$H	+1	1.007277 amu
Neutron	n, $^1_0$n	0	1.008665 amu
α-Particle	α, $^4_2$He++	+2	4.002604 amu
Neutrino	V	0	<1/2,000 m_0
Pi mesons	π+, π^-	+1, −1	273 m_0
	π°	0	264 m_0
Mu mesons	μ+, μ^-	+1, −1	207 m_0
K mesons	K+, K^-	+1, −1	967 m_0
	K^0	0	973 m_0

1 amu = 1.66043×10^{-27} kg. m_0, rest mass of an electron, 9.1091×10^{-31} kg.

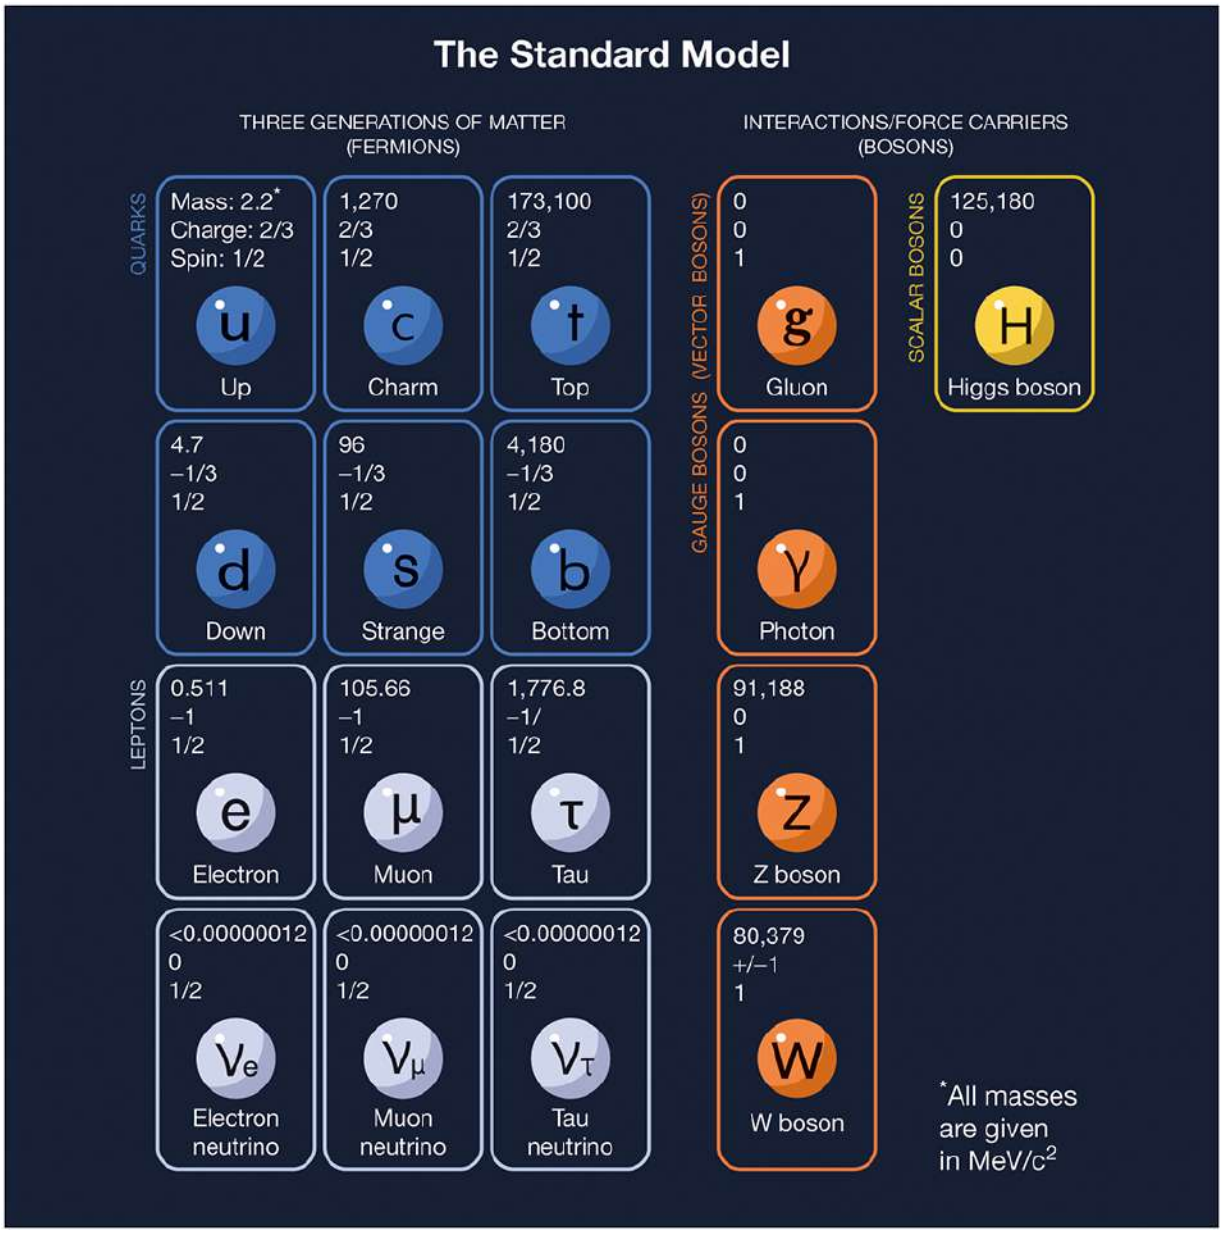

FIGURE 6.2 Schematic drawing showing the 17 fundamental particles of the Standard Model, grouped into four categories: quarks, leptons, gauge bosons, and scalar bosons. Quarks are the building blocks of protons and neutrons, while leptons are the building blocks of atoms. The quarks are further divided into three generations, each with two quarks. The leptons are also further divided into three generations, each with two leptons. A gauge boson is a force carrier that acts as the glue that holds fundamental particles together. The Higgs boson is the only known fundamental particle that is scalar, meaning it has no quantum spin. It is associated with the Higgs field, which gives mass to other fundamental particles like electrons and quarks.

The atom of an *element* is specified by its *atomic number*, denoted by the symbol Z, and its *mass number*, denoted by the symbol A. The atomic number is equal to the number of protons in the nucleus, and the mass number is equal to the number of nucleons (protons and neutrons) in the nucleus. Hence, A minus Z is equal to the number of neutrons, denoted by the symbol N, within the nucleus. In addition, each element has an associated chemical symbol (eg, Co for cobalt). When these definitions are used, the standard notation to specify an atom is ${}^{A}_{Z}\mathrm{X}$, as illustrated by ${}^{60}_{70}\mathrm{Co}$, which is a radioactive isotope of the element cobalt that has an atomic number of 27 (ie, 27 protons) and a mass number of 60 (ie, 60 nucleons, or 27 protons and 33 neutrons).

Isotopes of an element (eg, ${}^{58}_{27}\mathrm{Co}$, ${}^{59}_{27}\mathrm{Co}$, and ${}^{60}_{27}\mathrm{Co}$) have the same atomic number but different numbers of neutrons and therefore different mass numbers. Isotopes have the same chemical properties but have different physical properties. Atoms such as ${}^{60}_{27}\mathrm{Co}$ and ${}^{60}_{28}\mathrm{Ni}$, which have the same mass number but different numbers of protons and neutrons, are called *isobars*. Atoms such as ${}^{57}_{27}\mathrm{Co}$ and ${}^{56}_{26}\mathrm{Fe}$, which have the same number of neutrons but different atomic and mass numbers, are called *isotones*.

Every atom has a characteristic atomic mass A_{m} (sometimes referred to as atomic weight). The *gram atomic mass* of an isotope is the amount of isotope in grams that is numerically equal to the isotope's atomic mass. For example, 1 g atomic mass of carbon-12 is 12 g. One gram atomic mass contains 6.0228×10^{23} atoms, a constant that is called *Avogadro's number*

(N_A). Useful parameters that can be calculated using Avogadro number are as follows:

Number of atoms/gram = N_A / A_m
Number of electrons/gram = $(N_A Z)/A_m$
Number of grams /atom" = A_m / N_A

The closer the electrons are to the nucleus, the more tightly bound they are to the nucleus. This results from the attraction between the negatively charged electrons and the positively charged nucleus and is referred to as the *Coulomb* or *electrostatic force*. To move an electron from an inner shell to an outer shell (*excitation*) or to remove it completely from the atom (*ionization*), energy must be supplied. The energy required to remove an electron completely from an atom is called the *binding energy* for the electron. Binding energies are considered negative because energy must be supplied to remove the electron from its orbit. Atomic shells often are described in terms of binding energy, as shown in Figure 6.3 for the tungsten atom. The binding energies for the *K*, *L*, and *M* shells are −69,500, −11,000, and −2,500 eV, respectively. The electrons in the outermost shells are called *valence electrons* and have a binding energy of only a few electron volts because they are very loosely bound. These electrons determine the atom's chemical properties.

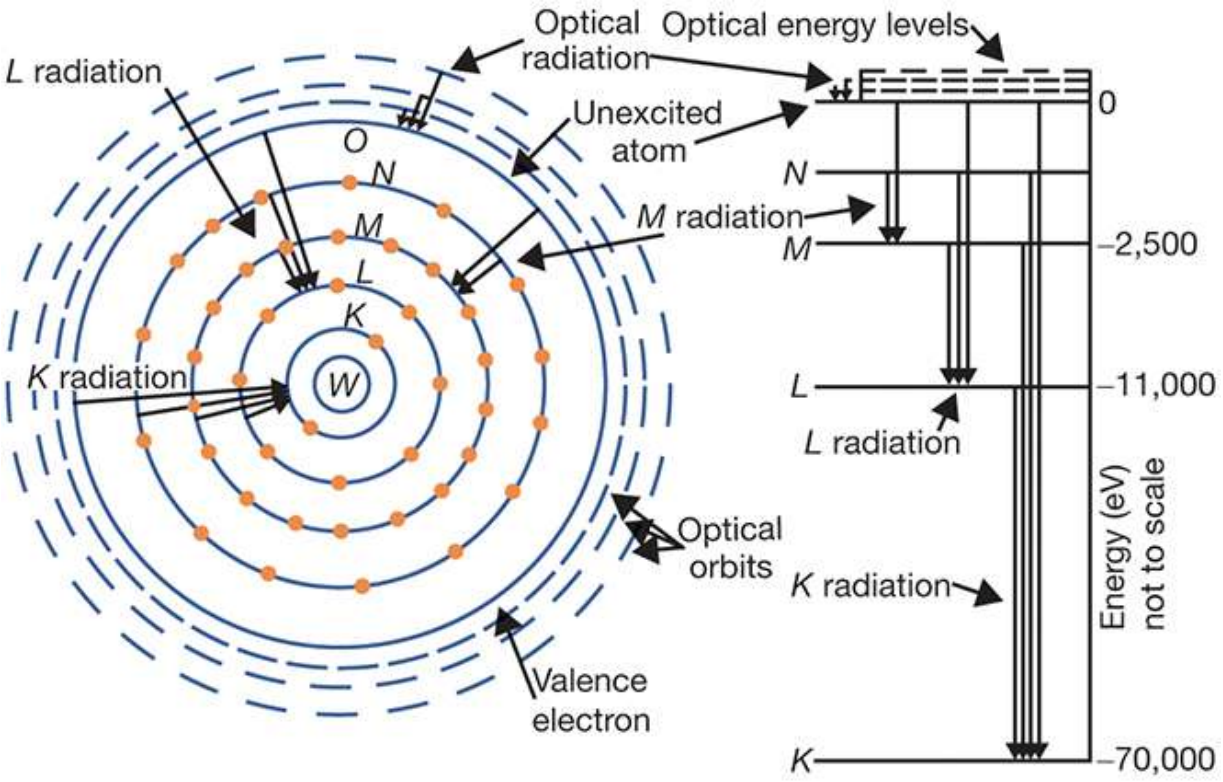

FIGURE 6.3 Schematic drawing of tungsten atom showing electron configuration and energy levels. (From Johns HE, Cunningham JR. *The Physics of Radiology*. 4th ed. Charles C Thomas; 1983:19. Courtesy of Charles C Thomas Publisher, Springfield, Illinois.)

ELECTROMAGNETIC RADIATION

Electromagnetic radiation can be represented by a varying electric and magnetic field that is conveniently described using a sine-wave model. The sine wave is characterized by two parameters: the *frequency*, represented by the Greek letter ν, and the *wavelength*, represented by the Greek letter λ. The wavelength is the distance from one crest of the sine wave to another; the frequency is the number of complete cycles or oscillations per second and is measured in *hertz* (Hz). The product of the frequency and wavelength is the speed with which the wave is propagated, which in a vacuum is the speed of light ($c = 3 \times 10^8$ m/s).

Electromagnetic radiation wavelengths extend from approximately 10^7 to 10^{-13} m. The frequencies associated with these radiations are approximately 10^1 to 10^{21} Hz. The electromagnetic spectrum shown in Figure 6.4 includes the radio and television bands; radar and microwaves; the infrared, visible, and ultraviolet regions; and x-rays and cosmic rays.

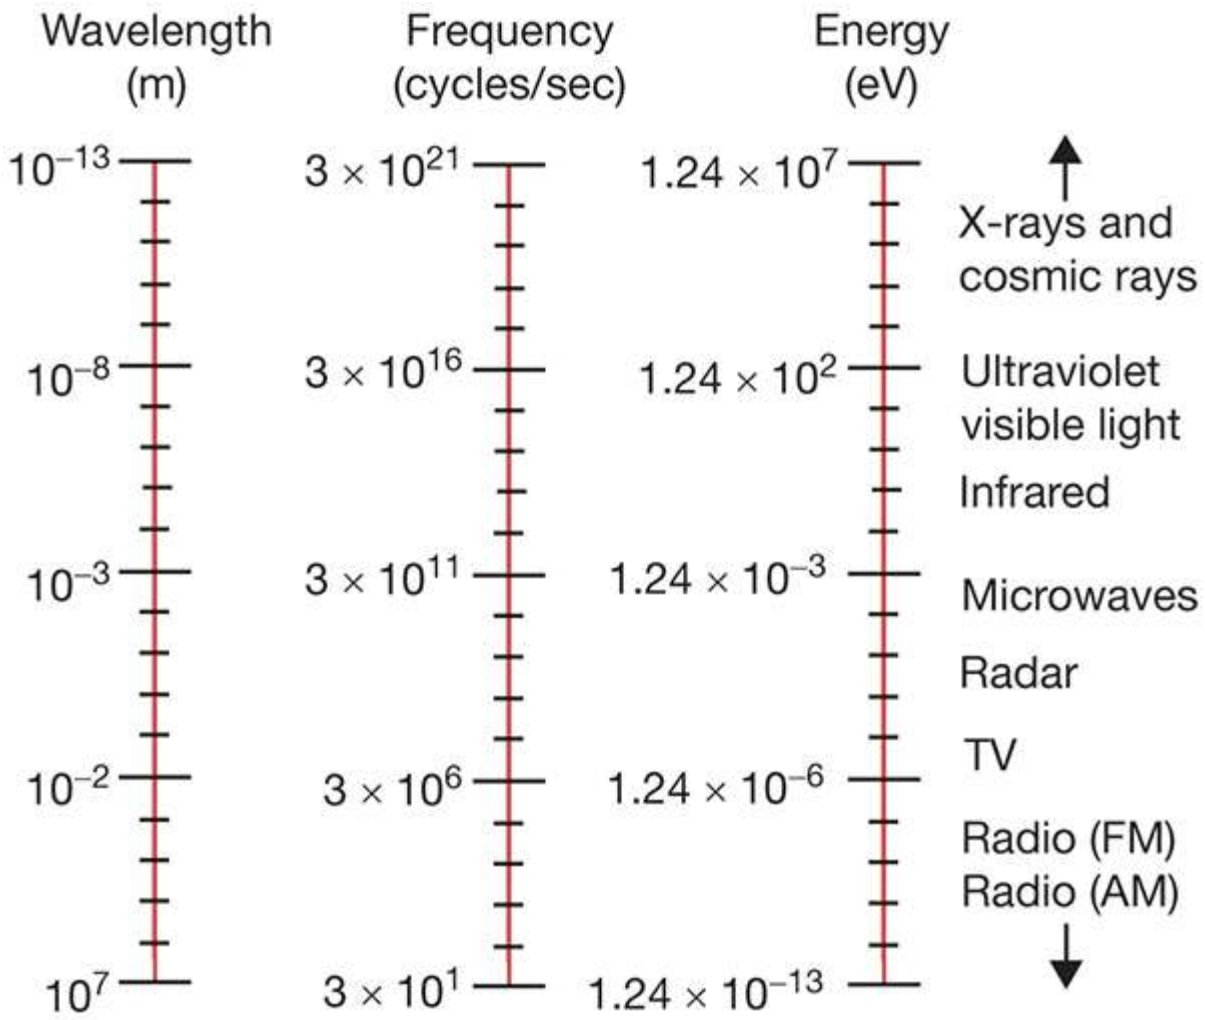

FIGURE 6.4 Electromagnetic spectrum extending over several orders of magnitude, with values of wavelength and frequency, and identifying values in some of the more common regions of the spectrum.

Quantum physics allows electromagnetic radiation to be represented as waves and also as particles, called *photons*. This is referred to as the *wave-particle duality of nature*. The photon energy is directly proportional to the classic wave frequency and is related to it through a constant of proportionality known as *Planck constant* (h), which has a numerical value of 6.625×10^{-34} J-sec. The relationship between energy, E, and frequency, v, is given by the following equation:

$$E = hv$$

The relationship between photon energy and photon wavelength is given by the following equation:

$$E = hc/\lambda$$

in which c is the speed of light in a vacuum. These relationships show that as the wavelength becomes shorter or the frequency becomes larger, the energy of the photon becomes greater.

X-RAYS

Wilhelm Conrad Röentgen discovered x-rays on November 8, 1895.[10] He observed that a paper screen coated with fluorescent material glowed when placed in the vicinity of a tube of gas at low pressure through which electricity was being passed. We now know that the x-rays were produced where the electron beam struck the anode. Energetic electrons that impinge on matter interact with either the orbital electrons or the nuclei of target atoms. The kinetic energy of the electrons then is converted into thermal energy or electromagnetic energy (in the form of x-rays).

The impinging electron's kinetic energy is converted into thermal energy through interaction with an outer shell electron of a target atom, which raises it to a higher energy level (referred to as *excitation*). The excited electron then returns to the normal energy level with the emission of low-energy electromagnetic radiation (*infrared*).

If the impinging electron's kinetic energy is high enough, the interaction can free an orbital electron (referred to as *ionization*), which then can result in the production of electromagnetic radiation (*characteristic x-rays*) when an outer orbital electron moves to the electron vacancy produced via ionization (Figure 6.5). The characteristic x-ray energy is equal to the difference in the binding energies of the two orbital electrons involved. Occasionally, this excess energy is transferred directly to another orbital electron, causing it to be emitted from the atom. Such electrons are called *Auger electrons*.

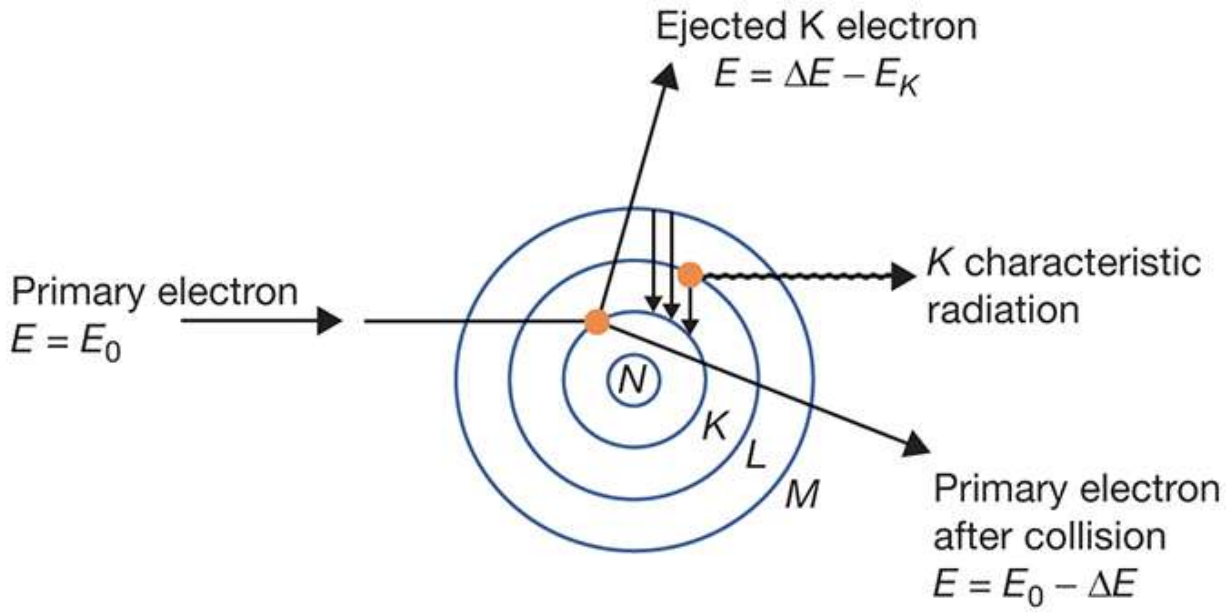

FIGURE 6.5 Schematic diagram illustrating characteristic x-ray production.

The impinging electron also can lose its kinetic energy via a process called *bremsstrahlung* (braking radiation), which occurs when the incident electron interacts with the electric field of the nucleus (rather than the orbiting electrons) and is deflected and loses energy. This loss of energy reappears in the form of an x-ray photon. The impinging electron can lose any amount of its kinetic energy in the bremsstrahlung process. Thus, the x-radiation produced via the bremsstrahlung process is characterized by having a continuous range of energy values, unlike characteristic x-rays, which have only discrete energy values. A bremsstrahlung spectrum (ie, a graph of x-ray intensity vs energy) is shown in Figure 6.6. Superimposed on the continuous bremsstrahlung x-ray spectrum are the characteristic x-rays. The maximum energy of a bremsstrahlung x-ray is numerically equal to the maximum energy of the incident electrons. The direction of emission of the bremsstrahlung x-ray depends on the energy of the incident electron, with higher-energy electrons producing more forward-directed x-rays.

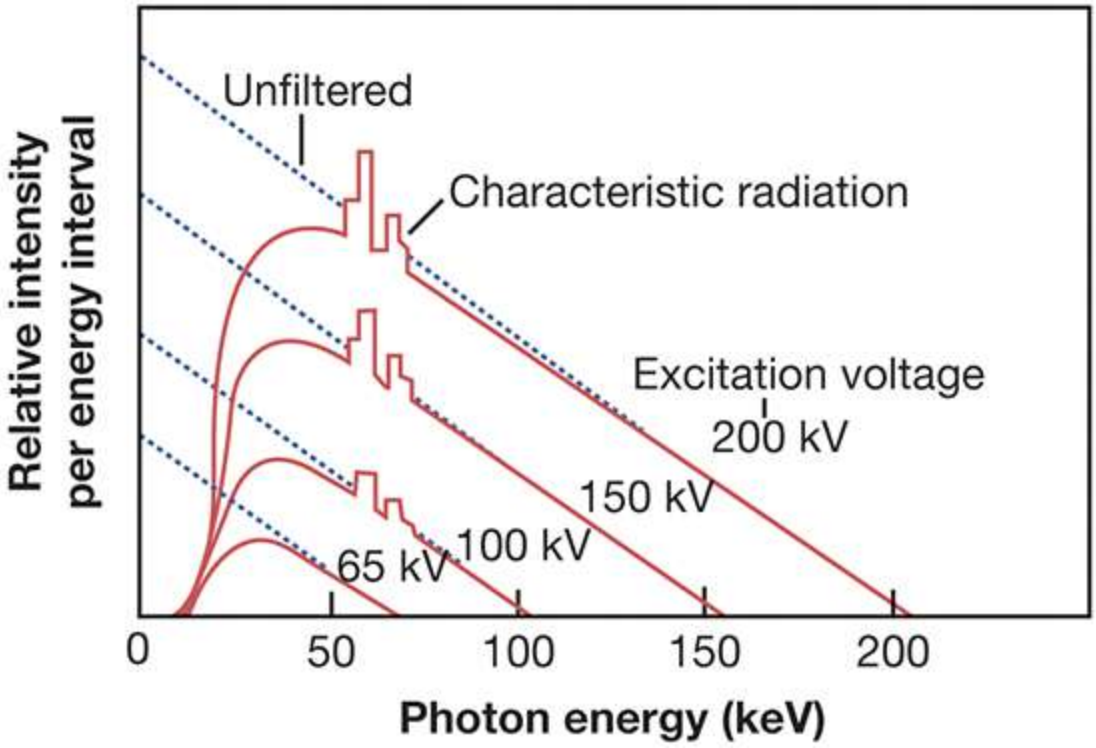

FIGURE 6.6 A bremsstrahlung x-ray spectrum calculated for a thick tungsten target extending from zero to the maximum energy of the electron. The dotted lines are for no filtration, and the solid curves are for a filtration of 1-mm aluminum. Note the superimposed characteristic x-ray emission spectrum. RADIOACTIVITY

In 1896, Henri Becquerel conducted experiments in which he wrapped a photographic plate in black paper to keep out the light and then placed pieces of various elements against the wrapped plate.[11] He discovered that the mineral pitchblende emitted x-rays. Other elements—such as thorium, actinium, and two new elements (polonium and radium) discovered by Pierre and Marie Curie[12]—also emitted x-rays. Further experiments showed that the radioactive elements emitted three types of radiation: *α-particles*, having a positive electrical charge; *β-particles*, having a negative charge; and high-energy *γ-rays*, having no charge at all. We now know that an *α*-particle is a helium nucleus, *β*-particles are electrons, and *γ*-rays are electromagnetic radiation that is similar to x-rays except that they originate from within the nucleus of the atom.

The radioactive decay processes are related to the forces involved. Huge electrostatic (Coulomb) forces of repulsion exist between the positively charged and closely spaced protons in a nucleus. However, a nuclear force of attraction (called the *strong nuclear force*) exists among the neutrons and protons, binding them together to form the nucleus. The strong nuclear force is much more complicated than the *electrostatic* (*Coulomb*) *force* and is still not completely understood. However, it is known that the strong nuclear force between nucleons depends on the distance between them and is effective only over a very short distance, whereas the electrostatic force decreases with the square of the distance. The strong nuclear force easily overcomes the repelling electrostatic force as long as the protons are very close together. However, for a large nucleus, the strong nuclear force binding the nucleons together may be weaker on opposite sides of the nucleus than the repelling electrostatic force. Therefore, a large nucleus is not as stable as a smaller nucleus.

Because neutrons interact through the attractive strong nuclear force and not the repelling electrostatic force, they can be considered stabilizing particles for the nucleus. For example, in light nuclei, only equal numbers of neutrons and protons are required, but in heavier nuclei, the number of neutrons must be about 1.5 times greater than the number of protons to counteract the repelling electrostatic forces of the protons. A nuclide having significantly more protons than neutrons is said to have an unfavorable *N*-to-*Z* ratio and thus undergoes *radioactive decay* to reach a stable configuration.

The *decay constant* of a radioactive nucleus is defined as the fraction of the total number of atoms that decay per unit of time and is denoted by the symbol λ. The decay process can be represented mathematically. If N_0 radioactive nuclei are initially present in a particular sample, the number of radioactive nuclei, N, remaining at a particular time, t, is given by the following equation:

$$N = N_0 e^{-\lambda t}$$

Activity, which describes the radioactivity of a sample and is denoted by the symbol A, is defined as the total number of disintegrations per unit of time and is given by the following relationship:

$$A = \frac{\Delta N}{\Delta t} = -\lambda N$$

This decay constant equation can be expressed in terms of activity:

$$A = A_0 e^{-\lambda t}$$

where A is the activity at time t and A_0 is the initial activity. The *curie* (Ci), a unit of activity, is equal to 3.7×10^{10} disintegrations per second, the approximate number of decays per second by 1 g of ^{226}Ra. The *becquerel* (Bq), the special name in the International System of Units (SI) for the measure of activity, is equal to one disintegration per second (Table 6.2).

TABLE 6.2 INTERNATIONAL SYSTEM OF UNITS (SI UNITS) FOR RADIATION THERAPY

Quantity	SI Unit (Special Name)	Non-SI Unit	Conversion Factor
Exposure	C kg^{-1}	roentgen (R)	1 C kg^{-1} ≈ 3,876 R
Absorbed dose, kerma	J kg^{-1} (gray [Gy])	rad	1 Gy = 100 rad
Dose equivalent	J kg^{-1} (sievert [Sv])	rem	1 Sv = 100 rem
Activity	s^{-1} (becquerel [Bq])	curie	1 Bq = 2.7 × 10^{-11} Ci

The *half-life* of a radioactive nuclide is the time required for the number of atoms in a particular sample to decrease by one-half. The half-life, $T_{1/2}$, is related to the decay constant by the following equation:

$$T_{1/2} = \frac{0.693}{\lambda}$$

The *average life,* T_a, of a radioactive nuclide is related to the decay constant and the half-life by the following equation:

$$T_{\mathrm{a}} = \frac{1}{\lambda} = 1.44 T_{1/2}$$

The average life represents the time period that a hypothetical source would need—if it retained its original activity for that time period and then suddenly decayed to zero activity—to produce the same number of disintegrations as produced over an infinite time period by the source if it decayed exponentially.

Gamma decay occurs when a nucleus undergoes a transition from a higher to a lower energy level. In this process, a high-energy photon, called a *γ-ray*, is emitted. These *γ*-rays are identical to the x-rays emitted by excited atoms, except that *γ*-rays originate from within the nucleus and x-rays originate from outside the nucleus. Half-lives for *γ* decay are usually very short, typically 10^{-15} second.

Closely related to *γ* decay is the process called *internal conversion*. Instead of emitting a *γ*-ray, the excess energy from the excited nucleus is transferred to an electron in one of the inner atomic shells, causing ejection of the electron from the atom with emission of characteristic x-rays. The probability of internal conversion occurring increases as the atomic number increases.

In *β decay*, a neutron within the nucleus is converted into a proton, and an electron and an *antineutrino* are emitted, or a proton is converted into a neutron, and a *positron* and a *neutrino* are emitted:

$$\beta^- \text{ decay: } n \rightarrow p + \beta^- + \bar{\nu}$$
$$\beta^+ \text{ decay: } p \rightarrow n + \beta^+ + \nu$$

The positron was discovered in cosmic ray experiments in 1932. It is a positively charged particle with the same mass and spin as the electron and is considered the antiparticle of the electron. The neutrino and its antiparticle, the *antineutrino*, are massless particles (or at least have only a very small mass) having no charge that carry opposite spins and account for the conservation of energy and continuous energy spectrum observed for *β* decay. Particle-antiparticle pairs interact by annihilating each other, converting all their mass into electromagnetic energy (two *γ*-ray photons,

each of 0.51 MeV). In β decay, the emitted particles may vary in the kinetic energy they possess, which is rarely >3 MeV. Half-lives for β decay are long compared with those for γ decay, varying from seconds to years. The forces responsible for the β decay processes are weak compared with both the *strong nuclear force* and the *electrostatic force* among the nucleons. Accordingly, the force responsible for β decay is referred to as the *weak nuclear force*.

Electron capture is an alternative to *positron decay*. In this process, an electron, usually in the *K* shell, is captured within the nucleus and combines with a proton to create a neutron. Electron capture most often is followed by γ decay to release any excess nuclear energy.

Alpha decay occurs in nuclides with atomic number >82 and where the ratio of neutrons to protons is low, thus resulting in the repulsive Coulomb force of the protons overcoming the attractive strong nuclear force. The emitted α-particle is a helium nucleus (two protons and two neutrons). The kinetic energy for a particular α decay is monoenergetic (ie, the transition may be to an excited energy state with subsequent γ emission) and often 4 to 5 MeV. Half-lives range from 10^{-3} to 10^{10} years. The radioactive decay of radium to radon is an example of α decay, where the Q term represents the total energy release in the transition (called *transition energy*). For example,

$$^{226}_{88}\mathrm{Ra} \rightarrow {}^{222}_{86}\mathrm{Rn} + {}^{4}_{2}\alpha + \gamma + Q$$

The most recent version of the periodic table of the elements shows a grouping of 118 elements. Only the first 92 occur naturally; the remaining ones have been produced artificially. In general, the elements with high atomic number tend to be radioactive; in fact, all but one of the elements with atomic number higher than 82 (lead) are radioactive; only Bi is stable.

The naturally occurring radioactive elements have been grouped into three radioactive series called the *uranium series*, the *actinium series*, and the *thorium series*, all of which terminate with a stable isotope of lead. The uranium series provides an example of radioactive nuclides undergoing

successive transformations through α and β decay in which the parent nuclide produces a radioactive product called the *daughter nuclide*.

When the half-life of the parent nuclide is longer than the half-life of the daughter nuclide, an equilibrium condition exists. When this occurs, the ratio of the activity of the daughter nuclide to the activity of the parent nuclide becomes constant, and the apparent decay rate of the daughter nuclide is controlled by the parent nuclide's decay rate. Two types of radioactive equilibrium conditions are defined: *transient equilibrium* and *secular equilibrium*. Transient equilibrium is established when the parent nuclide's half-life is not much greater than the daughter nuclide's half-life (Figure 6.7). In secular equilibrium, the half-life of the parent nuclide is much greater than that of the daughter nuclide (Figure 6.8). The two types of equilibrium are described mathematically by the following equations, in which A_P and A_D represent the activity of the parent and daughter nuclides, respectively:

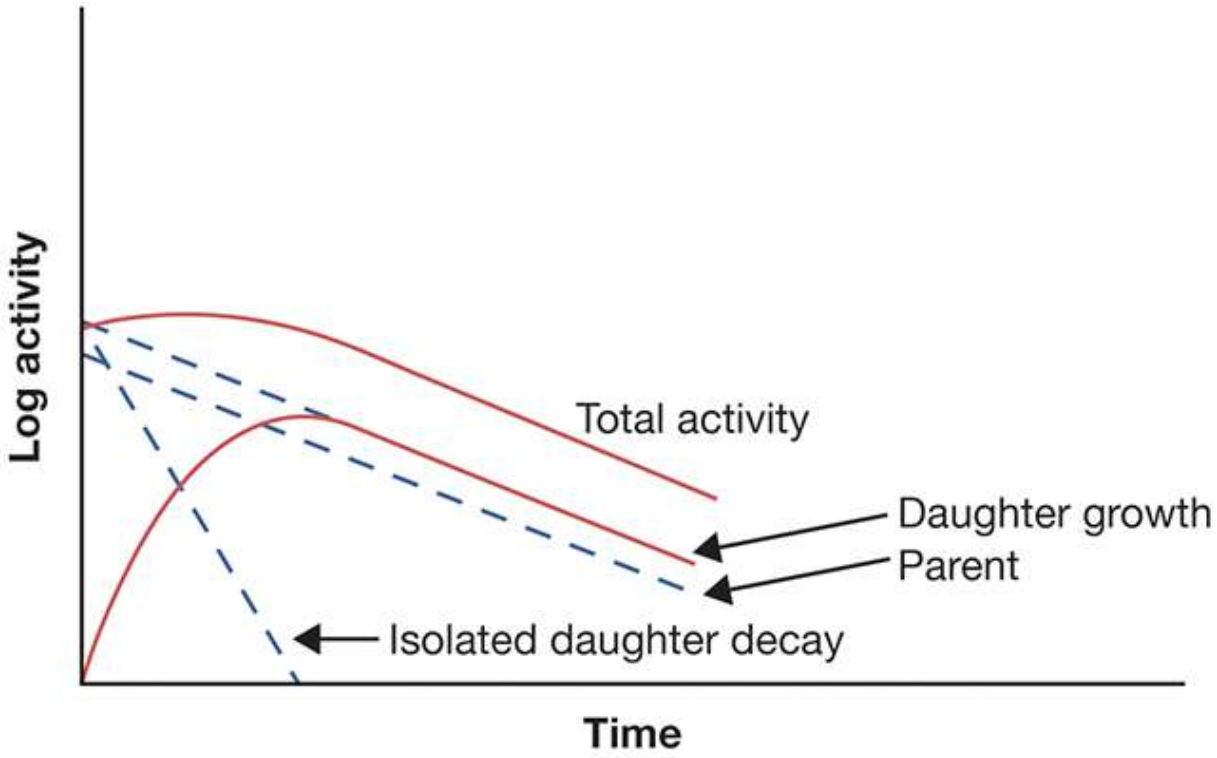

FIGURE 6.7 Transient equilibrium. Shown is a semilog plot of activity versus time for parent and daughter radionuclides illustrating conditions of transient equilibrium that may be achieved when the parent nuclide's half-life is not much greater than the half-life of the daughter nuclide. Once equilibrium is established, the daughter activity exceeds the parent activity, and both decay with the half-life of the parent.

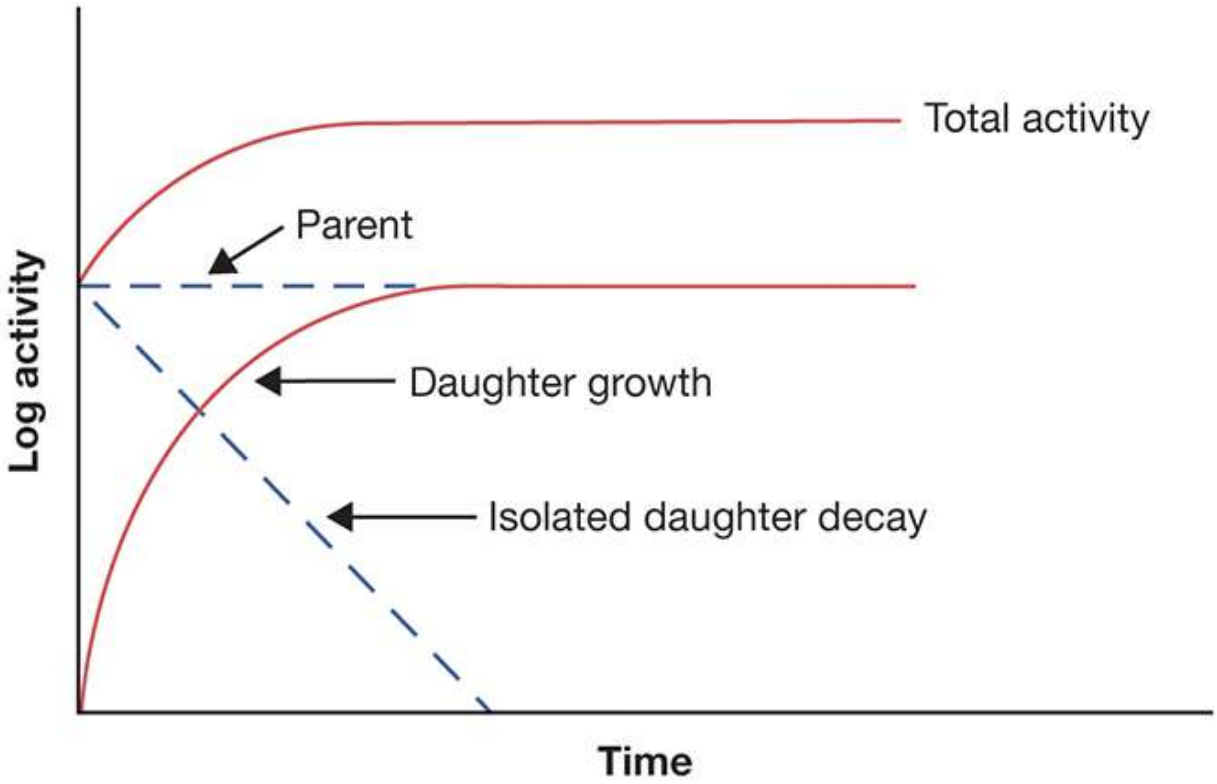

FIGURE 6.8 Secular equilibrium. Shown is a semilog plot of activity versus time for parent and daughter radionuclides illustrating conditions of secular equilibrium that may be achieved when the parent nuclide's half-life is much greater than the half-life of the daughter nuclide. Once secular equilibrium is established, activities of both parent and daughter are equal.

$$\text{Transient equilibrium: } \frac{A_D}{A_P} = \frac{\lambda_D}{\lambda_D - \lambda_P}$$

$$\text{Secular equilibrium: } A_D = A_P$$

INTERACTION OF PHOTONS WITH MATTER

As stated previously, x-rays and γ-rays may be considered as bundles of energy called *photons*. If an x-ray photon enters a thin layer of matter, it is possible that it will pass through without interaction, or it may interact (usually with the atomic electrons, but sometimes with the atomic nuclei) in one of five different ways (*coherent scattering*, *photoelectric effect*, *Compton scattering*, *pair production*, and *photodisintegration*). The probability that a photon will interact when it traverses through a given

thickness of material is the product of the individual interaction probabilities for each of these processes. The attenuation process can be described mathematically by the following equation:

$$N = N_0 e^{-\mu x}$$

where N_0 is the number of photons in the beam impinging on an absorber of thickness x, e is the base of the natural logarithms, and μ is the linear attenuation coefficient. The quantity μ is actually the sum of the individual attenuation coefficients for the five processes. Its numerical value depends on the energy of the photon and the type of attenuating material.

There are a variety of tabulated attenuation coefficients, including the *linear attenuation coefficient* (μ), the *mass attenuation coefficient* (μ/ρ), the *mass energy-transfer coefficient* (μ_t/ρ), and the *mass energy-absorption coefficient* (μ_{en}/ρ). Each type of coefficient is intended for use in the solution of different types of attenuation or energy-absorption problems; division by ρ, the physical density of the medium, makes the coefficient medium independent. Figure 6.9 shows the mass attenuation coefficient for lead and water as a function of incident photon energy. The discontinuities where the attenuation coefficient suddenly increases are called *absorption edges* and occur at photon energies just equal to the binding energy of a specific electron shell.

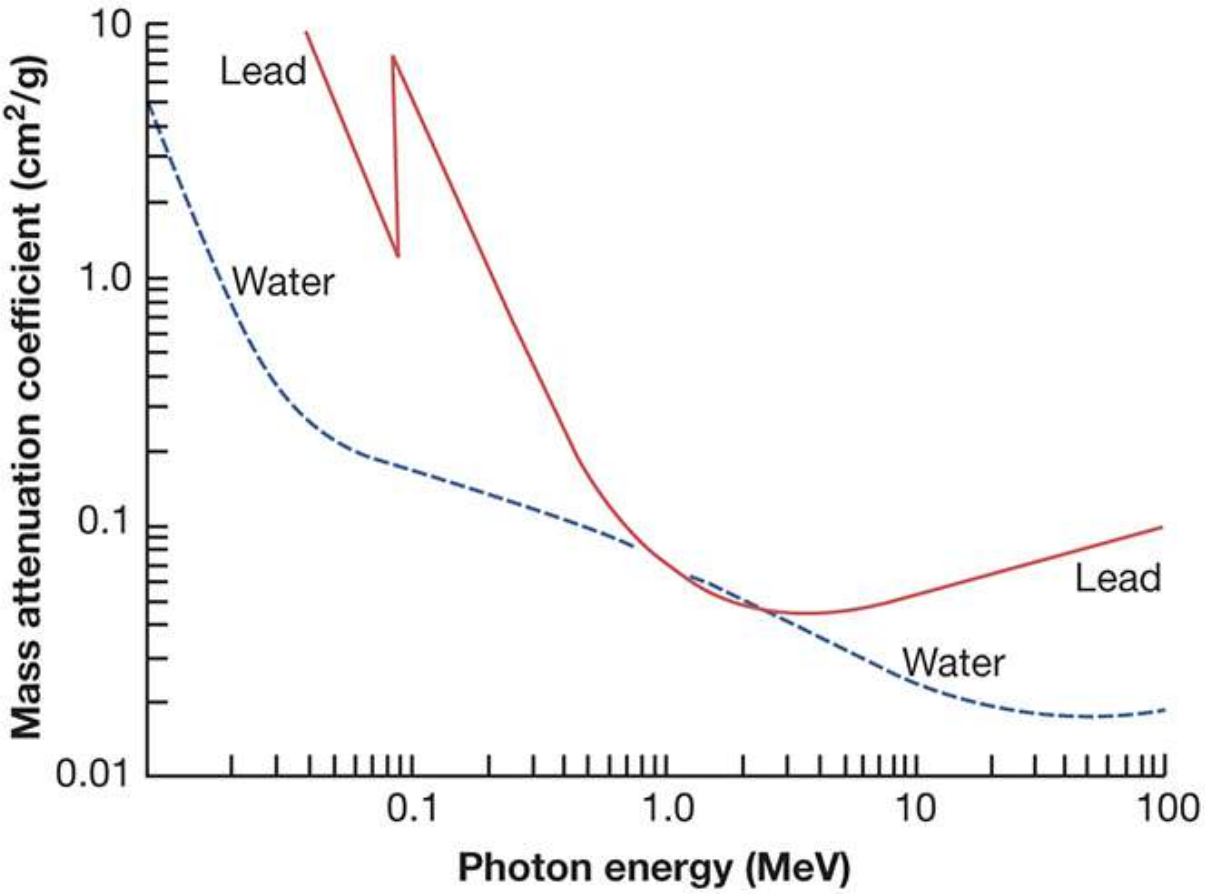

FIGURE 6.9 Mass attenuation coefficient for lead and water. Note sharp discontinuities, which are called *absorption edges*. (From Johns HE, Cunningham JR. *The Physics of Radiology*. 4th ed. Charles C Thomas; 1983:147. Courtesy of Charles C Thomas Publisher, Springfield, Illinois.)

The thickness of material that reduces the number of photons transmitted to one-half the incident number is termed the *half-value layer* (*HVL*). The HVL is related to the linear attenuation coefficient by the following equation:

$$\text{HVL} = \frac{0.693}{\mu}$$

This parameter is used to describe the *quality* or *penetrability* of the radiation and is discussed later in this chapter.

Coherent or Classical Scattering

If the photon energy is low enough that the quantum effects of the interaction are unimportant and the bound electron(s) can be regarded as essentially "free," the interaction corresponds to the "classical scattering" situation (called *coherent scattering*), in which the incident electrical field accelerates one or more orbital electrons and causes them to radiate. There are two types of coherent scattering: *Thomson scattering*, in which a single orbital electron is involved, and *Rayleigh scattering*, in which the orbital electrons act as a single group. In coherent scattering, no energy is transferred; only the direction of the incident photon is changed. The coherent mass attenuation coefficient is denoted by σ_{coh}/ρ.

Photoelectric Effect

In *photoelectric effect*, the total energy of the photon is transferred to an orbital electron, usually close to the nucleus, and the photon disappears. The electron then is ejected from the atom with an energy equal to the energy of the photon minus the binding energy of the electron (Figure 6.10). The direction in which the electron is emitted depends on the energy of the incident photon. For low-energy photons (eg, 50 keV), the photoelectron is ejected at a large angle with respect to the incoming photon's direction, increasing in the forward direction as the photon's energy increases. After ejection of the electron, the neutral atom becomes a positively charged ion with a vacancy in an inner shell that must be filled. The atom returns to a stable condition by filling the vacancy with a nearby, less tightly bound electron farther out from the nucleus, and characteristic x-rays or an Auger electron is emitted.

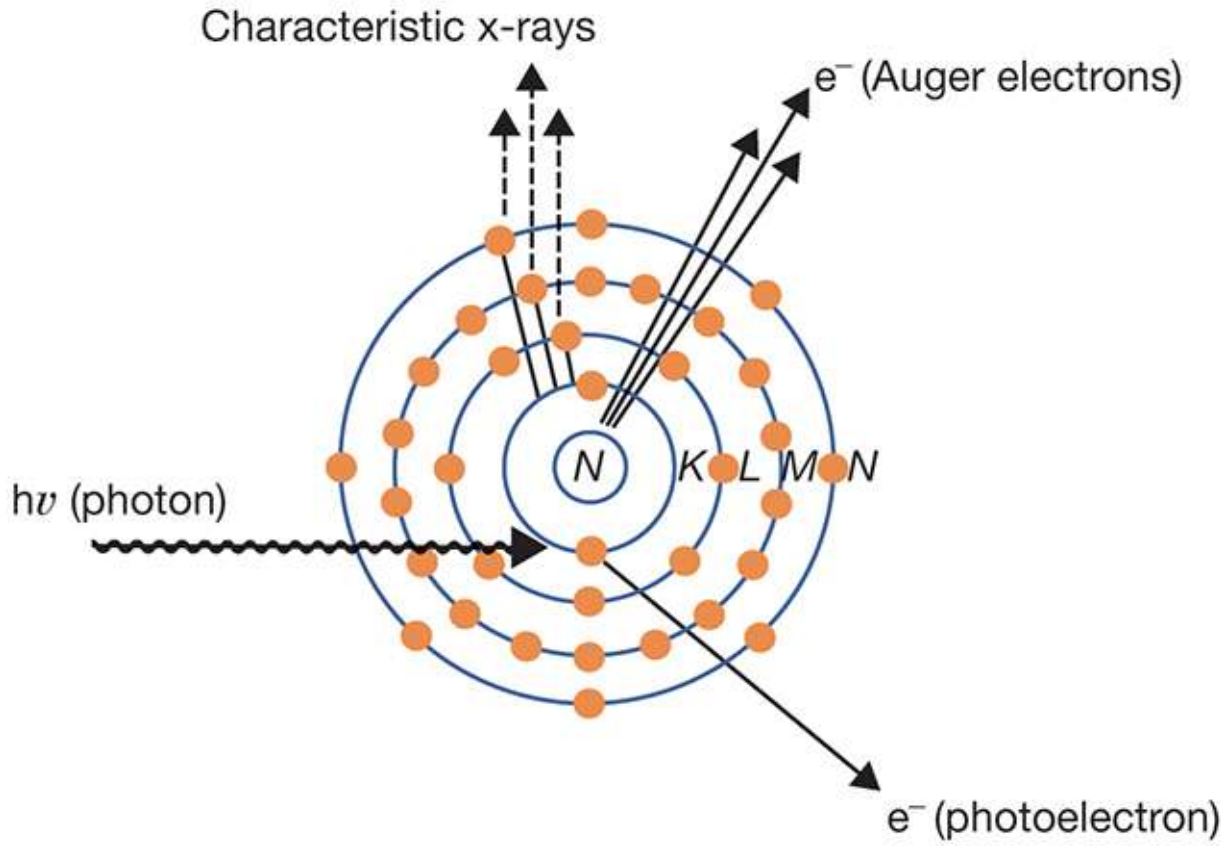

FIGURE 6.10 Photoelectric effect. In this type of photon interaction, the incident photon disappears, and an electron is ejected with kinetic energy equal to the incident photon's energy minus the binding energy of the electron. Characteristic x-rays and Auger electrons are emitted as the atom's electrons cascade to fill the vacancy created by the ejected electron.

The probability that a given photon will interact by means of the photoelectric process (denoted by τ/ρ) is a function of both the photon's energy and the atomic number of the target atom. For the process to occur, the incident photon must have energy greater than the binding energy of the involved orbital electron. In general, the probability per electron that a photon will undergo a photoelectric interaction is inversely proportional to the third power of the photon's energy and directly proportional to the third power of the atomic number of the target atom.

Compton Scattering

In *Compton scattering*, the incident photon interacts with a loosely bound orbital electron in which part of the photon's energy is transferred to the

electron as kinetic energy and the remaining energy is carried away by another photon (Figure 6.11). The binding energy of the electron is insignificant compared with the incident photon's energy and thus can be ignored. The energy of the Compton-scattered photon is equal to the difference between the energy of the incident photon and the energy transferred to the electron. If the incoming photon's energy is low (eg, 100 keV), very little energy is transferred to the electron. As the photon's energy increases, a greater proportion of the energy is transferred to the electron, so the scattered photon necessarily retains a smaller proportion of the incident energy. The photon may be scattered at any angle with respect to the direction of the incident photon, but the Compton electron is confined to angles between 0° and 90° with respect to the direction of the incident photon. If the incoming photon's energy is low, the distribution of the scattered photons is isotropic (equal in all directions). The scatter angles decrease for photons and electrons as the incident photon's energy increases (eg, at megavoltage [MV] photon energies, both are scattered predominantly in the forward direction).

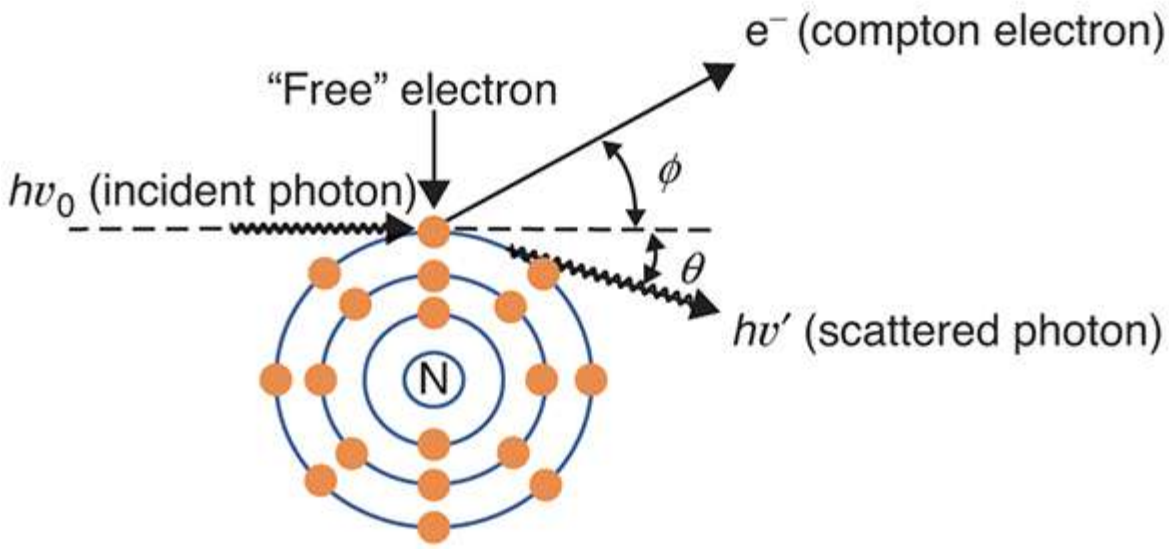

FIGURE 6.11 Compton effect. In this type of photon interaction, the incident photon interacts with one of the atom's outer electrons, and the energy is shared between the ejected electron and a scattered photon.

As a result of conservation of energy and momentum, the energies of the incident photon, $h\nu_0$; the scattered photon, $h\nu'$; and the scattered electron, E, are given by the following relationships:

$$E = h\nu_0 \frac{\alpha(1-\cos\theta)}{1+\alpha(1-\cos\theta)}$$

$$h\nu' = h\nu_0 \frac{1}{1+\alpha(1-\cos\theta)}$$

$$\cot(\varphi) = (1+\alpha)\tan(\theta/2)$$

where $\alpha = h\nu_0/m_0c^2$, and m_0c^2 is the rest energy of the electron (0.511 MeV). If $h\nu_0$ is expressed in MeV, then $\alpha = h\nu_0/0.511$.

The probability that a photon will interact with a target atom via the Compton process (σ_c/ρ) depends on the energy of the incoming photon, generally decreasing as the energy of the photon is increased. The probability of a Compton interaction is nearly independent of the atomic number of the absorber and is directly proportional to the number of electrons per gram.

Pair Production

Pair production (Figure 6.12) is possible only with photons having energies >1.02 MeV. When such an energetic photon approaches closely enough to the nucleus of the target atom, the incident photon energy may be converted directly into an electron-positron pair. Energy possessed by the photon in excess of 1.02 MeV appears as kinetic energy, which may be distributed in any proportion between the electron and the positron. When the positron comes to rest, it combines with an electron, and both particles then undergo mutual annihilation, with the appearance of two photons with energy of 0.511 MeV traveling in opposite directions. The probability of pair production (π/ρ) occurring increases rapidly with incident photon energy

above the 1.02 MeV threshold and is proportional to Z^2 per atom, Z per electron, and approximately Z per gram.

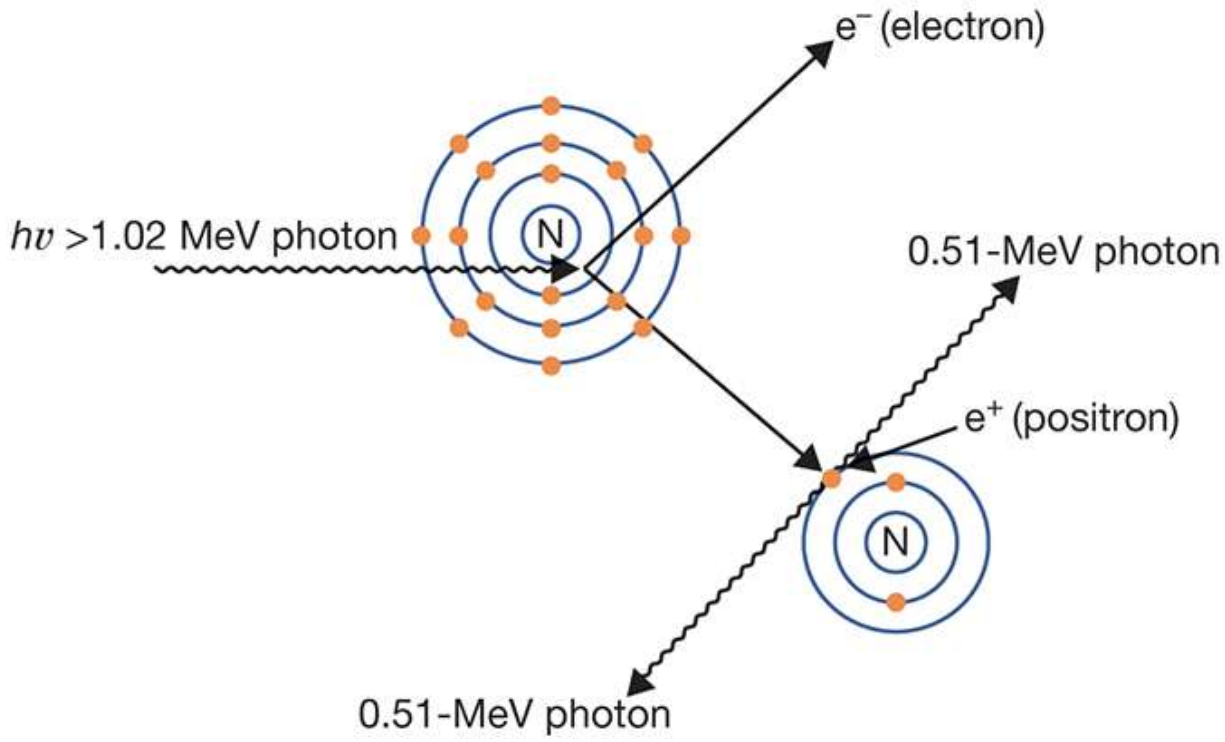

FIGURE 6.12 Pair production. In this type of photon interaction, the incident photon interacts with the electromagnetic field of the nucleus. The incident photon disappears, and two energetic electrons (a positron and a negatron) are produced. Two annihilation photons of energy 0.511 MeV then are produced when the positron interacts with its antiparticle, another electron.

Photodisintegration

In *photodisintegration*, a high-energy photon interacts with the nucleus of an atom, totally disrupting the nucleus, with the emission of one or more nucleons. It typically occurs at photon energies much higher than those encountered in radiation therapy. However, it is important to account for this in designing shielding around high-energy accelerators, as this interaction is a source of low-energy neutrons.

Relative Importance of Interaction Processes

Figure 6.13 illustrates the relative importance of the photoelectric, Compton, and pair-production processes—the three principal modes of interactions pertinent to radiation therapy—as a function of energy and atomic number of the absorber. For example, for an absorber with an atomic number approximately equal to that of tissue ($Z = 7$) and for monoenergetic photons, the photoelectric effect is the dominant interaction below about 30 keV. Above 30 keV, the Compton effect becomes dominant and remains so until approximately 24 MeV, at which point pair production becomes the dominant interaction. The total mass attenuation coefficient accounting for all the photon interactions discussed is given by the sum of the individual coefficients:

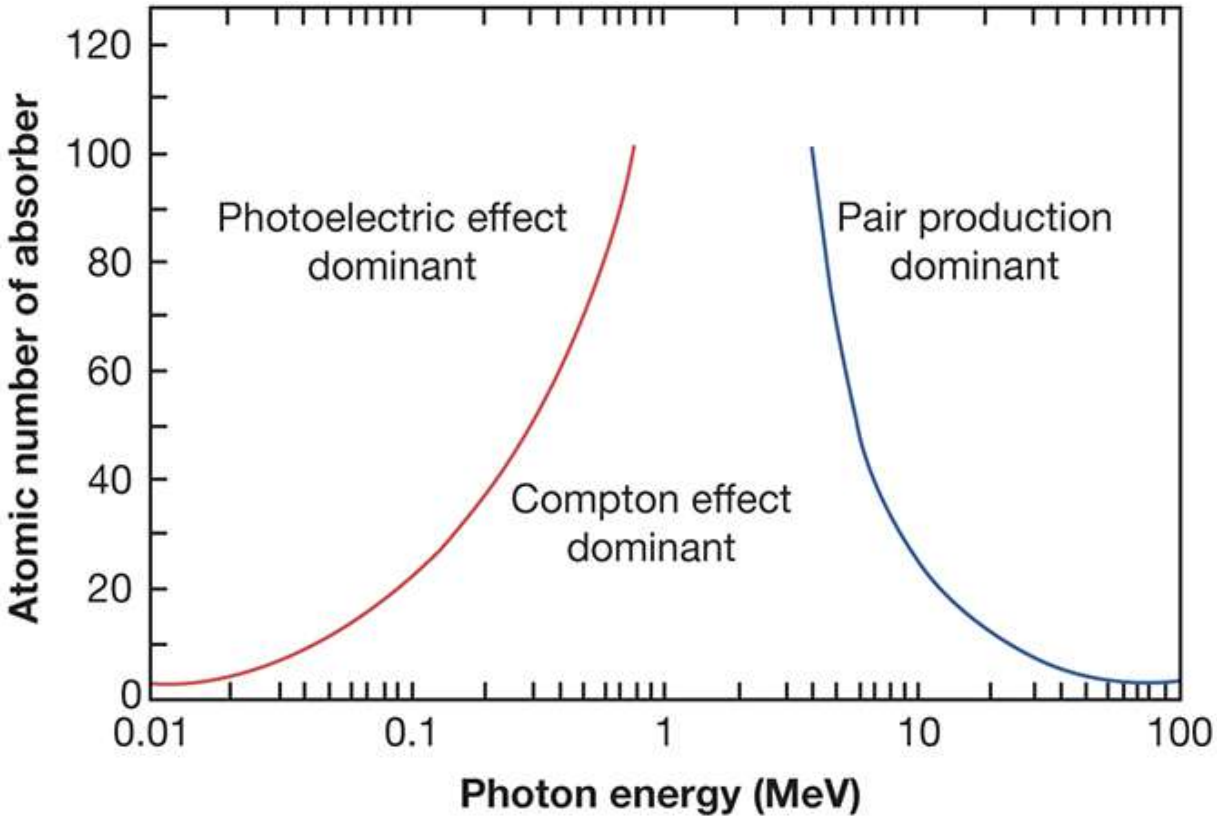

FIGURE 6.13 Relative importance of the three principal modes of interaction as a function of photon energy and atomic number of absorber. (Reprinted from Hendee WR, Ritenour ER. *Medical Imaging Physics*. 3rd ed. Mosby-Yearbook; 1992. Copyright © 1992 Elsevier. With permission.)

$$\mu_{en}/\rho = \sigma_{coh}/\rho + \tau/\rho + \sigma_{c}/\rho + \pi/\rho$$

INTERACTION OF PARTICLES WITH MATTER

Electrons

An electron loses its kinetic energy when traversing matter via interactions that can be either *elastic*, in which no kinetic energy is lost, or *inelastic*, in which some portion of the kinetic energy is changed into some other form of energy. The term *linear energy transfer (LET)* is used to describe how much energy an ionizing particle transfers to the material traversed per unit distance. Elastic collisions occur with either atomic electrons or atomic nuclei and are characterized by a change in direction of the incident electron with no loss of kinetic energy. Inelastic collisions can occur with atomic electrons, resulting in *ionizations* and *excitations* of atoms, or inelastic collisions with atomic nuclei, which result in the production of bremsstrahlung x-rays (*radiative losses*). In the case of ionization, it is possible for the ejected electron to acquire enough kinetic energy to cause additional ionizations of its own. These electrons are called *secondary electrons* or *Δ rays*, and they can go on to produce additional ionizations and excitations. The typical energy loss in tissue for a therapeutic electron beam, averaged over its entire range, is about 2 MeV/cm in water.

The complete description of the energy and depth of penetration of the moving electrons at any point in the medium is complicated by the fact that the electrons are very much lighter than the atomic nuclei. As a result, the electron can lose a very large fraction of its energy in a single process and thus can be deflected by very large angles. This means that even if the electron beam is monoenergetic when first impinging on a medium, there will be a large variation among all the moving electrons as to where in the medium each will stop. This is referred to as *range straggling*.

Protons and Heavier Ions

Protons traverse relatively straight paths through matter, slowing down continuously by interactions with atomic electrons and with atomic nuclei. This results in depth-dose characteristics that show an approximately constant absorbed dose value over most of the beam range until near the end of the proton's range, where a very sharp increase in dose occurs (called the *Bragg peak*), as shown in Figure 6.14. Dose at the peak is approximately 4 times the dose at the surface, and the distal width of the

peak is on the order of 1 cm, depending on beam energy and beam energy spread. Depth-dose characteristics customized for individual patients can be generated by superposition of multiple proton beams having different energies. This technique creates a *spread-out Bragg peak* that covers the target volume and decreases sharply to zero dose a few millimeters beyond the target. Protons are somewhat more effective biologically than photons, that is, a lower dose is required to cause the same biologic effect. This concept of *relative biological effectiveness (RBE)* of protons is defined as the dose of a reference radiation (typically ^{60}Co) divided by the proton dose to achieve the same biologic effect. Paganetti et al[13] have shown that proton RBE varies (≅10%) along the Bragg peak, particularly at the distal end where LET is high. Current clinical practice and International Commission on Radiation Units and Measurements (ICRU) recommendations[14] advocate that an overall RBE factor of 1.1 be applied.

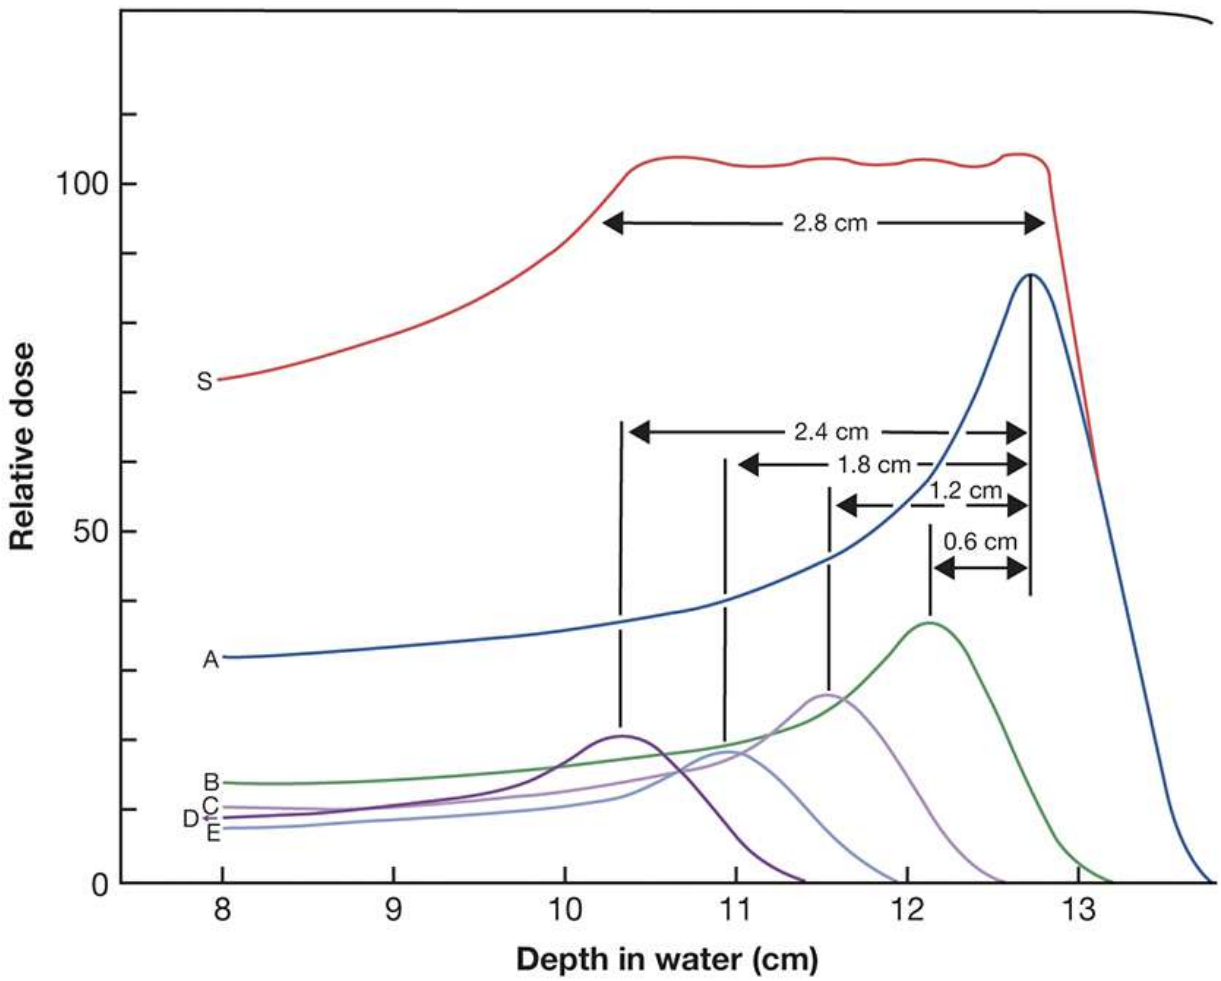

FIGURE 6.14 Drawing illustrating the way in which the Bragg peak for a proton beam can be spread out. Curve A is the depth-dose distribution for the primary beam of 160-MeV protons at the Harvard cyclotron. Beams of lower intensity and shorter range, as illustrated by curves B to E, can be added to give a composite curve, S, which results in a uniform dose of more than 2.8 cm. (Reprinted with permission from Hall *EJ. Radiobiology for the Radiologist*. 4th ed. J.B. Lippincott; 1994.)

Heavier ions, such as carbon, are also being used in modern radiation therapy at a few medical heavy-ion facilities in Europe and Asia.[15-17] Because of the greater mass of carbon ions, multiple scattering and range straggling are much less than protons, resulting in a sharper lateral and longitudinal edge. Also, because the LET in the peak of a carbon beam is larger than that of proton beams, the RBE is far greater for carbon ions.

Neutrons

Neutrons, like photons, are uncharged and thus are an indirectly ionizing radiation, which are exponentially attenuated by matter. The interactions are through processes that are primarily nuclear. They include elastic scattering with nuclei that make up the body's tissues (hydrogen, oxygen, carbon, nitrogen, etc). Neutron interactions result in recoil protons and charged nuclear fragments that have relatively low energy. The RBEs of these resultant particles are not fully known, thereby complicating the understanding of the relationship between clinical response and absorbed dose.

RADIATION THERAPY TREATMENT MACHINES

Kilovoltage Units

Before 1951, most radiation treatment units were kilovoltage x-ray machines capable of producing photon beams having only limited penetrability. Today, this type of machine is still used in some clinics for the treatment of skin cancer. In these machines, the electrons are accelerated by an electric field produced from a high voltage generated in a transformer that is applied directly between the filament (cathode) and the x-ray target (anode). A schematic diagram of a radiation therapy x-ray tube is shown in Figure 6.15. The potential difference (kVp) is variable on these machines, and metal filters can be added to absorb the lower-energy photons preferentially, changing the penetrability of the beam. The combination of variable kVp and different filtration provides the capability of generating multiple x-ray beams. The degree of penetrability is used to categorize the units as *contact*, *superficial*, and *orthovoltage* (deep-therapy) x-ray machines. A more detailed review of these type of treatment machines is provided by Biggs et al.[18]

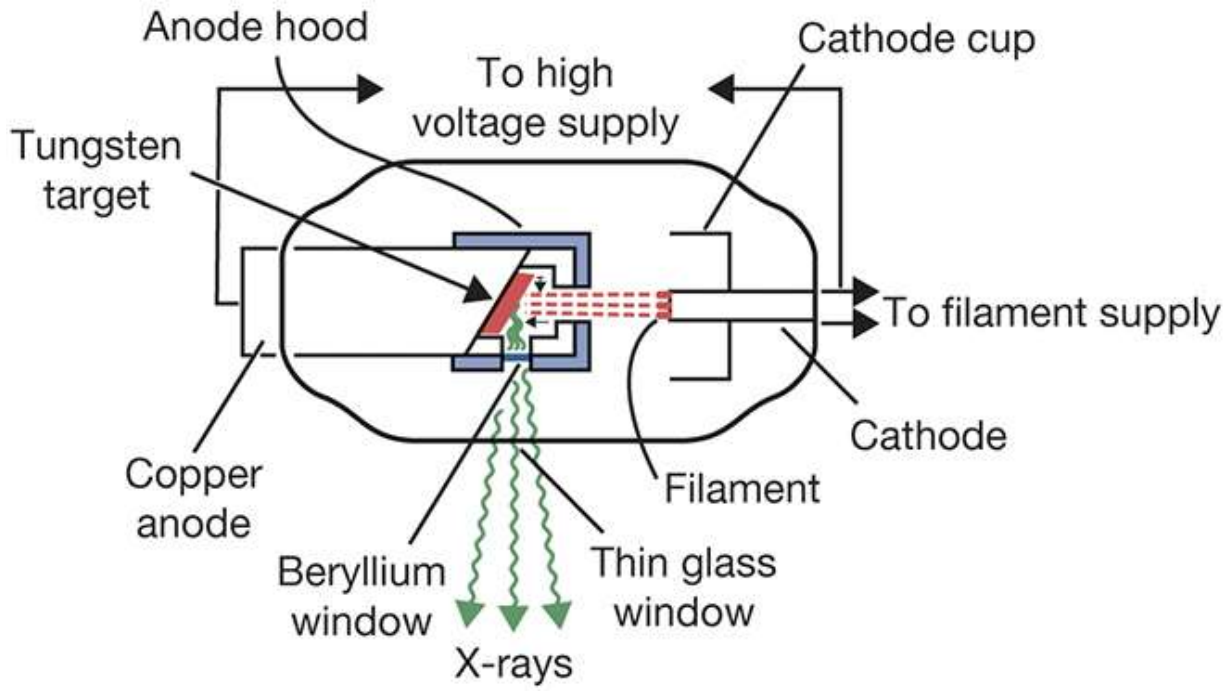

FIGURE 6.15 Schematic diagram of radiation therapy x-ray tube. (Reprinted with permission from Khan FM. *The Physics of Radiation Therapy*. 2nd ed. Williams & Wilkins; 1994.)

Contact Units

A contact x-ray machine typically operates at potentials of 40 to 50 kVp and at a tube current of 2 to 5 milliamperes (mA). Attached cones are used for a source-skin distance (SSD) of typically 2 cm or less. Filters of 0.5- to 1.0-mm aluminum are used to give a typical HVL of 0.6-mm aluminum. The x-ray tube is rod shaped with an extremely thin mica-beryllium window, having an inherent filtration of 0.03-mm-aluminum equivalence, and the radiation is emitted axially. The primary radiation therapy application of a contact x-ray unit is for endocavitary irradiation of selected small rectal carcinomas.[19]

Superficial Units

A superficial unit is an x-ray machine that operates at potentials of 50 to 150 kVp and 5 to 10 mA. Added thickness of filtration (1-mm Al to 1-mm Al + 0.25-mm Cu) produces HVLs of 1.0 to 8.0 mm of aluminum. Attached cones typically are used; lead masks are used to define irregular fields. The

SSD is typically 15 or 20 cm. These machines are used primarily to treat skin lesions.

Orthovoltage (Deep-Therapy) Units

Orthovoltage x-ray machines operate at potentials between 150 and 500 kV, with most operating between 200 and 300 kV, and with tube currents of 10 to 20 mA. HVLs of 1 to 4 mm of copper are common with the use of added filters, such as the *Thoraeus filter*, a combination of thin sheets of tin, copper, and aluminum arranged so that the highest atomic number sheet is always closest to the x-ray target, ensuring that the higher-energy characteristic x-rays are absorbed by the lower-*Z* metal. Treatment fields usually are defined using detachable cones. The SSD is typically 50 cm. Very few of these types of machines are still in clinical use.

Megavoltage Photon and Electron Beam Treatment Units

Radiation treatment machines that can produce beams 1 MV or greater have been designated as *MV therapy* machines. The *resonant transformer machine*, one of the first such treatment units, could generate x-rays between 300 kV and 2 MV.[20] Another early type of MV machine was the *Van de Graaff generator*, which operated at 1 to 2 MV. The *betatron*, first developed in 1941 by Kerst,[21] was adapted for use in radiation oncology and produced x-ray beams with energies of >40 MV. The *microtron*[22] and related *racetrack microtron*[23] combined the basic principles of the electron linear accelerator and cyclotron (both of which are discussed later in this chapter) and was one of the first intensity-modulated delivery systems. All of these machines are now obsolete and no longer in clinical use. Details on the history and development of these early accelerators used in radiation therapy can be found in the textbook by Karzmark et al.[24]

Cobalt-60 Teletherapy

The first *cobalt-60* (^{60}Co) *teletherapy* machine was loaded with its ^{60}Co source in August 1951 in the Saskatoon Cancer Clinic, Saskatoon, Canada, and the first patient was treated on November 8 of that year.[25,26] A very readable history of the development of the first ^{60}Co teletherapy machine in the United States is provided by Almond.[27] A technical review of ^{60}Co

teletherapy machines is provided by Glasgow.[28] The advantages of a ^{60}Co teletherapy machine are its relative constancy of beam output, predictability of decay because of a well-defined half-life, and lack of day-to-day small-output fluctuations typically found in electrical machines. Disadvantages include the need for source replacement approximately every 4 to 5 years, poor field flatness for large fields and large penumbra, and lower depth dose compared with high-energy photons generated by medical linear accelerators, which are discussed later. Isocentric units with source-to-axis distance (SAD) of 80 or 100 cm were designed with maximum field sizes of 40 × 40 cm at the machine isocenter for the 100-cm SAD machine. Source activities vary from about 5,000 to 13,000 Ci in 1.5- to 2.0-cm-diameter sources and yield exposure rates from 150 to 250 R/min at 1 m. The radiation consists of 1.17- and 1.33-MeV γ-rays having a $d_{1/2}$ in tissue (the depth at which the dose has been reduced to 50% of the maximum dose value) of about 10 cm.

Cobalt teletherapy machines became a mainstay for radiation therapy for nearly three decades but are rarely used in U.S. clinics today. Cobalt-based teletherapy machines do remain a valuable radiotherapy solution in developing countries, though there are several active programs to provide economic solutions that do not rely on radioactive materials.

Gamma Knife

Elekta *Gamma Knife* (Elekta AB, Stockholm, Sweden) is a dedicated stereotactic radiosurgical device that was developed in 1968 by Dr. Lars Leksell,[29] a Swedish neurosurgeon. This machine initially made it possible to deliver a single, large dose of highly conformal radiation (γ-rays) precisely to a number of intracranial sites using multiple fixed ^{60}Co sources aimed at a center point. As the field of cranial stereotactic radiosurgery evolved, Gamma Knife started offering solutions for fractionated treatments, named *stereotactic radiotherapy*. In stereotactic radiotherapy patients are treated with several fractions of highly conformal doses without use of ring frames and relying on thermoplastic masks for immobilization. The Gamma Knife traditionally consisted of three basic components—a spherical source housing/gantry, four collimator helmets, and a couch with electronic controls. The source housing (models U, B, and C) contains 201

^{60}Co sources distributed in a quasihemispherical arrangement. The γ-rays from each source converge to the *unit center point* (*UCP*), which is 40 cm away from each source. The UCP is analogous to the isocenter of a teletherapy machine and is the location where the target volume must be positioned during a treatment. This is accomplished by the three-axis coordinate system on the Leksell stereotactic frame. Each source has an activity of approximately 30 Ci when newly installed, and the 201 sources combined provide a dose rate of approximately 300 cGy/min at the UCP. Along the path to the UCP, the radiation beam from each source is collimated twice—once by a primary collimator and then by one of four secondary collimator helmets. For each helmet, 201 tungsten collimators define specified circular apertures (4, 8, 14, or 18 mm projected at the UCP). To conform the radiation dose to the shape of the target in the patient, various combinations of aperture diameters, aperture blocking (*plugging*), irradiation times, and head positions are used. A specific combination of these four parameters defines what is referred to as a *shot* in Gamma Knife terminology. Hundreds of thousands of patients have been treated using this type of treatment machine.

Since 2006, Elekta has introduced three new models of Gamma Knife, the Perfexion, Icon, and Esprit. The Perfexion model, which was a major change in design from the previous models, had several advanced features, including an enlarged internal patient cavity for extended access to peripheral cranial anatomy. Unlike the earlier models, the Perfexion moves the entire patient on the couch to each stereotactic x, y, and z coordinate. The collimation was also placed within the source housing part of the machine gantry, eliminating the external helmets. The sources are arranged radially and divided into eight moving sectors with 24 sources each. Each sector is independently selectable, thereby providing various sector combinations for aperture (collimation) size or blocking at each shot position during treatment. With the introduction of its associated Extend System accessory, the Perfexion has an increased reach to allow treatments to the upper cervical spine.

In 2015, Elekta introduced the Gamma Knife Icon (Figure 6.16), which added image-guided radiation therapy (IGRT) imaging capability. The Icon enables cone beam computed tomography (CBCT)-based patient localization capability and intrafraction patient monitoring with infrared

camera. CBCT isocenter is placed away from the cobalt sources isocenter, but the two isocenters are linked in software and hardware and the Icon provides workflows for patient localization, treatment evaluation, and adjustments when needed. In this sense the Icon offers modern IGRT capabilities in combination with cobalt radiotherapy. In 2022, Elekta introduced the Esprit model, which included more efficient and rapid planning, workflow improvement including remote review of plans, and a redesigned patient positioning system.

FIGURE 6.16 Elekta's Leksell Gamma Knife (Elekta AB, Stockholm, Sweden) is a dedicated stereotactic radiosurgery system developed in 1967 by Prof. Lars Leksell, a Swedish neurosurgeon, designed to noninvasively treat intracranial targets—such as brain tumors and lesions—with extreme precision. Shown is the most recent system, Elekta Esprit, which includes the option of frameless or frame-based workflows and stereotactic cone beam CT imaging technology. (Courtesy of Elekta.)

Linear Accelerators

The first microwave electron linear accelerator (8 MV) for medical use became operational in 1953 at the Radiation Research Center of the

Medical Research Council at Hammersmith Hospital in London.[30] The design for an isocentric gantry mount for the accelerator first was conceived by P. Howard-Flanders.[31] Shortly thereafter, Ginzton et al[32] at Stanford University developed a 6-MV isocentric medical linear accelerator (*linac*). The history of the development of this first medical linear accelerator in the United States is provided by Jacobs.[33] Since then, there have been continued advances in accelerator design and construction, and today, medical linear accelerators account for most of the operational MV treatment units in clinical use.[24,34]

Figure 6.17 is a block diagram of a high-energy, bent-beam medical linear accelerator showing the major components. The linac uses electromagnetic waves of frequencies in the *S-band* microwave region (2,856 megahertz [MHz]) to generate an electric field. The microwave radiation is propagated through a device called an *accelerator structure*, and the electrons injected into the structure are accelerated by the electric field in a straight line. The accelerator structure consists of a stack of cylindrical metal cavities having an axial hole through which the accelerated electrons pass. The accelerator structure's electric field produced by the microwaves can be either a *traveling wave* or *standing wave* design. In a traveling wave design, the electrons travel with the electric field as the field propagates through the structure with time, somewhat like a surfboarder riding the crest of an ocean wave. In a standing wave accelerator, the reflected microwave power is used to produce a standing wave electric field. In that case, the microwave power is coupled into the accelerator structure by side-coupling cavities rather than through the accelerator structure's axial cavity apertures.

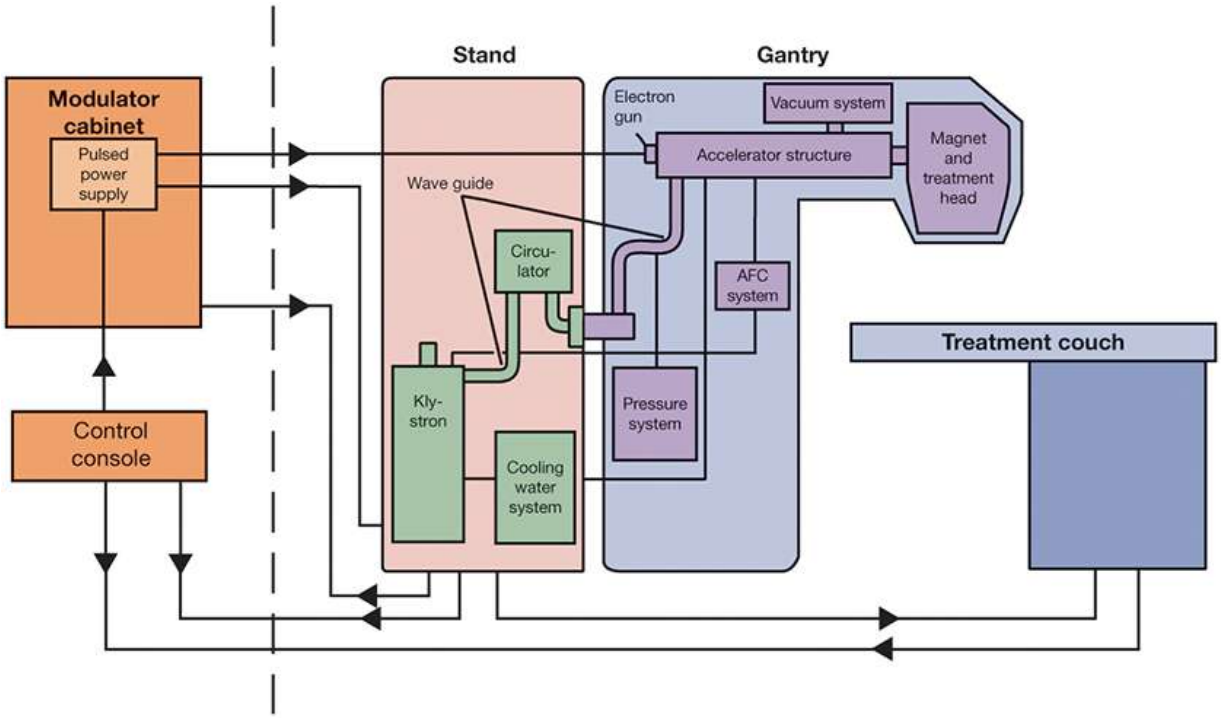

FIGURE 6.17 Schematic block diagram showing major components of a high-energy bent-beam medical linear accelerator. (Courtesy of Varian, Palo Alto, CA.)

The accelerator structure in low-energy (4-6 MV) linacs most often is mounted vertically in the treatment head collinear along with the components associated with producing, controlling, and monitoring the x-ray beam (Figure 6.18, left). High-energy (15-18 MV) linacs use a horizontally mounted accelerator structure with a beam-bending magnet system (Figure 6.18, right). Accelerator structure technology now makes multiple high-dose-rate photon beams of widely separated energies possible.

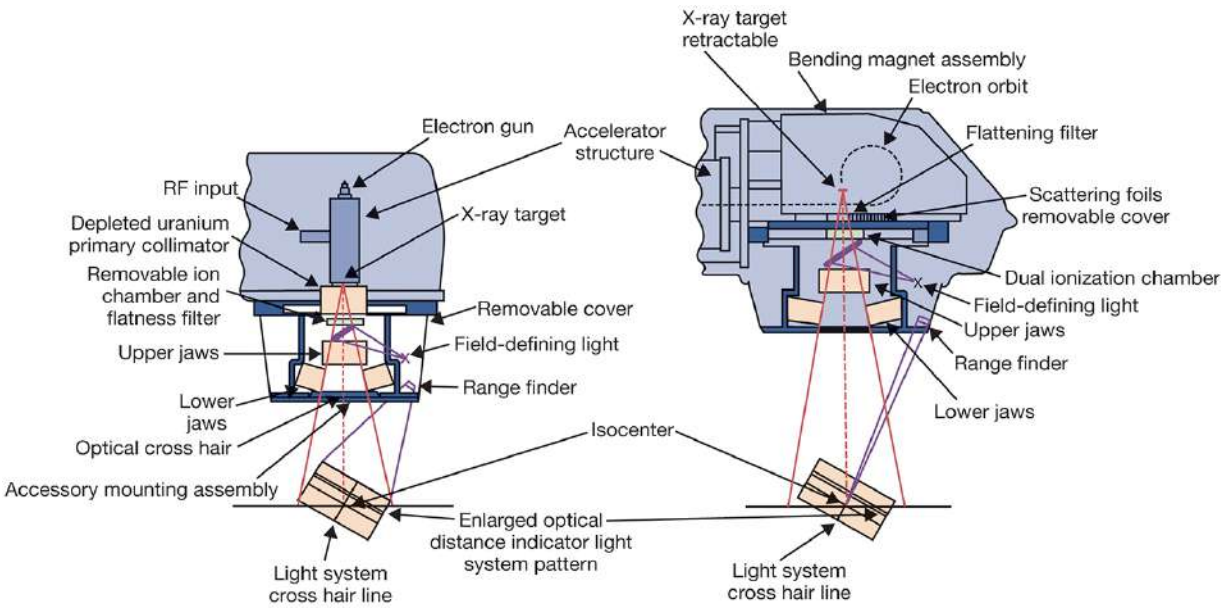

FIGURE 6.18 Schematic cutaway diagram of treatment heads for low-energy, straight-beam (left) and high-energy, bent-beam (right) medical linear accelerators. (Courtesy of Varian, Palo Alto, CA.)

Other important components of a linac are the modulator, microwave power sources, electron gun, and the beam-handling components. The modulator is the source of pulsed direct current (DC) power, needed for microwave power production. Pulsed DC power is also supplied to the *electron gun* (a hot-wire filament that serves as the source of the accelerated electrons). The electrons are bunched before acceleration by a device called a *buncher*. The electron beam thus consists of pulses of bunched electrons in the form of a narrow pencil beam. The magnetron serves as the source of microwaves and as a power amplifier. The *klystron* is a device used to amplify the microwave power that is generated from a separate microwave source (*radiofrequency driver*). The microwave power coming from the magnetron or klystron is transported to the accelerator structure by a metallic pipe called a *waveguide*. A device called the *circulator* is used to isolate the klystron/magnetron from the reflected microwave power.

Other important components in a linac are located in the treatment head. These include the *x-ray target*, *fixed primary collimator*, *scattering foils*, *flattening filter*, *monitor ion chamber, movable secondary collimator jaws and/or multileaf collimator* (MLC), *light field localizer*, and *optical distance indicator*. In addition, the treatment head contains a significant

amount of shielding material to minimize leakage radiation. A schematic diagram of all the treatment head subsystems for both x-ray and electron beams is shown in Figure 6.19.

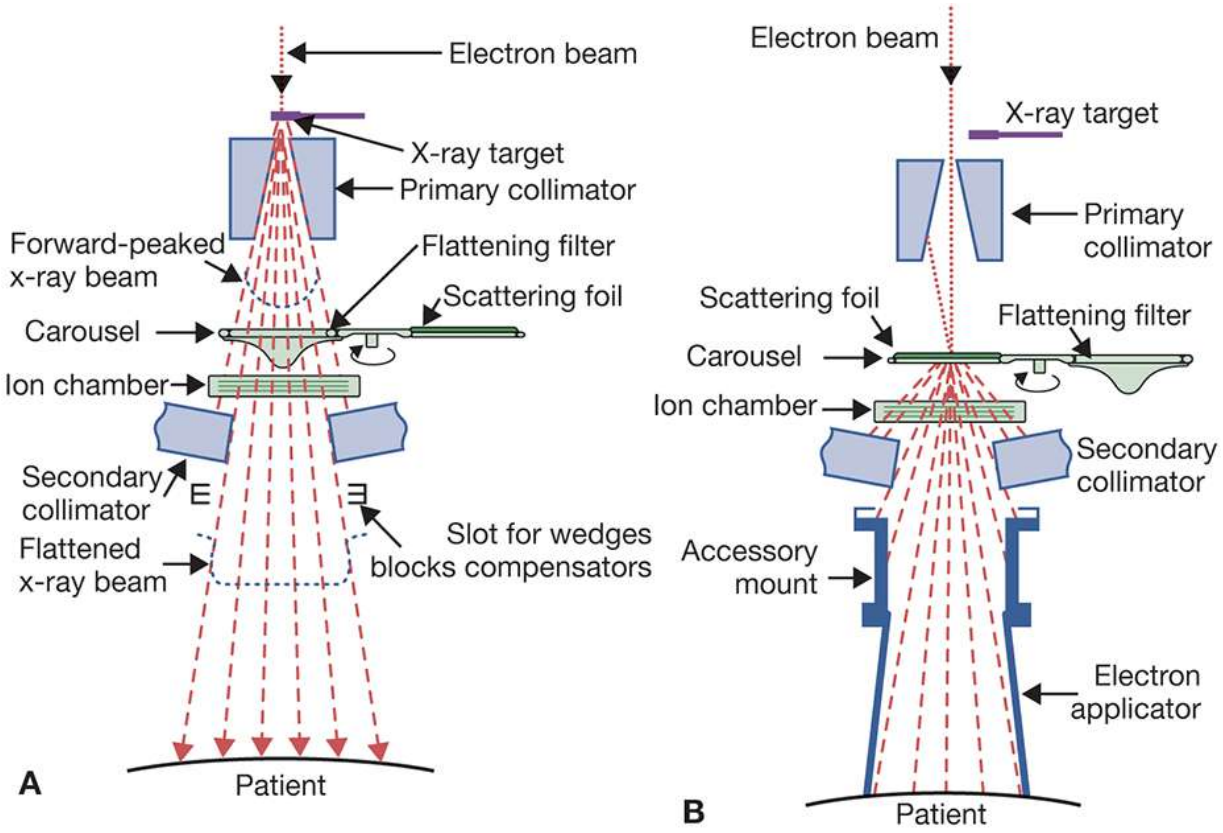

FIGURE 6.19 Schematic diagram of beam subsystems for x-ray beam (A) and electron beam therapy (B). (From Karzmark CJ, Morton RJ. *A Primer on Theory and Operation of Linear Accelerators in Radiation Therapy.* Department of Health and Human Services, Public Health Service, Food and *Drug* Administration, Bureau of Radiological Health; 1997.)

At the exit window of the accelerator structure, the high-energy electrons emerge as a pencil beam of about 2 to 3 mm in diameter. In a low-energy (4-6 MeV) linac, the accelerated electrons proceed in a straight line and strike an x-ray target when in photon mode, producing bremsstrahlung x-rays. In high-energy linacs, because the accelerator structure is much longer and is placed horizontally or at some angle with respect to the horizontal, the electrons must be bent through a suitable angle, usually 90° or 270° between the accelerator structure and the target. This is enabled by the beam

transport system, which consists of an *achromatic focusing and bending magnet*, as well as *steering* and *focusing coils*.

The *primary collimator* is a fixed collimator located just below the x-ray target and is used to collimate the x-ray beam in the direction of the patient treatment and reduces the leakage radiation from the x-ray source. The angular distribution of the bremsstrahlung x-rays produced by MV electrons incident on a target is forward peaked. To make the x-ray beam intensity uniform across the field, a conical metal *flattening filter* is inserted in the beam. Filters are constructed of lead, tungsten, uranium, steel, and aluminum (or some combination of these), depending on x-ray energy. The flattened x-ray beam then passes through a *monitor ionization chamber*. In most cases, this system consists of several transmission-type parallel-plate ionization chambers, which cover the entire beam. These ion chambers are used to monitor the field symmetry, dose rate, and integrated dose per monitor unit. In the 2010s, several linacs offering flattening filter-free beams were commercially introduced. Some of these systems provided only flattening filter-free beams, whereas some provided dual capability with and without flattening filters.

After passing through the monitor chamber, the beam can be further collimated by continuously and independently movable x-ray collimators consisting of two pairs of lead or tungsten jaws and/or an MLC system consisting of a large number of tungsten leaves arranged in an opposing configuration. Conventional linacs typically provided rectangular field sizes ranging from 0 cm to 40 × 40 cm at a distance of 100 cm. The field size can be defined by a *light localizer* and a *mirror assembly*. The introduction of independently movable collimators allowed simplified patient positioning and improved safety by avoiding overlapping field abutments without the necessity of using heavy beam-splitting blocks.[35] Independent jaw technology in conjunction with computer control of the dose rate can be used to create a wedge-shaped isodose pattern.[35]

Although the *MLC* systems (Figure 6.20) were initially developed to simplify beam shaping for 2D- and 3D-based conformal radiotherapy, their ultimate purpose excelled in *intensity-modulated radiation therapy* (*IMRT*) (discussed in Chapters 10), making them a prerequisite capability on all modern radiotherapy machines. The MLCs offered the ability to electronically and dynamically control beam shapes during treatment.

IMRT can be delivered in various combinations of MLC and gantry motions. With respect to MLC motion, IMRT can be delivered by (a) delivering multiple field segments (called *segmental MLC* or *step-and-shoot IMRT*) or (b) having the leaf pairs move across the field at a varying rate with the x-ray beam on (called *dynamic MLC* or *sliding window IMRT*).[36] With respect to gantry motion, the *volumetric modulated arc therapy* capability involves continuous gantry motion during delivery of typically coplanar beams,[37-39] while 4Pi delivery involves complex combinations of gantry, collimator, and couch rotations enabling highly conformal dose distributions with noncoplanar delivery.[40] Initial designs of MLCs relied on in-line opposing pairs of MLC leaves. Alternate MLC arrangements have been a long-standing topic of interest and double-focused and/or multilayer MLCs eventually became available. The double-focused MLCs offer improved penumbra compared to in-line MLCs by matching the leaf edge with the beam divergence across all field sizes. The in-line MLCs require a compromise of the beam penumbra as a function of the MLC position. The multilayer MLCs offer greater flexibility in field shape resolution, reduced leakage, greater speed, and simplification of operation. Recently, dual-stack MLCs have been introduced on O-ring accelerators, which are discussed later. Dual-stack MLCs offset one leaf bank by a half leaf width, effectively doubling the resolution of the MLC.[41] Additionally, the extra leaf bank provides sufficient attenuation that the secondary collimators can be eliminated.

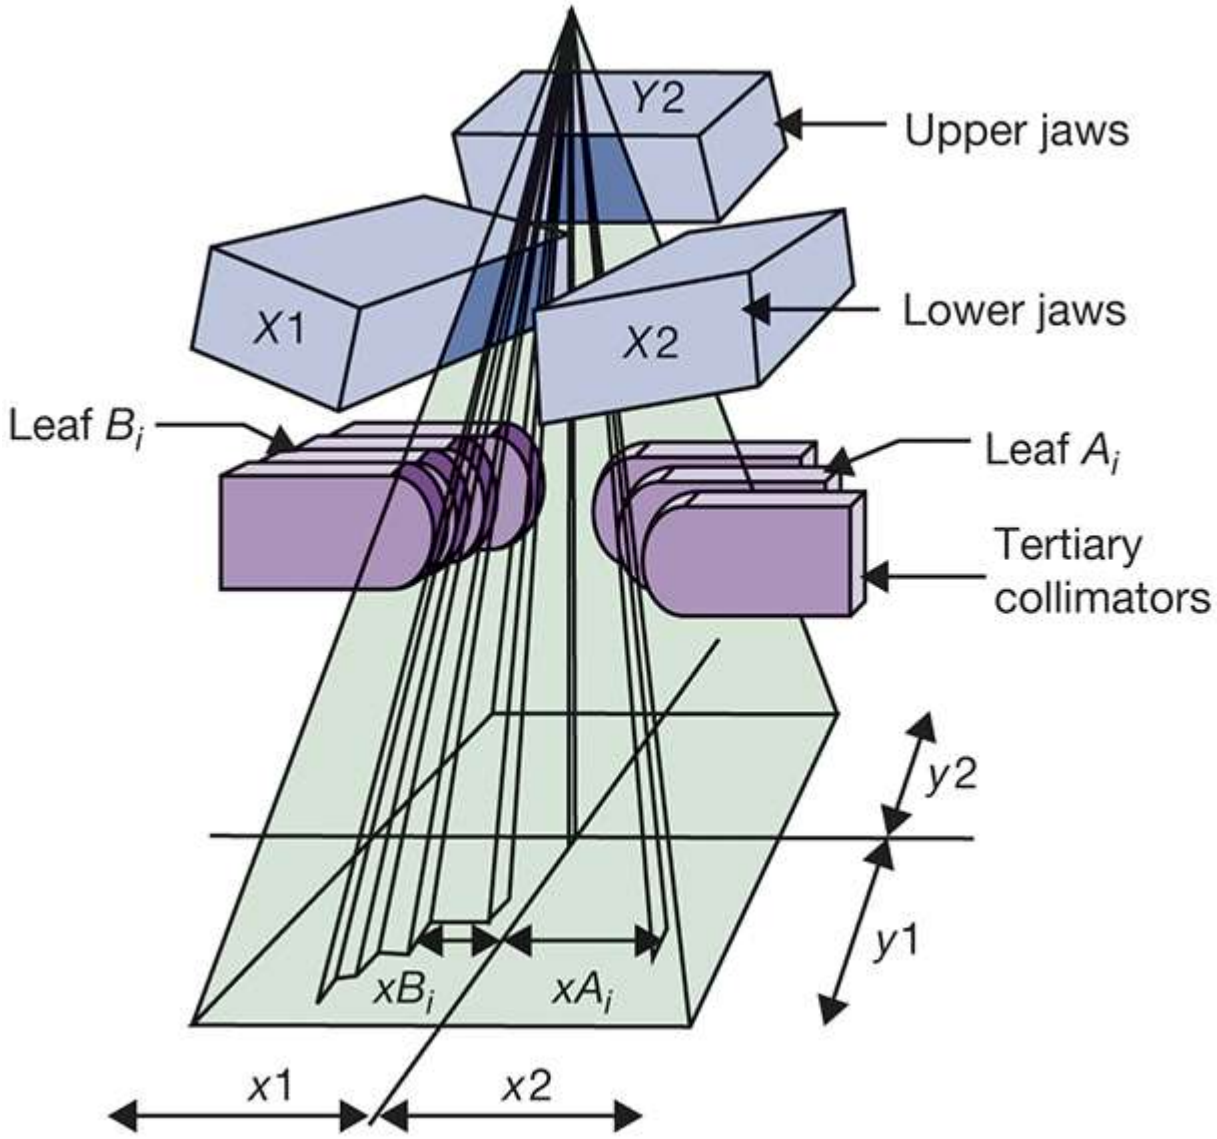

FIGURE 6.20 Schematic illustrating the geometry of a multileaf collimator for Varian linear accelerators. The *x*-direction is the field width across each leaf pair, and the *y*-direction is the field length. (Courtesy of Varian, Palo Alto, CA.)

In electron mode, the accelerator's beam current is reduced 1,000-fold and the x-ray target is retracted. An electron scattering foil is moved into place on the beam centerline so that the accelerated pencil electron beam strikes it to broaden the beam and produce a flat field across the treatment field. The scattering foil typically consists of dual lead foils. The thickness of the first foil ensures that most of the electrons are scattered with only a minimum of bremsstrahlung x-rays. The second foil is generally thicker in the central region and is used to flatten the beam across the field. The

bremsstrahlung produced appears as x-ray contamination of the electron beam and is usually less than 5% of the maximum dose. An *electron applicator* is mounted below the movable collimator jaws to provide the final field collimation.

Important new technical developments for improving external beam treatment planning and dose delivery for radiation therapy of cancer patients occurred in the late 1980s and early 1990s (see Chapters 10). Advances in medical imaging and computer hardware and software technologies led to the development of image-based 3D radiation treatment planning (3DRTP) systems and computer-controlled linacs having advanced delivery and treatment verification features. These advances were followed in the 1990s and 2000s with incorporation of volumetric imaging systems, either using the treatment beam or a standalone imaging source. The first commercial volumetric image-guided system was the tomotherapy system (see following section). Elekta integrated advanced imaging systems having kV *CBCT* capability on their C-arm linac (*Elekta Synergy*).[42,43] Such linacs are referred to as *IGRT* linacs (see Chapters 10). The Synergy IGRT system (referred to as XVI) consists of a retractable kilovolt x-ray source, an amorphous silicon flat-panel imager mounted on the linear accelerator perpendicular to the radiation beam direction, and a software module for processing the data and tools for registering the images (Figure 6.21). The XVI system provided planar, motion, and volumetric imaging capabilities. Registration software provided the ability to compare the daily patient setup image with the stored prescription computed tomography (CT)-planning image, after which table adjustments could be made prior to treating the patient. Other medical linac manufacturers also embraced the IGRT concept adding kV CBCT technology similar to the Synergy XVI, such as Varian Trilogy linac. Both Elekta and Varian have continued to improve their C-Arm IGRT linacs, the latest being the Elekta Harmony and Varian TrueBeam IGRT linacs. More detail about currently available IGRT systems is provided in the American Association of Physicists in Medicine (AAPM) Task Group Report 180.[44]

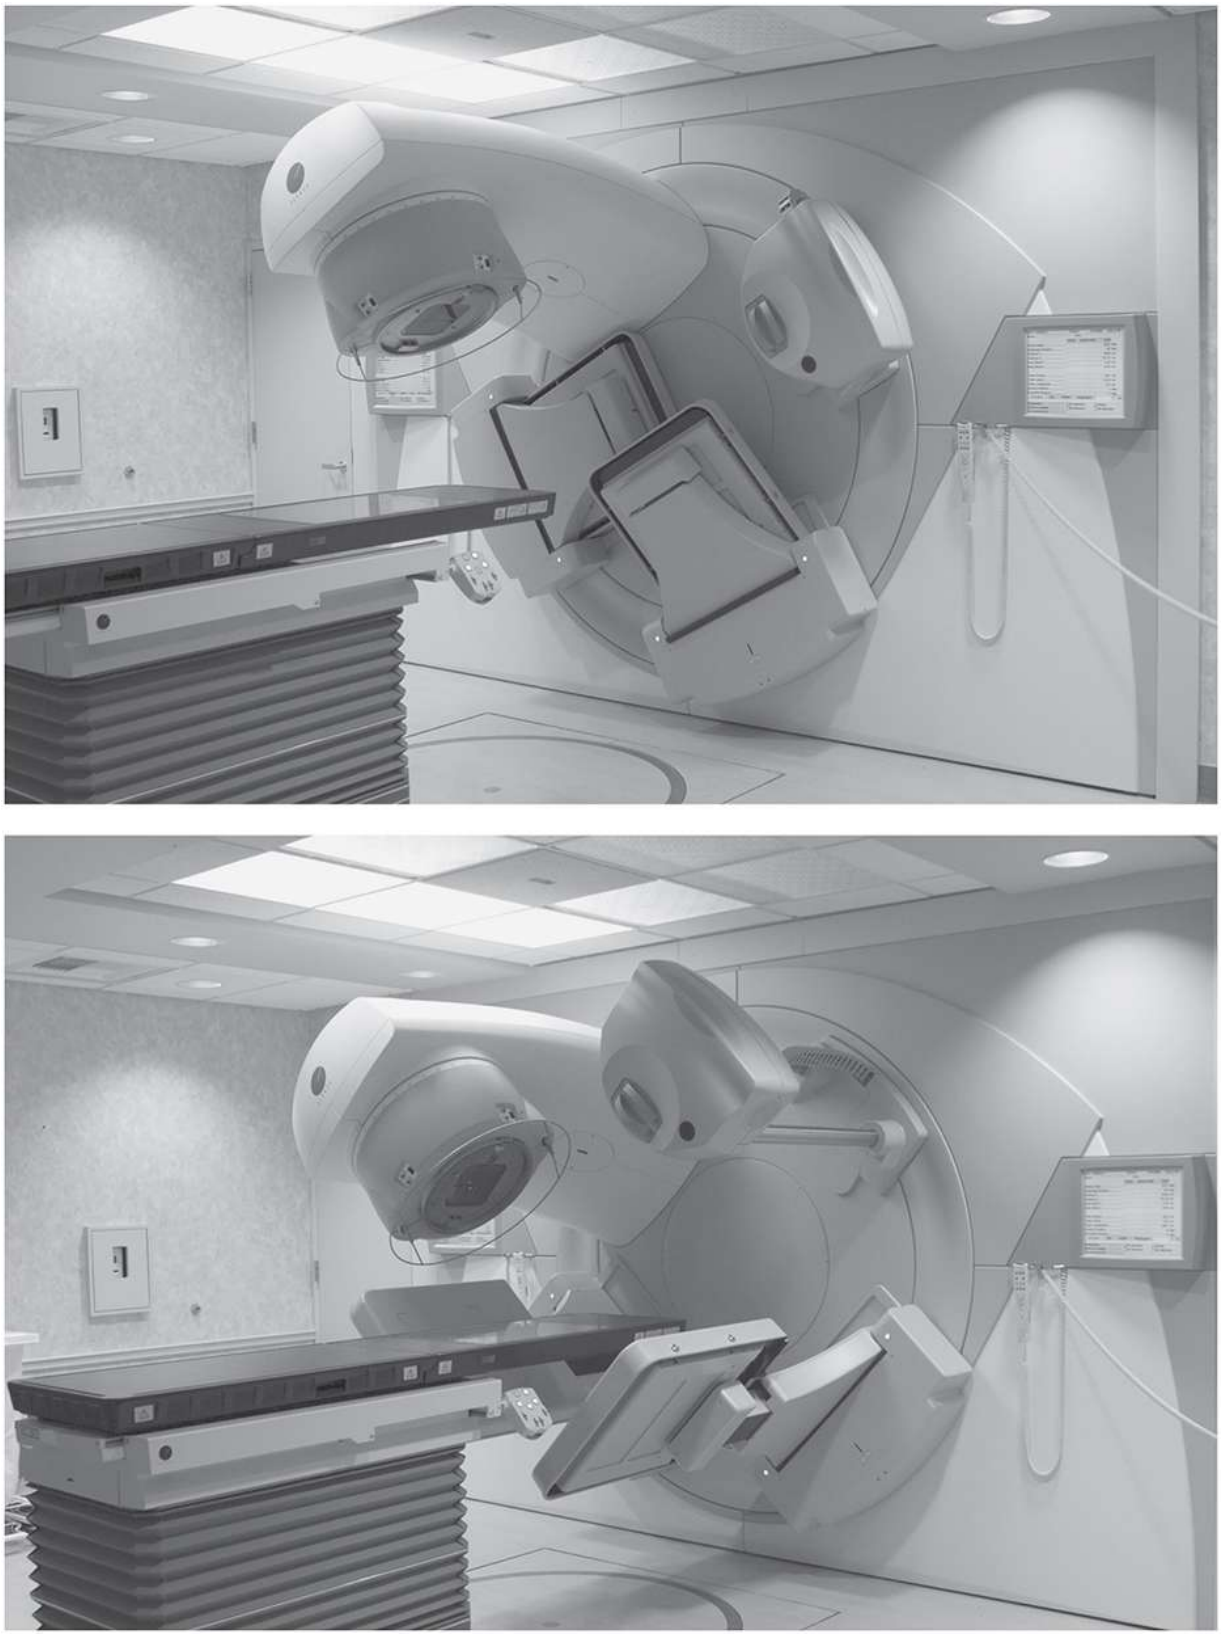

FIGURE 6.21 Elekta Synergy installed at the University of California Davis. The unit consists of a conventional multimodality medical linac with a retractable kilovolt x-ray

source, an amorphous silicon flat-panel imager mounted on the linear accelerator perpendicular to the radiation beam direction, and a software module (referred to as the XVI system). Top: The x-ray source, with the amorphous silicon flat panels retracted. Bottom: With the panels extended.

X-Ray-Guided O-Ring Linear Accelerators

Helical tomotherapy was first proposed by Mackie et al[45] and became commercially available as the TomoTherapy HI-ART system (Accuray, Madison, WI).[46] A short, in-line, 6-MV linac (Siemens Oncology Systems, Concord, CA) rotated on a ring gantry at a source-axis distance of 85 cm. This was one of the first IGRT systems, with CT-like detectors used to image the MV beam and generate a MVCT image. Figure 6.22 shows the unit installed at the University of California, Davis. The IMRT treatment is delivered while the patient-support couch is translated in the *y*-direction (toward the gantry) through the gantry bore in the same way as a helical CT study is conducted. Thus, in the patient's reference frame, the treatment beam is angled inward along a helix, with the midpoint of the fan beam passing through the center of the bore. Similar to helical CT, the treatment beam *pitch* is defined as the distance traveled by the couch per gantry rotation divided by the field width in the *y*-direction (typically between 0.2 and 0.5). The width of the beam in the y-direction is defined by a pair of jaws fixed for any patient treatment to one of three selectable values (1, 2.5, or 5 cm). Laterally, the treatment beam is modulated by a 64-leaf binary MLC, whose leaves transition rapidly between open and closed states. Each leaf has a projected width of 6.25 mm at the bore center, for a maximum possible open lateral field length of 40 cm. Intensity modulation is accomplished by varying the fraction of time different leaves are opened. The individual modulation pattern can change with angle (divided into exactly 51 projections over a full revolution). During the treatment, the gantry rotates at a constant velocity with a period ranging between 10 and 60 seconds/rotation. The extent to which a treatment beam projection is modulated is characterized through what is called the *modulation factor*, defined as the ratio of the maximum leaf open time to the average leaf open time for the projection. Pitch and maximum permissible modulation factor are new parameters that need to be specified by the treatment planner. Highly modulated treatments achieve greater conformality but inevitably

take longer to deliver. A helical MVCT image is acquired using the onboard xenon CT detector system and the 6-MV linac (detuned to 3.6 MV) with the leave fully opened when the patient-support couch is translated in the *y*-direction through the gantry bore. Registration software is provided to compare the daily patient setup image with the stored prescription CT planning image. More detail about currently available systems is provided in AAPM Task Group Report 306.[47]

FIGURE 6.22 TomoTherapy HI-ART system installed at the University of California Davis. A short, in-line 6-MV linac rotates on a ring gantry. Intensity-modulated radiation therapy treatment is delivered while the patient-support couch is translated through the gantry bore in the same way as a helical computed tomography study is conducted. The width of the beam in the patient-translated direction is defined by a pair of jaws that is fixed for any particular patient treatment, and laterally, the treatment beam is modulated by a 64-leaf binary multileaf collimator.

In 2017, Varian released the Halcyon system (Figure 6.23), an O-ring system with a straight-through 6-MV linac whose beam is collimated only by a dual-stack MLC[41] and was specifically designed to address challenges of deploying radiotherapy in low-resource settings. Some of the specific features include lower power consumption, a simpler installation process, easier serviceability, greatly simplified operation, and higher throughput than conventional machines. Halcyon is also designed to benefit from a treatment workflow that is purely IGRT based, whereby all treatments require MV image guidance and imaging dose is included in the treatment dose. The double-layer MLC is composed of offset 1-cm-wide leaves, which has been shown to provide significant dosimetric advantages.[41] In 2019, Varian released a second version that included a kV CBCT system. It is worth noting that all of the features that make this machine advantageous in emerging markets also make it attractive in developed settings. One pitfall is that the machine does not offer electron beam treatment capability. Another noteworthy point is that the system has an “O”-shaped design, as opposed to the conventional “C”-shaped design for Varian, Elekta, Siemens, etc, machines. This design joins a host of other advanced machines with “O” shape (Tomotherapy, ViewRay, and Elekta Unity) and potentially signals that this may become a more prevalent approach to radiotherapy patient treatments.

FIGURE 6.23 Varian Medical Systems' Halcyon introduced in 2017, which is specifically designed to provide highly efficient image-guided radiation therapy treatments. Note that the system does not offer electron beam treatment capability and has an "O"-shaped design, as opposed to the conventional "C"-shaped design used typically for other Varian and Elekta medical linacs.

Magnetic Resonance–Guided O-Ring Linear Accelerators

The ViewRay system (Figure 6.24), released in 2012, combines a 0.35-T split bore magnetic resonance imaging (MRI), which straddles a radiotherapy gantry housing three cobalt heads spaced 120° apart. Each head contains a nominal 15,000 Ci cobalt source mated to an MLC. The three sources contribute to the combined initial dose rate of approximately 600 cGy/min. The MRI scanner and radiotherapy gantry share a common isocenter enabling MR-based treatment localization as well as intrafractional treatment monitoring. The first MR-guided radiotherapy treatment occurred at Washington University in St. Louis on January 15, 2014. The clinical system relied exclusively on Monte Carlo–based dose calculation for treatments ranging from 2D-based radiation therapy to

IMRT. While ViewRay relies on cobalt sources, which inherently have a larger penumbra than linac-based systems (see further), the doubly focused MLCs offer superior collimation than those installed on contemporary linear accelerators, resulting in comparable treatment dose distributions between the two technologies.[48,49] In 2017, ViewRay released a linac version of the system that replaced the three cobalt units with a single 6-MV linac.

FIGURE 6.24 ViewRay system combines a 0.35-T split bore MRI with a radiotherapy gantry housing a single 6 MV linac with MLC for beam shaping and IMRT. The MRI scanner and

radiotherapy gantry shared a common isocenter enabling MR-based treatment localization as well as intrafractional treatment monitoring with MRI. IMRT, intensity-modulated radiation therapy; MLC, multileaf collimator; MRI, magnetic resonance imaging.

The initial ViewRay system also enabled a practical online adaptive radiotherapy workflow, during which patients could be imaged, a new plan generated, patient-specific quality assurance (QA) performed, and a treatment delivered, all within the same timeframe as conventional radiotherapy.[50,51] This also marked the initiation of the first practical online adaptive radiotherapy program, and Washington University treated the first online MR-guided adaptive radiotherapy treatment on September 8, 2014. This program quickly grew to include several hundred adaptive treatments within the first 2 years of operation.

In 2018, Elekta released the Unity system, an MR-guided system with a 7-MV linac and 1.5 T MRI unit.[52,53] The system uses an MLC with 7.1-mm-wide leaves and a single x-ray treatment head (Figure 6.25). Use of a diagnostic field strength enables use of standard sequences for both morphologic and functional (eg, diffusion-weighted) MRI. The Unity system is capable of on-table adaptation as described for the ViewRay system. Because the table cannot be moved laterally or vertically, plans for nonadaptive treatments can also be adapted to correct for patient setup variations instead of shifting the table.

Robotic Nonisocentric Treatment Systems

A small X-band (~10,000 MHz) linear accelerator mounted on an industrial robotic arm (Figure 6.26) was first developed for radiosurgery as the CyberKnife system.[54,55] The robotic arm provides the capability for aiming a narrowly collimated x-ray beam with any orientation relative to the target volume. The system uses two ceiling-mounted diagnostic x-ray sources and amorphous silicon image detectors mounted flush to the floor. The treatment is specified by the trajectory of the robot and by the number of monitor units delivered at each robotic orientation. During the patient's treatment, the CyberKnife system correlates live radiographic images with preoperative CT or MRI scans in real time to determine patient and tumor position repeatedly over the course of treatment.

FIGURE 6.26 CyberKnife robotic treatment system. This system is capable of non-isocentric treatment guided by ceiling-mounted stereoscopic x-ray units. (Reprinted from Ding C, Saw CB, Timmerman RD. Cyberknife stereotactic radiosurgery and radiation therapy treatment planning system. *Med Dosim*. 2018;43[2]:129-140. Copyright © 2018 American Association of Medical Dosimetrists. Proton, Heavy-Ion, and Neutron Beam Treatment Units

The first use of proton beams for radiation therapy is credited to Wilson,[56] who in 1946 pointed out the superior depth-dose characteristics provided by protons. Details on the history and development of proton beam radiation therapy (PBRT) machines are provided by Breuer and Smit[57] and DeLaney and Kooy.[58] PBRT is seeing increasing interest worldwide because its depth-dose characteristics show advantages over those of photon beams.[59]

In most existing or proposed proton and light-ion particle treatment facilities, either a *cyclotron* or a *synchrotron* is used to accelerate proton beams to sufficient energy (200-250 MeV) and beam intensity.

Cyclotron

The cyclotron (Figure 6.27) was invented by Ernest Lawrence of the University of California in 1929. It accelerates charged particles such as protons, deuterons, and light ions using a high-frequency, alternating voltage (potential difference) applied across two conducting D-shaped evacuated half-cylinders (Ds). A fixed magnetic field, perpendicular to the top of the two Ds, forces the charged particles to travel in a circular path. The charged particles accelerate only when passing through the gap between the two Ds. The beam spirals out to the edge of the container as the particle speeds increase. At this point, the particle speed approaches the speed of light. Proton beam energies of 200 to 250 MeV are considered adequate for most radiation therapy applications. Beam intensity from the accelerator must be adequate to overcome losses in the beam delivery system and provide tolerable treatment times.

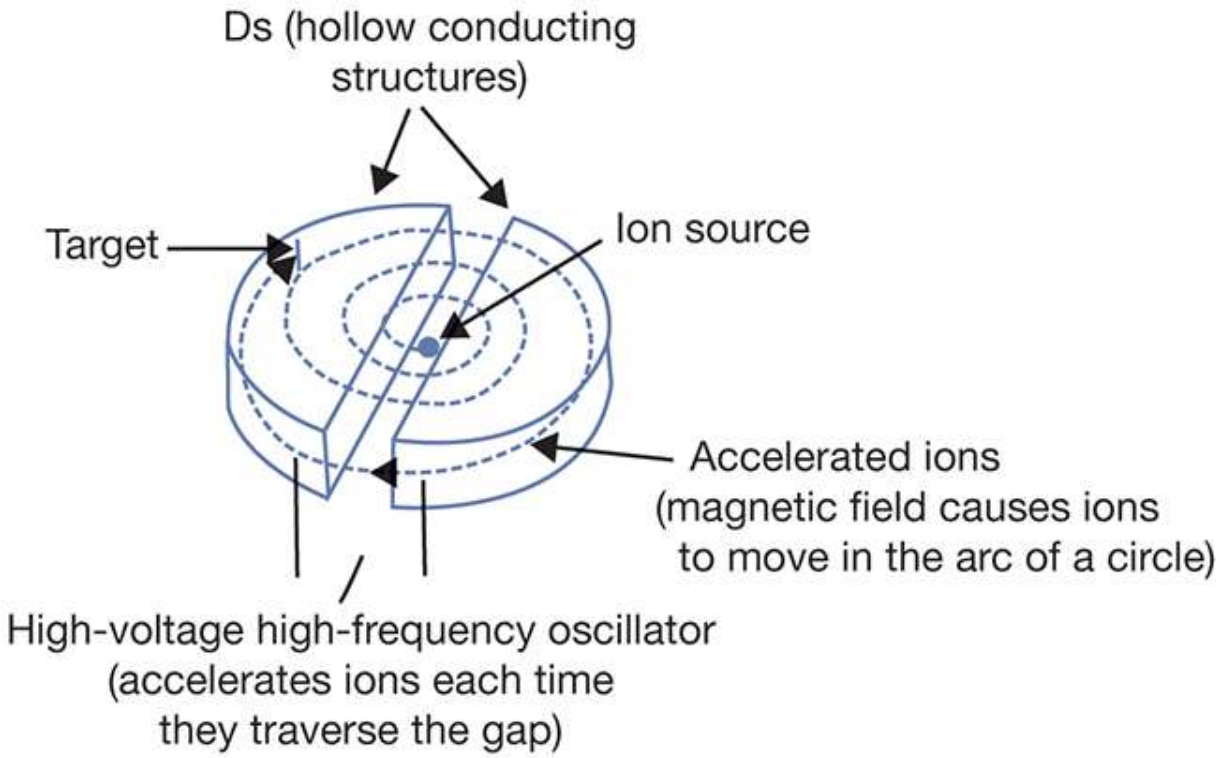

FIGURE 6.27 Schematic drawing showing principles of cyclotron operation. This machine is used for accelerating positive ions and is used clinically to produce proton and neutron beams. Metal half-disks (Ds) have an evacuated center through which the protons can travel. The protons are accelerated by an oscillating electric field operating between the half-disks. A magnetic field perpendicular to the plane of the half-disks confines the charged particles in the half-disks.

Synchrocyclotron and Synchrotron

A *synchrocyclotron* varies either the magnetic field or the frequency of the applied electric field; a *synchrotron* varies both. By increasing these parameters appropriately as the particles gain energy, one can hold their path constant as they are accelerated. This allows the vacuum container for the particles to be a large, thin torus. In reality, it is easier to use some straight sections and some bent sections using multiple bend magnets, thus creating the shape of a rounded-corner polygon. The proton beam facility at Loma Linda University Medical Center (Loma Linda, CA) uses this type of accelerator.[60]

The synchrotron has the advantage of simple energy variability, whereas the cyclotron produces continuous beams with a fixed energy and higher

beam intensity, making their design somewhat simpler. Beam-spreading mechanisms obtain suitable field sizes for radiation therapy by passive modulation (scattering foil) systems or by dynamic pencil-beam spot-scanning systems,[60] which allow dose conformation not only at the distal edge of the tumor but also at the proximal edge. Hall[61] pointed out that there is significant neutron leakage radiation for proton treatment machines that use a scattering foil and recommended moving to the pencil-beam scanning systems.

Proton and Heavy-Ion Treatment Machines

The initial clinical proton systems involved utilization of either physics research systems or commercial systems, which relied on multiroom solutions. Examples of early systems integrated with a hospital facility include multiroom proton centers at Clatterbridge Centre for Oncology, Loma Linda University Medical Center, and Massachusetts General Hospital. Currently, there are approximately 42 proton centers in the United States and 90 worldwide. Although the research systems enabled patient treatments, they did not allow broad-scale deployment of this technology. The commercial multiroom solutions enabled broader deployment of this technology, but the significant initial cost and the size of the operation limited deployment of this type of technology. Single-gantry proton systems reduced the overall cost of proton facility and offered a scale that was easier to deploy.

The first single-room proton solutions included the MEVION S250 Proton Therapy System (Mevion Medical Systems, Littleton, MA) shown in Figure 6.28 and IBA Proteus One (IBA, Louvain-La-Neuve, Belgium). The first Proteus One treatment occurred at Willis-Knighton Cancer Center in Shreveport, Louisiana, in September 2014, and the first Mevion S250 treatment occurred at Washington University in St. Louis, Missouri, in December 2014. This system uses a superconducting synchrocyclotron that is gantry mounted and incorporates image guidance and robotic patient positioning.

FIGURE 6.28 Single-room proton therapy system installed at Washington University. The system consists of a gantry-mounted 250-MeV synchrocyclotron specifically designed (uses

superconducting magnets) for proton therapy (with intensity-modulated proton therapy capabilities, high dose rate, high reliability, and easy maintenance). This photo shows the treatment room, including inner gantry and six-degree-of-freedom robotic couch. (Courtesy of Mevion Medical Systems., Littleton, MA.)

Several heavy-ion (carbon ion) radiation therapy facilities are now available in several centers in Asia and Europe,[15-17,59,62] and the first such facility in the United States will likely start construction in the next few years. Heavy-ion radiation therapy requires beams at much higher energies than proton therapy. For example, a proton beam of 150 MeV can penetrate 16 cm in water. To achieve the same penetration with carbon ions, energy of 3,000 MeV or 250 MeV/nucleon is needed. Synchrotrons are the only available sources for such high-energy ion beams, and they are large, complex machines requiring large facilities and similarly large capital expenditures.

Interest in heavy-ion radiation therapy is due primarily to its combination of two important physical advantages: its depth-dose characteristics and high LET in the Bragg peak region of the beam. For its depth characteristics, the ratio of the Bragg peak dose to the entrance region dose is even larger than for protons. In addition, there is a large increase in the radiation LET in the Bragg peak region of the beam. The combination of these two characteristics results in a potentially unique advantage of providing a high LET region that can be closely conformed to the target volume.

Neutron Therapy Treatment Machines

Modern neutron therapy machines use cyclotrons to accelerate protons or deuterons to energies of about 50 MeV to produce neutron beams with depth-dose characteristics equivalent to those of about 6-MV x-rays.[63] The p,Be (protons accelerated to strike a beryllium target) reaction is used most commonly because protons are much easier to bend around the gantry of an isocentric unit, and thus, the cyclotron can be much smaller and thus less expensive. The only exception is the superconducting cyclotron installed at Harper Hospital (Detroit, MI), which uses the d,Be (deuterons strike beryllium target) reaction.[64] With superconducting technology, the entire cyclotron is small enough to be rotated around the patient on isocentric

rings, thus eliminating the need for bending the deuteron beam around a rotating gantry. In addition, the neutron yield for the d,Be reaction is about 5 times that for the p,Be reaction. More details on the history and development of neutron beam therapy machines are provided in the review by Maughan and Yudelev.[65]

New and Evolving Treatment Machines

There are several other new treatment machine designs that show significant clinical promise.

Biologically Guided Radiotherapy

The functionality of positron emission tomography (PET) has been combined with that of a photon-producing linear accelerator in the RefleXion X1 (RefleXion Medical, Hayward, CA) (Figure 6.29). The goal is to use the PET emission signal as a tumor fiducial to guide radiotherapy in real time in a continuous feedback loop. To achieve this response with high speed while minimizing latency, several technologic innovations have been introduced including high rotational speed (60 rpm) and the design of high-speed MLCs that can move leaves at 100 MHz. The first clinical system was installed at Stanford University. More details about this technology can be found in the article by Shirvani et al.[66]

Very-High-Energy Electron Beams

Several investigators have also pointed out the utility of very-high-energy (VHE) electron beams (150-250 MeV).[67,68] Currently, only national and international laboratories are capable of producing such beams, but development is underway for a clinical system. The review article by Ronga et al provides more details about historical developments and the current status of VHE beams.[69]

Ultra-High-Dose-Rate Radiotherapy

Recent studies in animal models have demonstrated that treatment with ultra-high-dose rate radiotherapy, which is referred to as FLASH radiotherapy, may increase the therapeutic ratio due to normal tissue sparing.[70] For example, animal studies have demonstrated significant sparing of normal tissue in several organs.[71] Dose rates, which are on the order of 40 Gy/s, are much higher than can be produced by current clinical treatment machines. Thus, innovations in machine design are underway in order to facilitate the production of beams with FLASH capability for a variety of particle beams including electrons, photons, and protons[70] outside of large-scale beam lines such as synchrotrons. Access to such technology will enable investigators to probe the underlying biologic and immunologic mechanisms that are leading to the unexpected therapeutic advantage and facilitate the safe translation to clinical use.[72]

SIMULATORS

Conventional Simulator

Details on the development of the *radiation therapy simulator* and the selection, acceptance testing, and QA of conventional radiation therapy simulators are provided in the textbook by Van Dyk.[73] The conventional simulator mimics the functions and allowed motions of a therapy unit and uses a diagnostic x-ray tube to simulate the radiation properties of the treatment beam (Figure 6.30). A simulator allows the beam direction and the treatment fields to be determined to encompass the projection of the target volume. Radiographic visualization of internal structures in relation to external landmarks allows special shielding devices (Cerrobend blocks) to be constructed to help minimize the dose to normal critical structures. Gantry arms are rigid enough to support heavy shielding blocks and

simulated electron cones. Couch widths are similar to therapy-unit couch widths, and operating consoles feature digital displays of parameters and programmable settings for SAD, gantry angles, and field sizes. Older models of conventional simulators were equipped with an x-ray fluoroscopy system consisting of an image intensifier and video camera system to expedite field setup and beam angulations. Modern simulator design has replaced the image intensifier with amorphous silicon technology. The new imagers produce high spatial- and contrast-resolution images that approach film quality, facilitating the concept of filmless radiation oncology departments, and provide CBCT capability. Although this feature allows volumetric imaging on a conventional simulator, they have been nearly completely replaced with CT simulators.

Computed Tomography Simulators

In the 1980s and early 1990s, research led to the integration of a diagnostic CT scanner with what was essentially a 3D treatment planning system, which led to the concept of *virtual simulation*.[74-76] Such a system is now

referred to as a *CT simulator* and consists of a CT scanner, a flat-tabletop patient position–alignment system, including an orthogonal laser system, and a digital interface (Digital Imaging and Communications in Medicine) to a planning system that is equipped with virtual simulation software (Figure 6.31). Modern CT simulation systems incorporate large-bore CT scanners especially designed for radiation oncology, with multislice capability, high-quality laser patient positioning/marking systems, and sophisticated virtual simulation software features. Conventional diagnostic CT scanners are typically equipped with 70-cm-diameter bore, whereas large-bore scanners have openings 80 to 90 cm in diameter. While the CT scanners used for CT simulation tend to be specifically designed for radiation oncology, there has been a steady adoption of technology developed for diagnostic purposes to CT simulators. Most of this technology concentrates on ever-evolving image reconstruction improvements as well as improvements in image acquisition technology. For example, iterative image reconstruction techniques and dual kV acquisition have found application in radiotherapy. Details of the virtual simulation process are discussed in some detail in Chapters 10. More details on CT simulation can be found in the review article by Van Dyk[73] and articles by Mutic et al.[77,78]

New and Evolving Simulation Machines

PET/CT simulators and MR simulators have been available for radiotherapy purposes for a while. The adoption of this technology has been relatively modest and is somewhat limited by reimbursement practices and generally good access to these modalities through diagnostic radiology departments. Recent developments in radiotherapy treatment planning based on functional imaging and monitoring of response to therapy may increase the presence of MR- and PET-based simulators.[79,80] However, this will likely need to be facilitated by clinical evidence, which would result in modifications of reimbursement practices to allow broader use of multimodality scanners in radiotherapy departments.

QUALITY OF RADIATION

The penetrability of an x-ray beam, referred to as the *quality* of the beam, is completely specified by its spectral distribution curve (ie, the relative

intensities of photons of various energies), which is the result of fluctuations of tube potential, the bremsstrahlung radiation process, characteristic radiation, and multiple interactions of the incident electrons and the x-ray target. The distribution of the photon energies, including the peak photon energy, in the continuous spectrum is governed solely by the x-ray tube potential. However, the energy of the characteristic photons increases with increasing atomic number of the target element. All other factors being equal, the radiation intensity is proportional to the atomic number of the target element.

Spectral distribution of an x-ray beam can be modified by placing absorbing materials of various thicknesses (ie, filters) in the beam. In general, a filter removes relatively more low-energy photons than high-energy photons, although photons of all energies are removed to some extent. For radiation in the orthovoltage region (except for the absorption edge effect), the lower the energy of the photons, the larger is the total mass attenuation coefficient and therefore the greater is the likelihood that the photon will be absorbed. Thus, the beam emerges from the filter with a larger percentage of high-energy photons than it had on entering the filter. The beam has a greater penetration power and is said to have been "hardened" by the filter. The quality of an x-ray beam improves with increasing tube potential and with increasing thickness and atomic number of the filter.

A specification of beam quality based entirely on a spectral distribution is too cumbersome for radiation therapy. The usual method of specifying beam quality in superficial and orthovoltage therapy is to list the HVL and the accelerating potential. For MV beams, only the maximum energy of the electrons striking the x-ray target typically is used. The *homogeneity coefficient* denotes how homogeneous an x-ray beam is with respect to its photon energies. It is defined as the ratio of the first HVL to the second HVL. As the filtration is increased, the exposure rate decreases; therefore, there is a practical limit of filter thickness in orthovoltage therapy with a given combination of kilovolts, milliamperes, and treatment distance. In certain situations, it is convenient to express the quality of the x-ray beam in terms of an "equivalent energy," which can be derived from knowledge of the HVL. The type of x-ray beam that is used in radiation therapy is always heterogeneous; however, the x-ray beam can be considered to have

an *equivalent energy* of a monoenergetic x-ray beam that has a HVL equal to the measured HVL of the heterogeneous beam.

RADIATION EXPOSURE

In 1928, at the Second International Congress of Radiology, the ionization of air, called *exposure*, was adopted as the measurable effect of radiation of a photon beam.[81] As the beam passes through a material, it creates ion pairs via the ionization process. In air, these ion pairs have some mobility and can be collected by applying an electric field across the air. The number of ion pairs collected is a measure of the quantity of radiation passing through the air.

The *roentgen* (R), the unit for exposure, also was defined at the 1928 Congress. The definition has been modified slightly by subsequent congresses, but the basic concept remains the same. The roentgen is that amount of x- or γ-radiation that causes the associated corpuscular emission per 0.001293 g of air to produce, in air, ions carrying one electrostatic unit of charge of either sign. The value 0.001293 g is the mass of 1 cm^3 of air at 0 °C and 760 mm Hg pressure; "associated corpuscular emission" refers to the Compton and pair-production electrons set in motion by the interactions between the incident photons and the air molecules. By conversion of units, the roentgen can be expressed as follows:

$$1R = 2.58 \times 10^{-4}\ C/kg\ of\ air$$

With the advent of SI units, the roentgen no longer is used as a special name for a radiation unit, and the SI unit for exposure is Coulombs per kilogram (C/kg), which is equivalent to approximately 3,876 R (Table 6.2).

The condition of electronic equilibrium must exist for the definition of the roentgen to be satisfied (Figure 6.32). According to the definition, the electrons produced in a specified volume must spend all of their energies by ionization in air, and the total charge must be measured. However, because some electrons produced inside the specified volume create ion pairs outside the volume and some electrons produced outside the volume contribute ionization inside the specified volume, the gain and loss of ion pairs must be the same for the definition of the roentgen to be satisfied.

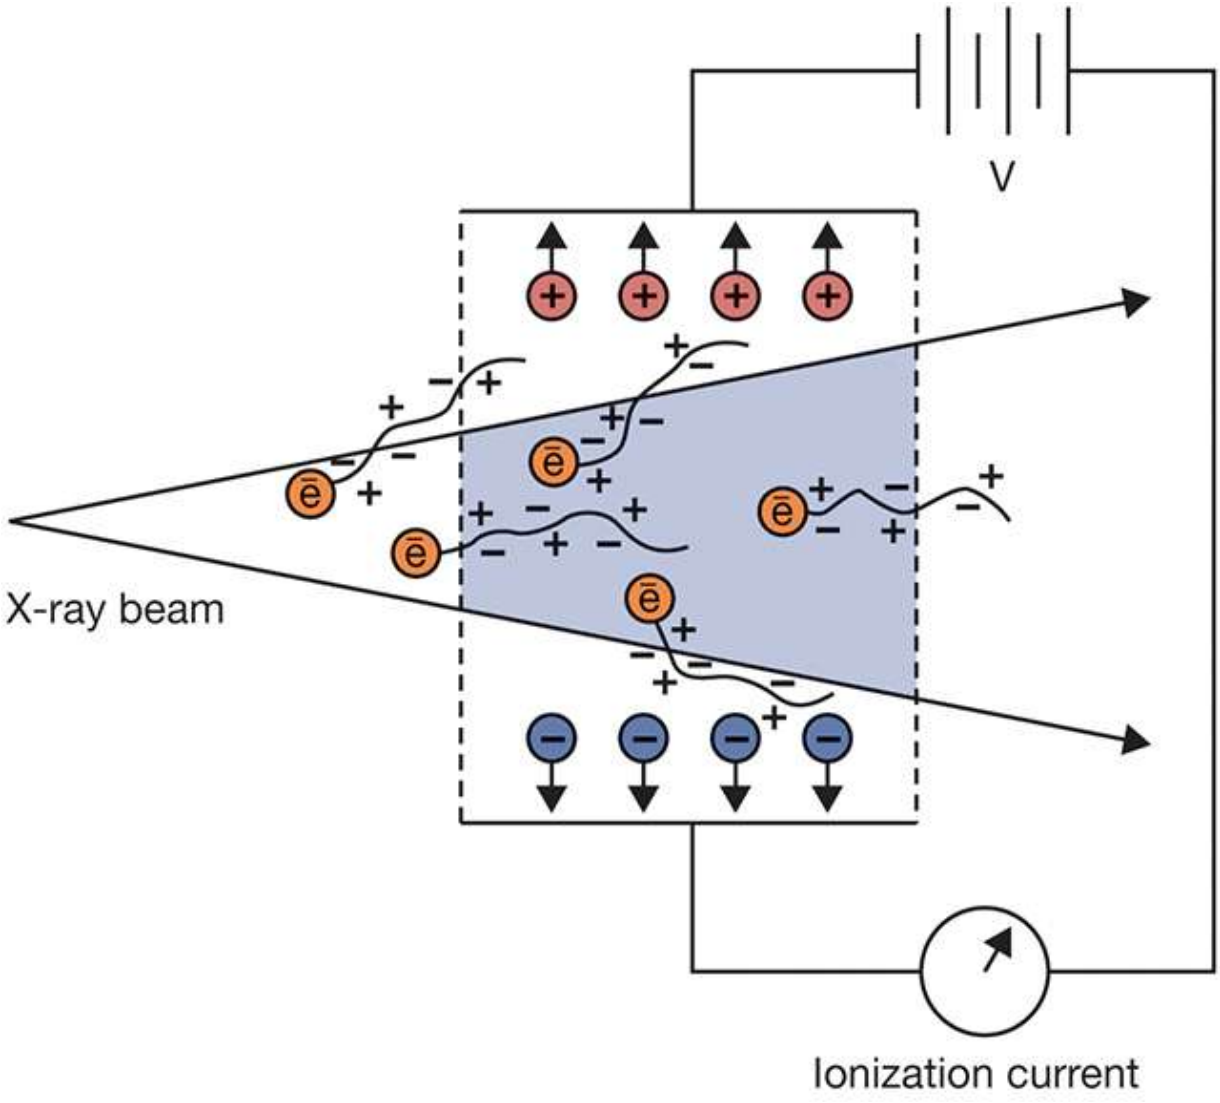

FIGURE 6.32 Schematic illustrating electronic equilibrium. (Reprinted with permission from Khan FM. *The Physics of Radiation Therapy*. 2nd ed. Williams & Wilkins; 1994.)

The free-air ionization chamber is used to measure exposure directly in roentgens.[1] It is designed to collect all the ions produced in a defined volume by the radiation beam and is used primarily by standards laboratories. Free-air chambers are bulky and too complicated to use for routine measurements. Instead, small ionization chambers called *thimble chambers* are typically used to measure exposure. The chamber measures the ionization produced, which is converted to exposure in roentgens by applying an exposure calibration factor, N_x, traceable to the National Institute of Standards and Technology (Gaithersburg, MD). Thimble

chambers are designed for use at specific energies; the thickness of the chamber wall is equal to the maximum electron range (electronic equilibrium established). If they are used at higher energies, at which the electron range is greater, an added wall thickness or *buildup cap* must be used.

To determine the exposure rate from an x-ray or γ-ray machine, an exposure-calibrated thimble chamber (with appropriate wall thickness) and connected to an *electrometer* is placed at the beam center, in air, at right angles to the beam's central axis and at the point where the exposure rate is to be specified. The field size for which the exposure rate is to be measured is set, and the radiation machine is turned on for a specified time, T, to achieve a reading, M, on the connected electrometer. The reading is corrected for *temperature and atmospheric pressure*, *timer error*, *stem effect*, and *ion-recombination effects*. The therapy machine exposure rate, X, is given in roentgens per minute by the following equation:

$$\dot{X} = \frac{M \cdot N_{\mathrm{x}} \cdot C_{\mathrm{tp}} \cdot C_{\mathrm{st}} \cdot C_{\mathrm{s}}}{T + \alpha}$$

where M is the raw ionization chamber reading, N_{x} is the exposure calibration factor obtained from a standards laboratory, C_{tp} is the temperature and pressure correction factor, C_{st} is the stem effect correction factor, C_{s} is the ion-recombination correction factor, T is timer (minutes) or monitor unit setting, and α is the timer error. The temperature-pressure correction factor C_{tp} is given by the following equation:

$$C_{\mathrm{tp}} = \left(\frac{t + 273.16}{295.16}\right)\left(\frac{760}{p}\right)$$

The timer error α is given by the following equation:

$$\frac{M_1}{T+\alpha} = \frac{M_2}{T+n\alpha}$$

where M_1 is the instrument reading for a single long exposure of T, M_2 is the instrument reading for n short exposures of total time T, and α is the timer error (monitor end effect for linacs) for a single exposure.[82]

Beyond 3 MeV, the roentgen cannot be measured accurately, and thus calibrations of radiation therapy machines at these higher energies are performed using an exposure-calibrated ionization chamber such as a Bragg-Gray cavity, and the ionization readings are converted to absorbed dose as discussed in the following section.

ABSORBED DOSE

In 1953 the ICRU introduced the concept of *absorbed dose* and defined its unit, the *rad*.[81] Before its definition can be presented, the reader must understand the concept of dose absorption. As a beam of radiation passes through an absorbing medium, it interacts with it in a two-stage process. The first step occurs when energy carried by the photons—the indirectly ionizing particles—is transformed into kinetic energy of high-speed electrons; the second step occurs as these electrons—the directly ionizing particles—are slowed down and deposit their energy in the medium.

Kerma, an acronym for "kinetic energy released in the medium," represents the transfer of energy from the photons to the directly ionizing particles (step 1). The subsequent transfer of energy from the directly ionizing particles to the medium (step 2) is represented by the absorbed dose and is defined in terms of the energy deposited by the radiation beam as it passes through the medium. The relationship between kerma and absorbed dose is illustrated in Figure 6.33.

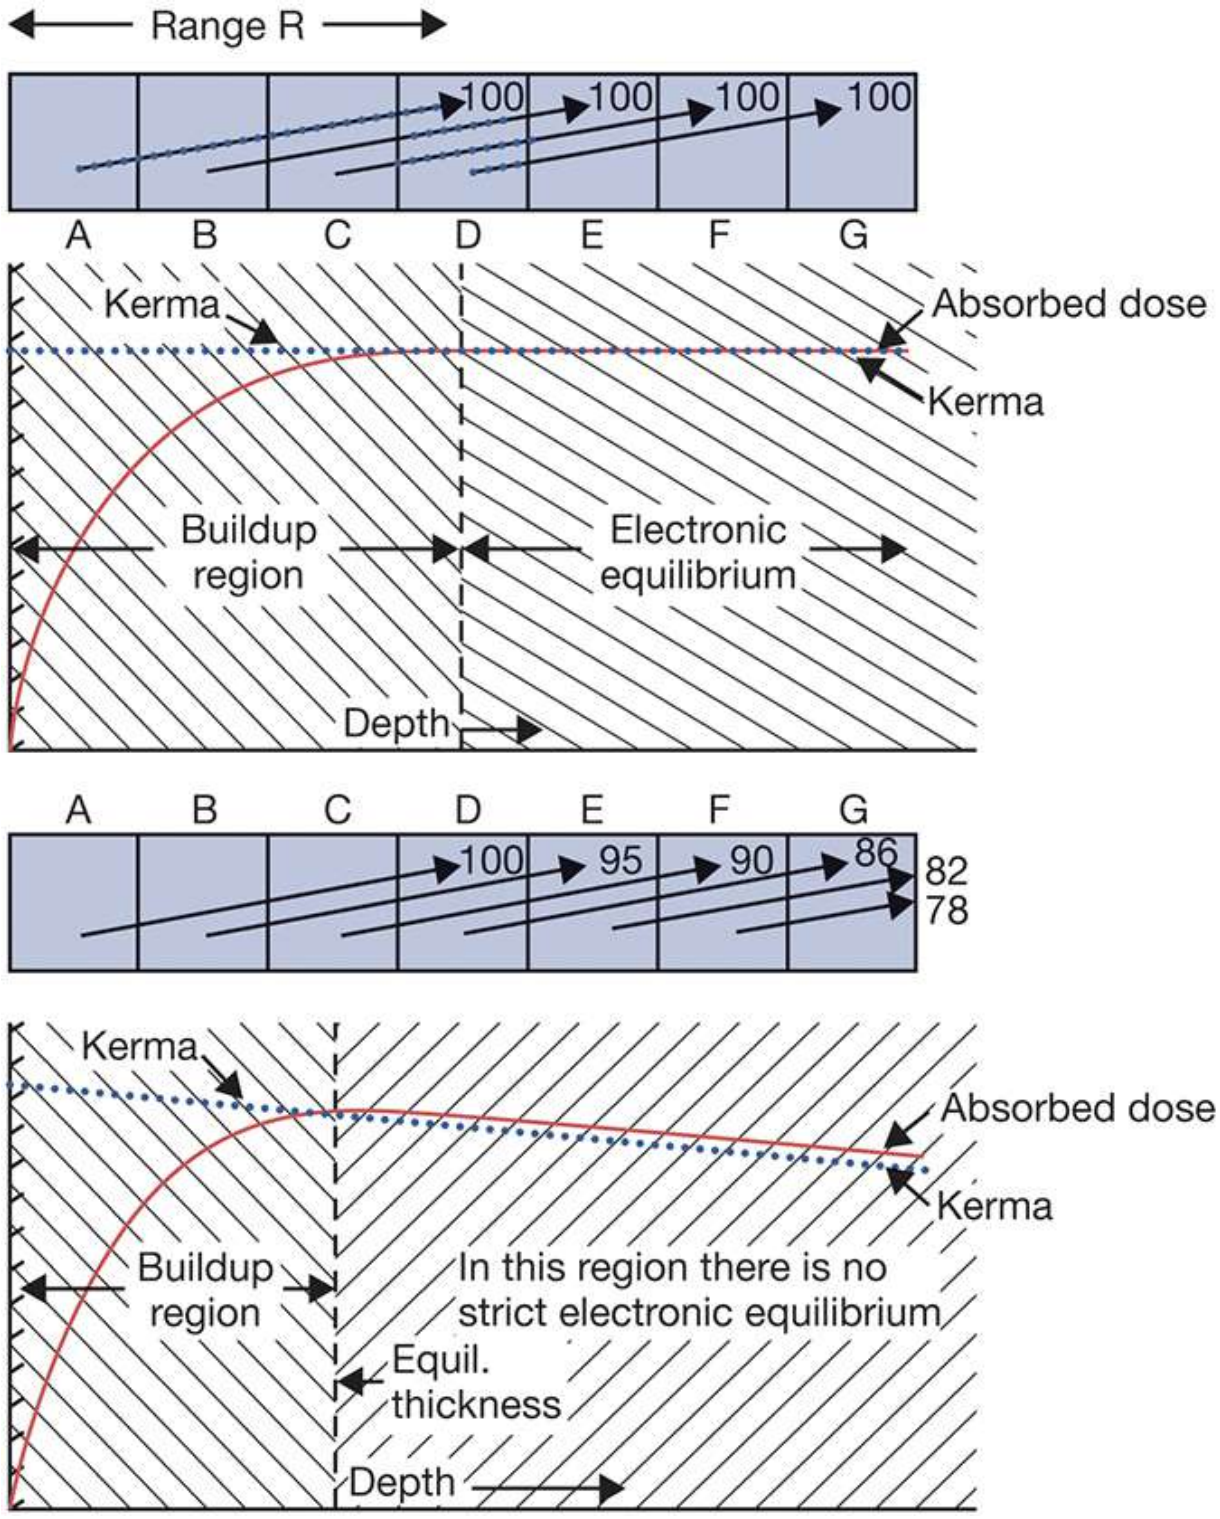

FIGURE 6.33 Graphs showing schematic relationship of kerma and absorbed dose. (From Johns HE, Cunningham JR. *The Physics of Radiology*. 4th ed. Charles C Thomas; 1983:222. Courtesy of Charles C Thomas Publisher, Springfield, Illinois.)

The *rad* represents the absorption of 0.01 J/kg of the absorbing material (1 rad = 0.01 J/kg). The rad now has been replaced with the SI unit for absorbed dose (1 J/kg) given the special name of *gray* (*Gy*) (Table 6.2). By conversion of units, the gray can be expressed as follows:

1 Gy = 1 J/kg= 100cGy = 100rad

Determination of Absorbed Dose

It is difficult to measure absorbed dose directly, but two direct methods—*calorimetry* and *Fricke dosimetry*—are available in some laboratories. Neither method is particularly practical nor widely used, and the reader is referred to the literature for more details.[83] Instead, a simpler, indirect method using an exposure-calibrated ionization chamber is used to determine absorbed dose.

Absorbed Dose Calculation From Exposure Measurement

For photon energies of ^{60}Co and lower, an ionization chamber having an exposure calibration factor assigned by an appropriate national calibration facility (eg, a dosimetry calibration laboratory accredited by the National Institute of Standards and Technology or the AAPM) can be used to measure exposure in air as described in the section "Radiation Exposure." Absorbed dose then can be calculated from the exposure as explained here. The energy deposited in a fixed mass of air from a known exposure can be calculated because it is known that an exposure of 1 R creates a finite number of ion pairs per unit mass of air (ie, 1.61×10^{15} ion pairs per kilogram of air) and that the mean energy required to create an ion pair in air (denoted by W) is equal to 33.97 eV per ion pair. When these values are used, the relationship between the exposure, X, and the dose to air, D_{air}, is given by the following expression:

$$D_{air}\,(\text{rad}) = 0.876\left(\frac{\text{rad}}{R}\right)\cdot X\,(R)$$

The *dose in free space*, D_{fs}, is defined as the dose at the center of a small mass of phantom-like material just large enough to provide electronic equilibrium (Figure 6.34) and can be derived from D_{air} using the ratio of the mass energy–absorption coefficients (u_{en}/ρ) and an attenuation correction factor, A_{eq}, that accounts for the photon attenuation in the small mass of phantom-like material:

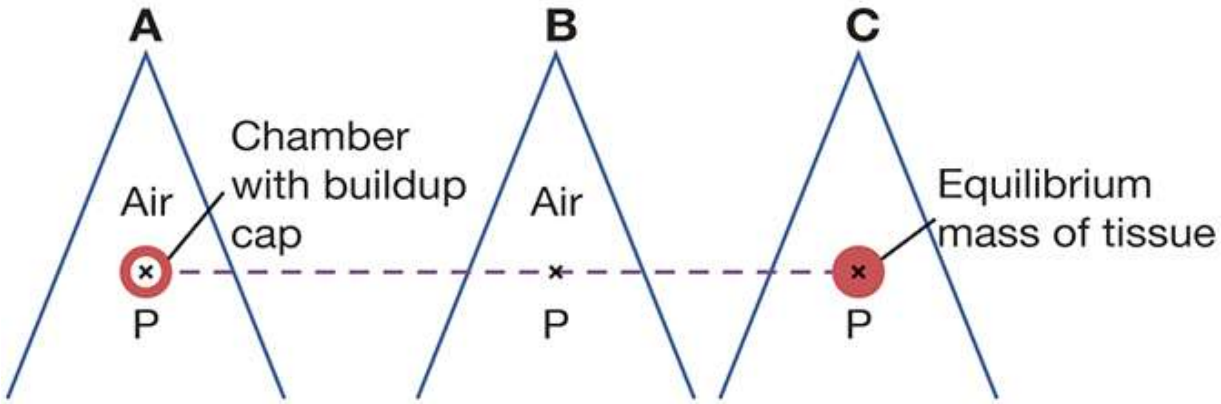

FIGURE 6.34 Schematic illustrating ionization measurement in air to determine dose in free space. (Reprinted with permission from Khan FM. *The Physics of Radiation Therapy*. 2nd ed. Williams & Wilkins; 1994.)

$$D_{fs} = \left[0.876 \frac{\mu_{en}\rho_{med}}{\mu_{en}\rho_{air}} \right] \cdot X \cdot A_{eq}$$

The term in brackets is called the *f-factor* or the *roentgen-to-rad conversion factor* and is represented as f_{med}, giving the dose in free space as follows:

$$D_{fs} = f_{med} \cdot X \cdot A_{eq}$$

Values of f_{med} are shown in Figure 6.35 over the energy range commonly used in radiation therapy. Notice that the *f*-factor is a function of the medium and the energy of the photon beam. Typical values of A_{eq} are 0.989 and 1.00 for ^{60}Co and 250-kV energies, respectively.

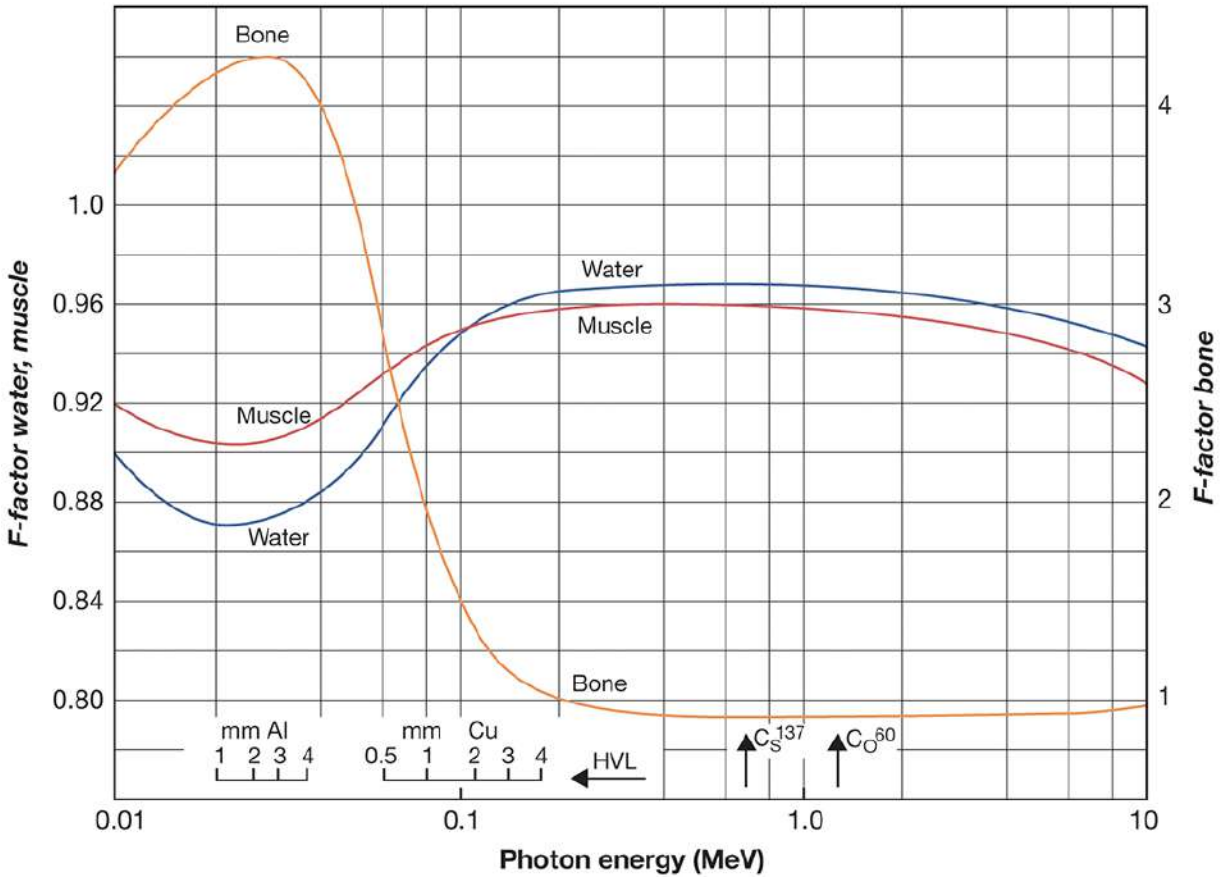

FIGURE 6.35 The roentgen-to-rad conversion factor for bone, muscle, and water as a function of photon energy. (From Johns HE, Cunningham JR. *The Physics of Radiology*. 4th ed. Charles C Thomas; 1983:287. Courtesy of Charles C Thomas Publisher, Springfield, Illinois.)

An in-air calibration procedure is performed as follows. The calibrated ion chamber (with wall thick enough to ensure electronic equilibrium) is placed in air with its sensitive volume on the central axis of the beam and its stem at right angles to the beam direction. The center of the chamber most often is placed at a distance from the source (or target) equal to the nominal SSD of the machine plus the buildup depth. A standard field size is set, usually 10 × 10 cm, using either movable collimators or the standard treatment applicator. An exposure is made for a known time or number of monitor units. The ionization chamber reading is converted to units of Gy/min at the depth of the maximum dose within a phantom, d_{med}, using the following equation:

$$\dot{D}_{\text{med}} = \frac{M \cdot N_{\text{x}} \cdot C_{\text{tp}} \cdot C_{\text{st}} \cdot C_{\text{s}} \cdot A_{\text{eq}} \cdot f_{\text{med}} \cdot \text{TAR}\left(d_{\text{max}}\right)}{T + \alpha}$$

where M, N_{x}, C_{tp}, C_{st}, C_{s}, A_{eq}, f_{med}, T, and α are used as defined earlier. The term TAR(d_{max}) represents the tissue-air ratio (TAR) at the depth of maximum dose (ie, the *backscatter* or *peakscatter factor*) and converts the dose in free space to the dose in a phantom at the depth of maximum dose. This parameter is discussed in more detail later. The preceding equation can be rewritten as follows:

$$\dot{D}_{\text{med}} = \dot{X} \cdot f_{\text{med}} \cdot A_{\text{eq}} \cdot \text{TAR}(d_{\text{max}})$$

and

$$\dot{D}_{\text{med}} = \dot{D}_{\text{fs}} \cdot \text{TAR}(d_{\text{max}})$$

This method is also valid when the measurements are made with the exposure-calibrated ion chamber embedded within a medium, such as a water phantom. In that case, the TAR(d_{max}) term is not included in the calculation, and the A_{eq} factor is replaced by a displacement factor, A_{m}. The numerical value of A_{m} is very close to that of A_{eq}, and for exposure measurements made within a water phantom, the dose rate is given by the following expression:

$$\dot{D}_{\text{med}} = \dot{X} \cdot f_{\text{med}} \cdot A_{\text{m}}$$

Absorbed Dose Calculation from Bragg-Gray Cavity Ionization Measurement

For energies above the level of ^{60}Co, exposure calibration factors are not available from the standards laboratories because of measurement limitations. In 1983, the AAPM introduced a protocol for the calibration of high-energy photon and electron beams that was based on *Bragg-Gray cavity theory* and allowed one to calculate dose directly from ion chamber

measurements in a medium for energies above the level of ^{60}Co.[84] The protocol updated physical parameters and procedures for calibration and measurement and accounted for the different phantom materials (eg, plastic and water) used for calibration and differences in ion chamber design and construction. The protocol introduced the *cavity-gas calibration factor*, N_{gas}, which is related to the ion chamber's ^{60}Co exposure calibration factor, N_x, and is used in conjunction with restricted stopping power ratios, $L- / \rho$, for the radiation beam in question to convert the ionization chamber reading to absorbed dose using the following expression:

$$D_{med} = M \cdot N_{gas} \cdot \left(\bar{L}/\rho\right)_{gas}^{med} \cdot P_{ion} \cdot P_{repl} \cdot P_{wall}$$

where M is the raw ionization chamber reading per monitor unit corrected for temperature and pressure, P_{ion} is the ion-recombination correction factor, P_{repl} is a correction factor for replacement of phantom material by the ionization chamber, and P_{wall} is a correction factor to account for ionization chamber wall composition.

In 1999, the AAPM published a new protocol (TG-51) for the calibration of high-energy photon and electron beams.[85] A practical implementation guideline was published in 2022.[86] This protocol uses ion chambers with absorbed-dose-to-water calibration factors, $N^{Co\text{-}60}_{D.W}$, which are traceable to national primary standards via the ^{60}Co standard. The absorbed dose to water D_W^Q at the point of measurement of the ion chamber placed under reference conditions is given by the following equation:

$$D_W^Q = M \cdot k_Q \cdot N_{D,W}^{Co\text{-}60}$$

where Q is the beam quality of the clinical beam, M is the fully corrected ion chamber reading, and k_Q is the *quality conversion factor* that converts

the calibration factor for a ^{60}Co beam to that for a beam of quality Q. An addendum to TG-51 was published in 2014 with updated quality conversion factor data.[87] The protocol is designed to be a simplification of the AAPM's TG-21 protocol in the sense that large tables of stopping power ratios and mass energy–absorption coefficients are no longer needed, and the user does not need to calculate any theoretical dosimetry factors.[88-90]

Other Dosimetry Methods

Thermoluminescent Dosimetry

Certain crystalline materials exhibit a phenomenon known as *thermoluminescence*. When a crystal capable of thermoluminescence is irradiated, a small portion of the energy absorbed is stored in the structure of the crystal lattice. If the material is heated, the energy is released in the form of visible light. Several thermoluminescent phosphors are available, but lithium fluoride, with an effective atomic number of 8.2, is the most commonly used.

The physical theory of thermoluminescent dosimetry (TLD) can be explained as follows. In the individual atom, electrons occupy discrete energy levels. However, in the crystal lattice, the electronic energy levels are perturbed by mutual interactions between atoms, giving rise to energy bands, so-called *allowed energy bands* and *forbidden energy bands*. Impurities in the crystal create energy traps in the forbidden bands, allowing metastable states to exist; for example, when the phosphor is irradiated, some of the electrons in the valence band (ground state) receive sufficient energy to be raised to the conduction band. If there is an instantaneous emission of light, the phenomenon is called *fluorescence*. If an electron in the trap requires energy to get out of the trap and return to the valence band, the emission of light is called *phosphorescence*. If the emission of light is slow at room temperature but can be sped up with heating, the process is called *thermoluminescence*.

Thermoluminescent dosimeters must be calibrated before they can be used for measuring an unknown dose. Because the response of the thermoluminescent material is affected by its radiation and thermal histories, the material must be annealed to remove residual effects. The standard preirradiation annealing procedure for lithium fluoride is 1 hour of

heating at 400 °C and 24 hours at 80 °C. More details can be found in the review article by DeWerd et al[91] and in AAPM Report TG-191.[92]

Optically Stimulated Luminescence Dosimetry

Optically stimulated luminescent dosimeters (OSLDs) are composed of carbon-doped aluminum oxide (Al_2O_3) with an effective atomic number of 11.28, and parallel TLDs in many ways. Not only are they passive dosimeters that are small in size but the underlying physical process for recording dose is also caused by charge trapping in electron-hole pairs, which can be read out by recombining the traps via optical rather than thermal stimulation. OSLDs also require a careful calibration process to account for dosimeter-specific sensitivity variations. Due to the efficiency of the overall readout workflow, which is on the order of minutes versus hours for TLDs, OSLDs have become the dominant method of in vivo patient dosimetry in many clinics. Some disadvantages include the fact that they are manufactured by a single vendor and require a light-proof encasing. More details can be found in AAPM Task Group Report 191.[92]

Film Dosimetry

When an x-ray film is exposed to ionizing radiation, the exposed silver bromide crystals form a latent image. In the film development process, the affected crystals cause a darkening of the film, and the unaffected crystals leave the film clear. The degree of blackening of the film is proportional to the energy absorbed and is measured by determining the optical density with a densitometer. The optical density is defined as follows:

$$\mathrm{OD} = \log(I_0/I_T)$$

where I_0 is the amount of light detected without the film in place and I_T is the amount of light detected with the film in place. For radiation dosimetry, the net optical density is obtained by subtracting the densitometric reading for the base fog (clear portion of the film) from the measured optical density. Most films are exposed to yield an optical density between 1.3 and 1.7 for optimal viewing.

A plot of net optical density as a function of radiation exposure or dose is called the *sensitometric curve* or the *Hurter-Driffield (H-D) curve*. If the curve is nonlinear, appropriate corrections must be applied to convert net optical density to absorbed dose.

The use of film is a relatively straightforward method of dosimetry for electron beams, but it must be done with extreme care in photon dosimetry. The problem is that the photoelectric effect depends on Z^3 ($Z_{silver} = 47$), and the film emulsion strongly absorbs radiation below 100 kV. A concise review of radiographic film dosimetry can be found in the article by Das.[93] Radiographic film has been replaced by radiochromic film in many countries where film processors have been discontinued in radiology departments following adoption of digital imaging.

Radiochromic Film Dosimetry

Radiochromic film consists of a thin (7-23 mm), radiosensitive, colorless leuco dye bonded to a 100-mm-thick Mylar base. Radiochromic films are colorless before irradiation and turn deep blue when irradiated without physical, chemical, or thermal processing. The film is approximately tissue equivalent, integrates simultaneously at all measurement points, and has a high spatial resolution (>1,200 lines/mm). It shows a stable, reproducible response if protected from ultraviolet light, unstable temperatures, and humidity. Because radiochromic dye is an aromatic hydrocarbon, like plastic scintillators, it has an energy response superior to that of diodes and comparable with TLD. Interest in radiochromic film as a quantitative dosimeter has been stimulated by the appearance of a 4-fold more sensitive film (model MD-55), which extends its response down to the 5-Gy level. More details on radiochromic film dosimetry are given in AAPM Report TG-235.[94]

Diode Dosimetry

Semiconductor diodes offer many advantages for clinical dosimetry, including high sensitivity, real-time readout, robustness, and independence of air pressure. Most semiconductor diodes are made from silicon, which is either *n* type (silicon doped with group V material, such as phosphorus) or *p*

type (silicon doped with group III material, such as boron). To form a diode detector, a *p*-*n* junction must be created.

The physical theory of semiconductor dosimetry can be explained as follows. During irradiation, electron-hole pairs are created both within and outside the depletion region in the body of the diode detector. The charge carriers are swept across the depletion region and collected rapidly under the action of the electric field that exists across it. In this way, a current is generated, flowing in the reverse direction to normal diode current flow, which can be measured and related to absorbed dose.

Dosimetry diodes are operated without an external reverse bias voltage and connected via cable to a simple electrometer. Details on their use for in vivo dosimetry are provided in AAPM Report 87.[95] Calibration of diodes typically is performed by comparison of readings against an ion chamber in a standard setup to establish a diode calibration factor for absorbed dose to water and the establishment of a series of correction factors to account for calibration differences when measurements are performed under various experimental conditions. Typical concerns are energy dependence, temperature sensitivity, directional dependence, and radiation damage. Each radiation therapy center should establish the responses of their diodes under the various conditions encountered and monitor them as the cumulative dose to the diodes' increases. Frequency of checks should be adjusted according to the frequency of use of the diodes and the variability encountered. More details on diode dosimetry are given in the article by Zhu and Saini.[96]

Metal Oxide Semiconductor–Field Effect Transistor Dosimetry

Metal oxide semiconductor–field effect transistors represent another example of a semiconductor dosimeter. Originally developed for space dosimetry, the operation is based on the buildup of charge in the silicon oxide transistor gate created by ionizing radiation. The reader is referred to the article by Cygler and Scalchi[97] for more details on this type of dosimeter.

Plastic Scintillation Dosimetry

In response to dose deposited by radiation, some plastic materials (eg, polystyrene) emit light that is linearly proportional to energy and independent of photon or electron energy above 125 keV. In the energy range where Compton interactions dominate, such plastic scintillators are also tissue equivalent. As a result, scintillating dosimeters require no correction factors when used for photon or electron beam dosimetry. The emitted light must first be collected by coupling the scintillator to an optical fiber and then quantified using a photomultiplier tube. Because optical fibers have an index of refraction that is higher than that in vacuum, Cherenkov light can be generated by electrons traveling faster than the speed of light. Such sources of optical noise degrade the light signal and must therefore be measured and removed using various strategies. Due to the direct relationship between light intensity and dose as well as the small size of a scintillation dosimeter (eg, 1 mm in diameter), it is well suited for small-field measurements, which are particularly challenging. The reader is referred to the article by Beaulieu and Beddar for more details on this dosimeter and its clinical applications.[98]

Polymer Gel Dosimetry

Gel dosimetry is based on quantifying the effects of radiation-induced chemical changes occurring within some volume of material filled with an aqueous gel matrix. The degree of chemical change in the gel is related to dose. The dose-dependent changes are determined by imaging techniques, including MRI, CT, and optical CT. Hence, gel dosimetry has the potential to provide full 3D dosimetry throughout the volume of the irradiated gel dosimeter.

For example, one form of this method exploits the radiation-induced free-radical chain polymerization of acrylic monomers dispersed in an aqueous gel. When irradiated, discrete, microscopic regions of cross-linked polymer are formed, the concentration of which is proportional to radiation dose. The water proton nuclear MR relaxation rates in the gel are strongly affected by local changes in the polymer molecular structure and dynamics; thus, the distribution of radiation dose may be visualized and quantified with high resolution using MRI. Because the polymer microparticles scatter

light, the dose distribution can also be visualized in the transparent gel as a dose-dependent 3D optical turbidity and read by optical CT.

Unfortunately, gel dosimetry, while having the potential for tissue-equivalent 3D dosimetry for almost three decades, has not come into common clinical use, as it has proven too difficult to use in the clinic setting.[99] Research continues in gel dosimetry, as there is clearly a need for a robust 3D high-resolution dosimetry system.[99,100] Recent publications indicate that these research efforts may result in viable clinical and commercial solutions.[101]

DOSIMETRY PARAMETERS

Percentage Depth Dose

Percentage depth dose (*PDD*) can be understood by reference to Figure 6.36. It is the ratio, expressed as a percentage, of the absorbed dose on the central axis at depth d to the absorbed dose at the reference point d_0. PDD is given by

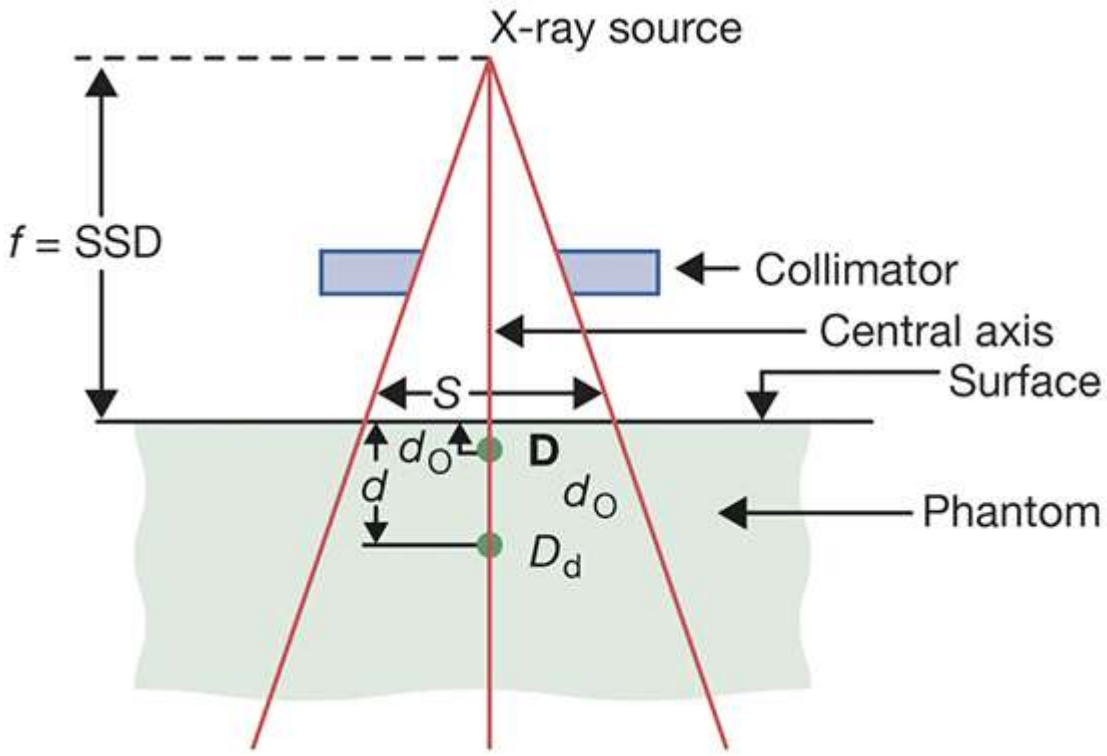

FIGURE 6.36 Schematic drawing illustrating definition of percentage depth dose, where d is any depth and d_0 is the reference depth, usually d_{max}.

$$\mathrm{PDD}\left(d, d_0, S, f, E\right) = \frac{D_d}{D_{d_0}} \times 100$$

The functional symbols have been inserted in the expression to make it clear that the PDD is affected by a number of parameters, including d, d_0, field dimension S, source-to-surface distance f, and radiation beam energy (or quality) E. S refers to the side length of a square beam at a specified reference depth. Nonsquare beams may be designated by their equivalent square. Field shape and added beam collimation also can affect the central axis depth-dose distribution. Photon-beam PDD increases with increasing energy, SSD, and field size. Figure 6.37 shows that the depth of the 50th percentile increases from approximately 14 cm for 4-MV x-rays to nearly 23 cm for 25-MV x-rays. The depth of the maximum dose varies from about 1 cm for 4-MV x-rays to >3.5 cm for 25-MV x-rays.

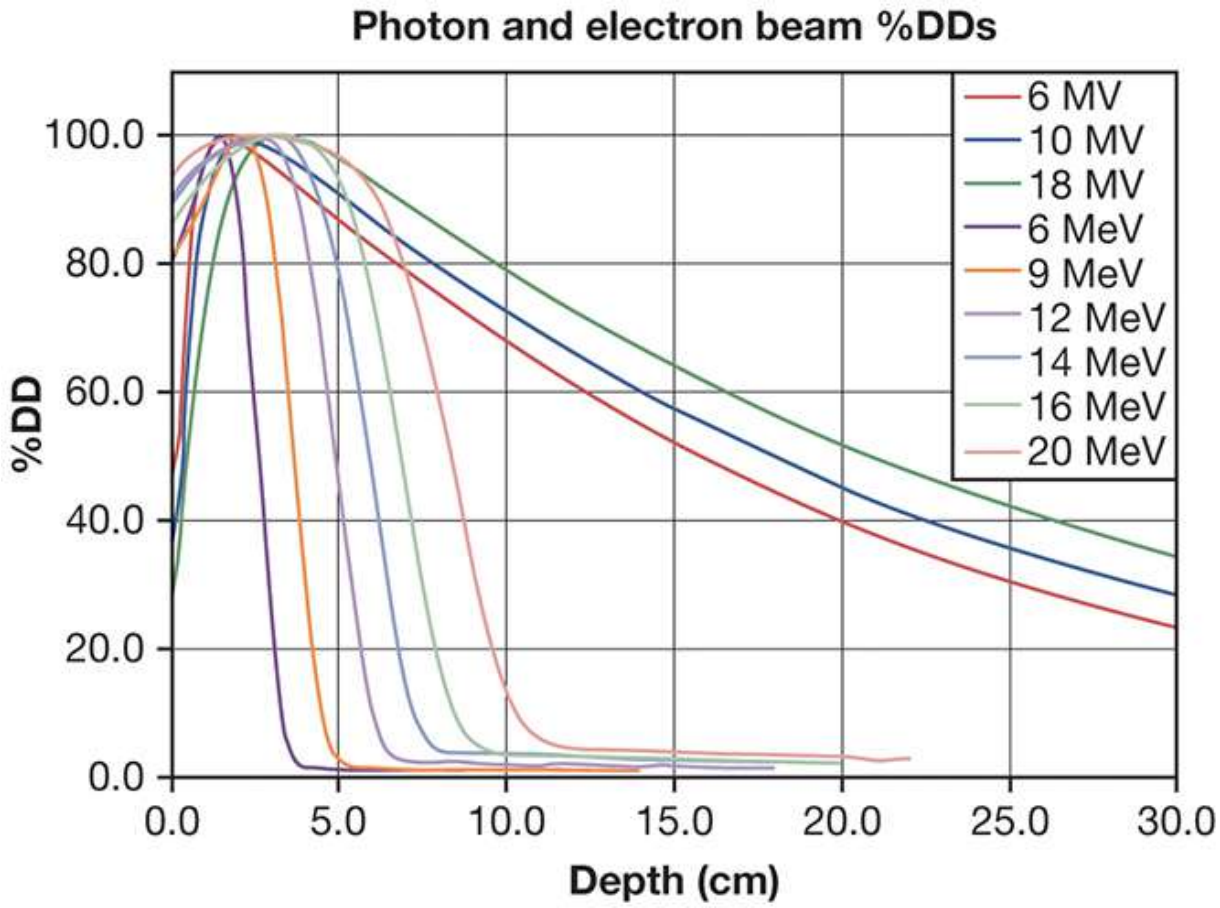

FIGURE 6.37 Examples of central axis percentage depth dose (DD) for megavoltage x-ray beams ranging from ^{60}Co to 18-MV x-rays and 6- to 20-MeV electron beams.

The PDD for one SSD is related to the PDD at a second SSD by the following equation:

$$\mathrm{PDD}\left(d, S, f_2\right) = \mathrm{PDD}\left(d, S, f_1\right)\left(\frac{f_1 + d}{f_2 d} \cdot \frac{f_2 + d_{\max}}{f_1 + d_{\max}}\right)^2$$

The term in brackets is called the *Mayneord F-factor*.[102]

Tissue-Air Ratio

TAR is defined as the ratio of the absorbed dose D_d at a given point in the phantom by the absorbed dose in free space, D_{fs}, that would be measured at the same point but in the absence of the phantom, if all other conditions of the irradiation (eg, collimator, distance from the source) are equal (Figure 6.38). The TAR is expressed as follows:

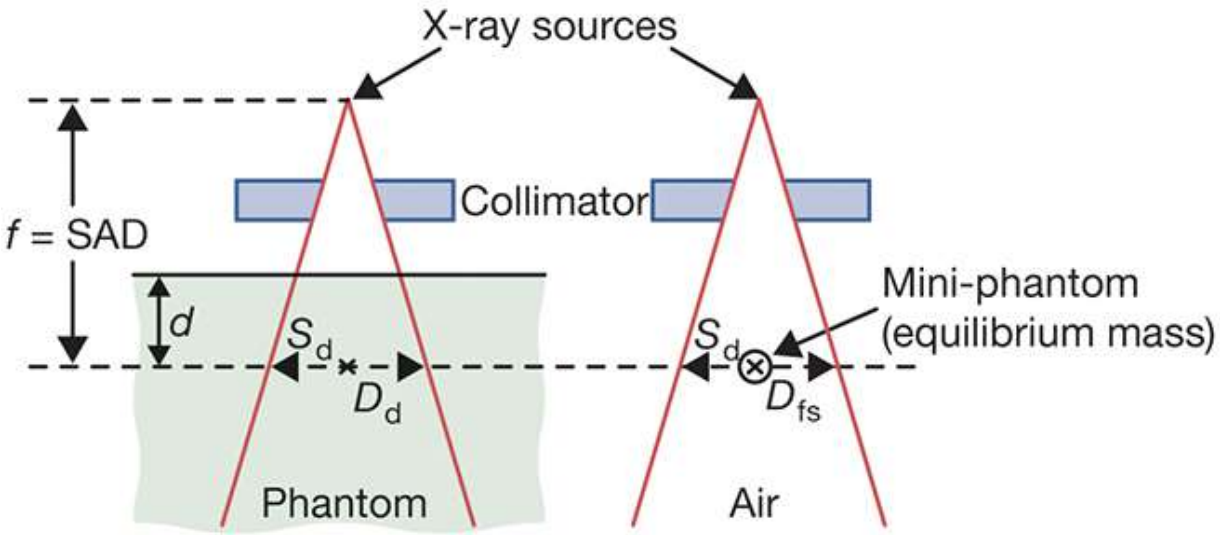

FIGURE 6.38 Schematic drawing illustrating the definition of tissue-air ratio, where *d* is the thickness of overlying material.

$$\mathrm{TAR}\left(d, S_d, E\right) = \frac{D_d}{D_{fs}}$$

where d is depth, E is radiation beam energy, and S_d is the beam dimension measured at depth d. TAR depends on depth, field size, and beam quality, but for all practical purposes, it is independent of the distance from the source.

The TAR at the depth of maximum dose is called the *peakscatter factor*. It is perhaps better known as the backscatter factor, but because of the finite depth d_0, this tends to be misleading. Figure 6.39 shows the peakscatter factors for various field sizes and beam qualities.

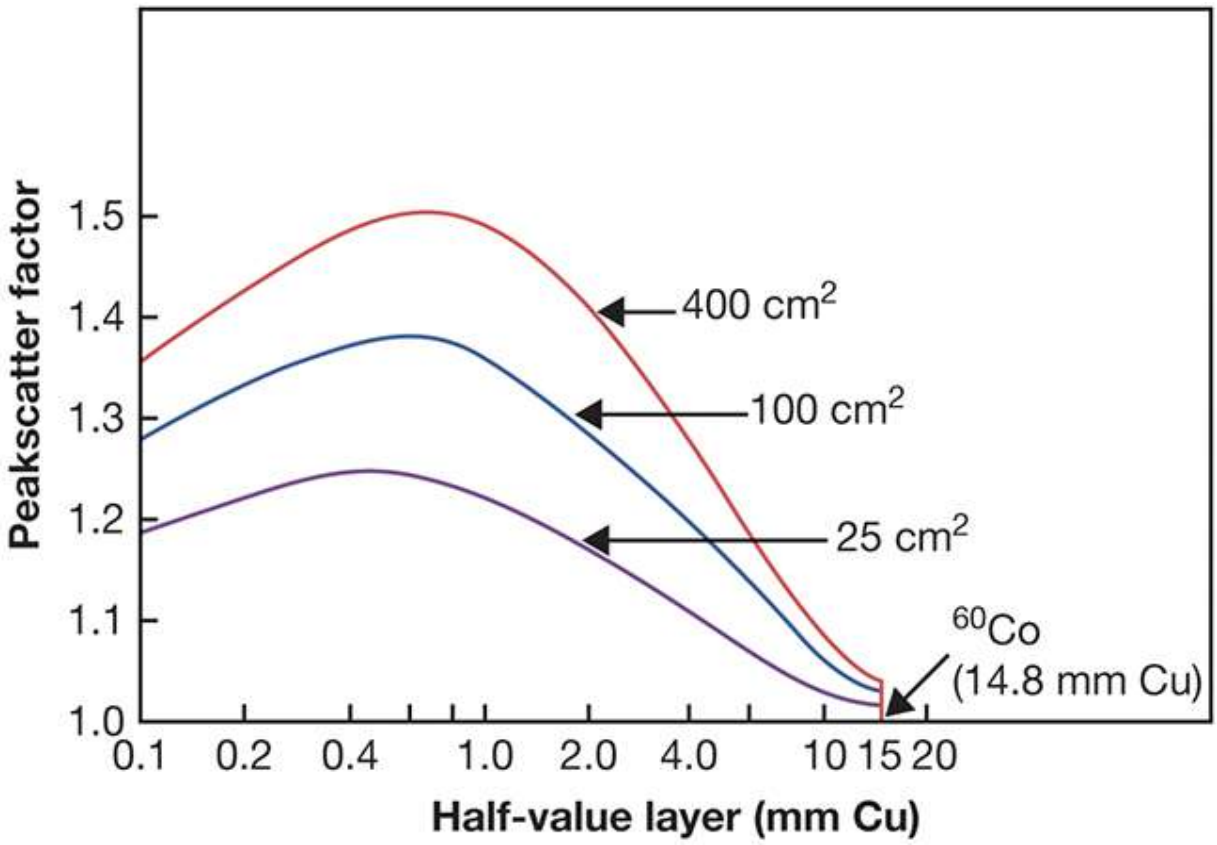

FIGURE 6.39 Variation of peakscatter factor with beam quality (half-value layer). (From Johns HE, Cunningham JR. *The Physics of Radiology*. 4th ed. Charles C Thomas; 1983:348. Courtesy of Charles C Thomas Publisher, Springfield, Illinois.)

Tissue-Phantom Ratio and Tissue-Maximum Ratio

The concepts of tissue-phantom ratio (TPR) and tissue-maximum ratio (TMR) were proposed for high-energy radiation as alternatives to TAR in response to arguments raised against the use of in-air measurement for a photon beam with a maximum energy >3 MeV.[103,104] As originally defined, TPR is given by the ratio of two doses:

$$\mathrm{TPR}\left(d, d_{\mathrm{r}}, S_{\mathrm{d}}, E\right) = \frac{D_{\mathrm{d}}}{D_{\mathrm{d_r}}}$$

where $D_{\mathrm{d_r}}$ is the dose at a specified point on the central axis in a phantom with a fixed reference depth, d_{r}, of tissue-equivalent material overlying the

point; D_d is the dose in the phantom at the same spatial point as before but with an arbitrary depth, d, of overlying material; and S_d is the beam width at the level of measurement (Figure 6.40). In each instance, the underlying material is sufficient to provide for full backscatter. There is no general agreement about the magnitude of the reference depth to be used for this quantity, particularly for high energies. The TPR is intended to be analogous to the TAR but has an advantage because the reference dose, D_{d_r}, is directly measurable over the entire range of x-rays and γ-rays in use, eliminating problems in obtaining a value for the dose in free space when the depth for electronic buildup is great.

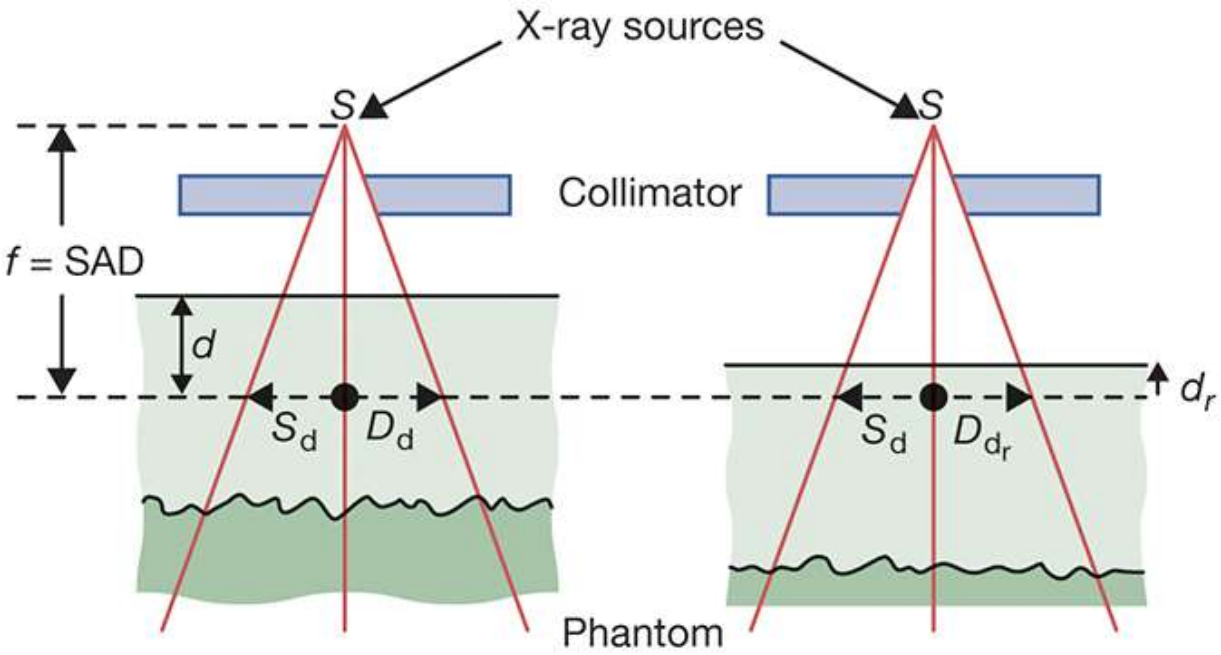

FIGURE 6.40 Schematic drawing illustrating the definition of tissue-phantom ratio and tissue-maximum ratio, where d is the thickness of overlying material and d_r is the reference thickness.

The original TMR definition is similar to the definition of TPR, except that the reference depth, d_r, is the depth of maximum dose. However, the depth of maximum dose for MV x-ray beams varies significantly with field size and also is a function of SSD. Thus, the definition of TMR creates a measurement problem because a variable d_r is required and the TMR

depends on SSD. A modification by Khan et al[105] proposed that the reference depth, d_r, must be equal to or greater than the largest depth of maximum dose.

Purdy[106] reported on the relationships between the central axis PDD and the TPR, TMR, and TAR. This work suggested that the degree to which the TPR and TMR are independent of distance from the radiation source depends largely on the linac's collimator/flattening filter scatter component of the beam.

Scatter-Air Ratio and Scatter-Maximum Ratio

The scatter-air ratio (SAR) can be thought of as the scatter component of the TAR.[107] It is defined as follows:

$$\mathrm{SAR}\,(d, S_d, E) = \mathrm{TAR}\,(d, S_d, E) = \mathrm{TAR}\,(d, 0, E)$$

SAR is the difference between the TAR for a field of finite area and the TAR for a zero-area field size. The zero-area TAR is a mathematical abstraction obtained by extrapolation of the TAR values measured for finite field sizes.

Similarly, the scatter-maximum ratio (SMR), the scatter component of the TMR, is defined as follows:

$$\mathrm{SMR}\left(d, S_d, E\right) = \mathrm{TMR}\left(d, S_d, E\right) \cdot \frac{S_p\left(S_d, E\right)}{S_p\left(S_0, E\right)} - \mathrm{TMR}\left(d, 0, E\right)$$

where S_p is a phantom scatter correction factor, which takes into account changes in scatter radiation originating in the phantom at the reference depth as the field size is changed.[105]

Output Factor

The output factor for a given field size is defined as the ratio of the dose rate at the depth of maximum dose for a given field size to that for the

reference field size (usually 10 × 10 cm) at its d_{max}. The output factor varies with field size (Figure 6.41) as a result of two distinct phenomena. As the collimator jaws are opened, the primary dose, D_p, at d_{max} on the central ray per monitor unit increases as a result of a larger number of primary x-ray photons scattered out of the flattening filter. In addition, the scatter dose, $D_s(d_{max}, r)$, at the measurement point per unit D_p increases as the scattering volume irradiated by primary photons increases with increasing collimated field size. These two components can vary independently of one another if nonstandard treatment distances or extensive secondary blocking is used.

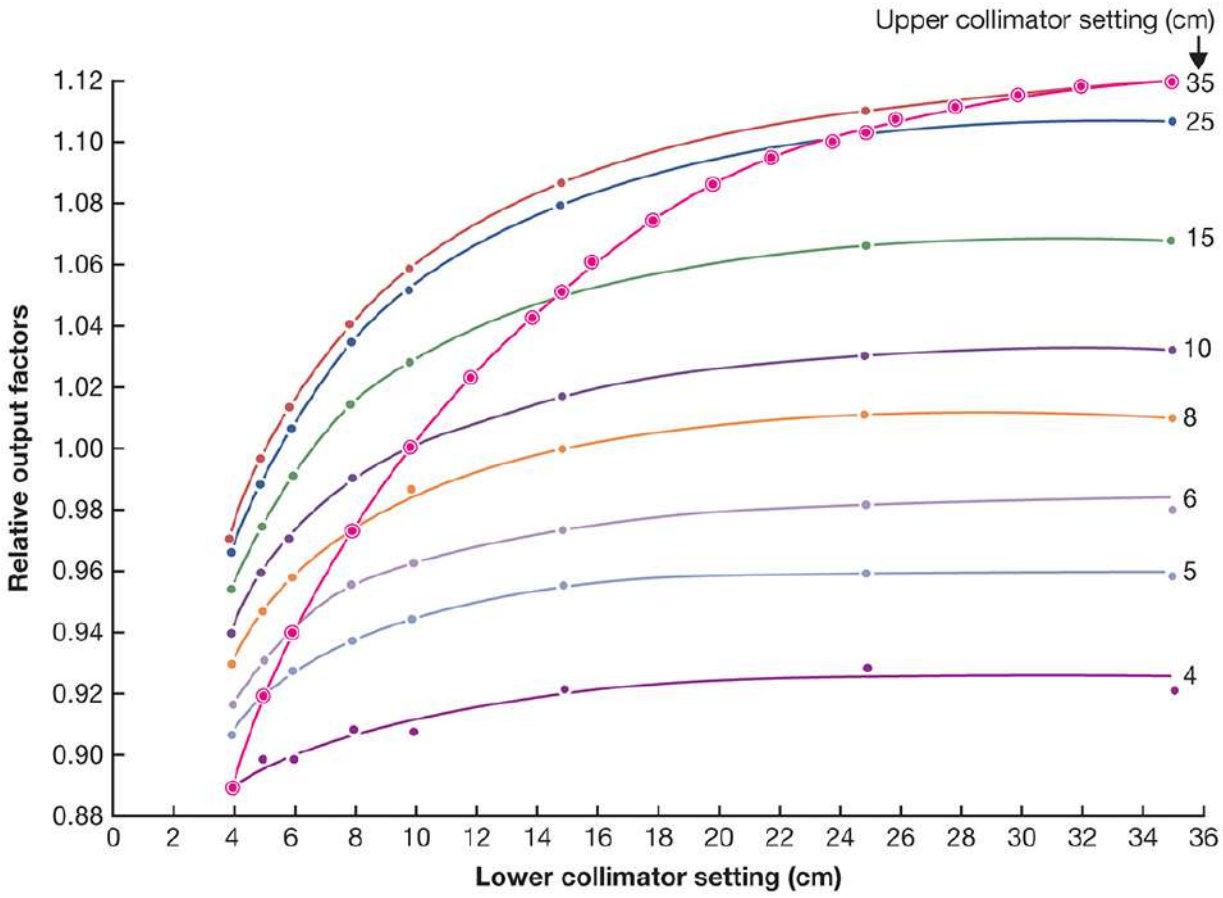

FIGURE 6.41 Example of output factor as a function of lower and upper collimator settings for a medical linear accelerator 18-MV x-ray beam.

Khan et al[105] described a method for separating the overall output factor, $S_{c,p}$, into two components. One is the collimator scatter factor, $S_c(r_c)$, which is a function only of the collimator opening, r_c, projected to the isocenter.

The other is the phantom scatter factor, $S_p(r)$, which is a function only of the cross-sectional area or effective field size, r, irradiated at the treatment distance. They demonstrate that

$$S_{c,p}(r) = S_c(r_c) \cdot (r)$$

In practice, the total and collimator scatter factors both are measured, and the phantom scatter factor is calculated using the relationship listed previously. $S_c(r_c)$ is measured in air using an ion chamber fitted with an equilibrium-thickness buildup cap and given by the ratio of the reading for the given collimator opening to the reading for a reference field (typically 10 × 10 cm) collimator opening. The overall output factor is measured in-phantom using the standard treatment distance and is given by the reading relative to that for a 10 × 10 cm field size. By carefully extrapolating this measured ratio to zero-field size, one obtains the zero-field-size phantom scatter factor, S_p (0). If a small ion chamber is positioned axially in the beam, it is possible to measure $S_{c,p}$ for field sizes as small as 1 × 1 cm. Because of the loss of lateral secondary electron equilibrium encountered near the edges of high-energy photon beams, S_p deviates significantly from unity. Consistent separation of primary and scatter dose components significantly improves the accuracy of dose predictions for irregular field calculations, especially near block edges and the resultant dose falloff resulting from lateral electron disequilibrium, and under blocks, overcoming many of the dose-modeling problems presented by use of extensive customized blocking.

Isodose Curves

An isodose curve represents points of equal dose. A set of these curves, normally given in 10% increments normalized to the dose at the reference depth, can be plotted on a chart (ie, isodose chart) to give a visual representation of the dose distribution in a single plane (Figure 6.42). Beam parameters, such as source size, flattening filter, field size, and SSD, play important roles in the shape of the isodose curve.

Dose Profiles

A dose profile is a representation of the dose in an irradiated volume as a function of spatial position along a single line. Dose profiles are particularly well suited to the description of field flatness and penumbra. The data most often are given as ratios of doses normalized to the dose on the central axis (Figure 6.43). The profiles, called *off-axis factor*s or *off-center ratio*s, may be measured in air (ie, with only a buildup cap) or in a phantom at selected depths. The in-air off-axis factor gives only the variation in primary beam

intensity; the in-phantom off-center ratio shows the added effect of phantom scatter.

Wedge Filter

Wedge filters, first introduced by Ellis and Miller,[108] have traditionally been physical wedges constructed of brass, steel, or lead. When placed in the beam they progressively decrease intensity across the field, causing the isodose distribution to have a planned asymmetry.

The wedge angle is defined as the angle the isodose curve subtends with a line perpendicular to the central axis at a specific depth and for a specified field size. Current practice is to use a depth of 10 cm. Past definitions were based on the 50th percentile isodose curve and, more recently, the 80th percentile isodose curve. The wedge angle is a function of field size and depth. The wedge factor is defined as the ratio of the dose measured in a tissue-equivalent phantom at the depth of maximum buildup on the central axis with the wedge in place to the dose at the same point with the wedge removed.

Wedge isodose curves can be normalized in different ways, as shown in Figure 6.44. The wedged isodose distribution on the left side of the figure has been normalized to 100% at d_{max} on the central axis with the wedge in place; on the right, the normalization is done without the wedge in place. Thus, it is imperative that the normalization and the use of the wedge factor should be clearly understood before wedges are used clinically.

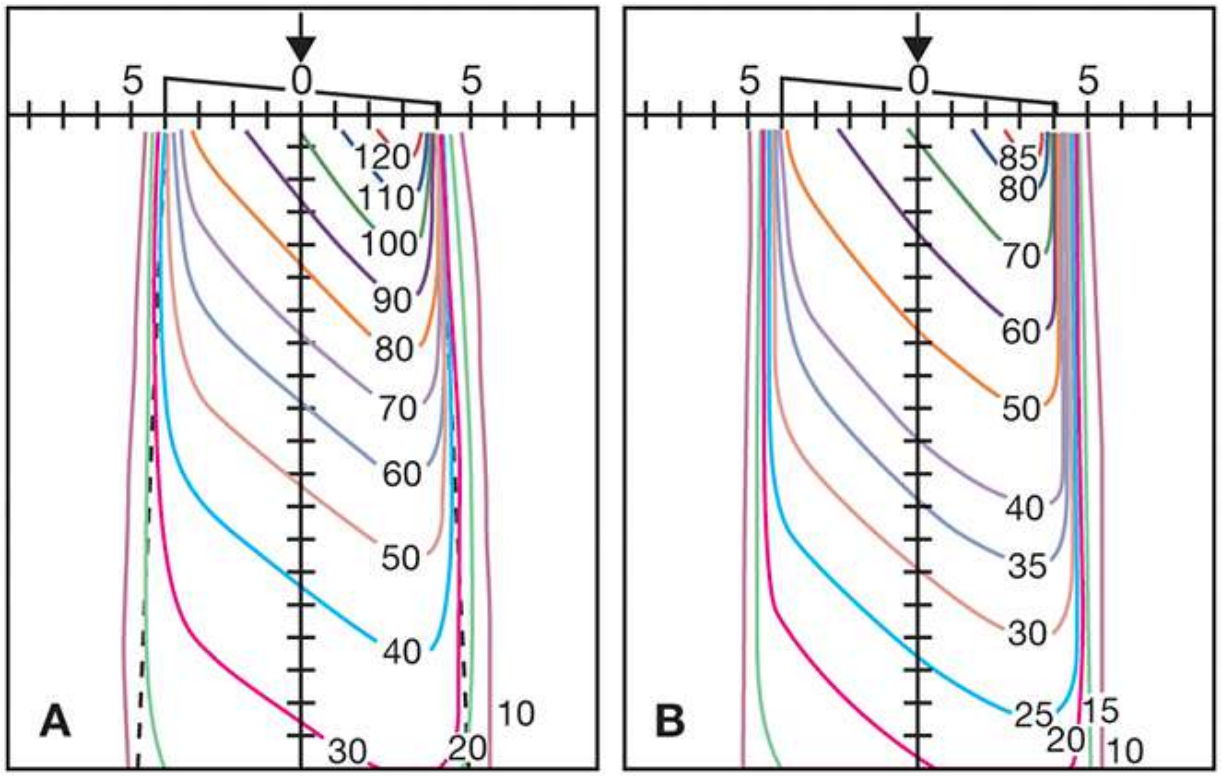

FIGURE 6.44 Isodose curves for a wedge filter. A. Normalized to D_{max}. B. Normalized to D_{max} without the wedge. ^{60}Co, wedge angle = 45°, field size = 8 × 10 cm, source-skin distance = 80 cm. (Reprinted with permission from Khan FM. *The Physics of Radiation Therapy*. 2nd ed. Williams & Wilkins; 1994.)

Beam hardening occurs when a wedge is inserted into the radiation beam. The PDD, therefore, can be considerably increased at depth. Differences in PDD of nearly 7% have been reported for a 4-MV x-ray, 60° wedge field, compared with the open field at a depth of 12 cm, and there have been reports of as much as a 3% difference between the 60° wedge field and the open field for a 25-MV x-ray beam.[109,110]

In many current machines, the physical wedge has been replaced by a dynamic or virtual wedge.[111,112] Based on similar principles as IMRT, one of the jaws or MLC banks is swept across the field while the beam is on. The velocity of the motion controls the steepness of the wedge angle. Details regarding QA for this technology are provided in AAPM Task Group Report 198.[111]

CHAPTER 7

Patient Positioning Methods: Immobilization, Stabilization, and Monitoring

Tianjun Ma, Kujtim Latifi, Bruce Libby, Joshua Evans, and Stanley H. Benedict

OVERVIEW OF EXTERNAL BEAM IMMOBILIZATION AND STABILIZATION

Rationale for Patient Immobilization and Stabilization

The success or failure of a radiotherapy treatment hinges on the accuracy with which the radiation is delivered. There are many sources of uncertainty in the radiation therapy delivery process that can result in a geometric miss of the intended target volume, which will not only decrease the probability of tumor control but also increase the volume of normal tissue that is irradiated, thus increasing the probability of a treatment-related complication. Geometric uncertainties may be broadly classified as mechanical inaccuracies, localization inaccuracies, and positioning inaccuracies. Mechanical inaccuracies include the coincidence of the light and radiation fields, mechanical stability of the couch, laser alignment, and correspondence of the simulation and treatment isocenters. Localization uncertainty relates to the difficult nature of defining the location and extent of the target volume during both planning and treatment delivery. Patient positioning uncertainties relate to misalignment of the patient for treatment or dynamic movement of the target volume out of the treatment field. This chapter focuses on devices and techniques designed to minimize this last group: patient positioning uncertainties.

The goal of daily setup is to reproduce the patient's position at the time of simulation as best as possible; however, setup variations will inevitably occur, which is generally appreciated as a tangible problem and has earned considerable attention in the literature. In an early example, Dunscombe et al[1] assessed components of positioning accuracy in patients with head and neck (H&N) cancer and concluded that observed field placement errors were primarily attributable to patient motion. Patients may fidget from being uncomfortable or anxious during the treatment delivery. Furthermore, organs can move internally with respect to bony anatomy, skin marks, and other soft tissues because of normal and unavoidable physiologic processes such as breathing, swallowing, and peristalsis.

The focus of this chapter is on describing devices and methods for the immobilization and stabilization of patients undergoing radiotherapy, in which the goal is to reduce positioning uncertainties during each fraction (intrafraction error) and to increase the reproducibility of the patient setup for each fraction (interfraction error). In addition, immobilization devices can decrease the time needed for daily setup and target localization, thus increasing a clinic's throughput. Certain immobilization devices may also allow setup marks to be made directly on the device instead of the patient's skin, which can improve the patient's psychological well-being while under treatment, and some devices may even confer dosimetric advantages in treatment planning. The immobilization system should be lightweight for ease of setup and transport, yet strong and durable so that the device does not break during the patient's course of treatment. Furthermore, the device should be made of materials that minimally affect the megavoltage (MV) treatment beam and do not cause imaging artifacts that could impact three-dimensional (3D) visualization of the patient's anatomy for target identification or patient alignment.

The devices and techniques for patient immobilization and stabilization described in this chapter have been shown to improve interfraction setup reproducibility as well as reduce intrafraction uncertainties. The overall accuracy of any immobilization system, however, is dependent on the skill and patience of the personnel forming the device at the time of simulation and setting the patient up on the treatment table for each fraction. Adequate training should be provided for each immobilization system employed in a given clinic, and adequate time should be scheduled for proper patient setup and immobilization. Furthermore,

some patients will be more challenging to reproducibly align than others such as patients in pain and/or with mobility issues. A variety of devices and positions should be available for each treatment indication to help create a treatment position that maximizes both inter- and intrafraction reproducibility for each patient.

Surface imaging technologies for aiding in the initial setup and for real-time monitoring of the patient during treatment have experienced rapid clinical adoption over the last decade, and high-dose-rate (HDR) procedures and techniques have continued to evolve, supporting broad updates in these sections mentioned further. And exciting new technologies and modalities, including Cherenkov cameras for treatment monitoring and total body irradiation (TBI) with volumetric modulated arc therapy (VMAT), have motivated new sections to introduce these systems in the context of reducing patient positioning uncertainties.

Finally, it must be noted that in some cases, even the most robust techniques for patient immobilization and monitoring do not guarantee accurate daily localization of the tumor volume and should not be a substitute for image guidance when indicated. Tumors are well known to change position relative to other soft-tissue anatomy, the external surface, and bony anatomy. Thus, strategies for daily target localization, described elsewhere in this textbook, are also important and are intimately tied to patient immobilization.

Simple Immobilization Devices

Simple methods to reduce intrafraction positioning uncertainty because of patient motion have been in use for decades to ensure that the patient is comfortable. Figure 7.1 shows a variety of simple devices that can be used to enhance the patient's comfort. For patients treated in a supine position, a wedge or roll (A in Figure 7.1) underneath the knees can help to reduce stress on the lower back. For arm-down positioning, a ring for the patient to grip (D in Figure 7.1) can increase comfort. For lung and liver treatments, it may be preferable to position the patient with the arms above the head. In these cases, the arms may be supported under the shoulder by foam wedges (B in Figure 7.1) to help the patient attain a restful position. For some patients with H&N cancer, the patient's shoulders may block the inferior portion of lateral treatment fields. In this case, a simple strap (C in Figure 7.1) can be used to pull the shoulders down and out of the treatment fields. A headrest is almost always used with supine positioning to elevate the head and reduce strain on the neck. Standard sets of "Timo" and "Silverman" headrests (E in Figure 7.1) come in a variety of shapes, sizes, and materials. For those not adequately accommodated by the standard set of headrests, several manufacturers offer customizable head cushions that can be molded to the patient's head contour. All of these devices are relatively inexpensive and are often reusable if they can be covered and/or cleaned between uses.

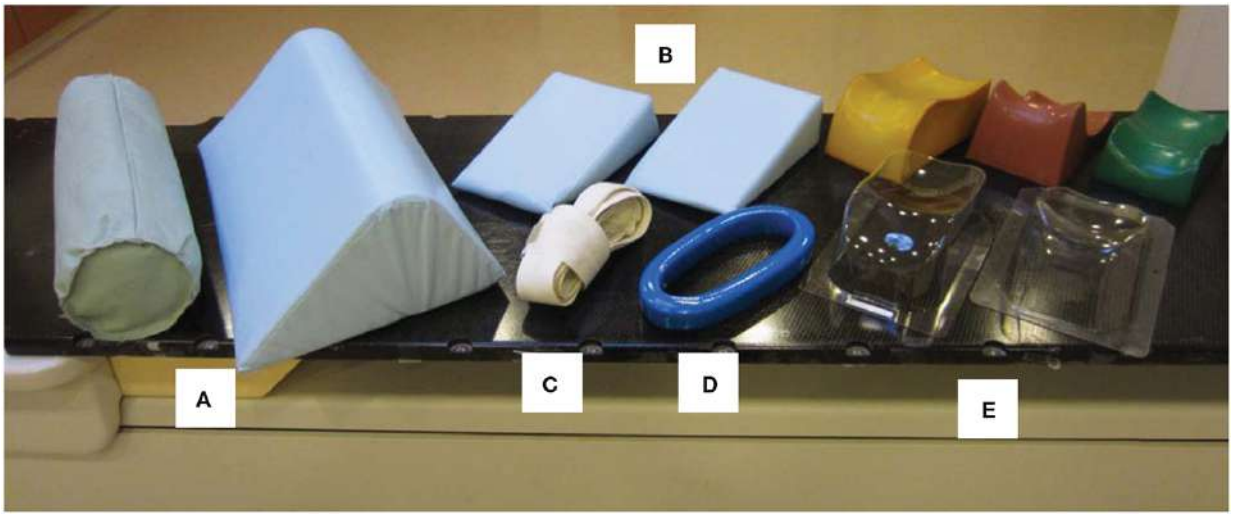

FIGURE 7.1 Simple devices are cost-effective and can reduce intrafraction positioning errors by increasing patient comfort. Shown here are rolls and wedges (A) that can be placed under the knees and wedges (B) to support the arms and shoulders. A simple strap can be used to suppress the shoulders in patients with head and neck cancer (C) and grip rings (D) for the patient to hold on to. Headrests are available in a wide range of shapes and sizes (E).

Immobilization Features of a Dedicated Radiation Oncology Computed Tomography Simulator

Simple devices incorporated during initial simulation can improve patient comfort and reduce intrafraction motion because of patient movement. However, they may not address day-to-day variations of overall patient setup and positioning accuracy. A major objective of a robust immobilization system is to reproduce the patient's anatomic geometry at the time of simulation for all subsequent treatment fractions. An example of a robust immobilization system to treat a patient with breast cancer is shown in Figure 7.2 to illustrate some of the desired features of a dedicated radiation oncology computed tomography (CT) simulator. With this immobilization system, the patient lies supine with an ergonomic wedge (E in Figure 7.2) under the knees. The arms are positioned above the head and out of the tangential treatment fields. A custom-formed, reusable vacuum-lock bag (C in Figure 7.2) helps to support the patient's arms, and a T-bar (B in Figure 7.2) may be used for the patient to grip. The angled baseboard (C in Figure 7.2) on which the vacuum-lock bag rests utilizes gravity to help the breasts fall into a more reproducible position and can be adjusted to minimize skin folds. Many of these devices provide indexing systems for the therapists to record the geometry used for each patient at the time of simulation. This example of a breast setup, where one or both arms may be positioned above the head, highlights the advantage of a wide-bore (eg, >85 cm diameter) CT scanner for radiation (B in Figure 7.2) oncology treatment simulation, as opposed to the more common 70 cm bore diameter, which may limit the options for positioning certain patients.

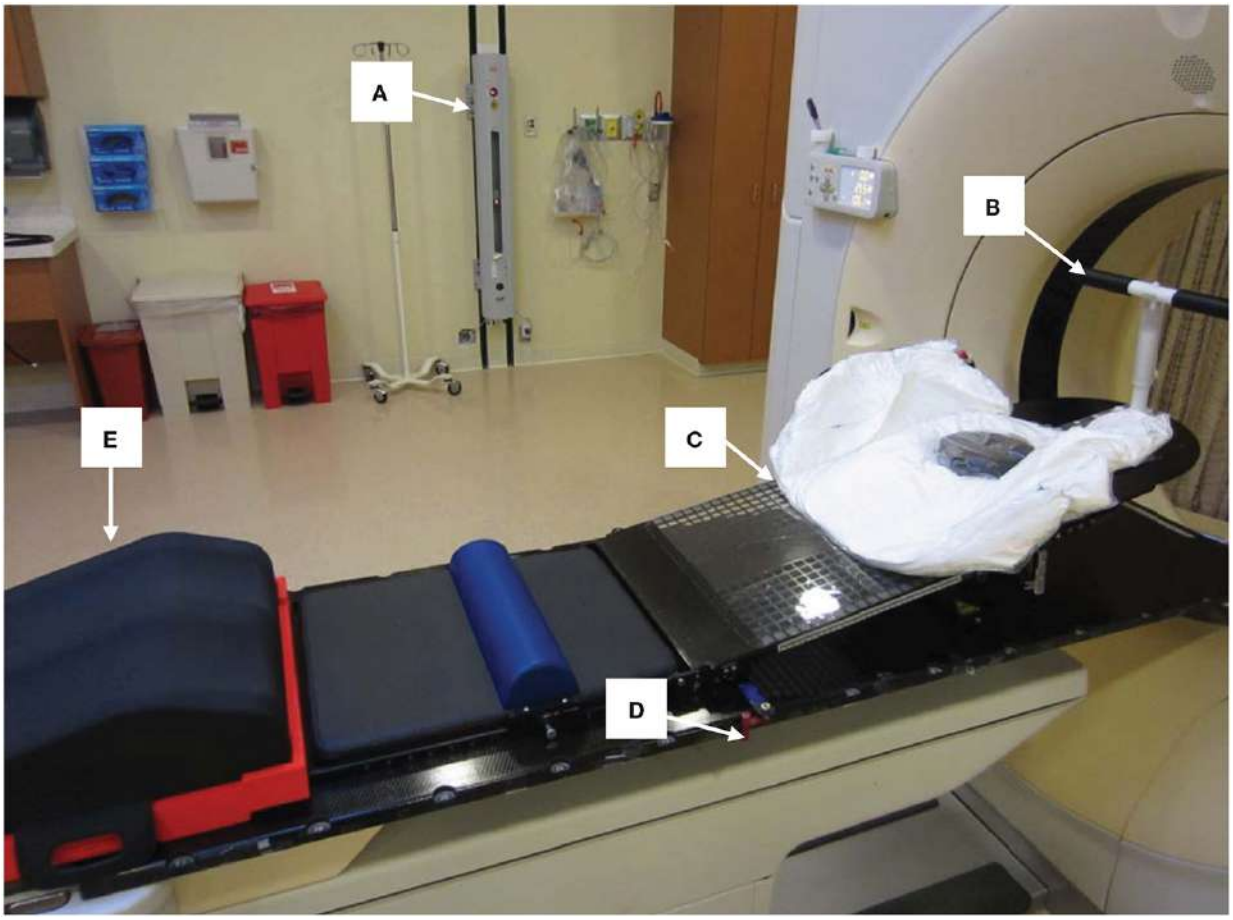

FIGURE 7.2 Displayed here is an immobilization system for a patient with breast cancer in the simulator suite at the University of Virginia. Some key features of a dedicated radiation oncology computed tomography (CT) simulator shown here include the following: A. An in-room laser system marks the reference point position. B. A wide-bore CT (85 cm diameter) allows more flexibility in patient positioning. A vacuum-lock mattress and a T-bar support the patient's arms above the head. C. An angled breast board can improve patient comfort and provide optimal positioning of the breast for radiotherapy. D. An indexed flat couch top overlay reproduces the geometry of the treatment table, with an indexing bar attaching the breast board to the flat couch top overlay. E. An ergonomic knee support can reduce stress on the lower back.

Flat couches are favored for radiation oncology treatments to accommodate a wide range of patient sizes, setup positions, and immobilization devices. Diagnostic CT scanners feature a curved couch for patient comfort; the geometry of a patient simulated on a curved diagnostic couch top will be challenging to reproduce on a flat treatment couch. Flat couch top inserts are offered by numerous vendors to reproduce the couch geometry of the treatment unit. An important feature of a couch top insert is the indexing system (D in Figure 7.2), which allows an assortment of immobilization devices to be rigidly affixed in concert to both the simulator and treatment tables with high accuracy. The indexing system improves the interfraction reproducibility of the patient setup and can also decrease the amount of time to set up a patient.

External marks placed on either the patient's skin or the immobilization devices are used for initial laser alignment on the treatment machine as a surrogate for the internal target anatomy. An in-room laser system in the CT simulator suite (A in Figure 7.2) is a necessary feature to provide external reference points that correlate to the internal reference point location. After the simulation CT scan is acquired, the isocenter is defined and the coordinates are transferred to the in-room laser system. The laser system and CT table are then moved to the defined setup point and external setup marks can be made, thus correlating the position of an internal setup point to the external markings.

HEAD AND NECK IMMOBILIZATION DEVICES

Thermoplastic Masks

Adequate immobilization is particularly critical in the treatment of H&N cancers as the target is frequently located in close proximity to critical structures. Thermoplastic masks have replaced traditional plaster casting methods in most clinics. Thermoplastic masks are heated to approximately 70 °C in a water bath or a dry heat oven. At this temperature, the thermoplastic material becomes malleable and can be stretched and shaped to conform to the patient's face, head, and neck. The patient's H&N region is supported by a simple preformed cushion, like those previously described and illustrated in Figure 7.1, or a custom-formed cushion may be made. The mask is connected to a base plate, which is attached to the couch via the indexing system. Setup marks can be made directly onto the thermoplastic mask, eliminating the need for unsightly marks to be placed on the patient's face for the duration of the treatment.

Early work with thermoplastic mask immobilization for H&N cancer by Bentel showcased the efficacy of the thermoplastic mask in comparison to the traditional plaster three-strip immobilization technique.[2] In terms of the rate of physician-requested shifts from port films, the thermoplastic mask had a frequency of 6.2% compared to 16.1% for the plaster casting method. However, this advantage was only observed when the mask was rigidly affixed to the couch, highlighting the importance of the couch indexing system.[2] Since then, numerous studies quantifying the accuracy of patient setup for H&N cancer have appeared in the literature. The bulk of these studies utilized two-dimensional (2D) portal imaging to quantify setup displacements, although studies utilizing 3D cone-beam CT (CBCT) data have become more common as this technology has recently gained widespread clinical adoption. Generally, systematic and random errors have been reported to have standard deviations ranging from 1 to 4 mm.[3-5] Based on a review of studies assessing setup errors using portal imaging, Hurkmans et al[4] suggest that random and systematic errors of 2 mm or less should be a practically achievable goal for patients with H&N cancer given current immobilization technology and methods.

Figure 7.3 illustrates the flexibility of patient positioning options with thermoplastic masks. Masks can encompass the head only or can extend inferiorly to cover the shoulders (Figure 7.3A, B). Gilbeau et al[3] compared the setup accuracy of the short and long thermoplastic masks in the treatment of H&N cancer. Portal images were acquired for isocenters placed at the level of the head, neck, and shoulders. Their results show similar setup accuracy with the long and short mask for the isocenters in the H&N. For isocenter placement at the shoulder level, the use of the long mask resulted in a random setup error of around 1.0 mm, which was significantly less ($P = .01$) than the 2.3 mm error of the short mask.[3] Thus, a long mask to immobilize the shoulders is recommended for patients receiving supraclavicular treatment in which the isocenter will be placed at the level of the shoulders.

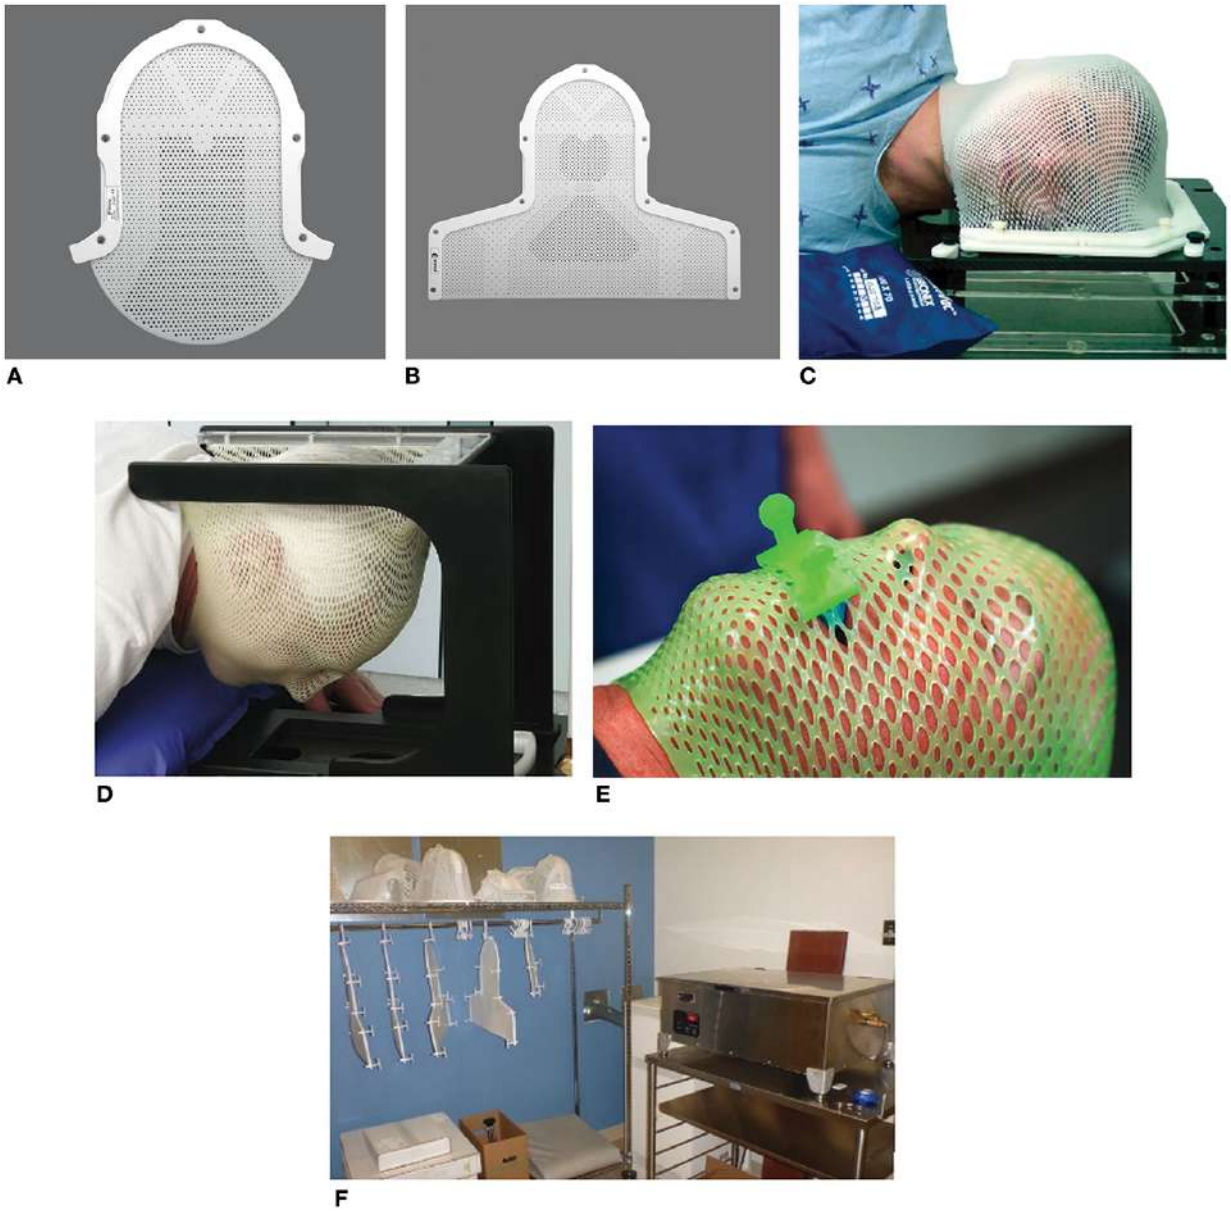

FIGURE 7.3 For treatment of targets in the head and neck, thermoplastic masks are routinely used for custom immobilization. A and B. Thermoplastic sheets are commercially available in short versions that cover only the head, as well as longer versions that extend over the patient's shoulders. C. They can also be used to treat patients in the prone and lateral positions. D. HeadStep Prone. E. BiteLok. F. Additional space is needed to accommodate the water bath used to warm the thermoplastic sheets. (A-C. Courtesy of Bionix. D. Courtesy of IT-V Medizintechnik GmbH. E. Courtesy of Klarity, and E. Taken at UVA by the author.)

Thermoplastic mask systems are available with a myriad of features including multilayer masks to increase rigidity and masks with cutouts for the patient's eyes to reduce anxiety and accommodate optically guided setup. They can also accommodate prone or lateral setups when these positions may be indicated (Figure 7.3C). Some commercially available base plates can be angled to allow for the patient to be set up with the neck in an extended or flexed position, which may be used to avoid critical structures such as the eyes. Neck extension can be used with prone positioning for craniospinal irradiation. For prone setup, a donut-shaped cushion supports the patient's face in the base plate and the thermoplastic mask is formed around the posterior aspect of the head to hold the patient's face in the donut. There is also a newer prone setup mask that can be archived through a board fixation accessory (Figure 7.3D). A potential disadvantage

of treatment with a flexed or extended neck position is the need for registration with different imaging modalities (eg, positron emission tomography [PET]-CT or magnetic resonance [MR]-CT) in which the PET or MR were not performed in the patient treatment position. Vendors have also developed H&N mask mouthpiece accessories such as Precise Bite from CQ-Medical and BiteLok from Klarity for accurately reproducing the position of the teeth and tongue, as illustrated in Figure 7.3E.

Every clinic must consider space limitations when selecting particular immobilization and stabilization systems. Thermoplastic H&N systems necessitate more equipment and thus more space in the simulation suite. The water bath or dry heat oven used to heat the thermoplastic sheets for the long H&N masks can be large (Figure 7.3F). It is recommended to consult with the hospital's infection control team to ensure water baths and dry heat ovens are properly cleaned and monitored since they are used for many patients. For clinics with insufficient space to house a large heating device, smaller devices are commercially available that will fit the short head-only masks. Furthermore, some commercially available base plates (eg, VersaBoard; Bionix Radiation Therapy, Toledo, OH) incorporate shoulder suppression systems, which consist of rigid plastic panels to push down on the shoulders. When a long thermoplastic mask is not indicated or not available, a base plate with shoulder suppression panels can help to keep the shoulders out of the beam path for lateral H&N beams (Figure 7.3A, B). In lieu of long thermoplastic masks or base plates with shoulder suppression panels, the patient can pull on a simple shoulder strap (C in Figure 7.1) to move the shoulders inferior and avoid unnecessary irradiation of the shoulders when opposed lateral beams are used to treat the neck.

Thermoplastic masks have been observed to shrink as they cool in the 24-hour period after formation, and this has been shown to lead to systematic setup errors if not taken into consideration.[6] Furthermore, a mask that has shrunk after the simulation process may be uncomfortable for the patient and may require a full resimulation. Bionix Radiation Therapy has attempted to address this problem with the Klarity Green and Blue line of thermoplastic material, which is designed to have reduced shrinkage coupled with increased rigidity. As with any immobilization system, the thermoplastic manufacturers' recommendations should be carefully followed, and adequate time should be allowed during simulation for the mask to harden properly while on the patient to minimize the effect of shrinkage.

Patients feeling claustrophobic may encounter difficulties in tolerating masks. One of the solutions is to use open face mask, which has been reported in the literature.[7] As a complementary feature, mouthpiece coupled with masks could help stabilize the location of the tongue.

Bite Blocks as an Alternative to Masks

Another alternative solution for patients with claustrophobia is the complete bite block systems that do not incorporate a mask. Elekta offers a flexible system that includes the option of using a bite block, the Fraxion, which is illustrated in Figure 7.4. A custom dental mold is formed to fit the patient's maxillary teeth, and a vacuum system creates suction between the mold and the hard palate. A custom cushion is placed under the patient's head, neck, and shoulders. The mouthpiece is attached to a carbon fiber frame, which is fixed to the treatment table's indexing system. The head is thus rigidly immobilized via the connection of the mouthpiece to the head frame. The carbon fiber design of the HeadFIX product allows for the use of in-room kilovoltage image guidance systems for target localization. The mold can be quickly released from the frame if the patient feels claustrophobic. Setup accuracy has been shown to be similar to thermoplastic masks, on the order of 1 to 3 mm.[8] These stand-alone bite block systems, however, require a high level of patient compliance and may not be suitable for patients with poor dentition or with edentulism. Bite blocks formed with a patient's false teeth are highly discouraged and may result in inaccurate setups or breakage of the patient's dentures. Custom-formed dental molds can also be incorporated in the conventional thermoplastic mask systems described earlier to provide an additional point of support for the patient. A custom bite block may also be formed with primary goals other than immobilization, for example, to separate the tongue from the roof of the mouth, which can be useful in treating sinus/nasal cavity tumors to decrease dose to the tongue and vice versa. Table 7.1 includes a top-level summary of the pros and cons of the available intracranial immobilization devices.

TABLE 7.1 INTRACRANIAL IMMOBILIZATION DEVICE SUMMARY

Device Name	Description	Pros	Cons	Typical Sites	Reusable?	Indexed?	Relative Cost
Timo and Silverman head rests	Foam and plastic head rests with various sizes for a range of body habitus	Inexpensive and reusable	Not custom formed	H&N, craniospinal, thoracic, abdominal, pretty much all supine patients	Yes	Some clip to baseplate, which is indexed to the couch; others do not clip to couch.	$
Custom-formed head rests	Vacuum-lock or water-activated custom-formed head rests	Custom formed to patient Some are reusable.	Added time to simulation process Some are not reusable.	H&N, craniospinal, thoracic, abdominal, Intracranial SRS	Some yes Some no	Can be molded around baseplate for reliable placement	$$
Thermoplastic masks	Thermoplastic mask material is warmed until pliable and then is stretched over the patient's face to create a customized device.	Accurate, custom-formed immobilization Can cut out treatment portals to reduce blousing	Potential for mask shrinkage Patient anxiety or claustrophobia Bolusing effect	H&N, craniospinal	No	Yes; clip to baseplate	$$
Elekta Fraxion	Relocatable bite block system designed for fractionated stereotactic and conventional radiotherapy	Noninvasive, relocatable Can be used with or without thermoplastic mask Allows for fractionated SRS High degree of patient setup accuracy	Requires operator skill to create custom maxillary dentition molds May not be the best option for patients with poor dentition	H&N, intracranial stereo and some extracranial SRS targets in neck	Frame = yes Bite block = no	Yes	$$$
Invasive, nonrelocatable stereotactic intracranial immobilization devices (eg, Leksell Stereotactic Coordinate Frame G)	Frame is attached to the patient's skull with four screws Used for single-fraction radiosurgery	Excellent accuracy in patient repositioning	Typically requires sedation Risk of infection and bleeding Patient discomfort Often not compatible with intrafraction monitoring	Intracranial	Frame = yes	Rigidly attached directly to treatment machine (Gamma Knife), table- or floor-mounted stand	$$$
Noninvasive, relocatable intracranial mask–based immobilization (eg, CQ-Medical Solstice,	Multiple thermoplastic shells or cushions molded to patient's head and face, which	Does not require placement of screws into the patient's skull Allows for fractionated	Thermoplastic mask may be undesirable in certain patients, such as those with claustrophobia or anxiety	Intracranial	Base frame = yes Thermoplastic masks/custom cushions = no	Attach to treatment table	$$$

Device Name	Description	Pros	Cons	Typical Sites	Reusable?	Indexed?	Relative Cost
BrainLab Cranial 4Pi)	are tightly secured in a clamshell design around the patient's head	SRS High degree of patient setup accuracy demonstrated with CBCT and intrafraction monitoring					

CBCT, cone-beam computed tomography; H&N, head and neck; SRS, stereotactic radiosurgery.

FIGURE 7.4 The Fraxion® is an example of a flexible system that offers a bite block system that can provide an alternative method for immobilizing head and neck patients who are not able to tolerate a thermoplastic mask due to anxiety or claustrophobia (Image courtesy from 3C-Medical Intelligence GmbH.)

BODY CONFORMAL IMMOBILIZATION DEVICES

Numerous commercial body conformal immobilization devices are available for a variety of treatment indications. One type of body conformal system uses a two-part foaming agent to form a permanent mold of the patient's body. One such system, the Alpha Cradle, is illustrated in Figure 7.5A, B. Forms are available for treatment of patients with a variety of disease sites, including the H&N, breast, thorax, abdomen, pelvis, and extremities. At the time of simulation, the appropriate body form is chosen and placed in a polyvinyl bag where the two-part chemical foaming agents are mixed together, initiating the chemical reaction that causes the foam to expand. The mixed foaming agent is distributed evenly throughout the body form and sealed inside the polyvinyl bag, and the patient is positioned inside the form as the foaming agent

expands and conforms to the patient's body contour. The foam continues to expand for approximately 10 to 15 minutes during which the therapists will need to vigilantly guide the foam around the patient to prevent the foam from escaping the bag and moving into locations of least resistance that may contribute little to immobilizing the patient. As with any immobilization device, adequate training is needed to form a high-quality customized patient mold and the manufacturer's instructions should be carefully followed. Chemical foaming agent systems generally require two therapists to form at the time of simulation, and the process can require approximately 30 minutes. Caution must be used to prevent chemicals coming in direct contact with skin as this may cause irritation.

FIGURE 7.5 Body conformal systems are used for treatment indications throughout the body. A and B. Two patients are shown in treatment position with the Alpha Cradle brand Patient Repositioning System, which uses a two-part foaming agent to create customized conformal body immobilization. C. Full-body vacuum-lock bag. D. Room used for storing vacuum-lock bags in the simulation suite at the University of Virginia. The simulation suite services multiple treatment machines at satellite locations. After simulation, the immobilization devices are transported to the satellite treatment sites via a courier service. (A and B. Images courtesy of Smithers Medical Products, Inc. Alpha Cradle™ is a registered trademark of Smithers Medical Products, Inc. C. Courtesy of CQ-Medical.)

Another class of body conformal systems, commonly referred to as "vacuum-lock bags," is comprised of an airtight bag filled with plastic mini-spheres. These bags are available in a variety of sizes to accommodate different treatment sites and patient positioning techniques. At the time of simulation, the bag is first conformed to the patient's body contour by pushing the mini-spheres to fill in around the patient. A vacuum pump is then connected to the bag and the air is evacuated from the bag, causing the plastic mini-spheres to lock together to rigidly retain the device's shape. During the evacuation, the therapists maneuver the mini-spheres within the immobilization device to provide optimal fit and stabilization of the patient's body contour. These vacuum-lock bags are made of a durable nylon material to resist tears or punctures and can be expected to retain their shape for 6 weeks or more. They are reusable and may require less time to generate a patient-specific mold than the expanding foam systems. Another advantage of the vacuum-lock bag is that if during the simulation process the device is found not to provide the intended level of immobilization or is found to be uncomfortable for the patient, it can be reinflated and remolded to achieve the desired shape as many times as necessary. Being reusable, the vacuum-lock systems do require a time commitment to clean and remove any setup marks prior to use with subsequent patients. Also, if a tear or puncture occurs during treatment, a new vacuum-lock bag would need to be formed and the simulation and treatment planning process may be repeated to deliver the remaining fractions. Each clinic is recommended to consider the benefits and drawbacks of each system and could consider utilizing both types of body conformal systems for different clinical scenarios.

As body conformal devices are used to treat a wide range of sites throughout the entire body, careful thought should be given to each specific case to ensure that the treatment site is properly immobilized, that the setup is reproducible from day to day, and that the patient is able to maintain the position for the duration of each fraction. An immobilization device that extends well beyond the treatment site to encompass adjacent anatomy can be more effective than a more local device that focuses only on the treatment region. Early work by Bentel et al[9] showed that for Hodgkin lymphoma a cradle that extends below the pelvis is more effective than a cradle that only includes the upper torso. Devices that extend around the patient also give the ability to make setup marks directly on the immobilization device for alignment. Aligning the beam to setup marks on the immobilization device can increase the daily setup reproducibility by reducing the reliance on skin marks, which can be especially troublesome for larger or older patients where the skin can be more mobile over the underlying anatomy. Marks can then be made on the patient to help align the patient within the immobilization device. Longer devices, for example, the full-body Vac-Lok from CQ-Medical shown in Figure 7.5C, also allow for longer setup marks to be made in the superior-inferior direction, which can help detect rotational setup errors.

As an early example of body conformal immobilization's efficacy, Bentel and colleagues at Duke University showed that immobilization with the Alpha Cradle expanding foam system reduced the frequency of physician-requested setup corrections based on portal images for a variety of treatment indications, including Hodgkin lymphoma and prostate, lung, and breast cancer.[9,10] It should be noted, however, that not all studies show a clear-cut advantage in setup accuracy with body conformal immobilization devices. For example, an early study by Song et al[11] showed no statistical advantage of using immobilization in the treatment of prostate cancer in terms of the number of deviations >5 mm as quantified on portal images. They did show that patients with bariatric needs tend to have larger setup errors, highlighting the fact that certain patient populations may be more difficult to set up than others.[11]

Hurkmans' assessment of setup accuracy based on portal imaging provides a good review of the early imaging-based immobilization assessment data up to 2001.[4] This work concludes that with appropriate setup, immobilization techniques, and portal imaging, systematic and random setup errors on the order of 2.5 to 3.5 mm should be achievable for treatments of the thorax, abdomen, and pelvis. The integration of CBCT units with treatment machines is an excellent tool for assessing setup accuracy and has proven to be highly valuable in studies comparing and evaluating various immobilization systems. CBCT has been especially helpful to study the setup accuracy of stereotactic immobilization devices, the subject of a later section in this chapter.

It should again be emphasized that the degree of interfraction setup accuracy achievable by a particular institution will depend on the skill and knowledge of the personnel involved in forming patient immobilization devices, setting up patients for daily treatments, making adjustments based on verification imaging, and the understanding of the limitations of each step of the process. Table 7.2 provides a top-level summary of the pros and cons of commonly available body conformal immobilization systems.

TABLE 7.2 EXTRACRANIAL IMMOBILIZATION DEVICE SUMMARY

Device Name	Description	Pros	Cons	Typical Sites	Reusable?	Indexed?	Relative Cost
Alpha Cradle	Expanding foam device custom-molded to patient body contour	Rigid immobilization for wide range of body sites	One time use One chance to achieve adequate and comfortable immobilization	Thorax, abdomen, pelvis, extremities	No	No	$$
Vacuum-lock bags	Nylon bag filled with plastic mini-spheres; upon evacuation, mini-spheres lock together to	Reusable Can quickly reinflate and re-form during simulation if necessary	Punctures, tears, or loss of vacuum may necessitate resimulation of the patient	Thorax, abdomen, pelvis, extremities	Yes	Some include indexing and, for those that do not, an indexing bar can be used	$$

Device Name	Description	Pros	Cons	Typical Sites	Reusable?	Indexed?	Relative Cost
	form a custom mold of the patient body contour.					to make indentations in the bottom of the bag for later setup with the indexing bar.	
Prone breast board	Prone breast board can improve dosimetry for patients with large, pendulous breasts.	Separates target tissue from chest wall to minimize skin folds and lung dose	May not be tolerated by all patients Poor visualization of treatment field alignment Not suitable for regional nodal irradiation	Breast	Yes	Yes	$$
Prone belly board	Prone board to help the small bowel fall out of the treatment fields	Displacement of bowel out of treatment field can reduce toxicity	May not be tolerated by all patients Variability in bowel sparing	Pelvis	Yes	Yes	$$
Modular stereotactic body immobilization systems	Indexed base board with a wide range of attachments for immobilization, localization, and motion management	Flexibility to treat variety of disease sites with SBRT Attachment of devices for abdominal compression, leg stabilization, etc	More room for storage More time for setup and indexing of attachments	Spine, lung, liver, abdomen, pelvis, neck	Yes	Yes	$$$

SBRT, stereotactic body radiation therapy.

Prone Positioning for Pelvic and Breast Treatments

The body conformal devices described earlier can help provide reproducible patient setup from day to day for a wide range of disease sites. The patient is most often positioned supine in these devices. For certain treatment indications, a prone setup may provide a dosimetric advantage. In pelvic and abdominal irradiation, the small bowel is an important organ at risk, and acute toxicity is correlated with the amount of small bowel that receives a high dose.[12] For patients receiving pelvic irradiation, a popular method is to use a belly board (Figure 7.6A) on which the patient lies prone with their stomach positioned over the cutout region. With the aid of gravity, the small bowel will fall into the board's cutout and can reduce the amount of bowel in the treatment fields. The use of a prone belly board has been demonstrated to reduce the volume of small bowel at all dose levels.[13-17] Even with intensity-modulated radiation therapy, the use of a belly board technique has been shown to further reduce the small bowel dose.[13,16,17]

A

B

FIGURE 7.6 Immobilization devices specifically designed for prone positioning. A. A prone belly board can be used in treating targets in the pelvis. Gravity assists small bowel migration out of the treatment fields, which can reduce treatment-related toxicity. B. A prone breast board can be advantageous for patients with large, pendulous breasts. The board features a cutout that is easily reversible for treatment of either breast. C. Prone breast board couch insert with right side breast opening from CQ-Medical, the setup shown was for CT simulation with gray risers below the couch insert. For actual treatment, the gray riser is not used. (A and B. Courtesy of Bionix.)

The magnitude of the small bowel reduction with prone belly board positioning can be highly patient dependent. Kim et al[13] correlated the amount of small bowel at the 50% isodose level with a patient's age, weight, and gender. For example, this work showed a larger amount of small bowel (total volume in milliliters) at the 50% isodose level for the subgroups of patients over 56 years old, female patients, and patients weighing <65 kg (143 lb). It must also be noted that some investigators have reported that the use of a belly board worsened the reproducibility of patient setup. For example, Martin et al[14] reported having to reposition the patient based on portal imaging 68% of the time with a prone belly board system, compared to 23% of the time with supine positioning. In contrast, Olofsen-van Acht et al[15] report similar setup reproducibility between prone positioning with a belly board and patients in the supine position. Each patient should be assessed at the time of simulation for the efficacy of the belly board method to displace the small bowel as intended, as well as the patient's ability to tolerate lying on the belly board itself. Kim et al[18] found nonsignificant dose differences in the bladder and small bowel between the prone and supine positions, but noted worse setup errors associated with the prone position, supporting the treatment of all preoperative patients with rectal cancer in the supine position with VMAT and CBCT image-guided radiation therapy (IGRT). Yang et al[19] reported that setup reproducibility in the supine position is better compared to prone position with belly board. And they observed potential dose reduction to the small bowel, in combination with affected target dose coverage.

Another site where prone positioning has been used is in the treatment of breast cancer. Figure 7.6B illustrates a patient positioned on a prone breast board offered by Bionix Radiation Therapy and Figure 7.6C shows the CQ prone breast couch insert solution. The patient is positioned on the cushioned platform with her face resting in a donut-shaped cushion. The patient can hold the hand posts to help improve reproducibility and comfort. The prone positioning is most efficacious for patients with large, pendulous breasts, although it may also be an effective option for patients with severe arthritis that may be unable to hold their arms over their head.[20] Patients with large breasts tend to have larger tissue separation, larger treatment volumes, worse surface irregularity, and an accentuated inframammary fold, which can cause these patients to have higher reported rates of toxicities such as high-grade dermatitis and fibrosis.[21]

The goal of prone positioning for breast treatment is to minimize the lateral tissue separation and thus improve dose homogeneity. Improved dose homogeneity may decrease the rate of late toxicities such as fibrosis—an undesirable cosmetic outcome, and decreased tissue separation can reduce the entrance dose

needed to provide target coverage at depth, which may decrease the overall hot spot for the treatment plan, particularly at the skin surface.[20] Improved dose homogeneity and decreased skin dose from prone positioning may also prove to be advantageous for hypofractionated breast regimens where larger doses per fraction are delivered. Five-year follow-up data from Stegman et al[20] have shown that the prone position offers comparable local control to traditional supine positioning for whole-breast irradiation, with lower levels of toxicity. With the breast hanging in the prone setup, it may also be possible to reduce the dose to other nearby normal tissues. The increased separation of the breast tissue from the chest wall has been shown to decrease the amount of irradiated lung in whole-breast irradiation.[22] Dose to the heart is more variable; for left breast patients, most heart doses (20-30 Gy levels) are decreased in the prone position, although some patients did exhibit higher heart doses when treated prone.[22]

It can be difficult to set up patients with large or pendulous breasts in a supine position because the breast can lie in a different position each day. In the supine position, a ring or tube can be used to keep the pendulous breast from folding over. With the aid of gravity, daily setup can be more reproducible with the breast hanging in the prone position. There are, however, potential disadvantages to the prone setup for patients with breast cancer, for example, reduced visibility of the breast for alignment purposes. Furthermore, the prone positioning may not be tolerable for patients who are elderly or have bariatric needs. And finally, the prone position may not be logistically suitable for patients requiring regional nodal irradiation as the prone position would severely limit visual alignment of an anterior supraclavicular field. Alternatively, immobilization bra could be an option for large or pendulous breast.[23,24]

Space Considerations

Whole-body expanding foam or vacuum-lock bag systems can provide excellent patient comfort and immobilization, but they are large devices that require storage space be considered. Adequate space is required to store each patient's custom-formed device for up to 6 weeks or more while a patient is under treatment. At the Emily Couric Clinical Cancer Center at the University of Virginia, a dedicated room next to the simulation suite and large closets in each treatment room are used for storing patient's body conformal immobilization devices (see Figure 7.5D). For clinics where one simulation suite is used to support multiple satellite clinics, the logistics of transporting the immobilization device must also be considered. At the University of Virginia, Virginia Commonwealth University, and Sanford Health, a courier service is used to transport large body conformal devices from the simulation site to satellite treatment facilities. Each clinic must assess space availability when deciding which systems to adopt in patient care.

DOSIMETRIC EFFECTS OF IMMOBILIZATION DEVICES

Any material placed between the patient and the radiation source can modify the dosimetric characteristics of the treatment beam. These materials, such as couch tops and immobilization devices, can have profound impact on patients, such as increasing skin dose, reducing tumor dose, or altering dose distribution. The American Association of Physicists in Medicine (AAPM) Task Group 176 has published an excellent report regarding the dosimetric effects of couch tops and immobilization devices including the basic physics rationale, a well-rounded literature review of relevant studies, and techniques that can be utilized to reduce and better model the dosimetric effects of these devices.[25]

Concerns regarding bolus effect have been reported for photon plans, resulting in clinically relevant skin toxicity due to the passage of beams through the couch top and immobilization devices.[25] Skin toxicity has been reported in the literature due to the failure to include the couch top and immobilization devices.[26-28] Hoppe et al[27] presented 7 out of 50 patients who experienced larger than grade 2 skin toxicity due to the lack of skin sparing from the immobilization device. An example is shown in Figure 7.7. And for inversely planned cases, even with the immobilization devices presented, skin can be contoured to lower its dose through the optimization process.[26]

FIGURE 7.7 Patient who developed grade 4 skin necrosis from stereotactic body radiation therapy. (Reprinted from Hoppe BS, Laser B, Kowalski AV, et al. Acute skin toxicity following stereotactic body radiation therapy for stage I non-small-cell lung cancer: who's at risk? *Int J Radiat Oncol Biol Phys*. 2008;72[5]:1283-1286. Copyright © 2008 Elsevier. With permission.)

Other than the observable skin effect, dose attenuation from couch top and immobilization devices is also a significant concern, which can result in tumor underdose and organs at risk overdose if not being taken care of. For photon plans, the average attenuation from couch tops is typically 2% to 5%, which can go up to 15% for certain parts of the couch top.[25] For proton beams, depending on the water equivalent thickness of the couch top or immobilization devices, the distal range of the particle beam will be shortened due to the material traversed if not incorporated into the calculation. This could, in theory, pull the dose completely away from the target to a shallower depth for small tumors and in the presence of thick attenuating materials.

It is recommended to incorporate couch tops and other immobilization devices (internal and external of the patient) and carefully verify the dimension and physical property of the material for accurate dose calculation.

STEREOTACTIC IMMOBILIZATION AND STABILIZATION

Introduction

Hypofractionated stereotactic techniques enable the radiation oncologist to deliver high-dose conformal radiation therapy with a sharp dose falloff to both intracranial and extracranial targets. Here, we describe stereotactic radiosurgery (SRS) as a single high-dose fraction to well-defined brain target(s), and stereotactic radiation therapy (SRT) as delivered over a small number (2-5) of high-dose fractions. Delivering a high dose to the target volume in only a few fractions increases the requirements for precise

delivery of the radiation. Advances in online image guidance have enabled the delivery of high-dose extracranial stereotactic treatments, and patient immobilization systems have evolved to help decrease interfractional variation in patient setup and intrafractional patient and target motion.

Intrafraction target motion occurs in lung and liver tumors because of normal physiologic processes such as respiration, and longer treatment times associated with high-dose SRT may increase the risk of intrafraction motion.[30] Numerous immobilization-based strategies to minimize this motion are discussed later in this section. In general, intrafraction error from patient movement within the device during treatment can be reduced by improving the comfort and stability of the immobilization system. As with all immobilization methods and devices, patients with poorer performance status may have worse interfractional setup reproducibility and more intrafraction motion within the immobilization device,[31] so patient- specific immobilization options may need to be considered.

Intracranial Immobilization Devices

Intracranial immobilization devices can generally be classified into two categories: invasive and noninvasive, which are reviewed in the following sections. Other important characteristics include if the device is relocatable or not, and what system is used to align the patient for treatment.

Invasive Cranial Immobilization

Invasive cranial immobilization devices enabled intracranial SRS treatments prior to the widespread adoption of in-room image guidance and are exemplified by rigid metal frames attached to posts and metal pins driven directly into the skull. The patient then undergoes imaging (CT, magnetic resonance imaging [MRI], or angiography, depending on device compatibility), a treatment plan is then developed, and at the time of treatment, the head frame is connected to either a floor-mounted stand or the treatment table to provide rigid cranial immobilization. The primary advantage of the invasive, frame-based, nonrelocatable stereotactic head frame is the rigid immobilization it provides, with accuracy generally reported on the order of <1 mm.[32]

For example, the Leksell Stereotactic Coordinate Frame G (Elekta, Stockholm, Sweden) (Figure 7.8) was shown in a phantom study on the gamma knife system using GafChromic film to achieve overall accuracy (mean ± standard deviation) of an MR-defined target to be 0.21 ± 0.32 mm and 0.15 ± 0.26 mm in the *x*- and *y*-axes, respectively, and 0.06 ± 0.09 mm and 0.04 ± 0.09 mm for a CT-based target.[32]

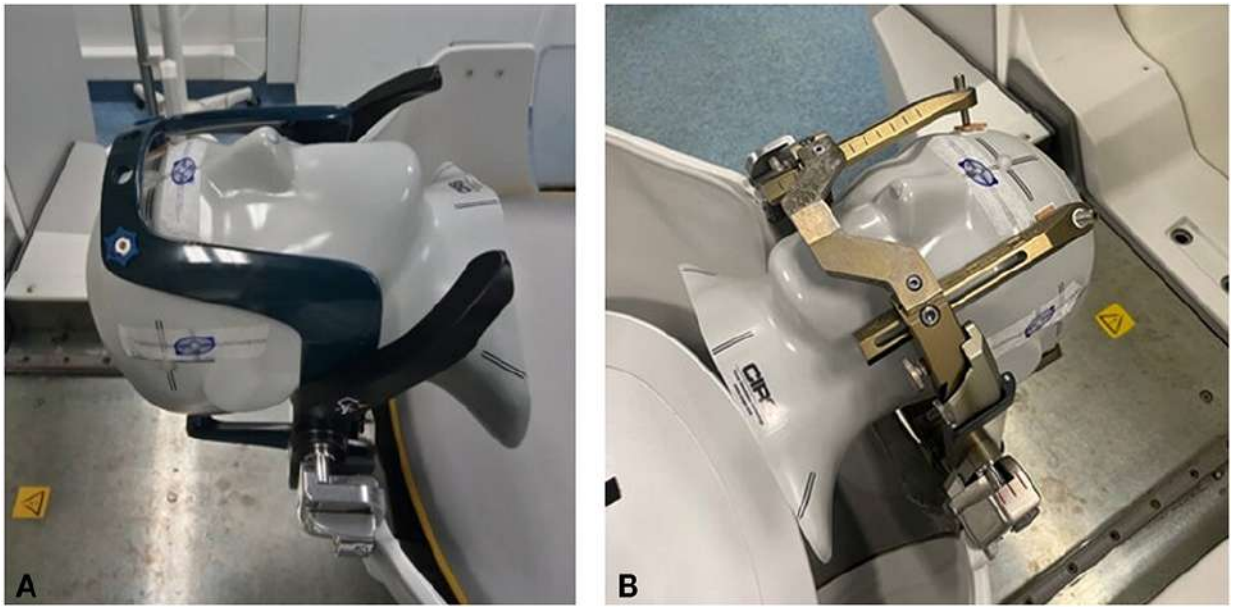

FIGURE 7.8 The Leksell® (A) Vantage Frame (B) G-Frame fixed to the head via screws. (From Vincent M, Michel-Amadry G, Nigoul JM, Beltaïfa Y, Régis J. Spatial accuracy of the stereotactic Leksell®Vantage™ head frame in comparison with the standard stereotactic Leksell®G frame for Gamma-Knife. *Biomed Phys Eng Express*. 2023;9[3]:035021. Copyright © Institute of Physics and Engineering in Medicine. Reproduced by permission of IOP Publishing. All rights reserved.)

A disadvantage of these invasive, nonrelocatable devices is that they are for the most part limited to single-fraction SRS, requiring frame placement, imaging, planning, quality assurance, and delivery to occur in the same day before the frame can be removed.

Noninvasive Cranial Immobilization

Invasive cranial immobilization devices have been successfully used for many years to deliver intracranial SRS, but these systems require placing of screws into the patient's head, which carries the risk of bleeding and infection and requires premedication and dedicated nursing support.[33] The compressed treatment planning time required for nonrelocatable systems may also be less desirable in certain scenarios. Numerous relocatable and noninvasive systems have been developed that can provide accurate and reproducible immobilization of the head without the use of screws driven into the skull and provide the flexibility to deliver multifraction SRT.

Frameless brain stereotactic immobilization systems aim to achieve sub-millimeter accuracy by minimizing both the initial setup difference between CT simulation and treatment sessions (interfraction uncertainty) and patient motion uncertainty during a treatment session (intrafraction error). Advanced thermoplastic mask systems specifically for brain stereo are designed to far exceed the performance of standard thermoplastic masks for conventionally fractionated treatments and often share a number of common features including custom immobilization of both the anterior and posterior aspects of the patient's head and some ability to "shim," that is, tighten or loosen the mask fit as needed for patient weight loss or swelling from steroids, respectively. Some systems, like the CQ-Medical Solstice System shown in Figure 7.9, include the ability to manually fine-tune rotations, in this case pitch. The radiation oncology field has leveraged the widespread adoption of in-room image guidance systems for patient positioning to increase our confidence in treating patients undergoing brain stereo with frameless thermoplastic mask systems by quantifying the stability that can be achieved when utilized appropriately.

FIGURE 7.9 The Solstice noninvasive mask system uses a rigid head cup to connect an open-faced thermoplastic mask. A patient-specific cushion is used to cradle the posterior head and neck. The open-faced mask design allows intrafraction monitoring and the rigid head cup includes a manual pitch adjustment, which can be used to perform pretreatment setup corrections or at CT simulation to optimize patient comfort and stability. (Courtesy of CQ-Medical.)

Early generations of frameless stereotactic brain masks have laid the foundation by confirming sub-millimeter intrafraction accuracy is achievable, for example, the BrainLab three-piece plastic mask system. Ali et al[34] evaluated the setup accuracy of the BrainLab mask system with the classic localizer box by acquiring verification onboard kilovolt images and reported mean shifts of 0.7 ± 2.0 mm, 1.6 ± 2.6 mm, and 0.1 ± 2.2 mm, respectively, in the *x*, *y*, and *z* dimensions. The random setup errors exhibited by standard deviations larger than 2 mm support the argument for daily pretreatment image guidance as opposed to relying solely on the localizer box.

The achievable intrafraction accuracy of open and full coverage mask systems for brain stereo has been confirmed with numerous studies utilizing pre- and post-CBCT imaging, for example, Ohira et al[35] compared two available systems used equally among 76 patients undergoing total brain stereo over 349 total treatments and reported similar sub-millimeter stability with both mask systems. An interesting analysis from Komiyama et al[36] assessed 89 patients undergoing brain stereo immobilized with the Encompass system by acquiring pre- and post-CBCT as well as MV images (anteroposterior [AP]/posteroanterior direction) at each couch angle before treating that beam. Using 2D-2D match data from the mid-treatment MV imaging, they convincingly show that on average, frameless brain stereo mask systems can provide sub-millimeter accuracy, although outliers with mid-treatment deviations >1 mm do happen. Building on lessons like these, many modern brain stereo mask systems offer an open face solution to support intrafraction patient monitoring in near real time, a topic treated in more detail in later sections. And finally, the recent expansion of commercially available systems to treat multiple brain met targets off-axis with a single isocenter should be noted to increase the importance of maintaining both sub- degree and sub-millimeter accuracy throughout treatment.

Extracranial Immobilization Devices

In 1995, Hamilton and colleagues from the University of Arizona published their preliminary clinical experience with linear accelerator–based SRS of the spine in five patients.[37] For immobilization, surgical clamps were secured directly to the spinous processes one to two vertebral levels above and below the target volume under local or general anesthesia, through a 2 cm incision. The spine was rigidly immobilized

by attaching the clamps to a frame consisting of a rigid box with two semicircular metal arches. After CT simulation and treatment planning, the patient and frame were transferred to a modified linear accelerator and setup according to stereotactic coordinates derived from the planning CT. While this highly invasive device was important in demonstrating the feasibility of extracranial stereotactic body radiation therapy (SBRT), modern immobilization systems for extracranial SBRT utilize noninvasive customizable devices like the previously described body conformal vacuum-lock bags, with added features and attachments to allow for more precise initial positioning and improved intrafraction stability.

One example of a modular immobilization system for extracranial SBRT includes the Alta platform from CQ-Medical depicted in Figure 7.10. SBRT-specific frames like these include indexing along the entire length of a lightweight carbon fiber platform allowing reproducible isocenter localization and for accessories to be attached. Attachment options typically include headrests, forehead restraints, upper arm supports, shoulder restraints, thigh and foot positioners, external fiducial arches, and abdominal compression devices. Newer platforms like the Alta are also designed to accommodate clam-shell-style mask systems for stereotactic brain treatments or angled breast boards.

FIGURE 7.10 The Alta platform is a modular immobilization system that can be used for many indications, including stereotactic body radiotherapy. A myriad of attachments are available to build a device customized to the needs of each patient. This particular setup uses an abdominal compression plate and a thigh arch for treating stereotactic targets in the lung. (Courtesy of CQ-Medical.)

Numerous investigators have assessed the reproducibility of these extracranial SBRT immobilization systems. Foster et al assessed pretreatment and mid-treatment CBCT data for 1,005 stereotactic treatment sessions, including lung, liver, prostate, and spine tumors, and reported interfraction setup errors of (mean ± standard deviation) 2.4 ± 3.8 mm in the AP direction and 1.3 ± 5.8 mm in the superoinferior (SI) direction, when using a dedicated stereotactic body immobilization system.[29] Purdie et al[30] evaluated the intrafraction positioning reproducibility by comparing pretreatment localization CT to a mid- or posttreatment CBCT with the Elekta Stereotactic Body Frame in 28 patients with lung SBRT. The mean 3D tumor position was within 2.2 ± 1.2 mm of the planned position when repeat imaging was performed within 34 minutes of target localization, and 5.3 ± 3 mm when performed more than 34 minutes after target localization ($P <$ .01). While this particular device is no longer commercially available, this study highlights the important consideration that longer treatment times can increase the intrafractional positioning error.

The Elekta BodyFIX is another example of a body conformal system with features specifically designed for SBRT. The distinguishing characteristic of the BodyFIX system is a thin clear plastic cover sheet that uses an active vacuum pump to create negative pressure providing additional immobilization of the patient. A study of 126 patients with lung SBRT used pre- and posttreatment CBCT to determine intrafractional stability of the BodyFIX system and reported the intrafractional variation of mean tumor position to be 2.7 ± 2.6 mm.[38]

Immobilization and Internal Motion Management

In addition to intrafraction error caused by patient movement within the immobilization device, internal target motion due to breathing must be accounted for in SBRT, particularly in the treatment of lung and liver tumors. The reports of AAPM Task Groups 76 and 101 address the management of respiratory motion in radiation therapy and present the results of a variety of studies showing that lung and liver targets exhibit a wide variation in motion amplitude during respiration.[39,40] While technology has continued to evolve since their publication, these reports are still highly regarded resources since the well-described mechanics of respiration and the risks of treating moving targets remain unchanged.

Numerous motion management strategies are available to account for and/or control internal target motion from respiration in radiotherapy, including abdominal compression, breath hold (BH), active breathing control, respiratory gating, and real-time tumor tracking. Brandner et al's review[41] provides an excellent overview of the risks and benefits associated with each motion management strategy for stereotactic treatment of lung and upper abdominal tumors.

Abdominal compression attachments are available with most modern stereotactic immobilization systems and are generally intended to physically limit a patient's respiratory amplitude. This technique is also referred to as forced shallow breathing. Abdominal compression devices typically consist of a plate attached to an arch that is indexed to a stereotactic body frame or the treatment couch. The plate is placed a few centimeters below the patient's xiphoid process and a screw is tightened until the desired amount of internal motion control is achieved. The screw is marked so that it can be reproducibly tightened for multiple fractions. This rigid plate is appropriate for lung targets since the treatment beams will not pass through the high-density arch and plate. For abdominal targets, inflatable compression belts are preferred as they are of lower density and thus affect the beams passing through it to a lesser extent.

Studies report varied results with the use of abdominal compression in reducing lung tumor motion amplitude. Bouilhol et al[42] studied lung tumor motion in 27 patients with lung SBRT using two four-dimensional (4D)CT scans at the time of simulation: with and without abdominal compression. As most practitioners would expect, abdominal compression reduced tumor motion for lower lobe lesions the most, with a modest average motion reduction of 3.5 mm. For upper lobe lesions, the average motion reduction was only 0.8 mm, and concerningly 5 of the 27 patients were observed to have increased motion with abdominal compression. Furthermore, the dosimetric gain of the compression on lung sparing in planning was shown to be minimal. Thus, a potential workflow for patients with lung SBRT could be to first assess target motion without abdominal compression, and then re-4DCT with abdominal compression added if motion is of a concerning magnitude.

The value of abdominal compression is clearer for abdominal targets like liver and pancreas. The mean amplitude for liver motion measured with fluoroscopy was shown to decrease from 40 mm with free breathing to 11 mm with the use of abdominal compression.[43] Another study showed that while abdominal compression reduced the SI and AP motion, an increased motion amplitude in the left-right dimension of 15% on average (maximum 1.6 mm) was observed,[44] indicating that compression may also be redistributing breathing motion.[39]

BH is another common technique that greatly changes the patient's natural respiratory pattern, so this topic will be discussed in the following section on optical surface imaging.

Respiratory gating and real-time tumor tracking are outside the scope of this chapter since they primarily rely on additional technology to treat the moving target in a subset of its observed motion range without modifying the patient's breathing in a fundamental way. Although not treated in detail here, clinics considering respiratory gating and/or real-time tumor tracking are referred to review AAPM recommendations due to the very real risk of missing the moving target due to intrafraction breathing changes leading to target displacement from isocenter, which have been observed to occur in as little as a few minutes while the patient is on the treatment table.[39,40,45,46]

REAL-TIME MONITORING OF PATIENT POSITIONING

Introduction to Intrafraction Monitoring with Surface-Guided Radiation Therapy

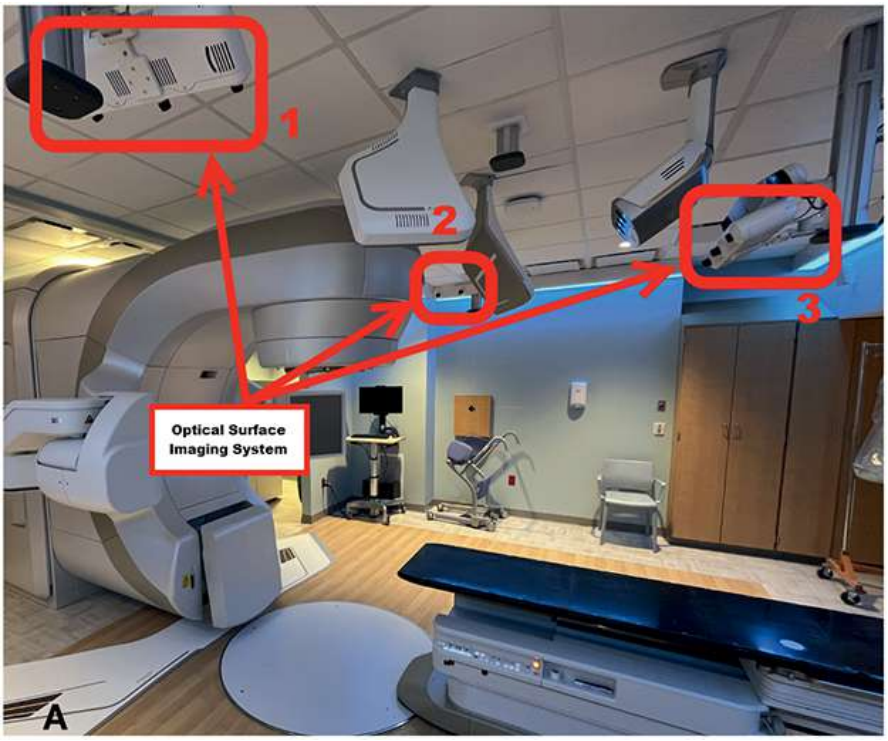
As established throughout this chapter, immobilization devices are crucial tools for the appropriate delivery of radiation treatments. They promote consistent setups throughout the course of radiotherapy and help patients hold their treatment position for the duration of each fraction. However, these systems have their limitations, and it cannot be assumed that the planned position is accurately replicated and maintained thanks to immobilization devices and pretreatment imaging alone. Moreover, these tools oftentimes must balance patient comfort with motion restriction. Hence, although immobilization devices conform to the patient and limit their mobility, patients can still move during treatment. This becomes progressively worrisome as margins are reduced and fraction doses escalate. Under these conditions, patient monitoring during treatment to detect undesired intrafraction motion becomes especially important.

Surface imaging systems can help facilitate patient setup and allow for intrafraction monitoring without the use of additional ionizing radiation, in what is known as surface-guided radiation therapy (SGRT). Optical surface guidance systems have become rapidly accepted in radiation oncology over the past decade due to sub-millimeter accuracy and sub-second feedback without any imaging dose. A system from BrainLab combines thermal and optical cameras to monitor patient's positions with sub-second temporal feedback paired with orthogonal in-room x-rays for periodic bony or fiducial imaging. Using Cherenkov radiation generated from the patient during beam-on is another interesting concept finding its way toward clinical utility.

Please note that while SGRT can be useful for initial positioning of any site, internal imaging must be performed when the target location might not properly correlate with the surface. Intrafraction monitoring with surface guidance systems can be used to detect external motion or even track breathing,[47] but this does not necessarily reflect the true target motion as not all internal involuntary movements will be revealed by the patient's surface. It is crucial to understand the technology, the information these systems provide, and their limitations to ensure they are used correctly and to their full potential. This section aims to give the reader a general overview of these systems, their characteristics, and some typical clinical uses, then finishes with two emerging technologies in radiation therapy monitoring.

Overview of Selected Optical Surface-Guided Radiation Therapy Systems

Optical imaging systems (Figure 7.11A) acquire a 3D map of the patient's surface in the treatment room and compare it to the patient's planned surface position, known as the reference surface. The reference surface is typically generated from the external CT contours and isocenter location from the Digital Imaging and Communications in Medicine (DICOM) files and is first used for initial patient in-room setup. A new reference surface can be captured at meaningful time points during the treatment, to create a re-zeroed patient surface reference for ongoing monitoring. For example, a reference surface captured shortly before, during, or after CBCT acquisition allows the team to verify, before applying the IGRT-indicated shifts, that the patient's surface has been stable during the time window needed for image matching, review, and approvals.



B

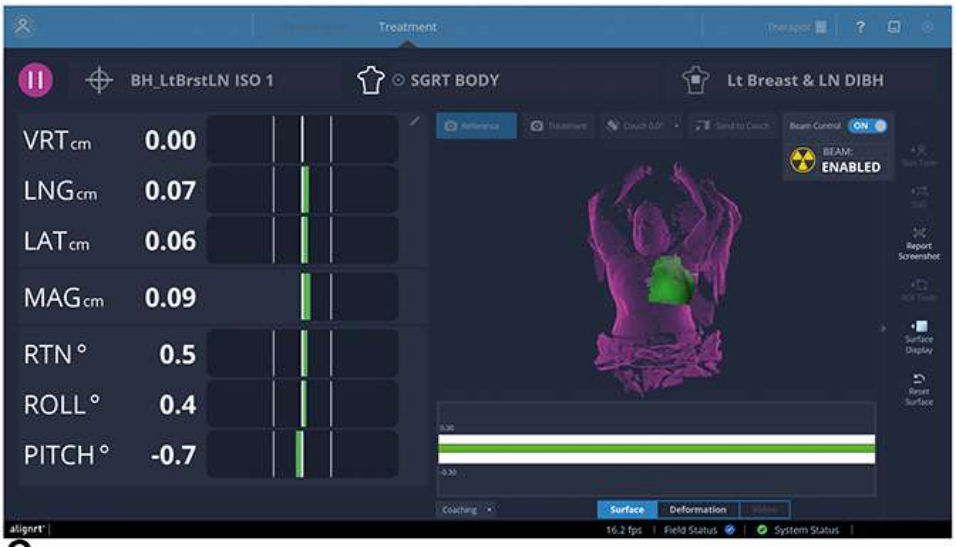


FIGURE 7.11 A. The optical surface imaging system consists of three ceiling-mounted camera pods to acquire a patient's surface in the treatment room. B. The system projects a visible pattern of light on the patient's surface to guide the therapists in aligning the patient to the reference surface. C. Monitors in the control and treatment rooms provide the therapists with real-time feedback about the current alignment of the patient's current and reference surfaces including rigid translations and rotations to help align the patient prior to treatment and track intrafraction surface motion during treatment.

The approach to obtain the real-time patient surface and its registration with the reference surface varies depending on the specific surface imaging system, although all provide six degrees-of-freedom (DoF) correction estimates to move the patient's observed surface closer to the chosen reference surface. Three main manufacturers of surface imaging equipment for radiotherapy are: Vision RT (London, UK) who manufactures the AlignRT system, C-RAD (Uppsala, Sweden) who manufactures the Sentinel and Catalyst systems, and LAP (Luneburg, Germany) who manufactures the LUNA 3D system. Each system uses a different approach in both physically acquiring the current surface and registering the acquired and reference surfaces. This list is not meant to be a comprehensive description of all available options but merely an introduction to a few examples that illustrate the current state of technology in optical surface imaging.

The C-RAD family of optical surface guidance systems includes Sentinel and Catalyst products. Sentinel is used at the CT simulator for respiratory tracking during 4DCTs and other gated scans, whereas the Catalyst family of systems is used for patient positioning and monitoring during treatment. The C-RAD Sentinel system comprises a sweeping visible red laser (635-690 nm wavelength) and a camera that captures the reflected light as the laser sweeps across the patient at discrete intervals to read their surfaces. It takes approximately 1 to 2 seconds to scan a length of 40 cm with a measurement reproducibility of 0.2 mm, and it detects respiratory signal with a frequency of 15 Hz. The C-RAD Catalyst system comprises one or three ceiling-mounted pods in the treatment room and facing the machine isocenter. In contrast with Sentinel, Catalyst uses light in the near-invisible violet range (405 nm), allowing the full patient surface to be read at once, instead of with discrete laser sweeps, which allows for scan speeds greater than 80 frames per second (fps). The position and motion detection accuracy is quoted as 1 mm for the standard system and 0.5 mm for the HD system. Details of the performance of these systems can be found in the literature.[48-50]

Vision RT offers a family of surface imaging systems that allow for patient positioning and monitoring during treatment (AlignRT), respiratory tracking at simulation for 4DCT acquisition (GateCT), and gating during treatment delivery (GateRT). AlignRT is typically a three-pod system mounted on the ceiling, with each pod containing two cameras and a projector that casts a red light speckle pattern on the patient. The stereoscopic cameras read the structured light projection pattern and reconstruct the patient's surface based on the deformation of the known pattern. The patient's current acquired surface is then rigidly registered to

the reference surface in the area defined by the user as the region of interest (ROI) (Figure 7.11B). The frame rate for this system depends on the size of the ROI and is typically at least 8 to 12 fps for thorax ROIs (Figure 7.11C). There is literature on its use in radiation therapy for all treatment sites, but especially in left-sided breast deep inspiration breath hold (DIBH) treatments[51-53] and SRS,[54-56] presented in more detail in later sections.

Thermal Imaging: BrainLab ExacTrac Dynamic System

The newer generation of BrainLab ExacTrac Dynamic, launched in 2020, comprises a kilovolt x-ray imaging system and a 4D thermal camera, which is made up of an optical surface tracking system and a thermal surface tracking system (Figure 7.12). Optical surface tracking systems, using the structured light scanning technique to determine the surface information, can struggle in tracking small, flat areas with little topographic variation. BrainLab claims the added thermal information integrates an additional dimension as depicted in Figure 7.13, allowing high patient positioning tracking accuracy compared to the surface-only option.[57]

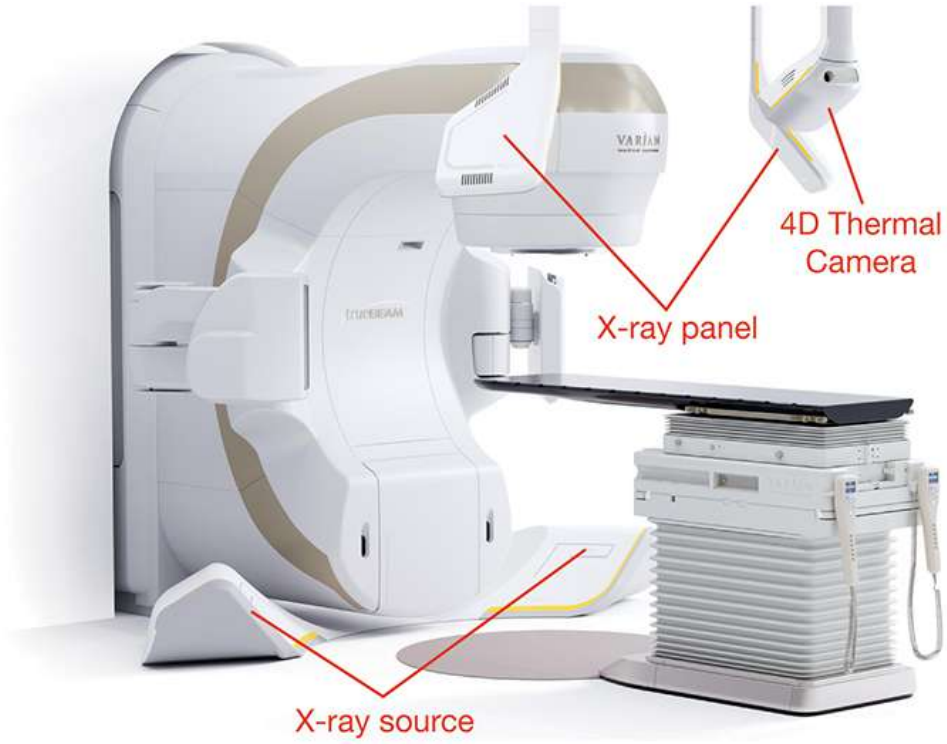

FIGURE 7.12 Room configuration for BrainLab ExacTrac Dynamic System. (Courtesy of Brainlab.)

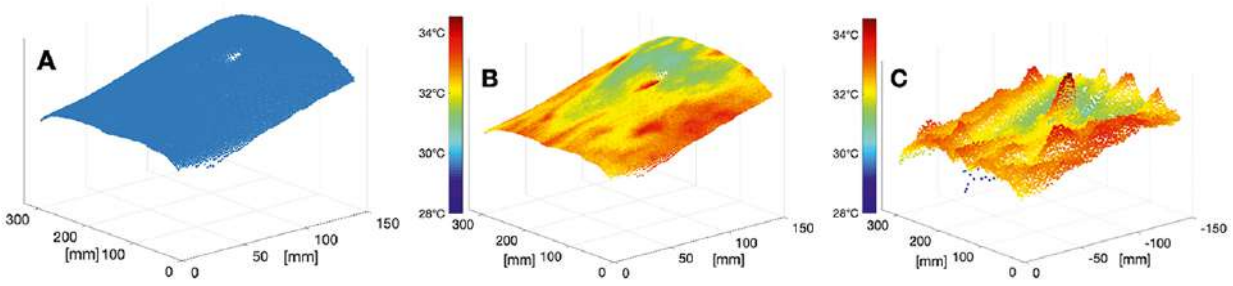

FIGURE 7.13 A. Preposition of the patient before treatment by matching the live three-dimensional (3D) surface with the reference contour. B. Combining the 3D and two-dimensional thermal data using the perspective-*n*-point algorithm to calculate a hybrid 3D/thermal matrix. C. Use of geometric and thermal data to match the reference data and the live surface. (Courtesy of BrainLab.)

Da Silva Mendes et al[58] concluded the ExacTrac Dynamic system is in close agreement (within 0.4 mm) with CBCT. Similar findings can be found by other authors.[59,60] Gutiérrez et al[61] published their verification study and stated with the help of both kilovolt x-ray and surface tracking that no margin is needed to compensate for intrafraction motion except for very small lesions (<0.1 mL). Additionally, BrainLab introduced ExacTrac Dynamic Surface in 2023, which consists of only the 4D thermal camera as their SGRT-only solution.

Current Clinical Applications

Initial Patient Setup

Current commercially available systems use a reference surface of the patient to guide therapists during initial in-room setup. The reference surface for daily alignment is generated from the CT planning data contours, acquired from a SGRT system at the time of simulation, or acquired during an earlier treatment fraction, typically following x-ray image-guided alignment.

As the patient's current surface is read and compared to the reference surface in near real time, six DoF shift information is displayed as three translations (vertical, longitudinal, lateral) and three rotations (yaw, roll, and pitch). Feedback about the deviation between the current surface and the reference surface is either projected on the patient's skin or shown on a screen, informing therapists what adjustments are needed to achieve the ideal match to the patient's reference surface. Once the desired external position has been achieved, anatomic alignment should be confirmed with internal image guidance techniques and a new reference surface acquired, if positioning adjustments are made.

Surface imaging systems give users the option to acquire a new reference surface with the optical cameras to guide patient alignment, and the pros and cons of acquiring a new reference surface should be considered in detail, for which the reader is referred to TG-302 (in particular table 6 of the reference).[62] The optical camera systems tend to capture a larger extent of the patient's external anatomy when compared to the DICOM reference from the CT. The purpose of updating the reference surface is 2-fold: (a) having a reference with extended external anatomy may facilitate setup for subsequent fractions, for example, of the elbows in arms-up positioning, and (b) re-baselining the reference position will allow for improved intrafraction monitoring sensitivity.

Although ideally the patient's external surface should exactly match the planning position every time, this is rarely the case in practice. If the patient's current position is found to be acceptable as confirmed with internal imaging, acquiring a new reference surface will zero out any residual surface offsets between the patient's approved treatment position and the original patient surface from the time of simulation. Hence, any change in the patient's surface ROI (ie, motion) throughout the fraction will become more obvious in the displayed shift values. This is even more important if the surface imaging system interfaces with the treatment machine to gate the beam. Removing the inherent shifts between the current approved treatment surface and the original reference will allow for tighter monitoring thresholds for any given

fraction and less beam interruptions from false large readings. It is important to note that for most commercial systems, the original reference surface based on the DICOM information remains available for selection throughout the course, giving the option to perform initial alignment with either an acquired reference surface or the DICOM CT sim surface at any time.

Surface imaging's usefulness in initial patient positioning is reflected in some clinic's decision to completely move away from permanent tattoos for initial setup marks on the patient's skin and instead rely entirely on the surface imaging system.

Surface imaging may be used for the initial positioning and monitoring of patients treated at any anatomic site; however, it has shown special utility for BH treatments for breast, lung stereo, and abdominal stereo as a surrogate for BH stability. It is also a highly valuable system for brain stereo because of the close correlation between the surface and the internal target position, sub-millimeter spatial accuracy, and near-real-time monitoring.

Deep Inspiration Breath Hold for Breast Radiotherapy

DIBH treatments for patients with left-sided breast cancer can provide cardiac sparing because the heart moves further away from the chest wall, and hence from the treatment volume, as the lungs inflate.[51] Surface imaging has emerged as a useful tool for voluntary DIBH treatments. The use of this technology can achieve reproducible patient setups and reasonably consistent distances between the heart and the chest wall during BHs, reliably minimizing cardiac side effects from radiotherapy.[51,62] When using SGRT for this purpose, the external surfaces from both a free-breathing and a DIBH scan are sent to the system. The patient is initially set up in-room to the free-breathing scan, and the BH reproducibility is checked with the DIBH DICOM CT sim reference surface, as recommended by TG-302 to help confirm BH reproducibility. An important point to describe clearly in the institutional workflow is which couch adjustments are allowed for initial setup and which are not. For example, adjusting the patient's vertical position with couch movement while in DIBH might mask BH reproducibility issues; if the BH was less deep than at CT sim, the couch vertical adjustment could bring the heart closer to the treatment beam than planned.

After the BH depth is confirmed in-room with SGRT, internal imaging such as CBCT should be acquired to calculate couch corrections and confirm target and heart position. Before applying the shifts, operators should have well-defined institutional workflows in place to confirm that the patient's BH level is consistent, then apply the shifts, and potentially capture a new reference. The choice of final reference surface used for confirming each BH's consistency prior to beam-on, with some systems allowing automatic BH using preset tolerances from the DIBH reference surface, typically is 3 to 5 mm.

Breath Hold for Body Stereo

BH for lung and abdomen stereo targets is commonly employed as it holds the promise of significantly reducing internal target volume (ITV) motion margins compared to free breathing. This promise does come with additional risk of geometric target miss that can be mitigated by understanding the subtleties of the BH maneuver, and the essential realization that BH-to-BH consistency is never guaranteed. In a survey of 87 clinics in Australia and New Zealand published in 2022, BH was reported in use at 41% of the clinics,[63] so it is relevant to outline how immobilization and monitoring can play roles in institutions creating and maintaining workflows to guide team members in this advanced procedure.

DIBH is commonly considered for lung stereo as it would naturally increase lung volume and thus confer improved lung sparing, although reports in the literature can provide a different perspective. Brandner et al's 2017 review[41] includes an excellent summary of literature on the topic of BH for body stereo and points to data that suggest that the end-exhale phase is often more reliable in reproducing the target's internal position. Lens et al[64] assessed abdominal organ velocity during both inhale- and exhale-BHs using cine MRI with 0.6-second time resolution and reported improved organ stability during exhale-BH, which is of interest for patients undergoing abdominal stereo. Wölfelschneider et al[65] shared their experience monitoring exhale-BH surface reproducibility for patients undergoing lung stereo, reporting that 15 of 20 patients showed end-exhale-BH surface reproducibility within 5 mm, showing exhale-BH could indeed be

potentially considered for select patients undergoing stereotactic procedures. The varying experiences with the efficacy of BH in radiotherapy reported in the literature hint at a bigger picture realization: that a workflow built around a single kind of BH (deep inspiration, normal inhalation, expiration, etc) may not be optimal or feasible for all patients undergoing stereotactic lung and abdomen procedures. Thus, when possible and practical, it is important to consider workflows that support patient-specific motion assessment and the application of meaningful motion management tools at the time of CT simulation.

Confirmation of BH-to-BH reproducibility at the time of treatment is another important point for body stereo workflows to consider. For example, at one author's institution (Sanford Health), three BH-CTs are acquired for three different BHs at the time of CT sim to provide an opportunity to assess BH-to-BH consistency and to generate a pseudo-ITV structure. For BH stereo treatment, each CBCT is consciously acquired with two to three independent BHs to allow some averaging of the internal target positioning on repeat BHs. This can increase confidence in the matching process that the BH-ITV is still adequate for the current treatment fraction.

Intracranial Stereotactic Radiosurgery

Patients with intracranial SRS can also benefit from SGRT setup and monitoring. Conventional masks used for frameless SRS are not suitable for SGRT because they cover the patient's entire face; SGRT technology requires uncovered skin for proper tracking. Open masks allow for immobilization of the patient while maintaining part of the face exposed for surface monitoring. Open mask immobilization in this scenario has the advantage of both allowing continuous tracking of the patient's surface directly, instead of monitoring infrared markers on the mask, and providing increased patient comfort. Several authors have published on the feasibility and accuracy of this technique, reporting the considerations necessary to achieve sub-millimeter accuracy for radiosurgery.[66,67] While initial positioning should always be confirmed with internal volumetric imaging to ensure the target alignment is within the tight planning margins, the use of surface imaging for these treatments allows for real-time monitoring of the patient without any additional ionizing radiation dose.

Emerging Technology for Monitoring

Ocular Tracking

A novel system of immobilization and tracking for uveal melanoma treatment is shown in Figure 7.14. The patient's head is immobilized in a thermoplastic mask, as is typical for H&N treatments, while the eye position was monitored in real time with an infrared camera. In this way the stereotactic treatment could be interrupted if the patient's eye position moved during the treatment.[68]

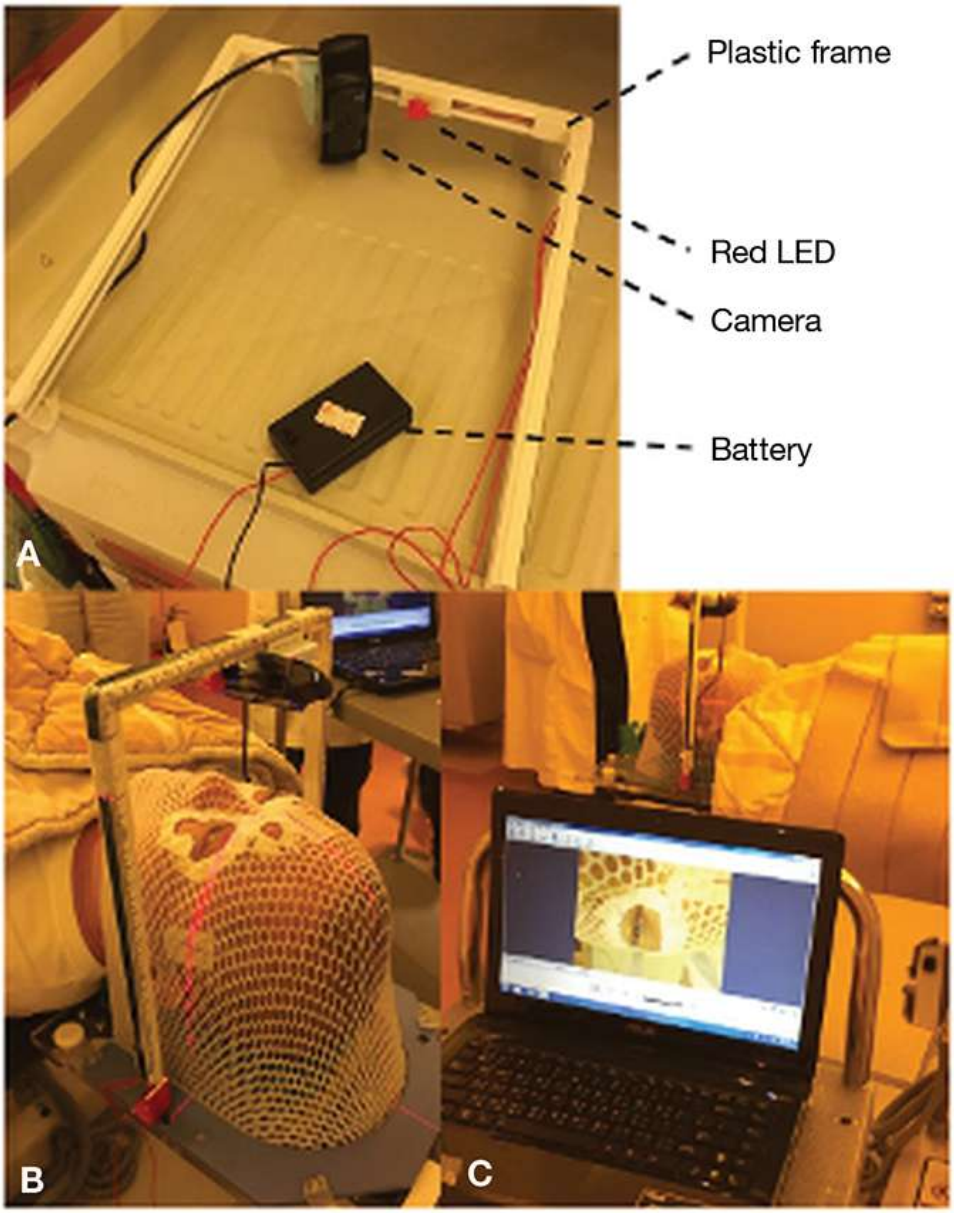

FIGURE 7.14 The noninvasive eye fixation device. A. The noninvasive eye fixation device consists of a plastic frame, a red light-emitting diode at the center, and a camera at the contralateral side. B. The device was customized and screwed on the thermoplastic head shell at the time of simulation. C. The eye position was monitored in real time and the eyeball was tracked with a camera. Cerenkov Radiation Camera Systems

Cerenkov radiation is a well-known phenomenon in which radiation is emitted when a charged particle, such as an electron, is traveling through a medium and its phase velocity is greater than the speed of light in that medium. It can be considered the equivalent of a "sonic boom." There has been growing work on the detection of Cerenkov radiation emitted from a patient's surface during radiation treatment; the clinical setup is demonstrated in Figure 7.15. Cerenkov imaging systems can be used in a variety of methods in radiation therapy. They can be used to confirm patient setup, to ensure that the patient radiation field does

not leak into unintended areas (such as the contralateral breast as shown in Figure 7.16), as well as a real-time dosimeter.

BRACHYTHERAPY IMMOBILIZATION

Introduction

Immobilization in external beam treatments has been developed commercially over a period of decades, with many vendors and devices available, whereas immobilization for brachytherapy treatments has historically relied more on homemade devices. While there are some commercial devices, there are complicating factors for brachytherapy treatments that need to be considered. For external beam treatments, it is only the patient that needs to be immobilized because the treatment machine has fixed geometric positions with respect to the patient. In brachytherapy it is not just the patient that needs to be immobilized but also the brachytherapy applicator itself. In these treatments, the combination of small treatment margins and high dose gradients requires a high degree of immobilization, within 2 to 3 mm, to ensure patients are properly treated. A typical example of the combination of patient and applicator immobilization is shown in Figure 7.17.[69] The patient is immobilized in a mask while the skin applicator is placed next to the patient and held in a clamp.

With permission.)

Simple immobilization devices for vaginal cuff brachytherapy, such as straps or underwear, can be used to hold the cylindrical applicator in place. For these fractionated treatments it is necessary that the applicator is placed and immobilized in a reproducible way to minimize treatment variations, with rotation being a key component if utilizing multichannel cylinders.

For gynecologic treatments, it is necessary to immobilize the applicator to minimize unintended dosimetric coverage of both the target and organs at risk. This has been demonstrated in the work of Balsdon et al,[70] which analyzed the effect of a 5-mm displacement of the applicator in tandem and ovoid brachytherapy on target dose as shown in Figure 7.18. Similar results for critical structure doses are also shown.

Fan et al[71] described a belt system used to immobilize a tandem and ring applicator in cervical brachytherapy. This system is used in conjunction with an inflatable balloon to displace the rectum away from the applicator, reducing rectal toxicity. Alatus balloons have also been used to immobilize cervical applicators for patients spending the night in the hospital.[72]

Workflow in Brachytherapy

Prior to initiating a new brachytherapy program, an analysis should be done to determine the needs for patient transport and immobilization. For departments with dedicated brachytherapy suites in which applicator placement, imaging, and treatment all take place, patient transport and immobilization needs are less than those departments in which these activities take place in multiple locations. In this case, the patient and applicator need to be immobilized together to minimize motion during patient transport. A comparison of workflow in three different departments was published by Prisciandaro et al,[73] which has a useful description of all the tasks that need to be performed to ensure applicator and patient immobilization. These steps include proper suturing of the template to the patient, locking or gluing the needles to the template, having reference marks on the patient to ensure needles do not move in relation to the patient, and having methods to transport the patient.

For fractionated treatment, stability of the implant over the course of the treatment needs to be assessed. Typically, this is done by imaging the patient immediately prior to treatment to determine if applicators have shifted with respect to the patient's anatomy. This is usually a qualitative assessment, looking for only gross shifts that will require either minor adjustments of the applicator or, in the case of large changes,

replanning of the treatment. Karius et al[74] performed a retrospective analysis of implant stability in interstitial breast brachytherapy that is performed in nine treatments over the course of a week. Various causes of implant instability are shown in Figure 7.19.

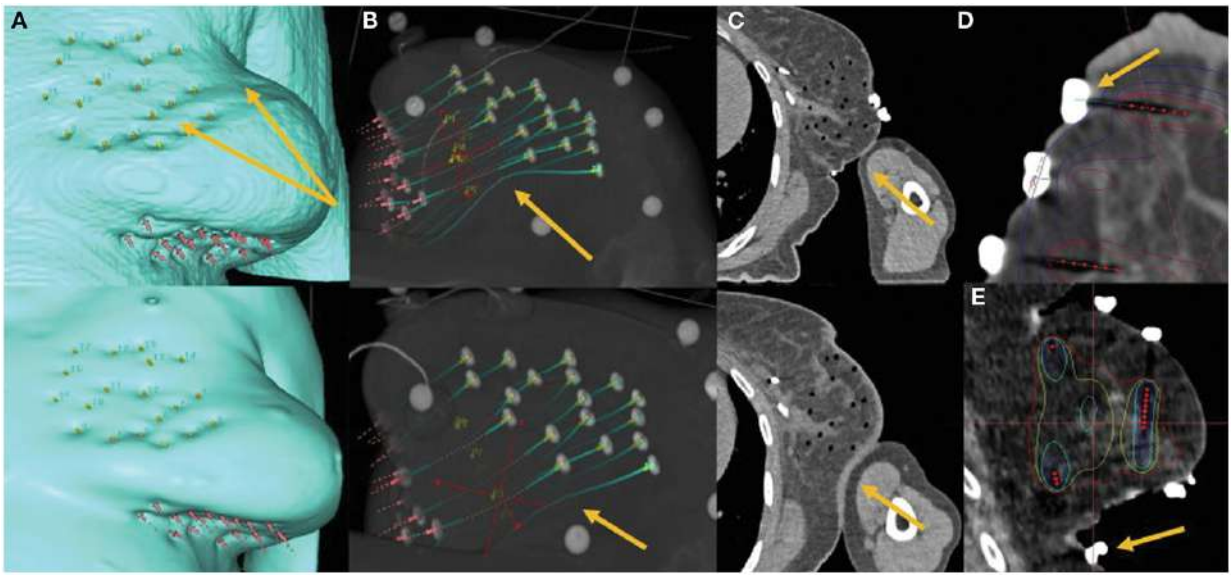

FIGURE 7.19 Causes for implant variations. Shown are the main causes for catheter changes. A. Skin contour of the breast from planning computed tomography (pCT; top) and control CT (cCT; bottom), where the breast was more contracted in the pCT (orange arrows). B. Implant reconstructed on the pCT (top) and cCT (bottom). One catheter (orange arrow) significantly changed its course in the tissue due to different muscle tension. C. Implant variation caused by different arm positioning (orange arrow). D. Slight indentation of the skin (orange arrow) due to a short-pulling of catheters, which resulted in a shortening of the button-to-button distance. E. Button shifted away from the skin (orange arrow), causing a change in the button-to-button distance. (Reprinted from Karius A, Szkitsak J, Strnad V, et al. On the implant stability in adaptive multi-catheter breast brachytherapy: establishment of a decision-tree for treatment re-planning. *Radiother Oncol*. 2023;183:109597. Copyright © 2023 Elsevier. With permission.)

Immobilization in genitourinary (prostate) brachytherapy was extensively discussed in the previous editions of this book and chapter. One advance has been the development of ultrasound-based treatment planning systems, such as Vitesse from Varian (Varian, Inc, Palo Alto, CA) or Oncura Prostate from Elekta. These new developments have allowed prostate brachytherapy to be performed without moving the patient from the brachytherapy suite to imaging. These solutions are used in conjunction with a tracked stepper, which connects the ultrasound to the treatment planning system and is a kind of Global Positioning System for the treatment. The planning system "knows" where the ultrasound is located in three dimensions, thus the needle positions can be monitored in real time along with the patient anatomy.

New Technologies

Three-Dimensional Printing in Brachytherapy

Over the last several years, various types of new technologies have come into clinical practice in brachytherapy. One of them is the development of 3D printed patient applicators. Rather than rely on commercial, one-size-fits-all solutions for clinical applications, 3D printing allows custom solutions that can be used for difficult cases, such as the nose, as shown in Figure 7.20.[75]

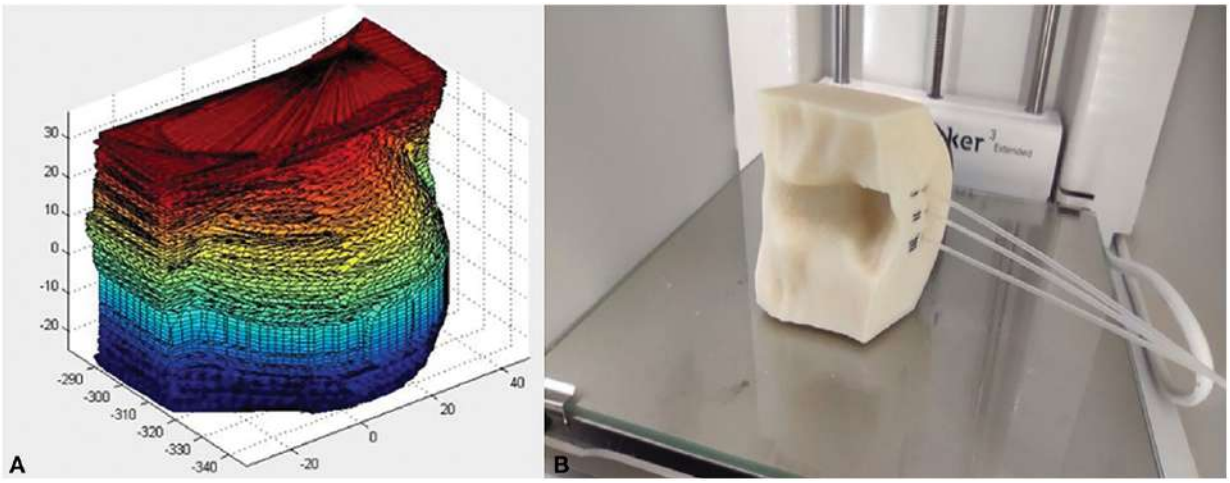

FIGURE 7.20 Applicator image (A) and printed applicator (B). (Reprinted from Membrive Conejo I, Pera Cegarra O, Foro Arnalot P, et al. Custom 3D-printed applicators for high dose-rate brachytherapy in skin cancer. *Brachytherapy*. 2021;20[6]:1257-1264. Copyright © 2021 American Brachytherapy Society. With permission.)

There are several different applications for 3D printing. In the simplest of these, an applicator can be created in which catheters are manually placed. More complex applicators can also be printed that incorporate both patient anatomy and catheter path optimization, as shown in Figure 7.21.[76]

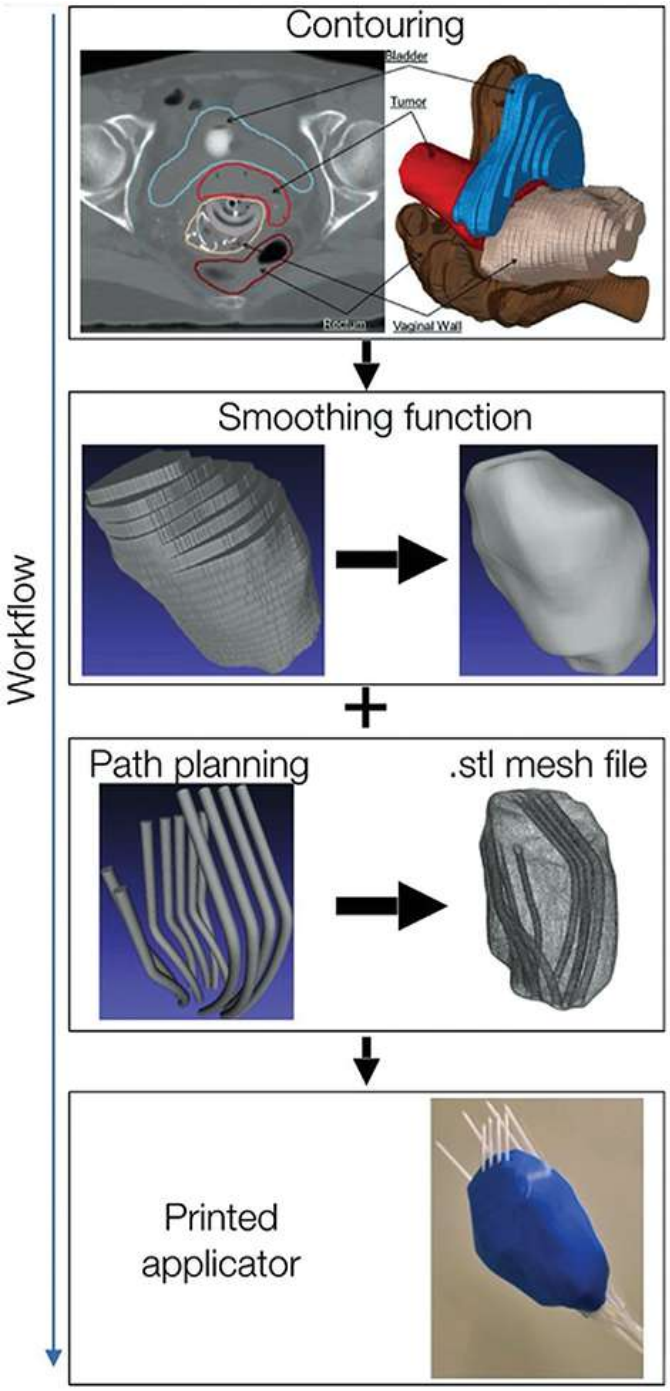

FIGURE 7.21 Example of a 3D printing workflow that incorporates both applicator shape and catheter path optimization. (Reprinted from Cunha JAM, Flynn R, Bélanger C, et al. Brachytherapy future directions. *Semin Radiat Oncol*. 2020;30[1]:94-106. Copyright © 2019 Elsevier. With permission.)

Electromagnetic Tracking

As discussed earlier, relatively small shifts in applicator, and thus source position, can lead to large changes in radiation dose distributions. Electromagnetic tracking technology, the equipment of which is shown in Figure 7.22,[76] has been shown to be capable of reconstructing catheter tips within 0.69 ± 0.29 mm in less

than 10 seconds. This compares favorably with the use of CT scanning in optimal conditions, which has been shown to provide catheter tip digitization accuracy on the order of 1.08 ± 0.67 mm.

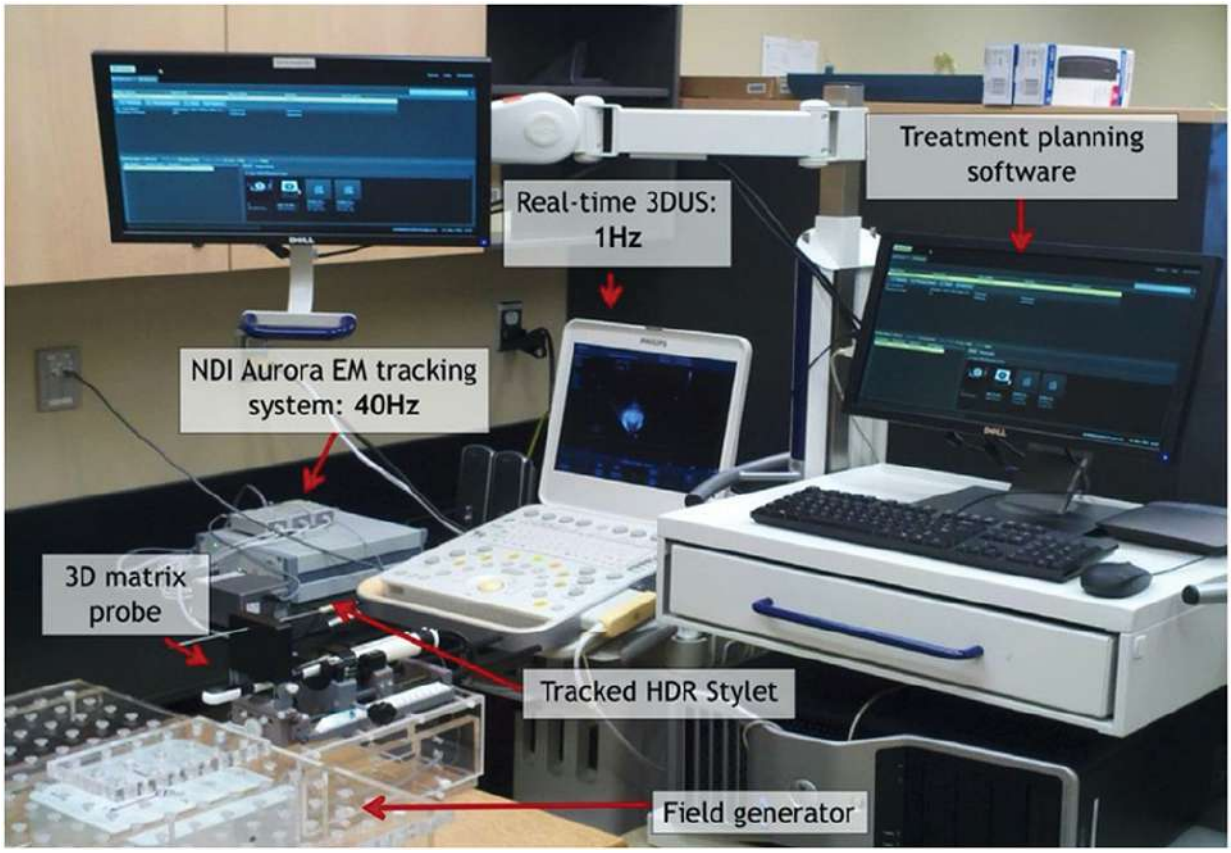

FIGURE 7.22 The components for an example electromagnetic tracking (EMT) system that may be used for brachytherapy. The system includes an ultrasound probe (3D matrix probe, Phillips), the EMT field generator and signal processor (Northern Digital Inc), and the treatment planning software. (Reprinted from Cunha JAM, Flynn R, Bélanger C, et al. Brachytherapy future directions. *Semin Radiat Oncol*. 2020;30[1]:94-106. Copyright © 2019 Elsevier. With permission.)

A recent clinical study has shown that the use of electromagnetic tracking for prostate brachytherapy treatments can be performed more rapidly with fewer interventions than the conventional ultrasound-based planning workflow.[77]

TOTAL BODY IRRADIATION IMMOBILIZATION

The setup for conventional TBI has been described in the AAPM Task Group 29.[78] Several devices are available for clinical programs that include conventional TBI with photons, generally utilized in preparation for bone marrow transplantation. These devices can also be designed to rotate and may also support total skin electron irradiation (TSEI) treatments for mycosis fungoides. Features of these systems generally include a beam spoiler, because a maximum dose at the skin entrance is preferred for TBI; systems for positioning partial lung blocks; and methods to keep the patient stable while standing for the treatments, which may take from 10 to 40 minutes, depending upon the treatment protocol. The major disadvantage for these systems is identifying storage in the treatment room since they are large and often take up vital space in the treatment area. It is important to note that these systems usually operate at a distance of several meters from the target, with the gantry at a horizontal angle (90° or 270°), so a large treatment vault is required. Figure 7.23 shows two representative TBI devices from Radiation Products Design, Inc. and Mick Radio-Nuclear Instruments, Inc. Features such as a bicycle seat, handgrips, and shoulder stabilizers are used

to help support the patient. Some photon TBI stands offer a harness that will provide an additional measure of security to prevent the patient from falling over in case the patient succumbs to fatigue and faints.

A

FIGURE 7.23 A stand is commonly used to help position patients for total body irradiation (TBI) with photons and electrons. A. Common features of TBI stands include hand grips and a seat to help support the patient. B. The harness used to prevent the patient from falling in the case of fatigue and/or fainting. (B. Courtesy of Radiation Products Design, Inc.)

Data suggest that higher dose TBI regimens can improve overall survival for some young patients with acute leukemia; however, total prescribed dose from conventional open-field TBI is limited by organs at risk receiving the prescribed dose as well.[79-84] Multiple isocenter VMAT for TBI has become a feasible option to improve dose homogeneity and conformality to the skeletal structure while reducing dose to the organs at risk, and whole-body immobilization is of paramount importance for accurate delivery. Multiple groups have described treatment planning for TBI using VMAT.[85-89] Typical prescriptions are 12 to 13.2 Gy delivered over 8 fractions BID 10. Multiple body conformal immobilization devices such as Vac-Lok, described in an earlier section, and thermoplastic masks are needed to immobilize the entire length of patients with VMAT TBI. An alternative immobilization method used at the Moffitt Cancer Center is described by Keit et al.[88]

Patient simulation for VMAT TBI is done in the supine position with arms on the sides. Patients are positioned on a long SBRT base plate shown in Figure 7.24 (Orfit Industries, NV, Belgium). Thermoplastic masks are added to the head, shoulders, chest, arms, abdomen, pelvis, and legs and locked onto the SBRT board to create a whole-body immobilization device. Patients then undergo CT simulation in the head-first supine (HFS) and feet-first supine (FFS) positions. The HFS scan is done from the head to the level of midthigh, the board is then rotated for the FFS scan from the toes to pelvis. Localization isocenters are placed near the base of the skull for the HFS scan and near ankles for the FFS scan. Additionally, to aid the treating therapists and ensure setup reproducibility, markings are placed on the immobilization system. A rotatable tabletop platform shown in Figure 7.25 and recently described by Losert et al[90] has the potential to make this process more efficient. This rotating platform can be used with either a specific SBRT board or multiple individual Vac-Lok and thermoplastic mask setups.

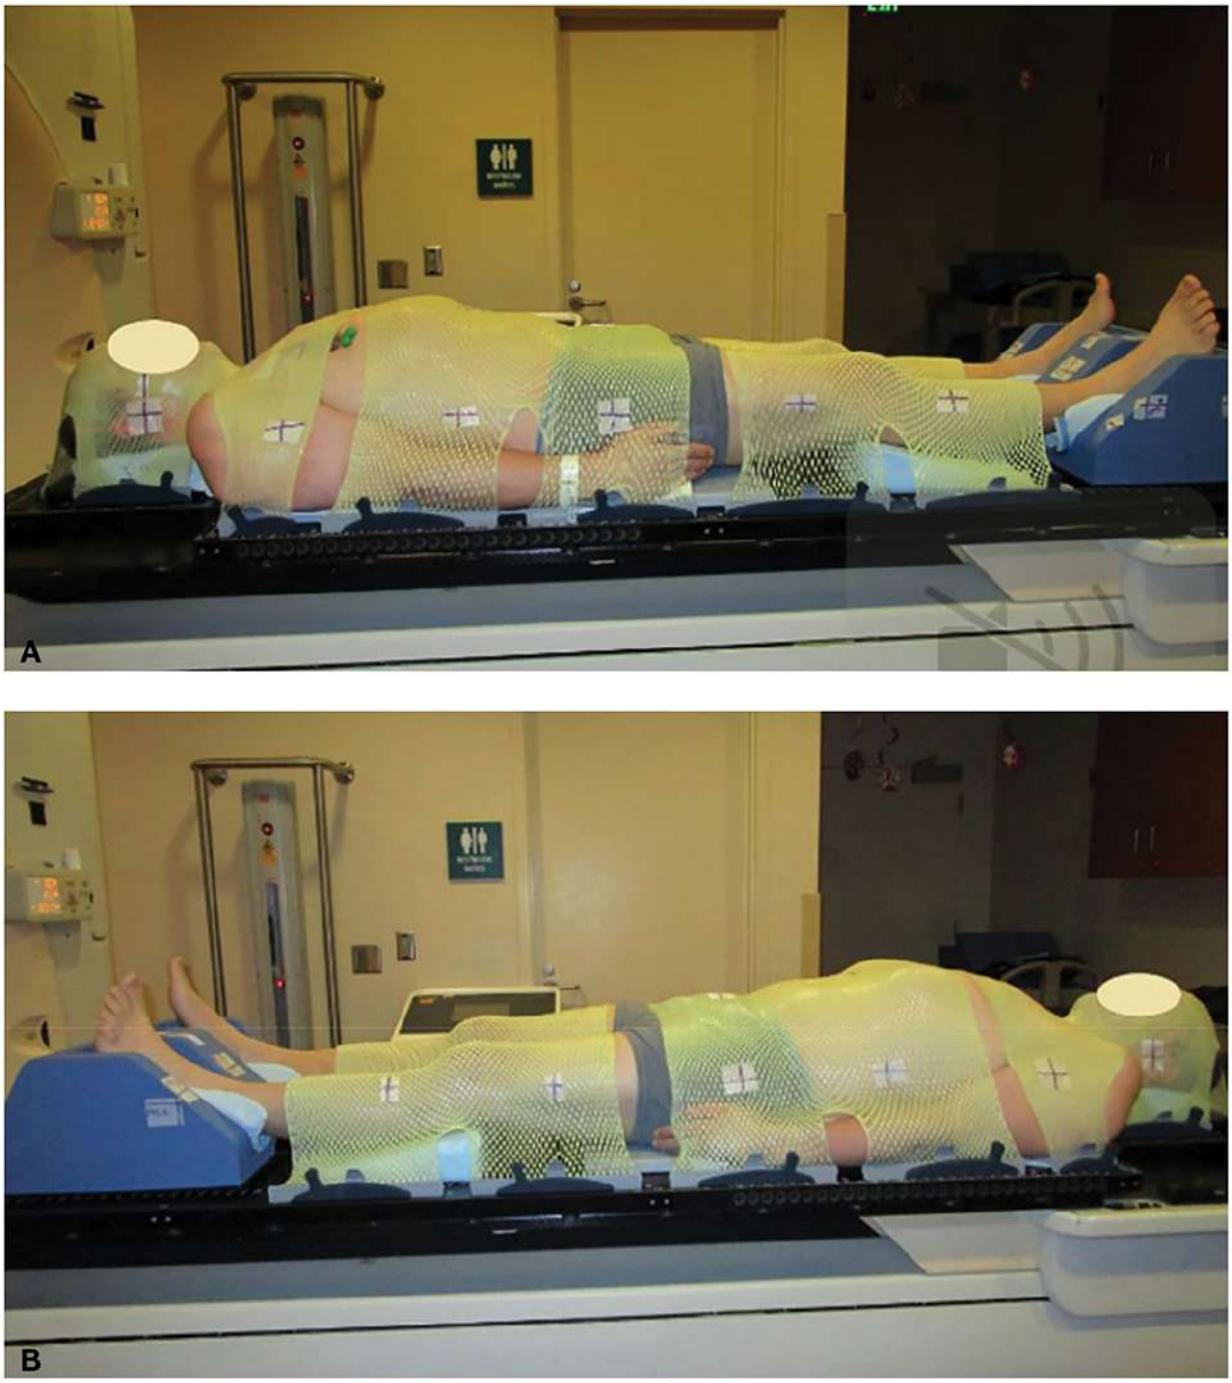

FIGURE 7.24 Example of a volumetric modulated arc therapy total body irradiation setup (A) and immobilization (B). (From Keit E, Liveringhouse C, Figura N, et al. Feasibility and toxicity of full-body volumetric modulated arc therapy technique for high-dose total body irradiation. *Technol Cancer Res Treat*. 2023;22:15330338231180779. FIGURE 7.25 Rotatable tabletop platform for volumetric modulated arc therapy total body irradiation.

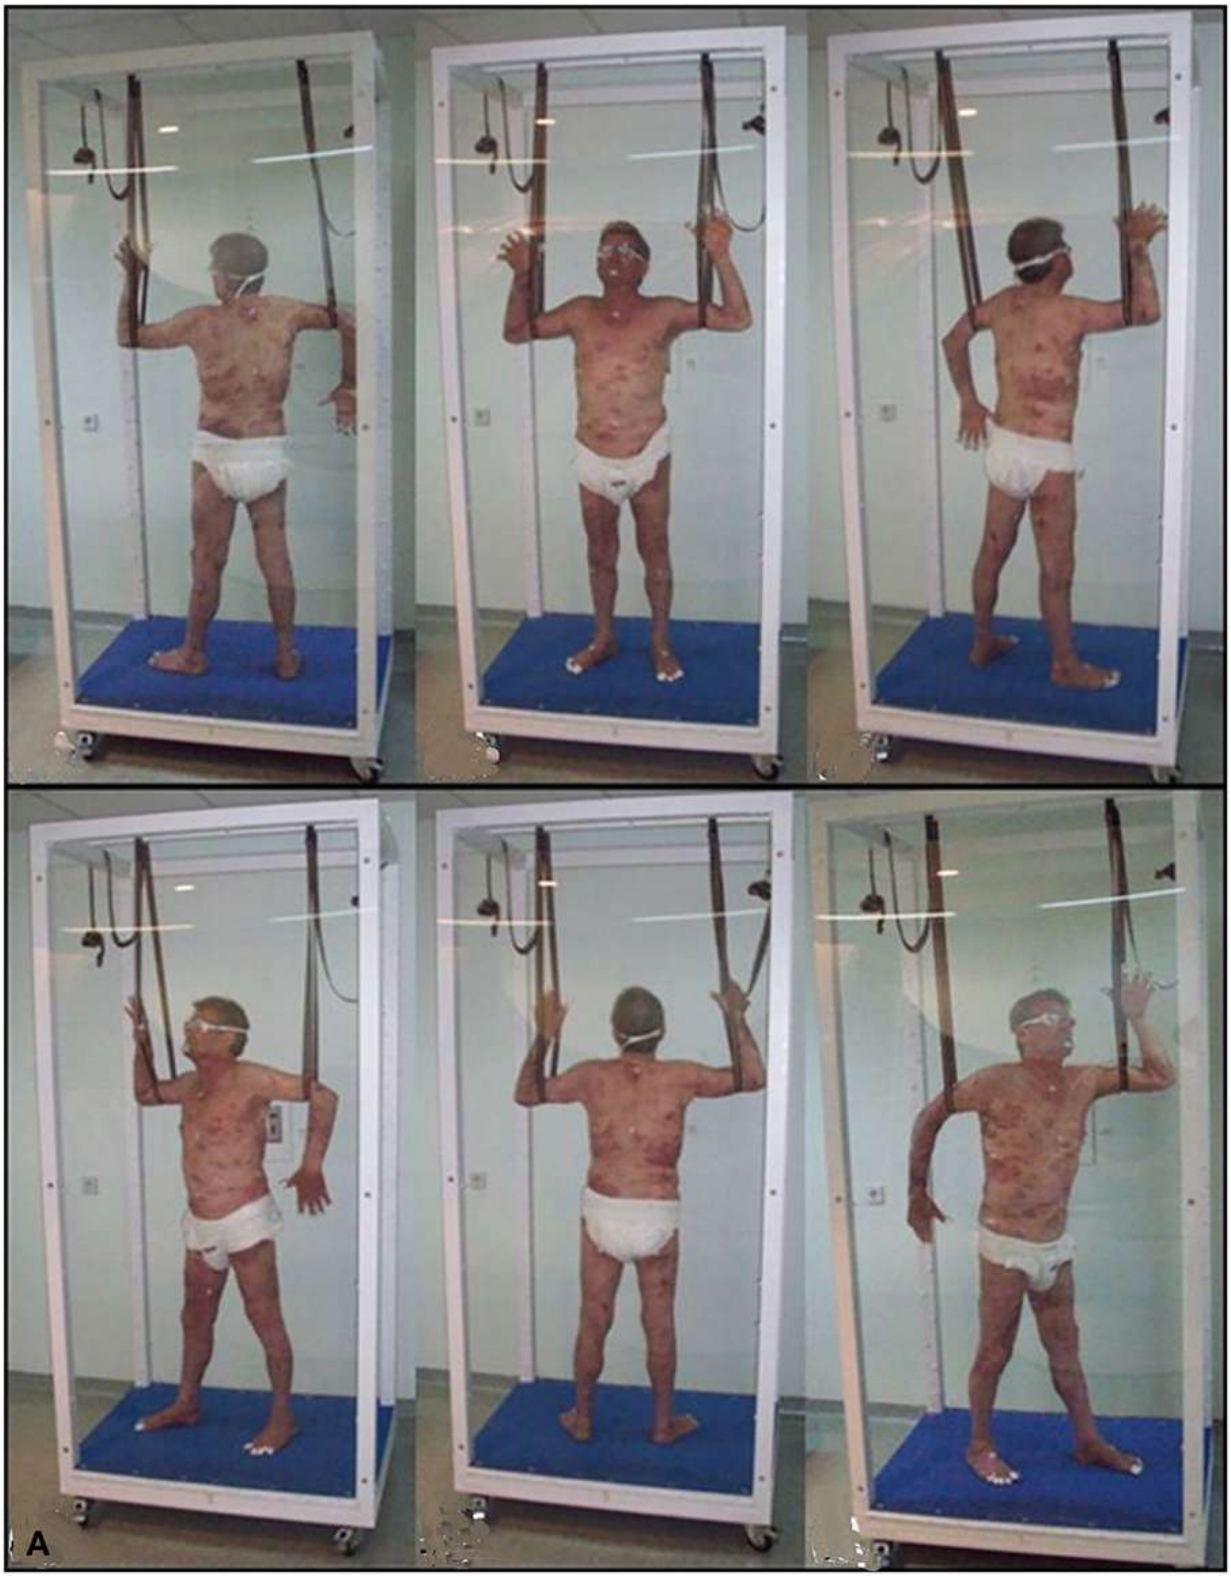
Treatment planning for VMAT TBI requires the use of roughly six to eight isocenters, so patient stability over very long treatment times and multiple shifts and rotations is crucial. Four to five isocenters are placed on the HFS scan and two to three on the FFS scan depending on patient height. Isocenters are on the same plane spaced approximately 25 cm apart to ensure sufficient overlap between arcs with one to two arcs per isocenter. Treatment delivery for each isocenter is verified with image guidance using extended CBCT to expand the field of view. Depending on the complexity of the plan and patient size, the total treatment length may take an hour or more. Therefore, the quality of immobilization is very important for VMAT TBI.

TOTAL SKIN ELECTRON IRRADIATION IMMOBILIZATION

TSEI or total skin electron therapy is most often used to treat cutaneous T-cell lymphoma, a chronic progressive lymphoma including mycosis fungoides and Sézary syndrome.[91,92] The treatment utilizes very large electron fields to irradiate superficial skin lesions. Two widely used techniques for TSEI are six-dual-field technique (or Stanford technique) and rotational technique.[92-94] Similar to TBI, to apply these two techniques, the patient will be asked to remain in the standing position during the entire treatment, on a platform with bars to hold on to for immobilization and safety belts or a seat for patient support as previously shown in Figure 7.23. Classic patient positioning of both treatment techniques is demonstrated in Figure 7.26. Personalized shielding, such as for head, eyes, fingernails, and toenails, may be prescribed accordingly.



A

(A. Reprinted from Diamantopoulos S, Platoni K, Kouloulias V, et al. First treatment of mycosis fungoides by total skin electron beam (TSEB) therapy in Greece. *Rep Pract Oncol Radiother*. 2013;19[2]:114-119. Copyright © 2013 Greater Poland Cancer Centre. With permission.)

For nonstandard scenarios, such as for patients who are nonambulatory who may not tolerate prolonged treatment time, a lying-on-the-floor TSEI with proper immobilization setup can be an alternative option.[95,96] Pediatric patients may also require specific customization of the immobilization devices due to the significant anatomic difference from adults. Several customized TSEI techniques for pediatric patients have been reported.[97]

INTRAOPERATIVE RADIOTHERAPY

Intraoperative radiotherapy (IORT) is the delivery of a single, high-dose radiation treatment to the tumor bed during the surgical session. There are a variety of devices that are used to deliver the radiation, including brachytherapy, with temporally implanted applicators, the Zeiss Intrabeam device (Carl Zeiss Meditec AG, Germany), which uses 50 kV x-rays, or the Intraop Mobetron (Intraop Medical Corp,

Sunnyvale, CA), which uses 6, 9, or 12 MeV electrons. Not only are various devices used, but the radiation is delivered to many different treatment sites, including the breast,[98] pancreas,[99] rectum,[100] sarcoma,[101] and brain.[102] The Intrabeam device is shown in Figure 7.27A, with its articulating arm design to immobilize the applicator, while for Mobetron, a remote control can be used to maneuver and lock the gantry head after properly aligning with the applicator, as demonstrated in Figure 7.27B. An issue that arises during IORT is that patients are under anesthesia during the treatment, with the care team remotely monitoring both the patient and the treatment. Care must be taken to ensure that the patient does not move during the treatment. One method is to deepen the analgosedation and insert a laryngeal mask, so the patient breathes normally.

A

FIGURE 7.27 A. Intrabeam stand and x-ray source shown with spherical applicator attachment. The floor stand provides full flexibility of movement for the x-ray tube with millimeter precision in six dimensions. B. Mobetron soft docking illustration. The Mobetron head aligns with but does not contact the applicator. Alignment is facilitated by lasers in the Mobetron head, which are reflected by mirrors in the applicator collar to provide feedback on positioning. The applicator and collar are clamped to the surgical table. (A. Reprinted from Sethi A, Emami B, Small W Jr, Thomas TO. Intraoperative radiotherapy With INTRABEAM: technical and dosimetric considerations. *Front Oncol*. 2018;8:74. http://creativecommons.org/licenses/by/4.0/. B. Commissioning, clinical implementation, and performance of the Mobetron 2000 for intraoperative radiation therapy. *J Appl Clin Med Phys*. 2017;18[1]:230-242. http://creativecommons.org/licenses/by/4.0/.)

While IORT devices are normally placed visually, with the surgeon and the radiation oncologist conferring to decide on applicator size and placement, a novel method using ultrasound to provide image guidance to the applicator placement is being developed.[103] This will be especially useful for the treatment of thicker targets or those targets in which coupling the applicator directly to the tissue can be difficult. Ultrasound can provide real-time quantitative feedback on proper applicator placement to ensure the patient is treated according to the plan.

IMMOBILIZATION FOR ADVANCED AND EMERGING TECHNOLOGIES

Immobilization for Magnetic Resonance Linear Accelerator

The marriage of MRI and linear accelerator brought a lot of interest, especially due to improved soft-tissue contrast and real-time nonionizing radiation image guidance during treatment.[104,105] Immobilization devices and accessories for MR linear accelerator (MR-linac) have a lot of unique requirements compared to the conventional ones. The first and most important consideration is safety. A standard process for the safety check has been described in figure 1 of AAPM Task Group 334 Report.[106] Additionally, these devices and accessories need to pass the imaging artifact evaluation. Some other general immobilization considerations different from conventional radiotherapy are the limited bore size (usually 70 cm), restricted/limited couch movement, arm positioning, coil positioning, patient safety devices (such as hearing protection, emergency squeeze bulb or push-button alarm, communication devices), patient on-couch time, etc.[107,108] Immobilization examples of MR-linac-specific patient setup can be seen in literature,[107,109,110] with some examples shown in Figure 7.28. Generally, (1) patient is dressed in gown for MR safety requirement and lying flat on the treatment couch, (2) the coil placement will center around the target level and sandwiching the patient, and (3) a comfortable and stable arm position is usually recommended due to the length of the treatment time. The treatment time can vary significantly between patients depending on whether adaptive replanning is needed and how the adaptive procedure is performed.[111]

Upright Radiation Therapy

Upright positioning devices are consistently being explored in particle radiation therapy for the past several decades.[112] Its unique treatment position enables another comfortable option when patients cannot tolerate classic supine or prone position.[113,114] Specifically, patients with certain clinical indications and palliative intent may find it difficult to lie down. Additionally, treatment couch weight limitation may prohibit traditional treatment position when dealing with patients with bariatric needs. It is also suggested that upright position can improve treatment delivery and potentially patient outcome for selected tumor sites.[112,113]

Various upright immobilization solutions have been described in the literature, from upright stabilization apparatus to versatile chair designs.[112,113] From those innovative ideas, there are several commercialized solutions, including products from P-Cure (P-Cure Ltd, Shilat Industrial Zone, Israel), BEC GmbH (Pfullingen, Germany), and Leo Cancer Care (Smallfield, Horley, Surrey, UK). Researchers are still actively developing prototypes.[115-118] One of the commercial solutions from Leo Cancer Care can be utilized for both photon and proton applications, depicted in Figure 7.29. In general, such a device usually consists of an adjustable backrest and seat to withhold the majority of the patient's weight plus additional accessories to hold the patient's head/torso and extremities. Depending on the patient's posture (leaned forward/leaned back/straight upright) and leg position, a leg support or shin rest may be chosen to further secure the patient.

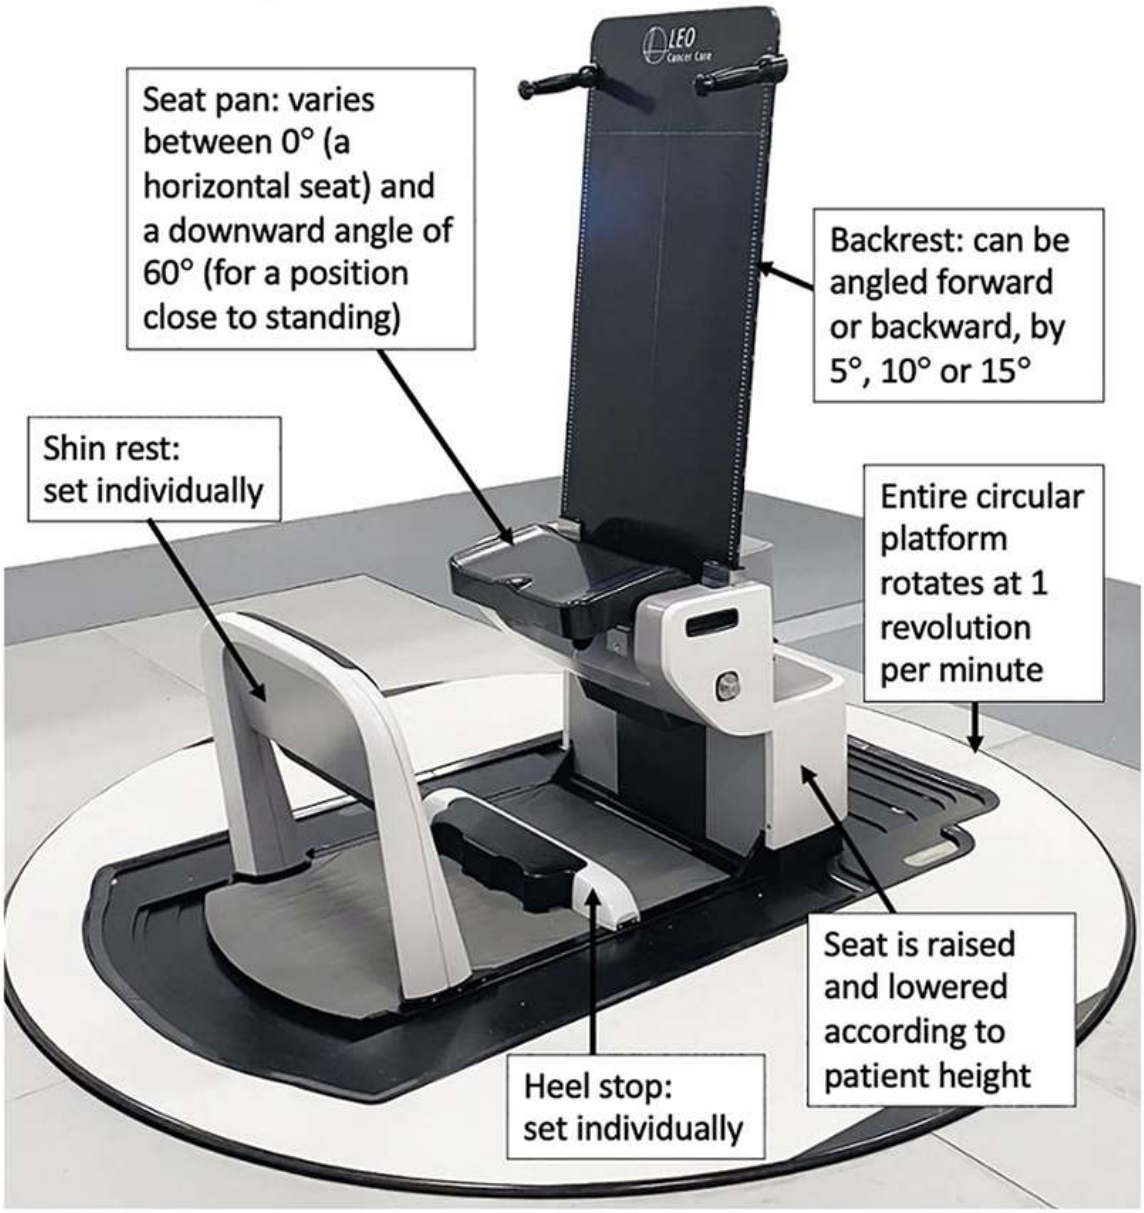

FIGURE 7.29 An upright patient positioner consists of seat pan, back rest, and shin rest. (Reprinted from Boisbouvier S, Underwood T, McNamara J, Probst H. Upright patient positioning for gantry-free breast radiotherapy: feasibility tests using a robotic chair and specialised bras. *Front Oncol*. 2023;13:1250678. http://creativecommons.org/licenses/by/4.0/.)

One of the difficulties in implementing upright treatment is the inability of acquiring upright simulation images such as CT or MRI with similar chair setup for radiation treatment planning purpose. Currently, vertical CT and MRI solutions exist but are not universally available in clinical practice. Vertical imaging system combined with upright immobilization solution can redefine the concept of upright radiation therapy in the future.

THE EVOLUTION OF PATIENT IMMOBILIZATION

Strategies to immobilize patients for radiotherapy have been developed since it was introduced as a treatment modality over 100 years ago. In this chapter, we have presented a wide array of simple devices that have continued to be used for decades, albeit with new designs and materials that make their use more

comfortable, convenient, and sanitary for the patient and the therapists. We have also presented highly specialized systems that may be used in the most sophisticated of radiation therapy treatment modalities that address specific needs of image guidance, highly conformal and high-dose stereotactic treatments, brachytherapy, intraoperative therapy, and other special procedures. Tables 7.1 and 7.2 have been included to provide a top-level summary of the pros and cons of the wide array of commercially available immobilization systems. Common themes in modern radiation therapy immobilization include striking a balance between patient comfort and stability, supporting effective and safe approaches for target localization during treatment, and supporting systems to verify the patient position prior to treatment using x-ray or allow monitoring with surface imaging. IGRT, immobilization, and monitoring are interlinked and should be considered together as part of the overall system to minimize patient alignment and stability uncertainties.

For brachytherapy, immobilization for both the patient and applicator has continued to be an important consideration for increasingly complex procedures, especially with the development of image-guided brachytherapy (IGBT), analogous to IGRT, in which the applicator is placed, simulation is performed, and the patient is treated with minimal motion of the patient or applicator. 3D printing has provided the ability for some clinics to design and fabricate patient-specific applicators, and electromagnetic tracking shows promise to increase the accuracy and efficiency of needle tip identification.

TBI has experienced renewed interest in dose escalation by using complex systems of immobilization to accurately translate and rotate between the multiple isocenter VMAT plan to conformally treat the skeletal structure.

CONCLUSION

Effective radiation treatment depends on both proper localization of the tumor and proper immobilization of the patient. As radiation therapy has evolved, so too have the strategies for immobilization of the patient. IGRT, including hypofractionated SBRT, as well as IGBT require that the patient be comfortably immobilized to ensure that the radiation is properly delivered to the tumor. Intrafraction monitoring has grown rapidly in clinical utility in recent years, due to the ability to monitor the patient in near real time without using ionizing radiation. This is especially necessary as the dose per fraction is increased, which could lead to serious complications should the normal tissue surrounding the tumor receive excessive dose because of poor localization and immobilization.

CHAPTER 8

Photon External-Beam Dosimetry and Two-Dimensional Radiation Treatment Planning

James A. Purdy, Geoffrey D. Hugo, and Hania A. Al-Hallaq

When planning the treatment of a patient with cancer, the radiation oncologist is faced with the problem of prescribing a treatment regimen with a radiation dose that is large enough to potentially cure or control the disease but does not cause serious normal tissue complications. This task is a difficult one because tumor control and normal tissue effect responses for most disease sites are typically steep functions of radiation dose; that is, a small change in the dose delivered (±5%) can result in a dramatic change in the local response of the tissue (±20%).[1-3] Moreover, the prescribed curative doses are often, by necessity, very close to the doses tolerated by the normal tissues. Thus, for optimum treatment, the radiation dose must be planned and delivered with a high degree of precision.

One can readily compute the dose distribution resulting from photons, electrons, protons, or a mixture of these radiation beams impinging on a regularly shaped, flat surface, homogeneous unit-density phantom. However, the patient presents a much more complicated situation because of irregularly shaped topography and having tissues of varying densities and atomic composition (called *heterogeneities*). In addition, beam modifiers, such as wedges, compensating filters, or bolus, are sometimes inserted into the radiation beam, further complicating the calculation of the absorbed dose.

Two-dimensional radiation treatment planning (2DRTP) refers to a technique used to plan the delivery of radiation to a target area within a patient's body. It is an older and less sophisticated approach compared to modern three-dimensional radiation treatment planning (3DRTP), which is discussed in Chapters 10, but it is still widely used for simple treatment scenarios where a 2D calculation of the dose distribution is sufficient, or in

institutions with limited resources where advanced imaging modalities and/or 3DRTP systems are not available.

The 2DRTP approach emphasizes beam portal design on a simulator radiograph based on standardized beam arrangements applied to entire classes of comparable patients. For dose calculations, the patient's anatomy is simplified to a series of flat cross-sectional images, typically obtained from x-rays or computed tomography scans. These images represent slices of the patient's body, and the targeted area and surrounding critical normal tissues are contoured manually on each slice, often based on published consensus guidelines.[4] The treatment planner then designs radiation fields by selecting the appropriate beam angles and sizes based on the patient's anatomy. These fields are essentially 2D projections of the treatment beams onto each slice. The goal is to deliver a therapeutic dose to the tumor while minimizing the dose to nearby healthy tissues.

During the 2DRTP process, the planner uses basic dosimetric calculations to estimate the dose distribution within the patient based on the geometry of the radiation fields and the patient's anatomy. However, this approach generally does not consider the variations in tissue density and shape in the 3D, leading to less accurate dose calculations.

In this chapter, we review several aspects of photon external-beam 2DRTP and pertinent dosimetry, including methods used for dose/monitor unit (MU) calculations, crude correction for the effects of the patient's irregular surface and internal heterogeneities on the calculated photon dose distribution, isodose distributions for combined fields, field junctions, field shaping and design of treatment aids, and related clinical dosimetry issues.

DOSE CALCULATION METHODS

For purposes of discussion, it is convenient to characterize photon beam dose calculation methods as either *correction based* or *model based*.[5] In the former method, the dose at a given point is calculated using measured central-axis data, for example, percent depth dose (PDD), tissue-air ratios (TARs), tissue-maximum ratios (TMRs), tissue-phantom ratios (TPRs), and off-axis ratios (OARs). These quantities are measured under reference conditions (ie, in a homogeneous water phantom with a flat surface normal to the incident radiation beam at a standard distance from the x-ray source).

Hence, specific correction factors (CFs) are used in planning the treatment of real patients to account for varying patient surfaces, tissue heterogeneities, irregular field shapes, and any beam modifiers used.

In the model-based algorithms, the dose distribution is computed in a phantom or patient from more of a first-principles approach accounting for lateral transport of radiation, beam energy, geometry, beam modifiers, patient surface topography, and electron density distribution rather than correcting parameterized dose distributions measured in a water phantom. These models utilize convolution energy deposition kernels that describe the distribution of dose about a single primary photon interaction site and provide much more accurate results even for complex heterogeneous geometries. Both methods are discussed in the following sections, and more details on model-based photon dose calculation algorithms can be found in the references listed.[5,6] It should be noted that with the evolution of advanced computing methods, modern treatment planning systems generally do not rely on correction methods and are included here for historic reference rather than for practical treatment planning purposes. The correction-based models remain relevant for purposes of manual dose calculations and secondary/independent dose verification applications. However, many of the modern-day independent dose calculation programs include more sophisticated dose calculation algorithms.

Correction-Based Dose Calculation Methods

Using the notation of Khan et al[7] the dose at a point (D_P) at a depth d of overlying tissue on the central ray for an irregularly shaped field is given by

$$D_P = D_{ref} \cdot S_c\left(r_c\right) \cdot S_p\left(r_d\right) \cdot TF \cdot WF\left(\frac{SCD}{SAD}\right)^2 \cdot TMR\left(d, r_d\right)$$

where S_c denotes the *collimator scatter factor*; S_p is the *phantom scatter factor*; and TMR is the tissue-maximum ratio. TF and WF denote the tray and wedge factors, respectively, and are defined as the ratio of the central ray dose with the tray or wedge filter in place relative to the dose in the

open-beam geometry. The collimated field size is denoted by r_c and is usually described as the square field size equivalent to the rectangular collimator opening projected to the isocenter. The effective field size is denoted by r_d and is specified to the isocenter distance (SAD). The inverse-square law factor accounts for the difference in distances from the source to the point of dose calculation relative to the source to calibration point distance (SCD). Note that when isocentric calibration is used, this factor is unity. Also, note that collimator-defined field size is used for the lookup of the collimator scatter factor, S_c, whereas effective field size projected to the isocenter is used for the lookup of the TMR value and the phantom scatter factor, S_p. By separately accounting for the effect of collimator opening on the primary dose component and the influence of cross-sectional area of tissue irradiated, most of the difficulties in accurately calculating a dose in the presence of extensive blocking are overcome. Details on determining the effective field size for an irregularly shaped field, taking into account both the primary and scatter dose components, are discussed in a later section.

Correction for Varying Patient Topography (Air Gaps)

In the previous equation, it is assumed that the beam is normally incident on a unit-density uniform phantom. The following CF methods can be applied to the equation to account for the nonnormal beam incidence caused by the patient's varying surface.[8]

Air Gap Correction Factor: Ratio of Tissue-Air Ratio Method

In the ratio of TAR (RTAR) or TPR method, the surface (along a ray line) directly above point A (source-to-skin distance [SSD] = S′) is unaltered, so the primary component to the dose distribution at this point is unchanged (and the scatter component is also assumed to be unaltered) (see Figure 8.1). Thus, the dose at point A can be considered unaltered by patient shape. However, for point B, where there are considerable variations in the patient's topography, both the primary and scatter components of the radiation beam are altered. The CF may be determined using two TARs or TPRs as follows:

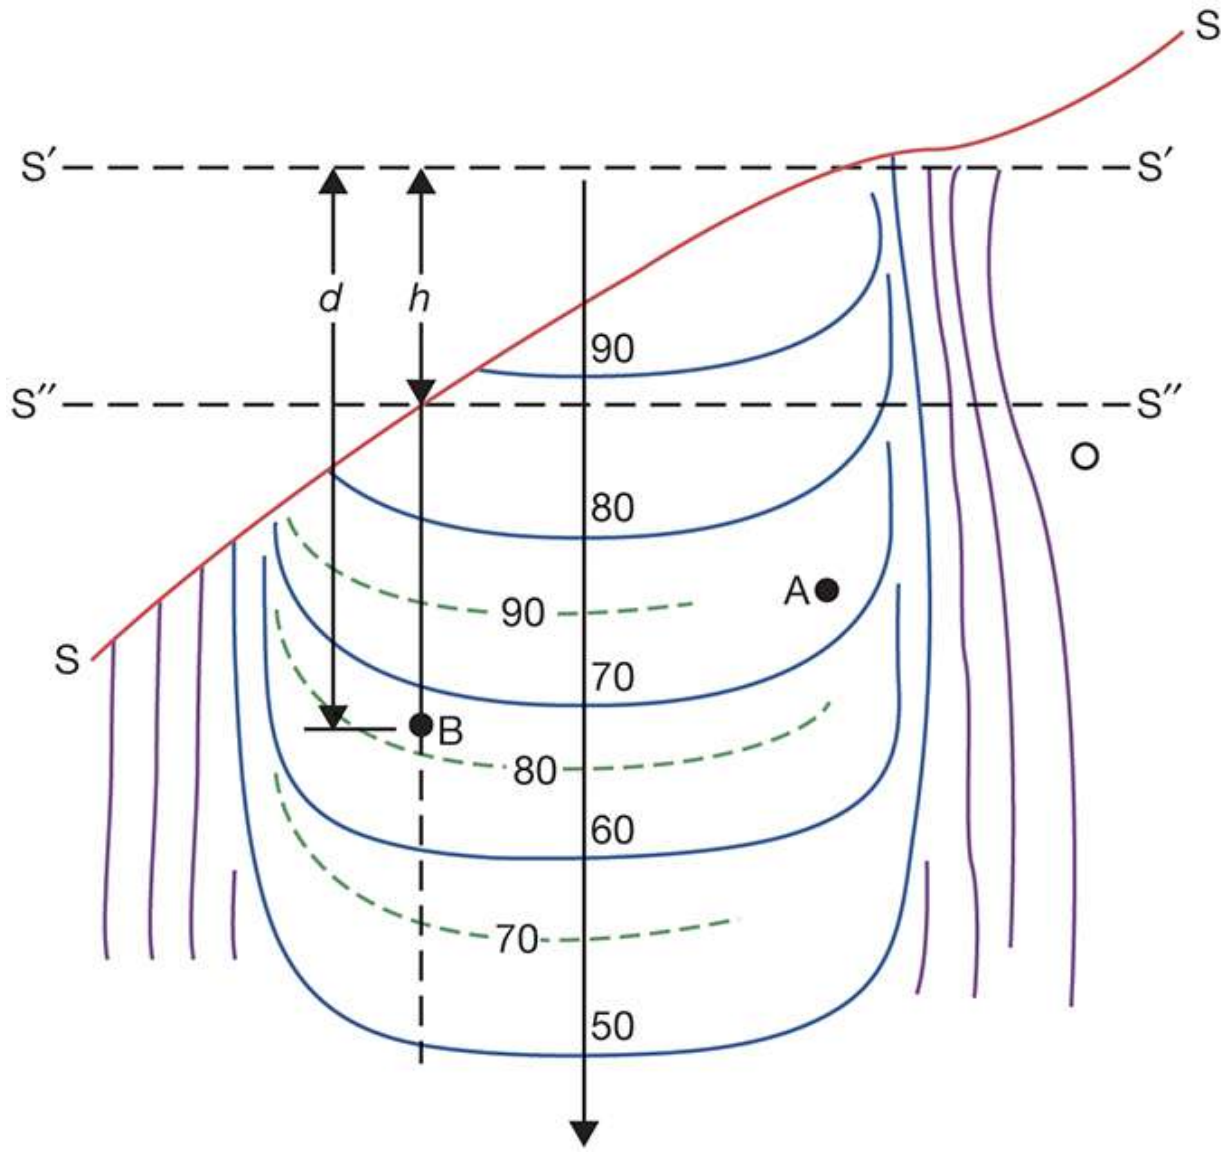

FIGURE 8.1 Schematic drawing illustrating tissue-air ratio and effective source-to-skin distance (SSD) methods for the correction of isodose curves under a sloping surface (solid lines for SSD = S′; dashed lines for SSD = S″). (From International Commission of Radiation Units and Measurements. Report 24: Determination of absorbed dose in a patient irradiated by beams of × or gamma rays in radiotherapy procedures. International Commission of Radiation Units and Measurements; 1976. Copyright © 1976 International Commission on Radiation Units and Measurements. Reprinted by permission of SAGE Publications.)

$$\mathrm{CF} = \frac{T\left(d-h, s_{\mathrm{d}}\right)}{T\left(d, s_{\mathrm{d}}\right)}$$

where h = air gap.

Air Gap Correction Factor: Effective Source-Skin Ratio Method

In the effective SSD method, the isodose chart to be used is placed on the patient's contour representation, positioning the central axis at the distance for which the curve was measured (Figure 8.1). It then is shifted down along the ray line for the length of the air gap, h, resulting in SSD = S″. The PDD value at point B is read and modified by an inverse-square calculation to account for the effective change in the peak dose. The CF can be expressed as follows:

$$\mathrm{CF} = \frac{P\left(d-h, d_0, S, f, E\right)}{P\left(d, d_0, S, f, E\right)} \cdot \left(\frac{f+d_0}{f+h+d_0}\right)^2$$

Correction for Tissue Heterogeneities

The following CF methods can be used to account for the tissue heterogeneities found within the patient.

Tissue Heterogeneities Correction Factor: Ratio of Tissue-Air Ratio Method

The RTAR method of correction for inhomogeneities is given by

$$\mathrm{CF} = \frac{T\left(d_{\mathrm{eff}}, S_d\right)}{T\left(d, S_d\right)}$$

where the numerator is the TAR for the equivalent water thickness, d_{eff}, and the denominator is the TAR for the actual thickness, d, of tissue between the point of calculation and the surface along a ray passing through the point. S_{d} is the dimension of the beam cross section at the depth of calculation. The RTAR method accounts for the field size and depth of calculation. It does

not account for the position of the point of calculation with respect to the heterogeneity. It also does not take into account the shape of the inhomogeneity; instead, it assumes that it extends the full width of the beam and has a constant thickness (ie, referred to as *slab geometry*).

Tissue Heterogeneities Correction Factor: Power Law Tissue-Air Ratio Method

The *power law TAR method* was proposed by Batho[9] and generalized by Young and Gaylord.[10] This method, sometimes called the *Batho method*, attempts to account for the nature of the inhomogeneity and its position relative to the point of calculation. However, it does not account for the extent or shape of the inhomogeneity. The CF for the point P is given by

$$\mathrm{CF} = \left(\frac{T(d_2, S_d)}{T(d_1, S_d)} \right)^{\rho_2 - 1}$$

where d_1 and d_2 refer to the distances from point P to the near and far side of the non–water-equivalent material, respectively; S_d is the beam dimension at the depth of P; and ρ_2 is the relative electron density of the inhomogeneity with respect to water.

Sontag and Cunningham[11] derived a more general form of this CF, which can be applied to a case in which the effective atomic number of the inhomogeneity is different from that of water and the point of interest lies within the inhomogeneity. The CF in this situation is given by

$$\mathrm{CF} = \frac{T(d_2, S_d)^{(\rho_b - 1)}}{T(d_1, S_d)^{(\rho_b - \rho_a)}} \times \frac{(\mu_{en} / \rho)_a}{(\mu_{en} / \rho)_b}$$

where r_a is the density of the material in which point P lies at a depth d below the surface and r_b is the density of an overlying material of thickness $(d_2 - d_1)$; and $(\mu_{en}/r)_a$ and $(\mu_{en}/r)_b$ are the mass energy absorption coefficients for the medium a and b, respectively.

Model-Based Dose Calculation Methods

Advanced 3D dose calculation algorithms, such as the convolution/superposition algorithm and Monte Carlo, have for many years now been the standard of practice.[5,6,12-14] These models provide accurate results even for complex heterogeneous geometries.

Convolution/Superposition Dose Calculation Algorithm

The convolution/superposition dose calculation algorithm is based on the following equation[5]:

$$D(\vec{r}) = \int\int\int\int T_E(\vec{S})\, h(E, \vec{r} - \vec{s})\, d^3s\, \mathrm{dE}$$

where D represents the dose at some point, T_E ($\vec{s}$) represents the total energy released by primary photon interactions per unit mass (or TERMA), and h (E, $\vec{r} - \vec{s}$) is the *point spread function* (also called *dose spread array, differential pencil beam*, and *energy deposition kernel*). The point spread function represents the fraction of the energy deposited (per unit volume) at a point that is subsequently transported to the calculation point. Hence, the DP is computed by integrating over all space the dose contributions from photons and electrons that are produced at all other points in the phantom or patient.

Ahnesjö et al[15] showed that the point spread function, h (E, $\vec{r} - \vec{s}$), changes only slightly as a function of energy and, thus, can be replaced by h (E, $\vec{r} - \vec{s}$) (defined as the average point spread function weighted by the

spectral components of the beam), reducing the basic convolution 4D integral to a 3D integral overall space. Point spread functions for monoenergetic photons are generally precomputed using Monte Carlo methods.[15] The energy dependence of the TERMA, T_E ($\vec{s}$), can be expressed by applying the inverse-square law and exponential attenuation to the photon fluence at the surface of the phantom or patient.

The 3D integral is typically evaluated in a two-step process. The first step takes into account the properties of the accelerator (including the finite source size, primary collimator, flattening filter, collimator jaws, multileaf collimators (MLCs), and any beam-modifying devices used for the treatment, such as wedges, alloy blocks, and compensating filters) to compute the energy fluence at the phantom or patient surface. The second step of the calculation takes into account the inverse-square law and exponential attenuation to this incident fluence to determine the TERMA, T_E ($\vec{s}$), at each point within the phantom or patient and convolve the result with the point spread function, h ($\vec{r} - \vec{s}$).

The convolution equation is strictly valid only for homogeneous media (ie, h ($\vec{s}$) must be spatially invariant). To account for the effects of tissue heterogeneities, all physical distances in the convolution integral are replaced with radiologic distances, that is, the physical distance multiplied by the average density along the line in question.[12,15] Hence, the convolution/superposition algorithm accounts for the effects of heterogeneities anywhere in the vicinity of the calculation point in 3D. In contrast, most CF-based dose calculation techniques require only a simple 1D evaluation of radiologic path length and can thus account for the effects of only those tissue heterogeneities that lie along a ray connecting the radiation source to the calculation point.

Several investigators have tested the convolution/superposition algorithm against measurements and Monte Carlo–generated data for complex phantom geometries including both homogeneous and heterogeneous phantoms and found that the convolution/superposition model gave accurate results, even in parts of the buildup region and penumbra.[16,17]

Dose Transport Methods

Dose transport calculations can be implemented either *deterministically* using linear Boltzmann transport equations (LBTEs) or *stochastically* using Monte Carlo.[18] Monte Carlo methods were introduced into treatment planning systems first but now both types of algorithms are available in clinical planning software.

Monte Carlo Method

Monte Carlo is, in principle, the only method capable of computing the dose distribution accurately for all situations encountered in radiation therapy, including being able to accurately predict the dose near interfaces of materials with very dissimilar atomic numbers, such as near-metal prostheses, or different densities such as tumors in lung tissue.[19] The Monte Carlo method uses the known cross sections for electron and photon interactions in matter and follows individual photons and the associated electrons set in motion through the entire heterogeneous phantom or patient. By calculating the trajectories and interactions of a very large number of photons and electrons, one can accurately model the dose distribution. Recently, Monte Carlo codes have been developed for radiotherapy treatment planning,[14,20] several of which have been implemented commercially. The reader is referred to the American Association of Physicists in Medicine (AAPM) Task Group (TG) 157 Report, which summarizes the commissioning and use of Monte Carlo for radiation therapy treatment planning.[21] The reader is also referred to the review article by Siebers et al for even more details on Monte Carlo calculation for external-beam radiation therapy.[19] More recently, Monte Carlo dose calculations have been extended to account for magnetic field effects on deposition of radiation dose for magnetic resonance (MR)-guided treatment machines.[22-24]

Linear Boltzmann Transport

LBTEs characterize the transport of radiation particles through a medium using physical principles, such as the interaction cross sections and conservation of energy. The flux of particles traversing a medium in a particular direction at a specific point of space can be quantified by tracking the addition of loss of particles due to scattering. In this regard, LBTE is

similar to Monte Carlo. But unlike Monte Carlo, the change in fluence is calculated in all directions for both photons and electrons, resulting in a set of simultaneous equations that can be solved to yield the composite fluence at any point in the medium, which, in turn, can be used to determine the absorbed dose at that point. As in Monte Carlo methods, approximations are utilized to ignore or simplify some interactions. More details about the equations, approximations used, and applicability to magnetic fields can be found in the review article by Bedford.[18] Currently, this algorithm has been implemented in the Eclipse treatment planning system (Acuros XB, Varian Medical Systems).[25]

Dose Calculation Algorithms and Tissue Heterogeneities

In 2004, the AAPM published Report 85 (TG 65) on tissue inhomogeneity corrections for megavoltage photon beams.[26] The task group recommended an accuracy goal for tissue heterogeneity corrections of 2% in order to achieve an overall 3% accuracy in dose delivery. The AAPM report recommended heterogeneity corrections be applied to plans and prescriptions, with the condition that the algorithm used for calculations be reviewed and rigorously tested by the medical physicist. A brief summary of the site-specific recommendations follows. For the head and neck region, a 1D path correction algorithm for point-dose estimations beyond mandible and ear cavities was thought to be reasonable. However, for soft tissue regions and volumes that are adjacent to these heterogeneities, superposition/convolution or Monte Carlo algorithms should be used. For the larynx, specifically, if the target volume is adjacent to the air cavity or if there is a severe case of disease in the anterior commissure, then either the superposition/convolution or Monte Carlo algorithms should be used. For the treatment of lung cancer, for interest points well beyond the lung interface, 1D path corrections were thought to be reasonable. However, accounting for doses at tumor-lung interfaces, the superposition/convolution or Monte Carlo algorithms should be used. Also, the report recommended that photon energies of 12 MV or less should be used for the treatment of lung cancer to minimize nonequilibrium conditions that exist with higher energies. For breast cancer treatment (particularly if the dose of interest of the target volume is considered to be chest wall), it is recommended that

calculations be performed with superposition/convolution or Monte Carlo. However, for simple intact breast planning, 1D algorithms were adequate. For the upper gastrointestinal tract, 1D corrections were adequate. However, one should be leery if barium contrast is used as it can erroneously impact the dose calculation because of its high Z. In terms of the pelvis and prostate, 1D corrections were quite reasonable, except in the presence of high-Z implanted hip prostheses. (Note that the dosimetric considerations for patients with hip prostheses undergoing pelvic irradiation are discussed in a later section.) The study by Frank et al[27] provides a clear method for safely transitioning clinical use from one based on planning that assumes a homogeneous unit-density patient to one using a heterogeneous patient model.

The Radiological Physics Center published the results of a study comparing measured results of irradiated lung phantoms having various geometries with dose calculations for similar conditions using commercial treatment planning systems. They found significant differences if algorithms less sophisticated than the superposition-/convolution-type algorithms were used.[28]

MONITOR UNIT CALCULATION METHODS

MU calculations refer to determining the linac MU setting per field to deliver the prescribed dose, taking into account the tumor depth, treatment distance, MLC setting or secondary blocking configuration, and primary collimator opening. This is accomplished by using the various dosimetric quantities described in the preceding chapter to relate the dose corresponding to an arbitrary set of treatment parameters to a normalization geometry where the output of the machine is specified in terms of cGy/MU. AAPM TG Report 71 differentiates between the reference geometry, where the output was calibrated, and the normalization geometry, where the output is specified.[29] While these may be consistent, it is also possible for a clinic to use a different normalization geometry than the calibration geometry. The normalization geometry including source-to-surface distance, field size, and depth of output specification is denoted by the symbols SSD_0, r_0, and d_0, respectively. For a fixed SSD normalization geometry,

$$MU = \frac{D}{D_0' * S_c(r_c) * S_p(r_d) * TPR(d, r_d) * WF(d, r_d, x) * TF * OAR(d, x) * \left(\frac{SSD_0 + d_0}{SPD}\right)^2}$$

Normal incidence and open-beam geometry (ie, absence of trays or any beam-modifying filters) are specified.

For treatment machines calibrated isocentrically, the point of MU specification is located at distance SAD rather than at distance SAD + d_{max} as stated previously. For isocentric calibration, $SSD_0 + d_0 = SAD$.

The linac is calibrated by adjusting the sensitivity of its internal monitor transmission ion chamber so that 1 MU equals D_0'cGy for the normalization geometry condition. Several reports providing more details on MU calculations and their verification are listed in the references.[29,30]

Monitor Unit Calculation for Fixed Fields

When the patient is to be treated isocentrically, the point of dose prescription is located at the isocenter, regardless of the target depth. Using the notation of Gibbons et al[29] the MU needed to deliver a prescribed tumor dose to the isocenter (D) for a depth d of overlying tissue on the central ray is given by

$$MU = \frac{D}{D_0' * S_c(r_c) * S_p(r_d) * TPR(d, r_d) * WF(d, r_d, x) * TF * \left(\frac{SSD_0 + d_0}{SAD}\right)^2}$$

where TF and WF denote the tray and wedge factors, respectively. They are defined as the ratio of the central ray dose with the tray or wedge filter in place relative to the dose in the open-beam geometry. The collimated field size is denoted by r_c and is usually described as the square field size equivalent to the rectangular collimator opening projected to the isocenter. The effective field size is denoted by r_d and is always specified to the isocenter distance (SAD). The inverse-square law factor accounts for the difference in distances from the source to the point of dose prescription relative to the point of MU specification. When isocentric calibration is used, this factor is unity. Note that collimator-defined field size is used for the lookup of the collimator scatter factor, S_c, whereas effective field size projected to the isocenter is used for the lookup of TPR and the phantom scatter factor, S_p. By separately accounting for the effect of collimator opening on the primary dose component and the influence of cross-sectional area of tissue irradiated, most of the difficulties in accurately delivering a dose in the presence of extensive blocking are overcome.

When a fixed distance between the target and entry skin surface (SSD) is used to treat the patient, a dose calculation formalism based on PDD is used rather than one based on isocentric dose ratios. When a dose D is to be delivered to depth d, MUs are given by

$$MU = \frac{\mathrm{D}*100\%}{D_0' * S_c(r_c) * S_p\left(r_{d_0}\right) * \mathrm{PDD}_N(d, r, \mathrm{SSD}) * \mathrm{WF}(d, r_d, x) * \mathrm{TF} * \mathrm{OAR}(d, x) * \left(\frac{\mathrm{SSD}_0 + d_0}{\mathrm{SSD} + d_0}\right)^2}$$

The field size (or its equivalent square) on the skin surface at the central axis is denoted by r and is used for the lookup of normalized PDD_N. The field size for S_p is r_{d0}, the field size at the patient surface. The collimated field size r_c at the isocenter must be used for the lookup of S_c. When an

extended treatment distance is used, the collimated field size at the isocenter differs significantly from that at the skin surface of the patient. Note that PDD is a function of SSD, depth, and effective field size. Collimator scatter factors measured at SAD are valid over a wide range of extended treatment distances.[7]

When this dose calculation formalism for highly extended treatment distances such as encountered in administering total-body irradiation is used, care must be taken to verify the validity of inverse-square law at these distances. It is recommended that such setups always be verified by ion chamber measurement at the extended distance. Because of the large scatter contribution to the effective primary dose originating from the flattening filter and other components in the treatment head, the virtual source of radiation may be as much as 2 cm proximal to the target of the accelerator.

All MU calculation formalisms require some means of estimating the square field size, *r*, that is equivalent, in terms of scattering characteristics, to an arbitrary rectangular field of width *a* and length *b*. Perhaps the most widely used rectangular equivalency principle is the "A/P" rule. It states that a square and a rectangle are equivalent if they have the same area/perimeter ratio; that is.

$$r = \frac{2(a \times b)}{(a + b)}$$

Another widely used approach to reducing rectangular estimates of effective field size to square field sizes is the equivalent square table published in the *British Journal of Radiology*.[31] Estimating the effective field size equivalent to an irregular field is best handled via irregular field calculations as discussed later in this chapter.[32,33]

Monitor Unit Calculations for Asymmetric X-Ray Collimators

Asymmetric x-ray collimators (also referred to as *independent jaws*) allow independent movement of an individual jaw and may be available for one jaw pair or both pairs. Because MU calculations and treatment planning

methods generally rely on symmetric jaw data, the dosimetric effects for asymmetric jaws must be fully documented before being implemented in the clinic. Several investigators have examined the effects of asymmetric jaws on PDD, collimator scatter, and isodose distributions.[34] MU calculations for asymmetric jaws are only slightly more complex than for symmetric jaws.[29] Typically, one simply applies an *OAR* or *off-center ratio (OCR)* CF that depends only on the distance from the machine's central axis to the center of the independently collimated open field.[35,36] PDD is only minimally affected, but the isodose curve shape can be altered and must be investigated for the particular treatment unit. Calculations for asymmetric wedge fields follow similar procedures by simply incorporating a wedge OAR or OCR.[37,38]

Monitor Unit Calculations for Multileaf Collimator

MLCs have nearly completely replaced conventional alloy field shaping for photon beams in most clinics around the world. Several investigators have examined the effects of the Varian MLC design (tertiary system) on PDD, collimator scatter, and isodose distributions, described in AAPM TG Report 72.[39] The effects due to field area shaped by this type of MLC on PDD and beam output parameters are similar to those resulting from Cerrobend field shaping. Thus, the dose/MU calculation methods discussed previously apply by simply using the equivalent area defined by the MLC. The collimator scatter factor and the dose in free space are determined using the x-ray collimator jaw settings, with an off-axis factor applied for any asymmetric jaw settings.

It should be noted, however, that for MLC systems that replace one of the collimating jaws, the MLC field shape can be a determining factor in selecting the appropriate output factor. For example, in the case of the Elekta linacs (Elekta AB, Crawley, United Kingdom), in which the lower jaws are replaced by the MLC system, the calculation takes into consideration the collective blocked area that is created by both the MLC leaves and the lower backup diaphragms. For an MLC system that replaces the upper jaw (eg, Siemens linac, Siemens Medical Solutions USA, Inc., Malvern, PA), the blocked area can be used for determining all the calculation parameters (mainly output, PDD, and scatter factor).

Hence, because of MLC design differences and the fact that vendors are continuing to modify/improve MLC designs, the authors caution that when a new linac is installed, the impact of the MLC on the institution's MU calculation procedure should be fully documented before clinical use. The reader is also encouraged to review AAPM TG Report 50, which provides more detail on various MLC types and discusses quality assurance (QA) and MU calculations.[39]

Monitor Unit Calculations for Irregular Fields

For large, irregularly shaped fields and at points off the central axis, it is necessary to take into account the off-axis change in intensity (relative to the central axis) of the beam, the variation of the SSD within the field of treatment, the influence of the primary collimator on the output factor, and the scatter contribution to the dose. Changes in the beam quality as a function of position in the radiation field also should be considered.[40,41]

The general method used for irregular field calculations consists of summation at each point of interest of the primary and scatter irradiation, with allowance for the off-axis change in intensity (off-axis factor) and SSD.[32,33] The MUs required to deliver a specified dose at an arbitrary point in an irregular field (Figure 8.2) can be calculated as follows:

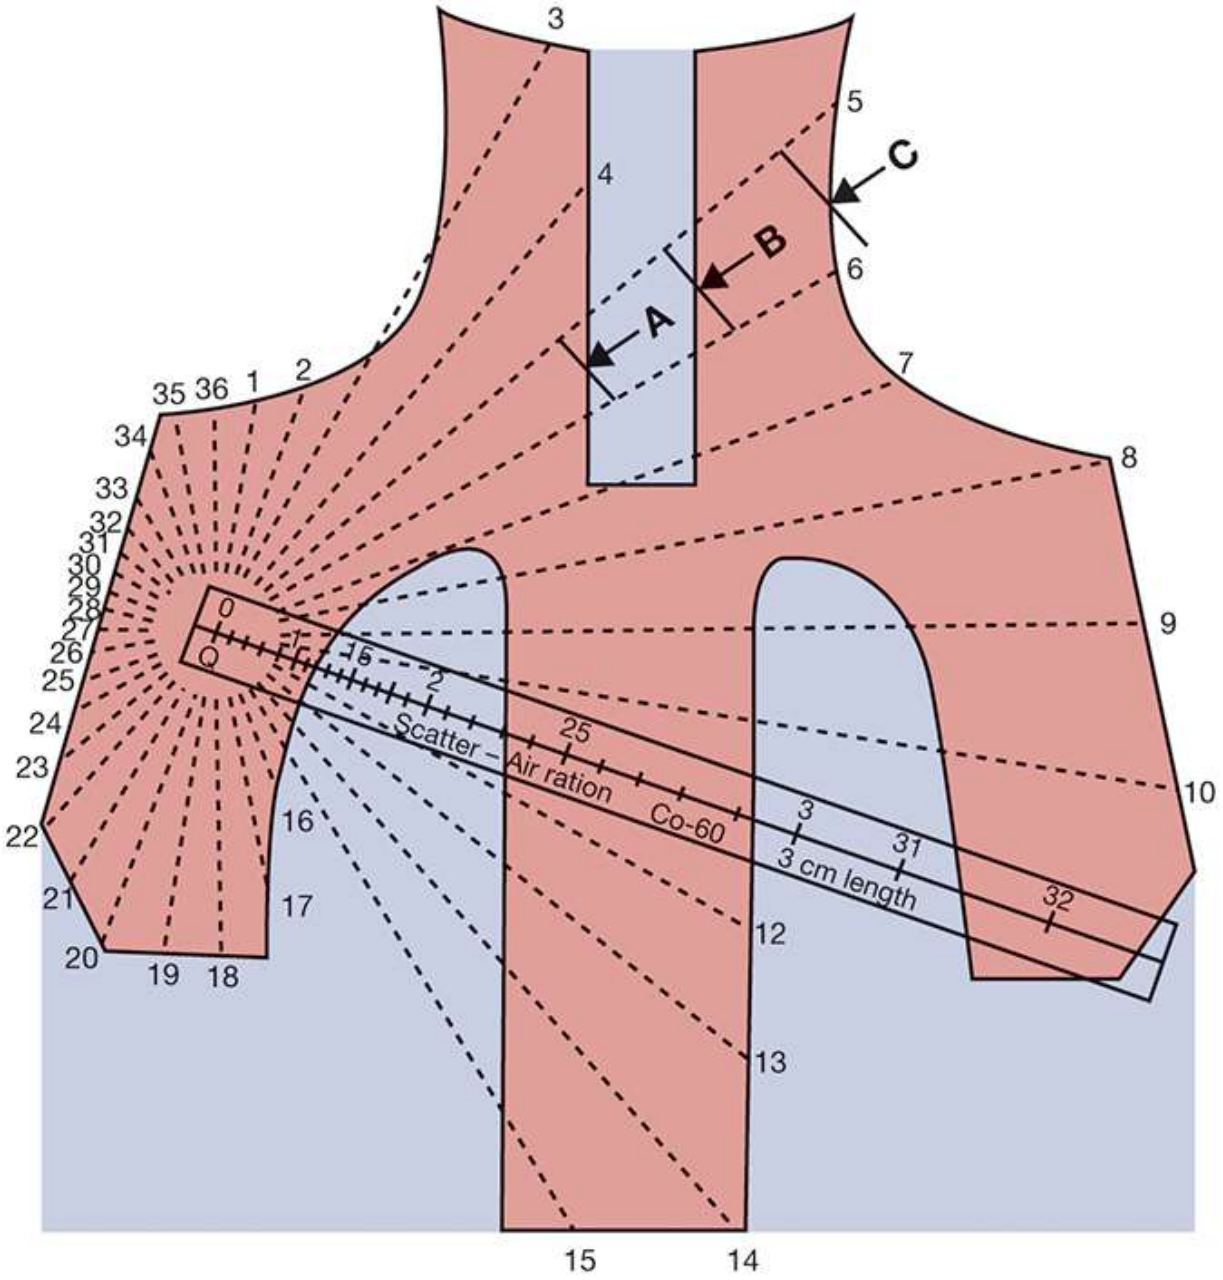

FIGURE 8.2 Outline of mantle field illustrating method of determining scatter-to-air ratio, used for irregular field dose calculations. (From Cundiff JH, Cunningham JR, Golden R, et al. A method for the calculation of dose in the radiation treatment of Hodgkin's disease. *Am J Roentgenol Radium Ther Nucl Med*. 1973;117[1]:30-44. Reprinted with permission from the American Journal of Roentgenology.)

$$MU = \frac{TD}{\left[TAR(d,0) + \overline{SAR}(d)\right] \cdot \dot{D}_{fs}\left(SSD + d_{max}, r_c\right) \cdot TF \cdot OAF\left(\frac{SSD + d_{max}}{SSD + g + d}\right)^2}$$

where the parameters used are

TAR (d,0) = zero-field size TAR at depth d

SAR (d) = average SAR for point in question at depth d determined using the Clarkson technique

D_{fs} = Gy/MU in a small mass of tissue, in-air, on the central axis at normal SSD + d_{max} for the collimated field size

SSD = nominal SSD for treatment constraints

d_{max} = depth of dose maximum

TF = blocking tray attenuation factor

g = vertical distance between skin surface over point in question and nominal SSD (beam vertical)

d = vertical depth, skin surface to point in question

OAF = in-air off-axis factor.

Computer implementations vary but typically include using the expanded field size at a depth for the SAR calculation, determining the off-axis factor using the distance from the central axis to the slant projection of the point of calculation to the SSD plane along a ray from the source and determining the zero-area TAR using the slant depth along a ray going from the source to the point of calculation. It is generally accepted that the off-axis factor should be multiplied by the sum of the zero-area TAR and the SAR as originally proposed.

Beam quality is a function of position in the field for beams generated by linear accelerators.[40,41] The TAR_0 may be expressed as a function of position in the beam so that changes in beam quality can be incorporated into calculations, and it can be related to the half-value layer (HVL) of water by the following equation:

$$\mathrm{TAR}\left(d,0,r\right)=e\left[\frac{-0.693\left(d-d_{\max}\right)}{\mathrm{HVL}\left(r\right)}\right]$$

where d is the depth of the point of reference, d_{max} is the depth of maximum dose, r is the radial distance from the central axis of the beam to the point of calculation, e is the base of the natural logarithm, and HVL*(r)* is the beam quality expressed as the HVL measured in water.

Monitor Unit Calculations for Intensity-Modulated and Rotational Therapy

The classic method for MU calculations for rotation therapy is given by the following equation:

$$\mathrm{MU}=\frac{\mathrm{ID}}{\mathrm{TAR}_{\mathrm{avg}}\cdot\dot{D}_{fs}\left(\frac{\mathrm{SCD}}{\mathrm{SAD}}\right)^{2}}$$

and the MU per degree setting is given by

$$\mathrm{MU/deg}=\frac{\text{monitor unit setting}}{\text{degrees of rotation}}$$

where the symbols have the previous meaning and $\mathrm{TAR}_{\mathrm{avg}}$ is an average TAR (averaged over radii [depth in the patient] at selected angular intervals, such as 10° or 20°).

Most recently, manufacturers of linacs and their associated planning systems have introduced features that provide rotational intensity-modulated radiation therapy (IMRT) capability[42] (eg, Elekta VMAT[43] and Varian RapidArc[44]), addressed in detail in Chapters 10. The linac-based

rotational IMRT concept was first proposed by Yu[45] and called *intensity-modulated arc therapy*, but planning software was not commercially available at that time. Rotational IMRT approaches on conventional linacs may provide even more conformal dose distributions delivered in a shorter treatment time, compared with *SMLC-IMRT (step and shoot)* or *DMLC-IMRT (dynamic)* approaches that use only a limited number of gantry directions. In addition, plan optimization is simpler because it eliminates the planner's iterative choices of beam number and direction. MU calculations for this more complex form of rotational therapy are generated via advanced treatment planning systems having this capability. All are techniques in which the MLC shape changes during a rotation therapy, and depending on the specific linac, other parameters, such as dose rate, may also change. This advanced type of treatment delivery is mainly checked via phantom measurements rather than manual calculations before the patient's treatment. AAPM TG 218[46] covers the role of such pretreatment, patient-specific QA measurements, and the use of electronic portal imaging devices for these measurements.

Secondary computer programs can also be used to perform independent dose calculations and MU as well as 3D dose calculations. It is apparent that the simple MU manual calculation methods described here are no longer adequate for the complex technologies in use today. Modern computer plans utilize dose weight points of interest, which classical MU calculation methods may not address; in addition, geometries that include the presence of heterogeneities, added tertiary devices such as MLCs and asymmetric jaws, and beam intensity modulation can all be problematic for manual check calculations. For example, when the dose weight point is within a small volume of mass surrounded by low-density tissue (eg, a coin lesion in lung) or one that is at the border of a chest wall and lung (as in a postmastectomy patient), MU calculations cannot easily be confirmed by simple hand-calculated MU methods, and one must rely on the planning system for calculations such as these, emphasizing the importance of fully testing such system prior to clinical use. Dedicated commercial software for MU verification is widely available; for example, RadCalc (LifeLine Software Inc, Austin, TX)[47,48] offers a variety of independent MU beam on-time calculations, including that for the Gamma Knife (software developed at Washington University and licensed to RadCalc).[49] Obviously, such

systems must be validated by the physics user prior to clinical use. AAPM TG 219 describes currently available MU verification software as well as recommendations for commissioning and use of such software.[50]

CLINICAL PHOTON BEAM DOSIMETRY

Percent Depth Dose and Single-Field Isodose Charts

The central-axis PDD expresses the penetrability of a radiation beam. Table 8.1 summarizes beam characteristics for x-ray and γ-ray beams typically used in radiation therapy and lists the depth at which the dose is maximum (100%) and the 10-cm depth PDD value. Representative PDD curves are shown in Figure 8.3 for conventional SSDs. As a rule of thumb, an 18-MV, 6-MV, and ^{60}Co photon beam loses approximately 2%, 3.5%, and 4.5% per centimeter, respectively, beyond the depth of maximum dose, d_{max} (values are for a 10- × 10-cm field, 100-cm SSD). There is no agreement as to what the single optimal x-ray beam energy is; instead, institutional bias or radiation oncologist training typically influences its selection, and it is usually treatment site specific. As pointed out in Chapters 6, most modern linacs are multimodality and provide a range of photon and electron beam energies ranging from 4 to 25 MV, with 6-, 10-, and 15-MV x-ray beams becoming the most common. It should be noted that in the case of IMRT, the impact of energy on the quality of the delivered radiation dose distribution is less compared to 2D and 3DCRT treatments and that all recent developments in radiotherapy use lower-energy beams exclusively (eg, CyberKnife, TomoTherapy, ViewRay, Halcyon).[51] The choice of high-energy beams in the era of predominantly IMRT delivery likely has a much larger effect on operational efficiency and facility design than on the quality of delivered radiation. Selection of treatment machines with the highest energy of 10 MV or less results in simplification of radiotherapy treatment rooms, typically allowing elimination of the maze and use of thinner and faster room entry doors. These shielding gains come from the elimination of shielding requirements for secondary neutron radiation.

TABLE 8.1 BEAM CHARACTERISTICS FOR PHOTON BEAM ENERGIES OF INTEREST IN RADIATION THERAPY

200 kVp, 2-mm Cu HVL, SSD = 50 cm

- Depth of maximum dose = surface
- Rapid falloff with depth due to (a) low energy and (b) short SSD
- Sharp beam edge due to small focal spot
- Significant dose outside beam boundaries due to Compton scattered radiation at low energies

^{60}CO, SSD = 80 cm

- Depth of maximum dose = 0.5 cm
- Increased penetration (10 cm PDD = 55%)
- Beam edge not as well defined—penumbra due to source size
- Dose outside beam low because most scattering is in the forward direction
- Isodose curvature increases as the field size increases

4-MV x-ray, SSD = 80 cm

- Depth of maximum dose = 1-1.2 cm
- Penetration slightly greater than cobalt (10 cm PDD = 61%)
- Penumbra smaller
- “Horns” (beam intensity off-axis) due to flattening filter design ≈14%

6-MV x-ray, SSD = 100 cm

- Depth of maximum dose = 1.5 cm
- Slightly more penetration than ^{60}Co and 4 MV (10 cm PDD = 67%)
- Small penumbra
- Horns (beam intensity off-axis) due to flattening filter design ≈9%

15- to 18-MV x-ray, SSD = 100 cm

- Depth of maximum dose = 3-3.5 cm
- Much greater penetration (10 cm PDD = 80%)
- Small penumbra
- Horns (beam intensity off-axis) due to flattening filter design ≈5%
- Exit dose often higher than entrance dose

HVL, half-value layer; PDD, percentage depth dose; SSD, source-to-skin distance.

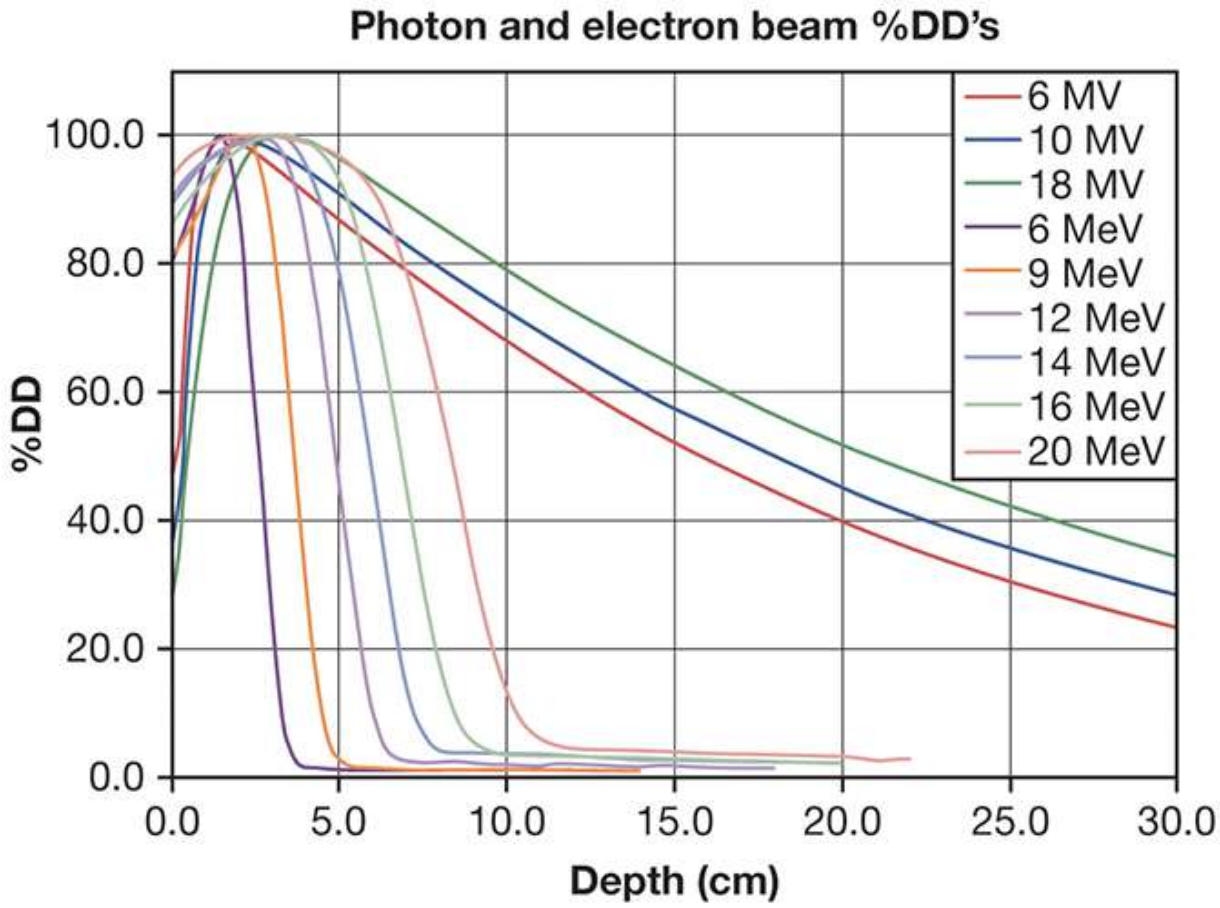

FIGURE 8.3 Typical photon and electron beam central-axis percentage depth-dose curves for a 10- × 10-cm beam for megavoltage beams ranging from ^{60}Co to 18-MV x-rays and 6- to 20-MeV electron beams.

Isodose charts provide much more information about the radiation beam characteristics than do central-axis PDD data alone. However, even isodose charts are limited in that they represent the dose distribution in only one plane (typically the one containing the beam's central axis) and are usually available only for square or rectangular fields. Isodose charts are usually measured in a water phantom with the radiation beam directed perpendicular to the phantom's flat surface. Isodose curves show the relative uniformity of the beams across the field at various depths and graphically depict the width of the beam's penumbra region. ^{60}Co teletherapy units exhibit a relatively large penumbra, and their isodose distributions are more rounded than those from linac x-ray beams. This is due to the relatively large source size (typically 1-2 cm in diameter vs only a few millimeters for linacs). Linac beam penumbra width does increase

slightly as a function of energy and if unfocused MLC leaves are used but is still much less than that for ^{60}Co units. The beam penumbra can be improved if focused MLCs are used. For example, the ViewRay's ^{60}Co could produce treatment plans equivalent in quality to that of modern linacs. This equivalence between ^{60}Co and linac plans was achieved through combining ^{60}Co with doubly focused MLCs on ViewRay.[52] This ability to improve the IMRT plan quality through MLC design will undoubtedly lead to further refinements in approaches to MLC design. ViewRay's double-layer doubly focused and Varian Halcyon's dual-layer MLCs are early indications of this possibility. In addition to the smaller penumbra, linac x-ray isodose distributions have relatively flat isodose curves at depth. However, at shallow depths, particularly at d_{max}, linac x-ray beams typically exhibit an increase in beam intensity away from the central axis; this beam characteristic is referred to as the dose profile *horns* and depends on flattening filter design. In general, each treatment unit has unique radiation beam characteristics, and thus, isodose distributions must be measured, or at least verified, for each specific treatment unit. Excellent dosimetric reproducibility between modern treatment machines has been observed, and there is now a trend toward verification of the expected beam dosimetry rather than attempting to fully characterize dosimetry for each machine.[53]

Another important point to understand is how the radiation field size is defined. The radiation field size dimensions refer to the distance perpendicular to the beam's direction of incidence that corresponds to the 50% isodose at the beam's edge. It is defined at the skin surface for SSD treatments and at the SAD for isocentric treatments.

Depth-Dose Buildup Region

When a photon beam strikes the tissue surface, electrons are set in motion, causing the dose to increase with depth until the maximum dose is achieved at depth d_{max}. As the energy of the photon beam increases, the thickness of the buildup region increases. The subcutaneous tissue-sparing effects of higher energy x-rays, combined with their great penetrability, make them well suited for treating deep lesions. In general, the dose to the surface and in the buildup region for megavoltage photon beams generally increases with increasing field size and with the insertion of blocking trays made of

plastic or other types of material in the beam (Figure 8.4). The blocking trays should be at least 20 cm above the skin surface because skin doses are significantly increased for lesser distances. Copper, lead, or lead glass filters beneath the blocking tray can be used to remove the undesired lower-energy electrons that contribute to skin dose, but this is nowadays rarely done routinely in the clinic.[54,55]

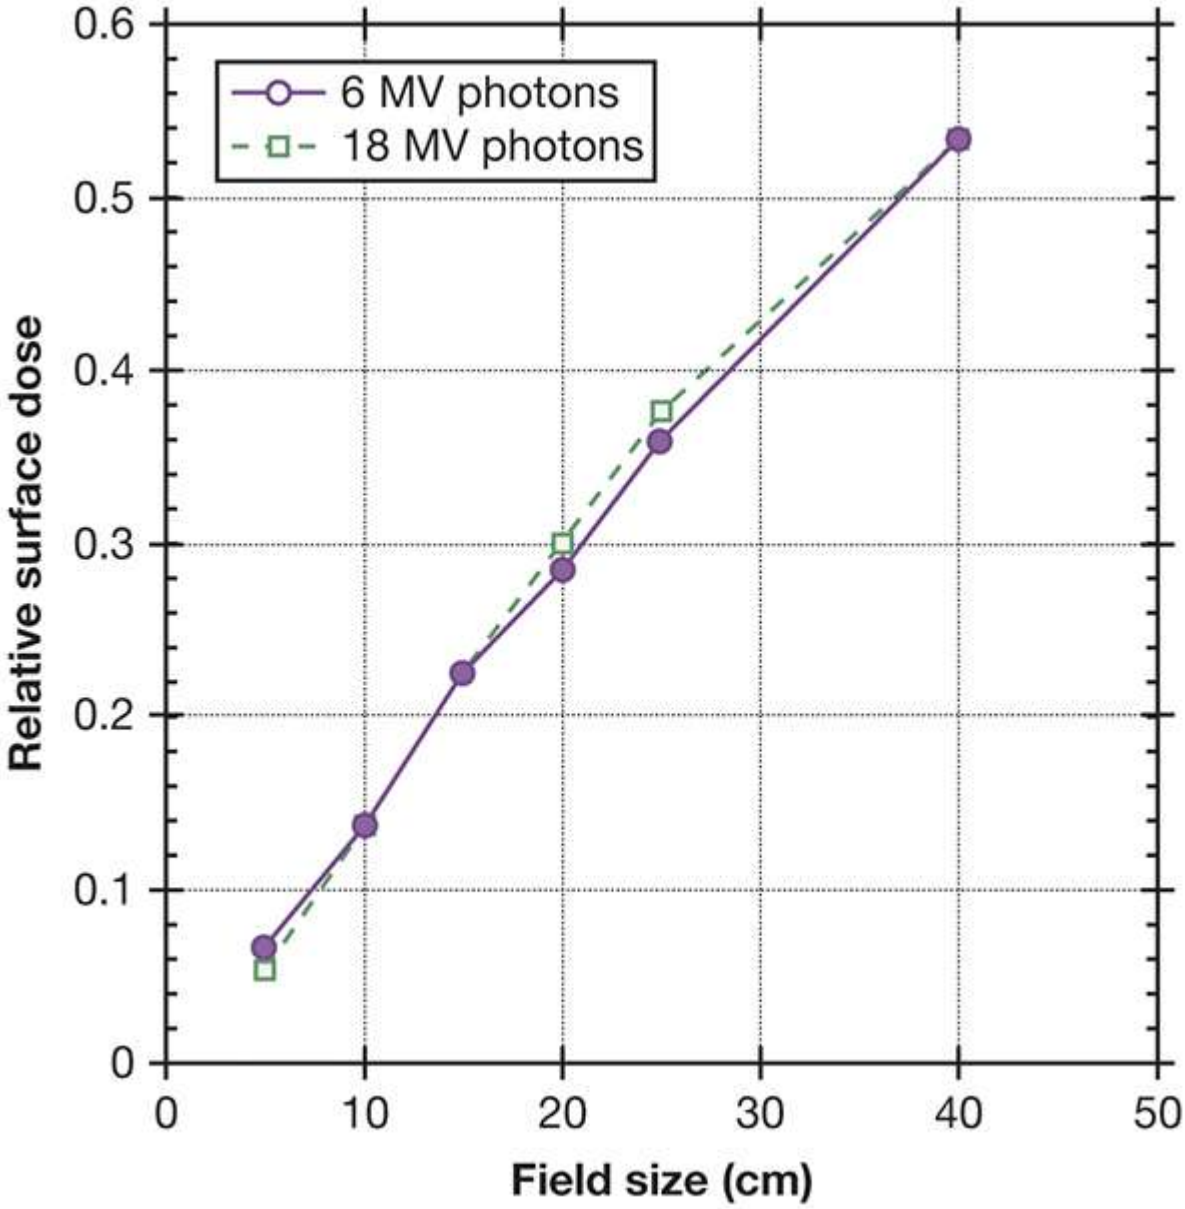

FIGURE 8.4 Relative surface dose versus field size with blocking tray in place for 6- and 18-MV photons. (Reprinted from Klein EE, Purdy JA. Entrance and exit dose regions for clinac-2100c. *Int J Radiat Oncol Biol Phys*. 1993;27[2]:429-435. Copyright © 1993 Elsevier. With permission.)

As the angle of the incident radiation beam becomes more oblique, the surface dose increases, and d_{max} moves toward the surface (Figure 8.5). This is primarily due to more secondary electrons' contribution from the media below the surface along the oblique path of the beam.[56]

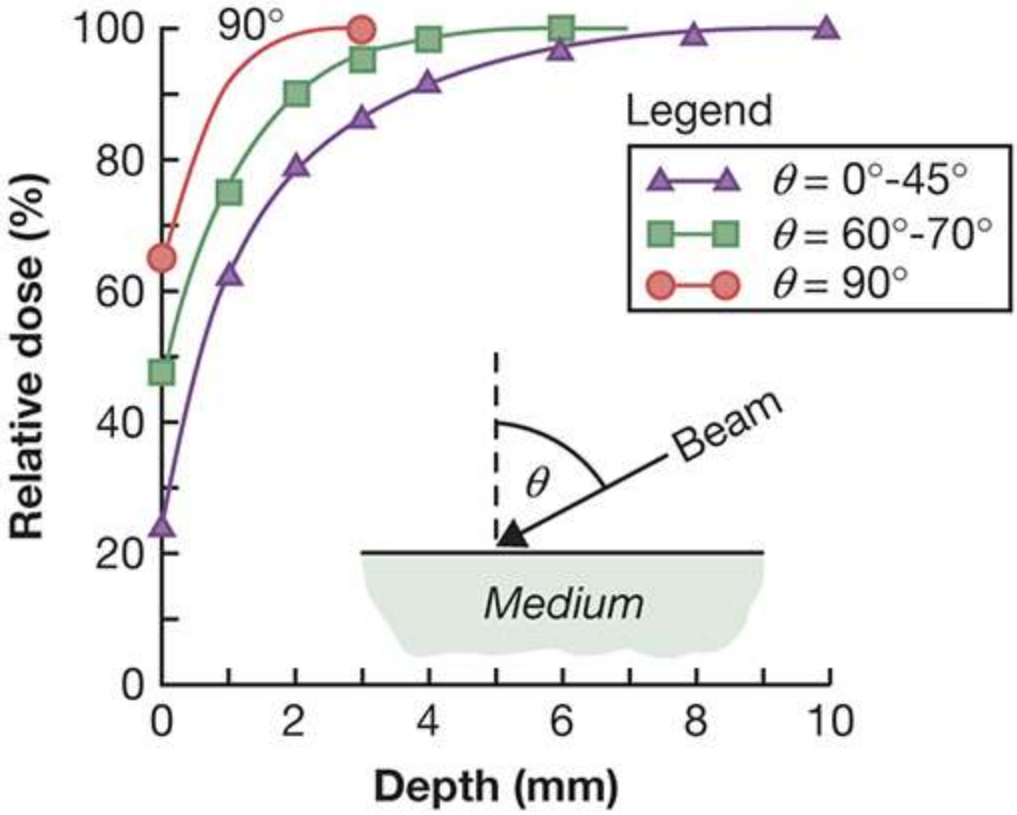

FIGURE 8.5 The variation of surface dose and depth of maximum dose as a function of the angle of incidence of the x-ray beam with the surface (4 MV, 10 × 10 cm^2).

Depth-Dose/Exit Dose Region

The skin and superficial tissue on the side of the patient from which the beam exits receive a reduced dose if there is insufficient backscatter material present. The amount of dose reduction is a function of x-ray beam energy, field size, and the thickness of tissue that the beam has penetrated reaching the exit surface. For a 6-MV beam, a 15% reduction in dose with little dependency on field size has been reported,[54] and for 18-MV beams, an 11% reduction in exit dose was measured.[57] In general, the addition of a thickness of tissue-equivalent material on the exit side equivalent in

thickness to approximately two-thirds of the d_{max} depth is sufficient to provide full dose to the build-down region on the exit side. Figure 8.6 shows the effects of various backscattering media when placed directly behind the exit surface.

Tissue Heterogeneities and Tissue Interface Dosimetry

The presence of tissue heterogeneities, such as air cavities, lungs, bony structures, and prostheses, can greatly impact the calculated dose distribution. The change in dose is due to the perturbation of the transport of primary and scattered photons and that of the secondary electrons set in motion from photon interactions. Depending on the energy of the photon beam and the shape, size, and constituents of the inhomogeneities, the resultant change in dose can be large.

Perturbation of photon transport is more noticeable for lower-energy beams. There is usually an increase in transmission, and therefore dose,

when the beam traverses a low-density inhomogeneity. The reverse applies when the inhomogeneity has a density higher than that of water. However, the change in dose is complicated by the concomitant decrease or increase in the scatter dose. For a modest lung thickness of 10 cm, there will be about a 15% increase in the dose to the lung for a ^{60}Co or 6-MV x-ray beam, but only about 5% for an 18-MV x-ray beam.[58]

When there is a net imbalance of electrons leaving and entering the region near an inhomogeneity (interfaces of different media), the condition of electron equilibrium is disrupted. The dose distribution in the patient in such transition zones depends on radiation field size (scatter influence), distance between interfaces (eg, air cavities), differences between physical densities and atomic number of the interfacing media, and the size and shape of the different media. Because electrons have finite travel, the resultant change in dose is usually local to the vicinity of the inhomogeneity but may be quite large. The effects are more noticeable for the higher photon energy beams because of the increased energy and range of the scattered electrons. Near the edge of the lungs and air cavities, the reduction in dose can be larger than 15%.[59]

For inhomogeneities with density larger than water, there will be an increase in dose locally due to the generation of more electrons. However, most dense inhomogeneities have atomic numbers higher than that of water so that the resultant dose perturbation is further compounded by the perturbation of the multiple Coulomb scattering of the electrons. Near the interface between a bony structure and water-like tissue, large hot and cold dose spots can be present. Several benchmark measurements have been reported for various geometries simulating clinical situations and are discussed briefly in the following sections.

Air Cavities

Air cavities that appear in various locations of the body, most particularly in the head and neck region, pose a problem because of loss of equilibrium at the air-tissue boundaries internal to the patient. Epp et al[60] reported that for cobalt beams, a reduction in dose of approximately 12% was found for a typical larynx air cavity, which recovered within 5 mm in the new buildup region. The loss was due to a lack of forward scattered electrons. Epp et al[61]

reported that for a 10-MV x-ray beam, a 14.5% loss was measured at the distal interface of the air cavity with a buildup curve that plateaued within 20 mm of the interface. Klein et al[62] measured distributions about air cavities for 4- and 15-MV x-ray beams in both the distal and proximal regions. The combined dose distribution in a parallel-opposed manner showed a 10% loss at the interfaces for both beam energies.

Lung Tissue

Although the problem of reestablishing equilibrium for lung interfaces is not as severe as with air cavities, a transition zone region at the lung-tissue interface still exists over the range of typical clinical photon beam energies. Rice et al measured responses within various simulated lung media for 4- and 15-MV x-rays using a parallel-plate ion chamber and a phantom constructed of solid water and simulated lung material (average lung material density, $\rho = 0.31$ g/cm^3; some additional measurements made with materials having densities of 0.015 and 0.18 g/cm^3).[63] Figure 8.7 shows the results in terms of measured CFs for the 15-MV beam. A considerable buildup curve was observed (10% change in CF) for small fields (5 × 5 cm^2) for the 15-MV beam, which began in the distal region of the lung and plateaued about 5 cm beyond the simulated lung interface.

Bone-Soft Tissue Interfaces

Das et al[64] measured dose perturbation factors (DPFs) proximal and distal for simulated bone-tissue interface regions using a parallel-plate chamber for both 6- and 24-MV x-ray beams. They reported DPFs of 1.1 for the 6-MV beam and 1.07 for the 24-MV beam at the proximal interface. At the distal interface, a DPF of 1.07 was measured for the 24-MV beam, whereas the 6-MV beam exhibited a DPF of 0.95, resulting in a new buildup region in soft tissue. Note that both buildup and build-down regions dissipate within a few millimeters from the interfaces and the perturbations are independent of thickness and lateral extent of the bone or radiation field size.

Metal Prostheses

Das and associates measured DPFs following a 10.5-mm-thick stainless steel layer simulating a hip prosthesis geometry.[64] They reported a DPF of 1.19 for 24-MV photons, but only 1.03 for 6-MV photons; on the proximal side, they reported a DPF of 1.30 due to the backscattered electrons that was independent of energy, field size, or lateral extent of the steel. These interface effects dissipated within a few millimeters in polystyrene. Other

reports dealing with dosimetry perturbations due to metal objects are included in the references.[65,66]

Niroomand-Rad et al reported on dose perturbation effects at the tissue-titanium alloy implant interfaces in patients with head and neck cancer treated with 6- and 10-MV photon beams.[67] They found at the upper surface (toward the source) of the tissue-dental implant interface DPFs of 1.22 and 1.20 for the 6- and 10-MV photon beams, respectively. At the lower interface, dose reduction was approximately −13.5% and −9.5% for the 6- and 10-MV beams, respectively.

The most complete information currently available on hip prosthesis dosimetry is found in AAPM Report 81 (TG 63).[68] The report provides the current state of scientific understanding and clinical dosimetry in use for patients with high-Z hip prostheses undergoing radiation therapy. Beam arrangements that avoid the prosthesis should always be a first consideration. If this cannot be done, valuable information is available in Report 81, including values for different prostheses' electron density, approximate attenuation of the beam passing through the prosthesis, and possible dose increase to the hip bone. It should also be noted that some of the data provided and recommendations are also applicable to patients having other implanted high-Z prosthetic devices, such as pins and humeral head replacements.

Silicone-Soft Tissue Interfaces

Klein and Kuske reported on interface perturbations with silicone breast prostheses.[69] Such prostheses have a density like breast tissue but a different atomic number. They observed a 6% enhancement at the proximal interface and a 9% loss at the distal interface.

Wedge Filter Dosimetry

When a wedge filter is inserted into the beam, whether a physical wedge or a virtual wedge, the dose distribution is angled at some specified depth to some desired angle relative to the incident beam direction over the entire transverse dimension of the radiation beam (Figure 8.8). For cobalt units, the depth of the 50% isodose usually is selected for specification of the wedge angle, whereas for high-energy linacs, higher percentile isodose

curves, such as the 80% curve, or the isodose curves at a specific depth (10 cm) are used to define the wedge angle.

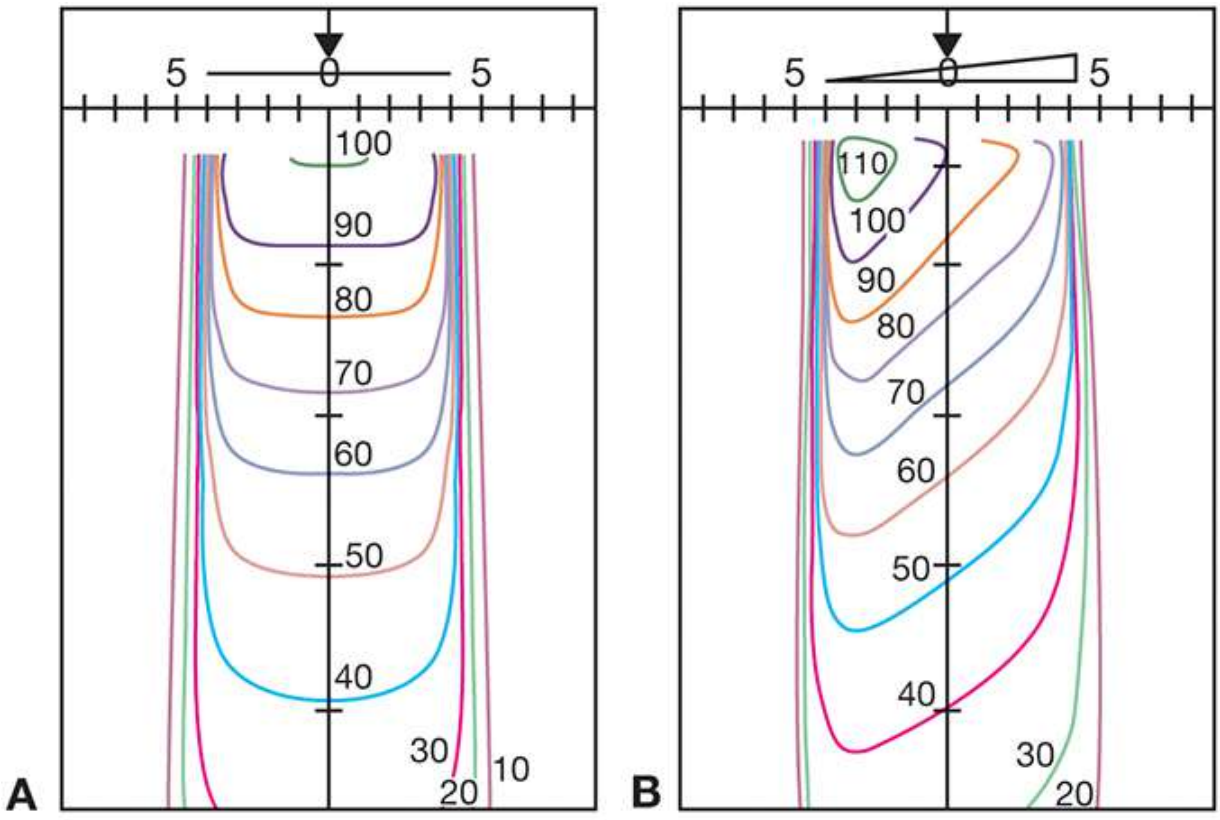

FIGURE 8.8 Isodose distributions for a 6-MV x-ray beam with an 8- × 8-cm field size. A. Open field. B. Field with a 45° wedge. (Reprinted with permission from Khan FM. *The Physics of Radiation Therapy*. 2nd ed. Williams & Wilkins; 1994.)

Linacs are typically equipped with multiple wedges that may be used with an allowed range of field sizes. Although linac wedges can be designed for any desired *wedge angle*, 15-, 30-, 45-, and 60° wedges are the most common.

Some linacs (Elekta AB, Sweden) feature a single wedge, referred to as a *universal wedge*, located in the treatment head, and the desired wedged dose distribution is obtained by the proper combination of wedged and unwedged treatment. A simple approximate model for combining open and wedged fields was first proposed by Tatcher,[70] in which the effective wedge angle q_E, resulting by the addition of a wedged and unwedged beam, is

equal to the nominal wedge angle q_W for the wedged beam, weighted by the fraction of wedged field B:

$$B = \theta_E / \theta_W$$

The Philips Medical Systems Division[71] proposed a slightly different method as follows:

$$B = \tan(\theta_E) / \tan(\theta_W)$$

Petti and Siddon[72] investigated both methods and showed that these are approximations of an exact theoretical solution, which is given by

$$B = f / ([\tan(\theta_E) / \tan(\theta_W)] + f - 1)$$

Most importantly, their investigations showed that Tatcher's approximation is good only for values of q_W <45° and thus is inadequate for accelerators such as Elekta, which use a 60° motorized universal wedge. They did show that for the field sizes studied (up to 20 × 20 cm^2), the Philips relationship was valid to within 3°.

The wedged isodose curves can be normalized in two different ways. In some older systems, the wedge dose distributions have the wedge factor (ie, the ratio of the measured central-axis dose rate with and without the wedge in place) incorporated into the wedged isodose distribution. More commonly, the wedge isodose curves are normalized to 100% at d_{max}, and a separate *wedge factor* is used to calculate the actual treatment MUs or time. McCullough et al[73] noted that wedge factors measured at d_{max} are usually accurate to within 2% for depths up to 10 cm but, at greater depths, can be inaccurate to 5% or more. The inclusion (or noninclusion) of the wedge factor is an extremely important point to understand because serious errors in dose delivered to the patient can occur if used improperly.

Sewchand et al[74] and Abrath and Purdy[75] pointed out that beam hardening results when a wedge is inserted into the radiation beam. The PDD, therefore, can be considerably increased at depth. Differences reported were nearly 7% for a 4-MV 60° wedge field PDD from the open field PDDs at

12-cm depth, and a 3% difference in depth-dose values between the wedge field and the open field for a 60° wedge using 25-MV x-rays was reported.

Modern computer-controlled medical linacs now have software features termed a *virtual wedge* that allow the user to create a wedge-shaped dose distribution by moving one collimator jaw across the field in conjunction with adjustment of the dose rate over the course of the daily single-field treatment.[76] This technology provides superior dose distributions and eliminates the previously mentioned beam hardening problem seen in physical wedges. This feature can deliver a greater number of wedge angles and over larger field sizes, including asymmetric field sizes (30 cm in the wedge direction, with 20 cm toward the wedge "heel" and 10 cm toward the wedge "toe"). The increased number of angles not only enhances planning options but also complicates commissioning and QA.[77] Unlike the physical wedge, beam hardening is not a consideration for the virtual wedge.

When the patient's treatment is planned, wedged fields are commonly arranged such that the angle between the beams, the *hinge angle (q)*, is related to the wedge angle (ϕ) by the following relationship (Figure 8.9):

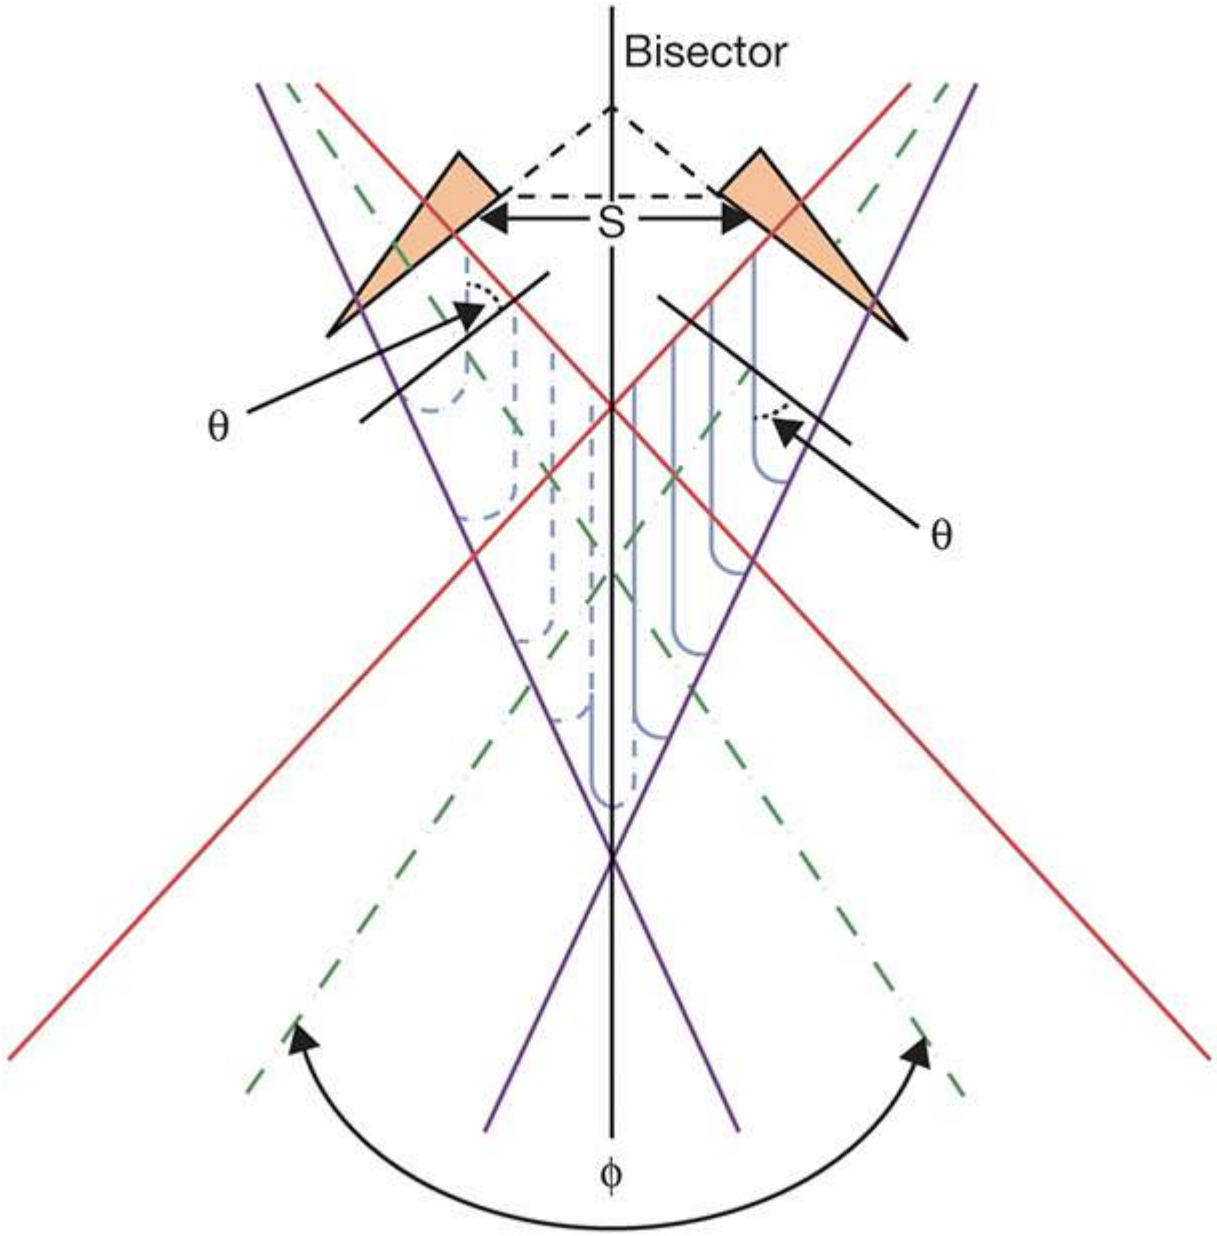

FIGURE 8.9 Parameters of the wedge beams: ϕ is the wedge angle, q is the hinge angle, and θ is separation. Isodose curves for each wedge field are parallel to the bisector. (Reprinted with permission from Khan FM. *The Physics of Radiation Therapy*. 2nd ed. Williams & Wilkins; 1994.)

$$\theta = 90° - \varphi / 2$$

For example, as shown in Figure 8.10, 45° wedge fields orthogonal to one another yield a uniform dose distribution.

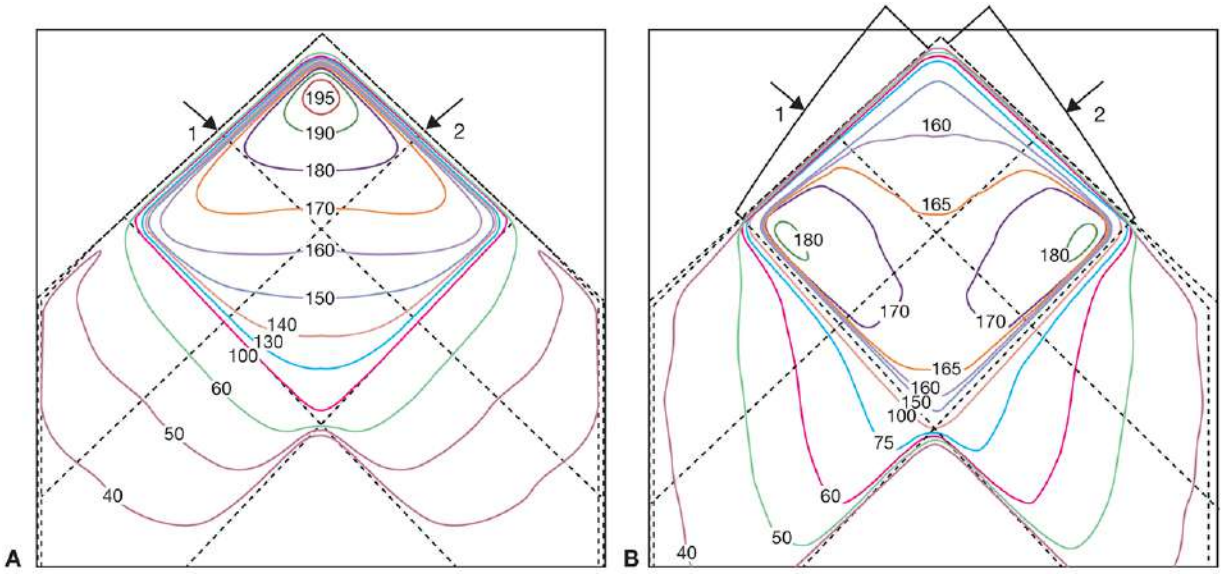

FIGURE 8.10 Isodose distribution for two angled beams. A. Without wedges. B. With wedges. Both: 4 MV; field size, 10 × 10 cm^2; source-to-skin distance, 100 cm; wedge angle, 45°. (Reprinted with permission from Khan FM. *The Physics of Radiation Therapy*. 2nd ed. Williams & Wilkins; 1994.)

TWO-DIMENSIONAL RADIATION TREATMENT PLANNING: COMBINATION OF TREATMENT FIELDS

Parallel-Opposed Fields

When only two unmodified x-ray beams are used in radiation therapy, they usually are parallel-opposed beams (ie, directed toward each other from opposite sides of the anatomic site with the central axes coinciding). Figure 8.11 presents the normalized relative axis dose profiles from parallel-opposed photon beams for a 10- × 10-cm field at an SSD of 100 cm and for patient diameters of 15 to 30 cm in 5-cm increments. The weight of a beam denotes a numeric value assigned to the beam at some normalization point. For SSD beams, the weight specifies the relative dose assigned to the beam at d_{max}, and for isocentric beams, at the isocenter. The beams shown are weighted 1 to 1 (ie, assigned equal value 100% at d_{max}), and the dose profiles have been normalized to the cumulative midline PDD.

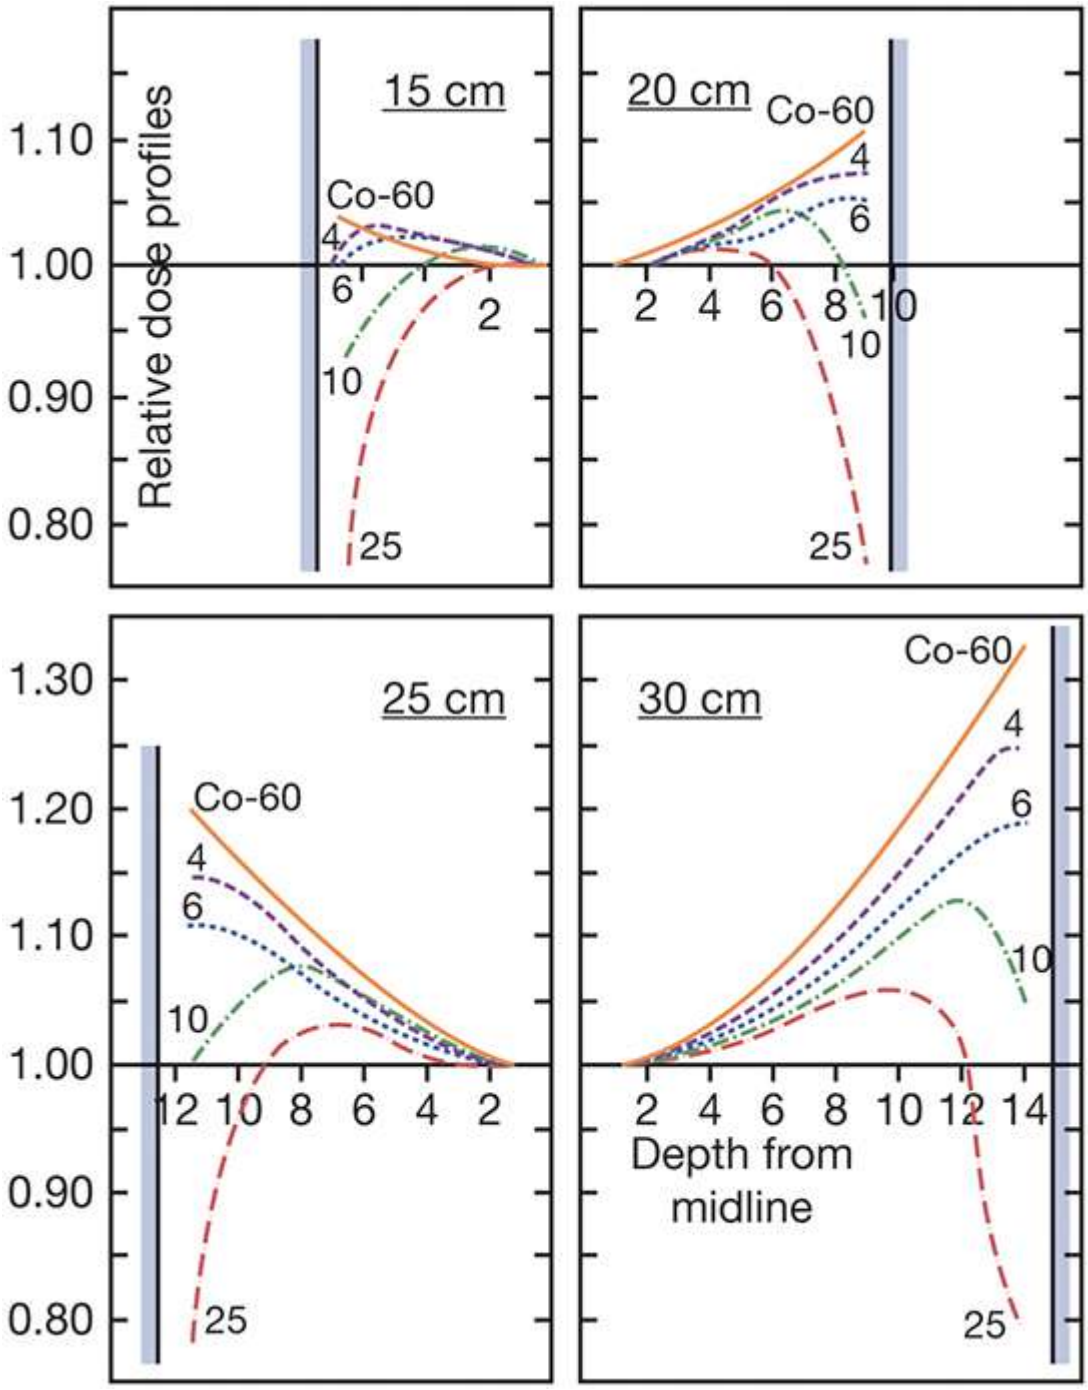

FIGURE 8.11 Relative central-axis dose profiles as a function of x-ray energy (^{60}Co or 4, 6, 10, and 25 MV) and patient thickness (15, 20, 25, and 30 cm). The parallel-opposed beams are equally weighted, and the profiles are normalized to unity at midline. Because of symmetry, only half of each profile is shown.

The maximum patient diameter easily treated with parallel-opposed beams for a midplane tumor requiring 50 Gy or less with low-energy

megavoltage beams is approximately 18 cm. For “thicker” patients, higher x-ray energies produce improved dose profiles with less dose variation along the central axis without resorting to more complex multibeam arrangements.

For some treatment sites, the underdosing achieved near the skin surface with very high-energy, parallel-opposed x-ray beams is a highly advantageous feature; but in others, it may be desirable to achieve a higher dose nearer to the skin. With very high-energy x-ray beams traversing small anatomic thicknesses, the exit dose can exceed the entry dose, and the exact dose distribution in the regions beneath the entry and exit surfaces from parallel-opposed high-energy x-ray beams must be carefully evaluated to consider properly the contribution from both entrance and exit components.

Unequal beam weightings are advantageous if the target volume is not midline. Figure 8.12 shows normalized central-axis dose profiles for other weightings, such as 2 to 1 and 3 to 1. The greater the unequal weighting, the greater will be the shift of the higher dose region toward one surface and away from midline. Although, in some anatomic sites, unequal weighting may be advantageous, special attention must be directed to the anatomic structures in the high-dose volume.

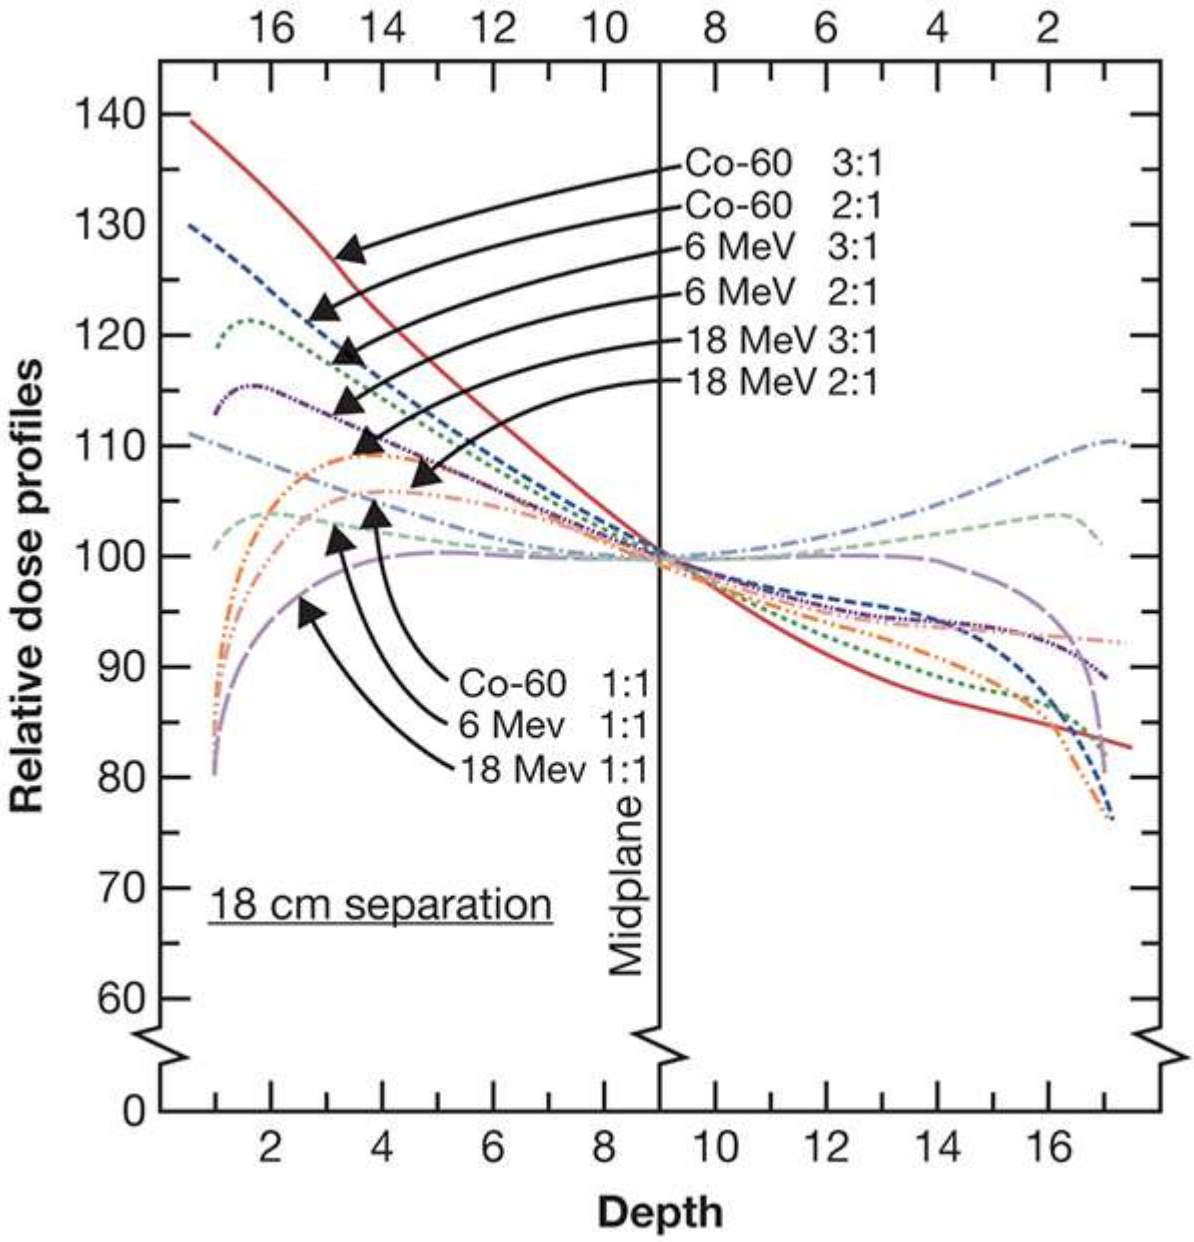

FIGURE 8.12 Dose profiles achieved with unequal weightings of parallel-opposed photon beams; profiles are normalized to unity at midline.

Multiple-Beam Arrangements

Figure 8.13 shows two commonly used coaxial three-field beam arrangements. A direct anterior field with two anterior oblique fields can be used to generate a high-dose region where the three fields overlap, whereas a low-dose region exists beyond this intersection point. For example, if this arrangement is used for treating the mediastinum, the spinal cord might be

included in the anterior beam but spared by the anterior oblique beams. Moving the anterior oblique fields laterally to form a parallel-opposed pair yields a rectangular isodose region with a more uniform dose gradient; however, the magnitude of the dose gradient is determined by the relative weighting of the beams and the thickness of tissue traversed. An anterior field with two symmetrically placed posterior oblique beams yields elongated isodose curves. The degree of elongation is determined by the relative thickness of tissue each beam traverses to the point of intersection and by the relative weights of the beams. Three-field arrangements are often useful for treating tumors lateral to the midline of a patient.

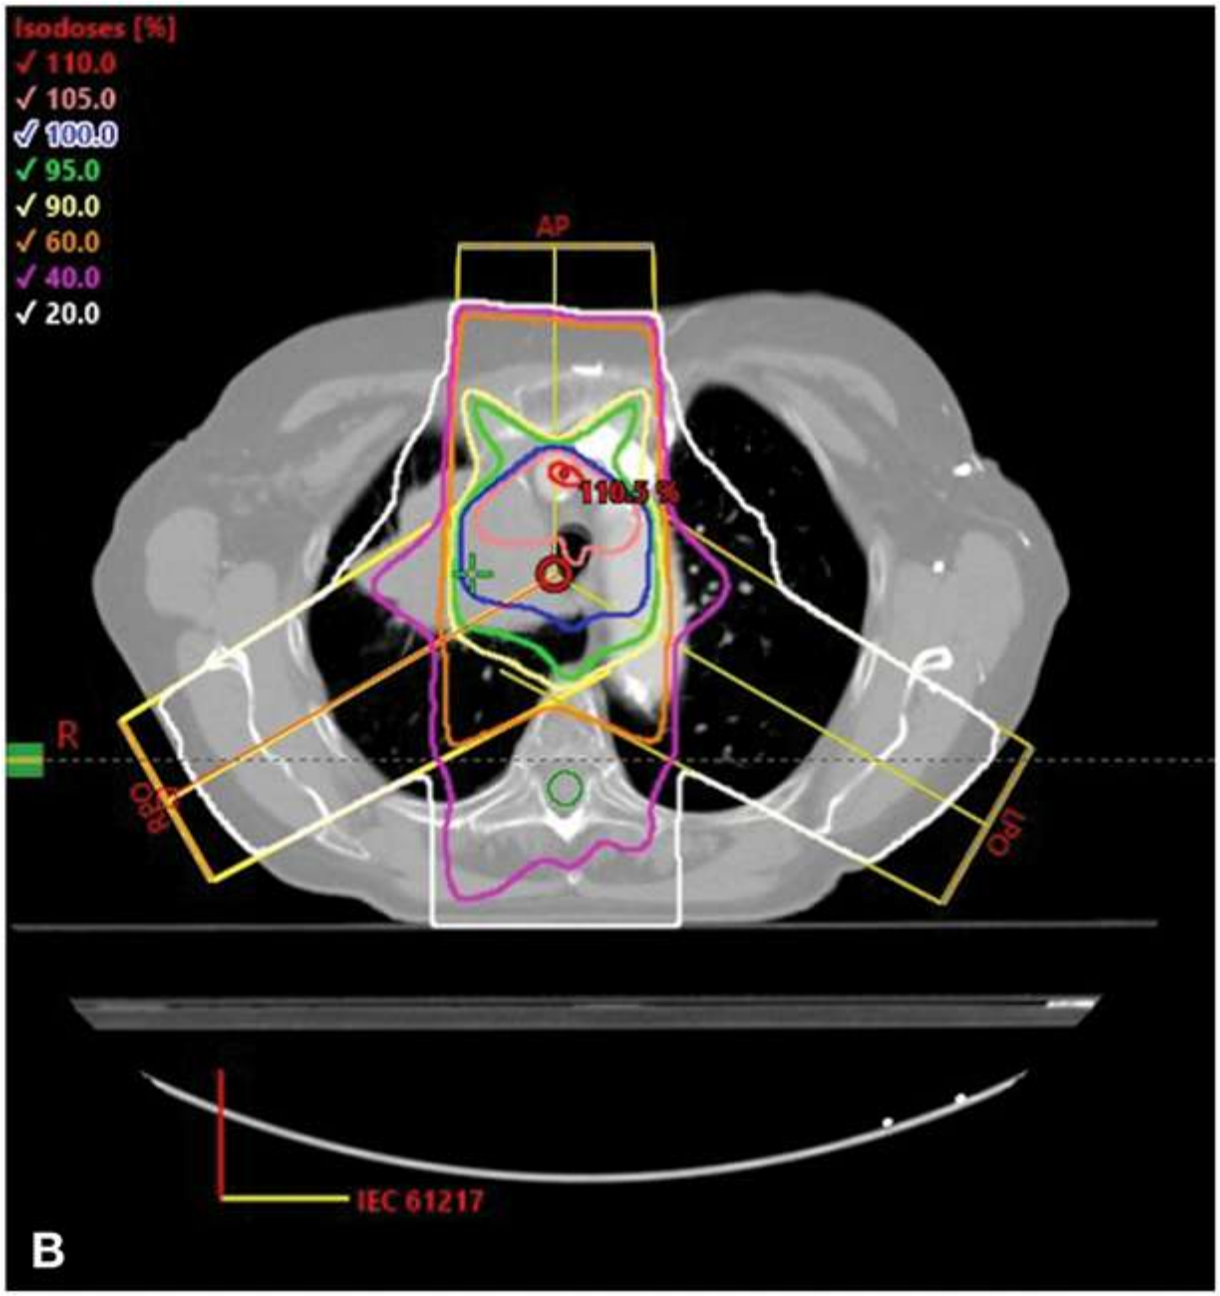

FIGURE 8.13 Three-field coaxial beam arrangements: dose distribution for two different beam arrangements using 6-MV x-ray beams. A. Anterior field with two anterior oblique fields at 40° off the midline. B. Anterior field with a weight of 0.8 with two equally weighted (1) posterior oblique fields separated by 120°.

Three-field nonaxial (noncoplanar) arrangements are readily achieved with linacs by rotating the table and gantry. A common technique for treating pituitary tumors uses two lateral fields and a vertex field with the beam entering through the top of the head. Astrocytomas are often treated

with parallel-opposed lateral fields and a frontal field entering through the forehead. A 90° couch rotation is used with the gantry rotated laterally for the vertex or frontal fields. The lateral fields are also rotated by collimator to ensure the “heels” of the wedges are in the plane of the vertex/frontal field trajectory.

Four-field techniques are typically used in sites such as the abdomen or the pelvis. In most instances, the arrangements consist of pairs of parallel-opposed fields, with a common intersecting point, which yield a “boxlike” isodose distribution. Figure 8.14 compares the dose distributions achieved with a four-field “box technique” for 6- and 18-MV x-ray beams. The central dose distribution is similar for all beam energies, but the greater penetrability of the higher energy beams yields a lower dose to the region outside the box. Variations in the dose gradient are achieved by differential weighting of each pair of beams. Figure 8.15 shows other possible four-beam arrangements. Angulation of the beams yields a diamond-shaped dose distribution. A butterfly-shaped distribution is achieved if each pair of beams has a point of intersection lying on a common line but separated by a few centimeters.

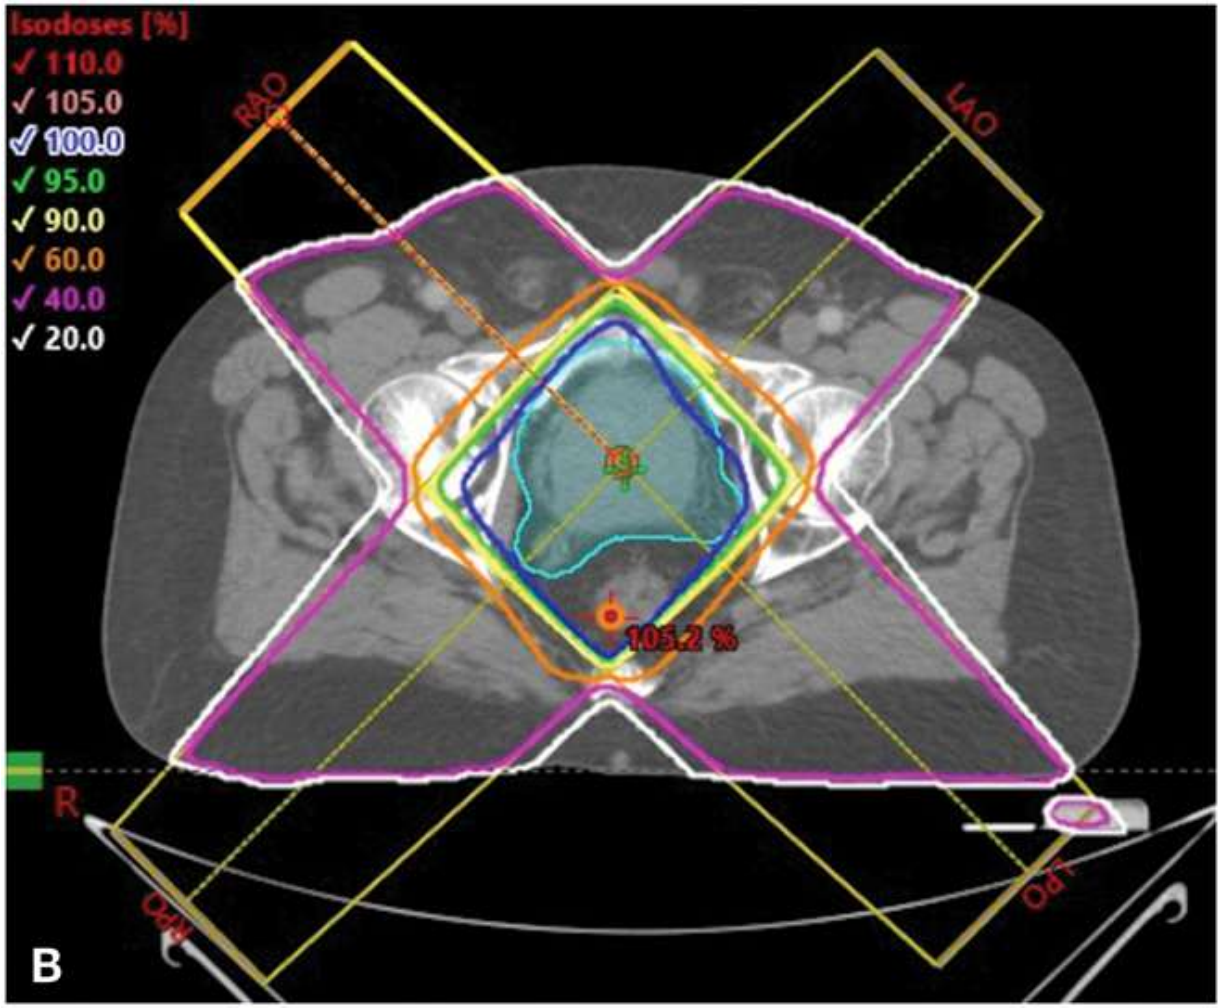

FIGURE 8.15 Four-field "oblique technique" coaxial beam arrangements (6-MV x-rays). A. With equal weighting, resulting in a loss of anterior coverage. B. With custom weighting to improve target coverage.

Treatments involving more than four gantry angles, historically required with orthovoltage x-ray units to treat deep, midline lesions, were originally rarely used with high-energy megavoltage therapy units. However, with the broad introduction of *three-dimensional conformal radiation therapy* (3DCRT) and IMRT (discussed in detail in Chapters 10), there has been an increase in multibeam treatments, such as the 3DCRT six-field technique commonly used for the treatment of prostate carcinoma[78] and the nine-field technique commonly used for head and neck cancer IMRT treatments.[79] More recently, these multibeam arrangements are further refined by adding segments of field with the same beam angle either to improve dose

homogeneity or to intentionally generate an inhomogeneous dose distribution (eg, the simultaneous integrated boost technique).[80]

Rotation Therapy

Rotational (or *arc*) *therapy* techniques, in which the treatment is delivered while the gantry (and thus the radiation beam) rotates around the patient, can be thought of as an infinite extension of the multiple-field techniques already described. Originally, this technique was most useful when applied to small, symmetric, deep-seated tumors and was limited to field sizes less than approximately 10 cm in width for the treatment of centrally located lesions (ie, there is approximately an equal amount of tissue in all directions around the lesion). However, intensity-modulated approaches such as VMAT coupled with modern linacs capable of higher dose rates and increased precision in gantry and MLC motion have enabled these techniques to be used throughout the body.

Dose distributions generated by rotational techniques are not very sensitive to the energy of the photon beam. Figure 8.16 illustrates this fact, showing the dose distribution achieved using a 6-MV x-ray beam in the pelvis and in the lung. There is sufficient coverage of the target without high entrance dose in both cases, despite the tissue-equivalent depth in the pelvis being much deeper.

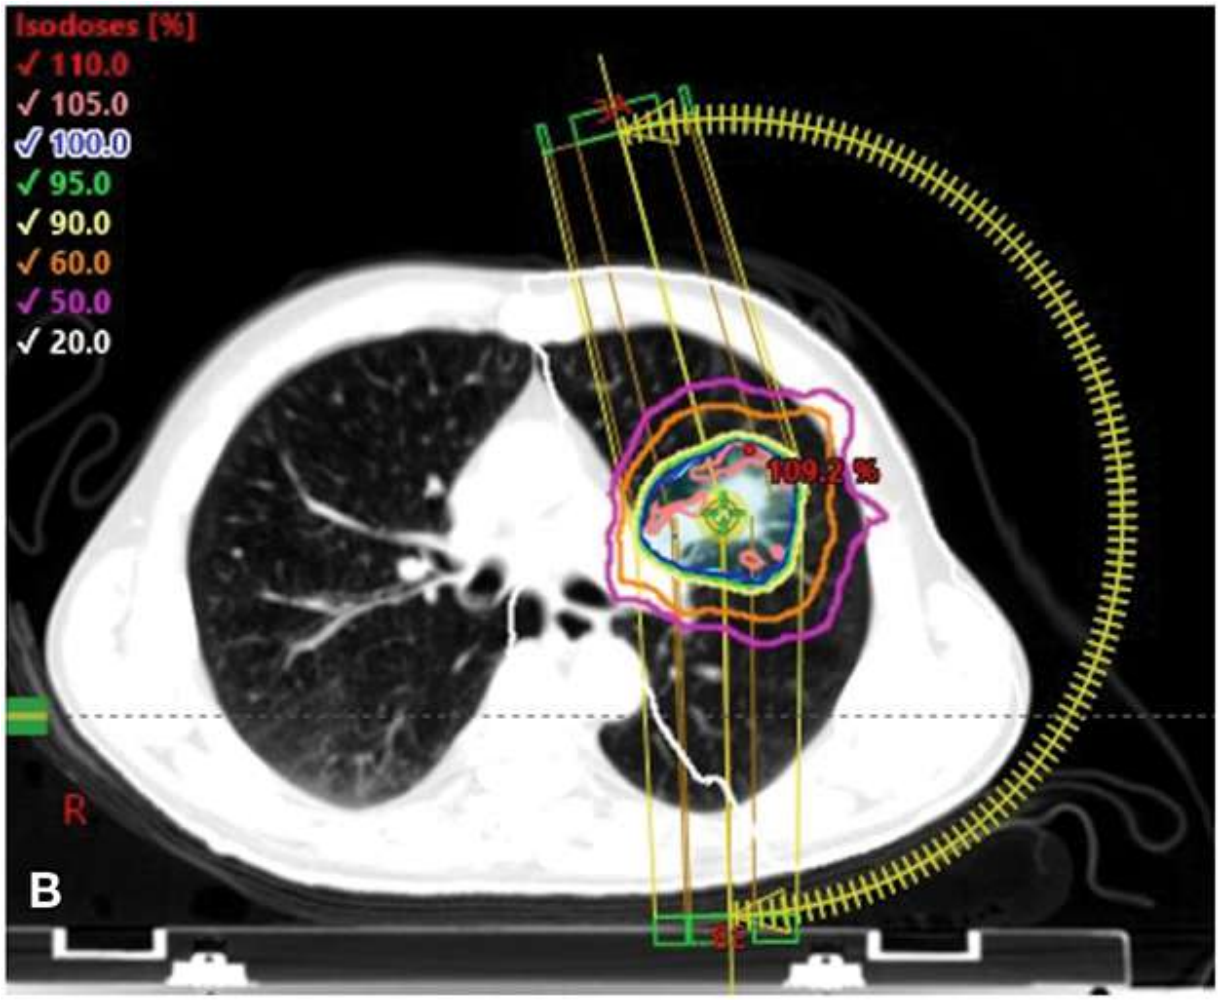

FIGURE 8.16 A 360° rotational therapy technique. A. 6-MV x-ray beams, in pelvis. B. 6-MV x-ray beams, in lung. Note that using the same energy in both cases despite the longer tissue depth in the pelvis results in similar target coverage, demonstrating the decreased sensitivity of planning to energy in rotational techniques versus a limited number of fixed fields.

In arc therapy techniques, one or more sectors of a 360° rotation are skipped to reduce the dose to critical normal structures. When a sector is skipped, the high-dose region is shifted away from the skipped region. Therefore, the isocenter must be moved toward the skipped sector; this technique is referred to as *past pointing*, as illustrated in Figure 8.17. Without past pointing (Figure 8.17A), multiple arcs must be used to gain coverage.

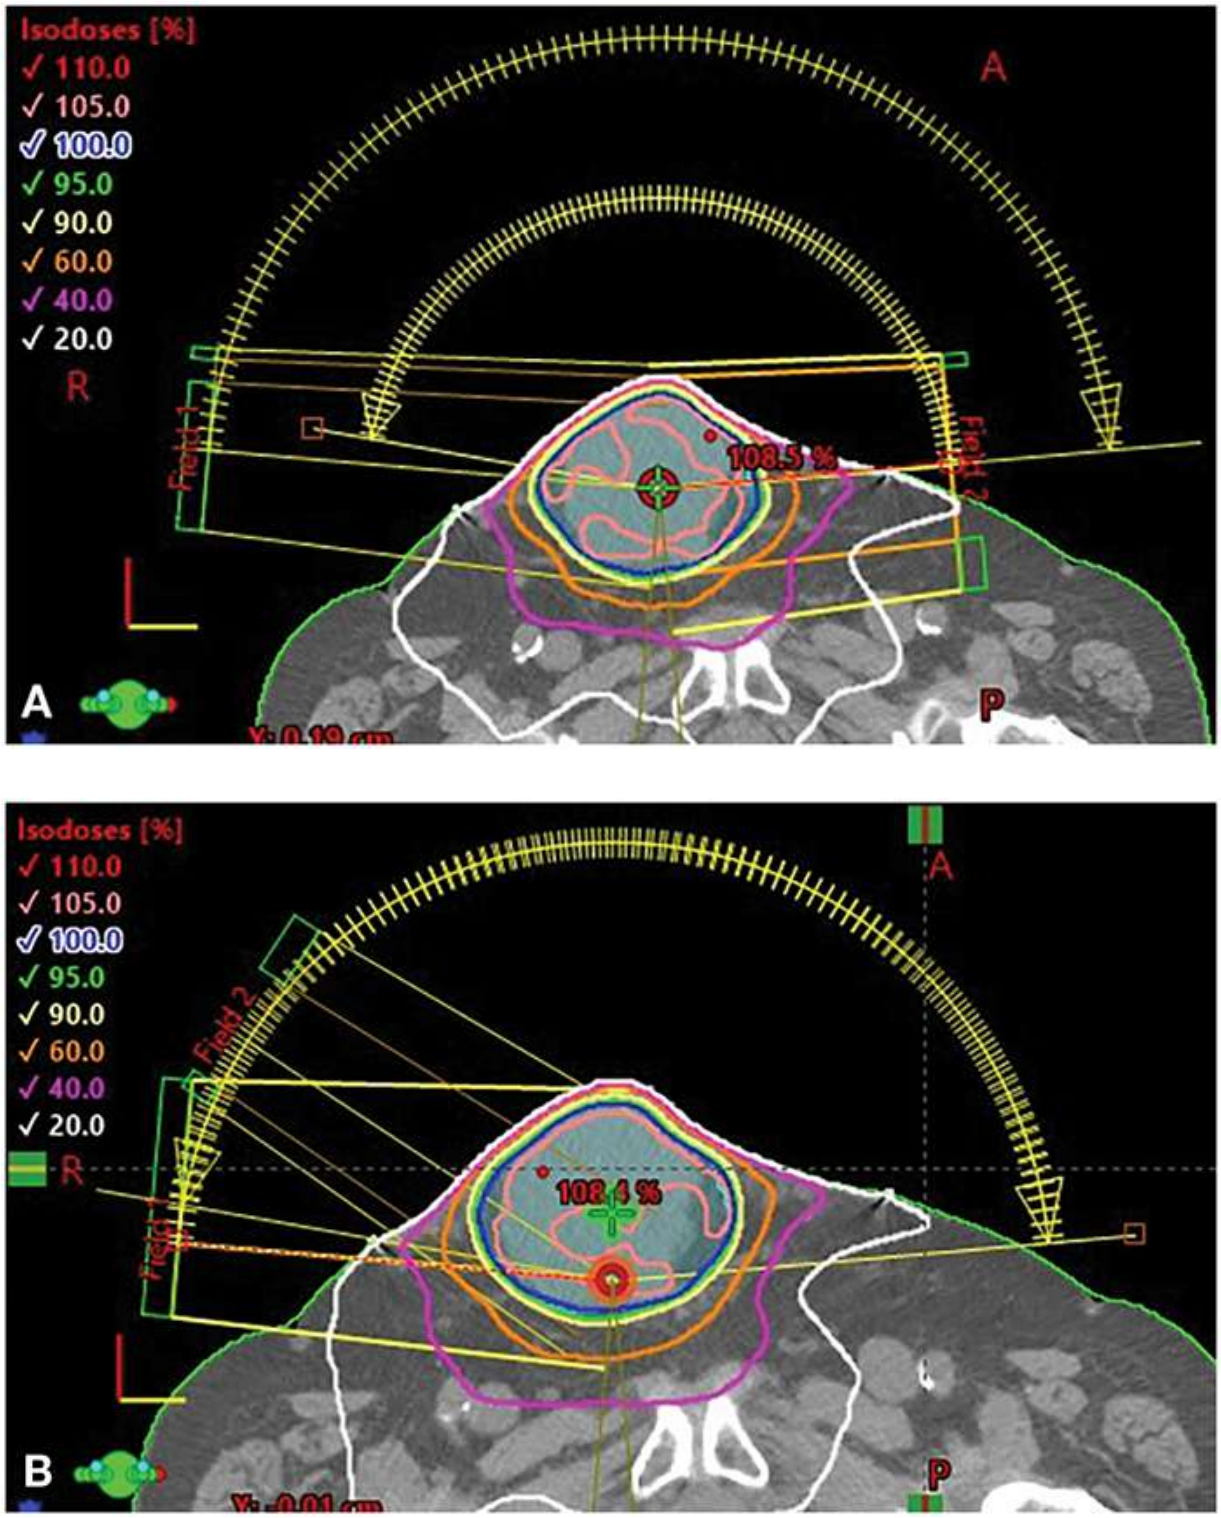

FIGURE 8.17 Arc therapy technique for 6-MV x-rays. A. Two 160° arcs. Two arcs can be custom weighted to obtain sufficient target coverage despite the tendency for higher dose superficial to the isocenter. B. Single 160° arc, but patient positioned so that isocenter is 2 cm lower toward the skipped sector (this technique is called *past pointing*). Note high-dose isodose curves encompass the target volume.

The prostate, bladder, cervix, and pituitary are clinical sites that have been treated, either initially or for boost doses, with rotational or arc therapy techniques. Although the dose distributions achieved by rotation or arc therapy yield high target volume doses, these techniques normally result in a greater volume of normal tissue being irradiated (albeit at low doses) than fixed, multiple-field techniques.

As previously indicated, modern-day rotational therapy is now delivered by a variety of techniques (eg, TomoTherapy, RapidArc, VMAT). Recent developments also include rotational therapy with *flattening filter-free* (FFF) beams.[81] The FFF feature allows dose rates up to 2,400 MUs per minute, thus greatly improving efficiency in dose delivery, which is particularly important for patients receiving treatments where very high daily doses are delivered, such as stereotactic body radiation therapy.[82]

FIELD SHAPING

A major constraint in the treatment of cancer using radiation is the limitation in the dose that can be delivered to the tumor because of the dose tolerance of the tissue (critical organs) surrounding or near the target volume. Shielding normal tissue and critical organs has allowed the radiation oncologist to increase the dose to the tumor volume while maintaining the dose to critical organs below some tolerance level. The frequently used tolerance doses for these organs are not absolute and depend on a number of clinical and treatment factors. Depending on the predominantly serial or parallel organization of the organ at risk, a large dose can sometimes be given to fractional volumes of organs with a parallel structure (liver, kidneys, lungs).[83,84] Shielding is usually accomplished using collimator jaws (with the asymmetric feature) and MLCs, in which the beam aperture (field shape) is customized for individual patients. The use of low melting point alloy blocks has been nearly completely replaced with the MLC technology.

Multileaf Collimator and Associated Dosimetry

Asymmetric Collimator Jaws

Field shaping and abutted field radiation therapy techniques have been made even more versatile with the asymmetric jaw feature found on modern-day linacs. This feature allows each set of jaws to open and close independently of each other (Figure 8.18). The collimator jaw provides greater attenuation than the MLC leaf or alloy block, thus providing an advantage (which is readily apparent on portal films) in reducing the dose to blocked regions.

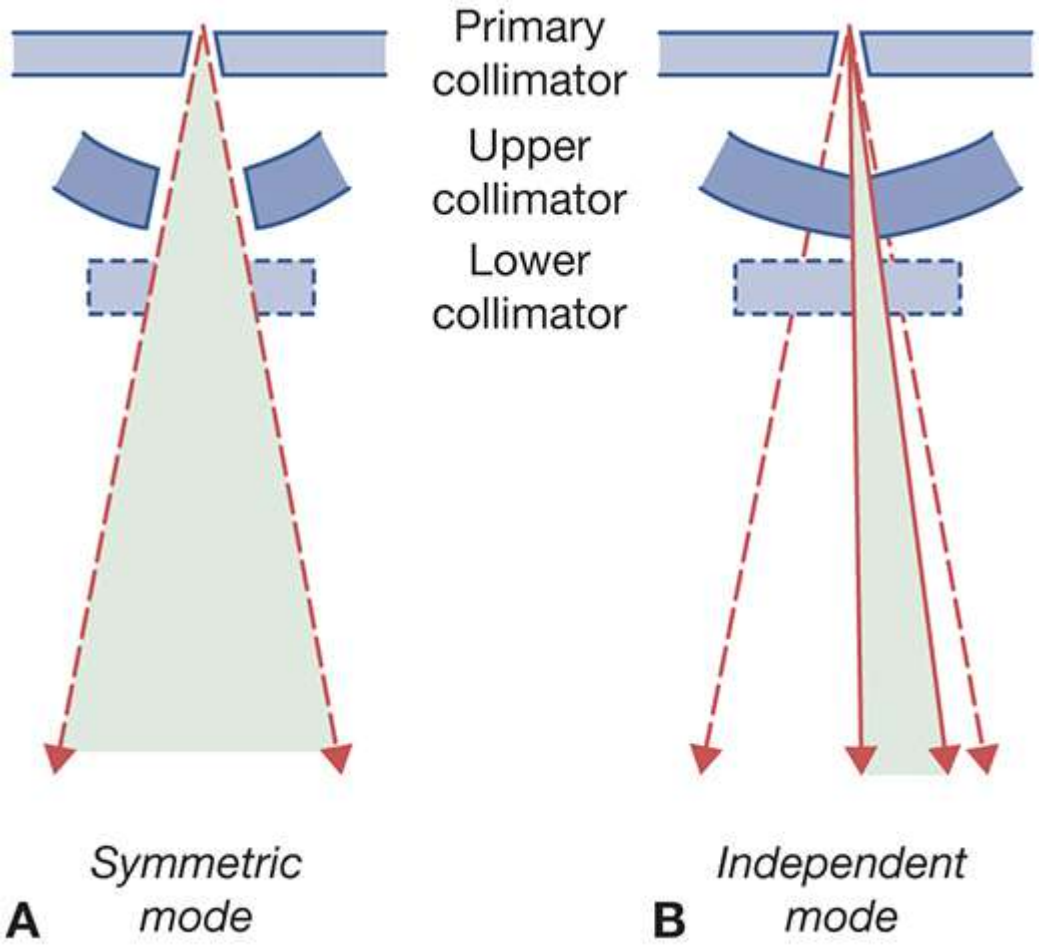

FIGURE 8.18 Independent or asymmetric collimators. A. Conventional symmetric pairs of collimators. B. Asymmetric collimators in which collimator jaws are allowed to move independently of each other.

Depth-dose characteristics for asymmetric fields are similar to those of symmetric fields as long as the degree of asymmetry is not too extreme. Clinical sites where asymmetric jaws are typically used include the breast

(Figure 8.19), head and neck, craniospinal, and prostate. In addition, the use of asymmetric jaws as beam splitters, for field reductions, and with MLCs is helpful for most sites. Several authors have reported on the use of asymmetric jaws to match supraclavicular and tangential fields for breast irradiation.[85,86] Such technology allows a single setup point for all of the treatment fields, including the posterior axillary field. The Y-jaws can beam split the caudal and cephalic regions for the supraclavicular and tangential beams, respectively, and the X-jaws are used to shield the ipsilateral lung and contralateral breast. Hence, a common match plane with one common isocenter can be used for all portals, eliminating the need to move the patient between portals, thus reducing overall patient setup time by almost a factor of two. In addition, the increased attenuation by the jaws reduces the dose to the contralateral breast and lung.[87] A technique for matching lateral head and neck fields and the supraclavicular field using asymmetric jaws was described by Sohn et al.[88]

Multileaf Collimation

Multileaf collimation, first introduced in Japan in the 1960s,[89] has now gained widespread acceptance and has replaced alloy blocking as the standard of practice for field shaping in modern radiation therapy clinics. The different manufacturers' MLC systems vary with respect to MLC location, leaf design, and field size coverage. The leaves are typically carried on two opposed carriages that transport the leaves in unison. The leaves have individual controls that are computer assigned and positioned.

Initially, most commercial MLC systems were designed to serve as a block replacement but now provide for dynamic IMRT delivery as well.

Elekta first introduced its MLC system in the late 1980s.[90] Their current MLC system replaces the upper photon collimator jaws, and therefore, the maximum field size can open to a full 40 × 40 cm^2. The MLC system is augmented by parallel diaphragms, which increase the leaf's attenuation by an additional two HVLs.

The Varian MLC system is considered a tertiary system placed below the photon collimator jaws. The latest Varian MLC (non-SRS) is a 120-leaf (60 on each side) system, in which the middle 20 cm consists of 0.5-cm-wide leaves, whereas the outer 20-cm leaves still project to 1.0-cm widths. This set of leaves projects to 16.0 cm in length at the isocenter, and the leaf span range (maximum-minimum positions on the same carriage) is limited to 14.5 cm. The leaves move perpendicular to the beam's central axis. The distance from the x-ray target to the bottom of the leaves (on the central axis) is 54.0 cm. The leaves fan away from the central axis so that their sides are divergent from the beam's fan lines. The leaves are interdigitated by a tongue-and-groove design. In May 2017, Varian introduced the Halcyon machine, which does not have movable jaws and only has a double-layer MLC, with the two layers being offset by half of a leaf width and with each leaf being 1 cm wide. This "stacked and staggered" MLC design aims to provide optimized modulation and reduce interleaf leakage. The Halcyon also supports 4 gantry rotations per minute (as opposed to 1 rotation per minute for conventional C-shaped linear accelerators), and the MLC has 5 cm/s speed to support this faster gantry rotation. The MLCs are also designed to have full overtravel and cover the full span of the field.

For the single-layer Varian MLC system, leaf transmission values of 1.5% to 2.0% for a 6-MV beam and 1.5% to 5% for an 18-MV beam have been reported.[91,92] These values are lower than those found for alloy blocks (3.5%) but higher than those for collimator jaw transmission (that being <1.0%). Transmission through abutted (closed) leaf pairs was as high as 28% for 18-MV photons on the central axis. The abutment transmission decreased as a function of off-axis distance to as low as 12%. The data for the double-layer MLC are not available as of this writing, but the MLC is specifically designed to reduce leaf transmission, and it is expected that this will translate into clinical benefits.

Figure 8.20 shows a comparison of MLCs and alloy blocks regarding penumbra. The discrete steps of the MLC systems introduce undulations in the isodose lines. This effect causes an apparent increase in penumbra with wave patterns after the undulations. Single, focused MLC systems have a slightly larger penumbra than do alloy shields and have an even larger difference in comparison with collimator jaws. Boyer et al found the penumbra (80%-20% isodose lines) generated by leaf ends to be wider than those generated by upper collimator jaws by 1.0 to 1.5 mm, and 1.0 to 2.5 mm compared with the lower jaws, depending on energy and field size.[93] Powlis and associates compared multileaf collimation and alloy field shaping and found few differences.[94] LoSasso and Kutcher found similar results and concluded that geometric accuracy is even improved with MLCs.[95] ViewRay recently introduced a double-layer, doubly focused MLC, with the design reviewed by Li et al[96] and the performance characterized by Cai et al.[97] The recently introduced Varian's MLC is also double layered with specially designed leaf tips to improve some of the above-described shortcomings of the conventional MLCs.[98]

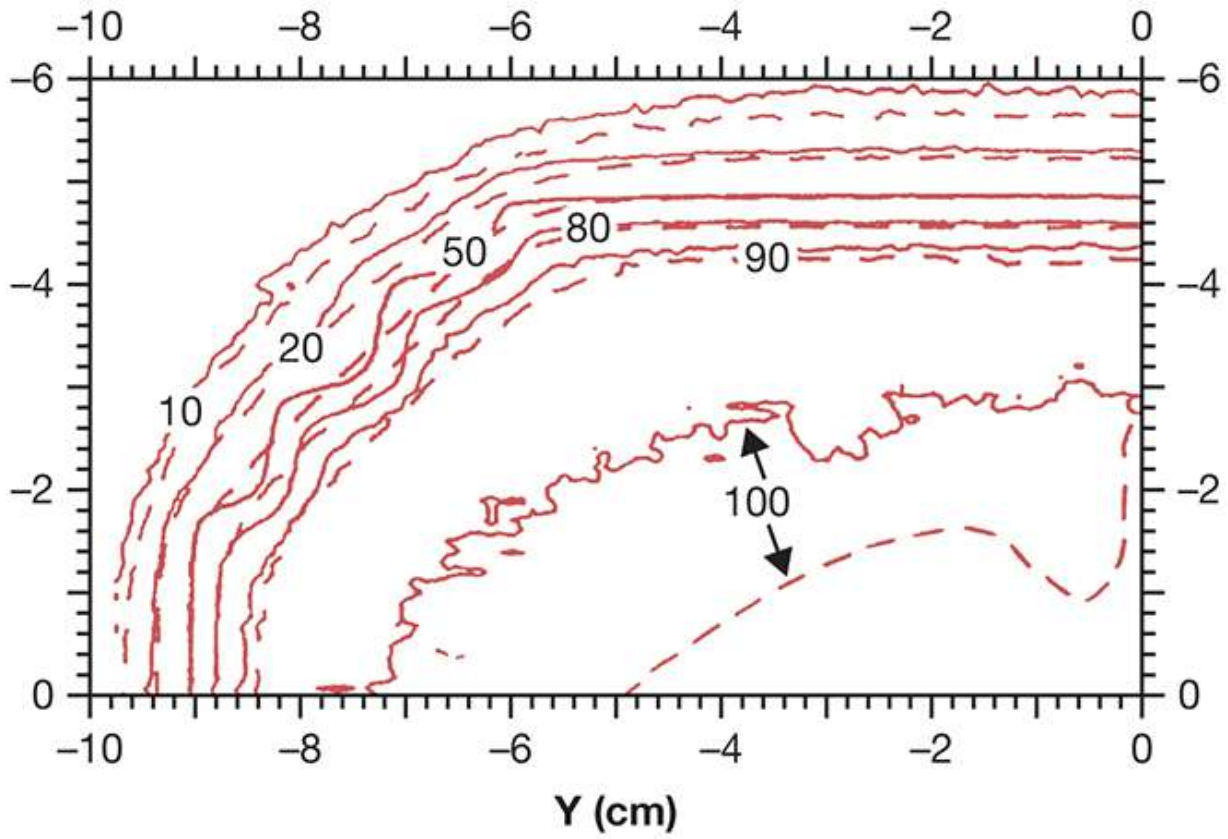

FIGURE 8.20 Comparison of beam's-eye view isodose curves at 10-cm depth for multileaf collimator (solid line) and Cerrobend-shaped (dashed line) beam apertures for 18-MV photons. (Reprinted from Klein EE, Harms WB, Low DA, Willcut V, Purdy JA. Clinical implementation of a commercial multileaf collimator: dosimetry, networking, simulation, and quality assurance. *Int J Radiat Oncol Biol Phys*. 1995;33[5]:1195-1208. Copyright © 1995 Elsevier. With permission.)

The penumbras measured for the leaf sides are comparable with those found for upper jaws because of their divergent nature. The penumbra increase and stair-stepping effect are most prominent at d_{max}. The effects diminish at depth because of the influence of scattered electrons and photons as the scatter-to-primary ratio increases with depth. Adding an opposed beam leads to further smoothing of the undulations, and penumbra differences become less significant. For multibeam arrangements, the differences in dose distribution between MLC and alloy shields are negligible.

The main limitation in optimizing the MLC leaf settings to conform to the shaped field is the discrete leaf steps. Most field shapes require only minor adjustment of the collimator angle to achieve minimal discrepancy

between the desired and resultant field shape. The criteria for optimizing the MLC leaf settings are governed by placing the most leaf ends tangent to the field and also maintaining the same internal area as originally prescribed. MLC shaping systems typically provide an option to place the leaf ends entirely outside the field (exterior), entirely within the field (interior), or crossing the field at midleaf (leaf-center insertion). The last is the most widely used criterion because the desired field area is more closely maintained. However, this choice leads to regions in which some treatment areas are shielded and some normal tissues are irradiated. Zhu et al reported on a variable insertion technique in which leaves are placed only far enough into the field to cause the 50% isodose contour to undulate outside and up to the desired contour.[99] LoSasso et al reported on a method in which each leaf is inserted such that the treatment area covered by the leaf equals the normal tissue area that is not spared.[100] Brahme also demonstrated optimal choices for choosing a collimator angle to optimize leaf direction, depending on whether the field shape is convex or concave.[101] Du et al reported on a method that defines optimal leaf positioning in combination with optimal collimator angulation.[102] Typically, the optimal direction for the leaf motion is along the narrower axis. For a simple ellipse, the optimal leaf direction is parallel to the short axis. Reports on the effects of tissue heterogeneities on penumbra and resultant field definition indicate that the penumbra in lung increases (especially for 18-MV photons), whereas in bone, it decreases for both alloy blocks and MLCs.[91]

As indicated previously, because MLC systems are still evolving, a careful evaluation of the effect of MLCs on MU calculations must be performed before clinical use. Extensive testing over the clinical range of field sizes and shapes should be undertaken before the MLC system is used clinically.

Low Melting Alloy Blocks

Although alloy blocks are rapidly disappearing from clinical use, a short section is included in this chapter for completeness. The Lipowitz metal (Cerrobend) shielding block system was introduced by Powers et al.[103] Lipowitz metal consists of 13.3% tin, 50% bismuth, 26.7% lead, and 10% cadmium. The physical density at 20°C is 9.4 g/cm^3, compared with 11.3

g/cm^3 for lead. The block fabrication procedure is illustrated in Figure 8.21, and more details on using this form of field shaping can be found in the review article by Leavitt and Gibbs.[104]

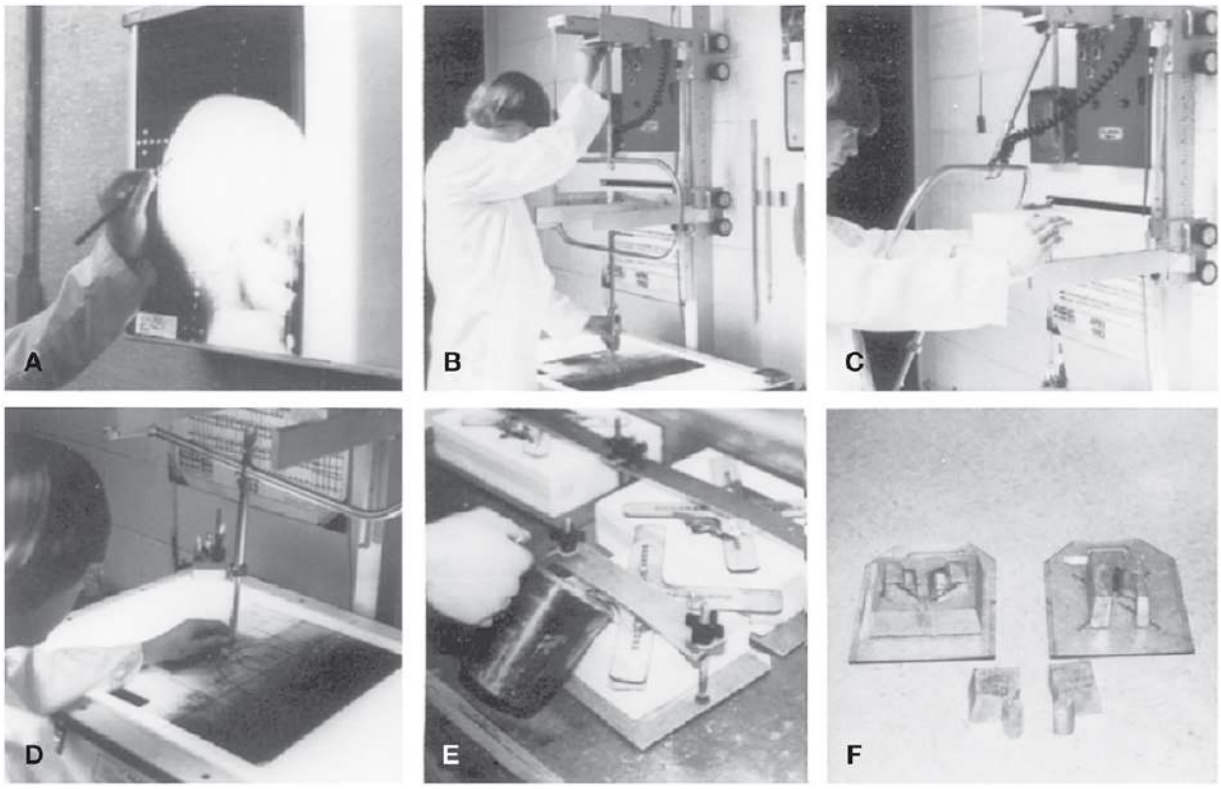

FIGURE 8.21 Composite photographs illustrating the low melting point alloy shielding block design and fabrication process. A. Physician defining the treatment volume on the x-ray simulator radiograph. B. Physics technician adjusting the source-to-skin distance and skin-to-film distance of a hot wire cutter to emulate simulator geometry. C. Proper-thickness foam block aligned to the central axis of the cutter. D. Foam mold cut with hot wire cutter. E. Foam pieces aligned and held in place using a special clamping device. Molten alloy is poured into the mold and allowed to harden. F. Examples of typical shielding blocks cast using this system. (From Purdy JA. Secondary field shaping. In: Wright AE, Boyer AL, eds. *Advances in Radiation Therapy Treatment Planning*. American Institute of Physics; 1983:456-476. Copyright © 1983 by American Association of Physicists in Medicine. Reprinted by permission.)

Specific doses to critical organs may be limited by using either a full-thickness block, usually five HVLs (3.125% transmission) or six HVLs (1.562% transmission), or a partial transmission shield, such as a single HVL (50% transmission) of shielding material. The actual dose delivered under the shielded area is usually greater than these stated transmission

levels because of scatter radiation beneath the blocks from adjacent unshielded portions of the field. The scatter component of the dose increases with depth as more radiation scatters into the shielded volume beneath the block. Thus, the dose to the blocked area is a function of block material, thickness (and width), field size, and energy. Figure 8.22 shows the attenuation of Lipowitz metal of x-rays produced at 2, 4, 10, and 18 MeV and ^{60}Co γ-rays.[105] Alloy blocks made from the standard thickness (7.6 cm) of foam molds reduce the primary beam intensity to 5% of its unattenuated value. Increasing the block thickness usually is not worthwhile because it makes the block heavier, whereas the scatter radiation contributes an equal or greater share of the dose under the blocks.

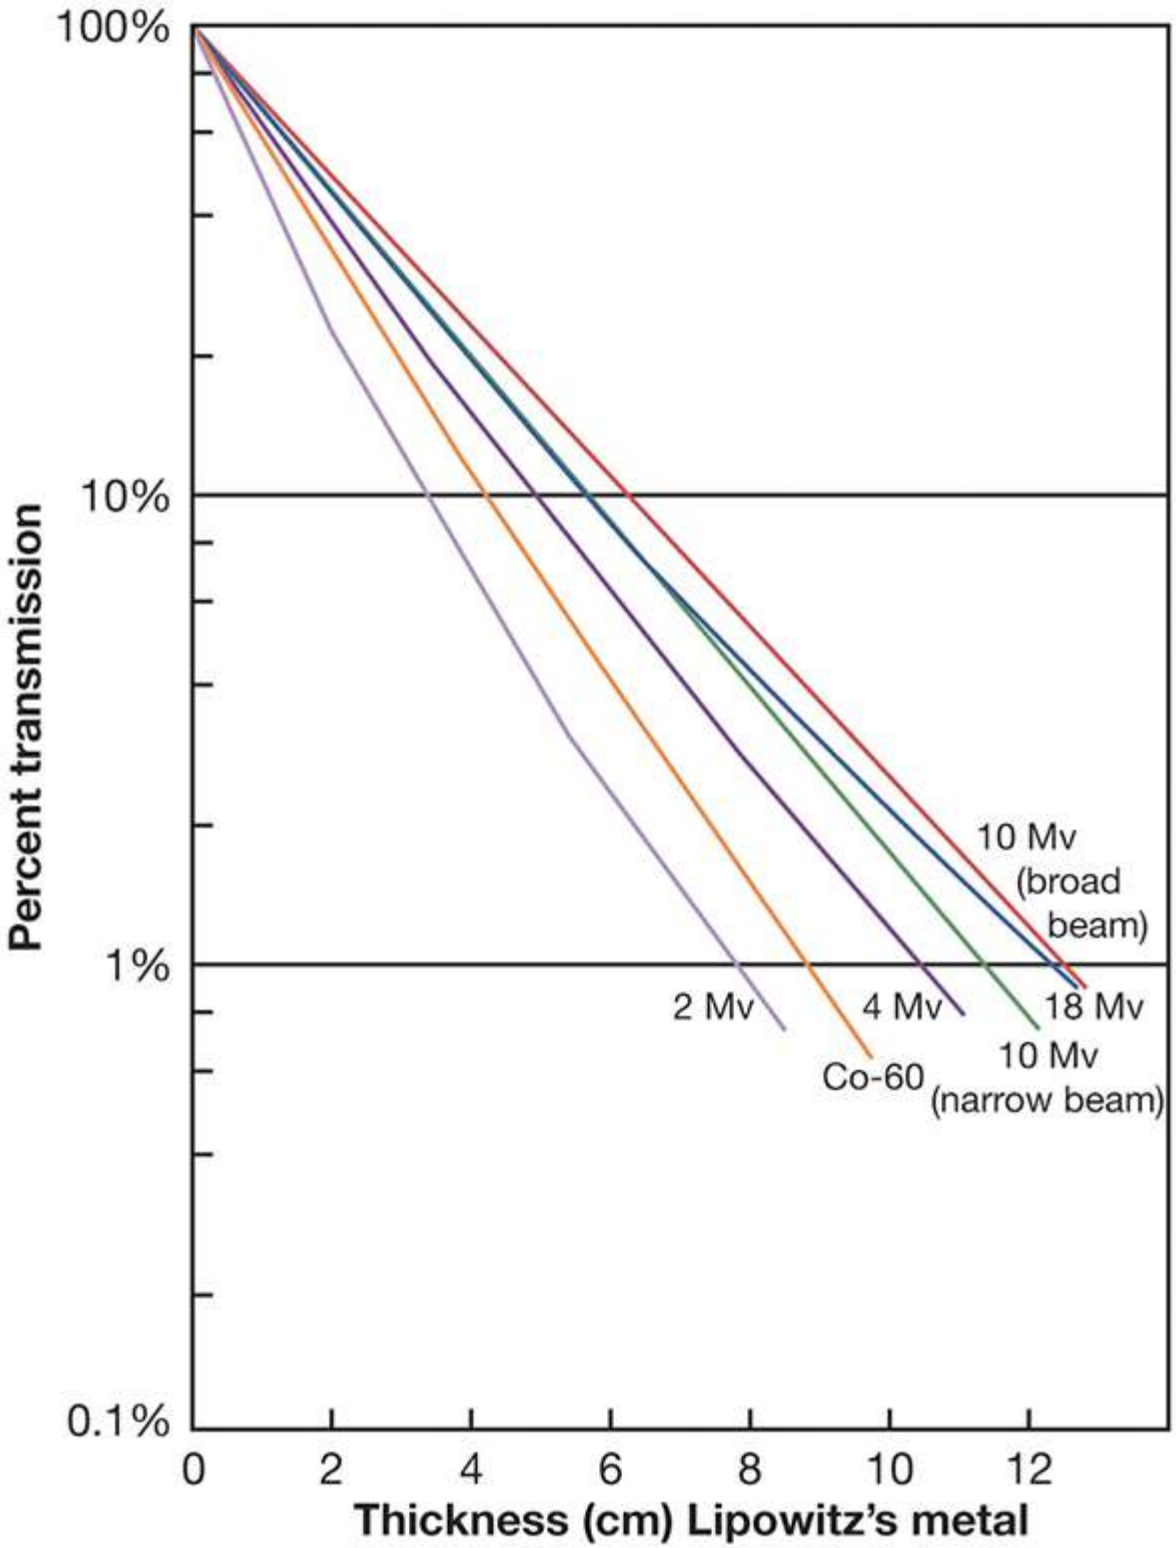

FIGURE 8.22 Attenuation in Lipowitz metal of x-rays produced at 2, 4, 10, and 18 MV and γ-rays from ^{60}Co. (From Huen A, Findley DO, Skov DD. Attenuation in Lipowitz's metal of x-rays produced at 2, 4, 10, and 18 MV and gamma rays from cobalt-60. *Med Phys*.

1979;6[2]:147-148. Copyright © 1979 American Association of Physicists in Medicine. Reprinted by permission of John Wiley & Sons, Inc.)

Because of the advent of multileaf collimation, metal blocks for photon beams are rarely used, as multileaf collimation allows there to be no room entry between treatment fields. In addition, the construction of blocks was time-consuming and expensive. Also, the materials themselves, as they were heated, gave off potentially toxic air, particularly because of the lead and cadmium. The one advantage of blocks is that they provide smooth boundaries by having a continuous shape around the field and incur no field size limitation. However, the weight of the blocks can be excessive, sometimes up to 15 pounds, leading to the potential for injury to therapists and patients should they be mishandled.

COMPENSATING FILTERS

The compensating filter, introduced by Ellis et al[106] counteracts the effects caused by variations in patient surface curvature while still preserving the desirable skin-sparing feature of megavoltage photon beams. This is accomplished by placing the custom-designed compensating filter in the beam, sufficiently "upstream" from the patient's surface, as illustrated in Figure 8.23. Several different compensator systems have been used in the clinic. However, the use of physical compensators to account for patient surface curvature is almost nonexistent in clinics today because of the advent of IMRT. But one particular IMRT delivery method does use a physical compensator, which is designed from the planning system and often constructed from a third-party vendor to deliver a modulated field.[107]

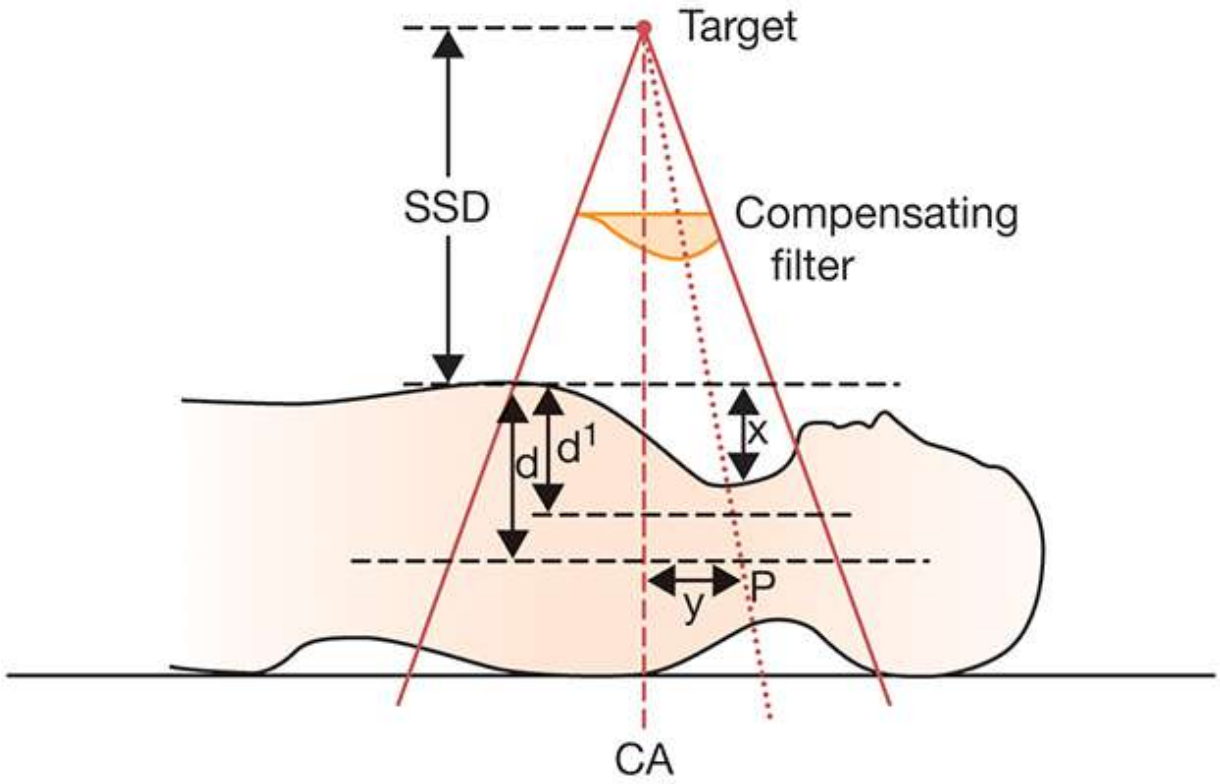

FIGURE 8.23 Schematic illustrating typical geometry used in the design of a compensator filter to account for patient's irregularly shaped surface. CA, central axis; SSD, source-to-skin distance.

One exception where the use of compensating filters or really custom bolus has increased is in electron beam applications.[108] The decimal company (Sanford, FL) offers a product BolusECT, which enables creation of custom 3D bolus to improve the conformality of electron beams at depth. These devices offer a simple and relatively inexpensive method to significantly improve electron beam dosimetry. The main shortcoming is the delay involved in ordering and shipping the devices, but overall, this approach appears to be clinically manageable.

BOLUS

Tissue-equivalent material placed directly on the patient's skin surface to reduce the skin sparing of megavoltage photon beams is referred to as *bolus*. A tissue-equivalent bolus should have electron density, physical density, and atomic number similar to those of tissue or water and be pliable so that it conforms to the skin surface contour. Inexpensive, nearly tissue-

equivalent materials used as a bolus in radiation therapy include slabs of paraffin wax, rice bags filled with soda, gauze coated with petrolatum, and synthetic-based substances, such as Superflab or Super Stuff.[109]

Thin slabs of bolus that follow the surface contour increase the dose to the skin beneath the bolus with a maximum reduction when the bolus thickness is approximately equal to the d_{max} depth for the photon beam. In addition, adding bolus to fill a tissue deficit may smooth an irregular surface. A bolus also can be shaped to alter the dose distribution, but normally, wedges are used to alter the dose distribution for megavoltage photon beams to retain skin sparing.

PATIENT POSITIONING, REGISTRATION, AND IMMOBILIZATION

Ensuring accurate daily positioning of the patient for treatment and minimizing patient movement during treatment is essential to deliver the prescribed dose and achieve the planned dose distribution. The reproducibility achievable when positioning a patient for treatment depends on several factors other than the anatomic site, including the patient's age, general health, and weight. In general, patients who are obese and small children are the most difficult to position.

Numerous patient restraint and repositioning devices have been designed and used in treating specific anatomic sites. For example, a disposable foam plastic head holder provides stability for the head when the patient is in the supine position. If more rigidity is needed, a bite-block system (Figure 8.24) or a thermoplastic face mask system (Figure 8.25) is commonly used to immobilize patients with head and neck tumors. Custom molds constructed from polyurethane formed to patient contours (Figure 8.26) have gained widespread use as aids in immobilization and repositioning of patients being treated for Hodgkin disease, cancer of the thorax, prostate, or involving extremities. These systems are discussed in detail in Chapters 7.

FIGURE 8.24 Example of a bite-block registration and immobilization system used in treatment of head and neck cancer. (Courtesy of Radiation Products Design, Inc.)

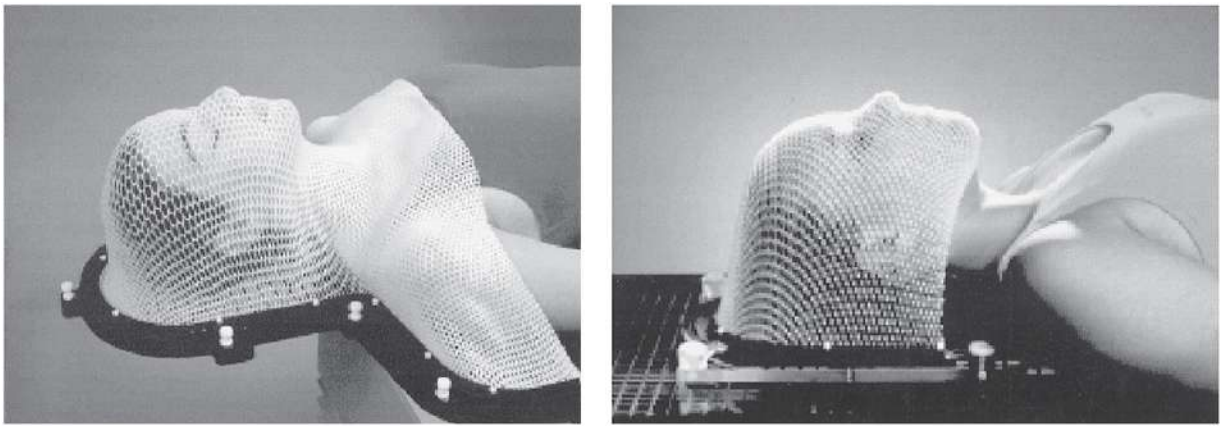

FIGURE 8.25 Example of a registration and immobilization system (thermal plastic mask) used in the treatment of head and neck cancer.

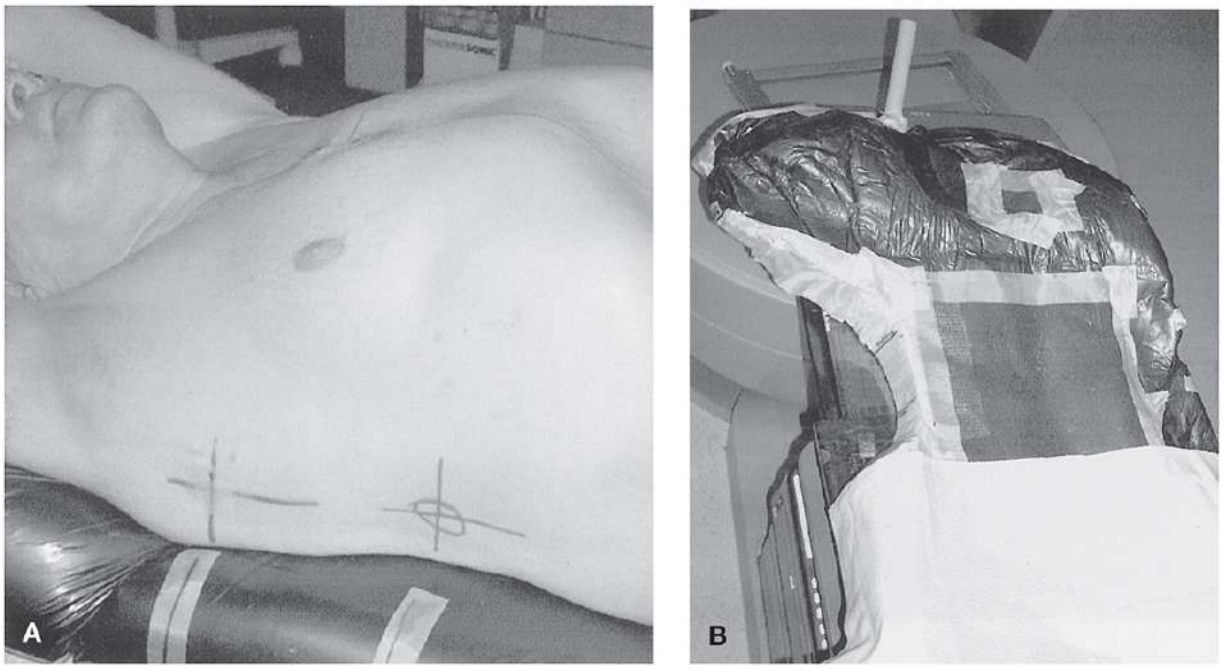

FIGURE 8.26 Examples of registration and immobilization systems (foam mold) used in the treatment of the thorax. A. Mold is registered to table and the patient is registered to the mold by fiducial markings. B. Mold with a cutout area to allow clear access to the treatment area and built-in handgrip.

The radiation fields to be treated are typically delineated in the simulation process using either visible skin markings or skin markings visible only under an ultraviolet light. In some instances, external tattoos are applied. These markings are used in positioning a patient on the treatment machine using the machine's field localization light and distance indicator and the laser alignment lights mounted in the treatment room that project transverse, coronal, and sagittal light lines (or dots) on the patient's skin surface.

It is vital that the rigidity of the immobilization system used maintain consistency over the course of treatment. Therefore, the systems that interface with the immobilization systems used in the simulation process and the treatment couch need to also be rigid and registered. As of now, patients are set up to treatment coordinates once they are fit into the immobilization systems.

One of the concerns with the use of plastic masks is that they occasionally shrink. This shrinkage can cause changes in patient positioning or can introduce discomfort. A problem with discomfort is that patients

often overcorrect their position to avoid pain caused because of poorly fitting immobilization. As a general rule, comfortable patients are easier to reproduce the daily setup and they tend to be less movable during an individual fraction. Note that it is important to carefully follow the manufacturer's instructions for making the masks and to monitor masks for shrinkage over the course of treatments. To overcome some of these hurdles, reduced or passive forms of immobilization are being introduced for clinical use in brain and breast treatments, which have primarily been enabled by 3D surface-guided radiotherapy.[110]

Dosimetric effects caused by immobilization devices as well as couch tops must also be addressed as noted by Olch et al.[111]

The final assessment of accuracy and reproducibility of the daily treatment is typically obtained by radiographic imaging of the area treated because there is the possibility of patient movement within the mask, especially if significant tumor shrinkage or weight loss has taken place. This is generally true for targets that are deep seated (eg, prostate, lung), but in the case of a treatment area located at the surface of a patient (ie, breast cancer), other surrogates including the surface may be acceptable.[110]

SEPARATION OF ADJACENT X-RAY FIELDS

Field Junctions

Different techniques for matching adjacent fields are illustrated in Figure 8.27. A commonly used gap calculation method for adjacent radiation fields is illustrated in Figure 8.28A. The separation between adjacent field edges necessary to produce junction doses similar to central-axis doses follows from the similar triangles formed by the half-field length and SSD in each field. The field edge is defined by the dose at the edge that is 50% of the dose at d_{max}. For two contiguous fields of lengths L_1 and L_2, the separation, S, of these two fields at the skin surface can be calculated using the following expression:

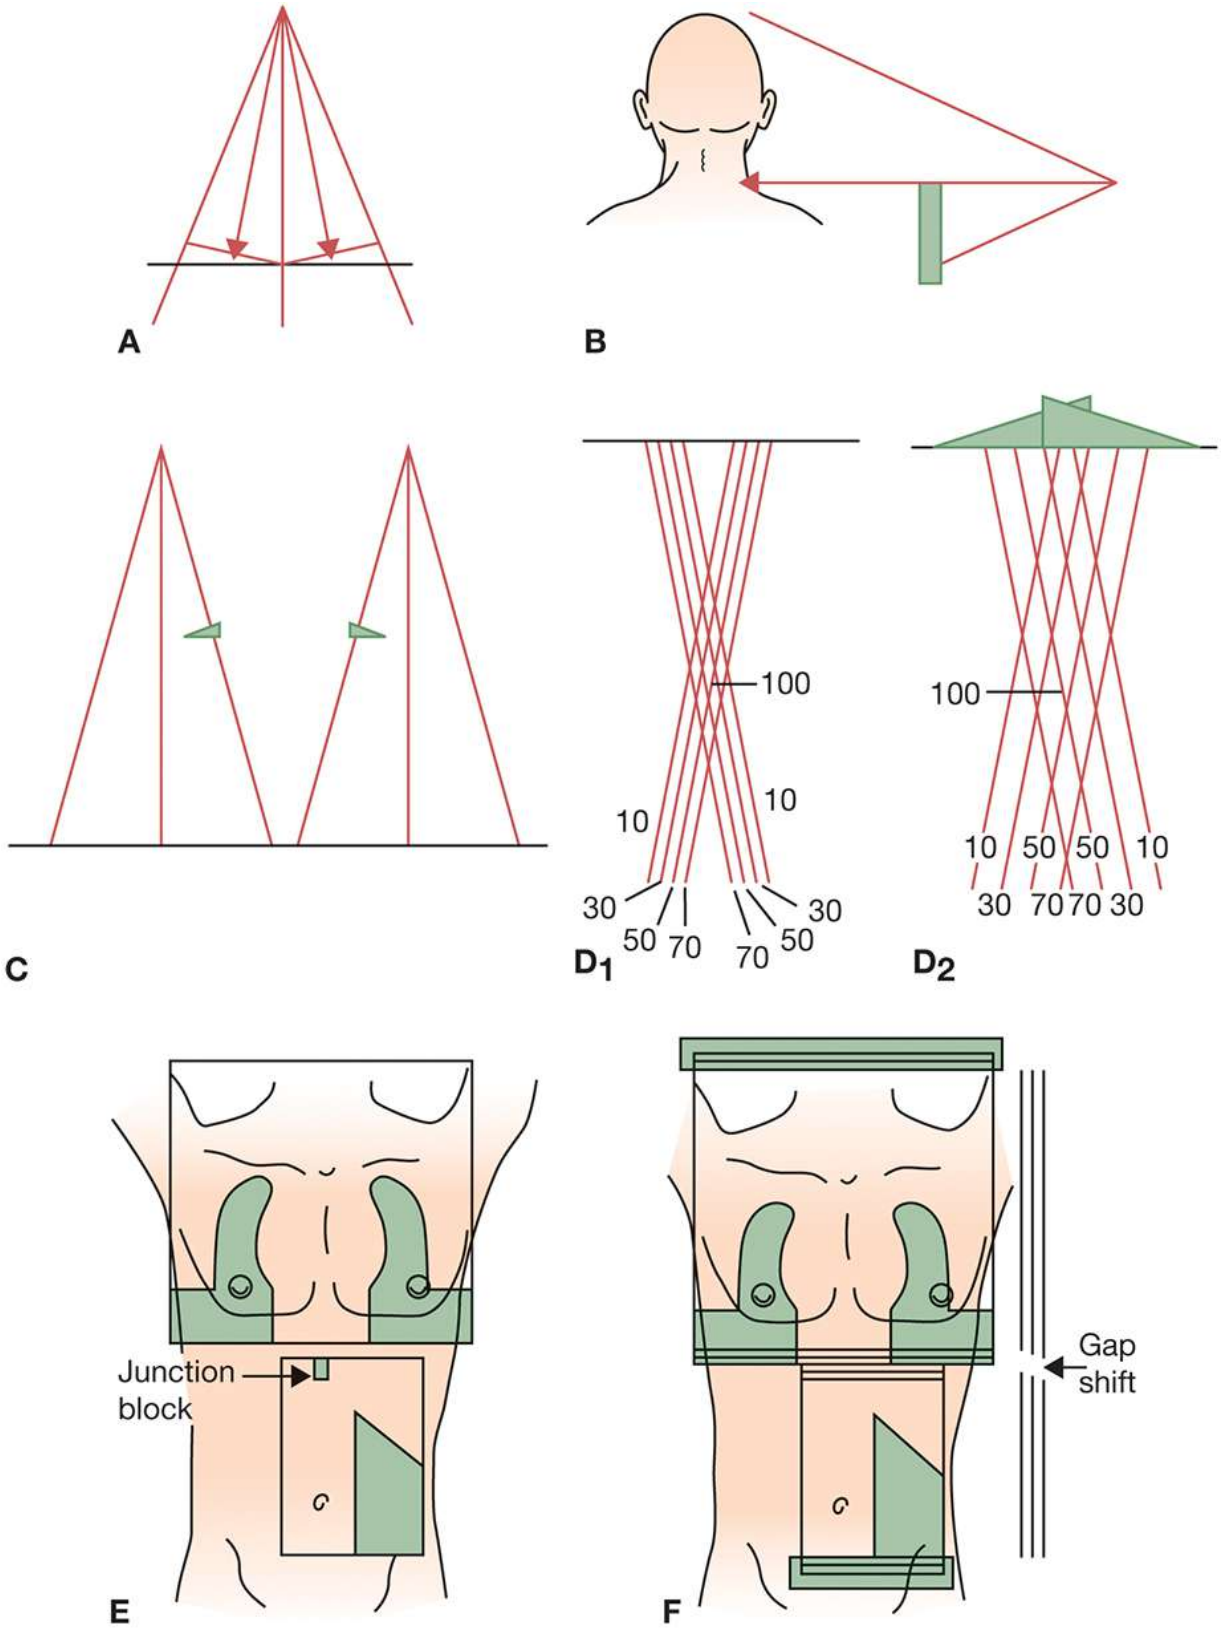

FIGURE 8.27 Different techniques for matching adjacent fields. A. Beam's central rays are angled slightly away from one another so that the diverging beams are parallel. B. Half-

beam block to eliminate divergence. C. Penumbra generators (small wedges) to increase the width of penumbra, as illustrated in D_1 and D_2. E. Junction block over spinal cord. F. Moving gap technique. (Used with permission of McGraw-Hill from Bentel GC, ed. *Radiation Therapy Planning*. 2nd ed. McGraw-Hill; 1996:141, Figure 6.44; permission conveyed through Copyright Clearance Center.)

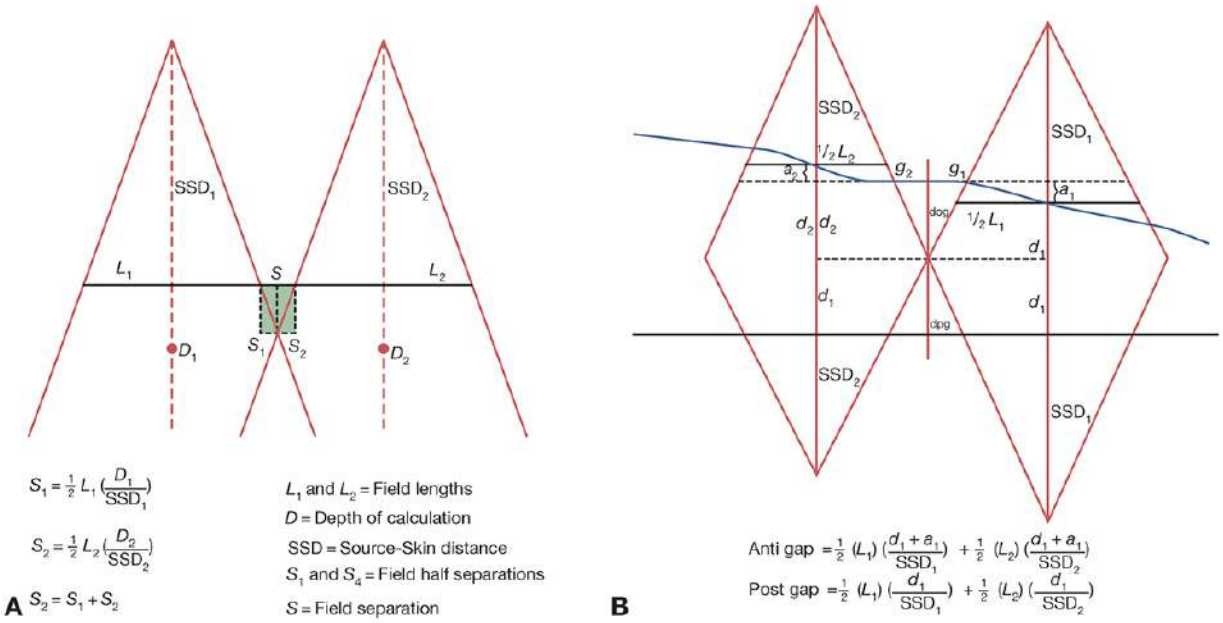

FIGURE 8.28 A. Standard formula for calculating the gap at the skin surface for a given depth using similar triangles. B. Modified formula for calculating the gap for matching four fields on a sloping surface. (Reprinted from Keys R, Grigsby PW. Gapping fields on sloping surfaces. *Int J Radiat Oncol Biol Phys*. 1990;18[5]:1183-1190. Copyright © 1990 Elsevier. With permission.)

$$S = \frac{1}{2} L_1 \left(\frac{d}{\text{SSD}} \right) + \frac{1}{2} L_2 \left(\frac{d}{\text{SSD}} \right)$$

A slight modification of this formula is needed when sloping surfaces are involved, as shown in Figure 8.28B.[112] Typically, the skin gap location is moved a number of times to reduce the hot and cold spots that arise with this technique. Figure 8.29 illustrates the dose distribution for three different field separations.[113]

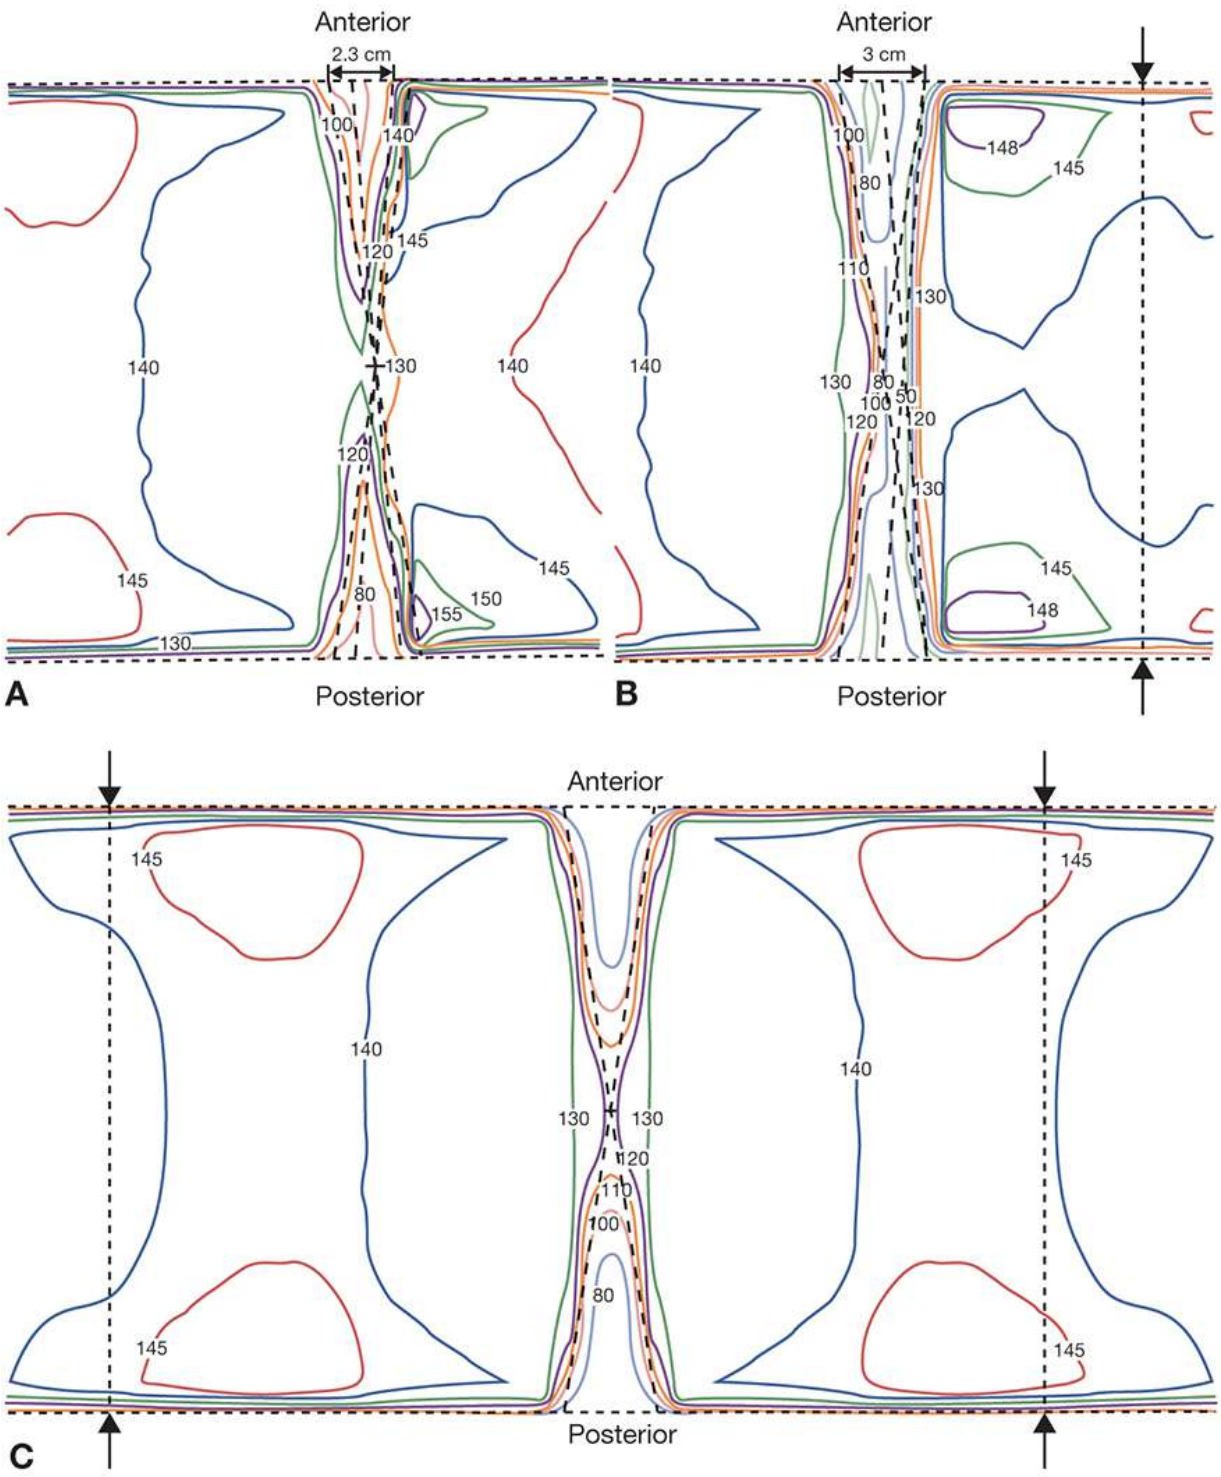

FIGURE 8.29 Dose distribution for geometric separation of fields with all four beams intersecting at midpoint. Adjacent field sizes: 30 × 30 and 15 × 15 cm^2; source-to-skin distance (SSD), 100 cm; anteroposterior thickness, 20 cm; 4-MV x-ray beams. A. Field separation at the surface is 2.3 cm. A three-field overlap exists in this case because the fields have different sizes but the same SSD. B. The adjacent field separation increased to eliminate three-field overlap on the surface. C. Field separation adjusted to 2.7 cm to

eliminate three-field overlap at the cord at 15 cm depth from anterior. (Reprinted with permission from Khan FM. *The Physics of Radiation Therapy*. 2nd ed. Williams & Wilkins; 1994.)

Beam divergence may be eliminated by using a "beam splitter," created using a five- or six-HVL block over half the treatment field. The central axes of the adjacent fields, where there is no divergence, are then matched. As previously discussed, this is a useful method on linacs with the asymmetric jaw feature. Match-line wedges or penumbra generators that generate a broad penumbra for linac beams have been reported but have not found widespread use.[114] Here, the intent is to broaden the narrow penumbra of the linacs so that it is not so difficult to match the 50% isodose levels. The resulting dose distributions are similar to those obtained with a moving gap technique. Finally, there are several reports of edge-matching techniques based on the mathematical relationships between adjacent beams and the allowed angles of the gantry, collimators, and couch.[115]

Orthogonal Field Junctions

Figure 8.30 illustrates the geometry of matching abutting orthogonal photon beams. Such techniques are necessary, particularly in the head and neck region where the spinal cord can be in an area of beam overlap, in the treatment of medulloblastoma with multiple spinal portals and lateral brain portals. A common method of avoiding overlap is to use a half-block, as previously discussed, so that abutting anterior and lateral field edges are perpendicular to the gantry axis. In head and neck cancer, a notch in the posterior corner of the lateral oral cavity portal is commonly used to ensure overlap avoidance of the spinal cord when midline cord blocks cannot be used on anteroposterior portals irradiating the lower neck and matched to the oral cavity portals. Other techniques rotate the couch about a vertical axis to compensate for the divergence of the lateral field.[116] The angle of rotation is given by

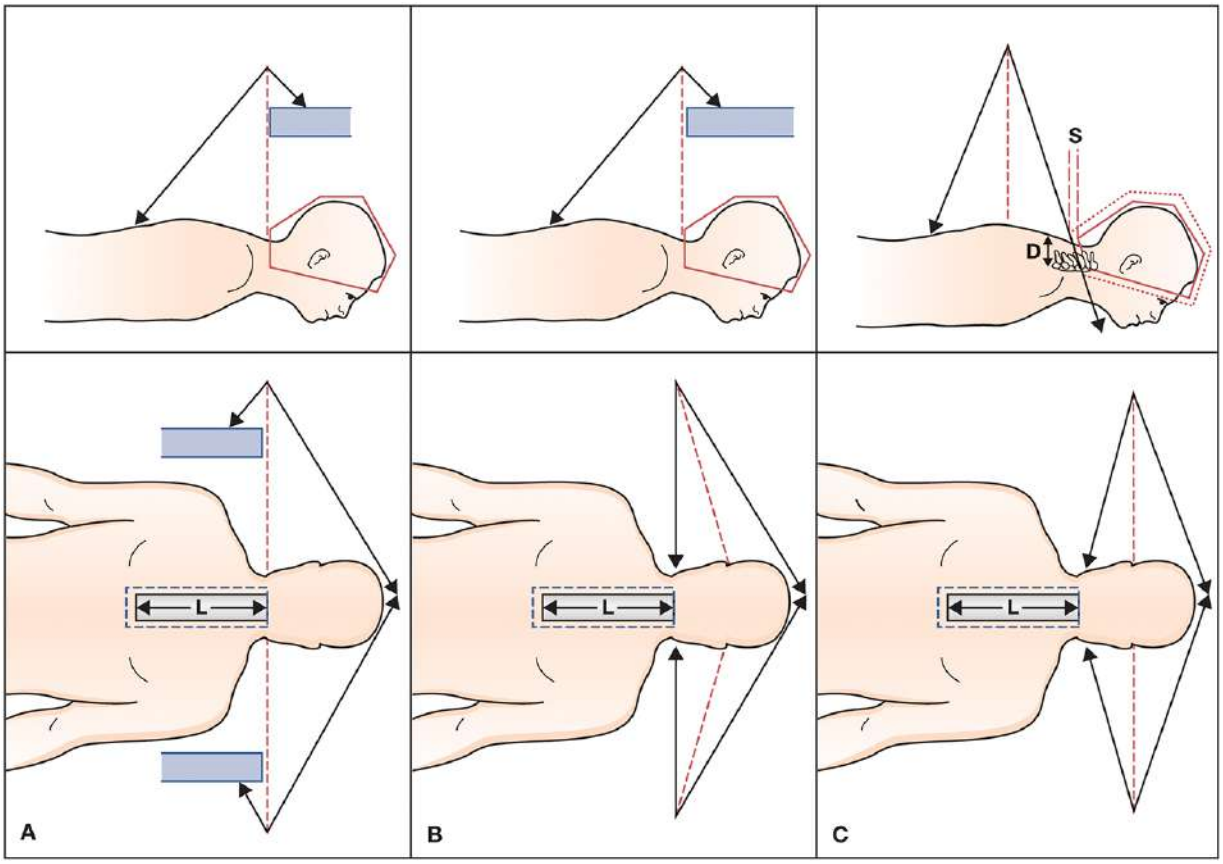

FIGURE 8.30 Some solutions for the problem of overlap for orthogonal fields. A. A beam splitter, a shield that blocks half of the field, is used on the lateral and posterior fields and on the spinal cord portal to match the nondivergent edges of the beams. B. The divergence in the lateral beams may also be removed by angling the lateral beams so that their caudal edges match. Because most therapy units cannot be angled like this, the couch is rotated through small angles in opposite directions to achieve the same effect. C. A gap technique allows the posterior and lateral fields to be matched at depth using a gap *S* on the skin surface. The dashed lines indicate projected field edges at depth *D*, where the orthogonal fields meet. (Reprinted from Williamson TJ. A technique for matching orthogonal megavoltage fields. *Int J Radiat Oncol Biol Phys*. 1979;5[1]:111-116. Copyright © 1979 Elsevier. With permission.)

$$\tan\theta^{-1} = \left(\frac{\frac{1}{2}\,\text{field width}}{\text{SAD}} \right)$$

Another technique is to leave a gap, *S*, on the anterior neck surface between the posterior field of length *L* and the lateral field edges.[117] *S* can be calculated using the following formula where *d* is the depth of the spine beneath the posterior field:

$$S = \frac{1}{2}(L)\left(\frac{d}{\text{SAD}}\right)$$

The potential for the occurrence of radiation myelopathy resulting from a potentially excessive dose from misaligned overlapping fields is always a concern when central nervous system tumors are treated. Craniospinal irradiation is well established as a standard method of treating suprasellar dysgerminoma, pineal tumors, medulloblastomas, and other tumors involving the central nervous system. Uniform treatment of the entire craniospinal target volume is possible using separate parallel-opposed lateral cranial portals rotated so that their inferior borders match with the superior border of the spinal portal, which is treated with either one or two fields, depending on the length of the spine to be treated.[118] Two junctional moves are typically made at one-third and two-thirds of the total dose. The spinal field central axis is shifted away from the brain by 0.5 cm and the field size length reduced by 0.5 cm with corresponding increases in the length of the cranial field, so that a match exists between the inferior border of the brain portal and the superior border of the spine portal. To achieve the match, a collimator rotation for the whole-brain portals must be done for an angle given by the following relationship:

$$\tan\theta^{-1} = \left(\frac{\frac{1}{2}\text{spinal field length}}{\text{SAD}}\right)$$

In addition to eliminating the divergence between the cranial portal and spinal portal, the table is rotated through a floor angle given by the following relationship:

$$\tan\alpha^{-1} = \left(\frac{\frac{1}{2}\,\text{cranial field length}}{\text{SAD}} \right)$$

RADIATION THERAPY PATIENTS WITH CARDIAC PACEMAKERS

As the population ages, the likelihood of encountering patients with either a pacemaker or an implantable cardioverter- defibrillator (ICD) who require radiation therapy for chest and lower neck neoplasms has become commonplace. Pacemakers are electrical devices that may stimulate the atria, ventricles, or both (single-chamber and dual-chamber models, respectively) in order to regulate the heart's natural rhythm.[119] ICDs are generally larger than pacemakers and also actively shock the heart to help control life-threatening, irregular heartbeats, especially those that could cause sudden cardiac arrest; most new ICDs can act as both pacemakers and defibrillators.[119] Modern pacemakers and ICDs incorporate complementary metal oxide semiconductor circuitry into their generator units (encompassing a sealed lithium battery pack and circuitry only). Several groups have shown that these modern devices are much more sensitive to radiation than the older models that utilized bipolar transistor circuitry.[120]

To treat such patients safely and adequately, it is important to understand the potential effects of radiation therapy on these devices' operation and to take steps to minimize any actions that could jeopardize the cardiac health of the patient. The AAPM TG 203 Report provides a list of widely accepted clinical management guidelines.[119] Potential interactions between a functioning pacemaker and the radiation therapy environment fall into two categories: (a) electromagnetic noise interference (EMI) created by the treatment machine in the course of producing high-energy photon and electron beams and (b) damage due to radiation. Most experts now believe

category 1 is no longer a source of concern. However, dose and dose rate are very much a concern.[120] Modern pacemakers are radiosensitive and have a significant probability of failing catastrophically at radiation doses well below normal tissue tolerance and, therefore, should never be irradiated by the direct beam. Also, several authors have shown that recommended maximum doses obtained from the manufacturers have not proven to be reliable and vary greatly among manufacturers. On the other hand, radiation-induced device malfunctions are rare and death associated with that malfunction is even more uncommon. Thus, it is important to consider all aspects of radiation therapy treatment, not just accumulated dose, including the effect of backscatter, dose rate, fractionation, and potential EMI with new technologies, such as IMRT and respiratory gating. Current guidelines recommend that each radiation oncology department employ their own policy for the management of patients with pacemakers and ICDs, potentially based on an updated standard national[119] or international[121] guideline similar to that released by the AAPM TG 203 Report (Table 8.2).

TABLE 8.2 MANAGEMENT GUIDELINES FOR RADIATION THERAPY PATIENTS WITH CARDIAC IMPLANTED ELECTRONIC DEVICES (CIED)

1. Management of patients should be based on device risk levels (low, medium, high) based on pacing dependent and expected dose to the device.
2. CT irradiation of CIED for longer than 3 s should be avoided, whenever possible.
3. CIED compatibility with MRI should be verified prior to MR simulation, and protocols for safe MRI scanning should be developed and implemented.
4. If >10 MV photon, proton, or neutron beams are used, the patient should be managed in the high-risk category.
5. Lower dose rates are preferred.
6. The generator for the device should be kept at least 5 cm from the collimated field edge if possible, including imaging fields, by selection of the appropriate beam angles that increase the distance between the field edge and the CIED.
7. Perform in vivo dosimetry for the first fraction if the device is <10 cm from treatment area. The treatment planning system should be used in lieu of a measurement if the device is within 3 cm (laterally) of the field edge or 5% isodose line for IMRT.
8. Lead should not be used for shielding CIED during treatment.
9. Cumulative dose should be kept at <5 Gy level for CIEDs (ie, low- to medium-risk categories), as much as possible or below the manufacturer's recommended dose threshold if higher.
10. Patients should be monitored with specified frequencies and techniques.

From Miften M, Mihailidis D, Kry SF, et al. Management of radiotherapy patients with implanted cardiac pacemakers and defibrillators: a report of the AAPM TG-203. *Med Phys*. 2019;46(12):e757-e788. New electronic devices for noncardiac applications including pain pumps and drug delivery systems are becoming more common on the market and in patients presenting for radiation therapy. Similar principles should be used as for ICDs, including contacting the manufacturer for guidance on maximum dose and dose rate, communicating with the physician and the clinical team responsible for overseeing the functioning of the electronic device, and developing a risk-based assessment and plan of action.

FETAL DOSE

Radiation therapy is the standard treatment for several malignancies (eg, Hodgkin lymphoma, breast cancer) in which the population of women is often of childbearing age. The issues are complex, and the patient along with the radiation oncologist must evaluate treatment risk to the fetus in such cases. Radiation effects on the fetus are not fully understood and cannot be comfortably predicted for each individual case. If the decision is to irradiate, the dose levels outside the treatment fields should be quantified, and every effort should be made to lower the dose to the fetus. This may require changes in irradiation technique (ie, modified mantle fields), elimination of double-exposure portal images, and the addition of special patient shields. The AAPM TG 36 Report provides data and techniques to estimate and reduce radiation dose to the fetus for beam energies ranging from ^{60}Co to 18 MV.[122] Before the pregnant patient is treated, the pregnancy stage should be known to estimate the size and location of the fetus throughout the treatment. Dose estimation points should be selected that allow estimation of dose throughout the fetus (eg, fundus, symphysis pubis, and umbilicus).

Two methods can be used to reduce the dose to the fetus, namely, modification of treatment techniques and the use of special shields. Modifications include changing field angle (avoiding placement of the gantry close to the fetus, ie, treatment of a posterior field with the patient lying prone on a false tabletop), reducing field size, choosing a different

radiation energy (avoiding ^{60}Co because of high leakage or energies of over 10 MV because of neutrons), and using tertiary collimation to define the field edge nearest to the fetus. When shields are designed, the shielding device must allow for treatment fields above the diaphragm and on the lower extremities. Safety to the patient and personnel is a primary consideration in shield design. As part of the management of a pregnant patient, the treatment planning tasks listed in Table 8.3 should be performed to ensure that the dose to the fetus is kept to a minimum.[122]

TABLE 8.3 TREATMENT PLANNING TASKS TO ENSURE THAT DOSE TO THE FETUS IS KEPT TO A MINIMUM

1. Complete all planning as though the patient were not pregnant.
2. Consider modifications of the plan that would minimize the fetal dose (eg, changing field size and angle, using a different energy).
3. Estimate dose to fetus without shielding using a phantom or data from the AAPM report.120
4. Design and construct special shielding if necessary; four or five HVLs of lead usually suffice.
5. Measure dose to fetus in a phantom during simulated treatment with shielding in place.
6. Document the treatment plan and discuss the treatment with all personnel involved with the treatment.
7. Check all aspects of safety, including the load-bearing limits of the couch and support and movement of the shields, to ensure that there will be no injury to the patient or to personnel. The setup of each field should be photographed for documentation.
8. Monitor fetal size and location throughout the course of therapy and update estimates of fetal dose if necessary.
9. Document the completion of treatment by estimating the total dose to the fetus because of the radiation therapy.

Modified from Stovall M, Blackwell CR, Cundiff J, et al. Fetal dose from radiotherapy with photon beams: report of AAPM Radiation Therapy Committee Task Group No. 36. *Med Phys*. 1995;22(1):63-82. http://creativecommons.org/licenses/by/3.0/.

Note that the AAPM TG Report was based on treatment machines that predated modern MLCs. One study showed that the use of tertiary MLC systems such as those found on Varian linacs actually reduced fetal dose during irradiation of a pregnant patient.[123] The leaf and carriage system provided some absorption, and if the MLC leaves were oriented in direction along the plane of concern, such as typically when a patient with Hodgkin

disease is treated (ie, leaves oriented along the length of the table), the reduction difference when compared to having no MLCs was on the order of 2.5 to 3. Recently, AAPM TG 158 has provided guidance on out-of-field calculations for modern, MLC-based treatment machines.

GONADAL DOSE

Many of the reports used to estimate peripheral dose and fetal dose apply to dose estimations to both testes and ovaries.[124-126] Simultaneously, there have been studies to determine the genetically significant dose (GSD) as it applies to peripheral radiotherapy dosage to ovaries and testes. Niroomand-Rad and Cumberlin[127] combined measured data and GSD data to determine the GSD for treatment techniques that deliver peripheral dose to ovaries and testes. They summarized that GSDs from conventional therapies are minimal. However, there are circumstances, such as treatment of seminoma, when it is necessary to use a testicular shield to surround the testes to reduce head scatter and leakage, and some internal scatter.[128]

CHAPTER 9

Electron-Beam Therapy Dosimetry, Treatment Planning, and Techniques

Angélica Pérez-Andújar and Eric E. Klein

Megavoltage photon–based radiation therapy treatment of shallow tumor volumes is complicated by the buildup and radiation transport properties of photon beams. These beams are capable of treating both shallow and deep tumors; however, when treating shallow tumors, the radiation beams transit through the entire patient, exposing distal normal tissues. Megavoltage electron-beams have the property of a finite range and, therefore, do not deliver significant radiation doses to distal depths. Electron-beam therapy is, therefore, suitable for shallow tumors (<5 cm deep), such as head and neck cancers, skin cancers, chest wall irradiation for breast cancer, and boost dose to nodes. Electrons typically provide dose uniformity in these target volumes, with minimal dose to distal organs. In fact, G. H. Fletcher[1] had gone as far as saying, "there is no alternative treatment to electron-beam therapy." Even the strongest proponents of photon or proton therapy acknowledge that electron therapy is necessary to complete any radiotherapy program.

In 1976, Tapley[2] published one of the earlier comprehensive treatises on electron radiation therapy, in which she states, "there is no practical way for every radiation therapy department, in either hospitals or private offices, to be equipped with all modalities of irradiation beams. Ideally, electron beams should be available for those clinical situations where electrons are indispensable or very clearly superior." Electrons are now used at most radiation therapy centers. It still might be advantageous to refer patients to regional centers for special treatment techniques utilizing electrons.

Since the late 1970s, there have been three developments in electron-beam radiation therapy technology that have improved significantly our ability to deliver electron therapy. First, the advent of computed

tomography (CT)-based treatment planning allowed for coverage of the planning target volume (PTV) by the therapeutic dose and the dose to normal tissues and structures to be more accurately assessed. The use of CT provides a physical description of the anatomy, which is required for accurate dose calculations.[3,4] Second, the development of the electron pencil-beam algorithms (PBAs) and their implementation into treatment planning systems in the early 1980s provided a mechanism for accurately calculating the dose.[5,6] More recently, the use of Monte Carlo calculations has moved development to commercial platforms.[7] They have demonstrated high degrees of accuracy, especially with the presence of inhomogeneities. Third, manufacturers have refined the quality of their electron beams (ie, depth dose, off-axis uniformity, and penumbral width) by providing dual-scattering foil systems and electron applicators. Klein et al[8] describe dosimetric improvement with the most recent Varian electron-beam delivery system. Presently, the differences in the electron-beam dose characteristics of various radiation therapy machines from different vendors are minimal. Kashani et al[9] described electron-beam characteristics of a newly configured beam line for the Varian TrueBeam machine.

Electron-beam therapy is advantageous because it delivers a reasonably uniform dose from the surface to a specific depth, after which the dose falls off rapidly, eventually to a near-zero value. The depth of treatment is controlled by selecting the appropriate energy and, when necessary, the bolus thickness. Using electron beams with energies up to 20 MeV allows disease within approximately 6 cm of the surface to be treated effectively, sparing distal normal tissues.

Electron-beam therapy is useful in treating cancer of the skin and lips, upper respiratory and digestive tract, head and neck,[10,11] breast, and a variety of other sites.[2,12,13] Treatment sites of the skin include the eyelids, nose, ear,[14] scalp,[2,15] and more widely spread diseases of the limbs (eg, melanoma and lymphoma)[16] or total skin (eg, mycosis fungoides).[17,18] Treatment sites of the upper respiratory and digestive tract include the floor of mouth, soft palate, retromolar trigone, and salivary glands.[10,19] Treatments of the breast include chest wall irradiation following mastectomy[2,20,21]; nodal irradiation, often internal mammary chain (IMC) and occasionally axillary; and boost to the surgical bed following mastectomy or lumpectomy.[22] Current techniques of using tangential photon adjunct fields abutting

supraclavicular and posterior axillary fields are difficult enough without the addition of treating a separate medial breast internal mammary field with a mixture of photons and electrons. Other sites of electron-beam therapy include the retina,[23] orbit,[24] paraspinal muscles,[3,25] pancreas and other abdominal structures (intraoperative therapy),[26] vulva,[27] and cervix (intracavitary irradiation).[28]

The purpose of this chapter is to discuss the treatment and treatment planning techniques necessary to deliver the most effective electron-beam therapy. This requires a basic knowledge of dose distribution in water, dose in the heterogeneous patient, treatment planning tools and principles, and special techniques using electron beams.

DOSE DISTRIBUTION IN WATER

To appreciate the clinical use of electron beams, their dose distributions in water must be understood. Understanding the properties of depth dose, off-axis ratios (OARs), and two-dimensional (2D) isodose contour plots will clarify the concept of dose distribution in water. As well, an understanding of the dependence of the dose distribution on incident energy, field size, and source-to-surface distance (SSD) is required. It is assumed that the dose distribution for a specified energy, field size, and SSD is machine dependent. Applicator design may have a minor influence on dose distributions.

Depth Dose

This section discusses the percentage of dose (values are normalized to 100% at the depth of dose maximum, R_{100}) versus depth in water. Central-axis depth dose implies that the electron field is symmetric about the central axis, and the focus initially is on square fields. Electron depth dose varies with field size; however, once the field reaches a certain size, side-scatter equilibrium is achieved, and further increasing the size has an insignificant effect on depth dose.[29,30] In the energy range of up to 20 MeV, a 10- by 10-cm^2 field size typically will achieve side-scatter equilibrium on the central axis. The energy dependence of depth dose is illustrated in Figure 9.1, where central-axis depth dose is plotted for a 10- by 10-cm^2 field for

energies in the range of 7 to 18 MeV. The family of curves illustrates how the dosimetric characteristics vary with the incident electron energy:

1. Surface dose (D_s) increases from approximately 75% to 95% as energy increases. The slow increase in dose from the surface to the depth of maximum dose (R_{100}) occurs as a result of electrons undergoing multiple Coulomb scattering in water.[29]
2. Depth of distal 90% (R_{90}), often the therapeutic prescription depth, increases as energy increases. A physician may also prescribe to the 80% or 100% depth.
3. The practical range (R_p) (maximum penetration) of the electrons increases as energy increases.
4. X-ray dose attributable to bremsstrahlung that lies beyond the electron dose component is characterized by its value (D_x) and is taken from the percentage depth dose (PDD) curve 10 cm beyond the practical range (R_p). D_x increases as energy increases. Machines are designed to provide D_x values to be <5%.
5. The R_{100} depth (d_{max}) can vary irregularly with the depth and model of electron treatment machine; its dependence is insignificant for treatment planning, although it is significant to the medical physicist for constructing percent depth-dose data and in beam calibration.

Table 9.1 gives dosimetric parameters for a modern (Trilogy, Varian) linear accelerator.

TABLE 9.1 VARIAN TRILOGY MEASURED ELECTRON DEPTHS (R_P, R_{50}) AND CALCULATED ENERGIES (E_P, E_0)

Nominal Energy	Measured E_o (MeV)	Measured E_p (MeV)	R_{90}: Depth of 90% (cm)	R_{50}: Depth of 50% (cm)	R_p (cm)	D_x (%)
6	5.55	6.08	1.53	2.38	2.95	0.1

Nominal Energy	Measured E_o (MeV)	Measured E_p (MeV)	R_{90}: Depth of 90% (cm)	R_{50}: Depth of 50% (cm)	R_p (cm)	D_x (%)
9	8.41	8.84	2.69	3.61	4.33	0.3
12	11.77	12.23	3.85	5.05	6.02	0.9
16	15.63	16.02	5.10	6.71	7.900	1.6
20	19.62	20.78	6.14	8.42	10.25	2.1

E_o: Average energy at the surface, where $E_0 = 2.33 \times R_{50}$.

E_p: Most probable electron energy at the surface, where $E_p = C_1 + C_2 R_p = C_3 R_p 2$ and where C1, C2, and C3 are constants, with C1 = 0.22 MeV, C2 = 1.98 MeV cm, and C3 = 0.01025 MeV cm^2.

Depth dose has a significant dependence on field size, which varies with incident electron energy. The primary reason for the field-size dependence is the loss of side-scatter equilibrium, which has been discussed in detail by Hogstrom[29] and Khan et al[30] Figure 9.2, which shows the field-size dependence of PDD at 9 and 20 MeV, clearly illustrates that it is a greater issue at higher energies. Loss of side-scatter equilibrium, which begins first at the deeper depths, results in R_{90} shifting toward the surface as field size decreases. As the field size gets even smaller, the maximum dose decreases; and when it is normalized to 100%, the relative dose at the surface, D_s, increases. In addition, the effects on the distal portion of the depth-dose curve are greater. The most clinically significant effect is the decrease in R_{90} with decreasing field size, which can require a greater energy than initially proposed for treatment using very small fields (<5 cm).

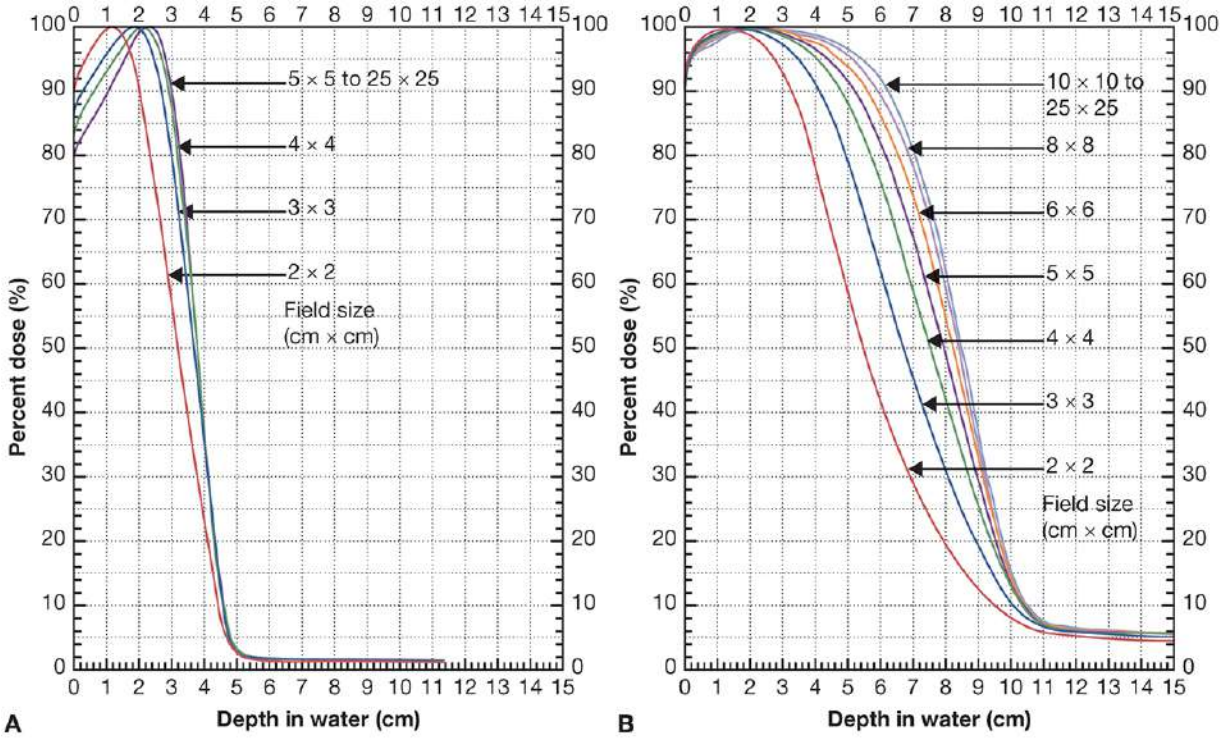

FIGURE 9.2 Field-size dependence of depth dose. Plot of percent dose versus depth for field sizes from 2 by 2 to 25 by 25 cm^2 for 9-MeV (A) and 20-MeV (B) beams on a Varian Clinac 2100C radiation therapy unit (source-to-surface distance = 100 cm). (Courtesy of Varian, Palo Alto, CA.)

Depth-dose variations with SSD are usually minimal. Differences in the depth dose resulting from the inverse square effect are small because electrons do not penetrate that deep (≤6 cm in the therapeutic region) and because the significant growth of penumbra width with SSD restricts the SSD in clinical practice to typically 115 cm or less. The primary effect of an inverse square is that R_{90} penetrates a few millimeters deeper at extended SSD at the higher energies, as illustrated in Figure 9.3. In relatively few cases (eg, when the electron beam has a large component of collimator-scattered electrons), the variation in depth dose with SSD can become more significant. In such cases, the collimator-scattered electrons are scattered out of the beam, resulting in a depth dose with a lower D_s and greater R_{90}.[31]

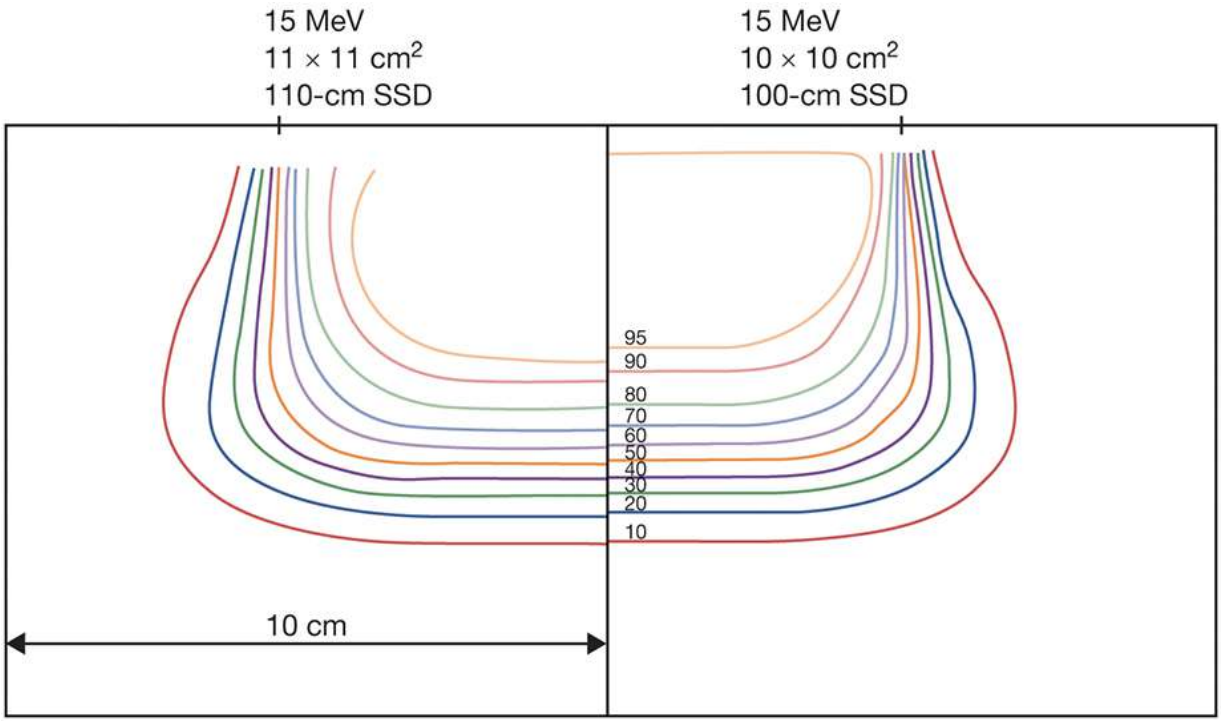

FIGURE 9.3 Source-to-surface distance (SSD) dependence of depth dose. Comparison of isodose plots for 15-MeV beam, 10 by 10 cm^2 at 100-cm SSD with 11- by 11-cm^2 field at 110-cm SSD. (From Hogstrom KR. Clinical electron-beam dosimetry: basic dosimetry data. In: Purdy JA, ed. *Advances in Radiation Oncology Physics: Dosimetry, Treatment Planning, and Brachytherapy*. American Institute of Physics; 1992:390-429. Copyright © 1992 by American Association of Physicists in Medicine. Reprinted by permission.)

For rectangular fields, Hogstrom[32] derived and others have confirmed[31,33] that the percentage of depth dose can be calculated by taking the geometric mean of the percentage of depth doses for a square field of length dimension (L) and one of width dimension (W). That is,

$$D\,(d; L \times W) = \sqrt{\%D\,(d; L \times L) \cdot \%D\,(d; W \times W)} \qquad (1)$$

If the square field percentage of depth-dose curves does not have a common R_{100}, then the result of Equation 1 must be normalized such that its maximum equals 100%. This method is referred to as the square-root method.

In some instances (eg, intraoperative, intraoral, or intravaginal cones), circular fields are used. In such cases, it is necessary to measure dose distributions, independent of those determined for square or rectangular fields.

Usually, a collimating insert is placed inside an electron applicator to form an irregular-shaped field, occasionally blocking the central axis. In this instance, the central-axis depth dose makes little sense, and the term *central-field depth dose* should be used, provided that the field has an axis of symmetry. In cases where the insert is irregular, the depth dose can be approximated using a rectangular-shaped field that approximates the irregular-shaped field.[34] In highly irregularly shaped fields, the dose distribution should be calculated using an appropriate dose algorithm in a three-dimensional (3D) treatment planning system. For very small fields, irregular or otherwise, it is highly recommended that PPD measurements be performed to properly determine prescriptive choices (ie, R_{90}).

Off-Axis Dose

Dose profiles in the dimensions perpendicular to the central axis can be described by OARs. The OAR is defined as the ratio of dose at an off-axis position to that on the central axis at the same depth. The OARs measured in water are used to assess off-axis beam quality, which is characterized by flatness and symmetry in the uniform portion of the beam and by its falloff in the region of the penumbra (eg, 90%-10%, or 80%-20%).

Manufacturers should be able to provide electron beams with a symmetry specification of 2% for opposing points in the beam and a flatness specification of ±3% of the *central-axis value* along the major axes (±4% along diagonals). The American Association of Physicists in Medicine (AAPM) Task Group 25 recommended that flatness and symmetry should be evaluated along the major axes (lines containing the central axis and perpendicular to the collimator edges) and along the diagonal axes.[30] Task Group 25 also recommended that flatness and symmetry be evaluated at depths near the surface and therapeutic depth. Practically, this is performed at R_{100}.

Flatness and symmetry are evaluated inside the penumbra, which is usually ensured by setting the boundaries of evaluation 2 cm inside the

collimating edge (2√2 cm along diagonals). When physicist performs acceptance tests for a treatment machine, and during subsequent annual reviews, they use the AAPM Task Group 142, and the AAPM Medical Physics Practice Guideline 8.b[35] recommendations of 2% symmetry and 5% flatness.[36] This is usually performed for each energy with an average-size applicator but should be tested for each applicator during acceptance. Subsequently, the profiles acquired during acceptance should be reviewed monthly and be consistent to within 1% of the acceptance values.[36,37]

Penumbra of electron beams is predetermined by the design of the beam flattening system, the air gap between the final collimator and the scatter of electrons in water. The penumbra is a function of depth and is the root mean square addition of two penumbral components: one the result of the air gap and one the result of scatter in the water.[6] This dependence is complex but can be appreciated qualitatively by the illustration in Figure 9.4, which compares isodose plots for normal (100 cm) and extended (110 cm) SSD at 6 and 16 MeV, respectively. These data show that penumbra grows in a nonlinear manner with depth, that air gap is more significant at the lower energies, and that scatter in water dominates at the higher energies. Fortunately, the complex dependence of penumbra can be modeled accurately in treatment planning systems using the PBA or more sophisticated dose algorithms.[29,32,34,38]

Isodose Plots

Combining depth dose with OARs results in the 3D dose distribution, and the properties of the 3D dose distribution can be appreciated by viewing 2D isodose contour plots in a plane containing the central axis and a major axis. Examples of these plots for a 15- by 15-cm^2 field are illustrated in Figure 9.5. As field width decreases or increases, the penumbra shape changes insignificantly because it is most significantly influenced by air gaps and collimation type. Collimating on the skin, for example, reduces penumbra significantly.

Data required for isodose contours are acquired for an inclusive spread of field sizes at each energy. 2D isodose contour plots and data are useful for manual treatment planning, input data required by dose algorithms, verification of dose calculated by a treatment planning system, and quality assurance standards.[29,30,39]

DOSE IN THE HETEROGENEOUS PATIENT

For most clinical circumstances, the ideal irradiation condition is for the electron beam to be incidentally normal to a flat surface with underlying homogeneous soft tissues. The dose distribution for this condition, similar to that for a water phantom described previously, contains a reasonably uniform dose inside the penumbra from the surface to R_{90}, and it has the sharpest possible falloff laterally and with depth. As the angle of incidence deviates from normal, as the surface becomes irregular, and as internal heterogeneous tissues (eg, air, lung, and bone) become present, the qualities of the dose distribution degrade.[40] Internal heterogeneities can change the depth of beam penetration as a result of differences in the rate of energy loss, which can result in PTV underdose and critical structure overdose. Both irregular surfaces and internal heterogeneities create changes in side-scatter equilibrium, producing volumes of increased dose (hot spots) and decreased dose (cold spots), potentially leading to an increased dose to critical structures and decreased dose to the PTV.[3,40] These perturbations can be reduced or eliminated by modifying the treatment technique.

Irregular Surfaces

Two geometries that illustrate the effects on the dose distribution caused by an irregular patient surface are the sloped skin surface and the stepped skin surface. Figure 9.5 illustrates changes in the depth-dose curve as a result of nonnormal incidence of an electron beam onto a flat surface. Compared with normal incidence, the nonnormal incident electron beam, central-axis, depth-dose curve shows an increased surface dose, an increased maximum dose, a decreased penetration of the therapeutic dose (R_{90}), and an increased range of penetration.[30,41] These changes can be clinically significant, particularly at angles of incidence >30° from the normal. Such conditions can occur when irradiating curved patient surfaces with large fields (eg, chest wall, limbs, neck, and scalp). In addition, it should be appreciated that the depth of R_{90} is specified along the central axis of the beam; and if the depth is taken perpendicular to the surface, then the depth is further reduced (approximately) by a factor cos (φ), where φ is the deviation of the incident angle from the normal.

Any time a sharp gradient (stepped surface) occurs on the patient's surface, side-scatter equilibrium will be lost, resulting in a cold spot beneath the proximal surface and a hot spot beneath the distal surface.[32,40,42,43] This can occur as a result of a sharp bolus edge, surgical defects, or within normal anatomy. For example, in the use of a uniform-thickness bolus that partially covers a field, a 90° step can result in hot or cold spots as great as 20%, as illustrated in Figure 9.6. In such a case, the bolus should be tapered as much as possible. The results of a 45° tapered bolus in Figure 9.6 show a reduction in the hot spot but more significantly an increased coverage of the 90% isodose contour. The nose is a protrusion that creates a cold spot, often the location of the tumor.[5,33,40] The ear canal (Figure 9.7) and surgical voids, which are characterized by a depression in the patient's surface, can result in hot spots in excess of 50%, depending on void dimension and beam energy.[44,45] Such depressions normally should be filled with some type of bolus material. Normal anatomy contains many irregular surface depressions and protrusions (eg, the ear canal and the nose, respectively) and should be accounted for by accurate treatment planning.

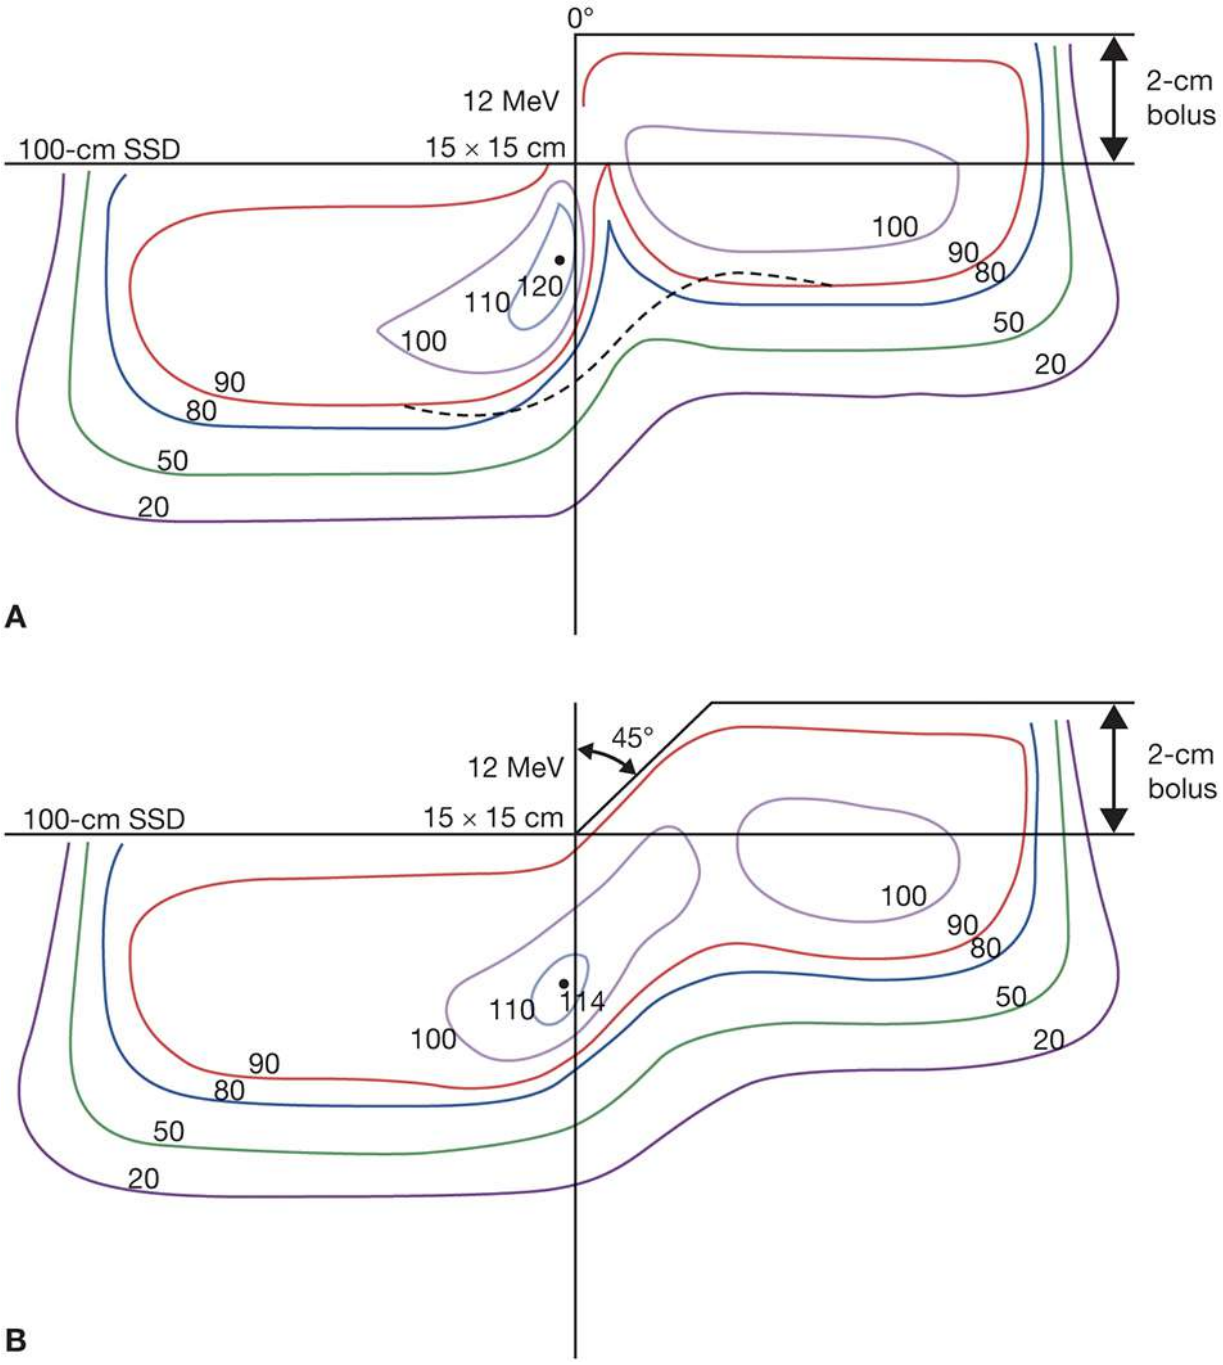

FIGURE 9.6 Effect of irregular patient surface on dose distribution. Plot of isodose contours for a 12-MeV, 15- by 15-cm^2 beam incident on water at 100-cm source-to-surface distance (SSD) having a stepped surface resulting from a 2-cm slab of bolus (A) and a beveled edge (45°) on the stepped surface (B). The dashed line in the top figure shows the location of the 90% isodose contour in the bottom one. (From Hogstrom KR. Treatment planning in electron-beam therapy. FIGURE 9.7 Impact of irregular surface anatomy on dose distribution. A 15-MeV electron beam irradiates the left side of a patient treated for dermal squamous carcinoma with perineural invasion. A beeswax bolus protects the posterior cranial fossa and the maxillary sinus. Isodose contours, expressed as a percentage of a given dose, show how the ear canal results in an unacceptable hot spot of 160% to the middle ear (A) and how filling the ear canal with bolus (saline solution) eliminates that hot spot (B). The residual hot spot of 125% is a result of the external ear. (Reprinted from Morrison WH, Wong PF, Starkschall G, et al. Water bolus for electron irradiation of the ear canal. *Int J Radiat Oncol Biol Phys*. 1995;33[2]:479-483. Copyright © 1995. With permission of Elsevier.)

Air Cavities

The influence of an internal air cavity is illustrated in Figure 9.8, which compares isodose contours beneath an air cavity to those without the air cavity. Results show that (a) the isodose contours in the shadow of air are shifted distally, (b) the dose beneath the air cavity increases as a result of loss of side-scatter equilibrium, and (c) the influence of the air increases laterally with depth. Internal air cavities of clinical interest primarily occur in the treatment of the head and neck (eg, nasal passages, ethmoid sinuses, maxillary sinuses, larynx, and mastoids).[32,40]

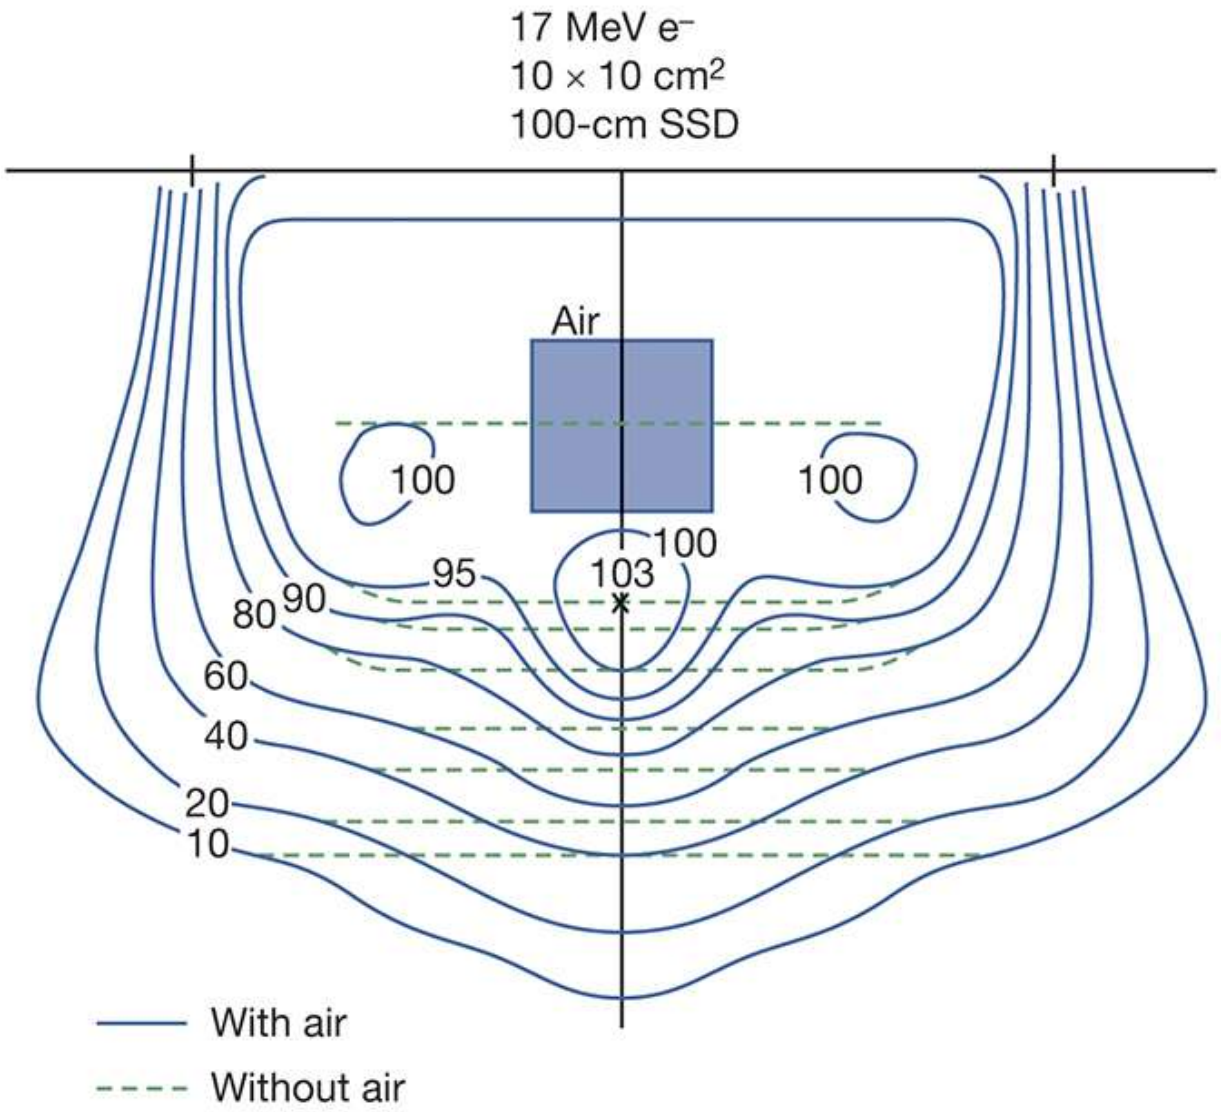

FIGURE 9.8 Effect of internal air cavity on underlying dose distribution. Dose calculated by the pencil-beam algorithm for a 2- by 2-cm^2 cylinder of air located 2 cm below the surface in water is compared to that in its absence. SSD, source-to-surface distance. (From Hogstrom KR. Dosimetry of electron heterogeneities. In: Wright AE, Boyer AL, eds. *Advances in Radiation Therapy Treatment Planning*. American Institute of Physics; 1983:223-243. Another significant effect is the reduction in dose in unit density tissue lateral to an air cavity. Electrons scattering from the unit density tissue into the air are not replaced because air is unable to scatter an equal amount back into the unit density tissue. Frequently, nose tumors can spread into

the septum, in which case bolus should be used to eliminate or reduce underdosing.

Lung

In the lung, electrons can penetrate 3 to 4 times farther than in the unit density tissue. This is demonstrated in Figure 9.9, where isodose contours from a typical electron chest wall treatment are compared with those in which the lung is assumed unit density. Assuming a given dose of 50 Gy, the 40% isodose contour corresponds to 20 Gy, approximately the threshold for pneumonitis, if significant lung volume is irradiated. Ignoring the low density of the lung would grossly underestimate the volume of the lung receiving more than 20 Gy.[32]

FIGURE 9.9 Effect of lung on dose distribution underlying chest wall. Comparison of dose calculated by the pencil-beam algorithm (PBA) for 8-MeV chest wall irradiation, assuming patient's water (A) and heterogeneous anatomy (B) based on computed tomography data.

This effect increases with energy. For example, increasing the beam energy from 9 to 12 MeV results in an additional 1.5 cm of penetration in water-like tissue (electrons lose energy at a rate of ~2 MeV per centimeter in water), and this corresponds to as much as 6.0 cm in the lung (assuming a lung physical density of 25%). Consider the patient whose chest wall thickness requires an energy of 10 MeV for treatment and that 12 MeV must be selected. This results in as much as 4 cm in depth of needless irradiation in the lung, unless 1 cm of bolus is used to effectively lower the energy incident on the patient to 10 MeV.

Care must be taken when irradiating targets where the lung is immediately distal, such as with entire chest wall postmastectomy irradiation.

Bone

Interactions of electrons with bone are complex and interesting. The influence of bone is illustrated in Figure 9.10, which compares isodose contours beneath the hard bone to those without the bone. The results show that:

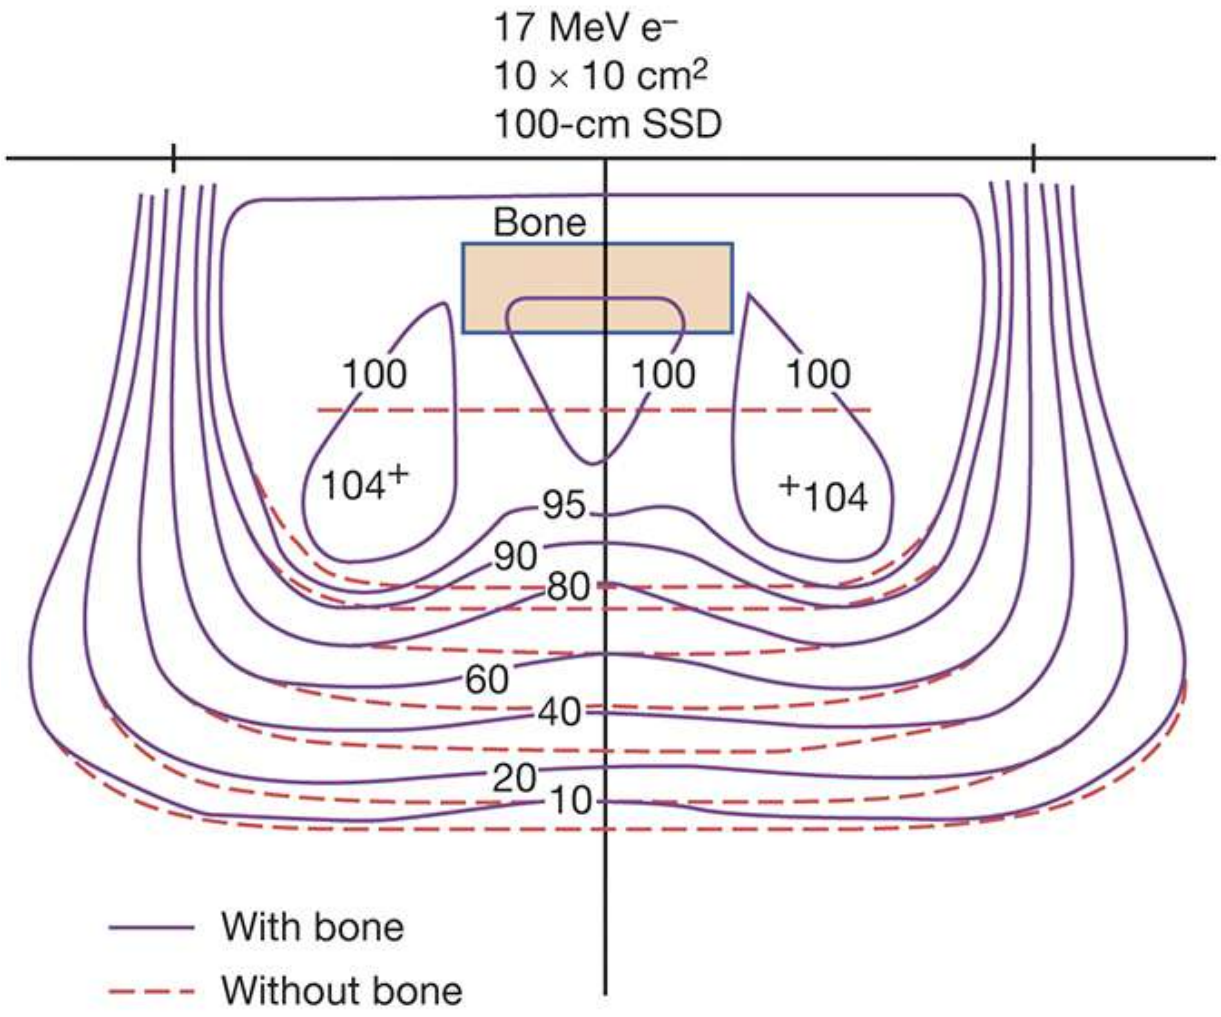

FIGURE 9.10 Effect of hard bone on underlying dose distribution. Dose calculated by the pencil-beam algorithm for a 3- by 1-cm^2 cylinder of hard bone substitute located 1 cm below the surface in water is compared to that in its absence. SSD, source-to-surface distance. (From Hogstrom KR. Dosimetry of electron heterogeneities. In: Wright AE, Boyer AL, eds. *Advances in Radiation Therapy Treatment Planning*. American Institute of Physics; 1983:223-243. Copyright © 1983 by American Association of Physicists in Medicine. Reprinted by permission.)

1. The isodose contours in the shadow of the bone are shifted proximally.
2. Dose outside (inside) the bone-water interface increases (decreases) by approximately 5% as a result of loss of side-scatter equilibrium.
3. The lateral dimension of the region having its dose perturbed by the bone increases with depth.

Living bones are not uniformly dense throughout their cross section, and in most cases, their edges are not parallel to the incident beam. Both differences decrease the influence of bone in generating inhomogeneity in the patient's dose distribution. Dense bones that significantly affect the dose distribution include the mandible, bones of the skull (eg, frontal bone and zygoma in orbit treatment or temporal bone in treatment of parotid), clavicles, and vertebral processes (eg, craniospinal irradiation).

One might ask, "What is the clinical significance of the increase in dose in or around bone because of increased scatter?" The maximum dose increase expected as a result of backscattered electrons is 5%, and the maximum dose increase expected inside the bone and in adjacent exit tissues is approximately 7%.[46] These increases represent maximum dose estimates because actual bones are not as dense through and through as are the bone substitute in which these data were taken. These estimates of the increased dose are not expected to be clinically significant. In fact, untoward effects in or around bone that can be attributed to dosimetry have not been observed in patients treated with electron-beam therapy.

DOSE PRESCRIPTION AND CALCULATION OF MONITOR UNITS

Dose Prescription

It is recommended that dose be prescribed to the given dose or 90% of the given dose. Intermediate or lower prescription (95%, 85%, 80%) can be prescribed if the energy (typically stepped in 3- to 4-MeV increments) choices are too coarse to maintain a single baseline prescription recipe. Given dose is defined as the maximum central-axis dose in a water phantom at the SSD of the patient for the energy, applicator, and field size identical to that used for patient treatment. If the field shape is irregular, then the field size is taken to be a rectangular field representative of the irregular field shape. The most representative rectangular field is not well defined; however, Hogstrom et al[38] have provided one methodology for determining its estimate.

It is recommended that the dose is prescribed to the given dose or a percentage of it and not to a point in the patient. It is quite possible that a dose prescription point in the patient could be in a region of increased or

decreased dose because of tissue heterogeneity or irregular surface, which could result in PTV underdose or overdose, respectively.

Calculation of Monitor Units

Monitor units can be determined by

$$\mathrm{MU} = \frac{D_{\text{prescribed}}/\%D}{O\,(E,C,L \times W,\mathrm{SSD})}, \tag{2}$$

where $D_{\text{prescribed}}$ is the prescribed dose, $\%D$ is the percentage of the given dose to which dose is prescribed (eg, 90%), and $O(E, C, L{\times}W, \mathrm{SSD})$ is the output (dose per monitor unit) for a beam of energy E, applicator C, field size $L{\times}W$, and SSD. To use this methodology, the medical physicist must measure dose output as a function of square field size and SSD for each energy-applicator combination at the time of commissioning the accelerator. Output for rectangular fields can be determined using the square-root method of Mills et al[14,47] and Shiu et al[31]:

$$\mathrm{O}\,(E,\ C,\ L \times W,\ \mathrm{SSD}) = [O\,(E,\ C,\ L \times L,\ \mathrm{SSD}) \cdot O\,(E,\ C,\ W \times W,\ \mathrm{SSD})]^{1/2} \tag{3}$$

Output for rectangular fields can also be determined using an equivalent square method[30,33,48,49]; however, Biggs et al[48] recommend limiting this method to an aspect ratio (L:W) of 2:1. The square-root method is not limited to the aspect ratio, and Shiu et al[31] have shown it to be more accurate. Figure 9.11 illustrates beam output data at 9 MeV for four common applicators used on the Varian Clinac 2100C (Varian Medical Systems, Palo Alto, CA) at 100-cm SSD.

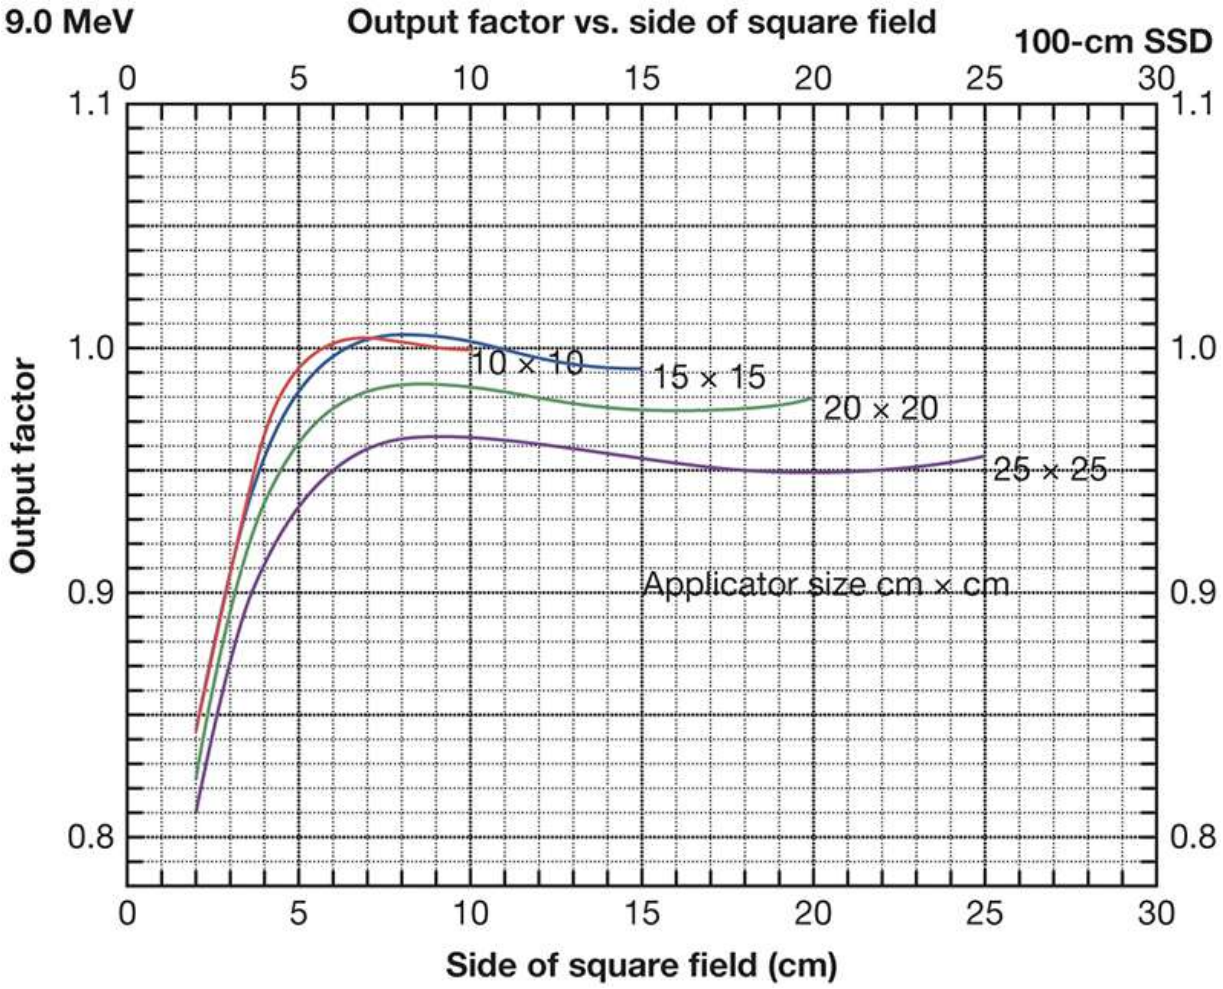

FIGURE 9.11 Field-size dependence of output (dose/monitor unit). Plot of output factor (cGy/MU) versus side of square field from 2 by 2 cm^2 to the open applicator for four applicators and for the 9-MeV beam of a Varian Clinac 2100C. SSD, source-to-surface distance. (Courtesy of Varian, Palo Alto, CA.)

Output at an extended SSD can be determined by either the air-gap method or the effective-source method.[30] The effective-source method is covered in detail by Khan.[49] The air-gap method has a sounder physical basis. Although both methods give similar answers, only the air-gap method is covered here.[33] Output at an extended SSD is given by the product of output at the nominal SSD (SSD_0), the air-gap factor (f_{air}), and an inverse square term as

$$O\,(E, C, L \times W, \mathrm{SSD}) = O\,(E, C, L \times W, \mathrm{SSD})\, f_{\mathrm{air}}\,(E, L \times W, \mathrm{SSD}) \times \frac{\mathrm{SSD}_o + R_{100}}{\mathrm{SSD} + R_{100}} \quad (4)$$

f_{air} is determined by measuring dose output for square fields at the extended SSD and then solving Equation 4. For rectangular fields, the air-gap factor is determined using the square-root method[31]:

$$f_{\mathrm{air}}(E, L \times W, \mathrm{SSD}) = \sqrt{f_{\mathrm{air}}(E, L \times L, \mathrm{SSD}) \cdot f_{\mathrm{air}}(E, W \times W, \mathrm{SSD})} \quad (5)$$

As f_{air} is assumed independent of an applicator, the dose output needs to be measured only for the smallest applicator that contains the square field size. Figure 9.12 plots the square field air-gap factors for the 9-MeV beam of the Varian Clinac 2100C for SSD from 100 to 120 cm. For a more detailed explanation of dose output and sample calculations of monitor units for electron beams, refer to Hogstrom et al[34] Another practical option is to fix incremented SSDs to be used clinically (ie, 100, 105, 110, 115 cm) and establish tabular outputs for each energy-applicator SSD combination.

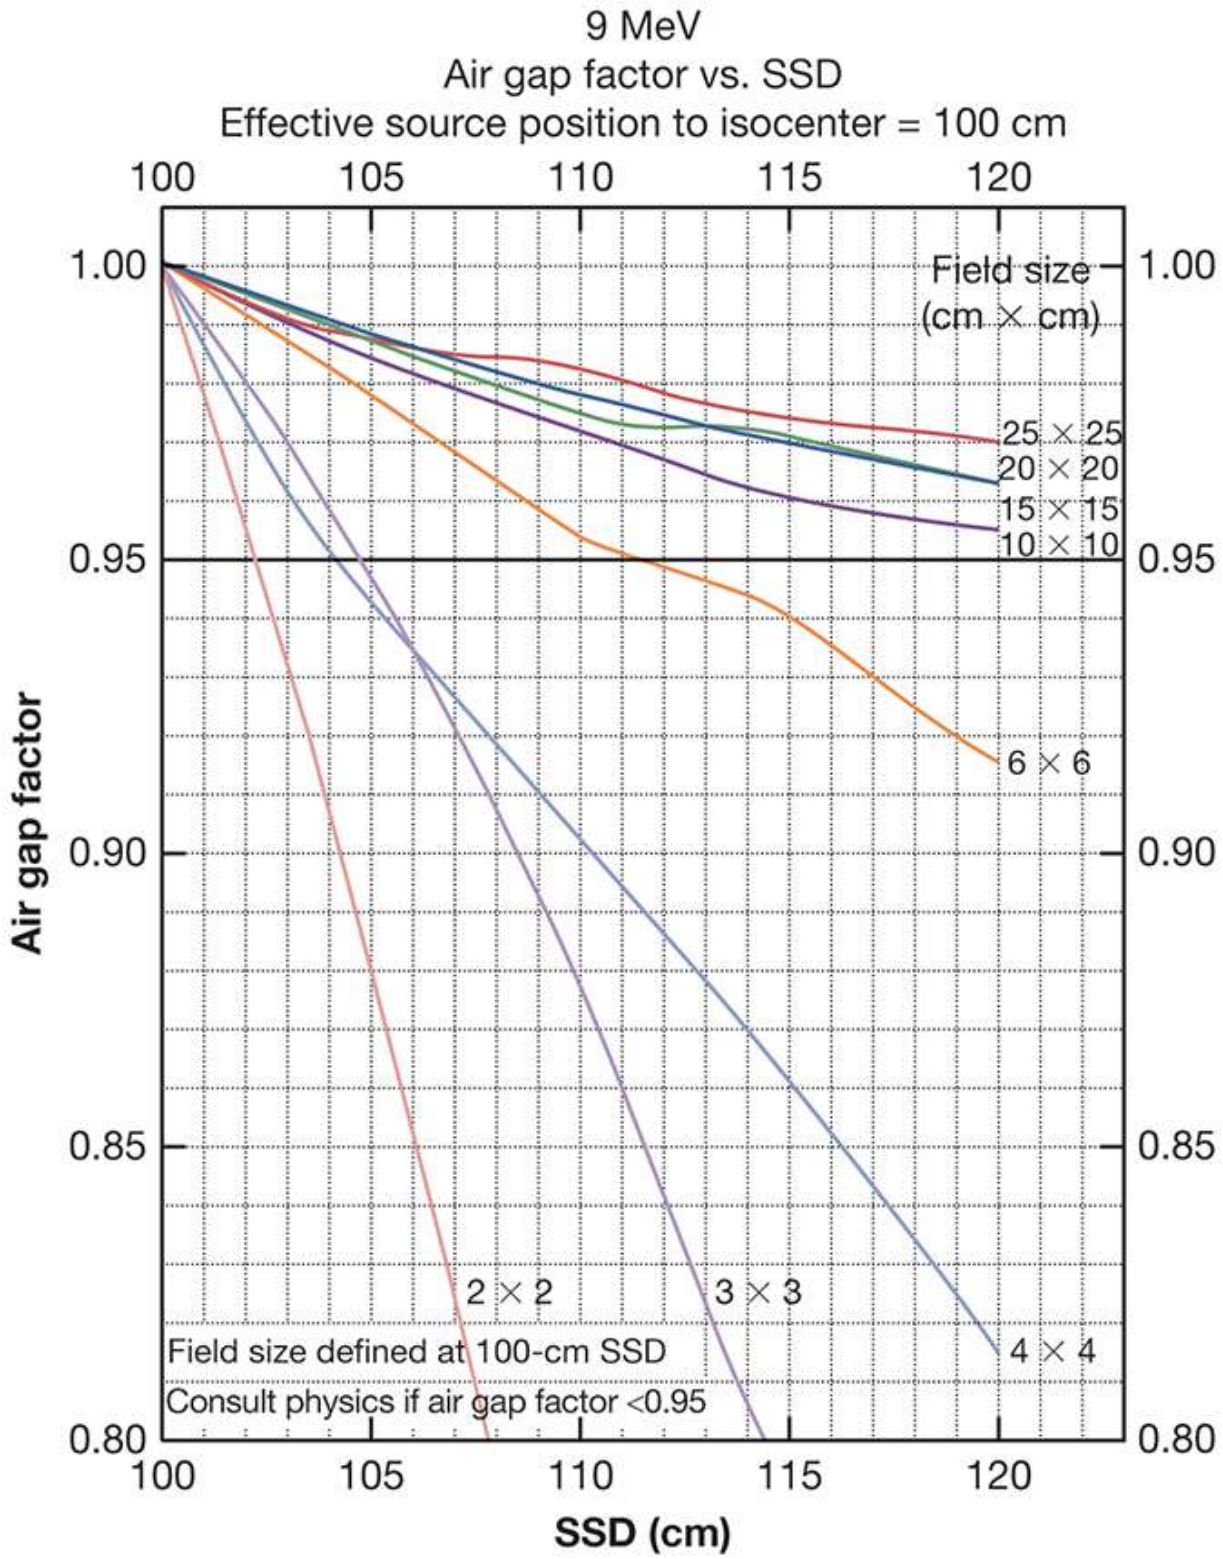

FIGURE 9.12 Dependence of air-gap factors on source-to-surface distance (SSD) and field size. Plot of f_{air} versus SSD for field sizes ranging from 2 by 2 to 25 by 25 cm^2 and for the 9-MeV beam (Varian Clinac 2100C). (Courtesy of Varian, Palo Alto, CA.)

CALCULATION OF DOSE IN PATIENT

Standards for Patient Dose Calculations

Sound treatment planning decisions require accurate dose calculation in the patient. Therefore, the following recommendations are made for electron-beam treatment planning. First, dose should be calculated in the full three dimensions to allow for evaluation of dose homogeneity in the PTV, coverage of the PTV by the 90% isodose contour, and dose to critical structures. Second, the dose algorithm should account for patient heterogeneity. Failure to properly account for patient heterogeneity can result in failure to appreciate dose heterogeneity, PTV underdose, or normal tissue overdose.[5,40,50] Third, the dose algorithm should be accurate; and for those conditions for which this is not the case, physicians and physicists should discuss the proper interpretation of the dose calculations.

To expand on the final recommendation, a dose algorithm must meet certain criteria to be most effective in the clinic.[51] First, it should be accurate to within 4% in regions of low-dose gradients or within 2 mm in regions of high-dose gradient (eg, penumbra or depth-dose falloff region).[39,52] Second, the dose algorithm should be commissioned easily by a qualified medical physicist. Third, the accuracy of the dose algorithm should be well documented. Since 1981, the PBA has best met this requirement. Presently, several new, more accurate algorithms, both analytical and Monte Carlo based, are being implemented into commercial treatment planning systems and will replace or supplement the PBA in due time.[53] Regardless of the algorithm, it is the medical physicist's responsibility to commission the algorithm, to understand its accuracy, and to train medical dosimetrists and radiation oncologists in its use and limitations.

Dose Algorithms

As stated, the standard methodology for dose calculation in the patient has been the PBA. As computing power increased, it was possible to implement the algorithms into 3D format.[54] Detailed instructions for commissioning the dose algorithm and documentation of its accuracy have been published.[5,6,53] The PBA has been shown to be quite accurate in water at the standard and extended SSD, correctly predicting the changes in the

penumbra.[29,32,34] It is also quite accurate in predicting changes in dose resulting from oblique incidence and irregular surfaces.[5,51] Regarding internal heterogeneities, the PBA correctly predicts the penetration in lung and the growth of the penumbra width in lung[51]; however, it tends to underestimate the dose in lung near the mediastinum as a result of its central-axis approximation.[51] In bone, it correctly predicts the shortening of the dose penetration behind the bone, and it slightly underestimates (<5%) the magnitude of the *hot* and *cold* spots under the edge of a thick hard bone, such as the mandible.[5] The PBA does not predict the increased dose (<5%) resulting from backscatter at the proximal tissue-bone interface, nor does it predict the increased dose (>7%) in bone resulting from increased scatter. The PBA underestimates the hot and cold spots under the air-tissue interfaces.[5,51]

New dose algorithms that are accurate to 4% or better are becoming available in commercial treatment planning systems. Many of these algorithms have been reviewed by Hogstrom and Steadham.[51] One of these is the pencil-beam redefinition algorithm (PBRA), whose commissioning is similar to that of the conventional PBA, although its accuracy is significantly improved.[55-57] Figure 9.13 illustrates the improvement of the PBRA.

Many of the newer algorithms are based on Monte Carlo methods, which allow them to be quite accurate.[56,58-62] Cygler et al[53] published a report on the first commercial system using Monte Carlo–based electron calculations, demonstrating excellent results. Ding et al[63] demonstrated outstanding results for a macro–Monte Carlo algorithm, along with a companion report showing superior results for Monte Carlo compared with PBA.[64]

TREATMENT PLANNING PRINCIPLES, TOOLS, AND METHODS

Electron therapy is usually restricted to a PTV that is within 6 cm distal from the patient's surface. Electrons may be used either alone or in conjunction with photon beams. In the case of the former, the objective of the treatment planner is usually to select the appropriate beam direction, energy, and field size to provide as uniform a dose as possible to the PTV while delivering a minimal dose to normal tissue and structures. To optimize dose homogeneity, the beam direction should be as close to normal incidence to the patient surface as practical. Once beam direction is specified, the selection of energy and field-size specification follows. Figure 9.14 compares the isodose contours in water with the beam edges and R_{90}. Electrons are unique in that the uniform region of dose lies inside the 90% isodose contour. Dose outside the 90% isodose contour falls off rapidly. However, the patient's anatomy can differ significantly from water so that the effects resulting from patient heterogeneity make the resulting treatment plan unacceptable, according to the original prescription. In addition, the PTV can be at a variable depth beneath the surface so that a single-beam energy is inadequate. The treatment plan can be improved by utilization of special treatment aids, such as skin or internal collimation, bolus, field abutment, or other special techniques.

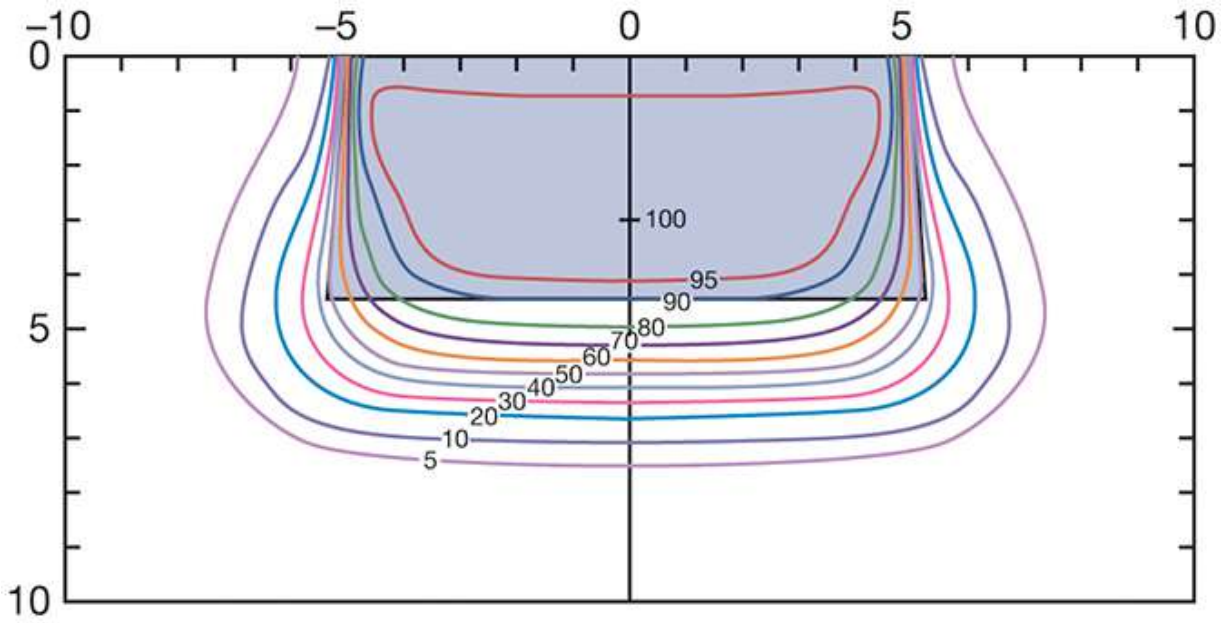

FIGURE 9.14 Plot of isodose curves for a 15-MeV, 10- by 10-cm^2 electron beam in water (source-to-surface distance = 100 cm). Note the shape of the 90% isodose contour with respect to the shaded area, which is framed by the diverging field edges and the R_{90} depth.

Selection of Energy

The energy of the incident electron beam should be selected so that the distal surface of the 90% (of the given dose) dose surface encompasses the PTV and that critical structures lie beyond the maximum penetration of the electrons or at an acceptable dose level. For planning purposes, a general rule is the following:

$$E_{p,0}\ (\text{MeV}) \sim 3.3 \cdot R_{90}\ (\text{cm}), \tag{6}$$

where $E_{p,0}$ is the most probable incident electron energy in MeV. The energy should be selected such that R_{90} just exceeds the maximum depth of the PTV. This approximation is true in water for field sizes large enough to have side-scatter equilibrium on the central axis. For small field sizes that do not have side-scatter equilibrium, R_{90} will be less; thus, a higher energy might be required. As well, heterogeneous tissue (eg, bone or air) can affect the penetration, requiring greater or lesser energy, respectively.

Similarly, for planning purposes, a general rule is the following:

$$E_{p,0}\ (\text{MeV}) = 2 \cdot R_p\ (\text{cm}), \tag{7}$$

where R_p is the practical range in centimeters of the electron beam.[32] The treatment planner can select an energy such that R_p is less than the minimal depth of a critical structure. This approximation has no field-size limitation; however, as before, heterogeneous tissue (eg, bone, lung, or air) can affect the penetration, allowing greater or lesser energy.

As an example of how to use these general rules, consider treating the posterior cervical nodes of the neck with electrons to spare the spinal cord because its dose is already near tolerance. If the maximum depth of the nodes is 3 cm and the minimum depth of the spinal cord is 6 cm, then Equations 6 and 7 indicate that the minimum energy to cover the PTV is 9.9 MeV and the maximum energy that protects the spinal cord is 12 MeV, respectively. Hence, beam energies in the range of 10 to 12 MeV are acceptable. In all cases, the energy of the beam should be confirmed by performing a 3D dose calculation for the planned treatment using a CT representation of the patient. Bolus may be strategically used to tune the beam penetration either globally or in discrete areas and ideally should be placed at the time of the CT.

Design of Electron Collimation

Electron collimation consists of multiple collimating components; however, the electron field shape is usually defined by an applicator's collimating insert and/or skin collimation. Custom electron collimators are constructed from lead or low melting point lead alloy (Lipowitz metal). The lead thickness in millimeters required to stop the primary electrons equals one-half the incident of the most probable energy of the electron beam in MeV.[29,30] To account for small variations in thickness resulting from the lead sheet manufacturing process, a 1-mm surplus can be added. That is,

$$t_{pb}\ (\text{mm}) = 0.5 \cdot E_{p,0}\ (\text{MeV}) + 1 \quad (8)$$

For example, an 18-MeV beam requires 10 mm of lead. Lipowitz metal is comprised mostly of lead along with bismuth that has a density of 20% less lead; therefore, its thickness should be increased by 20%. For example, an 18-MeV beam requires 12 mm of Lipowitz metal. Lipowitz metal collimating inserts are usually fabricated at a constant thickness—namely, that sufficient for the greatest energy on the treatment machine. For a machine whose maximum energy is 20 MeV, the Lipowitz metal thickness should be at least 13 mm.

Skin Collimation

The closer the field-defining collimator to the patient, the sharper the beam's penumbra; hence, skin collimation provides the sharpest possible penumbra. Because of the significant effort often required to fabricate skin collimation, its use is restricted to applications for which it has the greatest benefit, for example, (a) small-field (<4 cm) treatments providing maximal protection to adjacent critical structures, (b) sharpening penumbra (c) reducing penumbra when treating at an extended air gap, (d) reducing penumbra in electron arc therapy, and (e) where patient motion may be an issue. Proper use of skin collimation requires that it be in contact with the skin surface and that it extend sufficiently inwardly and outwardly to intercept the penumbra from upstream collimation.

Skin collimation absorption can be accomplished using lead sheets and normally is taken to be the minimum thickness necessary to shield the maximum. The maximum possible dose beneath the skin collimation occurs at the skin surface with no air gap between the two.[30,33] The transmitted dose, which is the result of bremsstrahlung photons from the incident beam and those generated by electrons stopping in the lead, is slightly greater than that with no lead present. It is recommended that a table of measured dose under the lead, as a function of lead thickness, is available for each beam energy.[29] As the air gap between the lead and the patient increases, the transmitted dose to the patient decreases. These values can be measured at the time of beam commissioning. If not, and for cases where precise

determination of dose beneath a block is critical, in vivo dosimetry (eg, thermoluminescent dosimetry) should be used. Other materials beyond lead have been developed for electron skin collimation. These include leaded vinyl foils and moldable systems like the Heat-Malleable Matrix Thermo shield system, whose production has been stopped, and the most recently developed gamma putty, composed of 91% bismuth. These materials work similarly to lead sheets; nonetheless, it is necessary to commission such materials before using them clinically and determine the minimum thickness necessary to minimize electron transmission.[65-67]

In designing the shape of the aperture of a collimating insert, due consideration is made for the penumbra. Typically, there is approximately a 1-cm margin between the projected edge of the collimator and the outer boundary of target volume when both are projected to the isocenter. This margin varies with energy, depth, and air gap; and it only can be appreciated by utilization of isodose curves (see Figures 9.4 and 9.14). Again, the adequacy of the margin between the aperture and PTV should be confirmed by performing 3D dose calculations using CT images.

The utility of skin collimation for small-field treatments is illustrated in Figure 9.15. A 6-MeV, 3- by 3-cm^2 field with a 10-cm air gap (collimator to surface) is essentially all penumbra, resulting in an unsatisfactory dose distribution. However, by opening the collimator to 6- by 6-cm^2 and then forming the 3- by 3-cm^2 field using skin collimation, the dose distribution becomes clinically satisfactory. This application is used for the treatment of the eyelid, nose, and other small target volumes.

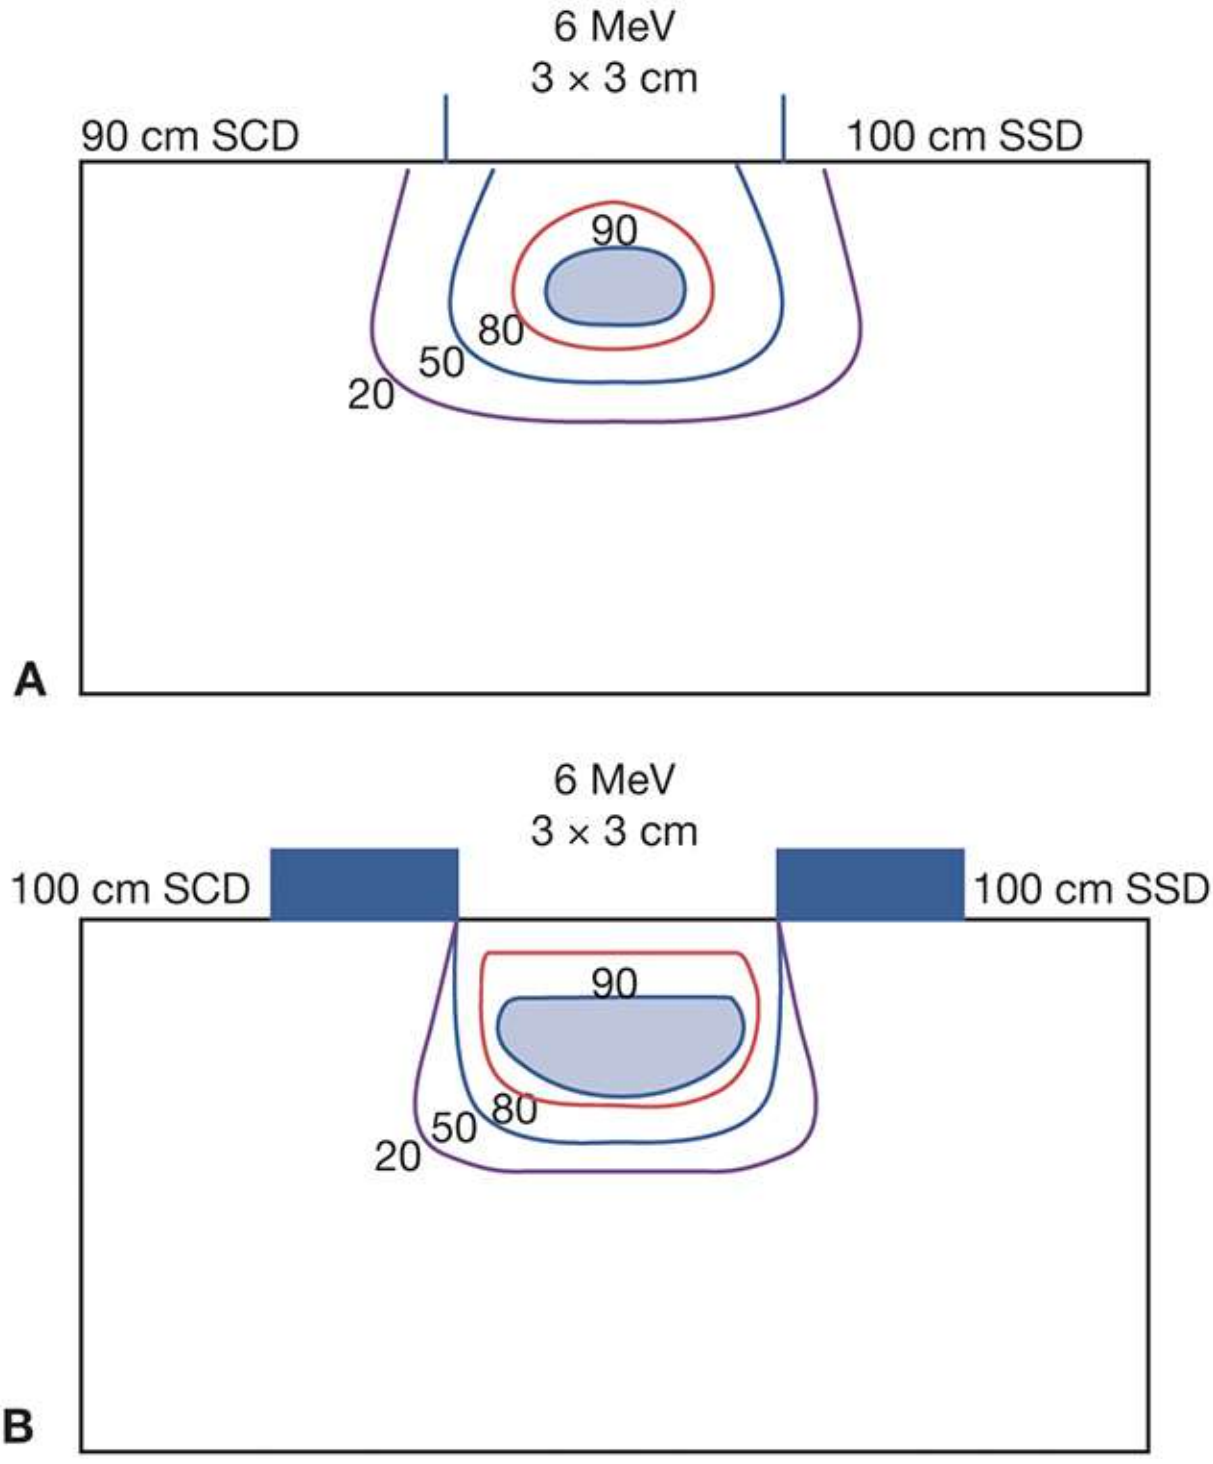

FIGURE 9.15 Impact of skin collimation for small electron fields. Isodose plots are compared for results of a computer simulation of a 6-MeV electron beam in water for a 3- by 3-cm^2 field formed by an applicator insert 10 cm above the patient (A) and a 3- by 3-cm^2 field formed by collimation at the surface with a 6- by 6-cm^2 applicator insert 10 cm above the patient (B). SSD, source-to-surface distance. (From Hogstrom KR. Clinical electron-beam dosimetry: basic dosimetry data. In: Purdy JA, ed. *Advances in Radiation Oncology*

Physics: Dosimetry, Treatment Planning, and Brachytherapy. American Institute of Physics; 1992:390-429. Copyright © 1992 by American Association of Physicists in Medicine. Reprinted by permission.)

In the presence of skin collimation, the depth dose is approximated by that for the field size on the skin surface (ie, that defined by the skin collimator). In contrast, the dose output is approximated by that for the field-size incident on the skin collimation (ie, that defined by the applicator cutout). For the example in Figure 9.15, the depth dose is taken to be that of the 3- by 3-cm^2 field; the dose output is taken to be that of the 6- by 6-cm^2 field. This simple approximation slightly overestimates dose output, if the depths of maximum dose for the two field sizes differ. In such a case, the output of the larger field is multiplied by the depth-dose factor of the larger field at the depth of maximum dose of the smaller field.[34]

Multileaf Collimation

The use of existing photon multileaf collimators (MLCs) to modulate electron beams has been shown to be somewhat feasible, although a report by Klein et al[68] showed that an SSD of 70 cm was necessary to provide clinical acceptable fields using the photon MLC. This is because of the dispersion of the electrons in air. They performed a feasibility study of using existing photon MLC to modulate electron beams, which was shown to be somewhat feasible. An important aspect from that work demonstrated that when using existing photon MLC to produce narrow electron-beam segments, the large penumbra generated could be an advantage in terms of beam matching.

The other possibility is not to use the existing photon MLC but rather to have a tertiary electron MLC system that is closer to the patient, thereby narrowing the penumbra that is produced when the MLC is far from the patient. Lee et al[69] found that replacing air with helium in the treatment head made a significant impact in the predicted dose distributions. Karlsson et al[70] demonstrated that penumbra, effective-source position, field shape, and matching could be optimized by replacing air with helium in the treatment head below the MLC leaves and by shifting the position of the scattering foils, monitor chamber, and MLC position.

Bolus

Bolus is an essential tool for the delivery of optimal electron radiation therapy. Electron bolus is defined as water or near-water equivalent material that normally is placed in direct contact with the patient's skin surface, close to the patient's skin surface, or inside a body cavity. This material is designed to provide extra scattering or energy degradation of the electron beam. Its purpose is usually to shape the dose distribution to conform to the target volume or to provide a more uniform dose inside the target volume.[29,32] More specifically, electron bolus has three primary applications:

- To shape the coverage of the treatment volume in the depth direction to conform as closely as possible to the target volume while avoiding critical structures
- To increase dose to the patient's external surface
- To serve as a missing tissue compensator for surface irregularities and internal air cavities

In the second application, bolus is being used to either eliminate or decrease the adverse effects of patient heterogeneities on the dose distribution, which can result in a geographic miss at depth, dose nonuniformity within the target volume, and excessive dose to distal critical structures.[29,32]

Because dose is typically prescribed to 90% of the given dose, it is often desirable to increase surface dose to 90% or higher when treating with low-energy electrons. To accomplish this, a higher energy beam is selected and a uniformly thick bolus is placed on or near the skin surface. The surface dose of the higher energy electron beam is greater, and the bolus places the skin at a deeper depth, further increasing the surface dose. The energy-bolus thickness combination is selected to place R_{90} at the prescription depth while increasing the surface dose (D_s) to near 90%. To assist in usage of this technique, a table that allows selection of the optimal energy-bolus thickness combination is recommended. Table 9.2 illustrates a sample for the five electron-beam energies of a typical radiation therapy machine.

TABLE 9.2 VALUES OF SURFACE DOSE AND THERAPEUTIC DEPTH FOR VARIOUS ENERGY-BOLUS COMBINATIONS

Superflab Thickness (cm)	0.0	0.3	0.5	1.0	1.5	2.0
Energy: 6 MeV						
D_s (%)	72	79	83	93	100	—
R_{90} (cm)	2.0	1.7	1.5	1.0	0.5	—
Energy: 9 MeV						
D_s (%)	78	83	85	89	95	99
R_{90} (cm)	3.0	2.7	2.5	2.0	1.5	1.0
Energy: 12 MeV						
D_s (%)	83	88	89	91	94	96
R_{90} (cm)	4.0	3.7	3.5	3.0	2.5	2.0
Energy: 16 MeV						
D_s (%)	87	92	93	96	97	98
R_{90} (cm)	5.0	4.7	4.5	4.0	3.5	3.0
Energy: 20 MeV						
D_s (%)	91	96	97	98	99	100
R_{90} (cm)	6.1	5.8	5.6	5.1	4.6	4.1

Two bolus methods are used for this function. One places flexible sheet material (eg, Superflab) directly on the skin surface. Materials are approximately water equivalent and come in thickness increments of 0.3 to 4 cm. It is particularly useful for chest wall irradiation, for both fixed-beam and arced-beam therapies. In some treatments, the bolus is used for only a portion of the field, in which case care must be taken to ensure the edge of the bolus is tapered to reduce the magnitude of the hot or cold spot created by the surface irregularity (such as is seen in Figure 9.6).[29,32]

For highly irregular or sensitive skin surfaces, which are often encountered in head and neck or postsurgical irradiations, it is advantageous to have a rigid bolus sheet (often referred to as a scatter plate because it not only degrades the energy of the electron beam but also scatters the beam) close to but not necessarily in direct contact with the patient.[32] For such cases, standard thicknesses of polymethylmethacrylate (0.125-0.25 inches) are placed perpendicular to the beam. To restore a sharp penumbra, skin

collimation is usually recommended with use of the scatter-plate bolus method. Rules for using skin collimation with the bolus have been discussed by Hogstrom.[32] It is important that the bolus be in contact or close to the patient because too large of an air gap can create an exceedingly large penumbra.

Bolus is considered part of the beam; however, it also can be considered part of the patient, effectively shortening the SSD. For uniform bolus thickness (t), it is recommended to adjust the dose output for inverse square.[34] That is,

$$O_{\text{bolus}} = O \cdot \left[\frac{\text{SSD}+t+R_{100}}{\text{SSD}+R_{100}} \right]^2 \tag{9}$$

A more sophisticated use of bolus is to design custom bolus for the purpose of electron conformal therapy. In this application, the bolus is usually designed to conform the 90% isodose line to the PTV while minimizing dose to nearby critical structures and maintaining dose uniformity as much as possible within the 90% dose contour. Proper design of custom bolus requires the use of a 3D treatment planning system[71] that uses bolus design operators[72] and a 3D PBA.[54] The methodology of bolus design to optimize target coverage and critical structure searing is seen in Figure 9.16. Perkins et al[20] showed the use of custom bolus for chest wall irradiation in the cases of highly distorted anatomy and of a chest wall recurrence (Figure 9.17), and Kudchadker et al[73] have demonstrated its use in head and neck treatment. And Low et al[25] have shown its utilization for sparing spinal cord, lung, and kidney in the treatment of the paraspinal muscles.

A custom three-dimensional electron bolus technique for optimization of postmastectomy irradiation. *Int J Radiat Oncol Biol Phys*. 2001;51[4]:1142-1151. Copyright © 2001 Elsevier. With permission.)

It is recommended that the intent of bolus be verified by measurement or calculation. Bolus used to increase skin dose can be verified by performing in vivo dosimetry measurements (eg, using thermoluminescent dosimetry). Complex bolus shapes, as used to remove surface irregularities or for

electron conformal therapy, can be verified by CT scanning the patient with the bolus in place.[20,25] The dose distribution then can be recalculated using the electron dose algorithm in a treatment planning system.

This method of electron conformal therapy may be facilitated by a commercial vendor that can create the custom bolus from treatment plan machinist coordinates.[74]

Along these lines, customization could also be achieved with the use of a 3D printer.[75-77] In this process, a customized bolus is made using the patient's CT with a commercial treatment planning system. Figure 9.18 shows an example of such process. The bolus' structure is sent to a 3D modeling software that will convert the file to the appropriate language (standard tessellation language), which will be used by the 3D printer to manufacture the bolus.[75]

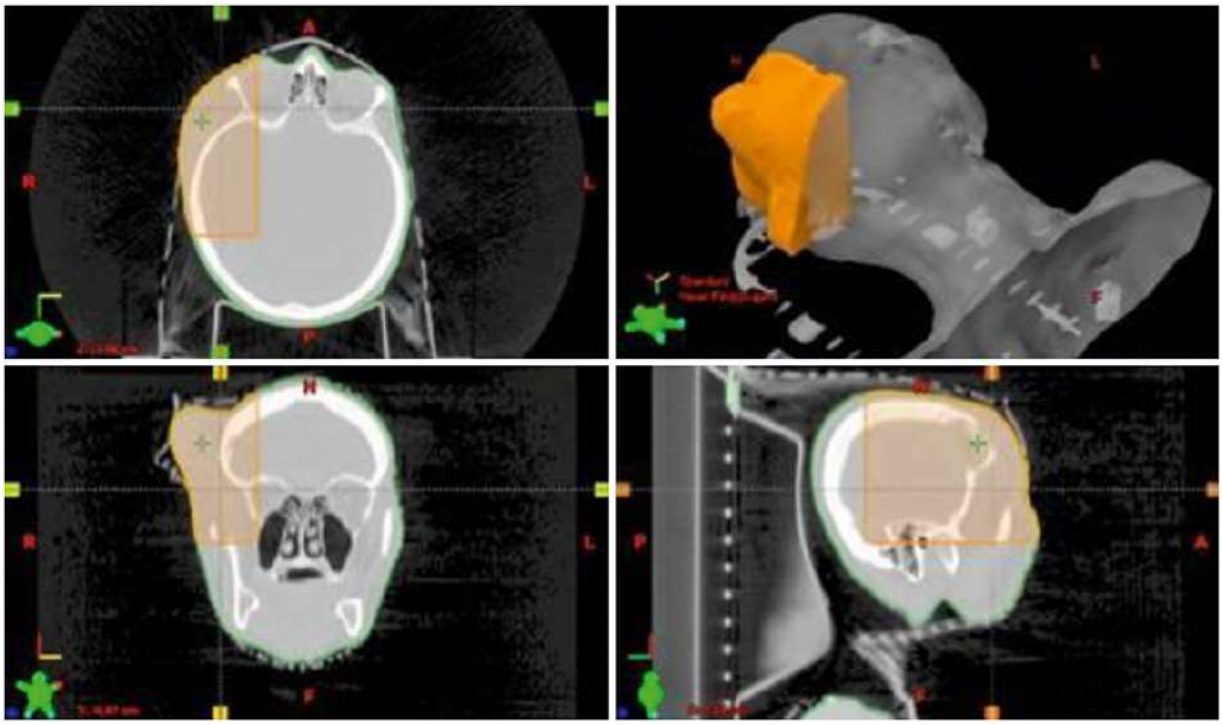

FIGURE 9.18 Example of a bolus structure (shown in orange) defined on the treatment planning system that was subsequently made by a three-dimensional printer. (Reprinted from Burleson S, Baker J, Hsia AT, Xu Z. Use of 3D printers to create a patient-specific 3D bolus for external beam therapy. *J Appl Clin Med Phys*. 2015;16[3]:5247. http://creativecommons.org/licenses/by/3.0/.)

The dimensions of the bolus are dependent on the type of 3D printer available, which will also determine the composition of bolus material. There are printers that could print using only one material, whereas there are others that can print multiple materials at once.[75] Mainly, the materials used are some type of variation of acrylonitrile butadiene styrene and polylactic acid. It is important to clearly characterize the material's electron density in order to calculate the correct dose that will be delivered to the patient. In addition, the 3D printed bolus might have air bubbles, which will affect the dose distribution. It is recommended, as for any type of bolus, to perform the necessary measurement to characterize the 3D printed bolus as well as to develop the necessary quality assurance procedures before using the bolus for any patient.

Two of the main limitations of using 3D printed bolus routinely for radiotherapy are the availability of a 3D printer and the time that it takes to print a complete bolus. Although 3D printers should become more affordable as these are gaining popularity in radiotherapy. The printing time could also vary widely among printers. The time that it takes to print a bolus is highly dependent on the type of printer's filament and, of course, on the dimensions and complexity of the bolus. Printing could take from 4 to 24 hours.[75,76] This time could be doubled if by any chance there is any failure in the printing process. Some companies offer services to print patient 3D boluses. Usually, the patient's CT scan is transferred to the company's software to design the bolus. The bolus is then reimported back into the clinical treatment planning system, and it's integrated into the patient's plan to ensure that the dose distribution is appropriate. The design and dimension of the bolus are then sent to the company, which will manufacture it and send it back before patient treatment takes place. It's important also to account for the additional time that will take to receive the bolus from the company.[74,78,79]

Internal Shielding

Internal shields stop electrons that enter the body before they reach critical structures and deposit any significant dose. Examples of clinical utilization of internal shielding are intraoral blocks protecting salivary glands during head and neck treatments[2]; eye blocks protecting the lens in irradiation of

the eyelid,[80] orbit, or retina; and sheets of lead used to protect internal structures during intraoperative therapy.

There are two important concepts to remember in the use of internal shielding. First, the collimator must be sufficiently thick to stop the energy of the electrons in the beam at depth. Electron-beam energy is reduced by 2 MeV per centimeter in unit density tissue; hence, the energy of a 12-MeV beam at a depth of 2 cm is 8 MeV. The thickness of lead required to stop 8-MeV electrons is 4 mm (8 MeV-0.5 mm/MeV).

One application was ensuring that collimation is sufficiently thick that has been sometimes overlooked is the use of internal eye shields. Shiu et al[80] showed that x-ray eye shields constructed of plastic-coated lead and designed to shield the eyes from kilovoltage x-rays did not stop 6-MeV electrons, resulting in penetration of approximately 50% of the given dose. However, electron eye shields constructed of enamel-coated tungsten can stop electrons with energies as great as 9 MeV (Figure 9.19). By using higher density tungsten (ρ = 19.3 g/cm^3) instead of lead (ρ = 11.5 g/cm^3), the eye shields remain sufficiently thin to fit under the eyelid. If only x-ray eye shields are available, bolus should be placed on top of the eye and eye shield to ensure that the electron energy is reduced sufficiently so that electrons do not penetrate the eye shield.

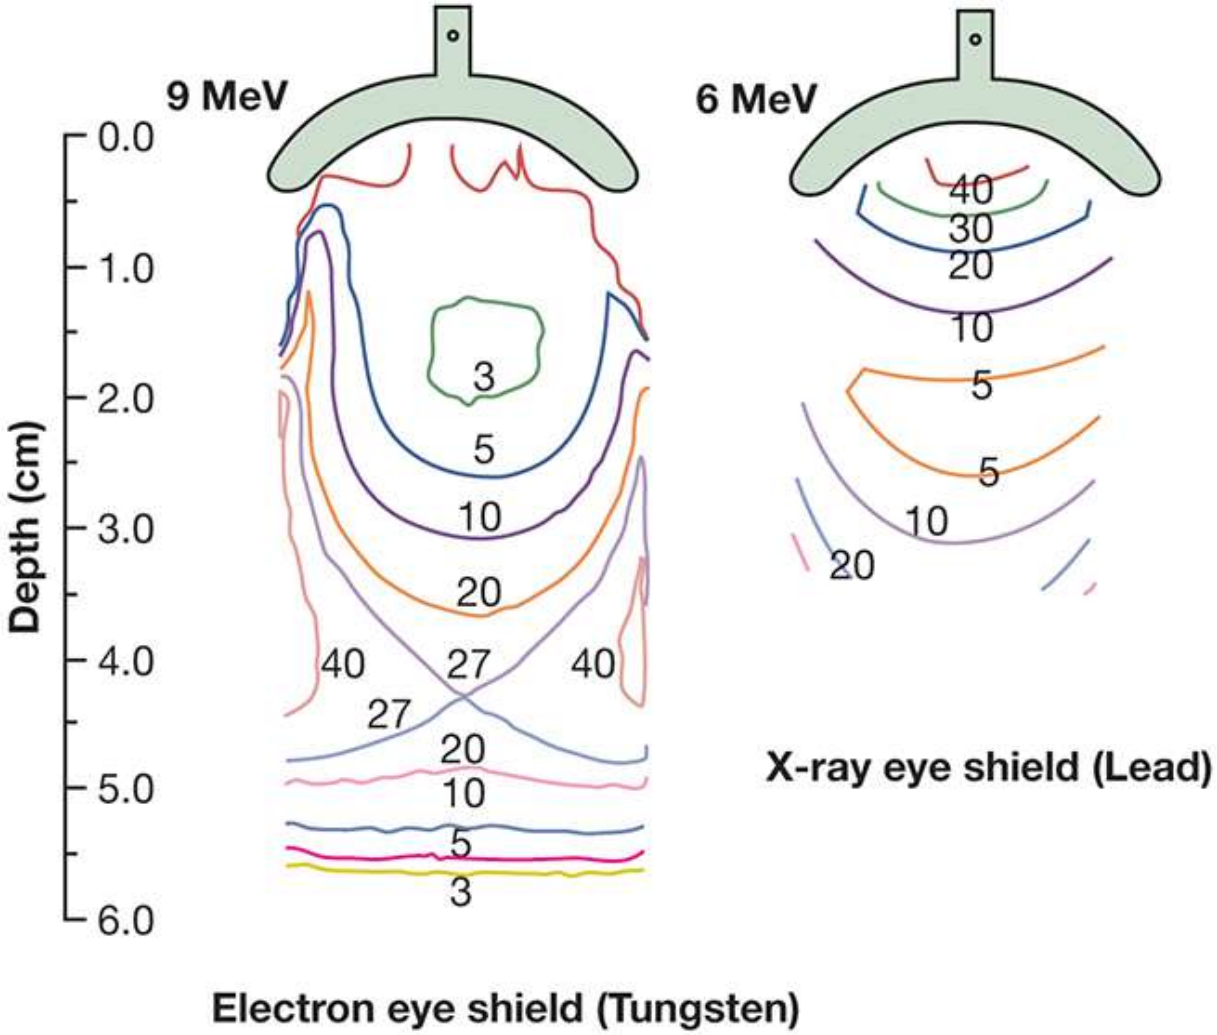

FIGURE 9.19 Electron eye shields. The dose distribution under tungsten electron eye shields demonstrates its ability to stop 9-MeV electrons. The dose distribution under a lead x-ray eye shield shows its inability to stop 6-MeV electrons. (Reprinted from Shiu AS, Tung SS, Gastorf RJ, Hogstrom KR, Morrison WH, Peters LJ. Dosimetric evaluation of lead and tungsten eye shields in electron beam treatment. *Int J Radiat Oncol Biol Phys*. 1996;35[3]:599-604. Copyright © 1995 Elsevier. With permission.)

Second, electrons backscattered from lead at a lead-tissue interface increase dose, the increase ranging from approximately 20% at 20 MeV to 60% at 4 MeV, where the energy is the average energy of electrons incident on the lead.[30,81] Das and Bushe[82] published a comprehensive data set demonstrating the range for backscatter electrons as a function of energy, on the order of a few millimeters, and increases as a function of energy. Inserting two half-value layers of bolus between the lead and the tissue usually reduces the dose to upstream tissue to a clinically acceptable value.

The thickness of one-half-value layer ranges from approximately 1 cm at 10 MeV to 0.5 cm at 3 MeV.[30,83] Intraoral lead stents are routinely coated with acrylic,[28] and a material such as dental wax can be applied easily to lead sheets placed between the mucosa and the gums. Eye shields, however, only have clearance for 1 to 2 mm of coating; hence, backscatter dose to the eyelids is an important consideration in treatment management.[83] When determining lead thickness for an internal shielding at a particular depth, one must first determine the energy of the electron beam at that location. The energy of the electron beam on the surface is $E_{o,p}$, typically close to the nominal stated energy. As electrons lose energy by 2 MeV per centimeter, one can determine the remaining energy of any depth. For example, 12 MeV beams at surface would be approximately 6 MeV after 3 cm.

Recent studies claim that the thickness of lead and bolus, usually calculated for internal shielding considerations, is overestimated.[84] This calculation is usually based on the method explained in Task Group 25.[30] The overestimation is likely to be on the safe side; regardless, these new studies questioned the use of this thicker layer when the shielding is usually used in smaller anatomic spaces. Mc Dermont et al[84] used the work of deVries and Marsh[85] to determine the minimum amount of lead and bolus necessary to keep the dose to a 10% enhancement at the distal end of tissue. They created a looked-up figure (ask how we can get that figure) for the thicknesses of lead and bolus for electron energies going from 4 to 10 MeV.

Field Abutment

The purpose of field abutment is to enlarge the radiation area by using parallel matched beams or to change the beam energy or modality. In either case, beam uniformity requires that three criteria be met. First, the beams must abut along the entire border.[29,30,32,86] If the edges of the two beams coincide exactly (Figure 9.20A), then the two beams will be equivalent to a single beam and optimal uniformity will be achieved. If the central axes of the two beams are parallel (Figure 9.20B), then the diverging beam edges will overlap, creating a cold spot upstream and a hot spot downstream of the region of intersection. This is least significant for narrow fields, as encountered in irradiation of the cervical nodes of the neck or abutting the internal mammary and medial chest wall fields. If the central axes are

converging (Figure 9.20C), then there is an even greater amount of overlap. This is the case for abutting lateral and medial chest wall fields. In such cases, feathering the beam edge ±1 cm can reduce the dose heterogeneity. This is illustrated in Figure 9.21 for a standard postmastectomy chest wall irradiation using electrons.

B

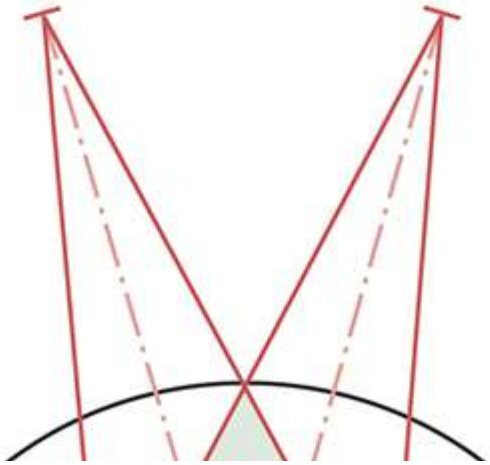

FIGURE 9.20 Comparison of abutment geometries. A. Common edge is created by having diverging central axes. B. Parallel central axes result in overlapping edges. C. Converging central axes result in the greatest overlap. (From Svensson H, Almond P, Brahme A, et al. *ICRU Report 35. Radiation Dosimetry: Electron Beams with Energies Between 1 and 50 MeV*. International Commission on Radiation Units and Measurements; 1984. Copyright © 1984 International Commission on Radiation Units and Measurements. Reprinted by permission of SAGE Publications.)

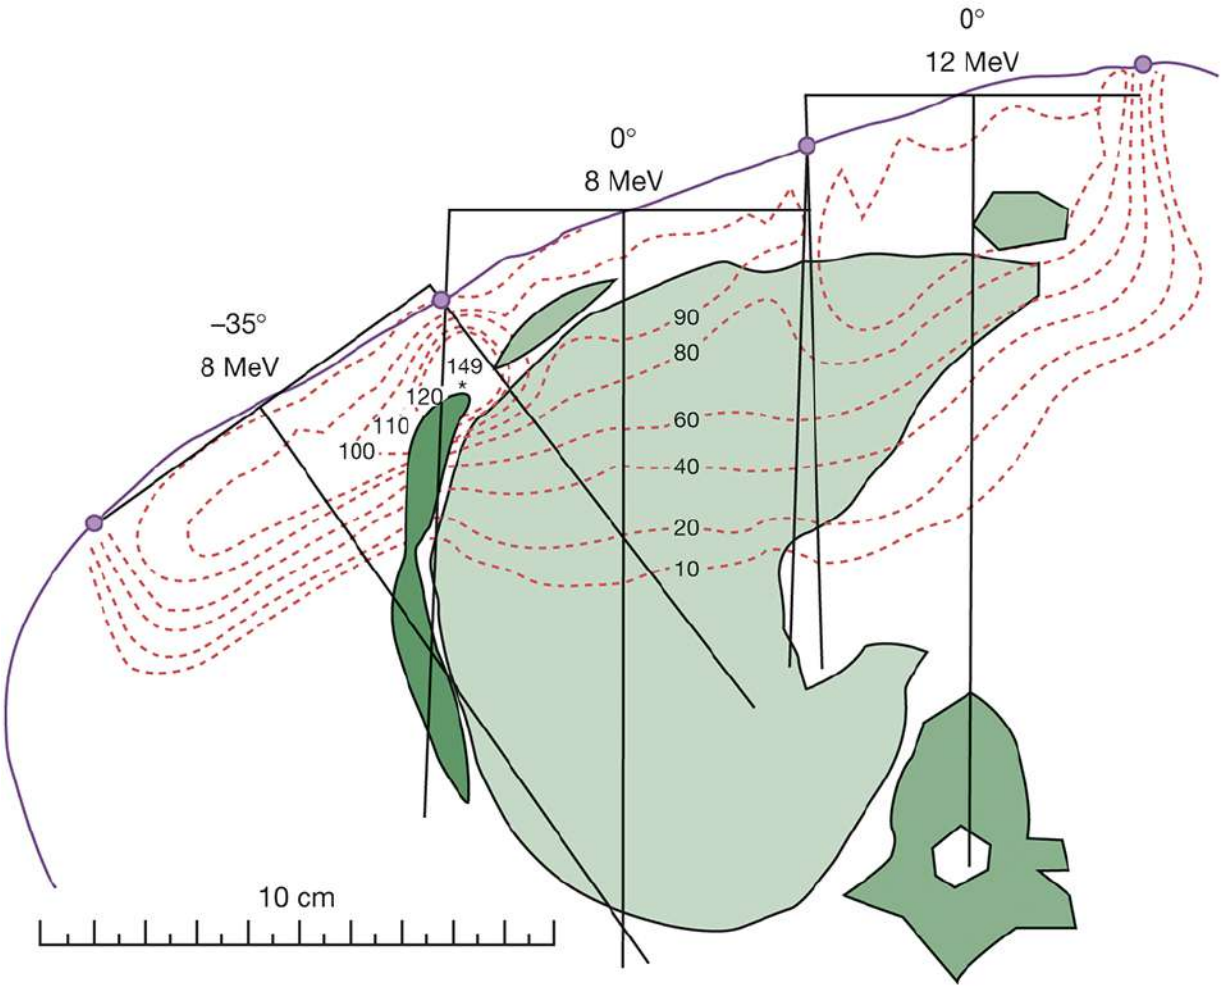

FIGURE 9.21 Clinical example of abutting electron fields in chest wall treatment. Dose homogeneity is acceptable at the border of internal mammary chain and medial chest wall fields because central axes are parallel and field widths are small. Dose homogeneity is unacceptable at the border of medial and lateral chest wall fields because central axes are converging (see Figure 9.10B). Dose homogeneity is improved at the border of medial and lateral chest wall fields by delivering equal doses with the match line being moved 1 cm twice during treatment.

The second criterion is that the beam penumbra must be matched. This is the case for the two spinal fields referred to earlier; however, it is not the case in general, particularly in abutting electron to photon fields. In such cases, either one or both of the field edges must be feathered. Third, it is best that the penumbra be somewhat broad. This reduces the impact of misalignment on the uniformity of dose in the abutted region. Harms and Purdy[50] demonstrated the influence of SSD energy and match bolus on match-line dosimetry. Figure 9.22 displays dose homogeneity for abutted

12-MeV fields depending on gap. In addition, the matching of electron and photo fields is a planning challenge, as two differing penumbra are abutted. Johnson and Khan[87] performed a study of matched electron-photon fields as a function of energy and SSD. Figure 9.23 demonstrates match-line profiles for a typical head and neck field match.

Mixed-Beam Therapy

Electron beams are frequently mixed with photon beams to create an appropriate treatment. The mixed beams can irradiate a common volume of tissue, or they can be abutted. In the former case, an electron field may be added to a primarily photon-beam treatment, or a photon field may be added to a primarily electron-beam treatment. For example, electron boosts are used to deliver localized dose to the surgical site following photon breast irradiation, to treat the postcervical nodes once spinal cord tolerance is reached, and to reduce spinal cord dose (eg, in lymphoma treatment).[88] In some head and neck treatments, the photon beam is a surrogate to the electron beam, being used to reduce skin dose and to increase dose penetration while still sparing the contralateral salivary gland.[2,10] With the future availability of intensity-modulated photon and modulated electron therapy, the effectiveness of mixed-beam therapy can be expected to increase in breast and head and neck radiation therapy.

Abutted mixed beams are used when separate portions of the anatomy can benefit from two individual beams. The most common application of this process is the utilization of electron fields for irradiation of the IMC, supraclavicular, or axillary lymph nodes as part of breast or chest wall irradiation.[2] Matching of tangential photon fields and IMC electron fields is complex because of surface irregularities and heterogeneities. Careful treatment planning must be performed, especially if prescriptive decisions for electron energy and dosage are predicated on the resultant dose distribution. Figure 9.24 displays a tangential photon IMC electron field initial plan with a plan performed with partially wide tangent, a technique suggested to remove the field abutment dilemma.[89] This technique is also used for irradiating the total scalp or for craniospinal irradiation, which are described later. The use of combined modulated photon and electron fields has been reported. This has the potential to be an ideal therapy for particular

treatment sites. Thus far, this combined therapy has been demonstrated with microtron (helium head) machines. Early publications demonstrated conventional (nonmodulated) use of photons and electrons as collimated by MLC. Zackrisson and Karlsson[90] described a technique for matching of electron and photon beams for conformal therapy of target volumes at moderate depths. Mu et al[91] showed that mixed photon and electron was superior in obtaining planning goals versus intensity-modulated radiotherapy (IMRT) alone. One essential aspect was the reduction of integral dose. The same computer-controlled MLC of microtron model is used for photons and electrons. Das et al[92] developed an algorithm using automated beam orientation and modality selection for optimal beam arrangement selection in IMRT of mixed photon and electron beams. Finally, Ma et al[93] performed a comparative study on tangential photon beams, IMRT, and modulated electron radiotherapy (MERT) for breast cancer treatment. This type of treatment delivery can simplify the use of both techniques, but more electron scatter is also created due to the use of the MLC instead of an electron cut out. This creates a different level of complexity. These types of plans will need a robust QA program to ensure that the plan doses are, in fact, what the patient will be received during treatment. There are publications on the results for quality assurance measurements based on ion chambers and films,[94] the use of log files similar to what is regularly use for photon IMRT plans,[95] and the use of commercial systems with diode arrays.[96]

Breast radiotherapy with inclusion of internal mammary nodes: a comparison of techniques with three-dimensional planning. *Int J Radiat Oncol Biol Phys*. 2003;55[3]:633-644. Copyright © 2003 Elsevier. With permission.)

SPECIALIZED ELECTRON TECHNIQUES

Although electron-beam therapy is used less frequently than is photon-beam therapy, it remains an essential modality. To fully use electron-beam therapy, there must be access to comprehensive electron treatment and treatment planning techniques. This includes specialized electron techniques, which, in the present context, are defined as those that are seldom required and that use a complex treatment geometry, special treatment delivery hardware, or special treatment planning software. It is not recommended that all radiation therapy facilities offer all techniques. However, radiation oncologists should be aware of these techniques and should be able to refer patients to a regional center for those that are impractical in smaller settings. This recommendation is based on the significant time, resources, and costs of implementing, maintaining, and providing some of the more complex special electron procedures. The American College of Medical Physics (absorbed into the AAPM) has reviewed the manpower effort and cost associated with several special procedures, which include electron arc therapy, intraoperative electron therapy, and total skin electron irradiation.[97]

Four types of special techniques are discussed here. First, the treatment of internal tissues is exemplified by intraoperative radiation therapy and intracavitary radiation therapy. Second, the utilization of abutted electron and photon fields is exemplified by craniospinal and total scalp treatment techniques. Third, the treatment of superficial tissues for a cylindrical geometry is exemplified by the total limb and total skin treatment techniques. Fourth, an alternative to fixed-beam therapy of the chest wall is exemplified by arc therapy.

Intracavitary Irradiation

Applicators of appropriate design can be used for intracavitary electron irradiation, which delivers an improved dose distribution over that traditionally delivered using orthovoltage x-rays. Intracavitary irradiation is most frequently used to boost the primary site while sparing nearby normal tissues. Intracavitary irradiation has been a choice for intraoral, transvaginal, and intraoperative treatments. Wang[19] showed the benefit of intraoral cones for boosting the oral lesions of the floor of the mouth, soft palate, tongue, and retromolar trigone while sparing mandible, teeth, gum, and salivary glands. McGinnis et al[28] reported using a transvaginal applicator to boost carcinoma of the cervix with electrons, reducing bulk tumor to subsequently allow intracavitary brachytherapy. Intraoperative radiation therapy can be used in many sites[13]; however, it is used primarily for abdominal sites. Merrick et al[26] reviewed the experience in the United States of using intraoperative radiotherapy for the treatment of pancreatic, biliary, and gastric carcinomas.

The criteria for intracavitary electron irradiation are similar, regardless of site. A treatment applicator is necessary so that healthy tissue can be restrained from intercepting electrons irradiating the tumor. The applicator wall must be sufficiently thick to stop electrons from escaping to outside tissue while being thin enough not to interfere with tumor access. Guidelines for accomplishing this for intraoperative applicators have been discussed by Hogstrom et al[98] Another issue is how to ensure accurate alignment while maintaining patient safety with an applicator. Appropriate cone positioning requires having a method for looking down the cone to view the tumor. Proper alignment of the applicator after inserting it into the

patient requires methods for docking it to the machine. For soft docking, the applicator is not physically attached to the machine[98,99] (Figure 9.25). For hard docking, the applicator is physically attached to the machine, and there are methods for breaking away under stress.[28,100]

INTRAOP

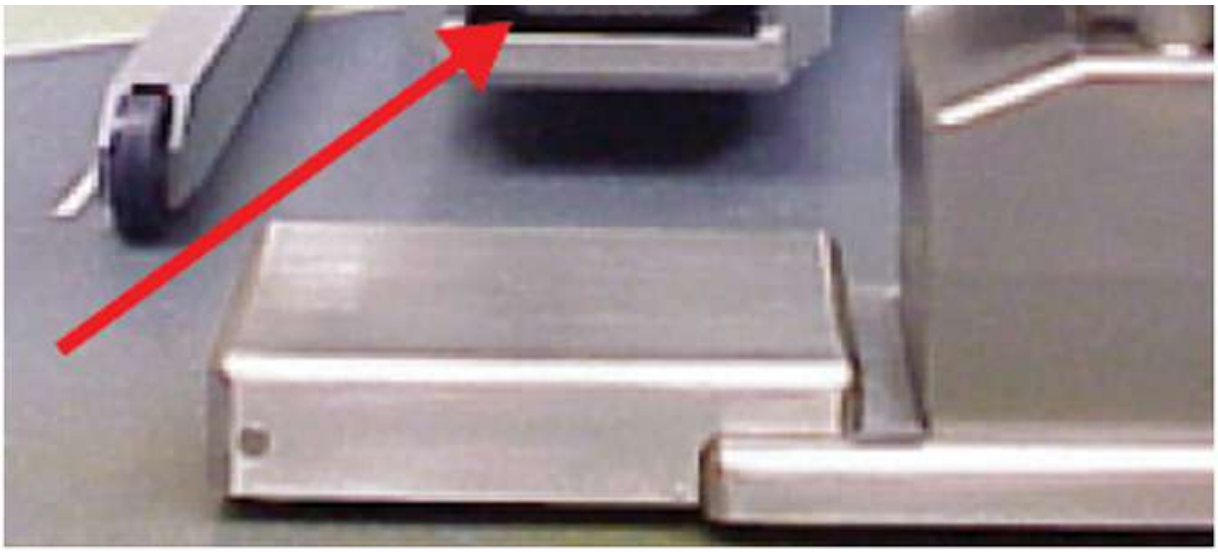

FIGURE 9.25 Intraoperative electron radiation therapy accelerator. View of the Mobetron self-shielded mobile intraoperative radiation therapy unit by IntraOp Medical Corporation. (From Beddar AS, Biggs PJ, Chang S, et al. Intraoperative radiation therapy using mobile electron linear accelerators: report of AAPM Radiation Therapy Committee Task Group No. 72. *Med Phys*. 2006;33[5]:1476-1489.)

Treatment planning for intracavitary cones is typically done manually because it is not possible to CT scan the patient in the treatment position or under operating room conditions. The electron energy and cone size are selected to match measured isodose distributions to the dimensions of the clinical target volume. Examples of dose distributions for intraoperative applicators are shown in Figure 9.26.[101] These examples show two characteristics of such applicators. First, for the larger diameter applicators, scattering off the wall of the applicator can lead to hot spots near the applicator's periphery. Second, ends of the applicator are often beveled to make it easy to establish contact when the anatomic plane is not perpendicular to the direction of approach (ie, the central axis of the beam). Note how the depth of the 90% isodose contour beneath the surface decreases from 3.6 cm at 0° incidence to 3.0 cm at 30° incidence, as a result of the effects described earlier.

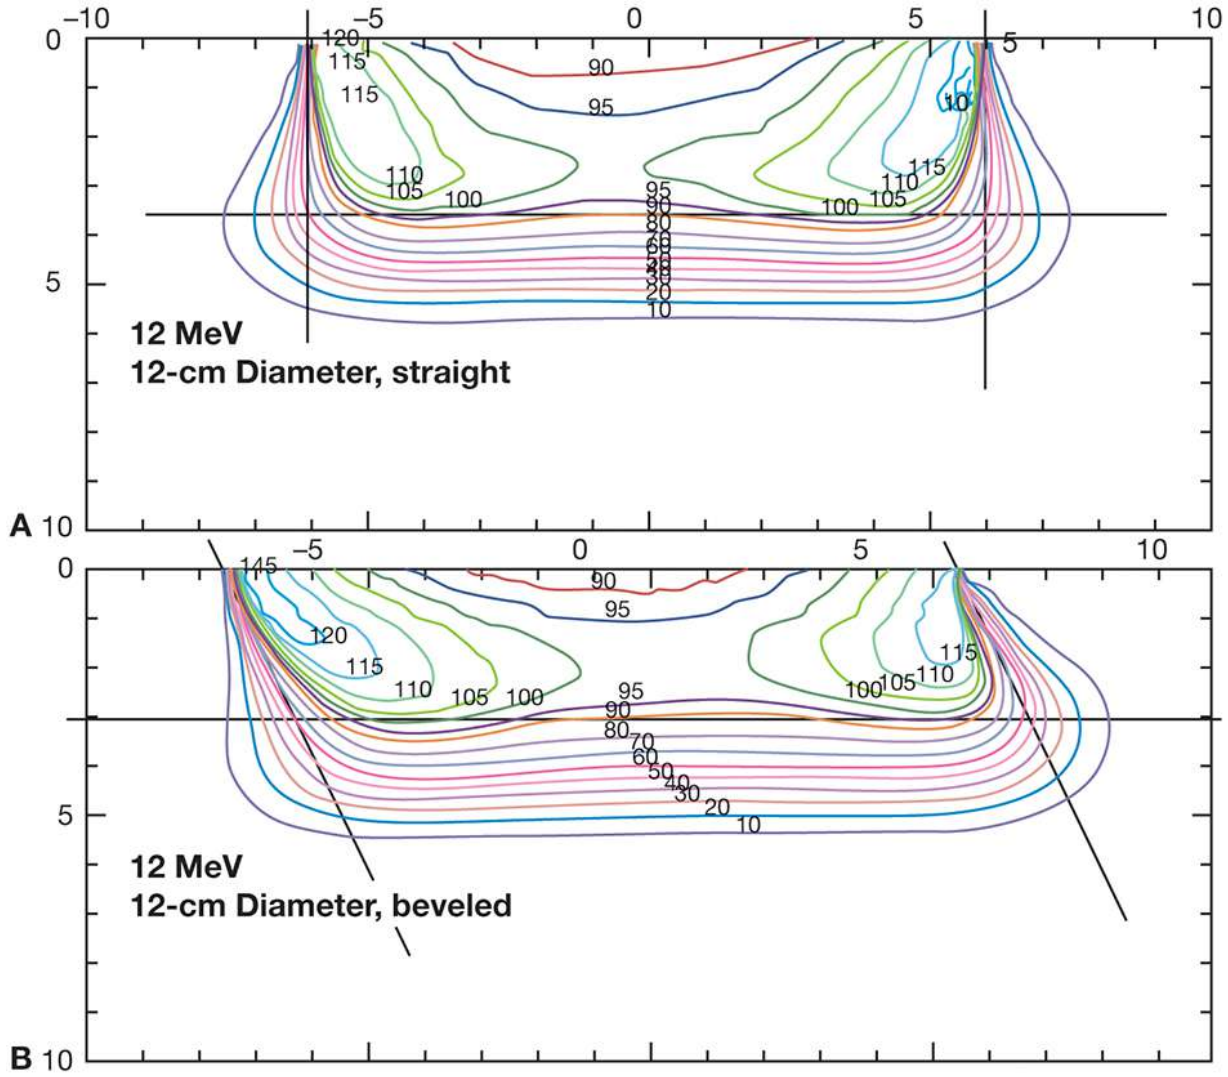

FIGURE 9.26 Isodose plots illustrating typical intraoperative dose distributions at 12 MeV. A. 12-cm diameter cone, normal incidence. B. 30° beveled, 12-cm diameter cone. Note the decreased depth of the 90% dose beneath the surface for the beam 30° from normal incidence relative to that for normal incidence. (Reprinted from Nyerick CE, Ochran TG, Boyer AL, Hogstrom KR. Dosimetry characteristics of metallic cones for intraoperative radiotherapy. *Int J Radiat Oncol Biol Phys*. 1991;21[2]:501-510. Copyright © 1991 Elsevier. With permission.)

Total Scalp Irradiation

Total scalp irradiation is sometimes necessary in the management of malignancies (eg, cutaneous lymphoma, melanoma, and angiosarcoma) that present with widespread involvement of the scalp and forehead.[2,15] Electron-beam therapy is a practical means of achieving the therapeutic goal of delivering a uniform dose to the scalp with minimal dose to underlying

brain. For many years, total scalp irradiation was achieved by patching multiple electron fields.[2,102] Although effective, the treatment was tedious as a result of the large number of fields, their requirement for skin collimation, and the need to move the abutment border to improve dose homogeneity.[102] Akazawa[103] from the University of California-San Francisco reported a simpler technique that abuts lateral electron fields to parallel-opposed photon fields, the latter of which treats the rind of the scalp while avoiding brain tissue. Tung et al[15] modified the abutment scheme to account for beam divergence and demonstrated improved dose uniformity by comparing 3D dose calculations with in vivo dose measurements. Figure 9.27 illustrates the abutment scheme. The outer edge of the electron field overlaps the inner edge of the 6-MV x-ray field by 3 mm to account for the divergence of the contralateral 6-MV x-ray field. Because the electron and x-ray penumbras are not matched, their common border is moved 1 cm toward the beam center halfway through treatment to improve dose homogeneity. Figure 9.28 shows the dose distribution in a transverse CT plane, which illustrates the dose homogeneity achieved in the region of abutment and the sparing of brain tissue. Initially, the common border is set at approximately 0.5 cm inside the inner table of the skull. Moving the common border farther toward the inner table of the skull reduces brain irradiation at the expense of the x-ray beam being replaced by an electron beam that would begin to graze the skull. As discussed earlier, grazing radiation penetrates less deeply, possibly underdosing the scalp in this region. Also noticeable in Figure 9.28 is a 6-mm-thick wax bolus, which increases the surface dose for both the electron and x-ray fields. Although this technique is straightforward to plan and implement, there is a concern of hot spots along the midline superior brain tissue along the plane.

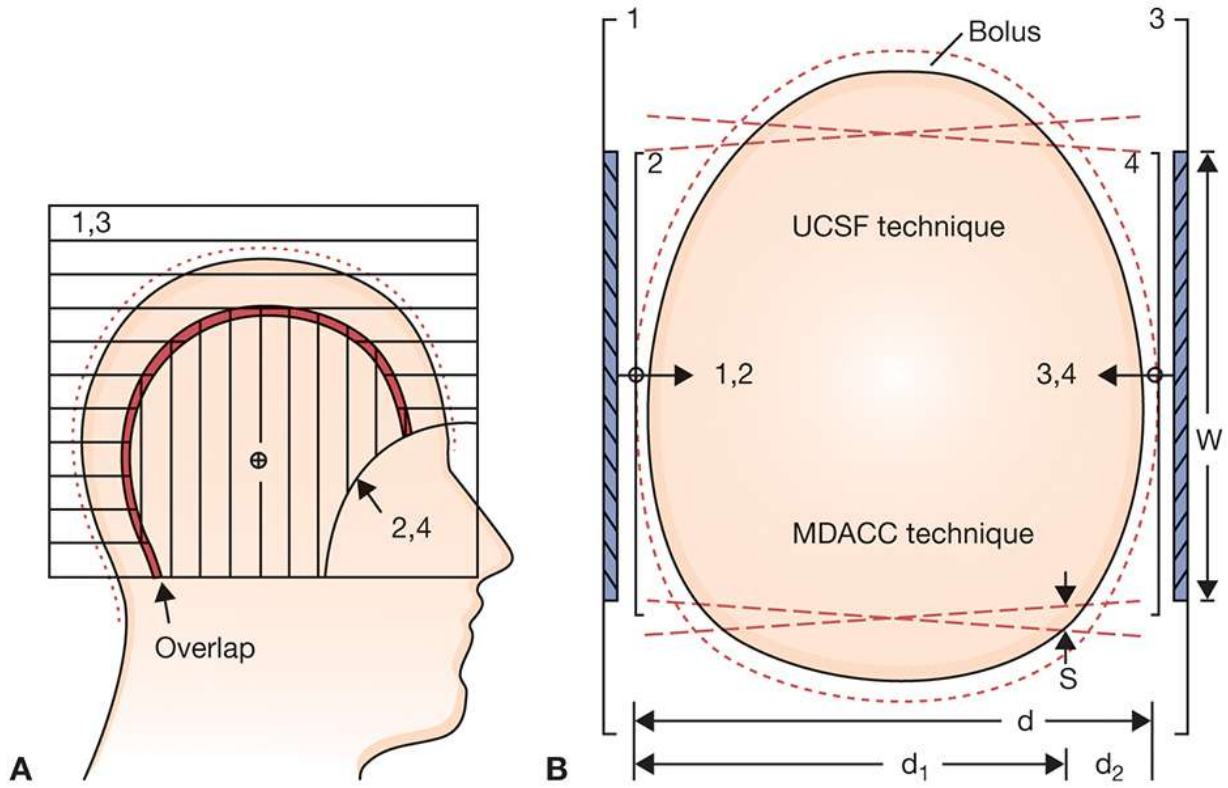

FIGURE 9.27 Abutment scheme for total scalp irradiation (x-ray fields, 1, 3; electron fields, 2, 4). A. The electron field edge, placed just inside the skull, overlaps the edge of the ipsilateral x-ray field by approximately 3 mm to account for divergence of the edge of the contralateral x-ray field. Halfway through treatment, the field edges are moved 1 cm to improve dose homogeneity in the region of abutment. B. The need for the 3-mm overlap (MD Anderson Cancer Center [MDACC] technique) is better appreciated viewing the divergent edges of all fields in a transverse plane. Walker et al[104] described a six-field electron-beam technique for the treatment of mycosis fungoides of the scalp. This technique of overlapping beams was verified with thermoluminescent dosimetry measurements. The dose prescriptions were 20 and 30 Gy for the two patients in this study. Yaparpalvi et al[105] developed a technique for scalp irradiation that used a single posterior-superior field with concentric circles that varied in electron energy. This interesting technique was not confirmed with anthropomorphic phantom dosimetry studies. Peters[106] described the use of an electron reflector to improve dose uniformity to the scalp during total skin electron therapy.

Total Limb Irradiation

It may be advantageous to irradiate the superficial anatomy of a limb for the management of cancer (eg, melanoma, lymphoma, Kaposi sarcoma). If the depth beneath the surface is 2 cm or less, electrons offer a uniform dose while sparing deep tissues and structures. This technique has been described by Wooden et al[16] for the treatment of the lower calf of a patient with Kaposi sarcoma. Illustrated in Figure 9.29, six equally spaced 5-MeV electron beams are used to irradiate a 9-cm diameter cylinder. Each beam is sufficiently wide so that the entire circle falls within the uniform portion of each beam. Tangential radiation to the surface of the cylinder delivers a greater dose as a result of oblique incidence, which is partially offset by the inverse square effect. In addition, the tangential radiation penetrates less deeply. The utilization of six or more beams begins to simulate 360° arc therapy (which is not feasible because of collisions). The resulting dose distribution illustrates three interesting characteristics. First, the average maximum dose along each radius is approximately 2.5 times the given dose of each of the six fields. Second, 90% of the average maximum dose penetrates 8 to 10 mm, reduced from the value of 15 mm for a single-beam incident normally on a flat surface (Figure 9.30). Third, the surface dose has increased to 90% or greater of average maximum dose compared with approximately 70% of the given dose for a single-beam incident normally on a flat surface. This is the result of the self-bolusing effect of tangential electron radiation.

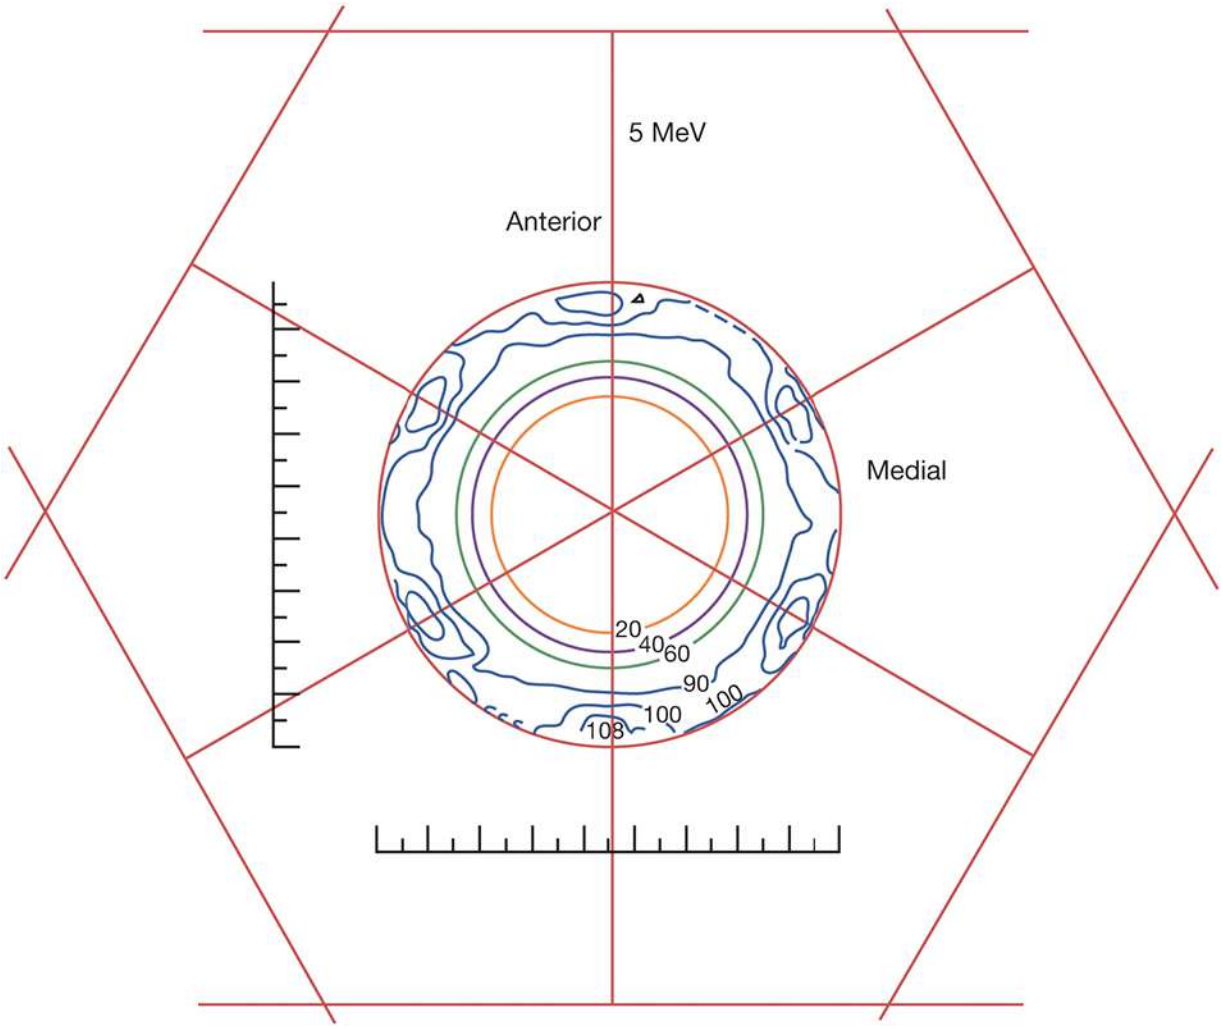

FIGURE 9.29 Dose distribution for total limb irradiation. Six equally spaced 17-cm wide 5-MeV electron beams are used to irradiate a 9-cm diameter cylinder. 100% equals 2.55 times the given dose from a single field. (Reprinted from Wooden KK, Hogstrom KR, Blum P, Gastorf RJ, Cox JD. Whole-limb irradiation of the lower calf using a six-field electron technique. *Med Dosim*. 1996;21[4]:211-218. Copyright © 1996 Elsevier. With permission.)

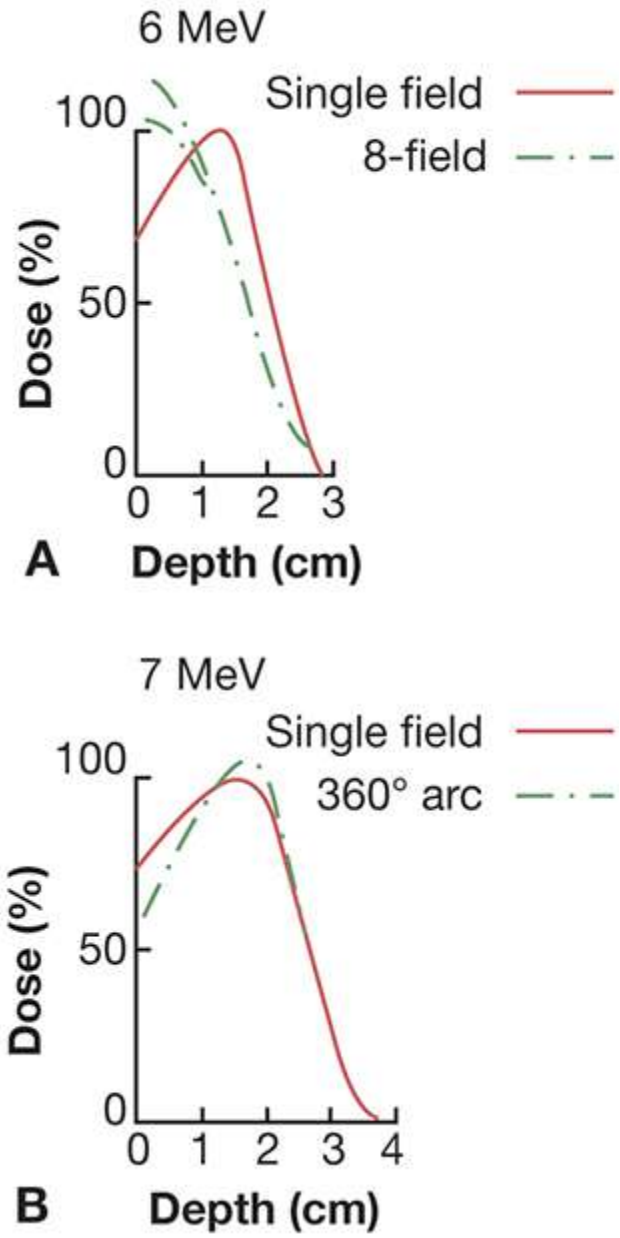

FIGURE 9.30 Treating circular anatomy with multiple beams spaced over 360°. Depth dose along a radial axis depends on the field width. A. Depth dose for a broad, 6-MeV beam, resulting from an eight-field technique around a 20-cm diameter water cylinder, is governed by grazing radiation, typical of total skin and total limb irradiation. B. Depth dose for a narrow, 7-MeV beam, resulting from rotating around a 20-cm diameter water cylinder, is governed by focusing of the radiation toward isocenter, typical of arc electron therapy.

The dosimetric characteristics should be carefully evaluated using one's treatment planning system.

Total Skin Irradiation

Total skin electron irradiation is a modality designed for the management of diseases that require irradiation of the entire skin surface or a significant portion of it. The technique is used most frequently for the treatment of mycosis fungoides, whose management is reviewed by Hoppe,[17] and Kaposi sarcoma.

Multiple techniques for total skin electron therapy have been reviewed in AAPM Report No. 23.[18] The underlying principles of the various techniques are similar, which are exemplified by the modified Stanford technique, illustrated in Figure 9.31. First, the treatment requires a broad beam from right to left, which can be achieved by a combination of treating the patient at an extended SSD (300-400 cm). The beam is made uniform from head to foot by abutting two fields at the 50% OAR (Figure 9.31A). (Note that the 50% OAR lies outside the edge of the light field; thus, when properly abutted, there is a gap between the edges of the respective light fields.) By aiming the beams up and down, the largest bremsstrahlung contribution (central axis) misses the patient. The dose is made uniform around the circumference of the patient by irradiating from six different directions (Figure 9.31B). Similar to total limb irradiation, tangential radiation results in a higher surface dose and a less penetrating dose. Placed upstream of the patient is a plastic screen that serves as both an energy degrader and a scatterer. Dose homogeneity depends on patient's position, and reproducing the positions of the Stanford technique (Figure 9.31C) is important. Despite efforts to create a homogeneous dose, there always will be areas that are underdosed (eg, top of scalp, sole of feet, perineum, and under the breast or under the panniculus of individuals who are obese). These areas and sometimes tumorous lesions require separate treatment and boosting, respectively. In contrast, fingers, feet, and toes typically receive excess dose and are shielded for a portion of the treatment. In vivo measurement of patient dose on an individual basis is important when making decisions on prescriptions for supplemental treatments.

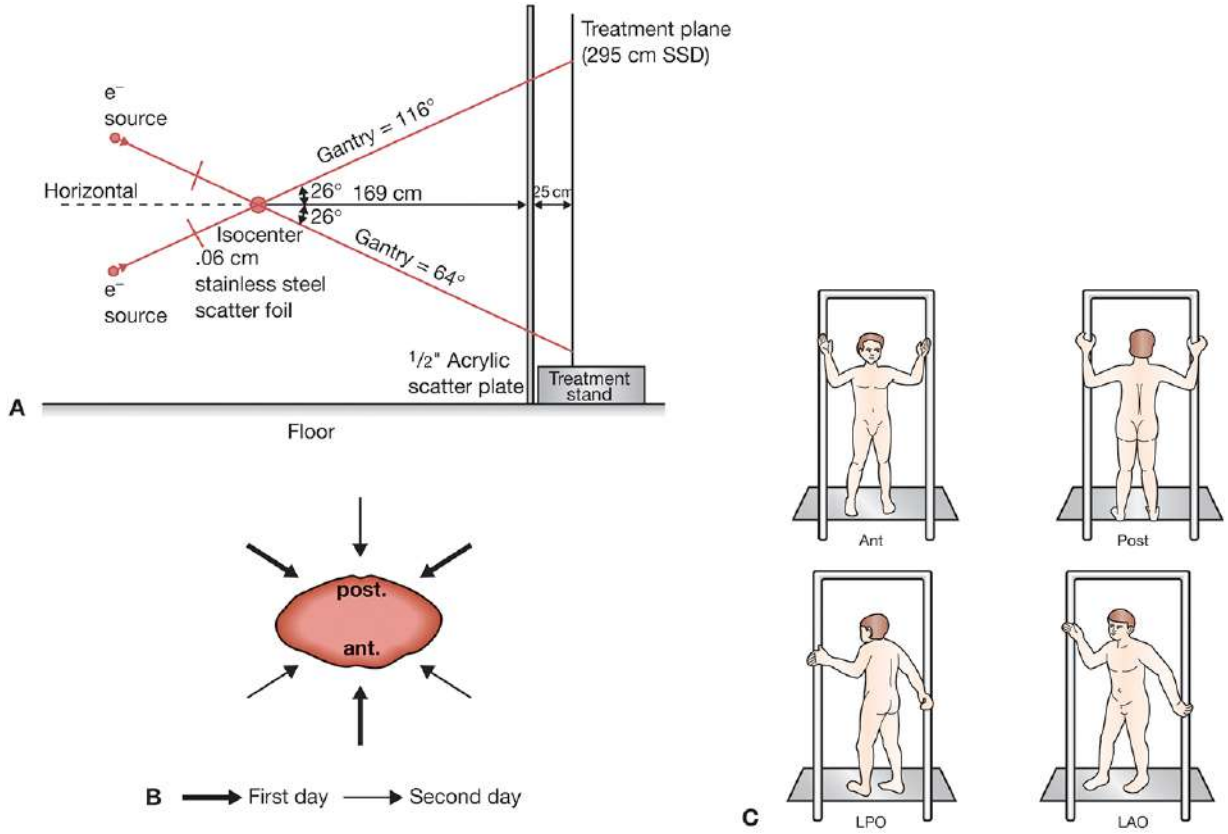

FIGURE 9.31 Schematic of modified Stanford technique for total skin irradiation. Side view of setup shows the relative position of patient plane, scatter plate, isocenter, and gantry angles (A). Six beam directions (B) are achieved by placing the patient in six patient positions (C). SSD, source-to-surface distance. (From Almond PR. Total skin electron irradiation technique and dosimetry. In: Kereiakes JG, Elson HR, Born CG, eds. *Radiation Oncology Physics 1986*. American Institute of Physics;1987:296-332; and Karzmark CJ, Anderson J, Fessenden P, et al. *AAPM Report No. 023—Total Skin Electron Therapy: Technique and Dosimetry*. American Institute of Physics; 1987. Reprinted with permission of American Association of Physicists in Medicine.)

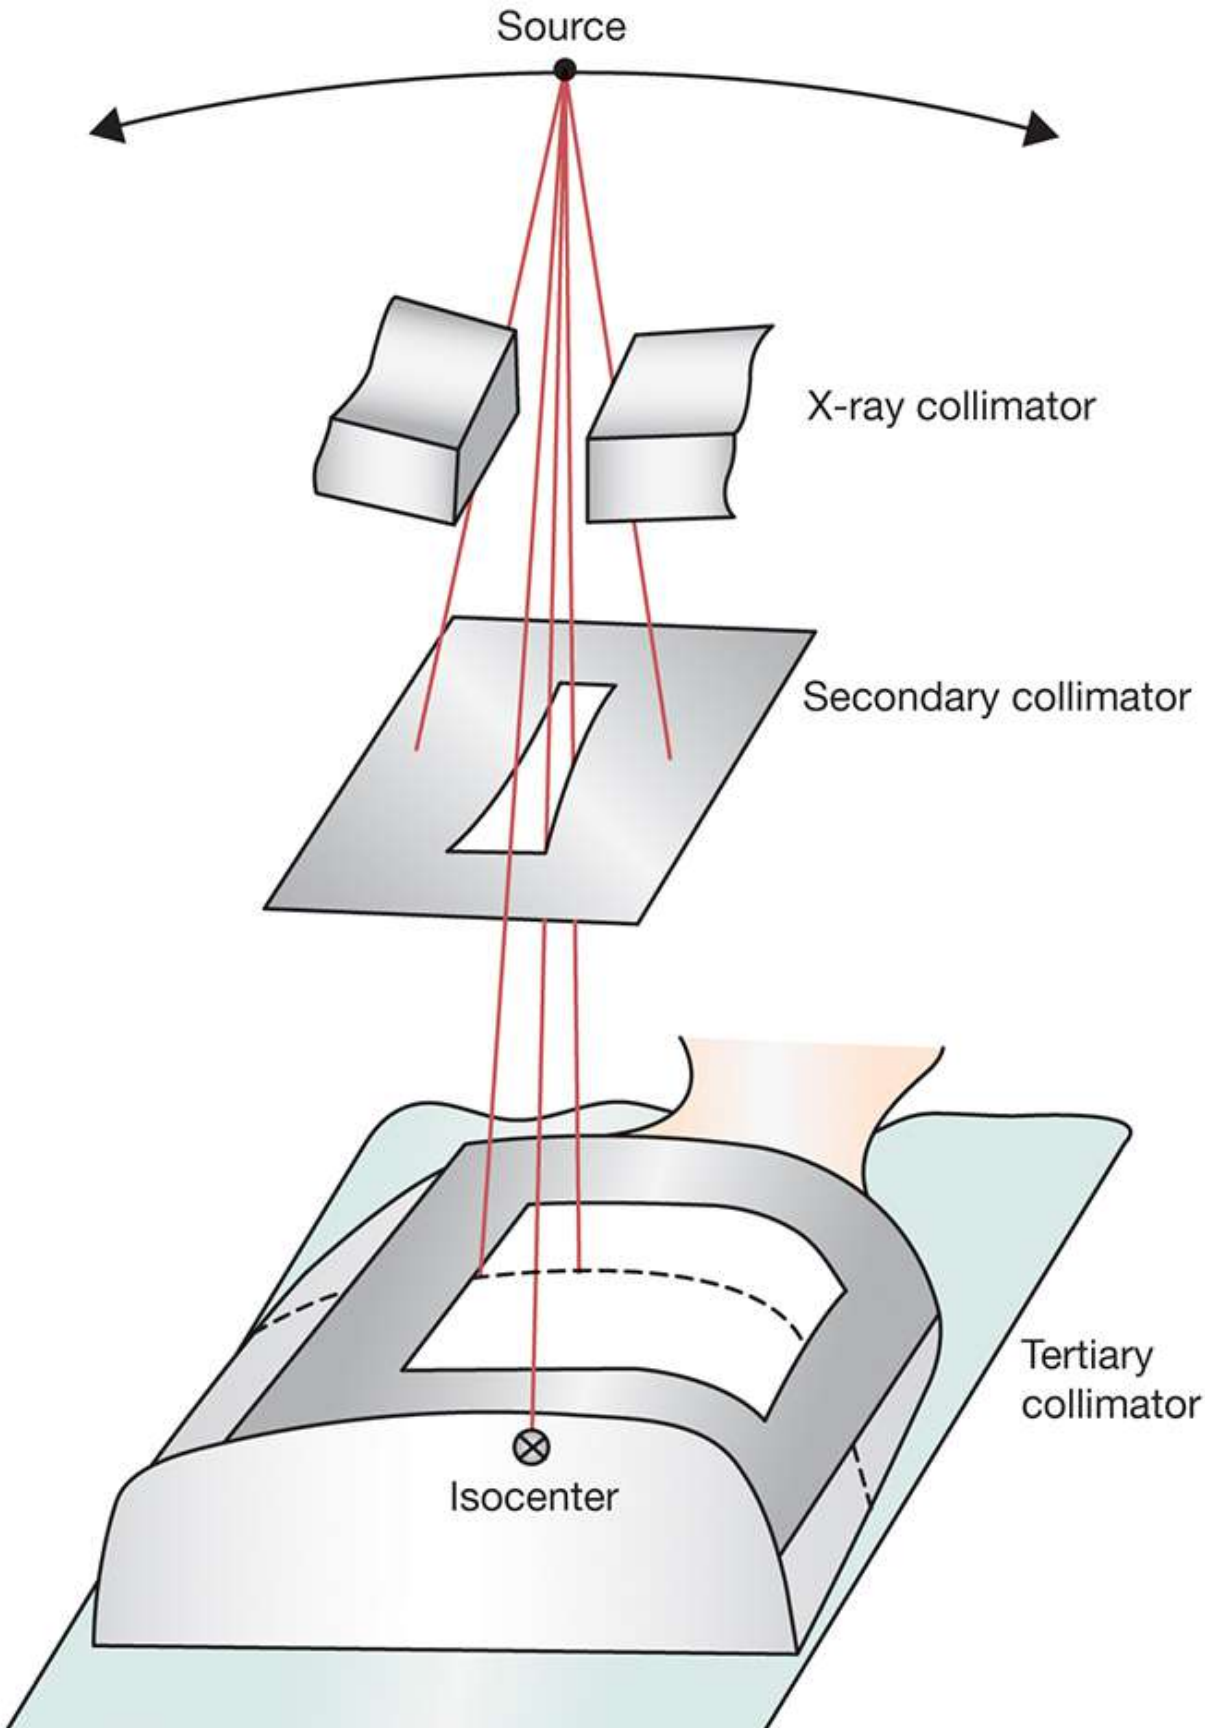
Implementation of this technique is complex. It requires an external patient stand with a plastic diffuser, special dosimetry equipment for quality assurance and calibration, special shields for selected parts of the patient, and access to in vivo dosimetry.[107] It is also necessary for the radiation therapy accelerator to have a high-dose rate mode and interlocks for electron energy, gantry angle, and x-ray jaws. Implementation of this technique has been estimated at 105 hours.[97] An institution must have a warranted patient population requiring this technique.

Electron Arc Therapy

Electron arc therapy is a useful technique for treating postmastectomy chest wall(s).[21] It is used in lieu of parallel-opposed tangential photon irradiation. It is more useful in "barrel-chested" women, where tangential beams can irradiate too much lung. It is also difficult to achieve homogeneous dose in the region where the medial tangential beam used for the chest wall abuts the anterior beam used for the IMC. In such cases, treating both areas with only opposed tangent photon beams irradiates too much lung. In such cases, electron arc therapy is a viable option. This can be particularly important in patients with bilateral disease.

The treatment geometry and dosimetry for arc therapy are unique. There are three levels of collimation in electron arc therapy: the primary x-ray collimators, a shaped secondary Cerrobend insert, and skin collimation (Figure 9.32). The secondary collimator typically projects a 5- to 6-cm beam width at isocenter. There is typically a large air gap between the secondary collimating insert and the patient, resulting in a large penumbra; in addition, the finite width of the field results in a broad edge at the end of the arc. The sharpness of the penumbra is restored utilizing skin collimation. This requires that the edge of the field of the secondary collimator extends well beyond the edge of the field defined by skin collimation. In the plane of rotation, this is achieved by rotating approximately 15° beyond the treatment field edge (Figure 9.33).



Source
X-ray collimator
Secondary collimator
Tertiary collimator
Isocenter

FIGURE 9.32 Schematic of treatment geometry for electron arc therapy. Skin collimation is required because of the large air gap between secondary collimator and patient, which is needed to allow rotation of the gantry around the patient.

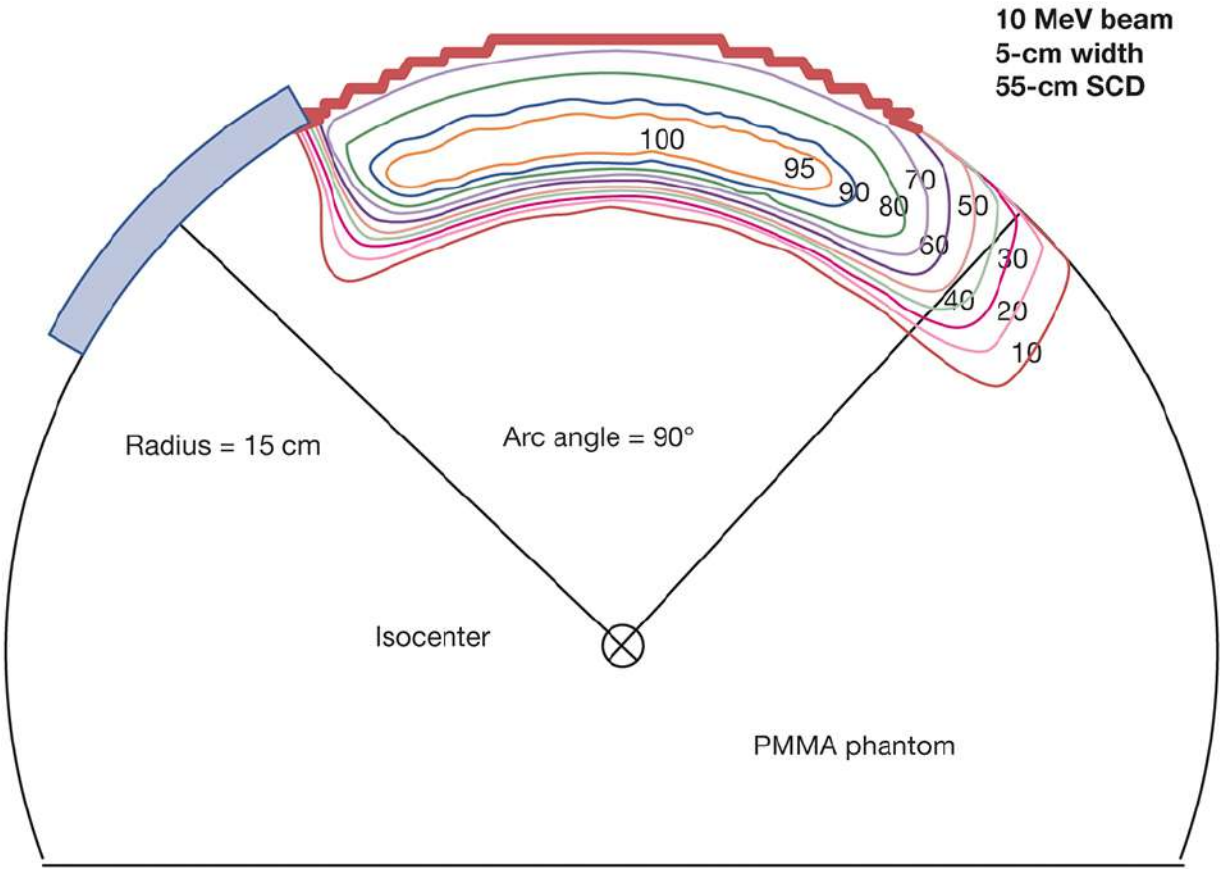


FIGURE 9.33 Comparison of dose distribution with and without skin collimation. The uncollimated edge has a slow dose falloff that is useful for abutting to other arced fields. The skin collimation restores the beam edge but requires rotating the beam 15° beyond the edge of the skin collimator. SSD, source-to-surface distance.

As discussed previously, the depth dose for an arced beam differs from that for a fixed beam (see Figure 9.24B); the surface dose is significantly less, and the dose falloff becomes slightly sharper. Consequently, bolus may be required to deliver adequate dose superficially. Another consequence of beam arcing is that a constant width of the secondary collimator results in dose inhomogeneity in the cephalocaudal direction. The radius of curvature of the patient with respect to the accelerator isocentric axis is typically less

superiorly, as the neck is approached. If the radius of curvature is less, then the skin is farther from the electron source (ie, a greater SSD). Contrary to fixed-beam therapy, the dose to that region increases rather than decreases as a result of focusing of the electron fluence toward isocenter. However, by reducing the collimator width, the dose can be made more uniform.

The treatment planning process for arc therapy requires patient CT scanning, delineation of PTV, selection of isocenter location, specification of electron arc boundaries, energy and slab bolus selection, design of secondary collimator, and calculation of dose and monitor units. Figure 9.34 shows a typical dose distribution that can be achieved using arc therapy for irradiation MERT of the IMC and chest wall. Physics commissioning to initiate this procedure is on the order of 4 to 6 weeks.

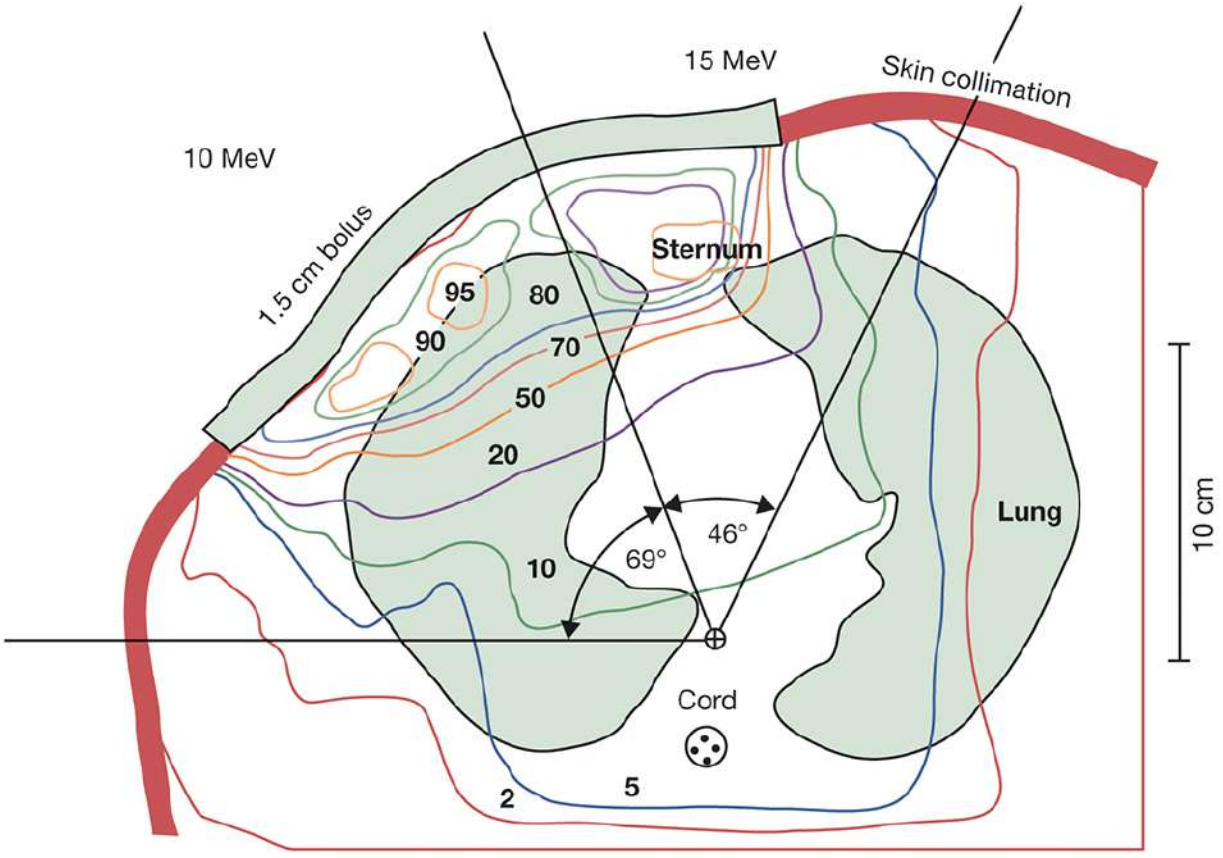

FIGURE 9.34 Typical dose distribution achieved by arc electron therapy. Note the different energies used for the internal mammary chain (IMC) and chest wall fields, the exact abutment of the IMC and chest wall fields, the rotation 15° beyond the skin edges of the skin collimator, and the use of bolus to increase the surface dose. (From Hogstrom KR, Kurup RG, Shiu AS, Starkschall G. A two-dimensional pencil-beam algorithm for calculation of arc electron dose distributions. *Phys Med Biol*. 1989;34[3]:315-341. Copyright © Institute of Physics and Engineering in Medicine. Reproduced by permission of IOP Publishing. All rights reserved.)

Electron radiotherapy has not advanced beyond conventional therapy because of the labor-intensive (cutouts and bolus) tasks to shape and modulate beams, limited conformity in the depth direction, limited lateral conformity, no inverse planning, and no dynamic beam delivery. If these were overcome via an automated method, the conformation of dose distributions to shallow tumors might greatly improve—hence the advent of MERT. There is a definitive niche for MERT to complement a photon IMRT program. MERT will be able to achieve lateral dose conformity by intensity modulation (such as photon IMRT) and dose conformity along the depth direction using energy modulation (unique to electron beams). In

addition, MERT may increase dose uniformity in the target both laterally and along the depth direction, reduce high or moderate concomitant dose to distal organs (eg, lung, heart, and contralateral breast for breast treatments), and improve skin coverage or sparing when combined with photon IMRT.[99,108]

Disease sites such as postmastectomy chest wall, mycosis fungoides or any cutaneous manifestation of lymphoma of the scalp, and so forth are likely best suited for modulated electrons, either with or without photons, or perhaps a combination of both. However, the inherent collimation systems in modern accelerators were optimized for megavoltage photons and are not conducive to electron-beam delivery (in lieu of extended applicators), nor do commercial treatment planning systems model electrons collimated without applicators.

As an example of targeted sites that would be improved with MERT, treatment to the chest wall stands out. Current techniques of using tangential photon adjunct fields abutting supraclavicular and posterior axillary fields are difficult enough without the addition of treating a separate medial breast internal mammary field with a mixture of photons and electrons. Although there has been extensive work to optimize these techniques,[109] there are shortcomings because of match-line problems and delivery of unacceptable doses to volumes of heart, lung, and contralateral breast. Clinical side effects include edema, fibrosis, heart disease, and pneumonitis. Delivery by tangential photon beams to the chest wall is also not ideal because of the heterogeneous dose delivered in the secondary electron buildup region of the breast. Bolus may be used; however, this unfortunately reduces skin sparing. Electron arc therapy was developed in the 1980s to address the limitations of tangential photon-beam treatments,[110] although it was extremely time-consuming to implement. The use of MERT will phase out electron arcs.

Many centers have used photon IMRT to improve dose conformity; however, the fundamental limitations because of megavoltage photon beams, such as excess distal dose and the buildup dose, are still challenges. MERT has been proposed as an alternative, particularly for postmastectomy patients.[8,63] The principal advantage is the rapid distal dose falloff. In principle, electron beams are well suited for these shallow targets, as they will spare distal regions, such as lung and heart.

Optimization is another important aspect for an MERT program. Many people have come up with inverse planning techniques for photons and even more recently for electrons. Al-Yahya et al[111] came up with a method of optimizing electron-beam planning for a few leaf-electron collimator (FLEC). Planning was performed via Monte Carlo calculations and optimization using simulated annealing—a powerful mathematical tool that is the basis for inverse planning. The FLEC system consists of four motor-driven trimmer bars at the end of an applicator that creates rectangular shapes. The report claims potential treatment times of 15 minutes or less. Very comprehensive work by Lee et al[69] described a Monte Carlo optimization scheme for modulated electron-beam radiotherapy based on a stop-and-shoot technique. One of the most challenging things in both calculating and optimizing is the leaf scatter, where distributions could vary up to 20% depending on leaf positions. Lee et al[69] performed MLC planning accomplished by calculating composite distributions for electron beamlets as collimated by tertiary electron MLC. Scatter and leakage contributions were included in the final dose calculation. An inverse planning dose optimization engine designed weights for each beamlet. The particle generation and absorption within the MLC leaves created demanding calculations but were necessary for accurate organ at risk calculations. Therefore, modeling of leaf scatter and transmissions is vital for accurate dose calculations. It is key that a multiple source model be developed. Publications describing the use of photon MLCs to modulate electrons have promoted an effective method to reform conformal electron therapy.[112-114]

SUMMARY

Electron-beam therapy remains an important modality to the practice of radiation therapy. As discussed earlier, its effective use requires knowledge of the unique properties of electron-beam dose distributions, the impact of the patient on the dose distribution, and the basic principles for good practice. It requires access to and the proper use of comprehensive treatment planning and delivery tools. It also requires access to special techniques that offer unique treatment solutions for a limited number but broad range of patient conditions.

Electron therapy can be expected to become more sophisticated in the future as the enthusiasm for MERT grows. Advances in electron dose calculations, methods for electron-beam optimization, and availability of MLCs for electrons will enable the practice of combined intensity-modulated photon and energy-modulated electron therapy. This will advance both electron conformal and mixed-beam therapy.

CHAPTER 10

Conformal and Intensity-Modulated Radiation Therapy Physics: Treatment Planning and Techniques, and Clinical Applications

James A. Purdy, Geoffrey D. Hugo, and Hania A. Al-Hallaq

Modern anatomic imaging technologies, such as x-ray computed tomography (CT) and magnetic resonance imaging (MRI), provide a fully three-dimensional (3D) model of the anatomy of the patient with cancer, which is often complemented with functional imaging, such as positron emission tomography (PET) or magnetic resonance spectroscopy. Such advanced imaging allows the radiation oncologist to more accurately identify tumor volumes and their relationship with other critical normal organs. Powerful x-ray CT simulation and three-3D treatment planning systems (3DTPS) have now been commercially available since the early 1990s, and 3D conformal radiation therapy (3DCRT) has become the standard of practice for many years.[1-3]

Radiation treatment delivery technology continues to advance through increasing the precision of delivery both spatially and temporally in hopes of continuing to improve clinical outcomes. Recent examples of such technologic advancements include MRI-Linac technology[4] by Elekta (Stockholm, Sweden) and ViewRay (Oakwood Village, OH) as well as developments in proton beam delivery.[5] Specifically, efforts at improved precision rely on improving imaging localization and intrafractional patient monitoring, increasing delivery efficiency, and improving the quality of delivered dose distributions by better aligning the treatment plan with the anatomy of the day through adaptive techniques. Efforts are also being made to reduce the cost of the equipment and simplify use, thus improving global access to modern-day radiotherapy. 3DCRT treatment plans generally use an increased number of radiation beams that are shaped to conform to the target volume. To improve the conformality of the dose

distribution, conventional beam modifiers (eg, wedges, partial transmission blocks, and/or compensating filters) are sometimes used. This *forward planning* approach used for 3DCRT (Figure 10.1) has been supplemented by an *inverse planning* approach used for *intensity-modulated radiation therapy* (IMRT) (Figure 10.2), which can achieve even greater conformity by optimally modulating the individual beamlets that make up the radiation beams.[6,7] IMRT dose distributions can be created to conform much more closely to the target volume, particularly for those volumes having complex/concave shapes, and also shaped to avoid critical normal tissues in the irradiated volume. This increased conformality results in IMRT treatments being much more sensitive to geometric uncertainties than the two-dimensional (2D) or forward-planned 3DCRT approaches and has spurred the development of treatment machines integrated with advanced volumetric imaging capabilities.[2,3,8-10] This has pushed the frontiers in 3DCRT practice from IMRT to what is now referred to as *image-guided radiation therapy* (IGRT).[2,3,11] Of course, the concept of image guidance is not revolutionary and really should be viewed as an evolutionary component in the development of 3DCRT. In the past, many systems and/or processes have been developed to help better localize the patient for treatment (and hence conform the dose), including dedicated x-ray simulators, megavoltage radiographic port films, electronic portal imaging devices (EPIDs), implanted radiopaque markers, ultrasound imaging systems, optical surface tracking systems, etc.[12,13] Even the early isocentric cobalt-60 teletherapy machines in the 1960s came equipped with a kilovolt x-ray tube attached to the beam stop.

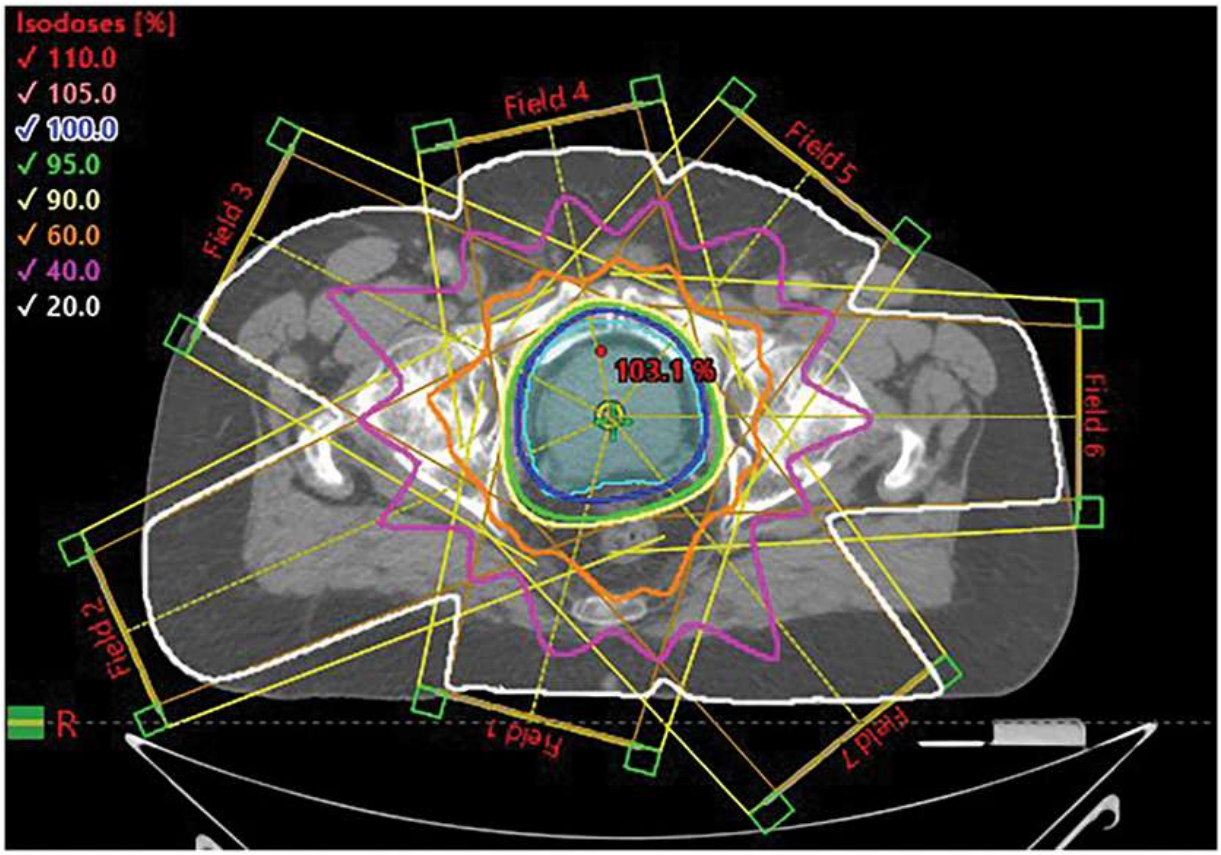

FIGURE 10.1 Three-dimensional conformal radiation therapy is considered a "forward planning" approach that uses an increased number of radiation beams shaped to conform to the target volume. To improve the conformality of the dose distribution, beam modifiers (eg, wedges, partial transmission blocks, and/or compensating filters) are sometimes used. Shown is a prostate seven-field coplanar beam arrangement.

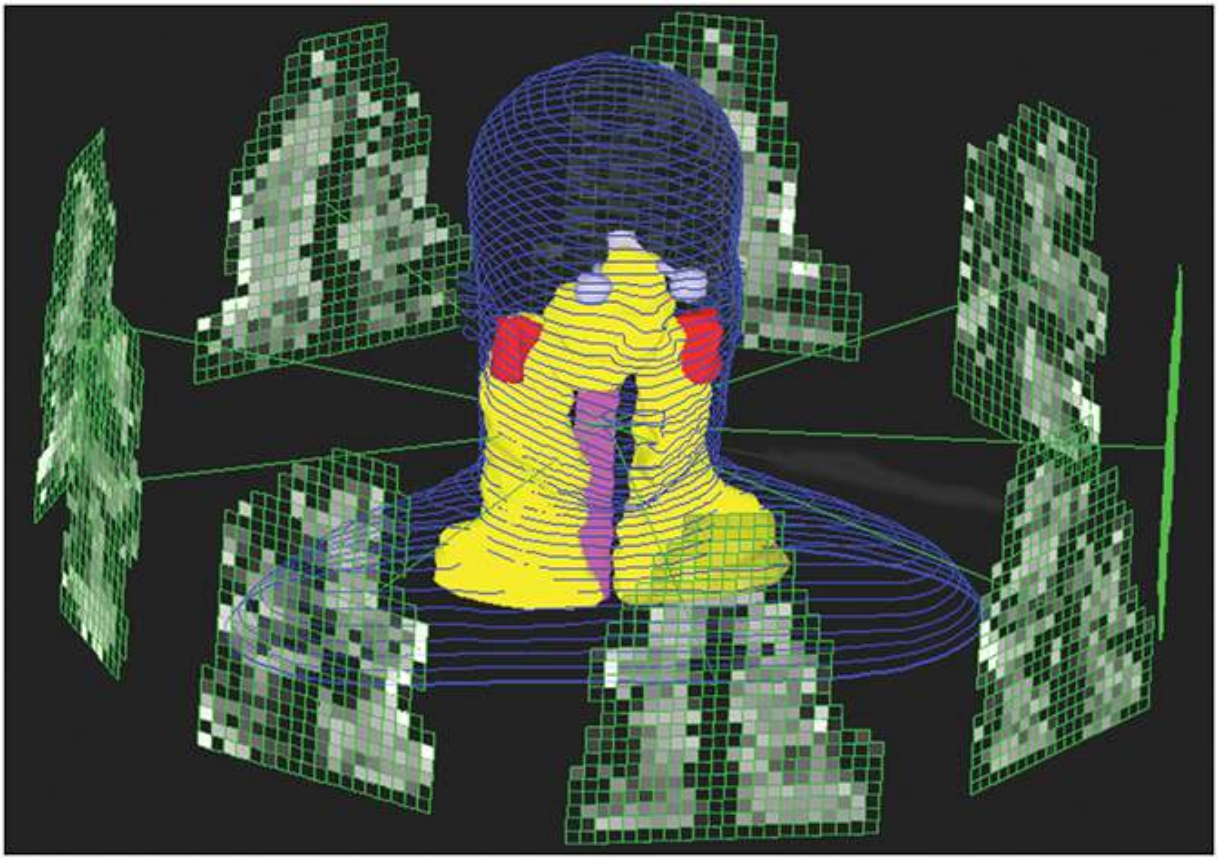

FIGURE 10.2 Intensity-modulated radiation therapy (IMRT) is considered an " inverse planning" conformal radiation therapy approach that can achieve even greater conformity than three-dimensional conformal radiation therapy by optimally modulating the individual beamlets that make up the radiation beams. IMRT dose distributions can be created to conform much more closely to the target volume, particularly for those volumes having complex/concave shapes, and also shaped to avoid critical normal tissues in the irradiated volume.

This chapter will review the critical components that make up the 3DCRT planning and delivery process. The reader should understand that the use of the terms *two-dimensional*, *three-dimensional*, and even *four-dimensional* (4D)[14] as descriptors for the 3DCRT planning and delivery process refers to a process and the various tools used and not merely to beam arrangements. For example, 3D treatment planning certainly does not require the use of "noncoplanar" beams, but does require the ability to plan and visualize volumetric dose distributions for such beam arrangements. Even today, newer tools are being developed that allow 4D, image-based 3DCRT planning, that is, target volume segmentation and dose calculation in the presence of moving organs and target volumes. Hence, the reader will

be able to appreciate the 3DCRT approach much more fully if it is viewed as a constantly evolving planning and treatment delivery workflow process using ever-advancing computer software and technology.

HISTORICAL DEVELOPMENT OF CONFORMAL RADIATION THERAPY AND THREE-DIMENSIONAL TREATMENT PLANNING SYSTEMS

Conformational treatment methods were pioneered in the 1950s and 1960s by several groups, including Takahashi[15] in Japan; Proimos[16] and Trump et al[17] in the United States; and Green et al[18] in Great Britain. Work continued into the 1970s, when several groups actually implemented computer-controlled radiation therapy, including a project of the Joint Center for Radiation Therapy in Boston led by Bjarngard and Kijewski[19] and the Tracking Cobalt Project led by Davy and Brace[20] at the Royal Free Hospital in London.

Sterling et al[21,22] are credited with the first 3D approach to treatment planning (dose calculation and display). They demonstrated a technique by which a computer-generated film loop gave the illusion of a 3D view of the patient's relevant anatomic features and the calculated isodose distribution (2D color washes) throughout a treatment volume. However, this effort did not result in a practical 3DTPS and was viewed as simply a demonstration project. The Rhode Island Hospital/Brown University group made the first real step in implementing a clinically usable 3DTPS based on a new type of display, called beam's eye view (BEV), which simulated the treatment planner's viewing point from the perspective of the radiation source looking out along the axis of the radiation beam, similar to that obtained when viewing a simulation radiograph.[23,24]

The advent of CT spurred further development of 3D planning systems. In 1983, Goitein and coworkers[25,26] reported on their system, which took advantage of CT and increased minicomputer capabilities. The system produced high-quality color BEV displays and could display radiographic images computed from the digital CT data; such computed radiographs are now called digitally reconstructed radiographs (DRRs). By the latter half of the 1980s, several other academic groups had developed 3D planning systems having powerful new features.[27-30]

One of the keys to this development was a series of research contracts funded by the National Cancer Institute (NCI) in the 1980s and 1990s to evaluate the potential of 3D planning and to make recommendations to the NCI for future research in this area.[31] Each of the research contracts funded a collaborative working group (CWG). The participating institutions in each CWG are shown in Table 10.1. Their charge was to evaluate various aspects of this new planning process and develop new software tools needed. The CWGs were composed of physicists, clinicians, and computer scientists. Many important developments and/or refinements in 3D planning came from these NCI research CWGs, particularly planning evaluation software tools such as *dose-volume histograms* (DVHs),[32,33] *electronic view box*,[34] and biologic effect models such as *tumor control probability* (TCP) and *normal tissue complication probability* (NTCP) models.[35] Even IMRT has benefited from the CWG approach, as a consensus statement was developed in 2001 that helped clarify many issues and pointed to important research areas regarding that form of 3DCRT.[36]

VOLUME SPECIFICATION FOR CONFORMAL RADIATION THERAPY

The International Commission on Radiation Units and Measurements (ICRU) first addressed the issue of consistent volume and dose specification in radiation therapy with the publication of ICRU Report 29 in 1978.[37] That report defined the *target volume* as *the volume containing those tissues that are to be irradiated to a specified absorbed dose according to a specified time-dose pattern* (Figure 10.3A). It is interesting to note that this report (even though published in the 2D era) attempted to address spatial uncertainties by pointing out that the size and shape of a target volume may change during the course of a treatment and that one should take into account the following parameters when describing the target volume:

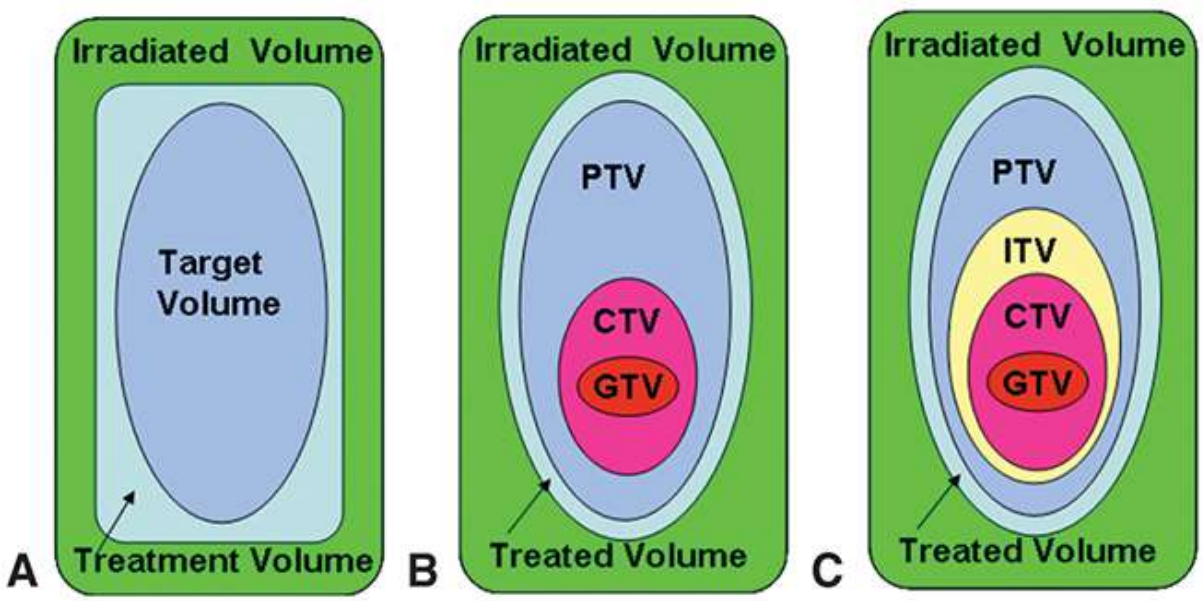

FIGURE 10.3 A. Schematic illustration of the boundaries of the volumes defined by International Commission on Radiation Units and Measures (ICRU) Report 29: target volume, treatment volume, and irradiated volume. B. Boundaries of the volumes defined by ICRU Report 50: gross tumor volume (GTV), clinical target volume (CTV), planning target volume (PTV), treated volume, and irradiated volume. C. Boundaries of the volumes defined by ICRU Report 62: GTV, CTV, internal target volume (ITV), PTV, treated volume, and irradiated volume.

- Expected movements (eg, caused by breathing) of those tissues that contain the target volume relative to anatomic reference points (eg, skin markings, suprasternal notch)
- Expected variation in shape and size of the target volume during the course of treatment (eg, urinary bladder, stomach)
- Inaccuracies or variations in treatment setup during the course of treatment

In addition to the target volume, ICRU Report 29 defined two other volumes: the *treatment volume* and the *irradiated volume*. These volumes were not based on anatomy, but instead were based on the dose distribution. The treatment volume was defined as *the volume enclosed by the isodose surface representing the minimal target dose*, and the irradiated volume was defined as *the volume that receives a dose considered significant in relation to normal tissue tolerance* (eg, 50% isodose surface).

Report 29 defined *organs at risk* (OARs) as *especially radiosensitive organs in or near the target volume whose presence influences treatment planning and/or prescribed dose*. The report also recognized the importance of tissues outside the target area that received a dose higher than 100% of the specified target dose. This was defined as a *hot spot* and was considered clinically meaningful only if the corresponding isodose curve enclosed an area of at least 2 cm^2 in a section.

In 1993, the ICRU updated its recommendations for specifying dose/volume in Report 50, which were well suited for conformal therapy.[38] The target volume definition was separated into three distinct volumes: (1) visible tumor, that is, *gross tumor volume* (GTV); (2) a volume to account for uncertainties in microscopic tumor spread, that is, *clinical target volume* (CTV); and (3) a volume to account for geometric and other uncertainties, that is, *planning target volume* (PTV), as illustrated in Figure 10.3B.

GTV and CTV are anatomic-clinical concepts that should be defined before a choice of treatment modality and technique is made. Labels or subscripts with the GTV nomenclature can be used to distinguish between primary disease and other areas of macroscopic tumor involvement such as involved lymph nodes that are visible on imaging studies (eg, $GTV_{primary}$ and GTV_{nodal}, or GTV-T and GTV-N). Similarly, the GTV together with this surrounding volume of local subclinical involvement that defines the CTV can be denoted as CTV-T. Note that even if the GTV has been removed by radical surgery, the volume can be designated as CTV-T. In specifying the CTV, the physician must consider not only microextensions of the disease near the GTV but also the natural avenues of spread for the particular disease and site, including lymph node, perivascular, and perineural extensions. These may be designated CTV-N (and, if necessary, CTV-N1, CTV-N2, etc).

The *PTV* is defined by specifying the margins that must be added around the CTV to manage the effects of organ, tumor and patient movements, inaccuracies in beam and patient setup, and any other uncertainties. The PTV is a static, geometric concept used for treatment planning and for specification of dose. Its size and shape depend primarily on that of the GTV/CTV and the effects caused by internal motions of organs and the tumor and technical aspects of treatment technique (eg, patient fixation).

The PTV can be considered a 3D envelope in which the tumor and any microscopic extensions reside and move. Once the PTV is defined, appropriate beam sizes to account for penumbra and beam arrangements must be selected to ensure the desired dose coverage of the PTV. Note that multiple PTVs may be defined for a patient's radiation therapy treatment. For example, it is common practice to plan a higher dose to the PTV enclosing the GTV and a lower dose to the PTV containing the CTV. Such planning volumes are typically subscripted using the dose level prescribed; for example, PTVs for 66 and 54 Gy can be represented as PTV_{66} and PTV_{54}, respectively.

ICRU Report 50 essentially retained the definition of the two dose volumes present in ICRU Report 29, changing the treatment volume name to *treated volume* and refining the definition as *the volume enclosed by an isodose surface*, *selected and specified by the radiation oncologist as being appropriate to achieve the purpose of treatment* (eg, tumor eradication, palliation), and the irradiated volume as that *tissue volume that receives a dose that is considered significant in relation to normal tissue tolerance*.

Report 50 refined the definition of OARs as *normal tissues whose radiation sensitivity may significantly influence treatment planning and/or prescribed dose*. The report did state that any possible movement of the OAR during treatment, as well as uncertainties in the setup during the whole treatment course, must be considered, but did not provide a method to do so.

The hot spot definition was modified to be *a volume outside the PTV that received a dose larger than 100% of the specified PTV dose*. This was considered clinically meaningful only if the minimum diameter exceeded 15 mm (note: previously, it had been 2 cm^2). However, if the hot spot occurs in a small organ, such as the optic nerve, a dimension smaller than the recommended 15 mm should be considered.

While Report 50 was well suited to conformal therapy, irradiation techniques continued to evolve (eg, IMRT, IGRT), and advances in imaging procedures (eg, PET, MRI) provided even more information on functionality, the location; shape, and limits of tumor/target volumes; and OARs. In response to these developments, the ICRU in 1999 published Report 62,[39] which expanded on some of the definitions and concepts of

Report 50 and took into account the consequences of the technical and clinical progress referred to previously. However, it should be clearly understood that Report 62 is intended to complement the recommendations contained in Report 50 and not to replace it.

ICRU Report 62 refined the definition of PTV by introducing the concept of an *internal margin* to take into account variations in size, shape, and position of the CTV in reference to the patient's coordinate system using anatomic reference points, as well as the concept of a *setup margin* to take into account all uncertainties in patient beam positioning in reference to the treatment machine coordinate system. Identification of these two types of margins is needed, as they compensate for different types of uncertainties and refer to different coordinate systems. Internal margin uncertainties are due to physiologic variations (eg, filling of the rectum, movements because of respiration) and are difficult or almost impossible to directly control from a practical viewpoint. Setup margin uncertainties are related largely to technical factors that can be dealt with by more accurate setup and immobilization of the patient and improved mechanical stability of the machine. However, exactly how these margins should be combined is still not clear. This point will be discussed further in a later section, but for now, it is necessary to understand that the selection of an overall margin and delineation of the border of the PTV typically involve a compromise that requires the experience and judgment of the radiation oncologist and the treatment planning team.

ICRU Report 62 defines the volume formed by the CTV and the internal margin as the *internal target volume* (ITV) (Figure 10.3C). The ITV represents the movements of the CTV referenced to the patient coordinate system and is specified in relation to internal and external reference points, which preferably should be rigidly related to each other through bony structures. In cases not involving significant internal organ motion, the radiation oncologist can simply ignore having to explicitly define the ITV and use only the GTV, CTV, and PTV concepts. However, in cases involving significant motion, such as often is the case with lung cancer, the ITV concept has proven useful and should be used.[40]

ICRU Report 62 refined the definition of the two dose volumes defined by ICRU Report 50 as follows:

> The treated volume is the tissue volume that (according to the approved treatment plan) is planned to receive at least a dose selected and specified by radiation oncology team as being appropriate to achieve the purpose of the treatment, e.g., tumor eradication or palliation, within the bounds of acceptable complications.

The irradiated volume is the *tissue volume that receives a dose that is considered significant in relation to normal tissue tolerance*.

Report 62 refined the definition of OARs as *normal tissues* (*eg, spinal cord) whose radiation sensitivity may significantly influence treatment planning and/or prescribed dose*. The report also included a discussion regarding a system of classifying OARs as "serial," "parallel," or "serial-parallel." Report 62 also addressed what was perhaps the most criticized limitation of Report 50, which was that it did not provide a method to account for OAR movements and changes in shape and/or size, as well as setup uncertainties. To account for such spatial uncertainties, Report 62 introduced the concept of the *planning organ at risk volume* (PRV), in which a margin is added around the OAR to compensate for that organ's geometric uncertainties. The PRV margin around the OAR is analogous to the PTV margin around the CTV. The introduction of the PRV concept is timely, as its use is even more important for those conformal therapy cases involving IMRT because of the increased sensitivity of this type of treatment to geometric uncertainties. For example, it is common practice to add a 0.5-cm rind around the spinal cord contour. Note that the PTV and the PRV may overlap, and often do so, which implies searching for a compromise in weighing the importance of each in the planning process. A summary of the ICRU volume nomenclature recommendations per report is presented in Table 10.2.

TABLE 10.2 SUMMARY OF THE INTERNATIONAL COMMISSION ON RADIATION UNITS AND MEASUREMENTS (ICRU) NOMENCLATURE FOR VOLUMES (1970S TO PRESENT)

ICRU Report 29: 1970s-1993	ICRU Report 50: 1993-Present	ICRU Report 62: 1999-Present	ICRU Report 83: 2010-Present
Target volume	GTV	GTV	GTV
	CTV	CTV	CTV

ICRU Report 29: 1970s-1993	ICRU Report 50: 1993-Present	ICRU Report 62: 1999-Present	ICRU Report 83: 2010-Present
	PTV	ITV	ITV
		PTV	PTV
Treatment volume	Treated volume	Treated volume	Treated volume
Irradiated volume	Irradiated volume	Irradiated volume	Irradiated volume
Organ at risk	Organ at risk	Organ at risk	Organ at risk
		PRV	PRV
			RVR
Hot spot (area outside target that receives dose >100% of specified target dose; at least 2 cm^2 in a section)	Hot spot (volume outside PTV that receives dose >100% of specified PTV dose; >15 mm diameter)	Hot spot (volume outside PTV that receives dose >100% of specified PTV dose; 15 mm diameter)	High dose to RVR
Dose heterogeneity (no value given)	Dose heterogeneity (+7% to −5% of prescribed dose)	Dose heterogeneity (+7% to −5% of prescribed dose)	Not specified

CTV, clinical target volume; GTV, gross tumor volume; ITV, internal target volume; PRV, planning risk volume; PTV, planning target volume; RVR, remaining volume at risk.

CONFORMAL RADIATION THERAPY PLANNING PROCESS

As previously stated, 3DCRT treatment planning and delivery are best considered as a process along with the tools used. This process is summarized in Table 10.3 and includes the following tasks, which are discussed in the ensuing sections:

TABLE 10.3 CONFORMAL RADIATION THERAPY PROCESS

1. Patient treatment position, immobilization, and planning imaging
   a. Position patient in proposed treatment position.
   b. Fabricate immobilization devices.
   c. Place radiopaque markers, and mark repositioning lines on patient and immobilization devices.

d. Obtain topograms to check patient alignment.
e. Perform volumetric computed tomography (CT) scan of patient in treatment position.
f. Make illustrative photographs to assist in repositioning the patient at the treatment couch.
g. Transfer CT images to three-dimensional treatment planning system (3DTPS).
h. Perform imaging studies (eg, magnetic resonance imaging, positron emission tomography/CT, etc) as requested by the treating physician, and transfer image data to 3DTPS.

2. Delineation of tumor/target volumes and organs at risk
   a. Physician contours target volume(s).
   b. Physician or dosimetrist contours organs at risk.
3. Dose prescription
   a. Physician provides prescription dose for planning target volume (PTV) and dose-volume constraints for organs at risk.
   b. Forward planning (3D conformal radiation therapy)
      i. Set up initial beam configuration and design field shapes; wedges/bolus/no beam modifiers; beam weights.
      ii. Compute 3D dose matrix.
      iii. Compute treatment machine monitor units.
   c. Inverse planning (intensity-modulated radiation therapy [IMRT])
      i. Set up initial beam configuration.
      ii. Enter desired dose-volume constraints for PTV(s) and all regions of interest
      iii. Initiate treatment planning system optimization process, which generates beam fluences, resulting dose distribution, monitor units, and leaf motion files.
4. Plan evaluation and improvement
   a. Evaluate plan (dose-volume histograms, planar isodose display, 3D isodose display) and modify until plan is found to be acceptable by treating physician.
   b. Transfer patient's plan to patient's chart (electronic medical record) and treatment machine verify and record (R&V) system.
5. Plan implementation and treatment verification
   a. Physicist performs second check of treatment plan and transfer of data to R&V system.
   b. For IMRT plans, perform phantom dosimetric verification.
   c. Verify patient position and isocenter placement on treatment machine using orthogonal portal electronic portal imaging devices (EPIDs) vs digitally reconstructed radiograph (DRRs) or using onboard CT vs planning CT.
   d. For 3DCRT, check field shapes by comparing treatment field DRRs with treatment beam EPIDs.
   e. Capture treatment machine settings in R&V system.
   f. Check first-day treatment with in-vivo dosimeter measurements (as needed).

g. Perform periodic imaging verification checks during treatment (eg, orthogonal EPIDs/DRRs or beam EPIDs/DRRs, cone-beam CT/planning CT).

1. Establishing the patient's treatment position, constructing a patient repositioning immobilization device when needed, and obtaining a volumetric image data set of the patient in treatment position
2. Contouring target volumes and OARs using the volumetric planning image data set
3. Specifying a prescription dose for the PTV and dose- volume constraints for any OARs
4. For 3DCRT forward planning, determining beam orientation and designing beam apertures and computing a 3D dose distribution according to the dose prescription; or, for IMRT or volumetric modulated arc therapy (VMAT) inverse planning, setting up initial beam orientations (for IMRT) or arc trajectories (for VMAT) and entering optimization parameters (ie, dose-volume constraints for PTVs and all regions of interest) and initiating the TPS optimization process, which generates beam fluences, resulting dose distribution, monitor units (MUs), and leaf motion files
5. Evaluating the treatment plan and, if needed, modifying the plan (eg, beam orientations, apertures, beam weights, etc) until an acceptable plan is approved by the radiation oncologist
6. Implementing the approved plan on the treatment machine and verifying the patient's treatment using appropriate quality assurance (QA) procedures throughout the treatment

Patient Treatment Position and Immobilization and Planning of Imaging

In the initial part of the 3DCRT process (preplanning), the proposed treatment position of the patient is determined, and the immobilization device to be used during simulation/treatment is selected. It should be clearly understood that repositioning patients and accounting for internal organ movement for fractionated radiation therapy in order to accurately reproduce the planned dose distribution remain difficult technical aspects of the 3DCRT process. Errors may occur if patients are inadequately

immobilized, with resultant treatment fields inaccurately aligned from treatment to treatment (interfraction). In addition, patients and/or their tumor volume may also move during treatment (intrafraction) because of either inadequate immobilization or physiologic activity. Accounting for all of the uncertainties in the 3DCRT planning and delivery process remains a challenge for radiation oncology, and research and development is ongoing.

Determination of the treatment position of the patient and constructing the immobilization device are typically accomplished in a dedicated radiation therapy CT simulator facility. A radiation therapy CT simulator consists of a diagnostic-quality CT scanner, laser patient positioning/marking system, virtual simulation 3D treatment planning software, as well as various digital display systems for viewing the DRRs.[41,42] The CT scanner is used to acquire a volumetric planning CT scan of a patient in treatment position. The use of intravenous or other contrast to help delineate target volumes needs to be considered during simulation in some cases. CT topograms should be generated first and reviewed prior to acquiring the planning scan to ensure that patient alignment is correct, with adjustments to be made if needed. Radiopaque markers can be placed on the patient's skin and the immobilization device to serve as fiducial marks to assist in any coordinate transformation needed as a result of 3D planning and eventual plan implementation. An example of a typical immobilization repositioning system used for patients undergoing radiation therapy for head and neck cancer is shown in Figure 10.4. PET-CT simulators[43] are also used in a number of departments. The trend for replacement of CT simulators with PET-CT simulators was especially active in the 2000s. More recently, there is a trend for use of MR simulators in RT- and MR-only-based simulation, and treatment planning has been an active topic of research and development.[44,45]

FIGURE 10.4 Example of immobilization repositioning system used for patients undergoing radiation therapy for head and neck cancer. It should be clearly understood that being able to accurately reposition the patient and account for internal organ movement in order to accurately deliver the planned dose distribution is one of the most important steps in the conformal therapy process. (Courtesy of CQ Medical.)

Planning CT scan protocols are tumor site dependent and typically range from 2 to 5 mm in slice thickness and 50 to 200 slices. In general, a 3-mm slice thickness provides adequate-quality DRR. In some sites, such as those of head and neck cancer, slice thicknesses of 1 mm are often needed for delineation of very small volumes, such as the optic chiasm and the optic nerves. The same holds true for optimal reconstruction of the position of any implanted markers used, such as in prostate cancer radiation therapy.

The planning CT data set is typically transferred to a 3DTPS via a computer network. The planning CT data set provides an accurate geometric model of the patient, as well as the electron density information needed for the calculation of the 3D dose distribution that takes into account tissue heterogeneities.

Delineation of Tumor/Target Volumes and Organs at Risk

Delineation of tumor/target volume and OAR contours using the volumetric CT data set is typically performed by the radiation oncologist and the medical dosimetrist working as a team. The CT data are displayed at the 3DTPS or a specialized RT image processing workstation (Figure 10.5), and contours are drawn manually by the radiation oncologist/dosimetrist, most often using a computer mouse or stylus on a slice-by-slice basis. Some OARs with distinct boundaries (eg, skin, lung) can be contoured automatically or semi-automatically (eg, through interpolation of intermediate slices between manually contoured slices), with only minor editing required; others (eg, brachial plexus) require the hands-on effort of the radiation oncologist.[46] With modern 3DTPS image segmentation software, contouring generally takes 0.5 to 1 hour, depending on the disease site. However, for some complex sites, such as head and neck cancer, where many OARs and complex tumor/target volumes are the norm, this task can take several hours. Consensus guidelines for delineation of targets and OARs for various anatomic sites are often developed by a panel of experts, through national[47] and international[48] clinical trial organizations. Use of the most recent consensus guidelines aids in standardizing organ delineation and thereby improves overall treatment quality.[49] For reference, the National Research Group (NRG) has developed consensus contouring guidelines for many anatomic sites.[50] To prepare organ contours for use in big data applications including development of treatment planning models, TG-263 recommends an ontology for labeling contours that many clinics have begun to adopt.[51]

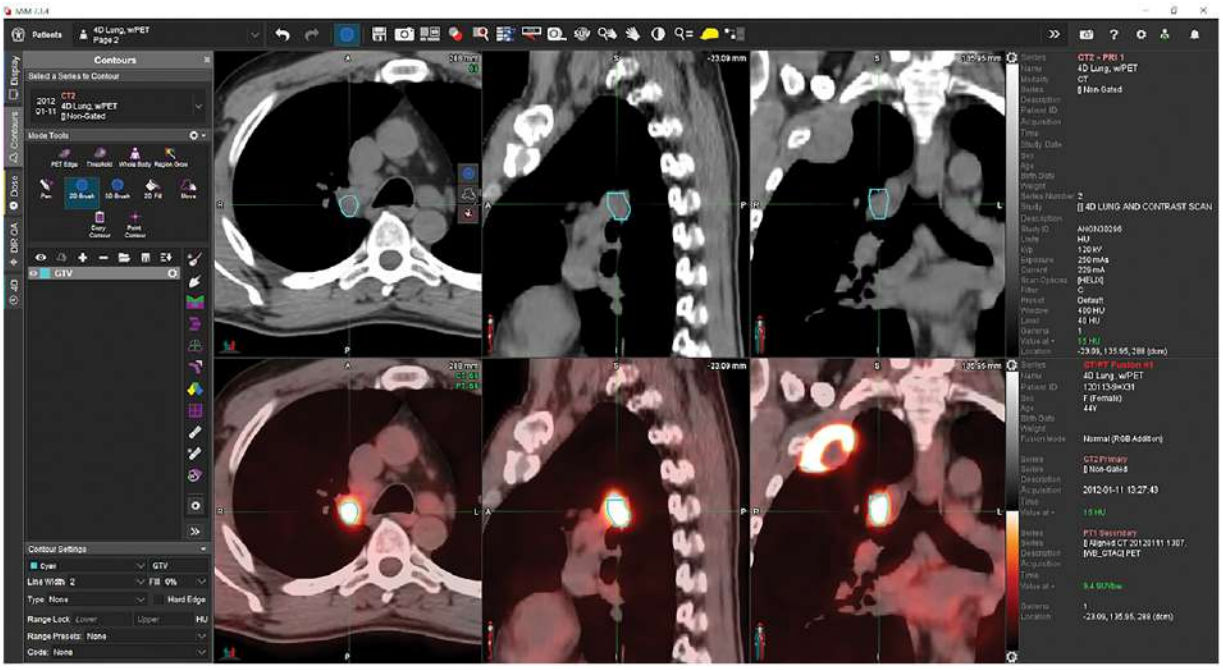

FIGURE 10.5 Advanced image segmentation software provides tools for radiation oncologists and treatment planners to determine critical structures and tumor and target volumes for three-dimensional planning. Computed tomography (CT) data along with ancillary images such as positron emission tomography (PET) are displayed, and contours are drawn by the treatment planner/radiation oncologist around the tumor, target, and normal tissues on a slice-by-slice basis. The bottom row shows PET data with overlying contours after image registration with the CT data.

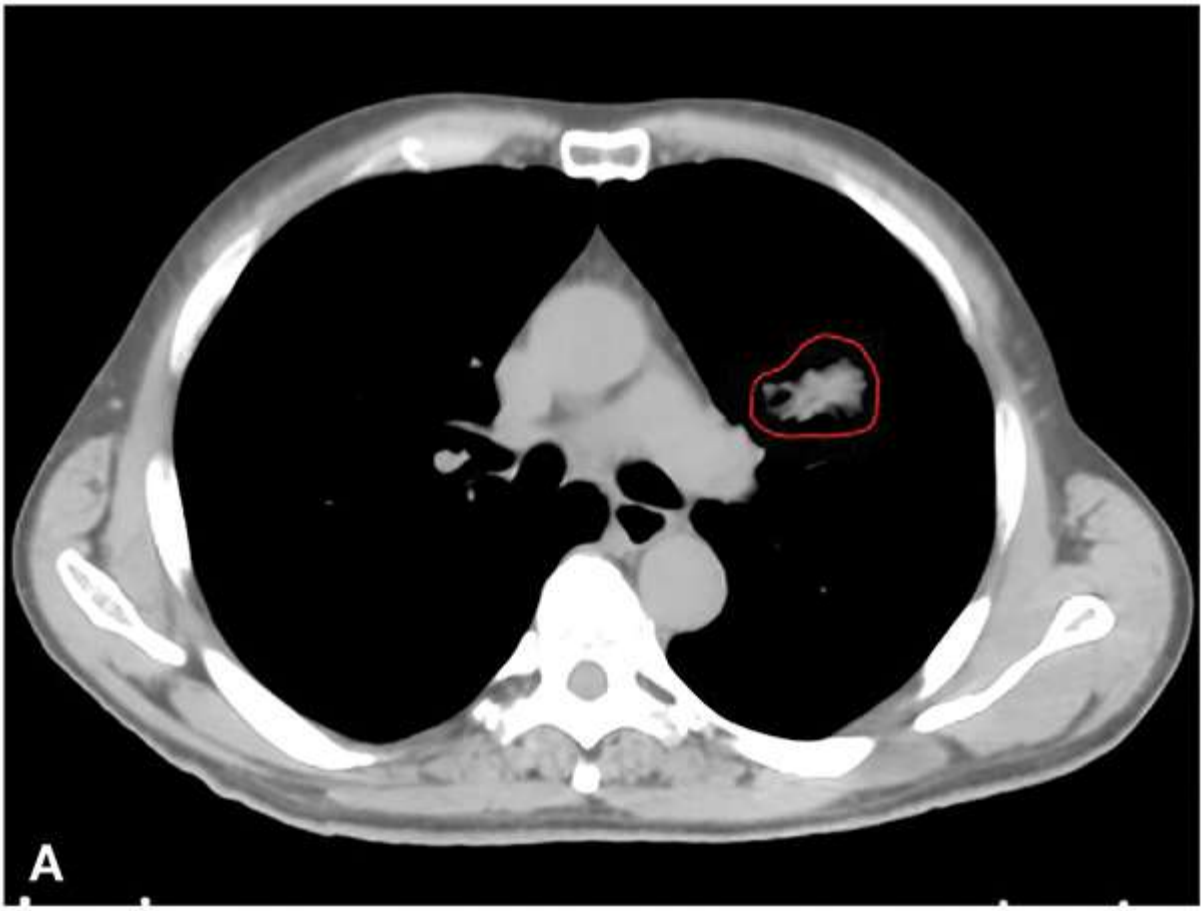
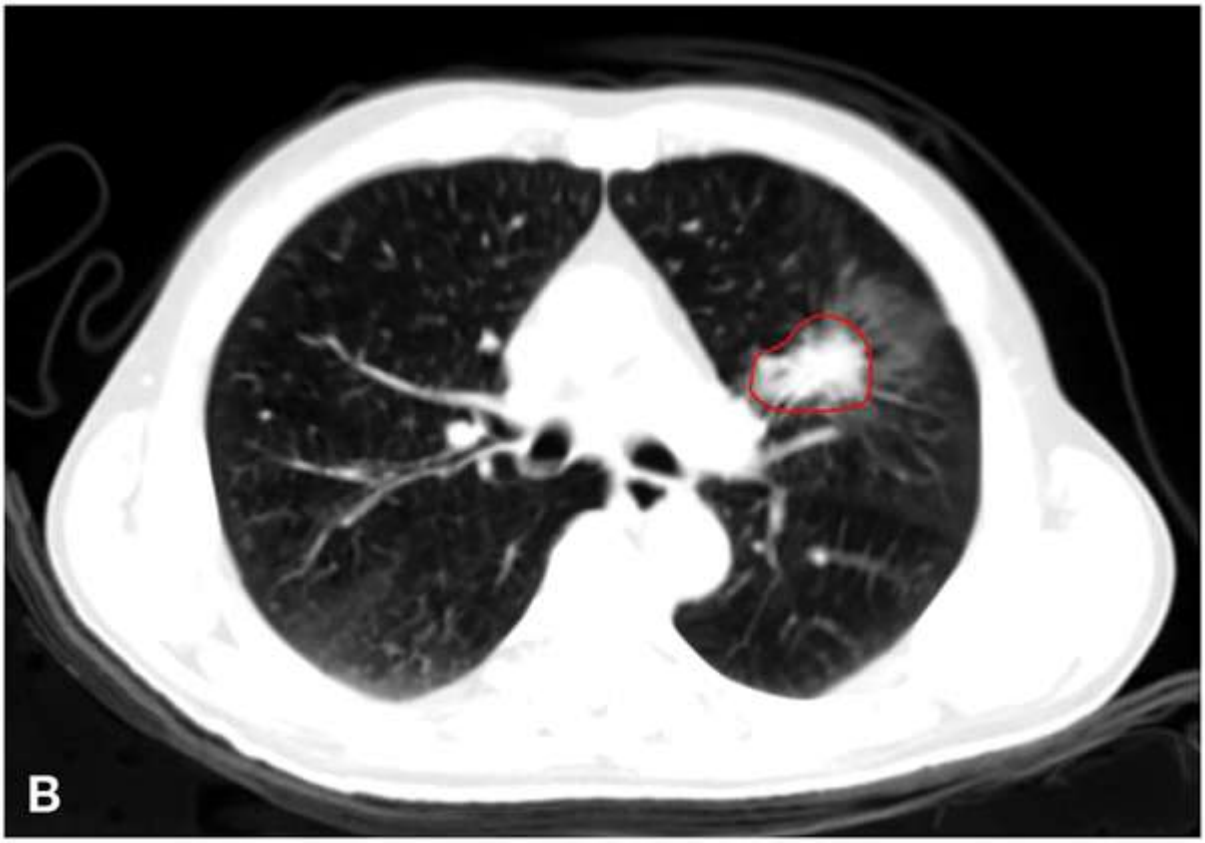
CT is still the principal source of imaging data used for defining the GTV for most sites, but this imaging modality presents several potential pitfalls. First, when contouring the GTV, it is essential that the appropriate CT window and level settings be used in order to determine the maximum dimension of what is considered potential gross disease (Figure 10.6), often in combination with other imaging modalities such as PET or MRI. Second, for those treatment sites in which there is considerable organ motion, such as for tumors in the thorax, conventional CT acquisitions do not correctly represent either the time-averaged position of the tumor or its shape, and hence 4D CT technology must be used to appropriately capture both the shape and position of the anatomy.[52-54] This can be understood by appreciating the fact that CT simulators rely almost exclusively on the use of fast helical CT technology and thus acquire data essentially in limited width slices and combine them to construct a 3D matrix. This has the effect of capturing the tumor cross-sectional images at particular positions in the

breathing cycle. If the tumor motion is irregular, transverse sections of the tumor could be imaged at different points of the breathing cycle, leading to volume uncertainties. The interpolation process in spiral CT technology adds further to the uncertainty. As a result, the 3D reconstruction of the GTV from temporally variant 2D images often results in a poor representation of the tumor and its motion.



A



B

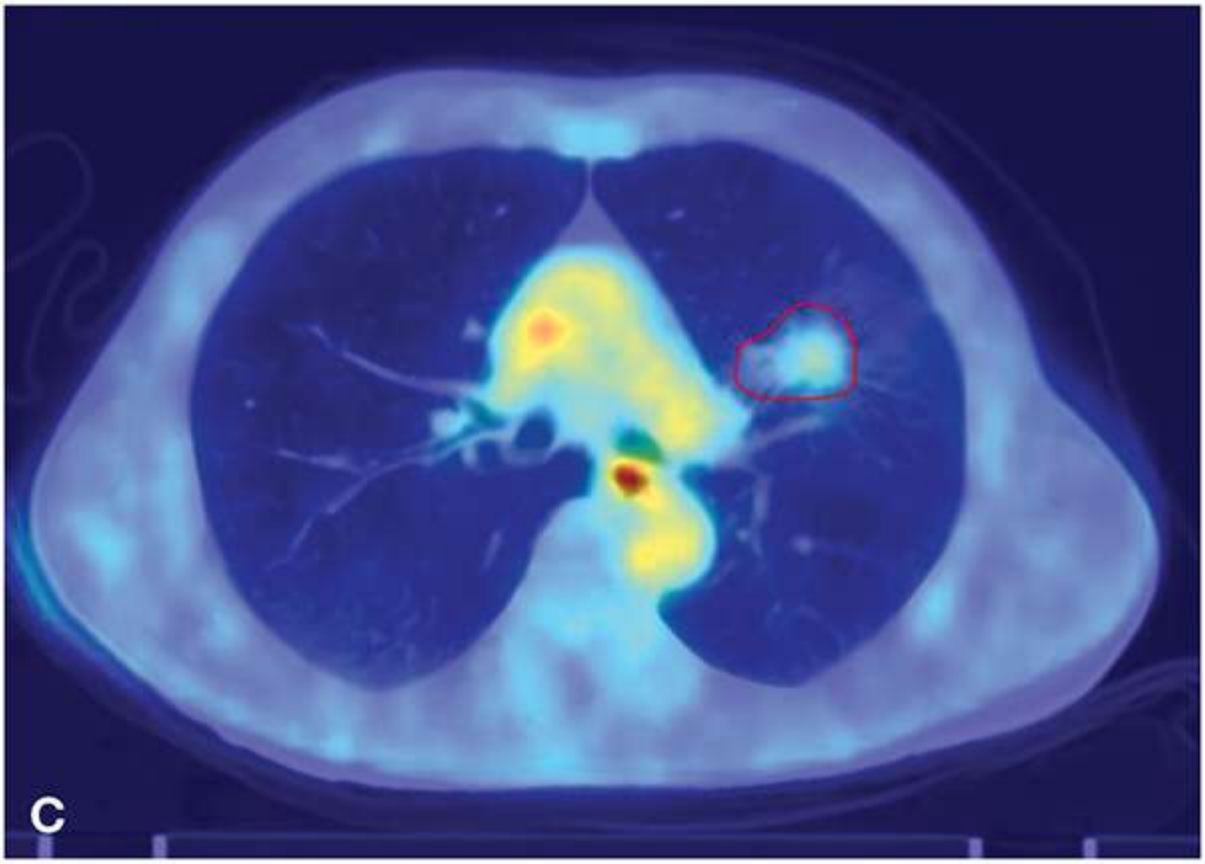


FIGURE 10.6 Computed tomography (CT) slices from a patient with lung cancer demonstrate that the appropriate CT window and level settings must be used to determine the maximum dimensions of the gross tumor volume (GTV). For a lung nodule, a lung window (B) is more appropriate than a soft tissue window (A), although the soft tissue window may be useful to differentiate disease infiltrating the soft tissue, such as the hilum and mediastinum. Note that a much smaller GTV would have been contoured with the settings used in A. C. Positron emission tomography image used to help differentiate tumor from adjacent normal tissue.

4D CT technology has become the standard for CT simulators, making it possible to capture images in each phase of the respiratory cycle.[55,56] In addition, other technologies and methodologies to explicitly help manage the movements induced by the respiratory motion (to the order of <5 mm during treatment preparation and delivery) continue to be developed, including respiratory-gated techniques, respiration- synchronized techniques, breath hold techniques, and forced shallow breathing methods.[57-59] However, a recent survey[59] on clinical practice of respiratory motion management showed that the majority of respondents use a passive (ITV-based) method of management, with a smaller percentage using breath

hold or abdominal compression, and less than 15% using gating or other active management methods.

Critical factors in 4D CT deployment include establishing a high-quality respiratory surrogate, as this signal determines the respiratory phase for sorting of the data during reconstruction. Various systems including belt strain gauges, laser or infrared range finders, or surface imaging can be used as the respiratory surrogate. As the 4D CT acquisition is a slow helical acquisition, typically the tumor and surrounding anatomy is only captured during one or a few breaths. Irregular breathing can thus influence the quality of the 4D CT reconstruction, and the user should understand that the ITV generated from this 4D CT only represents a "snapshot" of the true, underlying respiratory motion expected during treatment.

Delineating the CTV is even more difficult and must be done by the radiation oncologist based on clinical experience (and/or the use of published CTV atlases for certain clinical sites) because current imaging techniques cannot be used to directly detect subclinical tumor involvement. This field has seen a virtual explosion in the use of multimodality imaging over the last decade, and radiation oncologists have developed considerable imaging expertise in order to accurately define GTVs and be able to define nonvisible CTVs. However, the need for a higher level of image-based cross-sectional anatomy training in this field is well recognized.[60] The American Association of Physicists in Medicine (AAPM) Task Group 132 addresses integration of multimodality imaging in the treatment planning and treatment processes.[61]

The PTV margin is specified by the radiation oncologist, often in consultation with the radiation oncology physicist and/or dosimetrist. On most occasions, it is based on published clinical experience that is not calculated based on measurements performed by the department for a particular treatment machine/technique and team. Alternatively, van Herk and colleagues[62,63] reported extensively on the influence of systematic and random errors/variations on the required margins to account for setup error and organ motion and developed margin recipes for calculating individualized (eg, for each department, machine, and team) margins as given by the following equation:

$$\text{PTV margin} = 2.5\sigma + 0.7\sigma$$

where σ is the standard deviation of the systematic setup errors and σ is the standard deviation of the random setup errors.

When defining the PTV, the radiation oncologist should account for the asymmetric nature of positional uncertainties (Figure 10.7). For example, it is recognized that prostate organ motion and daily setup errors may be anisotropic (side-to-side or rotational shifts of the position of the patients are likely to have a different result compared to movement in the anterior-posterior direction). Thus, the PTV margin around a CTV generally should not be uniform.

FIGURE 10.7 Computed tomography images of a patient with prostate cancer showing the contour outlines for the gross tumor volume (GTV), planning target volume (PTV), bladder, and rectum. The physician made the decision that no additional margin around the prostate for the clinical target volume (CTV) was required (ie, CTV = GTV). Note that a nonuniform margin around the GTV/CTV was used to define the PTV in the region of the rectum. Also note the additional PTV contours needed to cap the GTV/CTV.

Typically, when the beam portal is defined, additional margin beyond the PTV is required to obtain dose coverage because of beam penumbra and treatment technique. This emphasizes that treatment portal margins in relation to the PTV must be set according to the dosimetric characteristics of the beams being used. Often for conventional fractionation, a 5-mm margin (portal edge to PTV) is a good starting point, which can be increased if needed, but one must be knowledgeable about the characteristics of the actual beams used to make this starting-point determination. An additional point to understand is that in the case of

coplanar treatment techniques, the margins required across the plane of treatment and the margins orthogonal (say superior-inferior) to this plane will be different. To clarify this point, consider a pelvic four-field axial technique as an example. Portions of the lateral aspects of the PTV that are in the low-dose regions (near the penumbra) of the anterior-posterior and posterior-anterior fields will be in the high-dose regions (well away from the beam penumbra) of the lateral fields. However, the superior and inferior aspects of the PTV will always be in the same low-dose regions of all four fields, so there will be no dose filling from any of the fields. Thus, a larger portal margin in the inferior-superior dimension is needed to ensure that the prescription isodose resulting from all beams contains the PTV, whereas the lateral and anterior-posterior portal margins for each field may be reduced due to the other beams filling in the dose. The same holds true for the portals of the boost fields used in the so-called integrated boost technique, in which the beams used for treating the large volume fill up the dose in the buildup region of the boost volume. Last, the size of the margins will also be affected by the relative beam weighting. Hence, making hard rules about margin sizes is impossible and requires some planning iteration to find the right mix of beam margins.

When a PTV overlaps with a contoured normal structure, it is important to be explicit as to which volume the overlapping voxels are assigned for optimization purposes and for DVH calculations. Planning systems should allow the overlapping voxels to be included in both volumes for plan evaluation and reporting purposes. This ensures that the clinician is aware of the potential for the high-dose region to include part of the normal structure as well as the PTV when reviewing the DVHs. For example, Figure 10.8 illustrates the dosimetric prioritization that is required in clinical trials NRG-BR001 and NRG-BR002 when the PTV overlaps with certain OARs as described by Al-Hallaq et al.[64]

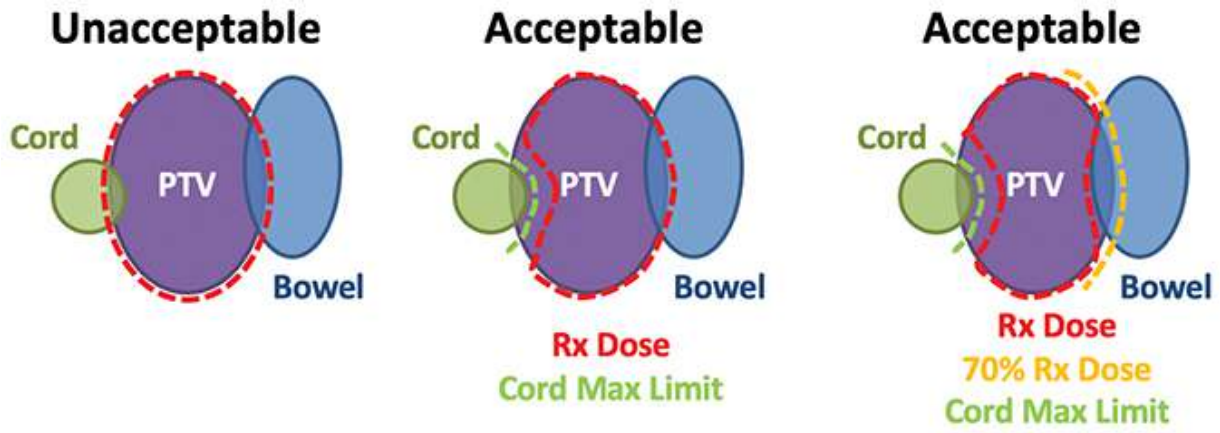

FIGURE 10.8 The treatment protocol for multiple metastases developed for clinical trials National Research Group (NRG)-BR001 and NRG-BR002 prioritizes protection of certain critical organs (eg, spinal cord) that overlap with the planning target volume (PTV) while leaving the decision of whether to cover the PTV or spare the organ at risk to the discretion of the treating physician for other critical organs (eg, bowel). (Reprinted from Al-Hallaq HA, Chmura S, Salama JK, et al. Rationale of technical requirements for NRG-BR001: the first NCI-sponsored trial of SBRT for the treatment of multiple metastases. *Pract Radiat Oncol*. 2016;6[6]:e291-e298. Copyright © 2016 Elsevier. With permission.)

In addition, most 3DTPS cannot accurately account for a PTV contour that extends outside the skin surface, resulting in a DVH that does not reflect clinical reality because of the lack of dose generated in air and in the buildup region just below the skin. In those cases, the best solution is to delineate a planning structure (often termed the *PTV eval*) formed by truncating the PTV 3 to 5 mm below the skin surface. This will also help reduce acute skin reactions by preventing the optimization process from increasing the skin dose to excessive levels in an attempt to compensate for the lack of soft tissue in the PTV outside of the skin surface. In all cases, however, the treating physician should be aware of this approximation when setting or approving actual field margins.

All of the issues discussed in this section point out the fact that the PTV/PRV concept is a useful tool that simplifies accounting for geometric uncertainties. However, its use does give rise to several dilemmas. Particularly important is the loss of actual tumor and normal organ volume information reported for researchers developing TCP and NTCP models. Although it does not appear possible to totally eliminate the PTV concept at this time, it does appear possible to use smaller margins for some sites if more frequent imaging, adaptation of the treatment plan to anatomic

changes, or other technical innovation is used to reduce geometric uncertainties. For example, for prostate cancer, the use of daily imaging and other technologies to relocate the target volume in reference to the machine isocenter does allow for a smaller margin for the PTV.[13,65,66] However, one must still be prudent in the amount of margin reduction for the prostate PTV when using these technologies. The different methods include various trade-offs ranging from treatment machine control, which is not dependent on the patient, to systems that are completely dependent on the patient. Again, regardless of which technique is used to reduce the overall PTV margin, one must be prudent in deciding the amount of margin reduction. Data do exist for support of margin reduction, but one must be systematic in approaching such reductions and ensure that there are no adverse effects on expected patient outcomes.[67]

Dose Prescription

Dose prescription is the responsibility of the radiation oncologist, generally using institutional protocols based on evidence published in the literature combined with institutional experience. Typically, the 3DCRT prescription is specified as a dose at or near the center of the PTV or (particularly for IMRT) as a dose covering a certain percentage of the PTV—for example, $D_{95\%}$, a dose that covers 95% of the PTV. Because the resulting dose distribution can be quite different depending on the dose prescription methodology, it is imperative that publications provide a clear and unambiguous description of the dose specification for the radiation treatment results being reported. The ICRU recently updated their recommendations for dose specification regarding IMRT and these will be discussed in a later section.[68]

Conformal Planning

For 3DCRT planning, beams can be arranged, and beam apertures shaped with multileaf collimator (MLC) leaves or shielding blocks to help conform the prescribed dose to the PTV and avoid OARs using BEV displays. This "forward planning" approach to 3DCRT has now been supplemented—but

not replaced—by an "inverse planning" approach as used for IMRT, which can achieve even greater conformity and OAR dose avoidance.

Forward Planning: Three-Dimensional Conformal Radiation Therapy

Design of the beam arrangement is the next step in the planning process for 3DCRT. The ability to orient beams in 3D allows one to develop treatment plans that use noncoplanar beams. However, when noncoplanar beam arrangements are used, care must be taken to avoid the selection of gantry and couch angles that result in table/gantry collisions or a conflict with other treatment room restrictions. The *BEV* and the *DRR display*,[26,69] as shown in Figure 10.9, allow the planner to easily view the target volume and OARs so that shielding blocks or MLC apertures can be drawn using a computer mouse or, as available with most current 3DTPS software versions, automatically generated with a chosen margin around the selected volume. DRRs also provide planar reference images that can be used in facilitating the plan implementation and treatment verification phases of 3DCRT.

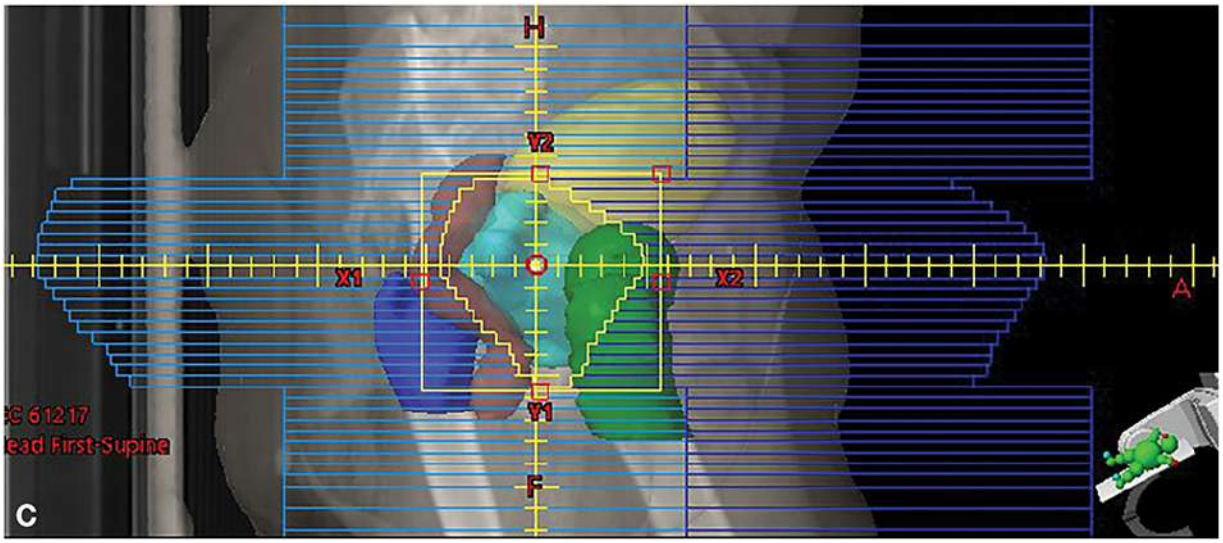

FIGURE 10.9 Anteroposterior (A) and lateral (B) digitally reconstructed radiographs and beam's eye view (BEV; C) display of three-dimensional radiation therapy treatment planning for a patient with prostate cancer. BEV display is useful in identifying best gantry, collimator, and couch angles at which to irradiate the target and avoid irradiating adjacent normal structures by interactively moving patient and treatment beam. Critical structures and target volumes are outlined on the patient's serial computed tomography sections. Contours are seen in perspective, as though the observer's eye is at the radiation source looking out along the axis of the radiation beam. The beam shape is defined by multileaf collimator.

Inverse Planning: Intensity-Modulated Radiation Therapy

The major differences between 3DCRT forward planning and IMRT inverse planning are the use of a computer optimization program that requires a formal description of the requirements using a mathematical *objective function* and constraints that are used by the program to find the solution. For example, after the design of the initial beam geometry, the physician/treatment planner puts into the TPS the desired dose-volume constraints for the PTVs and all OARs. The TPS optimization algorithm then divides each beam into many small *beamlets* (ie, pencil beams that together make up the IMRT beam) and then iteratively alters the beamlet intensities until the 3D dose distribution best conforms to the a priori specified dose-volume objectives. After the optimal beam intensities and resulting dose distribution have been determined, the TPS then calculates the MLC leaf sequence motions that will achieve this dose distribution and the dose recalculated. Typically, there may be some differences in the optimized dose distribution and the final dose distribution that are delivered

with the computer- controlled MLC system, but this difference is usually acceptable.

Noncoplanar Multibeam Delivery

Dong and colleagues[70] recently investigated the benefits of increasing the number of beams in noncoplanar delivery and showed that significant normal tissue sparing and dose conformality gains can be achieved when 14 to 22 beams are used for delivery. In this approach, an optimization algorithm, in addition to conventional fluence optimization, also optimizes noncoplanar beam orientations considering a patient-specific deliverable beam geometry solution space, parameterized with patient and linear accelerator (LINAC) gantry orientations. This delivery technique, dubbed 4π, has been extended to other disease sites and has shown that research can lead to additional improvements in radiotherapy photon dose distributions.[71,72]

Multilesion, Single Isocenter

The increased geometric precision and accuracy of MLCs and linac movements in C-arm systems recently has enabled treatment of highly "off-axis" targets, where an isocenter can be located several centimeters from the intended target. These developments have enabled a host of treatment techniques using a single isocenter to treat multiple targets, starting with brain metastases.[73,74] These methods have been commercialized by Varian (HyperArc) and Brainlab (Elements Multiple Brain Metastases), among other offerings. Treatment plans can be optimized to balance between target conformality while reducing low-dose spillage between targets, particularly through the use of multiple, noncoplanar arcs.

Dose Distribution Calculation

A rectilinear coordinate system affixed to the patient's 3D CT image set is typically used for calculating the dose distribution. This "patient or CT system" coordinate system typically has its x-axis along the horizontal axis of the transverse CT images, the y-axis along the vertical axis, and the z-axis along the couch motion. Contour points are specified as a sequence of points having x-, y-, and z-coordinates in this system. The center of each

voxel in the 3D CT image matrix is computed relative to the same coordinate system and is used to look up the relative electron density values that are related to the CT numbers (see later discussion). The selection of grid spacing for the 3D dose matrix is an important consideration regarding dose computational accuracy, calculation speed, and computer hardware requirements. Drzymala et al[33] pointed out that a 2% dose accuracy or 2-mm isodose positional accuracy can generally be achieved with a grid spacing of 5 mm. However, in regions of high dose gradients, a finer grid is typically needed, which creates larger computer files and increases the 3DTPS memory and mass storage requirements. With modern computing capabilities, these issues are not a practical limitation, and high-resolution dose computations are achievable that can lead to dosimetric benefits.[75]

The reader should also understand that CT numbers are not used directly in photon dose calculations. Instead, the CT numbers are correlated with the electron density of the corresponding tissues at each voxel relative to the electron density of water.[76] This is because Compton scattering is the dominant mode of interaction for the type of photon beam used in radiation therapy (cobalt 60 through 25-MV x-rays), and the absorption and scattering of photons in tissue depend primarily on the electron density of the tissue. Errors in CT numbers can result in inaccurate dose calculations. Generally, however, errors of 10% or less in electron density (CT numbers) will not result in significant errors in the dose distribution.[76] A recent development has been direct electron density imaging[77]; full clinical impact of this technology remains to be investigated.

Details on specific dose calculation algorithms are discussed in a separate chapter, and so only issues pertinent to the 3DCRT planning process are discussed in this section. In the past, dose calculation algorithms were traditionally based on parameterizing dose distributions measured in water phantoms under standard conditions and applying correction factors to the beam representations for the nonuniform surface contour of the patient or the obliquity of the beam, tissue heterogeneities, and beam modifiers such as blocks, wedges, and compensator. However, more advanced models, such as the superposition/convolution method, have been developed for 3DCRT planning[63] and are now the standard of practice for 3DCRT planning. The study by Frank et al[78] provides a clear method for safely

transitioning from a clinical experience based on planning assuming a homogeneous unit density patient to a heterogeneous patient model.

Plan Evaluation and Improvement

The 3DCRT plan evaluation/improvement process involves an iterative, interactive approach. Typically, the initial beam arrangement has been selected based primarily on clinical experience using BEV displays. The generated dose distribution is reviewed by the planner/physician, and the beam arrangement is then modified based on the review of DVHs (Figure 10.10) and multilevel 2D displays showing isodose lines superimposed on CT images (Figure 10.11); sometimes, the display is in the form of a *color wash*, that is, a spectrum of colors superimposed on the anatomic information. Historically, the planned dose distribution approved by the radiation oncologist is most often one in which a uniform dose is delivered to the target volume (eg, +7% and −5% of the prescribed dose), with doses to critical structures held below tolerance levels,[79-82] as well as within the constraints for the absolute maximum dose, median dose, or a volume (eg, V_{20Gy}) that has been specified by the radiation oncologist. With IMRT and stereotactic body radiation therapy (SBRT) approaches, there is an increased acceptance of larger-dose heterogeneities, whereas the approach to other evaluation parameters remains unchanged.

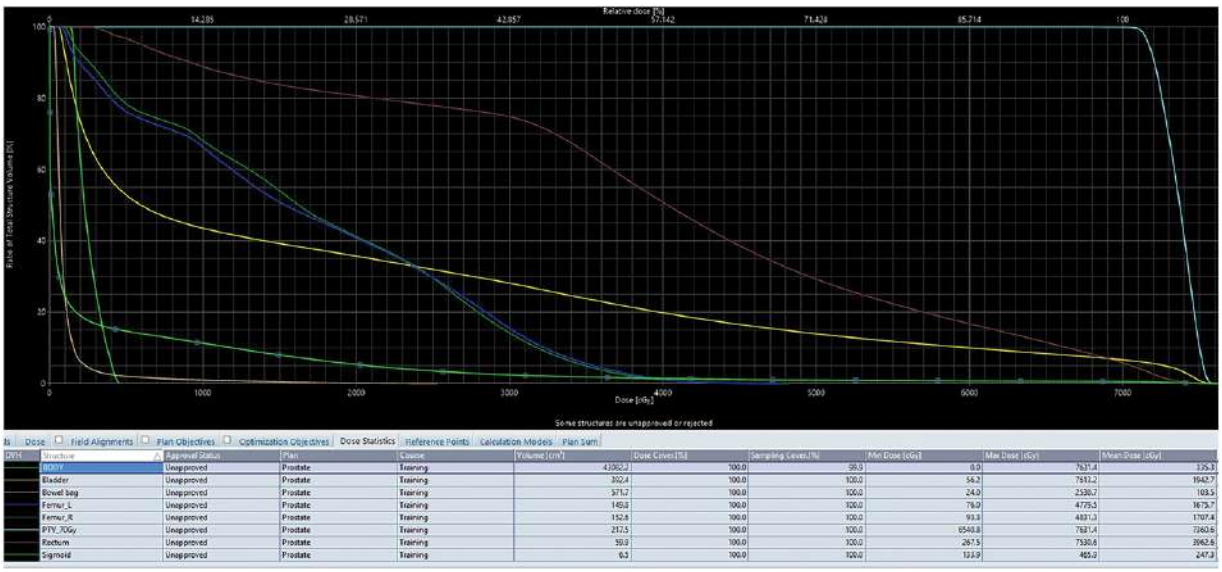

FIGURE 10.10 Example of a treatment planning system display (Varian Eclipse), showing the cumulative dose-volume histograms for the plan of a patient with typical prostate cancer: the prostate planning target volume (cyan) and multiple organs at risk (left and right femurs, rectum, sigmoid colon, bowel bag, and bladder). Also shown are associated dose statistics for the various defined volumes.

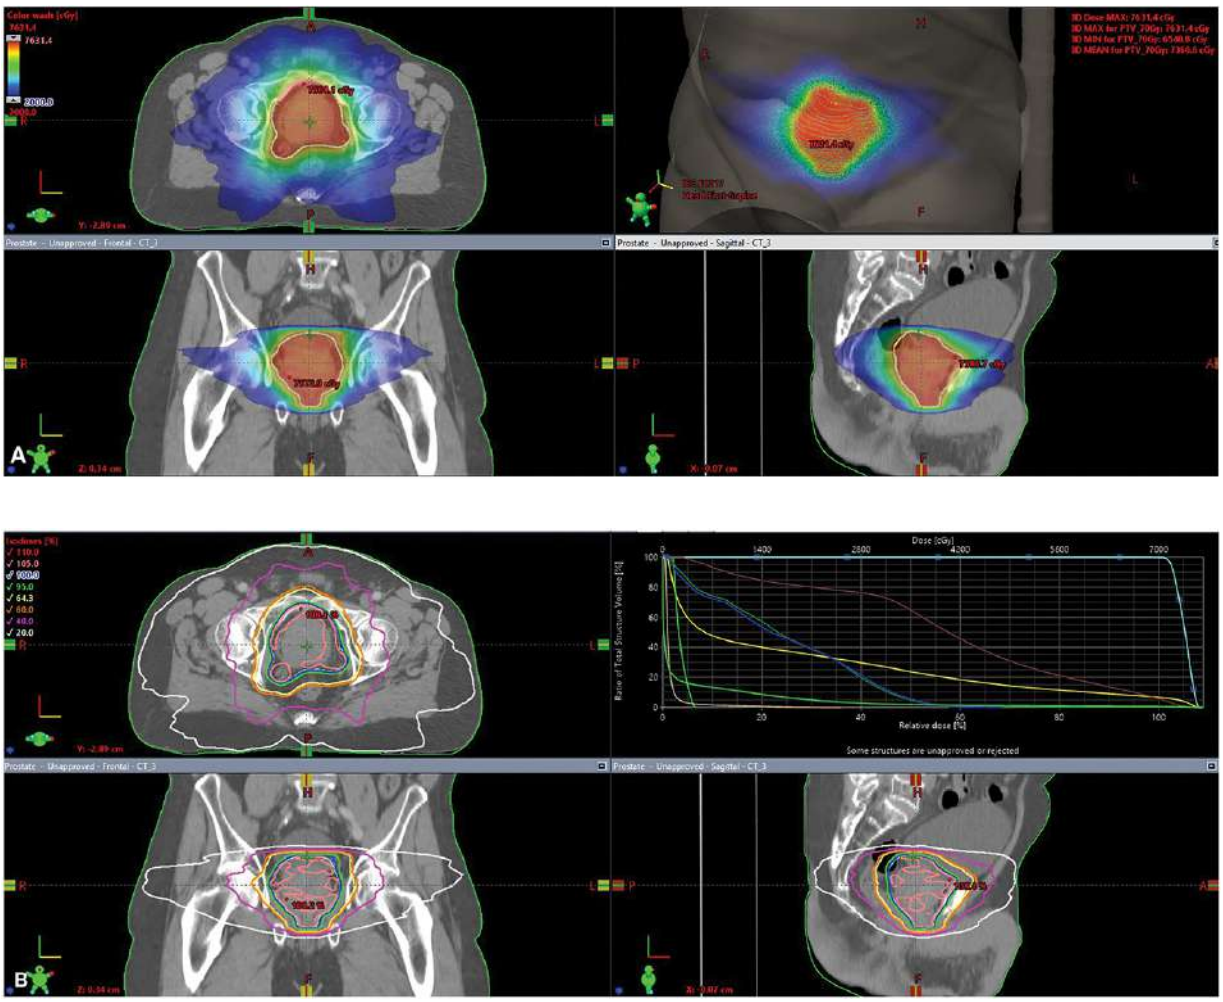

FIGURE 10.11 Dose distribution displays for a patient with prostate cancer showing coronal, sagittal, and two axial computed tomography (CT) sections with superimposed colorwash isodose display (A) and color-coded isodose lines (B). Vertical and horizontal lines displayed on each CT indicate the positions of each section. Evaluating volumetric three-dimensional (3D) dose distributions using only this type of two-dimensional display is difficult and time consuming. Also shown are a 3D dose display (A) and a cumulative dose-volume histogram (B).

In recent years, the plan creation and evaluation process has significantly evolved adding several new options and tools to the process. The calculation of Pareto surfaces in multicriteria optimization (MCO)-based IMRT treatment planning involves creation of several treatment plan options where each plan offers a combination of different dose-volume trade-offs.[83] Pareto optimal plans offer a plan bundle where each plan favors an OAR or a combination of OARs at the expense of some other organ or organs. In other words, radiotherapy treatment planning is all about trade-

offs between doses delivered to target volumes and various OARs. These trade-offs involve physicians making decisions regarding dosimetric sacrifices and sparing, that is, which critical organs to protect from radiation dose at the expense of other organs, or they involve compromises in the balance of dose delivery between targets and OARs. In MCO, a set of plans optimized for unique combinations of dose trade-offs is combined with tools to offer a physician an efficient way to navigate among these trade-offs to select a plan offering the trade-offs favored by that physician. This approach has been shown to have quantifiable dosimetric advantages.[84] Both RaySearch (Garden City, NY) and Varian (Palo Alto, CA) offer MCO approaches. The advantages of this technique include the flexibility offered to physicians in guiding the treatment delivery; however, this cannot mitigate the clinical variability that may result due to differences from a physician's decision to favor one trade-off over another.

In knowledge-based planning (KBP), treatment plans of previously treated patients are used to create models of achievable dose distributions for future plans.[85,86] The historical plans constitute a training data set, and machine learning–like approaches are used to create DVH range predictions unique to a patient's specific organ geometry (Figure 10.12). In the KBP approach, a DVH or 3D dose prediction can be created as soon as there are contours of the patient geometry and the prescription.[87] The proposed solution is driven by prior treatment planning practices and results in a single treatment plan rather than multiple plan options as in the MCO. In this approach, treatment models can be created at one institution or globally and transferred to other, presumably less experienced, institutions[85,86] as well as used to standardize treatment planning quality in multi-institutional trials.[88,89] The ability to standardize plan quality in multi-institutional trials minimizes a significant source of historical variability and shortcoming in these trials, which should translate to an increased confidence in trial outcomes. Another potential benefit is the minimization of variability of transfer of planning protocols from multi-institutional trials to individual clinics if the KBP models used in a trial are made available to individual clinics. The KBP approach is commercially available through Varian's RapidPlan software and has been proposed to alleviate some of the resource challenges that exist in various clinics including in low- and middle-income countries.[90]

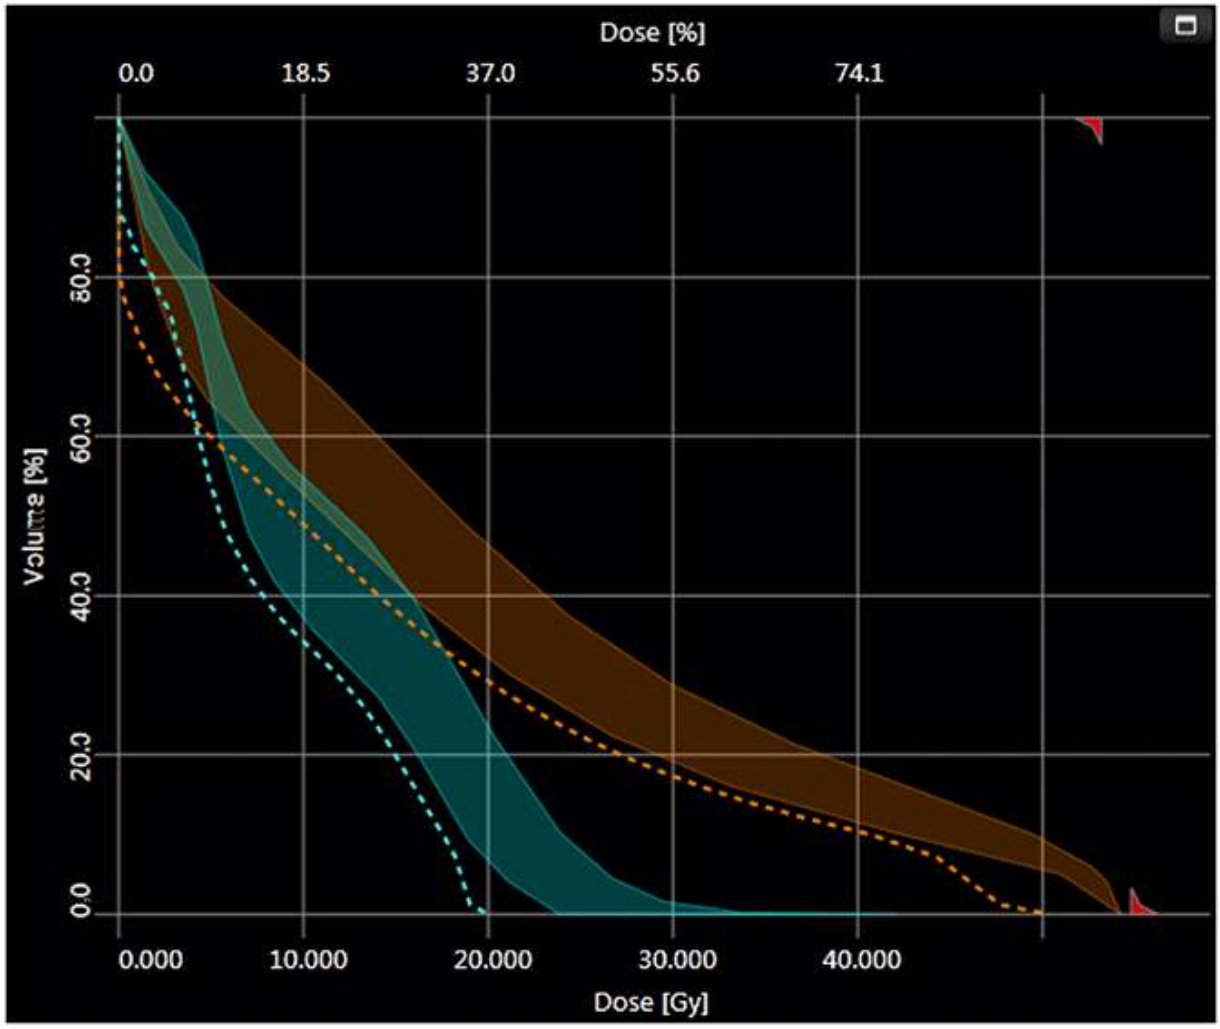

FIGURE 10.12 Colored range is the dose-volume histogram prediction range for two organs at risk, and the dotted lines are treatment planning objectives, which are set at the lower bound of these predictions and are automatically passed to the optimization engine for treatment planning purposes. The use of lower bound setting in the optimization ensures that the system is driven in the direction of optimal dose distributions.

Another powerful display feature in a 3DTPS is the *room view* or *room's eye view* (*REV*) (also referred to as 3D view), in which the planner can simulate any arbitrary viewing location within the treatment room.[29,91] The REV display is used to display *dose clouds* along with rendered PTVs and OARs. Hot or cold spots that occur in the volumes of interest are clearly seen, as shown in Figure 10.13. Another valuable REV display is the so-called skin view, in which the beam aperture projection can be clearly seen on the skin of the (virtual) patient (Figure 10.14).

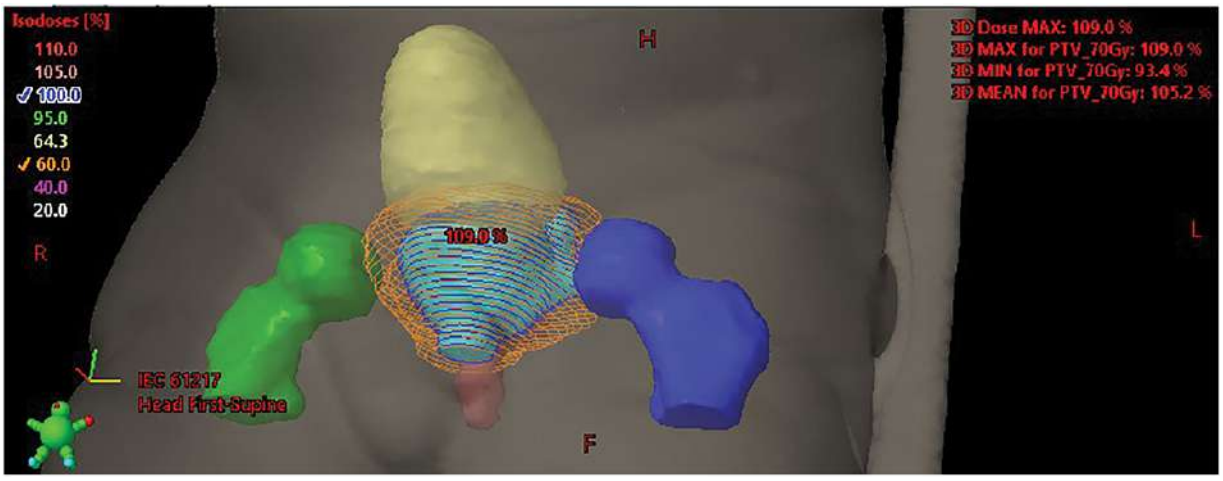

FIGURE 10.13 Room's eye view (REV) three-dimensional (3D) isodose surface display with real-time interactivity is a valuable tool for the evaluation of 3D dose distributions in terms of adequate coverage of target volumes and sparing of critical structures. The REV display enables radiation oncologists to view target volume or normal tissue volume with superimposed isodose surfaces or "dose clouds" from any arbitrary viewing angle. Shown is a four-panel REV display of the 100% and 60% isodose volume, the prostate planning target volume (PTV), bladder, femurs, and rectum of a patient with prostate cancer. The location of the PTV region not covered by the specified dose level is easily discernible using the REV display.

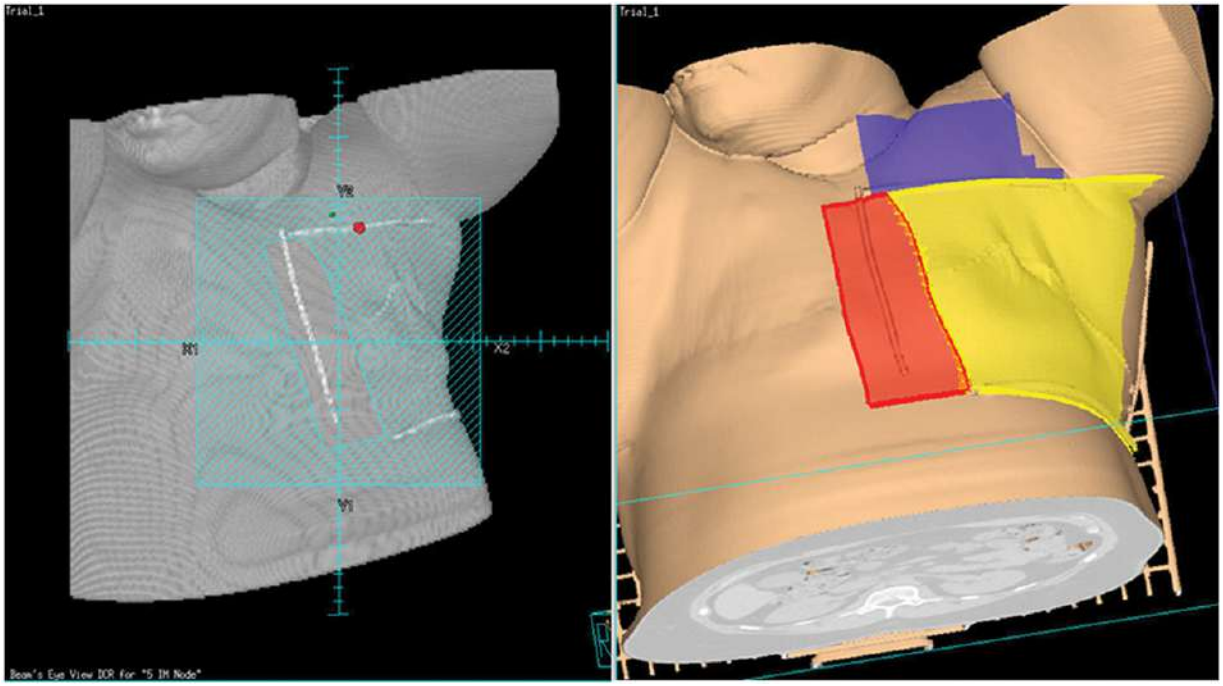

FIGURE 10.14 Room's eye view display showing simulated skin surface for a patient with breast cancer undergoing radiation therapy using tangential, supraclavicular, and internal mammary fields. Beam aperture projection can be clearly seen on the skin of the (virtual) patient.

Plan Implementation and Treatment Verification

Once the treatment plan has been designed, evaluated, and approved, documentation for plan implementation must be generated. Documentation includes beam parameter settings transferred to the treatment machine record and verify (R&V) system. Initially these R&V systems captured beam parameter settings for the treatment unit and, separately, for the MLC parameters communicated over a network to the treatment machine's computer system that controls the MLC system, and transfer of setup or reference images (DRRs, CTs, etc) and the machine's image database. Most modern treatment units now use integrated control systems that manage all of these aspects of treatment imaging and delivery parameters through a centralized control system.

Validation of patient position and treatment setup historically involved acquiring portal images of all individual treatment beams. However, with IMRT, SBRT, TomoTherapy, ViewRay, etc, these processes are not practical and are generally not done, although the portal transmission images may be captured for retrospective review and/or documentation. Instead, orthogonal radiographs, cone-beam CTs (CBCTs), MRIs, or other images of the patient (rather than of treatment beams) are now the preferred method to ensure correct isocenter positioning. When available, the optical distance indicator is also useful in assessing the correctness of the setup of a particular beam. Documentation provides the depth of isocenter below the skin surface on the central ray of the beam, which can then be compared with the isocenter depth measured on the simulator or treatment machine after the beam is set up using the couch and gantry positions specified by the treatment plan.

QA checks used to confirm the validity and accuracy of the 3DCRT plan typically include an independent check of the plan and MU calculation by a physicist; radiation therapists also evaluate the integrity of the plan information that is passed to them for treatment (ie, therapist new start check). Most importantly, careful scrutiny must be given to the input of data into the R&V system to ensure that it is correct. These checks are discussed in more detail in a separate section. Additional information on standards for 3DCRT plan verification can be obtained from the most current AAPM Task Group reports, American College of Radiology, and American Society for Radiation Oncology (ASTRO) practice accreditation guidelines.

Dose Reporting

ICRU Reports 50 and 62 define a series of doses, including the minimum, maximum, mean dose, and *ICRU reference dose* (defined at the *ICRU reference point*), for reporting dose relevant to 3DCRT. The *ICRU reference point* for a particular treatment plan should be chosen based on the following criteria: It should be (1) clinically relevant and defined in an unambiguous way, (2) located where the dose can be accurately determined, and (3) located in a region where there are no steep dose gradients. In general, this point should be in the central part of the PTV. In cases in which the treatment beams intersect at a given point, it is recommended that the intersection point be chosen as the ICRU reference point.

ICRU Report 83[68] updates the previous ICRU recommendation on 3DCRT dose reporting and recommends moving from single-spatial-point reporting (ie, the ICRU reference point dose, minimum and maximum dose) to dose-volume reporting. This is justified based on the availability of more accurate dose calculation algorithms and the advances and ubiquity of modern-day anatomic/functional imaging.

It should also be understood that in the past, *minimum dose* and *maximum dose* referred to point doses in the dose calculation grid assigned to a single voxel. It is now acknowledged that the minimum dose may not be accurately determined because it is often located in a high-gradient region at the edge of the PTV, making it highly sensitive to the resolution of the calculation and the accuracy of delineating the CTV and determining the PTV. Moreover, treatment planning today represents only one single representation of the calculated dose distribution, whereas over the full course of a radiation treatment, the minimum and maximum dose points are likely to shift slightly from one day to another. For all those reasons, ICRU Report 83[68] recommends discontinuing the use of maximum dose and minimum dose and instead recommends for dose reporting the use of the *near-maximum* (corresponding to $D_{2\%}$) and the *near-minimum* ($D_{98\%}$). In addition, the *median dose*, specified by $D_{50\%}$, should be reported, as it is considered to best correspond to the previously defined dose at the ICRU reference point.

The maximum dose as specified by a single calculation point ($D_{\max}$ or $D_{0\%}$) has often been reported for serial-like organs or structures. Previously,

such a reported maximum dose was considered relevant only if the involved organ had a minimum diameter of at least 15 mm, whereas an even smaller dimension was considered appropriate for some organs, such as the eye, optical nerve, or larynx.[38] The ICRU acknowledged that the minimum diameter for the maximum dose region in a structure is not always easy to establish and hence recommended that $D_{2\%}$ be reported. However, the ICRU pointed out that care should be taken in a change from maximum dose to the near-maximum dose, $D_{2\%}$.

As stated previously, with regard to dose homogeneity, ICRU Report 50 recommends that the dose coverage of the PTV be kept within specific limits, namely, +7% and −5% of the prescribed dose.[38] However, this level of dose homogeneity might not be achieved in all cases (particularly for current IMRT techniques), and ICRU Report 50 explicitly states that if this degree of homogeneity cannot be achieved, it is the responsibility of the radiation oncologist to decide whether the dose heterogeneity is acceptable. Similarly, a slight underdose to the PTV might be required (particularly if in close proximity to an OAR) or result for lung tumors surrounded by low-density lung tissue as a result of electronic disequilibrium.

Note that ICRU Reports 50 and 62 do not make strict recommendations regarding dose prescription; instead, the ICRU states that "the radiation oncologist should have the freedom to prescribe the parameters in his/her own way, mainly using what is current practice to produce an expected clinical outcome of the treatment."[38] For dose reporting, however, it is recommended to also state the original prescribed dose if the actual prescription was not done accordingly.

It is now recognized that there is a large variability among institutional results in IMRT planning and reporting.[92,93] Studies strongly support the ICRU Report 83 recommendation to move away from single-spatial-point prescription/reporting to dose-volume prescription/reporting. In addition, ASTRO has gone even further and recommends that specific details of the inverse treatment planning and image-guided treatment processes be recorded in four ways—in an *IMRT treatment planning directive*, a *treatment goal summary*, an *image guidance summary*, and a *motion management summary*.[94] Das et al[95] recently evaluated compliance with ICRU Report 83 prescribing guidelines and found that the overwhelming

majority of patient treatments in the surveyed institutions do not comply with these guidelines. The KBP planning approach and automatic DVH analysis are both aimed at reducing these variabilities. More extensive and standardized methods and supporting software for treatment prescribing currently do not exist. Just as the tools have emerged for more consistent plan creation and evaluation, it is critical that a process be developed, which will improve the standardization and quantification of radiation therapy prescribing. It would be very beneficial if the prescription parameters (treatment planning goals) and the evaluation metrics overlap.

Dose-Volume Histograms

The large amount of dosimetric data that must be analyzed when a 3DCRT plan is evaluated has prompted the development of methods of condensing and presenting the data in more easily understandable formats. One such data reduction tool is the *DVH*.[32,33] Two types of DVHs, *differential* and *cumulative*, are available in 3DCRT planning, with the latter now universally used in plan evaluation for assessing PTV coverage and dose to OARs, as displayed in Figure 10.15. However, it must be clearly understood that the DVH does not provide any spatial information and thus can only complement and not replace spatial dose distribution display tools such as isodose displays.

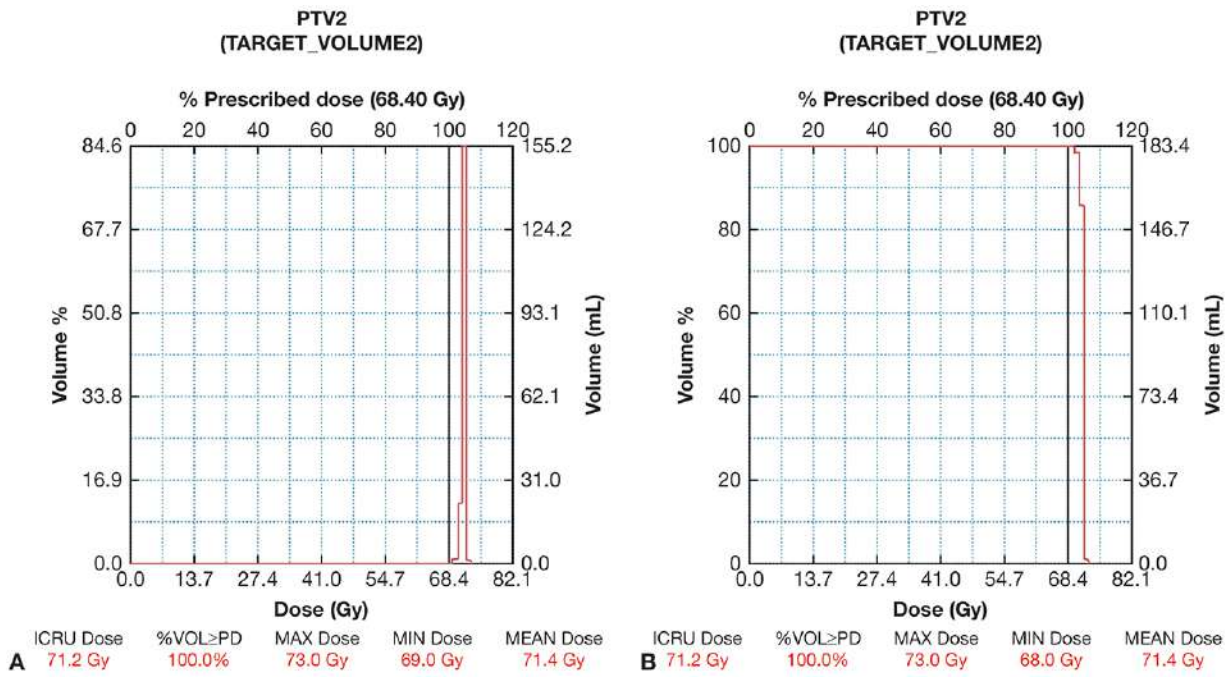

FIGURE 10.15 A. The differential dose-volume histogram (dDVH) for a specified target volume (planning target volume [PTV]2)—the volume is subdivided into individual elements (called voxels) and tagged according to dose received as determined from the three-dimensional dose grid. Voxels are then grouped according to each specified dose bin value without regard to their spatial location. A plot of the number of voxels in each bin (*y*-axis) versus the bin dose range (*x*-axis) is by definition a dDVH. B. The corresponding cumulative DVH is generated by summing for each dose bin all of the voxels of the PTV2 dDVH to the right of each dose bin; the *y*-axis gives the volume, or percentage of volume, that receives a dose equal to or greater than the indicated dose on the *x*-axis. ICRU, International Commission on Radiation Units and Measurements.

The *differential DVH* (dDVH), as shown in Figure 10.15A, is essentially a plot of the frequency distribution of the individual dose distribution elements (called dose voxels) obtained from the dose grid. Typically, the grid size is small enough so that the dose can be assumed to be constant within each voxel. The volume's dose distribution is then divided into *dose bins*, and the voxels are grouped according to their dose bin value without regard to their spatial location. A plot of the number of voxels in each bin (*y*-axis) versus the bin dose range (*x*-axis) is by definition a dDVH. The size of the dose bin used determines the height of each bin of the dDVH. For example, if the bin widths were increased, the heights of the histogram bins would increase because more voxels would fall into any given bin. Thus, it should be clearly understood that the detailed shape of a dDVH depends on

the dose bin size used, even though the underlying dose-volume data are the same.

A *cumulative DVH* (*cDVH*), as shown in Figure 10.15B, is a plot in which each bin represents the volume, or percentage of volume (*y*-axis), that receives a dose equal to or greater than the indicated dose on the *x*-axis. The cDVH is generated by summing all of the voxels of the corresponding dDVH to the right of each dose. The volume value for the first bin (dose origin) is the full volume of the structure because the total volume receives at least zero dose and the volume for the last bin is that which receives the maximum dose. Note that in the literature, the "c" in the cDVH is generally dropped, leaving just DVH.

Explicit values of dose-volume parameters can be extracted from the DVH data and are called dose-volume statistics or simply *dose statistics*. Examples for target volumes include maximum dose, minimum dose, mean dose, and percentage volume receiving greater than or equal to the prescription dose; for OARs, they typically include maximum point dose, mean dose, and percentage volume receiving greater than or equal to an established tolerance dose. As previously stated, ICRU Report 83[68] recommends replacing the *minimum dose* and *maximum dose* point doses with *near-maximum* (corresponding to $D_{2\%}$) and *near-minimum* ($D_{98\%}$).[68]

There is an ever-increasing reliance on DVH-based evaluation of treatment plans. Because the majority of planning objectives in clinical trials and Quantitative Analyses of Normal Tissue Effects in the Clinic (QUANTEC) recommendations are based on dose-volume tolerances of individual organs, it is natural to extend the plan evaluation with a primary focus on DVH or derived metric (eg, R_{50}) evaluation. There are now also several commercial and homegrown software packages for automatic extraction and evaluation of these parameters, with easy to assess indicators for which parameters meet the planning goals and which ones fail. Although the automatic evaluation is fundamentally more efficient, its main advantage is reduced likelihood for error and greater efficiency in the evaluation process. Also, the transfer and implementation of multi-institutional plan evaluation parameters are easier and more systematic to implement with automated dose- volume metric evaluation. It should be reemphasized that DVH review is not a substitute for reviewing the actual

isodose distributions, and plans are best evaluated combining all these review parameters.

Biologic Models for Dose-Volume Response

Evaluation of the quality of a treatment plan (ie, is plan A better than plan B?) is difficult and at best a qualitative procedure. For example, it is not clear what degree of dose uniformity within the PTV is optimum, as dose levels can be significantly escalated using 3DCRT techniques, nor is it always clear which plan is best if the two DVHs for a specific OAR cross each other (ie, difficulty in weighing importance of dose vs volume).

Researchers have developed biophysical models that attempt to translate the dose-volume information into estimates of biologic response—TCP and NTCP models.[81,82,96,97] Most authors agree that the TCP and NTCP models developed thus far are not accurate enough such that the absolute values can be used to predict clinical outcome; however, they are used to compare rival plans and as such help to rank plan quality. In any case, such biologic indices should be used clinically only when their utility has been firmly established for well-defined clinical conditions. ICRU Report 83 is clear in stating that if biologically based metrics are to be reported, the assumptions used in the models, their parameters, and the model itself must be unambiguously specified.[68]

Tumor Control Probability

TCP plotted as a function of dose has a classic sigmoid shape, having zero control at some low dose to control at some high dose. Rather than attempt to review in detail the various models, here some relevant issues are discussed. Readers are referred to the article by Moiseenko et al[98] for more details. Simple phenomenologic TCP models can be represented by the logistic function as follows:

$$\mathrm{TCP} = \frac{1}{1 + \left(\frac{D_{50\%}}{D} \right)^{4\gamma_{50\%}}}$$

where $D_{50\%}$ is the dose at which the TCP is 50%, $\gamma_{50\%}$ is the slope of the dose-response curve at 50% tumor control, and D is the dose administered.[99] Note that the use of the logistic function assumes an approximate uniform cell response and a uniform dose distribution.

For a nonuniform dose distribution, the total tumor volume is reduced to smaller volumes having "uniform" doses within each subvolume element v_i. The TCP value for each volume element, TCP(v, D), can be inferred from the TCP for uniform irradiation of the entire tumor volume, TCP(1, D), using the following equation:

$$\text{TCP}(v, D) = \text{TCP}(1, D)^v$$

Thus, the TCP for the tumor receiving an inhomogeneous dose is given by the product of the individual volume element TCPs as follows:

$$\text{TCP} = \prod_{i=1}^{N} \text{TCP}(v_i, D_i)$$

Here, TCP(v_i, D_i) is the TCP for the ith volume element receiving dose D_i, and N is the total number of tumor volume elements. Recall that the validity of this equation is highly dependent on the validity of the assumptions that the individual tumor volume elements are uniformly distributed throughout the tumor volume and are equally radiosensitive.

Normal Tissue Complication Probability

There are mainly two different approaches used in radiation therapy in modeling NTCP: the *empiric model* introduced by Lyman and Wolbarst[100,101] and *functional models* that introduced concepts of *serial* and *parallel* tissue organization and *functional subunits* (*FSUs*).[99,102-104]

The *Lyman NTCP model* can be expressed in terms of an error function of dose (D) and volume (v) as follows:

$$\mathrm{NTCP}\left(D,v\right)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{1}\exp\left(-t^{2}/2\right)\mathrm{d}t$$

where

$$t=[\,D-D_{50}\,(v)]\,/\,[\mathrm{m}\cdot D_{50}\,(v)]$$

with v equal to the partial volume (V/V_{ref}) and the tolerance dose-volume dependence given by the following power-law relationship:

$$D_{50}\,(v)=D_{50}\,(1)\cdot v^{-n}$$

$D_{50}(1)$ is the tolerance dose for 50% complications for uniform whole-organ irradiation, and $D_{50}(v)$ is the 50% tolerance dose for uniform partial-organ irradiation to the fractional volume v. The arbitrary variables m and n are found by fitting tolerance doses for uniform whole- and uniform partial-organ irradiation, where m characterizes the gradient (slope) of the dose-response function at D_{50} and n characterizes the effect of volume. When n is near unity, the volume effect is large; conversely, when n is near zero, the volume effect is small. When NTCP is plotted against dose, the NTCP equation demonstrates a sigmoid shape.

Two methods are used to extend this model to nonuniform organ irradiation. The *interpolation method*, proposed by Lyman and Wolbarst,[101] modifies the DVH to one in which the whole organ receives an effective uniform dose, D_{eff}, that is less than or equal to the maximum organ dose. The second method, called the effective volume method, proposed by Kutcher and Burman,[105] modifies the DVH to one in which a fraction of the organ, v_{eff}, receives the maximum organ dose. The Lyman model coupled with the Kutcher-Burman DVH reduction scheme (now called the Lyman-Kutcher-Burman model) is the most widely used NTCP model.[96]

Other NTCP models include two developed by Niemierko and Goitein—the *critical element model*,[106] used for serial-like organs, and the *critical*

volume model,[107] for parallel-like organs. These are similar in form to that of Lyman and Wolbarst[100] but include additional terms to better account for the radiosensitivity of the FSUs.

Equivalent Uniform Dose

Equivalent uniform dose (EUD) is a concept first introduced by Niemierko[108] for use in evaluating and reporting inhomogeneous dose distributions and later redefined by the following equation[109]:

$$\mathrm{EUD} = \left(\sum_i v_i \, D_i^{\alpha} \right)^{1/\alpha}$$

where v_i is the volume of the dose-volume bin with a dose D_i and the exponent α is a complication-specific parameter.

The EUD concept assumes that any two dose distributions are equivalent if they cause the same radiobiologic effect and appears well suited for use in evaluating competing conformal plans. However, McGary et al[110,111] pointed out that there are conditions in which EUD is not adequate as a single parameter to report or analyze inhomogeneous dose distributions—for example, when the minimum dose is significantly lower than the mean dose.[112]

PRECISION MEDICINE MODELS

In contrast to population-based models such as TCP/NTCP, patient-specific models may be developed to guide precision medicine. While imaging scientists have long posited that patterns in medical images are manifestations of the underlying biology, it has become possible to investigate this relationship with recent advances in computing and the increased availability of medical images.[113,114] Mathematical and statistical calculations performed on medical images (ie, radiomics) have been shown to correlate with tumor outcomes[115] and normal tissue toxicities[114,116]

following radiotherapy. Because genetic variations lead to biologic differences, studies have also shown that genetic variations can be detected in medical images (ie, radiogenomics).[115] As these models continue to be refined and investigated, it is important to understand the underlying sources of uncertainty and associated limitations of such models[114,117] in order to enable safe clinical implementation.

ARTIFICIAL INTELLIGENCE IN PLANNING, DELIVERY, AND TREATMENT VERIFICATION

As in many other areas of medicine, machine learning and artificial intelligence (AI) algorithms are beginning to supplant more traditional rule-based algorithms for solving a variety of problems in radiation oncology. Most recently, AI-based auto-contouring has emerged commercially as the state of the art for contouring OARs[118] and is now being investigated for CTV delineation,[119] although GTV delineation remains a challenging problem for AI auto-contouring. As discussed earlier, KBP represents an initial machine learning approach to treatment planning, but fully AI-based approaches are in development.[120] Plan verification through AI rather than measurement remains controversial but is an active area of research.[121]

Because, generally, AI systems are trained models rather than fixed rule-based algorithms, the approach to deployment, commissioning, and QA differs markedly from that used for traditional algorithms.[122,123] Critically, AI systems must be commissioned to ensure that the commercial model is consistent with the expected performance in the clinic, as differences in input data (eg, imaging data) from that used to train the AI model by the vendor can result in unexpected performance degradation of the AI system. Continuous monitoring and tools for ongoing QA of AI systems are in active development currently.[118,124]

MANAGEMENT OF CONFORMAL RADIATION THERAPY DATA

To accurately perform the steps involved in 3DCRT, several forms of patient imaging and other data must be acquired, displayed, manipulated, and stored. Typically, patient image data acquired from several imaging subsystems must be communicated to a TPS to permit these images to be used for treatment planning. Several software components also must be

integrated so that the output of one processing step can be made available for use as input to the next step. Daily IGRT imaging also places large demands on data storage, and the need for more robust image processing tools is evident. These issues in data management in 3DCRT are complex and continue to be somewhat problematic, although some progress is being made through the Integrating the Healthcare Enterprise in Radiation Oncology effort initiated by ASTRO.[125]

This issue is just a part of larger informatics issues facing radiation oncology. There is an explosion in the types and volume of data that must be made available for scientific inquiry. Difficulty in accessing the data in practical ways has become a critical limitation to investigators in the field and to its advancement. Unfortunately, the commercially available radiation oncology information systems are not yet adequate to meet this challenge. The great volume and diversity of the data have rendered their storage, management, and processing extremely problematic, resulting in situations in which important data and information are inefficiently disseminated and sometimes lost. In the busy clinic, failure to manage critical information may compromise patient safety. Here, a major issue is the lack of integration of the radiation oncology electronic medical record (EMR), based on systems such as Elekta-Impac MOSAIQ (Sunnyvale, CA) or Varian ARIA, with the electronic hospital record (EHR), based on systems such as those provided by Epic (Verona, WI). In most cases, one must resort to hybrid charting systems (ad hoc combinations of EMR, EHR, and paper charting), which entails risks and gives rise to a dangerous situation. Immediate and focused efforts in achieving these integrations and improving the radiation oncology informatics infrastructure are urgently needed.

QUALITY ASSURANCE FOR CONFORMAL RADIATION THERAPY

It is most important to realize that a QA program for 3DCRT is an interdisciplinary effort involving radiation oncologists, radiation physicists, dosimetrists, radiation therapists, clinical engineers, and information technology specialists and that the efforts of each group often overlap

substantially. To be effective, it is also essential to have the full support of the department chair and hospital administration.

Although, in general, radiation therapy has a long, successful history of QA, most authors have come to realize that the current approach (which relies heavily on prescriptive QA tests, tolerances, and frequencies as provided by consensus expert groups from national/international professional/scientific organizations) is likely inadequate by itself for more advanced modalities.[126-128]

For example, today's image-guided 3DCRT planning and delivery processes have become much more complex and much less intuitive. These complexities, coupled with the inadequate informatics infrastructure and possibly outdated national QA guidelines, have created enormous QA challenges. Communication among members of the planning team, including physician, resident, simulation therapist, dosimetrist, physicist, and treating therapist, is often rushed, cryptic, and complicated by the lack of integration of the radiation oncology EMR (eg, Elekta-Impac MOSAIQ) with the hospital's EHR (eg, Epic software). In fact, in most cases, one must resort to a hybrid charting system (ad hoc combinations of EMR, EHR, and paper charts), which is a dangerous situation. In addition, multiple imaging modalities are often used to define target volumes, all complicating the processing of the information. 3DCRT plan data, transferred over a network to the R&V system and computer-controlled LINAC systems, carry complex specifications for treatment, including positioning of MLC leaves, sometimes variable dose rates, collimator rotation, gantry angles, and, in some instances, a moving treatment table or gantry or both. In some cases, different vendor software systems are used, and interoperability is not always robust. This continuing increasing complexity of devices and systems is clearly problematic for a totally prescriptive QA approach, and it results in increased time demands on staff and groups where there are already shortages. A series of *New York Times* articles[127] brought needed attention to this issue and spurred national organizations to work to improve the current QA situation.[129,130]

Although it is believed that the prescriptive QA approach is valid and valuable for much of the 3DCRT technology and procedures currently in place, new and different approaches need to be developed in parallel.[131,132] These must be risk/evidence based and process oriented rather than device

and procedure oriented; they likely need to be multidisciplinary in nature, resource and risk optimized, and flexible enough to cope with current and anticipated changes in technology.[133] Such process-oriented QA includes risk-based analysis, process mapping, application of failure modes and effects analysis, and fault tree analysis, including analyses of human actions and responses.[134]

In support of this direction, the AAPM recently published recommendations of Task Group 100 on the application of risk analysis methods to radiation therapy quality management.[135] This report provides a mechanism for individual facilities to create custom QA protocols based on their individual situation and risk profile. This task group also calls on the future AAPM task groups to embrace the same methodology. The significance of Task Group 100 is the shift from more or less purely prescriptive QA guidelines to the provision of a tool kit for individual clinics to establish their own QA methods. Advantages of this approach, as described earlier, include the ability to create custom QA protocols considering the unique needs and circumstances of the particular institution. Shortcomings include the time required to create these QA protocols and potential absence of local expertise that can objectively assess individual facility needs. However, both of these are likely transient limitations as efficiency and proficiency in this process will be developed over time. Another great advantage of this approach is the evaluation of new processes and establishment of QA methods and QA tool development based on that analysis. For example, Noel et al[136] analyzed QA processes and tools needed for implementation of online adaptive radiotherapy, and Acharya et al[137] subsequently relied on that analysis for clinical implementation of an actual online adaptive radiotherapy program. The Task Group 100 Report is poised to make a major impact on QA practices in radiotherapy and our future practices should proceed with that in mind.

That said, radiation oncology departments must take all necessary steps to ensure that processes for the safe planning and delivery of 3DCRT are in place and appropriately resourced. Table 10.4 provides a list of guiding principles to help a department prioritize QA efforts for improving patient safety and quality for 3DCRT. This list is a compilation of pertinent key recommendations made by several national and international groups.[126,129,138-142]

TABLE 10.4 GUIDING PRINCIPLES FOR CONFORMAL RADIATION THERAPY QUALITY ASSURANCE PROGRAM

1. Establish a safety-conscious culture within the department and ensure that the processes for safe delivery of three-dimensional conformal radiation therapy (3DCRT) are in place and appropriately resourced. To that end, perform the following:
   a. Establish a formal covenant and commitment to safety. The radiation therapy team should work under a radiation safety covenant, and each member of the team should pledge a commitment to protect the safety of each and every patient.
   b. Make sure it is clear that each member of the treatment team has the right and the responsibility to declare a "time-out" if they have concerns or questions about the plan or course of treatment for a patient.
   c. Make sure that the quality assurance (QA) program is properly resourced.
2. Seek practice accreditation by the appropriate national body, for example, the American College of Radiology/American Society for Radiation Oncology.
3. Participate in external dosimetric audits such as provided by the Radiological Physics Center (now referred to as IROC-Houston) annual External Reference Dosimetry Audit.
4. Expand the use of checklists in 3DCRT treatment planning and treatment delivery.
5. Implement a formal policy that ensures that 3DCRT policy and procedures (P&Ps), including checklists, are in place and are regularly updated and reviewed on an annual basis (require documentation that this is actually done).
6. Conduct periodic reviews of staffing levels to ensure that the staffing and skills mix are appropriate for the numbers of patients treated and the complexity of treatments delivered.
7. Implement a Clinical Operations Committee, with supervisor representatives from each group, to address any problematic issues in the clinic and to help ensure that good communication exists among all groups involved in the 3DCRT treatment process.
8. Conduct town hall meetings (with QA program being a major focus) with department faculty/staff at least quarterly to help ensure good communication exists among all groups involved in the treatment process.
9. Maintain training records for all staff involved in radiation therapy. They should be detailed and specific to particular procedures, that is, an internal form of 3DCRT credentialing.
10. Maintain funding to support training and continuing education, particularly when new 3DCRT techniques are introduced.
11. Introduction of new 3DCRT techniques always needs to be carefully planned with a thorough risk assessment, review of staffing levels and skills required, and development of pertinent P&Ps. All staff involved in the process should undergo specific training in the new treatment technique or process prior to clinical use.
12. Working environment, particularly in two areas—treatment machine console and treatment planning—needs to be conducive to safety and designed such that it ensures that staff can work without inappropriate interruptions.
13. Prescriptive QA program should be in place but continually evaluated to ensure that each specific test adds value and that those that do not add the required value are

eliminated.

14. Perform systematic risk analysis and improvement using industrial engineering–based tools such as process mapping, failure modes and effects analysis, and fault tree analysis for all advanced treatment modalities.
15. Implement a treatment table registration system (CT simulator and treatment machines) so that all patient/immobilization device positions on the table can be registered.
16. Use treatment planning/delivery systems tolerance tables for specific procedures, and monitor setup variability (ie, any therapist overrides of treatment couch, gantry, collimator position, etc, settings in order to treat patient).
17. Perform on-treatment verification imaging as needed, but be mindful of imaging dose, and look for ways to become more efficient.
18. Perform in vivo dosimetry (eg, diode checks) at the beginning of treatment for all patients undergoing 3DCRT when physically possible.
19. Conduct weekly peer review chart rounds (review prescription, verification images, dose distribution, and other pertinent documentation, eg, signed consent, pathology, etc).
20. Conduct weekly peer review planning conference to review 3DCRT plans. Review of gross tumor volume, clinical target volume, and planning target volume contours, digitally reconstructed radiographs, and dose distributions helps to develop a consistent approach in implementing International Commission on Radiation Units and Measurements 50/62/83 methodology.
21. Implement a treatment planning workflow monitoring software system.
22. Implement a software system for reporting and analyzing errors and near misses, with feedback to the staff at town hall meetings.
23. Strive to have the right balance between accountability and openness in the department's incident reporting culture. Department should strongly endorse a national/international incident reporting system for radiotherapy incidents.

Quality Assurance for the Treatment Planning System

The complexity of 3DTPS continues to increase to better facilitate the accurate delivery of 3DCRT. In a number of instances, the TPS is an integral component of the treatment machine. Hence, this results in having more than one planning system in the department, thus increasing QA complexity.[143] Rigorous acceptance and commissioning of the TPS are essential to ensure it is functioning accurately before it is used clinically; in this respect, it is no different than other medical devices. The AAPM recently published Medical Physics Practice Guideline (MPPG) Report 5.b on commissioning and QA of TPS.[143] There has also been activity in automating QA of TPS, and the automation in this area should offer

improvements in consistency and efficiency as well as reduction in errors.[144] More details on acceptance, commissioning, and periodic QA tests are available elsewhere.[143,145-147]

The accuracy of dose calculations must be examined thoroughly during the 3DTPS commissioning process. Periodic checks of calculations versus measured dose are also essential because of possible data corruptions in the TPS itself and to how well treatment machine parameters such as flatness and symmetry are maintained. It should be appreciated that the 3DTPS can never be fully tested, nor can the manufacturer ensure the user that the system is "bug free." Rather, the system should be tested over a range of parameters that are typical of those used in the clinic. For example, tests should include consistency of input/output data; MU calculations; relative dose distributions; graphical data, including BEV and field aperture display; and plan evaluation tools such as DVHs and DRRs. The test procedures and results should be fully documented, as they will provide the baseline data to which the periodic QA tests can be compared.

It has been a practice to validate IMRT treatments with patient-specific dose measurements. However, for online adaptive radiotherapy, it is not practical to perform a phantom-based measurement, and an alternative approach to validation of dose calculation accuracy is needed.[137] The prevailing method for assurance of online adaptive treatment is to perform a secondary independent dose calculation combined with a rules engine to verify integrity of the treatment plan. As online adaptive radiotherapy becomes more mainstream practice, it is expected that the patient-specific measurement-based QA will diminish in prevalence.

Quality Assurance for Patient Positioning and Immobilization and Imaging Data Acquisition

CT, MRI, PET, and ultrasound imaging are used, depending on the disease site, for acquiring imaging data to determine patient external contours and target and OAR volumes. Hence, there are a number of additional QA demands placed on imaging units that are specific to 3DCRT treatment planning.[42] Guidance specifically on MRI for simulation is available from a recent report of the AAPM Task Group 284.[148] Because the patient needs to be repositioned reproducibly on the treatment machine, special patient

positioning immobilization devices are needed. Such devices should be constructed so that they can be attached in a similar manner to the treatment machine couch and the CT, MR, or PET imaging system couches used in obtaining the planning imaging data. These devices should not only attach and lock to all couches, but they also should do so in a configurable manner to allow indexing of the devices to the treatment couch for daily reproducibility. For MRI simulation, the presence of radiofrequency coils surrounding the patient requires careful design and selection of immobilization equipment, although many MR-compatible systems specifically designed for MRI simulation are now available.

In some instances, the composition of these devices is also important; for example, low atomic number materials are necessary for CT scanners, whereas carbon fiber devices are not compatible with MRI. In addition, patient motion can distort MRI and CT images, which can lead to inaccuracies in organ delineation and plan calculation. Large-bore CT simulators often offer extended or extrapolated field of view option.[149] With this option, the native image field of view can be extended by reconstructing the image in the portion of the CT scanner bore opening where partial data collection occurred. Depending on the scanner model and image reconstruction software age, there can be spatial and quantitative CT distortions in those areas of images, which ultimately can translate to treatment planning errors.

Geometric accuracy of all imaging modalities used for planning must be checked. This can be accomplished by imaging suitably designed phantoms on the various machines and comparing the results with the known values. Special care should be given to MRI units, which may suffer from appreciable spatial distortions. Selection of simulation-specific scanning sequences, if available, may help to reduce spatial distortion. If a PET-CT is used, special attention should be paid to the physical alignment of the table couch and both imaging rings. If images from CT, MR, and/or PET are registered and fused, a QA program must be implemented to ensure that the inherent algorithm used and departmental procedures are able to produce accurate composite images for planning.[61,150,151] Finally, for CT, it is necessary to obtain or confirm the relationship between CT number and electron density.

The transfer of image data routinely occurs directly via a computer network but should be checked on a regular basis. Vigilance is also necessary to eliminate any systematic errors; for example, an error in the specification of a scan diameter can lead to geometric distortions of the image.

Quality Assurance for Volume Delineation

Target volume delineation is viewed by many experts in the field as being the weakest link in the entire 3DCRT workflow chain. A high variation continues to be seen in all studies evaluating consistency of delineation of target volumes and OARs among physicians.[152-157] This can be explained by a lack of generally accepted guidelines for volume delineation and also, most likely, insufficient training of radiation oncology residents in modern cross-sectional imaging. It is clear that errors/inconsistencies in volume delineation can seriously undermine the goals of 3DCRT. One approach toward solving this difficult issue is to adopt guidelines and consensus volumes based on the delineation performed by a number of experts in the field.[156,158] Both the Radiation Therapy Oncology Group and the European Society for Radiotherapy and Oncology and Oncology have placed high priority on this approach and now offer more online guidelines for several sites. Standardization in naming convention of targets and OARs[159] should be a component of the effort to improve organ delineation process. To this end, the AAPM has formed the Task Group 263 on standardizing nomenclature in radiation therapy, and it is expected that the results of this work will lead to significant improvements in standardization in this area.[51]

It is also possible to improperly define an OAR because of faulty or incomplete CT procedures. For example, the base of the brain may be better defined on the CT slice if sagittal reconstructions are also available while contouring. In addition, if contrast is used, density overrides may be needed before treatment planning is performed to avoid the erroneous effects of the high-Z media. Related to this is the situation that occurs when high-Z materials like hip prostheses are found within the patient and density overrides are required to account for artifacts. Because of the likelihood and significance of contouring errors in radiotherapy, there is an ever-increasing emphasis on peer review of contoured volumes. In certain situations (eg,

solo practices, online adaptive radiotherapy), it may not be practical to perform peer review or independent review of contoured organs. It is expected that automatic contour checking will play a role in the future of radiotherapy.[160-162]

Quality Assurance for Designing Beams

MLC leaf settings or block apertures and beam orientation displays must be confirmed prior to clinical use and checked after any software modification. In addition, it is possible to define beam orientations that are physically impossible to set up, and this process requires use of clinical judgment by the dosimetrist generating the treatment plan. Thus, the ability to physically set up a particular beam orientation must be reviewed and verified, particularly for beam orientations involving couch rotation. In such cases, tests might have to be performed to verify clearance between the treatment machine gantry and the patient or the gantry and the treatment couch before finalizing the treatment plan. This is especially true for SBRT treatments and will likely be the case for 4π treatments.

Quality Assurance for Treatment Plan Review

A recent study describing the Radiation Oncology Incident Learning System reported that approximately one-third of all reported errors occurred during treatment planning and plan review.[163] All 3DCRT treatment plans should be reviewed, signed, and dated by the treatment planner. The treating physician should of course also review, approve, and sign the treatment plan. Because most of the clinics are paperless today, various combinations of TPS, R&V systems, and EMR pose unique challenges as to where to approve plans and how to document plan reviews by the treatment planner, medical physicist, and radiation oncologist. Each clinic should develop a process where there is a traceability of these approvals, and it is transparent as to who was involved in the planning and plan review processes. In addition, all plans should be independently checked prior to initiation of radiation therapy by a qualified medical physicist (QMP) who was not involved directly in the production of the plan. Because of the varied implementation of these processes, AAPM Task Group 275[164] and MPPG Report 11.a[165] suggest a risk-based approach in which the exact information

and manner of verification are determined based on potential risk of a safety incident. However, both reports specify key information that should be reported and verified. Most critically, major risk factors such as patient identifiers, treatment site, and prescription should be verified through multiple methods by several independent team members. Additionally, the independent plan check should ensure that setup instructions have been properly recorded—for example, field size, gantry angle, and so on. In addition, beam normalization points (typically at isocenter) can be problematic if they are near nontissue medium or under or near an MLC leaf edge and hence should be moved to a more suitable location. The number of MUs to realize the dose prescription is typically obtained directly from the 3DTPS. These values must be independently checked either by hand calculations or, more typically, independent computer calculations. An action level should be established based upon the accuracy of the computer algorithm and independent dose calculation procedure. Obviously, any MU check system must be tested prior to clinical use and following any change or software upgrade. The AAPM Task Group 114 Report provides valuable information on the verification of MU calculations for non-IMRT treatments.[166]

Note that IMRT plans require additional checks, including review of optimization parameters, plan deliverability checks, and maximum doses in and outside of the target. In addition, in the United States, the patient's plan must undergo phantom measurement checks on the intended treatment machine to verify both point dose and spatial dose distribution agreement.

AAPM plan checks are becoming largely automated through homegrown[167,168] and commercial solutions. These software packages range from basic secondary dose calculation to more sophisticated rules engine and industrial methods–driven software. The AAPM's Task Group 275 on Strategies for Effective Physics Plan and Chart Review in Radiation Therapy is in part charged with developing recommendations for software vendors for the development of patient plan checking software.[164] Although, in the past, most could afford the time needed to perform plan checks manually, the online adaptive radiotherapy process does not afford that time. In the age of adaptive radiotherapy, automated plan checks are becoming the necessity, and that will undoubtedly change the field's overall

approach to plan checks moving systematically away from manual work and toward computer-assisted checks.

Quality Assurance Through the Planning Conference

One of the most important components of a 3DCRT QA program is the establishment of a weekly planning QA conference that is attended by radiation oncologists, medical physicists, radiation therapists, and dosimetrists. This is in addition to the normal new-patient chart rounds conference, at which the patient's pertinent medical history, physical, pathology, and diagnostic imaging findings along with the tumor staging and proposed plan of treatment, including the prescription, are presented by the attending radiation oncologists or residents. In a planning QA conference, the group can review the 3DCRT plans using a high-resolution, large-screen video projector connected to the 3DTPS network. GTV, CTV, and PTV contours, DRRs, and dose distributions can all be reviewed very efficiently. This type of planning conference helps the staff to develop a very consistent approach in implementing ICRU 50/62/83 methodology for specifying volumes and provides a very effective peer review mechanism for a 3DCRT clinical program.

Quality Assurance in Plan Implementation and Treatment Verification

If a clinic is in the initial phases of implementing 3DCRT techniques or if experienced users implement new 3DCRT modalities using nonconventional beam orientations, a verification simulation procedure is recommended to confirm the correctness of the beam orientations. It is important to check that all treatment plan parameters are properly implemented. This can be best accomplished by having the treatment planning team available (or on call) during this procedure so that any detected ambiguities or problems can be addressed immediately. When a beam orientation cannot be simulated, EPIDs can be used to obtain orthogonal images for comparison with similar DRRs to ensure correct isocenter positioning. Today, even more advanced onboard imaging and other data localization systems (ie, ultrasound, video surfacing, static kilovolt imaging, kilovolt CBCT, megavolt helical CT, megavolt CBCT,

and MRI) are available.[13,65] Clearly written policy and procedures (P&Ps) should be in place with regard to (1) localization procedures, (2) therapist instructions and tolerance criteria to move (or not move) a patient, (3) whether post-imaging is required when a move is made, (4) subsequent reviews by physicians, and (5) the process for peer review of verification of images. Special care should be taken to ensure that all beam-modifying devices are correctly positioned. Although errors in MLC settings or block fabrication/mounting should be observed when reviewing the portal images, wedge or compensator misalignment is much more problematic and may only be revealed by careful observation during patient setup.

When available, the optical distance indicator or virtual measurement on volumetric setup imaging such as CBCT is also useful in assessing the correctness of the setup of a particular beam. Documentation provides a depth of isocenter below the skin surface on the central ray of the beam, which can then be compared with the isocenter depth measured on the simulator or treatment machine after the beam is set up using the couch and gantry positions specified by the treatment plan.

An R&V system should be used to ensure that the same parameters (within tolerance limits) are used each day. Such systems are valuable for the verification and recording of at least the following parameters: MUs, energy, mode, collimator settings (including independent jaws and MLC), collimator angle, gantry angle, table position, and wedge number and orientation. However, R&V systems must be used with care because they can give the user a false sense of security. For example, if a setup error is made on the first day and the machine geometry parameters are captured, the system will faithfully verify this erroneous setting from day to day. To reduce the chance of this occurring, the patient should be carefully set up according to the treatment plan (best if there is a direct electronic transfer of plan parameters to the R&V system), and a robust P&P for approval of patient treatment position should be in place; upon approval, the parameters are captured with the R&V system. As vendor implementation of Digital Imaging and Communications in Medicine data exchange has matured significantly, the direct transfer of data from the TPS to the R&V system has undoubtedly reduced such errors; however, a careful check of patient position is still recommended. Guidance regarding testing and

commissioning R&V systems has been developed by the International Atomic Energy Agency.[169]

Thermoluminescent dosimeters, diodes, optically stimulated luminescence dosimeters, and metal-oxide-semiconductor field-effect transistor detectors are often used for in vivo dosimetry as described in Chapters 6. Recently, exit portal dosimetry using EPIDs has been used to provide full-field information, even for IMRT fields.[170] Transmission detectors are also playing an increasing role in patient treatment verification. In transmission dosimetry, a large-area detector is mounted on the exit surface of the gantry head, and it compares radiation (fluence and shape) exiting the LINAC with the expectations from the TPS.[171] There has also been a push to use machine log files for daily analysis of patient treatments.[172-174] It is difficult to determine which one of these methods is most effective as they all have some unique benefits, and a combination of techniques may be needed for in-depth defense. To the extent that some of these processes (eg, log file analysis) are passive and run in the background, they are easy and inexpensive to perform and potentially offer free information for prevention of patient treatment errors.

ROLES AND RESPONSIBILITIES OF A QUALIFIED MEDICAL PHYSICIST

A QMP has an important role to play in ensuring the safety and quality of radiotherapy treatment delivery.[175] While this role is integrated into an overall multidisciplinary team effort, which includes radiation oncologists, therapists, dosimetrists, and nurses, among others, the physicist is uniquely poised to serve as a leader to build consensus and elevate the communication and teamwork among the various members of the department. This is because the QMP has been trained in the scientific method, empowering them to logically implement and refine procedures while identifying accompanying potential pitfalls. In addition, the physicist is one of the few team members in radiation oncology who is not limited to a particular duty (eg, treatment planning) or location (eg, linac) throughout the day, which enhances both their perspective of the entire treatment workflow and the interactions among various team members. Finally, the physicist has been trained as an innovator and is able to identify and adopt

new technologic advances into the clinic. An example focused on supporting clinical trials is presented in AAPM Report 113[176] and enumerates the various responsibilities of the physicist at all stages of this specific workflow, highlighting the breadth and depth of duties of a QMP.

SUMMARY

The use of 3D planning and conformal therapy has had a major impact on the practice of radiation therapy. Advances in computing and medical imaging along with the emergence of AI-based RT tools continue to keep 3DCRT a fertile area for ongoing research and development efforts. Phase I/II and III 3DCRT dose escalation studies in several disease sites have been conducted by the Radiation Therapy Oncology Group, now part of NRG Oncology, under cooperative agreement with the NCI.[177] Current use of 3DCRT in clinical trials focuses more on fractionation alternatives including hypofractionation and SBRT and combination therapies (with chemotherapy, surgery, and/or immunotherapy). In addition, there are many other individual institutional studies that have shown the benefits of 3D planning and conformal therapy, particularly for prostate cancer, head and neck cancer, and lung cancer, as documented in the literature.[178] Patients identified to benefit most from 3D planning and 3DCRT are those with tumors in sites with complex anatomy, irregularly shaped tumor volumes, tumors adjacent to radiation-sensitive normal structures, and undergoing small-volume or high-dose treatments. However, as with any major technical advance in radiation oncology, 3DCRT use must be supported with enhanced QA from all members of the treatment team.

CHAPTER 11

Physics and Dosimetry of Proton Therapy

Brian Winey

PHYSICS OF PROTONS

As protons travel through media, protons interact with the media through electromagnetic interactions, nuclear interactions, and Coulomb scattering.[1,2] The electromagnetic interactions between the proton and the media can be described according to the stopping power equation, known as the Bethe equation:

$$\frac{S_{\mathrm{el}}}{\rho} = -\frac{1}{\rho}\frac{\mathrm{d}E}{\mathrm{d}x} = \frac{4\pi r_{\mathrm{e}}^2 m_{\mathrm{e}} c^2}{\beta^2}\frac{1}{u}\frac{Z}{A}z^2 L(\beta)$$

where r_e is the electron radius, $m_e c^2$ is the electron rest energy, u is the atomic mass unit, β is the particle velocity, Z is the atomic number of the medium, A is the relative atomic mass of the medium, and z is the charge number of the particle ($p = 1$, $C = 6$).

The term $L(\beta)$ can be expanded as:

$$L(\beta) = L_0(\beta) + zL_1(\beta) + z^2 L_2(\beta)$$

where the individual terms are defined as follows:

$$L_0(\beta) = \frac{1}{2} ln\left(\frac{2m_e c^2 \beta^2 W_m}{1-\beta^2} \right) - \beta^2 - ln(I) - \frac{C}{Z} - \frac{\delta}{2}$$

$$L_1(\beta) = g_1 \beta^{-2g2}$$

$$z^2 L_2(\beta) = -\left(\frac{z\alpha}{\beta} \right)^2 \sum_{n=1}^{\infty} \frac{1}{\left[n\left[n^2 + \left(\frac{z\alpha}{\beta} \right)^2 \right] \right]}$$

where W_m is the largest possible energy loss in a single collision with a free electron, C/Z is the shell correction to account for the bound state of K and L shell electrons, and $\Delta/2$ is the Fermi density effect correction. The second factor, L_1, is known as the Barkas correction factor and is an empirical fit with variable g dependent upon the medium. The final term can be approximated in the limit of the particle traveling faster than the atomic electron as the Bloch approximation:

$$z^2 L_2(\beta) = -\left(\frac{z\alpha}{\beta} \right)^2 \left[1.20 - \left(\frac{z\alpha}{\beta} \right)^2 \left(1.04 - 0.85\left(\frac{z\alpha}{\beta} \right)^2 + 0.343\left(\frac{z\alpha}{\beta} \right)^4 \right) \right]$$

This now gives the Bethe-Bloch equation that describes the proton-stopping power in a medium:

$$\frac{S_{\mathrm{el}}}{\rho} = -\frac{1}{\rho}\frac{\mathrm{d}E}{\mathrm{d}x} = \frac{4\pi r_{\mathrm{e}}^2 m_{\mathrm{e}} c^2}{\beta^2}\frac{1}{u}\frac{Z}{A}z^2$$
$$\left[\frac{1}{2}\ln\left(\frac{2m_{\mathrm{e}}c^2\beta^2 W_m}{1-\beta^2}\right) - \beta^2 - \ln(I) - \frac{C}{Z} - \frac{\delta}{2} + L_1(\beta) + z^2 L_2(\beta)\right]$$

In general, the electromagnetic interactions increase as the proton velocity (energy) decreases (Figure 11.1).

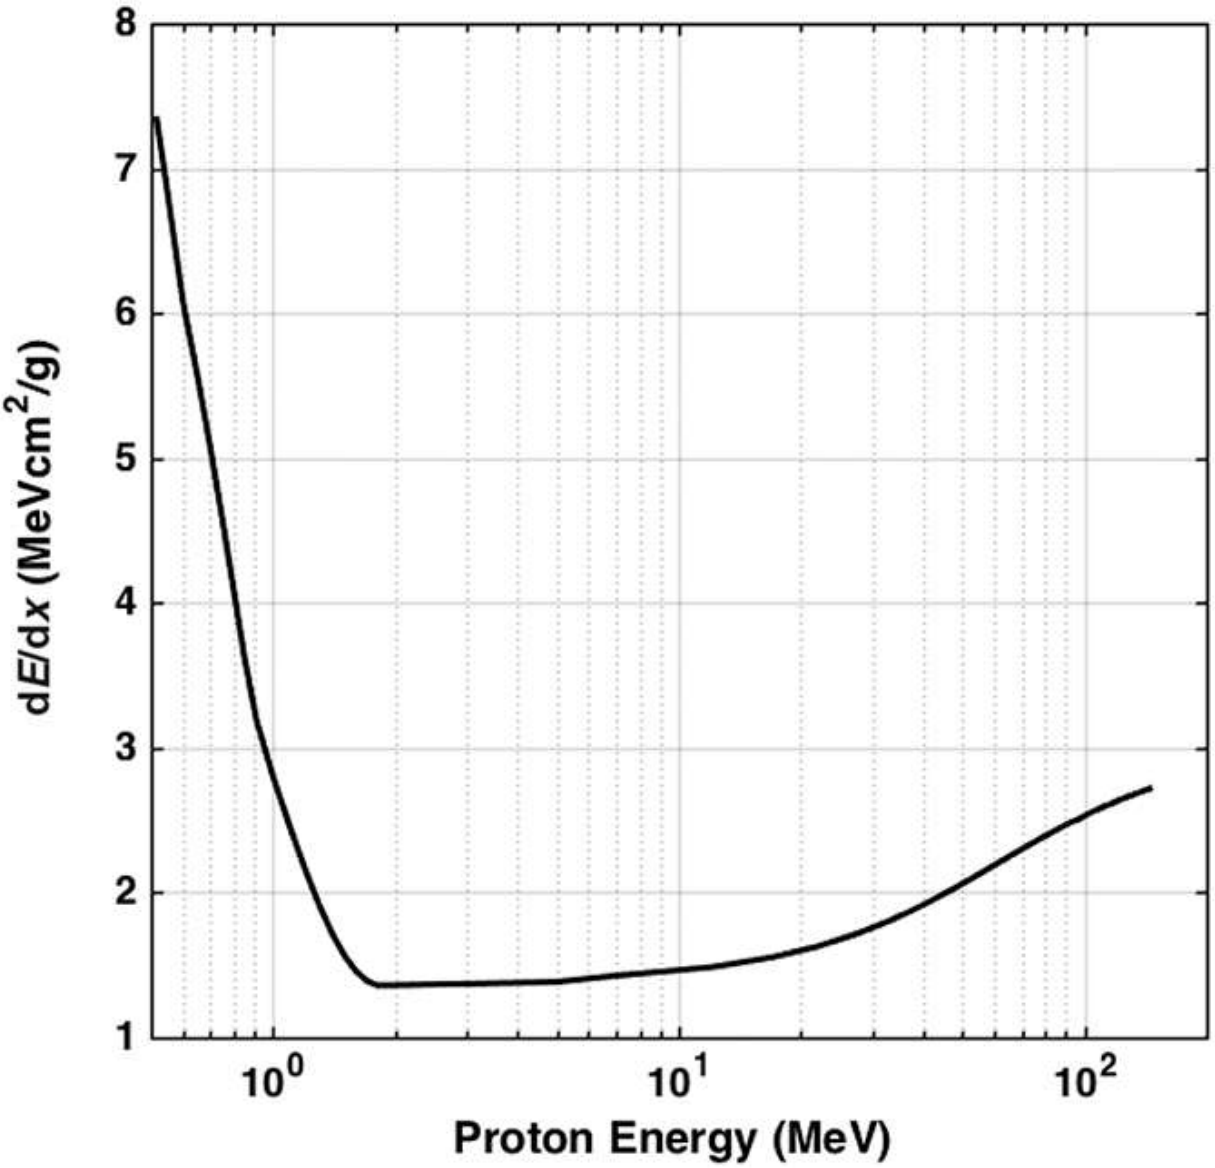

FIGURE 11.1 The energy loss (d*E*/d*x*) as a function of proton kinetic energy for protons traveling through water. Most importantly, the energy loss increases rapidly as the proton slows in the medium. This rapid energy loss gives rise to the Bragg peak.

In addition to the electromagnetic interactions, the nuclear interactions are composed of both elastic and nonelastic interactions with the majority of dose deposited by the nonelastic interactions that result in secondary nuclear particles, primarily protons along with gamma radiation. Some of the gamma radiations produced in the nuclear interactions are "prompt gammas" that can be measured to determine the Bragg peak location in the media (REF). Other nuclear interactions result in positrons, which can be

measured with positron emission tomography imaging as a signal proportional to the proton interactions (REF). The nonelastic nuclear interactions are mostly independent of particle velocity until the particle slows to a resonance velocity, which results in an increase in the nuclear interaction cross section, similar to the electromagnetic interactions. Combined, the nuclear and electromagnetic interactions give rise to the famous Bragg curve of particle therapy (Figure 11.2). The relationship between proton energy and proton range[3] is detailed in Figure 11.3. Typical clinical proton therapy centers provide proton energies from about 70 to 235 or 250 MeV.

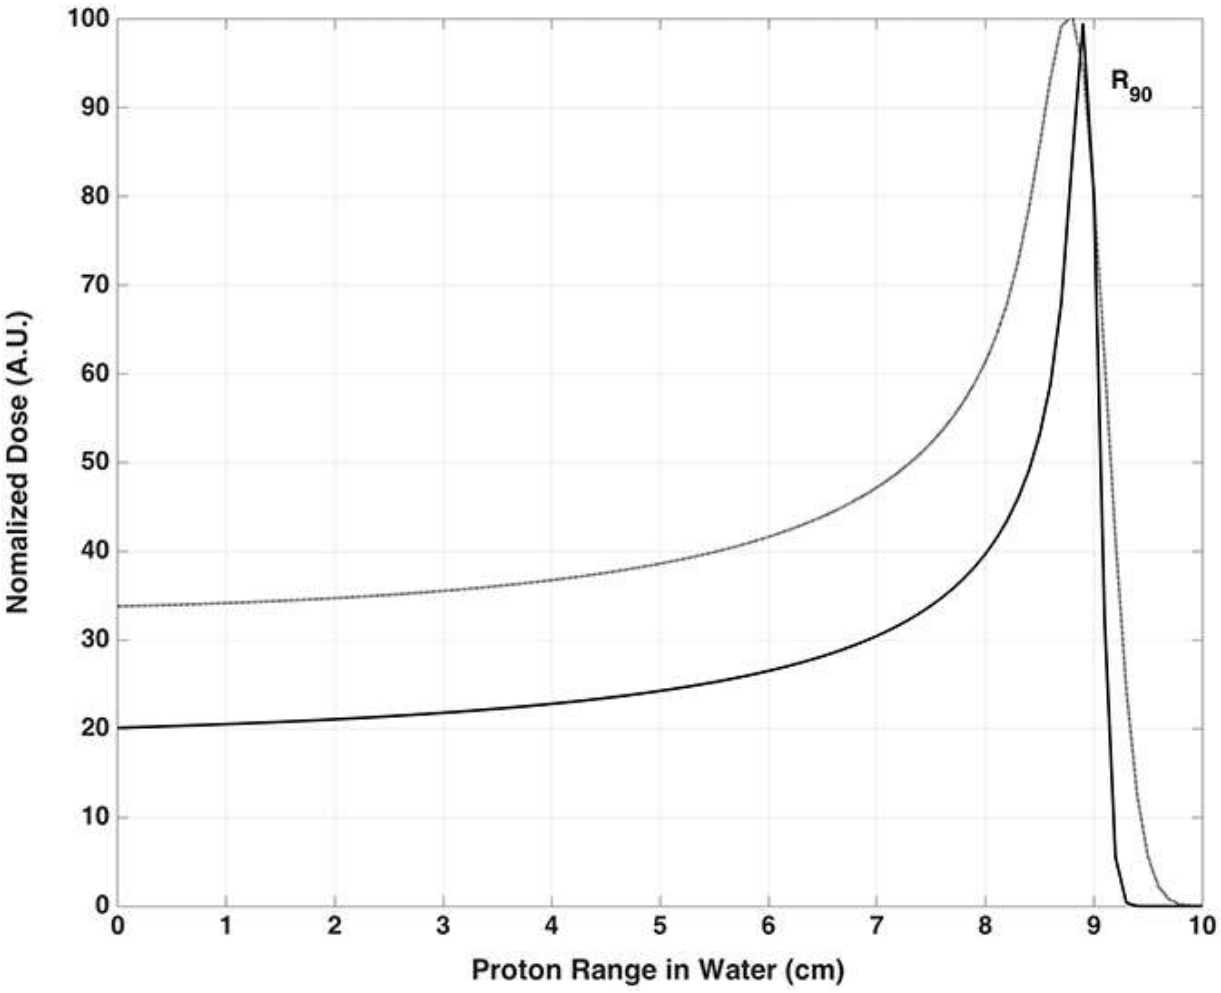

FIGURE 11.2 The proton energy deposited into the medium (water) as a function of proton range. The dotted line represents the effects of proton energy straggling as the protons stochastically interact with the medium. The R_{90} range is labeled.

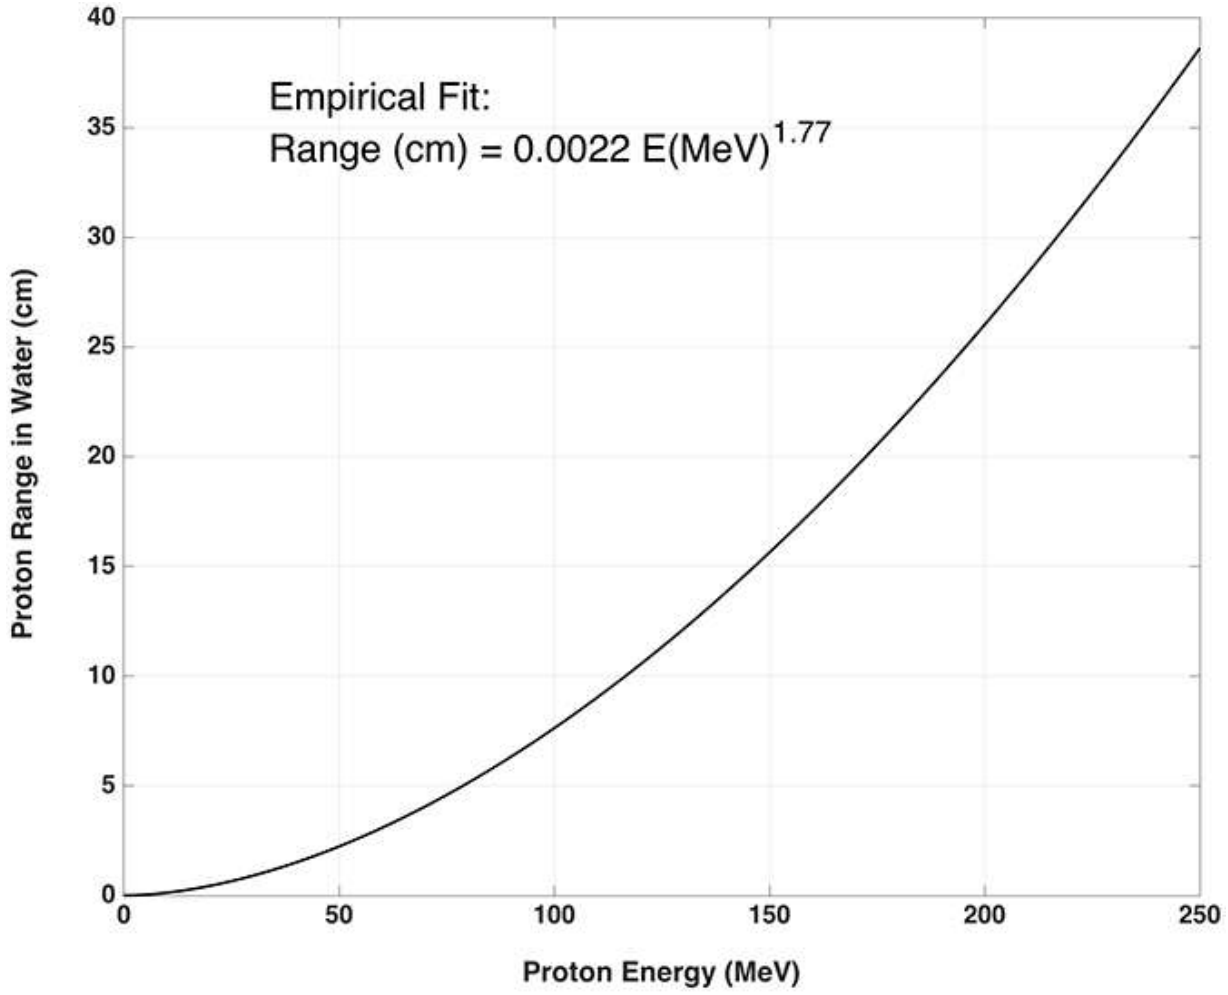

FIGURE 11.3 The relationship of proton energy and range (R_{90}) in water. The graph is a commonly cited fit[3] to empirical data that are not displayed. Typical clinical proton therapy accelerators provide proton energies from about 70 MeV (R_{90} = 4 cm) to 235 MeV (R_{90} = 35 cm).

Since the process of particles traveling through media is stochastic, the particles can lose energy at different rates. The energy straggling of the protons broadens the Bragg peak as the particles travel deeper into the media and the spectrum of energies in the beam increases in width. The clinical result is the broadening of the distal penumbra of the particle beam, particularly evident when treating deep targets (see Figure 11.2).

As the particles travel through the medium, the particles undergo Coulomb scattering events with the nuclei. Due to the elastic nature, little energy is lost in the Coulomb scattering events, but the effect is most pronounced in the shape of the beam as it progresses through the medium.

Multiple Coulomb scattering (MCS) affects the beam output for small fields, dose coverage of targets, dose homogeneity, range straggling, and increased lateral penumbra (Figure 11.4). In fact for small proton beams (diameter <1 cm for ranges >10 cm), the MCS events can result in a loss of the Bragg peak along the central axis and inside the treatment target (Figure 11.4).

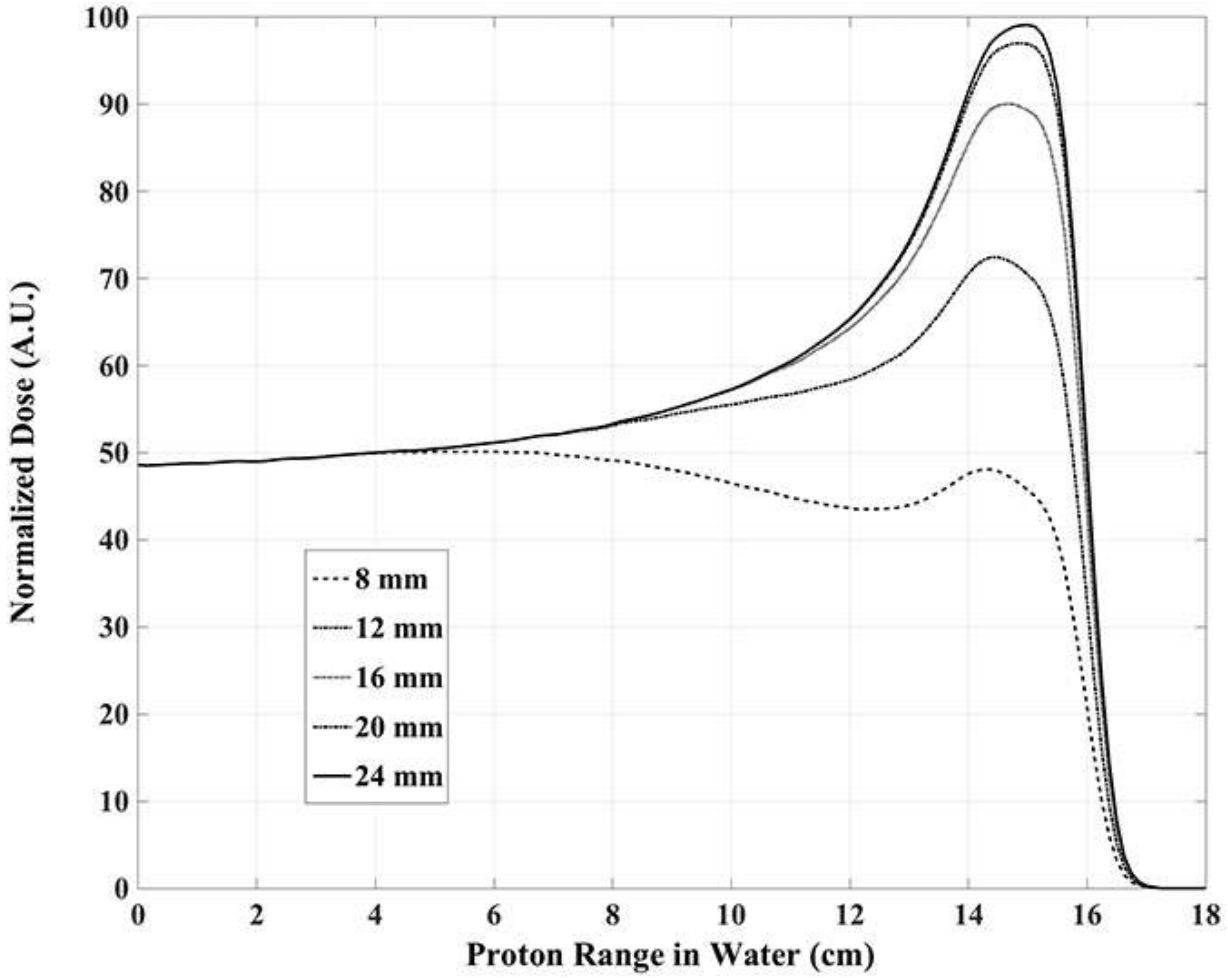

FIGURE 11.4 A central axis depth dose curve for a Bragg peak with a range of 15.5 versus field size. All fields are given for a range of 15.5 cm, and the field size decreases from 24 to 8 mm. Similar effects can be observed with single pencil beams. As the field size increases, the lateral scatter of neighboring pencil beams provides lateral equilibrium along the central axis and restores the Bragg peak.

DOSIMETRY

Absolute dosimetry in proton therapy is typically performed using Faraday cups or calorimetry, with Faraday cups being more common.[2] Aside from absolute dosimetry, most clinical proton therapy centers rely upon ionization chambers to perform beam calibrations. In many ways, proton beam dosimetry is similar to photon therapy. Dosimetry must be traceable to a primary standard radiation source (eg, National Institute of Standards and Technology in the United States) where the radiation dose is typically defined in a free air ionization chamber with a cobalt source. Institutions can rely on Accredited Dosimetry Calibration Laboratories to supply an absolute calibration factor for ionization chambers. Current protocols utilize dose-to-water calculations and correct for the proton beam quality relative to cobalt.

According to Technical Report Series (TRS) published by the IAEA (INTERNATIONAL ATOMIC ENERGY AGENCY) 398 and International Commission on Radiation Units & Measurements (ICRU) Report 78,[1] a calibrated ionization chamber can be used to perform calibration of a proton beam according to the following equation:

$$D_{w,Q_p} = M_{Q_p} N_{D,w,Q_{p0}} k_{Q_p,Q_{p0}}$$

where the measurement, M, is corrected for pressure, temperature, polarization, and recombination. The k_q factor is a function of residual range (R_{res}) of the proton beam, which is correlated with the spectrum of proton energies at the point of measurements.

Of particular note in scanned beam proton therapy, instantaneous dose rates in the volume of the ionization chamber can be significantly higher than the scattered proton beams and recombination can reduce the accuracy of the output measurements. Some proton therapy accelerators can deliver lower beam currents, or an institution can purchase ionization chambers designed for scanned proton beams. A proton beam calibration measurement must be performed in an irradiated volume large enough to reduce the effects of scattering, including Halo dose perturbations, and volume averaging in the volume of the ionization chamber. Typically, an

ionization chamber will be placed in the center of a field size of at least 10 cm × 10 cm and a modulation width of at least 10 cm (R_{res} = 5 cm, assuming the ionization chamber is positioned in the middle of the volume).

While the physical dose of protons is measured and recorded similarly to photon therapy beams, the biologic dosimetry is different. The historical and still common practice is to apply a relative biologic effectiveness (RBE) correction factor of 1.1 to the physical dose in order to correct for the increased clinical effectiveness of the proton physical dose delivered to the patient relative to a photon treatment of the same physical dose.[4] Proton beam radiation therapy is typically quoted in Gy RBE, such that the physical dose is multiplied by the RBE correction factor:

$$D_{Gy,\mathrm{RBE}} = 1.1\, D_{Gy}$$

The RBE factor of 1.1 is not constant for all cell types, clinical end points, or locations along the proton dose curve.[5] There are many studies analyzing the effects of variable RBE or measuring cell and end point–specific RBE values.[4-9] While the clinical use of 1.1 as the standard RBE multiplier continues, there remains uncertainty regarding the most accurate RBE factor for proton beam therapy. In addition to the uncertainty of the RBE value for proton therapy, more recent studies that have begun to explore the potential RBE differences for pencil-beam scanning (PBS) deliveries compared to historical data with scattered proton beams, particularly when the instantaneous dose rate is much higher that the scattered proton beams.[10-15] The biologic dose of proton therapy remains a research topic. Most clinical dose calculations rely upon a static RBE value of 1.1. Since the RBE of protons can depend upon cell type, the position of the cells in the cell cycle, linear energy transfer of the protons, and the local tissue environment, studies continue to evaluate the RBE[9,5,13,16-19] and the local (micro) dosimetry through biological Monte Carlo simulations.[20-22]

UNCERTAINTIES

Physical dose and particle interactions have long been described in the literature, and the fundamental physics is generally well understood. There remains some uncertainty in the cross section interactions between protons

and nuclei (I)[23] in the above equations, but commissioning measurements of clinical systems can greatly reduce the uncertainties of the underlying physics for water measurements and dose calculations.

Uncertainties in proton therapy delivery remain and affect the accuracy of the proton beam delivery to the intended target. Due to the sharpness of the Bragg peak, uncertainties that affect the proton range can result in large underdosing in the target when the Bragg peak stops prematurely or overdosing of the surrounding tissues when the Bragg peak travels farther than intended into the patient.

There are generally two classes of uncertainties that affect the range of the proton Bragg peak in the patient: systematic and random. Uncertainties in both categories can be mitigated with various methods during pretreatment imaging, treatment planning, and treatment room imaging. A summary of both categories of uncertainties can be found in Table 11.1. The important note is the larger dosimetric effect of systematic versus random uncertainties in the proton beam delivery. It is also important to note that many of the uncertainties are present in photon or electron beam therapy but the Bragg peak in proton therapy can create unique dosimetric uncertainties.

TABLE 11.1 A BRIEF AND NONEXHAUSTIVE LIST OF UNCERTAINTIES THAT AFFECT THE DOSIMETRIC DELIVERY OF PROTONS[24]

Systematic	Random
CT stopping power calibration	CT noise
Beam energy/range calibration	Beam energy tuning
Ion chamber calibration	Spot position and weight
Immobilization densities	Patient positioning
Implanted device densities/artifacts	Anatomic motion
Anatomic changes	Anatomic changes
Heterogeneities in silico	Heterogeneities in vivo

The magnitude of the uncertainties is not listed.
CT, computed tomography.

Many of the uncertainties have both systematic and random contributions due to the differences of calibration and delivery or treatment planning system (TPS) calculation versus delivery. For example, anatomy might not be accurately captured in the computed tomography (CT) in the case of a filled sinus cavity that can become a systematic range error for the treatment of a nasopharyngeal lesion if the sinus were to drain prior to the first treatment. Other anatomic changes such as motion can be more random if the motion and interplay with the proton beam delivery varies with each fraction.

To mitigate the dosimetric effects of the listed uncertainties, or increase the robustness of the treatment plan, there are multiple methods that can be employed. One of the simplest and most robust methods is to utilize more than one treatment beam. The use of multiple beams can spread the uncertainty of a single-beam direction and reduce the magnitude of a dose uncertainty to a single location. Depending upon the time scale of the random uncertainties, multiple beams can also reduce the magnitude of the random uncertainty simply by increasing the time of proton beam delivery.
