While the Bragg peak reduces both the entrance and exit doses compared to photon beams to greatly reduce the integral dose to organs outside the target, the use of multiple beams can increase the integral dose. It is a clinical decision whether the increase in robustness using multiple beams is worth the increased integral dose. In some treatment sites, the increased integral dose can be deposited in the surrounding tissues that have a low risk of radiation-induced toxicities. In other sites, the risk of toxicities is greater and the clinical decision leads to the use of a single-treatment beam, for example, sacral sarcomas or ocular melanomas.

A second method to increase the robustness of the treatment delivery is to use margins, similar to photon therapy. Specific to proton therapy, the margins at the distal edge of the target are often determined separately from the lateral margins specific to a beam angle geometry. In addition to margins, the distal edge of a treatment beam can be “smeared,” which decreases the distal conformality in the lateral direction of the beam such that tissue motion or patient setup uncertainties have a reduced effect on the target dose, although smearing is much less common in PBS deliveries compared to scattered deliveries.

A third method that can be used in more recent TPSs is a "robust optimization" technique. In addition to the more common dose objectives and constraints for the targets and organs used in common inverse plan optimization, the basic premise of a robust optimizer considers random and systematic uncertainties, including range uncertainties, in the dose optimization cost function that controls the plan optimizer.[25-28] In other words, the optimizer considers not only the dose to the target or organs at risk (OARs) but also the risk of overdosing the OAR or underdosing the target in the presence of range and setup uncertainties. The cost function penalizes plans that have higher risk of dose uncertainty and essentially reduces the presence of high-dose gradients in the optimized plan. More robust plans may have higher OAR doses, but the certainty of the delivery is much higher if the model accurately captures the uncertainties of the treatment workflow. Generally, more robust plans result in less sharp dose gradients in close proximity to avoidance regions, such that the effect of range or dose uncertainties will be reduced.[29-31]

Robustness has been demonstrated to account for systematic and random uncertainties that follow predictable or normal distributions. When an uncertainty is patient specific, varies in a nonnormal distribution, or exceeds predetermined (often site-specific) magnitudes, the robustness model often fails to account for the uncertainty, or the robustness model will require a large volume of normal to be irradiated to increase the probability of target coverage.[32] In these cases, a clinical decision is often made to reduce target coverage, increase dose to the normal tissues, ignore a fringe case of uncertainty, or rescan the patient to generate a new plan.

Robust planning methods can reduce the need for some margins and increase the certainty of the dosimetry calculated in the TPS being delivered to the patient.

In the case of generating a new plan, much work is being pursued to develop adaptive proton therapy following in the pioneering work in the photon clinics. When the dosimetric uncertainties are larger, particularly in the event of large anatomic changes from either weight loss, air pockets, fluid changes, or target migration, the need for triage and new proton planning are essential to increase the fidelity of the proton dose delivery to the targeted tissues. Many recent studies have demonstrated the need and potential avenues for pursuing adaptive proton therapy workflows.[33-38]

Some institutions, such as the Paul Scherrer Institute (PSI) in Switzerland, have begun to deliver adaptive proton therapy treatment plans.

TREATMENT PLANNING AND DELIVERY

While the Bragg peak is commonly known, it is a continual evolution to use the Bragg peak optimally for the treatment of a target volume. There are essential two methods for proton therapy delivery: scattered and scanned. Scattered therapy was the dominant solution for more than 50 years of treatment but has faded as most proton therapy centers now use scanning delivery systems.

Scattered Beams

Briefly, scattered systems use scatterers composed of various plastics and metals to increase the diameter of the proton pencil beam within a specified flatness and symmetry. A proton beam exits the accelerator with a sigma on the scale of millimeters or 1 to 2 cm, depending upon the system and energy selection method. A typical ocular line requires very little scattering, but targets larger than an ocular target require larger beam diameters. Common double-scattering systems use multiple scattering elements to achieve flat proton beams up to a clinically flat 25 cm diameter. Once the beam is scattered to the appropriately specified diameter, apertures are used to laterally shape the proton beam to the shape of the target volume.

In addition to the lateral shape of the proton beam, the size of the beam along the beam axis is variable and specified by the modulation of the Bragg peak. There are multiple methods of modulation, which essentially modulate the energy of the proton beam to change the range of the protons in the patient. The summation of the multiple energy proton beams results in a spread-out Bragg peak, which provides a flat dose distribution inside the target volume (Figure 11.5). The modulation of the proton beam energy can occur at the accelerator, in the energy selection system (ESS), with a modulation wheel, or generally with any technique that adds material in the beam path. One of the more common modulation methods paired with a cyclotron accelerator uses a modulation wheel that is composed of a wheel with increasing steps of material thickness. The wheel rotates through the beam path and essentially sweeps the proton Bragg peak through the

treatment volume multiple (hundreds) times each second. Synchrotron accelerators can generate variable energies, depending upon the number of accelerating revolutions in the ring, and do not require additional materials to change the energy of the protons. More details regarding the differences between accelerators will follow.

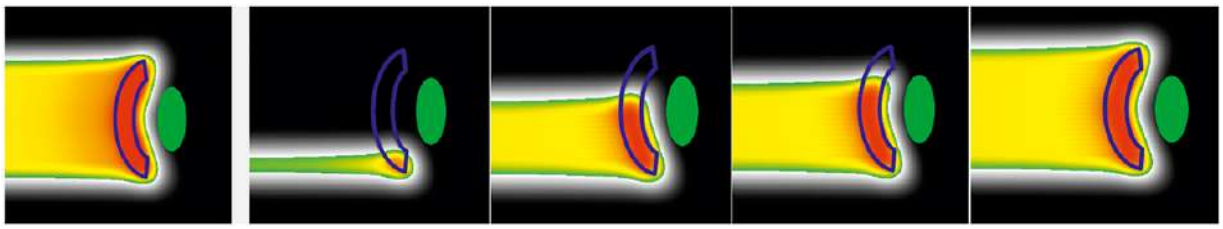

FIGURE 11.5 A comparison of the dose delivered by a scattered beam (left) and a scanned beam at different times in the field delivery beginning with the first pencil beam and scanned across the blue target volume.

Scanned Beams

While scattered beams spread the beam laterally, shaped by an aperture, to deliver a uniform dose to the specific target volume, scanned beams sweep a single proton pencil beam (Figure 11.5) orthogonally to the direction of the beam to deposit dose to a "layer" of tissue, either continuously or spot scanning, changing the energy of the protons to move the "layers" and irradiate a volume. In most scattered beam deliveries, the entire target receives a uniform dose, and the beam continues to deliver a uniform dose to the entire target until the time that the prescription dose is delivered. In a scanning system, a small portion of the target is irradiated with a single Bragg peak pencil beam until the prescribed dose of that pencil beam is delivered and then the pencil beam is scanned to the next location. The pencil beam is scanned over the entire volume, using energy changes when necessary to modulate the depth of the pencil beam, until the prescribed dose pattern is delivered (Figure 11.5).

While a scanned beam delivery does not require apertures to provide lateral conformality to the target volume, apertures can provide additional conformality for shallow targets and larger spot sizes.[39] The target depth when the apertures no longer provide a clinical advantage depends upon the spot size of the delivery system.

In addition to reducing the need for physical hardware, scanning systems can provide multiple dosimetric benefits over scattered beams. The primary benefits include:

- Reduced proximal dose in the entrance region
- Greater proximal conformality due to nonuniform modulation
- Ability to deliver nonuniform doses to the target (intensity modulation)
- Greater conformality and organ sparing for complex-shaped targets
- Gradient match lines for large targets, particularly craniospinal irradiation (CSI) treatments

Scanned beam dosimetry can be less robust to motion and other uncertainties listed above, but the robustness of the scanned beam delivery can be improved using robust optimization, margins, rescanning, rapid scanning, and variable spot sizes.

With greater effort toward the deployment of scanned beam systems, the challenges of robustness are being overcome, and the use of scattered beams is diminishing.

Beam Generation

Proton beam therapy relies on the acceleration of protons to speeds approaching the speed of light with energies around 250 MeV to treat most target locations, higher for proton imaging. There are two predominant accelerators, cyclotrons and synchrotrons,[2] with multiple design variations within each of the two general categories. Some have proposed linear accelerators and other novel acceleration technologies, including dielectric wall and laser driven.

Most of the earliest accelerators for proton therapy were cyclotrons due to the simple elegance of the physics and electronics needed for D-shaped cyclotron design. When proton speeds approach relativistic, the simple D cyclotrons require modifications to address the number of revolutions and increased B fields needed for protons that increase in mass at relativistic speeds. Many of the clinical systems use synchrocyclotrons to reduce the size of the cyclotrons.

Cyclotrons, even synchrocyclotrons, can generate quasi- continuous beams with large beam fluence. Higher and more continuous beam currents can allow for more rapid beam delivery, even at Flash dose rates, and reduce the treatment times. The primary drawback of cyclotrons for beam delivery is the need for a secondary ESS to adjust and reduce the nominal beam energy from the cyclotron to the requested beam energy for the specific “layer” to be delivered in the medium. The ESS can dramatically reduce the proton fluence and increase the pencil-beam dimensions. Much work has been done over the years to reduce the negative impacts of the ESS and maintain a higher dose rate and smaller spot size at the point of treatment.

The second dominant accelerator design is the synchrotron. Synchrotrons are composed of a ring of bending magnets combined with an injection line (typically a linear accelerator), an energy kicker that provides an energy increase to the protons with every revolution, and an extraction line to direct the protons to the therapy beamline. The bending magnets and timing of the energy “kick” are adjusted in both time and, in the case of the bending magnets, magnitude with each revolution such that the ring components are in synchrony with the protons.

The design of the synchrotron results in “bunches” of protons being accelerated together, the bunch revolving a specific number of rotations to achieve the specified energy (speed), the proton bunch being extracted to the beamline, and the process repeating until the total expected number of protons and energies are delivered. One of the primary advantages of a synchrotron is the ability to generate specific energies, depending upon the number of revolutions through the ring and passing through the “kicker,” thus removing the need for an ESS and potentially decreasing the size of the proton beam. Second, higher energies can be achieved with more revolutions in the ring so long as the bending magnets are capable of generating field strengths large enough to maintain the protons along the circular path. With stronger bending magnets, synchrotrons are most frequently used for higher mass particles including carbon ion therapy centers, although work is being done to develop a cyclotron-based carbon ion treatment center.

While synchrotrons can generate proton beams of specific energies without an ESS, the duty cycle of the accelerator can increase the total

beam delivery time due to the "dead" time needed to accelerate another "bunch" of protons. Much research and development have been completed to mitigate the time delays in synchrotron deliveries including larger spill sizes to deliver more protons per bunch, variable energy extraction to reduce the waste of protons at the end of a spill, faster accelerating cycles, and higher scanning speeds. Combined these improvements has allowed synchrotron delivery times to become very similar to cyclotrons, except in the largest treatment volumes.

A final comparison between cyclotrons and synchrotrons might be the practical concern of shielding and building construction. Cyclotrons can be deployed rapidly and can be small when using superconducting magnets in the cyclotron. However, cyclotrons, due to the need for ESS, can require larger amounts of shielding. Synchrotrons have smaller individual components, but the total size is larger than a cyclotron. Synchrotrons require less shielding, and the buildings can be cheaper. Institutions are still discovering which accelerator design is more cost-effective over the long-term use of the devices, including repairs and maintenance, particularly when a synchrotron is more modular and a cyclotron can be simpler. Overall, cyclotrons are used in more clinical installations, and both accelerators can be used to generate clinically stable proton therapy beams for scanned beam deliveries.

Site-Specific Proton Treatment Planning

The earliest proton therapy treatments were delivered to cranial (pituitary) and ocular targets. Currently, ocular proton therapy is the most common proton therapy site by patient numbers worldwide.[40] The primary reasons for the popularity of ocular treatment popularity are the target location, low proton energy, and small treatment fields. When proton therapy began in the physics accelerator laboratories, there were many accelerators capable of reaching 70 MeV and the beam delivery required little scattering to achieve the lateral field sizes needed for the ocular targets. While more details of proton therapy planning will be provided in a later chapter, some of the sites commonly treated with protons as well as some of the treatment planning considerations, given the prior context are highlighted below.

Brain

Cranial targets were the first recorded treatments with proton and ion beams.[41-46] The treatments were straightforward with opposed lateral beams targeting the sella for pituitary therapies. With the advent of three-dimensional (3D) imaging, more diagnoses in the brain are currently treated, including both conventional and stereotactic radiosurgery fractionation techniques.

When considering a treatment plan for a cranial target, protons can reduce the normal brain integral dose and dose to sensitive structures, such as the optic apparatus and the brainstem. The clinical significance of the dose reduction to normal brain is not discussed here. Cranial targets present an excellent proton therapy site due to the ability to use multiple beam entrance angles to increase the dose conformality, reduce the uncertainties from any single beam, and increase the overall robustness of the proton delivery. Typical treatment plans are displayed in Figures 11.6 and 11.7.

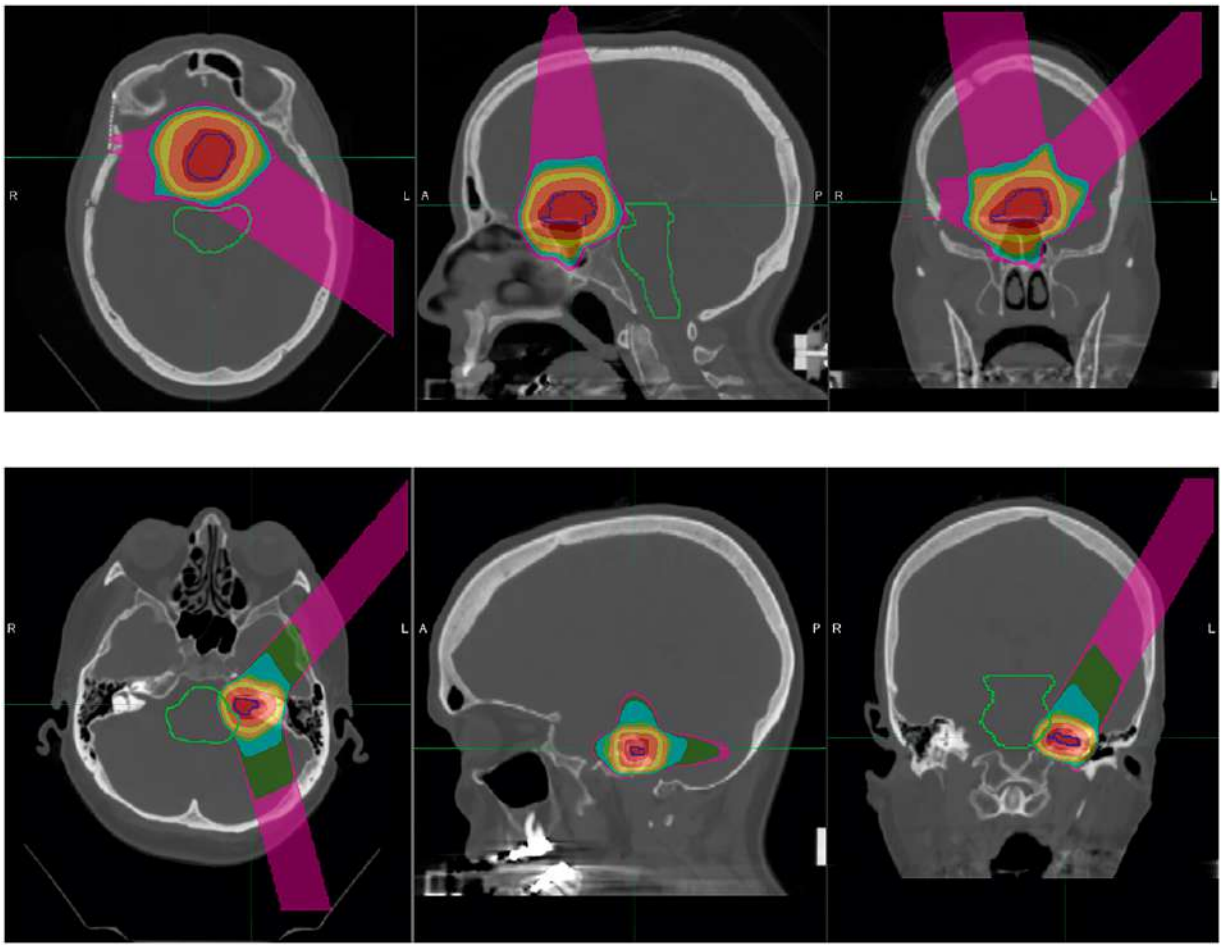

FIGURE 11.6 An example of cranial target treatment plans for a meningioma (top) and an acoustic schwannoma (bottom). The beam angles can be visualized by the low dose.

FIGURE 11.7 A representative treatment plan for a base of skull lesion utilizing beam angles in the axial plane as well as superior oblique beams.

Base of Skull

From a treatment planning perspective, the base of skull targets such as chordomas can be treated with protons to reduce the integral dose to the brain and spare many organs in close proximity to the target volume, particularly the brainstem. Prior to the clinical deployment of scanned beams, the treatment of concave base of skull targets with scattered beams required the use of matched beams inside the target volume. Scanned beam treatment plans can now provide more robust treatments with gradient match lines and increase the dose sparing of organs in close proximity to the targets. Similar to cranial targets, the base of skull lesions can be treated with multiple beam entrance angles, including superior oblique beams to increase the dose conformality, treatment robustness, and normal tissue sparing (Figure 11.7).

Head and Neck

The treatment of head and neck lesions can provide some challenges to treatment planning and delivery, irrespective of the method of proton delivery. Large anatomic variations due to sinus filling, tumor shrinkage, and patient weight loss can greatly affect the accuracy of the proton treatment. The treatment planning advantage for head and neck targets is typically the sparing of normal tissues to reduce acute and chronic toxicities.[47-49]

Typical treatment plans for targets in the nasal region employ two or more treatment fields, but the possible beam angles are often reduced due to the location of the target with respect to the eyes and optic nerves. Beam angles for lesions around the oral cavity and inferior have greater flexibility than nasal targets. In addition, simultaneous boost volumes can also be treated easily with scanned proton beams. Tumor shrinkage or sinus filling/draining can also increase the uncertainty of proton treatment. Adaptive proton therapy will greatly benefit targets in the nasal, oral cavity, and neck locations.

Breast

Proton therapy is now an option for breast radiation therapy.[50-53] The typical treatment employs a single en face proton beam. Breathing motion is mostly oriented along the beam angle such that the motion has little effect

on the treatment delivery. With the use of proton therapy, nodal target volumes can be included in a single scanned beam so long as the total target volume fits in the maximum field size of the treatment delivery system. In addition, simultaneous boost volumes can also be treated easily with scanned proton beams (Figure 11.8).

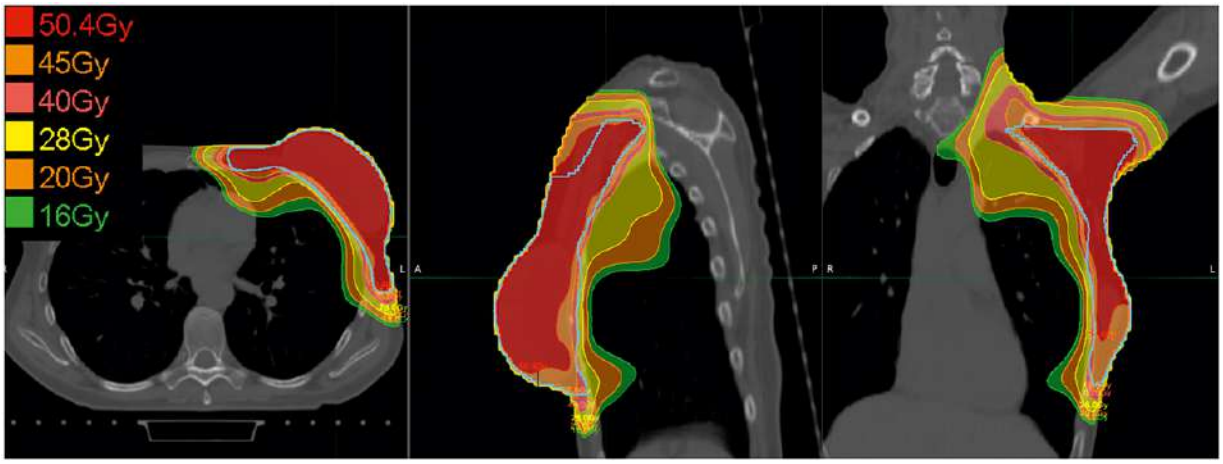

FIGURE 11.8 An example of a scanned beam breast treatment plan with nodal volumes. The treatment uses a single en face proton beam from the anterior oblique direction.

Compared to photon therapy, protons do not have a buildup region since protons are directly ionizing radiation. The increased surface dose can be reduced in the optimization process of a scanned beam plan. In addition, range uncertainties at the distal edge of the treatment volume in the region of the chest wall and lung interface should be accounted in the plan optimization.

Thorax and Abdomen

All thoracic lesions require extensive quality assurance (QA) to determine the optimal method of addressing the tissue heterogeneities in the region of the target volume. Range uncertainties in lung tissue can greatly increase the amount of healthy lung irradiated. In addition, shrinkage of thoracic lesions must be assessed during the course of treatment to reduce the risk of errantly irradiating healthy tissues.

The motion of thoracic and abdominal lesions has long been studied in the context of proton therapy.[2,54-62] Methods to provide robust treatment

plans include density overrides inside the internal target volume, use of 4D CT for optimization, gating, layer rescanning, volumetric rescanning, and tracking.[2,54-62] While there is not yet a consensus regarding the optimal method for treating lesions with large amplitudes of motion (>1-2 cm), it is necessary for any institution to perform a complete analysis of their treatment protocols since the dosimetry is dependent on spot size, scanning speed, dose rate, time for energy (layer) changes, and fractionation scheme.

Generally, as the spot size becomes smaller and the fraction number decreases, the effects of the interplay between the breathing motion and the treatment delivery increase the risk of dosimetric errors. Combinations of the previously mentioned motion management techniques can be deployed to reduce the magnitude of the interplay effects. Briefly, rescanning can effectively increase the number of "fractions" by scanning the same target volume or layer multiple times similar to repeating the same field over multiple fractions.

Sarcomas

Sarcomas can be located in various regions of the body. Some locations, such as the sacral, pelvic, and vertebral locations, can be treated with protons to avoid dose delivery to radiosensitive organs. Typical beam arrangements for sarcomas located along the vertebral column use a single or a couple posterior or posterior oblique beams to provide maximal sparing of organs located anterior to the treated volume.

Children

Pediatric treatments can cover many of the aforementioned treatment sites in the brain and other body sites. More specific and common in the pediatric population is CSI. Proton therapy is commonly used for CSI treatment delivery due to the zero dose exposure in the organs anterior to the vertebral column and whole brain.[63-67] The long-term secondary cancer risk is much lower for protons, especially for soft tissues of the abdomen and thoracic region. Since the in-field doses are similar for both photon and proton pediatric treatments, the secondary risk is assumed to be similar, that is, secondary meningiomas following brain irradiation.

In the past, proton CSI treatments with scattered fields required three levels to reduce the risk of dosimetric hot and cold spots at the match lines. Each level required four to five treatment fields, each with custom apertures and range compensators. The total of 12 to 15 fields and custom hardware can be challenging for treatment planning and delivery workflows. Scanned beams greatly simplified the CSI treatment due to the ability to easily delivery gradient match lines instead of feathering with three levels[26,68-71] (Figure 11.9).

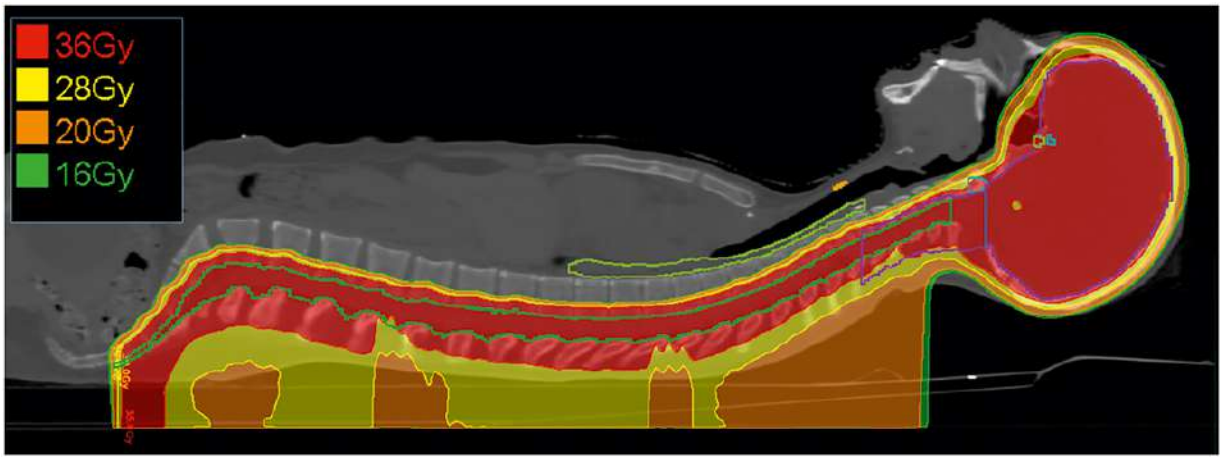

FIGURE 11.9 An example of a scanned beam craniospinal irradiation treatment. The plan uses gradient match lines.

QUALITY ASSURANCE

There are several distinct challenges for QA in a proton therapy clinic.[72] First, there are very few national or international protocols specific for proton therapy QA. The ICRU 78 Report[1] specifies the calibration procedure and recommends other QA measurements. The American Association of Physicists in Medicine (AAPM) has published two proton-specific protocols.[73,74] While the imaging and mechanical systems should operate with similar specifications as photon therapy protocols, the dose delivery systems and dose measurements are very different, including Bragg peak chambers and multilayer ionization chambers to measure Bragg peaks; scintillation screens to measure spot size, shape, and placement; and ionization chambers designed to be less prone to recombination in high-

dose rate PBS deliveries. To supplement the AAPM reports, previously published single-institution studies are often used.[2,75-88]

Second, there are two common TPS dose verification methods. Photon TPS dose verification is typically performed with a secondary dose calculation in an independent software application that is independently commissioned. Monte Carlo dose calculations might be the most similar independent check-in proton therapy, and several institutions have deployed such software for dose checks.[86,89-93] The second method employed by other institutions requires a measurement of every field prior to delivery.[75,81]

Third, the proton therapy user base is much more diverse than the photon radiotherapy clinic. Although there has been a reduction in the number of proton therapy vendors in recent years, there remain multiple proton therapy institutions with different vendors, including multiple beam delivery and verification systems. Each system can have different beam parameters, hardware, and software, in addition to the aforementioned scattered and scanning delivery techniques. Such diversity of systems can make consensus protocols, clinical trials, and credentialing processes difficult to design and requires extensive expertise at each center.

DEVELOPMENTS

Image guidance in proton therapy was the first to deploy 2D image guidance significantly earlier than photon treatment centers but much later to incorporate volumetric imaging solutions. The PSI was one of the first centers to install an in-room CT device. Other centers in Trento (Italy), Dresden (Germany), and the Mayo Clinic (Rochester, MN) have also installed in-room CT devices. The advantage is high-quality imaging and the option for 4D imaging. A diagnostic CT cannot, however, perform imaging at the isocenter and always requires transferring the patient from an imaging position, up to several meters from the isocenter, to the treatment position.

Other institutions have deployed cone beam computed tomography (CBCT) as a volumetric imaging solution. Recent advances in CBCT image quality improvement have allowed for better soft tissue visualization and Hounsfield unit accuracy for dose calculations.[37,35,36,94-100] Some proton vendors have deployed CBCT using the proton gantry as the mechanical

rotation mount, and others have deployed C-arm or couch-mounted 0-ring systems (Figure 11.10).

FIGURE 11.10 Example of a novel cone beam computed tomography design such that the imaging ring is attached to the patient positioner.

Simultaneously with the deployment of in-room volumetric imaging, there are multiple institutions attempting to integrate 3D imaging into adaptive workflows.[38,35,36,94-99] Previously, adaptive proton therapy required separate imaging sessions with external imaging systems such as a CT or magnetic resonance (MR). In-room options can provide more streamlined workflows for adaptations based upon CT information. At this time, there is one in-room MR deployment in Dresden and there have been multiple feasibility studies.[34,101-106]

More than photon therapy, proton therapy greatly benefits from adaptive workflows when the patient has anatomic variations or the target has

motion due to breathing or bowel movements. Even in other target locations, online adaptive proton therapy might reduce the need for some margin expansions. As noted above, adaptive proton therapy can address many of the larger anatomic variations that robust optimization cannot.

While patient setup, anatomic, and dosimetric uncertainties have been addressed by the previous developments, range uncertainties remain in the delivery of proton therapy. There are multiple methods being explored to measure the in vivo range of the proton beam during or after treatment. A simultaneous measurement of the range can be accomplished using implanted devices for lesions located in close proximity to the rectal or vaginal cavity.[107-109] As noted above, protons undergo nuclear interactions to produce prompt gammas and positrons and so methods have been developed to measure these nuclear products of the directly ionizing radiation, both the prompt gammas[110-115] and positrons[116-123] (Figure 11.11). With the in vivo range information, margins might be reduced.

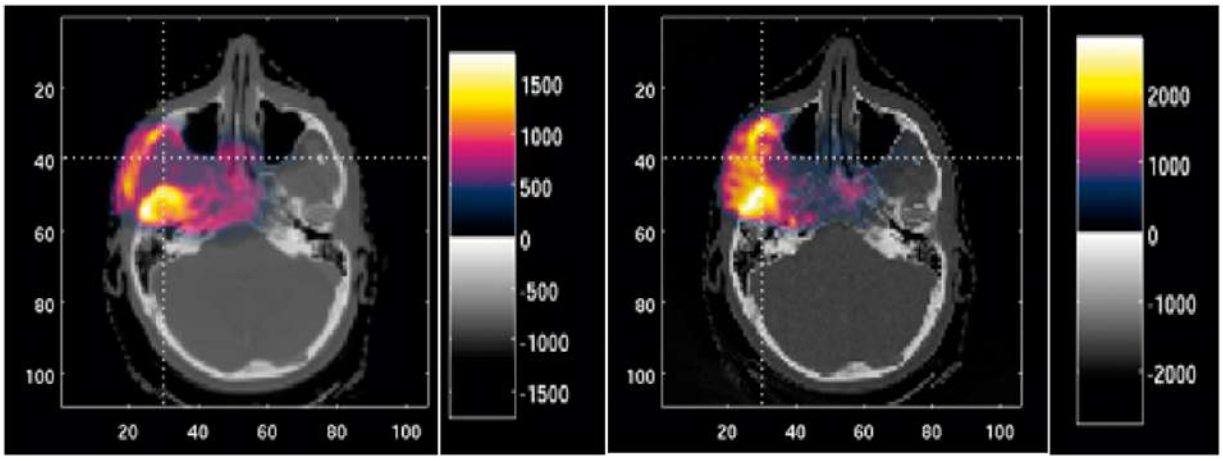

FIGURE 11.11 A sample of a positron emission tomography signal following a proton beam irradiation as simulated in Monte Carlo (left) and measured (right).

CONCLUSION

The physics of proton therapy are generally well understood, and the physical dose distributions greatly reduce the integral dose to healthy tissues as well as organs in close proximity to the targeted volume. There are many topics for further discovery including the integration of 3D

imaging, adaptive workflows, range measurements, and biologic modeling, and more discoveries will increase the therapeutic ratio of proton therapy.

SECTION II

Techniques, Modalities, and Modifiers in Radiation Oncology

CHAPTER 12

Late Effects, QUANTEC, and HyTEC

John P. Kirkpatrick, Michael T. Milano, Jimm Grimm, Louis S. Constine, Zeljko Vujaskovic, and Lawrence B. Marks

Modern cancer therapy is largely predicated on the safe intensification of radiation, chemotherapy, biologic, and now, immunologic adjuvants. This has resulted in a markedly increased survivorship, which now exceeds 64% overall, and for some malignancies, such as breast and prostate cancer, it is much higher. Malignancies resistant to therapy may demand an aggressive treatment approach that often resides at the limit of, or even exceeds, normal tissue tolerance to some "acceptable" degree. Clearly, the potential to ameliorate or prevent such normal tissue damage, or to manage and rehabilitate affected patients, requires an understanding of tissue tolerance to therapy. Because "late effects" manifest months or years after cessation of treatment, therapeutic decisions intended to obviate such effects can be based only on the probability, not the certainty, that such effects will develop. In making such decisions, the balance between efficacy and potential for toxicity should be considered, as well as the influence of host, disease, and treatment-related risk factors.

Historically, radiation therapy (RT) fields and doses were selected empirically, based largely on physicians' clinical experience and judgment. They understood that these empiric guidelines were imprecise and did not completely reflect the underlying anatomy, physiology, molecular biology, and dose distributions. The introduction of three-dimensional (3D) treatment planning offered the promise of quantitative correlates of doses/volumes with clinical outcomes. This promise was partly delivered. When 3D dosimetric information became widely available, guidelines were needed to help physicians predict the relative safety of proposed treatment plans, although only limited data were available.

In 1991, investigators pooled their clinical experience, judgment, and information regarding partial organ tolerance doses and produced the "Emami paper."[1] As discussed later, this paper clearly stated the uncertainties and limitations in its recommendations, and it is rightly admired for addressing a critical clinical need. Numerous studies have since reported associations between dosimetric parameters and normal tissue outcomes. In 2007, a joint task force of physicists and physicians was formed, with the support of the American Society for Therapeutic Radiology and Oncology and the American Association of Physicists in Medicine (AAPM), to summarize the available data in a format useful to clinicians and to update/ refine the estimates provided by Emami et al.

The resulting QUANTEC reviews[2] (*qu*antitative *a*nalysis of *n*ormal *t*issue *e*ffects in the *c*linic) were published in a special issue of the *International Journal of Radiation Oncology, Biology and Physics* in March 2010. Subsequent similar reviews focused on Hypofraction/High Doses per fraction (HyTEC).[3]

HISTORICAL BACKGROUND

The relationship between dose-volume parameters and outcome has been the focus of numerous investigators for decades. A brief summary of historical landmarks is provided to follow, along with our opinion regarding the key contributions and limitations of these reviews (Figure 12.1; Table 12.1).

TABLE 12.1 HISTORICAL OVERVIEW OF SUMMARIES OF DOSE/VOLUME/OUTCOME INFORMATION

Report	Key Contributions	Key Shortcomings
Rubin et al[4]	Introduced the concept of $TD_{5/5}$ and $TD_{50/5}$	Minimal dose-volume data
Emami et al[1]	Concise summary addressing most clinically meaningful end points in a uniform manner	Dose-volume relationship based on limited data (mostly from 2D treatment planning) and, thus, much expert opinion
QUANTEC[2]	Driven largely by the available 3D dose/volume/outcome data. Systematic review addressing many challenges such as organ delineation and confounding factors such as chemotherapy	Dose/volume/outcome data on meaningful clinical outcomes are *not* available for many organs and issues. For some sites, data from published studies were reviewed, but not amenable to data pooling or modeling of outcomes.
HyTEC[3]	Modern dose/volume/outcome data specific to SBRT and SRS. Some reports were specific to tumor control probability (which was not addressed in the other efforts described here). All reports pooled data for modeling outcomes.	Dose/volume/outcome data on meaningful clinical outcomes are *not* available for many organs and issues.

SBRT, stereotactic body radiotherapy; SRS, stereotactic radiosurgery.

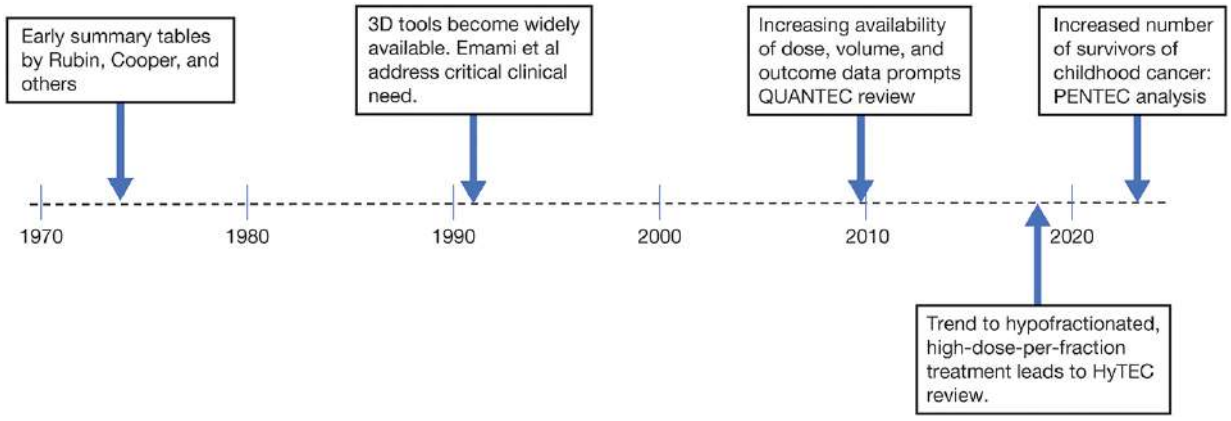

FIGURE 12.1 Key events in the development of dose-volume and normal tissue toxicity relationships in radiation oncology.

INCORPORATION OF 3D DOSE-VOLUME INFORMATION INTO CLINICAL GUIDELINES

The pre-Emami reports[4] were novel in that there were typically no good tools available (to either the authors or clinicians) to accurately quantify the fraction of various organs that were being irradiated. Thus, the dose/volume/outcome information presented consisted largely of estimates based on expert opinion. Similarly, clinicians needed to estimate the partial volumes

of different organs that were being irradiated in their patients in order to apply the provided information.

In the late 1980s and early 1990s, 3D planning systems were providing clinicians with a plethora of information. However, systematic dose/volume/outcome data to guide clinical decisions based on this information were limited. There was an urgent need for clinicians to have some guidance in making clinical dose-volume decisions. The report by Emami et al[1] met this critical need. This report was, and remains, a landmark summary of decades worth of data for a wide variety of organs, supplemented with expert opinion where evidence was lacking.

During the 1990s and 2000s, a large number of studies related dose-volume data to clinical outcomes. The QUANTEC review was an attempt to refine the guidelines based on the available 3D dose/volume/outcome data.

DOSE-VOLUME HISTOGRAMS AND ASSOCIATED FIGURES OF MERIT

Three-dimensional dose-volume data can be difficult for clinicians to readily digest. Visualizing isodose distributions is challenging, and comparing competing distributions is almost impossible. Therefore, dose-volume histograms (DVHs; essentially two-dimensional [2D] representations of the 3D data) were embraced as a rapid way to summarize the dose distribution. Note that DVHs inherently discard information regarding the spatial character of the dose, but it is important to account for and report the variations in fraction size along with the DVH. However, DVHs can also be challenging for clinicians to consider and compare. Therefore, it has become attractive to extract "figures of merit" from the DVH, such as the V_x (the percentage of an organ receiving $\geq x$ Gy). Thus, DVHs and their associated figures of merit are necessary tools to enable clinicians to readily apply 3D information clinically. They are excellent tools but obviously have their shortcomings.

MODEL-BASED ESTIMATES OF OUTCOMES

The Emami et al report systematically used the same DVH-based construct across many organs, for example, the $TD_{5/5}$ and $TD_{50/5}$ for the uniform irradiation of one-third, two-thirds, and the whole volume of an organ. This uniform approach enabled the application of "single unifying models" of dose/volume/outcome across organs. For example, the dose/volume/outcome estimates from Emami et al were used by Burman et al,[5] Kutcher et al,[6] and Lyman et al[7] to generate a set of organ-specific model parameters. Such a uniform approach is attractive to modelers and busy clinicians.

Subsequently, many clinical dose/volume/outcome reports computed parameters for these "unifying models" (eg, Ten Haken et al[8-10]). Other investigators have suggested alternative models that appeared to be better suited to specific organs (vide infra).

The dose/volume/outcome data available for the QUANTEC review were not of a uniform format. Outcomes across organs were correlated with a diverse array of dose-volume metrics (eg, threshold volumes [V_x], threshold doses [D_x], mean doses). Therefore, the QUANTEC review included model-based parameters for just a few organs, and not always in a systematic fashion.

MAJOR DIFFERENCES BETWEEN THE QUANTEC AND EMAMI REVIEWS

Emami et al[1] provided information for 26 organs, judged necessary to support protocols for "three-dimensional treatment planning for high-energy photons (RFP #NCI-CM-36716-21)." Conversely, the QUANTEC review was focused on organs for which the steering committee believed there were meaningful dose/volume/outcome data (Table 12.2).

TABLE 12.2 COMPARISON OF THE CHARACTER/CONTENT OF EMAMI ET AL AND QUANTEC

Characteristics	Emami et al[1]	QUANTEC[2]	HyTEC[3]
Number of organs/tissues reviewed	26	16	7[a]
Data type	Minimal 3D data, Data primarily from 2D era (with 3D exposures inferred)	Mostly 3D data (published in 18-y interval after Emami report)	All 3D data
Format dose-volume limits	Uniform $TD_{5/5}$ and $TD_{50/5}$ for one-third, two-thirds, whole organ	Nonuniform	Nonuniform
End points	Specific, complete	Specific, incomplete	
Expert opinion	Dominant	Much less	None
Impact of chemotherapy	Not explicitly discussed	Addressed individually for each organ	Addressed in each report (but insufficient data for modeling)

[a]Two organs (rectum and bladder) were analyzed specifically for risks after prostate stereotactic body radiotherapy (SBRT).

Emami et al addressed a wide variety of clinical outcomes and thus provided the reader with a set of dose-volume parameters for *essentially* all clinical situations. Conversely, the QUANTEC review was focused on end points where there were dose/volume/outcome data. In this regard, the Emami tables are more complete. For example, consider the QUANTEC summary for the small bowel. A volume restriction is provided for the end point of acute grade greater than or equal to 3 toxicity. No guidance is provided for late small bowel injury, as the authors did not believe that there was meaningful dose/volume/outcome data for late injury. This is a shortcoming of the QUANTEC review, as it is not "complete." When evaluating a proposed 3D treatment plan, one obviously must consider both acute and late injury.

Emami et al presented information in a systematic/uniform manner, facilitating interorgan comparisons and model-based parameter estimates. The QUANTEC review presented dose/volume/outcome data in an organ-specific diverse manner in which they were available in the literature.

DOSE-VOLUME EFFECTS IN HYPOFRACTIONATED HIGH-DOSE-PER-FRACTION TREATMENT

A similar methodology to QUANTEC has been applied to stereotactic body radiotherapy (SBRT) and stereotactic radiosurgery (SRS), in a multidisciplinary effort termed HyTEC, for

High-Dose-per-Fraction, Hypofractionated Treatment Effects in the Clinic,[3,11] addressing hypofractionated treatments versus the predominantly conventionally fractionated regimens in QUANTEC. In addition, whereas QUANTEC focused primarily on normal tissue tolerance, HyTEC addressed tumor control. This collaboration of physicians, physicists, radiobiologists, and biomathematicians was officially organized as the SBRT Working Group (WGSBRT) within the AAPM. The working group received the following charge from AAPM:

> The radiobiology of hypofractionated treatments may differ considerably from that of standard fractionated treatments, in regards to repair, reoxygenation, dose-rate effects, volume effects, fraction size effects, etc. The working group will generate reports, including but not limited to, critically surveying the published data regarding: 1. Tumor response: review of the effect of hypofractionation on local control. 2. Normal tissue response: review of the effect of hypofractionation on normal tissue tolerances. 3. Radiobiology of hypofractionated treatments. 4. Clinical rationales for the diverse prescription schemes in current use (e.g., 20Gy × 3 fractions vs 24Gy × 1 fraction). 5. Standards for reporting outcome, including end points, defining/contouring of target and normal structures, dose definitions.

In this chapter, the HyTEC reviews,[3] published in a special issue of the *International Journal of Radiation Oncology, Biology and Physics* in May 2021, are compared to and synthesized with the QUANTEC studies.

DOSE-VOLUME EFFECTS IN CHILDREN

Pediatric Normal Tissue Effects in the Clinic (PENTEC[12]) is an international multidisciplinary effort to address quantitative dose-volume-outcome relationships for survivors of pediatric cancer. Particular focus was placed on developing tissues that are uniquely sensitive in children; all reviews attempted to account for the impact of biodevelopment[13] on the risks of RT-associated injury.[14] Given the prominent role that chemotherapy plays in the care of children with cancer, the effects of systemic therapies on RT-associated risks were also emphasized.

Because of the often-long latency between RT and the associated late effects in survivors of pediatric cancer, many of the PENTEC reports used decades-old data (eg, from the pre-computed tomography [CT] era). To mitigate this limitation, the physicists involved attempted to estimate the delivered doses (where able) and also semi-objectively scored the quality of the dosimetric data underpinning each of the analyses.[15] This detailed approach was taken by the physicists and modelers in PENTEC—to check the reported doses in the published literature and then modify the doses inputted into their pooled data and associated modeling—is a relatively unique and challenging effort.

Although PENTEC was modeled after QUANTEC, PENTEC was a "more formal" process; *for example*, the Preferred Reporting Items for Systematic Reviews and Meta-Analyses methodology was utilized, and statisticians and epidemiologists played an important role. As with QUANTEC, the PENTEC data were modeled when feasible (which was the case for most of the reports).[16] The full suite of PENTEC papers is expected to be published in early 2024, and several of the early findings from PENTEC are included in this chapter.

MOLECULAR MECHANISMS OF LATE RADIATION DAMAGE

The design of optimal radiation treatment plans and identification of therapeutic strategies to prevent radiation-induced damage would benefit from an understanding of the underlying late effects of ionizing radiation. Both of these issues are further complicated by the variability in sensitivity to radiation observed across disease types and between patients, as well as the current absence of identifiable factors that predict a propensity for radiation-induced toxicity.[17-20]

An early theory for describing the development of acute and late side effects after radiation exposure was based on the target cell hypothesis. This hypothesis is focused on radiation as a direct cause of cell killing in tissues and organs, thus depleting crucial cell populations and resulting in functional deficiency. Radiation is thought to cause irreversible damage to predominantly rapidly proliferating cell populations. These damaged cells in turn lose their ability to replicate and induce a regenerative response. The latent period between radiation exposure and repopulation appears to depend on both tissue turnover time and radiation dose. Both parenchymal cell loss and vascular endothelium damage occur; vascular hyperpermeability and venous exudation follow and have been theorized to contribute to clinically devastating toxicities, such as radiation myelopathy. Although the target cell hypothesis may explain some of the mechanisms by which acute side effects occur, it does not appear to fully explain the development of late side effects. Recent research has shown a complex interaction between multiple cell types, leading to persistent overexpression of reactive oxygen species (ROS), activation of signaling pathways, and production of proinflammatory and profibrotic cytokines.

Although the initial damage done to the DNA, proteins, and membrane lipids of cells by exposure to ionizing radiation is well known, the mechanisms behind the sustained changes in gene expression and signaling pathways that contribute to latent and permanent tissue injury are less clear. This section will focus on the established mechanisms of radiation-induced tissue injury and identify areas in which further efforts are needed to determine the mechanisms driving tissue injury and prognostic markers for the development of radiation injury.

Early Cellular Effects of Radiation

Exposure to ionizing radiation causes direct DNA damage through linear energy transfer as well as indirect damage by radiolytic cleavage of water, yielding hydroxyl radicals capable of abstracting hydrogen from the backbone of DNA to cause double-stranded breaks.[21,22] This damage to genomic DNA causes cell death by apoptosis, mitotic catastrophe, senescence,[23] autophagy, necroptosis, and necrosis.[24,25] Although the ability of hydroxyl radicals to cause DNA damage is significant, the initial increase in hydroxyl radical and other ROS attributable to radiation exposure is negligible compared to the baseline presence of ROS in the cell.[22] Within a few hours of radiation exposure, however, the cell responds by increasing ROS production, creating a cellular environment capable of exacerbating the initial injury by causing oxidative damage to proteins and lipids.[26] This is thought to occur via ROS-mediated activation of mitochondria-dependent and mitochondria-independent metabolic enzymes, including nitric oxide synthases and oxidoreductase enzymes.

Sources of Reactive Oxygen Species

NADPH Oxidases

Nicotinamide adenine dinucleotide phosphate (NADPH) oxidases are a family of broadly distributed oxidoreductase enzymes. Membrane-associated NADPH oxidases are the primary source of ROS in nonphagocytic cells.[27] Under normal conditions, NADPH oxidase–derived superoxide anion is a mediator of maintenance and smooth muscle tone of the vasculature.[28] When these enzymes are induced to begin pathologic overproduction of ROS, however, they can contribute to the development of oxidative stress, resulting in cell damage and disruption of signaling pathways.[29] Nox4, a hydrogen peroxide–producing isoform, is of particular interest, as overproduction of hydrogen peroxide by Nox4 has been shown to be a necessary element of transforming growth factor-β1 (TGF-β1)–mediated cell death.[30]

Mitochondria

Under normal conditions, electrons from the electron transport chain can leak into the mitochondrial matrix and react with oxygen to form a superoxide anion.[31] Following radiation, Leach et al[32] observed that mitochondria in squamous carcinoma cells undergo a permeability transition, causing the release of high levels of ROS into the cytoplasm. They further showed that inhibition of this transition not only attenuates the increase in cytoplasmic free radicals but also prevents radiation-induced activation of mitogen-activated protein kinase, suggesting a causal link between mitochondrial ROS/reactive nitrogen species (RNS) generation and a large group of signal transduction pathways. The role of mitochondrial-generated ROS/RNS in radiation injury is further supported by the radioprotective effect of Mn porphyrin superoxide dismutase (SOD) mimetics, which accumulate preferentially within the mitochondria.[33]

Augmentation of Reactive Oxygen Species From Other Sources

Superoxide anion from any source can react with nitric oxide to form peroxynitrite (ONOO–), which is itself a powerful oxidizing species capable of reacting with other molecules and cellular elements to perpetuate free radical overproduction and cause oxidative damage to the cell.[34]

Free Radicals and the Tissue Response to Radiation

When the increase in ROS production exceeds the antioxidant capacity of the cell, the intracellular environment becomes strongly oxidizing. This change results in altered gene expression as a part of the response to oxidative damage to genomic DNA, modification of redox-sensitive protein activity, and membrane lipid oxidation.[35] All of these insults can affect the structure, function, and signaling capacity of the cell. Of particular importance to the radiation response is the persistent upregulation of transcription factors, including hypoxia-inducible factor-1α (HIF-1α) and nuclear factor κB (NFκB), and cytokines, including TGF-β, TNF-α, bFGF, PDGF, and IL-1, which contributes to the development of radiation-induced tissue injury.[26,36] These molecules all contribute to the vascular changes, inflammation, and cell death observed in response to radiation, but their roles in complex signaling pathways suggest that early changes in the activity of these molecules may also contribute to the disease

process of latent injury. The role of ROS in radiation-induced tissue injury has been confirmed by the finding that SOD overexpression and the use of SOD mimetics can mitigate tissue injury following ionizing radiation exposure.[18,33,37-40] A recent clinical study has shown that targeting ROS-upregulated proinflammatory factors, such as cyclooxygenase-2, interleukin (IL) 1β, tumor necrosis factor (TNF)-α, and TGF-β by synthetic genistein nanoparticles (BIO 300), has a potential to reduce radiation-induced lung toxicity (RILT).[41]

The Role of Inflammation in the Response to Radiation

Although the manifestations of radiation injury can be divided into early and late effects, irradiated tissues show a dynamic population of different inflammatory cell types throughout the "latency" period, suggesting that, on a cellular level, radiation injury is an ongoing disease process.[42] Localization of inflammatory cells is mediated by vascular adhesion markers, and preferentially blocking intercellular adhesion molecule-1 (ICAM-1) does indeed reduce the inflammatory response to radiation in the lungs of C57BL/6 mice.[43,44] The resulting reduction in inflammation was, however, not sufficient to suppress the development of latent pulmonary damage, suggesting that there are other mechanisms at work during this latent period that contribute to disease processes.[43] With the changing inflammatory cell populations come changes in cytokine activity, specifically ILs, TNF-α, TGF-β, monocyte chemoattractant protein-1, and keratinocyte chemoattractant.[42,45,46] Expression of IL-1 messenger RNA (mRNA), together with a two-part upregulation of TGF-β expression, is known to coincide with the development of fibrosis in C57BL/6J mice, suggesting that the inflammatory response does indeed contribute to the development of latent tissue injury.[47] This idea is further supported by the finding that early inhibition of TGF-β reduces radiation-induced pulmonary fibrosis and improves lung function.[48-50] Further studies indicate that administration of exogenous SOD following thoracic radiation reduced the early upregulation of IL-1, TNF-α, and TGF-β and extended postradiation survival.[47] The apparent link between ROS, inflammatory signaling, and latent injury development suggests that early changes in ROS production do affect delayed tissue damage through ongoing perturbations of signaling pathways.

Radiation-Induced Vascular Changes

Exposure to ionizing radiation causes damage to endothelial cells and vascular structural elements, causing increased vascular permeability.[51,52] This vascular dysfunction results in edema as well as decreased perfusion, which can lead to the development of hypoxic regions within the affected tissues.[53] Hypoxia exacerbates the initial injury by increasing the recruitment of inflammatory cells that, in the process of undergoing the respiratory burst, produce ROS and increase tissue hypoxia by consuming the available oxygen.[54] Hypoxia also results in the activation of HIFs. HIF-1α is an ROS-stabilized transcription factor that, under hypoxic conditions, forms a heterodimer with HIF-1β. This heterodimer is translocated to the nucleus, where it binds the hypoxia response element, inducing transcription of genes involved in migration, proliferation, apoptosis, and angiogenesis.[55] This element of the hypoxia response contributes to endothelial cell damage, increasing vascular permeability and, as a result, leakage of fibrin into the extracellular matrix.

Vascular endothelial growth factor (VEGF) is an HIF-mediated growth factor. Under hypoxic conditions, VEGF expression is increased, resulting in aberrant vascular network formation, which leads to irregular perfusion.[56] The resulting cycles of hypoperfusion and reperfusion contribute to oxidative stress, further damaging tissue.[49]

Macrophage accumulation further contributes to the self-perpetuating nature of radiation-induced tissue injury. Accumulation of macrophages is known to occur in areas of low perfusion and inadequate supply of oxygen and is observed in tissues following radiation exposure.[57,58] When activated, these cells produce HIF-1α in order to initiate angiogenesis to correct low perfusion.[58] This response on the part of macrophages increases the level of oxidative stress, continuing the spread of damage through inappropriate continuation of wound healing mechanisms. Inhibition of radiation-induced activation of macrophages has been shown to promote radioprotection of lung tissue.[59,60]

Possible Metabolic Changes

Carbonic anhydrase-9 (CA-9) is commonly used as a hypoxia marker because CA-9 transcription is dependent on HIF-1α. Because carbonic anhydrases act to catalyze the conversion of metabolically produced carbon dioxide to bicarbonate,[61] this increase in CA-9 suggests that cells may also be undergoing a metabolic shift in response to their hypoxic environments. The observed changes in mitochondrial morphology and activity[62] would support altered metabolism in postradiation cells, but further work is necessary to determine the nature of such a change.

Implications

Exposure to ionizing radiation disrupts DNA, causing cell death, but it also causes increased production of ROS in viable cells. The oxidizing environment that results from ROS production exceeding the antioxidant capacity of the cell causes further damage by disrupting cell function and signaling pathways. This disturbance results in changes in vascular integrity, an ongoing inflammatory response, and aberrant angiogenesis. Because the overproduction of ROS is self-perpetuating, these effects are amplified, increasing the area and severity of damage.

Though many of the mechanisms through which ROS production affects the development of late radiation effects remain unclear, it is likely that these early changes initiate disease processes that progress over time to cause the observed late injury. Based on that assumption, the identification of predictive biomarkers of radiation-induced normal tissue injury would individualize radiotherapy and improve treatment outcomes.

SUMMARY BY ORGAN SYSTEM

To provide a consistent summary of the extensive information in the individual organ reviews, the following outline is utilized:

1. Clinical Significance
2. End points
3. Challenges Defining Volumes

4. Dose/Volume/Toxicity Data
5. Factors Affecting Risk
6. Mathematic/Biologic Models
7. Special Situations
8. Recommended Dose-Volume Limits
9. Future Studies
10. Toxicity Scoring Criteria

Note that the brief summaries for each review do not substitute for reading and understanding the original papers and, as necessary, the underlying literature. In addition, the dose-volume limits described in the QUANTEC and HyTEC reviews are intended to supplement, not supplant, clinical judgment.

CENTRAL NERVOUS SYSTEM

Brain

Clinical Significance

The acute and late effects of radiotherapy on the brain are common and represent a significant source of morbidity.[63] In particular, patients with tumor-related neurocognitive dysfunction may exhibit exacerbated deficits after radiotherapy. In addition, the radiation fields used to treat the upper aerodigestive tract (eg, sinuses and pharynx) often include a portion of the brain.

End Points

The acute side effects of RT on the brain include nausea, vomiting, and headache; seizures, visual disturbances, and vertigo are less common.[63] These symptoms are typically transient and generally respond well to medication. The end points for assessing long-term radiation-induced complications are typically radiation necrosis or asymptomatic radiologic changes as seen on serial magnetic resonance imaging (MRI) scans.[63] Other measures have included steroid usage, preservation of performance status, and neurocognitive function.[64-67]

Challenges Defining Volumes

Contouring the entire brain is straightforward, and with appropriate immobilization, there is little intra- or interfraction motion. In contrast, the delineation of subregions (eg, the border between the brainstem and thalamus) and functional segments (eg, the Broca area) of the brain is challenging, and the utility of defining such areas has been difficult to prove.[63] However, recent studies of hippocampal avoidance in patients with brain metastases undergoing whole-brain radiotherapy have shown that minimizing the dose to this structure (contoured with the aid of a high-resolution MRI atlas) can significantly reduce neurocognitive decline.[68,69]

Dose/Volume/Toxicity Data

For fractionated radiotherapy to the brain, the relationship between dose and radiation necrosis for partial brain irradiation is shown in Figure 12.2 for various fractionation schemes.[70-77] Lawrence et al compared different fractionation schemes by calculating the biologically effective dose (BED),[78] with an α/β ratio of 3 Gy.[63] For standard fractionation, a dose-response relationship appears to exist, such that an incidence of side effects of 5% and 10% occurs at a BED of 120 Gy_3 (range, 100-140) and 150 Gy_3 (range, 140-170), respectively (corresponding to 72 Gy [range 60-84] and 90 Gy [range, 84-102] in 2-Gy fractions). For twice-daily fractionation, a steep increase in toxicity is apparent when the BED exceeds 80 Gy. For daily large-fraction sizes (>2.5 Gy), the incidence and severity of toxicity are unpredictable. Lawrence et al[63] caution against overinterpreting this analysis, given the heterogeneity of the data pool (ie, different target volumes, end points, sample sizes, and brain regions).

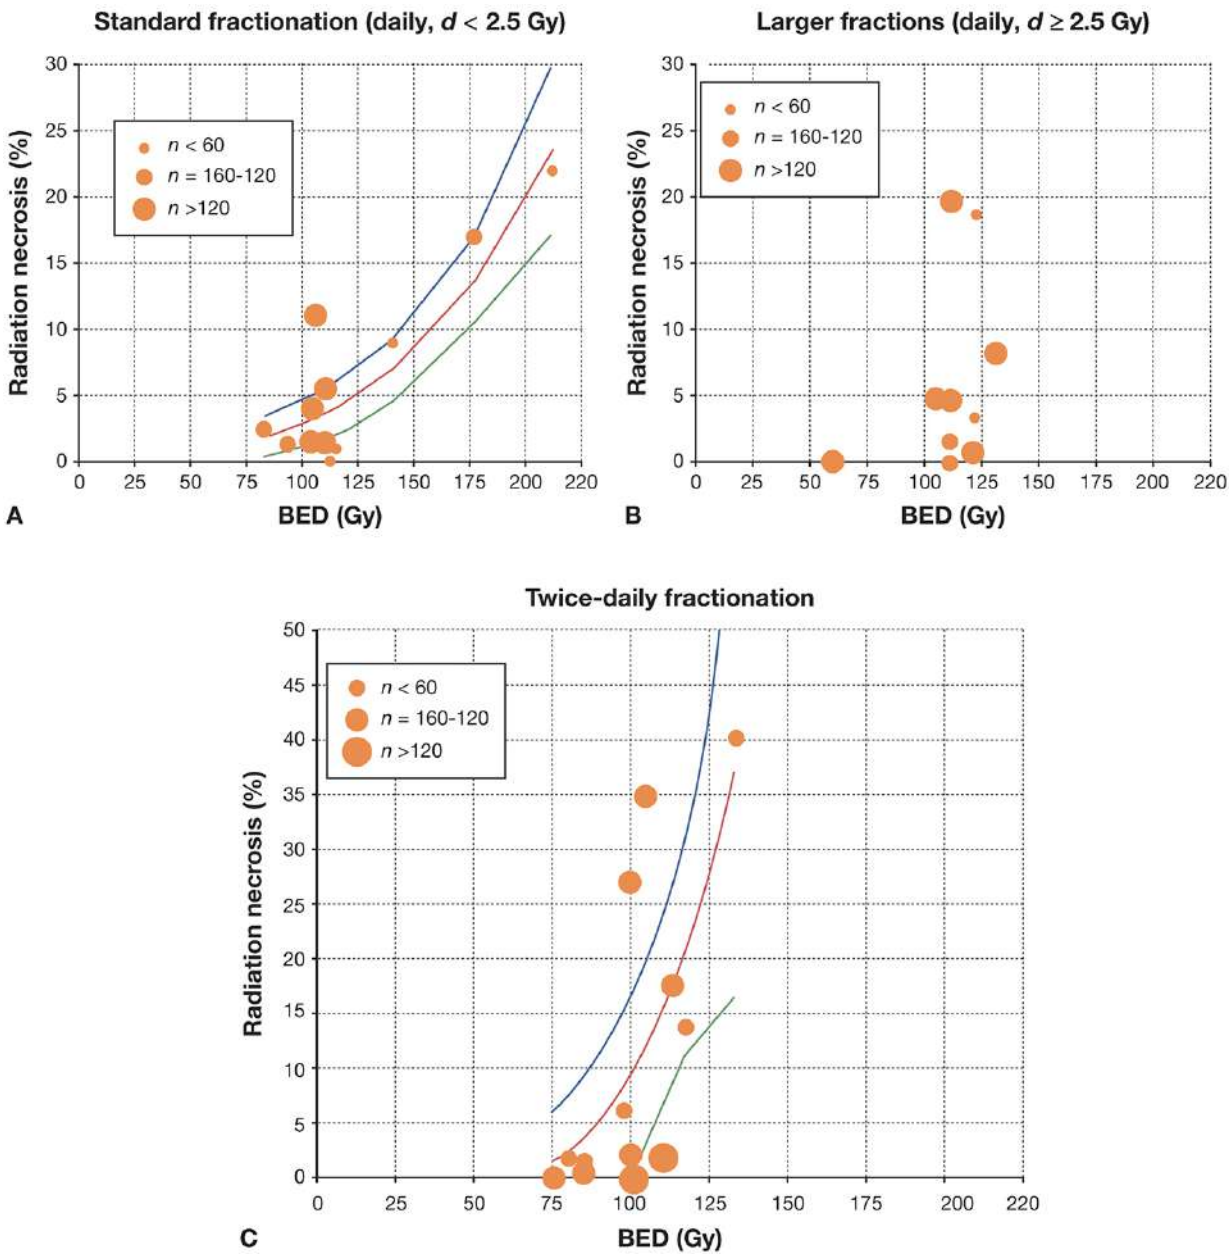

FIGURE 12.2 Incidence of radiation necrosis in brain irradiation from selected studies. Biologically effective dose (BED) calculated from the linear-quadratic model with α/β = 3 Gy; *n* = patient numbers as shown. The solid line represents the least-squares best fit of data to probit model; *dotted lines* represent 95% confidence limits. A. Once-daily fractions <2.5 Gy. B. Once-daily fractions ≥2.5 Gy (data too scattered to allow plotting of "best fit" line). C. Twice-daily radiotherapy. (Reprinted from Lawrence YR, Li XA, el Naqa I, et al. Radiation dose-volume effects in the brain. *Int J Radiat Oncol Biol Phys*. 2010;76[3 suppl]:S20-S27. Copyright © 2010 Elsevier. With permission.)

In children, whole-brain radiotherapy appears associated with neurocognitive decline. With central nervous system prophylaxis for acute lymphoblastic leukemia, the addition of 24-Gy radiation to the whole brain (to a chemotherapy regimen) is associated with a median 13-point intelligence quotient reduction at 5 years after radiotherapy, as well as poorer academic performance and greater psychological distress.[79] Reported toxicities have been lower when 14 to 18 Gy was used.[80-82] In medulloblastoma, the post-RT intelligence quotients were 10 to

15 points higher after a total whole-brain dose of 23.4 versus 36 Gy.[83,84] The PENTEC report[85] provides the following estimates of risks for neurocognitive compromise and necrosis. There is a 5% risk of a subsequent IQ less than 85 when 10%, 20%, 50%, or 100% of the brain is irradiated to 35.7, 29.1, 22.2, or 18.1 Gy, respectively (all at 2 Gy/fraction and without methotrexate). Methotrexate (MTX) increased the risk for an IQ less than 85, similar to a generalized uniform brain dose of 5.9 Gy. The model for predicting expected IQ also includes the effect of dose, age, and MTX. Each of these factors has an independent, but probably cumulative effect on IQ. The necrosis model estimates a 5% risk of necrosis for children after 58.9 Gy or 59.9 Gy (2 Gy/fraction) to any part of the brain if delivered as primary RT or reirradiation, respectively.

In adults, the neurocognitive effects of whole-brain irradiation are now established. The Radiation Therapy Oncology Group (RTOG) 0933 phase II study of hippocampal sparing (which required that 100% dose and maximum dose not exceed 10 and 17 Gy, respectively) analyzed 113 adult patients with brain metastases. With hippocampal sparing, memory preservation at 4 and 6 months was significantly better than that in historical controls (ie, whole-brain radiation therapy [WBRT] without hippocampal sparing). NRG Oncology CC001,[68] a phase III study of hippocampal-sparing WBRT + memantine versus standard WBRT + memantine, randomized 518 adult patients with brain metastases to the two study arms. The risk of cognitive failure was significantly lower after in the hippocampal-sparing arm (adjusted hazard ratio, 0.74; 95% CI, 0.58-0.95; $P = .02$), with this difference attributable to less deterioration in executive function at 4 months (23.3% vs 40.4%; $P = .01$) and learning and memory at 6 months (11.5% vs 24.7% [$P = .049$] and 16.4% vs 33.3% [$P = .02$], respectively). No significant difference in overall survival (OS), intracranial progression free survival (PFS), or toxicity was observed between the two arms. At 6 months, using all data, patients who received hippocampal-sparing WBRT reported less fatigue ($P = .04$), less difficulty with remembering things ($P = .01$), and less difficulty with speaking ($P = .049$) and using imputed data, less interference of neurologic symptoms in daily activities ($P = .008$), and fewer cognitive symptoms ($P = .01$) than those who received standard WBRT (plus memantine in both arms).

Limiting the volume of normal brain irradiated by treating lesions via SRS versus WBRT appears also to reduce neurocognitive deterioration. A trial of patients with one to three intact brain metastases randomized 218 patients to SRS versus SRS + WBRT. Less cognitive deterioration was observed at 3 months after SRS alone (40/63 patients [63.5%]) than when with SRS + WBRT (44/48 patients [91.7%]; difference, −28.2%; 90% CI, −41.9% to −14.4%; $P < .001$). Quality of life was higher at 3 months with SRS alone, including overall quality of life (mean change from baseline, −0.1 vs −12.0 points; mean difference, 11.9; 95% CI, 4.8-19.0 points; $P = .001$). Although time to intracranial failure was significantly shorter for SRS alone (hazard ratio, 3.6; 95% CI, 2.2-5.9; $P < .001$), there was no significant difference in functional independence at 3 months and median overall survival between the treatment groups.[86] Similarly, NCCTG N107C/CEC·3 randomized 194 patients with resected brain metastases to SRS versus WBRT.[87] Cognitive-deterioration-free survival was longer in patients assigned to SRS (median 3.7 months [95% CI 3.45-5.06], 93 events) than in patients receiving WBRT (median 3.0 months [2.86-3.25], 93 events; hazard ratio [HR] 0.47 [95% CI 0.35-0.63]; $P < .0001$), and cognitive deterioration at 6 months was less frequent in patients

who received SRS (28 [52%] of 54 evaluable patients assigned to SRS vs 41 [85%] of 48 evaluable patients assigned to WBRT). As in the treatment of intact brain metastases, there was no significant difference in overall survival between the arms receiving SRS versus WBRT (12.2 months vs 11.6 months, HR 1.07 [95% CI 0.76-1.50]), despite poorer local control with SRS alone.

In SRS of brain lesions, normal tissue toxicity appears to be a function of dose, volume, and location in the brain. The RTOG conducted a dose escalation study (RTOG 9005) of radiosurgery to recurrent brain metastases and primary tumors in patients who previously received whole or partial brain irradiation.[88] The goal of this study was to determine the maximal tolerated dose as a function of the maximum diameter of the lesion. Unacceptable toxicity was defined as acute irreversible severe neurologic symptoms requiring inpatient or outpatient medications, any life-threatening neurologic toxicity, or death. This study found a maximum tolerated prescription dose to the tumor margin of greater than or equal to 24, 18, and 15 Gy for tumors with a maximal diameter of less than or equal to 2.0, 2.1 to 3.0, and 3.1 to 4.0 cm, respectively. The rates of acute and late unacceptable toxicities in patients treated at these doses were 0% and 10%, 0% and 14%, and 0% and 20%, respectively. The dose limits appear to be validated by the results of the RTOG 9508, a randomized study of SRS + WBRT versus WBRT alone in 333 patients with brain metastases.[64] Using the dose constraints developed in RTOG 9005, this study found a 3% and 6% rate of grade 3 and 4 acute and late toxicities, respectively, in the group of 167 patients receiving radiosurgery.

The results of dose-volume studies of the development of "radionecrosis" following single-fraction radiosurgery are shown in Table 12.3.[89-98] Although a common element in many of these studies is the volume receiving a dose of 10 or 12 Gy or more (V_{10} or V_{12}, respectively), there is a broad variation in the crude rate of radionecrosis as a function of volume irradiated. This is likely due to differences in the definition of radionecrosis, the location irradiated, the proximity to and sparing of critical structures, and the length and intensity of clinical follow-up.

TABLE 12.3 SELECTED STUDIES OF RADIONECROSIS IN PATIENTS RECEIVING BRAIN STEREOTACTIC RADIOSURGERY

For single-fraction SRS to brain metastases, the HyTEC analysis[100] showed that tissue volumes (*including* target volumes) receiving V_{12} of 5 cm^3, 10 cm^3, or greater than 15 cm^3 were associated with risks of symptomatic radionecrosis of approximately 10%, 15%, and 20%, respectively. SRS in the treatment of AVM was associated with modestly lower rates of symptomatic radionecrosis for equivalent V_{12}. In hypofractionated SRS of brain metastases, brain plus target volume V_{20} (three fractions) or V_{24} (five fractions) less than 20 cm^3 was

associated with less than 10% risk of any necrosis or edema and less than 4% risk of radionecrosis requiring resection.

These results suggest that the rate of complications increases rapidly as the V_{12} increases beyond 5 to 10 cm^3. Note, however, that V_{12} will far exceed these limits for lesions 2 cm or greater in mean diameter when the RTOG guidelines are utilized. For example, assume that spherical lesions 1, 2, 3, and 4 cm in diameter are treated under the RTOG guidelines with single-fraction radiosurgery with the plans yielding V_{12}'s of 6, 5, 4, and 3 times the lesion volume, respectively. Then, the calculated V_{12}'s are 3, 21, 57, and 101 cm^3, respectively. So, when two (or more) lesions are each treated with SRS, it might be reasonable to apply these dose/volume data independently to each lesion, whereas if the lesions are close together, it is likely more appropriate to consider the lesions in concert. With the trend toward simultaneously treating an increasingly large number (>4) of brain metastases, it has been suggested that the aggregate volume of the brain receiving 12 Gy should also be considered,[101] though the optimal predictor of adverse radiation effects in this setting is unclear.[100,102]

The location of the lesion is important as the severity of expressed damage is greater in the more eloquent parts of the brain. For example, for a V_{12} of 10 cm^3, Flickinger et al[91] found a less than 5% symptomatic postradiosurgery injury for arteriovenous malformations (AVMs) in the frontal, temporal, and parietal lobes versus greater than 20% for AVMs in the brainstem, thalamus, and basal ganglia.

Factors Affecting Risk

Younger age is associated with a higher risk of neurocognitive decline in children undergoing cranial irradiation.[103,104] Other risk factors include female gender, neurofibromatosis-1 (NF1) mutation, extent of surgical resection, hydrocephalus, concomitant chemotherapy (especially methotrexate), location, and volume of brain irradiated.[105] No evidence has shown that children are at particular risk of radiation necrosis,[106,107] however.

Mathematic/Biologic Models

Although the linear-quadratic model appears useful in comparing dose/fraction for conventionally fractioned radiotherapy schemes, its utility at high doses per fraction (≥8 Gy) is controversial. In general, quantitative dose/volume/clinical toxicity relationships have not been established for neurocognitive function in partial brain irradiation. The apparent increased risk of radionecrosis in twice-daily partial brain irradiation suggests that the time constant for repair of radiation-induced damage may be longer than the typical interfraction interval, but this has not been modeled for this specific system.

Special Situations

Reirradiation of the whole brain is frequently performed in the setting of recurrent, multiple brain metastases. A meta-analysis of whole-brain reirradiation (interval between courses, 3-55 months) found no cases of necrosis when the total radiation dose was less than 100 Gy (normalized to 2 Gy/fraction with an α/β ratio = 2 Gy).[108] In primary central nervous system lymphoma, whole-brain radiotherapy has been associated with an atypically high risk of cognitive decline, especially in those older than 60 years.[109,110] The heightened sensitivity of

this population to irradiation might be explained by the tumor's highly diffuse, angiocentric growth pattern and that most patients receive high-dose methotrexate, a potent neurotoxin. As a result, up-front full-dose RT is now often avoided in older patients with this disease. A lower radiation dose of 23.4 Gy delivered in 1.8-Gy daily fractions appears to be associated with minimal cognitive toxicity, even in older patients.[111]

Recommended Dose-Volume Limit[63]

For partial brain irradiation at a conventional dose per fraction, there is a predicted 5% and 10% risk of symptomatic radiation necrosis at a BED of 120 Gy_3 (range, 100-140) and 150 Gy_3 (range, 140-170), respectively, which corresponds to 72 Gy (range 60-84 Gy) and 90 Gy (range 84-102 Gy) for 2-Gy daily fractions. This is a less conservative estimate than the 5% risk of radionecrosis for one-third of the brain irradiated to 60 Gy in the Emami paper.[1] The authors stress that for most cancers, there is no clinical indication for partial brain dose above 60 Gy and that, in some scenarios, an incidence of 1% to 5% radiation necrosis at 5 years would be unacceptably high. The brain appears especially sensitive to fraction sizes greater than 2 Gy and, surprisingly, twice-daily irradiation.

For radiosurgery, the available data suggest that it is prudent to minimize the volume of normal brain receiving greater than 12 Gy in a single fraction and to consider both target diameter and anatomic location when prescribing dose. However, the QUANTEC authors admit that "the substantial variation between the reported treatment parameters and outcomes from different centers has prevented [more] precise toxicity risk predictions."

The HyTEC authors endorse the limits for single-fraction SRS established in RTOG 9005 but highlight the potential for hypofractionated treatment (eg, 27 Gy in three fractions vs 18 Gy in a single fraction for lesions 2-3 cm in maximum dimension) to improve local control without increasing toxicity.[112]

Future Studies

Key questions that would benefit from systematic study include the following:

1. What is the dose/volume/location/clinical toxicity relationship for brain metastases and other common lesions treated with single-fraction versus multifraction SRS?
2. What is the rate of local and distant failure for the aforementioned sets of patients as a function of the prescribed dose?
3. How does the gross tumor volume (GTV) to planning target volume (PTV) expansion influence the incidence of normal tissue toxicity and failure rates in SRS for brain metastases and in conventionally fractionated conformal radiotherapy for primary brain tumors (particularly GBM)?
4. How do systemic treatments, particularly immunotherapy, affect the incidence of normal tissue toxicity?
5. What is the time interval for repair of radiation-induced damage in the brain? This would be most informative to help guide retreatment.
6. Further clarity is needed in determining if dose/volume metrics should optimally include or excluding the target volume.

Toxicity Scoring Criteria

Studies of brain radiotherapy should report detailed dosimetric and outcome data, including neurocognitive and neurologic dysfunction (eg, per the Common Terminology Criteria for Adverse Events, version 4.0 [CTCAE v. 4.088]), patient-reported quality of life, the prescription dose, dose/fraction, target volume, V_{12}, anatomic location treated, and clinical outcome data (eg, adverse events, patterns of failure).

Optic Apparatus

Clinical Significance

The optic nerves and chiasm frequently receive a substantial dose during therapeutic irradiation of the brain, base of the skull, and head and neck targets, and the optic apparatus is frequently the dose-limiting structure in these cases. Although rare, damage to the optic apparatus can produce devastating and, at present, irreversible visual deficits.[113]

End Points

The primary end point for radiation-induced optic neuropathy (RION) is visual impairment, defined by visual acuity and the size/extent of visual fields.[114] Of course, damage to the lens (development of cataracts), retina (retinitis), lacrimal apparatus, and trigeminal nerve (dry eye syndrome) can also produce impaired vision.[115] Although toxicity may be objectively scored using CTCAE version 4[116] and late effects of normal tissues and subjective, objective, medical management, and analytical (LENT-SOMA) evaluation of injury criteria,[117,118] it is important to obtain a comprehensive ophthalmologic examination of patients with suspected RION.

Challenges Defining Volumes

The optic nerve originates roughly at the posterior center of the globe and is bracketed by the rectus muscles as it tracks posteriorly through the orbit to pass through the optic notch, just medially to the anterior clinoid process. The optic nerves join and decussate to form the optic chiasm, an X-shaped structure that sits just superiorly to the sella turcica with the center immediately anterior to the pituitary stalk.[119] The optic nerves and chiasm are thin (<5 mm diameter), and visualization is best performed using thin-cut (≤3 mm) T1- or T2-weighted MRI. Contouring the optic nerves/chiasm is challenging, and it is important to ensure that these structures are drawn in continuity (ie, there is no gap in the contours). Appropriate contouring of these structures is facilitated by visualizing this region in multiple planes and using fused imaging modalities (eg, utilizing the magnetic resonance images in the axial and coronal planes to track the optic nerves/chiasm and sagittal CT views to see the sella turcica).

Dose/Volume/Toxicity Data

The data for the incidence of RION with conventional fractionation for selected studies[120-127] are summarized in Figure 12.3. The risk of RION appears to rise steeply past 60 Gy. None of the patients in the study by Parsons et al[125] with a maximum point dose (D_{max}) to the optic nerves/chiasm less than 59 Gy developed RION. In the study by Martel et al,[124] the average maximum chiasm and nerve dose was 53.7 Gy (range 28-70 Gy) and 56.8 Gy (range 0-80.5

Gy) for patients without RION. The optic nerves had received a D_{max} of 64 Gy, with 25% of the volume receiving greater than 60 Gy for patients with moderate to severe complications. Jiang et al[122] reported no incidence of ipsilateral RION for a dose less than 56 Gy and a less than 5% incidence at 10 years for a dose less than 60 Gy at approximately 2.5 Gy/fraction.

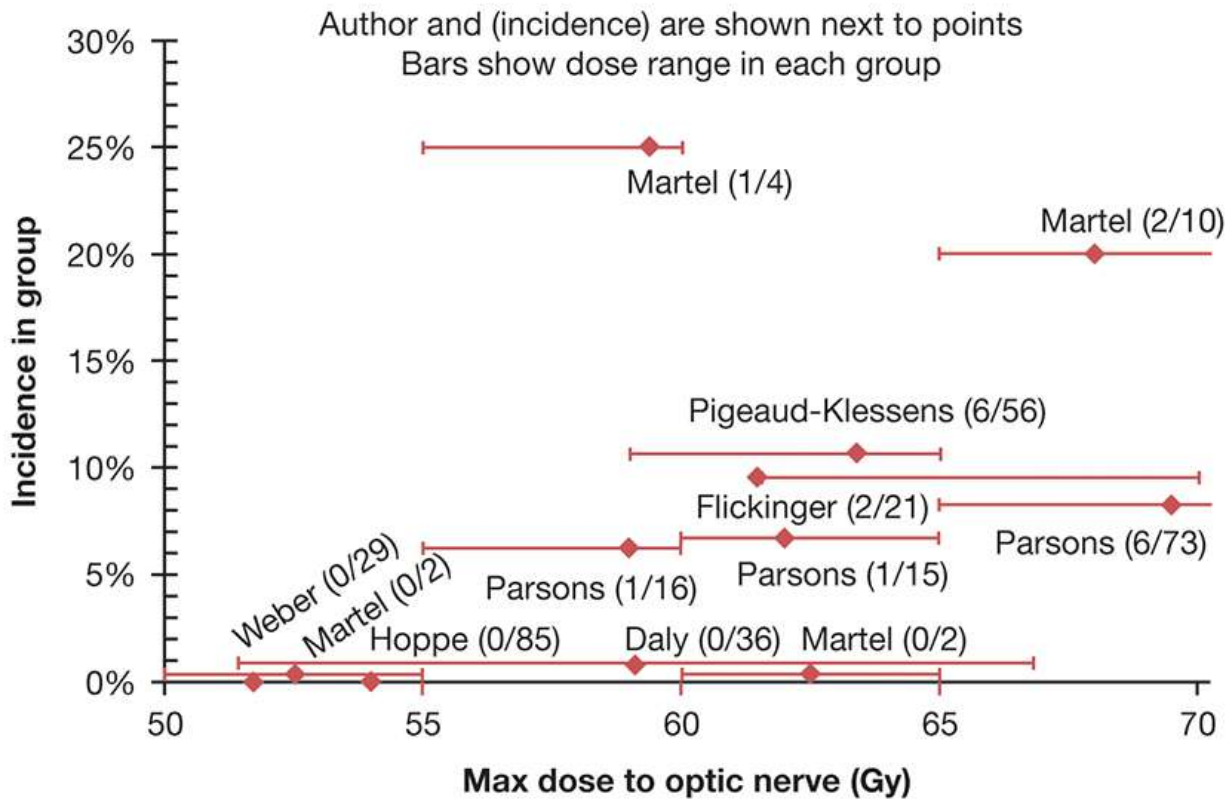

FIGURE 12.3 Incidence of radiation-induced optic neuropathy (RION) in selected studies.[120-127] Points offset from 0% to 1% were shifted to clearly show range bars. The single patients in the studies by Parsons et al[125] and Martel et al[124] with events in the 55 to 60 Gy range were treated to 59 Gy and 59.5 Gy, respectively. (Reprinted from Mayo C, Martel MK, Marks LB, Flickinger J, Nam J, Kirkpatrick J. Radiation dose-volume effects of optic nerves and chiasm. *Int J Radiat Oncol Biol Phys*. 2010;76[3 suppl]:S28-S35. Copyright © 2010 Elsevier. With permission.)

The risk of RION appears to be related to the fraction size. Parsons et al[125] reported 15-year actuarial rates of RION for total doses of 60 to less than 70 Gy of 50% versus 11% at greater than or equal to 1.9 versus less than 1.9 Gy dose/fraction, respectively. No patients treated twice daily with 1.2 Gy/fraction developed RION. At total doses of 70 to 83 Gy, the incidence was 33% versus 11% for greater than or equal to 1.9 versus less than 1.9 Gy/fraction and 12% for 1.2 Gy twice-daily fractions. Bhandare et al[128] noted reductions in RION rates for twice- versus once-daily treatment.

Results from proton treatments appear consistent with those utilizing photons.[127,129-131] Note that the proton doses are reported as cobalt gray equivalent (CGE), reflecting their greater biologic effect, and that photons were often used in combination with protons. Most proton series have reported a very low incidence of RION, and in the few cases of reported RION, a

threshold dose in the range of 55 to 60 CGE has been observed, consistent with the photon experience. As with photons, many patients exceeding this threshold did not develop RION. Wenkel et al, [131] Noel et al,[130] Weber et al,[127], and Nishimura et al[129] used a D_{max} constraint to the optic structures of 54, 55, 56, and 60 CGE, respectively.

Because of the small size of the optic nerves/chiasm and steep dose gradients in radiosurgery, most studies of RION involving SRS use the D_{max} to the optic nerves/chiasm as the critical dose metric.[113] As shown in Table 12.2, single-fraction SRS studies describe a range of threshold D_{max} for RION. In analyzing their early experience with radiosurgery, Tishler et al[132] reported RION at D_{max} as low as 9.7 Gy and recommended 8 Gy as the dose limit for the optic nerves/chiasm in SRS. Stafford et al[133] found RION in 4 of 215 patients receiving a median D_{max} of 10 Gy. The D_{max} in the patients ranged from 0.4 to 16 Gy, and three of the four had received previous external-beam radiotherapy to this area. They estimated a 1.7%, 1.8%, 0%, and 6.9% incidence of RION for D_{max} of less than 8, 8 to 10, 10 to 12, and greater than 12 Gy, respectively.

Pollock et al[134] observed no cases of RION in 62 patients with nonfunctioning pituitary adenomas receiving a median D_{max} of 9.5 ± 1.7 Gy to the optic apparatus during single-fraction SRS, using a 12-Gy D_{max} as the dose constraint for the optic apparatus. From a study of 50 patients with benign base of the skull tumors treated with single-fraction SRS and a median follow-up of 40 months, Leber et al[135] estimated a 0%, 27%, and 78% risk of RION for D_{max} of less than 10, 10 to less than 15, and greater than or equal to 15 Gy, respectively. No data for dose-volume and RION were available for hypofractionated stereotactic radiotherapy (HFSRT) (4-8 Gy/fraction).[113]

In the HyTEC study,[136] 34 studies (1578 patients) were included in the analysis of RION at a high dose/fraction. The authors concluded that the risk of RION was low (<1%) when less than 12 Gy in one fraction, 20 Gy in three fractions, and 25 Gy in five fractions were delivered to optic pathways that were not previously irradiated. Surprisingly, prior resection (76% of patients) was not associated with an increased risk of RION ($P = -0.60$).

Few reports describe the risks of late ocular toxicities after RT for childhood cancers despite their effect on quality of life. The PENTEC group analyzed the available data, and the model for the development of retinopathy suggests a 5% and 50% risk of toxicity at 42 and 62 Gy, respectively.[137] The model for the development of optic neuropathy suggests a 5% and 50% risk of toxicity at 57 and 64 Gy, respectively. More extensive data were available to evaluate the risk of cataract, separated into self-reported versus ophthalmologist-reported versus ophthalmologist-diagnosed cataract. The models suggest a 5% and 50% risk of self-reported cataract at 12 and greater than 40 Gy, respectively, and a 50% risk of ophthalmologist- diagnosed cataract at 9 Gy (>5% long-term risk at 0 Gy in patients treated with chemotherapy only).

Factors Affecting Risk

There appears to be an increased risk of RION with increasing age.[125] Parsons et al[125] reported that none of the 38 patients in the 20- to 50-year-old range developed RION, even though the reported optic nerve doses were greater than 60 Gy for 58% and greater than 70 Gy for 26%.

In contrast, for patients with doses greater than 60 Gy, the incidence was 26% and 56% for the 50- to 70- versus greater than 70-year-old age groups. RION in children is poorly characterized, but the treatment of the developing optic apparatus should be approached cautiously. Reports on the effect of other factors such as adjuvant chemotherapy, diabetes, and hypertension have been inconsistent.

Minimal data are available on the reirradiation of the optic apparatus and the effect of the interval between courses on RION. Flickinger et al[138] found that 1 of 10 patients undergoing reirradiation of the optic apparatus developed RION—the affected received an initial 40 Gy and, after a 7.5-year interval, an additional 46 Gy, both at 2 Gy/fraction. The HyTEC analysis suggested that the risk of RION appeared 10-fold higher in the setting of previous irradiation of the optic pathways.[136]

Mathematic/Biologic Models

The original Lyman-Kutcher-Burman normal tissue complication probability (NTCP) volumetric modeling[5] estimated TD_{50} = 65 Gy, n = 0.25, and m = 0.14. The dose-response data from Jiang et al[122] (1.5-2.2 Gy/fraction) suggest $TD_{50} \approx$ 72 to 75 Gy. Martel et al[124] and Brizel et al[139] estimated TD_{50} at 72 and 70 Gy, respectively. Extrapolation of the Parsons dose-response data[125] suggests that TD_{50} exceeds 70 Gy.

Special Situations

There is a suggestion that RION may occur at lower doses in patients with pituitary tumors, as complications at doses as low as 46 Gy at 1.8 Gy/fraction have been reported.[123,140,141] Mackley et al[123] and van den Bergh et al[141] constrained the optic structure D_{max} to 46 and 45 Gy, respectively. The RION latency also appeared shorter in patients with pituitary tumors. The average latency was 10.5 and 31 months (range 5-168 months) in patients with pituitary targets and nonpituitary targets, respectively.[123,140] The apparent increased sensitivity in these patients could be related to tumor-associated compression and/or postsurgical trauma of these nerves.

Recommended Dose-Volume Limits

The estimate by Emami et al[1] of a 5% risk of blindness within 5 years of treatment for a dose of 50 Gy appears *inaccurate*. The QUANTEC review[113] suggests that the incidence of RION was unusual (<2%) for D_{max} less than 55 Gy, particularly for fraction sizes less than 2 Gy. The risk increases (3%-7%) in the region of 55 to 60 Gy and becomes more substantial (>7%-20%) for doses greater than 60 Gy when a dose per fraction of 1.8 to 2.0 Gy is used. *The patients with RION treated in the 55- to 60-Gy range were typically treated to doses in the very high end of that range (ie, 59 Gy)*. For particles, most investigators found that the incidence of RION was low for a D_{max} less than 54 CGE. One exception to this range was for pituitary tumors, in which investigators used a constraint of D_{max} less than 46 to 48 Gy for 1.8 Gy/fraction.

The aforementioned studies suggest that the incidence of RION in single-fraction radiosurgery is rare for D_{max} less than 10 Gy, increases in the range of 10 to 12 Gy D_{max}, and

begins to rise steeply when D_{max} exceeds 12 Gy. The HyTEC study recommends limiting the maximum point dose to the optic apparatus to less than 10 Gy for single-fraction radiosurgery, 20 Gy for three-fraction radiosurgery, and 25 Gy for five fractions (in patients without prior RT).[136] It is also important to recognize that the low risk of toxicity can only be consistently realized when the radiosurgery practice employs high precision, high accuracy techniques, supported by excellent quality control, appropriate equipment, and well-trained, experienced staff.[142]

Future Studies

In addition to reporting detailed dose-volume data for patients with and without RION receiving radiation to the optic apparatus, investigators must consistently, completely, and accurately contour the optic apparatus, ensuring continuity of the optic nerves and chiasm.

Toxicity Scoring Criteria

Visual deficits should be scored using the CTCAE v. 4.0.[48]

Brainstem

Clinical Significance

As with the optic apparatus, irradiation of the brain, base of the skull, and neck can deliver a significant dose to the brainstem, which is frequently the dose-limiting structure.

End Points

Radiation-induced damage to the brainstem may be manifest as specific cranial neuropathies; focal motor, sensory, or balance deficits; or mild to life-threatening global dysfunction. This is reflected in the CTCAE,[116] which scores brainstem-related toxicity on the basis of symptoms. The study of radiation-induced brainstem injury is challenging because (a) the reported incidence of injury is low, (b) survival time is short for many patients, (c) formal grading of brainstem effects is subjective and is often characterized categorically (ie, “yes-no”) for cranial neuropathy, and (d) for patients with intracranial tumors, it is often difficult to distinguish between side effects and disease progression.[143]

Challenges Defining Volumes

Contouring the brainstem on axial MRI is usually straightforward, although it requires special attention to the superior extent and interfaces at the cerebral and cerebellar peduncles where the borders are indistinct. Coronal and sagittal views, in addition to axial images, are frequently helpful in visualizing the brainstem and its interfaces. The adult brainstem volume is on the order of 35 ± 8 mL.[144]

Dose/Volume/Toxicity Data

Studies of potential radiation-induced brainstem toxicity in the conventionally fractionated partial brain, base-of-skull, or neck irradiation variably report crude radiographic and functional toxicities over typically short follow-up periods.[120,127,129-131,145-154] Reported toxicities

attributable to radiation of the brainstem and dose constraints are presented in Table 12.4. Uy et al[153] reported brainstem necrosis in 1 of 40 adult patients with meningioma treated with intensity-modulated radiation therapy (IMRT). For this patient, the D_{max} was 55.6 Gy, and the absolute volume of the brainstem that exceeded 54 Gy was 4.7 mL. Jian et al[149] noted a grade 1 neurologic deficit in 3 of 48 patients with nasopharyngeal cancer treated with 1.2 Gy twice-daily photons to 74.4 Gy and concomitant chemotherapy.

TABLE 12.4 SELECTED STUDIES OF RADIATION-INDUCED BRAINSTEM TOXICITY WITH CONVENTIONAL FRACTIONATION OR HYPERFRACTIONATION

Reference	Patients/Disease	Modality	Dose Constraint	Radiation-Induced Brainstem Toxicity
Jian et al[149]	48 Adults/nasopharyngeal cavity	Photons	V_{65} < 3 mL, V_{60} < 5 mL	3 grade 1 neurologic toxicities
Hoppe et al[148]	85 Adults/nasal cavity and/or paranasal sinus	Photons	D_{max} < 50 Gy	
Daly et al[120]	36 Adults/nasal cavity and/or paranasal sinus cavity	Photons	$D_{1\%}$ < 54 Gy	
Schoenfeld et al[152]	100 Adults/pharynx or larynx	Photons	V_{55} < 0.1 mL	
Uy et al[153]	40 Adults/intracranial meningioma	Photons	Unknown	1 BS necrosis @ D_{max} 55.6 Gy, V_{54} 4.7 mL
Merchant et al[150]	68 Children/infratentorial ependymoma	Photons	No separate brainstem constraint	1 BS necrosis @ D_{mean} 59 Gy
Freeman et al[147]	136 Children/brainstem glioma	Photons	Prescribed 54-60 Gy at 2 Gy once daily or 75.6 Gy at 1.26 Gy twice daily	None reported
Packer et al[151,154]	98 Children/brainstem glioma	Photons	Prescribed 72 or 78 Gy total @ 1 Gy twice daily	One treatment-related death at 72 Gy total @ 1 Gy twice daily and concurrent β-IFN
Weber et al[127]	29 Adults/chordoma, chondrosarcoma	Protons	Surface ≤ 63 CGE Center ≤ 54 CGE	None reported
Nishimura et al[129]	14 Adults/olfactory neuroblastoma	Protons	Surface < 64 CGE Center < 53 CGE	None reported
Noel et al[130]	45 Adults/BOS tumors	Photons + protons	Surface ≤ 63 CGE Center ≤ 54 CGE	
DeBus et al[145,146]	367 Adults/BOS tumors	Photons + protons	Surface ≤ 64 CGE Center ≤ 53 CGE	19 BS toxicities, including three deaths
Wenkel et al[131]	46 Adults/BOS meningiomas	Photons + protons	Surface ≤ 64 CGE Center ≤ 53 CGE	One BS injury, two neurologic toxicities

β-IFN, recombinant β-interferon; BOS, base of the skull; BS, brainstem; CGE, cobalt gray equivalent.

In the largest study, Debus et al[145,146] reported on 367 patients with base-of-skull tumors with a combination of conformal photon and proton RT. Nineteen late brainstem-related

toxicities were observed, including three deaths. On univariate analysis, significant predictors of toxicity were D_{max} greater than 64 CGE, V_{50} CGE greater than 5.9 mL, V_{55} CGE greater than 2.7 mL, V_{60} CGE greater than 0.9 mL, two or more skull-based surgeries, diabetes, and high blood pressure. On multivariate analysis, only V_{60} greater than 0.9 mL, two or more skull-based surgeries, and diabetes were predictive. In a study of 46 patients with recurrent base-of-skull meningiomas treated to a median brainstem D_{max} of 58.0 CGE, Wenkel et al[131] found that one patient developed brainstem injury at a dose that exceeded an unspecified constraint value by 10%. Two others with neurologic toxicities had brainstem doses that exceeded the constraints as shown in Table 12.4.

In pediatric patients with brainstem glioma (treated with opposed lateral fields that encompassed the majority of the brainstem), no toxicity was reported at doses of 54 to 60 Gy at 2 Gy/fraction, 75.6 Gy at 1.26 Gy twice daily,[147] or 78 Gy at 1 Gy twice daily.[151] The primary limitation of these studies was the short median survival, less than 12 months. Of 32 patients treated to 72 Gy twice daily in combination with recombinant β-interferon, there was at least one treatment-related death.[154]

Most pediatric protocols for central nervous system tumors recommend doses greater than 54 Gy, and separate brainstem dose constraints are often absent. Merchant et al studied 68 patients with infratentorial ependymoma treated with surgery and conformal RT (54-59.4 Gy).[150] In patients with full recovery, a considerable portion of the brainstem received over 60 Gy (V_{60} = 7.8 ± 1.4 mL). There was no difference in brainstem recovery based on absolute or percentage volume of the brainstem that received more than 54 Gy. Differences in these values for patients without full recovery were not statistically significant. One patient died with an autopsy-confirmed residual tumor and focal areas of brainstem necrosis. The mean brainstem dose was 59 Gy, and the patient also exhibited severe perioperative morbidity after two surgeries.

A limited number of studies report brainstem toxicity in single-fraction SRS or HFSRT.[155-159] A broad range of prescription isodose levels and dose metrics are reported, making it difficult to develop a predictive dose-volume model for brainstem toxicity.[143] In the study with the largest number of patients, Foote et al[155] analyzed the outcome in 149 vestibular schwannoma patients treated with SRS between 1988 and 1998; 41 were treated before 1994 when radiosurgery was primarily based on CT imaging, and 108 after 1994, when planning was MRI based. Large single-fraction doses (10-22.5 Gy) were used. Their analysis revealed a "learning curve," with a 5% and 2% actuarial 2-year rate of facial and trigeminal neuropathies, respectively, for patients treated after 1994 compared with 29% for both neuropathies for the earlier patients. This study found a significant difference, with a 2-year actuarial rate of facial and trigeminal neuropathies of 29% and 7% for patients treated before and after 1994, respectively. The authors ascribe this difference to the use of MRI rather than CT-based imaging and lower prescription doses in the latter years. A univariate analysis showed an incidence of cranial nerve neuropathy of 2% for less than 12.5 Gy versus 24% for greater than 12.5 Gy ($P < .0003$). On multivariate analysis, the prescription dose greater than 12.5 Gy, prior surgery, and treatment prior to 1994 were significant variables.

Mathematic/Biologic Models

The Emami review estimates a 5-year, 5% rate of complications, defined in that study as "necrosis/infarct," at 50, 53, and 60 Gy delivered to the whole, two-thirds of, and one-third of the brainstem, respectively.[1] The corresponding Lyman-Kutcher-Berman (LKB) parameters for calculation of the NTCP were $n = 0.16$, $m = 0.14$, and a tolerance dose for 50% probability of these complications (TD_{50}) equal to 65 Gy.[36] These estimates and model parameters appear overly conservative. For example, the LKB model estimates a 12% risk of severe complications for 54 Gy to the whole brainstem or a 3% risk of complications when the proton dose constraints (see Table 12.4) are utilized. The clinical data would suggest that a larger TD_{50}, smaller m, or larger m values might produce more reasonable estimates of toxicity. For example, an LKB model with a larger TD_{50} (72 Gy) or smaller m (0.1) would reduce the predicted risks to less than 5% or less than 1%, respectively. However, there are insufficient existing dose/volume/complication data to generate a more accurate model estimate at this time.

Recommended Dose-Volume Limits

The QUANTEC study concludes that the entire brainstem may be treated to 54 Gy using conventional fractionation with limited risk of severe or permanent neurologic effects.[143,150] Although the precise dose-volume relationship is unclear, partial volumes of the brainstem (1-10 mL) may be irradiated to a maximum dose of 59 Gy for dose fractions less than or equal to 2 Gy. The risk appears to increase markedly at doses greater than 64 Gy. In radiosurgery, it appears that a maximum brainstem dose of 12.5 to 13 Gy is associated with a low (<5%) risk of cranial neuropathy in patients with vestibular schwannomas treated with single-fraction SRS. The risk appears to increase rapidly when the marginal prescription dose is greater than 15 Gy or when the target volume exceeds 4 mL.[143,155,160,161] However, doses of 15 to 20 Gy have been used to treat brainstem metastases with a low reported rate of complications, potentially because of the limited survival time for these patients.[157,162]

Future Studies

Uniform, complete reporting of patient-specific dose/volume/outcome data for patients with and without complications is required.

Toxicity Scoring Criteria

Patients should undergo a complete history and physical examination at regular intervals with particular attention to the neurologic exam. Toxicity should be scored and reported using the CTCAE v. 4.0.[116]

Auditory Apparatus

Clinical Significance

Radiation therapy for brain tumors and head and neck cancers may damage the cochlea and/or acoustic nerve, leading to sensorineural hearing loss (SNHL) and compromised quality of life.[163]

End Points

SNHL following conventionally fractionated radiotherapy is typically measured by a decrease in the bone conduction threshold (BCT) at 0.5 to 4 kHz,[163] the primary range for human speech, using pure-tone audiometry (PTA). Although the technique is well established and standardized, a broad range of specific audiometric parameters are used to characterize SNHL, including the frequency (range) used for testing, the threshold chosen for a clinically significant change in the BCT (10-20 dB), and the control/standard used for comparison. In SRS, SRS, or HFSRT, hearing status is more commonly evaluated using the Gardner-Robertson scale, which is based on both PTA and speech discrimination. HL after SRS/HFSRT may be characterized by changes in Gardner-Robertson hearing grade or retention of serviceable hearing (ie, functional hearing with the aid of a hearing aid) or any measurable hearing. In addition, the length of follow-up will influence reported HL, as deficits may develop more rapidly following single-fraction SRS than HFSRT, and HL increases over time in both situations (Table 12.5).

TABLE 12.5 HEARING PRESERVATION IN STEREOTACTIC RADIOSURGERY AND RADIOTHERAPY

Reference	Technique: Number of Patients	Treatment Dose, Gy	Mean/Median Follow-Up, Months (Range)	Tumor Control, %	Rate of Hearing Preservation, %

Challenges Defining Volumes

Contouring of the acoustic nerve and brainstem is best accomplished on high-resolution, contrast-enhanced T1-weighted, and fast imaging with steady-state precession MRI. The cochlea and associated bony anatomy are better delineated on fine-cut (≤1 mm slice thickness) CT scans. Both the acoustic nerve and cochlea are small structures, and the dose gradient at the latter structure is often quite steep. Moreover, the acoustic nerve anatomy is distorted by the tumor, significantly increasing its apparent diameter. Thus, the dose to these structures is typically characterized by an average or maximum dose, rather than a dose-volume distribution. In many studies, the primary dose metric was the dose to the acoustic neuroma, rather than the normal tissue structures per se, which is not unreasonable as the dose to the tumor appears to be correlated with the dose received by the acoustic nerve.[56]

Summary of QUANTEC, HyTEC, and PENTEC

The QUANTEC authors[163] summarized nine reports on risks of SNHL after conventionally fractionated radiotherapy for head and neck cancer; four of the studies modeled SNHL based on dosimetric factors (Figure 12.4). The authors recommended a mean dose of less than or equal to 45 Gy to the cochlea (and also considered a more conservative ≤35 Gy) to minimize risks of SNHL, though they conceded that a threshold for SNHL could not be derived from the reviewed data. With a mean dose of less than or equal to 45 Gy, the authors predicted a less than 30% risk of SNHL at the 4-kHz level. The QUANTEC authors also reviewed studies of patients treated for vestibular schwannomas, specifically seven studies of single-fraction SRS (including one with NTCP modeling) and four studies of conventionally fractionated stereotactic radiotherapy, hypofractionated radiotherapy, and/or fractionated SRS. They estimated that a single-fraction SRS prescribed dose of less than or equal to 14 Gy for vestibular schwannoma was associated with a less than 25% loss of serviceable hearing. The HyTEC authors for tumor control probability (TCP) of vestibular schwannomas[175] chose not to pursue pooling and modeling data for hearing preservation due to the multiple confounding factors, including tumor- related susceptibility to HL, multiple organ at risk (OARs) (eg, auditory nerve, cochlea, and brainstem—for which dosimetric exposures are interdependent and directly correlate with prescription dose) and inadequate data to facilitate pooling and NTCP modeling (personal communication, Michael Milano). A non-HyTEC systematic review of 23 studies suggested marginal tumor doses of less than 13 Gy and cochlea maximum doses less than 4 to 5 Gy were the main prognostic factors for hearing preservation.[176] Another systemic review of 21 studies that focused on cochlear exposures

concluded that striving for a mean cochlear dose less than 4 to 6 Gy (without compromising tumor coverage) would be practical but that no clear association was found between cochlear exposures and hearing preservation.[177]

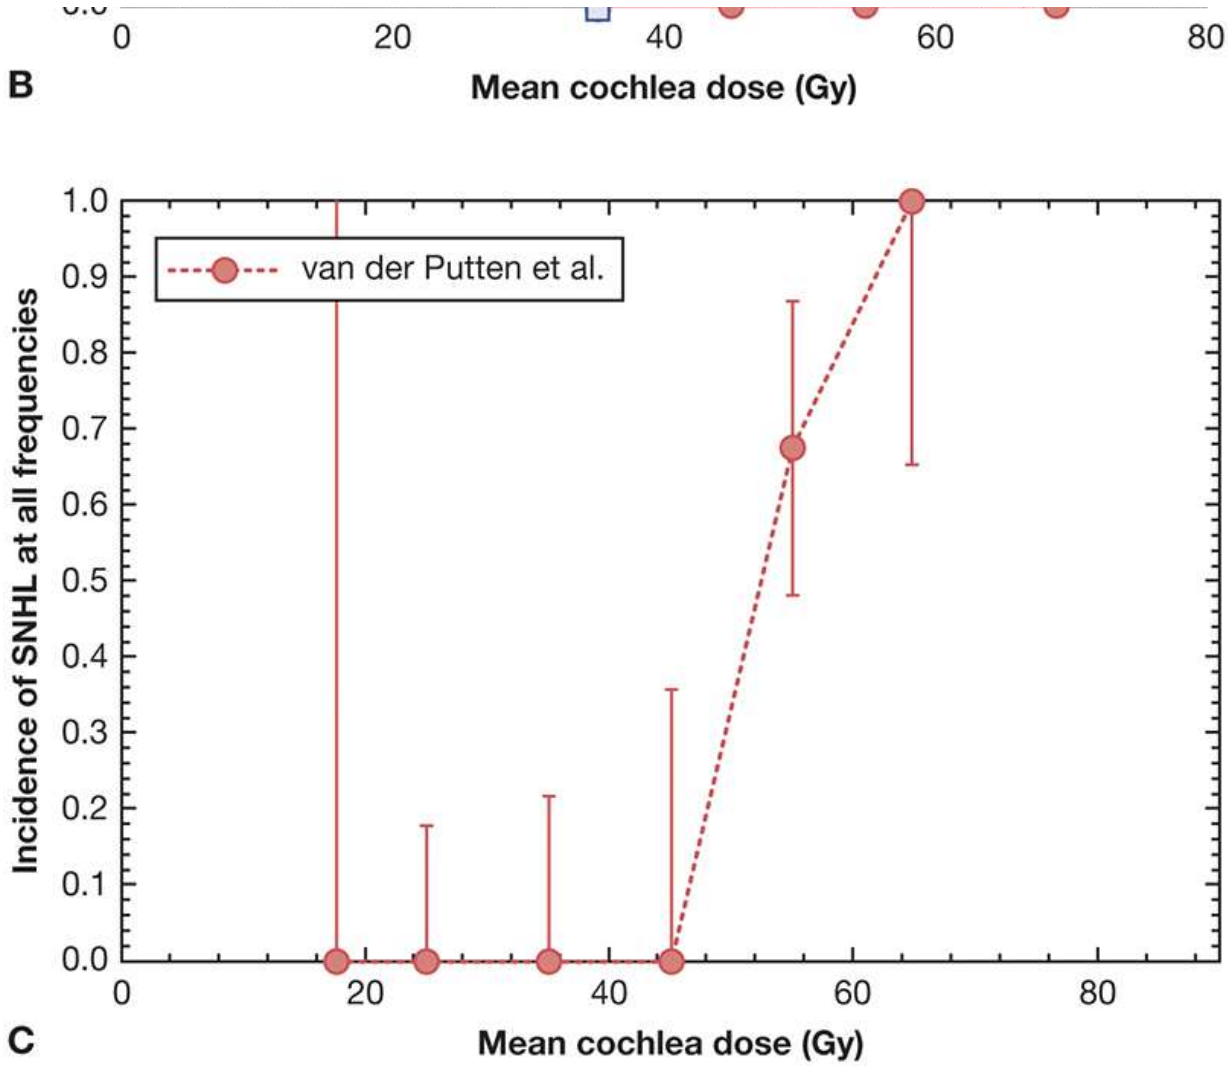

FIGURE 12.4 Mean dose response for sensorineural hearing loss (SNHL) at (A) 4 kHz,[178-182] (B) 0.5 to 2 kHz,[178-182] and (C) all frequencies[182] (0.25-12 kHz). (Reprinted from Bhandare N, Jackson A, Eisbruch A, et al. Radiation therapy and hearing loss. *Int J Radiat Oncol Biol Phys*. 2010;76[3 suppl]:S50-S57. Copyright © 2010 Elsevier. With permission.)

HL in children is particularly important due to its potential to compromise neurocognitive function. The PENTEC analysis demonstrates that the incidence and severity of cochlear HL from RT exposure alone are related to dose and age.[183] Risk of HL was less than 5% in cochlea receiving a mean dose less than 35 Gy but increased to 30% at 50 Gy. HL risk ranged from 25% to 40% in children under the age of 5 years at diagnosis, declining to 10% in older children for any radiation dose. The probability of similar severe HL occurring at doses of 18.3 Gy is higher for children less than 3 versus older than 3 years of age. High-frequency HL was most common, with average onset occurring 3.6 years (range, 0.4-13.2 years) after RT exposure to platinum-based chemotherapies added to the rates of HL at a given cochlear dose level, with 300 mg/m^2 shifting the dose response by 7 Gy.

Factors Affecting Risk

The QUANTEC authors emphasized that cisplatin, administered during or after radiotherapy, may exacerbate SNHL. Other factors that adversely impacted risks include worse preradiotherapy hearing function and older age.

Future Studies

The effects of concurrent chemotherapy in radiotherapy for head and neck cancer, of acoustic nerve length irradiated and fractionation in vestibular schwannomas, and of the absolute dose to the cochlea in all settings would benefit from prospective, multi-institutional studies.

Toxicity Scoring Criteria

An audiometric evaluation should be performed for both ears immediately before radiotherapy and biannually thereafter. The QUANTEC authors recommend that a "clinically significant hearing loss" should be defined as an increase in the threshold of 10 dB in postradiotherapy BCT or a decline of 10% in a speech discrimination evaluation.[163]

Spinal Cord

Clinical Significance

Although the spinal cord proper is from the base of the skull through the top of the lumbar spine, individual nerves continue down the spinal canal to the level of the pelvis. Thus, portions of the spinal cord and canal are often included in radiotherapy fields during the treatment of malignancies involving the neck, thorax, abdomen, and pelvis.[184] In addition, metastatic disease to the bony spine is encountered in approximately 40% of all patients with cancer,[185] and this disease is often treated with radiotherapy. Though rare, radiation-induced spinal cord injury (ie, myelopathy) can be severe, resulting in pain, paresthesias, sensory deficits, paralysis, Brown-Séquard syndrome, and bowel/bladder incontinence.[186]

End Points

Myelopathy is defined as a grade 2 or higher myelitis, per CTCAE v. 4.0.[116] Under this definition, asymptomatic changes in the cord detected radiographically and mild signs/symptoms, such as the Babinski sign or L'hermitte syndrome, would not be classified as myelopathy. Consequently, a diagnosis of myelopathy is based on the appearance of signs/symptoms of sensory or motor deficits, loss of function, or pain, now frequently confirmed by MRI. Radiation myelopathy rarely occurs less than 6 months after completion of radiotherapy and, in most cases, appears within 3 years.[187]

Challenges Defining Volumes

In conventional external-beam RT, the field generally encompasses the entire circumference of the cord, vertebral body, and spinal nerve roots, and precise organ definition is not critical apart from correctly identifying the level of the involved cord. Delineation of the cord in radiosurgery is unsettled, with various studies contouring the critical organ in the axial plane as the spinal cord, the spinal cord expanded 2 to 3 mm, the thecal sac and its contents, or the entire spinal canal.[188] As the volume receiving a high dose often extends superiorly and inferiorly to the target, several studies expand the critical organ volume above and below the

target volume. For example, RTOG protocol 0631, a study of image-guided radiosurgery of spine metastases, defined the cord as the unexpanded cord itself visualized in MRI and extended the volume of the partial spinal cord 5 to 6 mm above and below the target volume.

Summary of QUANTEC and HyTEC

The QUANTEC authors[184,189] analyzed the risk of radiation myelopathy in 335 and 1,946 patients receiving radiotherapy to the full circumference, never previously cervical and thoracic spinal cord/canal,[190-201] respectively (Figure 12.5). Although a small number of these patients received relatively high doses per fraction, none were treated using stereotactic techniques to exclude a portion of the circumference of the cord, and the QUANTEC analysis essentially represents the risk for conventionally fractionated treatment. Note that the dose to the cord is the prescribed dose reported in those studies; typically, dosimetric data were not available to calculate the true cord dose. The rate of myelopathy appears very low below total doses of 50 Gy for conventional radiation delivered at 2 Gy per fraction, as discussed below.

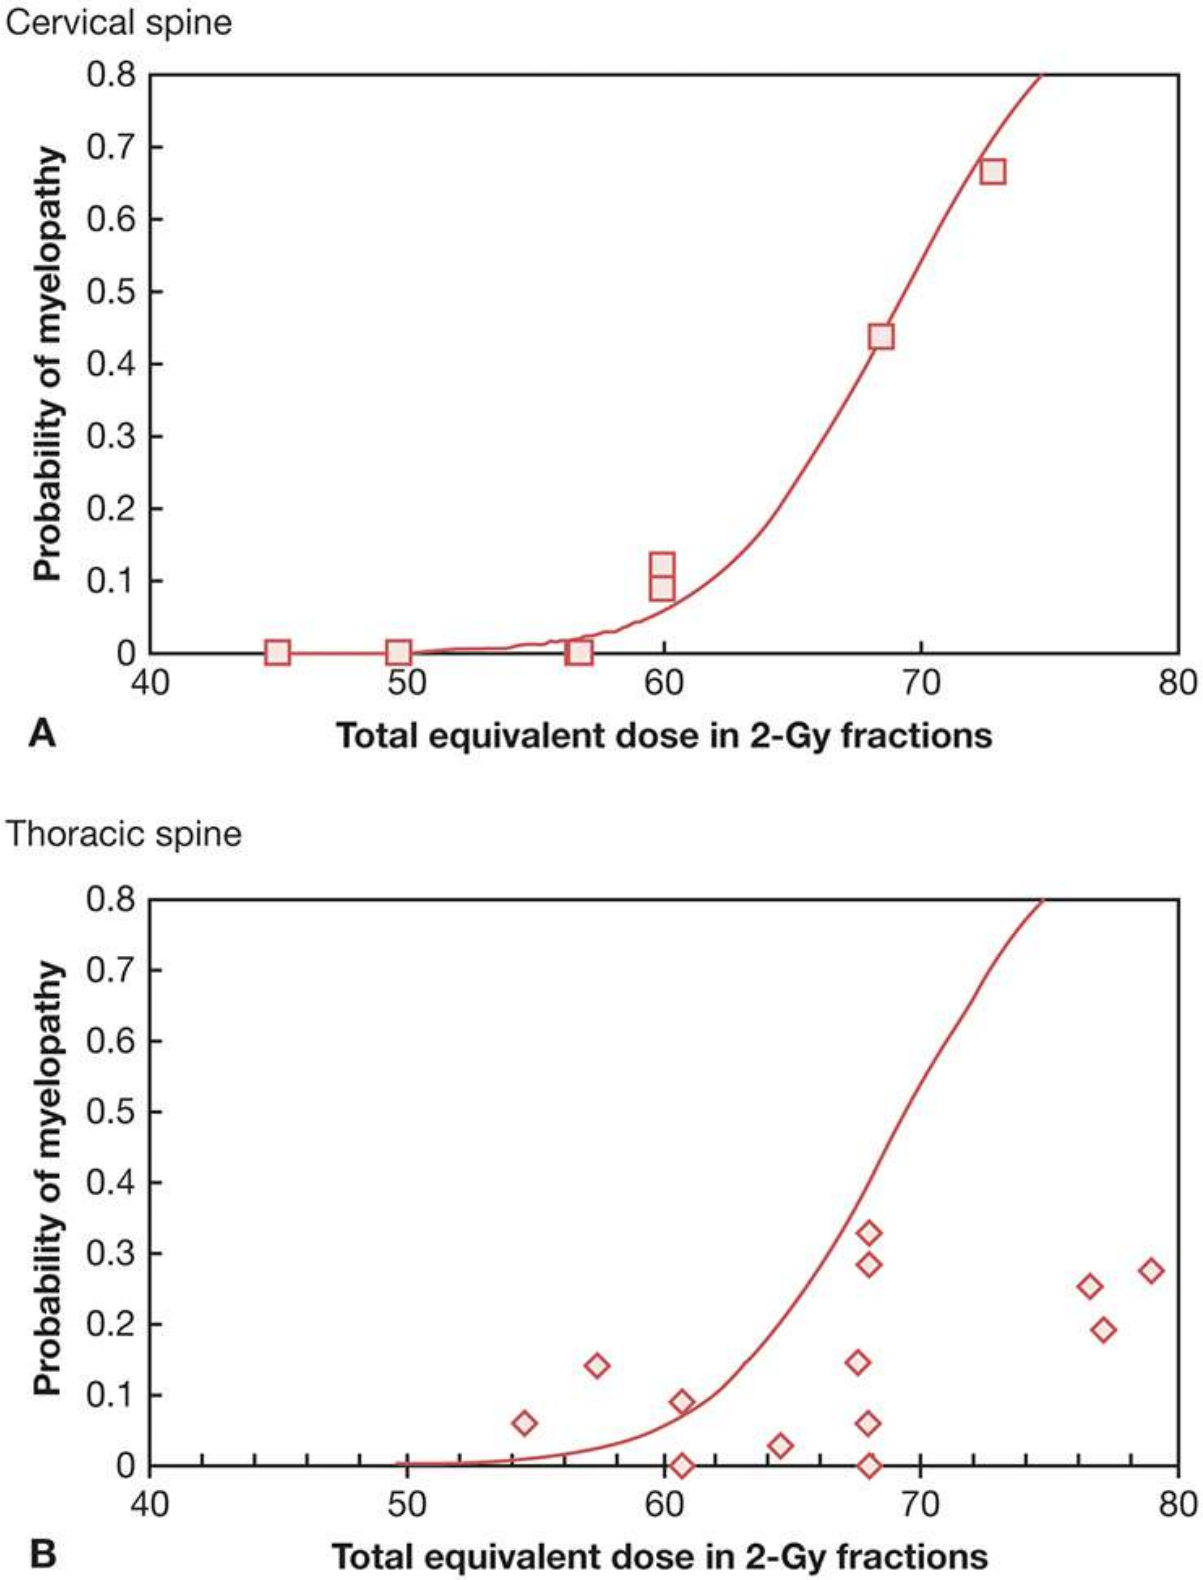

FIGURE 12.5 Incidence of transverse myelopathy from selected studies. A. Cervical cord: data for selected studies[187,202-205] shown by *γ* with probability of myelopathy corrected for estimated survival and solid line fit to these data by the method of Schultheiss. B. Thoracic cord: data for selected studies[190-201] shown by ◊ with probability of myelopathy corrected for estimated survival. A solid line is the best fit for the cervical cord data, as

thoracic cord data were insufficient to permit an adequate fit. (Adapted from Schultheiss TE. The radiation dose-response of the human spinal cord. *Int J Radiat Oncol Biol Phys*. 2008;71[5]:1455-1459. Copyright © 2008 Elsevier. With permission.)

The QUANTEC authors also reviewed the risk of radiation myelopathy to the spine from radiosurgery, summarized in Table 12.6.[206-213] Of the exactly 1,400 cases of spinal radiosurgery presented in the published literature, there are only 12 reported instances of radiation-induced myelopathy, equaling a crude rate of 0.8%. Applying the Schultheiss model[189] to spinal radiosurgery appears to overestimate the risk of myelopathy. For example, using the α/β ratio of 0.87 Gy, the model yields an estimated risk of myelopathy of 0.8%, 13.6%, 50%, and 73% for 12, 13, 13.7, and 14 Gy, respectively, delivered in a single fraction. In contrast, Ryu et al[214] found only one case of myelopathy in 86 patients treated with single-fraction spine radiosurgery at a mean cord D_{max} of 12.2 Gy (±2.5 Gy standard deviation) and no cases in the subset of 39 lesions prescribed 18 Gy and treated to a mean cord D_{max} of 13.8 Gy. Note that the Medin et al[215] study of single-fraction irradiation of the swine spinal cord shows a steep dose-response curve with a median effective D_{max} of 20 Gy. At the high doses per fraction encountered in radiosurgery, the applicability of the linear-quadratic model is controversial, and the biologically equivalent doses presented in Table 12.6 should be used solely for making rough comparisons of the different dose regimens. In particular, the QUANTEC authors stress that data obtained at a low dose per fraction should not be extrapolated to regimens employing doses of 10 Gy or more per fraction.[184,216]

After Kirkpatrick JP, van der Kogel AJ, Schultheiss TE. Radiation dose-volume effects in the spinal cord. *Int J Radiat Oncol Biol Phys*. 2010;76(3 suppl):S42-S49. Copyright © 2010 Elsevier. With permission.

The HyTEC authors[217] reviewed radiation myelopathy in patients undergoing spinal SBRT, drawing data from seven studies[212,218-223] meeting strict inclusion criteria. A total of three cases of radiation myelopathy were observed in the aggregate cohort of 496 patients (0.6%). They also modeled the risk of radiation myelopathy using nine cases observed in the literature with 66 normal controls, yielding a "greater than expected" risk of radiation myelopathy at doses below 12 Gy cord maximum dose for single-fraction treatment. The authors attribute this difference to the inclusion of a case of radiation myelopathy observed at only 10.6 Gy and to the low number of normal control cases. A significant uncertainty in the analysis revolves around the reporting of the maximum dose and contouring of the organ at risk; small differences in the cord/thecal sac volume yield very large difference in the maximum point dose, and the authors make a strong argument for using the D0.03cc as a better estimate of the maximum dose.

Factors Affecting Risk

Animal studies suggest that the immature cord is somewhat more susceptible to radiation-induced complications and the time to manifestation of damage is shorter.[224-227] Though the literature on radiation-induced myelopathy in children is sparse, care should be exercised in irradiating a child's spine because of the increased sensitivity of the developing central nervous system and bone to ionizing radiation.[228] There are a handful of reports of myelopathy at relatively low radiation doses to the spine postchemotherapy.[229] Many chemotherapeutic agents are directly neurotoxic[230] and should be used with caution during irradiation of the central nervous system.[231]

Special Situations

The need to reirradiate previously treated cord is often encountered in the setting of recurrent spine metastases following spinal irradiation or new spine lesions within, for example, a previously treated lung, pancreas, or esophageal field. In evaluating reirradiation of the spinal cord, the dose regimen for each course, the volume and region (re)irradiated, and the time interval between the courses of RT must be considered.[232] Animal studies support a time-dependent model of repair for radiation damage to the spinal cord.[224,233-237] For example, Ang et al[224] treated the thoracic and cervical spines of rhesus monkeys to 44 Gy and then reirradiated these animals with an additional 57 Gy at 1 to 2 years or 66 Gy at 2 to 3 years,

yielding aggregate doses of 101 and 110 Gy, respectively. Of the 45 animals evaluated, four developed myelopathy by the end of the observation period. The reirradiation tolerance model developed from these and similar data[233] estimates a recovery of 34 Gy (76%), 38 Gy (85%), and 45 Gy (101%) at 1, 2, and 3 years, respectively. Under conservative assumptions, an overall recovery of 26 Gy (61%) was calculated.

Table 12.7 summarizes published reports involving reirradiation of the spinal cord in humans using both conventionally fractionated, full-circumference external-beam radiotherapy and SBRT.[232,238-250] For purposes of comparing different regimens, an α/β ratio of 3 Gy was used to calculate the biologically equivalent dose in Gy_3. In all of these studies, the median interval between courses was at least 6 months, and only a small number of cases were treated at intervals less than 6 months. Note that few cases of myelopathy are reported despite large cumulative doses, with essentially no cases of myelopathy observed for cumulative doses less than 60 Gy in 2-Gy equivalent doses. These observations are consistent with the predictions of postradiotherapy repair observed in the animal models. The HyTEC authors[217] identified five papers that met their inclusion criteria for rigorous dose/volume reporting, noting the small numbers of radiation myelopathy events and the heterogeneity of the data. Nonetheless, they developed criteria for minimizing radiation myelopathy based on the cumulative and reirradiation doses to the thecal sac and the time between the initial and reirradiation courses.

After Kirkpatrick JP, van der Kogel AJ, Schultheiss TE. Radiation dose-volume effects in the spinal cord. *Int J Radiat Oncol Biol Phys*. 2010;76(3 suppl):S42-S49. Copyright © 2010 Elsevier. With permission.

Recommended Dose-Volume Limits

With conventional fractionation of 2 Gy/day including the full cord cross section, total doses of 50, 60, and approximately 69 Gy are associated with a 0.2%, 6%, and 50% rate of myelopathy. The level of acceptable risk will depend on the clinical scenario; that is, a 5% risk of myelopathy may be acceptable in the treatment of a primary spinal cord tumor but not in the irradiation of a lung lesion. For reirradiation of the full cord cross section at 2 Gy per daily fraction after prior conventionally fractionated treatment, cord tolerance appears to increase at least 25% 6 months after the initial course of RT.

In spine radiosurgery, the HyTEC authors recommend a maximum cord dose of 12.4 to 14.0 Gy in one fraction, 17.0 Gy in two fractions, 20.3 Gy in three fractions, 23.0 Gy in four fractions, and 25.3 Gy in five fractions to limit the risk of radiation myelopathy to 1% to 5%. In comparison, RTOG 0631 specified a cord D_{10} and $D_{0.35\ mL}$ of 10 Gy and D_{max} of 14 Gy for the involved spine. For reirradiation of the cord, HyTEC authors suggest cumulative thecal sac equivalent dose in 2 Gy fractions with an α/β of 2 D_{max} be held below 70 Gy, the SBRT thecal sac $EQD2_2$ D_{max} limited to 25 Gy, thecal sac SBRT $EQD2_2$ D_{max} be limited to less than 50% of the cumulative thecal sac $EQD2_2$, and a minimum time interval to reirradiation of 5 months or more.

Future Studies

A model of dose/volume/outcome for spinal cord toxicity will require that more extensive and detailed data be collected over many years, including data on entire cohorts of patients treated with radiotherapy and radiosurgery, not just those with myelopathy. Extensive dosimetric

parameters should be collected, specifically D_{max}, D_1, D_{10}, D_{50}, $D_{0.1\ mL}$, $D_{0.35\ mL}$, and $D_{1\ mL}$, and the volume of the involved segment of the spinal cord, as well as the prescribed total dose, dose per fraction, involved spinal level(s), portion of the vertebral body irradiated, irradiation technique, patient characteristics/demographics, and, in the case of irradiation, the time interval between courses of spinal RT. In addition, preclinical studies identifying the fundamental mechanisms of radiation-induced toxicity would be valuable.

Toxicity Scoring Criteria

Toxicity should be scored and reported using CTCAE v. 4.0.[116]

NECK

Larynx and Pharynx

Clinical Significance

Radiation therapy is often utilized as the primary treatment of early-stage laryngeal cancers in an effort to preserve speech and swallowing. However, radiation-induced progressive edema and associated fibrosis can lead to long-term problems with phonation and swallowing.[251] Irradiation of the pharynx and larynx, particularly in combination with concurrent chemotherapy, can produce severe dysphagia, compromising nutrition, protection of the airway, and quality of life.

End Points

The critical larynx-specific end points examined were laryngeal edema and vocal function.[252] Dysphagia, resulting from laryngeal and/or pharyngeal dysfunction, may be assessed by instrument-based swallowing studies,[253] by observer-based criteria (eg, CTCAE v. 4.0), or by patient-reported quality of life questionnaires. Pretherapy vocal and swallowing function should be considered when assessing the functional response to RT of the larynx and pharynx.[254]

Challenges Defining Volumes

Phonation and swallowing are complex processes involving multiple anatomic structures in close proximity to one another. The relative importance of various normal tissue structures affecting vocal function and swallowing is controversial. In studying vocal dysfunction, doses to the epiglottis, base of the tongue, lateral pharyngeal walls, preepiglottic space, aryepiglottic folds, false vocal cords, upper esophageal sphincter, and cricoid cartilage have been considered.[252,255,256] Radiation-induced dysphagia has been correlated with the dose to the pharyngeal constrictor muscles and specific points in the supraglottic and glottic larynx.[255,257-260] Precise identification of these structures for treatment planning requires a high-resolution, contrast-enhanced CT scan.

Summary of QUANTEC

The QUANTEC report[252] summarized three studies on radiotherapy dose-volume measures correlated with laryngeal toxicity (edema or vocal function); one study modeled the risks of

laryngeal edema. Based on these studies, the authors estimated less than 20% toxicity risks with whole-organ laryngeal exposures as follows: D_{max} less than 66 Gy (for vocal dysfunction) and mean less than 50 Gy (for aspiration) in patients treated with concurrent chemoradiation for head and neck cancer. Among those treated with radiotherapy alone, a mean dose of less than 44 Gy and $V_{50} < 27\%$ were associated with less than 20% risks of laryngeal edema. The QUANTEC authors also reviewed eight papers on dysphagia as correlated with laryngeal and pharyngeal exposures and developed a model (from two studies) for aspiration risks relative to supraglottic laryngeal mean doses, shown in Figure 12.6. From that model, a supraglottic laryngeal mean dose of 47 Gy was correlated with approximately 20% aspiration risk. From their data review, a pharyngeal constrictor mean dose of less than 50 Gy was estimated to result in less than 20% aspiration risk. The 2023 dysphagia-optimized intensity-modulated radiotherapy versus standard intensity-modulated radiotherapy in patients with head and neck cancer randomized patients undergoing chemoradiotherapy for head and neck cancer to two arms; in one required less than or equal to 50 Gy mean dose to the superior and middle pharyngeal constrictor muscles or inferior pharyngeal constrictor muscles outside the high-dose target volume.[261] The MD Anderson Dysphagia Inventory (MDADI) composite score 12 months after radiotherapy was significantly improved in the arm undergoing pharyngeal constrictor sparing.

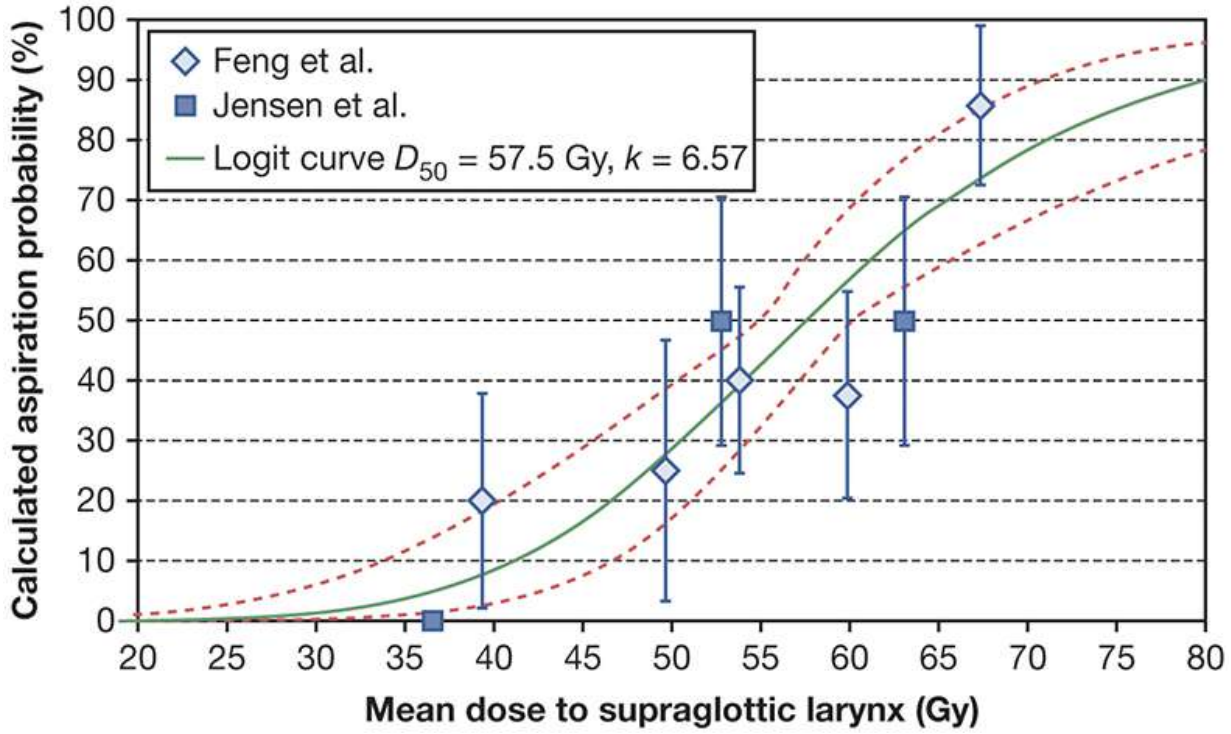

FIGURE 12.6 Probability of aspiration (a proxy for dysphagia) versus larynx dose for selected studies.[258,259] Solid line fit of logit model to combined data; *dotted lines* represent 68% confidence area. (Reprinted from Rancati T, Schwarz M, Allen AM, et al. Radiation dose-volume effects in the larynx and pharynx. *Int J Radiat Oncol Biol Phys*. 2010;76[3 suppl]:S64-S69. Copyright © 2010 Elsevier. With permission.[69])

Factors Affecting Risk

The addition of concurrent chemotherapy to high-dose RT appears to at least double the risk of laryngeal edema and dysfunction.[252] Severe laryngeal dysfunction secondary to the tumor will often persist following radiotherapy, and a laryngectomy may be preferred to chemoradiation in this setting.

Future Studies and Toxicity Scoring Criteria

Prospective studies that include pretherapy assessments of vocal and swallowing function should be conducted to correlate observer-rated scores such as the CTCAE v. 4.0 system,[116] patient-reported quality scores, and objective swallowing.[252] Such studies should focus on patients receiving concurrent chemoradiation, as this population is at the greatest risk of laryngeal/pharyngeal toxicity. Although CTCAE-based scoring is simple and widely utilized, objective measurement by a speech pathologist is often necessary to quantify swallowing dysfunction following radiotherapy.

Salivary Glands

Clinical Significance

In radiotherapy of head and neck tumors, the parotid, submandibular, and minor salivary glands often receive substantial doses of radiation. Reduced salivary production is a common toxicity and adversely affects the patient's quality of life. Inadequate salivary function leads to multiple problems, including poor dental hygiene, a propensity to oral infections, sleep disturbances, pain, and difficulty chewing and swallowing.[262] The majority of stimulated salivary production comes from the parotid glands, whereas resting (unstimulated) salivary production is due primarily to the submandibular, sublingual, and numerous small oral salivary glands.[263]

End Points

Xerostomia (dry mouth secondary to inadequate saliva production) can be assessed based on the patient's symptoms (altered taste or sensation of dryness) and/or quantitative saliva production.

Challenges Defining Volumes

Parotid and submandibular salivary glands can be adequately delineated on contrast-enhanced CT scans. However, parotid glands typically shrink during radiotherapy, potentially resulting in decreased gland sparing. For example, Robar et al[264] found that while the medial position of the parotid gland was stable over the course of RT, the lateral borders shrank approximately 1 mm/week, yielding total displacements of 4 to 6 mm.

Summary of QUANTEC

The QUANTEC authors[262] reviewed several studies on dosimetric predictors of xerostomia as measured by stimulated or unstimulated salivary flow at specific endpoints (ie, 1, 6, and 12 months after treatment; Table 12.8). Some recovery of salivary function occurs over time, with the dose required to obtain an equivalent reduction in salivary flow increasing at longer follow-up times. The QUANTEC report described a wide variation in the observed

dose/volume/toxicity relationships, depending on the patient population, treatment technique, and endpoint selected. As a result, models predicting the risk of xerostomia as a function of dose-volume parameters have yielded a broad range of parameters. Notably, parotid glands seem to respond independently to irradiation of the whole mouth and should be considered separately.

TABLE 12.8 DOSIMETRIC PREDICTORS OF XEROSTOMIA

Reference	Patients (*n*)/Follow-Up	Total Prescribed Target Dose (Gy)[a]	Dose-Volume Parameters	
			Unstimulated	Stimulated
Eisbruch et al[265]	88/1-12 mo	58-72	Mean dose ≤ 22-25 Gy[b] V_{15} < 66% V_{30} < 43% V_{45} < 26%	Mean dose ≤ 25-26 Gy[c] V_{15} < 67% V_{30} < 45% V_{45} < 24%
Maes et al[266]	39/1-4 mo	66-70	–	Mean dose ≤ 20 Gy[d]
Blanco et al[267]	55/6 mo 29/12 mo	50-71	Mean dose < 25.8 Gy	–
Li et al[268]	142/1-24 mo	60-75	Mean dose < 25-30 Gy	Mean dose < 25-30 Gy

[a]Treated at 1.5 to 2.0 Gy per fraction.

[b]24 Gy at 1 and 3 months, 22 Gy at 6 months, and 25 Gy at 12 months; threshold dose defined as mean dose above which saliva production appeared to abruptly approach zero.

[c]26 Gy at 1, 3, and 6 months, 25 Gy at 12 months; threshold dose defined as mean dose above which saliva production appeared to abruptly approach zero.

[d]Corresponds to the probability of 70% that loss of salivary excretion fraction was <50%.

V_x, percentage of gland volume receiving >*x* Gy.

Based on the summary of data, the QUANTEC authors[262] estimated less than 20% risks of long-term parotid function reduced to less than 25% of preradiotherapy level with a mean dose less than 25 Gy when considering bilateral parotid irradiation and a mean dose of less than 20 Gy when considering exposure of one parotid when the other is exposed to higher, potentially injuring, doses, as shown in Figure 12.7. Keeping the mean dose to the submandibular glands at modest levels (<35 Gy) may reduce the severity of xerostomia.[262]

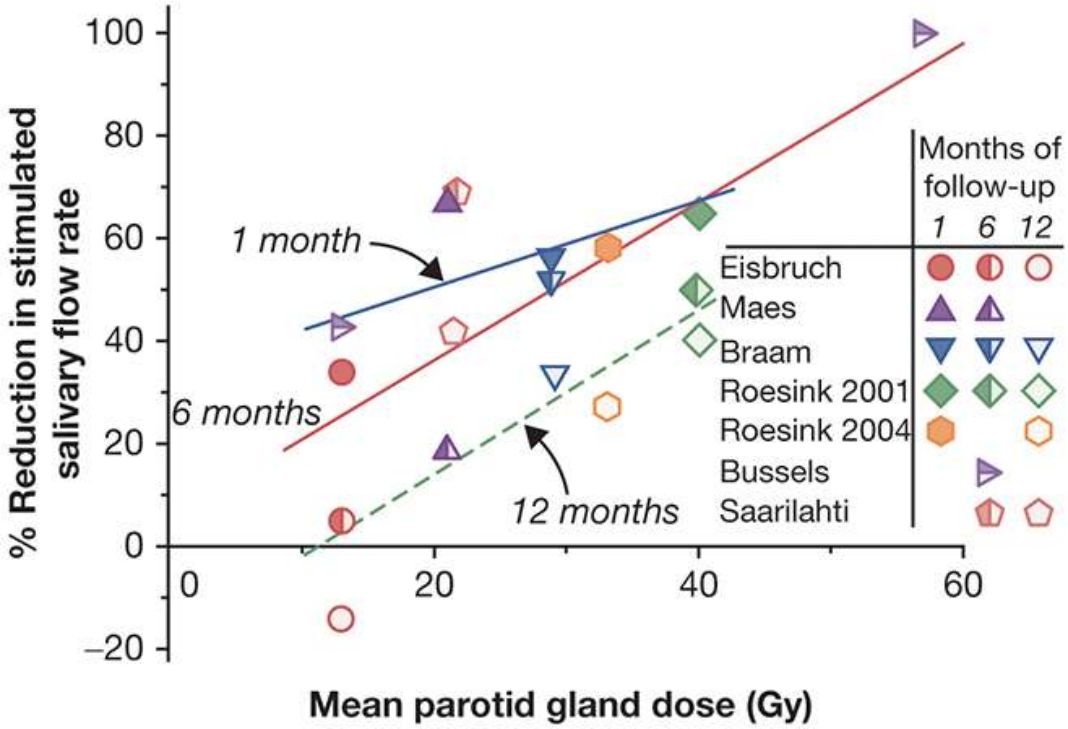

FIGURE 12.7 Mean percentage of reduction in stimulated salivary flow rate versus mean parotid gland dose for selected studies[269-274] using different follow-up durations. Nominal follow-up intervals of 1, 6, and 12 months represent ranges of 1 to 1.5, 6 to 7, and 12 months, respectively. *Lines* represent least-squares fit of data for each nominal follow-up interval. (Reprinted from Deasy JO, Moiseenko V, Marks L, Chao KS, Nam J, Eisbruch A. Radiotherapy dose-volume effects on salivary gland function. *Int J Radiat Oncol Biol Phys*. 2010;76[3 suppl]:S58-S63. Copyright © 2010 Elsevier. With permission.)

Factors Affecting Risk

Patient factors (eg, gender and age) and the use of chemotherapy have typically not correlated with xerostomia risk. However, pretreatment salivary function and medications affecting salivary function can influence the risk of xerostomia.[262]

Future Studies

Key questions on radiation-induced salivary gland dysfunction and xerostomia include the following:

1. Does partially sparing the submandibular glands or salivary minor glands have a positive impact on quality of life (QOL)?
2. Is the (arbitrary) 25% salivary threshold the best quantitative measure with respect to QOL?
3. Should parotid gland shrinkage during RT explicitly be accounted for in functional predictions?
4. How should submandibular sparing be incorporated into predictive salivary function models?
5. How does oral cavity sparing quantitatively affect xerostomia?

6. Does the radioprotector amifostine provide a clinically significant benefit for whole-mouth salivary function?
7. How does the use of lower tumor target doses (as are being increasingly suggested in patients with HPV-associated cancers) impact the dose/volume limits?[275]

Toxicity Scoring Criteria

The QUANTEC authors recommend that an observer-based system (eg, CTCAE v. 4.0) be supplemented by a validated quality of life instrument (eg, the xerostomia questionnaire[269]) and/or quantitative salivary measurements.

CHEST

Lung

Clinical Significance

The lung's primary function is the exchange of oxygen and carbon dioxide. Radiation-associated lung injury is one of the most common side effects seen in clinical oncology, and its risk sometimes limits the dose of radiation that can be used for the treatment of thoracic tumors.

End Points

Radiation damage to the lung can result in symptomatic pneumonitis and fibrosis. Symptomatic radiation pneumonitis is characterized by dyspnea, cough, and occasionally a low-grade fever, typically occurring several weeks to months after radiation. Long-term lung fibrosis can lead to respiratory insufficiency. It is often challenging to distinguish radiation-related pulmonary symptoms from comorbid illnesses (eg, exacerbation of the chronic obstructive pulmonary disease, infection, cardiac events).[276] Objective reductions in the lungs' ability to move and exchange gas can be measured by formal pulmonary function tests (PFTs). The various end points shown in Table 12.9 are segregated by their manifestation (clinical vs subclinical) and whether they reflect regional or global lung function.

TABLE 12.9 END POINTS FOR RADIATION-INDUCED LUNG INJURY

	Geographic Distribution	
Manifestation	**Regional**	**Global**
Clinical	Symptomatic bronchial stenosis	Respiratory symptoms (dyspnea, cough)
Subclinical	Radiologic abnormalities (eg, from computed tomography, perfusion/ventilation scans)	Pulmonary function tests, exercise testing results

The HyTEC study considered both radiation pneumonitis and radiation-induced pulmonary fibrosis in the setting of lung SBRT.[277] Acknowledging that a variety of endpoints were utilized, complicating comparison, the HyTEC study elected to focus on Grade 2+ toxicity, as this was similarly defined by RTOG, LENT-SOMA, and CTCAE criteria.[116,278,279]

Challenges Defining Volumes

Because the lungs move and their volume changes with respiration, there are inherent inaccuracies when defining the lung volume. As the mass of the lung is relatively constant during respiration and its density must decline with increased lung volumes, one could consider using dose-mass histograms rather than DVHs. To our knowledge, this approach has not been widely applied. Because of this variation in volumes with respiration, it is very likely that the dose/volume/outcome data are dependent on the type (if any) of respiratory control. The vast majority of dose/volume/outcome data are derived from free-breathing scans/treatment. These may not apply to patients being treated under, for example, breath hold techniques. Further, there are uncertainties in defining the lung borders in the vicinity of the central airways. Variable inclusion of the conducting airways in the "defined lung" can influence interpatient/institutional comparisons.

Summary of QUANTEC[280] and HyTEC[277]

Several parameters have been shown to be associated with the risk of radiation pneumonitis, including V_5 to V_{70}, mean lung dose (MLD), and model-based parameters.[10,281] These dosimetric parameters are mutually correlated, accounting for the fact that in most studies examining a range of V_x's, many appear statistically significant.[282-297] Figure 12.8 summarizes the studies discussed in the QUANTEC analysis.

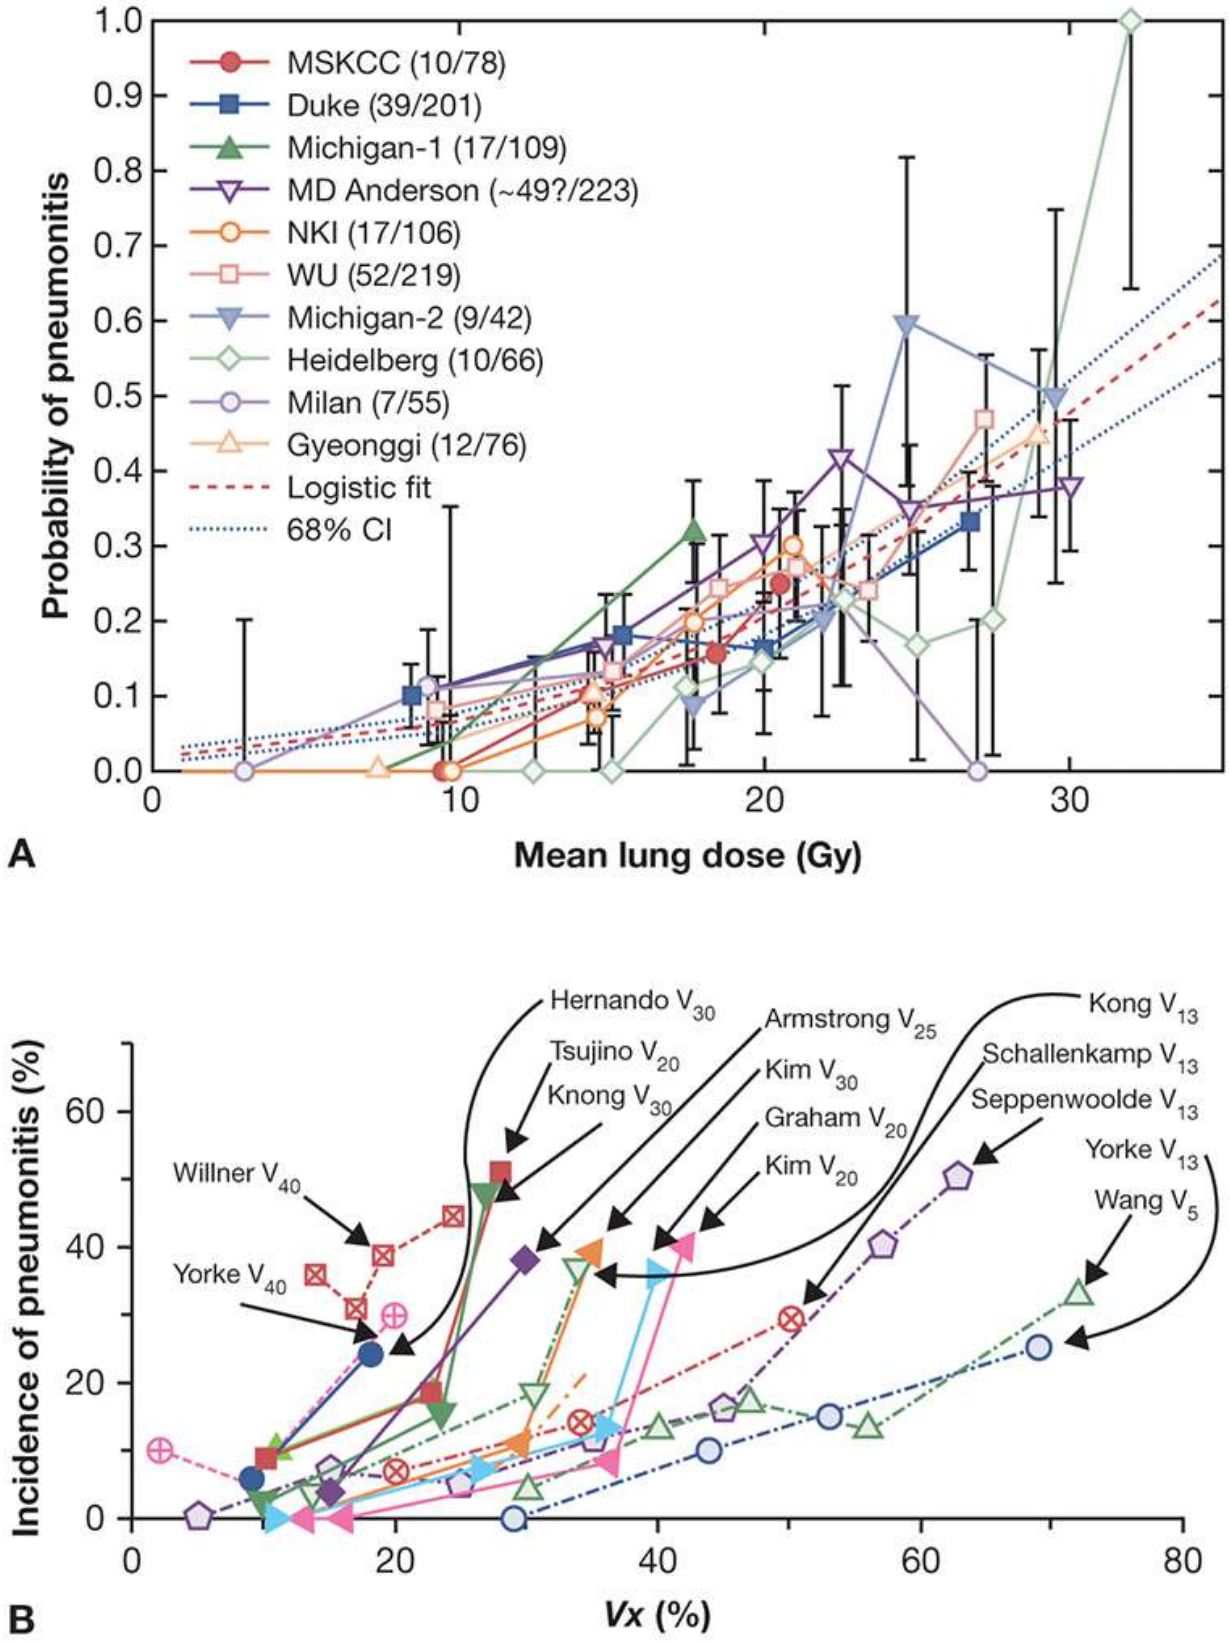

FIGURE 12.8 The rate of radiation pneumonitis after fractionated partial lung radiotherapy as a function of (A) mean lung dose (MLD) and (B) lung volume receiving *x* Gy (V_x). A. MLD: Confidence intervals (bars) represent ±

1 standard deviation. Results from Memorial Sloan-Kettering Cancer Center (MSKCC),[296] Radiation Therapy Oncology Group (RTOG) grade 3 or higher pulmonary toxicity at 6 months; Duke,[285] Common Terminology Criteria for Adverse Events (CTCAE) grade 1 or higher at 6 months; Michigan,[298] Southwest Oncology Group (SWOG) grade 2 or higher at 6 months; MD Anderson Cancer Center,[293] CTCAE grade 3 or higher, 1 year actuarial—includes concurrent chemotherapy patients; Netherlands Cancer Institute (NKI),[299] SWOG grade 2 or higher at 6 months; Washington University (WU),[286] SWOG grade 2 or higher; Michigan,[300] SWOG grade 1 or higher; Heidelberg,[301] RTOG acute grade 1 or higher; Milan,[302] SWOG grade 2 or higher, no time limit, patients without chronic obstructive pulmonary disease, includes induction chemotherapy patients; Gyeonggi,[287] RTOG grade 3 or higher at 6 months, includes concurrent chemotherapy patients. Dashed line is the best fit of these data fit to the logistic expression of the form [*f*/(1 + *f*)], where *f* = exp(b0 + b1 × MLD). Best fit values (95% confidence intervals) are b0 >= −3.87 (−3.33, −4.49) and b1 = 0.126 (0.100, 0.153), corresponding to TD_{50} = 30.75 (28.7, 33.9) Gy and γ_{50} = 0.969 (0.833, 1.122), where γ_{50} represents the increase in response (measured as percentage) per 1% increase in dose around the 50% dose-response level. B. V_x: Data from Yorke et al,[296] Willner et al,[294] Hernando et al,[285] Tsujino et al,[303] Kong et al,[298] Armstrong et al,[304] Kim et al,[287] Graham et al,[281] Seppenwoolde et al,[291] Wang et al,[293] and Schallenkamp et al.[290] Some of the above data were modified or derived from the original publications, as described in Marks et al[280] (Reprinted from Marks LB, Bentzen SM, Deasy JO, et al. Radiation dose-volume effects in the lung. *Int J Radiat Oncol Biol Phys*. 2010;76[3 suppl]:S70-S76. Copyright © 2010 Elsevier. With permission.)

Several total dose escalation studies have used V_{20}, V_{eff}, and/or NTCP to stratify the risk of toxicity as a function of dose.[305-308] In the RTOG 9311 dose escalation study,[305] patients with a V_{20} of less than 25% experienced a 7% to 16% 18-month actuarial rate of grade 3 or higher late lung toxicity with prescribed doses of 70.9 to 90.3 Gy; the absolute risk of grade 2 or higher late lung toxicity was 30% to 45%, with one fatal lung complication at the 90.3-Gy dose level. Patients with a V_{20} of 25% to 36% treated to doses of 70.9 to 77.4 Gy experienced 15% grade 3 or higher late toxicity at 18 months and a 40% to 60% risk of grade 2 or higher late lung toxicity. D_{15} was the most predictive variable for radiation pneumonitis.[283]

SBRT generally involves a few large fractions (eg, three 18-Gy or five 10-Gy fractions) given over 5 to 14 days.[309,310] Typically, the high-dose volumes in SBRT are small, and dose gradients are steep, minimizing the dose to surrounding critical structures. Nonetheless, large volumes of lung receive low to medium doses.[310] Consequently, the dose-volume characteristics of lung SBRT are quite different from those of conventional RT and deserve special consideration.

The HyTEC study of RILT in SBRT[277] considered the findings in 97 papers. In the meta-analysis by Zhao et al,[311] total prescription dose was not significantly correlated with RILT. Although MLD was also not significantly correlated with RILT in that analysis, many of the individual studies identified an increased risk of RILT with elevated MLD.[312-320] The lack of correlation in the meta-analysis was attributed to interstudy variations (eg, in defining lung volumes as well as toxicity)[277]; this is a common phenomenon known as Simpson Paradox (discussed at the end of this chapter). Similarly, many[312,315,318,320-326] but not all[327-329] studies of RILT as a function of V_{20} or other lung volume receiving dose greater than the specified Gy suggested an association between higher V_{dose} and greater risk of RILT. The rate of RILT was low in most studies, making quantification of risk and correlation with dosimetric parameters difficult.

In the PENTEC study, 277 and 507 patients aged 0.04 to 22.7 years were evaluable for acute and late recursive partitioning (RP) analysis, respectively.[330] After partial lung RT, there were 0.4% acute and 2.8% late grade 2, 0.4% acute and 0.8% late grade 3, and no grade 4 to 5 RP. RP risk after partial thoracic RT with MLD less than 14 Gy and total lung V_{20Gy} less than 30% is low. Clinical and self-reported pulmonary outcomes data included 8,628 patients treated from 1970 to 2013, aged 0 to 21.9 years. At a median 2.9- to 21.9-year follow-up, patients were often asymptomatic; abnormal PFTs were common and severity correlated with lung dose. At greater than or equal to 10-year follow-up, multi-institutional studies suggested associations between total or ipsilateral lung doses greater than 10 Gy and pulmonary complications and deaths. After whole-lung irradiation (WLI), pulmonary toxicity may be higher; and no dose-response relationship was identified (though the dose ranges reported were fairly narrow). Bleomycin and other chemotherapeutics at current dose regimens do not contribute substantially to adverse pulmonary outcomes after partial lung irradiation but appear to increase risk with WLI.

Factors Affecting Risk

Recent meta-analyses have shown that patient-related adverse risk factors for radiation pneumonitis among patients with NSCLC[331-333] and patients with breast cancer[334] include older age,[332,333] history of chronic lung disease, or diabetes.[331] The impact of smoking on risk has been inconsistently reported in the literature. Smoking was noted to be an adverse risk factor in one meta-analysis[331] and a *protective* factor in others.[333] This discrepancy may be due to inaccuracies in how smoking history is collected and reported in the medical record and also due to the complex relationship between smoking, chronic lung disease, and pneumonitis.[331] Chemotherapy concurrent with RT, particularly carboplatin/paclitaxel chemotherapy,[332] has been reported to increase the pneumonitis risk.

The effect of dose to regions of the lung was investigated in a Dutch study,[299] dividing the lung into central and peripheral, ipsilateral and contralateral, caudal and cranial, and anterior and posterior subvolumes. The mean regional doses to the posterior, caudal, ipsilateral, central, and peripheral lung subvolumes were significantly correlated with the incidence of steroid-requiring radiation pneumonitis. In a similar study from MSKCC, the risk of radiation pneumonitis was better correlated with the radiation dose to the inferior, as opposed to the superior, aspect of the lung.[297]

Tumor location within the chest may also be a factor affecting the risk of pneumonitis. In the study from Washington University,[286] inferior tumor location was the most significant predictor of radiation pneumonitis. Tumor location was not a strong correlate with radiation pneumonitis in RTOG 9311, perhaps attributable, in part, to differences in treatment (with RTOG 9311 treating smaller volumes to higher doses) and differences in tumor size and location (the RTOG 9311 tumors tended to be smaller and more superiorly located).[283] Using a combined dataset of patients from RTOG 9311 and Washington University, tumor location and MLD were significant predictors of toxicity.

The HyTEC study of RILT post-SBRT highlights the substantially higher rates of radiation pneumonitis reported in patients with interstitial lung disease (ILD).[277,312,320,335,336] For example, in a study of 404 patients treated with lung SBRT, Bahig et al[312] found the rate of G3+ RP was 3.8% for the entire cohort versus 32.1% in the 28-patient subset with ILD. However, a recent

prospective study of patients with ILD treated with SBRT reports much lower rates of toxicity.[322]

Special Situations

IMRT provides unique dose distributions for some patients with advanced-stage non–small cell lung cancer,[337] potentially reducing the risk of normal tissue injury. In a retrospective review of patients treated with lung cancer and concurrent chemotherapy at MD Anderson Cancer Center (MDACC), the rates of grade greater than or equal to 3 pneumonitis following IMRT versus 3D planning were ≈ 8% versus 25% (P = .017), respectively.[338] Similarly, a study from MSKCC found a low rate of clinical lung injury in patients with non–small cell cancer treated with IMRT.[339] Furthermore, a secondary analysis of RTOG 0617 noted lower rates of RP in the patients treated with IMRT versus 3D.[340]

In a study from Dana-Farber,[341] in which patients received thoracic IMRT after pneumonectomy for mesothelioma, 6 of 13 patients developed fatal pneumonitis. The median V_{20}, V_5, and MLD for patients who developed pneumonitis were 17.6%, 98.6%, and 15.2 Gy, respectively, versus 10.9%, 90%, and 12.9 Gy for those who did not develop pneumonitis. Although these differences were not significant, the severity of the toxicities suggests caution in treating patients with large volumes after a pneumonectomy. In a study from Duke,[342] 1 of 13 patients treated with IMRT for mesothelioma died from pneumonitis, and two others developed symptomatic pneumonitis. The median V_{20}, V_5, and MLD for patients developing pneumonitis were 2.3%, 92%, and 7.9 Gy, respectively, versus 0.2%, 66%, and 7.5 Gy for those who did not develop pneumonitis and 6.9%, 92%, and 11.4 Gy for the patient who developed fatal pneumonitis. In a study of patients with mesothelioma treated at MDACC with IMRT,[343] 6 of 63 died from pulmonary-related causes (including two patients with fatal pneumonitis). The V_{20} was significant in univariate and multivariate analyses (P = .017), with V_{20} greater than 7% corresponding to a markedly increased risk of pulmonary death. Lower rates of pulmonary death were seen in patients with absolute lung volumes receiving less than or equal to 10 Gy of greater than 1,200 cm^3, and absolute lung volumes receiving less than or equal to 5 Gy of greater than 300 cm^3.[325]

Radiation pneumonitis is relatively uncommon after SBRT, usually less than 10%[344-346] but as high as 25% in one study.[347] Bronchial injury/stenosis, an unusual complication with conventional dose fractionation,[348] has been associated with SBRT to perihilar/central tumors.[345] The NRG/RTOG dose escalation study (0813) has suggested that a five-fraction SBRT regimen might be associated with a clinically acceptable toxicity rate.[349]

Recommended Dose-Volume Limits

Individual studies note a dose-response relationship for radiation pneumonitis based on a variety of metrics. However, the QUANTEC analysis[280] of the pooled data shows that there is no specific threshold for pneumonitis, with risks increasing gradually as the dose increases. Because many dose-volume parameters of the lung (ie, V_5 through V_{30}, MLD) are correlated with each other, there likely is not an "optimal" parameter. For patients with non–small cell lung cancer, it is prudent to limit the V_{20} to less than 30% to 35%, and the MLD to less than 20 to 23 Gy, in order to reduce the risk of pneumonitis to less than 20%. In patients irradiated

after pneumonectomy for mesothelioma, it is prudent to limit the V_5 to below 60%, V_{20} to less than 4% to 10%, and the MLD to less than 8 Gy.

For SBRT, the HyTEC study notes that there was no apparent threshold "tolerance dose-volume" level. However, they observed that most studies reported safe treatment with a rate of symptomatic RILT of less than 10 to 15% after lung SBRT for an MLD to the combined lungs of less than 8 Gy in three to five fractions and the percentage of total lung volume receiving more than 20 Gy (V_{20}) less than 10% to 15%.

Future Studies

Radiation-induced pneumonitis appears more commonly in patients with lower versus upper lobe tumors and may be better correlated with radiation doses to the lower versus upper lung. The cause of this correlation is presently unknown and requires further investigation, though it may be related to heart irradiation. Additional work is needed to better understand the impact of clinical factors (eg, preradiotherapy functional status, ILD, and tobacco use) and systemic agents (particularly immunotherapy) on the risk of lung injury. The biologic underpinnings to explain the possible protective effect of smoking on risk need to be further refined. Studies aimed at determining and exploiting the ability of biomarkers such as TGF-β (measured before and/or during lung radiotherapy) on radiation pneumonitis would be valuable. Studies are needed to better understand how best to apply hypofractionation for centrally located lesions.

Toxicity Scoring Criteria

The QUANTEC study recommended that the LENT-SOMA system[278] be used for scoring toxicity, as it explicitly captures symptomatic, functional, and radiographic end points. A global score can be generated, but the granular data should be recorded and maintained. The HyTEC paper[277] preferred the RTOG system[279] but considered the RTOG, LENT-SOMA, and CTCAE criteria in its analysis.

Heart

Clinical Significance

The heart is a muscular organ typically located in the left hemithorax, which, via continuous rhythmic contraction, pumps blood throughout the blood vessels. The functional and structural complexity of the heart places it at risk for a spectrum of radiation and chemotherapy injuries that can manifest months to years following therapy.[350]

End Points

All components of the heart and pericardium are susceptible to radiation damage. Radiation-induced cardiac injury includes pericarditis, congestive heart failure, restrictive cardiomyopathy, valvular insufficiency and stenosis, coronary artery disease, ischemia, and infarction.

Challenges Defining Volumes

The substructures of the heart, as well as the intersection/border of the heart, great vessels, liver, diaphragm, and stomach, can be challenging to delineate on CT imaging. The heart moves during the respiratory and cardiac cycles, with different regions moving to different degrees. The uncertainties that accompany these anatomic/physiologic realities must be considered when contouring targets and normal tissue structures and when interpreting DVHs.

Dose/Volume/Toxicity Data

Multiple studies show an increased risk of cardiac morbidity following left-sided versus right-sided thoracic radiation in patients undergoing treatment for breast cancer. It is generally recognized that reducing the dose prescribed to the mediastinum and reducing the volume of the heart in the radiation field reduce the risk of late toxicity. Studies from Duke demonstrated that an increased percentage of the left ventricle irradiated correlates[351-353] with a greater risk of subsequent cardiac perfusion defects.[354-356] Even over the range of low-dose exposure (~8-20 Gy) to small volumes of the cardiac apex, an increased risk of heart disease has been reported.[357]

A study from Stockholm used NTCP modeling to predict the risk of late heart toxicity in women treated for breast cancer.[358] The models predicted a TD_{50} of 52 Gy for the dose to the myocardium. A 5% risk of excess cardiac mortality at 15 years was associated with a myocardial dose of approximately 30 Gy, V_{33} greater than 60%, V_{38} greater than 33%, *or* V_{42} greater than 20%. Calculations using the whole-heart volume (as opposed to myocardium) yielded equivalent results.

The same group from Stockholm used a similar analysis to assess cardiac risk in patients with Hodgkin disease.[359] Patients were stratified based on a V_{38} greater than 35% versus less than 35%. The excess mortality risk at 15 years was 7.9% and 4.7%, respectively. The TD_{50} was calculated to be 70 Gy. Heart doses of 42 and 53 Gy resulted in a 5% and 10% risk of cardiac complications, respectively. The corresponding values in the patients with breast cancer were 37 and 44 Gy, respectively (lower threshold doses and steeper gradient). The differences in complication probabilities and TD_{50} between the breast cancer and Hodgkin disease cohorts (Figure 12.9) suggest that radiation exposure to different portions of the heart results in differences in cardiac risk, though there may be other confounding variables (ie, patient age at treatment, overlapping breast cancer, cardiac disease risk factors, etc).

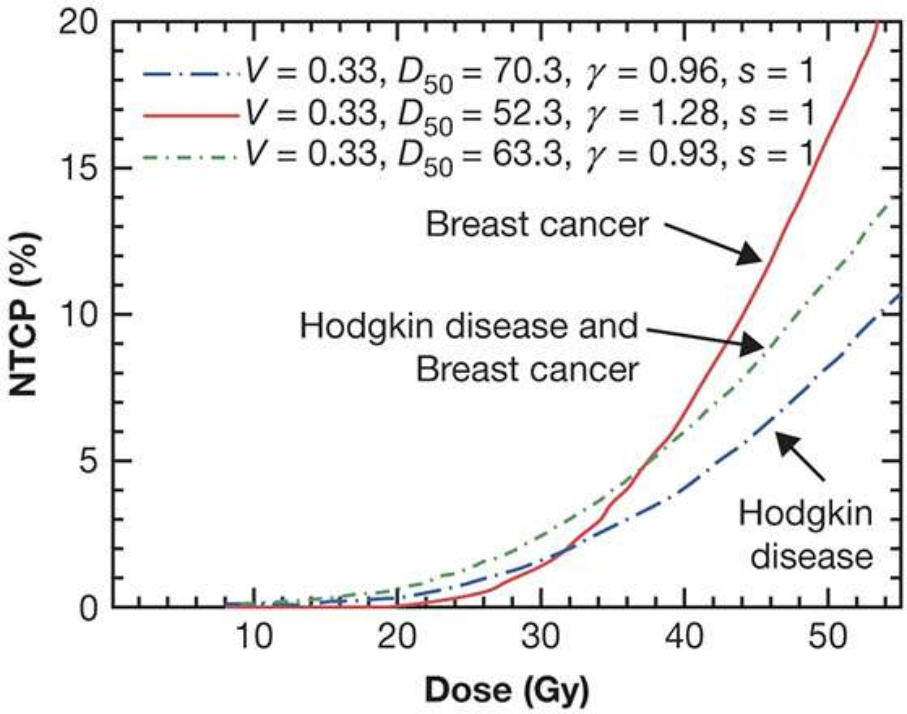

FIGURE 12.9 Dose-response curves for long-term cardiac mortality in patients with Hodgkin disease (HD) and breast cancer treated with thoracic radiotherapy. NTCP = normal tissue complication probability, defined in that study as the excessive risk of ischemic heart disease. *Curves* were obtained by fitting data from breast cancer trials, a cohort of patients with Hodgkin disease, and the combined dataset. *Plotted curves* correspond to uniform irradiation of one-third of the heart volume. (Reprinted from Eriksson F, Gagliardi G, Liedberg A, et al. Long-term cardiac mortality following radiation therapy for Hodgkin's disease: analysis with the relative seriality model. *Radiother Oncol*. 2000;55[2]:153-162. Copyright © 2000 Elsevier Science Ireland Ltd. With permission.)

A study from MDACC described the risk of pericardial effusions in patients treated for esophageal cancer.[360] A mean dose greater than 26 Gy and relative volumes of the pericardium treated at doses greater than 3 to 50 Gy (V_3-V_{50}) showed the greatest risk, with the association strongest at V_{30}. For V_{30} less than 46% versus greater than 46%, the rate of pericardial effusion was 73% versus 13% (P = .001) 18 months postradiation. For a mean pericardium dose less than 26 versus greater than 26 Gy, the rate of pericardial effusion was 73% versus 13% (P = .001). A study from the University of Michigan[361] also demonstrated that a mean dose greater than 27 Gy and a maximum dose of 47 Gy correlated with the risk of pericardial effusion. However, only patients treated with 3.5-Gy fractions developed pericardial effusions.

The incidence of valvular disease has been related to mediastinal radiation doses greater than 30 Gy and younger age at irradiation.[362] Subclinical valvular disease has been detected at 2 to 20+ years postradiation, but it appears to take much longer for clinical symptoms to become apparent (median interval 22 years from radiation to symptoms). For patients treated for Hodgkin lymphoma more than 10 years prior with radiation, aortic disease, usually consisting of mixed stenosis and regurgitation, is more common than mitral and right-sided valvular disease.[362,363]

Studies have demonstrated a clear dose response for RT-associated heart injury. For example, in an analysis of 112 patients irradiated to 70 to 90 Gy for lung cancer, the 2-year

competing risk–adjusted cardiac event rates for patients with heart mean doses of less than 10 Gy, 10 to 20 Gy, or greater than 20 Gy were 4%, 7%, and 21%, respectively.[364] Similarly, distinct types of cardiac disease have been associated with doses to specific subvolumes of the heart.[365]

Factors Affecting Risk and Special Situations

Anthracycline chemotherapy can exacerbate radiation-related cardiac toxicity. In patients with Hodgkin disease, radiation exposure, in conjunction with anthracyclines, may impair ejection fraction and increase the risk of myocardial infarction, congestive heart failure, and valvular disorders. A Dutch study[366] of 1,474 Hodgkin lymphoma survivors showed that risks of myocardial infarction and congestive heart failure were significantly increased, with standard incidence ratios of 3.6 and 4.9, respectively, for these survivors versus the general population. Mediastinal radiation alone increases the risks of myocardial infarction, angina pectoris, congestive heart failure, and valvular disorders (2- to 7-fold). The addition of anthracyclines further elevated the risks of congestive heart failure and valvular disorders, with hazard ratios of 2.81 and 2.10, respectively. The 25-year cumulative incidence of congestive heart failure following combined radiation and anthracycline chemotherapy was 7.9%.

Other risk factors for cardiac disease, particularly coronary artery disease, also must be considered. For example, a University of Rochester study[367] assessed the risk of coronary artery disease in survivors of Hodgkin lymphoma and also the prevalence of cardiac risk factors. The relative risk of cardiac death was 3.1 for males versus 1.8 for females. Other risk factors were more common than in the general population; among patients with Hodgkin lymphoma experiencing morbid cardiac events, 72% smoked, 72% were male, 78% had hypercholesterolemia, 61% were obese, 28% had a positive family history, 33% had hypertension, and 6% had diabetes.

Evolving data from patients irradiated for breast or lung cancer suggest that RT-associated cardiac injury may occur earlier than previously believed (ie, within a few years of RT).[340,364,368,369] For example, in patients with non–small cell lung cancer prescribed to receive greater than 70 Gy, the mean heart dose and preexisting cardiac disease have been implicated as predictors for cardiac injury[340]; the 2-year competing risk–adjusted cardiac event rates for patients with heart mean doses less than 10 Gy, 10 to 20 Gy, or greater than or equal to 20 Gy were 4%, 7%, and 21%, respectively.

For children, PENTEC found that for each 10-Gy increase in corrected mean cardiac radiation dose in 1.8-to 2.0-Gy fractions, the estimated hazard ratio was 2.01 (95% confidence interval [CI], 1.79-2.25) for coronary artery disease, 1.87 (95% CI, 1.70-2.06) for heart failure (HF), 1.87 (95% CI, 1.78-1.96) for valvular disease, and 1.88 (95% CI, 1.75-2.03) for any cardiac disease.[370] From the same model, for each 100-mg/m^2 increase in cumulative anthracycline dose, the hazard ratio for the development of HF was 1.93 (95% CI, 1.58-2.36), equivalent to an increase in mean heart dose of approximately 10.5 Gy. Other nontreatment factors were inconsistently reported in the analyzed articles.

Mathematic/Biologic Models

There are no well-accepted models for cardiac toxicities. Nevertheless, several authors have computed model parameters for various cardiac end points, as summarized in the QUANTEC

review.[350]

Recommended Dose-Volume Limits

A heart V_{30} to V_{40} of approximately 30% to 35% is associated with an approximately 5% excess risk of cardiac death at approximately 15 years. A heart V_{30} of greater than 45% and a mean cardiac dose of greater than 26 Gy are associated with a higher risk of pericarditis. In patients with breast and lung cancer, it is recommended that the irradiated heart volume be minimized as much as possible without compromising target coverage. In patients with lymphoma, the whole heart should be limited to 30 Gy if treated with radiation alone and to 15 Gy for patients also receiving anthracycline chemotherapy. Although there is no direct evidence that eliminating traditional cardiac risk factors alters the natural history of radiation-associated cardiac disease, it seems prudent to minimize such factors.[350,371,372]

Future Studies

Issues that would benefit from further systematic study are the effects of radiation on *specific subvolumes* of the heart, the impact of modern radiotherapy techniques on cardiac toxicity, the relationship between heart irradiation and baseline cardiovascular risk factors on the development of cardiac disease, the effect of hypofractionation encountered in thoracic SBRT, and the global physiologic effects of thoracic radiotherapy (eg, interactions between simultaneous heart and lung irradiation).[350]

Toxicity Scoring Criteria

The QUANTEC authors recommend that the LENT-SOMA system[118,373] be considered to describe cardiac toxicity, as it explicitly includes clinical, radiologic, and functional assessments of cardiac dysfunction.

Esophagus

Clinical Significance

Acute esophagitis is very common and often severe in patients receiving radiation for intrathoracic malignancies (eg, primary lung cancer and esophageal cancer). Patients with severe esophagitis may require a feeding tube and/or treatment interruptions.

End Points

Because most patients with thoracic cancers have a poor prognosis, acute toxicity may be considered more clinically relevant than late injury. Late esophageal complications include dysphagia, stricture, dysmotility, odynophagia, and rarely necrosis or fistula.

Challenges Defining Volumes

The esophagus can be challenging to visualize on axial imaging, and the use of dilute oral contrast can assist in its identification. Also, the esophagus often has folds such that its external contour as seen on an axial image may not accurately represent its true circumference. Indeed, in CT imaging, the circumference of the esophagus appears highly

variable on different axial levels, when in fact the esophagus has a relatively uniform circumference. One study has suggested that the dosimetric parameters that apply this prior anatomic knowledge are better predictors of acute and late esophageal injury than are traditional dosimetric parameters.[374]

Dose/Volume/Toxicity Data

A variety of dose-volume parameters have been associated with the incidence of esophagitis.[360,375-412] Although a continuous dose-response curve for acute esophagitis is observed based on a range of dosimetric parameters, as shown in Figure 12.10, there is no consensus as to the optimal dosimetric predictors of esophageal injury.

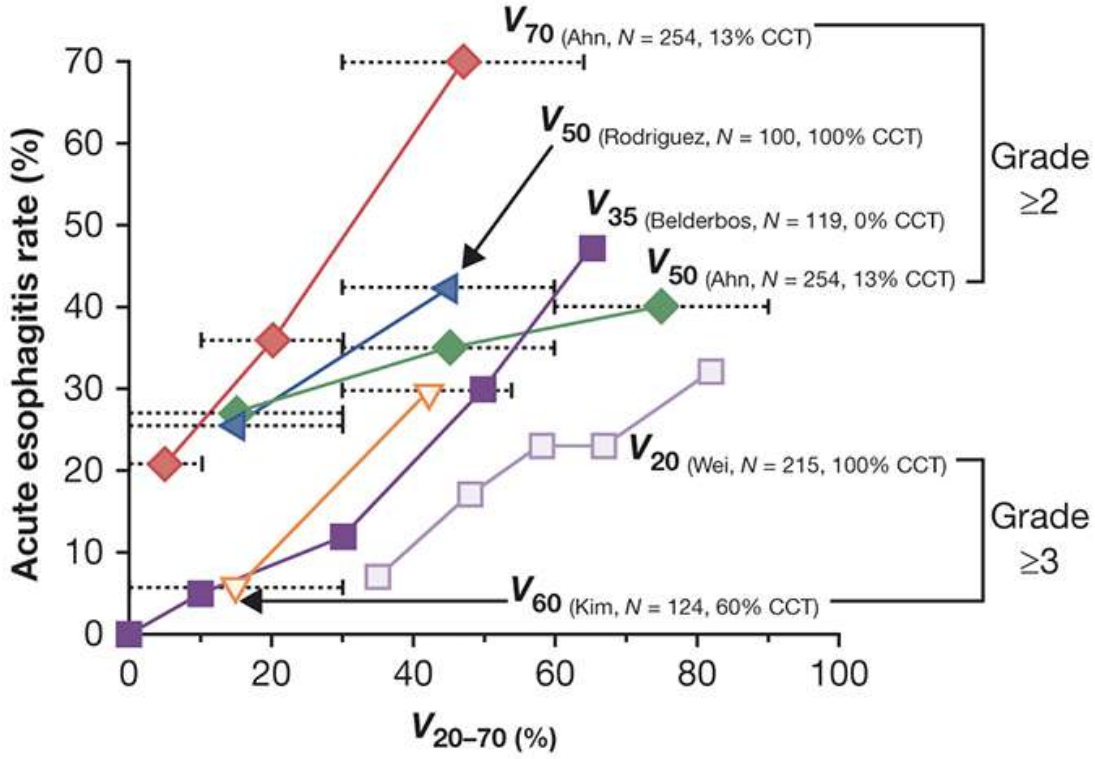

FIGURE 12.10 Incidence of acute esophagitis according to V_x (volume receiving more than x Gy) for selected studies. X-axis values estimated from the range of doses reported. Datasets annotated as follows: V_{dose} (investigator, number of patients, percentage with concurrent chemotherapy [CCT]). (Reprinted from Werner-Wasik M, Yorke E, Deasy J, Nam J, Marks LB. Radiation dose-volume effects in the esophagus. *Int J Radiat Oncol Biol Phys*. 2010;76[3 suppl]:S86-S93. Copyright © 2010 Elsevier. With permission.)

In a series from Washington University, grade 3 to 5 esophageal toxicity (acute and late) was associated with a maximal dose (D_{max}) of greater than 58 Gy, a mean dose of greater than 34 Gy, and the administration of concurrent chemotherapy.[407] The V_{55} was not significant. A study from China reported that a maximal dose greater than 60 Gy, as well as the use of concurrent chemotherapy, was a significant factor for esophageal toxicity (acute and late).[402] In a study from Duke, V_{50}, the surface dose receiving greater than or equal to 50 Gy (S_{50}), the length of esophagus receiving greater than 50 to 60 Gy, and a circumferential D_{max} greater

than 80 Gy were significant predictors of late esophageal toxicity.[396] A V_{50} greater than 32% or an S_{50} greater than 32% resulted in crude rates of approximately 30% late esophageal toxicity versus 7% below these thresholds. With greater than 3.2 cm of the esophagus receiving greater than 50 Gy, late toxicity occurred in approximately 30%, versus 4% in those with less than 3.2 cm receiving greater than 50 Gy ($P = .008$).

In another study from Duke, grade 1 or higher late toxicity was correlated with several dose parameters: the entire circumference receiving greater than or equal to 50 and greater than or equal to 55 Gy; 75% of the circumference receiving greater than or equal to 70 Gy; and the maximal percentage of circumference receiving greater than or equal to 60 to 80 Gy.[375] The rate of grade 1 or higher late toxicity was approximately 5% in patients with a V_{50} to V_{70} of 0% to 30% versus approximately 25% in those with a V_{70} of 31% to 64% and approximately 10% in those with a V_{50} greater than 60% (nonsignificant). Acute esophageal toxicity was the greatest predictor of late toxicity. In two studies, most of the patients who developed late grade 3 or higher toxicity had developed acute grade 3 or higher toxicity, though roughly 25% to 40% of patients who developed grade 3 or higher late toxicity had only grade 0 to 2 acute esophageal toxicity.[402,407]

A 2013 meta-analysis (published after QUANTEC) of 1,082 patients with NSCLC treated with chemoradiation analyzed esophageal V_5 to V_{70} parameters (in 5-Gy increments); all significant predictors of grade greater than or equal to 2 esophagitis and on multivariate analyses, V_{60} proved to be the most significant predictor of grade greater than or equal to 2 to 3 esophagitis.[413] Recursive partitioning identified three risk groups: low (29% and 4% risk of grade ≥2 and ≥3 esophagitis with $V_{60} < 0.07\%$), intermediate (41% and 10% risk of grade ≥2 and ≥3 esophagitis with V_{60} 0.07% to 17%), and high (59% and 22% risk of grade ≥2 and ≥3 esophagitis with $V_{60} \geq 17\%$).

Factors Affecting Risk

Greater rates of acute esophagitis have been observed with more aggressive radiotherapy regimens (eg, hyperfractionation, concurrent boost), the addition of concurrent chemotherapy, increasing age, and several other clinical factors (eg, preexisting dysphagia, increasing nodal stage). The incidence of grade 3 or higher acute esophagitis is approximately 1% for patients treated with once-daily radiotherapy alone versus as high as 49% with concurrent gemcitabine. Several studies have assessed the putative radioprotector amifostine. Three single-institution phase III studies suggested a benefit of amifostine in reducing the rate of grade 2 or higher esophagitis, but this result was not confirmed in a large cooperative group phase III randomized trial (RTOG trial 9801).[376,391,394,398]

Mathematic/Biologic Models

Using data on grade 2 or higher acute esophagitis, two studies obtained relatively consistent estimates of Lyman- Kutcher-Burman model parameters, including TD_{50} of 47 to 51 Gy.[8,378] Note that these parameters differ significantly from those derived from the Emami data,[5] which examined a more clinically severe end point (stricture and perforation).

Special Situations

Esophageal toxicity data for hypofractionated treatments in SBRT to central thoracic lesions are quite limited,[399] and long-term data in this and other altered fractionation settings (eg, accelerated fraction and concomitant boosts) have not been comprehensively reported.[410]

Recommended Dose-Volume Limits

Given the available data, there are no strict dose-volume limits for the esophagus. Several parameters are associated with the risk of adverse events, and clinicians can apply these data as seem reasonable for the clinical situation. Unfortunately, the anatomic reality for many patients with locally advanced non–small cell lung cancer is that the PTV (and certainly the GTV) is often immediately adjacent to the esophagus, and thus, it is not possible to limit the doses as desired without compromising the target coverage. The ongoing phase III intergroup trial, RTOG 0617, has recommended (but has not mandated) that the mean dose to the esophagus be kept to less than 34 Gy.

Future Studies

IMRT may provide increased flexibility in sparing the esophagus during lung irradiation,[414] and outcome as a function of dose-volume should be systematically studied for this treatment technique. As in other organ systems, detailed outcome and dosimetric data should be reported, based on clearly defined methods of contouring the target and organs at risk.

Toxicity Scoring Criteria

Esophageal toxicities should be scored using the CTCAE v. 4.0.[116]

ABDOMEN/PELVIS

Liver

Clinical Significance

The liver is a vital organ, involved in the metabolism of ingested nutrients, detoxification, protein synthesis, bile production, glycogen storage, and red blood cell decomposition. The liver may be incidentally irradiated during RT of abdominal or thoracic tumors and will be irradiated in patients undergoing partial hepatic radiation for liver metastases or hepatocellular carcinoma. There is no effective treatment to reverse the process of radiation-induced liver disease (RILD); therefore, prophylaxis and prevention are best. Anticoagulants, paracentesis, and diuretics can be used to mitigate symptoms, whereas liver transplantation is required for frank radiation hepatopathy.

End Points

RILD generally presents as vague to intense right upper abdominal pain followed by abdominal swelling because of hepatomegaly and ascites, resulting in weight gain. Anicteric ascites often develops 2 to 4 months after irradiation; chemoradiation-induced liver disease may occur more rapidly (eg, 1-4 weeks post RT in a bone marrow transplantation setting).

Other sequelae of RILD include elevation of liver enzymes, jaundice, asterixis (tremor), encephalopathy, or coma.

The basic pathophysiologic sequelae of classic RILD is central vein thrombosis at the lobular level, which results in retrograde congestion leading to hemorrhage and secondary alterations in surrounding hepatocytes. This often occurs between 2 weeks and 3 months after therapy. Severe acute hepatic changes often progress to fibrosis or cirrhosis and liver failure.

Nonclassic RILD implies dramatic elevations of liver transaminases (>5 times the upper limit) or a decline in liver function in the absence of classic RILD. The underlying pathology of nonclassic RILD is unclear.[401]

Challenges Defining Volumes

The liver parenchyma is composed of innumerable, redundant, parallel functional subunits, which allows the liver to potentially tolerate focal injury without clinical sequelae if adequate normal liver parenchyma can be spared. The liver is readily identified on CT and MRI. For radiation planning, it must be recognized that the liver moves with the respiratory cycle.[401]

Summary of QUANTEC, HyTEC, and PENTEC

The QUANTEC report on RILD (described as "anicteric hepatomegaly and ascites") summarized data from six studies that described risks of RILD from conventionally fractionated partial liver irradiation (Table 12.10; Figure 12.11), though these data were not amenable to pooling and NTCP modeling.[401] From their data summary, the authors predicted risks of RILD of less than 5% and less than 50% with mean doses less than 30 to 32 Gy and less than 42 Gy, respectively, in patients without preexisting liver disease or hepatocellular carcinoma (for whom risks are higher). Among those with preexisting Child-Pugh A liver disease or hepatocellular carcinoma, mean doses of less than 28 and less than 36 Gy, respectively, were associated with less than 5% and less than 50% risks. For patients undergoing palliative whole-liver radiotherapy, approximately 10% of risks of RILD occur with 33 Gy in 1.5-Gy fractions.

TABLE 12.10 RADIATION-INDUCED LIVER DISEASE IN PARTIAL LIVER IRRADIATION

Reference	*n*/% C-P A	Diagnosis	Dose Fractionation	Crude Rate of RILD	Mean Normal Liver Dose in Patients With vs Without RILD
Michigan[383,386]	203/100%	PLC + LMC	1.5 Gy bid	9%	37 vs 31.3 Gy
Taipei[381]	89/76%	HCC	1.8-3 Gy qd	19%	23 vs 19 Gy
Shanghai[395,412]	109/85%	PLC	4-6 Gy qd	16%	24.9 vs 19.9 Gy
Guangdong[411]	94/46%	HCC	4-8 Gy qd	17%	Not stated
S. Korea (Seong et al)[406]	158/74%	HCC	1.8 Gy qd	7%	Not stated
S. Korea (Kim et al)[390]	105/81%	HCC	2.0 Gy qd	12%	25.4 vs 19.1 Gy

% C-P A, percentage of patients with baseline Child-Pugh A score (in all studies, patients were either A or B); bid, twice-daily treatment; HCC, hepatocellular carcinoma; LMC, metastatic disease to the liver; PLC, primary liver

cancer; qd, once-daily treatment; RILD, radiation-induced liver disease.

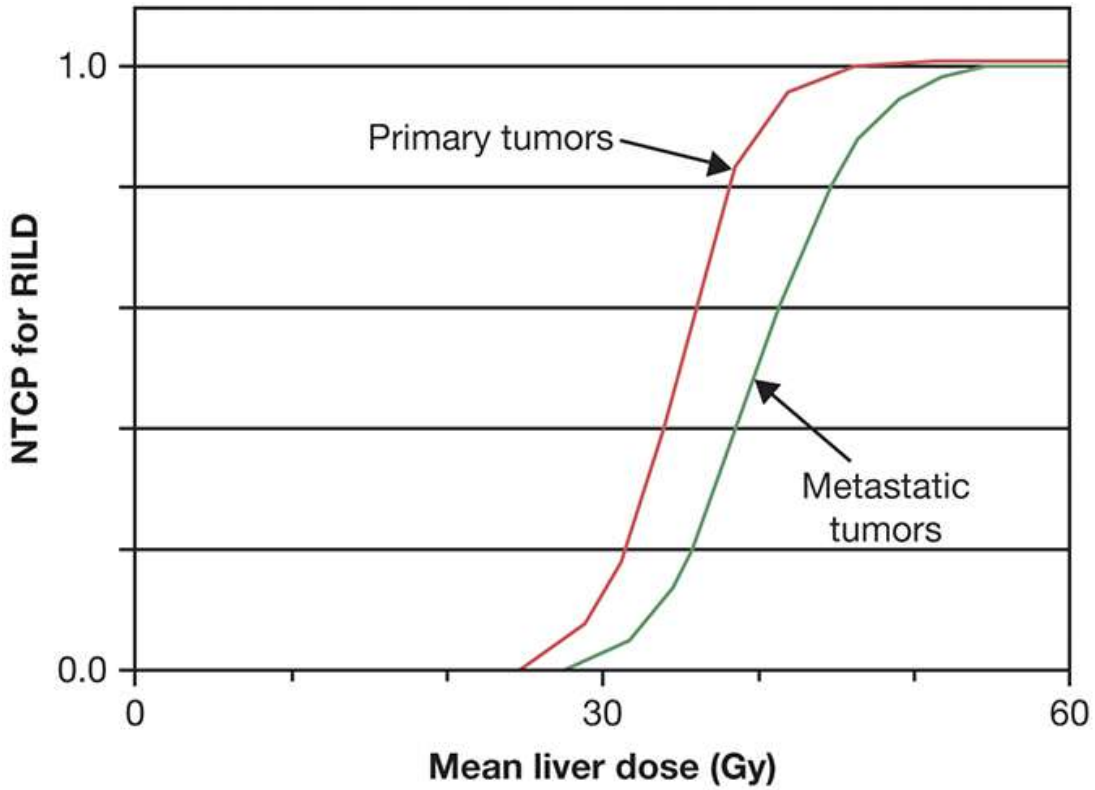

FIGURE 12.11 Mean liver dose, corrected with linear-quadratic modeling for 2-Gy fractions versus Lyman normal tissue complication probability (NTCP) of classic radiation-induced liver disease (RILD) for primary and metastatic liver cancer. (Reprinted from Pan CC, Kavanagh BD, Dawson LA, et al. Radiation-associated liver injury. *Int J Radiat Oncol Biol Phys*. 2010;76[3 suppl]:S94-S100. Copyright © 2010 Elsevier. With permission.)

The HyTEC report[415] summarized data from 12 studies to generate separate NTCP models for grade 3 liver enzyme toxicity as a function of physical mean dose (n = 5 studies), and grade greater than or equal to 2 (n = 7 studies) or grade greater than or equal to 3 (n = 8 studies) general gastrointestinal (GI) toxicity as a function of prescription dose in three to six fractions. From the NTCP models, approximately 5% of risks of grade 3 liver enzyme toxicity were associated with mean liver doses of approximately 12 Gy. For grade greater than or equal to 2 GI toxicity, 20% risks were associated with prescribed doses of approximately 27 Gy, and for grade greater than or equal to 3 GI toxicity, 10% risks were associated with prescribed doses of approximately 50 Gy. Based on published reports, the authors predicted less than 13% risks of liver dysfunction and grade 3 to 5 general GI toxicity with greater than or equal to 700 mL of liver (minus GTVs) receiving less than or equal to 15 to 17 Gy; these data were not amenable to modeling though.

The PENTEC group developed a model to calculate the risk of developing sinusoidal obstructive syndrome (SOS) after whole-liver RT.[416] RT dose (P = .006) and receipt of nonalkylating chemotherapy (P = .01) were significant. Age less than 20 years at the time of

RT was borderline significant (P = .058). The model predicted a 2% risk of SOS with zero RT dose, 6.1% following 10 Gy, and 14.5% following 20 Gy to the whole liver (modeled as the linear-quadratic equivalent dose in 2-Gy fractions [a/b = 3 Gy]). Patients with Wilms tumor treated with right flank RT had a higher observed rate of SOS than patients receiving left flank RT, but data were insufficient to generate an NTCP model for partial liver irradiation. Data were sparse regarding rates of late liver injury after RT, which suggests low rates of severe toxicity after treatment for common pediatric malignancies.

Factors Affecting Risk

A wide variety of systemic agents have been reported to elevate liver enzymes: nitrosoureas (BCNU), methotrexate, and some combinations of chemotherapy agents such as cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) and proMace-MOPP (prednisone, methotrexate, doxorubicin, cyclophosphamide, etoposide, and MOPP [mechlorethamine, vincristine (Oncovin), procarbazine, and prednisone]). In bone marrow transplantation, preparatory regimens can be toxic. Underlying liver disease and hepatobiliary carcinoma (as opposed to liver-metastatic disease) were described in the QUANTEC and HyTEC reports as added risk factors.

Recommended Dose-Volume Limits

For patients with liver metastases undergoing partial volume liver radiation, the risk of radiation-induced liver toxicity appears to be more dependent on the volume of liver irradiated. Partial volumes of the liver can tolerate relatively high doses. Liver tolerances, however, are lower for patients with primary liver cancer (who are more apt to have underlying liver disease). For whole-liver radiation, doses less than or equal to 28 to 30 Gy in 2-Gy fractions (28 Gy for liver metastases and 30 Gy for primary liver cancer) and less than or equal to 21 Gy in 3-Gy fractions are recommended. For partial liver radiation, treated with standard fractionation, the mean dose to normal liver (liver minus GTV) is suggested to be less than 30 Gy for liver metastases and less than 28 Gy for primary liver cancer.

Future Studies

Studies that better correlate dose-volume parameters with long-term clinical/objective outcomes are needed. The impact of treatment-related (including fractional dose and systemic therapies) and host-related variables should be better defined.

Toxicity Scoring Criteria

The CTCAE v. 3.0 grades hepatobiliary toxicity according to clinical criteria of jaundice, asterixis, and encephalopathy or coma for grades 2, 3, and 4, respectively. The much more commonly occurring alteration in liver enzymes, in the absence of symptomatic manifestations, is classified under the CTCAE metabolic/laboratory category of elevations of alanine aminotransferase (ALT) and aspartate aminotransferase (AST). The use of CTCAE criteria for elevations of AST and ALT and other metabolic effects is advisable to promote consistency of reporting.

Small Bowel/Stomach

Clinical Significance

The stomach and small bowel aid in the digestion and absorption of food and nutrients. Symptoms from radiation-related late toxicities include dyspepsia, gastric ulceration, diarrhea, bowel obstruction, and ulceration, fistula, or perforation.[387]

End Points

Nausea and vomiting can occur immediately or within hours after RT to the stomach or small bowel. The radiosensitivity of the gastric mucosa is reflected in the early depression of hydrochloric acid and pepsin secretion after modest radiation doses of 15 to 20 Gy. Although some recovery of cellular structure occurs, suppression can continue for 6 months to many years after irradiation. Usually, at total doses at or above 50 Gy, cellular and functional recovery is never complete. Ulcers are the most common complication of gastric irradiation and present clinically with dyspepsia, significant pain, and sometimes hemorrhage. An ulcer in this anatomic setting can lead to hemorrhage and perforation, which, although rare, can be fatal. Ulcerations have been described as typically antral, perhaps because of the placement of RT fields, and develop as early as 2 to 12 months after treatment. Pyloric obstruction may be a late development because of fibrosis after ulcer healing.

The early onset of malabsorption of fat and hypermotility after modest doses of radiation illustrates the radiosensitivity of the small intestine. Usually, recovery at dose levels below 40 to 45 Gy occurs, although some persistence of small bowel dysfunction and mesenteric cramping may be noted. Surgical intervention and adhesions can precipitate a more serious course of events. Higher doses result in diarrhea, malabsorption of fat, and leakage of albumin into the bowel. If an obliterative arteritis develops, the risk of infarction and perforation remains despite recovery. The underlying lesion is one of ulceration and segmental enteritis that can lead to stenosis of the bowel lumen, with varying degrees of obstruction during the chronic period.

Challenges Defining Volumes

The stomach and small bowel are well visualized, particularly with the use of intravenous contrast and/or oral contrast. The stomach and small bowel position can be variable, and it is therefore recommended that patients avoid large meals or carbonated beverages prior to simulation and treatment.

Summary of QUANTEC and HyTEC

The QUANTEC authors summarized data from studies of acute and late radiation-related risks of small bowel and stomach toxicity,[387] as shown in Figure 12.12. Because the stomach and small bowel are mobile and distensible, determining accurate dose-volume (or dose-surface) constraints is challenging. For acute small bowel toxicity, all or most of the patients (from 6 summarized studies) had received concurrent chemotherapy for rectal or cervical cancers. The QUANTEC report also summarized studies that modeled data for acute (most of the studies) or late (1 study) small bowel complications. Based on their summary of the data, the authors predicted less than 7% risk of stomach ulceration with whole stomach doses

(D100) less than 45 Gy. With small bowel delineated as individual loops of bowel, they estimated less than 10% risks of grade greater than or equal to 3 acute toxicity with a V_{15} less than 120 mL, while when the entire potential space (often referred to as "bowel bag") was contoured, they estimated less than 10% risks of grade greater than or equal to 3 acute toxicity with a V_{45} less than 165 mL. The HyTEC authors did not specifically evaluate dosimetric factors associated with risks to the small bowel or stomach after SBRT, though they discussed the importance of sparing these OARs with SBRT for pancreatic tumors.[417] Among patients undergoing three- to five-fraction SBRT for liver metastases, bowel toxicity has been reported to occur with maximal doses to the bowel of greater than 30 Gy.[401]

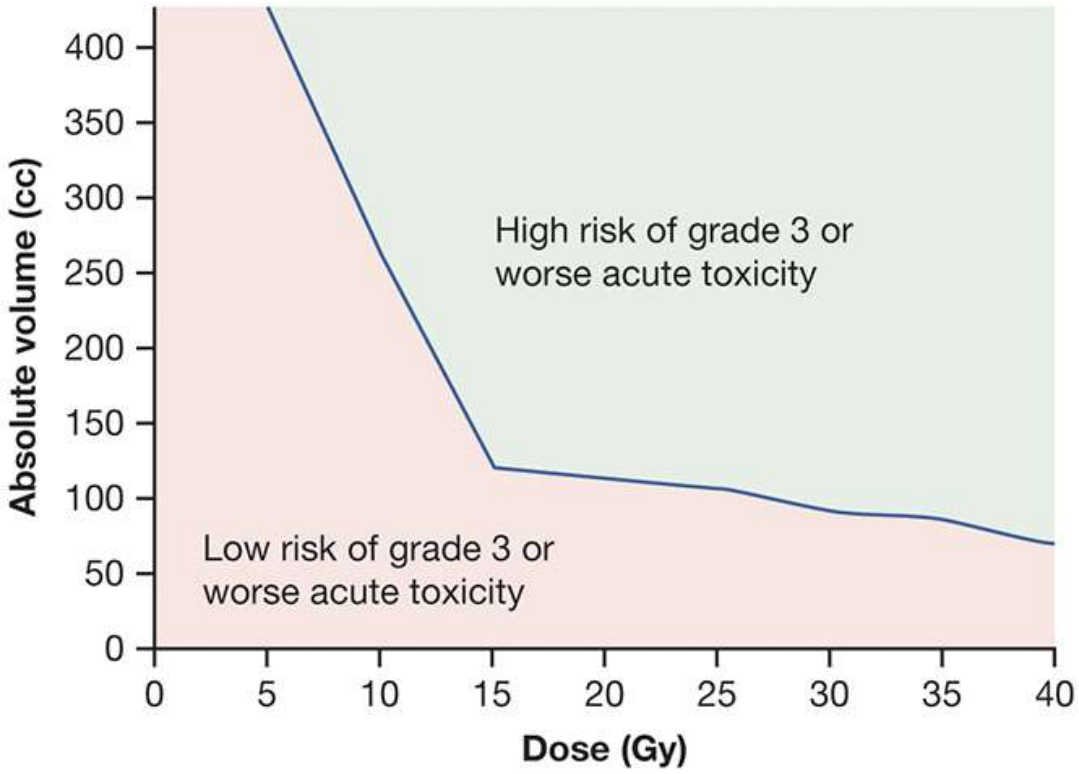

FIGURE 12.12 Graphic representation of the Baglan-Robertson[287,288] threshold model for acute small bowel toxicity. "Low risk" implies <10% and "high risk" >40% grade 3 toxicity. Absolute volume is based on contouring individual bowel loops, not the entire peritoneal space. (Reprinted from Kavanagh BD, Pan CC, Dawson LA, et al. Radiation dose-volume effects in the stomach and small bowel. *Int J Radiat Oncol Biol Phys*. 2010;76[3 suppl]:S101-S107. Copyright © 2010 Elsevier. With permission.)

Factors Affecting Risk

Factors affecting the risk of late toxicity include total dose (with doses in excess of 40 to 50 Gy increasing the risk of late complications), fractional dose, prior abdominal surgery (which increases the risk of bowel obstruction), and concurrent chemotherapy use. In the European Organization for Research and Treatment of Cancer (EORTC) Hodgkin lymphoma study, the rate of complications was 3% without prior abdominal surgery versus 12% with prior abdominal surgery.[382]

Future Studies

More detailed dose-volume effects for late bowel toxicity are needed, particularly for altered fractionation (ie, SBRT). As many GI cancers are treated with chemotherapy, data on the impact of chemotherapy on acute and late stomach and bowel toxicity are needed.

Toxicity Scoring Criteria

The CTCAE v. 4.0 is used to grade gastric and small bowel toxicity.[116]

Kidneys

Clinical Significance

The kidney functions to remove wastes; regulate electrolytes; produce erythropoietin, which stimulates red blood cell production; and modulate blood pressure through the renin-angiotensin pathway as well as through fluid/electrolyte balance. Radiation nephropathy is an uncommonly reported toxicity, not because kidneys are radioresistant but because clinicians carefully respect renal tolerance doses.

End Points

Five distinct clinical syndromes may overlap in symptoms, signs, and time sequence: acute radiation nephropathy, chronic radiation nephropathy, benign hypertension, malignant hypertension, and hyperreninemic hypertension secondary to a scarred encapsulated kidney (Goldblatt kidney). The signs (ie, decreased glomerular filtration rate) and symptoms of radiation nephropathy are not distinguishable from other causes of renal damage, and these should be excluded. Acute (within 6 months) radiation-induced kidney injury is generally subclinical. Urinary findings consist of microscopic hematuria, proteinuria, and urinary casts. Blood alterations in β_2-microglobulin correlate linearly with both inulin and creatinine clearance and with later elevations of blood urea nitrogen (BUN). There is a 6- to 12-month latency period before the clinical expression of acute radiation nephropathy. In this subacute phase, the signs and symptoms include dyspnea, headaches, ankle edema, lassitude, anemia, hypertension, albuminuria, papilledema, elevated blood urea, and urinary abnormalities (granular and hyaline casts, red blood cells). Death may occur from chronic uremia or left ventricular failure, pulmonary edema, pleural effusion, and hepatic congestion. Chronic radiation nephropathy and hypertension do not develop until after 12 to 18 months. When chronic nephropathy is severe, death may result.

Challenges Defining Volumes

The kidneys are readily defined on contrast and noncontrast CT imaging. Ideally, the "functional" kidney parenchyma as opposed to the collecting system should be contoured.

Summary of QUANTEC and PENTEC

QUANTEC summarized NTCP data of renal toxicity after total body irradiation (TBI; 12 studies), non-TBI, bilateral whole kidney radiation (six studies, of which all but two were from the 1950s to 1970s) as well as partial kidney radiation (14 studies).[418] Although

endpoints of proteinuria and hypertension were discussed, these endpoints were not addressed as separate outcomes. The QUANTEC authors estimated the risk of nephrotoxicity based on published data, including some NTCP models, though they conceded "substantial uncertainty" in these estimates. For partial kidney radiation, they estimated that bilateral kidney V_{12} less than 55%, V_{20} to V_{23} less than 30% to 32%, and V_{28} less than 20% were associated with less than 5% risks of clinically relevant renal dysfunction. For whole kidney radiation, mean doses of less than 15 to 18 Gy and less than 28 Gy were estimated to be associated with less than 5% and less than 50% risks of clinically relevant renal dysfunction, respectively (Figure 12.13). HyTEC did not include a report on renal toxicity.

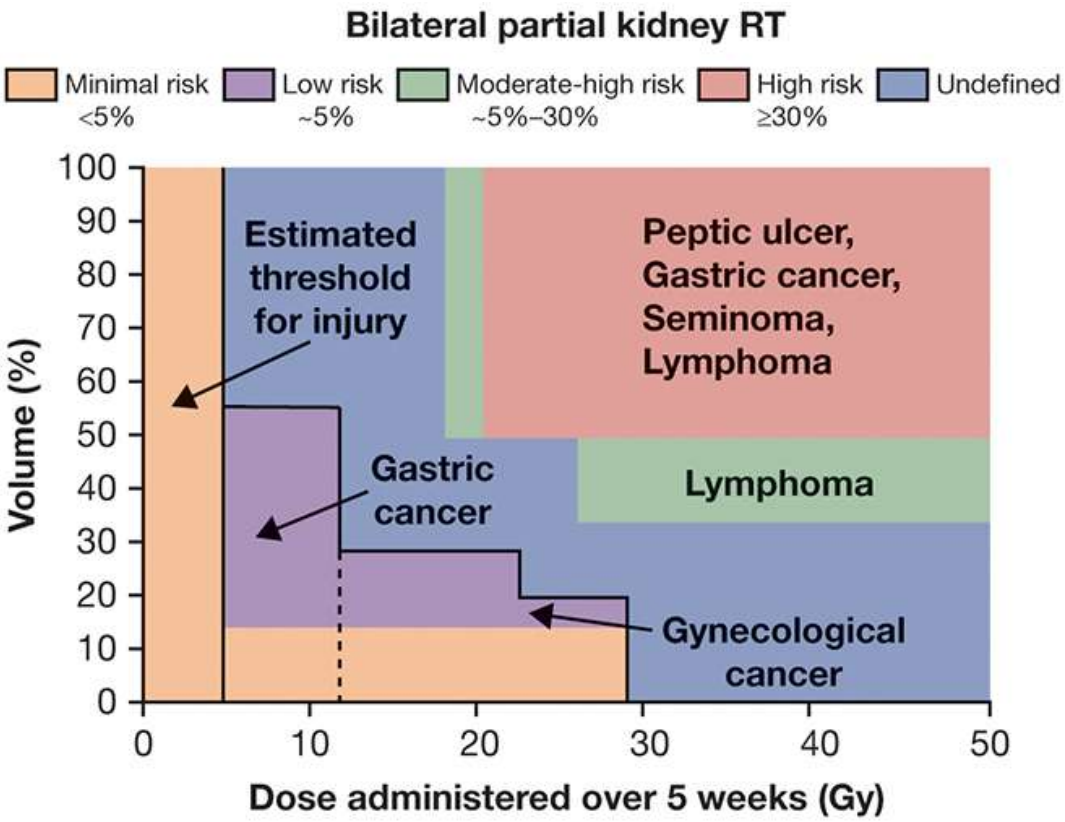

FIGURE 12.13 Schematic diagram of bilateral kidney dose-volume histogram from selected studies, represented as regions associated with minimal (<5%), low (~5%), moderate to high (~5%-30%), high (>30%), or undefined estimated risk of toxicity. Clinical situation that yielded risk estimates for each region is also indicated. Actual risks are patient and plan specific and are associated with substantial uncertainty. (Adapted from Dawson LA, Kavanagh BD, Paulino AC, et al. Radiation-associated kidney injury. *Int J Radiat Oncol Biol Phys*. 2010;76[3 suppl]:S108-S115. Copyright © 2010 Elsevier. With permission.)

In the PENTEC review, the risk of dysfunction was modeled by RT dose and grade of toxicity.[419] Normal tissue complication rates greater than or equal to 5%, expressed as equivalent doses of 2 Gy/fraction for whole kidney exposures, occurred at 8.5, 10.2, and 14.5 Gy for National Kidney Foundation grades greater than or equal to 1, 2, and 3, respectively. Conventional Wilms whole abdominal irradiation (WAI) of 10.5 Gy in six fractions had risks of greater than or equal to grade 2 toxicity 4% and greater than or equal to grade 3 toxicity

1%. For fractionated 12 Gy TBI, those risks were 8% and less than 3%, respectively. Data did not support whole kidney modeling with chemotherapy. Partial kidney modeling from 439 survivors who received RT (median age, 7.3 years) demonstrated that 5 or 10 Gy to 100% kidney gave a less than 5% risk of grades 3 to 5 toxicity with 1,500 mg/m^2 carboplatin or no chemo. With 480 mg/m^2 cisplatin, a 3% risk of greater than or equal to grade 3 toxicity occurred without RT and a 5% risk when 26% of kidney received greater than or equal to 10 Gy. With 63 g/m^2 of ifosfamide, a 5% risk of greater than or equal to grade 3 toxicity occurred with no RT, and a 10% toxicity risk occurred when 42% of kidney received greater than or equal to 10 Gy.

Factors Affecting Risk

A variety of agents have been implicated as toxic or as radiosensitizers (ie, retinoic acid, cisplatin, BCNU, actinomycin D), administered either singly or in combination with chemotherapy. Of note, angiotensin converting enzyme (ACE) inhibitors and angiotensin II receptor blockers have been shown to delay the progression of radiation injury in the experimental setting.[420] TBI dose rates (≤6 cGy/min vs ≥10 cGy/min) have been shown to significantly impact the risk of renal toxicity.[421] Patient-related factors may include underlying renal insufficiency, diabetes, hypertension, liver disease, heart disease, and smoking.[418]

Future Studies

Studies are needed to better define partial kidney tolerance to radiation, investigating the impact of underlying kidney function, dose-volume exposure (accounting for regional variation), fractionated dose delivery, and radiation protectors.

Toxicity Scoring Criteria

The CTCAE v. 4.0 can be used to grade renal toxicity.[116] Severity of injury can also be graded according to the glomerular filtration rate, serial urine protein, serum BUN, creatinine clearance, blood pressure, and symptoms of renal failure.

Rectum

Clinical Significance

The rectum is the terminal portion of the large intestines that functions as a temporary storage for feces, as well as providing the urge to defecate. A portion of the rectum is irradiated in patients undergoing radiation for prostate cancer, gynecologic cancers, and other pelvic tumors (such as sarcomas).

End Points

Acute rectal toxicity includes diarrhea or loose stools, tenesmus, proctitis, and rectal urgency and/or frequency. The most common late radiation-related rectal complication is bleeding. Rectal ulceration and fistula are much less common. Other late injuries include stricture and decreased rectal compliance, which can result in frequent small stool and/or tenesmus. The anus is also at risk of late complications including stricture and laxity, leading to fecal incontinence.

Challenges Defining Volumes

The rectum extends from the rectosigmoid junction to the anus, with the inferior extent variably defined as the level of the anal verge of the ischial tuberosities or 2 cm below the ischial tuberosities or above the anus (the most inferior 3 cm of the intestines). The rectum should be segmented from above the anal verge to the turn into the sigmoid colon, though the superior and inferior borders of the rectum are not always easy to define on CT imaging, and the definition of the cranial and caudal extents is variable.[422] The rectum is mobile and distensible, and therefore, its position and volume can vary between and during radiation fractions.

The percentage of rectum or rectal wall receiving a given dose can be somewhat subjective (ie, based on how much of the rectum is segmented); using the absolute volume of rectum[423] or rectal wall is less subjective, though defining the rectal wall is not standardized. William Beaumont Hospital demonstrated that the rectal volume as well as rectal wall V_{50} to V_{70} values predict late toxicity, with the rectal wall being more predictive of grade 2 to 3 late effects; acute toxicity is also predictive of late toxicity.[424] MDACC has also shown the rectal wall to be better predictive of late rectal bleeding.[425]

Summary of QUANTEC and HyTEC

Abundant dosimetric data have shown a correlation of risk with rectal volume and surface/rectal wall doses among patients undergoing radiation for prostate cancer. Figure 12.14 summarizes many of the relevant studies.

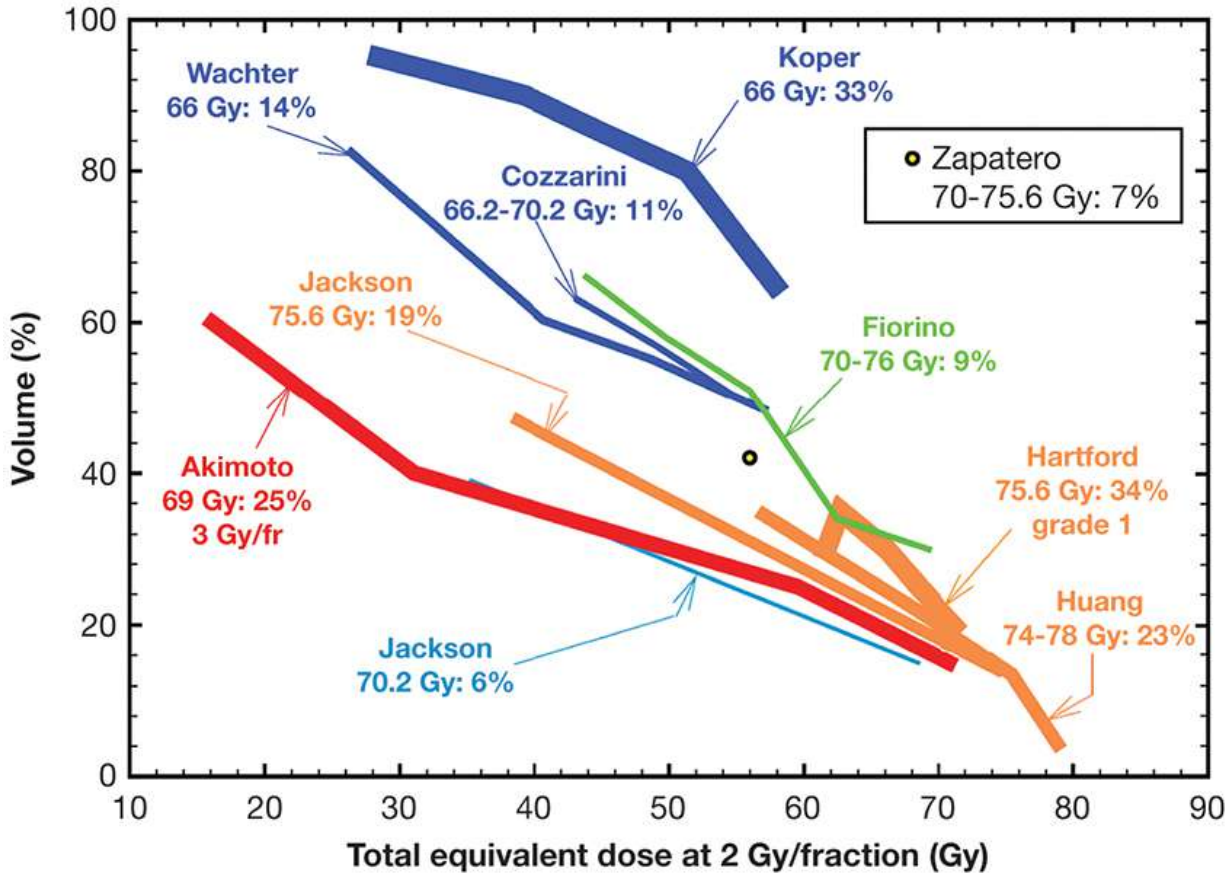

FIGURE 12.14 Dose-volume histogram thresholds for grade 2 or higher rectal toxicity from selected studies.[427-435] *Thicker lines* indicate higher rates of overall toxicity (percentages are indicated on the figure along with the physical prescription dose). Threshold doses are expressed as the total equivalent dose delivered in 2-Gy fractions, adjusted using the linear-quadratic model with α/β = 3 Gy. The associated equivalent prescription doses are coded by color spectrum from lowest (blue) to highest (red). Volumes shown in the graph are based on the full length of the anatomic rectum. Note that these curves converge in the high-dose range, implying that doses in this range are more consistently associated with rectal toxicity. (Reprinted from Michalski JM, Gay H, Jackson A, Tucker SL, Deasy JO. Radiation dose-volume effects in radiation-induced rectal injury. *Int J Radiat Oncol Biol Phys*. 2010;76[3 suppl]:S123-S129. Copyright © 2010 Elsevier. With permission.)

The QUANTEC report[422] summarized data from five studies that performed NTCP modeling for rectal toxicity among patients with prostate cancer treated with 3DCRT to doses less than 80 Gy, and also discussed a meta-analysis that included four of these studies. Various endpoints, and OAR contours (rectum plus contents vs anorectal wall) were used in these studies, with the QUANTEC authors ultimately recommending contouring of the rectum plus contents. The authors estimated that V_{50} less than 50%, V_{60} less than 35%, V_{65} less than 25%, V_{70} less than 20%, and V_{75} less than 15% would be associated with less than 15% risks of grade greater than or equal to 2 late rectal toxicity and less than 10% risks of grade greater than or equal to 3 late rectal toxicity when prescribing up to 79.2 Gy in 1.8- to 2-Gy fractions. They suggested greater priority on the V_{70} to V_{75} exposures, for which relatively small incremental increases had a greater impact on toxicity risks versus lower-dose exposures.

The HyTEC authors[426] summarized data from six studies on dosimetric predictors of rectal toxicity among patients undergoing SBRT for prostate cancer, as well as NTCP modeling from one study. A rectum (contoured as a solid organ) maximum dose of less than 35 to 38 was associated with less than 3% risks of grade greater than or equal to 3 late rectal toxicity with four- to five-fraction SBRT. Women undergoing radiation for gynecologic malignancies are also susceptible to rectal toxicity. With modern radiation delivery, particularly with IMRT planning, the rate of severe GI toxicity is low.

Factors Affecting Risk

The QUANTEC report summarized studies describing increased risk of late rectal toxicity associated with diabetes, hemorrhoids, inflammatory bowel disease, older age, androgen deprivation therapy, rectum size, and prior abdominal surgery. Those who develop severe acute rectal toxicity are also at increased risk of late rectal toxicity. Among 1,010 patients with prostate cancer enrolled in the RTOG 9406 trial, cardiovascular disease was significantly (P = .015) associated with a higher rate of late rectal toxicity, whereas diabetes, hypertension, rectal volume, rectal length, neoadjuvant hormone therapy, and prescribed dose per fraction (1.8 vs 2 Gy) were not significant factors.

Future Studies

Future studies should be directed at achieving accurate dose-volume distributions for the rectum, which is a mobile, distensible structure, and correlating these dosimetric characteristics with toxicity. More robust data are needed for hypofractionated radiation delivery to the rectum, as with SBRT or high dose rate (HDR) brachytherapy, as well as with low-dose brachytherapy and combined modality approaches.

Toxicity Scoring Criteria

The CTCAE v. 4.0[116] or RTOG scoring criteria can be used to grade rectal toxicity.

Urinary Bladder

Clinical Significance

The bladder is a highly distensible organ that collects urine. Symptoms from late radiation-related toxicities include increased urinary frequency, hematuria, and dysuria. Necrosis, contracted bladder, and hemorrhage are less common, severe effects. Perhaps late bladder toxicity is underreported due to its long latency as well as toxicity being attributed to more common causes.

End Points

Bladder injury can be broadly classified as focal damage (eg, bleeding) or more global injury (eg, reduced bladder capacity with secondary urinary frequency). Acute side effects from incidental bladder irradiation are common and include urinary frequency, urgency, and dysuria (symptoms that may also reflect acute urethral toxicity). Late effects attributable to global injury include dysuria, frequency, urgency, contracture, spasm, reduced flow, and

incontinence. In contrast, late effects arising from focal injury include hematuria, fistula, obstruction, ulceration, and necrosis.

Challenges Defining Volumes

The bladder is a mobile and distensible structure, depending on the volume of urine within the bladder. Postvoid residuals may vary due to variable emptying and constant filling. In contouring the bladder, either the volume of the bladder and contents or the bladder wall alone can be segmented (with the latter more representative of a surface).

Dose/Volume/Toxicity Data

Because the bladder is mobile and distensible, determining accurate dose-volume (or dose-surface) constraints is challenging. Detailed dose-volume (or dose-surface) constraints have not been published, in part because of the complexities of assigning dose-volume or dose-surface metrics to a mobile, distensible structure. Whole-bladder tolerances have been mostly studied in patients with urinary bladder cancer, whereas partial bladder tolerances have been mostly studied in patients with genitourinary (mostly prostate) and gynecologic cancers.[436]

For whole-bladder irradiation, doses in excess of 60 Gy, particularly with fraction sizes greater than 2 Gy and/or accelerated radiation regimens, result in a significant risk of grade 3 or higher late toxicity. Risks are lower when the whole bladder receives 45 to 55 Gy followed by a boost to greater than 60 Gy to a portion of the bladder, though toxicity risk has not been correlated to dose-volume metrics. With prostate cancer treated to high doses (≥72 Gy), the inferior portion of the bladder (eg, trigone area) also receives greater than or equal to 70 Gy. This tends to be well tolerated with respect to bladder toxicity. Arguably, the urinary toxicity that does develop after radiation is due in part to the prostatic urethra receiving suprathreshold doses.

Mean bladder dose and area under the DVH were significant predictors of grade greater than or equal to 2 genitourinary toxicity in a study of 503 patients with prostate cancer.[437] In a study of 296 patients with prostate cancer (in whom the bladder was contoured as a whole organ, after drainage and infusion of 120 mL of saline), no bladder dose-volume relationships were associated with the risk of grade greater than or equal to 2 genitourinary toxicity.[438]

Factors Affecting Risk

Prior pelvic surgery can result in an increased risk of bladder toxicity as a direct result of bladder or urethral trauma and/or denervation of the bladder, which can cause urinary hesitancy or retention, resulting in overflow incontinence.[436] Patients receiving anticoagulants may be at greater risk of hematuria. Cytoxan, independently or with radiation, can cause chronic hemorrhagic cystitis, incontinence, contractions, and vesicoureteral reflux. Radiation-sensitizing chemotherapy may increase the risk of acute and late bladder toxicity, though data supporting this are lacking.

Mathematic/Biologic Models

Quantitative mathematical modeling of bladder toxicity is lacking.

Special Situations

SBRT for prostate cancer is an emerging investigative approach. In one study, after SBRT (7.25 Gy × 5), grade 1 to 2 genitourinary toxicity occurred in 28%, and grade 3 toxicity was reported in 3% of patients (two patients required cystoscopies and dilation procedures for dysuria).[439] Urinary incontinence, complete obstruction, or persistent hematuria was not observed. In another study, after SBRT (9.5 Gy × 4), acute grade 1 to 2 and 3 acute genitourinary toxicity occurred in 71% and 0% of patients, respectively, and grade 1 to 2 and 3 late acute genitourinary toxicity occurred in 11% and 5%, respectively; grade 3 toxicity included temporary urinary catheterization and intermittent self-catheterization.[440]

Recommended Dose-Volume Limits

For whole-bladder radiation, the reported risks of grade 3 or higher toxicity in doses of 50 to 60 Gy range from less than or equal to 5% to 40%. This variation is likely attributable to the challenges of correlating toxicity with the dose delivered to a mobile structure, which is even more problematic when correlating partial volume exposures to toxicity. With the caveat of these issues, bladder constraints of approximately 15%, 25%, 35%, and 50% receiving greater than or equal to 80, 75, 70, and 65 Gy, respectively, as recommended in the RTOG 0415 study of prostate cancer, are suggested. The protocol advises an empty bladder at the time of simulation and treatment; the bladder is segmented from the base to the dome.

Future Studies

Studies that incorporate the changing size and shape of the bladder may provide a better understanding of the dose-volume tolerance of the bladder. Incorporating day-to-day variation with adaptive planning DVHs and/or the use of deformable modeling would be informative. More detailed studies are needed to assess regional variation in radiation susceptibility (ie, trigone vs dome).

Toxicity Scoring Criteria

The CTCAE v. 4.0 or RTOG scoring criteria can be used to grade genitourinary toxicity.

Penile Bulb

Clinical Significance

Radiation dose to the penile bulb can affect erectile function, as a direct result either of damage to this structure or of damage to surrounding structures, whose radiation-induced damage is correlated with the dose exposure of the penile bulb. The most common scenario in which the penile bulb is irradiated is in the treatment of prostate cancer. IMRT is often used to minimize the dose to the penile bulb.[441,442]

End Points

Erectile dysfunction reported by the patient can be the result of treatment or other confounding factors including age, medications (particularly hormonal therapy), or comorbid conditions (eg, diabetes, peripheral vascular disease, hypertension). Objective diagnostic tests can be performed to help establish the etiology of erectile dysfunction; these include nocturnal

penile tumescence, somatosensory-evoked potentials, bulbocavernosus reflex latency, penile electromyography, color duplex Doppler ultrasound, dynamic infusion cavernosometry, and pharmacologic testing.

Challenges Defining Volumes

The anatomy of the pelvic floor is challenging to visualize on CT or MRI, and hence, the definition of the penile bulb is somewhat subjective. The QUANTEC authors recommend defining the penile bulb as the most proximal portion of the penis sitting immediately caudal to the prostate.[442,443]

Summary of QUANTEC and HyTEC

The QUANTEC authors[443] summarized data from 10 studies on erectile dysfunction after external-beam radiotherapy. Six studies described the incidence of severe erectile dysfunction as a function of penile bulb D_{60} or D_{70}. Although the data were "conflicting" and "sparse," the authors surmised that they were "consistent with either a causal or surrogate relationship." They estimated a less than 35% risk of severe erectile dysfunction, with a mean dose of 95% less than 50 Gy, a D_{90} less than 50 Gy and D_{60} to 70 less than 70 Gy. A randomized controlled study of 117 men showed that although it was safe and feasible to spare the penile bulb and corporal bodies, doing so was not associated with improved potency preservation outcomes at 2 years.[444] The authors conceded that this was an unplanned analysis and that the statistical power for potency assessment was limited. Furthermore, even in the control arm, these structures were relatively spared (compared to historical non-IMRT treatments). The HyTEC authors summarized three reports on penile bulb exposure and concluded that "it is currently unclear how dosimetric factors contribute to sexual function outcomes after SBRT."[426]

Factors Affecting Risk

The etiology of erectile dysfunction following radiation is likely multifactorial. In addition to radiation effects, pretreatment erectile function, diabetes, smoking history, and a history of hypertension have been implicated as important factors affecting risk, though the data to date have been somewhat conflicting.[445]

Special Situations

Hormonal therapy, which is commonly used in patients with early-stage intermediate- to high-risk prostate cancer or advanced-stage prostate cancer, in and of itself can result in erectile dysfunction. However, the interaction (if any) of hormonal therapy and dose-volume delivery to the penile bulb is not well established.[443]

Future Studies

Studies should be directed at better anatomic definition of the putative anatomic sites impacted by erectile dysfunction and rigorous prospective correlation of dose-volume parameters with erectile dysfunction.

Toxicity Scoring Criteria

Pre- and posttreatment assessment of erectile dysfunction should be performed using the International Index of Erectile Function Scale.[443]

COMPOSITE SUMMARY OF DOSE/VOLUME/OUTCOME DATA

Table 12.11 summarizes the dose/volume/outcome findings in the QUANTEC reviews. Note that clinicians must understand the clinical situations from which the QUANTEC recommendations were derived, and there is no substitute for reading the original QUANTEC papers. At the same time, clinical judgment as applied to a specific patient is essential. In addition to the QUANTEC papers, the Emami paper continues to play an important role in estimating normal tissue toxicity during radiotherapy. Finally, as more comprehensive dose/volume/outcome data are developed—particularly in combination with emerging and evolving chemotherapy regimens—the radiation oncologist will need to continually and critically keep abreast of the clinical literature on normal tissue toxicity. There is an ongoing effort to perform a similar dose-volume outcome summary for organs that are of particular interest for pediatric patients (PENTEC) that is underway and expected to be complete in 2024.

TABLE 12.11 QUANTEC SUMMARY: CLINICAL DOSE/VOLUME/OUTCOME DATA

Organ	Volume Segmented	Irradiation Type (Partial Organ Unless Otherwise Stated)	End Point	Dose (Gy), or Dose-Volume Parameters		Rate (%)	Notes on Dose-Volume Parameters
Brain	Whole organ	3DCRT	Symptomatic necrosis	D_{max}	≤60 Gy	<3	
	Whole organ	3DCRT	Symptomatic necrosis	D_{max}	72 Gy	5	
	Whole organ	3DCRT	Symptomatic necrosis	D_{max}	90 Gy	10	
Brain, metastases	Whole organ, including the target	SRS (1 fraction)	Symptomatic necrosis	V_{12Gy}	≤5 mL	10	Prior whole-brain RT appears to not markedly increase risks in most reports (with the exception of the brainstem). However, repeat SRS/HF-SRS in the same area has been associated with markedly increased risks.
		SRS (1 fraction)	Symptomatic necrosis	V_{12Gy}	≤10 mL	≤15	
		SRS (1 fraction)	Symptomatic necrosis	V_{12Gy}	≤15 mL	≤20	

Organ	Volume Segmented	Irradiation Type (Partial Organ Unless Otherwise Stated)	End Point	Dose (Gy), or Dose-Volume Parameters		Rate (%)	Notes on Dose-Volume Parameters
		SRS (3 fractions)	Edema or necrosis	V_{20Gy}	≤20 mL	≤10	
		SRS (3 fractions)	Edema or necrosis	V_{20Gy}	≤30 mL	≤20	
		SRS (5 fractions)	Edema or necrosis	V_{24Gy}	≤20 mL	≤10	
		SRS (5 fractions)	Edema or necrosis	V_{24Gy}	≤20 mL	≤20	
Brain, AVM	Whole organ, including target	SRS (1 fraction)	Symptomatic necrosis	V_{12Gy}	≤10 mL	≤10	
Brainstem	Whole organ	3DCRT	Permanent cranial neuropathy or necrosis	D_{max}	<54 Gy	<5	
	Whole organ	3DCRT	Permanent cranial neuropathy or necrosis	$D_{1\text{-}10\ mL}$	≤59 Gy	<5	
	Whole organ	3DCRT	Permanent cranial neuropathy or necrosis	D_{max}	<64 Gy	<5	Point dose << 1 mL
	Whole organ	SRS (1 fraction)	Permanent cranial neuropathy or necrosis	D_{max}	<12.5	<5	For patients with acoustic neuromas/vestibular schwannomas
Optic pathways	Optic nerves and chiasm	3DCRT	Optic neuropathy	D_{max}	<55	<3	Given the small size, 3DCRT often covers the whole circumference of the organ.
		3DCRT	Optic neuropathy	D_{max}	55-60	3–7	
		3DCRT	Optic neuropathy	D_{max}	>60	>7–20	
		SRS (1 fraction)	Optic neuropathy	D_{max}	<10-12	<1	

Organ	Volume Segmented	Irradiation Type (Partial Organ Unless Otherwise Stated)	End Point	Dose (Gy), or Dose-Volume Parameters		Rate (%)	Notes on Dose-Volume Parameters
		SRS (3 fractions)	Optic neuropathy	D_{max}	<20	<1	
		SRS (5 fractions)	Optic neuropathy	D_{max}	<25	<1	
Carotid artery (reirradiation)	Each carotid artery	SRS (5 fractions)	Grade 3-5 bleeding	D_{max}	<20-30	<2-12	Dose-volume metric shown is for the reirradiation SBRT dose in patients with prior RT.
Spinal cord	Partial organ	3DCRT	Myelopathy	D_{max}	50	0.2	Including full cord cross section; no previous irradiation to the involved level of the spine
	Partial organ	3DCRT	Myelopathy	D_{max}	60	6	
	Partial organ	3DCRT	Myelopathy	D_{max}	69	50	
	Spinal cord, thecal sac, or canal	SBRT (1 fraction)	Myelopathy	D_{max}	<12.4-14	1-5	Partial cord cross section irradiated; no previous irradiation to the involved level of the spine.
		SBRT (2 fractions)	Myelopathy	D_{max}	<17-19.3	1-5	
		SBRT (3 fractions)	Myelopathy	D_{max}	<20.3-23.1	1-5	
		SBRT (4 fractions)	Myelopathy	D_{max}	<23-26.2	1-5	
		SRS (5 fractions)	Myelopathy	D_{max}	<25.3-28.8	1-5	
Cochlea	Whole organ	3DCRT	Sensory neural hearing loss	Mean dose	≤45	<30	Mean dose to the cochlea, hearing at 4 kHz
	Whole organ	SRS (1 fraction)	Sensory neural hearing loss	Prescription dose	≤14	<25	Serviceable hearing

Organ	Volume Segmented	Irradiation Type (Partial Organ Unless Otherwise Stated)	End Point	Dose (Gy), or Dose-Volume Parameters		Rate (%)	Notes on Dose-Volume Parameters
Parotid	Bilateral whole parotid glands	3DCRT	Long-term parotid salivary function reduced to <25% of pre-RT level	Mean dose	<25	<20	For combined parotid glands
	Unilateral whole parotid gland	3DCRT	Long-term parotid salivary function reduced to <25% of pre-RT level	Mean dose	<20	<20%	For single parotid gland At least one parotid gland spared to <20 Gy
	Bilateral whole parotid glands	3DCRT	Long-term parotid salivary function reduced to <25% of pre-RT level	Mean dose	<39	<50%	For combined parotid glands
Pharynx	Pharyngeal constrictors	Whole organ	Symptomatic dysphagia and aspiration	Mean dose	<50	<20	Based on Section B4 of the paper
Larynx	Whole organ	3DCRT	Vocal dysfunction	D_{max}	<66	<20	With chemotherapy
	Whole organ	3DCRT	Aspiration	Mean dose	<50	<30	With chemotherapy
	Whole organ	3DCRT	Edema	Mean dose	<44	<20	Without chemotherapy, based on a single study in patients without larynx cancer
	Whole organ	3DCRT	Edema	V_{50}	<27%	<20	
Lung	Whole organ	3DCRT	Symptomatic pneumonitis	V_{20}	≤30%	<20	For combined lung. Gradual dose response
	Whole organ	3DCRT	Symptomatic pneumonitis	Mean dose	7	5	Excludes purposeful whole-lung irradiation

Organ	Volume Segmented	Irradiation Type (Partial Organ Unless Otherwise Stated)	End Point	Dose (Gy), or Dose-Volume Parameters		Rate (%)	Notes on Dose-Volume Parameters
	Whole organ	3DCRT	Symptomatic pneumonitis	Mean dose	13	10	
	Whole organ	3DCRT	Symptomatic pneumonitis	Mean dose	20	20	
	Whole organ	3DCRT	Symptomatic pneumonitis	Mean dose	24	30	
	Whole organ	3DCRT	Symptomatic pneumonitis	Mean dose	27	40	
	Combined lungs minus target	SBRT (3-5 fractions)	Grade ≥2 toxicity	Mean dose V_{20Gy}	<8 Gy <10-15	10-15	Preexisting interstitial lung disease appears to increase toxicity risk.
Esophagus	Whole organ	3DCRT	Grade ≥3 acute esophagitis	Mean dose	<34	5-20	Based on RTOG and several studies
	Whole organ	3DCRT	Grade ≥2 acute esophagitis	V_{35}	<50%	<30	A variety of alternate threshold doses have been implicated. Appears to be a dose-volume response
	Whole organ	3DCRT	Grade ≥2 acute esophagitis	V_{50}	<40%	<30	
	Whole organ	3DCRT	Grade ≥2 acute esophagitis	V_{70}	<20%	<30	
Heart	Pericardium	3DCRT	Pericarditis	Mean dose	<26	<15	Based on a single study
	Pericardium	3DCRT	Pericarditis	V_{30}	<46%	<15	
	Whole organ	3DCRT	Long-term cardiac mortality	V_{25}	<10%	<1	Overly safe risk estimates based on model predictions
Liver	Whole liver—GTV	3DCRT or whole organ	Classic RILD	Mean dose	<30-32	<5	Excluding patients with preexisting liver disease or hepatocellular carcinoma, as tolerance doses are lower in these patients
	Whole liver—GTV	3DCRT	Classic RILD	Mean dose	<42	<50	

Organ	Volume Segmented	Irradiation Type (Partial Organ Unless Otherwise Stated)	End Point	Dose (Gy), or Dose-Volume Parameters		Rate (%)	Notes on Dose-Volume Parameters
	Whole liver—GTV	3DCRT or whole organ	Classic RILD	Mean dose	<28	<5	In patients with Child-Pugh A preexisting liver disease or hepatocellular carcinoma, excluding hepatitis B reactivation as an endpoint
	Whole liver—GTV	3DCRT	Classic RILD	Mean dose	<36	<50	
Liver, primary lesions	Whole liver—GTV	SBRT (3 fractions)	Grade ≥3 liver enzyme change	Mean dose	≤13	<20	
		SBRT (6 fractions)	Grade ≥3 liver enzyme change	Mean dose	≤18	<20	
Liver, metastases	Whole liver—GTV	SBRT (3 fractions)	Grade ≥3 liver enzyme change	Mean dose	≤15	<20	
		SBRT (6 fractions)	Grade ≥3 liver enzyme change	Mean dose	≤20	<20	
		SBRT (3-6 fractions)	Liver dysfunction and grades 3-5 general GI toxicity	≥700 mL	≤15-17	<13	
Kidney	Bilateral whole kidney	Bilateral whole-organ or 3DCRT	Clinically relevant renal dysfunction	Mean dose	<15-18	<5	
	Bilateral whole kidney	Bilateral whole organ	Clinically relevant renal dysfunction	Mean dose	<28	<50	
	Bilateral whole kidney	3DCRT	Clinically relevant renal dysfunction	V_{12} V_{20} V_{23} V_{28}	<55% <32% <30% <20%	<5	For combined kidney
Stomach	Whole organ	Whole organ	Ulceration	D_{max}	<45	<7	
Small bowel	Individual small	3DCRT	Grade ≥3 acute toxicity	V_{15}	<120 mL	<10	Volume based on segmentation of the individual loops of

Organ	Volume Segmented	Irradiation Type (Partial Organ Unless Otherwise Stated)	End Point	Dose (Gy), or Dose-Volume Parameters		Rate (%)	Notes on Dose-Volume Parameters
	bowel loops						the bowel, not the entire potential space within the peritoneal cavity
	Entire potential space within the peritoneal cavity	3DCRT	Grade ≥3 acute toxicity	V_{45}	<195 mL	<10	Volume based on the entire potential space within the peritoneal cavity
Rectum	Whole organ	3DCRT	Grade ≥2 late rectal toxicity Grade ≥3 late rectal toxicity	V_{50}	<50%	<15 <10	Prostate cancer treatment
	Whole organ	3DCRT	Grade ≥2 late rectal toxicity Grade ≥ late rectal toxicity	V_{60}	<35%	<15 <10	
	Whole organ	3DCRT	Grade ≥2 late rectal toxicity Grade ≥3 late rectal toxicity	V_{65}	<25%	<15 <10	
	Whole organ	3DCRT	Grade ≥2 late rectal toxicity Grade ≥3 late rectal toxicity	V_{70}	<20%	<15 <10	
	Whole organ	3DCRT	Grade ≥2 late rectal toxicity Grade ≥3 late rectal toxicity	V_{75}	<15%	<15 <10	
	Whole rectum (as a solid organ)	SBRT (4-5 fractions)	Late grade ≥3 bowel toxicity	D_{max}	35-38	<3	In the context of prostate SBRT
Bladder	Whole organ	3DCRT	Grade ≥3 late RTOG	D_{max}	<65	<6	Bladder cancer treatment

Organ	Volume Segmented	Irradiation Type (Partial Organ Unless Otherwise Stated)	End Point	Dose (Gy), or Dose-Volume Parameters		Rate (%)	Notes on Dose-Volume Parameters
							Variations in bladder size/shape/location during RT hamper the ability to generate accurate data.
	Whole organ	3DCRT	Grade ≥3 late RTOG	V_{65} V_{70} V_{75} V_{80}	≤50% ≤35% ≤25% ≤15%		Prostate cancer treatment Based on the current RTOG 0415 recommendation
	Whole bladder (as a solid organ)	SBRT (4-5 fractions)	Late grade ≥2 urinary toxicity	$V_{PrescribedDose}$	<5-10 mL		In the context of prostate SBRT
Urethra	Whole organ	SBRT (4-5 fractions)	Late grade ≥2 urinary toxicity	D_{max}	<38-42 Gy	<20	In the context of prostate SBRT
Penile bulb	Whole organ	3DCRT	Severe erectile dysfunction	Mean dose to 95% of gland	<50	<35	
	Whole organ	3DCRT	Severe erectile dysfunction	D_{90}	<50	<35	
	Whole organ	3DCRT	Severe erectile dysfunction	D_{60-70}	<70	<55

CLINICAL APPLICATION, LIMITATIONS, AND IMPLICATIONS OF QUANTEC AND HYTEC

Implications for Understanding the Underlying Mechanisms of Radiation-Induced Normal Tissue Injury

The consistent structure of the Emami dose-volume limits and the application of that information to predictive models may be taken to imply a uniform mechanism of radiation-induced injury. The diversity of the structure of the information obtained in the QUANTEC review suggests a more diverse mechanism of radiation-induced injury. An interorgan comparison of dose-response functions from the QUANTEC review is interesting (Figure

12.15) and may have implications for our understanding of radiation-induced normal tissue injury.

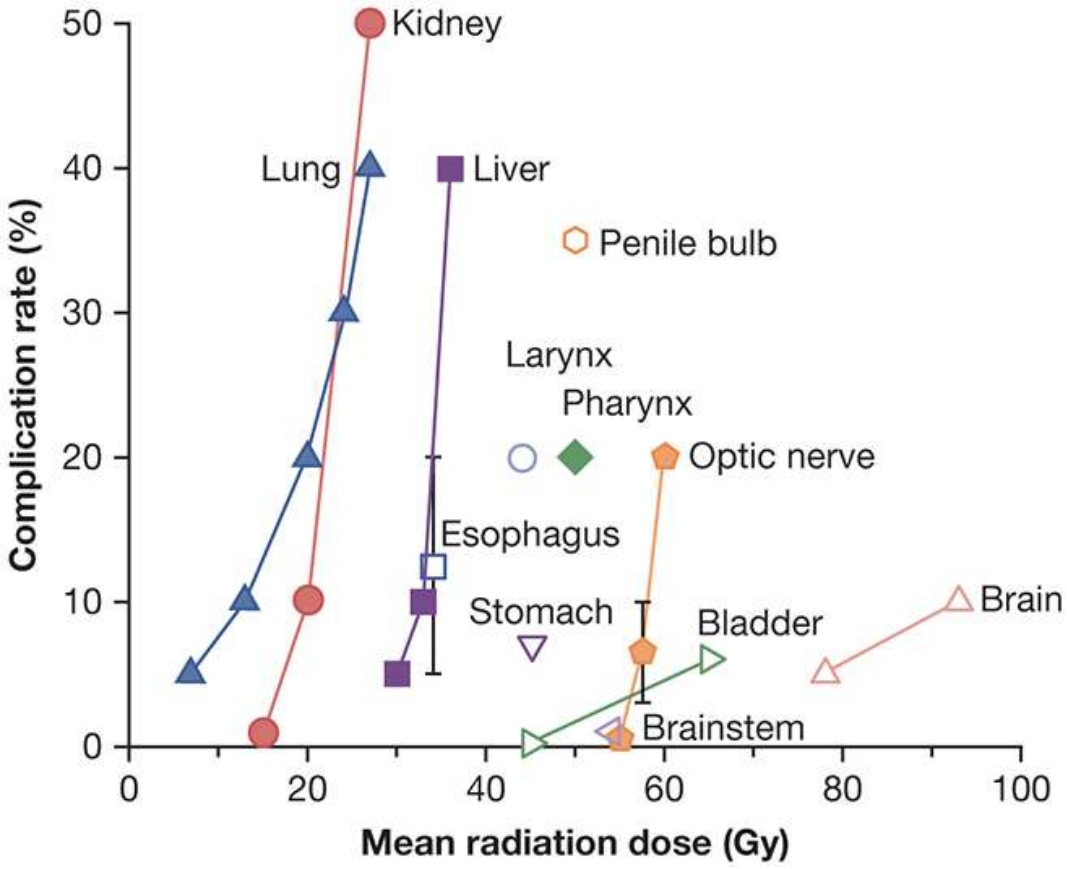

FIGURE 12.15 Composite diagram of normal tissue complication rates versus mean radiation dose.

1. There are marked variations in the dose-response curves for different organs, suggesting that there are different mechanisms for radiation-induced injury in different organs and/or that the end points selected for the different organs reflect a varied type of injury.
2. Organs that are classically considered structured in series (eg, spinal cord, optic nerve, and small bowel, analogous to electrical circuits in series) have steep dose-response curves at doses beyond an apparent critical threshold. This is expected based on our understanding of the structure/anatomy of the series of organs: damage to a functional subunit can render the entire structure dysfunctional.
3. Several neural structures exhibit a similar threshold dose for injury: ≈55 to 60 Gy (corresponding to a BED of ≈100 for an α/β ratio of 3 Gy) for the brain, brainstem, optic nerve, and spinal cord. This suggests that there may be a common mechanism of injury in these structures. Because all of these organs are dependent on the vasculature, it is tempting to implicate vascular injury as the common target for these organs.
4. Organs that are classically considered structured in parallel (eg, lung, liver, parotid, and kidney, analogous to electrical circuits) experience injury at far lower doses and have

more gradual dose-response curves compared to series organs. The presence of injury at lower doses suggests that a different mechanism of injury is occurring in these organs as compared to series organs. It appears that these organs each have critical components that are more sensitive to radiation than are the critical components within the neuronal tissues. It is thus tempting to conclude that subunits such as hepatocytes, nephrons, and alveoli are relatively radiation sensitive.

5. During heterogeneous organ irradiation, the predictive value of mean organ dose in some parallel-structured organs is interesting but counterintuitive. Consider the lung. Relatively uniform fractionated whole-lung doses as high as 15 to 23 Gy have a very low risk of symptomatic pneumonitis. Thus, the lung's "functional subunit" must generally be able to tolerate these doses. However, heterogeneous lung irradiation to an MLD of ≈15 to 23 Gy is associated with a 10% to 25% risk of symptomatic pneumonitis. Thus, during heterogeneous lung irradiation, it is likely that the mean dose is merely a surrogate for the percentage of lung exposed to various other doses of radiation. The same phenomenon may be true in other parallel organs as well.[446]

There are many hazards related to the pooling of data from several studies that may undermine the interpretation of the pooled data. A particularly interesting hazard of pooling data (often termed *Simpson Paradox) is* (for example) the masking of dose/response relationships. Consider several studies that each individually demonstrates a dose response; the pooling of data can mask this dose response (Figure 12.16A). The underlying reason for the "offset" between the data can be multifactorial but can include things such as differences in the tools used to assess toxicity, scales used to score toxicity, or perhaps interstudy differences in the vulnerability for toxicity. Similarly, the pooled data can suggest a dose response when indeed none really exists (Figure 12.16B).

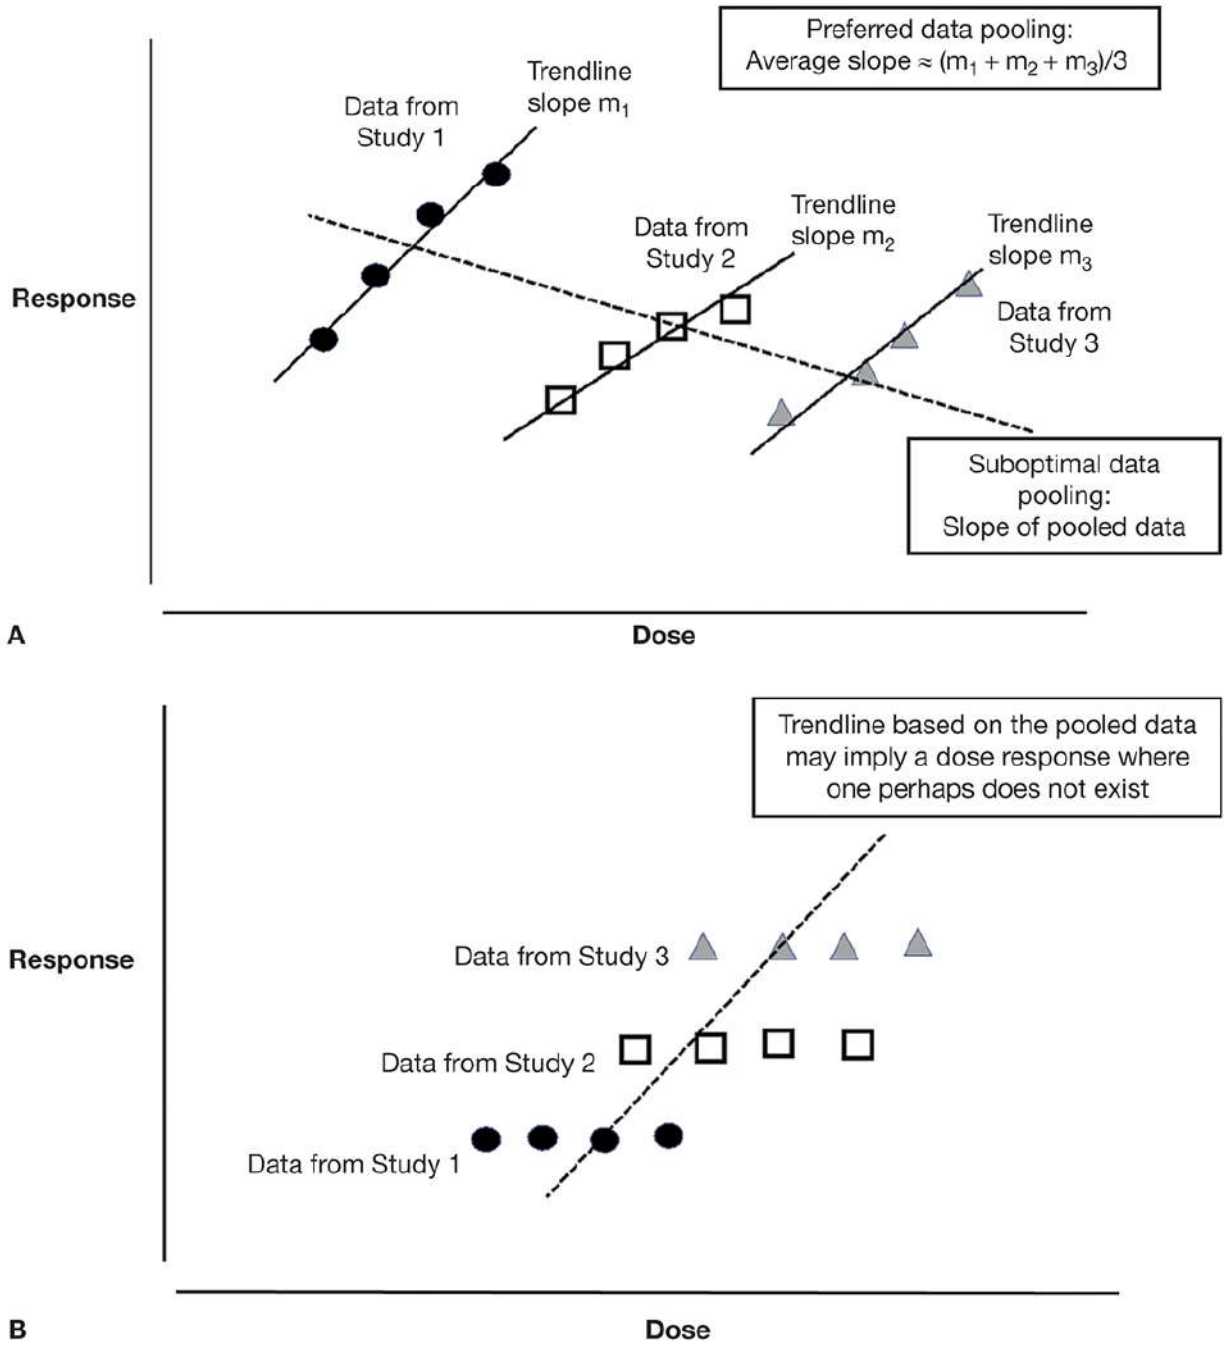

FIGURE 12.16 A cartoon of fictitious data illustrating a possible shortcoming of data pooling, often termed Simpson Paradox. In panel A, three separate studies, each individually with a clear dose response, are pooled. If the individual data points from each study are considered when pooling the data, the dose response might *not* be appreciated. A more appropriate approach might be to consider the slopes from the individual studies. In B, a similar situation is illustrated, in which a dose response might be inferred from the pooled data though no true dose response exists.

The tools of artificial intelligence (AI) will likely play an important role in assessing the risk of treatment, predicting toxicity, and ultimately optimizing the risk/reward ratio in clinical radiation oncology.[447] AI offers the potential for more readily extracting large quantities of

data, including full treatment planning data, patient demographics and outcomes, molecular pathology, longitudinal imaging, and details on adjunctive treatments, such as chemotherapy, immunotherapy, and surgery, and then analyzing these data. Of course, while AI facilitates data mining and analysis, it is essential that complete and accurate data be made accessible, as described earlier.

CONCLUSION

The QUANTEC and HyTEC efforts represent incremental improvements in our field's decades-long effort to better quantify the relationship between dose-volume parameters and clinical outcomes. As the scope of the QUANTEC and HyTEC reviews was largely limited to organ systems with meaningful dose/volume/outcome data, they are often not completely adequate tools to guide clinical care. Consistent and clear reporting of dose/volume/outcome data[448] will enable further refinements to clinical guidelines and will hopefully improve patient care.

CHAPTER 13

Quality Assurance and Error Avoidance in Radiation Therapy

Wesley J. Talcott, Kelly Paradis, Eric Ford, and Suzanne Evans

A man undergoing routine treatment for oropharyngeal cancer dies after four fractions due to failed transfer of multileaf collimator trajectories in an intensity-modulated plan.[1] Over 700 patients are overdosed due to a problem in dosimetry software, leading to 24 severe injuries and 5 deaths.[2] A pediatric patient experiences a potentially lethal overdose to their brain after an incorrect manual calculation of monitor units.[3]

Many in the field of radiation oncology (RO) have already heard of these tragic cases and may cite their occurrence as the need for continuous safety improvements in our field. Others may cite their relative rarity amidst the tens of thousands of treatments safely delivered each day as evidence of the success of our ongoing safety initiatives. Both perspectives are valid; while consequential clinical error or other deviation from effective treatment is not the norm in the day-to-day practice of RO, even the most confident practitioners of radiation medicine know that similar episodes could happen again today, including at their own practices. Though the aforementioned tragic incidents are indeed uncommon in RO, the underlying contributing factors and latent errors are not. There is not a department in the world that does not have a history of errors. In addition, even in the most experienced and diligent of departments, deviations in treatment quality occur. Centers of safety excellence cannot rest on their laurels, because as treatment paradigms and technology evolve, new pathways for error can appear. These factors conspire to threaten patient outcomes (as well as the sound sleep of radiation oncologists and medical physicists) everywhere.

Thus, it is in everyone's best interests (and for the benefit of a well-rested workforce) to continue to examine and improve the safety and quality of the medicine we practice. In a field rife with healthy disagreement, this

represents an area of universal consensus. We have already dedicated considerable energy and resources to improving in response to the past experience, but there is still substantial room for improvement. This chapter reviews the current quality and safety initiatives, while also providing actionable direction to those looking to improve quality and safety in their own programs.

ETIOLOGY OF ERROR

An important foundational aspect of quality and safety is to understand the terminology used in the literature and in practice. "Harm," "error," "mistakes," "slips," and "complications" and other terms are words that may seem interchangeable but actually represent different concepts in safety.

Harm is perhaps the most straightforward of these concepts. The World Health Organization defines health care– related harm as "impairment of structure or function of the body and/or any deleterious effect … arising from or associated with plans or actions taken during the provision of healthcare."[4] Avoidance of harm is fundamental to good medicine, a principle immortalized in modern translations of the Hippocratic Oath: "First, do no harm." Ultimately, the most important outcome of a safety program is the minimization of harm to patients, and when the term "getting to zero" is used, it refers to zero harm, not the unattainable state of zero errors. However, an absence of harm does not equal safety. An optimal safety program will record and assess all errors, whether they result in patient harm.

An "error" is an action preceding and contributing to potential harm. The inverse is not always the case, in that not all harm results from an error. Treatment can result in unintended, negative consequences due to the unpredictable and complex nature of medicine. A patient can have a previously undiagnosed connective tissue disorder resulting in unanticipated toxicity from radiation, but the initiation of radiation therapy in this setting was not an error. Similarly, necessary risks are required in medicine. A course of reirradiation with a known high morbidity rate may be the only option for a patient facing death or disability without

intervention. It may not truly be an error if a patient experiences morbidity or even death as a result of undergoing this high-risk procedure.

How then should error in the health care setting be defined? Intuitively, error arises from deviations from accepted practice standards in situations where adherence to practice standards is an option. It also involves a risk (but not guarantee) of harm that a patient might not experience under standard of care treatment. Thus, errors could reasonably be defined as "deviations from the process of care, which may or may not cause harm to the patient."[5]

An "event" refers to any deviation from normal operations or planned treatment parameters, even if minimal to no patient impact or harm occurred. This definition is broader than that of an error and would include not only errors but also treatment variations, such as machine downtime, nonadherence to treatment recommendations by a patient, or unanticipated anatomic change. An "incident" refers to an unplanned change from normal system behavior that could have or did result in harm, treatment variation, or dosimetric impact outside accepted criteria.[6] An incident can be caused not only by an error but also by nonhuman factors that cannot realistically be controlled, such as flooding or power outage. Implicit in the classification of an incident is expected harm as an outcome, though this is not always the case with an event or error.

A key goal in quality and safety activities is to understand what causes error. For this purpose, it is helpful to understand that errors can be classified as "active" or "latent." Active errors occur at the point of contact between caregiver and patient. For example, a surgeon performing a craniotomy incision at the wrong site would be committing an active error. In fact, active errors are described as occurring at the "sharp end" of care, referencing the point at which scalpel meets skin. Latent errors, also called latent conditions, instead occur at the "blunt end" of care—the layers of care that precede or exist in parallel to the point at which harm befalls a patient. Omission of a mandated pretreatment pause for independent patient and plan verification is one such latent condition, as is failure to book a translator at a simulation appointment for a non–English-speaking patient. Latent conditions, as defined by the American Association of Physicists in Medicine (AAPM), are "underlying inadequacies in the design organization, training, or maintenance that have the potential to lead to

operator errors."[6] Latent conditions may also arise from elements well outside the care team, such as departmental, institutional, or governmental policy makers, device or pharmaceutical manufacturers, and outside practitioners and support staff. For instance, an ambiguous error message from the treatment planning system (TPS) was a latent error implicated in the fatal error causing the death of a patient in one highly publicized case.[1] The radiation oncology incident learning system (RO-ILS) has identified a number of vendor targets for product improvements to reduce latent errors.[7] A patient safety incident typically involves many more latent errors than active errors. Potential error origination far removed from patient contact illustrates the need for engagement in and practice of safety culture principles throughout the health care machine.

Somewhat different than latent conditions is the concept of "contributory factors," as notably presented in the Systems Analysis of Clinical Incidents: The London Protocol (Table 13.1).[8] These can be thought of as the conditions in which errors occur. This framework is tremendously helpful in incident investigation. Especially in the setting of an excellent team who nonetheless has a significant error occur, one should approach incident investigation with full knowledge that there is a rich background of factors that drive error. Understanding this not only improves the quality of the investigation but also alleviates the causation from being falsely attributed to a single act. These events never happen in a vacuum, and multiple contributory factors are at work to make an error happen. One study in RO suggested a median of seven causal factors per event.[9]

TABLE 13.1 FRAMEWORK OF CONTRIBUTORY FACTORS INFLUENCING CLINICAL PRACTICE

Factor Types	Contributory Influencing Factor
Patient factors	Condition (complexity and seriousness) Language and communication Personality and social factors
Task and technology factors	Task design and clarity of structure Availability and use of protocols Availability and accuracy of test results Decision-making aids
Individual (staff) factors	Knowledge and skills Competence

Factor Types	Contributory Influencing Factor
	Physical and mental health
Team factors	Verbal communication Written communication Supervision and seeking help Team structure (congruence, consistency, leadership, etc)
Work environmental factors	Staffing levels and skills mix Workload and shift patterns Design, availability, and maintenance of equipment Administrative and managerial support Environment Physical
Organizational and management factors	Financial resources and constraints Organizational structure Policy, standards, and goals Safety culture and priorities
Institutional context factors	Economic and regulatory context National health service executive Links with external organizations

"Mistakes" and "slips" are other terms that are encountered and are closely related to active and latent error classifications. A mistake is the formulation of an inadequate plan of action, due to faulty knowledge, judgment, or thinking. Even if carried out exactly as intended, the plan will lead to medical error. A slip is a failure to execute an adequate plan in its intended manner, typically due to attentional lapses, forgetfulness, or fatigue. To take an example, a "slip" could cause a wrong site craniotomy if the surgeon correctly identified the site of the tumor preoperatively, but intraoperatively misidentified the intended site. However, if the motion artifact on preoperative imaging was incorrectly interpreted by the surgeon as an intracranial lesion, the error could be better classified as a mistake.

Not every adverse patient outcome is due to errors or poor quality care inflicting harm on patients. Problems that arise during an illness or treatment course (complications) can occur even when treatment is delivered in lockstep with best practices.[10] These complications should be

distinguished from harm resulting from error because they can occur without deviation from standards of care and are part of the inherent risk of cancer therapy. However, an unusual complication or an unusually high rate of complications may be indicative of systemic errors embedded in the workflow, such as a commissioning error.[11]

Finally, the harm caused by errors varies from clinically insignificant to devastating. Even two identical errors can differ dramatically in impact. An inappropriate setup may lead to a clinically inconsequential dosimetric deviation in a palliative case with large margins, or a lethal injury in a radiosurgery case. It is important, when analyzing events, to consider not only their actual impact but also their potential impact. The RO-ILS has select incidents reviewed by the Radiation Oncology Health Advisory Committee, a multidisciplinary group that (among other things) assigns a severity score to each incident (Table 13.2). This severity score notably includes both actual and potential harm. AAPM Task Group (TG)-100: Application of risk analysis methods to radiation therapy quality management[12] is a tremendous resource that also emphasizes that severity should be considered in potential as well as actual terms (Table 13.3). Although these scoring systems do not incorporate multiple scores for a single entry, the purpose of identifying workflows/processes that are the highest priority for corrective actions is kept in mind when scoring. A near miss that narrowly avoided a major overdose or wrong site administration would appropriately warrant a root cause analysis (RCA), whereas a harmless event involving a <5% dose deviation may not, despite the difference in error propagation. This is an important dimension and is discussed later in the chapter.

TABLE 13.2 ROHAC SEVERITY SCORE

Severity Index	Severity Description	Criteria
1	No potential or real harm	Event does not pose downstream risk in workflow. Event is not related to patient safety or quality of treatment.
2	Mild potential or real harm	Event may enhance the risk of other downstream errors.

Severity Index	Severity Description	Criteria
		Event may cause emotional distress or inconvenience to patient with no clinical impact.
3	Moderate potential or real harm	Event enhances the risk of other critical downstream errors. Temporary pain or discomfort for patient Deviations from best practices, but with no obvious clinical impact
4	Severe potential or real harm	Limited barriers to prevention of problem Event with potential clinical impact that is noncritical
5	Critical potential or real harm	Extremely limited barriers to prevention of problem Event with potentially critical clinical impact

TABLE 13.3 TERMINOLOGY RELATING TO SEVERITY AS USED IN THE TG-100 FMEA

Severity Term	*S* Values	Description
Wrong dose distribution	5-8	A failure in the delivery accuracy of the dose distribution that would be expected to increase adverse clinical outcomes (eg, reduced tumor control or increased likelihood of moderate-grade late toxicity) to a level that is statistically detectable in a large patient population. For definitive radiotherapy, a variation in the dose to the target or organs at risk of 5%-10% from the practice standard is suggested.
Very wrong dose distribution	9-10	A failure in the delivery accuracy of the dose distribution to an individual patient that is highly likely to cause a serious adverse clinical outcome (eg, tumor recurrence or grade III/V late toxicity) in that individual patient. For definitive radiotherapy, a threshold of about 10%-20% from the practice standard is suggested, depending on biologic sensitivities for the tissues under consideration.
Wrong absolute dose	5-8	A specific type of wrong dose delivery error in which the relative dose distribution is correctly delivered but the entire dose distribution is incorrectly scaled, due to variation in dose to the prescription point or isodose line, for example, caused by faulty machine calibration or MU calculation error. For definitive radiotherapy, a variation in the dose of 5%-10% is suggested.

Severity Term	*S* Values	Description
Very wrong absolute dose	9-10	A specific type of very wrong dose delivery error in which the relative dose distribution is correctly delivered but the entire dose distribution is incorrectly scaled, due to variation in dose to the prescription point or isodose line, for example, caused by faulty machine calibration or MU calculation error. For definitive high-dose therapy, a threshold of about 10%-20% is suggested.
Wrong location for dose	5-8	A failure in delivering the dose to the correct location that would be expected to increase adverse clinical outcomes (eg, reduced tumor control or increased likelihood of moderate-grade late toxicities) to a level that is statistically detectable in a large patient population. The size of the difference in positioning that constitutes such a failure depends on the anatomy of the target and OARs and the defined margins, but generally, differences of 3-5 mm between the locations of the reference and treated volumes are realistic for standard fractionation treatment.
Very wrong location for dose	9-10	A failure in delivering the dose to the correct location in an individual patient that is highly likely to cause a serious adverse clinical outcome (eg, tumor recurrence or grade III/V late toxicity) in that individual patient. The size of the difference in positioning that constitutes such a failure depends on the anatomy of the target and OARs, but generally, differences of more than 5 mm between the locations of the reference and treated volumes or inclusion of excessive normal tissue in the treated volume would be classified as “very wrong location.”
Wrong volume	5-8	A failure in delivering the dose to the correct target volume that would be expected to increase adverse clinical outcomes (eg, reduced tumor control or increased likelihood of moderate-grade late toxicities) to a level that is statistically detectable in a large patient population. Volume differences that constitute such a failure depend on the anatomy of the target and OARs and correspond to a marginal miss of the target volume or partial irradiation of an OAR to a sufficiently high dose that statistically detectable increases in complications are likely.
Very wrong volume	9-10	A failure in delivering the dose to the correct target volume in an individual patient that is highly likely to cause a serious adverse clinical outcome (eg, tumor recurrence or grade III/V late toxicity) in that individual patient Volume differences that constitute such a failure depend on the anatomy of the target

Severity Term	*S* Values	Description
		and OARs, and correspond to a geographical miss of the target volume or irradiation of an OAR to a dose sufficient to cause a complication or treatment failure in the patients.
Suboptimal plan	4	A treatment plan with characteristics unlikely to achieve the stated goals
Non–radiation-related physical injury	5-10	Injury resulting from causes other than radiation, for example, from physical trauma
Inconvenience patient	2-3	Failures that inconvenience the patient, for example, requiring an otherwise unexpected trip to the radiotherapy facility
Inconvenience staff or increased cost	1-2	Failures that inconvenience the staff, creating extra work, and cost of treatment or increasing stress

OAR, organ at risk.

The above definitions and concepts are synthesized into a model of errors and accidents in Figure 13.1. One can see that there are many factors driving error, from latent failures to active failures of various forms. There are also defenses or "barriers" that prevent an error (once it has happened) from reaching the patient and potentially causing harm. An example of such a safety barrier would be the time-out to verify the site of surgery prior to a craniotomy. Although there are safety barriers in place, there may be deficiencies in these barriers that allow an error to reach the patient and become an incident. This is the so-called Swiss cheese model of Jim Reasons, in which each barrier is visualized as a slice of cheese with the holes in the cheese representing defects in the barriers.

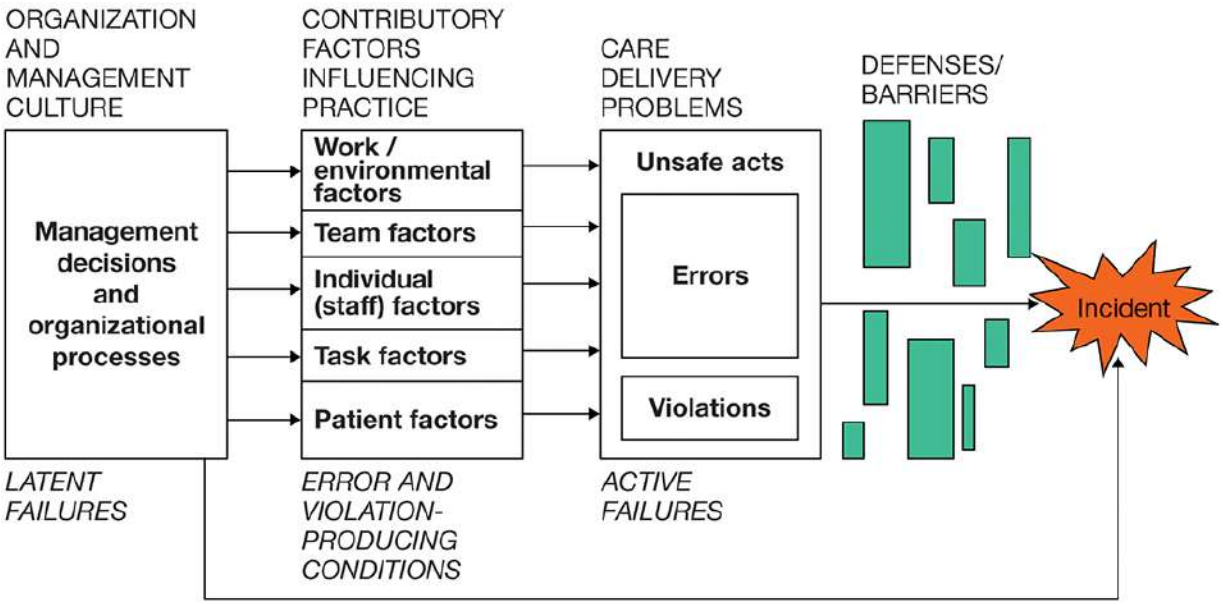

FIGURE 13.1 Adapted organization accident causation model. (From Taylor-Adams S, Vincent C. Systems analysis of clinical incidents: the London protocol. *Clin Risk*. 2004;10[6]:211-220. Copyright © 2004 SAGE Publications. Reprinted by permission of SAGE Publications.)

There are some data that indicate how permeable these safety barriers are in the RO context. Prospective studies of simulated error to gauge the effectiveness of chart rounds peer review[13] and the physics chart check[14] suggest detection rates well below 75%, with another study suggesting a chart round effectiveness of <20%.[15] Ultimately, we can conclude that errors are likely significantly more common than rates of reporting would suggest and are clinically consequential to the field on a day-to-day basis.

THE QUALITY GAP

Harm through error is not the only modifiable driver of suboptimal care in our field. Radiation therapy is an impressive product with great promise. Our understanding of disease biology continues to be refined, new technologies and therapeutics are incorporated into clinics, and practice patterns from even 10 years ago may diverge dramatically from modern guidelines. However, like any product, gaps exist between the expected and actual benefits to the consumer (or patient). This differential, known as the "quality gap," illustrates other important opportunities for improvement.

Error, as previously defined, does contribute to this gap in part. However, much of the gap arises from decisions that deviate from optimal clinical practice while still falling within acceptable practice standards. For example, using a nonstandardized dosing regimen may not meet the definition of error, but still undermine the quality of care; while a therapeutic breast radiation dose can be delivered with a 33-fraction course of breast radiation for a small, uncomplicated, resected primary in an older patient, a shorter course with a similar control benefit but with less treatment burden and fewer acute side effects would be a preferred solution. These choices that negatively impact the quality of radiation treatment delivered, despite being executed exactly as intended, represent a "leak" of therapeutic benefit. A review of treatment in even the most rigid, controlled settings suggests that this leak (and the resultant widening of the quality gap from radiation treatment) is substantial.

An excellent example of the quality gap comes from the quality assurance (QA) review of treatment plans as part of clinical trials. These studies are the most direct way one could measure the quality gap in a real-life scenario. These studies reveal that deviations in care are common and impactful. In a post hoc analysis of TROG 02.02, a phase III trial enrolling patients with head and neck cancer to chemoradiation with or without tirapazamine, 25% of radiation treatment plans were found to be noncompliant with the study protocol.[16] About half of these noncompliant plans were found to have a deficiency that predicted a potential impact on tumor control, despite receiving a complete course of radiation. These patients had a markedly inferior outcome compared with those whose treatment was protocol compliant, with a significantly lower overall survival (OS) at 2 years of 50% versus 70%. A similar analysis of RTOG 9704, which randomized patients with resected pancreatic cancer to two different chemoradiation regimens, found that 48% of plans assessed were not per protocol.[17] Remarkably, per protocol radiation treatment was found to be a stronger predictor for median survival than randomized treatment arm. Indeed, a meta-analysis of QA reports from cooperative group trials found that radiation plan deviations were associated with a statistically significant decrease in both OS and treatment failure.[18]

We can also see how treatment promise and outcome can diverge from suboptimal plan generation and approval. While there may be numerous

valid approaches to treatment planning a specific case, some will inevitably be better than others, in the sense of either improving prescription coverage, sparing organs at risk (OAR), or shortening time on the table. This was highlighted through planning competitions run by radiation societies[19,20] or vendors.[21] All submissions to these contests were required to meet set criteria and were subsequently scored on nonrequired quality metrics, such as the degree of OAR sparing. Submission scores covered a large range, from barely adequate to outstanding.[19,20] Ideally, all radiation treatment plans would be selected from the highest scoring plans of these treatment contests. However, many of these lower scoring plans were put forward as the best effort of the submitter. This missed opportunity for treatment plan optimization further contributes to the RO quality gap.

The concepts of safety and quality are linked because both attempt to achieve the same end: bringing the care we do deliver closer to the level of superior care we could deliver. While safety primarily focuses on reducing harm, narrowing the quality gap may lead to the additional benefit of reducing waste, delays, and both under- and overtreatment.[22] Thus, it is an important and effective framework to use when launching a quality improvement initiative.

CHALLENGES IN ERROR MONITORING

Errors in RO are reported at a rate of ~0.2 to 0.7 per patient.[23-25] However, it is reasonable to assume that many errors do not get reported. In fact, studies indicate that 80% to 90% of errors committed are not reported.[26]

The reason for this reporting gap is likely to be multifactorial. Reporting of errors may be avoided due to additional documentation burden.[27,28] Staff members who may observe an error may not report it under the incorrect assumption that someone else may do so ("bystander effect").[28-30] The reasons given may vary by professional group. An analysis of attitudes about reporting among the multidisciplinary team found that physicians were significantly more concerned about getting colleagues in trouble, liability, effect on departmental reputation, and embarrassment than their colleagues.[31] Some staff may prioritize fixing the immediate problem rather than reporting the issue.[32] Another significant factor is whether reporters receive feedback about the errors they submit. Lack of feedback may

disincentivize reporting due to the resulting perception that submissions are being ignored.[33] In a large Agency for Healthcare Research and Quality (AHRQ) survey, the most significant predictor for the frequency of reporting any type of event was feedback about errors.[34]

In addition to these issues with reporting known errors, there is also an entirely separate issue that not all errors will be discovered. It can be difficult to detect errors when there is uncertainty associated with the outcomes of therapy and there are multiple teams (medical oncology, pathology, surgery, and radiology) who all contribute to the outcome of a patient's treatment. Poor decisions can be made, but it is not possible to know with certainty that an error in judgment definitively was responsible for a poor outcome, especially with poor prognosis cancers. Some errors may not result in a noticeable clinical impact. A patient treated with suboptimally homogenized breast radiation may never experience symptoms from resultant fibrosis. Others may contribute to clinical outcomes but be overlooked due to the accepted treatment-related uncertainty. Grade 3 dermatitis is a known toxicity in head and neck cancer and is thus likely accepted as an unavoidable complication if an incorrect dose calculation led to a 10% increase in skin dose. Other errors may only result in clinically apparent findings years after treatment, obfuscating the connection between suboptimal radiation treatment and late toxicity in the setting of other treatments or progression that occurs in the interval. Some late toxicity may never manifest at all due to the competing risk of cancer-related mortality. Even if the resources existed to comb through every treated patient's chart, error detection rates are unlikely to be favorable. Many would be impossible to detect retrospectively due to unclear or lacking documentation. If treatment is delivered via clinical setup (ie, without imaging documentation) to the wrong location on a patient's body, for example, without photographic documentation, it can be almost impossible to "reconstruct" this error in retrospect.

Despite these challenges, maximizing error identification and reporting is an objective for centers of safety excellence. Strong patient safety culture has been associated with higher rates of error reporting. This relationship is likely bidirectional, as data from event reporting refine and improve organizational culture, and as trust in the existence of a "just culture" normalizes blame-free error reporting.[23,35-37] This leads to the paradox that

more events reports may actually indicate a safer work environment. Hartvigson et al[38] found that as the number of events increased, the severity of these events decreased.

We can draw upon reported data to better estimate error prevalence. The EORTC "dummy-runs" QA program—where each institution must segment and plan on a "dummy" computed tomography (CT) prior to credentialing—showed major deviation rates of 35% to 95% with first submission across disease sites.[39] This is confirmed by real-world data from RO-ILS demonstrating that "problematic plan approved for treatment" is a common error pathway.[40] Clinical trial QA review provides further insight, also discussed in section "The Quality Gap." Protocol deviations (often segmentation not per protocol or dose not per protocol, analogous to segmentation or dose not as per agreed standards of practice)[41] detected as part of QA for multi-institutional prospective trials were common and are found among all disease sites.[16-18,42] While there are multiple paths to a patient plan with a "major" deviation from mandated protocol, presumably, many are due to error.

CONTRIBUTORS TO ERROR

Now that we have defined errors and established their frequent occurrence, what contributes to error occurrence in the first place, and how do we mitigate these contributing factors?

Wellsprings of Error: Human Beings

Errors tend to originate from human beings ("human error"). However, this categorization is the least useful in error categorization, because it is immutable. The reality is that so long as human beings are involved in health care, then errors will be committed, though this does not mean we must resign ourselves to errors frequently reaching the patient and compromising health care provision. It seems logical that given the human origin of most errors, focusing energy on "exhortation" (encouraging vigilance) is the best way to improve safety. Unfortunately, this conclusion is misguided, as other than the rare case of a health care worker who is exhibiting poor judgment to the point of recklessness, exhortation is one of the least effective safety measures at our disposal[43] (Table 13.4), even

though it is commonly used.[56] As previously mentioned, instilling a "culture of blame" with fault attributed primarily to individuals after an error may disincentivize reporting, leading to more errors in the future as vulnerabilities of that system remain unilluminated. Instead, error occurrence, in the sense of a patient's treatments deviating from standard of care, is better attributed to failures of the overall system in which the error occurs and is propagated.

TABLE 13.4 HIERARCHY OF INTERVENTIONS

Intervention Type	Example
Forcing functions	A radiotherapy treatment plan cannot be delivered to a patient unless the plan has been approved by a physician and a medical physicist. Linear accelerator interlocks turn the treatment beam off if an error in delivery is detected.
Automation, computerization, and technology	Quality assurance tasks are automatically completed and uploaded into the patient record.[44] AI is used for the automation of SBRT treatments.[45]
Standardization and protocols	ASTRO publishes "Clinical Practice Guidelines"[46] and "Consensus Documents,"[47] and including many safety-focused white papers. A practice achieves APEx accreditation.[48]
Staffing organization	Published staffing guidelines[49] are followed at a minimum.
Policies, rules, and expectations	A centralized resource[50] is used to support the management of departmental policies and procedures.
Checklists and double-checks	An automated checklist[51,52] is used to verify treatment plan quality.
Risk assessment and learning from errors	RO-ILS publishes aggregate data reports[53] that show trends in events, as well as case studies that explore more deeply into a single event.
Education and information	An email is sent out to treatment team members to remind them how to perform a certain procedure. Team members participate in continuing education and competency review, with retraining as needed. New staff receive onboarding.
Personal initiative—vigilance	Workers remain in a state of "chronic unease," that is, they maintain "a healthy skepticism about one's own decisions

Intervention Type	Example
	and the risks that are inherent in work environments."[54,55]
Exhortation	Reminders to be more vigilant

The Importance of a Culture of Safety

Institutional culture is a critical driver of error occurrence, just as it is a driver of error detection. Any high-performing radiation safety program has a robust safety culture as its centerpiece. Safety culture has been defined as the "culture that allows the boss to hear bad news."[57] The American Society for Radiation Oncology Accreditation Program for Excellence (ASTRO APEx) thoroughly defines the standard for safety culture in RO (Table 13.5),[58] and other standards are available.[59]

TABLE 13.5 ASTRO APEX ACCREDITATION PROGRAM STANDARDS FOR A "CULTURE OF SAFETY"

The Radiation Oncology Practice (ROP) has a policy on patient safety that:

- Articulates the practice's approach to patient safety.
- Specifies that patient safety events, including patient safety incidents and near misses, are to be reported and tracked within the practice.
- Identifies methods for staff to report patient safety events and unsafe conditions, including a method for staff to report anonymously.
- Encourages timely reporting of patient safety events and unsafe conditions by all staff.
- Specifies periodic reporting back to staff on activities and findings of the culture of safety program.
- Specifies that procedures are not started until all questions and/or concerns are resolved.
- Provides assurances that there will be no reprisals based on reporting of patient safety events and unsafe conditions.
- Identifies a role for patients in the culture of safety programs.

Designates an accountable individual from the practice leadership who is:

- Responsible for implementing the requirements of Standard 7, which states that the ROP fosters a culture of safety in which all team members participate in assuring safety, the practice capitalizes on opportunities to improve safety, and no reprisals are taken for staff that report safety concerns.

- Responsible for collection of information and investigation of patient safety events and unsafe conditions.
- The lead on convening Interdisciplinary Safety Rounds.
- Evaluated in part for providing leadership to the practice's culture of safety program.

Conducts Interdisciplinary Safety Rounds at least quarterly to:

- Promote a team-based approach to safety.
- Review all patient safety event and unsafe condition data from patients, staff, and equipment.
- Proactively assess the ROP's structure and processes that promote safety.
- Develop, implement, and assess progress of action plans to improve safety.

If a patient safety incident occurs, the ROP:

- Undertakes an immediate review, with the goal of understanding underlying factors and taking action to prevent future occurrence.
- Complies with institutional, state, local, and national requirements for reportable patient safety incidents.

Reports to and participates in:

- A patient safety organization (PSO)

APEx, Accreditation Program for Excellence; ASTRO, American Society for Radiation Oncology.

However, organizational culture is not purely defined by stated policies. Rather, it is built by establishing a universal trust that these policies are valued and respected, even when they may come in conflict with competing practice priorities. For example, a high-performing safety culture necessitates time to be invested in performing the necessary checks designed to ensure safe care.[60] This conflicts with pressures in health care to increase patient volumes and revenue generation. Another example is the pressure in health care to avoid interfering with patients under the direct care of others (to avoid "stepping on toes"), in particular within a tertiary referral field like RO. This tendency may serve as an intrinsic barrier to airing concerns about the care plan of a colleague's patient, along with the desire to avoid ego dystonia for oneself and one's colleagues. Nonetheless,

a strong departmental and institutional culture will make such discussions better tolerated, as the desire to improve is the clear motivation for such discussions.

A poor culture will undermine sound policies by reducing adherence and implementation. Validated measures of organizational safety culture are inversely correlated with patient outcomes[61] and adverse events.[62] On a more granular level, a culture internally perceived as unsupporting of safety practices is associated with poorer performance in elements of RO QA. Using participation in peer review as an example, a published survey demonstrated that physicians in a pro-peer review environment were nearly 70 times more likely to be involved in peer review compared with physicians in hostile, anti–peer-review environments and that less than 2% of those who work in a hostile environment were involved in ongoing peer review.[35] Absence of a "just culture" or failure of leadership to inspire confidence that such a culture will be upheld in practice is a major contributor to disengagement from safety practice. Steps to build and maintain a strong culture of safety are described in the sections that follow.

Burnout

Professional burnout, a "syndrome characterized by exhaustion, cynicism, and reduced effectiveness," can drive error occurrence and impair detection and correction.[63] Burnout is markedly higher in medicine than in other fields nationally and has been directly associated with worse quality and safety outcomes. Radiation oncologists have high estimated rates of burnout at all career stages.[64] An individual displaying the symptoms of burnout is likely less attentive, more prone to circumventing safety procedures due to fatigue or apathy, and less effective at applying their knowledge to identify errors they encounter. The contributors to burnout are similar to those that threaten safety culture, including increasing productivity expectations, documentation burden not directly related to patient care, value misalignment between staff and leadership, and support staff turnover.

Hierarchy and Fear of Reprisal

Aversion to antagonizing more senior colleagues perpetuates the propagation of errors through to the patient. Medicine is hierarchical by

nature, and physicians, physicists, and other members of the radiation workforce typically spend many years as trainees in graduate school and internship/residency before becoming fully certified practitioners. A culture of deference to seniors is firmly instilled from these years of training, and even after board certification, there may be a pause to identify another practitioner's treatment as unsafe.[65] Stopping the treatment workflow of a colleague (or superior) to question an aspect of care being delivered is intimidating and can indeed lead to blowback if unchecked narcissistic personalities are involved.[66,67]

The threat of adverse consequences from error reporting, or operating in a punitive culture, clearly disincentivizes error reporting. Beyond concerns about coming off as noncollegial, the reputational consequences of publicizing an error can be embarrassing. Medical professionals may also be opening themselves up for civil or even criminal prosecution. In a particularly notable example of a punitive culture in action, a nurse who accidentally substituted vecuronium for Versed to a patient resulting in death was prosecuted and convicted of homicide after immediately disclosing their error to their employer.[68] This occurred even though they were operating in a weak system that allowed them to override it and obtain the potentially lethal drug. It is easy to see how such prosecutions disincentivize honesty and error disclosure. A "reporting culture" is ultimately beneficial to patients: Not only do greater numbers of reported events make emerging risks more apparent, but rapid reporting of serious events can ultimately save lives.[69]

Cognitive Biases

Beyond these environmental barriers, a major contributor to error is the very hardwiring of our brains. We are capable of deep and careful thought, but frequently find ourselves in time-constrained scenarios where we rely on mental shortcuts, or "heuristics." These heuristics will help us come to a solution more quickly, but unfortunately do not ensure we come to the optimal solution, or even a good solution. According to Gonzalez,[70] "heuristics are the 'shortcuts' that humans use to reduce task complexity in judgment and choice, and biases are the resulting gaps between normative behavior and the heuristically determined behavior."

Medicine is full of examples of cognitive bias affecting care. Particularly recognizable examples include confirmation bias, which is our tendency to interpret new information in a way that fits our preexisting narrative; search-satisfying bias, whereby an error detected in a plan may lead to a decrease in vigilance for a second concurrent error; expectation bias, where we see what we expect to see even when it is not present; anchoring, whereby one demonstrates a proclivity to their initial impression; sunk cost fallacy, where we are reluctant to abandon work put into achieving a task one way, even when a second, more efficient option presents itself; and even cutoff bias, whereby continuous variables are dichotomized into two groups of "larger" and "smaller," leading to irrational decision-making around the point of dichotomization.[71,72] All these examples have been shown to impact patients in the RO clinic (Table 13.6).

TABLE 13.6 DEFINITIONS AND EXAMPLES OF COMMON COGNITIVE BIASES PRESENT IN MEDICINE

Bias Name	Definition	Example
Confirmation bias	Tendency to interpret new information in a way that fits one's preexisting narrative	After documenting in the chart that a tumor histology has a low risk of nodal metastases, assuming suspicious regional nodes identified on staging imaging are reactive and forgoing further workup
Search-satisfying (bounded rationality) bias	Once an error has been detected during review, discontinuing the search for additional, concurrent errors.	After noting that a superior field border on a breast plan should be raised, adjusting that border and forgoing further review without noting simultaneous use of inappropriate dose/fractionation schema
Expectation bias	Seeing what we expect to see even when it is not present	After reviewing charts prior to consult and seeing a 65-year-old patient with early-stage breast cancer following lumpectomy, concluding adjuvant radiation is necessary even after the patient arrives and reports numerous other comorbidities making them a poor candidate.
Anchoring	A proclivity to their initial impression	Being unwilling to deviate from initial tumor board recommendation even

Bias Name	Definition	Example
		when a more favorable treatment regimen is suggested
Sunk cost fallacy	Reluctance to abandon work put into achieving a task one way, even when a more favorable path opens	Rationalizing keeping a treatment plan unchanged due to effort spent contouring and planning after significant modifications recommended at peer review rounds
Cutoff bias (left digit bias)	Dichotomizing continuous variables into two groups of "larger" and "smaller," leading to irrational decision-making around the point of dichotomization	Recommending adjuvant radiation therapy to all 69-year-olds with early-stage breast cancer evaluated in clinic, and observation to all 70-year-olds because they are "older"

There are internal and external contributors to the likelihood that cognitive biases manifest in a harmful way. These biases arise from mental shortcuts we subconsciously implement, so the more time restricted we are, the more likely we are to fall into using these tools.

Technology and Increasing Complexity

Technological advancement may make error occurrence more frequent and error detection more challenging.[73] As the pathway of treatment becomes more opaque to human users, it can be less clear when a poor-quality treatment is being delivered. With two-dimensional fields, the relationship between an incorrectly positioned light field and altered dose distribution would likely be more apparent to a planning and therapy team than if the same site were treated with a multiisocenter volumetric modulated arc therapy (VMAT) plan. Complexity of treatment may offer more pathways for failure, or more reliance on additional safety checks and QA features, further straining workflow and creating opportunities for skipped steps. The more staff are expected to know, the less experience they may have with any one of a diverse array of techniques; indeed, after introduction of a more modern treatment technique, one study showed that the error rate during performance of an older, simpler technique increased.[74] The authors speculate this may be due to decreasing familiarity with older (but still important) techniques as new ones are internalized. Adaptive treatment,

artificial intelligence (AI)-based delineation, decision support tools, and ablative treatment across multiple sites simultaneously may represent particular challenges for our field, given rapid adoption but limited safety reporting.[75] In particular, adaptive planning may require the involvement of multiple physicians, physicists, dosimetrists, and radiation therapists to cover replanning, and the need to communicate the clinical scenario, target location, necessary margins, directive priorities, and respiratory gating—all creating opportunities for error introduction within the cognitively more challenging cross-coverage situation.[76] Recommendations for personnel, communication, QA, and workflow requirements have been published, and further guidance is anticipated.[77]

Mistake-Prone Design

Finally, the systems we use in radiation therapy may not be designed with error prevention as a priority. No one benefits from medical error. Yet safety functions can be dissatisfiers to the end user and so not embraced by the vendor. Restricting permissions, mandatory warnings, and other forcing functions can slow the process of care. Economic or advanced technological benefits are more frequently factored into purchase decisions, and vendors may be more interested in promoting those benefits. In addition, while competition is welcome between vendors in RO to promote innovation, it can also prevent standardization between sites using different vendors. In a notable example, two of the most popular documentation systems used in RO display total prescription dose and dose per fraction in reverse order,[78] and as of this writing, vendors still have failed to adopt the ASTRO standard prescription or switch to cGy as the standard unit of dose. This choice of display works against reducing episodes of dose/fractionation reversal, a potentially impactful error known to occur with high frequency.[40,53] Nonstandardized character limits for structure name and variation in default coloration schemes for preloaded contours and isodose lines are further examples.[79] “Mistake proofing” is the concept of making errors more difficult to achieve, or more detectable once manifest. In *The Design of Everyday Things* by Donald Norman, the operation of a modern stove is used as an example.[80] By mapping the position of switches to that of the stovetop burners and using a light to signal the stove is on, the system

aligns user expectation and output, making unintended outcomes (activating the wrong burner and starting a kitchen fire) less likely. Similar principles have been applied to the design of therapy workstations.[81] Partnering with vendors to "mistake proof" increasingly complex hardware and software is an opportunity, and a responsibility, that should not be overlooked.

PREVENTION AND RESPONSE TO RISK AND ERROR

Building and Maintaining a Strong Safety Culture

As introduced above, a critical aspect of error prevention is the development of a strong safety culture among all members of the RO team. ASTRO's "Safety is No Accident" defines a safety-minded culture as an environment where "all staff are encouraged to suggest and effect change to improve safety, quality, and efficiency." RO departments are fast-paced environments where new technology and treatment strategies are continuously being implemented, and workflows are being updated to accommodate these changes. The exchange of information between team members, both intra- and interdepartmentally, is constant and occurs via multiple channels, such as email, text, phone calls, department or hospital-based electronic information systems, or even quick chats in the hallway. Each year new team members join, creating the opportunity for innovation and learning but at the same time increasing the risk of error due to incomplete onboarding, and others may leave, potentially leaving experience gaps in their wake. Because of these features, the focus on a culture of safety must also be continuous, such that all team members are empowered to speak up when there is a concern for patient safety or an opportunity for process improvement.

Quantitative survey instruments exist for evaluating and identifying any weak points in team safety culture that should be addressed. For example, the AHRQ developed the freely available Hospital Survey of Patient Safety Culture (SOPS).[82] These types of surveys can be used on an ongoing basis to track progress and highlight potential gaps. A 2010 study by Mardon et al[36] showed that there was an inverse relationship between hospital patient safety culture as quantified by AHRQ's Hospital SOPS and adverse events. Interestingly, safety culture as quantified by SOPS was significantly

associated with patient satisfaction, though the correlation was weak (r = 0.4).[83]

At Michigan Medicine, safety culture in the department of RO is evaluated on an annual basis using an all team member survey that asks about perceptions of safety culture and attempts to determine any barriers to achieving a stronger safety culture. Survey participants are also given the opportunity to provide qualitative feedback. Survey results are reported back to the department along with each of the (anonymized) qualitative comments and information about how each has been or will be addressed. To the extent that survey participant confidentiality can be maintained, (optional) demographic information such as gender, age, level of experience, and departmental role are collected. This allows the stratification of safety culture perceptions across groups by the four largest teams in the department (Figure 13.2).

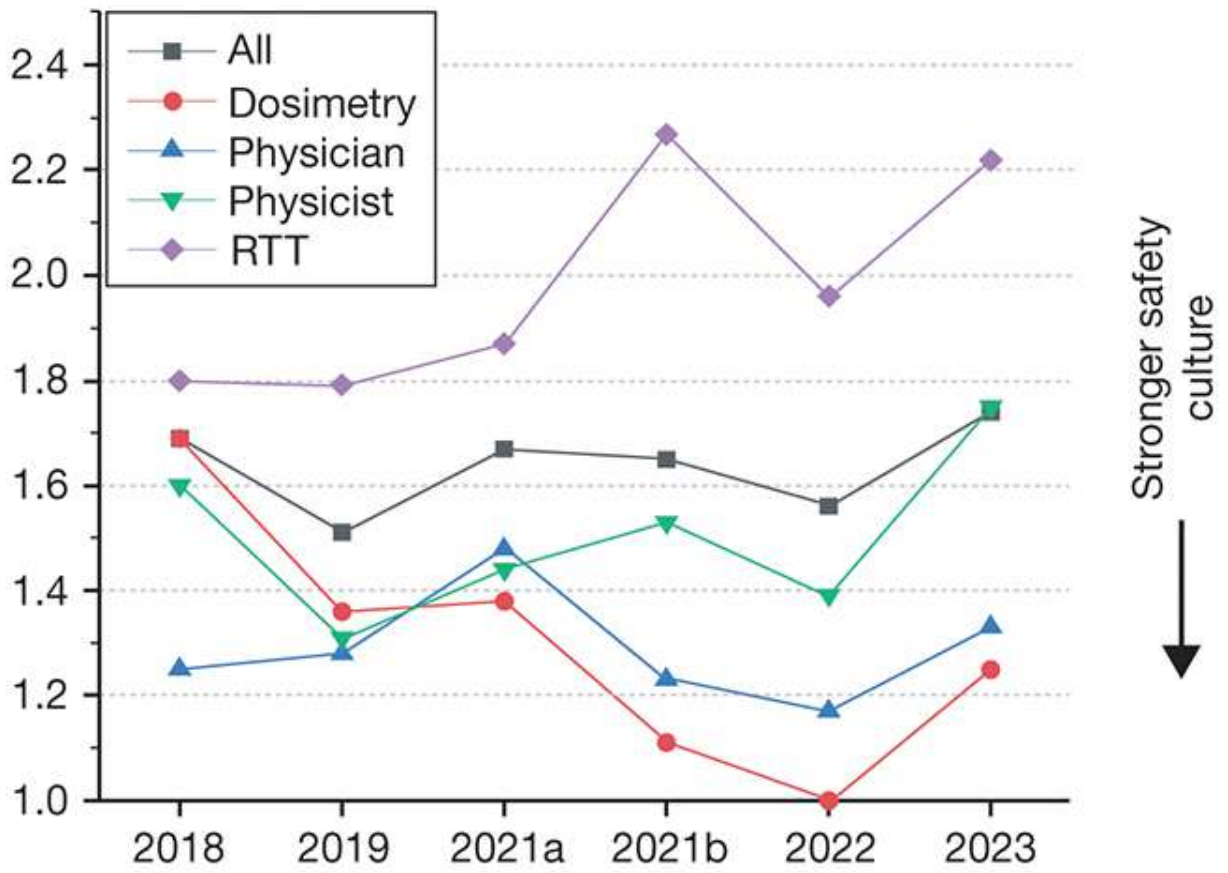

FIGURE 13.2 Results of the safety culture assessment survey in the department of radiation oncology at Michigan Medicine over 6 years. Responses graphed are to the question: Overall, I would rank the safety culture in our department as excellent (1), good (2), average (3), poor (4), or terrible (5). The 2020 survey was delayed by the COVID pandemic, resulting in two surveys separated by 8 months in 2021.

Work Environment and Leadership

Leadership in an RO department set the tone for the safety culture. In fact, one of the sections of the AHRQ Hospital SOPS focuses specifically on leadership, using the questions "[Leadership] seriously considers staff suggestions for improving patient safety," "[Leadership] wants us to work faster during busy times, even if it means taking shortcuts," and "[Leadership] takes action to address patient safety concerns that are brought to their attention."

The term "leadership" is deliberately left broad, because of the broad range of personnel involved in radiotherapy treatment. It includes not only the Medical Director or Chair but also administrative directors, division directors, team leaders, and those in supervisory or mentorship roles,

whether formal or informal. Leaders must support the open, nonjudgmental, and nonpunitive discussion of errors and safety events. The viewpoints and experiences of front-line staff are critical in both the prevention of and response to errors. These personnel should be approached with humble inquiry: "the gentle art of drawing someone out, of asking questions to which you do not know the answer, of building relationships based on curiosity and interest in the other person," rather than handing down decisions "from above."[84] The focus should be on creating a "just culture," which is different from a blame-free culture.[85] Each team member is held accountable for their actions, while at the same time acknowledging that most errors originate at the systems level. An example of a framework for determining consequences in response to incidents is given in Figure 13.3; this emphasizes punitive measures only for reckless or negligent behavior.

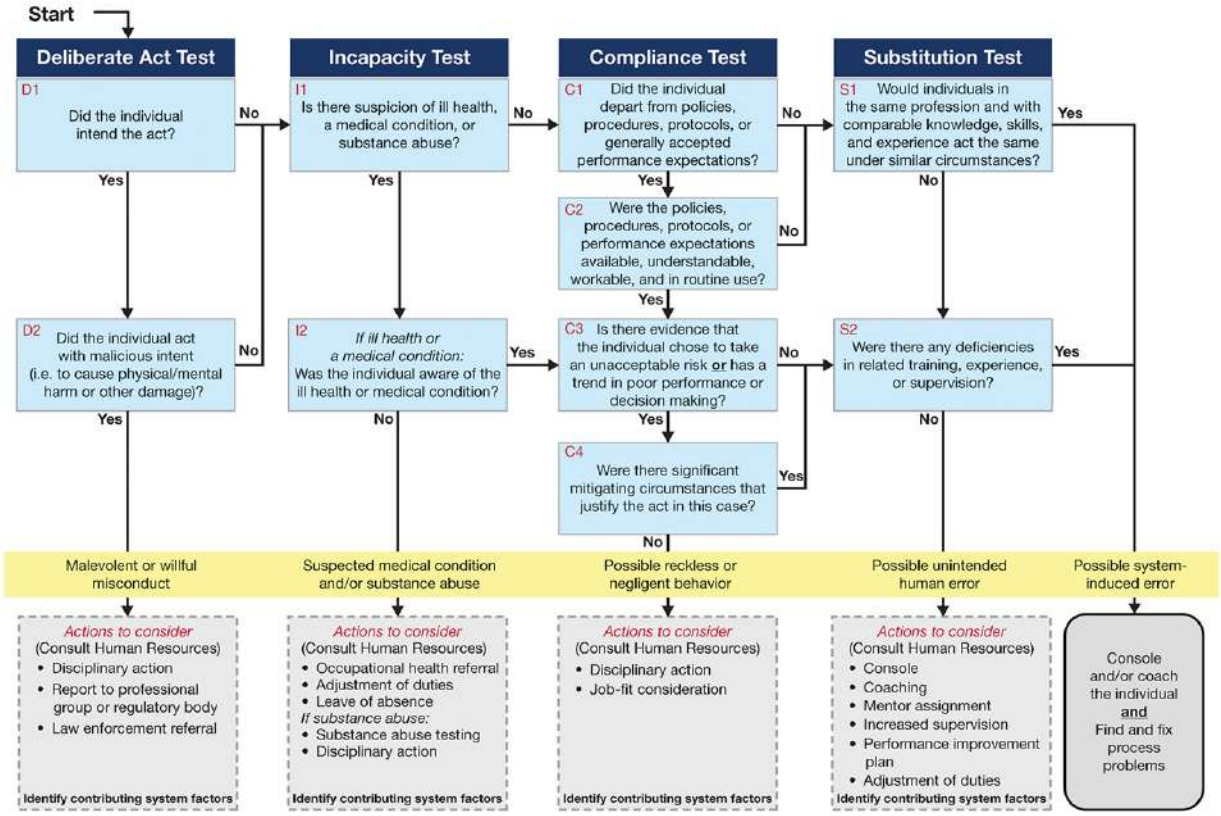

FIGURE 13.3 Performance management guide. (Adapted from James Reason's "Decision Tree for Determining the Culpability of Unsafe Acts" and the Incident Decision Tree of the National Patient Safety Agency. Reprinted with permission from Press Ganey Associates, LLC.)

The way that communication is conducted between team members forms the foundation of safety culture in an RO department. Fundamentally, everyone has a need to feel respected, that their contributions are valued and their work appreciated, and that their opinions are taken seriously. When an error happens, there may be many complex underlying and unspoken emotions. How each team member responds in the face of these events will impact not only the current situation but also the response to any future events that occur. Consider an example where a patient is being treated to a site that is nearby to a previously irradiated site. The treatment planning is complicated and requires considerable back-and-forth email communication between the physician and the dosimetrist. During these exchanges, an email message from the physician to create a composite plan with the prior treatment is not seen by the dosimetrist. During the physics chart check, the physicist creates a composite plan and finds that there is a high-dose overlap between the treatment sites.

Communication about this event now becomes paramount. The physicist could blame the dosimetrist, asking how they could forget when it is documented on the planning directive that a plan sum was needed. The dosimetrist could blame the physician, asking why they would approve a plan without documentation that it did not overlap with a prior treatment. The physician could blame the physicist, asking why the software and established workflows would allow them to approve a plan without sufficient documentation of the overlap. An email could be sent out reminding people that reirradiation status should be reviewed repeatedly during planning. A new checklist item could be added to remind everyone to check the status of prior radiation before moving on to the next workflow step. These are deeply unsatisfactory solutions that leave everyone feeling like they failed and that similar events could easily recur in the future and perhaps even would not be reported due to fear of blame or retribution.

Alternatively, the team could approach the event as a problem to be solved together without blame or focus on the individual, from a systems-level view. The team would examine the root causes, which likely also contribute to other similar events in the same department and identify solutions that not only make future events less likely but also leave the team feeling supported, valued, and respected.

Hierarchy of Interventions

When either prospectively trying to prevent or retrospectively responding to a safety event or process concern, there is often an inverse relationship between the difficulty of an intervention and its effectiveness. Interestingly, people favor additive solutions, where steps are added on to a process, despite the fact that there may be more elegant solutions that eliminate steps and improve the reliability of the process.[86] In addition, because of the limited time available in a busy department, the focus tends to be on the faster interventions first, such as reminders (exhortation) and reeducation, as described in the example above.

A hierarchy of interventions was developed by the Institute for Safe Medical Practices[87] to address the prevention of medication errors (see Table 13.6). This framework was later adapted more broadly with a focus on communication by Woods et al.[43]

Accreditation

Accreditation is an important component of establishing a robust safety program, not the least of which because it involves the review of a program from the outside, which may uncover issues that those working within the program may not be able to identify. The goal of accreditation is to "ensure patients receive consistently high-quality, team-based care."[88] Recent practice guidelines have emphasized this importance.[89]

The accrediting bodies for RO are ASTRO's APEx, American College of Radiology (ACR) Radiation Oncology Practice Accreditation (ROPA), and ACRO. APEx, established by ASTRO in 2014, has five pillars: the process of care, the RO team, safety, quality management, and patient-centered care.[58,88] The process begins with an internal self-assessment, followed by an external assessment ("facility visit"). The self-assessment allows an institution to clearly understand the expectations of the accreditation program, as well as to find and address any potential areas for improvement, increasing the chances that the external assessment will be successful. The ACR's ROPA program has been in place since 1987. It begins with an online application including equipment, staffing, and QA/QC (quality control) documentation, and like APEx, includes a detailed

assessment by board-certified surveyors. More details about both these programs can be found on their associated websites.

SPECIFIC QUALITY ASSURANCE TOOLS TO REDUCE ERROR

The sections above focus on factors or interventions at a system level, for example, culture of safety and practice accreditation. However, there are also many highly specific QA tools available in RO that work to reduce errors or minimize their impact. Here we consider a few of these.

QUALITY ASSURANCE OF PHYSICAL DOSIMETRY

There are numerous QA tools that lie in the professional realm of medical physics with the overall goal of delivering the prescribed dose to the intended target for each patient. While a full description of these is beyond the scope of this chapter, a comprehensive compendium can be found in Dieterich et al[90] as well as TG reports[91] and Medical Physics Practice Guideline (MPPG)[92] from the AAPM. Some of these QA tests are performed on each specific patient plan, such as the recommendation to perform a secondary dose calculation (see AAPM TG 219).[93] Other tests are more systemic in nature and affect all patient treatments, such as the recommendation to verify the radiation output of a linear accelerator each month to an accuracy of at least 2% (see MPPG 8).[94] This is an example of a QA test that is performed on a regular basis. Other QA tests are less frequent, such as the verification tests that are performed when installing and commissioning a new treatment planning system (see MPPG 5).[95]

PEER REVIEW

Peer review is a crucial concept in RO, health care, and scientific pursuit in general that refers to the review of one's work by an equally competent reviewer ("peer"). There are numerous forms of peer review present in radiation planning and treatment delivery, serving as QC checkpoints in the generation of a radiation treatment plan. Each instance of peer review in the RO process targets a specific dimension of treatment and planning (eg, the decision to treat, plan contours, dosimetric verification). Peer review may

also involve duplicative, overlapping checks of elements that are also included in other QA steps either upstream or downstream.

Two major forms of peer review in the RO workflow are physicist chart checks and chart rounds.

Physicist Plan and Chart Review

Physicist plan and chart review represent a universal element of the clinical workflow mandated by societies for accreditation (AAPM, ASTRO). They represent some of the highest performing safety checks in the RO workflow in terms of the breadth of errors detected.[96] These chart checks encompass pretreatment, on-treatment, and post-treatment review of the radiation plan quality, safety, technical feasibility, and treatment delivery. The AAPM TG 275 report and the MPPG 11.A both provide the contemporary guidance on the performance of this QA step.[97,98]

Chart Rounds

Chart rounds occur in some form in essentially every North American RO department and are the point at which many radiation oncologists most actively engage in departmental quality and safety.[99] Chart rounds have several components and are ideally conducted in a multidisciplinary manner. Physician peer review, "the evaluation of components of a radiation treatment plan by a second radiation oncologist … to ensure it is appropriate from both patient safety and treatment effectiveness perspectives," occurs here, but is by no means the only review.[100] To meet accreditation standards, the structure of chart rounds typically entails presentation of individual cases and review (at a minimum) of clinical background and targets.[35,101] Physicists, dosimetrists, therapists, and nurses all have a valuable role in this process. Therapists may comment about the reproducibility of a chosen immobilization device; physics might comment about the high Hounsfield units in a breast expander introducing unanticipated ambiguity about the accuracy of dose calculation; dosimetry might inquire about whether an avoidance sector was used in a VMAT plan to avoid a previously treated field; nursing might have valuable insight about a patient's understanding about their treatment or ability to adhere to the proposed course. Chart round is a time to globally assess the

appropriateness of treatment, and the contributions of all team members are to be valued and heard. An important concept to chart rounds is that as opposed to most QA processes, a major focus of chart rounds assesses if something was *done optimally* rather than simply *done*. It also serves as a uniquely comprehensive review at the treatment planning step, by offering the opportunity to review target volume delineation, OAR delineation, dose and fractionation schema, normal structure and coverage directives, and the decision to pursue radiation therapy in each clinical scenario. Many errors or suboptimal decisions that widen the quality gap involving these elements are either detected at this stage or are at high risk to go undetected. Despite its resource-intensive nature (potentially occupying the focus of a department's entire multidisciplinary cohort for hours each week), it provides a singular opportunity to close the quality gap, resulting in a demonstrable positive effect on quality of care.

This can be seen in practice: Almost everyone in the field of RO has a story of a "good catch" during chart rounds. For example, dose unnecessarily deposited into an overlooked portion of bowel to a degree that could have caused significant toxicity, or a situation where prior irradiation was not considered. By the nature of making these changes, peer review is clearly contributing to improved patient outcomes. We can also see the potential of QA when it was retrospectively performed on large cooperative group trials. As previously mentioned, protocol deviations were correlated with adverse outcomes across several large cooperative group trials.[18] Prospective review would have identified these deviations while there was still the opportunity to correct them, presumably "closing" the significant gap in survival outcomes between plans with and without deviations.

Finally, chart rounds may standardize practice across a health network where the multidisciplinary team may practice in silos, and as an educational opportunity not only for trainee but also for all team members.

Given the importance of chart rounds, one would expect it to be performed optimally. Unfortunately, there is no clear understanding of what "optimal" review looks like.[102] There is incredible heterogeneity in performance nationally, with variation in frequency (from daily to monthly or on demand), range of staff present, modifications made (active changes to contours to dictated addenda to the patient record to word-of-honor

follow-up), virtual versus in person (in some cases with the actual patient present), to the selection of cases for review (ranging from all cases, to only those submitted, to a random selection). Indeed, even within institutions, practice between disease groups can vary widely. Establishing guidance on optimal physician peer review performance remains a priority for the field, although it is complicated by the variety of practices that require it. Such guidance must be applicable to not only the 20 physicist and 26 physician academic practice but also the single physicist, single physician practice.

Limitations of Peer Review

Among this heterogeneity, we know that there is likely room for significant improvement in typical practice. Reports show detection rates of ~70% during the physics chart check and ~50% during chart rounds.[13,14] The challenges underlying this suboptimal performance look very similar to those threatening safety in general. Increasing complexity of treatment modalities, contour number, plan coverage goals, and constraints may increase the necessary intensity of review.[103] Time itself is in short supply, with competing priorities drawing physicians' and physicists' focus and physical presence away from review.[104] Cultural barriers (such as fear of critiquing plans originating from up the hierarchy)[65] and numerous cognitive biases (such as sunk cost and search-satisfying biases) also come into play.[71]

There is evidence to suggest some best practices for establishing optimal peer review. As mentioned, guidance for physics chart checks can be found in recent publications from medical physics professional groups.[97,98]

With regard to chart rounds, it may be most efficient to prioritize certain plan elements for assessment during review sessions. Multiple observational studies of peer review performance have shown that the most common elements altered during review include target volume delineation, dose and fractionation selection, OAR volume delineation, and normal tissue sparing.[101,105-107] Thus, these elements of the plan should be prioritized for physician peer review.

Prospective review, before plan start or treatment planning, is associated with higher rates of scrutiny and suggested modifications.[108,109] Incorporation of the suggested modifications was more likely if peer review

was conducted prior to treatment start.[110] This has been hypothesized to be due to a reduction of sunk cost fallacy, described earlier in this chapter. Given the amount of work that has already gone into planning, scheduling, or, in many cases, delivering treatment to a patient, the less likely one is to "start from square one" and begin the replanning process, and the less likely one is to put colleagues through that process by putting forward a modification suggestion. In addition, prospective review allows this process to be opaque to the patient, which can be important in maintaining trust of the treatment team. The aversion to more burdensome alterations was illustrated in a study of compliance with peer review recommendations, whereby "major" suggested plan alterations were less likely to be acted on than "minor" alterations.[111] The authors speculated this was due to the excess work needed to pivot to adopt a major recommendation versus a minor one and the increased incidence of rationalizing noncompliance to avoid this major inconvenience. Prospective contouring rounds during which the target and OAR contours are reviewed prior to plan initiation further decrease the inertia opposing implementation of feedback and may lead to additional input.[112] As the objective of peer review is to provide and implement meaningful treatment improvements and prevent any suboptimal treatment from reaching the patient, moving review further up in the workflow is likely beneficial.

Time and focus can be limited by performing efficient, structured peer review with a similarly structured accompanying clinical presentation. Excessive details about tangentially related prior therapies and medical episodes that did not influence the radiation decision only make effective review more challenging. Protected time for peer review during the day may lead to increased attendance and participation.[99]

Standardization of review elements may be helpful. One proposal has been for a sequence of plan element evaluation abbreviated CB-CHOP,[113] which stands for contours, beams, coverage, heterogeneity, OARs, and prescription. Following this abbreviation ensures review of the highest priority targets; standardization of the sequence of review decreases the likelihood of inadvertently neglecting an element. Standardization should extend to presentation of clinical history (age, stage, prior treatments, prescription, and target), structure and plan naming, and the appearance of any images projected (such as standardizing the color of the target and OAR

contours) to facilitate efficient presentation and pattern recognition. It should be noted that other forms of peer review exist in the RO workflow and may overlap with some elements of physicist plan checks and chart rounds. Many institutions hold tumor boards, in which treatment strategies for a patient are discussed in the multidisciplinary setting. Informal peer review may also take place during the planning phase, if dosimetrists, physicists, or physicians wish to confirm whether a plan has been adequately optimized. These varied other forms of peer review are important but beyond the scope of this chapter.

HAZARD AND RISK ANALYSIS

Risk analysis methods may be roughly broken up into two categories, those that are prospective (sometimes referred to as proactive), where analysis takes place before an event occurs, often as part of the initial design of a new procedure or program, and those that are retrospective, where analysis takes place after an event occurs, with the goal of reducing the likelihood of future similar events. These approaches are complementary and should not be considered exclusive of each other. For example, Yang et al[114] studied how failure modes identified via failure mode and effects analysis (FMEA—a prospective method of risk analysis) intersected with events that actually occurred in a radiotherapy clinic as reported in an ILS (a retrospective method of risk analysis). They found that for stereotactic body radiation therapy (SBRT) treatment planning, both methods missed potential failure modes and that using the two strategies simultaneously could yield an improved evaluation of the safety of a given process.

PROSPECTIVE RISK ANALYSIS

The most well-known method of prospective risk analysis in the field of RO is likely to be FMEA, which was described in detail as it applies to the field specifically by AAPM TG-100.[12] Other methods included in this report are process mapping (often a subcomponent of FMEA) and fault tree analysis.

FMEA begins with composing a multidisciplinary team of RO professionals. FMEA cannot be performed by a single individual—representatives from all parts of a given workflow should be included. One of the first steps is to create a process map, which is a visual representation

of the process being analyzed by the FMEA. Through the creation of the process map, it quickly becomes clear why a multidisciplinary team is needed, because one individual rarely understands the complete details of an entire workflow. TG-100 contains an example process map for intensity-modulated radiation therapy (IMRT), and numerous other publications have included process maps for other workflows in the field. However, because each radiotherapy program has unique aspects, it is encouraged that an individual institution creates its own process maps, even if a published example is used to start.

The next step is to use the process map to identify potential failure modes and their associated effect(s). The set of failure modes is then "scored," typically on a scale of 1 to 10, in three categories: severity, occurrence, and detectability. A risk priority number is generated by multiplying the three scores together. The purpose of the scoring is 2-fold: first, to identify any high-risk failure modes, which should be addressed urgently, and second, to order the remaining failure modes according to risk in order to prioritize additional safety interventions. TG-100 included example scales in each of the three categories; however, some publications have used alternative scales tailored to the specific process being addressed.[115] A key point is that all team members who score failure modes should have the same understanding of both the individual failure modes and effects, as well as how to apply the scales, such that the final ranking is accurate.

FMEA is a time-intensive process that has been used in the field of RO with varying degrees of success. Efforts have been made to streamline the process[116] to make it more accessible to the RO community.[117]

RETROSPECTIVE RISK ANALYSIS

Before appropriate changes can be made in response to a safety event, two things must occur: one, knowing that the event happened and two, understanding why it happened. Here, we discuss ILS, as a method of reporting events, and RCA, as a method of understanding the underlying causes of an event.

Incident Learning Systems

ILS allows patient safety events to be reported by individuals after an event has occurred. Perceived unsafe conditions may also be reported. These reports allow the retrospective analysis of events by a multidisciplinary team of individuals who can then provide and enact recommendations based on the report.

Efforts have been made in some countries to create a system of pooled incidents for large-scale learning. Examples include the Radiation Oncology Safety Information System sponsored by European Society for Radiotherapy and Oncology, Safety in Radiation Oncology (SAFRON) sponsored by the International Atomic Energy Agency, the RO-ILS sponsored by multiple professional societies and commercial organizations in the United States, and the Radiotherapy Incident Reporting and Analysis System in use by the U.S. Veterans Health Affairs enterprise. There are many other national ILS programs in operation.

Previously, Ford et al,[6,118] as part of AAPM's Work Group on Prevention of Errors in Radiation Oncology, described consensus recommendations for how ILS programs could be structured for use in RO. In 2018, Ford and Evans[119] provided an overview of ILS in RO, including how they can be used on a department level for patient safety improvements. Importantly, ILS programs can only be successful when there is a robust culture of safety in place, where individuals can feel safe to honestly report and openly discuss events. In 2020, the World Health Organization provided further guidance on how these systems can be used and their associated limitations, noting that their use in health care had still not matched "the scale and speed that compares with some other high-risk industries."[120]

Although there are limitations to retrospective risk analysis using ILSs, prior publications have described their use in RO and subsequent improvements in patient safety. For example, Kusano et al[37] and Mazur et al[121] both demonstrated an improvement in patient safety culture in the presence of a departmental ILS program. It must be emphasized that the objective of reporting is not to simply collect as many reports as possible but instead to learn from them, identifying issues that require further investigation or intervention.[122,123]

To begin an ILS program, departments must make a number of decisions as to how the system will be implemented, used, and maintained. The first such decision is whether the department will use an existing national system

or use a custom in-house or hospital-based system (or a combination of these). The use of a pooled system such as those listed earlier enables learning across multiple institutions. To support impactful event analysis, a standard terminology library and taxonomy should be used, such as the one developed by the AAPM.[6] The system should be designed for ease of use to mitigate one of the most common reasons for not reporting, which is a lack of time available to report.[124] Individuals should be trained in how to use the system and how to complete an event narrative that provides enough detail for investigation without directing blame at any individuals.

Root Cause Analysis and the London Protocol

RCA is a method of retrospectively determining the underlying cause(s) of an error. When a safety event occurs in the process of radiotherapy, it can be tempting to draw immediate conclusions as to the cause of the event. These causes are often defined in terms of a "lack of" something, such as lack of communication or lack of time to complete a task, the solution to which is then to add more of the thing that is lacking. However, this rush to implement solutions without fully understanding the causal factors of the event can lead to bloated and ineffectual workflows and QA programs.

The goal of an RCA is to fully understand the details of a safety event and why it happened, such that effective solutions can be put into place to reduce the likelihood of similar events happening again. Focusing first on understanding the event as opposed to proposing solutions is a key aspect. With the understanding that human beings are fallible and make mistakes, the RCA should look to workflow and process-based solutions instead of blaming individuals.

Understanding the underlying cause of an event involves asking a series of "why" questions, reaching as deep into the process as possible.[125] Similar to FMEA, the RCA team should be multidisciplinary and include team members from all relevant parts of the workflow so that the "why" questions can be answered correctly. An effort to be made to avoid giving an answer that involves the "lack of" something, as described above, because this presupposes that the solution is to add more of whatever is lacking. The VHA National Center for Patient Safety offers an overview of RCA with associated examples on their website.[126]

Similar to an RCA, the London Protocol, as mentioned earlier in this chapter, attempts to determine contributing factors to an event. In addition, this method takes the approach that often it is a chain of events that leads to the final outcome rather than one or a few "root causes." It also takes the goal of the investigation one step forward from RCA, from determining why a given event occurred to finding ways to achieve a safer health care system.[8]

As an example of determining root causes, consider a medical event where the wrong vertebral body was treated during a course of spine SBRT. The patient was treated with nonstandard immobilization because they were also being treated to other bony sites during the same course. Larger than normal shifts after imaging were noted during treatment, but this was attributed to the nonstandard immobilization and, therefore, the misalignment was not caught prior to treatment. A potential immediate reaction to this event description is that nonstandard immobilization should not be allowed for spine SBRT and that the patient in question should have used two independent immobilization methods at the treatment unit. However, upon closer investigation of the event, it was discovered that a narrow field of view cone-beam CT was acquired as part of image guided radiation therapy (IGRT), such that there were no indisputable anatomic landmarks present and that the use of auto-registration software created an anchoring bias that was difficult to overcome. The complexity of the patient's treatment (multiple sites, patient in pain and needing to get off the table quickly, specialty SBRT workflow, multiple personnel present at the treatment unit and varied personnel by day, pressure to complete treatment within a given treatment times lot) were all contributing factors that together produced the negative outcome, and a change to any one of these may have altered the outcome. Often, one of the first urges in error analysis is to add additional checks or disallow certain workflows. However, care must be taken to ensure that these changes produce the desired impact, which always must be to create a safer health care system. Additional checks and QA procedures are not added without cost. They take away time that team members have to perform other work that may be equally as vital. The patient in this example was treated in a single immobilization because they were in a great deal of pain and the goal was to complete treatment as quickly as possible. Before enforcing restrictions on the types of allowed

immobilization, all relevant team members should be consulted to ensure the consequences of these decisions are fully understood.

ARTIFICIAL INTELLIGENCE AS A QUALITY AND SAFETY TOOL

Integrating AI algorithms into the quality and safety workflow is a rapidly evolving area of investigation.[127] One of the most appealing use cases for AI is as an additional "set of eyes" to confirm optimal plan creation and delivery. In some clinical contexts, auto-segmentation of both targets and OARs by AI tools can result in contours on par with those created by human experts.[128,129] By extension, AI tools could be utilized to assess and correct contours from another source. Though such tools require additional layers of complexity (such as determining whether a contour deviation is clinically meaningful and warrants attention or integrating clinical information beyond the information supplied to AI), models have demonstrated an ability to flag deliberate contouring errors[130] or suboptimal auto-contours[131,132] in experimental validation data sets. Some models are undergoing prospective validation in the trial setting; for example, in ongoing cooperative group trials, AI scoring algorithms are being compared to human expert scoring of submitted patient contours as part of trial QA.[133,134] Physics plan and chart review can also be supplemented with the addition of AI tools. Error detection algorithms have been developed that have the capability to assist pretreatment plan checks by flagging plan parameters (ie, stage, dose, and treatment technique) that have low probability of coexisting based on historical practice patterns.[135,136] Patient-specific and machine QA have been performed by validated AI tools in such contexts as IMRT QA[137] and predicting machine failure[138] and may serve to augment current human-performed workflows. It must also be understood that AI offers new potential pathways for failure; prospective risk analysis should be performed with the introduction of AI tools into clinical practice, along with ongoing monitoring of output accuracy over time.[139] Finally, supplanting human performance of QA and safety checks entirely with AI or other automated processes would be a grave error, given the known existence of automation bias[140] and the need for decision-making currently beyond the capability of AI.

ETHICS OF ERROR DISCLOSURE

Despite our best efforts, any health care provider reading this chapter is statistically likely to have an error reach a patient at some point during their career.[141,142] When this occurs, it can have long-lasting effects on patients, the provider-patient relationship, and the providers themselves. The steps taken after an error occurs can mitigate or exacerbate these potential consequences. Thus, aside from analyzing the event to prevent future occurrences, the immediate effects of the error must be managed responsibly.

After an error that impacts a patient is recognized, it should be promptly disclosed to the patient. Does this mean all errors? Debate exists about this, but some suggest that a reasonable threshold for disclosure is that which requires additional care (more frequent lab draws, a replan, etc).[143] This can be an extremely challenging conversation, and providers should prepare by learning about the error in as much detail as time allows prior to the meeting and rehearse what they intend to communicate. Some institutions have disclosure coaches who are specially trained to prepare a physician for this conversation (typically, but not always, the physician involved in treatment will disclose the error). The ultimate objective is disclosure in a manner that serves the patient's needs. This includes delivering the bad news in a straightforward manner, assuming a humble conversational posture, nonjudgmental listening, providing ample opportunity for the patient to express their feelings, and, ultimately, provide a path forward for remedy of the situation in a manner that fits with the patient's goals and desires.[144] Risk management involvement can provide guidance and assist providers through this process and provide resources to patients and their families to help address the consequences of the error. It is important to note that conjecture has no place in this disclosure. Prompt disclosure means that much is yet to be known about the event, and the patient should be advised that some of their questions cannot be answered, and a date for a follow-up conversation should be given.

It must be acknowledged that a stance of "deny and defend" was prevalent through much of the 20th century. This was rationalized by the assumption that informing patients of an error would only harm them further by jeopardizing the doctor- patient relationship or contributing to

psychological distress. Both ethical and practical arguments can be made for prompt error disclosure. First, it is the only way to uphold patient autonomy, a key tenant of patient-centered care. Knowing a mistake was made may understandably lead a patient to reassess their future options—whether that means seeking care elsewhere, seeking a different type of care, or seeking additional care (such as additional lab or imaging testing) on top of the current regimen. Autonomy is absent from care if relevant information is being kept from a patient. Second, error disclosure has been shown to reduce medical legal costs and improve patient satisfaction following an error. If a patient is suspicious that information is being withheld, they are more likely to hire a lawyer and begin a costly and contentious discovery process. While early settlements are often provided on ethical grounds, they also reflect the understanding at an administrative level that open acknowledgment and apology are of interest to all parties involved.[144-146] (Sue Paper on error disclosure, citation on decreased costs with early disclosure/settlement, citation on provider perception correlating with litigiousness.)

THE IMPAIRED COLLEAGUE

In a "just culture," it is not only acceptable but expected that departmental members hold each other to account.[85] If one staff member notices a potential mistake during their practice, they are expected to report that mistake, even if they were not directly involved. This action is performed with the understanding that the purpose of reporting is not to distribute blame, but to make systematic changes that improve outcomes. This holds true in the situation of an impaired colleague.

Colleagues may be impaired for several reasons. Sleep deprivation, distraction, and, in more severe cases, mental health crises or substance abuse issues may compromise a staff member's ability to perform their role safely. In the event of a report of this nature, a confidential investigation should be undertaken to determine whether suspected impairment did indeed occur, if there has been a pattern of such behavior occurring, corrective steps and appropriate monitoring for the impaired individual going forward, and institutional safeguards to prevent future episodes from compromising care (should they arise).[147] Although tremendously

challenging, it is critical to be able to get help for impaired colleagues, ideally without affecting their future ability to practice once recovered.

SECOND VICTIM PHENOMENON

Errors, even if detected before the patient comes to any resulting harm, can have a lasting effect on those involved. Intrusive feelings of guilt, doubt, fear, and regret are common, and this emotional distress can impair a provider's ability to provide care and diminish interest in further practice.[5,142] Health care workers experiencing trauma from a committed error have been referred to as "second victims."[148,149] The consequences of error can thus ripple outward, depriving a community of a practitioner who is most likely skilled, compassionate, and no more risk prone than anyone else in their role.

The second victim phenomenon is perpetuated by long-standing toxic components of the health care system. Health care settings are high stress with long work hours, high patient volume, and regular interaction with complex patient cases, all of which can instill doubt and vulnerability. A blame-oriented culture, where errors are met with inquisitional, punitive measures rather than a focus on improvement, exacerbates the distress experienced by second victims. Lack of support for providers managing these feelings of failure or inadequacy further compound the distress experienced.

Preventing disengagement, burnout, and dropout because of the second victim phenomenon is an important element of a robust safety culture. Making provider workload reasonable and shifting away from a culture of blame are obvious steps with other safety benefits. Active steps in the event of a case of second victimhood may be beneficial as well.[149] Surveys of health care providers suggest that early, proactive intervention leads to subjective improvement in undesired "symptoms" of second victimhood after the episode.[149-151] These interventions may include peer counseling with a focus on the emotions and experience of the provider. To ensure this occurs rapidly, at some centers, this "emotional first aid" has been triggered by activation of an on-call pager (much like medical "codes" for other urgent care issues).[150,151] Longer term counseling with psychologists may be helpful, given the risk of symptoms similar to post-traumatic stress

disorder.[152,153] Finally, support from colleagues during clinical duties immediately following a safety event can be reassuring. Interestingly, this has long been a practice in other industries with a strong safety track record.[154] Time-off clinical duties following an incident can provide space to process and come to terms with the acute feelings naturally accompanying a safety event. It can be difficult to effectively engage in care with clarity and presence of mind until the acute feelings associated with an error are processed, and a majority of surveyed providers expressed strong support for emergent cross-coverage in the event of a significant error.[149]

Not all errors induce the "second victim phenomenon," but when they do, the consequences can be severe. History of error has been associated with suicidality and substance abuse, and while data suggest most individuals do recover from the effects of an error, a significant proportion reports never recovering.[149,155,156] Any departmental quality and safety committee should thus ensure that involved staff receive careful and empathetic attention.

FUTURE DIRECTIONS

The U.S. aviation industry has long been touted as exemplifying the gold standard safety framework. The industry has a historic track record of avoidance of catastrophic failure despite operation of advanced technology in circumstances that can be unpredictable and pressured, and parlance from the aviation industry has penetrated other industries looking to replicate its success. However, it is humbling and frightening that even this highly tuned system has in recent times come under stress, resulting in an uncomfortable spike in close calls.[157] Similarly, though we have arguably produced few high-profile RO safety incidents over the past decade, this is not a sign that we can coast on current practices. We must continue to adapt to the challenges to patient safety that come our way and be humble in acknowledging our limitations as health care workers. It will be important to prospectively test and continuously improve features increasing the quality, reliability, and efficiency of the treatment we deliver, and for everyone in our field to keep abreast of developments in this research space.

This should start with instructing our trainees in the importance of quality improvement and being open about our own experiences. We must share teachable moments and overcome the embarrassment of sharing our own

failings with colleagues. As previously referenced, there is unlikely to be an experienced health care provider who has not committed a significant error in the span of a career.[141,142] Those who do not have such cases to report are possibly just the ones who are unwilling to examine their work closely. Contributions to ILS are a way to identify patterns of error early and make the appropriate adjustments at the department or national level. Providing staff the time, instruction, and encouragement to regularly report in these systems allows for them to be used to their full potential.

Finally, while every department should aspire to a culture of safety and consistent, high-quality treatment, this does not mean we should shy away from all risk. Medicine, even the relatively calm waters of RO, is full of uncertainty, incomplete information, and time pressure. A weekend clinical setup for a pediatric cord compression is a physically, emotionally, and intellectually taxing process even with the guardrails discussed above. Every effort can be made to optimize the quality of treatment delivered. However, some degree of risk will always be present, and a cautious embrace of risk is part of our duty to our patients. With a strong safety culture in place, we can at least walk into these challenging situations with confidence and peace of mind.

CHAPTER 14

Methodology of Clinical Trials

Ethan B. Ludmir, Ruitao Lin, Abigail T. Berman, Clifton D. Fuller, and Charles R. Thomas, Jr

In this chapter, we discuss the design, conduct, and analysis of oncology clinical trials, along the way pointing out areas of particular interest to radiation oncology and reviewing some recent ideas in clinical trials and related research studies. This chapter provides only a brief and essentially nontechnical sketch of the main concepts and current research areas, and we refer the reader to comprehensive texts on clinical trial conduct in oncology for further details. A recent monograph[1] and focused texts, including the *Handbook of Statistics in Clinical Oncology*,[2] *Clinical Trials in Oncology*,[3] and *Oncology Clinical Trials: Successful Design, Conduct and Analysis*,[4] provide the fundamentals, as well as up-to-date discussion of new challenges and active research in statistical methods for oncology clinical trials. We have elected to emphasize interventional therapeutic trials.

Clinical trials enable physicians to advance medical care in a safe, scientific, and ethical manner. Formally defined, clinical trials are a set of procedures in medical research conducted to allow safety and efficacy data to be collected for health interventions. A more detailed definition for our purposes would describe a clinical trial as a prospective study that includes an active intervention, carried out in a well-defined patient cohort and producing interpretable information about the action of the intervention; notably, this definition characterizes an interventional trial, contrasted with an observational trial that is largely outside the scope of this chapter.[5] Although in some ways similar to a well-designed laboratory experiment, the involvement of living human subjects demands adherence to strict ethical principles, while also adding to the complexity of interpretation of the results. The last 70 years have witnessed an unprecedented appreciation of the importance of clinical trials and a consequent surge in the number of clinical trials performed.

Over the course of less than a century, the evidence upon which medicine is practiced has evolved from being entirely empirical into a highly regulated scientific process based on vigorously designed prospective clinical trials tightly overseen by numerous scientific and governmental agencies. Cardinal chapters in the history of clinical trial design and implementation include:

- 1747: James Lind's work on the effect of citrus fruits in the prevention of scurvy among sailors in the Royal Navy.
- 1863: Austin Flint's use of a placebo group for comparison with an experimental treatment in the treatment of rheumatic fever.
- 1947: Nuremberg Codex, a result of the appreciation that much of the medical experimentation performed by physicians in Nazi Germany was both ethically wrong and scientifically uninterpretable.
- 1948: The first double-blind trial, performed by the British Medical Research Council to assess the value of streptomycin in the treatment of tuberculosis.
- 1964: Declaration of Helsinki, ethical guidelines for the performance of clinical trials developed by the World Medical Association, and frequently updated since.
- 2000: Creation of ClinicalTrials.gov website, a registry of clinical trials under the auspices of the National Institutes of Health (NIH).

The performance of high-quality cancer clinical trials involves the cooperation of multiple bodies, so-called stakeholders, including patients with cancer and their families, physicians (who accrue the patients), their operating environment (academic institution or practice), the research team (who run the trial on a day-to-day basis), sponsors (who oversee and fund the trial), independent monitors (to ensure the correct performance of the research team), government regulatory agencies, contract research organizations (who may carry out specific aspect of the trial such as auditing), and medical insurance companies. Modern clinical trials may often require the involvement of translational scientists, clinical psychologists, and experts in quality of life, cost-effectiveness, and myriad other disciplines. The complexity of clinical trials adds to the regulatory work involved; for instance, a multi-institutional federally sponsored

clinical trial protocol will require the approval of at least three different research ethics oversight committees (institutional review boards [IRBs]); within the group coordinating the trial, at each institution that opens the trial to accrue patients, and at the sponsor.

While many phase I and phase II trials are carried out by investigators within a single institution, many larger phase II and most phase III trials are multi-institutional. Thus, clinical trial investigator networks have emerged as important components in the performance of large phase II and III clinical trials. Integrated national cooperative group structures have led to the United States National Cancer Institute's National Clinical Trials Network (NCTN), which includes amalgamated cooperative group structures (including groups now known as Alliance for Clinical Trials in Oncology [Alliance], ECOG-ACRIN Cancer Research Group [ECOG-ACRIN], Children's Oncology Group [COG], NRG Oncology, and SWOG [formerly the Southwest Oncology Group]); the US-based NCTN further includes partnership with the Canadian Cancer Trials Group, and parallels similar groups elsewhere including the European Organisation for Research and Treatment of Cancer.[6] One key cooperative group in the context of radiation oncology is the Radiation Therapy Oncology Group (RTOG), founded by Simon Kramer in 1968, which in 2014 was incorporated into the current NRG Oncology cooperative group (which merged RTOG, the National Surgical Adjuvant Breast and Bowel Project, and the Gynecologic Oncology Group). During its history through 2014, the RTOG activated over 500 protocols and accrued over 110,000 patients to cooperative group studies. This included earlier studies that sought to answer questions regarding radiation dose and fractionation. As cancer therapy became multimodal, the group addressed questions relating to combining systemic therapy (primarily chemotherapy) with radiation therapy. Many recent cooperative group trials through NRG Oncology and other groups seek to combine targeted agents or other novel therapeutics with contemporary radiation therapy techniques.

Clinical trials are exceedingly expensive to perform, with costs continuing to rise due to both increased regulatory oversight and greater trial complexity. For instance, it has been estimated that implementation of the European Union's Clinical Trials Directive (laws and regulations relating to the implementation of good clinical practice (GCP) in the

conduct of clinical trials) led to a doubling of the cost of running noncommercial cancer trials in the UK.[7] Large phase III trials can cost in excess of $250 million, and as a result, clinical trials are frequently financed by the pharmaceutical industry. An unfortunate consequence is that clinical trials are rarely performed on established "generic drugs" where there is little commercial interest in establishing new indications. Conversely, the performance of rigorous clinical trials contributes significantly to the costs involved in the development of new pharmaceutical agents, which are subsequently reflected in the commercial pricing of the product.

This collective dynamic has led to a marked shift in the funding of cancer clinical trials over the last 40 years. Whereas previously the vast majority of late-phase (phase II/III) cancer trials were supported by cooperative groups and their forebears, in the 2010s and early 2020s, over 85% of phase III cancer clinical trials were supported by the biopharmaceutical industry.[8] "Generic drugs" may, conceptually, include many local therapies, including radiotherapy as well as surgery; a recent analysis of ClinicalTrials.gov highlights that only 3% of identified phase III cancer clinical trials from 2002 to 2020 assessed a local therapy.[9] With radiotherapy-based trials underrepresented and underfunded in the current clinical trials landscape, the future of radiotherapy clinical trials remains uncertain, requiring innovative approaches likely with increased collaboration with the biopharmaceutical industry.

RESPONSIBILITIES OF THE PRINCIPAL INVESTIGATOR

Although much progress has been made over the past several decades since the Tuskegee Study and other unethical research debacles came to widespread public attention, there persists an inconsistency in the conduct of rigorous research, both preclinical and clinical, to the extent that it is becoming well known that a significant portion of research results are not readily reproducible.[10] The radiation oncology research community is not immune to this quandary and must be committed to improving the research climate on multiple levels.

High-quality research involving human subjects demands accountability on multiple levels, starting foremost with the *responsibilities* of the principal investigator (PI). While we recommend that prospective PIs

proactively enroll in courses that have been developed by one's IRB, we will briefly summarize some of the essential elements.

All clinical trials must include testable objectives that are based on a sound scientific hypothesis. This necessarily means that a trial must utilize appropriate endpoints that can actually measure whether the objectives have been met. The eligibility, trial design, and statistical power (including estimate of the effect size, accrual, specimen availability, imaging interpretation, and more) must be defined upfront. Molecular assays and imaging should be performed by qualified personnel, ideally in a blinded fashion such that those personnel do not have any knowledge of the outcome for patients enrolled in the study. The study data must be maintained in a secure database at a recognized institution; this is particularly crucial, as increased attention is given to threats of cyberterrorism and the importance of cybersecurity, especially in the field of radiation oncology.[11]

The PI is responsible for making sure that research is conducted in a manner that is consistent with the guidelines of the International Council for Harmonization (ICH) by using accepted best practices, also known as good clinical practice (GCP). To participate in the conduct of clinical trials, the PI will need to review and sign the investigator statement (form Food and Drug Administration [FDA] 1572), which essentially is a voluntary commitment to follow the IRB-approved protocol and related requirements, including all applicable federal, state, and institutional regulations. The PI is responsible for controlling all investigational devices and/or agents for a protocol. For the radiation oncologist, this requires a cadre that may include a diverse collection of members of the research team, including but not limited to nurses, research associates, protocol coordinators, regulatory and budget coordinators, medical physicists, dosimetrists, lead radiation therapists, and multidisciplinary coinvestigators. Finally, the PI must be committed to protecting the rights, safety, and overall welfare of patients who are evaluated and eventually enrolled in the trial.

There are core *qualifications* of the PI. Primarily, the PI should possess the necessary qualifications with respect to educational training and experience to make sure that research, including a clinical trial, can be conducted properly and ethically. The PI should be cognizant of the essentials of GCP and be committed to complying. While intuitive to most

readers, it is necessary to reiterate that the PI should be familiar with the use of investigational treatment approaches, including devices and/or agents. The PI should have a dedicated and substantial time commitment to the successful execution of the trial. This commitment includes reading and approving the protocol as well as being involved in a rational plan to identify and enroll patients, proactively addressing barriers to the conduct of increasingly common ancillary or translational research components of trials, such as procurement of blood, tissue, and/or novel imaging tests. The PI should have an assessment plan to make sure that endpoints are designed and calibrated to measure the objectives of the trial, especially the primary objective. The PI needs to have a team and the necessary resources to conduct the trial; if not, then it is not ethical to open a trial regardless of the scientific enthusiasm or merit; generally, absent sufficient resources and infrastructure, an IRB will prevent a protocol from opening, emphasizing the importance of all of these key components preactivation. The PI must understand that certain tasks are delegated to qualified members of the research team; among these, one important task that may be overlooked is the analysis of trial results—a function for the dedicated biostatistician. Trial analysis and review must be conducted per institutional policy and procedure, often including the role of the Data Safety Monitoring Board (DSMB); anecdotally, many PIs have run afoul of the DSMB by engaging in their own analysis and interpretation of trial results without appropriate involvement of the DSMB. Regulatory considerations are similarly important, as there should be an expectation that routine auditing and expectation by sponsoring organizations, as well as government and institutional regulatory bodies, is normal. Finally, it is critical that the PI is committed to evaluating the results and dissemination to the scientific community via a peer-reviewed manuscript submission, as above, with the involvement and assent of the dedicated biostatistical team as well as DSMB. Presenting meeting abstracts alone undermines the credibility and impact of cancer research.[12]

All patients must submit truly *informed consent* that includes both verbal and written components. The consent *process* is not transactional, but part of a relationship between the patient and the PI. The phases of the consent process include the following:

1. Prestudy review and approval by the IRB
2. During the recruitment of subjects with a number of caveats, the patient must understand, primarily that any conflict of interest (COI) on the part of the PI is proactively disclosed and that subjects can withdraw from the study at any time without prejudice.
3. Prior to beginning the trial, a signed copy of the consent must be given to the patient (or qualified surrogate such as a parent in the case of a pediatric radiation oncology trial) and also remain on file in the official medical record as well as the protocol office.
4. During the trial, any revised consent form must have IRB approval, and new information that can impact the outcome for patients must be proactively shared.

Earlier, we mentioned the concept of GCP. The essential values of GCP are listed below[13]:

- Comply with ethical principles.
- Minimize risk to human subjects.
- Maintain dignity, welfare, and human rights.
- Accurate investigational study product information
- Rigorous peer-reviewed protocol
- IRB review and approval of protocol
- Bioethics review (either separate or in concert with IRB approval)
- PI must be qualified.
- The research team must be qualified to carry out delegated responsibilities.
- Enrolled patients must sign uncoerced and voluntary informed consent (written and verbal).
- Data generated must be accurate and verifiable.
- Study records must be kept confidential in a secure environment and readily made available to auditing and/or regulatory authorizes.
- Investigational produce functionality and manufacturing standards should be verifiable.

- Quality assurance (QA) and quality control must be in place.

Table 14.1 lists questions for the primary investigator to consider.

TABLE 14.1 ESSENTIAL QUESTIONS FOR THE PRIMARY INVESTIGATOR TO CONSIDER

1. It is absolutely critical that the PI be clear on why it is of value to perform the trial and what the rationale is. The scientific insights, including the robustness of the preclinical and other published data, must be understood. Is there a gap in efficacy?
2. If the trial is positive, will a meaningful vertical impact and penetration in the field result? Some trials may prove a proof of concept and others may have a clinical impact.
3. Where does the trial concept lay within the innovation spectrum? If low-risk question, will the field really care about the results, and is the research question worth the investment in resources (ie, time, money, and patients)? If a high-risk question, will the feasibility and dissemination be limited to a few very specialized centers?
4. Does the study have a primary clinical endpoint and what are the pros/cons of candidate endpoints? It is important to have an idea as to how quickly one can determine an early endpoint (ie, response rate), reliability (ie, overall survival), clinical significance, and impact of subsequent factors on the endpoint (ie, PFS vs overall survival). Since no endpoint will be perfect to show an increase in the therapeutic ratio, the PI should have a rationale justification for choosing it.
5. The study must be feasible with respect to scientific, pragmatic, financial, and ethical boundaries.
6. Are you able to assemble the nonphysician investigative team, beginning with an experienced biostatistician? Other component personnel include imaging and basic science investigators, research nurses, study coordinator, pharmacist, regulatory affairs, and IRB.
7. The PI must have dedicated (protected) time to remain engaged in the study.
8. Barriers always exist. It is important that the PI learn, early on, which barriers are permanent vs temporary, which require a doable work-a-round vs a fatal flaw. A mentor who is committed to helping navigate the oncopolitical landscape is valued.
9. It should be clear who and what are competing in this research space. Is a more capable investigator at another institution more capable of executing your original idea? Are your colleagues as enthusiastic about your concept as you are? Is there a competing institutional and/or multi-institution trial that will limit patients? If so, is this a temporary concern?
10. The PI needs to discern if they are ready to start working on the protocol immediately or perhaps at a time in the future. Time management is paramount.
11. Will the study maintain relevancy over the course of the study and for the time it takes for the endpoint results to mature? (see #2 and #4 above)

IRB, institutional review boards; PFS, progression-free survival; PI, principal investigator.

Informed consent remains a key area of focus for clinical trial design and optimization. The Common Rule provides federal guidance on protection of human research subjects.[14] Data suggest that 10% to 20% of modern cancer clinical trials did not appropriately complete or obtain informed consent from patients.[15,16] Furthermore, it is noteworthy that informed consent is not a static concept, but rather continues to evolve now into the 21st century and beyond.[17] Novel trial designs, continued efforts to ensure patients are receiving acceptable therapies irrespective of treatment arm,[18] and the integration of genomic data as well as artificial intelligence all warrant continued attention to the central role of informed consent in patient participation in clinical trials.

OVERVIEW OF ETHICAL CONSIDERATIONS

Parallel to these considerations regarding informed consent, medical ethics are based on the principles of autonomy (the patient's right to refuse or choose their treatment), beneficence (a practitioner should act in the best interest of the patient), nonmaleficence (first, do no harm), justice (fairness and equality), dignity, and honesty. Without due diligence, physicians may infringe upon these principles when encouraging patient participation in clinical trials. Are the physicians confident that the proposed treatment is beneficial and not harmful? Are the potential subjects fully aware of the implications of participation? Do all segments of the population have an equivalent chance to participate and receive potentially better treatment? Despite the universal acceptance of these principles, there have been numerous examples of grossly unethical research being performed in the Western world within living memory. Documents seeking to address these issues include the Nuremberg Code, the Declaration of Helsinki, and the Belmont Report. Emanuel has listed seven requirements that provide a systematic and coherent framework for determining whether clinical research is ethical.[19]

Ethical principles themselves and the creation of guidelines are insufficient to ensure the ethical conduct of medical research. Physicians within Nazi Germany performed atrocities despite the existence of German guidelines published in 1931,[20] reflecting the need for legislation. The International Conference on Harmonisation of Technical Requirements for

Registration of Pharmaceuticals for Human Use (ICH) brought together the regulatory authorities of Europe, Japan, and the United States and experts from the pharmaceutical industry to regulate scientific and technical aspects of pharmaceutical product registration. The ICH guidelines are legally binding in many countries (although not the United States) and are updated every few years, reflecting the increasing sophistication of the field. An example of a recent addition is the introduction of data and safety monitoring committees (DSMCs), an independent group of experts who monitor patient safety and treatment efficacy data while a clinical trial is ongoing (this may include a DSMB as highlighted earlier). Another recent advance is the requirement for the registration of clinical trials, such as through ClinicalTrials.gov. Such registration both improves transparency concerning what clinical trials have been/are being performed and empowers patients to find relevant clinical trials. Notably, while registration has aimed to improve trial transparency, many concerns remain regarding poor compliance with reporting requirements.[21]

OVERVIEW OF TRADITIONAL CLINICAL TRIAL DEVELOPMENT

Traditionally, a new anticancer agent is tested in a three-step process, starting with a small dose-finding trial (phase I), followed by a pilot efficacy trial (phase II), and culminating with a large comparative randomized (phase III) trial. While this development paradigm was created and established in the era of cytotoxic chemotherapies, it continues to be used today in the era of targeted therapies, immunotherapies, and cellular therapies, with some adaptations and innovations that we discuss later. Here, we review the traditional paradigm without technical details, which can be found in many excellent sources for clinical trials design and conduct.[3,5]

Phase I

Phase I trials are the first step in evaluating a treatment in humans. As each treatment carries unique risks, the primary objective of a phase I trial is to assess the safety and tolerability of the treatment at preselected dose levels, with secondary objectives of collecting preliminary efficacy data.[22,23] The dose-limiting toxicity (DLT), commonly defined as any grade 3 to 4

nonhematologic or grade 4 hematologic toxicity at least possibly related to the treatment, is a widely adopted primary endpoint. However, the DLT definition may vary depending on disease types or stages. Given the exploratory nature of phase I trials, researchers typically study three to six dose levels with a limited sample size, usually ranging from 10 to 30 participants. Upon completion, a key goal is to identify the recommended phase II dose (RP2D) for further investigation in subsequent trials. Consequently, phase I oncology trials are often referred to as dose-finding or dose escalation studies.

In the era of cytotoxic chemotherapies, the RP2D is frequently selected as the maximum tolerated dose (MTD), defined as the dose level with a DLT rate closest to or below a prespecified target, typically 25% or 30%. This approach is based on the monotonicity assumption that treatment toxicity and efficacy increase with dose. To ensure patient safety and adherence to ethical standards, phase I trials employ staggered enrollment, starting at a relatively low dose and gradually escalating. Dosing decisions are adaptively made based on the outcomes of previously enrolled patients. Popular designs for MTD determination include the 3+3 rule, the Bayesian optimal interval (BOIN) design, and other Bayesian model-informed designs.[24,25]

The landscape of phase I oncology trials is evolving due to advancements in targeted therapies, immunotherapies, and cellular therapies. These novel agents are generally safer, and efficacy often plateaus at a middle dose rather than continuously increasing with the dose. Consequently, a lower dose may offer similar efficacy with lower toxicity compared to the MTD, optimizing the risk-benefit profile. Traditional phase I trial designs, primarily developed for scenarios where higher doses are assumed to be better, may identify an unnecessarily high RP2D. To address this challenge, innovative phase I/II designs have been developed that concurrently utilize early toxicity and efficacy endpoints to guide dose escalation/de- escalation and final dose selection for targeted agents.[25,26] The Bayesian EffTox design and the BOIN12 design are two widely used examples in both academia and industry. Recently, the US FDA launched the “Project Optimus”[27] initiative to reform dose finding and optimization for anticancer treatments. As a result, an increasing number of novel designs that leverage the totality

of data and employ adaptive strategies are being developed to facilitate dose optimization in oncology.

Phase II

The primary purpose of the phase II trial is to determine the response rate of the treatment, seeking early evidence of clinical activity. An important secondary purpose is to gather more robust adverse event (AE) information at the established dose (eg, RP2D). The primary efficacy endpoint of the phase II trial has traditionally been tumor response, but the duration of response, progression-free survival (PFS), and site-specific activity such as locoregional control are all relevant and well-used among phase II studies. Measures of patient survival (such as overall survival [OS]) are usually secondary endpoints in phase II trials, due to the limited sample size and follow-up duration of these trials. In general, phase II trials are not designed to provide definitive evidence that the test treatment is superior to current options. Modern phase II trials may incorporate several interim analyses over the course of the trial to make "go/no-go" decisions. For example, under Simon's two-stage design framework, a treatment will be terminated early if there is insufficient efficacy observed during the first stage of the trial.

Many phase II trials have traditionally been single-arm studies comparing against a benchmark historical response rate. Reliance on this nonconcurrent external control rate can be highly problematic.[28-30] Furthermore, patient selection factors can influence the results, for example, overall response rates in single-institution phase II trials can be significantly higher than in multicenter studies or subsequent phase III–controlled trials.[31] Randomized phase II trials have historically had a role in multi-arm trials aimed at selecting the best treatment(s) to take forward for further testing,[32] and have more recently become favored as a means of providing more reliable pilot efficacy data.[33] However, the preferred approach is changing as described later.

Phase III

Phase III trials are randomized comparisons between a new treatment regimen that has already shown promise in phase I/II trials and the current

best standard of care (ie, the control). Randomization offers a critical advantage over nonrandomized studies. Specifically, randomization balances the distribution of prognostic factors between treatment arms and assures that treatment is assigned independent of these factors, thereby minimizing or eliminating these effects when comparing outcomes by treatment. When randomization is combined with treatment blinding of patients, researchers, or both, then even subjective outcomes can be assessed with minimal bias. Also, in multicenter studies, randomization can balance any systematic bias of the treating physicians or institutions.

Phase III trials can address one of several types of primary questions. For example, a study can be designed to determine if standard treatment is better than best supportive care. More often, phase III studies are designed to compare a new treatment with the current standard treatment. Phase III studies can also compare two or three different regimens with each other, as well as with standard treatment. Finally, a trial may be designed to demonstrate that a given treatment option is not worse than another by more than a tolerable margin. This last group of trials, known as noninferiority trials, plays an important role in the development of less invasive or less burdensome treatment regimens.

The primary endpoint of phase III trials is the subject of substantial discussion as well. Historically, phase III trials generally utilized a primary endpoint of OS (time to death from any cause), or in certain cases an endpoint such as disease-free survival (DFS). However, only a minority of modern phase III cancer trials utilize OS as the primary endpoint, instead generally favoring a so-called surrogate endpoint such as PFS.[9] Much ink has been spilled regarding the role of such surrogate endpoints, which in the case of PFS are based on radiographic size changes of lesions; surrogate endpoints may or may not be valid based on a number of criteria,[34,35] and similarly may or may not be clinically meaningful to patients if they do not reasonably reflect changes to either quantity or quality of life.[36,37] Given the general acceptance of surrogate endpoints by regulatory agencies such as the Food and Drug Administration in the United States, and the European Medicines Agency in Europe, much attention continues to be given to the selection of appropriate and patient-centered endpoints for phase III trials. This includes ongoing considerations regarding the selection of patient-reported quality of life outcomes as primary endpoints,[38] high-resolution,

targeted, and valid surrogate endpoint for precision oncology trials,[39] and beyond.

Phase III trials aim to definitively demonstrate benefit and potentially change the current standard of care. Therefore, the number of participants and follow-up period required for a phase III trial are generally significantly greater than in phase II trials. Notably, surrogate endpoints aim to mitigate these factors in phase III trials by measuring "earlier" events (such as lesion growth as an "event" for PFS, compared with death for OS), conceivably allowing trials to reach primary endpoint results sooner and with fewer patients enrolled (concomitantly decreasing trial costs). Important secondary endpoints can include locoregional control and other site-specific failure or disease control endpoints, AE profiles, and quality of life measures.

Phase IV

Phase IV trial is also known as postmarketing surveillance trial. Phase IV trials involve the safety surveillance of a drug after it receives regulatory approval for standard use. The safety surveillance is designed to detect any rare or long-term adverse effects over a much larger patient population and longer time period than was possible during the phase I-III clinical trials.

Phase 0 or Window Studies

The goal of phase 0 trials is to evaluate the pharmacodynamics (PD) and/or pharmacokinetics (PK) of an antitumor modality prior to traditional phase I studies[40].

PD is considered to represent "what the modality does to the body," while PK measures "what the body does to the modality," be it radiation and/or a systemic agent.[41] PD parameters may include nadir hematologic counts, nonhematologic toxicity, molecular correlates, and/or imaging endpoints. PK parameters such as C_{max}, AUC (area under the curve drug exposure), half-life, and clearance, all help to quantitate absorption, distribution, metabolism, and/or excretion of an agent. This can impact the bioavailability of an agent that is intended to sensitize radiation. Phase 0 studies can help to refine a target or biomarker assay for drug impact in

human samples by incorporating methods developed and validated in representative preclinical models.

Therapeutic clinical trials in radiation oncology typically involve the introduction of new technologies (eg, the use of stereotactic body radiation for a new indication) or more frequently the novel combination of radiation therapy with a systemic agent. There are unique challenges—biologic and clinical—that characterize clinical trials in radiation oncology compared to those not involving radiation.

Response rate is frequently used in early-phase medical oncology trials to indicate activity for a systemic therapy; however, since radiation therapy itself is highly effective at shrinking tumors, this endpoint is not useful in radiation trials. A more appropriate "activity" endpoint for radiation trials may be PFS, but this itself is often difficult to objectively assess. Modern imaging endpoints (such as FDG uptake or other radiomic features) show promise as early read-outs of activity, but still require vigorous validation for individual disease sites. Furthermore, efficacy and toxicity endpoints in radiation trials are dependent on multiple biologic factors including size of the target, the proximity of the tumor to sensitive normal tissues, accuracy of target volume definition, degree of patient immobilization, dose of radiation, and fractionation scheme. Consequently, quality assurance measures are an essential feature of radiation trials, especially in the multi-institutional setting.[42,43,209] Inadequate QA and lack of consistency in radiation delivery have led to the conclusions obtained from large expensive clinical trials being questioned.[44-50] As an example, we turn to the RTOG 9704 trial that evaluated postoperative adjuvant chemoradiation treatment of pancreatic cancer; subtle protocol violations in target definition influenced both toxicity and survival.[51] The impact of high-quality radiotherapy QA on patient outcomes in clinical trials has been demonstrated numerous times,[52-54] and the importance of such QA has only grown with increased sophistication and diversity of radiation oncology tools and techniques, including intensity-modulated radiotherapy, stereotactic body radiotherapy, stereotactic radiosurgery, particle therapy, brachytherapy, and more.[43]

In medical oncology trials, AEs typically occur during or within days of completing treatment. In contrast, toxicity following radiation therapy may follow a biphasic course, early (within 3 months of starting treatment) and

late (months to years later). Late toxicity is typically irreversible and hence important in determining the tolerability of an experimental treatment. Although utilizing long-term toxicity as the primary endpoint in clinical trials is not practical, it is nonetheless imperative to collect and report robust information on long-term outcomes from radiation therapy trials. In fact, even in phase I radiation therapy trials, the follow-up period can be substantially longer than for those evaluating chemotherapy. An approach to dose escalation in phase I trials that considers late toxicities when deciding whether to advance to the next dosing level is discussed later.[55]

A further difference relates to the population studied. In medical oncology early-phase trials, participants have often received several lines of treatment and lack further therapeutic options. In contrast, patients on phase I radiation trials typically receive full-dose radiation treatment, and subjects may be treatment naive. Furthermore, phase I trials in medical oncology are frequently "first in human" experience for the agent; toxicity is unpredictable, and pharmacokinetic studies are essential. Conversely, most multimodality phase I trials in radiation oncology involve systemic agents that have already been through extensive clinical testing; systemic toxicity is known, and pharmacokinetic studies are of generally more limited utility. The purpose of the trial is to define the extent of local toxicity within the radiation field or the extent of radioprotection afforded by a combination radioprotective agent; consequently, radiation oncology phase I trials are more likely to be organ specific/field confined. One study demonstrated that in reality, radiation phase I trials rarely utilize "first-in human" agents, are associated with qualitatively predictable toxicity, and are comparatively safe.[56] Other data suggest that phase I assessments of combination approaches of radiotherapy with novel anticancer agents occur earlier and earlier in the "life cycle" of novel systemic therapies.[57]

STATISTICAL ISSUES IN CLINICAL TRIAL DESIGN

Patient Population Definition and Stratification

A key issue in a clinical trial is a well-defined patient population to which the potential therapy applies. This is typically defined in terms of traditional disease characteristics reflecting putative prognosis, such as stage or its components. Increasingly, tumor pathology or marker features, as well as

genomic data, may be included. In any case, these must be unambiguously defined. Because factors defining eligibility are often critically related to prognosis, any randomized comparative study may use a stratified randomization approach to ensure equal representation of prognostic risk among treatment arms. Stratification factors need to be limited to a reasonable number since the total number of strata equals the product of the number of categories for each. For example, in a completed RTOG prostate cancer trial (RTOG 9408), stratification factors consisted of two levels of Prostate-Specific Antigen (PSA) (<4 vs 4-20), three cell differentiation categories (well, moderate, poor), and nodal status (N0 vs NX).[58] The possible combinations of these variables create $2 \times 3 \times 2 = 12$ strata within which treatments are to be balanced in allocation.

Randomization

Randomization is used differently in different phases of development but serves a similar purpose, which is to render treatment groups similar (to each other) with respect to factors other than treatment allocation that can influence outcomes. In phase I trials, there typically are no comparative groups, although there are situations where parallel cohorts of patients are being evaluated, and thus randomization into cohorts assures that these groups can be compared later for response biomarkers or other factors of interest. In phase II trials, randomization has been used in two similar but distinct ways. First, so-called selection designs have been used to help decide which of several potential candidate treatments to take forward to further definitive testing ("pick the winner," so to speak).[32] In these trials, interest is not in statistically significant differences between treatments, but rather the ability to nominally rank candidate therapies or approaches in terms of best potential efficacy. It can be shown that this approach has a high probability of identifying the most likely superior arm, but at the cost of false-positive findings, particularly if misused.[59] A second role of randomization in phase II trials is to provide evidence, albeit at a less stringent criteria, that a test treatment is indeed promising, conceivably against the current standard of care.[33] In phase III trials, randomization is critical for definitive unbiased evaluation of an experimental therapy against a standard-of-care control.

Regarding implementation, randomization assignments can be simple, or more commonly, implemented using blocking or dynamic approaches with respect to balancing treatment arms by key factors, such as stratification variables mentioned earlier. A number of proven methods are available.[5] Innovative adaptive randomization strategies have been developed to achieve important goals beyond balancing patient populations between arms. In adaptive randomization, the probability of assigning patients to each arm is adaptively modified based on predefined rules and observed trial data.[60,61] For instance, outcome-adaptive randomization can allocate more patients to the better-performing arm or the arm that provides the highest inference precision. The strategy of adaptively allocating more patients to the better-performing arm has several appealing features, such as increasing patient enthusiasm for enrollment and addressing ethical concerns. Similarly, covariate-adaptive randomization periodically assesses imbalances in patient characteristics between treatment and control arms and assigns new patients to minimize these imbalances.

It is important to note that investigators must protect against practices that can erode or nullify the benefits of randomization. Any breach of the random assignment process has an irreparable effect on the validity of the trial. Second, a large number (or differential number per treatment arm) of patient withdrawals can make the validity of the comparison suspect. Similarly, differential follow-up and consequently ascertainment of patient status between treatment arms can bias the treatment effect estimate; differential censoring by the treatment arm can also create a substantial source of bias.[62,63] Third, bias in the assessment of outcomes can have a major impact on the estimated treatment effect, and thus objective outcome measures and blinding of treatment assignment become important. Treatment assignment blinding is often not feasible for radiotherapy and other local therapy trials (in contrast to systemic therapy trials which may more readily be amenable to blinding of both patients and investigators —“double-blinding”). Irrespective of blinding, and particularly for trials where patients and/or investigators are unblinded, unambiguous and objectively defined endpoints are crucial. In cases where determination of the endpoint involves possible observer subjectivity, such as when reading a diagnostic scan to determine disease progression, keeping assessors unaware of treatment assignment may be necessary. This is relevant for the

commonly utilized method of assessing PFS in late-phase cancer clinical trials, which is the use of blinded independent central review for assessment of progression on radiographic scans.[64]

Phase 1 Studies

The phase team includes the patients, caregivers, biostatisticians, oncologist investigators, clinical trial nurses, research associates and data coordinators, pharmacologist and/or pharmacists, imaging and pathology specialists, along with sponsoring agencies (government, industry, academic, or combinations thereof).

There are multiple types of phase I trials. They may be testing an investigational agent plus another investigational agent, an investigational agent plus an approved modality (ie, radiation therapy [RT]) or agent(s), an approved modality (ie, RT) or agent plus another approved agent(s), an approved or investigational agent with a PK focus (ie, adding a poly (ADP-ribose) polymerase [PARP] inhibitor), or an approved or investigational agent with a PD focus (eg, evaluation using functional imaging).

If RT is tested with a systemic agent, there should be a preclinical rationale to pursue an early-phase human trial. Ideally, there should be convincing preclinical data that indicates the combination is either efficacious (radiation sensitization) and/or shows no overlapping toxicities (toxicity independence). There should be evidence of *in vitro* radiosensitization in human tumor cell lines, in-*vivo* radiosensitization in human tumor models, lack of sensitization of normal tissues, preclinical use of clinically relevant doses, and schedules of agents & RT. Similarly, conceptual frameworks apply for combination approaches that assess radioprotection rather than radiosensitization.

Generally, in the phase I setting, the primary objective is to determine the MTD based on scientifically defined DLTs. The MTD found in phase I stage is often used as the RP2D. DLT is often defined as a toxicity (or toxicities) that is considered serious, typically based on standard criteria of toxicity such as the most recent Common Terminology Criteria for Adverse Events (CTCAE). DLTs must be defined in advance prior to beginning the trial, are protocol specific, and usually based, in the case of a systemic agent, on toxicity seen in the first cycle. The MTD is a dose level that yields

a reasonable rate of DLTs in targeting patient populations. It is a dose that is believed to be efficacious and adequately safe. A dose higher than the MTD is considered unacceptable. The secondary objectives of phase I studies are to define the toxicity profile of new therapy(s) or schedule of an existing modality, such as radiotherapy, under evaluation. The PK and PD effects in tumor and/or normal tissues can be determined along with a preliminary assessment of antitumor activity.

Phase I

Broadly, the main objective of the phase I trial is to determine the maximum tolerable dose of an agent to be subsequently used in testing for efficacy. Although initially developed in the setting of drug testing, this concept has been adapted to test radiation alone and combined drug/radiation regimens. The basic conceptual approach is that of sequential dose increases, or escalation, in small patient cohorts until the treatment-related AE rate reaches a predetermined level or unexpected toxicity is seen. This stepwise testing in phase I trials determines what is known as the MTD, which is putatively the most effective level at which to evaluate efficacy.

The key parameters to be defined at the outset of a phase I trial include patient eligibility criteria, starting dose and the schedule of dose escalation (which should frame the expected MTD), events comprising the AE/toxicity response and the expected MTD, and finally the escalation design plan.[65] The dominant design for the phase I setting has been the so-called 3+3 approach, where cohorts of three patients are exposed to a given dose, and based on the outcomes in that cohort, de-escalation, escalation, or additional enrollment takes place. There are a large number of other designs, one of which may be particularly suited for radiation therapy trials, as we discuss shortly. It should be appreciated that the MTD is a relative concept that can change over time. For example, hematologic toxicity may be less dose-limiting today than it was before the development of bone marrow stimulators.

Design Challenges

When setting up an early-phase RT trial, it is critical to keep in mind the next step in development. There are several considerations that are paramount, including What should the study doses (including the starting dose) be? How many patients should each cohort include? What is the standard therapy for the tumor site being treated? How quickly can doses be escalated? What is the role of conventional chemotherapy? How should surgery (if appropriate) be integrated? How should chemotherapy be integrated? Can the validation of biomarkers be assessed? and To what extent will a subsequent phase II/III trial utilize a selected or unselected patient population?

A phase I trial can include RT as the single modality undergoing testing. Often, a second modality, such as concomitant systemic therapy, is included. In the latter case, data that will be helpful for the design of the study should include single-agent pharmacokinetic data from a pragmatic and relevant scheduling regimen such as consideration of continuous dosing during RT versus once-a-week dosing. Single-agent pharmacodynamic data including the agent's effect (if known) on a molecular target that is relevant to the interaction between RT and radiation are necessary, alongside safety data.

Dose escalation guidelines have been developed and refined to effectively identify the RP2D. Basic principles of dose escalation include starting with a safe starting dose, minimizing the number of patients treated at subtoxic (potentially subtherapeutic) doses, escalating the dose rapidly in the absence of toxicity, and adjusting the dose slowly in the presence of toxicity.

The Fibonacci sequence typically includes three patients per cohort until the DLT is reached, then an additional three patients are accrued at the dose level. Some of the accelerated titration designs attempt to minimize patients within the early dose levels. Typically, a single patient is enrolled at each cohort until greater than or equal to grade 2 toxicity and then the number of patients accrued at the dose level is increased to three (or perhaps a total of six if that turns out to be the MTD). Standard dose escalation rules are acceptable, especially if multiple agents are being utilized (including conventional chemotherapy). The maximum administered dose (MAD) and MTD may have variable definitions by trial and country of origin but can be conceptually framed as per Figure 14.1. Importantly, the RP2D is often one

dose level below which the DLT occurred in a prespecified proportion of patients (eg, ≥33%).

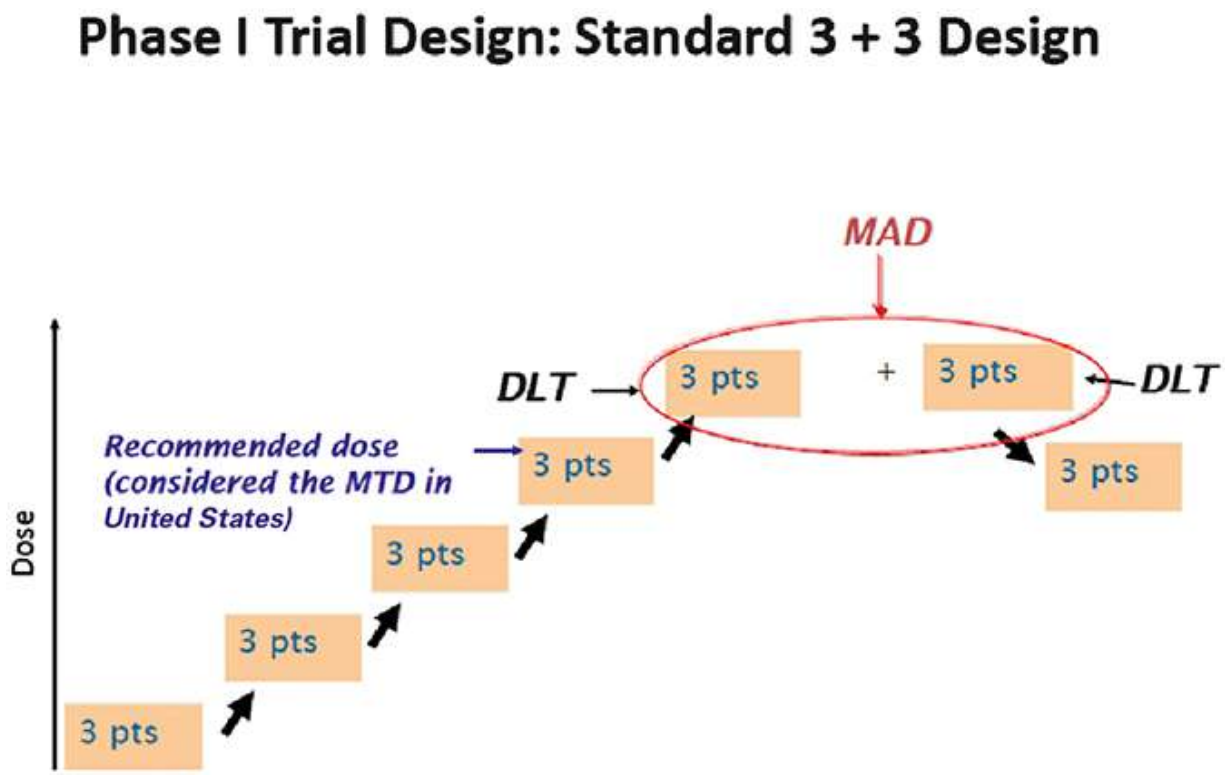

FIGURE 14.1 Example of standard 3+3 phase I design. DLT, dose-limiting toxicity; MAD, maximum administered dose; MTD, maximally tolerated dose.

It is recommended to consider using a toxicity assessment in association with clinical or biologic endpoints. With targeted agents, it may be necessary to define the optimal biologic dose (OBD) as opposed to MTD. OBD is the dose associated with a prespecified desired effect on a biomarker or tumor response while being safe enough (eg, not exceeding the MTD). For example, the OBD may be the modality dose at which greater than or equal to XX% of patients have inhibition of a key target in tumor/surrogate tissues. It may also be the modality dose at which greater than or equal to XX% of patients achieve a prespecified immunologic parameter. Caution is advised since such a biologic endpoint is often considered a surrogate for therapeutic effect, and the validity as well as interpretability of such a surrogate may not be completely understood during the early drug development period.

Patient selection is important in early-phase study design. For example, the tumor site(s) to be studied needs to be defined since this will impact the assessment of toxicity. Not all normal tissues are equal. The selection of tumor site may also be impacted by the agent being used in combination with RT. Also, are the patients being enrolled in a phase I study going to receive curative, palliative, or consolidative radiotherapy? This will affect the total radiation dose and fractionation utilized. This will affect the patient population and perhaps the ability to tolerate combined modality therapy. In general, phase I data are generated from studies that are cancer specific and/or site specific.

Starting dose and schedules of the modality under investigation will need to be defined. If the goal is radiosensitization, then delivery of the agent during as many fractions of radiation is desirable. Timing may be critical. A typical approach, especially in the curative setting, is to start with a standard radiation dose; however, escalation (or even de-escalation) of the radiation dose may be desirable in certain clinical situations.

A limited dose escalation design is also utilized. DLT may include, though are not limited to, the following: grade 4 hematologic toxicity, grade 3 nonhematologic toxicity with exceptions for grade 3 gastrointestinal (nausea and emesis) in the setting of upper abdominal RT, unscheduled breaks during the RT course, inability to administer systemic agent, and/or surgical morbidity for trials where the dose escalation component occurs in the preoperative setting.

As stated earlier, not all normal tissues are equal. A parallel track dose escalation design may allow one to test the combination of one (or more) agent(s) plus different doses of RT for different anatomic disease sites. After the RP2D of the dual-targeted agents is identified and thereafter fixed, the RT dose is escalated.

Lead-in administration of a novel agent, prior to piggybacking onto a standard combined modality backbone, may allow for independent assessment of toxicity as well as evaluation of a biomarker with respect to proof of principle preliminary exploration of possible mechanisms of target inhibition.

In addition, this approach may be particularly helpful in selecting patients for phase II studies. Furthermore, an expanded cohort at the final dose may allow for a more precise evaluation of the biomarker.

Endpoints

In clinical trials, endpoints must be unambiguously defined, be assessable and reproducible, and reflect the action of the intervention. Typically, there is a single primary endpoint in a clinical trial, but there may be numerous secondary endpoints.

Traditionally, in phase II cancer trials, treatment activity has been defined in terms of reduction in tumor burden. The most recent criteria for measuring activity are known as the Response Evaluation Criteria in Solid Tumors (RECIST).[66] The criteria require the identification of target and nontarget lesions at baseline and their largest single dimensions. Categories of response are then defined, for example, complete response (CR, disappearance of all target and nontarget lesions and no new lesions), partial response (PR, 30% or greater decrease in the sum of the longest diameter of all target lesions, no progression of nontarget lesions, and no new lesions), and progressive disease (PD, 20% or greater increase in target lesions, progression of nontarget lesions, or the occurrence of new lesions). A patient not satisfying either response or progression criteria is classified as having a stable disease (SD). Those achieving either a CR or PR are typically defined as objective responders, and the proportion of patients responding is then the primary endpoint of interest. Although widely used, there has long been concern that response defined this way is an inadequate substitute for more clinically relevant and objective endpoints such as survival time. In one study, less than 25% of agents that produced tumor response were eventually found to extend survival in comparative trials,[67] while others suggested that tumor response is a reasonable surrogate for survival extension.[68] Additional problems with the use of response rates in phase II trials include subjectivity and lack of reproducible assessments.[69]

As mentioned earlier, tumor response is not as frequently used when radiation therapy (and local therapies more broadly) is the test question, and in any case, other discrete binary endpoints can readily be used. For example, the proportion free of a given event (ie, proportion alive, proportion recurrence free, etc) at a fixed time landmark such as 2 years is a common and straightforward endpoint. Notably, however, fixed single-timepoint endpoints (eg, 1-year OS or 5-year recurrence-free survival) often

do a disservice in comparative trials in that they ignore information from the "full" survival curves.

A more informative endpoint that is used in many phase II and most phase III trials is the elapsed time from trial entry until the occurrence of some event. The most straightforward of these is OS time or time to death from any cause. This simple endpoint does not depend on adjudication of cause of death and its attendant complexities and naturally corrects for both favorable and unfavorable consequences of treatment. Although it can be verified or even ascertained from public records due to its simplicity, active follow-up per protocol remains of paramount importance. Cause-specific survival endpoints may also be considered, although as mentioned, assigning cause of death is not simple, and one must account for "other cause" deaths and whether these have any relationship to treatment. Also, whenever cause-specific deaths or other site-specific failure endpoints are used, methods for appropriately dealing with competing risks are required.[70,71] Time-to-event outcomes are often subject to censoring due to patient dropout or trial termination. Special care must be taken when analyzing these outcomes in the presence of censoring. Summary statistics such as median survival and restricted mean survival time are widely used to quantify the treatment effect on time-to-event endpoints.

Other commonly used time-to-event endpoints include DFS (time to recurrence or death from any cause) or PFS (time to disease progression, possibly determined via imaging or other assessments at regular intervals), although definitions of these are not standardized (see, for example, Hudis et al[72]) and the specific failure events comprising a given endpoint should be carefully specified. The main advantage of using DFS or PFS is the more rapid rate of events, leading to a smaller required sample size. In many cancer types, benefit with respect to these endpoints does not necessarily imply subsequent lengthened survival, although they may still represent clinical benefit for patients. For other disease settings (eg, adjuvant therapy in colon cancer), DFS may be a reliable and well-accepted primary endpoint that is correlated with survival.[73] This raises the topic of so-called surrogate endpoints, which are endpoints upon which treatment benefits can be reliably measured. Various biomarkers and clinical endpoints have been studied and have been proposed as surrogate endpoints in clinical trials. Prentice specified criteria that a surrogate endpoint must fulfill if it is used

to substitute for a clinical endpoint: the therapeutic intervention must exert benefit on both the surrogate and the clinical endpoint; the surrogate and clinical endpoint must be associated; and the effect of intervention on surrogate endpoint must mediate the clinical effect.[34] An example of a widely studied surrogate marker is a PSA, applied either as a static measure or as dynamic measures (PSA velocity; PSA doubling time; time to PSA nadir, particularly useful after radiation therapy of the intact prostate), to assess time to biochemical failure in patients with nonmetastatic adenocarcinoma of the prostate.[74,75] This continues to be a developing area, and there remain many caveats and cautions regarding surrogate endpoints in clinical trials.[76] We encourage the reader to explore this issue further, particularly regarding the commonly encountered situation in oncology of utilization of surrogate endpoints such as PFS as part of regulatory approvals, potentially in the absence of validity of PFS as a surrogate in diverse disease settings.[37,77-79]

Statistical Power and Sample Size

The overarching design consideration in clinical trials is to obtain sufficient information about an intervention so that a reliable decision can be made regarding its further development or use. In the frequentist statistical hypothesis testing paradigm, one sets up a null hypothesis of no treatment effect and an alternative hypothesis (which one hopes to validate) indicating a treatment effect. The type II or b error equals the probability that a statistical test fails to produce a decision in favor of a treatment effect when in fact the treatment is superior in the population. The complement of this probability (1 − b) is referred to as *statistical power* and equals the probability of correctly deciding in favor of a treatment benefit. Statistical power depends on the other principal parameters considered when planning the trial, specifically the probability of incorrectly finding in favor of a difference when none exists (type I or α error, usually set to 0.05 or 0.01 by convention), the *a priori* specification of a treatment effect that is considered both realistic and clinically material, and of course the sample size. It is imperative that trials be designed to achieve adequate statistical power, typically 0.80 to 0.90 is desirable, so as not to obtain equivocal findings concerning the potential worth of new treatments under

consideration. Studies with low statistical power can cause delay or even abandonment of the development of promising treatments, and waste valuable resources, not least of which is the participation and goodwill of patients.[80] In contrast, a "negative" trial that does not find the test treatment to be superior, if adequately powered, is informative, in that resources can be directed to other more promising alternatives.

Thus, the sample size to satisfy the type I error and the power desired for the specified effect of interest is a key calculation in phase II and III clinical trials (phase I trials generally do not rely on hypothesis-driven sample size calculations, and the sample size derives from the specific design used). The specific sample size calculation depends on the endpoint and technical details will not be provided here, but the two most common types of endpoints can be summarized as follows.

For a discrete binary endpoint in a phase II trial, for example, responded/did not respond, sample size calculations are straightforwardly performed using formulas for comparison of proportions. In a single-arm study, one aims to compare the observed response rate for the new agent to some historical response proportion, p_0, the response rate achievable with standard therapy in the target population. The main objective is to determine whether there is sufficient evidence to conclude that the response rate for the new regimen is greater than p_0. We designate p_A a response rate which, if true, would be clinically material. We test the null hypothesis H_o : $p = p_o$, against the alternative hypothesis H_A : $p = p_A$, The values of p_0 and p_A (and more importantly the difference between p_0 and p_A), along with the sample size, will determine the power of the study. Note that detecting a small improvement (say, ≤10%) requires a large sample size to achieve the desired level of statistical power. For example, given a one-sided type I error rate of 10%, to detect an improvement from a historical value of 20% to 30% with 85% power, over 120 subjects are required. Also, the value for both p_o, and p_A must be realistic; it is of little value to design and carry out a study to detect an effect size $p_A - p_0$ that is unlikely to be realized, simply because it is compatible with the number of patients that can be recruited.

For two-arm randomized phase II trials with discrete endpoints, the above is simply redefined in terms of two-sample comparisons of

proportions, and the sample size is consequently much larger. Finally, if the endpoint is a fixed time landmark such as proportion event-free or alive at 1 year, then the estimates of the proportions may be derived from survival analysis methods to appropriately account for losses to follow-up.

In many randomized phase II and nearly all phase III trials, the time from randomization until the occurrence of the event is of principal interest, rather than the event status at some fixed time landmark. In larger phase II and phase III trials, recruitment may take place over a lengthy interval and each patient will have a different follow-up duration, and the use of follow-up time per patient is more efficient than waiting until all patients have reached some fixed time. The treatment effect measure is then specified in terms of failure *hazards*, which can be thought of as failure rates per unit of time. Hypotheses are thus usually formulated in terms of the hazard ratio (HR) as $H_0 : \lambda_A / \lambda_B = HR = 1.0$, where λ_A and λ_B are the hazards for treatments A and B, versus alternative $H_A : HR < 1.0$, for some value of the HR that represents a clinically important difference in outcomes. A key assumption for many HR-based analyses is that the HR is relatively constant over time (over the length of the survival curve); this assumption can be routinely violated and is discussed later in this chapter. Notably, a common error in the interpretation of the HR is that an HR of 0.75 corresponds to a 25% reduction in the relative risk of the endpoint of interest (eg, a 25% reduction in risk of death for an HR of 0.75 for an endpoint of OS). However, although this is commonly how HR values are reported and interpreted, this does not address the statistical distinction between reduction in hazard versus reduction in risk, which is outside the scope of this chapter but is elaborated on elsewhere in the literature.[81]

From the specification of difference of interest or effect size, then the sample size in terms of the number of *events* required to detect this difference with desired statistical power and significance level is determined. Depending on the anticipated accrual rate and the prognosis (eg, rapidity of failure events) in the control treatment group, the number of *patients* required can then be approximated. The number of events required depends strongly on the HR, becoming dramatically larger as the HR approaches 1.0. The number of patients required, and the total duration of the trial depend on the rate of patient accrual and the failure rate in the

control group, both of which contribute to the determination of how rapidly the requisite events will be observed. The accrual rate is typically estimated from previous experience and may also involve querying investigators to project the accrual rate per unit of time. Similarly, the failure rate for patients under standard therapy is derived from available data. The final computations are often straightforward but generally require computer programs,[82] but under certain assumptions, can be approximated.[83] Sample size methods have been extended to take into account other factors that will influence power, such as patients withdrawing from treatment (drop-out), switching from the assigned treatment to the other group (crossover), or deviating from protocol treatment (noncompliance).[84-86]

Traditionally, the sample size of a phase I trial has been determined based on practical or budgetary considerations. For the 3+3 design, the maximum sample size is theoretically the number of study dose levels multiplied by six. However, due to the early-stopping rules used in the 3+3 design and many other phase I designs, the actual sample size required for a trial may vary. For innovative Bayesian dose-finding designs, a practical approach to specify the sample size is to use the maximum sample size of the 3+3 design. However, computer simulation studies are strongly recommended to calculate the operating characteristics of the design, such as the percentage of correct dose selection and the number of patients overdosed, under a variety of dose-response scenarios to justify the sample size selected.

Interim Analysis and Stopping Rules

Primarily for ethical considerations but also to make the best use of resources, interim analysis plans are used in all phases of clinical trials. These plans provide for early decision-making in a trial regarding continuation, disclosure of findings, or modification of the trial, while preserving integrity of the study with respect to power and type I error control described earlier. These methods are needed because, with repeated hypothesis tests, the probability of at least one test resulting in an erroneous rejection of the null hypothesis increases.

Phase I trials rely on observed cumulative AE rates at a given time to inform dose escalation/de-escalation decisions and determine when to

terminate enrollment at a specific dose level, which are integral components of the trial design. We refer to a review of the designs for more details.[2]

Phase II trials more formally incorporate go/no-go stopping rules, usually restricted to futility/safety stopping, or discontinuation when results do not appear promising. For trials with discrete endpoints such as tumor response, this is accomplished through multistage study designs, whereby a cohort of patients is enrolled and assessed for response, and if a specific minimum response proportion is observed, the trial continues to accrual, otherwise, it discontinues enrollment. Likewise, early stopping for toxicity can occur when an excessive number of patients have experienced the DLT during the trial. The most commonly used designs are those proposed by Simon,[87] although there are other similar approaches. In trials with time-to-event primary endpoints, futility rules similar to those for phase III trials (discussed next) can be used to discontinue after a period of follow-up if results appear unpromising. Early stopping of single-arm phase II trials for extraordinary efficacy is unusual though not prohibited. Early stopping for efficacy can limit patients' access to promising treatments and may result in insufficient data (for other endpoints) at the time of analysis.

Phase III trials commonly use repeated testing strategies derived from an area of statistics known as group sequential methods. Briefly, the primary hypothesis is evaluated at predefined increments (typically 3-5 looks) of the total information (usually in the form of failure events) needed for definitive analysis. The individual tests are designed to (a) protect against spurious early stopping due to the unstable nature of "early" results and (b) correct for the effect of repeated testing on type I error, which can also lead to spurious declaration of treatment effects that may not be reliable. Conceptually, this can be considered through the lens of "alpha spending," where interim analysis boundaries are controlled to prevent inflation of the type I error rate.[88] Commonly used approaches include the Haybittle- Peto approach, for which each test through the penultimate look requires a constant highly significant result, such as $P < .0001$ in order to stop,[89,90] and the O'Brien-Fleming approach and its subsequent approaches,[91] in which the required significance level decreases over the looks, becoming less extreme as more information accumulates. There are many variations and extensions of the latter approach, with different properties and advantages in special circumstances. In addition to efficacy monitoring rules, phase III

trials increasingly incorporate formal futility-stopping rules, although methods such as conditional power calculations have been available and used for some time.[92,93] Futility-stopping rules similarly involve setting a boundary such that when the test statistic falls beyond it, then one considers stopping because the new treatment will not ultimately prevail. Stopping for futility is a complex decision requiring careful consideration,[94] and methods continue to be studied and developed.[95,96]

Definitive Analysis and Secondary Analyses

When the trial reaches maturity either as planned or earlier as a result of the monitoring plan, then definitive analysis takes place. Prior to this, it is not conventional or recommended to disclose any results from the trial.[97]

A critical aspect of clinical trial analysis is the definition of the analyzed cohort. The concept of analysis by *intention-to-treat* (ITT) is often cited for randomized trials, but the definition of this term can sometimes be unclear, so it is best to explicitly describe which patients are included.[98] In the strictest sense, the ITT cohort includes all patients randomized, regardless of eligibility, adherence to assigned treatment, or any other postrandomization deviations from the protocol. However, it is often the case that patients found ineligible for the trial after randomization due to having been incorrectly staged or for other reasons are excluded from the primary analysis, and this practice (used with caution) is sometimes advocated, as it allows for evaluation of the therapy in the population for whom it was intended.[3] A rarely acceptable practice involves exclusion of patients who did not or could not comply with assigned therapy regimens or received nonprotocol therapy, or other postrandomization conditions. Such exclusions can easily lead to biased comparisons, and in general *post hoc* analyses of treatment benefit by dose received carries interpretational difficulties.[99] That said, a more nuanced view of ITT and alternatives is increasingly coming into the fore, with sensitivity analyses for those treated per-protocol or “as-treated” analyses potentially playing an increasing role in trials assessing medical devices, for instance. Depending on the trial design, consideration may be given to non-ITT approaches in consultation with expert statisticians as well as other key stakeholders (including those with regulatory interface or expertise).[100]

The primary analysis methods follow naturally from a well-written protocol (see below) and thus should be straightforward. Given that major journals now generally mandate that study protocols be provided at the time of publication and that regulatory agencies and public sponsors do likewise, it behooves the trialist to outline the analysis plan in the protocol and then carry it out at study conclusion.[101] This does not suggest that additional analyses cannot be carried out, but having a framework for the planned analysis adds credibility to the findings. Deviation from study protocol in the primary endpoint analysis in particular carries substantial implications regarding the veracity and believability of reported data.[102]

Secondary prognostic factor analysis using statistical models or other techniques often follows a primary analysis of phase III trials. Of particular interest is whether there are particularly responsive or nonresponsive subsets of patients, in an attempt to render the findings more relevant to practice. The modeling process, which entails deciding which factors to include, determining the correct way to represent a given factor (ie, in categories, on a continuous scale, etc), consideration of interrelationships (eg, interactions) among factors, and many other issues, can be complex, and it should be recognized that these analyses will be largely viewed as exploratory. While possibly worth exploring, true differential effects of treatment by other factors usually require a large sample size, unless the effects are very large.[103] Analysis of differential treatment effects within subgroups is further subject to low credibility absent appropriate interaction testing, among other elements.[104,105] A comprehensive review of current modeling methods applied to oncology data is provided by Schmoor et al.[103]

PRACTICAL ISSUES IN THE DESIGN, CONDUCT, AND REPORTING OF CLINICAL TRIALS

Protocol Document and Study Conduct

The goal of a clinical trial is to answer a well-formulated question that will change clinical practice. To achieve that, the investigators must know the current state of knowledge on the studied disease; clearly describe the eligibility criteria of the studied population; understand the number of patients who will be eligible in their institution/cooperative group; choose simple and achievable endpoints; establish statistical assumptions based on

a thorough review of preexisting data; and collaborate with a biostatistician to decide on study design, sample size, and power.

The clinical trial protocol document must contain the title, investigators and sponsor's name, phase (I, II, or III), protocol synopsis, background knowledge, study design and schema, objectives, methodology, subject selection criteria, registration procedures, treatment plan, dosing modifications, AEs reporting, data and safety monitoring plan, study calendar, outcome measures, data reporting, statistical considerations, and the informed consent.[106]

Choosing the right study endpoints is crucial, as it needs to reflect the primary goal of the trial. Any number of endpoints may be of suitable scientific and clinical value, but if there is interest in regulatory approval, then obviously the endpoint must reflect the requirements of those parties involved. Overall survival largely remains the "gold standard" for a registration trial designed to gain marketing approval. However, survival length may be affected by effective salvage therapies or by the patient's "crossing over" to the other study arm. Endpoints such as DFS and PFS have been used for either expedited drug approval or regular approval, depending on the disease site.[107] If endpoints subject to assessment bias are to be used (eg, PFS or tumor response), then appropriate bias reduction measures are needed. One approach to circumvent this problem is an independent review panel (eg, radiologists reviewing baseline and follow-up images to quantify tumor responses and note the moment of tumor progression), consisting of experts not associated with the trial and unaware of the arm to which the patient was enrolled; this is discussed further earlier in this chapter. One must also consider the validity of modern endpoints even under unbiased review. For example, the phenomena of pseudoprogression and pseudoresponse have made imaging-based end points, including overall radiographic response and PFS, problematic.[108]

Successful completion of a clinical trial requires constant attention to its practical aspects. Sufficient personnel are necessary in order to ensure the smooth running of the study and the safety of the participating subjects. Clinical research nurses, clinical research associates, data managers, and investigational pharmacists are crucial components of the research team.[109] Of particular importance is the careful and immediate recording and attribution of all AEs. Severe AEs have to be reported promptly to

appropriate regulatory agencies (IRB in the institution where the study is open; FDA and others) and to the study sponsor. Since most protocols have amendments added during their lifetime and new toxicities are reported from other studies, the research protocol commonly evolves over several successive versions. It is highly recommended that in reporting results from clinical trials, trialists not only provide the study protocol as a supplemental material but also a history of protocol changes over the course of a trial's lifetime; this practice is increasingly encouraged to augment transparency and reduce risk of incomplete or incorrect analyses or results reporting.[102] As a result of protocol changes over the course of a trial, new versions of consent forms may be created as well, and IRB approval may again be required. It is imperative that patients enrolled in the study sign the most current version of the consent form. All the prescribed follow-up tests (imaging, blood work, etc) must be scheduled ahead of time and coincide with the study calendar, requiring coordination and organization by research personnel. Departures from any of the procedures are often scored as protocol deviations during periodic audits and will adversely impact the study's validity. Additionally, designated independent medical monitors are assigned to high-risk trials (such as most single-institution investigator-initiated trials) to continuously review any reported events, which are later evaluated periodically by the institutional data safety monitoring committee.

Data and Safety Monitoring Committees

The decision to alter clinical trial in progress, including discontinuation of accrual and/or treatment, depending on its current state), and early release findings is typically vested in an independent DSMC. In addition to evaluating according to the monitoring rules described earlier, the DSMC considers the information available from the trial as well as external information that bears on treatment for the disease under study. Specifically, it should be noted that the early stopping rules described previously are meant to serve as guidelines, and there may at any decision point be additional considerations that must be taken into account.[110] The policies and procedures for cooperative group trials provide a good overview of DSMC structure and function.[111]

Trial Reporting

Once the study is completed and the data are fully analyzed, results should be reported promptly. Publication of the results of the trial in a scientific journal represents the culmination of the investigators' efforts and allows wide distribution of the findings. However, lack of precise requirements for reporting may lead to inaccurate or biased results presentation. The CONSORT (Consolidated Standards of Reporting Trials) statement is used worldwide to improve the quality of reporting of randomized controlled trials (RCTs).[112] It provides a 25-item checklist of all required elements and a flow diagram to ensure that all patients enrolled are accounted for. Most journals require authors to follow the CONSORT guidelines, since "diligent adherence by authors to the checklist items facilitates clarity, completeness, and transparency of reporting."[112] The ICMJE (International Committee of Medical Journal Editors) similarly publishes guidelines on uniform requirements for manuscripts submitted to biomedical journals.[113] There have also been calls for improvements in reporting of phase I and II trials.[114,115] In addition to quality with respect to content, a full disclosure of the financial COI by the investigators to the readers is necessary as well. It is particularly important for investigators to publish negative studies, decreasing the overall incidence of publication bias and trial "dark matter" (unpublished trial results).[12] Study of the publication rate of cancer cooperative group trials regardless of findings shows there is room for improvement with respect to a responsible approach to clinical trial conduct.[116]

In the United States, reporting requirements are currently trending toward an expansion to more "open access" sources, based on mandates arising from legislation. ClinicalTrials.gov is the largest clinical trials database in the world and is led by the National Library of Medicine in the NIH in the United States. Initially, including information only on NIH-sponsored studies, NLM now also contains studies sponsored by pharmaceutical companies and demands "basic results" information not later than 1 year after the study's primary completion date (ClinicalTrials.gov). The requirements for results reporting were prompted by the removal of several drugs from the market due to earlier unrealized toxicity, knowledge about which was obscured by lack of publication or other public documentation.

However, analysis of clinical trials suggests that compliance with federally mandated reporting requirements in ClinicalTrials.gov remains poor, and further efforts at multiple stakeholder levels aim to improve this compliance and transparency.[21]

RECENT APPROACHES TO CLINICAL TRIAL DESIGN

Alternative Phase I Trial Designs for Radiation Oncology Trials

As mentioned earlier, phase I trials in radiation therapy present a unique challenge in that toxicities may occur long after treatment and need to be incorporated into dose evaluation. The traditional stepwise designs do not accommodate this, and thus an extension of the Continual Reassessment Method (CRM)[117] that incorporates the time-to-event (ie, time to toxicity) information for each patient was developed.[118] Designated the TiTE-CRM approach, a dose-response model is first posited that identifies the starting dose and range to be considered, along with a time frame for events occurring anywhere up to T time units from the administration of therapy. Rather than waiting for each cohort of patients to be followed for this length of time, however, one can enter new patients at, say, half-month intervals. As in the original CRM, the first patient is assigned to a dose level based on prior information or, as in the modified CRM, to the lowest candidate dose. At the time the next patient(s) is (are) to be enrolled, the observed toxicities and follow-up up times of patients already entered are used to form an updated estimate of the β parameter that defines the dose-response curve, and the dose level for the next patient(s) selected according to the usual CRM or modified CRM criteria. In simulation studies, the TiTE-CRM produced results comparable to its CRM counterpart, while significantly reducing the average duration of the trial. However, the TiTE-CRM method was associated with slightly more toxicities, particularly in situations where events tend to occur near the end of the observation period, since escalation to the next dose may have already occurred before toxicities were observed.[118] Another problematic issue is rapid accrual, where premature escalation of dose may be indicated. A recent review and suggested modifications may make this approach even more suitable for radiation oncology trials.[119]

The TiTE-CRM design is a model-based design that uses a parametric dose-response model to make dose escalation/de-escalation decisions. Despite its statistical appeal and generally good performance, its application in real clinical trials is limited. Many practitioners consider it statistically and computationally complex due to the requirement of specifying the model and prior, as well as the need for repeated model fitting and estimation. This leads practitioners to perceive dosing decisions as coming from a "black box." On the other hand, model-assisted designs combine the simplicity of the 3+3 design with the good performance of model-based designs. To address late-onset toxicities or rapid accrual, the Time-to-Event Bayesian Optimal Interval (TiTE-BOIN) design,[120] built on the BOIN design (the first FDA-designated fit-for-purpose design for oncology dose finding), has emerged as an easy-to-implement alternative to TiTE-CRM. One of the prominent features of the TiTE-BOIN design is that its rules for dose escalation/de-escalation can be pretabulated before the trial begins, making the trial decision-making process more transparent. For example, the TiTE-BOIN design has been applied to the first-in-human VOYAGER study (NCT03192578) to determine the maximum safe radiation dose of the TheraSphere Prostate Cancer device in patients with clinically localized prostate cancer.

Due to the flexibility and good performance, Bayesian adaptive design for early-phase trials can be further modified to accommodate unique features of radiation oncology.[121] In one recent example, trialists aimed to assess whether an investigational radioprotection agent (vs placebo) would reduce late-onset toxicity for patients with pancreatic cancer; concurrently, investigators were including an RT dose-finding component to the study.[122] Collectively, statisticians developed a Bayesian adaptive approach using two co-primary endpoints of 90-day toxicity rates and 90-day tumor control. This late-onset efficacy/toxicity (LO-ET) design allowed trialists to adaptively randomize enrolled patients to receipt of the investigational radioprotector (vs placebo) as well as RT dose level and identify an "optimal" combination based on both receipt of investigational radioprotector plus RT dose. Promising results of this trial highlight successful implementation and utilization of advanced and adaptive early-phase trial design approaches within radiation oncology.[123]

Alternative Phase II Trial Designs

As indicated earlier, the value of traditional single-arm phase II trials has been called into question in terms of providing a reliable basis for further pursuit of promising treatments. The currently favored design is a randomized phase II trial with a standard-of-care comparison group[29],[33],[124] This approach and the goal of accelerating development has led to consideration enhancements to the phase II design, including adaptive randomization, where one favors enrollment to the arm(s) that seem to be prevailing while reducing probability of enrollment on other arms, and even dropping some treatment arms. This is an idea with a long history,[125] but recent innovations in computing and Bayesian methods, as well as a newfound interest in accelerated development, have brought it to wider use in some settings.[126] In some instances, it may offer advantages but must be weighed against simpler approaches with similar or even greater efficiency.[127]

Changes in therapeutic approaches also suggest design changes. Because primarily cytostatic agents are not expected to necessarily result in tumor response in the traditional sense, there is a need to consider alternative phase II designs based on endpoints other than response rates. For trials enrolling patients who have failed prior therapy, Mick et al[128] propose a method that uses each patient as their own control, comparing the time to progression (possibly censored) under the new agent with the time to progression under prior therapy. Rosner et al[129] propose a randomized discontinuation design to evaluate cytostatic drugs in which all patients are initially treated with the experimental agent. After a specified interval, responders remain on drug and those who progress discontinue, while those patients with SD are randomized to either continued active treatment or placebo. This randomized comparison allows one to assess whether the drug is truly slowing the rate of growth of the tumor, as opposed to the investigators having simply selected patients with slow-growing tumors. Since the patients with SD form a more homogeneous subgroup, this design also requires a smaller sample size than would a trial that randomized all patients at entry. It is important to note that the purpose of this design is to determine whether the drug is active in an explanatory sense. Whether the percentage of patients exhibiting SD is high or low has a bearing on the

efficiency of the approach, since in the latter case the total sample size required may be quite large and any demonstration of activity in the randomized component would only be relevant to a small subset of the population. Korn et al point out other caveats with this design; for example, patients may find it unattractive to potentially discontinue a treatment that they perceive to be helping their disease.[130]

Using Biomarkers as Inclusion Criteria

It is increasingly understood that the response of tumors to targeted agents is highly dependent on their molecular subtype. Consequently, trials increasingly screen for molecular characteristics of tumors to use as eligibility criteria, or at a minimum, stratification factors. Consider, as examples, brain tumor trials requiring specific O[6]-methylguanine-DNA methyltransferase (MGMT) status or head-and-neck cancer trials requiring tumor human papillomavirus (HPV) status at entry for eligibility. When studies enroll sufficient numbers of patients, then treatment by marker synergisms, referred to statistically as interaction effects, can be investigated. Robust evaluation of true differential benefit according to markers requires that treatments be randomized, and so randomized phase II and phase III trials are ideal settings for developing tailored treatments.

In many instances, potentially responsive subsets of patients may be small and may also be identified after trials have initiated enrollment. For instance, anaplastic lymphoma kinase (ALK) inhibitors are highly effective, but only in the 3% to 5% of lung cancers that have *ALK* gene rearrangements. It may simply not be feasible to perform separate phase III trials for each molecular subtype. One possible alternative is "adaptive randomized" trial designs in which the data gathered as the trial progresses are used to change some aspect of the trial as it progresses. Some recent examples are the Biomarker-integrated Approaches of Targeted Therapy for Lung Cancer Elimination (BATTLE) trial in lung cancer[131] and the I-SPY trials in breast cancer.[132] However, there are limitations and challenges to these trial designs. For example, in order to be able to acquire information rapidly enough to undertake weighted randomization favoring more promising arms or eliminate nonresponsive arms, surrogate endpoints such as "disease control rate at 8 weeks" must be used. It is not clear if such

short-term endpoints are relevant to radiation oncology where durable local control is often achieved, and more nuanced considerations may exist still in an emerging field of trials where local therapy is utilized as the primary randomization intervention for patients with metastatic disease. This may include patients with oligometastatic or oligoprogressive disease, and we would direct readers to recent reviews on this subject, including nuances in trial design and execution for the use of radiotherapy in the setting of metastatic cancer.[133,134]

A number of papers in the clinical literature have further provided excellent reviews of the opportunities and challenges involved in incorporating modern molecular medicine into clinical trial design.[135,136]

Innovative Designs

The process of developing drugs, particularly in the field of oncology, is associated with high costs and lengthy timelines. Conventional clinical trials in oncology often employ a "one-treatment-one-cancer-at-a-time" strategy, which can be inefficient and may compromise scientific integrity, resulting in a low rate of success. To address the unmet need for identifying promising therapies for specific patient populations with cancer, researchers have developed sophisticated and innovative trial designs. These include umbrella trials, which investigate multiple treatments for a single cancer type; basket trials, which evaluate a single treatment across multiple cancer types; adaptive enrichment trials, which adaptively modify enrollment criteria based on accrued data; and platform trials, which study multiple treatments and diseases within a master trial infrastructure. Most of these designs are guided by a "master protocol," enabling the concurrent evaluation of several drugs, potentially from different pharmaceutical companies, or various cancer types and subtypes.

An umbrella trial is a type of clinical trial design that evaluates multiple therapeutic agents in patients with the same cancer type but different subtypes, which are determined by genetic mutations or biomarkers. The primary objective of an umbrella trial is to identify the most effective treatment for each specific cancer subtype. A well-known example of an umbrella trial is the BATTLE trial, led by the MD Anderson Cancer Center. This trial investigated four targeted therapies based on biomarkers in

patients with advanced non–small cell lung cancer (NSCLC). The cancer subtypes in the BATTLE trial were defined according to the presence of EGFR mutation/amplification, KRAS and BRAF mutations, VEGF and VEGFR expressions, and CyclinD1/RXR. One notable finding from this trial was that sorafenib demonstrated a higher disease control rate in patients whose tumors expressed KRAS and BRAF mutations.

Basket trials are a type of clinical trial that evaluates the efficacy of a single therapeutic intervention across multiple cancer types sharing a common genetic mutation or biomarker targeted by the treatment. This approach expedites the drug development process by concurrently assessing treatment effectiveness in various cancer types and rapidly advancing those showing promising results to later stages of development. Numerous Bayesian adaptive information borrowing techniques have been developed to facilitate the design and analysis of basket trials. These methods enable information sharing among different cancer types, thereby enhancing trial efficiency and reducing the required sample size. In the field of radiation oncology, the lead-in phase of the EXTEND[137] trial (NCT03599765) serves as an example of a basket trial. This phase investigated the efficacy of local consolidative therapy across diverse histologies, including colorectal, sarcoma, lung, and head and neck cancers, among others. Prostate, breast, pancreatic, and kidney cancers exhibited the highest enrollment rates and were selected for independent accrual in the randomization phase of the trial.[138,139]

Platform trials, also known as “multi-arm, multi-stage” (MAMS) trials, provide an efficient means of evaluating multiple treatments or treatment combinations by comparing their effects to a shared control arm. This design eliminates the white space between traditional one-treatment-versus-control trials, reduces the number of patients allocated to the control arm, and allows for the addition of new treatment arms and adaptive randomization between arms during the trial. The I-SPY2 trial[140,141] is a well-known example of a platform trial, designed as a phase II, multicenter, adaptively randomized study investigating various experimental agents in combination with standard neoadjuvant chemotherapy for patients with high-risk neoadjuvant breast cancer. The primary objective of the I-SPY2 trial is to expedite the identification of promising agents and biomarker profiles that are likely to succeed in subsequent phase III trials. A key

feature of the I-SPY2 trial is its ability to graduate successful regimens, drop unsuccessful ones, and add newly available regimens during the trial, without the need to initiate a new protocol. This approach saves considerable time and accelerates the entire drug development process. To date, the I-SPY2 trial has successfully identified two treatment combinations that demonstrate higher rates of pathologic CR compared to standard therapy alone, warranting further evaluation in phase III trials.

MOVING BEYOND CLINICAL TRIALS

Comparative Effectiveness Research

The randomized phase III clinical trial is considered the most robust method of comparing the efficacy of a new treatment with the standard of care. Grading systems for evaluating clinical evidence universally place "Randomized controlled trials" above observational trials.[142] More recently, this hierarchical approach to scientific evidence has been attacked,[42] and criticisms include the high fiscal cost of clinical trials, the length of time that it takes to obtain a conclusion (by which time the results are frequently no longer relevant since the standard of care has changed), and the large number of trials with negative results.

A specific criticism relates to clinical protocols that typically allow enrollment of only the fittest patients who lack comorbidities and have good performance status, criteria that subsequently limit the generalizability of the results. Studies have indeed shown that, for example, older patients are excluded unnecessarily out of concern for potential AEs[143-146] There have indeed long been calls for simpler and more inclusive eligibility criteria.[147,148]

In some sense, the desire to reduce exclusivity and broaden trial enrollment to more closely match the population is antithetical to "personalized medicine" and more focused trials as mentioned earlier. However, there are some ways in which the two concepts can possibly work in concert. Larger trials that can robustly support subset analysis according to biologic, clinical, and health history/behavior factors can at once be more inclusive and address questions about particularly responsive subgroups.

Another response to the criticism of phase III trials has been a reappreciation of the importance of population-based retrospective studies

as a means to appreciate and assess a treatment's effectiveness in the "real world."[149] Even more useful are well-designed prospective cohort studies, such as the Cancer of the Prostate Strategic Urologic Research Endeavor (CaPSURE) study in prostate cancer, which will provide information on both factors driving treatment choice and the effects of specific intervention strategies[150,151] Another key strategy is conducting trials in parallel with concurrent registries of patients treated according to physician and patient choice and/or common convention, such as the **T**rial **A**ssigning **I**ndividua**L**ized **O**ptions for Treatment (**Rx**) (TAILORx) trial.[152] In this trial, over 10,000 women with breast cancer were screened using a molecular profiling tool, and for those with profiles in the range where the utility of the tool is uncertain, randomization between "hormonal therapy alone" and "hormonal therapy plus chemotherapy" was performed. Although efficacy was similar for the two arms, this trial highlights the effective integration of a molecular profiling tool in trial design.[153]

Meta-Analysis

A formal quantitative means of combining evidence from multiple clinical trials is by meta-analysis, a widely used analytic tool in many areas of social and medical science. Meta-analysis refers to a process whereby data from independent studies are combined to form a quantitative summary estimate of a given effect. Meta-analyses are considered by some to represent so-called level I evidence source along with (often large/phase III) randomized clinical trials. A meta-analysis combines the results of several studies, all of which ask a similar research question, but may be individually too small to have enough statistical power to definitively answer the question. Performing a systematic analysis of data from all identified randomized trials can define a modest but real advantage associated with a new therapeutic approach.

TIME-TO-EVENT CONTINUAL REASSESSMENT METHOD

The TiTE-CRM was initially described by Cheung and Chappell[118] where the time to toxicity was incorporated for each patient. This allows both acute and late toxicity to be accounted for, all while patient enrollment continues. Studies have shown that the TiTE-CRM design is usually more

efficient, treating more patients closer to the MTD and shorter trial durations. Here we will briefly discuss TiTE-CRM in further detail, but note to the reader as highlighted earlier that the ongoing evolution of optimized early-phase trial design continues, with Bayesian methodology (ie, TiTE-BOIN) and other paradigms gaining increased utilization and prominence.

Statistically, the TiTE-CRM design assumes that the hazard of developing toxicity is constant over time. In radiotherapy, that is often not the case. For example, pneumonitis is a subacute toxicity after thoracic radiotherapy that occurs 1 to 6 months after the end of radiotherapy, but not before or after. Therefore, assuming a constant risk for pneumonitis over time is inaccurate.

In radiotherapy, where late toxicity is a major concern, the TiTE-CRM has multiple advantages. Normolle and Lawrence performed a Monte Carlo simulation and found that, compared with a traditional 3+3 design, it can produce more accurate estimates of the MTD and not expose patients to significant excess risk.[55]

One concern in chemoradiotherapy trials is that with fast patient accrual and late toxicities, the TiTE-CRM could lead to overdose. Polley has proposed a modification to the TiTE-CRM[119] using accrual suspension. Bekele et al proposed yet another variation on the TiTE-CRM using time to toxicity. In this model, if the anticipated risk to patients while conducting a trial becomes too high, but then normalizes, the trial is restarted. The authors propose that this affords greater safety than the classic TiTE-CRM, although the trial may take longer (Figure 14.2).[154]

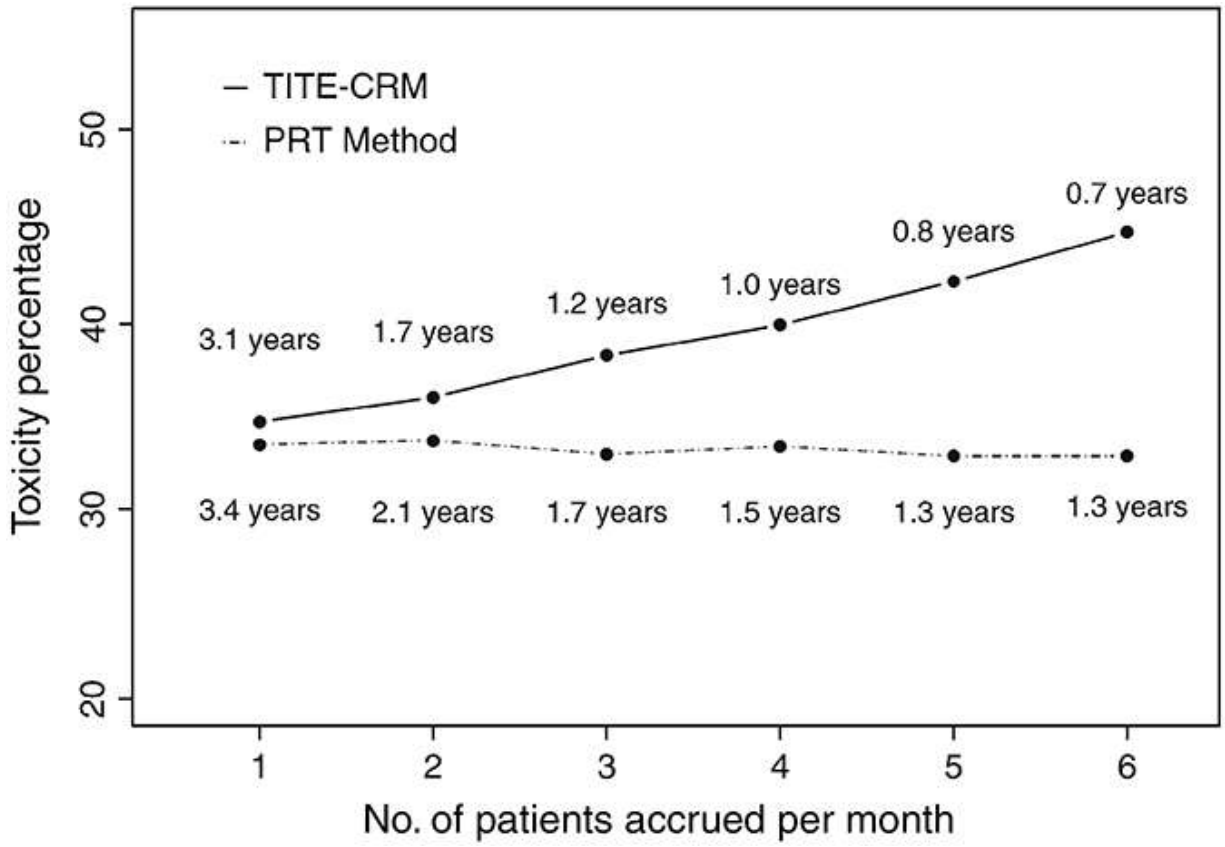

FIGURE 14.2 Comparison of toxicities seen using both methods with different accrual rates. (From Bekele BN, Ji Y, Shen Y, Thall PF. Monitoring late-onset toxicities in phase I trials using predicted risks. *Biostatistics*. 2008;9[3]:442-457. Reproduced by permission of Oxford University Press.)

A radiotherapy-specific model-based method has also been developed. Mehta et al reported on an alternative Bayesian methodology, which determines the probability of pneumonitis as a function of mean normalized lung dose and the dose per fraction is escalated accordingly.[155]

Despite the advantages of CRM design, Rogatko et al have shown that only 1.6% of 1235 phase I cancer trials published between 1991 and 2006 used Bayesian designs.[156] Le Tourneau et al found that only 3.3% of 181 evaluable phase I trials performed from 2007 to 2008 used CRM design (five modified CRM, one TiTE-CRM).[157]

Multiple combined modality therapy studies have used the TiTE-CRM design. For example, in pancreatic cancer, TiTE-CRM has been used in a phase I/II to dose escalate the radiotherapy dose with fixed-dose gemcitabine.[158] It has been used to dose escalate both oxaliplatin and

gemcitabine with fixed-dose radiotherapy.[159] And, lastly, it has been used to escalate cisplatin with fixed-dose gemcitabine and radiotherapy.[160]

Lawrence et al published on the early-stage development of radiosensitizers.[161] They advocated for the use of the TiTE-CRM design in its ability to enroll new patients while simultaneously monitoring for the development of late toxicity and incorporating that data into the model. They specifically note that intrapatient dose escalation is likely not appropriate in trials that use radiotherapy because of the cumulative nature of radiation toxicity. Likewise, TiTE-CRM has been used to dose escalate radiotherapy when combined with radioprotectants, for example, in liver radiation and concurrent amifostine.[162]

Accordingly, there is an urgent need for predictive biomarkers of normal tissue toxicity, particularly for late effects. Finding such biomarkers may hold promise; for instance, the use of troponin and/or N-terminal pro-B-type natriuretic peptide (NT-proBNP) blood levels along with strain analysis of 2D speckle tracking echocardiography may correspond to cardiac toxicity risk.[163-166]

Pitfalls

Chronic and cumulative toxicities usually cannot be assessed and may be missed if long-term follow-up is not incorporated into these study designs effectively. Furthermore, uncommon toxicities may be missed since few patients are enrolled in early-phase trials. Finally, the variations in target delineation by different investigators have the potential to inadvertently impact the toxicity profile. The use of anatomic atlases may help mitigate this critical variable.

History of Phase I RT-Drug Trials

Over the past several decades, most early-phase clinical trials (n = 162 phase I only, n = 66 phase I-II) have utilized a rule-based design for dose escalation, usually a 3+3.[167] RT has only been tested for dose escalation approximately one-eighth of the time when combined with a drug. In these trials, RT was the only modality being tested for dose escalation two-thirds of the time. Only a single anatomic site has been usually studied (98%), with head and neck (20%), lung (18%), brain (11%), and pancreas (10%)

being the most common. Over 90% of published studies did report grade 3 to 4 AEs, with two-fifths (42%) comprising hematologic AEs and 50% nonhematologic (with the plurality being mucositis). The mean number of events described as DLT per number of grade 3 to 4 AE was reported to be four, and the description of the DLT period (mean of 69 days) was only described in nearly two-thirds (62%) of the studies. This published benchmark while helpful cannot account for the much larger number of trials that were never written up in full manuscript form. Career development courses, including those through ASCO (American Society of Clinical Oncology)/AACR (American Association for Cancer Research) Methods in Clinical Cancer Research Vail Workshop, the ECCO (European CanCer Organisation) Methods in Clinical Cancer Research Zeist (formerly Flims) Workshop, and other smaller courses, suggest that the future of an ever-growing cadre of radiation oncology trialists is brighter.

Phase II Trials

The decision to proceed with phase II study is generally dependent on the safety (and often early efficacy) results from the corresponding phase I trial. A major goal of a combined modality study, for instance, is *efficacy* or clinical activity, as defined as increasing the therapeutic window (or therapeutic ratio).[168,169] These trials can screen out suboptimal treatments and identify promising strategies worthy of further validation in a more definitive or confirmatory trial setting. Phase II trials can also provide a more extended safety profile than may have been possible in the phase I trial.

Design

When designing phase II trials involving RT, there are a number of challenges, some of which are unique to the modality and others that are compounded by combined modality therapeutic designs. These include the fact that (1) many phase II studies are of relatively unselected patient populations, (2) they may be introduced in the curative setting (ie, plus/minus RT boost for ductal carcinoma in situ) such that the interval for observation may be extended (ie, years or longer), and (3) the low prioritization from the drug development industry. Because of this latter

reality, there is a prolonged delay (median 6 years [interquartile range 5-8 years]) between the opening of the phase I trial without RT and the opening of phase I with RT.[57] In addition, the median lag time-P between the *published* phase I trial without RT and the *opening* phase I with RT was 3 years (interquartile range 1-6 years).

An important consideration is cost efficiency in the design of the trial, as the PI should seek to minimize the number of patients exposed to an ineffective treatment by enrolling as few patients as "necessary" to show benefit or futility.

One of the most important design decisions is to determine if a single-arm study will suffice or whether a multi-arm trial is preferable. The latter may be required if the historical data for comparison are lacking or considered generally weak, and historical control arms are fraught with anachronistic (among other) challenges. Single-arm studies may include a two-stage design with early stopping rules for futility or lack of response. The most common single-arm trial designs are the Simon 2-stage,[87] the Balanced Design,[170] Gehan 2-stage,[171] and the Fleming 2-stage.[172] These are considered frequentist approaches (as opposed to Bayesian designs). A multi-arm phase II trial may include a (1) phase II selection design (prioritization) or (2) phase II design with a reference control arm (control). The former involves parallel single-arm studies that do not directly compare the arms to each other. They compare each to the "null rate." The Simon "pick the winner" design is an example.[32] This approach is useful when there are more than one candidate for new drugs, new schedules, new doses, or even combinations of different drugs, schedules, and doses to be evaluated. It is not powered to directly compare the treatment efficacies and hence the number of patients needed to complete the study is smaller. On the other hand, a randomized phase II design with a reference control arm directly compares the new treatment with the control treatment. The randomization is effective in removing potential biases that are often unavoidable in single-arm trials where treatment effect of the new treatment (represented by efficacy endpoints, eg, local control, response rate, colostomy-free survival, nodal failure, etc) is indirectly compared with the historical controls. The comparison is indirect in that the point estimate from historical controls is often treated as the null hypothesis in the single-arm trials. Therefore, the uncertainty associated with the estimate is

neglected in the testing. As a consequence, single-arm trials often require a one-third or a smaller sample size compared to randomized two-arm trials with the same hypothesis to be tested. As a trade-off, the findings in the single-arm trial are often much unreliable compared with randomized trials.[173] A practical approach to addressing the issue of large sample sizes in clinical trials is to relax the stringency of the type I error rate. For instance, researchers may consider designing trials with a 15% or 20% type I error rate, rather than adhering to the conventional 5% threshold. However, it is crucial to carefully consider the potential implications of increased type I error rates on the reliability and interpretability of trial results. Much interest in the statistical community also centers on the use of external, synthetic, or other combination control arm approaches.[174]

Phase II studies may often include patients for whom RT is a standard and definitive therapy. In these instances, the savvy radiation oncology investigator has an opportunity to carefully define goals, strategic diagnostic, and/or therapeutic interventions, to achieve a well-defined and clinically meaningful endpoint for the patient's benefit. Adaptive designs are becoming more common in cancer medicine, including radiation oncology-based trials. For instance, the definition of response rate is important to consider. Some data suggest that a well-defined *a priori* change in metabolic response rate via functional imaging assessment with FDG-PET (positron emission tomography) may harbor useful imaging biomarkers of tumor response or resistance much earlier than classic pure anatomic imaging using conventional CT scanning.[175-177] Along similar lines, recent phase II data suggest that integration of functional imaging for hypoxia may allow for safe and effective treatment de-escalation for patients with HPV-related oropharyngeal carcinoma.[178] Adaptive trials will need to incorporate serial data inputs, including though not limited to imaging, -omic (genomic and proteomic), and anatomic changes during treatment to enhance response and get ahead of the tendency of tumors to develop radioresistant phenotypes (Figure 14.3).

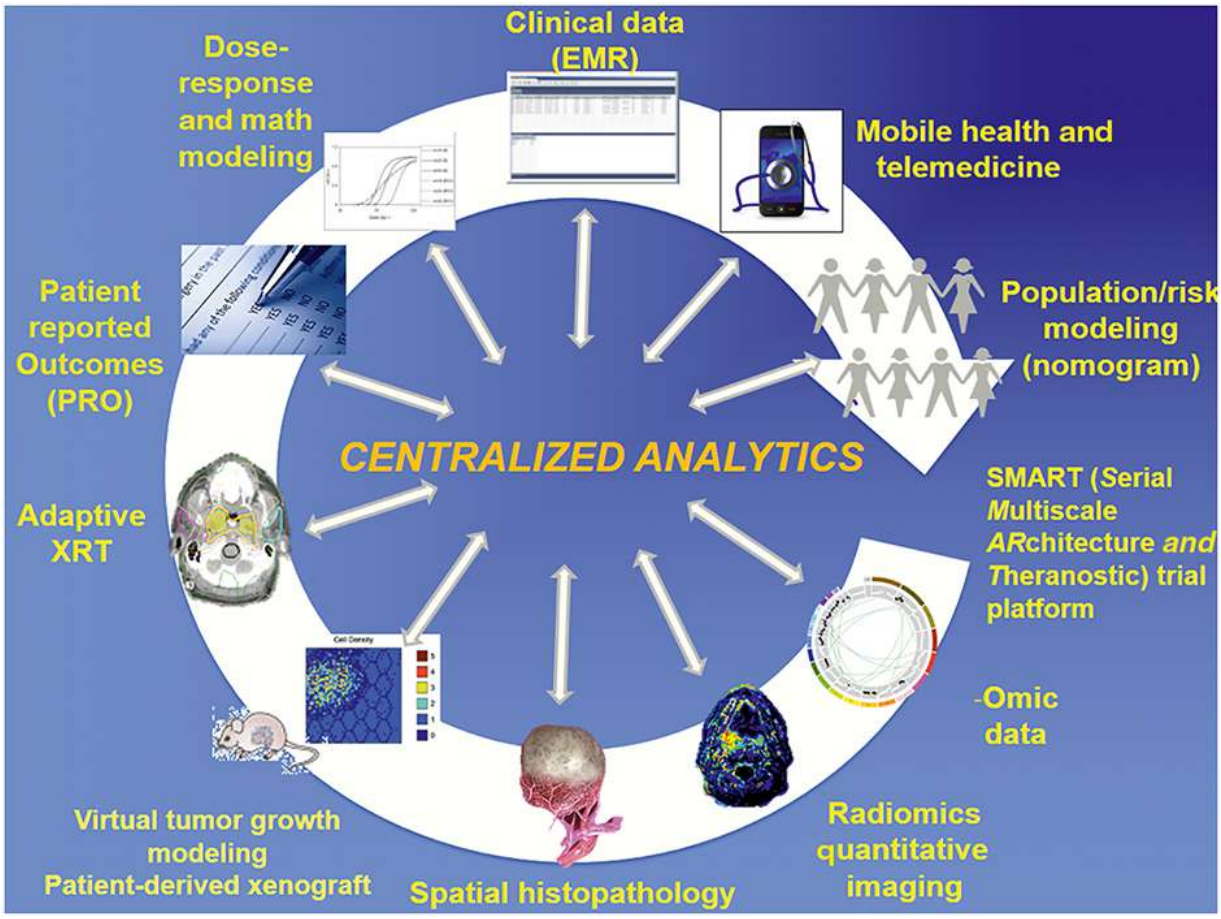

FIGURE 14.3 Centralized analytics allows for phenotyping using all patient and tumor-specific data.

To exploit the promise of precision medicine, alternative phase II designs have emerged in the form of umbrella and basket trials.[179] The umbrella trial is set up to test one type of cancer (ie, lung) which may harbor multiple mutations, some of which may be actionable with various therapeutic interventions. The basket trial can include patients with multiple anatomic types of cancer though each tumor must harbor a common genetic mutation for which the same candidate therapy is tested. Relevant for radiation oncologists, basket approaches may similarly be designed to allow disease-site-specific baskets for shared clinical scenarios, such as oligometastatic disease.[138]

Endpoints

Response rates alone may be challenging for selecting efficacious regimens, due to several factors, including delayed time to response with RT, residual unevaluable masses versus scarring or fibrosis, PD outside of the RT field, and underlying high local response rates to RT.

Response rate is commonly measured by the RECIST and sometimes the PRECIST (Positron Emission Tomography Response Criteria in Solid Tumors) criteria. A CR plus a PR are added together to determine the overall objective response rate. If patients whose best response is an SD or no change, that may also be important since many of the targeted agents (which may be cytostatic in activity) inactivate a driver tumor target though not objective shrinkage of the tumor may be noted by conventional imaging.

Efficacy endpoints commonly used include (1) CR rate, (2) pathologic CR rate based on examination of tissue, (3) undetectable blood biomarkers such as circulating tumor DNA and/or circulating tumor cells, (4) local or locoregional control rates, (5) time to progression, (6) survival, and/or (7) a decrease in toxicity. In the instance of the latter endpoint of decreased toxicity, RTOG-0529 is a good example of a clinical trial that was primarily designed to show that the way that RT was delivered (ie, Intensity-Modulated Radiation Therapy [IMRT]) may yield a preferable therapeutic window compared to historical experience for invasive anal cancer.[180,181] The endpoint selected will depend on the tumor and the current standard therapy.

Robust documentation of both acute and late toxicities is essential. Collection of late toxicity data is particularly important for subsequent phase III trial design. This should involve provider assessment via the usual tools such as the CTCAE, as well as validated patient-related outcome (PRO) tools. There is emerging data that the concordance of AE documentation between patients and providers in cancer cooperative group setting could even impact OS.[182]

To account for late-onset toxicities that may be induced by radiation treatment, it is important to specify a meaningful patient evaluation window that will be used in decision-making. However, adaptive designs with go/no-go decision-making generally require a short-term evaluation window so that treated patients' outcomes are available by the time the next trial decisions are made. Although there are some available adaptive design

methodologies to account for late-onset events, such as the time-to-event Bayesian optimal phase II (TOP) design,[183] their implementation in real clinical trials requires ever- increasing close collaboration among the investigational team, including clinical faculty and biostatisticians.

Summary

Phase II trials are designed to generate a signal of antitumor activity and to inform the phase III decision. The ideal phase II trial, in one framework, uses a PK/PD-optimal drug against a validated target and shows convincing antitumor activity. Results of phase II trials must be interpreted cautiously, in the context of the availability of other therapies. That said, phase II estimation of clinical activity as well as safety is crucial in the subsequent "go/no-go" decision for a phase III trial. A randomized phase II trial is still generally considered exploratory and does not obviate the need for a larger confirmatory phase III trial. Adaptive designs can be very efficient for selection but require more trial-level maintenance.

Phase III Trials

These trials usually involve two or more arms, including one that is considered a standard of care. The goal may be to show superiority of a new therapeutic approach, such as the addition of postoperative (adjuvant) chemoradiotherapy for resected gastric cancer,[184] or perhaps to demonstrate noninferiority, the latter which can lead to a more cost-effective treatment approach, such as hypofractionated radiotherapy for breast cancer.[185] The essential components to consider for phase III trials are study design, randomization approach, blinding strategy, and monitoring of endpoints. The CONSORT checklist (www.consort-statement.org) summarizes information that must be considered when analyzing phase III trial reports.[186]

Design

Randomization in phase III trials allows for comparison of treatment arms; notably, this does not mean that arms are intrinsically balanced in all variables. Often trialists will report baseline (pretreatment/prerandomization) characteristics in a "Table 1" for their trial

report and report inferential testing results (*P* values) for those characteristics. However, this practice is discouraged, as randomization does not guarantee balance, but rather decreases systematic differences in baseline variables.[187,188] also known as the *Table 1 Fallacy*. For prognostic variables, these should generally be included in a stratification/blocking schema as part of the study design.

Within phase III studies, a *parallel* design involves randomization to a standard (or control) intervention versus an experimental (new) intervention. The experimental intervention may include more than one arm. *Factorial* designs, such as those utilized in 2 × 2 design in the ACT II anal cancer trial, allow for more multiple intervention variables to be compared to a single gold standard or control.[189] Crossover designs allow for patients randomized to arm A to undergo crossover therapy to Arm B after the efficacy endpoint of arm A has been measured. This may occur when the efficacy endpoint is PFS.[190] Crossover is an important consideration, as it may impact or bias subsequent OS estimates (or estimates of postprogression survival); crossover is further crucial in considering patient centeredness of trials and enthusiasm for patient accrual.[37,191] Patients may be more willing to enroll in the study if control-arm-randomized patients are still eligible to receive the experimental therapy at the time of progression.

Randomization

Randomization generally provides each patient an equal chance of being assigned to an intervention arm or a control arm, unless it has been predetermined that an unequal randomization allocation (ie, 2:1) is warranted (for instance, to enhance accrual). Ideally, the patient and the PI should not influence or be aware of which arm the former will be randomized to prior to the decision being made to provide informed consent to participate in the study. This requires equipoise on the part of the investigator, an area of active controversy among the radiation oncology community when deciding how to study new and expensive technology, such as particle therapy. The following section on statistical issues will provide a more in-depth discussion of randomization and blinding considerations in clinical trials.

Superiority, Noninferiority, and Equivalence Designs

A superiority design is common and seeks to show that a new approach (ie, higher dose of radiotherapy) is superior to that standard of care.

A noninferiority design is often used to show that a less aggressive (or potentially toxic) approach (ie, lower dose of radiotherapy or less intense systemic therapy) is not worse to a clinically meaningful degree compared to the standard intervention. The difference or delta (Δ) in the *a priori*–defined endpoint should only be slightly worse (or inferior) to the standard. Confidence intervals estimate the difference in outcome between the control and experimental arms as an approach to confirm the hypothesis. Sample sizes of noninferiority trials are often bigger than superiority trials.[192] Several studies have been *a priori*–designed and reported on for localized prostate cancer,[193] resectable rectal cancer,[194] and brain metastases.[195] Some trials combine noninferiority and superiority testing into one study. This is because the noninferiority and superiority can both be evaluated at a 0.05 significance level without a need to adjust for multiple testing due to the closed testing principle.[192] Two things need to be paid attention to when conducting such combination testings: (1) the study needs to be powered for noninferiority and (2) the noninferiority needs to be tested before testing for the superiority. Noninferiority trials in general, though, should be justified in the use of this approach; this may include cost reduction or increased convenience for patients (ie, an oral agent compared with an injectable agent) and may also include improved toxicity.[196] We submit that improved toxicity generally should be assessed via established toxicity metrics, and therefore a "purely" noninferiority study may not be appropriate as compared with a combined superiority/noninferiority approach (in which oncologic efficacy is the "noninferiority" component of the trial, while toxicity is the "superiority" component). Much ink has similarly been spilled regarding the noninferiority "margin" used in such trials, which may be excessively wide, and therefore allow declaration of noninferiority when the observed difference in oncologic outcomes is not acceptable clinically.[197]

An equivalence design seeks to show that the control and the experimental arm(s) are equal with respect to the primary outcome. Equivalence can be defined as the treatment effect residing between

negative delta ($-\Delta$) and delta (Δ) (two-sided problem). This design *is not* the same as a noninferiority design. RTOG 87-04 was a phase III trial that sought to show that by excluding mitomycin C (an antitumor antibiotic with a well-known profile of significant hematologic and renal toxicity) from a backbone of fluorinated pyrimidine chemotherapy (5-fluorouracil) and external-beam radiotherapy for anal canal cancer, the therapeutic outcomes would remain equal while the therapeutic ratio would be increased by lessening the toxicity.[198] This study showed that the doublet, including mitomycin C, was in fact *superior*. It is problematic to routinely rely on null hypothesis testing of equality if the statistical significance of the *a priori* differences is not met.

Quality Assurance/Contouring

In the era of highly conformal radiation treatment, safe and effective treatment planning depends increasingly on precisely identifying tumor and normal tissues through contour delineation, with evidence from clinical trials emerging that correlates poor contouring with inferior outcomes. In head-and-neck cancer, both TROG 02.02 and RTOG 0129 found a 20% decrease in OS for patients with radiation protocol violations.[52,199] Similar trends have been identified in pancreatic cancer and Hodgkin lymphoma.[51,200] While multiple aspects of the radiation planning process can lead to protocol violations.[201,202] between 13% and 83% of protocol violations have been attributed to contouring.[51,52,200,203] In response, an increasing emphasis is being placed on trial QA programs that actively perform contour evaluation and train providers.

First, the development of a visual atlas for anorectal cancer was shown to reduce contour variation[204] and improve predicted toxicity[205] among providers that intended to enroll patients in a SWOG-sponsored study (SWOG S0713). This atlas was initially developed for RTOG 0529 in response to the observation from the first five cases submitted that coverage of the mesorectum and elective nodes.[180] Visual atlases have been duplicated in contouring studies performed outside of the clinical trial setting for disease sites that have a well-defined high-risk clinical target volume such as prostate fossa[206] and nasopharyngeal cancer.[206] However, RTOG 1106 reported that the development of a visual atlas for lung cancer,

which relies primarily on the identification of gross tumor, did not reduce variation in contours submitted through its trial QA credentialing process.[207]

Given the limitations of a visual atlas, disease sites such as lung cancer have moved toward prospective centralized contour review prior to patient treatment. However, the administrative burden and potential for treatment delays warrant consideration by the QA committee when determining the feasibility of their contouring QA program. Multiple trials show that radiation protocol deviations are more frequent among low-accruing treatment centers,[52,199-201,208] so perhaps a risk-stratified approach should be considered. It is important to keep in mind that the more stringent the trial QA, the less generalizable the results may be to routine practice. Instead, the development of robust resources and training processes that could be implemented and easy to use in routine practice would be ideal.[43,209]

STATISTICAL ISSUES IN TRADITIONAL CLINICAL TRIAL DESIGN

Patient Population and Subject Eligibility

Defining the eligible patient population is an essential step in the design of clinical trial. The inclusion and exclusion criteria of the subject should be carefully defined and specified for any clinical trial before study initiation. Several aspects need to be considered when defining the subject eligibility of enrollment to specific trials: (1) generalizability, (2) feasibility, (3) competing risks, (4) projected AEs, and (5) homogeneity. The patient inclusion and exclusion criteria of a trial should be the result of balancing all the above aspects.

Generalizability and Feasibility

To begin with, investigators should first think about the target patient population to which the new treatment will be adopted. Ideally, a phase III clinical trial should relax the exclusion criteria as much as possible to mirror the target patient population. Less restrictive eligibility criteria will make the findings in the trial more generalizable to the target population. In addition, relatively relaxed inclusion criteria are likely to lead to brisker accrual and make the study treatment more available to a broader patient population who may benefit from it.

Adverse Events, Competing Risks, and Homogeneity

Although inclusive eligibility criteria will boost the generalizability and feasibility, it can be risky and harmful to include subjects who should be excluded. For instance, if participants with HIV/AIDS are suspected to have an exceptionally high risk of experiencing treatment-related toxicity in a given cancer trial, they may be excluded; however, in the era of highly active antiretroviral therapy, justification for exclusion based on HIV status alone (rather than CD4 count or presence of AIDS-defining conditions) has become more challenging.[210,211] Indeed, we recommend trialists to consider each eligibility criterion carefully and to the greatest extent possible utilize liberal eligibility criteria to optimize generalizability as well as trial access equity.[212-214] However, in cases where select subgroups of patients are exposed to a particularly high risk of toxicity, including them may put the whole trial at the risk of closure for excessive toxicity. Even if the trial continues as planned, these subjects are likely to add complexity to the efficacy and toxicity analysis of the trial.

Another thing to keep in mind is the notion of competing risks. For example, if a trial is to evaluate the response rate after six cycles of a given therapy, then including subjects with a high risk of dying before completing the six cycles is undesired. In this example, the competing risk is the death of cancer or other disease before treatment completion or before the primary endpoint becomes available/is measured.

The last thing to be aware of is the homogeneity of subjects as defined in the eligibility criteria. Exclusive eligibility criteria often help select more homogeneous subjects, which could add signal to the "signal-to-noise" ratio in detecting a true treatment effect if the certain type of subjects as defined in the eligibility criteria has a good response to the treatment. However, as discussed previously, findings of a trial with exclusive eligibility criteria lack generalizability, and exclusive eligibility criteria may also jeopardize the speed of accrual. Furthermore, exclusionary eligibility criteria impact trial access equity and could contribute toward clinical trial disparities, as noted above. Therefore, it is often understandable to have more exclusive eligibility criteria in earlier-phase trials, but these criteria should be relaxed to be more inclusive in the phase III setting. A relatively heterogeneous patient population in a phase III trial may also allow the detection of

efficacy differences in subgroups of subjects, which is a bonus of having inclusive eligibility criteria in a clinical trial with a relatively large sample size; naturally, ensuring that subgroup-based analyses are done appropriately is critical as well and preplanned to the greatest extent possible.[105]

Randomization

Randomization is an effective way to assign patients to treatment groups without systematic imbalances in important factors and patient characteristics. A well-designed and implemented randomized trial is often viewed as the gold standard for evaluating an experimental treatment when compared with either placebo or standard treatment.

In this section, we introduce a few randomization schemes that are most well known or widely used for implementing random treatment assignments.

Simple Randomization

Considering a randomized controlled study where subjects are to be 1:1 assigned to either an experimental treatment or a control group, the simple randomization paradigm is no different from flipping a fair coin and assigning subjects to the experimental group if "Heads" and to the control group if "Tails." While in theory, the assignment can be reasonably balanced in treatment assignment and in patient characteristics between groups on average, very few trials choose to use simple randomization in practice. This is because reasonable balance can only be achieved using simple randomization if the sample size is large. However, large clinical trials often are multisite and have interim analyses. A multisite trial typically requires stratified randomization by site, and interim analyses require balance in assignment to be achieved with a relatively smaller sample size.

Permuted Block Randomization

One easy way to address the unbalanced group size at interim analysis or at other time points during the trial is to use permuted block randomization (PBR), which imposes a balance restriction by blocks. The size of the block

can be prefixed or be selected at random. If we again consider a 1:1 RCT, implementing PBR with a block size of 4 will ensure balance in group size for every four subjects. That means for every four subjects, two must be assigned to the experimental group (E) and two must be assigned to the control group (C). We can easily permute the potential sequences for the assignment of two treatments for a block size of 4: EECC, CCEE, CECE, ECEC, CEEC, and ECCE. The same can be done essentially for any block size. Common choices of block sizes are 2, 4, 6, and 8. We may randomly pick one of the generated sequences for any block if using PBR with a fixed block size. For using PBR with random block size, one additional random pick needs to be made before starting any block: randomly pick the block size for the coming block from all available choices, say, 2, 4, or 6. Once the size of the coming block is determined, we can use the same procedure as PBR to implement the randomization.

We discourage using a block size of 2 for PBR with fixed block size because that adds an excess restriction on randomization. We also discourage using a block size of 8 or more for any PBR as the imbalance can still be substantial with larger block sizes. A well-known and criticized drawback of PBR with fixed block size is that it may hinder blinding. With a relatively small block size, there is a good chance for physicians or researchers to determine or suspect which patients are assigned to which treatment when they should be blinded to such assignment. Therefore, we suggest using PBR with random block size over PBR with fixed block size whenever appropriate and necessary.

Stratified Randomization and Covariate-Adaptive Randomization

Achieving balance in the number of subjects assigned to each arm throughout the trial is often not sufficient for most randomized clinical trials in oncology. It is also important to ensure balancing on known covariates that may affect outcomes. If the covariates to be balanced are all categorical variables and the number of covariates is less than three, stratified randomization is often appropriate for achieving balance in covariates. The idea of stratified randomization is straightforward: we first create different strata based on the covariates to be stratified, then conduct population

reference bureau (PRB) or simple randomization within each stratum. The number of strata is jointly determined by the number of stratifying covariates and the levels of each covariate. For k stratifying covariates with levels of each covariate denoted by l_1, l_2, . . . , l_k, the number of strata is $l_1 \times l_2 \times \ldots \times l_k$. For example, if a randomized trial has two stratifying covariates: site (three participating sites) and type of cancer (breast and prostate cancer), then the number of strata is 6. The number of strata increases quickly with more stratifying covariates. Once the number of subjects in each stratum becomes too small, there is an increased chance of imbalanced assignment within each stratum, which influences the balance of the whole trial. Similarly, with too few patients in each stratum, interpretation of such small cohorts for a stratum becomes challenging in assessing possible differential treatment effects by subgroups. Therefore, when the number of stratifying factors exceeds 3, or if one or more continuous covariates are to be balanced, we suggest using covariate-adaptive randomization, also called minimization. The covariate-adaptive randomization assigns treatment to a new subject to minimize the covariate imbalances within treatment groups. There are multiple ways of doing so, such as Zelen rule, the Pocock- Simon procedure, and Wei marginal urn design.[215]

Response-Adaptive Randomization

Most adaptive clinical trials that use Bayesian designs adopt response-adaptive randomization, which has a changing probability of assigning a new patient to treatments based on the observed data from previously treated patients in the trial. The response-adaptive randomization allows more subjects to be assigned to the more promising treatment arm and thus is viewed as a design with ethical benefits. The response-adaptive randomization is preferred for many trials, but not all, because it typically requires added complexity in designing, implementing, managing, and analyzing the trial, and may have slightly reduced power in detecting treatment differences for a fixed sample size.

Statistical Power and Sample Size

All clinical trials require the computation and justification of sample size because the number of subjects evaluated in the trial is a key factor that determines the quality of scientific findings in the study. A clinical trial with too small a sample size fails to yield meaningful scientific results, while a trial with too large a sample size will waste resources in finding a result, and may expose more subjects than necessary to inferior treatment. Notably, a trial with incomplete accrual may have insufficient power to meaningfully address the study question, a situation that happens not infrequently even in the phase III setting and should be strenuously avoided through optimization of expected and obtained accrual as well as associated funding for the study.[8]

We need to know the design of a clinical trial and the variable type of the primary endpoint before doing sample size computation. In general, if hypothesis testing is going to be conducted, we should specify the desired power, the null and the alternative hypothesis, the statistical test procedure to be conducted, and the type I error rate. The type I error is the probability of rejecting the null hypothesis when the null hypothesis is true. In other words, it is the chance of claiming a new drug is effective while it is not. As type I error can be a very serious error for all clinical trials, it is typically controlled at a low rate (a) of 0.05 or less. Another error we take into consideration when computing sample size is the type II error, the probability of not rejecting the null hypothesis when the alternative hypothesis is true. It can be viewed as the chance of incorrectly determining a therapy is not effective when it is. Generally, it is acceptable for a trial to have a 20% or less type II error rate (b). The power is simply 1 − b. Therefore, clinical trials are typically designed to have 80% or greater power.

For certain early-phase pilot studies, the major goal may not be to determine whether a treatment is effective or not, but to gain preliminary information on the level of effectiveness for planning future studies. For such a trial, it makes sense to plan the sample size based on the precision of a confidence interval. The precision of an estimate is directly based on the width of a confidence limit. The smaller the width, the narrower is the confidence interval, and the better precision is the estimate. For example, if we want to gain preliminary information on the 6-month objective response rate for a new radiation therapy in a single-arm phase II pilot trial, and we

believe a 95% confidence limit ± 0.15 is narrow enough no matter what the estimated response rate locates, we can then propose a sample size of 47 evaluable subjects to ensure the computed width of the confidence interval is within 0.3.

Figure 14.4 shows the relationship between width of confidence limit, sample size, and the estimated proportion computed using the Clopper-Pearson exact method (produced by Power Analysis and Sample size Software, 2017, NCSS, LLC. Kaysville, Utah). We can tell the width of the confidence limit monotonically gets smaller as the sample size increases, and the width of confidence is also influenced by the point estimate of the response rate. The width is always the widest at a point estimate of 0.5 and gets narrower as the point estimate moves away from 0.5 in either direction.

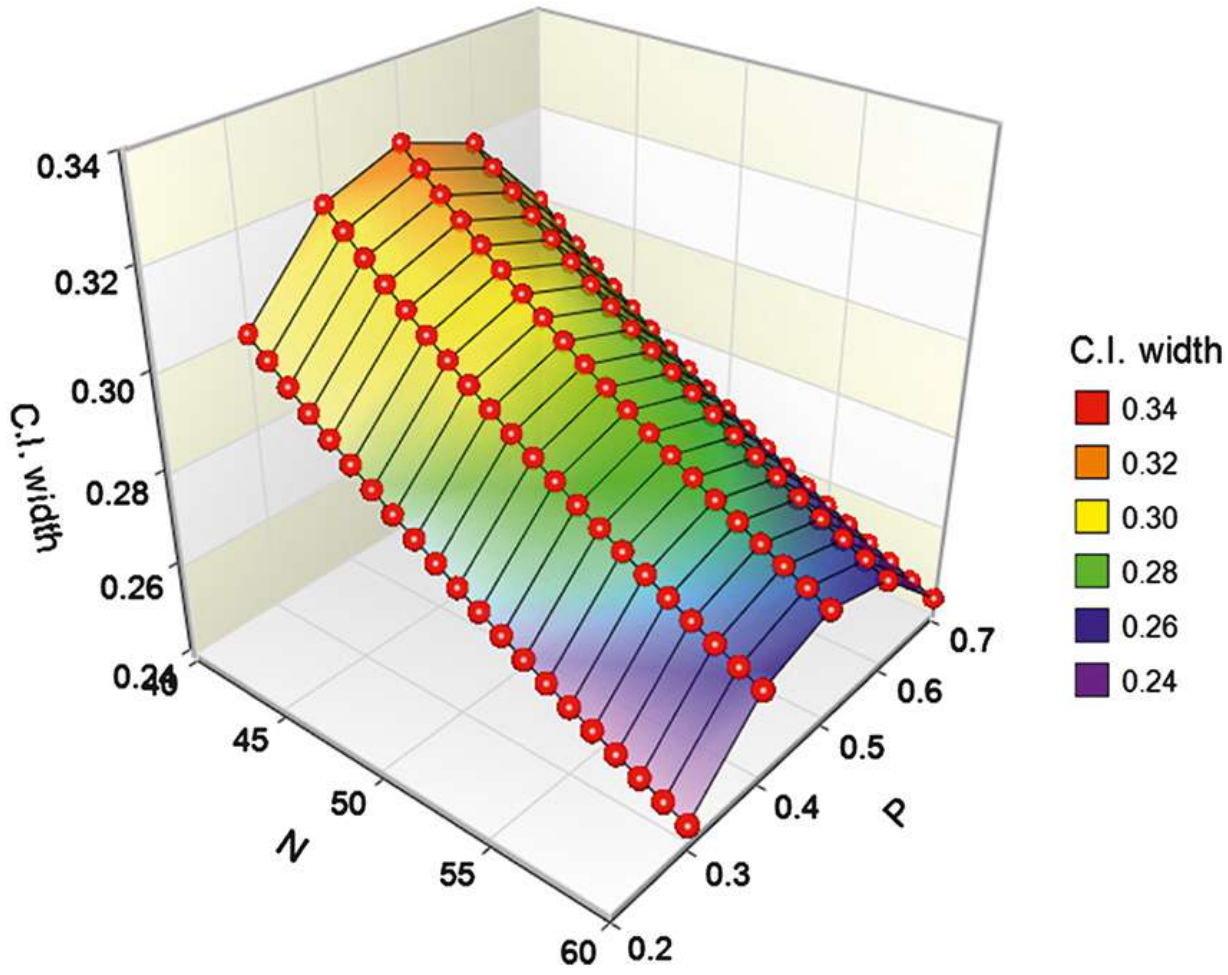

FIGURE 14.4 Relationship between width of confidence limit, sample size, and the estimated proportion.

We should keep in mind that the proposed sample size of enrollment in a clinical trial typically is larger than the computed sample size, owing to some fraction of patients that drop out of the trial or else are unevaluable for analysis. The proposed sample size should be inflated accordingly to ensure that the final evaluable sample size has adequate power.

Although most trials require a predetermined fixed sample size at the design stage, some allow flexible total sample size depending on the findings during the trial. For example, the well-known 3+3 design, continual reassessment design, and Simon's two-stage design all allow flexible total sample size. Any clinical trial with interim analyses and associated stopping rules allow flexible total sample size. However, the procedures of determining the sample size based on findings in the trial and the potential range of the trial need to be specified clearly in the protocol at the design stage.

Interim Analysis and Stopping Rules

Most phase III clinical trials and some phase II trials are designed to have interim analyses that allow the trial to be stopped early based on the findings in the interim analysis. A major purpose of a stopping rule is to protect patients from unsafe and/or ineffective drug. Many trials with interim analysis only allow early stopping due to evidence of futility or excessive toxicity. For example, Simon's two-stage design only stops the trial for futility (rather than efficacy). In this design, n_1 subjects are enrolled to Stage 1. If only r_1 or fewer subjects had successes, the trial would be stopped early. Otherwise, it will continue to enroll other n_2 subjects. The final analysis is based on all $n_1 + n_2$ subjects. In general, the decision on whether to stop early for futility is predetermined based on the conditional power, the conditional probability of having statistically significant result if the trial continues to the end, given the accumulated data in the interim analysis.[216] If such a probability is very low, lower than a prespecified threshold, then the trial may be terminated early due to futility.

Many other trials with interim analyses also incorporate efficacy in some or all interim assessments. For such trials, it is critical to make sure the overall type I error rate is not inflated by the interim looks, as discussed

previously in the context of "alpha spending."[88] For example, the well-known Pocock group sequential design[217] and the O'Brien-Fleming group sequential design proposed stopping boundaries for interim analyses with appropriate alpha spending functions.[91] The Pocock design makes interim analyses equally spaced and requires the same level of evidence (ie, using the same *z*, the boundary of rejection for the test statistic) for early and late interim analyses. These requirements may be overly restrictive. Therefore, O'Brien and Fleming proposed a group sequential design that makes it less likely a trial will stop in early interim analyses by having the boundaries of early stopping decrease with the sequential number of analyses being conducted.

Many other sequential or group sequential designs have been proposed and implemented. The key requirements for such trials are as follows:

- The endpoint for interim analysis is relatively quick to evaluate. It is not desirable to use an endpoint that requires a long time follow-up (eg, 10-year OS), because the trial will be halted for each interim analysis.
- The number of interim analyses, when to take the looks, and under which condition the trial will be stopped early should all be clearly specified in the protocol before the initiation of the trial.
- An appropriate spending function is used to control for the overall type I error rate.

In general, unplanned interim analyses are not authorized for clinical trials. An exception is when the unplanned interim analysis is proposed by the DSMB in the interest of protecting patients. In such situations, stopping boundaries can be constructed and modified for the additional or unplanned interim analysis.[218]

Many sequential and group sequential clinical trials are designed using Bayesian methods. Unlike the frequentist methods that completely rely on the data in the current trial to make inferences and decisions, Bayesian methods incorporate outside information (eg, published similar studies, pilot data, expert's opinion) into the procedure. A Bayesian method typically starts with specifying a prior distribution for the parameters of interest and updates the distributions using data from the trial. The updated distribution is called the posterior distribution, and the updates can be

applied as many times as necessary, in theory. The stopping rule of a Bayesian group sequential design is based on the posterior probability of efficacy or futility, which is computed by combining the prior and the current data of the trial. We encourage the reader to explore Bayesian statistical inference, including in literature within radiation oncology.[219]

SURVIVAL ANALYSIS AND CATEGORICAL DATA ANALYSIS

Many oncology clinical trials include OS or time to PFS as primary or secondary endpoints. Such endpoints are called time-to-event endpoints, and statistical analysis for time-to-event endpoints is called survival analysis. Patients are followed sufficiently long so that a subset of subjects will experience the event of interest during the trial. The event of interest is death for OS and is progression or death for time to PFS.

Without loss of generalizability, we use OS as the event of interest from now on. The method is the same for all other time-to-event endpoints, and as noted earlier, there are specific considerations and caveats for the use of surrogate endpoints, including surrogate time-to-event endpoints such as PFS.[36,37]

The survival endpoint is a combination of two measures: (1) a binary variable indicating whether the subject died by the end of the study or at the last follow-up of the subject and (2) a continuous variable measuring time from a common starting point (eg, the initiation of treatment or at the time of randomization) to death if the subject has died. For those subjects who are still alive by their last follow-up time, the component b of the survival time is not known and is thus treated as missing. Notice that the information is only partially missing for these subjects because we do know they were still alive by the time of their last follow-up. A special term is used in survival analysis for such partial "missingness": *censored*.

For most survival data, the first step is to use the Kaplan-Meier estimate to describe the distribution of survival time.[220] The Kaplan-Meier method utilizes the information of all subjects, including those who had observed death and those who were censored, to describe the cumulative survival over time, which is the product of the survival ratio of the number of subjects still alive to those who are at risk.

We can illustrate the computation and the plot of the Kaplan-Meier curve using a simple example. Suppose that we have 20 patients randomized to two arms. The observed survival time for subjects in each arm is as follows (the unit is months, and + indicates a censored observation):

A: 8+, 11+, 16+, 18+, 23, 24, 26, 28, 30, 31

B: 9, 13, 13, 14, 14, 16, 19+, 22+, 23+, 29+

Figure 14.5 shows the plot of the Kaplan-Meier curve. Using Arm A as an example, we can show step by step how the Kaplan-Meier curve was determined. Before plotting, the data should be sorted from low to high, regardless of whether the subject is censored or not. The Kaplan-Meier plot is a step function with steps formulated at one or more observed deaths. Starting at baseline, all 10 patients are alive, so the initial ratio of subjects still alive to those who are at risk is 1 (= 10/10). This is also the cumulative survival at baseline. At 8 months, one subject had been censored, so the ratio of subjects still alive to those at risk remains the same 1 (= 9/9). As the baseline cumulative survival is 1, the cumulative survival at 8 months is still 1 (= 1 × 1). Afterward, three more subjects were censored, which did not change the ratio while the number of subjects at risk dropped to 6. The fifth subject died at 23 months. This makes the ratio drop to 0.83 (= 5/6). The cumulative survival at 23 months is still 0.83 because the cumulative survival at 18 months (the previous time point) is 1, thus 0.83 × 1 = 0.83. The ratio was further dropped to 0.8 (= 4/5) in the 24^{th} month, making the cumulative survival 0.664 (= 0.8 × 0.83). The seventh subject died at month 26, with the computed ratio being 0.75 (= 3/4) and the cumulative survival being 0.498 (= 0.75 × 0.664). The ratio for the last subject at 31 months was 0 (= 0/1), making the cumulative survival become 0 as well. For a Kaplan-Meier plot, the cumulative survival is always 0 if the last subject is an observed death, as shown in the plot for Arm A. Otherwise, if the last subject is censored, the Kaplan-Meier plot is flat with a positive cumulative survival, as seen in the plot for Arm B.

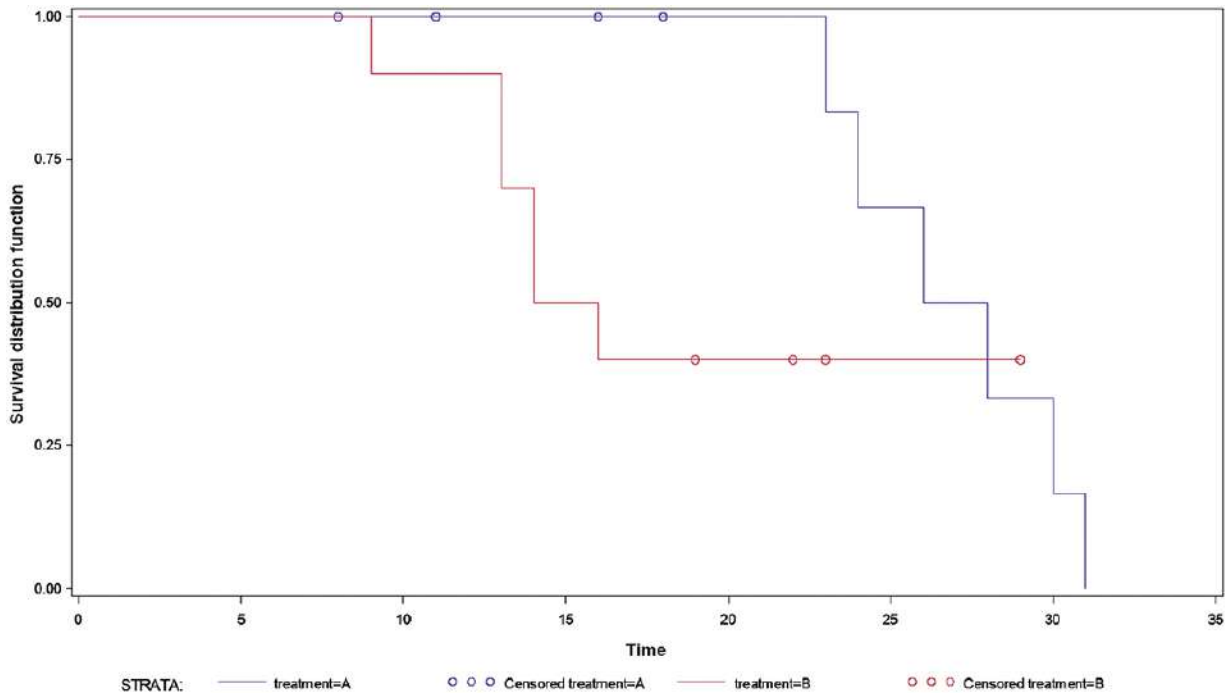

FIGURE 14.5 Plot of the Kaplan-Meier curve for example given in text.

The Kaplan-Meier plot can be used to compute the median survival time, a common statistic of interest showing the estimated time that half of the patients will have died. Again, using the Arm A plot as an example, the median survival is month 26, when the cumulative survival first fell under 0.5. The median survival time is often reported with a confidence interval because this is an estimate. We omit the computation of the confidence interval here due to limited space. The median survival time and its associated confidence interval typically can be computed by almost all software for survival analysis. However, sometimes the median survival is not estimable. This is because the Kaplan-Meier curve never fell below 0.5 for the study or for the arm under evaluation. It should be noted that as a single-timepoint estimate (the estimated point in time when 50% of patients had an event), the median survival time may be unstable, with a wide confidence interval; conceptually, a single-timepoint estimate such as the median, or for instance, 2-year survival time, are "local" measures, and do not include full information from the entire Kaplan-Meier survival curves.[221]

As the observed survival data rely a lot on the length of follow-up, it is important for any clinical trials with survival analysis to report the follow-

up time.

The Kaplan-Meier plot is often accompanied by a log-rank test, a nonparametric test for comparing the survival distribution in two treatment groups. A "significant" log-rank test suggests the survival distribution in the Kaplan-Meier plot differs for the two treatment arms.

The log-rank test only compares the survival distribution of the two arms without considering and controlling the effect of other influential factors, potential confounders, and effect modifiers. To control for those covariates, the Cox proportional hazards regression model is typically used to estimate the HR of the two treatments.[222] In survival analysis, the hazard rate is the instantaneous risk of death at a given time and can be thought of loosely as the probability of death at time t, given that the patient is alive just before time t^2. Please see above for a discussion of the HR and its correct (and incorrect) lay interpretations. The Cox model is appropriately termed the Cox proportional hazards regression model because it assumes the HR for two specified arms is constant over time. In the era of immunotherapy, this assumption of proportional hazards may be increasingly violated; this may be related to subsets of patients (such as those with high expression of specific immune checkpoint markers) that differentially benefit from immunotherapy. In this example, all-comer patients may benefit earlier from cytotoxic chemotherapy, making the chemotherapy arm look "better" earlier in the time course of the survival curve, but then the curves may "cross" such that the patients who are immunotherapy treated, now enriched for those excellent responders such as those with high immunotherapy-related markers, outperform chemotherapy-treated patients.[223] Proportional hazard violations occur frequently in late-phase cancer clinical trials, and many methods to address these violations have been described.[224] Use of the restricted mean survival time, for instance, allows investigators to compare "areas under the curve" for survival curves, leading to robust measures of treatment effect in the absence of proportional hazards.[225]

Another type of endpoint often seen in oncology clinical trials is the categorical endpoint, such as tumor response or objective response rate. The first thing to describe for categorical endpoints is the response rate and the associated confidence interval in each arm if this is a randomized trial. Pearson Chi-square test is the most often used test to evaluate the difference in response rate for two treatments without controlling for other factors.

When the sample size is small, *P* values from Fisher's exact test are often reported instead. Logistic regression model is the most common choice for comparing treatment effects using statistical modeling. It provides an estimation of the odds ratio of treatment after controlling for important covariates other than the treatment.

In addition to traditional statistical modeling, machine learning methods may be increasingly utilized to analyze survival endpoint and categorical endpoints, in addition to other areas of possible integration of machine learning methodology in cancer clinical trials.[226,227]

PRACTICAL ISSUES IN THE DESIGN, EXECUTION, AND REPORTING OF CLINICAL TRIALS

The Institutional Review Board

Several different groups share responsibility for the monitoring and oversight of ethical and safety issues in clinical trials. According to US federal regulations, the role of the institutional review board is primarily to ensure that "risks to subjects are minimized" and "risks to subjects are reasonable in relation to anticipated benefits."[143] This involves a review of the study protocol, informed consent document, background information, and proposed research plan.

Data and Safety Monitoring Committees

Once trials are initiated, ongoing monitoring of accumulating data regarding safety, effectiveness, and trial conduct is required. In the late 1960s, federal agencies (such as the NIH and the Department of Veterans Affairs in the United States) began to mandate an *external* review by a DSMC, since investigators may not be fully objective in their interim data analysis. Some data suggest that industry-sponsored trials have been slower to incorporate this practice.[127] However, not all trials warrant the cost of a DSMC, including trials of short duration or those that have endpoints such as relief of symptoms (rather than survival or severe toxicity). For this reason, the IRB review serves to inquire about the safety monitoring plan and can request the establishment of a DSMC, if warranted due to perceived potential risk to patients.

Conflict of Interest

Industry sponsorship of clinical trials in oncology has increased over the past several decades, as discussed previously. Compared to the pharmaceutical industry, radiation oncology is limited to a relatively small number of equipment vendors. Nonetheless, one study found that among clinical trials led by radiation oncologists and reporting conflicts of interest, over half of COI was related to industry sponsorship.[228] A literature review of COI in radiation therapy trials for breast cancer from 2004 to 2014 found that 13% of studies reported funding from for-profit organizations, while an additional 49% of trials were supported by not-for-profit organizations.[229] They found that funded trials and those with a positive conclusion were more likely to be published in journals with a higher impact factor, but the presence of COI did not influence study conclusions. In a randomized survey of internal medicine physicians, the perceived impact of trial results from industry-sponsored studies was lower than that from NIH-sponsored studies.[230] Nonetheless, any financial support should be reported, given the potential for COI to arise.

Registry on ClinicalTrials.gov

As noted previously, ClinicalTrials.gov serves to inform researchers, physicians, and patients of ongoing and completed clinical trials both in the United States and worldwide. The website was created as part of the Food and Drug Administration Modernization Act of 1997, which mandated that both federally and privately funded trials conducted under investigational new drug applications be registered in a publicly accessible platform. Requirements for registration were expanded in 2007, and as noted previously, requirements for reporting via ClinicalTrials.gov continue to have challenges as regards compliance.[21] The trial sponsor or PI is responsible for registering trials at ClinicalTrials.gov at study initiation, as well as providing timely updates and submitting summary results in accordance with this federal legislation.

CONsolidated Standards of Reporting Trials

By the early 1990s, medical journal editors and clinical trialists identified a need for a scale to assess the quality of RCTs. Groups of these experts meeting separately in Canada and the United States created the SORT and Asilomar reports, respectively, which merged in 1996 into a single, coherent evidence-based recommendation known as the CONSORT Statement. Most notably, this guideline statement includes both a checklist and flow diagram to enable readers to understand a trial's design, conduct, and analysis, and to encourage adherence and transparency by authors.[231]

NOVEL APPROACHES TO CLINICAL TRIAL DESIGN

Seamless Phase I-II Trial

As have been discussed thus far, typically, phase I trials evaluate toxicity, and phase II trials evaluate efficacy. However, seamless phase I/II trials—or trials that achieve the goals of both phase I and II in one umbrella protocol —have been developed to address both questions.[45] In these two-stage designs, information from the initial phase I study is incorporated into the phase II study. Different variations of this have been developed. Figure 14.6 shows the concept behind a seamless phase I/II trial using two drugs, A and B, given either concurrently or sequentially in one of the 10 dose combinations indicated by the yellow dots.[232] This adaptive randomization considers the toxicity and efficacy of these combinations.

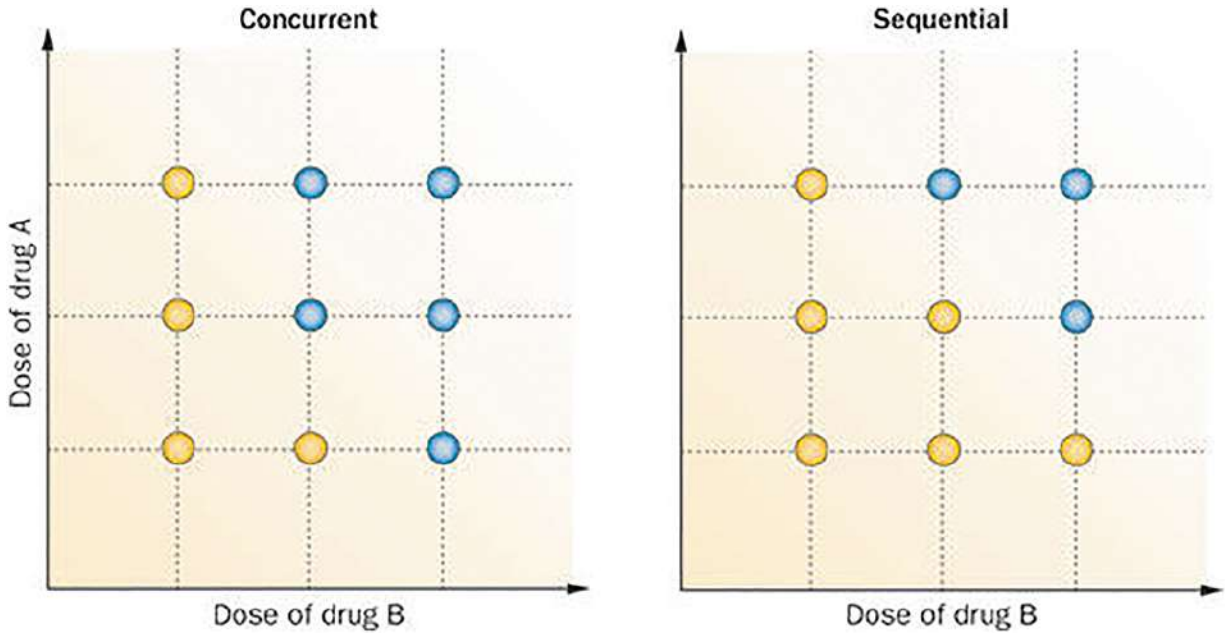

FIGURE 14.6 Different schedules of two drugs given concurrently or sequentially. (Reprinted by permission from *Nature*: Berry DA. Adaptive clinical trials in oncology. *Nat Rev Clin Oncol*. 2011;9[4]:199-207. Copyright © 2011 Springer Nature..)

Another Bayesian adaptive phase I/II clinical trial has been designed for evaluating efficacy and toxicity with delayed outcomes,[233] which, as previously discussed, is crucial in radiotherapy trials. This approach evaluates both efficacy and toxicity as binary outcomes, both as time-to-event models. The authors' simulations showed that this method significantly reduces the study duration.

Pan et al propose a phase I/II seamless dose escalation/expansion with adaptive randomization scheme (SEARS).[234] There are three critical components to this model: first, it applies the modified toxicity probability interval (mTPI) method as a way of monitoring toxicity. Then, in the phase II portion, it adaptively randomizes, based on efficacy, patients to any doses showing promising efficacy and safety. Posterior probabilities are calculated using both the phase I and II information[234] (Figure 14.7). Further integrated novel phase I/II approaches with Bayesian methodology have been piloted within radiation oncology as noted previously with the use of the LO-ET design for assessment of a radioprotector with ablative-dose RT for locally advanced pancreatic cancer.[122,123]

REDEFINING THE APPROACH TO CLINICAL TRIALS

The randomized phase III clinical trial is considered the most robust method of comparing the efficacy of a new treatment with the standard of care. Grading systems for evaluating clinical evidence universally place RCTs above observational trials. However, multiple features of modern medicine challenge the feasibility or rigidity of this traditional approach. First, as medicine progresses through incremental improvements in treatment as well as earlier detection, the potential effect size of the next intervention decreases while the time to event increases. The result of increasing trial size and duration of follow-up increases the cost. The age of the patient population diagnosed with cancer continues to increase, as mortality from competing comorbidities such as cardiac disease decreases. Because this population of older patients with comorbidities is often excluded from clinical trials, the applicability of trial results to this population is

difficult.[146,214] Meanwhile, technologic advances in imaging and treatment as well as the incorporation of molecular profiling can cause the question being addressed to become obsolete by the time trial results have matured. Specifically in radiation therapy, rapidly evolving technology has often led to increasing complexity of treatment, such as with improvements in treatment conformality and target volume assessment/image guidance through IMRT, stereotactic body radiation therapy (SBRT), biologically guided radiotherapy, magnetic resonance imaging–guided radiotherapy, and beyond. Increasing complexity often warrants stricter QA mechanisms to ensure that the intervention is applied appropriately to adequately test its utility, thereby reducing the ability to generalize the results to routine clinical practice.

Pragmatic Clinical Trials

The concept of pragmatic clinical trials arose out of the concern that clinical trials were being optimized to determine efficacy, while potentially overestimating benefit and underestimating harm when applied to the general population.[235] Pragmatic trials thus focus on the applicability of a new intervention to general practice, while explanatory trials aim to address questions of biologic mechanisms. In 2009, a tool called the PRagmatic-Explanatory Continuum Indicator Summary (PRECIS) was published to provide clinical trialists with a guide to understanding how different components of design would impact the applicability, or pragmatism, of the trial.[236] An updated version (PRECIS-2) was published in 2013 in which nine domains were scored on a Likert-type scale (1 = most explanatory, 5 = most pragmatic).[237] The primary goal of PRECIS-2 is to match the trial design to the intended application of trial results.

Meanwhile, CONSORT published an "extension for pragmatic trials" that specifies that trial publications include all the information on the context of their conducted trial so that future readers can judge the applicability of the results to their own clinical context, where they may be considering implementing the intervention tested in that randomized trial.[238] So, while PRECIS-2 encourages appropriate trial design, CONSORT ensures trial results and information are reported adequately for health

system decision-makers to determine the applicability of trial results to their clinical setting.

A study design often employed in pragmatic trials is cluster randomization. This allows the intervention to be implemented at the group level rather than the individual level, which affords more opportunity for the training of interdisciplinary teams of professionals and assurance that implementation is appropriate for the clinical context. Furthermore, as a result, all patients within a center are treated uniformly, which improves efficiency and reduces the risk of errors. The comparator arm, meanwhile, is generally usual or standard care. By facilitating training, cluster designs also help to address differences in provider experience, which have been shown in radiation oncology to influence outcomes and must be considered to avoid confounding. While pragmatic trials often include providers with a representative mix of experience levels to increase generalizability, trial quality must always be closely monitored. A pragmatic trial conducted poorly is of limited to no use for decision support.

Pragmatic trials rely more heavily on electronic health records (EHR) and patient registries to collect patient information, as this reduces the cost of trial coordinators. Of note, many registries were established prior to the implementation of EHRs, so they often collect data in parallel, with work ongoing to synchronize the system. Some health systems have developed robust national quality registries that are disease based or intervention based, which has facilitated large clinical trials. For example, the Thrombus Aspiration in ST-Elevation Myocardial Infarction in Scandinavia (TASTE) trial was a multicenter, prospective, open-label, randomized, controlled clinical trial that used the infrastructure of a population-based registry in 29 Swedish centers and 1 Icelandic center, to facilitate enrollment and long-term data collection on 11,709 patients treated for heart attacks from 2008 to 2009.[239]

Comparative Effectiveness Research

The 1999 Institute of Medicine's report "To Err is Human" called attention to serious concerns about patient safety in the United States. The Agency for Healthcare Research and Quality (AHRQ) was established to address these concerns by focusing on the safety and quality improvement in health

care delivery. The AHRQ defines comparative effectiveness research as that which is "designed to inform health-care decisions by providing evidence on the effectiveness, benefits, and harms of different treatment options."[135] Then in 2010, an independent nonprofit, nongovernmental organization called the Patient-Centered Outcomes Research Institute (PCORI) was authorized by Congress to further address the need for information to guide better-informed health decisions by patients, providers, and policy makers. PCORI is the single largest public funder of clinical effectiveness research (CER) in the United States, supporting primarily large pragmatic studies and large-scale observational studies.[136]

Over the past few decades, government agencies, professional societies, and private corporations have established patient registries that collect standardized data from patients diagnosed and treated in a variety of settings, to provide data regarding patterns of care and patient outcomes.

The Surveillance, Epidemiology, and End Results (SEER) Program of the National Cancer Institute was established in 1974 to provide cancer statistics in order to reduce the burden of cancer.[132] SEER is a population-based registry representing 17 regions and 28% of the US population. It is therefore a useful epidemiologic tool for calculating incidence (new cases per population), prevalence (existing cases per population), and mortality (deaths per population) for different cancers, and it documents tumor-specific information. SEER, a clinical database, is often linked to the Medicare claims data, to provide more detailed indirect information regarding the treatment of cancer (including the number of fractions of radiation) as well as diagnosis codes and interventions that could relate to toxicity (such as cystoscopy, colonoscopy, coronary angioplasty). The use of Medicare linkage restricts the data to over 65 years, however. This parallels the separate entity known as the Medicare Chronic Conditions Warehouse (CCW), which is an administrative database that can be used independently to investigate broader patterns of care than SEER-linked data, though it lacks detailed cancer information that is available in SEER, such as stage.

The National Cancer Database (NCDB) is jointly sponsored by the American College of Surgeons and the American Cancer Society. It includes patients from 1,500 Commission on Cancer (COC)-accredited programs, representing 70% of cancer diagnoses.[131] The initial goal of

NCDB was to monitor patterns of care at the local hospital level and provide feedback regarding quality measures. NCDB requires COC accreditation and therefore does not represent all patients in a population. It is therefore technically not a population-based database and thus not appropriate for incidence/prevalence but can be used to assess outcomes after diagnosis. NCDB includes details of margin status, radiation dose, and technique, which are not captured in the SEER database. While NCDB enables important patterns of care studies, it lacks robust outcomes data, including cancer-specific survival, and recently has been used extensively to assess the efficacy of radiation treatment with OS as the primary endpoint, which has significant limitations. Because of the observational nature of this registry, confounders exist in treatment selection (including patient performance status) which can bias the perceived efficacy of the treatment. In a retrospective database, one can never fully control for this selection bias and therefore should interpret OS results with extreme caution. Indeed, data suggest that there is minimal agreement beyond what is expected by chance between registry-driven observational studies and matched RCTs, reinforcing the persistent and continued centrality of late-phase randomized trials in defining the standard of care.[240]

A major limitation of SEER, NCDB, and CCW, however, is the lack of patient-reported outcomes. The CaPSURE represents a prostate-specific registry that was initiated in 1995 to enable prospective cohort studies in men with prostate cancer that focused on incorporating patient-reported outcomes.[241] Approximately 40 urology practices, primarily community-based, enroll patients in a database that tracks over 1,000 clinical and patient- reported variables. Though this is not a population-based sample, it provides much richer clinical detail than SEER. Given the long natural history of prostate cancer, CaPSURE is regarded as a cost-effective alternative to randomized trials that reflects “real-world” practice and has resulted in numerous publications.

Newer registries are being developed to address the limitations of current databases, and therefore include a robust interface for data collection that facilitates prospective clinical trials (such as the Swedish TASTE trial), and incorporation of radiation-specific information (including that captured in Digital Imaging and Communications in Medicine [DICOM] files). Cancer Learning Intelligence Network for Quality (CancerLinQ) is a national

initiative sponsored by the ASCO that involves a cloud-based platform that communicates nightly with the EHR at each individual practice to collect, de-identify, and update patient information, which serves as both a database to evaluate quality metrics and a real-time decision support tool that recommends guideline-concordant therapies.[242] By 2016, CancerLinQ had registered over 1 million patients treated at 70 clinics by 1,500 oncologists, and shortly thereafter, the American Society for Radiation Oncology (ASTRO) announced a partnership to incorporate critical radiation-specific data into the database.[130] Developing a DICOM-based registry for radiation oncology requires first standardizing naming conventions to enable harmonization of the digital information. This process is in progress in the United States, with American Association of Physicists in Medicine (AAPM) Task Group 263 defining the naming convention and the Radiation Oncology Institute developing the National Radiation Oncology Registry and piloting it in prostate cancer at 30 centers. Meanwhile, Sweden has successfully implemented the naming convention and is collecting RT data in DICOM files through their Medical Information Quality Archive at most of their radiation centers.[243]

Meta-Analysis

A formal quantitative means of combining evidence from multiple clinical trials is meta-analysis, a widely used analytic tool in many areas of social and medical science. Meta-analysis refers to a process whereby data from independent studies are combined to form a quantitative summary estimate of a given effect.

Meta-analyses are considered by some to be a source of level I evidence along with large randomized clinical trials. A meta-analysis combines the results of several studies, all of which ask a similar research question but may be individually too small to have enough statistical power to definitively answer the question. Performing a systematic analysis of data from all identified randomized trials can define a modest yet real advantage associated with a therapeutic approach, such as OS associated with adjuvant radiation in breast cancer[244] and concurrent chemotherapy with radiation in head-and-neck cancer.[245] To address the likelihood of publication bias (ie, a greater representation of trials with positive results appearing in the

literature), a meta-analysis should include unpublished studies as well, though assessing quality is critical, given the lack of peer review.

Meta-analyses can be performed with or without access to the raw data, though the methods employed are critical to ensuring quality results. Cochrane is an independent, nonprofit, nongovernmental organization consisting of a group of more than 37,000 volunteers in more than 130 countries that aims to improve access to high-quality reviews that guide decision-making.[128] Researchers interested in undertaking meta-analyses are encouraged to contact the Cochrane Methods groups, which provide access to methodologists who can assist with responsible conduct of meta-analyses (http://methods.cochrane.org/methods-groups).

Clinical trials in radiation therapy often restrict access to raw patient data, including detailed treatment planning information in DICOM files, much of which is not reported or even investigated in the primary publication. For example, multiple trials have reported the presence of major protocol deviations predicting inferior OS.[208] Even determining the reason for the deviation can be difficult to find, since the process has been retrospectively defined until only recently. Access to the original images, treatment plans, and setup images could elucidate important information regarding details in QA that could better explain the differences in patient outcomes. An ideal system would promote the public availability of trial data to facilitate further research with a currently available resource, such as FigShare (https://figshare.com/).

NEXT-GENERATION RADIATION ONCOLOGY TRIALS

Next-generation trials will need to include iterative, adaptive designs that are not *a priori* committed to studying uniform fraction intervals (ie, q daily, Monday to Friday *or* qod, Mon, Wed, Fri), but are based on the constant incorporation of serial imaging and liquid biopsies which can serve as surrogates of early response and/or resistance for most or a small component of the tumor. Growth of -omic information, and even patient-derived xenograft generation, all portend increasingly complex and innovative clinical trials in radiation oncology. With a growing role for the integration of immunotherapy with radiotherapy, an emerging landscape of combined modality therapy trials with immunotherapies, cellular therapies,

and beyond will challenge existing paradigms and classical designs in clinical trials for radiotherapy (Figure 14.8).

Emerging fields of radiomics[246] and mathematical modeling,[247] an outgrowth of evolutionary biology, will provide personalized radiotherapy prescriptions that may change multiple times during a course of treatment.[248-252]

Although the patient and providers may not know the length and schedule of the prescription at the time of the initial consultation, positive results will demand that trials incorporate disruptive algorithms to test promising and disruptive treatment paradigms. Figure 14.9 provides just one of many potential snapshots of the next-generation clinical trial approaches for radiation-based cancer research.

CHAPTER 15

Stem Cell Transplantation and Radiation Therapy Techniques

Christopher R. Kelsey, Jeffrey W.C. Wong, Pranalee Patel, Mitchell E. Horwitz, Qiuwen Wu, and Sarah Jo Stephens

Historically, total body irradiation (TBI) was used without stem cell support for palliation of radiation-sensitive diseases such as chronic lymphocytic leukemia (CLL) and follicular lymphoma. Currently, TBI is primarily performed in the context of hematopoietic stem cell transplantation (SCT) for its cytotoxic and immunosuppressive effects. The patient's hematopoietic system is reconstituted after high-dose chemotherapy, with or without TBI, from either the patient's own stem cells (autologous) or stem cells from a donor (allogeneic). In the case of donor stem cells from an identical twin, the term "syngeneic transplantation" is appropriate. Total marrow irradiation (TMI) and total marrow and lymphoid irradiation (TMLI) utilize more targeted delivery of radiation therapy (RT) with increased sparing of surrounding normal tissues. This chapter will also briefly address hemibody irradiation (HBI), which is occasionally utilized for palliation of diffuse metastatic disease, and total lymphoid irradiation (TLI), which is utilized in a variety of clinical settings. Stem cell support is not required in these settings.

RATIONALE FOR STEM CELL TRANSPLANTATION

Hematopoietic SCT, while utilized in a variety of settings, is primarily pursued for patients with high-risk or relapsed/refractory hematologic malignancies to decrease the risk of disease recurrence. Multipotent stem cells have the capacity to differentiate into all blood cell lineages and can be obtained from several sources including bone marrow, peripheral blood, and umbilical cord blood. Stem cells can be harvested directly from the marrow or through apheresis of the peripheral blood following administration of granulocyte colony-stimulating factor. The conditioning regimen for hematopoietic SCT has several important functions and depends on the type of transplant—autologous (auto-SCT) or allogeneic (allo-SCT). For the former, the sole purpose of the conditioning regimen is cytotoxicity. For allo-SCT, the conditioning regimen also facilitates immunosuppression (helping to prevent host rejection of donor stem cells) and creates space in the bone marrow for the graft. Conditioning

regimens can consist of chemotherapy alone or a combination of chemotherapy and TBI.

Autologous Transplantation

Autologous transplantation relies upon higher doses of chemotherapy to overcome the resistance of malignant cells with subsequent reinfusion of stem cells to reconstitute the hematopoietic system. The most common indications for auto-SCT are multiple myeloma, relapsed diffuse large B-cell lymphoma, and relapsed Hodgkin lymphoma. Peripheral blood stem cells are the graft product of choice for auto-SCT and are associated with improvements in rates of engraftment, quality of life, and reduced cost when compared with cells derived from bone marrow.[1] Patients undergoing auto-SCT must be reasonably fit to tolerate high-dose chemotherapy and/or TBI. With modern supportive care and increasing experience with this procedure, the risk of mortality from auto-SCT is quite low (~1%).

The timing of auto-SCT depends on the underlying disease. For most patients with relapsed aggressive lymphomas, auto-SCT is preceded by a salvage chemotherapy regimen. If the patient has chemotherapy-sensitive disease, ideally demonstrated by achievement of a negative positron emission tomography-computed tomography (CT) scan,[2] then the patient proceeds with high-dose chemotherapy and auto-SCT. Choice of high-dose chemotherapy regimen is based on the underlying disease. For example, in the setting of relapsed Hodgkin lymphoma, BEAM (carmustine, etoposide, cytarabine, melphalan) is often utilized. High-dose melphalan is the most common conditioning regimen for multiple myeloma.

When consolidation RT is indicated, it is typically administered after recovery from the auto-SCT procedure. However, there is increasing experience with giving it before, especially in patients not achieving a complete response with salvage chemotherapy. Some concern exists for administering RT to the chest prior to auto-SCT as a higher risk of pneumonitis has been observed.[3]

Allogeneic Transplantation

As opposed to auto-SCT, which relies completely on cytotoxicity from high-dose chemotherapy and/or TBI to eradicate persistent tumor clones, allo-SCT relies on an immunologic graft-versus-tumor effect to eradicate malignant cells. The most common indication for allo-SCT is high-risk and relapsed acute leukemia, particularly acute myelogenous leukemia (AML) and acute lymphocytic leukemia (ALL). Allo-SCT may be preceded by full-dose (myeloablative) conditioning designed to have maximal antitumor effect and also to condition the patient for the infusion of the donor cells as an immunologic therapy. Increasingly, allo-SCT is preceded by a non-myeloablative or reduced-intensity conditioning program. In this latter situation, the

major antitumor effect is postulated to derive from the infused donor stem cells, and the intensity of the conditioning regimen is reduced to allow the procedure in patient populations previously ineligible due to age or other medical conditions. Non-myeloablative allogeneic transplants are associated with lower treatment-related morbidity compared with myeloablative allogeneic transplants. Most transplant centers utilize peripheral blood progenitor cells, as opposed to bone marrow, for allo-SCT.

Thus, allo-SCT is largely an immunologic therapy. Allogeneic hematopoietic cells are ideally matched with the recipient for all the major histocompatibility antigens to avoid rejection and minimize graft-versus-host disease (GVHD). For patients with matched donors, differences in minor human leukocyte antigens (HLAs) facilitate the graft-versus-tumor effect that enhances transplantation efficacy. Transplantation with half-matched family members (haploidentical transplantation) or mismatched unrelated cord blood stem cell grafts now provides comparable outcomes to a matched donor transplant. Early studies demonstrated improved leukemia control with allogeneic bone marrow cells as compared to syngeneic (identical twin) donor cells.[4] Further evidence for graft-versus-tumor effect derives from the efficacy of donor lymphocyte infusions after relapse of leukemia following allo-SCT.[5]

Despite HLA matching, allo-SCT is limited by GVHD. GVHD results from the release of inflammatory cytokines as a result of activation of mature donor T cells that recognize recipient HLA allo-antigens, presented as peptide molecules by antigen-presenting cells. Acute GVHD includes clinical damage to the skin, gastrointestinal tract, and liver, but other organs can also be involved. GVHD may evolve, or develop de novo, later after transplantation with distinct clinical features resembling sporadic autoimmune diseases (termed chronic GVHD). Common presentations include sicca syndrome, sclerotic or lichenoid skin disease, and immune hepatitis. Fasciitis/myositis and bronchiolitis obliterans syndrome are less common presentations, which may cause significant morbidity.

Posttransplant high-dose cyclophosphamide is the current standard to prevent acute and chronic GVHD.[6] Increased immunosuppression may ameliorate symptoms from GVHD but may also abrogate the graft-versus-tumor effect and place patients at higher risk for posttransplant infections. Acute GVHD can also be effectively prevented by T-cell depletion of the donor cells prior to stem cell infusion, but this may also lead to an increased risk for infections as well as the concern that the desirable graft-versus-tumor effects will be diminished or lost. Nevertheless, there has been clinical success with T-cell-depleted allo-SCT in reducing GVHD. Such techniques require more intensive immunosuppression to prevent graft rejection and therefore often employ TBI in the conditioning regimens.

Myeloablative Allogeneic Stem Cell Transplantation

TBI has been a central part of allo-SCT for leukemias since the late 1950s. Historically, a single dose of 10 Gy utilizing a low dose rate (~10 cGy/min) was used. The premise that TBI had to be given as a single fraction was challenged in the late 1970s. It was concluded that with the same total dose, an improved therapeutic ratio would be expected from a reduction in the dose rate of single-fraction TBI or by TBI fractionation. A variety of fractionated TBI schedules are currently employed in clinical practice with no one regimen clearly superior to another. Currently, most myeloablative TBI programs use a 2 or 3 times a day fractionation scheme over 3 to 5 days to deliver a total dose of 12 to 15 Gy.

Non-myeloablative or Reduced-Intensity Allogeneic Stem Cell Transplantation

In the past decade, growing recognition of the immunotherapeutic potential of allografts has led to a reconsideration of the need for high-dose myeloablative conditioning regimens traditionally administered prior to transplantation. Numerous clinical trials have established that a spectrum of non-myeloablative conditioning regimens of varying intensity may allow engraftment of donor cells with reduction in transplant-related toxicity, permitting transplantation of patients traditionally excluded from allo-SCT because of age or medical comorbidities.[7] The primary purpose of a non- myeloablative preparatory regimen is to suppress the patient's immune system sufficiently to allow the engraftment of donor cells with minimal host toxicity. The graft-versus-tumor effect is relied upon to eradicate tumor cells.

Common to these regimens is sufficient immunosuppression to overcome host resistance to engraftment using either the purine analog fludarabine, TBI, or both, in combination with other agents. Other factors, such as patient age, HLA disparity with the donor, tumor burden, and prior therapy, may also affect the degree of engraftment. For example, a series from the Seattle transplant group demonstrated that a single 2-Gy fraction of TBI, in combination with postgrafting cyclosporine and mycophenolate mofetil, is sufficient to achieve a high rate of donor engraftment in patients with a prior history of auto-SCT, but additional immunosuppression in the form of fludarabine is necessary to ensure engraftment in less heavily pretreated patients or patients receiving unrelated donor grafts.[8]

Reduced-intensity transplants now account for a significant number of all allo-SCTs. While reduced-intensity transplants allow older and less robust patients to undergo allogeneic SCT, in many circumstances, myeloablative conditioning is superior. In a randomized trial, patients aged 18 to 65 with a comorbidity index of 4 or less with acute myeloid leukemia and myelodysplastic syndromes were randomized to myeloablative versus reduced-intensity conditioning.[9] The trial was discontinued early after 272 patients were enrolled due to excess relapses in the reduced-intensity arm. Relapse-free survival (RFS) at 18 months was 47% versus 68%, favoring the

myeloablative arm ($P < .01$). As expected, treatment-related mortality favored the reduced-intensity conditioning arm (4.4% vs 15.8%, $P = .02$).

PURPOSES OF CONDITIONING

The purpose of high-dose chemotherapy, with or without TBI, prior to auto-SCT is simply to give a higher intensity of treatment to overcome intrinsic tumor resistance, thereby decreasing the risk of a relapse. The purpose of conditioning in the setting of allo-SCT is more complex and serves three key functions: to provide sufficient immunosuppression in the recipient to prevent rejection of the graft, to create space in the bone marrow for donor stem cells, and to provide further cytoreduction to achieve a minimal residual disease state prior to transplant. Myeloablative regimens address all three, whereas reduced-intensity regimens provide immunosuppression and create space for the donor stem cells but with variable, and lesser degrees of, further cytoreduction.

The choice of conditioning regimen prior to transplantation depends upon a variety of factors that include the type of transplant (allogeneic vs autologous), conditioning intensity (myeloablative vs non-myeloablative), disease type (eg, AML vs ALL), expected patient tolerance (eg, age, medical comorbidities), and disease status.

Total Body Irradiation–Based Conditioning Regimens

There is wide variability between centers in regard to the techniques utilized for TBI including total dose, fractionation scheme, dose rate, lung shielding, and technique/patient positioning. Some aspects have been formally evaluated with randomized studies, whereas many others have not.

In regard to total dose, two randomized trials have compared 12 versus 15.75 Gy in patients with AML and chronic myelogenous leukemia (CML). In the AML study, patients randomized to the higher-dose arm were noted to have improved RFS ($P = .06$) but at the cost of increased non-relapse mortality (NRM) ($P = .04$) and moderate-to-severe GVHD ($P = .02$).[10] There was no difference in overall survival (OS). In the CML series, a disease that is rarely transplanted anymore given the efficacy of tyrosine kinase inhibitors, the investigators also noted improvement in RFS ($P = .008$), with a nonsignificant trend toward increased NRM ($P = .13$) and moderate-to-severe GVHD ($P = .15$) in patients receiving the 15.75 Gy regimen.[11] As OS was not improved in either study, more moderate total doses seem preferable.

Several studies have evaluated single fraction compared with multifraction regimens. Deeg et al[12] evaluated 75 patients with acute non-lymphoblastic leukemia in first remission. The first 22 patients enrolled on the study received 9.2 Gy in a single fraction at 4 to 6 cGy/min utilizing opposed cobalt sources. The remaining patients were randomized to either 10 Gy in a single fraction or 12 Gy in six fractions.

Survival was improved in the patients receiving either 9.2 Gy in a single fraction or 12 Gy in six fractions compared to 10 Gy in a single fraction (P = .04). There was an increase in early toxicity, particularly hepatic veno-occlusive disease/sinusoidal obstructive syndrome (VOD/SOS), in patients receiving 10 Gy in a single fraction. Pneumonitis appeared more common in single fraction (both 10 and 9.2 Gy) compared to the fractionated regimen. Girinsky et al[13] randomized 160 patients to either 10-Gy single-fraction (12.5 cGy/min instantaneous dose rate, 4.5 cGy/min average dose rate) or hyperfractionated TBI to 14.85 Gy in 11 fractions (25 cGy/min instantaneous dose rate). They noted no difference in OS or cause-specific survival. There was an increase in incidence of VOD/SOS in patients who received single-fraction TBI (P = .044). In a study from the Hôspital Tenon in Paris, 157 patients were randomized to single-fraction TBI with variable dose rate (6 vs 15 cGy/min) or fractionated TBI with variable dose rate (3 vs 6 cGy/min).[14] No significant differences were noted between the single-fraction and fractionated TBI schedules, or by dose rate. The preponderance of data favors a fractionated regimen using a low-dose-rate approach.

The choice of chemotherapy agents used in conjunction with TBI depends on the underlying disease. For AML, and in many other settings, high-dose cyclophosphamide is utilized given its effectiveness in both immunosuppression and cytotoxicity. A typical dose is 120 mg/kg over 2 days. In other settings, agents such as etoposide, melphalan, and/or fludarabine are combined with TBI. Reduced-intensity or non-myeloablative transplant regimens using low-dose TBI are often combined with fludarabine.

Chemotherapy and TBI are given sequentially rather than concurrently to avoid any potential increase in normal tissue toxicity. Whether chemotherapy should be given before or after TBI is unclear. One study of 1,769 patients undergoing myeloablative allo-SCT for acute leukemia did not show any differences in outcomes with cyclophosphamide given before or after TBI.[15] Typically, TBI over 3 to 5 days is best delivered during the regular work week, when the full technical support staff is available. TBI may be better tolerated if given first when the patient is less fatigued and not experiencing the side effects of chemotherapy. The risk of nosocomial infections may be marginally lower when the patient travels to the RT department before becoming neutropenic later in the conditioning course. Alternatively, TBI at the end of the preparative regimen allows the SCT to proceed immediately thereafter. Unlike chemotherapy, there is no washout period needed for TBI, theoretically decreasing the time the patient spends neutropenic prior to engraftment.

Chemotherapy-Alone Conditioning Regimens

Although the evolution of TBI has led to significant reduction in toxicities, initial concern about the risk of fatal radiation pneumonitis led to the development of non-

TBI regimens. In addition, conditioning with chemotherapy alone can be used in practice settings where TBI is unavailable. Combinations have been developed based on biologic activity of a particular drug, drug tolerability, and non-overlapping drug toxicities. The most commonly used ablative regimens to condition patients with AML are the combination of busulfan and cyclophosphamide (BuCy) or busulfan and fludarabine. Single-agent high-dose melphalan is also used frequently prior to auto-SCT for treatment of multiple myeloma. For patients with aplastic anemia, the combination of cyclophosphamide and antithymocyte globulin is often used for immunosuppression while avoiding excessive myelotoxicity. There is interfacility variation in dosing and drug delivery schedules, making it somewhat difficult to make direct comparisons between these regimens.

Most of the initial trials using BuCy used high-dose oral busulfan, which has highly variable pharmacokinetics, poor gastrointestinal tolerability, high rates of VOD/SOS, and increased frequency of seizures. An intravenous formulation of busulfan has been developed, which is much better tolerated, has more predictable pharmacokinetics, and has been associated with less toxicity.

Total Body Irradiation–Based Versus Chemotherapy-Alone Conditioning Regimens

Randomized studies comparing chemotherapy-alone conditioning regimens to TBI-based regimens are few, often enrolled multiple leukemia subtypes, included a variety of patients (eg, first complete remission, relapse, etc), and used antiquated TBI and chemotherapy platforms. These limitations make it difficult to reach firm conclusions.

Considering AML (Table 15.1), a French randomized trial compared BuCy to TBI-Cy before allo-SCT for adult AML in first remission.[16] TBI-Cy was superior for disease-free survival (DFS) ($P < .01$), leukemia relapse ($P < .04$), and NRM ($P < .06$). Long-term follow-up also demonstrated worse OS and leukemia-free survival (LFS) in the patients receiving BuCy compared to TBI-Cy, felt to be the result of higher transplant-related mortality and relapse rates.[17]

ALL, acute lymphocytic leukemia; AML, acute myelogenous leukemia; Bu, busulfan; CML, chronic myelogenous leukemia; Cy, cyclophosphamide; GVHD, graft-versus-host disease; IV, intravenous; LFS, leukemia-free survival; NS, not significant; OR, odds ratio; PO, by mouth; RR, respiratory rate; SWOG, Southwest Oncology Group; TBI, total body irradiation; VOD/SOS, veno-occlusive disease/sinusoidal obstructive syndrome.

[a]Included data from patients with ALL/CML.

Several retrospective series, most using registry data, have evaluated TBI-based versus chemotherapy-alone conditioning regimens in AML. Most retrospective analyses demonstrate equivalent outcomes when comparing oral busulfan-containing regimens compared to TBI-Cy.[18,19] A single-institution retrospective series from Duke showed superior LFS and OS in patients with AML treated with TBI-Cy compared to BuCy, at the expense of increased pulmonary toxicity.[20] Intravenous busulfan has the added advantage of better tolerability and pharmacokinetics. The data are inconsistent whether intravenous BuCy is more effective than TBI-Cy regimens.[21,22]

In regard to ALL (Table 15.2), Bunin et al[23] published a randomized series of pediatric and adolescent young adult (AYA) patients with ALL treated with either etoposide- cyclophosphamide-TBI or etoposide-BuCy. The authors found an improvement in event-free survival (EFS; $P = .03$) for patients in the TBI arm. The For Omitting Radiation Under Majority age (FORUM) trial was a multicenter, noninferiority study comparing TBI-etoposide to fludarabine/thiotepa and either treosulfan or busulfan in pediatric and AYA patients with high-risk ALL in complete remission. Two-year OS was significantly higher following the TBI-based regimen ($P < .01$), with decreased incidence of relapse ($P < .01$) and NRM ($P = .027$). Based on the interim analysis, the futility stopping rule was applied and random assignment was discontinued.[24] Finally, a multi-institutional Chinese trial randomized patients with standard-risk ALL undergoing allo-SCT in first complete remission to TBI-Cy or BuCy and found no difference in OS, incidence of relapse, DFS, or NRM at 2 years with no difference in regimen-related toxicity, GVHD, or late effects.[25]

[c]Relapse rate.

A randomized trial from the French Society of Bone Marrow Graft, which also evaluated the impact of single- fraction versus fractionated TBI, showed no difference in overall 5-year OS or DFS for patients with CML treated with BuCy versus TBI-Cy.[26] Similarly, the study by Clift et al[27] showed no significant difference for 3-year OS, relapse, EFS, or speed of engraftment for BuCy versus TBI-Cy for CML.

Multiple trials have evaluated conditioning regimens in patients with different underlying diagnoses. A randomized study from the Southwest Oncology Group 8612 compared fractionated TBI plus etoposide versus high-dose BuCy in patients who had failed prior conventional therapy for ALL (36%), CML (35%), and AML (29%). Patients were stratified as "good risk" (second complete remission for acute leukemia or accelerated phase CML) or "poor risk" (more advanced stages of leukemia). There was no difference noted in OS or DFS between the two treatment groups.[28]

Ringdén et al[29] of the Nordic Bone Marrow Transplantation Group compared BuCy to TBI-Cy in patients with AML (41%), CML (36%), and ALL (23%). Patients treated with BuCy had higher rates of VOD/SOS ($P = .009$), hemorrhagic cystitis ($P = .003$), NRM in those with advanced disease ($P = .002$), seizures ($P = .03$), high-grade chronic GVHD ($P = .04$), and death associated with GVHD ($P = .003$). There were similar rates of acute GVHD between the two groups. RFS was similar upon analysis of all patients, but in the subgroup of adult patients ($P = .05$) and advanced disease ($P = .005$), the TBI-containing regimen appeared superior. Long-term follow-up of this study demonstrated a 7-year relapse rate of 29% in both groups. In patients with advanced disease, there was a significant increase in NRM in patients who received BuCy ($P = .004$). There was no difference in LFS in patients with early disease, but there was an improvement in LFS in patients with advanced disease receiving TBI ($P < .01$).[30]

Socié et al[31] published long-term follow-up of four randomized controlled trials. For patients with AML, there was a strong trend toward improved OS ($P = .068$) and DFS ($P = .051$) with TBI-Cy. A meta-analysis by Hartman et al[32] evaluated five prospective randomized controlled trials with 652 patients treated from 1966 to 1996 and showed trends not reaching statistical significance in favor of TBI for both OS and DFS. Another meta-analysis by Shi-Xia et al[33] evaluated 18 trials with a total of 3,172 patients. For patients with ALL or AML, TBI-Cy was associated with lower rates of leukemia relapse, lower NRM, and higher rates of DFS. However, for patients with CML, the TBI-Cy regimen was associated with higher rates of leukemia relapse, lower NRM, and similar DFS. The risk for cataracts ($P = .01$), pneumonitis, and growth/developmental problems ($P = .008$) was higher with a TBI-containing regimen. Alternatively, the risk of VOD/SOS ($P < .00001$), hemorrhagic cystitis, and transplant-related mortality appeared higher for patients treated with BuCy.

To summarize, limited randomized data, with obvious limitations, have not demonstrated any difference in outcomes with TBI and non-TBI-based regimens for

CML. For AML, the available randomized studies and meta-analyses favor TBI-Cy, although this is controversial given negative findings from nonrandomized registry studies (Table 15.1). For ALL, TBI appears to be an important component of the conditioning regimen (Table 15.2).

The side-effect profile of different conditioning regimens is also an important consideration. Although there can be significant overlap in treatment-related toxicities between chemotherapy and TBI-based conditioning regimens, such as fatigue and nausea, some toxicities are more common with one modality versus another. Although both chemotherapy and TBI can cause lung toxicity, TBI-based regimens appear to be associated with a higher risk of pneumonitis and other lung complications.[16,20] Prior thoracic RT may increase the risk of fatal pneumonitis. One study demonstrated a 32% risk of fatal pneumonitis after TBI in patients with prior chest radiation doses above 20 Gy.[34] Avoiding TBI may be prudent in such patients. One contemporary series of allo-SCT documented a 33% risk of severe pulmonary toxicity after TBI-based conditioning, with the number of prior chemotherapy regimens being the only independent risk factor for lung toxicity.[35] Cataracts and endocrine deficiencies are also more common with TBI.

In contrast, hepatic VOD/SOS and hemorrhagic cystitis are more common with BuCy.[32] The Nordic Bone Marrow Transplantation series showed a VOD/SOS incidence of 12% in patients treated with busulfan compared to 1% for the TBI-treated patients (P = .009). Hemorrhagic cystitis risk was 24% for busulfan-based therapy versus 8% for TBI (P = .002).[29]

A relative advantage in using TBI for SCT is that the dose delivery throughout the body is highly controllable. In contrast to chemotherapy, dose distribution is independent of such factors as blood supply, and there are no concerns about agent activation, metabolism, excretion, or dose modifications based on liver or kidney function. TBI may also reach chemotherapy sanctuary sites, which is of particular concern in patients at risk for testicular or central nervous system (CNS) involvement.

GRAFT FAILURE

Failure to engraft is a potential life-threatening complication of allo-SCT. Approximately 6% of patients fail to engraft with myeloablative conditioning, with a similar number of patients experiencing secondary graft failure thereafter.[36,37] Not surprisingly, graft failure is associated with worse outcomes. For those patients who fail to engraft after a myeloablative conditioning regimen, salvage allo-SCT with a TBI-based regimen is possible. Several small, single-institution studies have described using a non-myeloablative regimen in this setting,[38,39] Reduced-intensity regimens can be used to escalate host immunosuppression and increase the probability of successful engraftment without exposing patients to the risks of a second myeloablative regimen.

TOTAL BODY IRRADIATION

Radiobiology

Radiobiologic Effects on the Normal Hematopoietic System

In addition to the hematopoietic elements, the bone marrow also contains mesenchymal stromal cells that play a critical role in the formation of blood cellular components. Hematopoietic stem cells reside in specialized niches within the bone marrow and are regulated by bone marrow stromal cells.[40] Successful hematopoietic stem cell engraftment in the setting of an allo-SCT requires (a) eradication of the recipient's own stem cells, (b) immunosuppression to prevent rejection of donor stem cells, and (c) relative sparing of the recipient's bone marrow stromal cells. Ionizing RT appears to have a differential effect on hematopoietic stem cells and marrow stromal cells.

The use of the classic radiobiologic parameter D_0 gives a rough indication of the radiosensitivity of various cell populations. With the caveat that many factors can affect observed D_0 values (eg, dose rate and fractionation), the reported D_0 values of hematopoietic cells usually range from 0.5 to 1.6 Gy, with little or no shoulder associated with dose-survival curves.[41,42] This intrinsic radiosensitivity is due, in part, to a limited capacity to repair sublethal damage. Hematopoietic cells are consequently affected less by changes in dose rate or fractionation.

If bone marrow stromal cells and their progenitors (colony- forming unit fibroblasts) are damaged, delayed engraftment or even graft failure may follow. Progenitors of human bone marrow stromal cells have been found to have a D_0 of 1.46 Gy.[42] D_0 values in mice and dogs have been shown to be higher, with a broad shoulder on dose-survival curves. Thus, radiation fractionation and utilization of low dose rates are expected to spare bone marrow stromal cells and their progenitors.

Immunosuppression in the setting of allogeneic SCT is necessary to avoid rejection of donor stem cells. TBI is a very efficient immunosuppressant. In animal work by Storb and colleagues, equivalent doses of fractionated TBI were significantly less effective than single-dose TBI to condition dog leukocyte antigen–identical littermate dogs before bone marrow transplantation.[43] The investigators concluded that significant repair of DNA damage by lymphoid cells occurs during interfraction intervals. In a murine model, Salomon et al[44] looked at three TBI schemas from schedules that had been developed for human TBI therapy (8.5 Gy single-fraction TBI, 2 Gy × 6 fractions of TBI, and 1.2 Gy × 12 fractions of hyperfractionated TBI). In terms of the immunosuppressive effects, the results favored single-fraction TBI. A marked initial shoulder on the dose-survival curve has been reported for T-lymphocyte precursors[45] and for a human lymphoblastoid cell line.[46] The immunosuppressive effects of TBI show marked fractionation sensitivity, leading one to conclude

fractionated TBI might be associated with more graft rejections than the same dose delivered in a single fraction.

Radiobiologic Effects on Leukemia

In the setting of allo-SCT, TBI achieves significant leukemia cell killing in conjunction with chemotherapy and the subsequent graft-versus-tumor effect, leading to eradication of malignant clones in a significant portion of cases. Most D_0 values for both animal and human leukemia cell lines range from 0.8 to 1.5 Gy,[47,48] although extreme values range from 0.3 to more than 5 Gy. Leukemia cells do retain some degree of sublethal repair capacity, which is likely more operational in more differentiated leukemias. Further, heterogeneity in inherent radiosensitivity inevitably exists between leukemic cell lines. Most studies suggest that fractionated TBI is likely less effective than single-dose TBI (utilizing the same dose) for leukemia cell killing.[42]

Techniques and Dosimetry

Basic Requirements

Historically, radiation oncologists have aimed to deliver a relatively homogeneous dose of radiation throughout the body to (a) eradicate host stem cells that are localized to bone marrow niches, (b) eliminate residual circulating leukemia cells, and (c) deplete host immune cells, where both microscopic leukemia cells and host immune cells are likely widely distributed throughout the body. Hence, *total body irradiation*. Newer techniques including TMI and TMLI have challenged this paradigm. With any approach, where there is concern for a higher burden of disease, boost radiation fields may be utilized. Augmented doses of radiation may be delivered to the brain in the setting of CNS involvement or to the testes in males with ALL, for example.

To ensure the planned dose distribution is accurately delivered, all TBI techniques must undergo a rigorous and comprehensive dosimetric characterization. Because of large variations in body geometry and tissue density between patients, it is recommended that dose homogeneity remain within a specified window of plus or minus 10% of the prescribed dose, although plus or minus 5% is typically attainable. For TBI and HBI, there is evidence that a 5% change in lung dose could result in 20% change in the incidence of radiation pneumonitis, a complication that is sometimes fatal.[49,50] Therefore, the basic dosimetry of TBI (and HBI) techniques should be performed as precise as readily achievable. Accurate dosimetry coupled with an effective quality assurance program, including adjustments to dose delivery after in vivo measurements on the first day of treatment, will ensure not only safe delivery of TBI treatments but also accurate dosimetry data for meaningful dose-response analysis. Once a patient begins a course of TBI, within a comprehensive conditioning

program, the timing of successive fractions becomes critical to the outcome of the procedure. It is imperative to have a backup TBI system either within the same institution or in a nearby RT department when establishing a TBI program. When the primary system is down, a fully commissioned backup TBI system can be utilized to complete the remaining treatments.

Standard Total Body Irradiation Techniques

Many TBI techniques have been described and improvements in both the irradiation technique and physical dosimetry continue.[51] Nuances and specifics of particular techniques are outside the scope of this chapter. To be brief, many centers have facilities designed specifically for large-field irradiation. Although a few dedicated systems still exist, current TBI procedures are largely performed with techniques established on linear accelerators that are also used for conventional RT. Common to these TBI techniques is the use of radiation fields that are larger than the maximum field size (~40 by 40 cm) available at standard source-to-surface distance (SSD), requiring patients with TBI to be treated at extended SSDs of 200 to 600 cm. For treatment rooms large enough to accommodate an SSD of 5 m or more, a single square field at maximum collimator opening is usually sufficient to completely encompass patients of typical height placed along the diagonal of the field (Figure 15.1A-E). At shorter SSDs, multiple abutting fields may be necessary, and irradiation of the whole body can be achieved by translating the radiation field or the patient, or by sweeping the radiation field over a stationary patient (Figure 15.1F-H). For these irradiation techniques, patients are typically treated with two parallel-opposed fields. When a single radiation source is used, this can be accomplished by rotating the patient 180° along the patient's longitudinal axis between the two fields. In a dedicated system with two radiation sources mounted opposite to each other, the treatment can be accomplished by irradiating the two fields simultaneously without changing the patient's position. Various patient positions, ranging from sitting, standing upright, to lying horizontally in a supine or lateral decubitus position, have been used (Figure 15.1A-H).

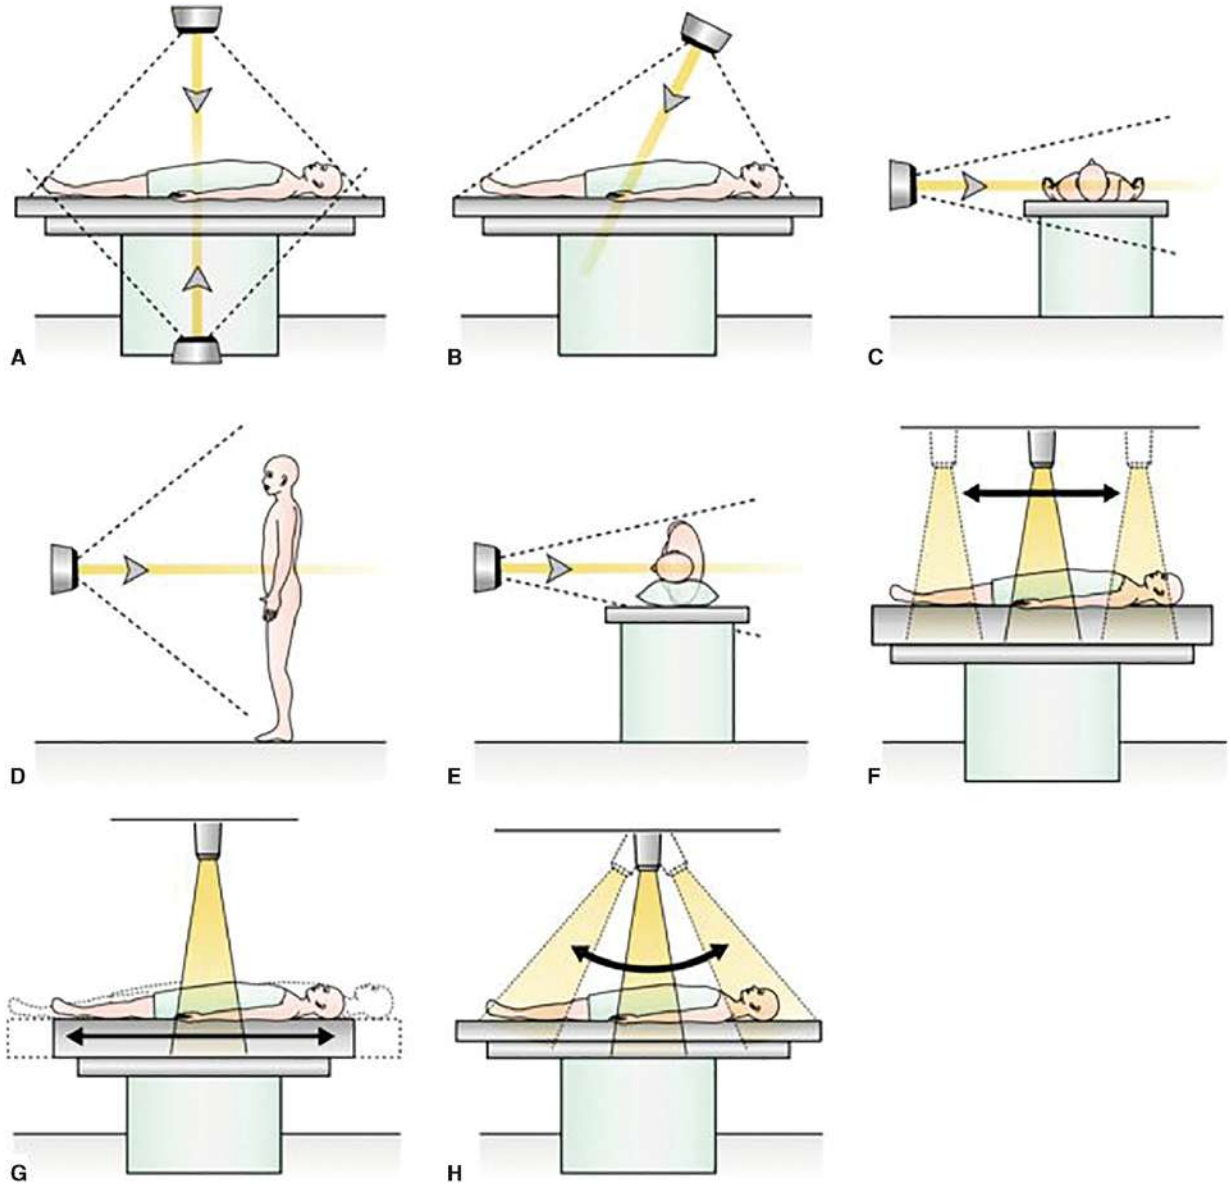

FIGURE 15.1 Some of the traditional large-field total body irradiation (TBI) techniques in which patient and beams are stationary. A. Two vertical beams. B. One vertical beam. C. One horizontal beam, patient in supine position. D. One horizontal beam, patient standing or sitting. E. One horizontal beam, patient in lateral decubitus position. F-H. Some of the small-field TBI techniques in which patient or beam moves. F. Source scans horizontally. G. Patient moves horizontally. H. Sweeping beam.

Techniques using a single large field encompassing the entire patient at extended SSD is by far the simplest and the most prevalent TBI technique used today. Such approaches eliminate the dosimetry complications occurring in the junctions of multiple abutting fields. They also alleviate the concern that cells circulating through the body may potentially receive a reduced dose when abutting fields are delivered sequentially.

Dosimetric Characterization of Total Body Irradiation Techniques

Once an irradiation technique is chosen, a careful characterization of the dosimetric properties of the technique should be performed by a qualified medical physicist. The dosimetric data needed to model the treatment planning system for accurate planning of TBI for individual patients should be carefully measured and validated. The technical issues and method of radiation dosimetry for TBI have been reviewed in several reports. In particular, a report from the American Association of Physicists in Medicine (AAPM) task group 29 (TG-29) on the physical aspects of TBI and HBI provides a comprehensive discussion on dosimetry issues and techniques specific to large-field TBI.[51] It is a good resource for medical physicists charged to commission a large-field TBI technique.

Since publication of the TG-29 report, the reference dosimetry protocol for external beams at standard treatment SSD, known as the TG-21 protocol, has been updated by a new calibration protocol (TG-51). For photon beams at standard SSD, the TG-51 protocol produces similar results as the TG-21 protocol. However, the TG-51 protocol cannot be applied directly for large fields at extended SSD as encountered in TBI. The calibration of a TBI beam can be established with direct traceability to TG-51 by using an approach similar to that proposed by Curran et al.[52] In this approach, the photon source of the TBI beam is first calibrated under the TG-51 reference condition at standard SSD. The dose per unit beam-on time at a reference point of the TBI beam under TBI treatment conditions is then related to the dose per unit beam-on time of the same photon source at the TG-51 reference point by a correction factor that accounts for the TBI setup geometry and scattering conditions. This correction factor, as well as the relative dose factors that characterize the spatial distribution of the TBI beam, such as the percent depth dose or tissue maximum ratio along the central axis, can be measured directly under the TBI treatment conditions using a phantom with size similar to that of a typical patient. In-phantom off-axis beam profiles at various depths, especially along the diagonal near the corners of the field, should also be measured at TBI treatment distances to evaluate the dose variation across the radiation beam. Independent verification of the TBI calibration should be performed after the initial commissioning. The modeling of the treatment planning system should also be verified on an anthropomorphic phantom.[53,54] A thermoluminescent dosimeter (TLD) or optically stimulated luminescence dosimeters (OSLDs) calibrated on an independent linear accelerator can be used to verify TBI calibration and doses at other points of interest. Other types of dosimeters such as ion chambers and film may be used to assess dose distributions.[55]

Skin Surface Dose

Although skin sparing is often a desirable feature of megavoltage irradiation in conventional RT, for TBI it may be desirable to have the skin surface receive close to

the full prescription dose, such as the setting of leukemia cutis. When needed, the skin dose can be increased by using either bolus placed on the skin or a beam spoiler positioned between the source and the patient. As photons of the TBI beam pass through the beam spoiler, scattered electrons are produced, which deposit most of their energy at shallow depths near the skin surface. The aim is to increase the skin dose to more than 90% of the prescription dose. In addition to the attenuation of the photon beam, use of a beam spoiler alters the depth-dose characteristics of the TBI beam in the buildup region. The magnitude of this modifying effect depends on the photon energy of the beam, the composition and thickness of the scatter screen, and the distance between the screen and the patient. It should be carefully evaluated as part of the commissioning task for the TBI technique. The dosimetric effect of the beam spoiler can be treated separately or included in the TBI beam calibration. When the beam spoiler is included in the calibration, choice of the calibration depth becomes an important consideration. Calibration measurements performed at a depth of 5 cm or greater decrease the influence of beam spoiler–generated electrons significantly.

Dose Rate

As discussed in the preceding sections, the rate of TBI dose delivery can have an impact on the clinical outcome after TBI.[56] Many clinical protocols require low-dose-rate treatment (0.05 to 0.20 Gy/min). Modern linear accelerators offer a wide range of dose rates (eg, from 1 to 6 Gy/min in increments of 1 Gy/min), to the depth of maximum buildup at standard SSD. At extended SSD, the nominal dose rate will be smaller because of inverse-square falloff of photon fluence with SSD. The dose rate at the TBI treatment distance is dependent on the combination of SSD and the nominal dose rate programmed at the linear accelerator console. The correct dose rate should be selected based on the prescription and patient geometry so that the absorbed dose rate in the patient does not exceed the limit. If a given combination of SSD and nominal dose rate does not produce a desired dose rate, a custom-made attenuator can be placed in the beam path to help achieve a desired dose rate.

Patient Positioning

As treatment times may last up to 30 or 40 minutes for each fraction of a TBI protocol (even longer for single-fraction protocols), patients must be placed in a comfortable and reproducible position. When a pair of parallel-opposed fields is used, irradiation along the anteroposterior/posteroanterior (AP/PA) direction is advantageous as the body thickness in the AP/PA direction is usually smaller than in the lateral direction, which results in better dose uniformity along the beam path for a given photon energy. As depicted in Figure 15.1A and B, this may be accomplished with the patient lying in the supine/prone position under a vertical beam arrangement or with the patient lying

on the side in a lateral decubitus position when a horizontally directed beam is used (Figures 15.1E and 15.2A, B). Irradiation with the patient lying supine using a horizontally directed beam (Figures 15.1C and 15.2E) is also a reasonable technique, especially for patients with small lateral separations, such as pediatric patients, or when a higher- energy photon beam is employed. Because of clinical problems associated with patient fatigue and orthostatic hypotension, special patient stands are used in some institutions to facilitate upright patient positioning (Figure 15.1D). For most children and all adults, an extended SSD will still be required for full body coverage.

Treatment Planning

Radiation beam-on times for a prescribed TBI dose are often calculated with a specialized in-house program or by manual computation. This is because most commercial treatment planning systems are designed and commissioned using standard datasets for conventional RT at SSD near 100 cm, which do not automatically apply to a TBI configuration at extended SSD of up to 400 cm. Some newer versions of commercial treatment planning systems can be adapted for isodose planning of TBI at extended SSDs by using depth dose, beam profiles, and other parameters measured directly under TBI conditions.

In addition to TBI beam characteristics, an accurate description of patient geometry is needed for patient-specific treatment planning. The external body contour of a patient with TBI in the treatment position can be reconstructed from the measurements of body thickness at representative anatomic points judiciously distributed over the patient's body. A CT scan of the entire body provides the best description of patient geometry and is required for intensity-modulated radiation therapy (IMRT)-based TBI/TMI techniques. For extended SSD TBI techniques using two parallel-opposed beams, dose variation over the patient's body arises primarily from (a) photon attenuation along the beam path, (b) the changing body contour across the patient, (c) variations in tissue density, and (d) dose profile dependence on off-axis distance.

The dose variation caused by photon attenuation along the beam path is dependent upon both the beam energy and the body thickness. It decreases with decreasing body thickness and increasing photon energy. Because the body is typically thinner in the AP direction, treating patients using an AP/PA technique with higher photon energy will improve the dose uniformity along the beam path. Using lateral-opposed beams will usually result in greater dose variation compared to AP/PA treatments, especially for adult patients. The dose variation caused by changing body contour may be reduced by using missing-tissue compensators or tissue-equivalent bolus material placed directly on the patient. The ability to compute isodose distribution across the body is highly desirable for compensator design. Missing-tissue compensator for TBI is typically constructed to even out the variation of body thickness along the head to toe direction. Such a one-dimensional compensator can be constructed manually using multiple thin brass (or other material) plates. As the compensator is usually mounted at the head of the linear accelerator (blocking tray), small variations in the placement of compensating plates will be magnified at extended SSD distance. Care must be exercised in constructing these compensators and placement during treatment. For example, when compensating plates are used for the head and neck region, mounting the compensator too far inferiorly could result in a lower dose to the shoulders. In addition, careful alignment of the patient to the planned position becomes important to achieve the desired missing-tissue compensation.

Dose variation caused by tissue heterogeneity in the thoracic region requires special attention because the lungs are a critical dose-limiting structure with TBI. Without compensation for air density, particularly for AP/PA treatments, dose inhomogeneity can exceed the prescribed dose by 10% to 24%, depending on the energy of beams used.[51] In order to reduce lung toxicity, correction for lung air density should be taken into account. Further, many institutions attenuate the dose to the lungs further using lung shielding. This can take many forms including customized lung blocks (typically in the setting of AP/PA fields; Figure 15.2B, C) or attenuation using brass compensators (typically in the setting of lateral fields; Figure 15.2F). The use of lung

blocks increases the complexity of the TBI procedure, and accurate repositioning of lung blocks can be a challenge for fractionated treatments. At some institutions, individualized thin lung blocks (with ~85% photon transmission) are mounted close to the patient on an acrylic resin tray using a hook and loop fastener system that allows easy repositioning of lung blocks for each fraction. At Duke, partial transmission blocks made of cerrobend alloy are mounted on a plastic tray placed 10 cm from the patient skin (Figure 15.3). Verification of correct lung block positioning is carried out by using customized online electronic portal imaging. For the lateral technique, the arms can be used, in addition to shielding using brass compensators, to decrease dose to the lungs (Figure 15.2E). For pediatric patients, the arm may not be large enough laterally to cover the entire lung.

FIGURE 15.3 Partial transmission blocks for lungs and kidneys made of cerrobend alloy mounted on a plastic tray placed 10 cm from the patient skin.

Dose Description and Reporting

Because there is no standard treatment technique for TBI, significant differences in dose distributions can exist with different treatment methods. Two institutions can prescribe the same dose at some selected prescription point, but dose to other points could vary considerably if different treatment techniques are used. Without supplemental information on the dose distribution, it would be difficult to assess the clinical effectiveness of different TBI programs based on the reported prescription dose alone. To facilitate treatment comparison among institutions, various methods for prescribing the dose for TBI treatments have been reported.[57,58] One method uses a single-point prescription dose supplemented with the specified limits of highest and lowest dose levels acceptable for any point within the body. In addition, dose limits are also set for certain tissues, such as the lungs. An example of such a TBI prescription is given in AAPM TG-29, which uses the midpoint at the level of the umbilicus as the prescription point. A prescription would read as follows: “The dose

to the midpoint at the level of the umbilicus is 14 Gy to be delivered in 8 fractions with 2 fractions on each day separated by at least 6 hours. All points in the body should receive doses within the limits of −5% and +10% of prescription dose. The dose to lung should be no more than 85% of the prescription dose." When reporting results from a TBI-based conditioning regimen, ideally, the actual values of the corresponding dose descriptors would be provided. When CT-based TBI treatment planning is available, dose statistics or a dose-volume histogram of the target volume and critical organs should be reported.

Quality Assurance

To improve dosimetric accuracy and consistency, periodic assessment of TBI calibration and beam characteristics should be performed as part of an ongoing quality assurance program. Each patient's treatment plan, including the design of customized tissue compensators when used, should be checked by an independent physicist. In addition, in vivo dosimetry verification of the treatment plan should be performed during the first fraction for all patients with TBI. Changes in patient body shape (eg, due to weight loss between the time of simulation and treatment delivery) and positioning can alter the dose distribution. Adjustment of radiation beam-on time and tissue compensators may be needed for subsequent treatments based on the in vivo verification (assuming the accuracy and confidence of in vivo measurement have already been established). TLD (or OSLD) and diode detectors are typical choices for in vivo monitoring of doses delivered to patients. These dosimeters should be calibrated to be suitable in the TBI beam under the treatment condition prior to commencing patient treatment. A diode dosimetry system with multiple diode detectors is especially convenient for these types of measurements because they allow simultaneous measurement of doses at multiple anatomic sites in nearly real time.

Lung (and Other Organ) Dose Attenuation

Many transplant centers use lung blocks or lung shielding during TBI in order to correct for the dosimetric effects of lung density or to specifically reduce the dose to lung tissue, thereby reducing the risk for pneumonitis. This is particularly important in patients who have baseline lung dysfunction.[59] Lung shielding will reduce the risk of pneumonitis, all other factors being equal.[60] Overcompensation, however, risks an increase in leukemia recurrence. A study from the Institut Gustave Roussy delivering 10 Gy as a single fraction of TBI over 4 hours showed a higher incidence of relapse in patients whose lung dose was reduced to 6 Gy with lung blocks compared with 8 Gy.[61]

There are many techniques to attenuate the dose to the lungs. Where lateral TBI fields are utilized, the dose to the lungs can be attenuated using brass compensators (Figure 15.2F). The required thickness and the size of the brass compensators can be estimated based on the patient chest x-ray and verified with portal imaging. The

downside of this approach is that the RT dose is reduced not only to the lungs but also to the mediastinum and chest wall. Where AP/PA fields are utilized, lung blocks can be utilized to reduce lung dose (Figure 15.2A-D). Some, but not all, centers employ electron boosts to the chest wall under the blocks. There are considerable dosimetric challenges with this technique: overlap issues of photon and electron fields; surface contour variability, especially from breast tissue in women; and delivering unwanted radiation dose to some limited volume of the lungs.

When TBI is used for non-neoplastic diseases (eg, aplastic anemia), where the main objective is immunosuppression, one may also consider shielding radiosensitive structures such as the gonads or eyes (ie, the lens).

Boosting of Selected Organs With Total Body Irradiation

A relative advantage of TBI is the treatment of chemotherapy sanctuary sites. This is particularly important when treating diseases with a propensity to involve the CNS or testes. Theoretically, regions of the body where there is a higher burden of disease at the time of transplant may be boosted with additional radiation to supplement TBI. In selected patients with acute lymphoblastic leukemia, CNS-preventative therapy may include cranial irradiation. When such patients are determined at diagnosis to be best managed with an allo-SCT, it is reasonable to defer prophylactic cranial irradiation until the time of TBI. Augmented doses of radiation may be delivered to the CNS, bringing the cumulative cranial dose to approximately 18 Gy (a current standard in children and many adults with ALL). Higher total doses to the brain and perhaps the spine can be considered in patients being managed with overt CNS leukemia. Boost doses to the brain using lateral fields may be given in 1.5 to 2.0 Gy fractions. Caution is necessary for additional CNS boost treatments when patients have received prior cranial irradiation because of toxicity concerns. Similarly, the testes in males with ALL may be boosted to a cumulative dose of approximately 16 to 18 Gy. The scrotum may be treated with en face electrons of appropriate energy or a single superior/anterior/oblique photon field. Dose prescriptions for testicular boosting are generally 4 Gy in a single fraction or 4 Gy in two fractions. Not all institutions pursue a testicular boost in ALL.

Total Marrow Irradiation and Total Marrow/Lymphoid Irradiation

TMI is the delivery of a targeted form of TBI using large-field IMRT. TMI allows targeting of dose and dose escalation to sites of disease while significantly reducing dose to multiple organs at risk (OARs). Since the first patient treated with TMI,[62,63] there has been rapid adoption driven by encouraging results from multiple centers and an expansion of technology platforms capable of delivering this therapy.[64-69] Figure 15.4 provides examples of TMI and TMLI dose distributions. Details regarding

planning, setup, and delivery have varied at each center and have been recently reviewed.[64,68,70]

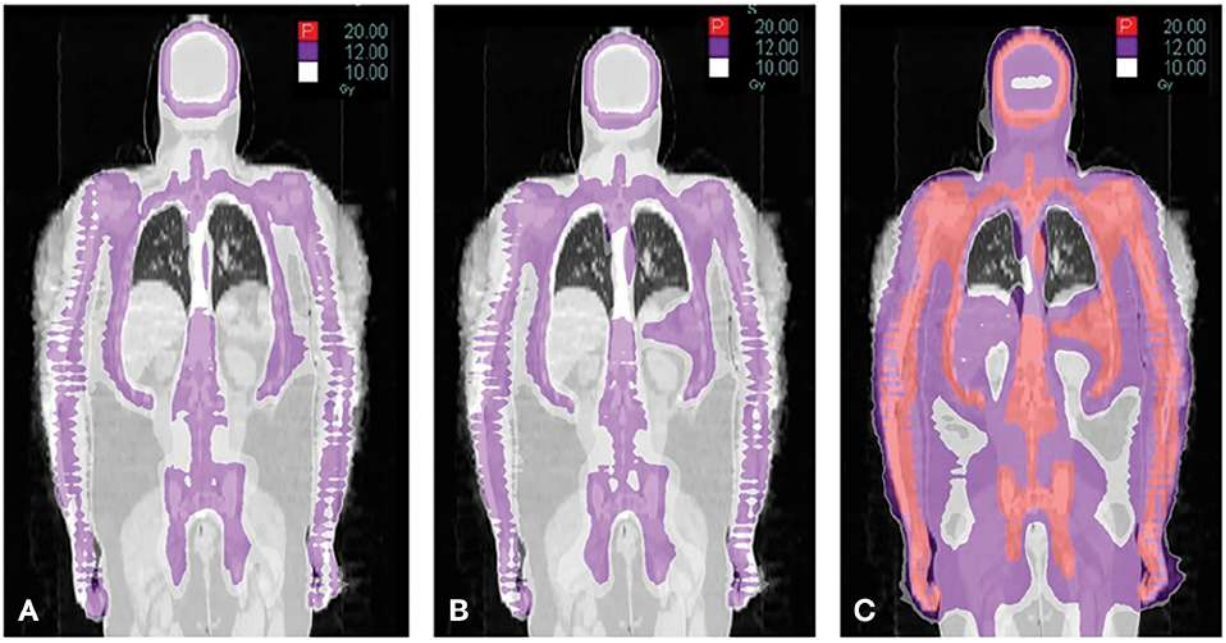

FIGURE 15.4 A. Total marrow irradiation (TMI) where the target is bone. B. Total marrow/lymphoid irradiation (TMLI) adds the major lymph node chains and spleen as target regions. C. In some studies, TMLI also includes the liver and brain to 12 Gy while other target regions (bone, lymph nodes, and spleen) are escalated to 20 Gy.

The concept of TMI, when introduced in 2002,[71] represented a significant departure from standard TBI, leading to a number of questions before the first patient was treated. Were the new helical tomographic and volumetric modulated arc therapy (VMAT)/IMRT technologies able to accurately deliver such a complex dose distribution? Was dose escalation feasible with acceptable toxicities? Would the higher average dose rates with TMI (70-200 cGy/min) compared to conventional TBI (less than 20-30 cGy/min) result in increased toxicities? Would dose reduction to organs and circulating leukemia cells increase relapse rates? Due to these concerns, the logical first step was to evaluate TMI in more advanced patients with refractory or relapse disease where survival rates are less than 20%,[72] who have no standard hematopoietic cell transplantation (HCT) options, and who typically are not transplanted. This offered the opportunity to expand the use of RT to a new HCT population and address an unmet need.[73]

Table 15.3 summarizes the results of select TMI and TMLI clinical studies to date. Early trials were in patients with multiple myeloma and investigated combining TMI with standard melphalan-based conditioning prior to autologous transplant.[74-78] Most studies have since focused on patients with acute leukemia undergoing allogeneic

HCT. Fraction sizes of 1.5-2.0 Gy delivered twice a day is used most frequently, with a few centers using 3, 4, or 5 Gy fractions. The target regions have been bone and bone marrow (TMI) or bone/marrow and lymph nodes and spleen (TMLI) for added immunosuppression needed with allogeneic HCT.

In younger patients (60 years of age or younger) with advanced relapsed/refractory acute leukemia, phase I and II studies[79-81] demonstrate that TMLI dose escalation up to 20 Gy with cyclophosphamide and etoposide is feasible, resulting in 2-year NRM rate of 9%, OS of 48%, and RFS of 33%, which are superior to historical results.[72] Dose escalation to 15-18 Gy using 3 Gy fractions or to 8-10 Gy using 4-5 Gy fractions has also shown promise.[82-85]

Older patients (>60 years of age), those with comorbidities or those who have relapsed after prior HCT, cannot tolerate myeloablative TBI regimens and are often conditioned with reduced-intensity chemotherapy (RIC) regimens. This can be associated with increased relapse rates especially in patients with active disease prior to HCT.[9] TMLI has been successfully added to established RIC regimens to reduce relapse rates with acceptable toxicities and with promising results. With a median follow-up of 7.4 years, TMLI 12 Gy added to the RIC regimen of fludarabine and melphalan was associated with a 5-year OS and EFS of 42% and 41%, respectively, which is superior to historical results where 3-year OS rates are less than 20%.[72,86-88] TMLI has also been utilized with radiolabeled antibody conditioning, which recently

reported a 6-month EFS of 26%.[89] Dose-escalated TMI has also been combined with fludarabine and busulfan, reaching a recommended phase II dose of 6 to 9 Gy in older patients.[90,91] Combining 9 to 12 Gy TMI with RIC regimens in patients who have recurred after prior allogeneic HCT also demonstrates promise.[92,93]

Transplants are now possible with haploidentical donors using posttransplant cyclophosphamide and other strategies to reduce GVHD.[94,95] Initial regimens used low-dose 2 Gy TBI.[94] To further reduce relapse rates, myeloablative doses of TMLI up to 20 Gy have successfully been incorporated into haploidentical HCT regimens.[96,97] Phase II studies are ongoing.

Recent studies have evaluated TMI and TMLI as a replacement for standard TBI in patients with acute leukemia in complete remission.[83,98-101] TMLI 20 Gy and posttransplant cyclophosphamide were associated with reduced moderate-to-severe GVHD (11%), no grade 3 to 4 toxicities, no treatment-related deaths, and 2-year OS of 86.7%, RFS of 83.3%, and GVHD-free/relapse-free survival (GRFS) of 59.3%.[98] This was superior to the 2-year GRFS of 39% and RFS of 62% with TBI and Cy or vincristine and prednisone (VP)-16 at the same institution.[102] Similar conclusions were reached with a study of TMLI 12 Gy with cyclophosphamide or etoposide, which reported a superior 1-year GRFS of 67.5% and time to engraftment compared to historical results with TBI at the same center.[100] TMI 12 Gy + cyclophosphamide has also been evaluated in older patients with acute leukemia in remission.[101]

IMRT is also being used to deliver standard TBI dose distributions with reduction in dose to the lungs and, at some centers, to the kidneys (Table 15.4). IMRT offers the advantage of eliminating the inaccuracy of positioning transmission blocks, better organ sparing, and reduced toxicities.[60,103-105] A recent analysis of patients receiving conventional TBI demonstrated a significant increase in OS if mean lung dose was 8 Gy or less.[106] As with conventional TBI, a limitation of IMRT TBI is the inability to dose escalate and treat older patients.

To date, hundreds of patients have received TMI and TMLI at multiple centers. Initial concerns regarding TMI have not been realized. Toxicities have been lower than reported for standard TBI. Shinde et al[107] reported a cumulative incidence of pneumonitis, nephropathy, cataract formation, and hypothyroidism of 0.7%, 0%, 7%, and 6%, respectively, in patients receiving TMI or TMLI up to 19 Gy. Mean lung dose of 8 Gy or less was associated with a significant reduction in lung infection and pneumonitis. Kim et al[108] reported no increase in extramedullary relapse rates when compared to TBI, suggesting that organ sparing does not increase relapse rates. There

has been no increase in non-engraftment with myeloablative doses of TMI. This collective experience suggests that the higher dose rates with TMI do not increase toxicities. This can be explained by preclinical[109,110] and clinical studies,[111] which demonstrate that dose rate effects are primarily seen below 30 cGy/min and become nonsignificant above approximately 50 cGy/min.

In summary, TMI expands the use of RT to a new population of patients undergoing HCT. Dose-escalated TMI regimens in younger patients and myeloablative TMI added to RIC regimens in older patients demonstrate superior results compared to current standard of care and should be further evaluated in multicenter studies. For patients with acute leukemia in remission, TMI or some form of multiorgan-sparing TBI may eventually replace conventional TBI given the promising results seen with TMI in this population.

Acute and Late Toxicities

Side effects from TBI in the setting of SCT have complex interactions with cytotoxic drugs and posttransplant immunosuppressive agents. In addition, GVHD has its own unique toxicities, which have complex interactions with the conditioning regimen. Infectious complications are also prevalent after transplant and subject to variable prophylactic treatment regimens. Isolating which toxicities are strictly related to TBI is not always straightforward.

Low-Dose Total Body Irradiation (Non-myeloablative Regimens)

With TBI-based non-myeloablative regimens, 2 Gy in a single fraction being commonly employed, the chief side effect immediately after treatment is nausea and vomiting, which can be ameliorated using prophylactic antiemetics. The primary long-term risk is cataract development, which can be corrected surgically. The risk of injury to other normal organs with a single 2 Gy fraction is probably very low.

Non-myeloablative regimens seem to be associated with less acute and long-term toxicity relative to myeloablative regimens.[112] This is particularly notable for noninfectious pulmonary toxicity. A number of studies have demonstrated reduced rates of noninfectious pulmonary toxicity following non-myeloablative regimens. Fukuda et al[113] first demonstrated a significantly lower risk of idiopathic pneumonia syndrome following non-myeloablative conditioning compared to myeloablative regimens for both malignant and nonmalignant indications at a single institution. A large study involving 21,574 patients from the Center for International Blood and Marrow Transplant Research showed that non-myeloablative TBI-based conditioning was associated with decreased risk of noninfectious pulmonary toxicity on multivariable analysis.[114]

Full-Dose Total Body Irradiation (Myeloablative Regimens)

Acute Toxicity

Nausea, vomiting, and diarrhea are the most common early side effects when a single fraction of 8 to 10 Gy TBI is given. Xerostomia, headaches, fevers, and hypertension were historically reported in roughly half of patients receiving single- fraction TBI.[115] The use of fractionated TBI reduces the incidence as well as the severity of these and other side effects. Moreover, fever and hypertension are rarely seen with fractionated TBI. Patients can also develop a transient xerostomia, reduction in tear formation, and mucositis within 10 days. Reversible alopecia develops at approximately 2 weeks in all patients. Parotitis, which usually occurs after the first day of irradiation and subsides within 24 to 48 hours, is unique to TBI and is very common with single-fraction RT but occurs in less than 10% of cases with fractionated regimens.[116]

Nausea may be controlled with the use of serotonin receptor-3 antagonists, as shown in several small randomized trials.[117,118] Mucositis, resulting from both radiation and chemotherapy, may be ameliorated by good dental hygiene[119] along with a variety of topical agents. Recombinant human keratinocyte growth factor was found to reduce mucositis after TBI and intensive chemotherapy, resulting in reduced narcotic and parenteral nutrition usage in one auto-SCT study.[120] Despite such supportive care, parenteral nutrition and narcotics are often necessary.

Late Toxicity

Lung. Interstitial pneumonitis is the major dose-limiting toxicity for TBI. Reduction in the risk of pneumonitis by fractionation is supported by the previously described randomized clinical trial comparing single-fraction TBI (9.2 or 10 Gy) with fractionated TBI (12 Gy in six fractions over 3 days) for patients with AML in first remission. This study demonstrated a significant improvement in EFS with fractionation, primarily due to a reduction in early mortality. Interstitial pneumonitis was decreased from 26% to 15% with fractionation.[12] Another radiobiologic approach to reduce the incidence of interstitial pneumonitis is to lower the radiation dose rate. Within the context of fractionated TBI schemes, instantaneous dose rates of 5 to 20 cGy/min have been generally employed and are often determined by the available output of linear accelerators at extended treatment distances. It is unclear whether or not higher instantaneous dose rates are detrimental despite theoretical concerns in this regard. Several nonrandomized studies have demonstrated an association between higher dose rates and the development of pulmonary toxicity, including interstitial pneumonitis.[121,122] Other studies have not shown dose rate to be an important predictor of pneumonitis from fractionated TBI, but rather total dose to the lung is the more critical determinant.[60]

Pneumonitis in the transplant setting has a multifactorial etiology, reflecting not only the effects of radiation but undoubtedly the effects of prior chemotherapy exposure,[35] underlying performance status, GVHD, baseline lung function,

development of opportunistic infections, patient age, and other risk factors. Many chemotherapy drugs are known to injure the lung. GVHD may cause lung injury directly and the drugs used to control GVHD may also cause pulmonary toxicity. T-cell-depleted transplants tend to have lower risk for pneumonitis.[123]

Lens. The lens of the eye is one of the most radiation-sensitive structures in the body. The risk of developing cataracts is markedly reduced with fractionation. For example, Ozsahin et al[124] calculated a difference in the 5-year estimated cataract incidence between single-fraction TBI (39%) and fractionated TBI (13%) while also showing a beneficial effect of lower dose rate. Studies also show that older age is associated with faster time to onset of cataract formation independent of TBI regimen dose.[112] Steroid therapy is also an independent risk factor for cataract formation after SCT, even in the absence of TBI. Lens shielding during TBI is not recommended because of the risk of retro-ocular relapse of leukemia but is a consideration in aplastic anemia and other non-neoplastic diseases managed with SCT.

Growth and Gonadal and Endocrine Effects. Almost all children who undergo bone marrow transplantation with TBI experience decreased growth velocity, which is less with fractionated than single-dose TBI.[125] Growth hormone deficiency may be detected in 34% of adults who received TBI in their childhood. Other endocrine effects in this setting include Leydig cell dysfunction in 23% and primary hypothyroidism in 34%.[126] High-dose TBI produces primary gonadal failure in almost all patients, but recovery may occur in females.[127] In children, puberty is usually delayed but can be induced by appropriate hormone replacement. Thyroid dysfunction is reported in as many as 43% of patients after TBI.[125] Subclinical hypothyroidism is the most common picture, with elevated thyroid-stimulating hormone but normal thyroxine levels. The incidence of thyroid dysfunction is lower when hyperfractionated TBI is used.[128]

Liver. Hepatic VOD has been renamed SOS given the recognition that this clinical problem, principally seen in myeloablative transplants, is an endothelial injury to hepatic sinusoids and hepatocyte injury and hepatic thrombosis are secondary late-stage effects. This syndrome, accounting for significant morbidity and mortality in high-dose transplant regimens, is characterized by hepatic enlargement, ascites, jaundice, encephalopathy, and weight gain. SOS, which needs to be distinguished from cholestatic drug injury and acute GVHD, is best diagnosed by transvenous hepatic biopsy where an elevated hepatic venous pressure gradient is documented along with characteristic histology showing hepatic sinusoidal and central vein fibrosis and accompanying hepatocyte necrosis. The etiology of VOD/SOS is thought to be related to acrolein, a cyclophosphamide metabolite also implicated in causing hemorrhagic cystitis, which acts as an endothelial toxin. Other toxic agents give rise

to this disease, but in the transplant setting, TBI, busulfan, cytosine arabinoside, and preexisting or concomitant liver disease are risk factors, possibly due to depletion of intracellular glutathione levels or matrix metalloproteinase activity. TBI-based regimens are associated with lower rates of VOD/SOS compared with regimens employing only chemotherapy.

The incidence of VOD/SOS has been minimized by fractionating TBI and keeping total doses below 13.2 Gy. The Seattle group has reported considerably more VOD/SOS after 10-Gy single-fraction TBI than after 12-Gy fractionated TBI in a randomized trial.[12] A lower dose rate may also reduce the risk. Prevention strategies for VOD/SOS include the administration of low-molecular-weight heparins and ursodiol as part of the pretransplant supportive care regimen. In one well-designed clinical trial, ursodiol prevented cholestatic liver injury and GVHD, but had no effect on VOD/SOS.[129] Standard of care treatment is defibrotide, a single-stranded polydeoxyribonucleotide drug with antithrombotic and anti-ischemic properties.

Kidney. Renal toxicity has been underreported as a major late complication of SCT. A report by Tarbell et al[130] in 1988 showed a 35% rate of renal dysfunction in patients with ALL receiving transplants. More contemporary reports place this risk at ~17%, influenced by the use of TBI, cyclosporine for immunosuppression, and presence of significant GVHD.[131] Because transplant patients also receive various nephrotoxic drugs (etoposide, teniposide, amphotericin B, aminoglycoside antibiotics) before, during, and after intensive cytoreductive therapy, the contribution of TBI to renal dysfunction can be difficult to determine. GVHD also has complex interactions with TBI in affecting the risk of transplant-related nephritis. Studies suggest that TBI and chronic GVHD are risk factors for posttransplant chronic kidney disease.[131,132] Miralbell et al[133] showed a high risk of renal dysfunction after TBI, independent of the presence or absence of GVHD. Some transplant programs have reduced the dose to the kidneys using partial transmission blocks and have suggested that such a strategy decreases the risk of posttransplant nephropathy.[134]

Secondary Cancers. The risk of developing a secondary malignancy 15 years after intensive chemotherapy and radiation followed by SCT is estimated to be 6% to 20%.[135-137] The risk of developing a secondary malignancy is approximately 4 times higher than the general population. A large series from combined registries of the International Bone and Marrow Transplant Research Centers and the Fred Hutchinson Cancer Research Center observed 189 solid cancers among 28,874 transplant patients, more than 6,000 of whom had survived more than 5 years.[138] Two-thirds of this cohort received RT as part of their conditioning and this was a major determinant for secondary cancer development along with chronic immunosuppression. Chronic GVHD and male age increased the risk for squamous cell cancers. Common posttransplant nonsquamous cell cancers included melanoma, cervical or uterine

cancer, thyroid cancer, breast cancer, and gliomas. Patients less than 30 years of age at the time of treatment had an approximately 9-fold increased risk for nonsquamous cell cancers over those who did not receive RT. Myelodysplastic syndrome and AML are the most common secondary tumors in patients treated for lymphoid malignancies. Patients who are older, who experienced acute GVHD, who were treated with antithymocyte globulin or anti-CD3 antibodies, or who receive TBI are at greatest risk. Some lymphoproliferative disorders that occur after allo-SCT are associated with Epstein-Barr virus and may be successfully managed with anti–B-cell antibodies such as rituximab, adoptive immunotherapy, or donor lymphocyte transfusions.

HEMIBODY IRRADIATION

Though utilized less frequently at present, HBI has been used for many years to palliate widely metastatic solid tumors, typically diffuse symptomatic bone metastases, often very late in the course of the disease. As the field of medical oncology has developed a larger array of systemic therapies for disseminated cancers, this form of RT has been less frequently employed.

Applications

Patients with osseous metastases tend to have multiple sites of disease, often with multiple painful areas that can be challenging to treat efficiently with conventional RT. The pain relief produced by single-fraction HBI for skeletal metastases is prompt, with nearly 50% of all responding patients doing so within 48 hours and 80% within 1 week after treatment.[139,140] More than 70% of treated patients experience pain relief as documented in a number of studies including various Radiation Therapy Oncology Group (RTOG) trials from the 1980s.[139,141] The most effective HBI dose found by the RTOG was 6 Gy for upper HBI and 8 Gy for middle and lower HBI. Doses beyond these levels do not appear to increase pain relief, duration of pain relief, or rapidity of response.

When treatment of the other half of the body is also indicated, it is advisable to wait 6 to 8 weeks to allow sufficient recovery of blood cells and irradiated marrow. Planned sequential upper and lower HBI 6 to 8 weeks apart has been used to treat multiple myeloma, malignant lymphoma, and other widely disseminated tumors. HBI should be utilized for symptomatic disease only. For example, a randomized trial in multiple myeloma did not support routine use of HBI as part of an overall treatment plan. In this trial, patients were initially treated with chemotherapy. Eligible patients were then randomized to 1 year of vincristine, melphalan, cyclophosphamide, and prednisone (VMCP) versus sequential HBI with VP. RFS and OS were better with VMCP than with HBI ($P = .04$ and $P = .018$, respectively).[142]

Technique

The physical considerations for HBI are similar to those for TBI. The field size required for HBI is much smaller than that for TBI, and HBI can often be delivered on a conventional linear accelerator, albeit using extended distances. The desired field can be customized based on the distribution of disease that requires palliation though classic fields have been described.[143] Treatment is traditionally delivered using AP/PA parallel-opposed fields. The patient is positioned with a vertical beam allowing coverage of the hemibody and the treatment table is lowered to the appropriate level or to the floor. Shielding of previously irradiated areas or other body regions to reduce toxicity, such as the salivary glands and the lungs, may be employed. The dose is prescribed to the midplane of the patient at the central axis of the beam.

Complications

In general, HBI is well tolerated. The most common side effects associated with single-dose HBI are nausea and vomiting, mainly when the abdomen is included within the fields. These occur shortly after radiation administration and last a few hours. Premedication with steroids and antiemetics is highly recommended. As these patients are frequently anorexic or cachectic from their underlying illness, dehydration and need for intravenous fluids are common with HBI and hospitalization for supportive care may be desirable. A series from the University of Maryland examined single-fraction HBI with escalating doses of 4 to 10 Gy, split-course HBI with two 4-Gy fractions separated by 2 weeks, and daily fractionated HBI with 15 Gy given in five fractions.[144] Fractionated HBI was found to be more acutely tolerable, similar to the experience with TBI. A subsequent randomized study demonstrated that a total dose of 6 Gy given over 2 days (3 Gy/fraction) was similarly efficacious.[145] Diarrhea occurs commonly when a significant volume of the intestines is irradiated and may last for several days. The severity of this side effect can be reduced utilizing lower doses. The risk of pneumonitis is very low if the single-fraction dose to the whole lungs is limited to 7 Gy (uncorrected for air density). If 8 Gy is delivered to the upper body, partial transmission lung block to limit the lung dose at 6 to 7 Gy is recommended. Hematologic recovery usually occurs in 4 to 6 weeks.

TOTAL LYMPHOID IRRADIATION

TLI was originally designed to treat Hodgkin lymphoma. TLI consists of a mantle field (encompassing all major supra- diaphragmatic lymph node regions) matched to an inverted-Y field (encompassing the spleen and major infra-diaphragmatic lymph node regions with the inferior extent including the inguinal lymph nodes) (Figure 15.5). A small gap is placed in-between these two fields. Using three-dimensional techniques, an extended SSD (eg, 120 cm) is necessary for the inverted-Y field given

its greater longitudinal dimensions but an SAD (source-to-axis) approach is almost always suitable for the mantle field. TLI can also be treated using more advanced techniques such as IMRT/VMAT or helical tomotherapy.[146]

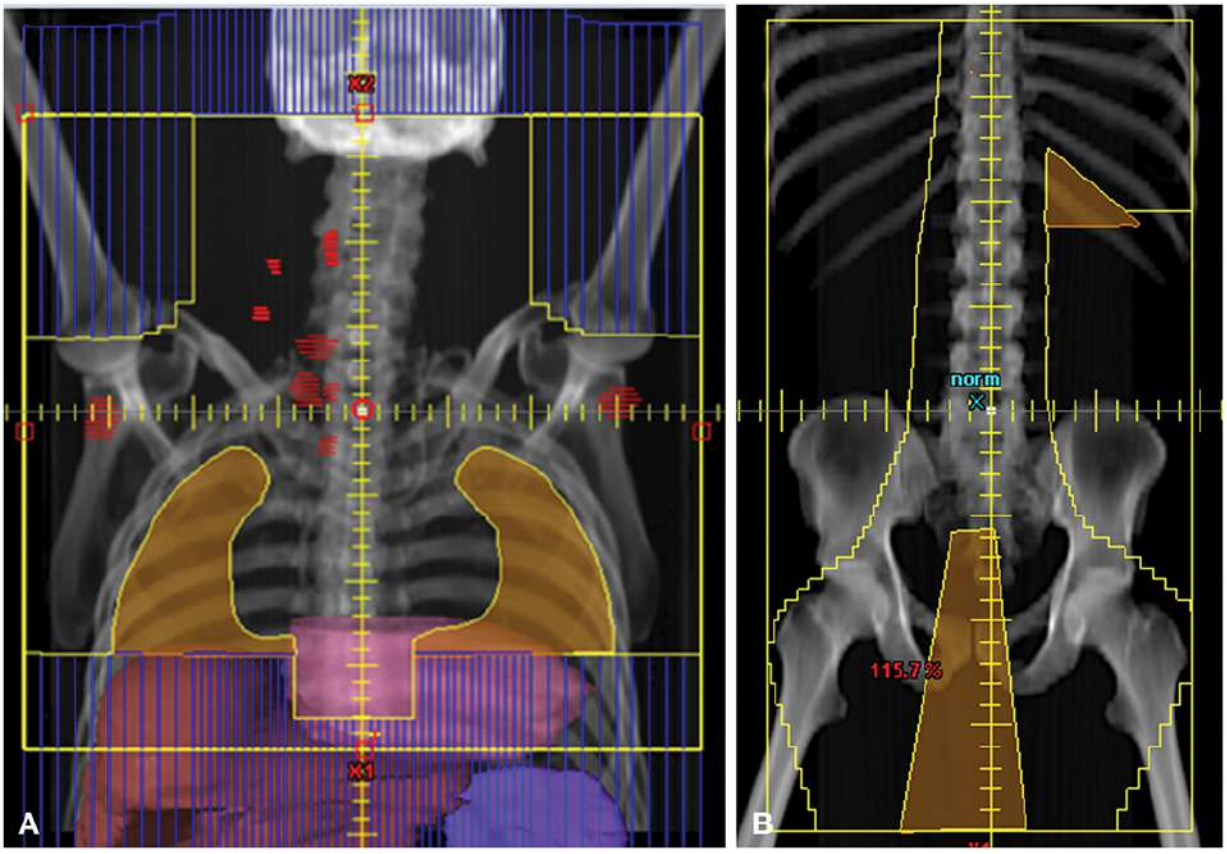

FIGURE 15.5 Total lymphoid irradiation fields including a mantle field (A), which encompasses all of the major lymph node bearing areas above the diaphragm, matched to an inverted-Y field (B), which encompasses the spleen and the major lymph node bearing areas below the diaphragm.

While uncommonly utilized at present, TLI has been investigated in numerous clinical scenarios with extensive published literature. First, while TLI is no longer employed for newly diagnosed Hodgkin lymphoma, it has been combined with high-dose chemotherapy prior to autologous SCT in relapsed and refractory disease.[147] Second, as discussed earlier, some centers are investigating replacing TBI with TMLI. In this circumstance, not only is the entire marrow space included in the clinical target volume but also the lymph node chains and spleen that would be encompassed in classic TLI fields. Some studies have used TLI alone with chemotherapy prior to non-myeloablative allogeneic SCT.[148] Third, TLI is occasionally used in the solid organ transplant setting as an immunosuppressive agent that can replace immunosuppressive medications.[149] Patients suffering from progressive bronchiolitis obliterans syndrome after lung transplant have been treated with TLI with some success.[150] Fourth, TLI has

been explored in the past as an immunosuppressive agent in intractable rheumatoid arthritis.[151] Fifth, TLI has been used for drug-resistant chronic GVHD.[152] Finally, in select patients, TLI can be utilized as an effective cytoreductive agent prior to allogeneic SCT in patients with lymphoma (eg, CLL/small lymphocytic lymphoma).

At our center, we have primarily utilized TLI in the setting of relapsed/refractory Hodgkin lymphoma when the disease involves diffuse lymph node regions on both sides of the diaphragm and for the occasional young patient with CLL, with RT being used to achieve a minimal residual disease state prior to allogeneic transplant. While total doses will vary depending upon the clinical scenario, we generally treat with small daily doses (eg, 1.5 Gy) with prophylactic antiemetics to decrease the risk of treatment-induced nausea.

CHAPTER 16

Stereotactic Irradiation of Tumors of the Central Nervous System

Trey C. Mullikin, John C. Flickinger, and Paul W. Sperduto

Stereotactic radiosurgery (SRS) and stereotactic radiotherapy (SRT) are techniques to administer precisely directed, high-dose irradiation that tightly conforms to a well-defined target to create a desired response while minimizing radiation dose to surrounding normal tissue. Compared to conventional radiotherapy with standard 5- to 20-mm treatment margins allowing for patient movement and setup error, stereotactic techniques reduce complication risks for any radiation dose delivered by minimizing or eliminating normal tissue treatment margins. Table 16.1 lists the key requirements for successful stereotactic irradiation. Significant advances in diagnostic imaging, treatment planning, and radiation delivery systems have led to the development of a variety of different SRS/radiotherapy techniques and broader applications. This chapter will review the role of SRS and SRT for benign and malignant neoplasms as well as functional indications within the central nervous system (CNS).

TABLE 16.1 KEY REQUIREMENTS FOR OPTIMAL STEREOTACTIC IRRADIATION

Requirement	Rationale
Small target/treatment volume	Reducing the volume of normal and target tissue irradiated to high doses improves tolerance.
Sharply defined target	Sharply defined targets can be treated with little or no extra margin of surrounding normal tissue and/or without unintentional underdosage of the target (marginal miss).
Accurate radiation delivery	No margin of normal tissue needed for setup error and/or reduced chance of underdosing target
High conformality	Reduces the treatment volume to match the target volume

Requirement	Rationale
Sensitive structures excluded from target	Dose-limiting structures (optic chiasm, spinal cord, etc) should be able to be defined and excluded from the target volume to limit the risk of radiation injury.

TERMINOLOGY

Stereotactic refers to using a precise three-dimensional mapping technique to guide a procedure. The terminology used in stereotactic irradiation can be confusing. The term *radiosurgery* or *stereotactic radiosurgery* (SRS) is best used for stereotactically guided conformal irradiation of a defined target volume in a single session but may also be used for two to five sessions, although *fractionated stereotactic radiosurgery* (fSRS) is a clearer description of that use. Radiosurgery or SRS can be delivered with Gamma Knife, modified linear accelerator (LINAC) radiosurgery systems (including CyberKnife and image-guided radiotherapy systems), TomoTherapy, or proton beam systems. The terms *stereotactic radiation therapy* (SRT), *stereotactic body radiotherapy* (SBRT), and *stereotactic ablative radiotherapy* can be used to refer to stereotactically guided delivery of highly conformal radiation to a defined target volume in six or more fractions, typically using noninvasive positioning techniques; however, they are often used with treatment courses with two to five fractions as well. Adding specific references to intensity-modulated radiation therapy (IMRT) to the nomenclature can further complicate or confuse the terminology. Any radiation treatment plan that uses individual treatment beams that irradiate only part of the target at a time is IMRT. Strictly speaking, multiple-isocenter radiosurgery (of a single target volume) meets the criteria for IMRT or stereotactic IMRT (SIMRT), although the term SIMRT is usually only used when multileaf collimators are employed. The terminology is useful to distinguish when the same LINAC is equipped to treat with either fixed circular collimators for radiosurgery (SRS or SRT mode) or to deliver IMRT using multileaf collimators (SIMRT mode).

RADIOBIOLOGIC CONSIDERATIONS

Before the introduction of radiosurgery, essentially all clinical irradiation was administered with radiation dose fractions between 1.2 and 3 Gy for intracranial targets. Extracranial targets were usually treated with 1.2- to 4-Gy fractions, and 6- to 8-Gy fractions were used occasionally to treat bone metastases or malignant melanoma. Before the adoption of radiosurgery into the clinic in the late 1980s, most radiation oncologists and radiation biologists believed that fractionating radiation treatment decreased the relative risk of injury to normal tissue compared to tumor in essentially all circumstances. Radiobiologic analysis of a limited number of malignant tumors in cell culture and clinical experience with conventionally fractionated radiotherapy of fast-growing malignant tumors established this radiobiologic dogma. Increasing the fractionation of radiotherapy for slow-growing benign tumors may not necessarily improve the balance between tumor control and radiation complication, however. Slow-growing benign tumors are challenging to study in either cell culture or animal models, so the effect of fractionation has not been well described. SRS allowed clinicians to administer high doses of radiation to intracranial targets with relative safety, thereby leading to a new appreciation of the underlying radiobiology. Laboratory studies suggest that the radiation response for the high-dose single fraction used in radiosurgery is likely related to the supporting endothelial cells.[1,2] Pathology studies of benign and malignant tumors treated by radiosurgery also support a vascular response dominated by the response of endothelial cells.[1-3] In addition to vascular effects, radiosurgery has been associated with immune modulatory effects creating antitumor immunity.[2,4-8]

RADIOSURGICAL TECHNIQUES

Gamma Knife Radiosurgery

After Leksell's initial experiences with stereotactic treatment using orthovoltage radiotherapy in 1951 and proton beam irradiation in 1957, Leksell and Larson created the first prototype of the Gamma Knife in 1967. The Gamma Knife uses a relatively hemispherical array of multiple fixed Cobalt-60 (Co-60) beams (201 in most models) that are sharply collimated to create small, relatively spherical treatment volumes of varied diameter with sharp dose falloff. The earlier model was originally referred to as the U

(for university) style and contained cobalt sources arranged in a hemispherical array, including sources at the pole of the hemisphere. These units present challenging loading and reloading issues with the cobalt-60 sources, particularly with radiation protection. To eliminate this problem, the B-unit (named after Bergen, Norway, the first site) was redesigned to arrange sources in an annular section of a hemisphere, similar to the northern hemisphere with the Arctic Circle excluded. In 1999, the Model C version of the Gamma Knife was introduced with the option to use robotic positioning to set treatment coordinates. This expedited the execution of multiple-isocenter treatment plans. Manual positioning was still needed for some targets away from the center of the head. The Model 4-C, introduced in 2005, was equipped with enhancements designed to improve workflow, increase accuracy, and provide integrated imaging capabilities. The Perfexion model introduced in 2006 uses a larger patient aperture and internally mounted secondary collimators that can be blocked or treated with different diameters of 4, 8, or 16 mm for any of eight different sectors around the circumference of the unit. Because of the larger patient aperture, the Perfexion unit is able to treat all intracranial and even C1-2 level spine targets quickly and efficiently with robotic positioning.

The latest version, the Icon unit, is equipped with a cone-beam computed tomography (CT) scan for use with a frameless thermoplastic mask system with infrared patient position monitoring to facilitate fSRS. Clinical experience with the Icon unit has found that despite the relatively tight thermoplastic immobilization mask used, patient motion exceeding 1.0- or 1.5-mm total deviation (requiring repeat cone-beam CT for realignment) tends to occur more frequently with treatments over 30 minutes and in patients who fall asleep during treatment. Patients requiring longer treatments or sedation are more easily treated with stereotactic frame-based techniques with this unit. In addition to reducing patient motion, another advantage of using a magnetic resonance (MR)-compatible stereotactic frame is to eliminate error (though usually small) from MR to CT image coregistration.

Rotating Gamma System

A radiosurgery device called the rotating gamma system (RGS) was developed in China. The RGS (OUR International Inc, Shenzhen, China) employs 30 cobalt-60 radiation sources in a revolving hemispherical shell. The secondary collimator is a coaxial hemispheric shell with six groups of five different collimators to produce spherical treatment volumes of varying sizes. The experience with this system is somewhat limited.

Proton Radiosurgery

The chief advantage of charged proton radiosurgery is that the beams stop at a depth related to the beam's energy. Electron beams also use charged particles but lack the sharp beam edge of the proton beam. The lack of an exit dose and the sharp beam profile of protons allow target irradiation with lower integral doses than are delivered with photon (LINAC x-ray or cobalt-60 gamma) irradiation. An unmodified proton beam deposits increased energy in the last 2 mm of the path length. This area of increased ionization, where cell killing is even higher because of an increased radiobiologic effect, is termed the Bragg peak or Bragg-Gray peak. To allow homogeneous irradiation of targets greater than a millimeter or two, the Bragg peak is spread out throughout the target or modulated with differing beam energies. The first treatment of a malignant tumor by irradiation with a proton beam Bragg peak was carried out in 1957, followed by functional neurosurgery done for advanced Parkinson disease in 1958. Presently, proton beam irradiation is available at a limited number of centers because of the high cost of equipment and maintenance.

Linear Accelerator Radiosurgery

The pioneering work of many researchers in the 1980s led to the gradual modifications of LINACs designed for conventional radiotherapy to be used for radiosurgery. LINAC technologies were modified by incorporating improved guiding (stereotactic) devices and methods to measure and improve the accuracy of various components. Most early LINAC-based radiosurgery techniques used multiple radiation arcs with circular secondary collimators to create spherical dose distributions for stereotactically defined 3-D targets. Improved hardware and advanced dose planning software have been developed to enhance conformity. These include beam shaping with

micromultileaf collimators and intensity modulation with inverse treatment planning algorithms. Many LINAC-based systems are commercially available. Most are modifications of standard LINACs equipped with more precise treatment couches and highly stable treatment isocenters, usually with cone-beam CT scans for targeting and often with patient monitoring systems.

The CyberKnife combines a miniaturized LINAC mounted on an industrial robot with a system for orthogonal x-ray target tracking and beam realignment. This system utilizes a 6-MeV LINAC with different-sized circular collimators attached to a six-axis robotic manipulator. Stereotactic frames are not normally used for targeting. CyberKnife plans employ multiple fixed beam positions and multiple isocenters. Before the radiation is delivered from any beam position, the target position is tracked using an integrated x-ray image processing system (IPS) consisting of two orthogonal diagnostic x-ray cameras and an optical tracking system. During treatment, the IPS acquires x-ray images of the patient's body multiple times throughout the treatment, while stealth tracking software compares the actual images with the target images to correct the alignment of the beam. The tracking interval is set by the user with many CyberKnife centers, usually using 1-minute intervals.

There are some other LINAC radiosurgery systems that have the capability for intratreatment patient movement monitoring and correction and others that do not. The combination of diagnostic 3-D imaging with highly conformal treatment delivery in a single unit to maintain accuracy is the basis of various treatment techniques and processes collectively known as image-guided radiation therapy (IGRT). Most IGRT techniques add CT imaging capability to a LINAC radiotherapy unit equipped for stereotactic and IMRT use. Because any patient movement between image acquisition and treatment delivery can introduce error, these IGRT systems utilize noninvasive immobilization devices and patient position tracking systems. Several manufacturers currently offer IGRT using LINAC technology capable of delivering SRS and radiotherapy.

TomoTherapy

TomoTherapy, literally “slice” therapy, is a form of radiotherapy that modifies the design of a diagnostic CT scan into a treatment delivery machine, thereby combining the precision of CT imaging with radiation treatment. This is done by adding a LINAC megavoltage treatment beam to the rotating x-ray source and moving table design of a diagnostic CT unit, which normally uses only a kilovoltage diagnostic x-ray beam. Unlike traditional radiation therapy systems with a slow-moving external gantry designed for positioning individual beams onto the tumor from a few different directions, TomoTherapy rapidly rotates the beam around the patient, thus allowing the beam to enter the patient from many different angles in succession. Beam intensity modulation (IMRT) is possible through a multileaf collimator system. The inclusion of CT imaging technology within the TomoTherapy unit allows precise target localization before and during treatment.

NORMAL TISSUE TOLERANCE IN CENTRAL NERVOUS SYSTEM RADIOSURGERY

Radiosensitivity

Estimating the risks of a proposed treatment plan with various radiation doses is essential to treatment planning and dose prescription for SRS and SRT. The ability of normal tissue to tolerate radiation without injury depends on the radiation dose administered, the volume of tissue irradiated, the sensitivity of the tissue affected, history of any prior radiation treatment to the region, and any individual variation in radiation sensitivity between different people. With the exception of patients with known increased radiation sensitivity, such as those with ataxia-telangiectasia and collagen vascular diseases, there is usually no information routinely available to modify treatment plans for individual differences in radiosensitivity. Prior fractionated radiotherapy appears to have limited effects on the risks of developing postradiosurgery parenchymal edema and neurologic sequelae after radiosurgery but has been observed to effect optic nerve tolerance.

Radiosurgery Dose Escalation Studies

The Radiation Therapy Oncology Group (RTOG) Radiosurgery Dose-Escalation Study (90-05) established tolerance doses for radiosurgery of recurrent brain metastases and high-grade gliomas not involving the brainstem.[9] They administered radiosurgery to 156 patients with brain metastases or primary brain tumors that recurred or progressed after conventional radiotherapy following a dose escalation protocol. Starting with initial doses of 18, 15, and 12 Gy for diameters less than 20, 21 to 30, and 31 to 40 mm, respectively, they escalated prescription doses in 3-Gy intervals until irreversible toxicity was seen in over 20% of patients within 3 months. The exception was with tumors less than 20 mm in diameter, for which dose-limiting toxicity was not reached, and investigators were reluctant to escalate above 24 to 27 Gy. The recommended tolerance doses from that protocol were 24, 18, and 15 Gy for diameters less than 20, 21 to 30, and 31 to 40 mm, respectively. The data with longer follow-up beyond 3 months to assess late toxicity were fitted to individual logistic dose-response curves in Figure 16.1. These tolerance doses have been widely used as guidelines for single-fraction radiosurgery of malignant tumors, often with interpolation for tumors close to 20 and 30 mm in diameter (eg, 20 Gy for 18- to 22-mm diameter and 16.5 Gy for 28- to 32-mm diameter treatment volumes).

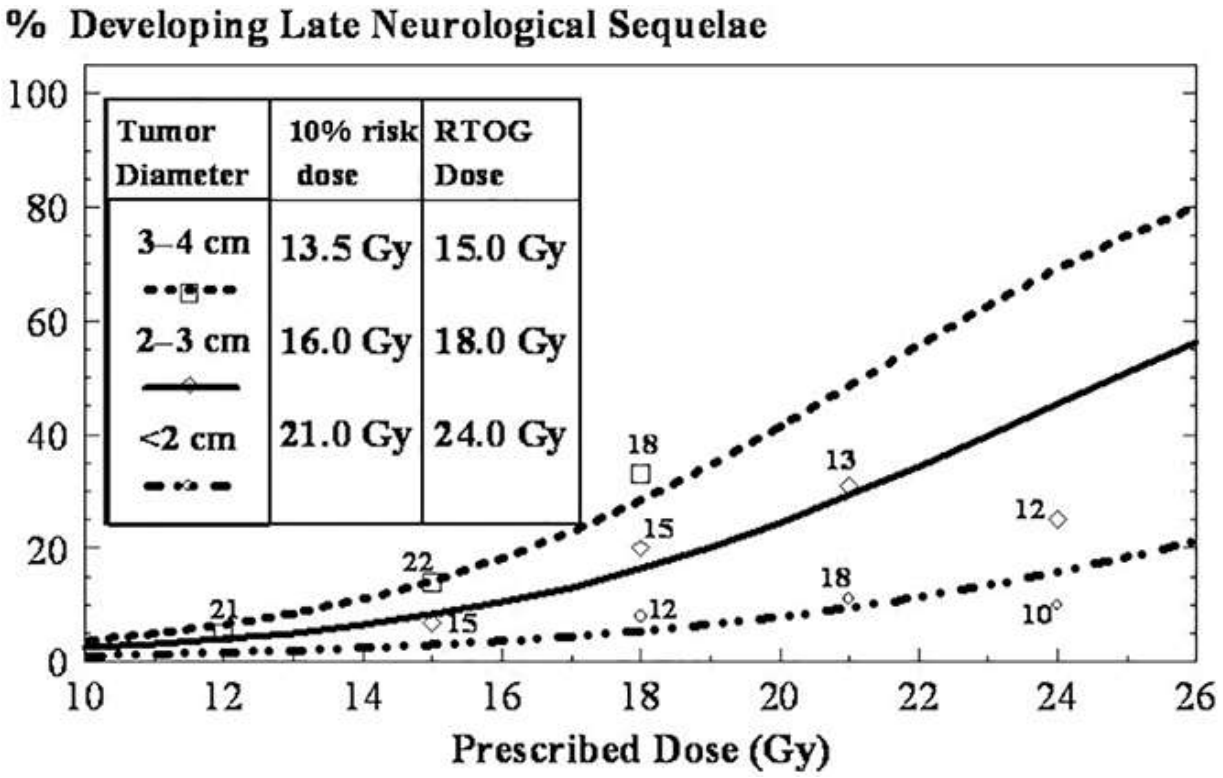

FIGURE 16.1 Phase 1 RTOG dose escalation data for radiosurgery of recurrent brain metastases and glioblastoma fit to logistic dose-response curves. The numbers at each data point indicate the number of patients in each dose/diameter group. (Derived from Dewan MZ, Galloway AE, Kawashima N, et al. Fractionated but not single-dose radiotherapy induces an immune-mediated abscopal effect when combined with anti-CTLA-4 antibody. *Clin Cancer Res*. 2009;15[17]:5379-5388.)

Murai et al[10] performed a limited dose escalation study of CyberKnife radiosurgery of 48 brain metastases 2.5 to 4 cm in average diameter with 18 to 30 Gy in three fractions and 13 metastases greater than 4 cm diameter with 21 to 35 Gy in five fractions. Grade 1 radiation necrosis developed in 1 of 20 patients at the penultimate level of the three-fraction regimen, and grade 1/2 radiation necrosis developed in 3 of 25 patients at the highest dose level (27 to 30 Gy in three fractions, 31-35 Gy in 5 fractions).

Schwer et al[11] performed a three-fraction fSRS dose escalation study from 18 to 36 Gy in 15 patients with recurrent gliomas treated in combination with gefitinib. With a median treatment volume of 41 cm^3 (8-151 cm^3), three patients were treated at the 18, 24, and 30 Gy levels and 16 at 36 Gy. They did not identify any radiation-related toxicity.

Kim et al[12] performed a three-fraction dose escalation study of 24, 27, and 30 Gy with fractionated Gamma Knife radiosurgery for large (>3 cm) brain metastases in 60 patients. Of 48 evaluable patients, the rate of radiation necrosis was 0% in 24 Gy, 13% in 27 Gy, and 37% in 30 Gy groups, while local progression-free survival (PFS) was 65%, 80%, and 75% in each respective group. Given the high rates of radiation necrosis in the 30 Gy group, 27 Gy was considered the most effective regimen.

Clarke et al[13] reported a dose escalation study of three fractions of radiosurgery delivered with 10 mg/kg bevacizumab q2 weeks to doses of 27, 30, and 33 Gy in groups of three, five, and seven patients, respectively, with recurrent glioblastoma and anaplastic astrocytoma after prior conventional chemoradiotherapy. They identified no cases of clearly symptomatic radionecrosis, but one patient in the 33-Gy level exhibited cognitive deterioration and grade 3 fatigue, which they counted as treatment-related toxicity.

The High Dose per Fraction, Hypofractionated Treatment Effects in the Clinic (HyTEC) analysis of tumor control probability for intact brain metastases identified 56 sufficient manuscripts with over 13,000 brain metastases for analysis. Local control for tumors was stratified by RTOG 90-05 size thresholds, and for tumors less than or equal to 20 mm, single-fraction doses of 18 and 24 Gy corresponded with greater than 85% and 95% 1-year local control rates, respectively. Notably, while 18 Gy resulted in excellent local control for most tumors less than or equal to 20 mm, patients with melanoma brain metastases required a mean dose of 23.4 Gy to achieve a 90% tumor control probability. For tumors 21 to 30 mm, an 18 Gy single-fraction dose was associated with 75% local control, and for tumors 31 to 40 mm, a 15-Gy single-fraction dose yielded approximately 69% local control. For fractionated radiosurgery, three- to five-fraction remove SRS using doses in the range of 27 to 35 Gy corresponded to 80% 1-year local control for tumors of 21 to 40 mm in diameter.[14]

Radiation Necrosis

Radiation necrosis, or treatment-induced necrosis, is a delayed and often progressive form of radiation-induced inflammation or injury to normal brain tissue.[15] The pathophysiology remains unclear. It is likely mediated

due to glial and vascular endothelial cell injury and can cause a cascade of inflammatory markers, which may lead to neurologic symptoms.[16] Almost half of patients with radiation necrosis will go on to develop neurologic symptoms,[17-19] requiring medical management typically first with corticosteroids. Other noninvasive management strategies include hyperbaric oxygen therapy, pentoxifylline, vitamin E, and bevacizumab. In some cases, surgical intervention is required. For a more detailed discussion of the management of radiation necrosis, please see Chapters 107.

For single-fraction radiosurgery, the risk of radiation necrosis has been correlated dosimetrically with the volume of the brain receiving 12 Gy or more or V12Gy(cm^3). The HyTEC analysis for brain tolerance summarized 51 reports in 9,828 patients and 13,913 targets receiving radiosurgery, often for brain metastases or arteriovenous malformations (AVMs).[20] For dosimetric reporting, the brain tissue volume included both the brain and target lesions. For single-fraction SRS for brain metastases, brain tissue volume receiving V12Gy of 5, 10, or greater than 15 cm^3 was associated with risks of symptomatic radiation necrosis of approximately 10%, 15%, and 20%, respectively. For fractionated SRS for brain metastases, brain tissue volume V20Gy (three fractions) or V24Gy (five fractions) less than 20 cm^3 was associated with less than 10% risk of any radiation necrosis or edema, and less than 4% risk of radiation necrosis requiring resection. Single-fraction radiosurgery for AVM was associated with modestly lower rates of symptomatic radionecrosis for equivalent V12Gy of 10 cm^3 less than 10%; however, this did not take into account AVM location.

Prior analysis of postradiosurgery injury reactions in patients with AVM revealed no difference in the likelihood of postradiosurgery injury imaging changes (increased signal developing in the surrounding brain on long relaxation time or T2 images) in different regions of the brain.[8,21] However, dramatic differences were seen in the rates of developing persistent neurologic sequelae after AVM radiosurgery among the brainstem, thalamus, and other regions of the brain, as shown in Table 16.2. Additionally, RTOG 90-05 and other large radiosurgery trials evaluating treatment of brain metastases have excluded patients with lesions located or abutting the brainstem due to concerns of toxicity.[9,22,23] As such, management of brainstem metastases has varied with differing single-fraction and fractionated radiosurgery approaches with favorable reported

results. A multi-institutional pooled analysis of 547 patients with 596 brainstem metastases treated with Gamma Knife radiosurgery showed that 7.4% of lesions developed grade 3 or higher toxicity.[24] Similarly, a meta-analysis including 1,446 patients with 1,590 brainstem lesions, treated mostly with single-fraction radiosurgery, found a grade 3 or higher toxicity rate of 2.4%.[25]

TABLE 16.2 PREDICTED RISKS OF DEVELOPING ANY SYMPTOMATIC (AND PERMANENT) NEUROLOGIC SEQUELAE AFTER ARTERIOVENOUS MALFORMATIONS RADIOSURGERY ACCORDING TO 12-GY VOLUME AND LOCATION FROM 755 PATIENTS WITH 2-YEAR MINIMUM FOLLOW-UP

12-Gy Volume (cm^3)	Brainstem (%)	Thalamus (%)	Other (%)
0.1	11 (8)	5 (3)	1 (0.3)
10	28 (15)	15 (7)	4 (1)
20	55 (30)	37 (15)	10 (2)
30	79 (50)	64 (28)	27 (5)
40	92 (69)	84 (48)	53 (12)

Derived from Kano H, Flickinger JC, Tonetti D, et al. Estimating the risks of adverse radiation effects after Gamma Knife radiosurgery for arteriovenous malformations. *Stroke*. 2017;48(1):84-90.

Radiation-Induced Malignancy

Radiation-induced malignancy is an established risk of exposure to ionizing radiation. In the setting of therapeutic radiotherapy, the risk of radiation-induced malignancy is dependent on many factors, including age, gender, radiation dose, technique, type, and site and volume of radiation exposure. Because radiosurgery is often used to treat patients with functional conditions and benign tumors with potentially long life expectancy, the patient's decision-making may be impacted by the potential risk of future malignant transformation of benign tumors or developing a new benign/malignant neoplasm. Prior reports of radiation-induced malignancy following radiosurgery are rare and typically published in case reports or small case series.[26] Estimation of risk is also challenging, given the rare occurrence and desired length of follow-up, as secondary malignancy can arise up to 30 years or more after treatment.[27]

The Mayo Clinic published their 25-year experience of 1,142 patients who underwent single-fraction radiosurgery for AVM and benign tumors, evaluating the risk of radiation-induced tumor or malignant transformations. This did not include patients who had received prior or concurrent radiotherapy, had a genetic predisposition syndrome, or had less than 5 years of follow-up imaging. With a median follow-up of 9 years, no radiation-induced tumors were identified in 11,262 patient-years of follow-up after radiosurgery. Of the 909 patients with benign tumors, malignant transformation was seen in 8 (0.9%) patients, of which 7 had meningioma and one had vestibular schwannoma.[28] Similarly, Wolf et al[29] reported a population-based, multi-institutional cohort study of 4,905 patients who underwent radiosurgery for benign tumors with at least 5 years of imaging follow-up and no prior radiation. With a median follow-up of 8.1 years, 2 (0.02%) of 3,251 patients developed suspected malignant transformation and 1 (0.02%) patient developed likely radiation-induced malignancy. Notably, these experiences included only single-fraction radiosurgery delivered with Gamma Knife Platform, did not account for possible extracranial malignancy from low-dose radiation exposure, and reported a median follow-up of 9 years.

Optic Nerve Tolerance for Radiosurgery

The first analysis of optic nerve tolerance to radiosurgery, a combined Harvard/University of Pittsburgh study of patients with cavernous sinus meningiomas, craniopharyngioma, and pituitary adenomas, recommended 8 Gy as a safe maximum dose limit for the optic nerves/chiasm, although most centers now use 10 Gy.[30] The lowest optic chiasm dose at which optic neuropathy developed in that study was reported as being 9.7 Gy. Optic nerve/chiasm doses were estimated from isodose distributions overlaid on CT images, unlike the present day when the entire optic system is usually outlined on detailed MR images and maximum doses are assessed from dose-volume histograms. It is highly likely that the true maximum doses to the optic system were higher and lay in portions of the nerve that were poorly visualized.

Stafford et al[31] reported a later analysis of four cases of optic neuropathy occurring out of 215 Mayo Clinic radiosurgery patients with a median dose

of 10 Gy to the optic chiasm. One case developed after an optic nerve/chiasm dose of 12.8 Gy with radiosurgery alone, at which the risk level appeared to be approximately 3%. The other cases developed in patients with prior fractionated radiotherapy (7 Gy after 58.8 Gy, 9 Gy after 45 Gy, and two procedures delivering 9, and later 12 Gy to the optic system after 50.4 Gy). In two more recent studies,[32,33] over 300 patients with no prior radiation treatment and with a median maximum dose to the optic apparatus of 9.2 to 10 Gy, there was one case of optic neuropathy. This occurred at a maximum dose of 12.8 Gy.

Leber et al[34] analyzed optic nerve injury risks in 50 patients with 24- to 60-month follow-up who underwent Gamma Knife radiosurgery for benign skull base tumors. The risks of optic neuropathy were 0% with 10 Gy. They found no cavernous sinus nerve injury with doses of 5 to 30 Gy.

Hiniker et al[35] found less than 1% risk of optic neuropathy with 12 Gy in one fraction, 19.5 Gy in three fractions, and 25 Gy among 262 patients with perioptic tumors treated with SRS. Similarly, the HyTEC analysis pooled 34 studies with 1,578 patients treated with single and fractionated SRS to evaluate the tolerances of the optic pathways.[36] With a calculated normal tissue complication probability of 1%, the recommendation was for maximum doses to optic structures as 10, 20, and 25 Gy in one, three, and five fractions, respectively.

Tolerance of Other Cranial Nerves

From clinical experience with fractionated conventional radiosurgery and radiosurgery, it appears that special sensory nerves (optic and auditory) are the most radiosensitive, followed by somatic sensory nerves (trigeminal), and, finally, the motor nerves (cranial nerves II, IV, VI, VII, and IX to XII). After acoustic schwannoma radiosurgery to doses of 12 to 13 Gy, fractionated SRS to 18 Gy in three fractions, or SRT to 45 to 50 Gy in 25 to 28 fractions, decreased hearing developed in 30% to 50% of patients, facial numbness in 2% to 3%, and facial weakness in 0.5% or less. Single-fraction radiosurgery with present techniques for meningiomas involving the cavernous sinus is associated with a risk of trigeminal neuropathy of approximately 3% of patients with radiation injuries to cranial nerves III,

IV, or VI more uncommon.[37-41] The risk of injury correlates with the length of nerve irradiated.[42]

CLINICAL USES OF RADIOSURGERY FOR CENTRAL NERVOUS SYSTEM CONDITIONS AND NEOPLASMS

Table 16.3 lists the most common indications for radiosurgery with representative references. Except for functional radiosurgery, there are varied levels of experience with SRT for each of these indications.

TABLE 16.3 COMMON INDICATIONS FOR RADIOSURGERY OR HYPOFRACTIONATED STEREOTACTIC RADIOTHERAPY

Indication	Experience	Value
Functional		
a. Trigeminal neuralgia	a. Extensive	1. Less numbness than rhizotomy
b. Unilateral tremor	b. Moderate	2. In poor candidates for deep brain stimulation
Vascular		
a. AVM	a. Extensive	a. High
b. Cavernous	b. Moderate	b. Controversial
Benign tumors: schwannoma, pituitary adenoma, meningioma, etc	Extensive	High tumor control, acceptable morbidity for selected small tumors
Rare benign tumors: glomus tumor, hemangioblastoma, neurocytoma	Moderate	High tumor control, acceptable morbidity for selected small tumors
Brain metastases	Extensive	Control rates ≥ surgery for small metastases
Primary malignant brain tumors	Extensive for GBM. Limited for other uses	Initial SRS appears ineffective for GBM. Helpful for recurrent tumors

AVM, arteriovenous malformation; GBM, glioblastoma multiforme.

Functional Radiosurgery

The most widely used functional application for radiosurgery is in the management of typical trigeminal neuralgia refractory to medical therapy.[42-47] Atypical or constant pain does not respond. Other alternatives for managing typical trigeminal neuralgia are medication, open surgery with microvascular decompression, and rhizotomy procedures using glycerol injection, balloon compression, or radiofrequency injury to the nerve. Typically, 4-mm collimators are used for radiosurgery to a maximum dose of 80 to 90 Gy. Response rates reach approximately 85%, typically 1 week to 4 months after the procedure, but can develop as late as 6 months afterward. Approximately 50% of typical trigeminal neuralgia patients remain pain free and off medication 5 years following radiosurgery. A typical radiosurgery plan for trigeminal neuralgia is shown in Figure 16.2. Kotecha et al[45] analyzed the dose response for trigeminal neuralgia in 352, 85, and 433 patients undergoing SRS with maximum doses of less than or equal to 82, 83 to 86, and greater than or equal to 90 Gy. They found 4-year pain responses of 79%, 82%, and 92% and 4-year rates of Barrow Neurological Institute (BNI) class 3 to 4 numbness developing in 25%, 49%, and 40% of patients at maximum doses of 90 Gy, respectively. The numbness in nine patients (1%) was classified as anesthesia dolorosa, all with maximum doses less than or equal to 86 Gy.

FIGURE 16.2 Typical radiosurgery plan for right trigeminal neuralgia. The right trigeminal nerve is outlined in white. The 30% and 50% isodose volumes from treating a single isocenter with 4-mm diameter collimators with a gamma unit are shown. A maximum dose of 80 Gy will deliver 40 Gy to the 50% isodose value and 16 Gy to the 20% volume.

Studies have suggested that radiosurgery within 4 years of onset of trigeminal neuralgia leads to better long-term pain control and that selective dose reduction to 70 to 75 Gy may reduce risks of radiation-induced trigeminal neuropathy in patients with larger treatment volumes resulting from having thicker trigeminal nerves.[46-48] In patients who have symptoms recur, repeat radiosurgery is feasible.[49-51] In a large series of 125 patients

with long-term follow-up, Helis et al[51] reported an 84% response rate of BNI IIIb or better pain relief with repeat Gamma Knife radiosurgery and 46% of patients reached BNI I response. Two patients developed anesthesia dolorosa, and one patient experienced bothersome numbness. Predictors of favorable outcomes for repeat treatment were facial numbness and a positive pain response after the first radiosurgery.

To alleviate medically refractory unilateral tremor in patients with essential tremor and/or Parkinson disease, a small destructive lesion in the ventralis intermedius nucleus of the thalamus can be created either invasively with a needle equipped with a radiofrequency generator or noninvasively with radiosurgery using 4-mm diameter collimators and a maximum dose of 130 Gy.[52-55] Nondestructive management through insertion of a deep brain stimulator is preferred in most patients, but not all patients are acceptable candidates and radiosurgery appears more cost effective.[55] Witjas et al[56] reported a prospective single-arm study of 50 patients with severe refractory tremors (36 essential, 14 parkinsonian). Upper limb tremor score improved by more than 50%, with all tremor components improved. There was one adverse event of transient hemiparesis due to posttreatment edema. Although targeting the globus pallidus for bradykinesia, rigidity, and dyskinesia from Parkinson has been successful with deep brain stimulation, limited early radiosurgical pallidotomy has not established success.[57,58]

There is limited experience with bilateral radiosurgical capsulotomy (targeting the anterior limb of the internal capsule) for managing severe, refractory obsessive-compulsive disorder, including a small randomized controlled study that was retracted after it was found that only two of eight patients responded to radiosurgery (vs three of eight as originally thought) compared to none of 8 without radiosurgery.[59]

The use of radiosurgery for medically refractory seizure disorders has shown promise. Radiosurgery versus Open Surgery for mesial temporal lobe Epilepsy (ROSE) trial randomized 58 patients between radiosurgery and anterior temporal lobectomy;[60] 24 Gy was prescribed to the 50% isodose line, targeting the mesial temporal lobe. Sixteen of 31 (52%) and 21 of 27 (78%) patients achieved seizure remission with radiosurgery and surgery, respectively, with quicker remission achieved with surgery. There were five serious adverse events in the radiosurgery cohort—one patient

with headache, one with cerebral edema, one with new neurologic deficit, and two with seizure exacerbation—and two serious events in the surgery cohort—two patients with wound dehiscence and infection. The trial was closed early due to slow accrual but did show that radiosurgery may be a potential option for nonsurgical candidates. Similarly, radiosurgery for hypothalamic hamartomas may help control refractory gelastic seizures.[61]

Vascular Malformations

Untreated intracranial AVMs have a bleeding risk of approximately 2% to 3% per year or higher if prior bleeds have occurred.[62-64] This results in an average of 1% of untreated patients with AVM dying per year from hemorrhage. Management options include observation, surgical resection, embolization, and radiosurgery. The ARUBA (A Randomized Trial of Unruptured Brain Arteriovenous Malformations) trial for AVMs with no prior bleeds compared observation to treatment intervention with institutional choices of embolization, resection, and/or radiosurgery.[65] Because the initial morbidity from intervention by surgery, embolization, and/or radiosurgery was compared to the relatively low annual bleeding risk of unruptured AVM with observation, the ARUBA trial identified observation as the best management option for their relatively short 33-month mean follow-up period. The final follow-up, published in 2020 (mean follow-up of 50.4 months), continued to favor observation over intervention.[66] Although this trial could be used to justify observation for older patients with low-risk AVMs, the relatively short follow-up ARUBA trial was inadequate to see the long-term benefits from definitive management of AVM with surgery or radiosurgery in younger patients.

After 3 to 5 years, radiosurgery can dramatically reduce the risk of hemorrhage. Radiosurgery obliterates the AVM nidus in approximately 75% of patients within 3 years of the procedure.[67-69] Individual obliteration rates vary from 50% to 88% depending on the marginal dose administered, as shown in the dose-response curve illustrated in Figure 16.3. Although AVM obliteration rates appear to be optimized with marginal doses of approximately 23 Gy, lower doses are selected for most patients to minimize complications. The risk of neurologic sequelae from radiosurgery averages approximately 3% but varies with treatment volume, dose, and

location (Table 16.2). The risk of hemorrhage while waiting for complete obliteration to develop seems unaltered.[62] All of these risks and benefits of radiosurgery need to be considered together to optimize the management of individual patients with AVM.

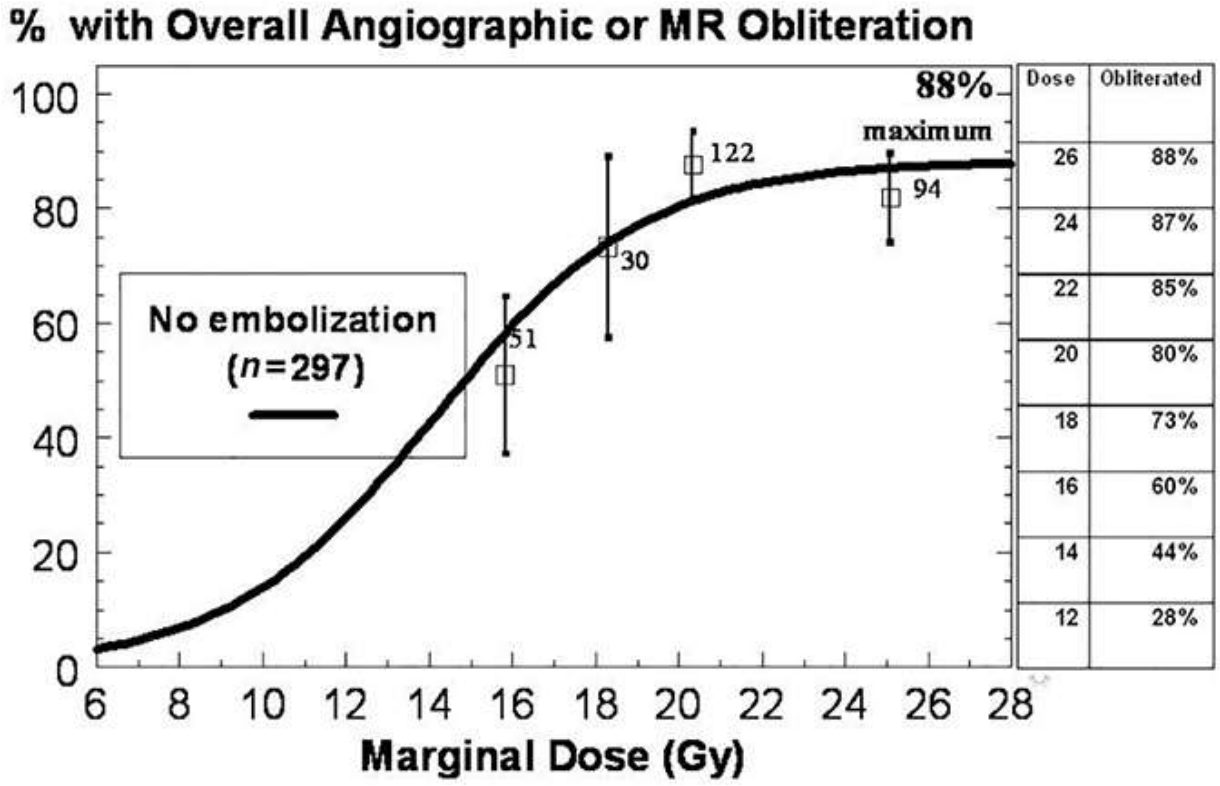

FIGURE 16.3 Dose response for obliteration of AVM after radiosurgery from 297 patients treated at the University of Pittsburgh without embolization. AVM, arteriovenous malformation; MR, magnetic resonance (From Flickinger JC, Kondziolka D, Lunsford LD. Radiobiological analysis of tissue responses following radiosurgery. *Technol Cancer Res Treat*. 2003;2[2]:87-92. Copyright © 2003 SAGE Publications. Reprinted by permission of SAGE Publications.)

When an AVM nidus fails to completely obliterate by 3 years after radiosurgery, irradiation can be repeated with acceptable morbidity.[70-72] Although some residual radiation injury effect would be expected within the previously irradiated unobliterated AVM nidus vasculature, retreatment appears to require similar, if not higher doses to achieve similar rates of complete obliteration as initial radiosurgery.[70-72]

Management of large AVMs is presently difficult because radiosurgery may be associated with high complication risks and low obliteration rates.

Improvements in embolization with liquid glue or onyx polymer can sometimes help reduce the target volume but add to the total risks of the overall management.[73] Another promising approach is staged radiosurgery, where large AVMs are treated in two or three sections separated by 4- to 6-month intervals to reduce acute toxicity.[74-76] A third approach has been fractionated radiosurgery using doses of 30 to 35 Gy delivered daily or every other day in five fractions.[77]

Cavernous malformations do not show detectable flow on angiography but nevertheless are vascular lesions with annual hemorrhage risks of 0.5% per year with no prior bleed, 4.5% with one prior hemorrhage, and approximately 32% per year after a history of two or more hemorrhages.[78-82] Lower pressures in these lesions lead to smaller bleeds than are typically seen with AVM. Repeated bleeds from brainstem cavernous malformations can cause considerable neurologic morbidity. Symptomatic, surgically accessible lesions should be resected. Radiosurgery of brainstem cavernous malformations with a history of two or more prior hemorrhages appears to reduce the risk of subsequent bleeds to approximately 1% per year with acceptable morbidity.[83-89]

Benign Tumors

Most small benign intracranial tumors are well managed with radiosurgery, fractionated radiosurgery, or SRT. Radiosurgery control rates are high with radiosurgery with single-fraction prescription doses on the order of 12 to 14 Gy or their equivalent with hypofractionation.[37-41,90-128] Kondziolka et al[37] evaluated long-term tumor control in 285 consecutive patients who underwent radiosurgery for benign intracranial tumors between 1987 and 1992, with a median follow-up period of 10 years. This included 157 patients with vestibular schwannomas, 10 with other cranial nerve schwannomas, 85 with meningiomas, 28 with pituitary adenomas, and 5 with craniopharyngiomas. In all, 44% had prior surgical resection and 5% had prior fractionated radiotherapy. They found that 95% of the 285 patients had imaging-defined local tumor control. The crude tumor control was 95% (271/285 patients) with a 15-year actuarial tumor control rate of 93.7%. In 5% of the patients, delayed tumor growth was identified. Resection was performed after radiosurgery in 13 patients (5%) for tumor growth.

Vestibular Schwannomas

Vestibular schwannomas, also known as acoustic neuromas, are benign tumors arising from Schwann cells. They are associated with the loss of genetic information on chromosome 22.93. Vestibular schwannomas either occur on one side as spontaneous mutations or bilaterally as the hallmark of type 2 neurofibromatosis (NF-2). Vestibular schwannomas usually arise within the internal auditory canal and later extend intracranially into the cerebellar-pontine angle. Because these tumors lack the ability to invade bone, the portion of tumor outside the canal in the cerebellar-pontine angle eventually grows into a globular extension that is larger than the intracanalicular portion (Figure 16.4). The differential diagnosis of a cerebellar-pontine angle tumor includes vestibular schwannoma (90%), meningioma (close to 10%), cholesteatomas, facial or trigeminal schwannoma, and rare primary or metastatic malignant tumors. Cerebellar-pontine angle meningiomas, which can be managed similarly to vestibular schwannomas, also may involve the internal auditory canal but usually are distinguished by a broad, flat, dural attachment.

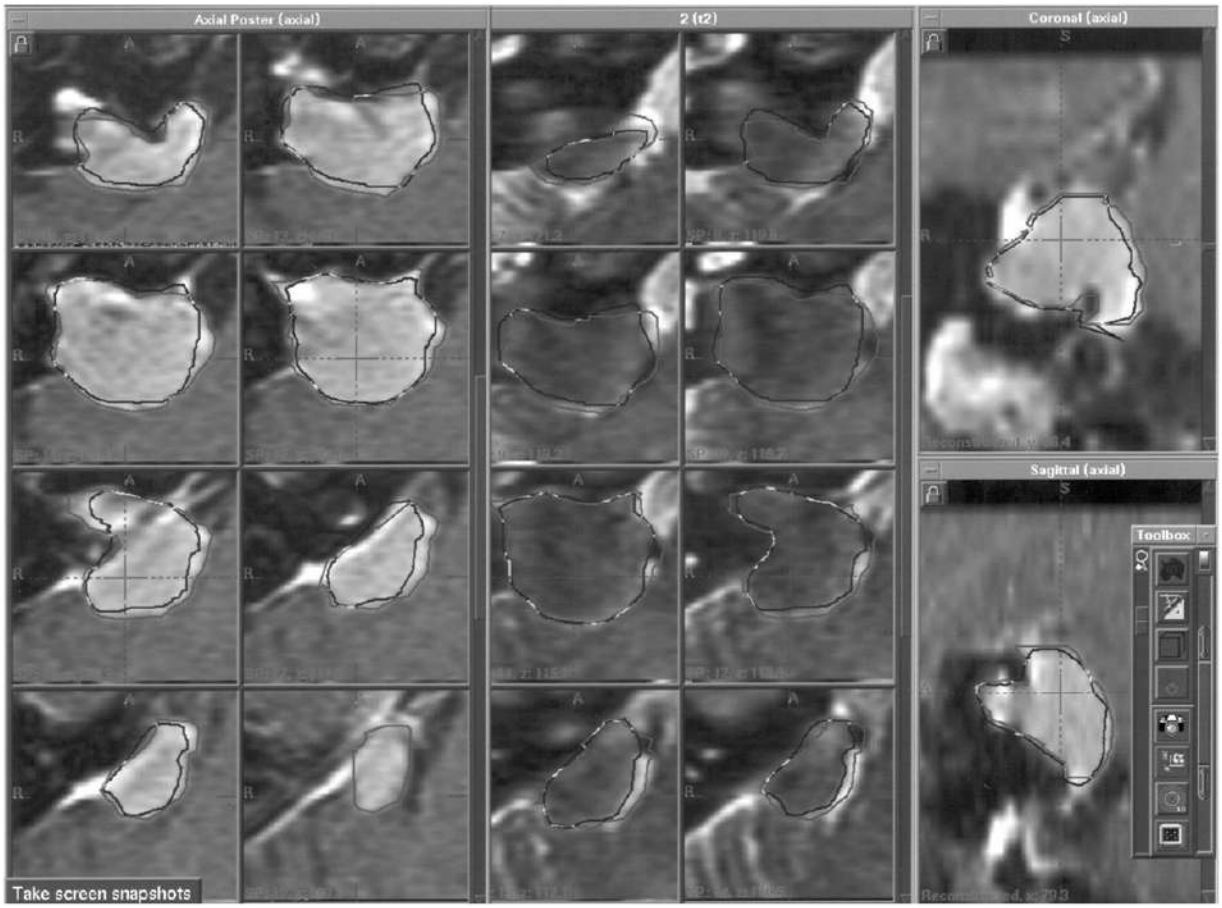

FIGURE 16.4 Comparisons of acoustic schwannoma contours drawn from T1 contrast MR images (eight axial images on the left side with coronal and sagittal images on the right side) with contours drawn from T2 MR images (the darker eight axial images in the center). T1 contours can sometimes slightly overestimate extension into the internal auditory canal and unnecessarily include adjacent blood vessels.

Observation and surgical resection were essentially the only management strategies offered to patients with acoustic schwannoma until favorable experiences with Gamma Knife radiosurgery were reported in the 1980s. For small to medium vestibular schwannomas, tumor control rates with radiosurgery or fractionated radiotherapy are comparable to surgical resection.[90-111,121-125] Observation may be appropriate in selected patients with NF-2 and some older patients with small, minimally symptomatic vestibular schwannomas, but early intervention appears to be the best strategy for long-term hearing preservation for most patients.[121,122]

Early radiosurgery series, including patients treated during the 1980s with higher doses (14-18 Gy) and less conformal treatment plans, had

higher rates of postradiosurgery cranial neuropathies (15%-20% trigeminal and/or facial and 67% with a drop in their Gardner-Robertson hearing level).[125] This prompted some groups to pursue SRT for vestibular schwannomas, whereas others pursued radiosurgery with refined techniques and lower doses. Both approaches led to improved results.[90-108,119-125] The University of Pittsburgh reported on 313 previously untreated patients with unilateral acoustic schwannoma who underwent Gamma Knife radiosurgery doses of 12 to 13 Gy between February 1991 and February 2001.[91] Median follow-up was 24 months and maximum follow-up 115 months, and 36 patients had greater than 60 months of follow-up. The actuarial clinical tumor control rate, free of surgical intervention, was 98.6% at 7 years. The 7-year actuarial rates for unchanged facial strength, unchanged facial sensation, unchanged hearing level, and useful hearing preservation were 100%, 95.6%, 70.3%, and 78.6%, respectively. Eight patients developed new trigeminal neuropathy, six of whom developed numbness (7-year actuarial rate = 2.5%), whereas the other two developed new typical trigeminal neuralgia (7-year actuarial rate = 1.9%). The risk of developing postradiosurgery trigeminal neuropathy was associated with increasing tumor volume. Similar results with low-dose radiosurgery of vestibular schwannomas were reported by Iwai et al,[94] Muacevic et al,[95] Paek et al,[97] and Rowe et al.[99]

Various hypofractionated schemes (18 Gy/3, 20 Gy/4 to 5, 25 Gy/5 fractions) have been used to treat vestibular schwannoma with minor differences in results.[102,129-132] For HyTEC, Soltys et al[133] evaluated 35 publications encompassing 5,162 patients undergoing one to five fractions of radiosurgery to estimate the tumor control probability for vestibular schwannoma. With typical doses of 12 Gy in one fraction, 18 Gy in three fractions, and 25 Gy in five fractions, the tumor control probability at 3 and 5 years exceeded 91% for all treatment regimens.

After accounting for length and quality of follow-up, results from hypofractionated[102,129-132] and conventionally fractionated[103,106] treatments seem similar to radiosurgery with 12 to 13 Gy, but an advantage for fractionation cannot be excluded entirely.[96] The University of California, Los Angeles reported unusually good hearing preservation (93%) for their experience with 50 patients with unilateral acoustic schwannoma irradiated to 54 Gy in 30 fractions to a 90% isodose treatment volume, including a 1-

to 3-mm margin around gross tumor.[109] All tumors were controlled with a median follow-up of 36 months (range 6-74 months). They defined useful hearing preservation as the ability to talk on the telephone with the affected ear. After radiosurgery, new facial numbness developed in one patient (2%) and facial weakness developed in one patient (2%).

Andrews et al[103] analyzed the Jefferson vestibular schwannoma experience, comparing 69 radiosurgery patients to 50 SRT patients who received 50 Gy in 25 fractions. Their first 25 patients with vestibular schwannoma were treated using a LINAC, whereas later radiosurgery patients were treated with Gamma Knife radiosurgery. The authors reported similar facial and trigeminal neuropathy rates for the radiosurgery and fractionated radiotherapy groups, but the rate of hearing loss was significantly higher in their radiosurgery group. There were only a small number of patients with serviceable (useful) hearing in each group prior to irradiation (12 in the radiosurgery and 21 in the SRT groups), and follow-up was limited. Meijer et al[102] also reported a single-institution comparison of radiosurgery (LINAC to 10 or 12.5 Gy) and SRT (20 Gy in four or five fractions) for vestibular schwannoma. They selected 49 edentulous patients (mean age 63 years) for radiosurgery and 80 patients (mean age 43 years) with intact dentition for SRT. They found a higher rate of trigeminal neuropathy following radiosurgery (8%) than SRT (2%) at 5 years, but similar hearing loss with radiosurgery (25%) and SRT (39%), similar, but higher than usual rates of new facial neuropathy (7% radiosurgery vs 3% SRT), and similar 5-year actuarial tumor control rates (100% with radiosurgery vs 94% with SRT). Combs et al[106] compared the results of vestibular schwannoma management with single-fraction radiosurgery (median dose of 13 Gy) in 169 patients to SRT at 1.8 Gy per fraction to a median dose of 57.6 Gy in 291 patients with a median follow-up of 67 months. Local control rates were similar at 95% and 94% at 5 and 10 years. Useful hearing preservation rates were also similar at 84% and 86% in the SRS and SRT groups, as was trigeminal and facial neuropathy at approximately 1% for both. Akpinar et al[111] reported the results of hearing preservation after single-fraction radiosurgery with a median dose of 12.5 Gy (11-13 Gy) to a median volume of 0.72 cm^3 (0.11-12.8 cm^3) in 88 patients with vestibular schwannomas with no subjective hearing loss at the time of diagnosis. With 75 months of median follow-up, for the 57 patients

who underwent SRS less than or equal to 2 years from diagnosis, the serviceable hearing (class 1-2) and normal hearing preservation rates (class 1) at 5 years after SRS were 88% and 77%, whereas those for the 31 patients who underwent late SRS (>2 years after diagnosis) were 55% and 33%, respectively.

More recently, the Vestibular Schwannoma, Radiosurgery or Expectation (V-Rex) trial,[134] which randomized 100 patients with newly diagnosed unilateral vestibular schwannomas less than 2 cm to upfront radiosurgery (12 Gy to 40%-60% isodose line) versus yearly surveillance imaging with treatment only upon growth, found at 4 years decreased size of the vestibular schwannoma in the upfront radiosurgery group as compared to the wait-and-see cohort. There was a similar hearing acuity decline in both groups. There was no reported radiation toxicity. Twenty-one (42%) patients in the wait-and-see required intervention upon tumor growth. A 10-year follow-up report is planned and will be more informative of the long-term clinical outcomes of this strategy for small to medium tumors.

For large tumors, typically greater than or equal to 2.5 cm and/or Koos grade IV designation,[135] surgery often appears to be the best initial strategy due to concerns of symptomatic brainstem compression with obstructive hydrocephalus. Single-fraction radiosurgery, however, is feasible in these patients who cannot or wish not to undergo surgical resection.[136-141] Pikis et al[140] reported from a large, multi- institutional analysis of 627 patients with Koos grade IV vestibular schwannoma treated with a median dose of 12 Gy. The median tumor volume was 8.7 cm^3. At a median radiologic follow-up of 38 (interquartile range [IQR] 54) months, tumor control was achieved in 94.1% of patients. Actuarial 5- and 10-year PFS rates were 92.3% and 87.6%, respectively. Facial nerve function deterioration occurred in 19 (3.0%) patients at the last follow-up and was associated with margin doses greater than or equal to 13 Gy (P = .03) and early tumor expansion (P = .04). Fifty-seven patients developed T2-weighted hyperintensities in the brainstem, and 37 developed cyst formation, requiring medical/surgical management in 34 and 18 patients, respectively. Notably, after SRS, 33 (6%) patients developed hydrocephalus requiring shunting.

Nonacoustic Schwannomas

Schwannomas may occasionally involve other cranial nerves. Tumor control rates are similar, but postradiosurgery neuropathies seem less common as somatic sensory and motor nerves, particularly, seem less sensitive to radiation injury than special sensory nerves like VIII.[112-115,142-146] Langlois et al[146] reported on a small, multicenter cohort study of 25 patients who underwent a single-fraction dose of 12.5 Gy for an oculomotor cranial nerve schwannoma (CN III, IV, or VI). Tumor control was 92%. Diplopia improved in 11 of 21 patients and worsened in 3 patients, 2 of which were due to tumor progression. Kano et al[142] reported on 92 jugular foramen schwannomas managed at multiple institutions with a median single-fraction dose of 12.5 Gy (10-18 Gy) to volumes of 0.8 to 22.6 cm^3 (median 4.1 cm^3). Tumor control rates at 5 and 10 years were 87% and 82%. Preexisting cranial neuropathies improved in 32% and 37% of patients. Because spinal schwannomas involving motor nerves are difficult to completely resect without causing motor deficits, they are often managed with radiosurgery. Shin et al[147] reported one of the larger series of neurogenic spinal nerve root tumors (47 schwannomas, seven neurofibromas, and four malignant peripheral nerve sheath tumors managed with radiosurgery). Local control for the schwannomas was 86%.

Meningiomas

Radiosurgery and SRS are both excellent management options for most small benign meningiomas with infield tumor control rates well above 90%, as seen with most other benign tumors.[37,116] Marginal recurrence rates as high as 25% may develop because of the tight margins used for radiosurgery or SRT treatment volumes limited to small recurrences or residual tumors after resection of large parasagittal meningiomas.[37,116,126-128] Marginal recurrences are far less of a problem with unresected (and usually unbiopsied) meningiomas. A University of Pittsburgh study[116] analyzed 219 imaging-diagnosed (unbiopsied) meningiomas managed with single-fraction Gamma Knife radiosurgery to a prescription dose of 8.9 to 20 Gy (14 Gy median) and treatment volumes of 0.47 to 56.5 mL (median 5.0 mL) with 2 to 164 months of follow-up (median 29 months). Tumors progressed in seven patients, two of which proved to be different tumors (metastatic nasopharyngeal adenoid cystic carcinoma and chondrosarcoma). Another

patient with local control of the lesion developed a subsequent brain metastasis, changing the diagnosis of the first lesion to the same. The actuarial tumor control rate was 93.2% at 5 and 10 years. The actuarial rate of identifying a diagnosis other than meningioma was at 5 and 10 years. No pretreatment variables, including dose, correlated with tumor control in univariate or multivariate analysis. The actuarial rate for developing any postradiosurgical injury reaction was 8.8% at 5 and 10 years but was lower (5.3%) after 1991 with stereotactic MRI and lower doses.

Atypical and malignant (anaplastic) meningiomas have higher rates of local and marginal recurrence after therapeutic intervention. Complete surgical resection is advocated whenever feasible and followed by a full course of conventional radiotherapy. Radiosurgery has been recommended to improve local control of unresectable tumor.[128,148-150] Malik et al[128] reported 5-year actuarial control rates of 87% for typical meningiomas, 49% for atypical, and 0% for malignant meningioma in the Sheffield Gamma Knife experience. Harris et al[149] reported the Pittsburgh Gamma Knife experience in 12 malignant and 18 atypical meningiomas. Their 5-year local tumor control was 72% for malignant and 83% for atypical meningiomas; however, 10-year actuarial survival rates were only 59% and 0%, respectively. Katz et al[150] could not substantiate that either accelerated fractionated radiotherapy or a radiosurgery boost improved tumor control or survival in their analysis of 27 atypical and nine patients with malignant meningioma managed at the University of Florida. Shepard et al[151] reported on 233 patients with atypical meningioma and 38 patients with anaplastic meningioma treated at 12 institutions with SRS. 98.5% had prior resections and 25.8% had prior radiotherapy. Five-year PFS and overall survival were 33.6% and 70%, respectively.

One controversy in the radiosurgical management of meningiomas is whether an additional dural margin or dural tail needs to be routinely included in the treatment volume. Dibiase et al[152] analyzed a series of 162 benign meningioma patients treated to a median single fraction of 14 Gy and found improved tumor control with the treatment of the dural tail (96% vs 78%). Most centers do not follow this policy, and other authors[153] have argued against this policy for World Health Organization (WHO) grade I meningiomas. Current consensus guidelines do not include dural tail in gross tumor volume definition for grade 1 meningiomas.[154,155] Outlining the

tumor target volume with T2 imaging sometimes discloses gross tumor extension into what otherwise appears to be normal dura adjacent to the tumor. Any WHO grade 2 or 3 meningioma should be treated with at least a 5- to 15-mm margin of additional normal dura whenever possible.[154,155]

Pituitary Adenoma

Management of pituitary adenomas requires a multidisciplinary approach to properly select which patients are suitable for different approaches with medical therapy, surgery, fractionated radiotherapy and radiosurgery, or combinations of these approaches. Most patients with visual compromise, particularly with hemianopsia or greater, will do better with initial surgical decompression. Prolactinomas are usually initially managed with medical therapy.[117] Most other small pituitary adenomas, where the target volume can be separated from the optic nerves, are reasonable candidates for radiosurgery.[37,117-119] Sheehan et al[119] reviewed 35 peer-reviewed reports of radiosurgery for pituitary adenoma, which included 1,621 patients. Most studies reported a greater than 90% control of tumor size (range 68%-100%). The weighted average tumor control rate for all published series (encompassing 1,283 patients) was 96%. In eight published series with mean or median patient follow-up periods of 4 or more years, tumor growth control rates varied from 83% to 100%.

Higher radiosurgery doses are required for functional pituitary adenomas. Twenty-two series results published radiosurgery results for 314 patients with Cushing disease. The mean radiosurgical prescription (margin) doses for these series varied from 15 to 32 Gy. In those series with at least 10 patients and a median follow-up of 2 years, endocrinologic remission rates range from 17% to 83%. Many of the patients in older series were treated in the pre-CT and MRI era of radiosurgery, sometimes as often as 4 times before their Cushing disease went into remission. Mehta et al[120] reported a multi- institutional experience with radiosurgery to a mean single-fraction dose of 23.7 Gy in 278 patients with Cushing disease with a mean follow-up of 5.6 years (0.5-20.5 years). Cumulative initial control of hypercortisolism was 80% at 10 years, with a mean time to cortisol normalization of 14.5 months. Recurrences after initial cortisol normalization developed in 18% of patients, which made the overall rate of

durable hormonal control to 64% at 10 years and 68% among patients who received SRS as a primary treatment. Acute radiation effects (AREs) included hypopituitarism (25%) and cranial neuropathy (3%). Development of visual deficits correlated with tumors involving the suprasellar cistern (P = .01), whereas both visual (P < .0001) and nonvisual cranial neuropathies (P = .02) were related to prior pituitary irradiation.

Lower radiosurgical doses are effective for nonfunctioning pituitary adenomas. The North American Gamma Knife Consortium series[121] of 512 patients with nonfunctioning pituitary adenoma reported 5- and 10-year tumor control rates of 91% and 85% with a mean dose of 16 Gy (range 5-35 Gy) to a mean volume of 3.33 Gy (range 0.08-33 cm^3). Higher tumor control rates were found in tumors <5 cm^3 and those without suprasellar extension. Tumor control rates in patients receiving <12 Gy, 12-20 Gy, and >20 Gy were 73.5%, 95.5%, and 92%. New or progressive cranial neuropathies developed in 9% of patients (including 6.6% optic). Decreasing age, increasing volume, history of prior radiation therapy, and history of prior pituitary axis deficiency correlated with new or worsening cranial neuropathy.

Glomus Tumors

Glomus tumors, or paragangliomas, are rare tumors of neural crest origin cells (chromaffin) of the extra-adrenal autonomic paraganglia. These tumors may arise from sympathetic or parasympathetic paraganglia and may have catecholamine-secreting functions. Parasympathetic-derived tumors are typically benign and nonsecreting and are often found in the skull base and neck near cranial nerves.[156] These tumors are subclassified further by location as carotid paraganglioma, glomus jugulare, glomus tympanicum, and vagal paraganglioma. Given the location, patients with head and neck paragangliomas often present with symptoms of pulsatile tinnitus, hearing loss, a nontender neck mass, or have ipsilateral cranial neuropathies.

Historically, resection has been considered the preferred approach, and radiation treatment was reserved for unresectable or recurrent glomus tumors. Radiosurgery has often been used for the treatment of glomus jugulare tumors because of the risk of surgical morbidity, particularly cranial neuropathies.[157,158] Multiple-dose fractionation regimens have been

used, including a single-fraction dose of 12 to 15 Gy or fractionated radiosurgery at 25 Gy in five fractions. Reported local control rates with radiosurgery typically approach 95% to 100% and are well tolerated.[157-168] Patel et al[165] reported a 5-year PFS rate of 98% in 85 patients undergoing Gamma Knife radiosurgery at Mayo Clinic, with only 2 patients (3%) developing a new lower cranial neuropathy. After 10 years of initial radiosurgery, three tumors did radiographically progress without the need for intervention, suggesting the need for long-term tumor surveillance.

Hemangioblastomas

Hemangioblastomas are rare, benign vascular tumors of the CNS that occur sporadically or are associated with von Hippel-Lindau syndrome (VHL). According to the WHO classification system, these tumors are grade 1 mesenchymal, nonmeningothelial tumors.[169] Management of hemangioblastomas includes observation, surgical resection, and radiation therapy, including radiosurgery or conventionally fractionated radiotherapy. Although surgical resection is the primary treatment, radiosurgery offers a noninvasive approach for lesions in eloquent locations in the brain or in patients with VHL, who may require multiple procedures over time.

Kano et al[170] reported the largest series of patients with intracranial hemangioblastomas treated with radiosurgery. In 186 patients with 517 lesions, local control was 89% and 79% at 5 and 10 years, respectively. Thirteen (7%) of patients experienced AREs, with one patient dying due to refractory peritumoral edema. Similar local control outcomes have been seen in other studies.[170-173] Improved tumor control has been observed for VHL-associated hemangioblastoma compared to sporadic tumors in other radiosurgery[170,171] and conventionally fractionated radiotherapy reports.[174]

Pan et al[175] conducted a systemic review and meta-analysis of 596 patients and 1,535 lesions receiving radiosurgery for intracranial and spinal hemangioblastomas. The calculated PFS at 5 years was 88.4%. The 10-year PFS reported by a small number of studies varied widely—50% to 96%. This included a small prospective observational study by Asthagiri et al,[176] which projected the control rate at 15 years to be 51%, drawing concerns that radiosurgery may lose effectiveness with time. However, this study was small and included only patients with VHL-associated tumors.

Central Neurocytomas

Central neurocytomas are rare, neuronal-glial brain tumors typically located in the supratentorial ventricular system. The WHO classifies central neurocytomas as grade II.[169] A more aggressive subset termed atypical neurocytoma is designated by a proliferation index greater than or equal to 2% (MIB-1 labeling index) and was established after a meta- analysis determined an increased risk of local failure and death in patients with MIB-1 indexes greater than 3.[177] Primary treatment of central neurocytomas is gross total resection[178,179]; however, because of their location, maximal safe resection is often achieved. Radiotherapy should be considered definitively for inoperable patients or adjuvantly for atypical histology, residual, or recurrent disease.[178,180-184]

Both conventionally fractionated radiotherapy and radiosurgery have been used in the treatment of these rare tumors. From an international retrospective cohort study, Hung et al[185] reported outcomes for 60 patients following radiosurgery for recurrence (12%), adjuvant therapy (72%), or definitive treatment (17%). Mean margin dose was 13 Gy. The 5- and 10-year PFS were 89% and 80%, respectively. Adverse events were observed in four (7%) patients. Yamanaka et al[186] reported similar 5- and 10-year PFS of 94% and 86% in 36 patients undergoing Gamma Knife radiosurgery, with a mean marginal dose of 15 Gy. Genc et al[187] reported on 18 patients, and local control of 93% followed single-fraction radiosurgery. Karlsson et al[188] reported a 5- and 10-year PFS of 91% and 81%, respectively, in 42 patients with a median prescribed dose of 13 Gy. Notably, in this study, 45% of patients experienced enlargement of the ventricular system, and six patients required interventions. Careful monitoring for treatment effects after treatment is necessary.

Malignant Central Nervous System Tumors

The overall management of brain metastases and malignant glioma is discussed elsewhere in this book. In 1989, the RTOG Brain Tumor Committee initiated an SRS clinical trials program. The first study, RTOG 90-05, evaluated patients with prior radiation for either brain metastases or malignant glioma and was designed as a phase 1 dose escalation study for single-fraction SRS. This patient cohort was chosen due to (1) high

expected numbers of potential patients due to poor local control with conventionally fractionated radiotherapy, (2) few subsequent therapeutic options for these patients, and (3) anticipation that the data would be used on future RTOG radiosurgery trials.[9] Over time, the management of brain metastases with radiosurgery has become much more complex due to the multitude and potential combinations of currently available treatment options, including surgery, SRS, whole-brain radiation therapy (WBRT) with and without hippocampal avoidance (HA-WBRT), chemotherapy, targeted drug therapies, and immunotherapies.[189] On the other hand, the management of malignant gliomas with radiosurgery has been more challenging and is typically reserved in special situations of low-volume disease recurrence.

Brain Metastases

Brain metastases are the most common and best-studied indications for SRS. Early clinical investigations found impressive tumor control with radiosurgery for brain metastases that progressed after prior WBRT. RTOG 90-05 dose escalation trial in recurrent brain tumors to some degree standardized dose prescription for brain metastasis radiosurgery.[9] Because of the success of radiosurgery in controlling brain metastases after WBRT and the high rate of eventual local tumor progression in brain metastases after conventional WBRT, radiosurgery has been increasingly used in the initial management of brain metastases.[190] The RTOG's subsequent phase III randomized trial, RTOG 95-08, established that radiosurgery immediately following standard WBRT (37.5 Gy in 15 fractions) improves local control and quality of life for patients with one to three brain metastases while also improving overall survival for patients with solitary metastasis, all compared to patients initially managed with only WBRT.[191]

Although RTOG 95-08 established radiosurgery's role after WBRT in managing one to three brain metastases, questions remained about managing brain metastases with radiosurgery alone and preserving full-dose WBRT as an option for later managing cases with subsequent progression. Aoyama et al[192] published the outcome of a prospective randomized controlled trial to evaluate whether initial WBRT provides better outcomes when added to SRS compared to using SRS alone. This study randomized

132 patients with one to four brain metastases less than 3 cm in diameter to radiosurgery with or without initial WBRT. They found the median survival time and the 1-year actuarial survival rates were not significantly different with or without WBRT. Later, Brown et al[193] demonstrated that SRS alone had less cognitive deterioration at 3 months compared with a combination of WBRT and SRS in patients with one to three brain metastases. The N107C/CEC.3 study compared SRS alone versus whole-brain radiotherapy in patients undergoing postoperative radiotherapy for resected metastatic disease and found more cognitive decline, no difference in overall survival, and worse quality of life with WBRT.[23,194] At the same time, Mahajan et al[195] reported a single institutional study of 128 patients comparing observation or radiosurgery after radiographic gross total resection of brain metastasis. With a median follow-up of 11.1 months, freedom from local recurrence was 43% in the observation arm and 72% with SRS. There were no adverse events or treatment- related deaths. Because four large prospective trials[192,193,196,197] have shown WBRT adds no survival benefit over SRS alone in patients with low-volume intracranial disease and a good performance status, SRS is the preferred radiotherapeutic option over WBRT for intact and resected brain metastases.[189]

The optimal number and volume of brain metastases treated effectively with radiosurgery remain unclear. Although large, prospective trials have included up to four brain metastases,[192,193,195-197] favorable cancer control and neurologic outcomes for SRS have been seen retrospectively in the upfront and repeat SRS setting in well-selective patients with five or more brain lesions.[198-202] To minimize the risk of radiation necrosis, fractionated SRS regimens have been utilized, showing favorable local control, while, at the same time, hippocampal avoidance whole-brain radiotherapy with memantine has become another option when feasible.[203] Currently, the Canadian Cancer Trials Group is accruing CE.7, a phase III trial randomizing patients with 5 to 15 newly diagnosed brain metastases to either SRS or hippocampal-avoidant whole-brain radiotherapy plus memantine with primary endpoints of overall survival and neurocognitive function (NCT03550391).

Guidelines endorsed by multiple specialty associations (ASTRO, SNO ASCO) have emphasized the importance of prognosis in order to appropriately individualize care.[189] Gaspar et al[204] published the RTOG

Recursive Partitioning Analysis for brain metastases in 1997, which comprised three classes: I (age < 65, Karnofsky Performance Score [KPS] > 70, controlled primary tumor, no extracranial metastases), II (all patients not in class I or III), and III (KPS < 70) which correlated with median survival of 7.7, 4.5, and 2.3 months, respectively. Over the past 25 years, Sperduto and colleagues[205-216] have expanded the graded prognostic assessment (GPA) dramatically by pooling RTOG trials and large multi-institutional databases. In their efforts, disease-specific GPAs now exist for multiple histologies, showing that the factors that predict survival vary by diagnosis. The GPA incorporates clinical factors and relevant molecular biomarkers such as PDL-1, *EGFR*, and *ALK* gene status for non–small cell lung cancer[215,216] and *BRAF* status in melanoma.[207,209,210] An online GPA calculator is available for clinical use at https://brainmetgpa.com. The GPA is a practical tool for estimating survival, individualizing treatment, guiding supportive care, and stratifying clinical trials. The GPA has been used for stratification in the initial design and secondary analyses of multiple prospective trials.[214,217-222] These data can also be used to improve surveillance and expand eligibility for clinical trials.[213] These studies have shown that although survival has improved overall, this patient population remains heterogeneous, and survival varies widely by prognosis (GPA score). Thus, the nihilistic approach of the past to these patients is no longer appropriate.

One of the more challenging patient scenarios in brain metastasis radiosurgery involves the management of larger brain metastases. For brain metastasis radiosurgery, both local tumor recurrence rates and complication rates increase with increasing tumor target volume, particularly for tumors greater than 3 cm in diameter. Strategies to improve the radiosurgical management of brain metastases include switching from single-fraction to fractionated SRS and combining radiosurgery with surgical resection. Two different types of fractionation strategies have been used. One strategy is to fractionate the radiation treatment for a single treatment plan over a short time period, usually within 1 to 2 weeks, to limit tumor repopulation. Cho et al,[223] for example, compared the outcome of treating 81 small brain metastases with a median volume of 1.0 cm^3 (range 0.12-4.4 cm^3), with single-fraction radiosurgery to a median dose of 22 Gy to that with 38 larger brain metastases with a median volume of 17.6 cm^3 (range 12.8-23.7 cm^3) treated with three to five fractions to a median dose of 35 Gy. Tumor

control rates at 1 year for single versus three to five fractions were similar at 89.7% versus 87%, as were radiation necrosis rates at 12.3% versus 15.8%, respectively. Likewise, Minniti et al[19] compared single-fraction radiosurgery and fractionated SRS (typically 27 Gy in three fractions) in 289 patients with brain metastases greater than 2 cm and found improved local control rates (77% vs 91%) and less radiation necrosis (18% vs 9%), favoring fractionated SRS. The second strategy for radiosurgery of large brain metastases is a two-staged adaptive radiosurgery with time in between to allow for tumor shrinkage. Angelov et al,[224] for example, treated 63 brain metastases with a median volume of 10.5 cm^3 in 54 patients with a median initial dose of 15 Gy (12-18 Gy) and to a median second dose of 15 Gy (range 12-15 Gy) to a median volume of 7.0 cm^3 (1.0-29.7 cm^3) and a median of 34 days later. Tumor control was 88% at 6 months, and only 11% developed adverse radiation effects.

The other approach for managing large brain metastases is combining surgical resection with radiosurgery to the tumor bed, which has historically been postoperative.[23,195,225,226] Similar to large, intact brain metastases, postoperative surgical beds may benefit from fractionated SRS. A large, multi-institutional cohort of 558 patients treated with fractionated SRS (median dose 30 Gy in five fractions) following resected brain metastases found 84% and 75% local control rates at 1 and 2 years, respectively. Radiation necrosis and leptomeningeal disease developed in 8.6% and 13.1% of patients, respectively.[227] Currently, Alliance A071801 is a phase III trial exploring postoperative single-fraction or fractionated SRS for resected brain metastasis (NCT04114981).

Because of the observation of higher rates of leptomeningeal disease (28% in Mahajan et al[195]) and radiation necrosis following tumor resection with postoperative radiosurgery, preoperative radiosurgery strategies have been and are currently being explored.[228-230] Patel et al[231] compared the results of surgical resection of brain metastases with radiosurgery delivered either preoperatively to a median dose of 14.5 Gy with no margin in 66 patients or postoperatively with a 2-mm margin in 114 patients. Although no significant differences were found in overall survival, local recurrence, or distant brain recurrence, patients undergoing postoperative radiosurgery developed significantly more leptomeningeal disease (16.6% vs 3.2%) and symptomatic radiation injury (16.4% vs 4.9%) at 2 years. In an expanded,

multi-institutional analysis totaling 404 patients with 416 indexed, resected brain metastases compared preoperative treatment with single-fraction (median dose 15 Gy) and fractionated SRS (median dose 24 Gy in three fractions). Most patients received single-fraction SRS (78.5%). Median volume was 9.9 mL. Local recurrence at 2 years with single-fraction SRS was 16.3% compared with 2.9% with fractionated SRS (P = .004). There was no difference in the incidence of any grade ARE, with the 2-year any grade ARE rate of 6.7% for single-fraction and 10.7% for fractionated SRS. There was no difference in leptomeningeal disease, with a rate of 6.1% for single-fraction and 3.8% for fractionated SRS (P = .94).[232] The role of preoperative SRS is currently being investigated on NRG-BN012, which is a phase III, randomized controlled trial presently evaluating preoperative versus postoperative SRS for patients with resected brain metastasis (NCT05438212).

High-Grade Gliomas

During the late 1980s and 1990s, many centers that had been using brachytherapy for recurrent high-grade gliomas and as boosts after conventional radiotherapy transitioned to radiosurgery. Although retrospective series appeared to show that initial brachytherapy or radiosurgery boosts after conventional radiotherapy improved the survival of patients with glioblastoma, prospective randomized trials of both modalities used prior to conventional radiotherapy of glioblastoma patients were negative.[233-235]

The use of radiosurgery in the management of newly diagnosed high-grade gliomas continues to be investigational. Pollom et al[236] and Azoulay et al[237] reported a dose escalation trial of five-fraction radiosurgery to doses of 25, 30, 35, and 40 Gy delivered with a 5-mm margin along with concurrent and adjuvant temozolomide in 30 patients with newly diagnosed supratentorial glioblastoma. Six patients were entered at each of the four lower-dose levels and 12 at the highest level of 40 Gy. With a median follow-up of 13.8 months, the median PFS and overall survival were 8.2 and 14.8 months, respectively. For quality-of-life (QOL) assessment, 8 of 30 showed evidence of ARE, which was symptomatic in 6 patients. The 12-month ARE rate was 38%, with four of five survivors with more than 2

years of health-related QOL follow-up developing ARE. Survival and tumor control seemed similar to that expected with standard chemoradiotherapy.[238]

For recurrent high-grade gliomas, there is no standard treatment approach, and multiple treatment options, including resection, systemic therapies, and reirradiation, are possible. Treatment decisions are often based on multiple factors, including patient performance status, disease volume, focal versus diffuse recurrence, prior interventions, and time since prior radiation treatment. Radiosurgery appears to be a reasonable option for small, well-circumscribed, high-grade gliomas that recur after prior conventional large-field radiotherapy and chemotherapy. At this time, there is no clear consensus on patient selection, treatment technique, radiosurgery dose, or volume for patients with recurrent high-grade gliomas.[239] Multiple studies have confirmed the safety of bevacizumab with radiosurgery, and the combination of the two may reduce the risk of symptomatic edema and radiation necrosis.[240-243] Clarke et al[13] reported dose-escalated radiosurgery delivered with bevacizumab to 27, 30, and 33 Gy for recurrent glioblastoma and anaplastic astrocytoma in three, five, and seven patients with no cases of clearly symptomatic radiation necrosis but with one patient in the 33-Gy level exhibiting cognitive deterioration and grade 3 fatigue. Three patients underwent subsequent resections for presumed local progression, and viable tumor and substantial radiation necrosis were found in each; of which one had necrosis in more than 90% of the specimen.

SUMMARY

SRS and radiotherapy techniques have become the standard of care for managing a large number of benign and malignant tumors and other conditions in the brain and CNS. The safety and effectiveness of these techniques continue to improve along with technical improvements in radiation targeting and delivery, as well as improvements in our understanding of radiobiologic responses.

CHAPTER 17

Stereotactic Irradiation of Tumors Outside the Central Nervous System and Oligometastases

Ambrosia J. Simmons, Brian D. Kavanagh, and Robert D. Timmerman

Departing from the established traditions of conventionally fractionated external-beam radiotherapy (RT), in the late 1980s and early 1990s, investigators in the United States, Sweden, and Japan began to explore the use of extremely brief hypofractionated radiation treatment regimens for the spine, lung, liver, and selected other malignant extracranial tumors.[1-3] In essence, these clinical researchers were modifying techniques proven clinically valuable in the context of cranial stereotactic radiosurgery to exploit the efficiency and biologic potency of high-dose per fraction irradiation.[4] This idea was soon appreciated for its clinical promise by other researchers in numerous countries worldwide.

As early as the late 1980s, investigators began exploring ultrahypofractionated treatment regimens for extracranial malignancies in the spine, liver, and lung, expanding on the success of intracranial stereotactic radiosurgical techniques.[1-4] Pioneers in the field initially used customized ancillary equipment constructed in their institutions to immobilize patients and adapt ordinary linear accelerators for precise internal tumor targeting. Now, however, the administration of high-dose, tightly focused external-beam radiation therapy is greatly facilitated by a wide assortment of commercially available systems that immobilize patients, address the problem of respiratory motion during treatment, and ensure accurate treatment with image guidance. The newest generation of linear accelerators from several manufacturers is either exclusively dedicated to cranial or extracranial stereotactic RT or equipped with a built-in package of features that provide an effective means of administering this type of treatment.

Stereotactic body radiation therapy, better known as stereotactic ablative radiotherapy (SAbR), is now a widely accepted form of radiation therapy for both primary and metastatic disease. These terms are used to describe radiation treatments that occur in typically five or fewer fractions and deliver significantly higher doses per fraction than conventionally fractionated RT. Delivery of such high ablative doses of radiation necessitates rapid dose fall off and precise tumor targeting, both externally with immobilization techniques and internally with image guidance and motion management. These techniques are greatly facilitated by the widely available array of commercial products.

BIOLOGIC AND ONCOLOGIC RATIONALE FOR STEREOTACTIC ABLATIVE RADIOTHERAPY

The appeal of SAbR is based on the nonlinear relation between radiation dose and cytotoxic effect, whereby one or a few large individual doses of radiation therapy may have substantially more cell-killing effect than the same dose of radiation given in smaller individual doses. Traditionally, the expected relation between radiation dose and tumor cell kill has been commonly estimated by the well-known linear-quadratic (LQ) model of radiation dose response, often relied on to compare the biologic potency of different conventionally fractionated radiation therapy schedules. However, in the range of dose per fraction used in SAbR, there has been an emerging appreciation that the LQ model overestimates the potency of fraction sizes on the order of 8 to 10 Gy or higher.

Various alternative mathematical models have been proposed to account for the observed inaccuracy of the LQ model for doses in this range. For example, Guerrero and Li[5] have proposed a modification of Curtis[6] lethal-potentially lethal model that accounts for ongoing repair processes that occur during an individual's radiation treatment, thus predicting lower cytotoxicity from high doses administered over time intervals resembling typical clinical treatment times. Experimental data modeling cranial radiosurgery offers support for this concept.[7] Alternatively, Park et al[8] have offered the universal survival curve formalism, which combines the LQ model for doses in the range used in conventional fractionation with a multitarget model for doses in the range used for SAbR. This piecewise

function effectively achieves the same key mathematical outcome as other deviations from the LQ model applied to SAbR, specifically a more linear relationship between dose and log cell kill in the high-dose region (exponential, nonrepairable cell killing).

None of the aforementioned in vitro models of high-dose per fraction tumor cell–killing effects explicitly incorporate a mechanism of tumor cell kill that might be of equal or greater importance than tumor DNA damage-based injury, such as the antiangiogenic effect of endothelial cell apoptosis occurring above an apparent threshold dose on the order of 8 to 10 Gy. First observed preclinically and reported by Garcia-Barros et al,[9] clinical evidence indirectly supporting the importance of this mechanism includes measures of an increase in serum markers of apoptosis post-SAbR.[10] Challenging the importance of this mechanism, however, is the work of Kirsch and colleagues,[11,12] who used a genetically engineered mouse model to evaluate the influence of endothelial cell apoptosis in a mouse sarcoma model, observing minimal impact on tumor radiosensitivity from the degree of endothelial apoptosis achieved.

The impact of high-dose per fraction RT upon immune responses has been of great interest in recent years. Radiation therapy has been shown to have an immunomodulatory effect through antigen presentation, stimulation of tumor antigen release, and maturation of T cells. One early preclinical study demonstrated that a single dose of 20 Gy, unlike a fractionated regimen of lower dose per fraction, can trigger a strong T-cell response that enhances the cytotoxic effect in a preclinical melanoma model.[13] Likewise Filatenkov et al[14] showed that a single ablative dose of radiation was sufficient to induce antigen presentation and increased T-cell tumor infiltration in a model of colon cancer, whereas a protracted conventional regimen did not yield similar results. Sharabi et al[15] demonstrated that SAbR not only induced an increase in immune cell tumor infiltration but also stimulated direct presentation of tumor antigens in preclinical models of melanoma and breast cancer. This group further demonstrated that the combination of SAbR with checkpoint blockade immunotherapy significantly enhanced the immune-stimulated effects of radiation.

OLIGOMETASTATIC DISEASE

Beyond its uses as primary therapy for selected early-stage cancers, SAbR can also be used as a noninvasive and efficient means of eradicating discrete tumors in the setting of oligometastatic disease. As articulated by Hellman and Weichselbaum,[16] the spectrum theory or theory of oligometastases proposes that there is a subgroup of patients with metastatic disease that is intermediate between completely absent and widely metastatic. For such patients, the entire systemic disease burden is confined to a finite number of individual sites of gross disease identified by the relevant imaging studies. This condition would reflect an intermediate point in the natural history of that individual's cancer; therefore, these patients might be cured if their limited numbers of metastatic sites are eradicated. There have been numerous reports of patients enjoying clinically significant rates of 3- to 5-year survival following various forms of aggressive local treatment (eg, surgical resection, radiofrequency ablation [RFA], cryotherapy) for limited metastases in the liver or lung from an assortment of solid tumor types.[17] SAbR is a valid, noninvasive substitute for other local modalities if it can provide similar efficacy and the same or less toxicity.

Many prospective studies have now evaluated the role of SAbR in oligometastatic disease, demonstrating the benefit of this aggressive local treatment on both progression-free survival (PFS) and overall survival (OS).[18] The Stereotactic Ablative Radiotherapy for the Comprehensive Treatment of Oligometastases[19] multicenter randomized phase II trial assessed the impact of a comprehensive oligometastatic SAbR treatment program on OS and quality of life in patients with up to five metastatic cancer lesions compared to patients who receive standard of care treatment alone. Patients were then stratified by the number of metastases (one to three vs four to five) and randomized between Arm 1: current standard of care treatment and Arm 2: standard of care treatment + SAbR to all sites of known disease with OS as a primary end point. Any primary was allowed, however; the trial was predominantly colorectal (CRC), lung, breast, or prostate cancers. They demonstrated significant improvement in OS for patients who received SAbR compared to those who underwent standard palliative treatment, with a median OS was 41 months in the SAbR group versus 28 months in the standard treatment group. Patients treated with SAbR also had a longer PFS. While most patients had minimal toxicity, this

group did experience significantly higher toxicity compared to the standard arm, with 4.5% succumbing to treatment-related death.

Another trial by Iyengar et al[20] showed that patients with limited metastatic non–small cell lung cancer (NSCLC) who received consolidative RT to both the primary and oligometastatic sites followed by maintenance chemotherapy had significantly improved PFS compared to patients treated with chemotherapy alone. No patients treated with SAbR had infield progression, and the toxicity was similar in the SAbR and chemotherapy-only arms. This was similar to the results of another trial by Gomez et al[21,22] investigating the role of local consolidative therapy in limited metastatic NSCLC; however, this study included other forms of consolidation, including surgery.

Analogous studies in metastatic prostate cancer have also shown promising results. In the phase II Optimal Radiation Treatment in Oligometastatic Disease trial,[23] patients with recurrent hormone-sensitive prostate cancer, limited to one to three metastatic lesions, were randomly assigned to either the observation or SAbR groups, with PFS at 6 months as the primary end point. Disease progression at 6 months was 19% in the SAbR group compared to 61% in the observation group. The results showed that patients who received SAbR had significantly improved outcomes compared to those in the observation group with no grade 3 toxicities. Likewise, the Systemic Therapy for Oligometastatic Prostate Cancer trial[24,25] reported a significant increase in 5-year androgen deprivation therapy (ADT) free survival (8% vs 34%, log-rank $P = .06$) in patients with aggressive metastases-directed therapy, either surgery or radiation, compared to surveillance alone.

Especially intriguing is the possibility that stereotactic irradiation can initiate immunologic responses that can trigger an abscopal response to novel agents. This approach has now gained much attention and has been reviewed extensively.[26,27] One such primary study reports patients with metastatic melanoma receiving ipilimumab and SAbR to one lesion, resulting in a response in 26% of nonirradiated tumors.[28] The optimal timing of immunotherapeutic agents and dose prescription for RT remains a topic of active investigation at numerous centers.

SAbR has revolutionized the management of oligometastatic disease by providing a highly precise and effective treatment option. As our

understanding of the biology of oligometastasis continues to evolve, the role of SAbR in achieving local control (LC) and potentially altering the natural history of metastatic disease becomes increasingly evident.

STEREOTACTIC BODY RADIATION THERAPY GUIDELINES, PHYSICS OVERVIEW, AND SAFETY CONSIDERATIONS

American Society for Radiation Oncology (ASTRO) and the American College of Radiology (ACR) have published guidelines that characterize the personnel qualifications and responsibilities, documentation, quality control, and clinical operations recommended for the safe and proper administration of SAbR and follow-up care for patients treated.[29] The ASTRO-ACR guidelines advise that the following components should be in place within an institution's SAbR program:

1. Qualified personnel
    a. Board-certified radiation oncologist
    b. Qualified medical physicist
    c. Licensed radiation therapist
    d. Other support staff as indicated (dosimetrists, oncology nurses, and so forth)
2. Ongoing machine quality assurance program
3. Documentation in accordance with the *ACR Practice Guideline for Communication: Radiation Oncology*
4. Quality control of treatment accessories
5. Quality control of planning and treatment images
6. Quality control of treatment planning system
7. Simulation and treatment systems that account for systematic and random errors associated with setup and target motion in a manner that is based on actual measurement of organ motion and setup uncertainty.

The American Association of Physicist in Medicine Task Group 101 (TG101) moved forward from the ASTRO-ACR guidelines to generate a report that considers additional important nuances in the planning and treatment delivery of SAbR.[30] Included within the TG101 report are

discussions of potential imaging artifacts and their impact on treatment planning, the challenges of small-field dosimetry, and the importance of using an acceptable dose calculation algorithm, among other issues.

Proper patient repositioning, target localization, and management of breathing-related motion are essential for SAbR. Various patient immobilization devices, including several body frames with external fiducial markers, are available. The so-called frameless systems incorporate ultrasound, kilovolt-range imaging, or near real-time computed tomography (CT) scanning to verify the location of internal targets relative to the beams used. Because SAbR treatment sessions are lengthier than conventional external-beam treatments, patient comfort is an important issue.

Breathing-related motion control devices and systems fall into three general categories: dampening, gating, and tracking or "chasing." Respiratory dampening techniques include systems of abdominal compression intended to diminish one of the most significant contributors to breathing-related motion, namely, diaphragmatic excursion, by obliging the inspiratory-expiratory lung motion pattern to involve more intercostal expansion provided by accessory muscles of respiration and shallower breathing overall compared to diaphragmatic breathing. Also included in this category are the systems employing breath-holding maneuvers to stabilize the tumor in a reproducible stage of the respiratory cycle (eg, deep inspiration). Gating systems for SAbR, as for any RT application, follow the respiratory cycle using a surrogate indicator for respiratory motion, for example, abdominal wall motion, and employ an electronic beam activation trigger allowing irradiation to occur only during a specified range of expected tumor locations. Tracking or "chasing" systems move the radiation beam or patient to mirror the movement of the tumor.

Regardless of the system employed, the treatment planning procedure must include the same consideration for respiratory motion management to be used during treatment. Despite available motion control equipment, some positional uncertainty will remain. The planning target volume (PTV) margins used to account for this residual motion of the gross tumor volume (GTV) will typically range from 3 to 5 mm.

The word *stereotactic* implies that some external reference markers indexed to internal structures facilitate internal target relocalization. The definition has expanded to include systems of image-guided radiation

therapy (IGRT) that relate the position of internal targets to a three-dimensional coordinate geometry registered to the treatment machine without the use of external markers on the patient. SAbR always involves some form of IGRT to guide treatment delivery.

Most reports describing SAbR published to date have employed high-energy photons (x-rays) as the therapeutic radiation source, although any type of radiation, including charged particles, can also be used. There is no absolute standard for the combination of beam or arc angles ideal for any given clinical situation, and each case can present unique challenges. In general, to achieve a tightly focused high-dose distribution within the PTV and rapid dose falloff outside the PTV, a combination of multiple (often 10 or more) ideally noncoplanar beams or multiple arcs are required. Intensity modulation across the individual beams or arc segments can be incorporated within SAbR.

As part of ASTRO's Target Safely campaign, the Multidisciplinary Quality Assurance Subcommittee of the Clinical Affairs and Quality Committee of ASTRO commissioned a white paper on the topic of cranial radiosurgery and SAbR titled "Quality and Safety Considerations in Stereotactic Radiosurgery and Stereotactic Body Radiation Therapy."[31] Of particular importance within the white paper are sections emphasizing the importance of creating a proactive culture of safety with procedural checkpoints and error analysis mechanisms.

CLINICAL EXPERIENCE WITH STEREOTACTIC BODY RADIATION THERAPY IN SELECTED SITES

Liver

The three major reasons for considering SAbR for hepatocellular cancer (HCC) are that underlying severe liver disease often renders patients medically inoperable, other nonsurgical therapies have generally achieved modest success at best, and HCC is more sensitive to large dose per fraction therapy. The natural history of untreated HCC has been reported to involve a median survival in the range of 3 to 8 months,[32-34] and so a safe and effective therapy is needed in this setting.

The earliest observations following SAbR for HCC were reported by a group at Karolinska Hospital,[2] followed by more recent formal prospective

studies. The Princess Margaret Hospital group utilized a six-fraction regimen in a prospective phase I study in patients with HCC (n = 31) or intrahepatic cholangiocarcinoma (n = 10).[35] Prescription doses were selected according to a normal tissue complication probability (NTCP) model based on conventionally fractionated RT for the liver. The median dose to the tumor was 36 Gy (range, 24-54 Gy). The NTCP model overestimated the chance of radiation-induced liver disease, and it is possible that the dose could have been escalated to a higher level in most cases. Nevertheless, in this group of heavily pretreated patients (over 60% had had at least one prior therapy for HCC), a remarkable median survival of 12 months was observed.

Previously, SAbR for HCC has been reserved for patients who had failed previous therapies, and most preliminary studies have been performed in this patient population. However, newer studies have emerged that evaluate SAbR in treatment-naïve patients. Durand-Labrunie et al[36] published a prospective phase II study of 43 treatment-naïve patients with a dose of 45 Gy delivered in 3 fractions, achieving a 2-year LC rate of 98% and an OS rate of 69%. Notably, 31% of the patients experienced toxicities classified as grade III or higher, most of which were abnormal liver function blood tests. In another prospective phase II study by Kimura et al,[37] 36 treatment-naïve patients received 40 Gy delivered in five fractions with a 3-year OS rate of 78% and an LC rate of 90%; however, they noted far fewer toxicities classified as grade III or higher in only 11% of the patients. Unfortunately, this trial was terminated early due to slow accrual.

Consideration of SAbR as a first-line therapy has prompted studies comparing it to other treatment modalities such as RFA and even surgery. Many meta-analyses have evaluated the results of SAbR compared to RFA. One analysis by Wang et al[38] evaluated 7 studies with 7,928 patients and demonstrated that SAbR was superior to RFA in LC (HR = 0.54, 95% CI = 0.35-0.84, P = .006). This improvement was driven by tumors larger than 2 cm (HR = 0.41, 95% CI = 0.23-0.74, P = .003) and was insignificant in tumors smaller than 2 cm (HR = 0.56, 95% CI = 0.25-1.28, P = .17). Another analysis by Facciorusso et al[39] evaluated 9 studies with 6,545 patients and found the recurrence-free survival at 2 and 3 years to be superior in patients treated with SAbR compared to RFA (OR = 2.06, 95% CI = 1.48-2.88 and OR = 1.86, 95% CI = 1.07-3.26, respectively). There

was no difference between the two treatments in 1-year recurrence-free survival (OR 2.11, 0.67-6.63). Neither analysis found any difference in OS or toxicity between the treatments. However, it should be noted that a smaller meta-analysis by Pan et al[40] found OS in patients treated with SAbR to be inferior to that of patients treated with RFA (1-year OS, OR = 1.52, 95% CI = 1.21-1.90, *P* = .0003; and 2-year OS, OR = 1.66, 95% CI = 1.38-2.01, *P* < .00001, respectively). This was attributed to higher tumor burden or liver profiles in the SAbR cohorts, and LC remained superior in these patients.

Comparisons to surgery have also been performed using propensity-matching analyses. Su et al[41] paired 82 patients who received SAbR with 35 patients who underwent liver resection. Before propensity score matching, the 1-, 3-, and 5-year OS was 96.3%, 81.8%, and 70.0% in the SAbR group and 93.9%, 83.1%, and 64.4% in the resection group, respectively (*P* = NS [NS, not statistically significant]). After propensity score matching, 33 paired patients were selected from the SAbR and resection groups revealing 1-, 3-, and 5-year OS was 100%, 91.8%, and 74.3% in the SAbR group and 96.7%, 89.3%, and 69.2% in the resection group, respectively (*P* = NS). There was a similarity in hepatotoxicity between the two groups. A subsequent propensity score-matched analysis by Sun et al[42] in treatment-naïve patients with hepatitis B or C cirrhosis similarly reported comparable OS and PFS outcomes for SAbR and resection with 5-year OS rates of 71.0% and 70.7%, respectively (*P* = .67) and 5-year PFS of 49.0% and 47.3%, respectively (*P* = .35). In contrast to these studies, however, another propensity score-matched analysis from Japan[43] found that OS and PFS favored surgery compared to SAbR, with rates of 75.2% versus 47.8% (*P* = .0149) and 33.8% versus 16.4% (*P* = .0512), respectively. In their study, patients with fewer and smaller tumors tended to benefit the most from surgery.

Beyond definitive treatment, SAbR is also employed as a method of downstaging or bridging to transplant. Maintaining LC while awaiting transplant is critical to ensure patients remain transplant eligible. One small study by O'Connor et al[44] reported that all 11 patients treated with 33 to 54 Gy in 3 fractions made it to transplant. Complete pathologic response was noted in 27% of patients overall but was as high as 60% in patients who

received 54 Gy. Albeit small, this study impressively reported 5-year OS and disease-free survival (DFS) of 100%.

With the advent of magnetic resonance (MR)–based treatment delivery, preliminary studies[45] have demonstrated the feasibility of this treatment modality for both primary and metastatic liver tumors. These areas remain active in research, and further work is needed to evaluate treatment outcomes.

Target delineation and image guidance can be difficult in the liver because liver metastases are poorly visualized on CT scans or in-room volumetric imaging used for IGRT. In many centers, radiopaque fiducial markers are placed in or near the metastases to facilitate IGRT. In all centers, the PTV is an expansion of the GTV considering the setup and intrafraction motion to be expected with the particular setup and delivery system employed. Typically, the margin used to expand a GTV into a PTV is on the order of 5 mm axially and 5 to 10 mm craniocaudally. Consideration of motion management is key, particularly in lesions near the dome, with some centers employing abdominal compression or breath-hold techniques.

A University of Colorado consortium first applied the critical volume approach to normal liver dose constraints in their initial phase I study[46] and subsequent phase II study. Assuming the liver is a functioning parallel structure, it was estimated that at least 700 cm^3 is essential for organ function in an average patient and should therefore receive less than 15 Gy in three fractions, a dose felt to be below a threshold for injury. This was derived from a combination of prior reports of outcomes after partial hepatectomy documenting approximate minimum volumes required and estimates of the effects of that dose of radiation extrapolated from prior reports of conventionally fractionated treatment.

Additionally, posttreatment imaging follow-up in the liver has some unique challenges and considerations. Evaluation of treatment response, failure, and expected normal tissue changes has been extensively reviewed in these articles.[47-49] Critical attention to follow-up imaging is imperative. Increasing use of MR in both diagnostic imaging and now MR-based treatment delivery will continue to evolve the treatment and follow-up of liver lesions treated with SAbR.

Case Study: Liver Stereotactic Body Radiation Therapy

A 25-year-old man with complex cyanotic congenital heart disease has developed cardiac cirrhosis. He developed multiple liver lesions which remained stable under close surveillance for 4 years with one progressive lesion in segment 2. Biopsy showed moderately differentiated hepatocellular carcinoma in the background of congestion and cirrhosis. He is not a surgical candidate and the lesion was not amenable to ablation or vascular approaches. He was offered SAbR as a bridge to heart/liver transplant.

The 12.9 cm^3 GTV was expanded by 3 mm radially and 5 mm in the superior-inferior direction to generate the 26.7 cm^3 PTV (Figure 17.1). The dose distribution shown was administered in three fractions within 1 week using two dynamic conformal arcs and a controlled breath-holding device. The nominal prescription dose was 48 Gy. The maximum point dose was 59 Gy, and the equivalent uniform dose was 53 Gy. The volume of normal liver receiving less than 15 Gy was 110 cm^3. The maximum dose to the heart was 1.3 Gy. The lesion remained controlled for nearly 3 years until he was able to undergo heart and liver transplant for definitive management.

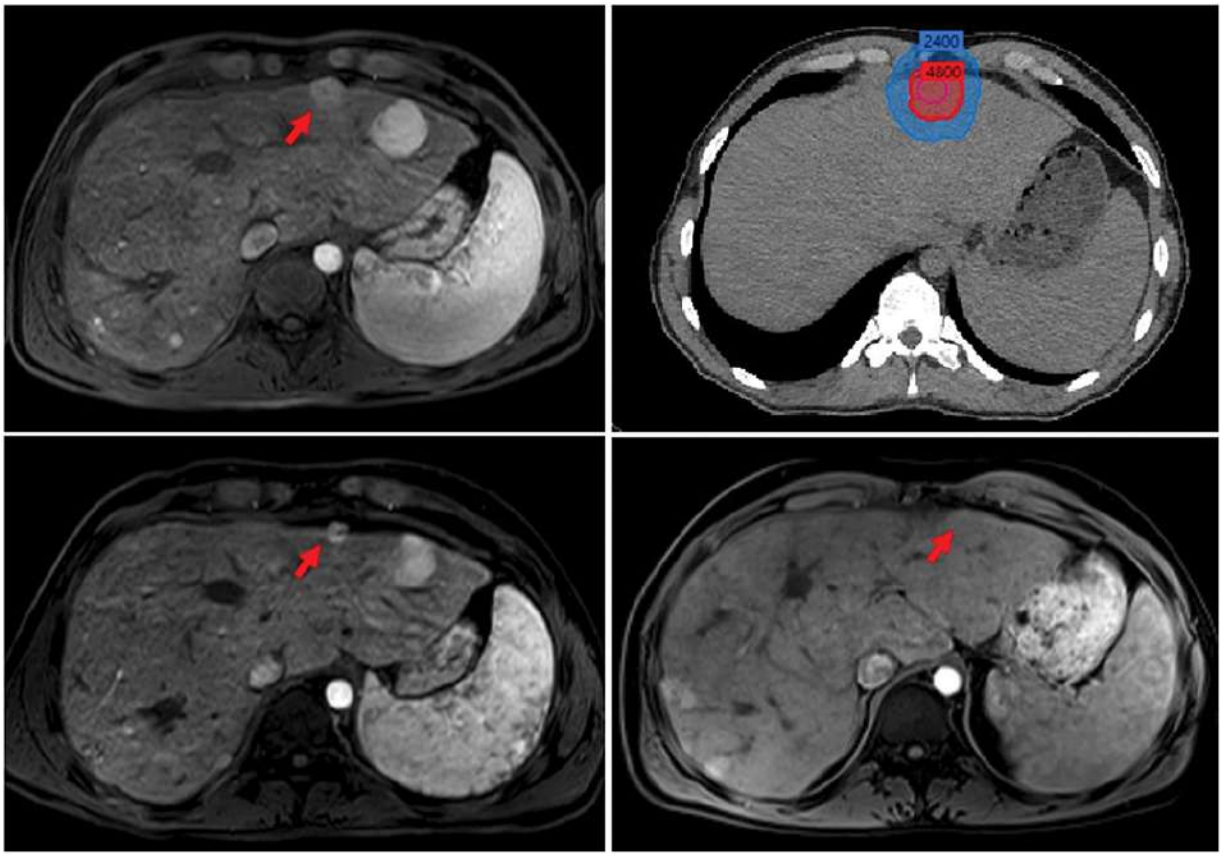

FIGURE 17.1 Example of liver stereotactic ablative radiotherapy (SAbR). Top: Pre-SAbR T1 post-contrast magnetic resonance (MR) image showing progressive segment II lesion (red arrow) and treatment plan with dose levels outlined (4,800 cGy red, 2,400 cGy blue). Bottom: MR image 3 months (left) and 3 years after SAbR with responding lesion (red arrow).

Lung

Medically inoperable early-stage lung cancer has historically provided a substantial management challenge. Conventionally fractionated RT has generally yielded unsatisfactory outcomes with high rates of local failure and 3-year survival rates of approximately 30%. For this reason, medically inoperable early-stage lung cancer was the first clinical indication for which SAbR was studied in prospective clinical trials. Following the early exploratory studies of lung SAbR for stage I NSCLC at the Karolinska Hospital in Stockholm[50] and National Medical Defense Hospital in Saitama,[3] numerous formal prospective studies of SAbR for medically inoperable NSCLC have now been reported. The consistent observation is that 3-year survival is achieved on the order of 50% to 60%. A randomized

clinical trial comparing SAbR (66 Gy in three fractions) to conventionally fractionated RT (70 Gy in 35 fractions) in this setting revealed equivalent OS despite slightly worse prognostic features in the SAbR arm. Patients who received SAbR also had lower rates of pulmonary toxicity and better self-reported quality of life.[51]

One important observation from the Indiana University studies was that although the treatment was generally well tolerated, tumor location near large airways near the pulmonary hilum (called the zone of the proximal bronchial tree) was associated with a markedly higher risk of toxicity. For this reason, in the Radiation Therapy Oncology Group's (RTOG) study RTOG-0236 of SAbR for medically inoperable NSCLC, patients with tumors located in the zone of the proximal bronchial tree were excluded.[52] The RTOG launched a separate dose-escalation study (ROTG-0813) in which tumors near the proximal bronchial tree were treated to doses of 50 to 60 Gy in five fractions.[53] Protocol specified dose-limiting toxicity (DLT) rates were low, though some late toxicity outside those definitions occurred. The ASTRO has issued a guideline on SAbR for early-stage lung cancer that addresses key questions of patient selection and dose regimen for peripheral and central tumors.[54]

Recent multicenter prospective studies have confirmed the superiority of SAbR to conventional RT for inoperable NSCLC in terms of toxicity outcomes and quality of life with equivalent disease control. The Scandinavian multicenter randomized phase II trial, Stereotactic Body Radiation Therapy for Patients With Peripheral Lung Cancer,[51] included 102 patients with inoperable peripheral T1-T2 tumors (6 cm or smaller) and compared SAbR (66 Gy in 3 fractions) with conventional RT (70 Gy in 35 fractions). With a median follow-up period of 37 months, the results showed NS differences in OS or LC between the two treatment groups. Likewise, the Convenient Hypofractionated Image-guided Stereotactic Ablative Radiotherapy for Lung Cancer[55] multicenter phase III trial based in Australia and New Zealand randomized 101 patients with inoperable peripheral T1-T2, N0, M0 tumors to SAbR or conventional RT. In the SAbR arm, patients received either 54 Gy in 3 fractions or 48 Gy in 4 fractions (if the tumor was <2 cm from the chest wall), while those in the conventional RT arm were treated with either 66 Gy in 33 fractions or 50 Gy in 20 fractions. The study reported a statistically significant

improvement in LC (HR 0.32) and OS (HR 0.53) in favor of SAbR with a median follow-up of over 2 years.

The use of SAbR in medically operable patients has also been the subject of retrospective studies and ongoing prospective trials. Zheng et al[56] conducted a meta-analysis of 63 (40 studies on SAbR involving 4,850 patients and 23 studies on surgery involving 7,071 patients) to compare treatment outcomes specifically for patients with T1-T2, N0, M0 disease. After adjusting for factors such as the proportion of patients suitable for surgery and patient age, the analysis revealed that SAbR and surgery exhibited similar results regarding LC, OS, and DFS. More recently, a prospectively collected cohort analysis compared long-term outcomes of patients treated with SAbR and surgery in patients with newly diagnosed cT1a-bN0M0 NSCLC. The study, which combined 2 separate prospectively collected cohorts (International Early Lung Cancer Action Program and Initiative for Early Lung Cancer Research on Treatment) for a total of 1,115 patients, found that 10-year-ling-cancer-specific survival was similar between surgery and SAbR (90% and 88%, respectively; $P = .48$).[57] RTOG-0618,[58] a single-arm phase II, evaluated SAbR outcomes prospectively in 26 operable patients with biopsy-proven peripheral T1-T2 (tumor size 5 cm or smaller), N0, M0 NSCLC. Patients received 54 Gy in 3 fractions. The study reported 4-year local-regional control of 88% and 4-year OS of 56%. Prospective analyses directly comparing SAbR with surgery have proven difficult with the SAbR for Lung Tumors: A Randomized Study, Stereotactic Ablative Radiotherapy for Early Stage Lung Cancer, and American College of Surgeons Oncology Group/Radiation Therapy Oncology Group), three randomized phase III trials, closing early due to poor accrual. A pooled analysis of these studies reported better OS and lower toxicities in the SAbR arm; however, this study has been criticized for reporting higher rates of surgery toxicity than historical data.[59] Multiple new prospective randomized trials, including the Joint Lung Cancer Trialist's Coalition STABLEMATES trial and the Veterans Affairs Lung Cancer Surgery or Stereotactic Radiotherapy trial, are ongoing.

Importantly, while LC of early-stage lung tumors has been demonstrated with SAbR, these patients not infrequently (~43%) develop regional or distant metastases.[60] To address this, a recent phase II randomized study evaluated the combination of SAbR and immunotherapy. They report

significantly improved event-free survival at 4 years in patients with early-stage lung cancer who were treated with nivolumab and SAbR over those treated with SAbR alone (77% vs 53%, respectively; $P = .006$).[61] Randomized phase III studies are needed to test the robustness of this observation.

As discussed earlier, SAbR to pulmonary metastases in oligometastatic disease is a widely accepted treatment with good LC and minimal toxicity. A recent review by a Japanese group[62] highlights treatment considerations based on the primary disease site and tumor location. These findings imply that certain pathologies, such as CRC metastasis, may warrant higher doses to increase better LC.

Case Study: Lung Stereotactic Body Radiation Therapy

A 90-year-old with a 40+ pack-year smoker with history of multiple strokes without sequela and coronary artery bypass graft developed shortness of breath or cough and was found to have a cT1cN0M0 squamous cell carcinoma of the right upper lobe. He was not a surgical candidate due to his multiple comorbidities and was offered SAbR. The patient did not comfortably tolerate a breath-holding technique; therefore, an abdominal compression technique was used during the simulation and treatment. An internal target volume (ITV) was generated by contouring the GTV over the breathing cycle. The 7.7 cm^3 ITV was expanded by 5 mm symmetrically to generate the 23.9 cm^3 PTV (Figure 17.2). The dose distribution shown was administered in 3 fractions within 1 week using 10 noncoplanar beams. The nominal prescription dose was 60 Gy. The maximum point dose was 88 Gy, and the equivalent uniform dose was 72 Gy. The portion of normal lungs receiving less than 15 Gy was 6.5%. Eighteen months following treatment, the patient was noted to have a new primary malignancy in his right lower lobe on follow-up imaging. He was again offered SAbR to the new lesion. The new 2.9 cm^3 ITV was expanded by 5 mm symmetrically to generate the 12.4 cm^3 PTV (Figure 17.2). The dose distribution shown was administered in 5 fractions over 2 weeks using 10 noncoplanar beams. The nominal prescription dose was 60 Gy. The maximum point dose was 90 Gy, and the equivalent uniform dose was 73 Gy. The portion of normal lung receiving

less than 15 Gy was 5.7%. Both lesions have remained controlled to date, greater than 4 and 2 years, respectively.

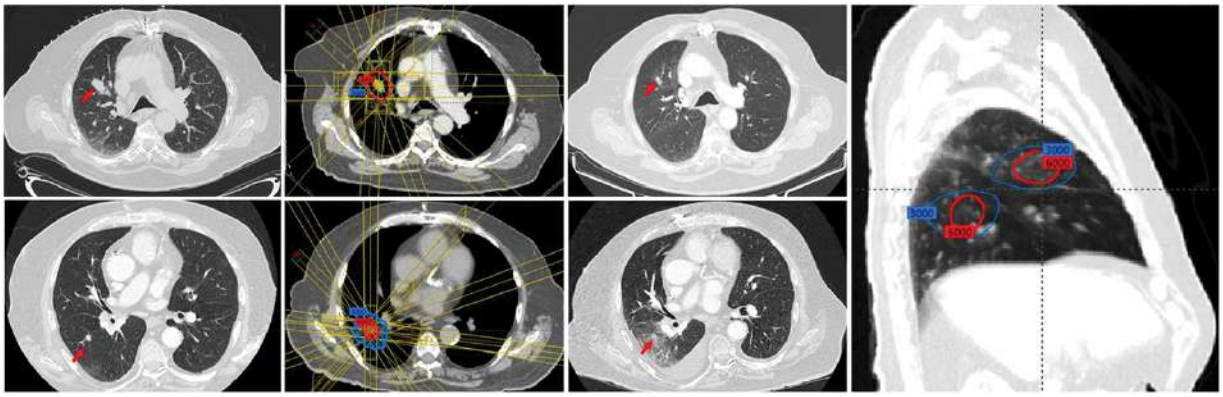

FIGURE 17.2 Example of lung stereotactic ablative radiotherapy (SAbR). Top: Pre-SAbR computed tomography (CT) image showing initial right upper lobe lesion (red arrow), treatment plan with fields and dose levels outlined (6,000 cGy red, 3,000 cGy blue), and CT image 6 months after SAbR. Bottom: Pre-SAbR CT image showing secondary right lower lobe lesion (red arrow), treatment plan with fields and dose levels outlined (6,000 cGy red, 3,000 cGy blue), and CT image 6 months after SAbR. Right: Sagittal CT showing dose distribution of two plans.

Spine Cancer

Early investigations of spine SAbR involved delivering a single-fraction boost of 6 to 10 Gy following conventionally fractionated therapy either as one course of treatment or for retreatment of recurrent disease. This had overall good outcomes with excellent pain relief and no complications.[1,63,64]

MD Anderson Cancer Center performed a prospective phase I dose-escalation study in treating spinal metastases.[65,66] The equipment used included a "CT on rails" that allowed for imaging immediately to guide patient repositioning. Approximately half of the 63 patients received 30 Gy in 5 fractions, and the other half received 27 Gy in 3 fractions. A conservative constraint of 9 to 10 Gy maximum dose to the spinal cord was applied. No neuropathy or myelopathy was observed during a median follow-up period of nearly 2 years. The actuarial 1-year tumor progression-free rate was 84%. The investigators noted two characteristic patterns of failure: (a) recurrence in the bone adjacent to the site of previous treatment and (b) recurrence in the epidural space adjacent to the spinal cord.

Several observations of reasonable tumor control and minimal toxicity have been reported from other centers. Commonly used fractionation schemes now include 16 to 24 Gy in one fraction, 24 Gy in two fractions, 24 to 40 Gy in three fractions, and 25 to 40 Gy in five fractions.[67] A review of 5,655 patients showed 1-year rates of local tumor failure of only 10% to 20% following spine SAbR.[68]

Fortunately, spinal cord toxicity has only rarely been observed after SAbR. Case-control comparisons offer some suggestions of parameters that might elevate the risk, but the paucity of events evaluable makes it challenging to draw firm conclusions.[69,70] Constraints used to guide spine SAbR have included maximum point dose to the cord in the range of 10 to 14 Gy and limiting the volume of adjacent spinal cord receiving more than 10 Gy in a single fraction to 0.35 mL or less.

The International Spine Radiosurgery Consortium (ISRC) group has published guidelines for target definition and response assessment after spine SAbR.[71] The SPIne response assessment in Neuro-Oncology Group has likewise issued guidance on response assessment.[72] While the ISRC recommends treating the entire vertebra segment based on disease location, it is unclear whether normal bone adjacent to the GTV needs to be treated to such ablative doses. Higher doses, such as 20 Gy in a single fraction, improve rates of LC; however, they are associated with a higher vertebral fracture (VF) risk, which is the most commonly reported toxicity, with rates of up to 40% in some series for spine SAbR.[73] Memorial Sloan-Kettering Cancer Center reported that lytic disease involving more than 40% of the vertebral body and location at or below T10 increased this risk.[74] MD Anderson Cancer Center found that VF was more common among patients over 55 years, those with a preexisting fracture, and those experiencing pain at the time of treatment.[75]

The group at the University of Texas Southwestern has established a treatment protocol designed to minimize the risk of single-fraction toxicities by applying a lower dose of 14 Gy to the ISRC-defined clinical target volume and a higher ablative dose of 20 Gy to the GTV followed by prophylactic vertebroplasty.[76] They report excellent pain control in 95% of patients at 3 months and LC of 92% with 9-month follow-up. The higher rate of pain control observed was durable, as the freedom from VF rate persisted beyond 90% past 1-year with ongoing follow-up.

Prostate Cancer

The first publication on SAbR for prostate cancer was the work of Madsen et al,[77] who recently updated their observations. In a prospective trial, 40 patients with low-risk cancer (Gleason score ≤6 and prostate-specific antigen ≤10 ng/mL) were treated to a dose of 33.5 Gy in 5 daily fractions. Most of these patients were treated with SAbR after being found ineligible for brachytherapy due to pubic arch interference. The median age was 69 years (50-82), and the median follow-up period was 5 years. The overall 5-year Phoenix definition (nadir plus 2 ng/mL) biochemical relapse-free survival (bRFS) rate was 93%. No patients died of prostate cancer. Late grade 3 genitourinary (GU) toxicity was rare, occurring in only one patient, and no late grade 3 or higher gastrointestinal (GI) was observed.[78]

Over the past several years, prostate SAbR treatments have rapidly increased. The Stereotactic Body Radiotherapy for High-Risk Localized Carcinoma of the Prostate Consortium[79] recently evaluated the results of seven institutional phase II trials and prospective registries. The group pooled individual data for 344 patients to assess the rates of bRFS and distant metastasis-free survival (DMFS). Patients were treated with five fractions of 7 to 8 Gy. ADT was used in 72% of patients. With a median follow-up of 49.5 months, they reported 4-year biochemical recurrence-free survival of 81.7% and DMFS of 89.1%. In addition, they found no acute grade 3 or higher GU and GI toxicities with a crude incidence of late grade 3 or higher GU and GI toxicity of 2.3% and 0.9%, respectively. Doses of 8 Gy or more were associated with higher GU and GI toxicities rates.

The Hypofractionated Radiotherapy for Prostate Cancer trial,[80] a randomized, noninferiority, phase III study comparing ultrahypofractionated RT 42.7 Gy in 7 fractions over 2.5 weeks with conventionally fractionated RT 78 Gy in 39 fractions for prostate cancer, revealed promising results at 5-year follow-up. The trial enrolled 1,200 patients from 2005 to 2015 with intermediate and high-risk prostate cancer. The results showed that ultrahypofractionated RT was not inferior to conventional fractionation, with a failure-free survival of 84.0% in both groups (P = .99). Patients treated with the SAbR regimen did have worse acute grade 2 or higher urinary and bowel toxicity upon completion of treatment; however, there was no longer an increase in bowel toxicity

observed at follow-up. Urinary toxicity remained increased in the SAbR group at 1-year follow-up (6% vs 2% of patients with grade 2 or higher, P = .018) but was similar to the conventional group at all subsequent time points. There were no differences in erectile function between the two groups.

In contrast, the Prostate Adaptive Conformal Radiotherapy: Evaluation of Stereotactic Body Radiotherapy trial,[81] which compared SAbR (36.25 Gy in 5 fractions over 1 to 2 weeks) with conventionally or moderately hypofractionated radiation (78 Gy in 39 fractions or 62 Gy in 20 fractions, daily) in patients with low- to intermediate-risk prostate cancer, found no significant increase in either GI or GU acute toxicity in patients receiving SAbR compared to those receiving other fractionations. SAbR provided a 5-year biochemical failure-free rate of 95.7% (93.2%-97.3%), compared to 94.6% (91.9%-96.4%) for those treated with conventional or moderately hypofractionated radiation, demonstrating that SAbR was noninferior to the other regimens (90% CI; P for noninferiority = .007).[82] The early safety signals also held up with a longer follow-up, with no significant difference seen in GU or GI grade 2 or higher toxicity at the 2- or 5-year time points.[81,82]

Boike et al[83] from the University of Texas Southwestern have completed a dose escalation for prostate SAbR, aiming for a more aggressive regimen potentially suitable for patients with intermediate- or high-risk disease. At the highest dose level of 50 Gy in five fractions, 6.6% of patients treated (6 of 91) developed high-grade rectal toxicity, five of whom required colostomy.[84] Grade 3+ delayed rectal toxicity was strongly correlated with the volume of the rectal wall receiving 50 Gy to more than 3 cm^3 (P < .0001) and treatment of over 35% circumference of the rectal wall to 39 Gy (P = .003). Grade 2+ acute rectal toxicity was significantly correlated with treatment of more than 50% of the circumference of the rectal wall to 24 Gy (P = .010).

The use of rectal spacers in patients receiving SAbR for prostate cancer has been associated with lower observed late GI toxicity rates. A recent meta-analysis[85] of 7 studies and 1,011 patients showed that the radiation dose (V70) to the rectum was 66% less in patients with a spacer than those without. This corresponded to comparable acute grade 2 or higher toxicities between the two groups (4.5% in the spacer group vs 4.1% in the control

group) and improved late grade 2 or higher toxicities (1.5% vs 5.7%, respectively; $P = .05$). Procedural complications ranged from 0% to 10% across studies but were mild and transient.

Outside of initial management, there is growing interest in SAbR for salvage treatment after intraprostatic relapse. European Society for Radiotherapy and Oncology-Advisory Committee on Radiation Oncology Practice released consensus recommendations for consideration of this treatment. They set no maximum age for treatment but recommended patients have an ECOG (Eastern Cooperative Oncology Group) score of 0 or 1 and recommended a thorough metastatic workup with choline-positron emission tomography. They do not recommend concomitant ADT with reirradiation. A full list of their recommendations was recently published.[86]

Pancreatic Cancer

The role of conventionally fractionated RT in combination with chemotherapy for locally advanced pancreatic cancer remains unresolved. An effect on OS is not seen consistently, though there is likely at least a moderate benefit in achieving treatment-free intervals in this challenging clinical scenario.[87,88] SAbR offers the ability to treat with greater biologic potency than conventional fractionation, which is associated with better LC rates, while also minimizing disruptions to chemotherapy due to the shorter duration of treatment.[89]

SAbR regimens for pancreas cancer have included treatments given in one to five fractions. The proximity to many radiosensitive organs at risk (OAR) demonstrated unacceptably high toxicities in early studies. This led to the incorporation of smaller treatment volumes and tighter margins, often very different than conventional fractionated RT approaches. However, as discussed later, treatment margins of high-risk areas may reduce local failure risk. Careful consideration must be given to balancing toxicity and local recurrence risk.

Koong et al[90] published one of the initial investigations on SAbR in pancreatic ductal adenocarcinoma. Their phase I dose-escalation trial involving 15 patients delivered a single fraction of 15 to 25 Gy with no instances of DLT observed. Metallic fiducial marker tracking and breath hold were used to minimize target motion. This treatment technique

remains widely used in clinical practice. Since then, many retrospective studies have demonstrated reasonable LC with low toxicity.

Newer studies have continued to evaluate the role of SAbR prospectively. The Alliance A021501[91] was a multicenter randomized phase II trial comparing patients with borderline resectable and unresectable pancreatic cancer receiving mFOLFIRINOX chemotherapy with or without SAbR. Patients were randomized to chemotherapy with conventional hypofractionated RT of 33 to 40 Gy in five fractions or 25 Gy in five fractions or to chemotherapy alone. Disappointingly, overall and event-free survival were adversely impacted by the addition of SAbR to chemotherapy. Both the AGITG MASTERPLAN[92] and the Stanford phase III PanCRS studies are currently evaluating the role of SAbR 40 Gy in five fractions in patients receiving FOLFIRINOX. These results may further elucidate the preoperative role of SAbR in this patient population.

Kharofa et al[93] reported their experiences on patterns of marginal local failure following SAbR in resectable and borderline resectable pancreatic cancer. In this phase II study, patients were treated with three cycles of gemcitabine/ nab-paclitaxel or FOLFIRINOX and restaged. Patients without evidence of progression after their systemic therapy were eligible for enrollment and were treated with SAbR 33 Gy in five fractions, followed by surgery 6 weeks later. The trial was amended to include radiation to at-risk vasculature at a dose of 25 Gy. Six patients had disease progression by the time of surgery, one of which was local. Following surgery, 60% of resected patients had local failure. Although limited by size, they reported a PFS and OS benefit in patients who received RT to the vasculature compared to those who received treatment to the primary alone. Likewise, a large series of 510 patients from China reported local recurrences in 42.5%, with over 50% of those occurring at the celiac trunk or superior mesenteric artery.[94] Although treatment volumes have yet to be fully defined, coverage of high-risk vasculature should be considered.

The addition of dismutase mimetics with SAbR is currently under investigation to improve outcomes in this setting. An initial phase I/II study using a selective dismutase mimetic has proven to be safe with promising overall and PFS.[95] This led to the ongoing multi-institutional study GRECO-2,[96] which is evaluating the effects of adding a selective dismutase mimetic to SAbR at a dose of 50 Gy in five fractions, following

gemcitabine doublet or FOLFIRINOX-based chemotherapy in patients with borderline resectable or unresectable nonmetastatic pancreatic cancer.

Additionally, the use of Magnetic Resonance Linear Accelerators to better delineate disease and OARs in pancreatic SAbR is another area of active investigation. A multi- institutional review of stereotactic MR-guided adaptive radiation therapy (SMART) evaluated 148 patients with borderline resectable, locally advanced, or medically inoperable pancreatic cancer who received 40 to 50 Gy in 5 fractions.[97] They found 1- and 2-year LC rates of 94.6% and 83%, respectively, with no grade 4 or 5 toxicities. The recent prospective, single-arm, phase II SMART trial, evaluating the outcomes of 136 patients with locally advanced or borderline resectable pancreatic cancer treated to 50 Gy in 5 fractions, reported a 1-year LC, distant PFS, and OS of 82.9%, 50.6%, and 65%, respectively.[98] Patients who were able to undergo resection had improved outcomes across each domain compared to those that did not. The authors also report an 8.8% rate of grade 3 or higher acute GI toxicities.

Renal Cancer

Renal cell carcinoma has long been regarded as radioresistant. SAbR in inoperable patients has been increasingly adopted and serves as an excellent alternative to more invasive techniques, such as RFA or cryoablation, especially for larger tumors or those in close proximity to vessels and ureters.

The International Radiosurgery Oncology Consortium for the Kidney (IROCK) released a consensus statement[99] outlining treatment recommendations for kidney SAbR. This was followed by a pooled analysis of 223 patients treated with SAbR.[100] Over half of the patients (118 of 223) received single-fraction SAbR with a median dose of 25 Gy (range 14-26 Gy). The multifraction cohort received a median of 40 Gy (range 24-70 Gy) in 2 to 10 fractions. LC at 4 years was 97.8% and did not differ between the single-fraction and multifraction groups. They did report that patients who received single-fraction treatment had better OS, PFS, and cancer-specific survival at 4 years due to improved distant tumor control. While patients who received single-fraction treatment were younger, had better ECOG scores, and had smaller tumors, these factors were not found to be

independently related to survival. Single treatment was associated with a higher rate of nausea compared to multifractionated treatments. Renal function was minimally affected in either group. Several groups have reported similar outstanding rates of LC.[101]

More recently, IROCK has published their meta-analysis of individual patient data providing 5-year outcomes in 190 patients treated with SAbR for primary renal cell carcinoma.[102] Most patients were treated in a single fraction (43%) with a median dose of 25 Gy. The estimated glomerular filtration rate decreased by a median of 14.2 mL/min/1.73 m^2 5 years after treatment. At 5 years, the cumulative incidence of local failure was only 5.5% for the group, with an estimated cancer-specific survival of 63.6%. Patients treated in a single fraction had improved PFS than those treated with multifraction treatment regardless of tumor size. LC was also improved in single-fraction regimens. However, this study has similar biases of younger, higher performing patients receiving single-fraction treatment, and fractionation regimens remain to be tested prospectively.

SAbR for metastatic renal cell carcinoma has also increased over the past several years, spurred on by the promising use of SAbR in other oligometastatic settings and the increased use of immunotherapy. Several phase II studies, such as RADVAX RCC and NIVES,[103] have shown safety and preliminary efficacy in patients treated with immune checkpoint inhibitors in combination with SAbR to one or two lesions. Longer-term follow-up and randomized phase III studies are still needed in this ever-growing setting.

CONCLUSIONS

SAbR has emerged as a versatile strategy with a wide range of applications for many different types and stages of cancer. As with any form of radiation therapy, careful attention to patient selection and technical quality assurance is essential for the effective and safe implementation of SAbR. Future advances will refine our understanding of the biologic mechanisms and optimal integration and sequencing of SAbR with other anticancer therapies. While the durable efficacy of SAbR is apparent in many clinical models described in this chapter, the lack of severe, late toxicity predicted

by many antagonists is also apparent even with widespread implementation and decades of follow-up.

High-Dose, Ultra-High Dose Rate (FLASH), and Spatially Fractionated Radiotherapy

Robert J. Griffin, Yolanda Prezado, and Nina A. Mayr

The discipline of radiation oncology and radiation therapy (RT) research has had a major infusion of interest in nontraditional uses of ionizing radiation, specifically in the FLASH, high-dose, and spatial fractionation domains in recent years, a notable trend since the last edition of this textbook. No longer exclusively seen as a "kill all the tumor cells," "fee for service" modality, radiation as one of the multiple available tools in multidisciplinary care plans against cancer has brought the concepts of FLASH and various forms of spatial fractionation (GRID, lattice, minibeam, and microbeam) to the forefront in the continual search for normal tissue–sparing and tumor-controlling treatment plans. Principally, this is due to the long-standing concept of dividing the dose into "on and off" or hot and cold regions, which spares/allows normal tissue damage recovery and repair, yet adds a boost dose to the tumor. More recent work also suggests that increased antitumor effects of these new delivery techniques are due to bystander effects, engagement of the inflammatory/immune system, and inducing a tumor environment that is susceptible to concomitant or subsequent rounds of chemoradiation. Similarly, but more recent, is the flurry of preclinical and early clinical results demonstrating a sparing of normal tissue relative to tumor tissue using dose rates in the 50 to 500 Gy/s window, a situation that has been coined "FLASH" radiotherapy. In both cases, spatially fractionated radiation therapy (SFRT) and FLASH, the dose per fraction has been higher than conventional wisdom, a feature that calls into question the ideas and mechanisms by which stereotactic body radiation therapy (SBRT) has now been defined by vascular damage, indirect cell death, and shorter overall courses of treatment. Hand in hand with these intriguing concepts and growing proof of responses that benefit the therapeutic ratio, the increasing capabilities of present-day radiation delivery technology are a major contributor to the explosion of these approaches. Figure 18.1 is an example of the dose deposition characteristics from all the modalities to be discussed in this chapter. It is our hope that we can illustrate the preclinical, translational, and clinical results and the challenges that remain in preclinical and clinical implementation. With more participation by wider portions of the radiation oncology field, it is expected that these value-added new beam parameters in a variety of formats will produce continued evidence of patient benefit. Among the most important concepts to remember when considering these unconventional radiation treatments is that due to the reduced normal tissue effects, prior or subsequent standard-of-care regimens are commonly administered, which further increases the chance of improved patient outcomes.

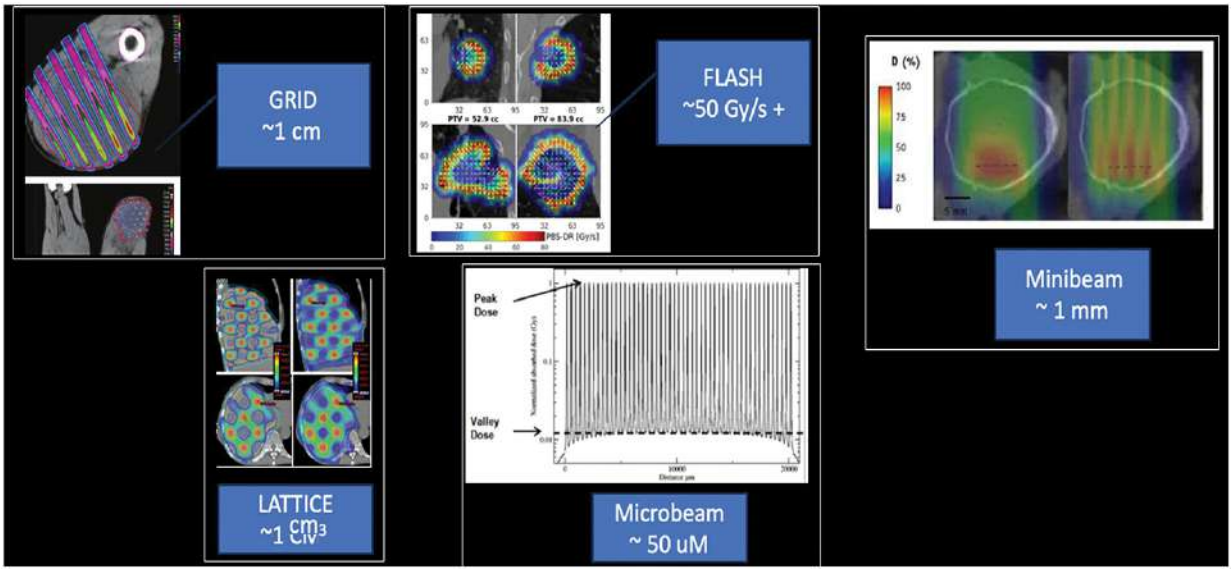

FIGURE 18.1 Examples of treatment planning and dosimetry (peak beam width and output) used in GRID, lattice, FLASH, and microbeam or minibeam preclinical or clinical studies.

HISTORY AND BACKGROUND

Spatially Fractionated Radiation Therapy

SFRT has been clinically defined as the treatment of tumors with highly heterogeneous dose distributions since its first installment in the early 1900s when Alban Köhler introduced the concept. In that era, SFRT was used to overcome the limitations of poor depth dose and high skin toxicity from kilo—and orthovoltage radiotherapy, which were the only available teletherapy technologies at the time.[1,2] Although SFRT fell out of favor with the introduction of megavoltage technologies with their improved depth dose properties, achieving local control in bulky voluminous tumors and therapy-resistant/refractory tumors continued to pose significant and persistent challenges. This dilemma gave rise to the reintroduction, development, and further advancement of SFRT as a megavoltage application in the late 1980s[3] and its subsequent expansion in clinical practice. The current SFRT addresses this challenge by combining megavoltage-generated dose heterogeneity with large dose fractions in the hypofractionation/ablative domain to both escalate tumor dose and reduce normal tissue dose.

In a variety of single-institution pilot studies over the past three decades, promising outcomes of unexpectedly robust tumor responses along with low toxicity rates have been observed with SFRT in challenging bulky, treatment-refractory recurrent/metastatic tumors.[4-6] More recent studies showed similar favorable responses to SFRT in several malignancies treated with curative intent.[5,7] Most of these studies have implemented two variations on spatial fractionation in terms of the geometry of dose deposition. The one with the longest history and most overall clinical experience is commonly referred to as "GRID" therapy, paying homage to the early 1900s when Köhler placed an actual metal screen over the skin to allow a well-defined geometric pattern of radiation exposure and blocking.[1] The other, more recently developed approach has been coined "Lattice" therapy since the dose deposition is targeted to deliver three-dimensional variably spaced high-dose spheres (vertices) within a tumor volume. Lattice treatment has been gaining steady interest and clinical implementation in a number of centers, and a growing number of clinical reports suggesting value for the treatment are available.[7-9]

Over the many years since it was first utilized, GRID has typically been applied using a fixed screen placed on the patient with open and closed apertures, or a "honeycomb" collimator has been placed in the beam of the linear accelerator or the multileaf collimation system in modern linear accelerators (MLC) is used to "shape" the GRID pattern. In all cases, the primary goal was, and continues to be, avoiding normal tissue damage, and most studies report just that very low, often negligible increase in any toxicity profile. A more advanced approach, termed Lattice therapy, can exploit the 3D dosimetry capabilities in current planning stations to deposit a lattice of nodes of high doses in a target tumor volume. More often than in the case of GRID, Lattice therapy has been studied when given in multiple fractions for pain relief or palliation, akin to a course of palliative SBRT.[8] An important aspect of both GRID and Lattice is that they are often followed by conventional chemoradiation regimens. Few

instances are available from the clinical literature of a single use of SFRT without additional radiotherapy. However, a more significant portion of the preclinical data available has been obtained from studies that only treated with SFRT. Regardless, it has been postulated multiple times that the effects of SFRT on the primary tumor may include mechanisms of sensitization or other sorts of priming to improve subsequent therapy effects.[6,10] This is a disconnect in the translational potential of these unconventional therapy approaches. To date, few if any multi-institutional or prospective randomized clinical trials using SFRT with or without other therapy have been conducted. However, in parallel with the growing database of preclinical information and increased focus on standardizing clinical SFRT delivery in single-center studies, there is more clinical trial rationale emerging that should provide answers for the broader field of radiation oncology to adopt. For example, new consensus statements have been recently published, derived from a survey of many radiation oncologists in the fields of radiosurgery and stereotactic radiation treatments for lung and ovarian tumors,[8,11] with other disease sites currently being surveyed in a similar fashion. Other groups are investigating and developing best practice recommendations for the physical aspects of treatment goals in heterogeneous dosing to produce results from a variety of centers that can be compared with confidence in how the treatments were applied.[9,12-15]

It is also worth recognizing here that versions of heterogeneous dosing are also being investigated related to the same theme but with slightly different features. Exciting work from multiple centers has emerged regarding the effects of low-dose radiation exposure and immune stimulation. Partial irradiation or purposeful low-dose/high-dose exposures to specific metastatic lesions in the same patient may have similar beneficial mechanisms of action to those hypothesized to be involved with GRID and Lattice.[16-18] Even more analogous to GRID and Lattice, microbeam/minibeam radiation therapy (MRT) has continued to develop a new rationale for implementation, thanks to a growing stream of compelling preclinical data.[19,20] Microbeam is mostly in preclinical stages, but many of the same principles apply as in GRID or Lattice-scale treatment fields, and there are several international groups working on the launch of initial clinical studies.[19,20] Minibeam therapy, especially with protons or photons using beams around 1 mm wide, has made a major increase in the pace of investigation in the past decade or so.[21-23] No matter the specific modality, the common features that apply to all SFRT methods employed to date are potential primary tumor debulking with lower damage to normal tissue and engagement of pro-antitumor immunity mechanisms, warranting the further development and study of the various approaches available to the radiation oncology clinic at present. However, even if the mechanisms of action might be generally the same, none are well understood at a detailed level at this time. Certainly, in addition to added direct cell killing by virtue of the high peak doses, bystander, abscopal effects, vascular damage, and angiogenic and immune responses are likely involved, and the current literature and understanding or gaps in knowledge will be discussed further on in this chapter.

Ultra-High Dose Rate (FLASH) Radiation Therapy

The availability of more advanced radiation technology in the mid-20th century led to some very early observations of what was coined the “FLASH effect” in recent years.[24-26] These possible normal tissue–sparing effects of ultra-high dose rates (UHDRs; many tens or hundreds of Gy/s) have now been the subject of an array of preclinical and emerging clinical testing of the paradigm (for an extensive review of the field, please refer to refs[1,27,28]). High, single-dose therapy at more conventional dose rates has been increasingly studied with the massive technologic advances available in our treatment machines and the growing database of safe, effective, and time-saving SBRT and stereotactic radiosurgery (SRS) regimens,[29,30] yet significant threat to normal tissue remains. Therefore, the seminal renewal of the use of UHDRs published by Favaudon and Vozenin et al nearly 10 years ago demonstrating the potential for high dose sparing of normal tissues only when delivered at extremely high dose rates has been a reawakening for the translational radiation oncology field. As things have progressed and very rapidly been transferred to clinical use, there has been a general realization that the beam parameters for true FLASH benefit are complex and the site of the tumor may dictate a very select set of disease conditions in which electrons or protons/photons could be successfully adopted for FLASH treatment and patient benefit.[31,32]

Indeed, negative results have also been recently reported from preclinical experiments and veterinary trials of FLASH radiation.[32] This indicates that parameters other than UHDR may contribute to the FLASH effect. These may include beam structure (ie, pulse width or repetition rate), radiation dose, irradiated volume, and oxygen concentration in radiation-exposed healthy tissue.[33] Concerning the latter, there have been several reports pointing to the disappearance of the FLASH effect in well-oxygenated tissues.[34] Moreover, in a recent study, it was observed that UHDR in oxygenated tissues induced even more severe damage than conventional irradiations.[35]

Further research is needed to investigate the impact of the dose, fractionation scheme and volume/dose conformality, oxygen content, and linear energy transfer on the FLASH effect.

To move toward FLASH-RT clinical trials of large radioresistant or recurrent tumors, further and comprehensive studies exploring FLASH-RT are still lacking. First, the current evidence on tumor control by FLASH therapy is much more limited than normal tissue sparing, and most of the studies use a single-dose scheme. Studies assessing the maximum dose and the time delay between fractions for which the FLASH effect still stands are requested. All those evaluations are necessary to critically evaluate its toxicity and efficacy under a more clinically relevant scenario. No evaluation of the FLASH effect in reirradiations has been carried out. The radiobiologic mechanisms governing the differential dose sparing in FLASH irradiations and the probability of occurrence are still unclear. To analyze these uncertainties, FLASH treatments require additional standardized reporting of the application and of the physical and technical parameters that may influence the efficacy of the FLASH effect, as argued in the previous review.

PRECLINICAL UNDERSTANDING OF MECHANISMS OF ACTION

Figures 18.2 and 18.3 illustrate a basic outlay of the major mechanistic factors that have been identified empirically or hypothesized and studied in the search for developing a complete mechanistic understanding of SFRT (Figure 18.2) and UHDRs (FLASH) (Figure 18.3). These topics have been investigated in varying levels of detail over the last century or more, with most of the results coming in the last 30+ years.

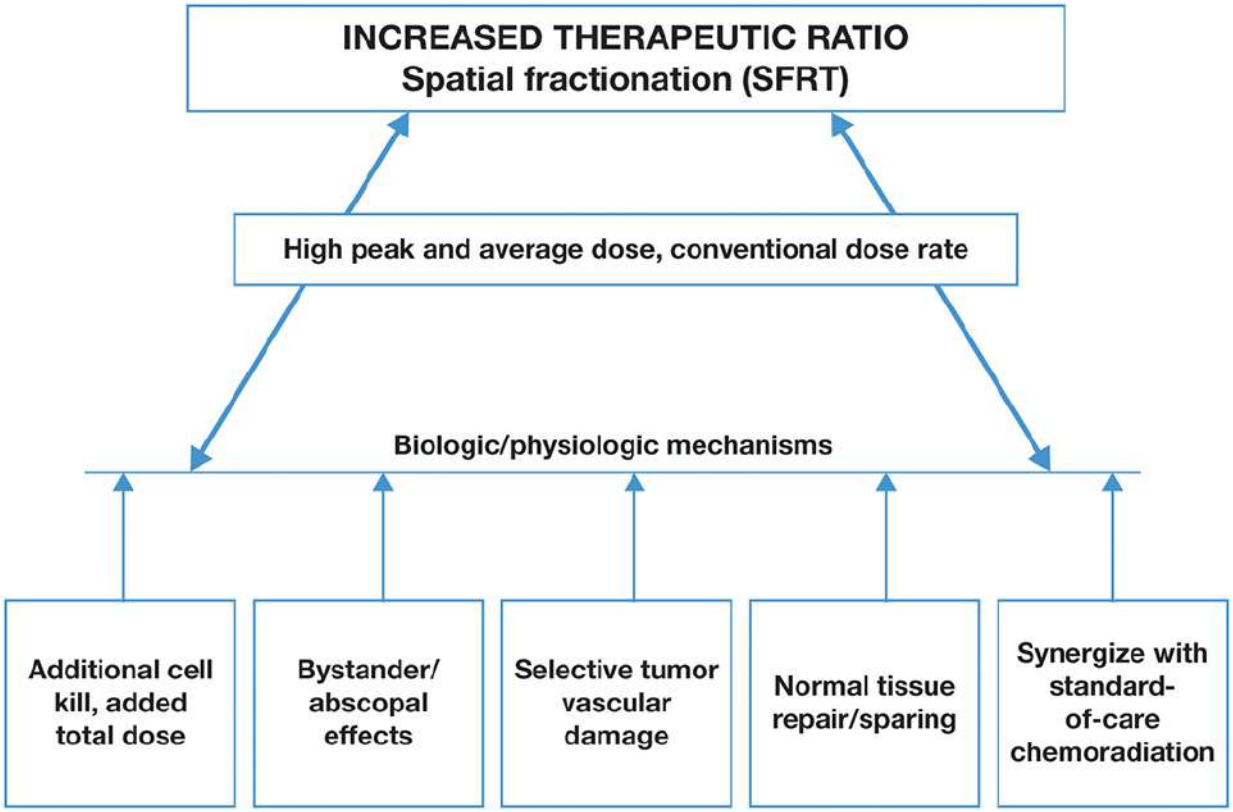

FIGURE 18.2 Current hypothesized mechanisms and effects of SFRT contributing to improved therapeutic ratio. Relatively more is known about the SFRT effects, but there are still large questions to be answered to standardize applications. SFRT, spatially fractionated radiation therapy.

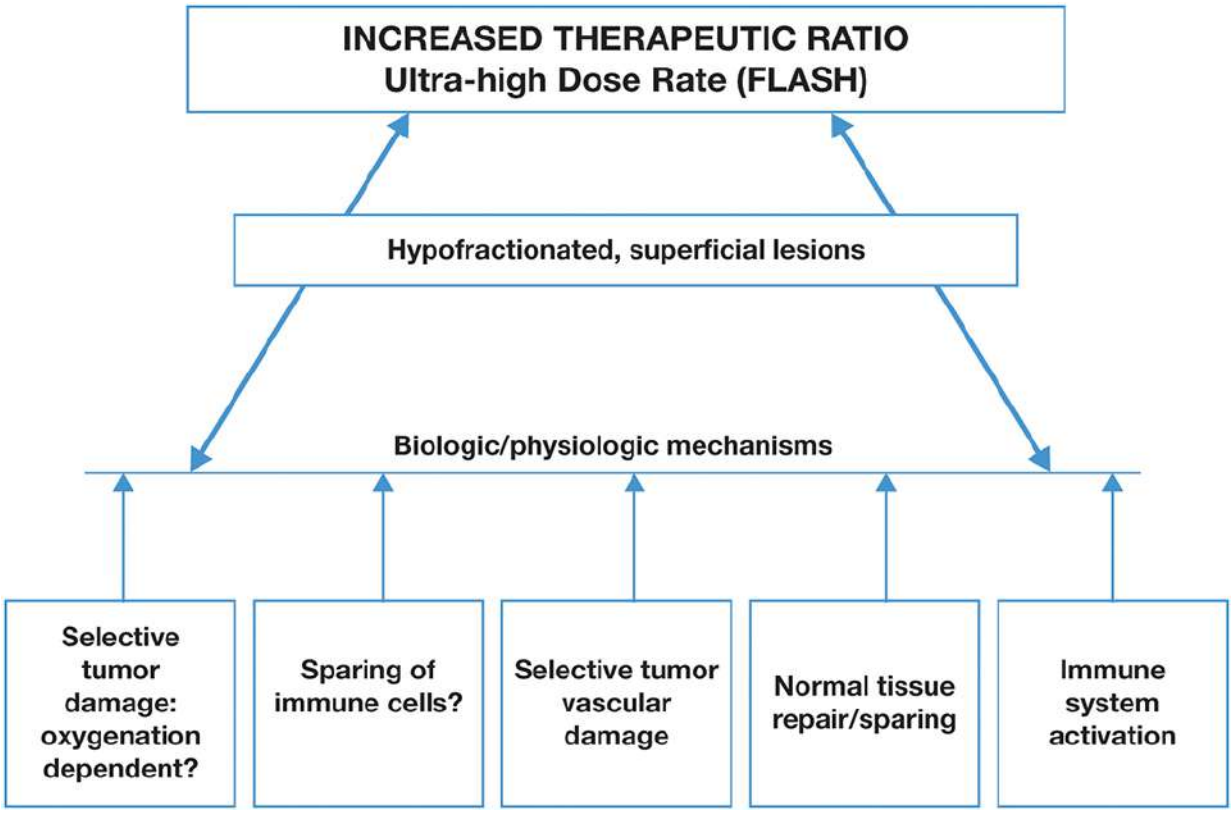

FIGURE 18.3 Current hypothesized mechanisms and effects of FLASH dose rate exposures contributing to improved therapeutic ratio. The combination of SFRT and FLASH occurs in some SFRT formats but has not been fully studied to date.[19] SFRT, spatially fractionated radiation therapy.

Spatially Fractionated Modalities Preclinical Research

The possible biologic mechanisms by which any form of SFRT contributes to overall tumor control alone or in the context of standard-of-care chemoradiation regimens are still not entirely clear. Important aspects of immune activation, vascular damage/modulation, tumor microenvironment, and bystander effects that contribute to the overall response to SFRT alone and with subsequent standard-of-care regimens are being gradually uncovered, and improved clinical trial designs may be the results in upcoming years. In between microbeam and GRID, there is the rapidly growing field of minibeam therapy, which is finding great potential and might be in the "sweet spot" considering all aspects of the physics and biology of SFRT. There are many studies in the recent literature that demonstrated better tumor control and normal tissue tolerance in rodent and canine studies at very high peak doses, especially for brain tumors; (bystander) induced differentiation may also play a role and could be used for benign conditions. In general, the orthovoltage minibeam may have value due to the very high peak-to-valley dose ratios (PVDRs) that can be obtained in comparison to high-energy/high-dose SFRT type of therapy. However, megavoltage photon as well as proton and heavier ion beams are also being actively investigated with promising preclinical results and demonstrated steps toward clinical implementation, taking advantage of improved energy deposition patterns possible, especially with proton or other particle beams.[22,36-42]

Preclinical studies employing small animal conformal irradiation systems have suggested that biologic mechanisms of action of SFRT are related to bystander killing as well as vascular damage and remodeling, leading to debulking and improved tumor oxygenation.[43-45] These aspects of biologic response by the tumor have been studied in both aerobic and hypoxic conditions, and it was found that hypoxia modifies the bystander killing in some cases.[46,47] In general, the bystander effect is short range between adjacent cells within the same tissue while the abscopal effect has been coined to describe a long-range, whole-organism phenomenon by which changes induced in the primary tumor are communicated to remote tissues, likely via cytokine release or extracellular vesicles. Traditionally, the bystander effect is often considered harmful and abscopal as beneficial, but these concepts are being rethought in the context of spatial fractionation effects. For example, the bystander effect could

play a protective role in normal tissue and at the same time induce cell death in tumors. In particular, induced differentiation and tissue recompartmentalization could be an underlying mechanism of the bystander effect in either normal or malignant tissue.

In addition, the role of vascular damage/repair and angiogenesis inhibition strategies has been demonstrated to affect the outcome of GRID or microbeam in several preclinical studies.[48,49] For all beam sizes between micron and millimeter width, the capillary blood vessels seem to repair themselves promptly in normal tissues, that is, within hours to days after SFRT exposure. In the tumor, there is less repair and evidence of permanent dysfunction in some cases induced by high peak dose SFRT. Most likely, these effects are modulated by the normal and tumor tissue microenvironment; however, mechanisms could be different depending on specific irradiation parameters.

A major factor in the recent rise of interest in unconventional radiation exposure scenarios such as SFRT has been the explosion of interest in immunotherapy, including the quest to solve the mystery of why some patients turn on immunity and others do not. Radiotherapy can certainly modify features of the immune response, and SFRT, in particular, seems to have the potential to "turn on" aspects of immune control of the primary tumor as well as metastasis. Therefore, this section will summarize what is known at present and the suggested paths for clinical engagement of using SFRT as a part of the immunotherapy armamentarium.

In many cases, advanced tumors are radio- and chemo-resistant due to poor blood flow, hypoxia, and low pH in the tumor. These factors may also influence the degree of immune surveillance generated by SFRT or the response to other standards-of-care regimens.[50] Clearly, large tumor volume and hypoxia have been found to correlate with decreased local control and survival in patients receiving chemoradiotherapy and/or subsequent immunotherapy in the form of checkpoint inhibiting antibodies. Thus, treatment modalities such as SFRT that can increase the tumor total dose and possibly activate beneficial bystander and abscopal immune effects while minimizing effects on normal tissues are an attractive proposition. A growing number of studies published in the preclinical literature of late suggest that there are primary tumor and abscopal/systemically expressed effects when spatial fractionation is applied to a locally advanced tumor and that they may be greater than those observed with conventional whole tumor fractionated or SBRT radiotherapy practices.[51-53] Other groups have reported similar and fascinating trends in tumor immunity and control with partial tumor or gradient radiation exposures.[54,55]

As an excellent example from the available literature, a recent study presents a group of preclinical studies using SFRT for single tumor volumes with detailed dosimetry and a biologic outcome study. In these studies, the investigators were able to compare several distinct partial, spatial, and whole tumor radiation exposures. These comparisons are critical to improve our understanding of which parameters may have the highest clinical impact and should be retained in treatment planning, when normal tissue dosimetry, tumor position/shape, and other factors become significantly influential in reaching planning goals.[53] A Kv source was used to create either 1-mm GRID peak dose openings or a 1 × 20 mm bar pattern (analogous to the microbeam radiotherapy field) or hemi-tumor and whole tumor radiation exposure. In terms of immunity, a big portion of the authors' attention was devoted to keeping the valley doses below a level that has been shown to be significantly toxic to T cells (3 Gy). Therefore, they constricted their treatment plans to allow only 1.5 Gy maximum in the valleys. Another important task included the assessment of motion on the accuracy of the dose deposition, which resulted in little to negligible effect of tumor motion during their exposures. This finding confirmed that the treatment outcomes were truly elicited from exposure to SFRT for various patterns and bode well for the results that could be expected when a carefully planned clinical version can be studied.

Although the results in tumor response were similar to those from other studies, they were different from those obtained in a tumor/mouse model in a recent hemi-irradiation protocol.[54] An important realization from this work and similar studies should be noted in that many, if not all, clinical PVDRs (ie, the degree of spatial modulation) are substantially less than preclinical studies that have observed potentially new types of radiobiologic responses. Therefore, there is a growing interest in research and clinical circles that PVDR quantification should be reported in as much detail as possible in every study that employs SFRT in any format to better understand and interpret the mechanisms of action.

Why is the peak and valley dose ratio so important? Maybe foremost is the attention to retaining or increasing an effective antitumor immune response using SFRT. One finer detail about having spatial dose modulation and dose gradients is that the immune system is activated by differing mechanisms across doses from low to high.[56] For example, the ablative damage in the peaks could produce new antigens; in the midrange, we may have ablation of the immune cells present during radiation, and in the lower valley dose, regions there may be immunomodulatory induction within the tumor microenvironment. It must also be remembered that the "Rs" of RT still apply, and there will be a significant repopulation in the valley dose regions, adjacent to peak dose areas where little cell

regrowth may occur. Intertwined with all these factors is the absolute percentage of target volume that receives either peak or valley dose, which is a variable that is rarely taken into account judging by the available literature.

The value of keeping the valley dose at or below a dose that would induce widespread lymphocyte killing (which is theorized to be in the 1- to 2-Gy range) is under debate. In theory, avoiding doses that kill resident lymphocytes would be beneficial to the antitumor immune response, yet there are plentiful examples of preclinical work using minibeams or microbeams where the valley dose is significantly higher than 1 to 2 Gy, yet induction of positive immune response has been observed. One possible explanation is that SFRT induces cellular damage in the peak dose areas and allows interaction with new antigens by dendritic cells in the valley areas that may not have as much vascular damage, leading to the generation of activated T cells against the tumor. Lymphocyte presence in the tumor either before or after SFRT treatment continues to be an important consideration that needs to be accounted for in the interpretation of tumor response to these regimens.

Temporal fractionation in SFRT is another relevant question, which has not been very well investigated, especially in the context of how to best induce immune priming and avoid immune suppression by subsequent fractions. A related approach termed personalized ultrafractionated stereotactic adaptive radiotherapy (PULSAR) in recent years to purposely give rest periods between radiation fractions to allow for immune adaptation is a clear example of what also may end up being a major consideration in optimizing the design of studies implementing SFRT.[29,57] However, it should be noted that very good survival and outcome results have been obtained in preclinical studies with as little as a 48-hour interval (80% long-term survival free of tumors). More attention to this paradigm-changing topic is clearly needed.[58,59]

To be clear, regardless of the SFRT approach, the interval between a single- or multiple-fraction GRID or lattice dose and the beginning of any conventional fractionation treatment remains to be optimized. Prior to the explosion of excitement around the immunotherapy field, it was generally thought that beginning chemoradiation within 3 days of the last SFRT fraction was optimal. Weighing the interval time for increased immune actions versus the risk of tumor repopulation or reassortment and progression continues to be discussed.[8,9,13,27,60] Overall, the evidence suggests that SFRT used at proven safe levels in combination with standard-of-care regimens is an acceptable and valid tool to increase beneficial patient outcomes.

Ultra-High Dose Rate (FLASH) Preclinical Research

The initial excitement of a tumor-selective effect of radiotherapy with decreased normal tissue response was largely theorized to be driven by the imbalance of oxygen levels between normal and tumor tissues. There are three major postulates being debated and studied, and no clear understanding has emerged at the time this chapter is being written. These are the facts that FLASH-induced transient oxygen depletion is possible; relatedly, there are cell type–specific differences in the ability to detoxify and recover from damage caused by reactive oxygen species, and finally, the idea that FLASH differs from conventional radiation in self-annihilation of radicals by bimolecular recombination.[61] Thereby, one or more of these differential effects FLASH will cause relatively less cellular damage in normal tissues than in solid tumor tissue. However, in a series of recent papers, this theory or variations on the oxygen theory have been introduced, which leave us without a clear answer at present.[61-63] Another aspect of FLASH mechanistic understanding is the potential differential vascular effects of FLASH between normal and tumor tissues. It seems that a general effect of vascular damage, lack of repair in tumor tissue, and vascular protection/sparing in normal tissue may help explain in vivo results on a tissue-by-tissue/model-by-model basis.[64] Some SFRT techniques such as MRT also lead to a similar differential effect between normal and tumoral vascular effects. However, even if MRT is delivered at UHDR, the presence of true FLASH effects in the tissue response is not certain since even the low-dose areas (valleys) usually receive doses higher than the maximum ones that demonstrated sparing in other FLASH studies in the same model (mouse brain).[30,65-67]

Finally, the immune system response FLASH has been suggested in a variety of studies to be greater than normal dose rate regimens due to sparing of circulating immune cells and immune organ function, while equal immune activation independent of dose rate has also been observed in other work.[68-70] After the initial excitement of the clinical potential, the field of FLASH has more quickly been introduced to clinical study with somewhat less preclinical work to establish mechanisms of action. Without that information, and the cautionary results coming from a comparative oncology setting where total dose was a major factor and may have clouded the occurrence of FLASH effects,[32] tissue/disease site selection and customization of treatment goals will be extremely important.

The current evidence on tumor control by FLASH therapy is, nevertheless, more limited than the normal tissue sparing, and most of the studies use a single-dose scheme. In contrast, conventional RT usually employs temporal

fractionation of the dose to profit from both a reoxygenation of the tumor and a redistribution of cells to more sensitive phases of the cell cycle (late G2 and M phases). Local tissue toxicity is also reduced due to the resulting increased time available for the repair of sublethal damage and cell repopulation. Thus, temporal fractionation effects might add up to the level of the inherent benefit of FLASH therapy for normal tissue preservation, and thus the value of either approach over the other is still not certain. Thus far, only one study evaluated the effect of temporal fractionation using FLASH dose rates, focusing on tumor control.[71] In this study, the tumor response following three hypofractionation schemes was assessed. As a result of the experimental design, the effects on normal tissue (FLASH effect) were only possible in the short term. To move toward FLASH-RT clinical trials of large radioresistant tumors (the ones that would most benefit from the normal tissue preservation potential of using UHDRs), we need comprehensive studies exploring temporally fractionated FLASH-RT, which have not been performed to date. Studies assessing the maximum dose and the time delay between fractions for which the FLASH effect still stands would be highly instructive. As with every new approach, these types of studies are necessary to critically evaluate the modality-associated toxicity and efficacy under a more clinically relevant scenario in radiation oncology terms.

CURRENT CLINICAL ACTIVITY

Spatially Fractionated Radiation Therapy

Best possible control of the primary or metastatic tumor sites remains a major goal of radiotherapy for both reduction of recurrence risk and improvement of survival in curative-intent radiotherapy; and symptom control and often lengthening of disease-free survival (DSF) in the palliative setting. Despite major advancements in radiotherapy technologies and delivery, the challenge of achieving adequate tumor control persists, owing to the inability to deliver a sufficiently high dose while effectively protecting normal tissues, particularly in therapy refractory and bulky/voluminous tumors. This challenge is further intensified in the current era of improved systemic therapy with ensuing prolonged survival, which calls for more effective local treatment of recurrent or metastatic tumor masses.

Current clinically practiced SFRT falls into two major categories: GRID therapy and the more recently developed Lattice therapy. Both deliver profoundly heterogeneous doses but with different geometric configurations of the heterogeneity dose pattern. Early clinical experience suggests that both have the potential to enhance tumor control in palliatively treated bulky metastatic and recurrent tumors and in selected advanced voluminous primary tumors. The reader is referred to recent reviews as an overview, and a summary of selected clinical approaches and data is given below.[28,3,72-77]

GRID Therapy

The original megavoltage SFRT modality was GRID therapy, delivered with a Cerrobend GRID block, which was subsequently developed into commercially available GRID collimators. The inaugural study showed 91% palliation (21/22) in 22 patients treated with 10 to 15 Gy in one-fraction GRID block–based SFRT for bulky tumors 6 to 25 cm in diameter.[3] Two subsequent palliative series corroborate these results in larger cohorts of 61 (72 tumor sites, predominately gastrointestinal [GI] lesions and sarcomas) and 71 patients (87 tumor sites, predominately lung, head, and neck tumors and sarcomas).[74] Overall response rates were 91% and 76%, toxicities were rare and minimal, with the exception of one carotid blowout after rapid tumor regression. These two studies established an important dose/response relationship. An SFRT dose higher than 15 Gy was associated with a higher response (100%) than a lower dose (79%). These early studies also established that durable response and local control require that conventional external radiation (cERT) with a dose of at least 40 Gy is added to the SFRT.[74] Therefore, most current SFRT regimens, with the exception of very short-term palliation, include both an SFRT and a cERT component. Further experience with GRID using commercial GRID collimators has confirmed high response and local tumor control rates and low toxicity.[4,6,10,73,76]

GRID options were broadened with the development of multileaf collimator (MLC)-based GRID therapy that emulates the principal dosimetric properties of the GRID collimator–generated treatment, and in addition, allows further individualization of the treatment volumes and normal tissue exclusion. Comparison between GRID collimator–based and MLC-based GRID therapy showed equivalent responses in an earlier study.[73]

Planning workflows have undergone further refinement, and both MLC-based and fixed collimator-based GRID are in use in about equal amounts according to recent clinical survey results.[78] For example, rapid-planning approaches are feasible with MLC-based GRID therapy.[79] These approaches allow for same-day treatment with a

spatial fractionation pattern, greatly improving the ability of many clinics to give SFRT dosing. Other recent reports highlight suggested workflows to integrate fixed collimator-based SFRT into treatment planning and a growing database of sarcoma and other disease sites.[5,15,80,81] The ease of implementation for MLC and fixed GRID block usage and same-day planning and treatment are a major advantage to the average clinical center. The recommended and most commonly used dose schedule for palliative SFRT is a single fraction of 15 Gy or 18 Gy, while larger fractions (20 Gy) or fractionated treatment are uncommon.[78]

Meanwhile, the favorable results of the palliative GRID experience have spawned exploration of SFRT to bulky primary tumor sites. The early series by Mohiuddin contained a small cohort of eight patients with far-advanced bulky but nonmetastatic head and neck (H&N) or skin cancer. Clinical complete response (cCR) was 63% (five of eight patients) and pathologic complete response (pCR) was 100% among four patients who underwent subsequent surgery.[74] The encouraging results in H&N cancer have been replicated by several smaller series of definitively treated patients.[4,10,76] GRID therapy has since also been explored in primary sarcoma.[6] Snider et al[6] showed in a retrospective series of bulky sarcomas (median 14.2 cm; all but 2 over 10 cm in diameter) a pCR of 32% (6/17 patients) among high-grade soft-tissue sarcomas, and of 50% (4/8) among extremity soft-tissue sarcoma, exceeding the pCR rate in major clinical sarcoma trials (19.4% and 27.5%).[82,83] Patients were treated with preoperative 15 Gy in one-fraction GRID therapy, followed by 45 to 50.4 Gy cERT and resection. Overall local control was 85%, and overall survival was 86%. Table 18.1 summarizes a selected range of representative series of SFRT to primary tumor sites, including GRID and Lattice-based applications.

Selected studies are presented. In some studies, treatment of patients with primary tumors that are also metastatic is also included in the series.

ca, cancer; cERT, conventional eternal radiation therapy; CR, complete response; Def, definitive; DSS, disease-specific survival; FDG, fluorodeoxyglucose; gr, grade; H&N, head and neck; IR, intermediate risk; LC, local control; LR, low risk; LRT, Lattice radiation therapy; NED, no evidence of disease; n/r, not reported; NSCLC, non–small cell lung cancer; OS, overall survival; Pall, palliative; pCR, pathologic complete response; PET, positron emission tomography; PR, partial response; PTV, planning target volume; RT, radiation therapy; SCC, squamous cell carcinoma; SFRT, spatially fractionated radiation therapy.

[a]Range of doses is given in parentheses when available.

[b]Fourteen of the total 79 patients in this mixed palliative and curative cohort had H&N cancer that was definitively treated; 4 patients with H&N cancer were treated preoperatively.

[c]The follow-up time of the group of patients with definitively treated H&N cancer was not separately reported.

[d]The cERT dose was not reduced because of the dose received from SFRT.

[e]Concurrent chemotherapy was given with the cERT.

[f]Responses reported for collimator (block)-based (first percentage) and multi-leaf collimator based GRID therapy (second percentage), respectively, as this study retrospectively compared the outcomes between the two techniques.

[g]The overall reported survival was calculated (based on the reported data) for the entire mixed palliative and curative cohort, as the study was not intended to report survival.

[h]Fourteen patients were treated with definitive radiation, and 13 with preoperative radiation.

[i]Concurrent chemotherapy was given with the SFRT fraction and the cERT.

[j]Study reported as abstract.

[k]Nine of the 21 patients were treated with definitive intent, and the remainder palliatively.

[l]The follow-up time was not reported; the survival time ranges from 2 to 44 (median 99) months.

[m]Concurrent chemotherapy with ifosfamide/mesna.

[n]Hypofractionated at 2.75 Gy/fraction.

[o]Nine of the 11 patients received concurrent chemotherapy.

[p]Concurrent weekly cisplatin with SFRT fractions and cERT.

[q]Four patients with surgery following radiation therapy reported in Amendola (2020), with 1 additional patient per information from the author.

Lattice Therapy

Approximately half of SFRT is currently delivered with Lattice therapy,[78] indicating the development of the SFRT toward leveraging advanced technologies, such as intensity-modulated radiation therapy (IMRT), volumetric modulated arc therapy (VMAT), and image-guided radiation therapy (IGRT). In contrast to collimator-based GRID therapy, which has a largely fixed heterogeneity pattern, Lattice therapy enables the highly variable placement of high-dose spheres within the tumor, and this is used to further reduce areas of closely approximated sensitive normal tissues, such as the bowel. Lattice therapy has been used clinically for palliative lesions and for primary advanced cervical cancer,[8] other gynecologic tumors,[84,85] and lung cancers.[86] A series of 10 patients with far-advanced cervical cancer with excessive tumor bulk of more than 7 cm or severe anatomic distortion was reported in 2020. A Lattice radiation therapy (LRT) dose of 24 Gy in three fractions LRT was delivered with VMAT and IGRT, and immediately followed by 45.0 to 50.4 Gy cERT to the pelvis and regional nodal involvement. The dose at the periphery of the internal target volume (ITV) was reduced to 9 Gy in three fractions, and Radiation Therapy Oncology Group (RTOG) criteria for normal tissue doses[87,88] were applied. Patients received concurrent weekly cisplatin during LRT and cERT. No brachytherapy was given.

This early data suggests a high complete response rate, with frequently rapid tumor regression during therapy, requiring adaptive replanning. Local (pelvic) tumor control was 100% at a median follow-up of 16 (range 1-77) months, 2-year disease-specific survival was 53.3%, and toxicity was minimal. Five of the 10 patients underwent posttherapy hysterectomy, and 3 of the 5 had a complete pathologic response. Nine of the total group of 10 patients were followed with fludeoxyglucose-18 (FDG) positron emission tomography/computed tomography (PET/CT), and 8 of the 9 maintained complete metabolic response at the last follow-up. This experience in cervical cancer mirrors prior results of rapid tumor regression and high local control in GRID therapy for H&N cancers[4,10,73,76]; however, these pilot results must be confirmed with future studies and clinical trials with larger patient numbers.

The first series of LRT in lung cancer was published by the Innovative Cancer Institute and builds on the experience with GRID therapy in lung cancer from previous multidisease studies.[74,73] The series consists of 10 patients with locally advanced or recurrent non–small cell lung cancer (NSCLC), with tumor sizes ranging from 5 to 14 (mean, 8) cm.[1] Patients received a single fraction of LRT, delivered with IGRT and respiratory motion management. The dose to the peripheral gross tumor volume (GTV) was limited to 3 Gy. LRT was followed by 45.0 to 59.4 Gy cERT and additional tumor boost as indicated for residual tumor. All but one patient with a large cavitary lesion had imaging-based response therapy with a 15% to 83% (mean, 52) tumor volume reduction at therapy completion. Five of the 10 patients were alive at the last follow-up (18-86 months after therapy), 3 maintained complete metabolic response by FDG PET/CT, and 2 had partial response in the lung along with extrathoracic disease. There was no toxicity higher than clinical grade 1. However, as for the overall GRID and LRT experience in the definitive treatment of primary malignancies, the promising early outcome results require rigorous further study through well-designed clinical trials with the outcome as well as translational components. Recent consensus efforts have been undertaken to facilitate clinical trial design.[8,11,13,60,9]

The low clinical toxicity to multiple critical normal structures observed in LRT for gynecologic cancer, lung cancer,[84-86,89] and in the GRID experience[4,6,10,74,76,73] suggests an early clinical outcome correlate as a strong feature of SFRT.[60] As nearly all of the available preclinical and clinical literature report, compared to tumor tissue, normal tissue can withstand higher peak doses of GRID or Lattice therapy due to the spatial features and well-proven ability of normal tissues to repair and recover to spatially fractionated doses. The avoidance of additional toxicity

provides further promise for SFRT as a feasible clinical modality. Once again, the clinical results from a selected set from different tumor sites for both GRID and Lattice SFRT studies to date are summarized in Table 18.1.

FLASH

After a few case reports and first in-clinic applications of dose rates in the FLASH range, there have been a number of trials planned and now begun in the United States and Switzerland. As mentioned, a comparative oncology trial was performed in companion cats with oral squamous cell carcinomas.[32] This study reported some severe normal tissue reactions at FLASH dose rates when large volumes and total doses were involved, which has been a stark reminder of the focus on using FLASH with moderate total doses and prioritized superficial targets. There are at least two other known veterinary oncology trials ongoing, one in Sweden with electrons and the other in U Penn with protons.[94] The Swedish study revealed that single- fraction high-dose FLASH-RT was generally effective in this mixed group of malignant oral tumors, but the risk of osteoradionecrosis is a serious clinical concern. It is possible that the risk of osteonecrosis can be mitigated through fractionation and improved dose conformity, which needs to be addressed before moving forward with clinical trials in patients with cancer.

In line with these realizations, two clinical studies of FLASH based on the use of electrons are actively being developed and/or recruited.[95,96] Another nonrandomized study in the United States has treated 10 patients with bone metastases using proton FLASH therapy and demonstrated clinical feasibility,[97,98] but no conclusions on reduction of side effects have been made, somewhat expected since to date the total doses were purposely kept below the tolerance levels as a precaution. A table or other summary of FLASH clinical outcomes has not been included since at the date of this writing there are not enough completed studies to indicate any trends or average characteristics in patient outcomes. However, the field is extremely active and the number of data sets from more expanded clinical series is sure to increase in the near future.

FUTURE OUTLOOK AND PERSPECTIVES

Considering the growing interest in exploiting both the implicated biologic (changes in perfusion, oxygenation, and immune activation) and dosimetric advantages (protection of normal tissues and preserving tolerance dosing), the use of heterogeneous, partial, or spatial dosing at conventional or UHDRs can now be considered to revolutionize modern radiation oncology. Furthermore, it has been demonstrated that the elusive goal of inducing remote effects by increasing the ability of the immune system to feed off antigens induced by high-dose radiation and adding low-dose radiation to stimulate vascular and inflammatory cascades to assist the host in controlling metastatic progression may be within reach. If indeed these new beam modalities prove to be widely useful, the field of radiation oncology becomes even more significant in the armamentarium of cancer care. Larger, well-controlled, multi-institution studies need to be performed to establish the realistic gains for different tumor types by either the spatial fractionation of primary tumor masses or the selective high- and low-dose treatment regimen to allow the desired immune interplay for each patient. At present, there is a growing database of clinical outcomes from SFRT to base new clinical studies on, potentially including immunotherapy. Refer to Table 18.1 for SFRT primary tumor studies from the literature and a more expansive tally in Tubin et al.[28]

Low-dose/high-dose synergies have similarities across the spectrum of spatial fractionation approaches when applied to a single advanced primary tumor, but also obvious distinctions. However, as we uncover more about the ability of radiation to induce abscopal effects between tumors and distant unirradiated metastases, a connection between low- and high-dose RT response within a single tumor versus multiple distant lesions is likely, that is, systemic antitumor effects driven by variations in radiation exposure levels. To update the major concepts at the time of printing this edition, we present a revised and updated version of the conclusions from the original 2018 National Institutes of Health (NIH) meeting on GRID/Lattice, FLASH, and microbeam in Table 18.2. Even with an intervening pandemic, strides have been made in the past 5 years, and more advances in the next 5 years are sure to accumulate.

TABLE 18.2 PROS AND CONS AND CURRENT STATE OF KNOWLEDGE (PRECLINICAL OR CLINICAL LITERATURE) FOR SPATIAL FRACTIONATION AND ULTRA-HIGH DOSE RATES

	GRID/Lattice	FLASH (UHDR)	Microbeam	Minibeam
PROS				
Reduction in treatment	Not determined	Not determined	Not determined	Not determined

	GRID/Lattice	FLASH (UHDR)	Microbeam	Minibeam
dose/time				
Normal tissue sparing	Yes	Yes, specific cases	Yes	Yes
Increased tumor response	Yes	ND	Yes	Yes
Mechanism of action	Yes, partially known	Hypotheses being tested	Yes, partially known	Yes, partially known
Enhanced antitumor immune activity	Yes	Equivalent	Yes	Yes
CONS				
Limited applications	Wide applicability, multiple modalities	Yes, still under study	Yes, facility dependent	No, orthovoltage, MV, and proton
Difficult to obtain technology	No	Yes/still developing	Yes	No (proton facilities more available)
Cost	Low	High	High	Low for photon
Site access	Nearly all sites (VMAT/tomotherapy)	Limited, safety of deep-seated still under study	Limited with traditional synchrotron	Moderate, depending on modality

Modified from Griffin RJ, Prise KM, McMahon SJ, Zhang X, Penagaricano J, Butterworth KT. History and current perspectives on the biological effects of high-dose spatial fractionation and high dose-rate approaches: GRID, microbeam and FLASH radiotherapy. *Br J Radiol*. 2020;93(1113):20200217.

Creating a standard for the treatment planning parameters required for spatial and ultra-high dose treatment will provide each patient the best chance of having a successful outcome, ultimately determining the value of these unconventional approaches to radiation medicine. This compilation of standards depends on efforts from a dedicated set of workgroups, physicians, and scientists, many of whom are actively working to fulfill these needs and inform and recruit the greater clinical community to participate. As with any new clinical modality, a careful approach to get the best outcomes possible and solidify the value of implementing cutting-edge rationale for novel effects will be required to expand clinical usage and establish new standards of care.

CHAPTER 19

Intraoperative Radiotherapy

William Sperduto, Jonathan B. Ashman, and Safia K. Ahmed

Intraoperative radiotherapy (IORT) is the delivery of a single, high dose of radiation during surgery to achieve higher effective target doses while displacing dose-limiting organs at risk (OARs). In the earliest preclinical studies and clinical trials, IORT was delivered as a solitary modality. Over time, IORT became part of multidisciplinary management as a boost dose in conjunction with conventionally fractionated external beam radiotherapy (EBRT) ± surgery ± chemotherapy. The EBRT-IORT combination theoretically can (1) improve locoregional control by reducing the risk of marginal relapse, (2) capitalize on the radiobiologic benefits of fractionated radiation, and (3) minimize normal tissue damage. Multiple methods of delivering IORT have been developed: intraoperative electron radiotherapy (IOERT), high-dose-rate intraoperative radiotherapy (HDR-IORT), and electronic brachytherapy/low-kilovoltage (kV) IORT. Despite advancements in techniques and technology, the bulk of IORT literature remains limited to small, retrospective, and often single-institution studies. Only five phase III randomized, controlled IORT trials have been published: four in Europe and one in the United States for patients with breast cancer and retroperitoneal sarcoma, respectively. National guidelines have no level I evidence, and there is no uniform expert consensus across US-based institutions on the appropriate use of IORT.

The following chapter begins with an abbreviated history of IORT followed by a discussion of the rationale behind IORT—using the linear-quadratic survival model and the four Rs of radiobiology. The physical and technical considerations, advantages, and disadvantages of each IORT technique— IOERT, HDR-IORT, electronic brachytherapy/low-kV IORT—will then be reviewed. Subsequently, the current evidence for using IORT and ongoing trials per disease site will be discussed. Two sections will be dedicated to discussing normal tissue tolerance and toxicity followed by a

practical step-by-step approach to an IOERT case. The chapter will conclude with a presentation of future directions for IORT as well as a list of suggested readings.

HISTORY OF INTRAOPERATIVE RADIOTHERAPY

A comprehensive history of IORT is beyond the scope of this chapter, but this section draws attention to some of the key developments in the evolution of the field. One of the earliest reported IORT-like procedures was performed on a 33-year-old woman with cervical cancer on March 11, 1905, in Barcelona, Spain.[1] After undergoing a total abdominal hysterectomy, pelvic lymph node dissection, and partial cystectomy, radiation was delivered through the open abdominal wall incision, which was protected by sterile lead sheets. She then received five additional fractions of postoperative EBRT and reportedly was alive and cancer free 10 years later.[1] From the 1930s through the 1950s, institutions in both the United States and Europe sought to treat a variety of malignancies by intraoperatively employing low-energy (50-250 kV) radiation, which was minimally effective due to poor tissue penetration. With the introduction of a linear accelerator (LINAC) producing megavoltage radiation in the early 1960s, Abe and Takahashi[2] at Kyoto University first combined tumor excision with a single high dose (25-40 Gy) of IOERT. In 1965, the first betatron was installed in an operating room, and these patients were treated with cobalt-60. Over the next 15 to 20 years, 717 patients with cancers of the stomach, pancreas, biliary tract, colon, prostate, bladder, lung, mediastinum, brain, and soft tissues were treated with IOERT at 27 Japanese hospitals.[2] Meanwhile, Howard University, Massachusetts General Hospital (MGH), the National Cancer Institute (NCI), and Mayo Clinic in Rochester, Minnesota, were the earliest US institutions to implement IORT programs, build IORT-dedicated operating rooms, and combine IORT with fractionated EBRT.[3-6]

Early IOERT had its limitations: LINACs and dedicated facilities were expensive, transporting anesthetized patients was not feasible, and applicators could not access deep and complex anatomic surfaces. During the late 1980s to early 1990s, these problems were overcome with the introduction of portable HDR-IORT and the flexible Harrison- Anderson-

Mick (HAM) applicator, allowing for greater target accessibility and treatments to be completed without patients being hospitalized overnight. Even as over 100 US institutions developed IORT programs, usage varied, and accrual of patients to phase III randomized trials remained difficult, which led to the dissolution of the Radiation Therapy Oncology Group (RTOG) IORT committee. Enthusiasm, collaboration, and widespread adoption of IORT have been promising across Europe, as evidenced by the formation of the International Society of IORT (ISIORT) in 1998 in Pamplona, Spain. Since the late 1990s, mobile HDR-IORT and IOERT units revitalized US interest and became cost-effective options for patients. The remainder of this chapter will provide an update on the IORT landscape from the early 2000s to the present day.

RADIOBIOLOGIC RATIONALE FOR INTRAOPERATIVE RADIOTHERAPY

The radiobiologic foundation for IORT is based on the linear-quadratic model (LQM) and the four Rs of radiobiology (*repair*, *repopulate*, *redistribute*, *reoxygenate*). The bulk of preclinical radiobiology research investigated the effect of single-fraction irradiation on tumor and normal tissue tolerance.[7] The LQM was developed to define a relationship between cell survival and radiation dose. The LQM suggests that cell killing is affected by two components—the linear (proportional to dose) and the quadratic (proportional to dose squared). These components contribute equally to cell killing at a dose equal to α/β. High α/β values (>7 Gy) correspond with acute-reacting tissues and most solid tumors, and low α/β values (<5 Gy) correspond with late-reacting normal tissues. Although the LQM has been widely adopted, ample evidence points to the overestimation of the effectiveness of cell killing at high doses.[8] One of the multiple proposed alternative models is the generalized LQM (gLQM), which predicts the high-dose response of cell lines based on the notion that high-dose radiation causes less sublethal damage and more lethal damage than low-dose radiation.[9] Each model has inherent weaknesses; for example, the gLQM does not account for cell cycle redistribution, reoxygenation, or the host immune response against tumor cells.[9] All models do, however, aim to

address the variable radiation sensitivities of normal tissues and tumors by producing dose-fractionation regimens that optimize the therapeutic ratio.

Modifications to the LQM have been made to better incorporate the four Rs of radiobiology. A single dose of radiation causes DNA double-strand breaks (DSBs) in tumor cells. Tumor cells either die or *repair* and *repopulate*. DNA DSBs are repaired via template-driven faithful homologous recombination or error-prone nonhomologous end joining, which are associated with radioresistance and radiosensitivity, respectively. Tumor cells can also become more radiosensitive by *redistributing* into late G1, G2, and M cell cycle phases and *reoxygenating* hypoxic areas.[10] The predominant benefit from IORT is derived from exposing the tumor to a single high dose of radiation and physically displacing normal tissues out of the IORT field. The four Rs justify the value of fractionated radiotherapy and why IORT is often combined with EBRT. Figure 19.1A demonstrates how IORT places normal tissues at a disadvantage and how a smaller dose per treatment is less toxic. For IORT to be successful, dose-limiting structures must be excluded from the radiation field. Maximizing tumor control and minimizing toxicity requires a knowledge of normal tissue tolerance and α/β ratios to estimate the biologically equivalent doses between single-fraction IORT and conventionally fractionated EBRT regimens (Figure 19.1B).

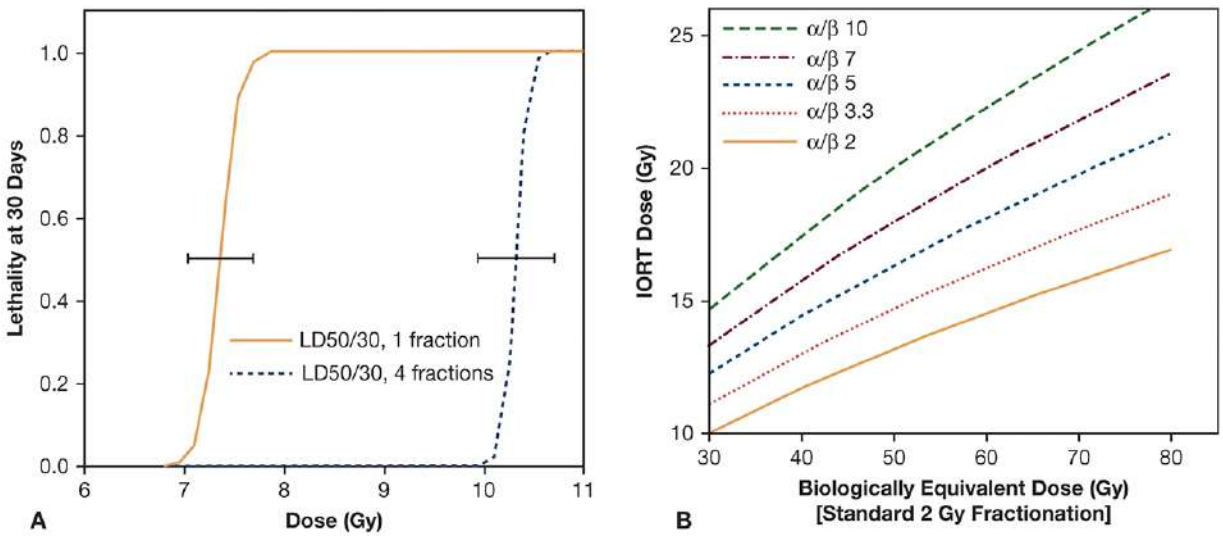

FIGURE 19.1 Lethal dose-fractionation benefit and biologically equivalent dose. A. Normal tissues benefit greatly from fractionation. $LD_{50/30}$ = dose of radiation expected to cause death to 50% of an exposed population within 30 days. Error bars represent a 95% confidence interval of $LD_{50/30}$. B. The estimated biologic effect of a given IORT dose is compared with that of radiation given in standard 2-Gy daily fractionation. α/β values = tumor (10), acute-reacting normal tissue (7), brain (3.3), and late-reacting normal tissue (2). IORT, intraoperative radiotherapy. (Reprinted by permission from Springer: Okunieff P, Sundararaman S, Metcalfe S, Chen Y. Biology of large dose per fraction irradiation. PHYSICAL AND TECHNICAL CONSIDERATIONS

Intraoperative Electron Radiation

IOERT was popularized in the 1970s and 1980s using conventional stationary LINACs; since 1999, mobile units have become more commonplace. The three commercially available mobile linear accelerators (LINACs)—Mobetron (United States), LIAC (Italy), and Novac 7 (Italy)—have transformed the delivery of IORT and made it more accessible by eliminating the need to transport the patient to a radiation suite. These LINACs produce electrons ranging from 4 to 12 MeV and benefit from low-stray, focused, straight beams.[11] Their design avoids high Z materials and minimizes bremsstrahlung. Electrons continuously lose energy as they traverse tissue, thus making them most effective at treating superficial tumors. Nevertheless, a bolus (0.5 or 1 cm thick) may be necessary, especially at lower electron energies, to improve surface dose. For IOERT

LINACs with electron energies up to 12 MeV, neutron production is minimal.[12,13] Mobile LINACs are lightweight and have no bending magnets, so low-penetrating photon leakage and electron scatter are relatively negligible.[14] With self-shielding and beam stoppers, there is little to no role for additional operating room (OR) shielding.[14]

Decision making surrounding IOERT dose (typically 7.5-20 Gy) and electron energy depends on the total EBRT dose and the amount of tumor remaining after surgical resection. Prescribed doses are often set to the 90% isodose line. IOERT disadvantages include, but are not limited to, fluid accumulation (such as in the posterior pelvis), which reduces beam penetration, and areas at risk may be too large to be covered within a reasonable treatment field.[15] Gantry and table movements enhance target localization, but some treatment fields remain anatomically inaccessible due to machine limitations. Cylindrical applicators come in various sizes and shapes with different bevel angles (Figure 19.2A). The applicator diameter must be slightly larger than the target diameter. Noncylindrical applicators also have been developed to address larger and more rectangular targets often encountered in the treatment of extremity and retroperitoneal sarcomas. Once the sterile applicator is positioned over the target and secured to the operating table, the LINAC is moved into position and docked. The Mobetron uses a laser guidance feedback system to achieve soft docking—the optical and mechanical alignment of the central axis of the LINAC and the applicator without forming a physical connection (Figure 19.2B). If there is unexpected movement of the patient, applicator, or machine, the decoupled soft-docking process reduces the risk of patient injury. Hard-docking systems, utilized by the Novac 7 and LIAC, directly connect a receptor on the radiation head to a thick-walled clear, plastic applicator.

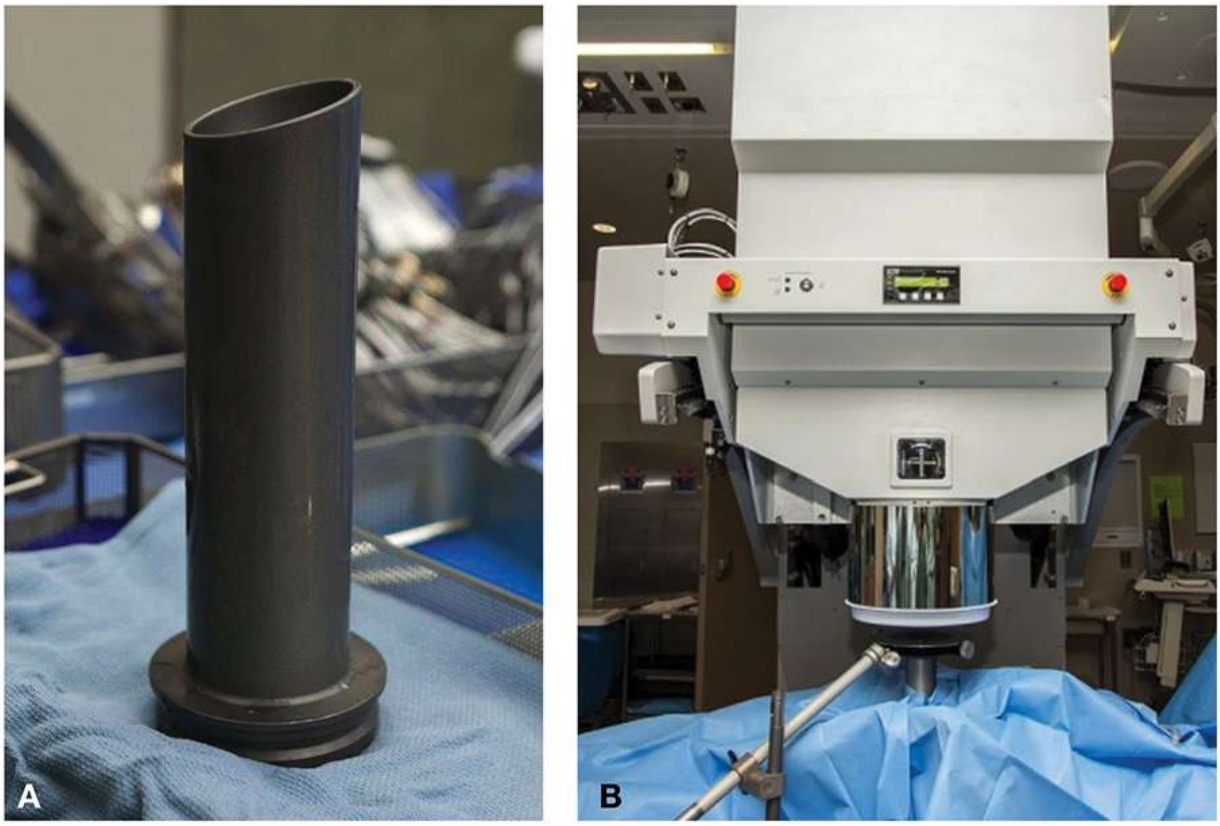

FIGURE 19.2 A. An 8-cm diameter circular applicator with a 15-degree bevel. B. Soft docking.

Quality assurance (QA) for a mobile IOERT LINAC is similar to that for a stationary LINAC, with a few distinguishing steps. Given the limited window of opportunity to deliver IORT, a careful, systematic, and efficient approach to QA is of the utmost importance. Mobile machines do not have adjustable collimators or bending magnets. Calibration at all electron beam energies determines scatter foil selection and is performed on the day of surgery. Output and docking must be scrutinized. Employing small water phantoms and limiting beam-on time in an unshielded OR improve QA efficiency. The American Association for Physicists in Medicine (AAPM) Radiation Therapy Committee Task Group published a report discussing the differences between stationary and mobile IOERT LINACs as well as recommendations for implementing an IORT program, given the unique issues of radiation protection, machine commissioning, and efficient QA.[16] Reducing uncertainties with treatment calibration and dosimetry (distribution, effect, inhomogeneity) and refining manufacturer

documentation and atlases will help standardize IORT procedures and establish its therapeutic benefit.[11]

High-Dose-Rate Intraoperative Radiotherapy

In the 1960s, IORT using HDR brachytherapy gained traction, thanks to the development of the remote afterloader and the HAM applicator. HDR-IORT takes advantage of physically displacing or shielding OARs to deliver a single high dose of radiation to a superficial target. Remote afterloaders direct the source, typically iridium-192, through a small catheter into the patient applicator, which must rigidly secure the catheter yet flexibly conform to the target. The HAM applicator is available in different sizes and can be cut lengthwise in the OR to customize the number of channels needed to cover the target. One of its strengths is physical flexibility, which allows for better conformality along curved surfaces like the pelvis and the ability to treat targets geometrically inaccessible to electrons, such as the anterior pelvis. The downside of HDR-IORT is longer treatment time, which increases surgical risk and OR cost. Also, ORs must be shielded similar to brachytherapy suites. Compared to IOERT dose distributions, those created by HAM applicators are more heterogeneous, which increases the risk of hot spots in nerves and in-field normal tissues like the duodenum in unresectable pancreas cancer. These advantages and disadvantages of HDR-IORT with the HAM applicator versus IOERT must be taken into consideration to select the most appropriate IORT technique. In mid-2022, the AAPM issued an HDR brachytherapy practice guideline presenting the infrastructure necessary to create an afterloader-based HDR brachytherapy program.[17] Two governing bodies, the US-based Nuclear Regulatory Commission (NRC) and the International Atomic Energy Agency (IAEA), have standardized regulations for the safe use of radioactive material (RAM) and nuclear technologies to minimize staff and patient exposure. The report outlines regulatory requirements (RAM licensing, personnel monitoring, shielding, source security, proper transportation, record-keeping), clinical practice recommendations (professional society and manufacturing guidelines), facility specifications (dedicated/shared suites, OR settings, mobile HDR units, kV/computed tomography [CT]/magnetic resonance imaging [MR] imaging), and staffing considerations (training,

certification, credentialing).[17] Afterloaders have intrinsic safety features: authorized use with a key and password, emergency switches, storage in a locked cabinet, and rechargeable batteries.[18] Additionally, source extension has numerous fail-safes. Automatic source retraction occurs when resistance is met, treatment is complete, or the treatment door is opened.[18]

QA for HDR-IORT involves a series of tests to verify the functionality of the remote afterloader, source, applicator, guide tubes, and treatment planning system (TPS). The AAPM-recommended frequency of these various tests has been tabulated.[17] Within 24 hours of an HDR-IORT procedure, a systematic checklist of tasks must be completed. The afterloader/source QA checks (1) source strength, positioning, and retractability; (2) door interlocks; (3) audiovisual monitoring and emergency response; (4) catheter connections; (5) calibration equipment; and (6) communication between console and TPS.[17] The length and integrity of the applicator and guide tube connections must be visually inspected before each treatment. Finally, before adopting a new modification or software update to the HDR-IORT process, a comprehensive dry run is warranted. A more in-depth review of the physics, biology, and clinical applications of low-dose and HDR brachytherapy will be covered in subsequent chapters.

Low-Kilovoltage-Intraoperative Radiotherapy and Electronic Brachytherapy

Two IORT devices—the Zeiss Intrabeam and the Xoft Axxent—have been developed using low-energy x-rays (30-50 keV) in an unshielded OR. The minimal radiation protection requirements make these technologies appealing to treatment modalities. The inherent steep dose gradient of low-energy x-rays minimizes normal tissue toxicity. Tungsten shields and wet gauze are used to protect normal tissue. The Zeiss Intrabeam system was introduced in the late 1990s and accelerates electrons down a miniature tube to hit a hemispheric gold target, producing an isotropic x-ray distribution. The unit is small, lightweight, and maneuverable. Meanwhile, the Xoft Axxent electronic brachytherapy has been in clinical use since 2008 and employs a microminiature tube and a Wolfram target. Its water-cooling system and heavier filtration enable higher dose rates and quicker dose

falloff. The Axxent can perform ^{192}Ir HDR brachytherapy. Source lifetime is over 10 years and about 2.5 hours for Intrabeam and Xoft Axxent systems, respectively.[19] More frequent source replacement necessitates new calibration and QA.

The Intrabeam uses a source centered within a solid, 1.5- to 5-cm-diameter spherical applicator, which produces a homogenous surface dose. The Axxent system utilizes three applicator types: 3- to 6-cm-diameter spherical or 5- to 7-cm-diameter ellipsoidal inflatable balloons, 2- to 3.5-cm-diameter vaginal cylinders, and skin applicators.[11] Spherical and balloon applicators must closely adhere to the surgical cavity. Dose is prescribed to the spherical applicator surface, and steep dose gradients allow for lower exposure to surrounding normal tissues. The multiple channels in balloon applicators enhance dose distribution and enable the treatment of asymmetrical targets. By using low-energy radiation, these portable IORT units can be safely operated in unshielded operating rooms. Poor tissue penetration, which limits the depth of treatment and restricts clinical application, is a major disadvantage to low-energy radiation. Both systems have safety features involving on/off status indicators, emergency switches, and real-time output dose monitoring. Intrabeam/Axxent commissioning, calibration, and QA processes have been summarized.[11,19] Nag et al[15] compared IOERT, HDR brachytherapy, and low-kV x-rays in regard to treatment field size and timing, the rationale for IORT multimodality, as well as the potential advantages and disadvantages.

EVIDENCE BY DISEASE SITE

Breast Cancer

Three IORT studies investigated the contemporary trend of de-escalating treatment time and treated breast volume—known as accelerated partial-breast irradiation (APBI)—in patients with early-stage breast cancer. Key findings from these trials are summarized in Table 19.1. Two randomized phase III equivalence trials (ELIOT and NSABP B-39/RTOG 0413) demonstrated that postlumpectomy APBI and whole-breast irradiation (WBI) were not equivalent.[20,21] In the ELIOT trial, patients who received IOERT experienced higher rates of ipsilateral breast tumor recurrence (IBTR) and no difference in overall survival (OS).[20] The ELIOT trial had

the longest follow-up among all randomized APBI studies and showed IOERT may be used for select patients at low risk of IBTR.[20] NSABP B-39/RTOG 0413 had a large heterogeneous patient population, included multiple APBI techniques not only IORT, and favored postlumpectomy WBI over APBI; however, the 10-year IBTR absolute difference between WBI and APBI was less than 1%—suggesting APBI may be an acceptable alternative.[21] One additional randomized phase III trial concluded that APBI was noninferior to WBI.[22,23] Risk-adapted single-dose 50-kV photon–targeted IORT delivered via a spherical applicator to the tumor bed at the time of breast-conserving surgery was found to be a suitable alternative to EBRT with similar 5-year local control and survival outcomes and reduced nonbreast cancer mortality.[22,23] Taken together, these three trials had mixed results, suggesting partial-breast IORT may be used in carefully selected patients. The results of two completed phase III trials conducted in Italy (NCT01276938) and England (NCT00983684) are eagerly awaited.

TABLE 19.1 SUMMARY OF THE PHASE III RANDOMIZED IORT TRIALS FOR EARLY-STAGE BREAST CANCER

Trial	*N*	Dose Regimen A: IORT B: WBI	IBTR % at 10 y A: IORT B: WBI	OS % at 10 y A: IORT B: WBI	Grade 3 Toxicity Rate (%) A: IORT B: WBI
ELIOT	1,305	A: 21 Gy/1 Fx B: 50 Gy/25 Fx (+10 Gy boost)	A: 8.1 (SS) B: 1.1	A: 90.7 B: 92.7	A: 0 B: 3
NSABP B-39 (RTOG 0413)	4,216	A: 34 Gy brachy or 38.5 Gy/10 Fx BID B: 50 Gy/25 Fx (±10 Gy boost)	A: 4.6 B: 3.9	A: 90.6 B: 91.3	A: 10 B: 7
TARGIT-A	2,298	A: 20 Gy/1 Fx B: 40-56 Gy (±10-16 Gy boost)	A: 3.2[a] B: 1.2	A: 96.3[b] B: 95.2	A: 0.2[c] (SS) B: 0.75

BID, twice daily; Fx, fraction; IBTR, ipsilateral breast tumor recurrence; IORT, intraoperative radiation therapy; *N*, number of patients; OS, overall survival; RTOG, Radiation Therapy Oncology Group; SS, statistically significant difference between A and B; WBI, whole-breast irradiation.

[a]IBTR rates at a median follow-up of 8.6 years.

[b]OS rates at 5 years.
[c]Reported as grade 3 or 4 toxicity.

A prospective registry trial accrued 1,367 patients with breast cancer treated to a dose of 20 Gy using 50-kV IORT at Hoag Memorial Hospital Presbyterian in California from 2010 to 2020 and observed similar local, regional, and distant recurrence rates to those reported in the TARGIT-A and ELIOT trials.[24] Although IORT achieved slightly higher recurrence rates compared to whole breast radiation therapy (WBRT), Silverstein et al[24] reported 10,000 to 100,000 patient-hours saved with IORT and encouraged physicians to gauge patient interest in receiving IORT and accepting a significantly increased risk of local recurrence with no apparent impact on survival in exchange for a single precise dose that saves time, money, medical environment exposures, and surrounding normal tissue. Another prospective trial investigated using a 10-Gy IOERT tumor bed boost (in 52 patients postlumpectomy with R0 resections) followed by 48-Gy/24-fraction WBI for early-stage breast cancer.[25] Wong et al[25] reported favorable 6-year local control and cosmetic outcomes but additionally advised caution in performing secondary surgical procedures on the lumpectomy bed after IOERT boost, given more pronounced breast fibrosis and wound healing difficulty. Nevertheless, in the United States, no randomized phase III trials evaluating IORT for patients with breast cancer have been conducted. Given that IOERT has achieved mild acute and late toxicities as well as minimally impaired cosmetic outcomes, the ESTRO/ACROP IORT Task Force supports the use of IOERT-boost and full-dose IOERT in patients at a higher risk (tumor size >2 cm, axillary nodal involvement, grade 3, triple-negative hormone receptor status) and low risk of in-breast recurrence, respectively.[26]

Brain Cancer

IORT has been used to treat primary and secondary brain tumors. The gold standard treatment for newly diagnosed glioblastoma (GBM) is surgical resection followed by concomitant EBRT and temozolomide chemotherapy and then maintenance temozolomide.[27] Unfortunately, GBM tends to progress over 6 to 7 months, and most recurrences occur within the

resection cavity.[27] Delayed adjuvant treatments allow tumor cells to repopulate, and IORT may be able to address these spatial and temporal issues. In phase I/II, dose-escalation Intraoperative Radiotherapy in Newly Diagnosed Glioblastoma (INTRAGO) trial, Giordano et al[28] demonstrated the delivery of Intrabeam low-energy IORT via a spherical applicator to the surgical cavity of 15 patients was safe with manageable toxicity and promising local control. The international phase III INTRAGO II trial is actively accruing, and results are eagerly awaited (NCT02685605).

GliaSite brachytherapy has been used to treat recurrent GBM and brain metastases. The GliaSite balloon catheter provides a precise, conformal, relatively homogenous, easily reproducible dose distribution. The goal is to deliver radiation near the resection margins—the area at the highest risk of recurrence. Twenty-four patients with unifocal recurrent GBM tumors (≤30 cc, not extending across the midline) underwent surgical resection followed by GliaSite radiotherapy at Johns Hopkins Hospital and experienced mild short- and long-term side effects, but survival was similar to patients who had re-resection, chemotherapy, or external beam reirradiation.[29] Performance status (KPS < 70 or ≥70) at the time of GliaSite was significantly associated with improved survival.[29] Two groups from Henry Ford Hospital and the Cleveland Clinic conducted nonrandomized prospective studies using GliaSite brachytherapy and Intrabeam mobile IORT, respectively, for solitary brain metastases and concluded these technologies were safe, effective, and well tolerated but only achieved comparable local control and survival to other treatment modalities.[30,31] With only modest results and the need for a second operation to remove the device, GliaSite manufacturing has largely been discontinued. A group in Barcelona, Spain, is actively recruiting for their phase II trial evaluating Intrabeam IORT after surgical resection of brain metastases (NCT05084092). IORT for solitary brain metastases is investigational at best, and stereotactic radiosurgery (SRS) remains the mainstay treatment for these patients.

Sarcoma

Adult

The role of IORT has been investigated in the management of primary and recurrent soft-tissue sarcomas predominantly located in the retroperitoneum or extremities. Retroperitoneal sarcomas are invasive, expansile, and challenging to manage with resection alone. These patients tend to experience high local recurrence rates, which is the most common cause of death. In the only phase III randomized controlled trial using IORT for retroperitoneal sarcoma, Sindelar et al[32] found patients receiving IORT experienced significantly lower locoregional recurrence and radiation-enteritis rates yet higher radiation-related peripheral neuropathy rates. In a German single-center, single-armed, prospective phase II clinical trial where 27 patients with retroperitoneal sarcoma received IORT, the study's primary endpoint of 5-year local control of 70% was not met likely due to enrollment of patients with recurrent disease, high-grade lesions, and leiomyosarcoma histology. These situations often derive less benefit from IORT.[33] Also of note, the STRASS trial comparing the efficacy of preoperative radiotherapy to surgery alone on abdominal recurrence-free survival in patients with primary retroperitoneal sarcoma did not include IORT.[34]

Postoperative EBRT boosts may not be effective, given the potential for tumor repopulation and hypoxia in the tumor bed as well as the presence of adjacent bowel, but IORT mitigates these factors.[35] Two Mayo Clinic retrospective series report encouragingly high long-term local control (LC), limb preservation, and survival rates in patients who received IORT for upper-extremity soft-tissue sarcoma.[35,36] Roeder et al[37] summarize the major IORT series published between 1988 and 2017 and the ESTRO/ACROP IORT Task Force recommendations informing the management of extremity and retroperitoneal soft-tissue sarcoma. The ESTRO/ACROP guideline discusses patient selection and care, IORT's role in multimodal therapy, and treatment dose, volume, and delivery.[37] Although favorable disease control and toxicity have been demonstrated, further phase III randomized clinical trials are needed to elucidate if IORT provides a true survival benefit for this disease entity.

Pediatric

Pediatric sarcomas are rare and heterogeneous, and data in support of using IORT for these patients primarily come from small, single-institution experiences. Nine children with incompletely resected sarcomas received IOERT (8-15 Gy) in combination with EBRT at the University of Heidelberg and achieved 3-year OS and actuarial disease-free survival (DFS) of 77% and 67%, respectively.[38] Given low toxicity and late morbidity rates, the group concluded that IOERT is safe and allows for a higher probability of local control than EBRT alone.[38] In a 20-year experience, the Mayo Clinic reported favorable long-term local control and survival outcomes for 13 pediatric patients with sarcomas who received IOERT (7.5-25 Gy) along with EBRT.[39] Memorial Sloan-Kettering Cancer Center (MSKCC) published a 20-year experience of 75 pediatric patients with sarcoma who received HDR intraoperative brachytherapy as part of their multimodal treatment.[40] The MSKCC study highlighted the strengths of intraoperative brachytherapy: versatility, flexible applicators, ease of access to anatomic locations, ^{192}Ir rapid dose falloff, and sparing of sensitive structures.[40] IORT may be suitable for select cases, but the routine use of image-guided, intensity-modulated, and proton radiotherapy has changed the treatment paradigm for pediatric malignancies.

Gastrointestinal Cancers

Gastric Cancer

Extended lymph node dissection and regional failure after surgical resection for gastric cancer contribute to poor prognosis in this patient population. Developing adjuvant tumoricidal approaches, like IORT, to treat recurrent/residual disease may improve regional control. Two studies from Jiao Tong University in Shanghai, China, have investigated adding IOERT to surgery and trimodality, respectively.[41-43] Between 1992 and 1998, 106 patients ages 25 to 80 with gastric adenocarcinoma were treated with total/subtotal gastrectomy combined with D2 or D3 lymphadenectomy plus IOERT, and survival rates were compared to 441 patients who underwent surgery alone.[41] Statistically significant improvements in 5-year survival rates by 15% to 20% were noted for stage II and III patients treated with IOERT, respectively.[41] Of the 48 stage III patients, those who had D2 resections achieved a 5-year survival benefit (60% vs 35.7%) and those

who had D3 resections achieved a 4-year survival benefit (85.5% vs 62.2%) when IOERT was performed compared to those undergoing surgery alone.[41] A prospective, nonrandomized series found adding IOERT to trimodality therapy was well tolerated and significantly improved 3-year locoregional control in patients with locally advanced (stage T3, T4, or N+) gastric adenocarcinoma.[42] Multivariate analysis showed statistically significant prognostic factors for locoregional control (adjuvant IORT, extent of residual disease [R0 vs R1], pN disease [pN0, N1, N2, N3]) and OS (pT category [pT1-T2, T3, T4] and pN disease [pN0, N1, N2, N3]).[42] A nonsignificant marginal increase in DFS was observed in this cohort treated with D2 gastrectomy and IOERT followed by adjuvant chemoradiotherapy.[43] To date, the largest phase II trial of patients with gastric cancer who underwent curative surgery plus IORT was conducted in Freiburg, Germany, and concluded that lower locoregional recurrence rates did not translate into a 5-year OS benefit.[44] Calvo et al[45] reported high local control and 5-year OS of 54.6% in their contemporary retrospective series of 32 patients with stage II or III primary gastric adenocarcinoma treated with a curative-intent D2 resection and IORT. The limited clinical data in this space can be attributed somewhat to gastric cancer being a rare disease entity and specialized IORT facilities being geographically scattered. Although the locoregional benefit of IORT in gastric cancer has been established, long-term survival outcomes across treatment modalities deserve to be examined in prospective, randomized controlled trials.

Pancreatic Cancer

Most patients with pancreatic cancer will present with metastatic disease or develop metastatic disease after local therapy. Only a selected group of patients may benefit from IORT. From 1978 to 2001, 150 patients at MGH with locally advanced pancreatic cancer (LAPC) received IOERT combined with definitive EBRT and 5-fluorouracil-based chemotherapy.[46] Although only modest 3- and 5-year survival rates (7% and 4%, respectively) were reported, long-term survival was achieved in eight patients, five of which were alive at or beyond 5 years, and improved OS was significantly related to smaller IOERT applicator diameter (tumor size surrogate).[46] Since 2006, MGH has used induction gemcitabine to screen for patients with LAPC

most likely to benefit from chemoradiation and IORT instead of post-IORT maintenance chemotherapy.[47] MGH studied 194 patients with LAPC treated with IORT and those who received chemotherapy, had small tumors, and had low pretreatment Charlson age-comorbidity indices achieved a median OS of 21.2 months and 3-year OS of 20%.[47] Between 2002 and 2010, 28 patients with borderline resectable or locally unresectable pancreas cancer underwent preoperative chemoradiation followed by restaging, surgical resection, and IOERT at Mayo Clinic Arizona.[48] Extent of surgical resection had a statistically significant impact on OS: 3-year OS was 36% after R0/R1 resection, whereas no patients with R2 resections were alive at 3 years.[48] Another contemporary MGH retrospective review of 158 patients with borderline resectable or LAPC reported the combination of IORT with surgical resection improved survival for those with positive/close margins or unresectable, nonmetastatic disease.[49] The disease control and survival outcomes findings were consistent across the studies described earlier.

Given the high propensity for patients with LAPC to develop abdominal relapses and distant metastases, more effective systemic therapies must be developed to see improved survival outcomes in this patient population. The MGH Phase II Pancreatic AdenoCarcinoma with Electron intraoperative Radiation therapy (PACER) trial is actively recruiting and is examining the efficacy of IORT in treating pancreatic cancer after 3 to 6 months of chemotherapy and EBRT (NCT03716531). The ESTRO/ACROP IORT Task Force formally published recommendations for IOERT in unresected and borderline- unresected pancreatic cancer, as it has been shown to be a risk-adaptive technique that improves local control and long-term survival in well-selected patients.[50,51] In the United States, however, no formal guidelines exist for treating pancreatic cancer with IORT, and it is only performed in specialized centers.

Colorectal Cancer

Optimal management of locally advanced rectal cancer (LARC) requires aggressive chemoradiotherapy and radical surgical resection. Complete resections are difficult to obtain due to the frequent involvement of pelvic bones. Only two randomized controlled trials have examined standard-of-care treatment plus IORT for rectal cancer. The Japanese study found

equivalent oncologic outcomes between the control (bilateral lateral lymph node dissection [LLND] + limited pelvic autonomic nerve preservation [PANP]) and IORT (bilateral LLND + complete PANP + IORT) groups and was limited by sample size (n = 44).[52] The French study enrolled 142 patients with LARC, randomized them to 4 weeks of preoperative radiotherapy + surgical resection ± IORT, and failed to demonstrate an LC and DFS benefit between groups.[53] The latter study may not have included the ideal candidates for IORT, as nearly 90% of patients had stage T3 disease.[53] Two prospective cohort pooled analyses have shown the benefit of IORT in local control and survival in patients with LARC and positive margins.[54,55] Alberda et al[56] retrospectively analyzed patients with microscopically involved circumferential resection margins and reported 5-year local recurrence-free survival favoring those who were treated with IORT versus without IORT (84% vs 41%, P = .01). The ESTRO/ACROP have formally published recommendations for using IORT in patients with primary locally advanced and locally recurrent rectal cancer, as IOERT has consistently achieved long-term local control and higher survival rates.[57,58]

Gynecologic Cancers

The evidence for a potential benefit of IORT in gynecologic cancers is predominantly from small, single-institution, retrospective series involving heterogeneous cancer types. A group at Stanford Cancer Center retrospectively reviewed 36 patients with gynecologic cancers treated with IORT between 1986 and 2005, and multivariate analysis demonstrated numerous significant prognostic factors.[59] Disease-free interval as a continuous variable was prognostic for locoregional control; smaller tumor size was associated with improved distant metastasis-free survival, and longer disease-specific survival correlated with cervix primary, prior surgery, and lower locoregional relapse rates.[59] Long-term survival was even demonstrated in two patients who received IORT for positive margins after pelvic exenteration.[59] Between 1994 and 2011, 32 patients with advanced or recurrent gynecologic malignancies were treated with IOERT at MGH, and 5-year OS was significantly improved in patients who had microscopic disease (40.9%) versus gross residual disease (9.1%).[60] Three Mayo Clinic studies have been informative in this space. A small but

significant number of women with recurrent endometrial cancer, locally advanced cervical cancer, or recurrent cervical cancer received combined modality therapy plus IOERT and experienced long-term survival even if extensive pelvic surgeries had to be performed.[61,62] Three-year progression-free survival and OS benefits were observed in patients with locally recurrent gynecologic cancer who experienced complete tumor resections with curative-intent radical extirpation, irrespective of whether or not patients received IORT.[63] Backes and Martin[64] published a literature review in 2015 summarizing the role of IORT in treating cervical, endometrial, and ovarian cancers. Altogether, promising results have been published; however, high-level evidence is lacking, and routine use of IORT to treat gynecologic malignancies remains controversial.

Other Sites

Clinical data supporting IORT remains limited for many disease sites. In 2017, Pilar et al[65] published a review article summarizing the IORT literature to date for both more commonly (breast, soft-tissue sarcoma, gastrointestinal) and less commonly (head and neck, gynecologic, genitourinary, pediatric) studied disease sites.

NORMAL TISSUE TOLERANCE AND TOXICITY

One of the primary goals of IORT is to deliver the maximal effective dose to the tumor while limiting toxicities. Preclinical research using canine models in the early 1980s helped establish normal tissue tolerance guidelines. Most of these studies focused on abdominopelvic tissue tolerance and were conducted at the NCI and Colorado State University (CSU). A comprehensive list of the NCI experimental studies and radiation parameters is provided.[66] Table 19.2 summarizes maximum IOERT dose tolerance values and toxicity thresholds for normal canine tissues observed in the foundational NCI studies.

TABLE 19.2 TOLERANCE DOSES TO IORT IN CANINE MODELS

System	Organ	Maximum Tolerated IORT Dose (Gy)	Maximum Follow-Up (mo)	Comments
Cardiothoracic	Aorta	30	60	Threshold for fibrosis, patency to 60 Gy
	Vena cava	30	60	Threshold for fibrosis, patency to 60 Gy
	Arterial anastomosis	30	36	Threshold for stenotic occlusion
	Arterial graft	30	24	Threshold for occlusion
	Heart	30	60	Threshold for fibrosis, no clinical effects to 40 Gy
	Tracheobronchus	30	60	Threshold for fibrosis, no clinical effects to 40 Gy
	Bronchial suture line	40	60	Intact to 40 Gy, bronchovascular fistulae at 20 Gy
	Lung	20	60	Threshold for fibrotic pneumonitis, no clinical effects to 40 Gy
Gastrointestinal	Esophagus	20	60	Ulceration and stricture with full-thickness exposure, no sequelae to 40-Gy partial thickness
	Duodenum	18	6	Threshold for ulceration, obstruction, or perforation
	Small intestine diverted loop	45	60	Defunctionalized bowel loop, no clinical effects, fibrosis at ≥20 Gy
Hepatobiliary-pancreatic	Bile duct	20	60	Threshold for fibrosis and stenosis
	Bile duct anastomosis	<20	12	Dehiscence at all doses ≥20 Gy

System	Organ	Maximum Tolerated IORT Dose (Gy)	Maximum Follow-Up (mo)	Comments
Urinary	Kidney	15	60	Threshold for tubular loss
	Ureter	30	60	Threshold for fibrosis and stenosis
	Bladder	30	60	Threshold for ureterovesical junction stenosis, normal contractility to 40 Gy
Nervous	Peripheral nerve	15	60	Threshold for motor neuropathy

IORT, intraoperative radiotherapy.

The canine experience with incremental dose escalation provides valuable insights into specific tolerances of common OARs.[66] Maximum single IOERT dose tolerated by any tissue is influenced by prior EBRT. The aorta and vena cava can tolerate large, single doses of radiation, but extrapolating to smaller vessels requires caution. Ureteral volume within the irradiated field must be considered to minimize the risk of ureteral stenosis and obstruction. IOERT doses above 20 Gy may cause ureteral and renal damage whereas doses below 20 Gy are unlikely to lead to chronic toxicity. IORT is often indicated when tumor compression or invasion causes painful peripheral neuropathy. In general, IORT doses of 10 to 12.5 Gy have been associated with low neuropathy risk compared to doses of 15 Gy or higher.[67] Vujaskovic et al[66] described in detail the above takeaways and other considerations for the spinal cord, bone, soft tissue, and gastrointestinal and thoracic organs. IORT-associated malignancies are exceedingly rare. Given that higher bone absorption is seen with orthovoltage compared to electron radiation, care must be exercised to minimize the risk of IORT-related bone necrosis and secondary malignancy.

PRACTICAL APPROACH TO AN INTRAOPERATIVE ELECTRONS RADIOTHERAPY CASE

Although clinical scenarios will vary by disease site, available technology, and physician expertise, the following steps provide a generalizable stepwise approach to an IOERT case using a Mobetron.

1. A pretreatment evaluation includes history and physical examination, routine labs, CT/MRI imaging, and often a staging positron emission tomography (PET)/CT scan. It is prudent to obtain a confirmatory biopsy prior to surgery when planning a potential IORT case.
2. Selecting appropriate candidates for IORT requires shared decision making. Localized disease with a high likelihood of incomplete resection and increased risk of local failure within the tumor bed are important selection criteria. Surgeons and radiation oncologists may hold a multidisciplinary tumor board discussion to determine the appropriate sequence of surgery/IOERT and EBRT. Preoperative EBRT is favored as it may downstage the tumor, facilitate curative-intent surgery, keep vasculature intact for improved oxygenation, limit OAR exposure, and limit IOERT dose.
3. Surgical and radiation oncologists review treatment goals, risks, benefits, alternatives, and logistics with the patient and obtain informed consent.
4. The patient is brought to the operating room. Surgical resection is performed. Frozen section pathologic analysis, if available, can guide the real-time decision to use IOERT or not. If there are close margins or microscopic/gross residual disease, the surgeon and radiation oncologist discuss further excision versus proceeding with IOERT. Multidisciplinary teamwork and communication between the surgeon, radiation oncologist, medical physicist, anesthesiologist, and operating room staff are crucial.
5. Normal uninvolved tissue is mobilized and excluded from the anticipated radiation field. Alternatively, lead shielding can be used for adjacent structures that are uninvolved by the tumor but cannot be mobilized, such as the ureter or nerve.
6. The radiation oncologist measures the treatment field and chooses a site-specific applicator based on size, shape, anatomic configuration, and whether a beveled applicator is necessary or not.

7. Choice of electron energy factors in real-time intraoperative measurements, presurgical imaging, and ensures the target is within the 90% isodose line with appropriate surface dose. Medical physics support is valuable for this decision-making process.
8. IOERT prescription dose depends on the extent of residual tumor, prior radiation received, and the normal tissue type and volume included in the radiation field. Generally, 10 to 12.5 Gy is used for microscopic close margins, 15 Gy for microscopic positive margin, and 17.5 to 20 Gy for gross residual disease. Bolus is considered to ensure adequate surface dose.
9. Once the applicator is docked and aligned with the gantry, everyone exits the operating room. Prior to treatment delivery, a timeout is taken and the medical physicist and radiation oncologist double-check the electron energy, applicator placement, and monitor unit calculations.
10. The treatment is delivered rapidly (typically over 1-2 minutes), and then the team enters the operating room to carefully remove the applicator. The surgery resumes, and afterward, documentation is completed, including the operative notes and anesthesiology report. Professional clinical photographs may be obtained at any point throughout the procedure.

FUTURE DIRECTIONS

Intraoperative Radiotherapy and Global Health

In resource-limited developing countries, single-fraction IORT is an attractive option. To our knowledge, two groups in South Africa have used IORT to replace EBRT in the treatment of breast cancer. Baatjes and Apffelstaedt[68] stress the value of IORT to extend breast conservation to underserved patients who cannot adhere to lengthy EBRT regimens. Ramdas et al[69] reported the viability of IORT and favorable short-term oncologic outcomes of the 107 patients with breast cancer treated at the first IORT facility on the African continent. The cost- effectiveness of IORT should be part of the shared decision-making process between physicians and patients. Two groups used Markov decision-analysis models over 10-year time spans to investigate the cost-effectiveness of IORT for patients

with early-stage breast cancer after breast-conserving surgery. When comparing single-dose IORT versus 6-week WBI in the TARGIT-A patients, IORT was the preferred, more convenient, cost-effective option, and demonstrated a quality-adjusted life-year benefit.[70] The model determined the local recurrence risk (LRR) for IORT would need to be over 23% at 10 years for a 6-week WBI to be a cost-effective strategy.[70] Meanwhile, Deshmukh et al[71] studied cost-effectiveness from societal and health care sector perspectives considering when radiation- associated disutility either persisted beyond or ceased at 5 years after treatment. Their comparison of conventional fractionation (CF)-WBI (5-7 weeks) versus hypofractionated (HF) WBI (3-4 weeks) versus IORT (1 day) revealed that HF-WBI was the most cost-effective option across all modeling scenarios.[71] With an increasing emphasis on climate change and sustainability, IORT has been estimated to save 20 million miles of travel when used to treat over 45,000 patients with early-stage breast cancer at 260 centers in 35 countries.[72] Patient values, therapy costs, local control rates, treatment time commitment, quality of life, and IORT accessibility will remain at the heart of this decision for women.

Intraoperative Radiotherapy and Novel Therapies

IORT may contribute to the abscopal effect—a radiation-induced, T-cell-mediated distant tumor inhibition—and has the potential to act synergistically with immunotherapy.[73,74] A small exploratory study of patients with early-stage breast cancer who received 20 Gy of IORT at the time of breast-conserving surgery used flow cytometry to assess peripheral blood samples (collected preoperatively and postradiation at 48 hours, 3 weeks, and 10 weeks) and found increased peripheral natural killer cells, which may harbor antitumor capacity.[75] SRS in conjunction with immune checkpoint inhibitors for patients with resected brain metastases may provide an OS benefit, and replacing SRS with IORT may have a similar effect while irradiating a smaller volume of normal brain and avoiding the healing time needed after brain metastasectomy.[76] Another exciting opportunity, currently under preclinical investigation, is the work exploring the effect of delivering radiosensitizing nanoparticles at the time of IORT.[74] Conceivably, as more is understood regarding proton beam and carbon-ion

radiation therapy, IORT may be delivered using these technologies.[74] Furthermore, one actively recruiting trial out of Columbia University will shed light on the molecular signatures of the luminal A and triple-negative breast tumor microenvironments before and after IORT is delivered (NCT03165487). The ongoing clinical trials mentioned throughout this chapter will enhance our understanding of the dynamic role of IORT. Inspired by ISIORT pooled analyses across Europe, international collaboration and data sharing will facilitate the much-needed prospective, randomized phase III IORT trials.

CHAPTER 20

Particle Therapy: Protons, Heavy Ions, and Neutrons

Nancy P. Mendenhall and Perry B. Johnson

This chapter discusses the rationale, current and emerging technologies, applications, outcomes, and challenges associated with particle therapy. While the terms *hadron* and *light ion therapy* are sometimes used in the literature to describe treatment with protons or various charged nuclei, their use has been inconsistent and overlaps with other terms, leading to some confusion. The nomenclature we use in this chapter and recommend for clarity in the future is as follows: "particle therapy" refers to treatment with any charged particle or neutrons; "charged particle therapy" refers to treatment with protons or any other charged particle; and "heavy ion therapy" refers to treatment with ions heavier than protons ($^{1}H^{+1}$)), including helium ($^{4}He^{+2}$), carbon ($^{12}C^{+6}$), and ($^{16}O^{+8}$).

RATIONALE

Therapeutic Ratio

With any medical intervention, there is an optimal balance between the potential to benefit and the potential to harm a patient, known as the therapeutic ratio. In radiation oncology, it is the balance between radiation effects on the tumor and normal, nontargeted tissues. This ratio informs every physician and patient decision. Different priorities drive different decisions in certain clinical situations. For example, in a sinonasal tumor, one physician might recommend a treatment that results in a lower probability of disease control but minimizes the risk of optic nerve damage, whereas another physician might recommend a treatment that results in a higher probability of disease control but carries a greater risk of optic nerve damage. In another example, the potential risks of low-dose radiation exposure to a large volume of brain tissue may be of greater concern to the parents of a young child than to an older patient with a short life expectancy. When radiation therapy is indicated in any clinical situation, the first question is whether there is a potential to improve the therapeutic ratio by using a specific radiation modality, delivery mechanism, or technique.

The Impact of Dose Distribution on the Therapeutic Ratio

Many factors influence radiation effects and the therapeutic ratio: total dose, dose intensity (the overall time), the number and size of daily radiation fractions, as well as the interfraction interval, dose rate, relative biologic effectiveness (RBE), and modifying factors, such as chemotherapy, patient age, and comorbidities. No factor is as important as the dose distribution—the dose to the target compared with the dose to nontargeted normal tissues—because radiation therapy is a nonspecific intervention that affects both normal and cancerous cells. A basic principle in radiation oncology is that the higher and/or more intense the radiation dose, the greater the probability of tumor control. Similarly, the higher and/or more intense the radiation dose to a normal tissue, the greater the probability of injury. A second less well-understood principle is that the volume of tumor or normal tissue exposed to various radiation dose levels impacts the effect. For example, a higher dose of radiation to an organ may be tolerated if the absolute or relative volume of exposure to the organ at risk (OAR) is limited. In addition, critical components of either an OAR or a tumor may require a higher or lower dose for a clinical response. For example, the hypoxic section or the positron emission tomography (PET)-avid portion of a tumor may require a higher dose than the rest of the tumor for disease control. These principles of dose- and volume-response relationships have been observed in both malignancies and normal tissues. However, these principles may not always be discernible if effective doses are not delivered to critical volumes (of tumor or normal tissue), if adequate tools for measuring response (toxicity or functional compromise) are not available, or if observation time is insufficient for the effect to manifest.

The primary barrier to maximizing local tumor control through dose escalation or intensification is the risk of damaging normal tissues, either by delivering too high a dose to a critical tissue or by exposing too great a volume of the critical normal tissue to a potentially harmful dose of radiation. *The most direct means of improving the therapeutic ratio is reducing radiation dose and exposure to nontargeted tissues, which both reduces toxicity and*

facilitates dose escalation for increased tumor control. Herein lies the primary rationale for charged particle therapy (proton [$^{1}H^{+1}$] and heavy ions [eg, $^{4}He^{+2}$, $^{12}C^{+6}$, $^{16}O^{+8}$]).

The Problem With Photons (X-Rays) and the Promise and Challenge of Charged Particles

The pattern of dose deposition with photon-based external beam radiotherapy (Figure 20.1) is problematic because the dose to tissues along the beam entrance path is always higher than the dose to the target and additional dose is deposited in nontargeted tissues along the exit path of the beam. *Thus, most of the radiation dose with photon-based therapy is deposited outside the target.*

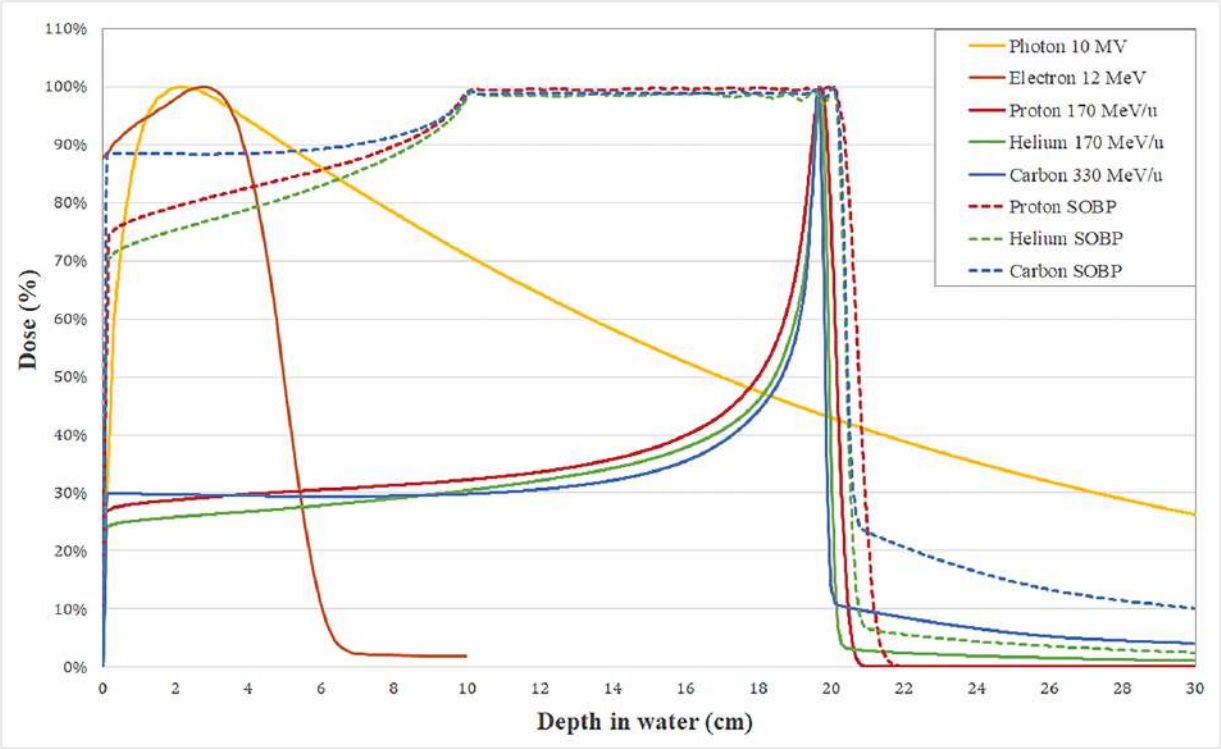

FIGURE 20.1 As shown here, the shapes of the relative depth-dose curves for 10 MV photons (yellow), 12 MeV electrons (orange), and pristine proton (red), helium (green), and carbon (blue) Bragg peaks. Compared to photons and electrons, the ratio of entrance dose to target dose is reduced when using proton, helium, or carbon ions. In addition, compared to electrons, the potential depth of penetration is significantly deeper and the dose falloff at the end of range is much sharper. With protons, there is no exit dose, while for helium and carbon, a small tail of dose exists due to nuclear fragmentation. This phenomenon is also responsible for the slightly higher entrance dose of carbon beams when compared to protons (not accounting for radiobiologic differences). Spread-out Bragg peaks (SOBPs) for protons (red dashed), helium (green dashed), and carbon (blue dashed) are shown in this graph. These curves are created by stacking multiple pristine Bragg peaks with varying acceleration energies. The width of the SOBP can be made to correspond to the thickness of the target.

Many elegant strategies have been developed for offsetting this basic problem (eg, three-dimensional conformal radiation therapy [3DCRT], intensity-modulated radiation therapy [IMRT], volumetric modulated arc therapy [VMAT], stereotactic radiosurgery [SRS], and stereotactic radiation therapy [SRT]), but with these technologies, radiation to nontargeted tissues is primarily redistributed rather than reduced. Because the total dose to a given tissue is one of the key determinants of toxicity, certain toxicities are reduced when using these sophisticated techniques. It is likely, however, that other toxicities will increase owing to methods that redistribute the integral dose over a greater volume of normal tissue. Some effects from low-dose exposure may require more time for clinical manifestation (second malignancies), and some may require more subtle tools for detection (neurocognitive testing), leading to an early underestimation of toxicity with these sophisticated photon delivery methods.

The dose deposition pattern with charged particles differs significantly from that of photons. Protons and heavy ions carry a positive charge, which means each particle type can be accelerated and directed by magnets. Charged

particles have mass, meaning they will not travel an infinite distance but only to the range or depth in tissue determined by the acceleration energy. In a patient, particles can be made to stop at a depth corresponding to the tumor depth. As charged particles traverse matter, they lose energy primarily through interactions with atomic electrons. Because of the significantly larger mass of protons (≈1,800×), carbon (≈21,600×), and other heavy ions relative to electrons, charged particles lose only a small portion of their energy in each interaction (in contrast to x-rays) and experience only small directional changes. The energy deposition pattern of a particular type of radiation is determined by the particle's track structure, including its core, which reflects interactions of the primary particle, and its halo, which includes secondary interactions.[1]

As charged particles traverse matter, the rate of energy loss in electronic interactions is described by the linear stopping power, S(E), defined as dE/dx, where dE is the mean energy lost by a particle in electronic collisions over a distance of dx in media. A more commonly used function is the mass-stopping power, s = S(E)/ρ, which denotes the energy loss dE when particles travel through a distance of dx in a media of mass density ρ. Mass-stopping power can be described by the Beth-Bloch formula. In this formulation, mass-stopping power is inversely proportional to the square of the particle's velocity. Thus, as velocity (energy) decreases, the mass-stopping power rapidly increases, creating the characteristic pattern of dose deposition known as the Bragg peak, a sharp peak in energy deposition immediately before the particle stops in the media. With heavy ions such as carbon, nuclear fragmentation at the end of range results in a small tail of dose deposition beyond the Bragg peak (see Figure 20.1).

Linear energy transfer (LET) is closely related to stopping power and defines the density of energy deposition along a particle track. As charged particles lose velocity, the distance between consecutive energy deposition events decreases. As a result, the density of the ionization pattern, that is, LET, increases, particularly within the Bragg peak. When protons are used in particle therapy, LET ranges from 2 to 10 keV μm^{-1}; for heavy ions such as helium, LET ranges from 4 to 40 keV μm^{-1}; and for heavier ions such as carbon, LET can exceed well over 100 keV μm^{-1}. LET is important in relation to the propensity of the radiation for causing double-stranded DNA breaks (DSBs), which are the principal mechanism for inducing cell death. Low LET radiation, such as photon therapy, often requires the conjunction of several tracks to produce DSBs, while a single track of high LET radiation is independently capable of producing multiple DSBs. Thus, for a given dose, high LET radiation is more effective at inducing cell death than low LET radiation. While the LET with particle therapy increases with reduced velocity in the Bragg peak at the end of the particle's range, the highest LET for a given particle beam is just downstream or beyond the Bragg peak.

Much work has been done toward modeling the correlation between LET, a physical quantity, and RBE, a biologic parameter defined as the ratio of the doses of two different radiation modalities necessary to cause the same biologic effect.[2] In vitro studies suggest the correlation is complex and sensitive to the α/β value and potentially the genetic profile of individual cell lines. Several phenomenologic models have been developed based on these studies; however, many models produce different results when considering the α/β values of different tissues.[3,4] Of importance, the current clinical practice in charged particle therapy is to prescribe an RBE-weighted absorbed dose, Gy (RBE), equal to the measured physical dose in Gy multiplied by either a constant or model-based RBE factor.[5] In proton therapy (PT) treatment planning currently, an RBE multiplicative factor of 1.1 is uniformly applied to the physical dose without explicitly accounting for the increase in RBE values near the end of a proton-beam range.[5] However, RBE ratios within the Bragg peak can range from 1.3 to 2.2 depending on which model is utilized.[3]

RBE effects are more significant for ions such as carbon. The lack of convergent and validated RBE models, particularly for heavy ions, is a major source of uncertainty. Two carbon ion therapy models are in current use: the Microdosimetric Kinetic Model developed at the National Institute of Radiological Sciences and largely in use in facilities in Japan,[6-8] and the Local Effect Model (LEM) developed at Gesellschaft fur Schwerionenforschung mbH, validated and largely in use by German carbon facilities.[9,10] Ishikawa et al reported a large and successful experience in prostate treatment using an RBE value of 3.[11] Kang et al, in reviewing the outcomes achieved with various dose fractionation schema with carbon in low-risk prostate cancer, determined an effective RBE of 2.19 to 2.12 for Gy (RBE) delivered in fractions of 3.3 to 4.3 Gy (RBE), with a decreasing RBE associated with increasing fraction size.[12] A recent prospective controlled trial comparing protons and carbon in prostate cancer using the LEM reported similar acute effects between protons and carbon[13] but significantly lower disease control rates with carbon compared to protons[14]; the inferior disease control rates with carbon were attributed by the investigators to an overestimation of the RBE of carbon by the LEM. Although much work has been done, more research on

carbon effects at various doses, doses per fraction, and tissue types is needed to inform treatment planning for clinical applications with carbon ion therapy.[15]

While such challenges exist, the broad relationship between LET and RBE can be used to inform the treatment planning approach. LET evaluation, whereby the LET distribution is displayed during treatment planning, is now widely available in PT and can be used to help select beam arrangements and design blocking structures that preferentially place higher LET values within the target and outside organs at risk (OAR). Going further, LET-guided optimization is now available in at least one treatment planning system and is primed for widespread adoption. The technique affords a low barrier to entry in that treatment plans that mimic the physical dose of current plans can be created to provide optimized LET distributions. It is possible that these techniques will unlock unrealized benefits of PT for several treatment sites and/or explain unanticipated normal tissue effects. As an example, in treating the prostate with protons, the classic beam arrangement involves opposed lateral beams that end up placing many of the proton Bragg peaks distal to the clinical target in the expanded planning target volume (PTV); this is done to account for uncertainties related to radiologic beam path and target motion. However, with LET-guided optimization, the beam arrangement can abut the prostate's interior, leading to a boost in LET within the clinical target that may be significant for an organ such as the prostate with a low α/β value. Such solutions offer hope for improved outcomes in the future but have not yet been tested clinically.

In addition to energy loss through electronic collisions and their impact on dose and LET, high-energy charged particles also experience nuclear interactions in media. Such interactions remove particles from the initial fluence and produce secondary protons, neutrons, and heavier particles, such as deuterons, tritons, and α particles; these particles contribute only a small percentage of the dose along the beam path.[1] Although negligible, most of the dose from the neutrons produced in these nuclear interactions is deposited downstream from the stopping point of the particle beam, beyond the Bragg peak. The neutrons produced by protons within the patient, as well as those produced in the beam delivery mechanical components, have been under intense investigation for their potential secondary cancer-inducing effects. Hall raised concerns that such scattered neutrons may increase the incidence of secondary tumors in patients treated with historical PT systems,[16] similar to concerns with the transition from conventional 3DCRT to IMRT.[17] Much research has been done to estimate secondary cancer risks from contemporary PT systems using scattering beam or scanning beam techniques.[18] Consistent reductions in secondary cancer induction have been predicted with protons compared to photons in studies of medulloblastoma, prostate cancer, and liver cancer.[19-21] A clinical outcome study comparing actual secondary cancers between a cohort of patients treated with protons at the Harvard Cyclotron and a cohort of photon-treated patients matched by age and tumor type from the Surveillance, Epidemiology, and End Results database showed nearly twice as many secondary cancers in the photon cohort.[22] A more recent analysis of the National Cancer Database (NCDB) showed a statistically significant increase in secondary malignancies (5×) after photon radiation with either 3DCRT or IMRT compared with protons apparent as early as 2 years after treatment for men with prostate cancer.[23] A retrospective study comparing secondary cancer incidence in men treated for prostate cancer with carbon therapy, photon therapy, and surgery has similarly demonstrated a significantly lower risk of secondary cancer with carbon compared with photon radiation and no demonstrable increase in secondary malignancies with carbon compared with surgery.[24] Given these results and the fact that modern PT techniques contribute fewer neutron contaminants than early PT sources, it is evident that neutron production is of much less concern for late effects than excess integral doses as delivered in photon therapy.

The primary rationale for an improved therapeutic ratio with charged particles, compared with photons, is thus the significant reduction in integral dose (dose to nontargeted tissues) that stems from a lower entrance path dose and the absence (protons) or near absence (heavy ions) of any exit path dose. These dosimetric differences should translate into a lower risk of complications for a given target dose, a greater probability of tumor control, and potentially lower secondary cancer risks for patients. A lower risk of complications could also be leveraged to permit dose escalation or intensification (yielding higher disease control in certain settings) or to facilitate hypofractionation (reducing patient inconvenience and treatment costs in other settings).

It is also important to note that aside from differences in integral dose, differences between photon and charged particle interactions with tissue may impact clinical effects through differences in cell-killing efficiency, DNA damage patterns, response signaling and repair pathways, and variation in sensitivity due to genetic variations. Recently, much work in this domain has been well summarized in a series of recent reviews.[25-35] However, much more work will be necessary to understand whether differences between photon and charged particle interactions with tissue can be leveraged to improve clinical outcomes.

TECHNOLOGY

Beam Production and Transport in Proton Therapy

Protons are produced from either hydrogen gas obtained from the electrolysis of deionized water or commercially available sources of high-purity hydrogen gas. Applying a high-voltage electric current to hydrogen gas strips the electrons from the hydrogen atoms, leaving positively charged protons. The protons are then accelerated to energies applicable to clinical PT with either a cyclotron or a synchrotron (Figure 20.2). In a classic cyclotron, protons are magnetically confined by a static magnetic field that exists orthogonal to the direction of travel. Due to this magnetic field, protons originally move in circular orbits, gaining energy as they cross the gap between two D-shaped electrodes aptly described as "dees." An oscillating electrical field is induced between the dees by radio frequency (RF) energy and timed such that particles are bunched and accelerated together in a resonant process. Each time protons cross the gap, they gain more energy and their orbit increases. Once reaching the exit energy of the cyclotron, they are extracted and enter the beamline.

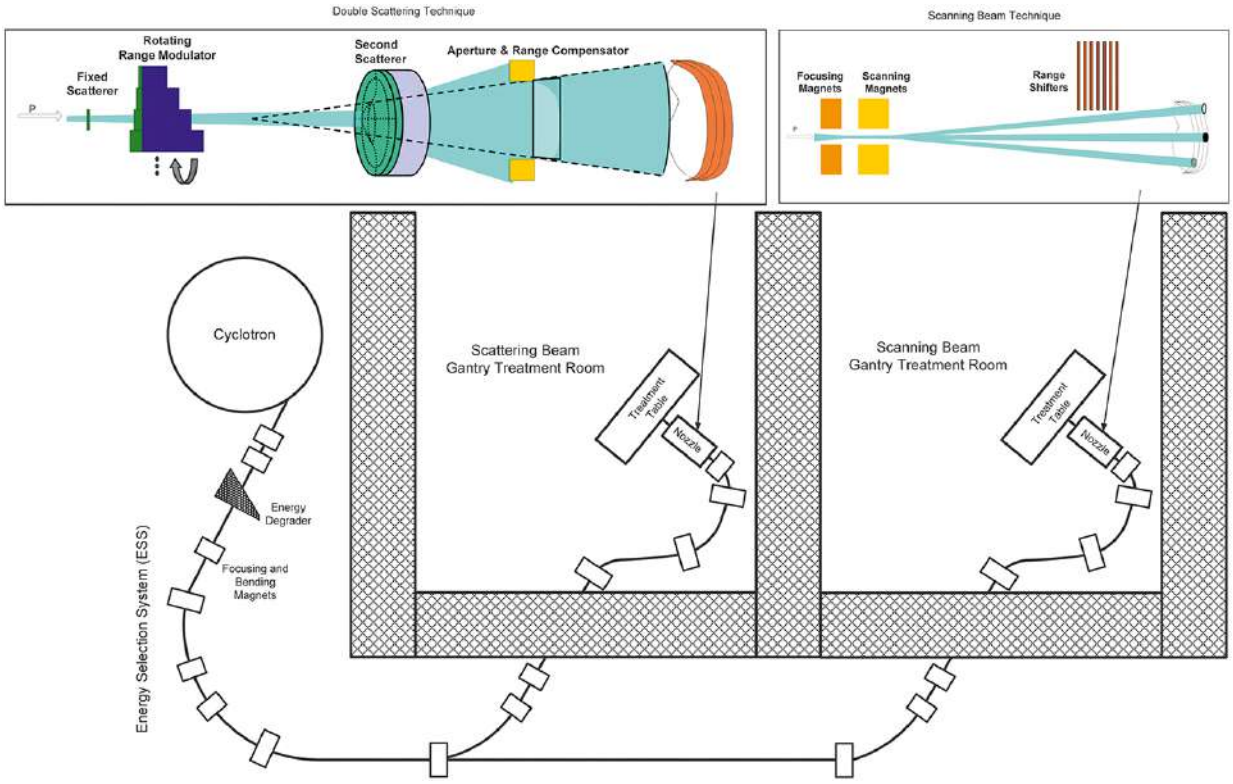

FIGURE 20.2 A proton therapy system with a cyclotron, energy selection system, beamline, gantry, and nozzle. Scattering is illustrated in the nozzle on the left and scanning in the nozzle on the right.

Energies as high as 230 MeV are required to penetrate deep into the body. At these energies, protons travel at approximately 60% of the speed of light, and relativistic effects cannot be ignored. Medical cyclotrons, therefore, must be designed to accommodate for the relativistic increase in the mass of the protons as they gain energy. In an isochronous cyclotron, this is handled by increasing the magnetic field strength along the radius of the proton orbits. As protons gain mass, it takes more magnetic focus to keep them in a tight orbit and in phase with the constant RF field. In a synchrocyclotron, the magnetic field remains constant with respect to the radius, but the RF is adjusted to maintain resonance. Because the RF is variable with respect to time, the system operates as a pulsed beam versus the isochronous cyclotron, which effectively operates as a continuous beam. Isochronous cyclotrons are typically larger and require a higher power consumption than synchrocyclotrons but are also generally better understood, involve a less complex RF system, and can produce higher peak beam intensities. Both systems have been configured with superconducting magnets to increase the magnetic field strength and confine the protons to tighter orbits. In such cases, the cyclotron's diameter, weight, and space requirements can be greatly reduced. For

example, the diameter of IBA's C230 isochronous cyclotron is approximately 4.5 m, and the system weighs nearly 240 tons. However, IBA's superconducting S2C2 synchrocyclotron has a diameter of 2.2 m and weighs only 46 tons. The drawback of a superconducting system is that it requires more complex ancillary systems and can experience several hours of downtime if cooling is lost and superconductivity is interrupted.

Cyclotrons produce nearly monoenergetic and unidirectional protons. Once the protons are accelerated to the preconfigured extraction energy of the cyclotron, they enter the energy selection system (ESS), which consists of a degrader, collimator, bending magnets, and momentum or "energy slits." The degrader has movable segments that introduce a variable amount of material, typically graphite, into the beam path. The beam energy is degraded (reduced) through interactions within the material to provide the appropriate range for a given treatment field. This process introduces an unfavorable dispersion in the energy spectrum. To mitigate this effect, achromatic bending is introduced using electromagnets whereby protons with higher energy follow a larger bending radius than protons with lower energy. The spread-out beam then passes through energy slits, which eliminate protons with bending radii that are different from that of the desired energy. The minimum energy achieved by the ESS is typically 70 to 100 MeV. Further energy reduction requires using an acrylic block or "range shifter" located on the beam exit immediately prior to the patient.

In contrast to the systems described above, synchrotrons produce proton beams of varying energies, which can be selected, eliminating the need for energy degraders and selection devices. A proton pulse exiting a preaccelerator, with energy typically up to 7 MeV, is injected into the ring-shaped accelerator. Each complete circuit of the proton pulse through the accelerator ring structure incrementally increases the proton pulse energy. When the desired beam energy is reached, the proton pulse is extracted from the accelerator. The time segment between pulses depends on the final energy required of the proton beam, ranging from subseconds to several seconds for the highest beam energy. Beam currents from synchrotrons are typically much lower than with cyclotrons, thus limiting the maximum dose rates that can be used for patient treatment, especially for larger field sizes. The maximum dose rate from a commercially available synchrotron-based PT system for a 25-cm × 25-cm field has been specified at 0.8 Gy/min.[36] The elimination of the energy degrader and selection system removes a major source of neutron production and, thus, the subsequent activation of beamline components in the accelerator vault. A synchrotron vault is, therefore, accessible for maintenance immediately after the beam is stopped, whereas approximately 30 minutes is necessary to allow the neutron-activated parts of a cyclotron and ESS to "cool down" before maintenance can be performed, sometimes longer if access to internal parts of the cyclotron is required. The shielding requirements for cyclotrons are also higher than for synchrotrons because of the higher neutron radiation produced by the ESS. However, the overall footprint of a cyclotron vault, including the additional shielding required, is actually similar to or smaller than that of a synchrotron vault because of the smaller physical dimensions of cyclotrons.

The proton beam is transported to the treatment room(s) by the beam transport system on exiting the ESS for a cyclotron-based system or exiting the accelerator for a synchrotron-based system. The ability to maintain beam focusing, centering, spot size, and divergence throughout the beam transport system is critical to delivering high-quality PT. Paganetti et al performed Monte Carlo calculations of the dosimetric effect of proton-beam energy spread, spot size, and angular energy spread on the shape of the Bragg peak.[37] They found that small deviations in these parameters from their nominal values result in a widening of the Bragg peak and increased entrance doses. Beam transport systems in clinical proton facilities, therefore, include bending (dipole) and focusing (quadrupole) magnets and beam profile monitors so that the proton-beam quality may be monitored and adjusted ("tuned") as it is transported through the beam transport system. At the end of the transport system, the beam enters the room either at a fixed angle (eg, horizontal beam), a combination of fixed angles sometimes termed an "inclined beamline" (eg, horizontal beam and one angled 30° off the vertical), or at various angles through the use of a movable gantry. Gantry-based systems are extremely large (up to 10 m in height) due to the wide radius needed to bend high-energy beams (up to 250 MeV) using magnetic fields.

The beam transport system can be configured to accommodate single- or multi-room facilities. With a multi-room system, queuing is necessary as the beam can only be available in one room at a time. Large multi-room facilities were the dominant format for PT until the mid-2010s when single-room designs were introduced. Since then, single-room systems have grown in popularity due to their lower cost of entry. These systems are often designed with compact gantries (approximately 200° of rotation) that utilize a robotic couch to rotate the patient along a vertical axis. In this way, the system can achieve all of the beam angles of a standard gantry but within a smaller footprint and with a more open design. Taking this concept further, upright delivery is a reemerging technology/technique that combines a fixed treatment beam with a rotating chair-based platform. Here, the patient

is rotated around a superior-inferior axis to deliver PT from multiple directions without needing a large gantry. Several challenges exist in translating the imaging and treatment paradigm from a supine to an upright position, but if successful, the concept will further reduce the size and cost of the equipment needed for PT.

Beam Delivery in Proton Therapy

The proton beam exiting the transport system (Figure 20.2) is a pencil-shaped beam with minimal energy and directional spread. The beam has a small cross-sectional (spot) size and a narrow Bragg peak at the end of its range in water. Two basic techniques have been developed to convert this narrow pencil beam into a dose distribution suitable for treating a 3D target, broadly categorized into the "scattering" or "passive scattering" techniques and the "scanning, active scanning, or pencil beam scanning (PBS) technique." These techniques are implemented in the machine treatment head or "nozzle," which is the section of the system that extends into the treatment room.

The scattering technique produces a dose distribution with a dispersed, typically flat lateral profile and a depth-dose curve that includes an entrance "plateau region" with a lower dose, and a high-dose region known as the "spread-out Bragg peak" (SOBP). The SOBP is produced by summing several individual Bragg peaks, each with progressively reduced maximum energy and range, to produce a sufficient width (along the beam path) to cover the thickness of the target. The weights of the individual Bragg peaks are optimized to achieve dose uniformity within the SOBP. A proton beam that produces constant energy may be used for such treatments, with range-reducing materials inserted into the beam path to create the individual Bragg peaks that form the SOBP. Range modulation wheels consisting of variable thicknesses of "acrylic glass" (polymerized methyl methacrylate) or graphite steps are traditionally used for this purpose.[37] The proton beam travels through the variable thickness steps, with each step creating a Bragg peak of a precalibrated range. When the desired width of the SOBP is reached, the beam is turned off. Alternatively, a "ridge filter" may be used to create an SOBP[38] with the advantage of eliminating sensitivity to organ motion in the formation of the SOBP but with the added complexity that each ridge filter is designed to achieve a single SOBP width.

The scattering technique produces a large, dispersed lateral dose profile through physical scattering filters placed in the proton-beam path. One scattering filter may be used, which creates a wide beam with a Gaussian dose profile known as a single scattering beam. A single scattering beam, with limited field sizes, is used primarily in dedicated treatment rooms for PT of ocular tumors, such as choroidal melanoma, and proton SRS treatments of brain lesions. Alternatively, and more often, a second scattering filter (double scattering [DS]) can be added to the beam that flattens the lateral dose profile. Apertures fabricated out of brass or other metals are used to confine the treatment field to the target. A tissue-equivalent range compensator, or bolus, is designed to adjust the beam range within the field to conform to the distal profile of the target. With the scattering technique, it is not possible to achieve conformity of the dose distribution to the proximal contour of the target. The passive scattering technique is an analog to 3DCRT historically used in photon therapy.

In the scanning technique, as the pencil beam exits the transport system, it is magnetically steered laterally to deliver the dose across the treatment field. The technique is colloquially known as "spot scanning" or "pencil beam scanning" (PBS), in that the dose is delivered as a series of individual spots within a given layer. The depth of the layer is determined by the beam energy, which is sequentially decreased to deposit the dose at multiple layers, moving from distal layers first to proximal layers through the target until the prescribed dose has been delivered to the target volume. A given layer may have hundreds of spots, and the intensity of each spot can be modulated to achieve intensity-modulated proton therapy (IMPT). The size of the spot, represented by the σ of the Gaussian function describing the pencil beam profile, is a critical parameter of the pencil beam. Smaller beam σ values allow intricate sculpting of the intensity-modulated dose distribution but require increased control system complexity and delivery time; larger beam σ values result in faster dose delivery but produce a greater lateral penumbra and a reduced dose gradient at interface regions of the target and critical organs.

Similar to the interplay effect reported for IMRT,[39] scanning techniques are sensitive to respiratory motion because time is required to move the pencil beam across a given layer and between layers. During this time, target or organ motion can occur, resulting in underdosage and/or overdosage of parts of the target. A potential strategy for mitigating this interplay effect is to deliver multiple smaller, incremental doses to each spot either by "repainting" each layer multiple times before changing the beam energy to scan the next layer (layer repainting) or by consecutively scanning each layer of a given target volume once, followed by rescanning of the entire target volume several additional times during each treatment fraction (volumetric repainting). Studies have shown that limiting each volumetric repainting to approximately 4% of the prescription dose can significantly reduce the

interplay effect in certain cases.[40] Standard motion mitigation measures, such as breath-holding, gated therapy, and abdominal compression, may also be necessary to minimize the dosimetric effects of organ motion. Other motion mitigation strategies include using a larger spot size, selecting beam angles along the trajectory of motion, balancing the dose evenly among multiple beams, and/or using 4D accumulated or dynamic accumulated dose calculation.[41]

The advantages of active scanning over passive scattering are the reduction in dose proximal to the target, the ability to create complex dose distributions through intensity modulation, the decreased need for apertures and compensators, and the reduction in secondary neutron contamination, which affords less radiation shielding in the design of the facility. The advantages of passive scattering over active scanning include a faster beam delivery, which negates the interplay effect and improves operational efficiency. Of the two, active scanning is the newer technique, and over the past several years, proton vendors have switched to active scanning both in their new systems and as upgrades to legacy, passive scatter systems.

Treatment Planning in Proton Therapy

Treatment planning for PT requires a volumetric computed tomography (CT) scan data set that includes the target volume and surrounding tissue through which beams will pass. The CT Hounsfield unit (HU) numbers are converted to proton-stopping power values to calculate the proton range required for the treatment field.[42] Unlike the relatively reliable conversion of CT numbers to relative electron density for photon dose calculations, errors and uncertainties in converting CT numbers to proton-stopping power in proton dose calculations translate into proton range calculation uncertainties and errors. In clinical practice, these uncertainties are handled during the treatment planning process by bracketing the target with a distal and proximal margin in the range calculation of each treatment field. Other considerations in determining the values for distal and proximal margins include target motion, daily setup errors, beam delivery uncertainties, and uncertainties in patient anatomy and physiology changes throughout treatment that could affect the water-equivalent depth of the target. It is worth noting that the concept of a PTV, as defined in the various International Commission on Radiation Units and Measurements reports,[43,44] does not strictly apply to PT. Generally, a PTV expansion, with either uniform or nonuniform margins, is used for photon planning, accommodating maximum target motion and setup error in each of the patient axes (longitudinal, lateral, and anterior/posterior). In contrast to photon planning, the PTV for PT is specific for each treatment field. In the lateral direction of the beam's eye view of a proton field, margins are identical to traditional definitions, but the distal and proximal margins along the beam axis are calculated to account for proton-specific uncertainties. The lower entrance dose and absence of exit dose of a proton beam afford additional flexibility in selecting beam angles for which lateral target motion and setup error are minimal.

With its additional ability to modulate dose intensity within and outside the target region, the active scanning technique requires additional considerations in treatment plan optimization. Single-field optimization (SFO) allows the treatment planning system to optimize the plan on a field-by-field basis so that each field will deliver a nearly uniform dose that covers the target to the extent that OAR constraints permit. SFO improves plan robustness by reducing the plan's sensitivity to deviations in the delivery of any single treatment field. Multifield optimization (MFO), on the other hand, allows each treatment field to deliver a heavily modulated dose distribution to a subvolume of the target and relies on the accurate delivery and combination of all fields to achieve plan goals. The MFO optimization technique can thus achieve the highest plan quality but potentially increases sensitivity to the effects of delivery uncertainties. IMPT plans may use either SFO, MFO, or a combination. IMPT plans are further optimized with consideration for various sources and magnitudes of delivery uncertainties, such as range uncertainties, setup errors, and breathing motion that are included within the optimizer through various perturbed plan scenarios. The number of scenarios to include within the robust optimization process can be as high as several thousand, significantly increasing the computational burden on the treatment planning system. However, the recent utilization of graphical processing units for robust optimization has mitigated these concerns, and IMPT plans can now be robustly optimized within a few minutes or hours instead of several hours or days. Robustly optimized plans are evaluated by calculating the nominal treatment plan on a number of perturbed CT data sets, which simulate various range uncertainties and patient shifts, for example, +3.5% HU and +3 mm anterior shift. The resulting dose-volume histogram (DVH) bands can be assessed with regard to their spread, and individual scenarios can be compared against institutional standards.

Even with strategies to account for proton range uncertainties, comparisons of treatment plans involving proton and photon techniques generally demonstrate a striking advantage with protons for reducing the volume of

nontargeted normal tissue receiving a low to medium dose. In some cases, the volume of nontargeted tissue receiving a moderate to high dose is also reduced. With passively scattered proton delivery modes, the target dose homogeneity and conformity index can sometimes, but not always, be inferior to IMRT/VMAT. With scanned proton delivery modes, IMPT plans can, in addition to reducing low and moderate integral doses, also improve dose homogeneity and conformity indexes when compared with IMRT/VMAT.

State-of-the-art PT dose calculations use pencil beam algorithms that model proton interactions and scattering in various media of the beam path, including the nozzle, range compensators, and patient. Monte Carlo calculations have been used to study the accuracy of such dose calculation algorithms, with results indicating errors near-tissue interfaces, particularly near interfaces of media differing in density and composition, such as the air cavity and bone in head and neck treatments.[45,46] Several fast Monte Carlo calculation algorithms are now included in modern treatment planning systems and greatly improve PT dose calculation accuracy.

Technical Summary of Heavy Ion Therapy

Carbon Ion Therapy

In many ways, the treatment planning and delivery of heavy ion therapy is very similar to PT. Charged nuclei, specifically carbon ions, are accelerated using large synchrotrons to energies between 400 and 480 MeV. Most facilities incorporate fixed-beam lines (either horizontal, vertical, or both), though at least three offer rotating gantries. The first such gantry was installed in 2009 at the Heidelberg Ion Therapy Center (HIT) in Germany; it had a diameter of 13 m and an overall weight of 600 tons! Due to the impressively large but prohibitively costly size of the system, subsequent designs have incorporated superconducting magnets in the gantry to increase the magnetic field strength and decrease the bending radius. The system installed at Yamagata University in Japan, for example, uses this technique to reduce the diameter of the gantry to 11 m and the overall weight to 200 tons (for reference, proton gantries currently have diameters of 7.5-11 m and weights of 100-200 tons).[47,48] Older carbon ion systems rely on passive scattering for beam delivery, while newer and upgraded systems offer active scanning. For the latter, both SFO and MFO planning techniques are utilized, and the interplay effect is managed for moving targets through a variety of techniques, including gating and volumetric repainting.[49]

Compared to protons, carbon ion beams have a sharper lateral penumbra and a more distinct Bragg peak. This is due to the additional mass of carbon ions, which leads to less coulomb scattering and less range straggling. Alternatively, a "fragmentation tail" exists in carbon ion beams, representing a small percentage (2%-5%) of a dose beyond the Bragg peak. This is due to nuclear reactions that produce light ions that travel beyond the range of the primary beam.[50] Regardless of these conditions, in clinical scenarios where treatment plans are created using multiple beams and robust optimization is used to purposefully blur sharp dose gradients, the physical dose distributions between the two modalities are not very different. The main rationale for using carbon ions over protons is thus their superior biologic effectiveness, which, while theoretically sound, remains a controversial topic due to the uncertainty in translating LET to RBE and the lack of clinical evidence supporting better outcomes.[51] Several recent studies, in fact, have demonstrated no significant difference between PT and carbon ion therapy for skull base chordomas[52,53] and head and neck cancers.[14] Indeed, one recent report of a randomized trial of carbon versus protons in prostate cancer demonstrated significantly lower disease control rates with carbon, attributed by the authors to an overestimation of the carbon RBE.[54] One area where differences are expected is in the treatment of hypoxic tumors. There is strong evidence that ions with LET greater than 200 to 300 keV μm^{-1} can reduce the oxygen enhancement ratio (OER), defined as the ratio of the dose needed for the same cell survival in anaerobic and aerobic conditions.[55,56] While clinical outcomes are sparse, encouraging results have been seen in pancreatic adenocarcinoma[57,58] and uterine cervical cancer,[59,60] two malignancies with a high level of hypoxia. As carbon ion therapy matures and more centers come online, there will be further opportunities to explore these unique advantages and establish best practices for clinical use.

Various Other Ion-Based Therapies

In addition to carbon ions, other species have been investigated, including helium, oxygen, and neon. Given their size, the latter two choices require further acceleration to 500 MeV or greater to achieve the same maximum treatment depths (approximately 30 cm) available in proton or carbon ion beams. As previously discussed, this increase in energy necessitates a larger bending radius for both the synchrotron and treatment gantry (if configured in this manner), increasing the system footprint and driving up costs. As such, any future development may focus on intermediate and superficial targets that can be reached with lower energy. While the theoretical RBE is higher

for oxygen and neon ions, fragmentation also plays a larger role, creating unwanted dose beyond the Bragg peak. Similar to carbon ions, the high LET in and around the Bragg peak is predicted to reduce the OER and help overcome resistance in hypoxic tumors.

In the modern era, treatment with oxygen, neon, or heavier ions has yet to occur. However, the first modern delivery of helium ion therapy took place in 2021 using an actively scanned beam at HIT.[61] Helium ions represent, in many ways, a balance between the benefits and limitations of proton and carbon ions for radiotherapy. Compared to protons, helium ions have sharper distal and lateral penumbra and are associated with higher LET and potentially higher RBE (1.3-3 Gy). The variability in their biologic effect, while nontrivial, is expected to be less than what is seen with heavier ions,[62] and the fragmentation tail due to nuclear interactions is significantly reduced. Because helium ions have an equivalent range to protons in water for the same energy per nucleon,[63] the maximum energy produced by the accelerating structure only needs to be on the order of 230 MeV. This enables several possible designs, with various novel, compact systems having been proposed.[64] That said, no vendors offering technology for helium ion therapy currently exist, and upgrades to existing PT equipment are not feasible. Presently, HIT is the only carbon ion facility to have enabled helium delivery, though other centers are readily equipped for a similar transition. Ultimately, the early experience from HIT will be very important in driving the adoption of this technique and an emerging interest in "multi-ion" radiotherapy whereby lower LET beams (protons and ^{4}He) are used near normoxic, healthy tissues, and higher LET beams (^{12}C) are used within hypoxic regions.[65] These new methods are also expected to foster new technological developments and clinical implementations.

Technical Summary of Neutron Therapy

Fast Neutron Therapy

The rationale for neutrons is similar to that of other particles used for radiotherapy but with some differences. Fast and ultrafast neutrons with energies of 1 to 70 MeV are recognized to have relatively high LET (20-100 keV μm^{-1}) with correspondingly low OER and high RBE. The latter is conventionally valued around 3 but is also quite sensitive to fractionation and the elemental composition of the tissue medium. Notably, neutrons are more likely to undergo scatter reactions with low Z materials (eg, hydrogen) than with higher Z materials (eg, carbon, oxygen, nitrogen, or calcium). When compared to low LET photon therapy using conventional fractionation (≈2 Gy/d), studies have reported RBE values of 3 to 3.5 Gy for normal tissue late effects, 4 to 4.5 for damage to the central nervous system, and up to 8 for malignant disease in the salivary glands.[66]

Unlike charged particles, fast neutrons do not exhibit a Bragg peak and are instead continuously attenuated, primarily through elastic scattering with hydrogen nuclei (≈85% of the dose comes from recoil protons). As such, the physical depth dose in tissue is more similar to photon therapy than PT or carbon ion therapy. A variety of systems have been used for fast neutron therapy (FNT), including cyclotrons, linear accelerators, D-T neutron generators, and both research and commercial nuclear (fission) reactors. Generally, cyclotron-based systems produce neutrons with energies between 20 and 70 MeV (considered ultrafast), while D-T neutron generators produce neutrons with energies between 10 and 20 MeV (fast). Fission neutrons have much lower energies (<4 MeV) and correspondingly different radiation transport in human tissues. The term "fission neutron therapy" has been used to demarcate a difference between FNT using higher energy neutrons.[67,68] Only the higher energy, fast, and ultrafast beams can effectively treat deep-seated targets. In terms of delivery, fixed-beam lines with rotating chairs, as well as gantry-based systems, have been used to enable treatment from multiple angles.

Over the years, approximately 41 centers have offered FNT, with over 35,000 patients treated worldwide.[69] Usage peaked in the early 1990s but waned in the following years for a variety of reasons, including the emergence of better photon therapy techniques, the focus on PT and carbon therapy, the absence of explicit guidelines for FNT, and the lack of broad superiority in early comparative trials of FNT versus 3D conformal photon therapy.[70] Another important but somewhat contentious factor in the decline of FNT was the apparent increase in severe toxicities for several treatment sites, particularly those with late-responding normal tissues. This can be attributed to (1) the inherent physics of neutron beams, which lack a Bragg peak and impart high LET radiation throughout the beam path, and (2) the early technology, which began with low-energy beams that produced hotter plans, lacked sophisticated planning tools, and provided no way to modulate the intensity of the beam nor provide dose conformality. In order to reduce normal tissue toxicity, later studies frequently incorporated a photon component (2/5 neutrons, 3/5 photons) as a form of "mixed beam therapy."[71] This resulted in dose distributions with better depth-dose profiles and moderation of the late effects in normal tissues.

As of 2023, only one institution still offers FNT using ultrafast neutrons. The University of Washington Medical Cyclotron Facility (UWMCF) was commissioned in 1984 as the first hospital-based facility in North America to offer 3D conformal FNT with an isocenter gantry, wedge fields, and a multileaf collimator–based collimation system. The facility has continued to design new technology and techniques and recently implemented intensity-modulated neutron therapy (IMNT) through the adaptation of a commercial treatment planning system and upgrades to its control and quality assurance processes.[72-74] The first patient was treated with IMNT in October 2022, and early clinical studies show an improved therapeutic ratio compared to 3D conformal FNT with no evident concerns about acute radiation toxicity.[75] Consequently, IMNT has largely supplanted 3D conformal treatments as the preferred method of FNT for the treatment of head and neck cancers at UWMCF.

FNT has historically shown promise for malignancies of the salivary gland(s), such as adenocystic carcinoma.[76] The site is favorably suited for the modality due to its superficial location, slow growth rate, and distinctly high RBE for neutrons. As with other high LET radiation, FNT is assumed to be most beneficial for radioresistant cancers, including recurrent Merkel cell carcinoma,[77,78] sarcomas, and head and neck cancers.[79] Hybrid treatment approaches that combine and respectively leverage the strengths of high LET neutrons and lower LET protons,[80] or neutrons and photons,[81] have also been shown to be beneficial for some patients. FNT may also be useful as a way to stimulate out-of-field responses with potential synergies with immunotherapy.[77] The new technological capabilities at UWMCF may offer further benefits for properly selected patients, although longer follow-ups and new prospective trials are needed to expand knowledge in this area.

Boron Neutron Capture Therapy

An alternative approach to neutron therapy is through the capture of thermal neutrons (≈0.025 eV) by boron-10, which is introduced into the body as a radiosensitizing agent. Boron-10 has a very high cross section for thermal neutron capture, with the dominant reaction resulting in the fission of boron-11 into an energetic α particle and lithium-7 isotope ($^{10}B + {}^{1}n_{(th)} \rightarrow {}^{4}He$ [1.47 MeV] $+{}^{7}Li$ [0.84 MeV] + γ [0.48 MeV]). The range of each particle in tissue is on the order of a few microns, and thus, the energy deposition (≈180 keV μm^{-1}) and associated cell kill are highly localized to the immediate area surrounding the boron-10 agent. The rationale for boron neutron capture therapy (BNCT) is thus the uptake of boron-10 in cancerous tissues, which are subsequently targeted by an external neutron beam and destroyed by high LET interactions with the fission products resulting from the boron neutron capture reaction.

BNCT has a long but sporadic history, with estimates of less than 1,000 patients treated as of 2012, primarily in Japan and Finland.[70] Before this date, nuclear reactors were the predominant source of thermal or epithermal (≈10 keV) neutrons for BNCT. The more energetic epithermal spectrum provides better neutron penetration for treating deeper tumors (up to 10 cm). Epithermal neutrons are moderated to the thermal range within the first few centimeters in tissue. A limitation is that this expands the type of nuclear interactions, potentially making the dosimetry and radiobiology more complex.[82] Over the past decade, there has been a dramatic shift from nuclear reactors to accelerator-based systems for BNCT, leading to its reemergence as a modality of interest. This was prompted by the Fukushima nuclear disaster in Japan in 2011 and the desire for a more accessible and compact delivery system. A limited number of systems are currently in operation in Japan and Finland, with others planned worldwide.[83-85] The platforms are designed to accelerate protons to bombard either a lithium-7 or beryllium-9 target to generate (*p*,*n*) reactions. In both cases, the resulting neutron beam must be moderated, filtered, reflected, and collimated using a beam-shaping assembly (BSA). The goal of the BSA is to reduce contamination from γ rays and fast neutrons while maximizing the thermal/epithermal neutron yield. For delivery, patients are treated using a robotic chair or couch and either horizontal or vertical fixed beams, depending on the system design.

Although several boron-containing compounds have been investigated, boronophenylalanine (BPA) and sodium borocaptate (BSH), the so-called “second-generation” agents, are the only two that have been examined in clinical trials. BSH has a very high boron content and accumulates in tumors such as gliomas by diffusing across an impaired blood-brain barrier.[86] BPA is a phenylalanine analog that attaches to cell membranes and has also been used to treat gliomas as well as glioblastoma multiform, melanoma, and recurrent head and neck cancers.[87] Unfortunately, neither agent has a particularly strong specificity for malignant tissue, though of the two, BPA has shown a greater affinity for tumor cells in clinical trials. Uptake, quantified as the tumor-to-normal tissue ratio (*T*/*N*) or tumor-to-blood ratio (*T*/*B*), is assessed from blood samples acquired after the intravenous administration of the boron agent. Values are calculated based on tissue-to-blood concentration ratios taken from biodistribution studies. Criteria for effective treatment include a boron-10 concentration ≥ 20 to 35 μg/g (≥10^9 boron-10 atoms per

cell) and a *T*/*N* or *T*/*B* ratio greater than 2.5 to 3. To improve accuracy, BPA can be tagged with radioactive fluorine to assess boron uptake through PET.[88] Since these types of images can be acquired beforehand, PET scans can be used to screen patients for BNCT treatment.

As noted, BNCT has primarily been used to treat radioresistant brain tumors, melanomas, and recurrent disease in the head and neck. Work is ongoing to expand the number of treatment indications by developing third-generation delivery agents. Such compounds are intended to improve the *T*/*N* ratio by specifically targeting uptake in tumor cell nuclei and DNA. Various biomolecules, including peptides, proteins, and liposomes, are currently under investigation, some of which have been further enhanced through the attachment of boron nanoparticles.[89,90] Whether these efforts should take precedence over optimizing the current clinical paradigm using BPA and BSH is an ongoing debate.[86,90] Notably, several hurdles exist in translating preclinical BNCT research into phase I trials, including the cost of clinical biodistribution studies and that historically, there has been little enthusiasm from the pharmaceutical industry in sponsoring such studies, be it lack of convincing experimental evidence or otherwise.[90] However, as with FNT and He ion therapy, enough therapeutic potential exists to warrant further research.

APPLICATIONS AND OUTCOMES

Many publications have reported significant differences in dose distribution between proton- and photon-based treatment plans in a wide range of malignancies and benign lesions throughout the body. The integral dose with proton plans is typically ≤50% of the integral dose with any photon-based plan. Frequently, the dose to critical structures such as heart, lung, brain, brain substructures, optic structures, mucosa, bowel, bladder, kidney, and liver can be reduced with protons compared with photon-based plans, particularly if IMPT is available.

Despite the relatively few facilities with technology capable of proton delivery to most cancers, the efficacy and safety of PT have already been demonstrated in a variety of malignancies and clinical situations.

The following examples demonstrate deep-seated tumors where protons may offer advantages over conventional radiation. Figures 20.3 through 20.13 illustrate comparative treatment plans for 12 common clinical settings where the improved dose distribution possible with PT may improve clinical outcomes. The examples are not comprehensive but representative and accompanied by highlights from the current clinical literature. Currently, some proton facilities provide only double-scattering proton therapy (DS PT), an increasing number provide only PBS, and a few provide both. Most of the following examples, therefore, are IMPT versus IMRT comparisons. The term “intensity-modulated proton therapy” (IMPT) in the examples below refers to PBS using single-field and/or multifield optimization. Treatment planning techniques, particularly with IMPT and VMAT, are rapidly evolving, and current dose prescription and treatment planning methods are not standardized across the field. Thus, it may be possible to improve upon some of the treatment plans depicted below with other techniques, delivery modes, and better treatment planning systems.

FIGURE 20.3 A. Axial, sagittal, and coronal displays of the dose distributions achieved with intensity-modulated proton therapy (IMPT), with a 3-mm spot size, double-scatter proton therapy (DS PT), and photon-based volumetric modulated arc therapy (VMAT) for a **skull base chondrosarcoma of the clivus**. The thick red line indicates the target volume containing gross residual tumor, the thin yellow line indicates the spinal cord, and the thin red line indicates the brainstem. The color wash indicates the radiation dose levels achieved with each treatment plan; the inner bright blue wash and line indicate the isodose volume receiving 104% of the prescribed radiation dose. The colored shaded areas indicate the following volumes: red, isodose volume receiving the prescribed dose of 73.8 Gy (RBE); bright green, volume receiving 98% of the prescribed dose; magenta, volume receiving 95% of the prescribed dose; yellow, volume receiving 90% of the prescribed dose; aqua, volume receiving 80% of the prescribed dose; dark green, volume receiving 50% of the prescribed dose; and orange, volume receiving 10% of the prescribed dose. B. Dose distribution goals for skull base tumors. Different institutions use different dose distribution goals for evaluating skull base tumor plans. In this case, the target coverage goals were to deliver a dose of 50.4 Gy (RBE) to at least 95% of the planning target volume (PTV1), a dose of 73.8 Gy (RBE) to at least 95% of the PTV2, and a dose of 73.8 Gy (RBE) to at least 99% of the gross target volume (GTV). As is apparent in the goal sheet above, target coverage goals for the PTV1 were met with all three plans, but target coverage goals for PTV2 could not be achieved with any of the plans. The goals for the GTV likewise were not achieved with any of the plans but were better met with the proton plans than the volumetric modulated arc therapy (VMAT) plan and best met with the pencil beam scanning proton therapy plan, with the GTV receiving 96%, 92%, and 79% of the prescribed dose with intensity-modulated proton therapy (IMPT), double-scatter proton therapy (DS PT), and VMAT plans, respectively. With respect to OAR, several parameters must be considered simultaneously, including “hot spots” reflected by the absolute dose to at least 0.1 cm^3 (D0.1 cm^3) and max dose, mean organ doses, and various relative or absolute volumes of an organ receiving certain doses. The DS PT plan involved the use of matched “patch” fields that treat partial target volumes to achieve better coverage of the target but can result in hot spots or higher mean organ doses in some cases. In this case, all three plans produced “hot spots” in the brainstem that exceeded the very conservative planning goal of D0.1 cm^3 ≤55 Gy. Using a volumetric definition of the outer 3-mm rim of the brainstem as the “brainstem surface” and the remaining volume inside the brainstem surface as the “brainstem core,” it was felt that all plans would carry only a very small risk of brainstem injury, because the “hot spots” were small. None of the plans could avoid a significant risk of injury to the right cochlea, but both proton plans provided a good chance of preserving the left cochlea, with mean doses to the left cochlea of 18 Gy (RBE), 31 Gy (RBE), and 41 Gy with IMPT, DS PT, and VMAT, respectively. Considering both target coverage and OAR protection, the best plan for this patient was the IMPT plan. Although mean and maximum doses of some structures were better with VMAT than DS PT, the

improved target coverage with DS PT would generally warrant selection of the DS PT plan over VMAT, if IMPT were not available. RBE, relative biologic effectiveness.

Skull Base Sarcomas

Skull base sarcomas are typically not amenable to complete resection and require very high radiation doses for disease control. Their adjacency to the brainstem, optic chiasm, and optic nerves often precludes the delivery of optimal tumor doses for fear of fatal or severe functional radiation injuries. PT, in these cases, can achieve dose distributions that often provide better target coverage and permit the delivery of potentially curative doses of radiation to the tumor with minimal risk of brainstem necrosis or blindness; in some cases, PT may offer the patient the only realistic chance of cure. Outcomes from several institutions suggest that up to 81% of chordomas and 94% of chondrosarcomas of the skull base can be controlled with PT with a low risk of serious toxicity such as brain necrosis.[53,91-98] In one of the larger experiences with 112 patients with skull base chordoma, Holtzman et al from the University of Florida reported 5-year overall survival, disease-specific survival, local control, and freedom from distant metastasis rates of 78%, 83%, 74%, and 99%, respectively.[98] A systematic review of PT outcomes among seven studies reporting on 478 patients found 2- and 3-year local control rates of 93% and 87% and survival rates of 99% and 89%, respectively, with only rare grade 3 or higher toxicities.[99] A meta-analysis found PT to be more effective for chordoma than conventional radiation for survival at 3, 5, and 10 years,[100] and a retrospective study of the NCDB also demonstrated improved 5-year survival rates with PT compared with conventional radiation.[101] A review restricted to pure PT not admixed with a photon component has also reported excellent outcomes in the skull base chordoma and chondrosarcoma.[99] A more recent review of particle therapy for skull base tumors provides an algorithm for approaching both unresectable and resectable skull base tumors with definitive or adjuvant particle therapy and suggests a potential role for carbon therapy in unresectable skull base tumors. Hug et al and Nikoghosyan have described ongoing prospective randomized controlled trials of protons and carbon in skull base chondrosarcoma.[102,103]

Figure 20.3A shows axial, sagittal, and coronal color wash displays of the dose distributions for IMPT, DS PT, and photon-based VMAT treatment plans for a skull base chondrosarcoma. Figure 20.3B shows an analysis of DVH data for the three plans. The VMAT plan delivers low-dose irradiation to a much larger volume of nontargeted tissue than either proton plan, specifically to the nose and posterior fossa, and provides inferior target coverage compared with the proton plans. To deliver ≥70 Gy (RBE) to the gross residual tumor volume, the doses achieved (D99%) were 71 Gy (RBE) with IMPT, 69 Gy (RBE) with DS PT, and 60 Gy with VMAT. Sparing of all OARs was best with IMPT. Conformality was similar between IMPT and VMAT, whereas homogeneity was similar between DS PT and VMAT.

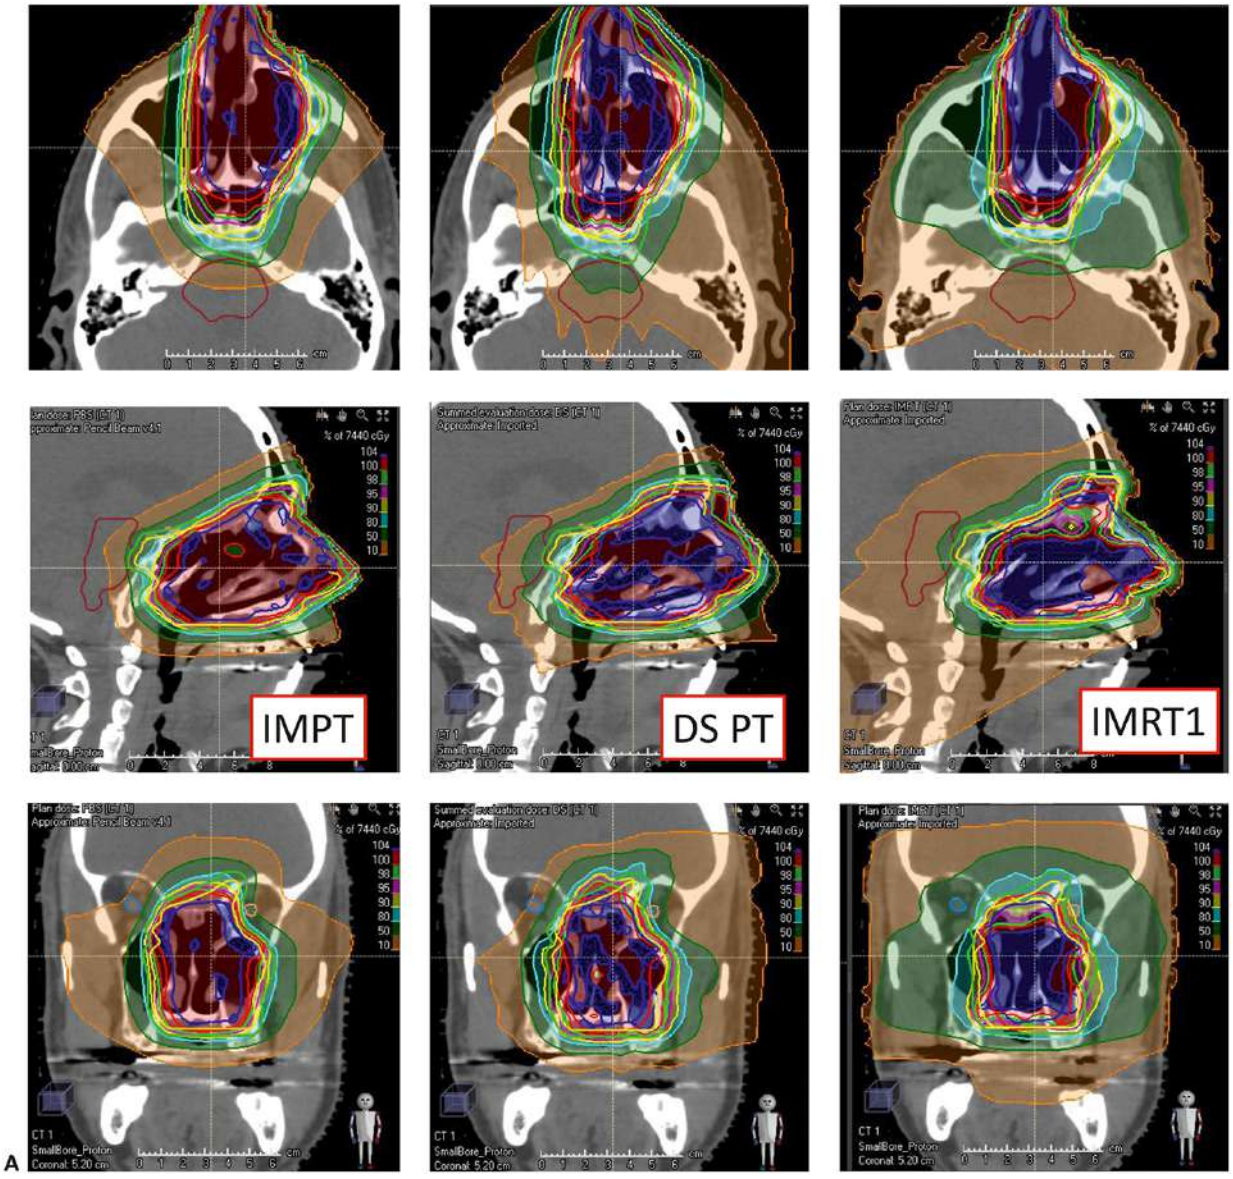
Additional factors in comparing plans include the complexity of delivery, the robustness of the treatment plan, and the number of fields and time required for delivery. DS PT generally requires more fields and treatment delivery time; “through and patch” fields, which cover only parts of the target volume, are often necessary, with some fields treating “through” the target, whereas others are “patched” in to fill gaps in dose coverage. Care must be taken to avoid placing potential hot spots in critical structures.

Advantages of IMPT over DS PT are the avoidance of patch fields, less need for apertures and compensators, increased dose homogeneity within the target, and reduced utilization of room time; however, depending on spot size, the penumbra of the scanned beams for IMPT may preclude its use in some cases. In this case, with minimal concern for organ motion, IMPT provided the best treatment plan. In other skull base sarcomas, the benefits from PT may differ in degree.

Multiple investigators have documented excellent outcomes with particle therapy for sarcomas involving other sites such as the sacrum,[104,105] spine and facial bones,[106-112] chest wall,[113] and retroperitoneum.[114]

Paranasal Sinus Tumors

Paranasal sinus tumors frequently extend into the orbit or anterior cranial fossa adjacent to critical optic structures, such as the chiasm, optic nerves, retinae, lacrimal glands, cornea, and lens. With photon-based therapy, delivering adequate doses to the entire tumor target without injury to at least one of the critical optic structures is often difficult.[115] The physician often must choose between prioritizing tumor control and preserving vision. Figure 20.4 shows a comparison of IMRT and proton plans with both DS PT and IMPT delivery in a patient with a paranasal sinus tumor. All three plans were specified to deliver the prescribed dose of 50.4 Gy to the volume at standard risk for clinical and subclinical disease and 74.4 Gy to the high-risk volume containing gross disease.



IMPT
DS PT
IMRT1
A

Targets	Goal Value	IMPT	DS PT	IMRT1	IMRT2
PTV SR (N/A PT)	D95% ≥50.4 Gy	53.35	53.22	44.45	67.08
PTV HR (N/A PT)	D95% ≥74.4 Gy	69.91	71.46	53.34	76.68
CTV SR	D99% ≥50.4 Gy	58.11	58.07	55.58	66.10
CTV HR	D99% ≥74.4 Gy	74.70	74.22	62.41	74.22

OARs	Goal Value	IMPT	DS PT	IMRT1	IMRT2
Brainstem	D0.1 cc <55 Gy	46.83	59.12	48.55	57.74
Brainstem	D0.01 cc <60 Gy	51.64	61.58	51.04	60.69
Brainstem core	D0.1cc ≤50 Gy	35.14	56.18	43.64	51.69
Brainstem surface	D0.1 cc ≤55 Gy	46.86	59.03	48.45	57.62
Cochlea, left	Mean dose < 36 Gy	3.49	12.66	26.37	31.36
Cochlea, right	Mean dose < 36 Gy	1.28	4.38	20.82	24.75
HippoHead, left	Mean dose ≤5 Gy	20.81	32.94	41.61	49.48
HippoHead, right	Mean dose ≤5 Gy	6.32	8.45	23.38	27.80
HippoTail, left	Mean dose ≤20 Gy	1.16	8.37	18.08	21.50
HippoTail, right	Mean dose ≤20 Gy	0.20	0.14	8.50	10.11
Hypothalamus	Mean dose ≤5 Gy	13.76	15.60	22.13	22.13
Optic chiasm	D0.1 cc ≤55 Gy	43.76	49.49	43.23	51.42
Optic nerve, left	D0.1 cc ≤55 Gy	66.96	64.06	68.49	81.46
Optic nerve, right	D0.1 cc ≤55 Gy	57.22	54.07	56.37	67.03
Pituitary	Mean dose ≤30 Gy	58.09	64.47	55.06	65.48
Temporal lobe, left	V20 Gy ≤10%	11%	17%	46%	54%
Temporal lobe, right	V20 Gy ≤10%	5%	5%	26%	31%
Brain	Mean dose (Gy)	3.25	5.13	10.60	12.61

B

FIGURE 20.4 A. Axial, sagittal, and coronal displays of the dose distributions achieved with intensity-modulated proton therapy (IMPT), double-scatter proton therapy (DS PT), and intensity-modulated radiation therapy (IMRT) for a **paranasal sinus tumor**. The thick red line indicates the gross target volume (GTV), and the thin red line indicates the brainstem. The color wash indicates the radiation dose levels achieved with each treatment plan; the inner bright blue wash and line indicate the isodose volume receiving 104% of the prescribed radiation dose. The remaining colored regions indicate the following: red, isodose volume receiving the prescribed dose of 74.4 Gy (RBE); bright green, volume receiving 98% of the prescribed dose; magenta, volume receiving 95% of the prescribed dose; yellow, volume receiving 90% of the prescribed dose; aqua, volume receiving 80% of the prescribed dose; dark green, volume receiving 50% of the prescribed dose, and orange, volume receiving 10% of the prescribed dose. The goals of the plans were to deliver at least 50.4 Gy (RBE) to the standard-risk planning target volume (PTV SR), at least 74.4 Gy (RBE) to the high-risk planning target volume (PTV HR), and a dose of 74.4 Gy (RBE) to 99% of the high-risk clinical target volume (CTV HR) while respecting dose constraint goals for organs at risk (OARs). The treatment plan delivered a total daily dose of 2.4 Gy (RBE) divided into 2 fractions of 1.2 Gy (RBE) delivered at least 6 hours apart. Two IMRT plans were created for comparison with the two proton plans, one prioritizing OAR protection (IMRT1) and one prioritizing target coverage (IMRT2), which is not shown. B. A dose-volume histogram (DVH) analysis of IMPT, DS PT, and IMRT for the **paranasal sinus tumor** depicted in (A). The goals of the plans were to deliver at least 50.4 Gy (RBE) to the PTV SR, at least 74.4 Gy (RBE) to the PTV HR, and a dose of 74.4 Gy (RBE) to 99% of the CTV HR while respecting dose constraint goals for the OARs. Treatment was planned to deliver a total daily dose of 2.4 Gy (RBE) in 2 fractions of 1.2 Gy/d (RBE) as smaller doses per fraction have been associated with improved radiation tolerance in the optic structures, which, in this case, are partially contained within the PTV HR. Two IMRT plans were created for comparison with the two proton plans, one which prioritized OAR protection (IMRT1) and one which prioritized target coverage (IMRT2). Both proton plans and the IMRT2 plan were significantly better able than the IMRT1 plan to deliver the prescribed dose of 50.4 Gy (RBE) to the PTV SR with doses of 53, 53, 44, and 67 Gy (RBE) to 95% of the PTV SR with IMPT, DS PT, IMRT1, and IMRT2, respectively. Although the IMRT2 plan best achieved the goal of delivering at least 74.4 Gy (RBE) to at least 95% of the PTV HR, it did so with a "hot spot" of 98.85 Gy (RBE) to 2% of the PTV HR (not shown). Although not achieving the PTV HR goal, the proton plans both provided acceptable coverage of the PTV HR, in contrast to the IMRT1 plan, with doses of 70, 71, 53, and 77 Gy (RBE) to 95% of the PTV HR with IMPT, DS PT, IMRT1, and IMRT2, respectively. With respect to OAR protection, all four plans would likely preserve optic chiasm function but result in left optic nerve injury and unilateral blindness. Therefore, preservation of the right optic nerve was a high priority. The IMRT2 plan would almost certainly result in right optic nerve injury and thus bilateral blindness; the DS PT plan provided the lowest dose to the right optic nerve and thus the best hope of preserving unilateral vision. The better sparing of the right optic nerve with DS PT compared with IMPT is related to the penumbra at a depth of even a 3-mm pencil beam scanning spot size and the sharper penumbra achievable with apertures with the DS PT. The best preservation of unilateral vision with DS PT would carry a small risk of brainstem injury. Most of the other OARs show significant dose reduction with both proton plans compared to both IMRT plans, generally with the best sparing achievable with IMPT. In this case, the IMRT2 plan would be rejected due to the risk of bilateral blindness and an unacceptable hot spot of 98.9 Gy (RBE). The IMRT1 plan would be rejected due to inferior target coverage. The choice between IMPT and DS PT would be difficult

but probably favors DS PT for the best chance of unilateral vision preservation with only a very small risk of brainstem injury. RBE, relative biologic effectiveness.

As indicated in Figure 20.4A and B, target coverage with the IMRT1 plan (which was optimized for OAR protection) is inferior to both proton plans; the doses to 95% of the PTV1, 95% of PTV2, and 99% of the gross tumor volume (GTV) were only 44, 53, and 62 Gy with the IMRT1 plan, respectively, compared to 53, 71, and 74 Gy (RBE) with the DS PT plan and 53, 70, and 75 Gy (RBE) with the IMPT plan. The IMRT2 plan, which was optimized for target coverage, produced excellent target coverage but was considered unacceptable because of OAR exposures and hot spots in the PTV. As apparent in Figure 20.4A, compared with both proton plans, the IMRT plan exposes a much larger volume of nontargeted tissue to low-dose radiation, which includes the right temporal lobe, posterior fossa, oral cavity, and supratentorial brain. For example, the volumes of left and right temporal lobes receiving 20 Gy are 54% and 31% with the IMRT2 plan, respectively, 46% and 26% with the IMRT1 plan, 17% and 5% with the DS PT plan, and 11% and 5% with the IMPT plan.

All four plans struggle with the difficulty of target coverage and sparing of the critical structures. With each of these plans, there is only a small risk of brainstem and optic chiasm injury. However, none could sufficiently spare the left optic nerve to avoid a high risk of vision loss in the left eye. Despite adding apertures to the IMPT plan to increase the sharpness of the dose gradient between the optic nerve and target volume, the DS PT plan still offered the best chance of preserving the right optic nerve. Although the proton plans both offer obvious advantages over the photon-based plan, neither avoids the necessity of prioritizing either tumor control or avoidance of injury to a critical organ.

Dagan et al from the University of Florida have reported on 143 adult patients with a variety of sinonasal tumors treated with PT, most with accelerated hyperfractionated regimens and chemotherapy.[116] Local control, disease-free survival, and overall survival rates at 5 years were 80%, 62%, and 59%, respectively, with grade 3 or higher unilateral vision loss rate of 6%. Russo et al from the Massachusetts General Hospital reported very similar results on 54 patients with nasal cavity and paranasal sinus tumors treated with PT with a median follow-up of 82 months[117]; 2- and 5-year local control rates were 80%, and 2- and 5-year survival rates were 67% and 47%, respectively. Similar results have been reported with recurrent tumors, other histologies, and other clinical situations in this anatomic area.[118-127] Similar to sinonasal tumors, it is likely that PT will improve outcomes in skin cancers with clinical perineural invasion where treatment fields include neural pathways to the base of skull[128] and radioresistant tumors in this location.[129] A comparative study by McDonald et al has demonstrated a reduction in acute toxicity with PT compared to IMRT.[130] Because of the difficulties in treatment planning for this challenging anatomic site, a collaborative network was formed between European proton centers to harmonize treatment planning and conduct trials.[131]

Oropharyngeal Cancers

Oropharyngeal carcinoma is the most common head and neck cancer. There is a rising incidence of p16-positive oropharyngeal carcinomas related to human papillomavirus exposure. In contrast to tobacco-related carcinomas, this p16-positive population is generally younger and healthier, has a better chance for disease control, and is thus more likely to experience the late effects of radiation than their tobacco-related p16- negative counterpart.

Figure 20.5 depicts IMRT, DS PT, and IMPT plans in a patient with oropharyngeal carcinoma. As apparent in the figure, there is significant sparing of the oral cavity, posterior neck, and contralateral parotid with both proton plans compared with the IMRT plan, likely impacting the risks of acute mucositis, alopecia, and xerostomia and the need for a feeding tube. The mean OAR doses (Gy [RBE]) for the IMRT, DS PT, and IMPT plans were 39, 22, and 10 for the esophagus, respectively; 26, 26, and 5 for the right cochlea; 53, 27, and 18 for the left submandibular gland; 46, 18, and 11 for the larynx; 58, 45, and 38 for the pharyngeal constrictors; 39, 19, and 16 for the oral cavity; 40, 20, and 17 for the mandible; 22, 11, and 10 for the left parotid; and 51, 48, and 40 for the right parotid. Although DS PT has some advantages over IMRT, the benefits with IMPT are more striking and consistent and suggest the possibility of significant improvements in xerostomia and swallowing compared with IMRT.

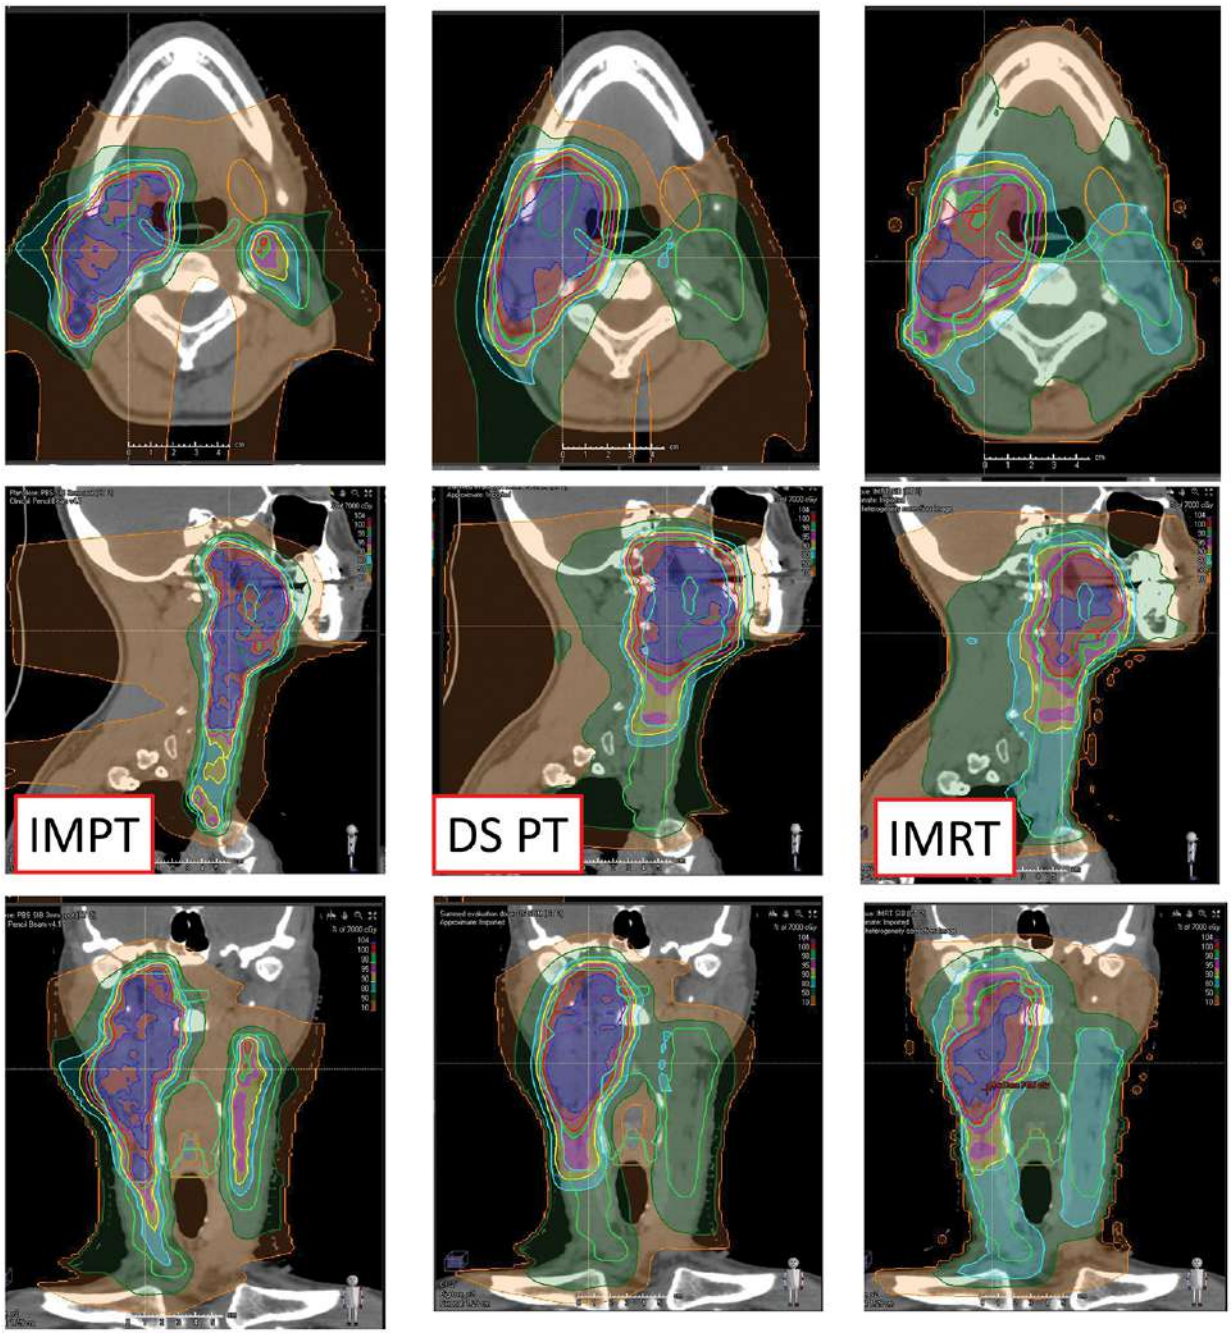


FIGURE 20.5 Intensity-modulated proton therapy (IMPT), double-scatter proton therapy (DS PT), and intensity-modulated radiation therapy (IMRT) plans for a patient with a node-positive right-sided **oropharyngeal cancer**. The high-risk clinical target volume (CTV HR) is indicated by the thick red line. The goals of the treatment plans were to deliver at least 50 Gy (RBE) to the standard-risk planning target volume (PTV SR), 63 Gy (RBE) to the intermediate-risk planning target volume (PTV IR), and 70 Gy (RBE) to the high-risk planning target volume (PTV HR). All plans provided adequate and similar doses to the PTV SR, PTV IR, and PTV HR, with the IMPT plan slightly below goals. However, with the exception of the right (ipsilateral) submandibular gland, the doses to all organs at risk (OARs) were significantly reduced with IMPT compared with the DS PT and IMRT plans. The DS PT plan provided reduced doses to the esophagus, left submandibular gland, mandible, pharyngeal muscle constrictors, and larynx compared to the IMRT plan. In this case, both proton plans appear to be superior to the IMRT plan, but the IMPT plan was also superior to the DS PT plan for OAR protection. RBE, relative biologic effectiveness.

An early report from Slater et al from Loma Linda University suggested better tolerance of oropharyngeal radiation therapy with the use of protons for a portion of the treatment.[132] In an updated 12-year experience with PT in head and neck cancer in 573 patients, Gunn reported 5-year overall and disease-free survival rates in

advanced oropharyngeal carcinoma of approximately 90% and 80%, respectively.[133] Blanchard et al[134] reported a case-matched analysis of patients treated for oropharyngeal cancer at the MD Anderson Cancer Center with either IMRT or IMPT and showed equal disease control and survival rates but reduced rates of feeding tube dependency and severe weight loss among the patients treated with IMPT.[134] Similarly, Youssef et al from Memorial Sloan Kettering Cancer Center reported a retrospective cohort study of 292 patients with human papillomavirus p16-positive oropharyngeal cancer,[135] 20% of whom were treated with IMPT and 80% with IMRT. At a median follow-up of 26 months, there was no difference between 3-year overall survival rates or locoregional recurrence. However, there was a significantly higher rate of acute toxic effects with IMRT compared with IMPT, including oral pain (93% vs 72%), xerostomia (29% vs 21%), dysgeusia (57% vs 28%), dysphagia (12% vs 7%), mucositis (70% vs 53%), nausea (8% vs 0%), and weight loss (59% vs 37%). Four of the 215 IMRT patients required endoscopic gastrostomy tubes for longer than 6 months compared to none of the IMPT patients. Bahig et al reported patient-reported quality of life outcomes after IMPT,[136] suggesting rapid recovery after acute side effects, with most patient concerns resolved by 4 weeks after treatment. A review of current outcomes for PT in oropharyngeal squamous cell carcinoma identified technical factors that can affect the improvement in therapeutic ratio with protons compared with conventional radiation.[137]

A key driver for PT in head and neck cancer is the reduction of both acute and late toxicity. Langendijk et al used photon-based normal tissue complication probability (NTCP) models to identify patients with head and neck cancer likely to benefit from PT and have thus secured broad access in the Netherlands to PT for patients meeting dosimetric criteria.[138] In an excellent discussion of modeling late effects, Stieb et al cite the current photon-based NTCP algorithms and the problems with applying these to patients treated with PT.[139] As the population affected by oropharyngeal carcinoma is shifting to a younger and otherwise healthier cohort, late effects are an increasing concern, and de-escalation of treatment is a major initiative, potentially increasing the attraction of PT. A consensus paper on guidelines for the use of particle therapy in head and neck cancer has been published by the Proton Therapy Co-Operative Group (PTCOG) Head and Neck Subcommittee.[140] Similar to the oropharynx, PT may improve outcomes in nasopharyngeal carcinoma,[141,142] unknown primaries,[143] unilateral head and neck cancers,[144] and major salivary gland tumors.[145] Because of anatomic locations near critical structures, it is also likely that protons will be useful in other tumors in the head and neck region, including angiosarcoma,[146] skin cancers,[147] thyroid cancer,[148,149] radioresistant tumors such as adenoid cystic carcinomas and melanoma,[150] and in reirradiation after initial photon-based therapy.[151]

Craniopharyngioma

Craniopharyngioma is usually diagnosed in children and adolescents. Its suprasellar location places the temporal lobes, hippocampi, hypothalamus, optic chiasm, and optic nerves at risk for radiation injury. Figure 20.6 shows VMAT and IMPT plans in an adolescent patient. Both plans achieve target coverage goals of 54 Gy. Mean nontarget brain doses are 5.8 cobalt gray equivalent (CGE) Gy with the IMPT plan and 8.5 Gy with the VMAT plan. Right and left mean cochlea doses were 6.8 and 7.2 CGE, respectively, with the IMPT plan versus 17.2 and 16.7 Gy with the VMAT plan. Right and left hippocampi doses were 10.3 and 7.4 CGE, respectively, with the IMPT plan versus 20.5 and 18.2 Gy with the VMAT plan. The volumes of right and left temporal lobes receiving 20 CGE/Gy were 17.8% and 15.6%, respectively, with the IMPT plan versus 46.1% and 42.7% with the VMAT plan. Integral dose was 12.3 J with the IMPT plan versus 21 J with the VMAT plan.

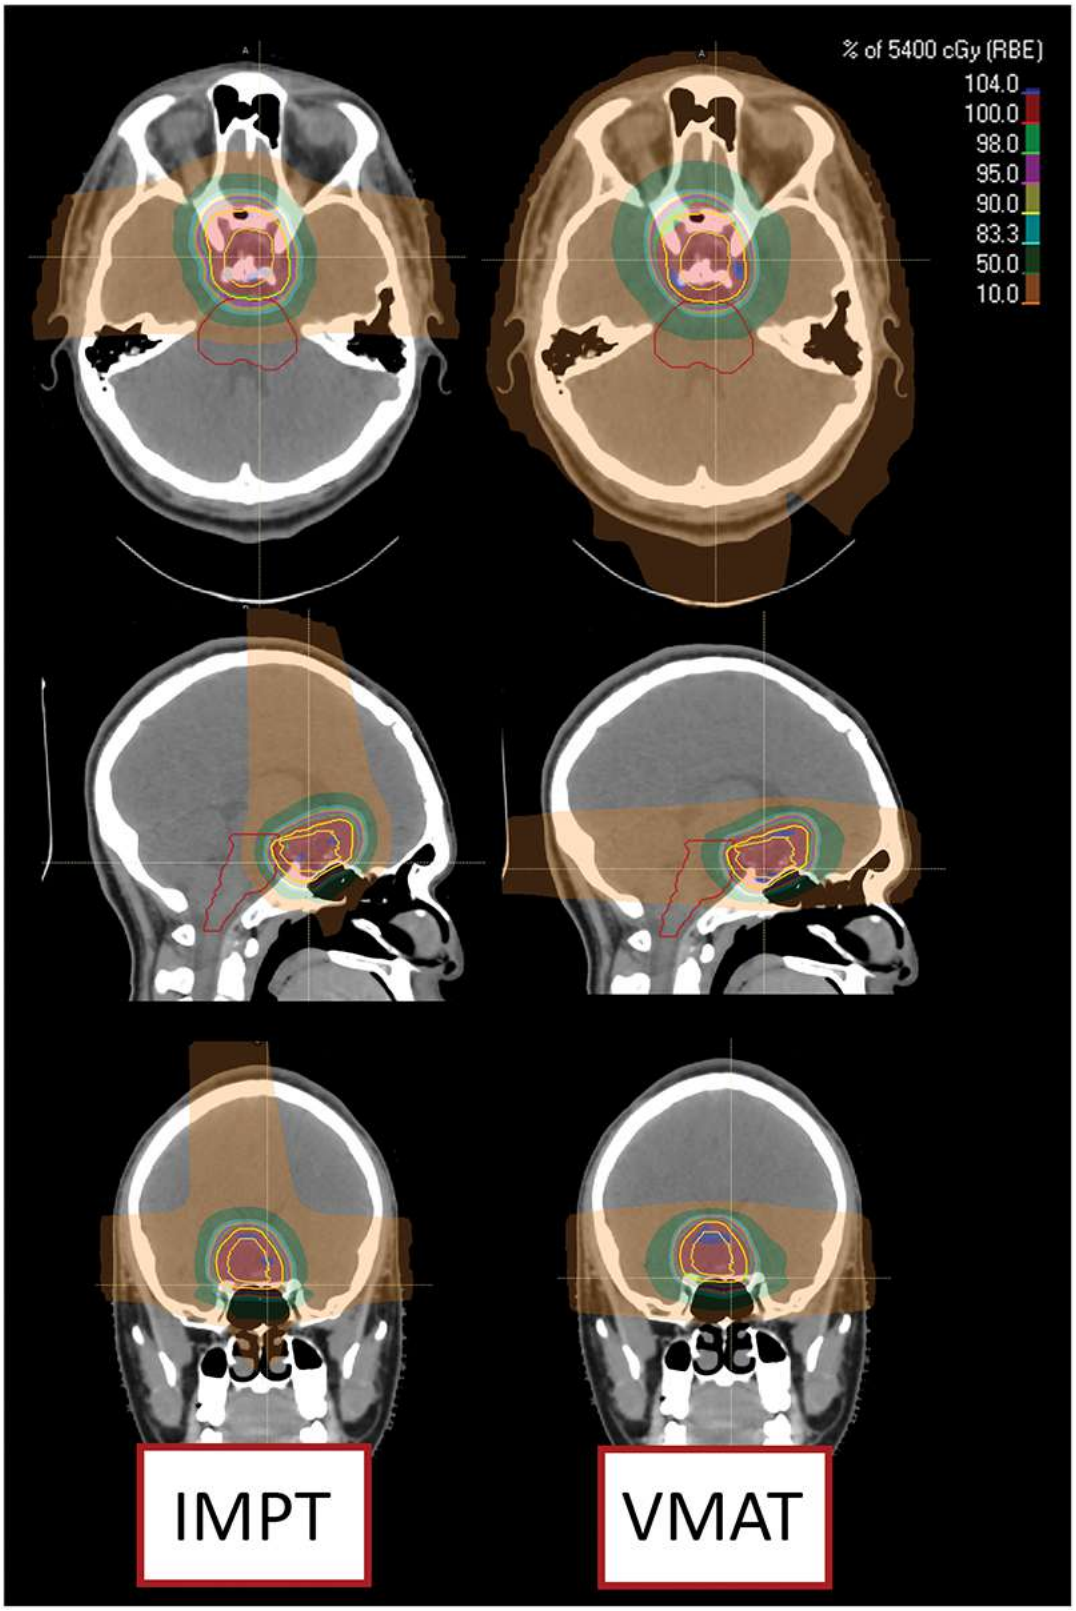

FIGURE 20.6 Axial, sagittal, and coronal displays of the dose distributions achieved with intensity-modulated proton therapy (IMPT) (left) and volumetric modulated arc therapy (VMAT) (right) plans for a small **craniopharyngioma**. The prescription dose was 54 Gy (RBE) to the planning target volume. Both treatment techniques provided excellent conformal coverage of the target. As apparent, the volume of tissue exposed to low- and intermediate-dose irradiation is reduced with the IMPT plan. Where integral dose means dose delivered to

nontargeted tissue, a dose-volume histogram comparison of doses to organs at risk showed integral doses of 12.3 and 21.0 J for the IMPT and VMAT plans, respectively. The volumes of right and left temporal lobes receiving 20 Gy (RBE) were 17.8% and 15.6% with the IMPT plan, respectively, compared with 46.1% and 42.7% with the VMAT plan. The mean absolute doses to the right and left hippocampi were 10.3 and 7.4 Gy (RBE) with the IMPT plan compared with 20.5 and 18.2 Gy with the VMAT plan. The absolute dose received by 50% of the brainstem was 4.6 Gy (RBE) with the IMPT plan compared with 23 Gy with the VMAT plan. Mean absolute doses to the right and left cochlea were 6.8 and 7.2 Gy (RBE) with the IMPT plan compared with 16.7 and 17.2 Gy with the VMAT plan. RBE, relative biologic effectiveness.

A number of investigators have reported early outcomes in medulloblastoma, ependymoma, craniopharyngioma, and other tumors. Indelicato et al reported on a variety of pediatric brain tumors referred for treatment from overseas[152]; within this cohort, the 3-year disease control rate for craniopharyngioma was 100%. PT outcomes in 91 adult patients with craniopharyngioma reported by Beddok et al were similarly excellent.[153] Of note, three of the five patients developing local recurrence were among the five (of 31 patients with on-treatment reimaging) who required replanning, suggesting a need for a routine policy of reimaging (particularly in patients with a cystic component) and adaptive therapy.

Extensive work from Merchant et al at the St Jude Children's Research Hospital in a variety of pediatric brain tumors has correlated the risk of radiation-related neurocognitive decline to radiation dose level and distribution.[154] Early outcomes provided evidence that PT may cause less neurocognitive decline than conventional radiation, consistent with dosimetric predictions.[155] Gross et al reported a retrospective study of a variety of midline brain tumors in children,[156] showing better long-term neurocognitive outcomes in children treated with PT compared to IMRT. A prospective comparative study of neurocognitive outcomes between children treated with IMRT and PT for craniopharyngioma from St Jude Research Hospital and the University of Florida showed a decline over time in IQ after IMRT, but not after PT.[157] Indelicato et al carefully detailed the incidence and dosimetric parameters associated with pediatric brainstem toxicity after PT[158]; while the incidence of toxicity in the high-dose volume is low, it is unclear whether the same dosimetric guidelines that are useful in photon-based radiation are optimal for PT and whether all factors affecting toxicity are well understood. It is likely that many other brain and central nervous system tumors in both children and adults will benefit from the dosimetric advantages of PT for similar reasons.[159-164] It is clear from a phase II randomized study that the smaller volume of brain exposed to low-dose radiation with PT compared with photon-based radiation produces less radiation-induced lymphopenia,[165] which offers improved opportunities for combined modality therapy and positively affects disease control in tumors, such as glioblastoma. The European Particle Therapy Network consensus has conducted a literature search in the neuro-oncologic literature to identify papers that include dose constraints for OARs and generated a consensus report to guide future treatment decisions using a dosimetry model approach and for future comparative studies.[166]

Craniospinal Axis Irradiation

Craniospinal axis irradiation is required in most medulloblastomas and occasionally in other brain tumors, such as advanced or metastatic germ cell tumors, primitive neuroectodermal tumors, and ependymomas. Most patients with these tumors are young and at risk for the late effects of radiation. As shown in Figure 20.7 from an adolescent girl, the exit dose from photon therapy exposes the thyroid, heart, lung, gut, and gonads to functional and neoplastic risks that can be minimized with PT. As expected, doses to all target structures within the craniospinal irradiation (CSI) field are similar between the IMPT and VMAT plans. However, in this case, the total-body integral dose is 175 J with the IMPT plan compared with 331 J with the VMAT plan. The mean doses to the right and left lacrimal glands are 13.5 and 8.6 CGE with the IMPT plan, respectively, compared with 19.4 Gy bilaterally with the VMAT plan. Mean right and left lens doses are 1.6 and 1.8 CGE with the proton pan, respectively, compared to 12.9 and 18.5 Gy with the VMAT plan. The mean absolute lung dose with the IMPT plan is 3.4 CGE versus 8.3 Gy with the VMAT plan. The mean thyroid dose with the IMPT plan is 0 versus 19.3 Gy with the VMAT plan. The mean heart dose is 0.1 CGE with the IMPT plan versus 9.2 Gy with the VMAT plan. Mean right and left kidney doses were 1.6 and 2.6 CGE with the IMPT plan, respectively, versus 7.4 and 8.9 Gy with the VMAT plan.

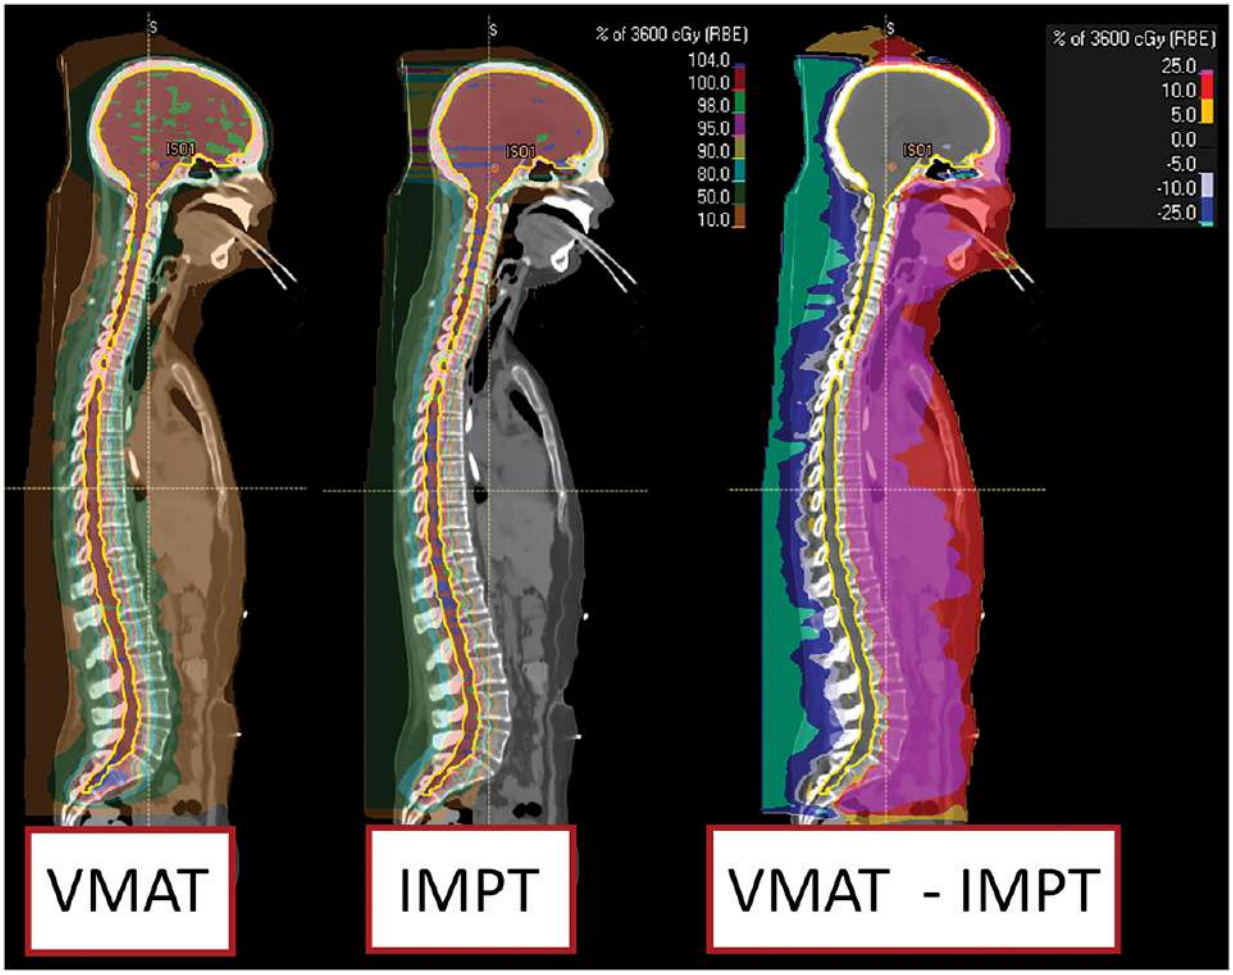

FIGURE 20.7 **Craniospinal irradiation** is necessary in a variety of brain tumors, most of which occur in young patients at risk for late effects. This figure of a 13-year-old female shows sagittal planes from volumetric modulated arc therapy (VMAT) plans (left) and intensity-modulated proton therapy (IMPT) plans (center) and integral dose in which the dose deposited by the IMPT plan is subtracted from the dose deposited by the VMAT plan (right). As apparent in the figure, the risks for functional and neoplastic effects in the thyroid, heart, lungs, breasts, gut, and gonads from photon therapy can be significantly minimized with proton therapy because of the lack of an exit dose. The integral doses are 175.4 J with the IMPT plan compared with 331.3 J with the VMAT plan. A comparison of plan metrics showed mean absolute doses with the IMPT and VMAT plans of 0.1 Gy (RBE) and 9.2 Gy to the heart, 1.6 Gy (RBE) and 7.4 Gy to the right kidney, 2.6 Gy (RBE) and 8.9 Gy to the left kidney, 8.6 Gy (RBE) and 19.4 Gy to the left lacrimal gland, 1.8 Gy (RBE) and 18.5 Gy left lens, and 3.3 Gy (RBE) and 8 Gy to the left lung. RBE, relative biologic effectiveness.

In a multi-institutional cohort study of 88 children treated with chemotherapy and either photon or proton radiation for standard-risk medulloblastoma, Eaton et al found no significant difference in disease control, survival, or patterns of failure rates between proton and photon radiation, suggesting equivalent efficacy.[167] Barney et al, reporting on 50 patients treated with proton CSI at the MD Anderson Cancer Center between 2007 and 2011, documented extremely low median radiation doses to the thyroid of 0.003 Gy (RBE); the lung, 1.1 Gy (RBE); heart, 0.002 Gy (RBE); kidney, 0.04 Gy (RBE); bowel, 0.02 Gy (RBE); testicles, 0.003 Gy (RBE); and ovaries, 0.003 Gy (RBE).[168] Treatment-related morbidity in this series included grade 3 leukopenia in 9%, thrombocytopenia in 2%, and median weight loss of 1.1 kg (1.6% loss from baseline). Progression-free survival rates at 2 and 5 years were 82% and 68%, respectively, with 80% of treatment failures involving a local recurrence. Vázquez et al reported on the outcomes of 71 children and young adolescents treated with proton CSI for medulloblastoma and ependymoma,[169] including overall survival, with a median follow-up of 24 months, the estimated local control, distant control, overall survival and freedom from late grade ≥3 rates were 86.3%, 80.5%, 84.7%, and 92.6%, respectively. These data suggest that CSI with PT is effective but potentially much less acutely toxic and much less likely to result in late effects. While CSI is most commonly used in medulloblastoma and other aggressive pediatric brain tumors, it may also be used for the control of leptomeningeal metastases in solid

tumors in adults. In the palliative setting, photon CSI is not often used because of the acute morbidity associated with lung and gastrointestinal exposure. Involved field photon irradiation is considered standard of care and achieves temporary palliation but does not stop disease progression along the craniospinal axis. Yang et al reported on a randomized phase II trial of proton CSI versus photon-involved field radiotherapy for patients with solid tumor leptomeningeal metastases, which showed improved central nervous system progression-free survival rates in the proton arm without increased treatment-related adverse events.[170]

Lymphomas

Lymphomas frequently involve the mediastinum and often require a low-to-moderate dose of radiation therapy in conjunction with chemotherapy for maximum probability of disease control. Unfortunately, even low-to-moderate radiation doses place the patient at risk for late cardiac injury and second cancers, particularly breast cancers. Figure 20.8 shows a comparison of an IMPT and IMRT plan in a young woman with Hodgkin lymphoma who had disease in the left axilla and mediastinum. The proton plan shows a significant reduction in the volume of the heart, lung, right breast, spinal cord, and other soft tissues exposed to low-dose irradiation. The mean heart dose is 10.4 CGE with the IMPT plan compared with 14.6 Gy with the IMRT plan. The mean lung dose is 8.4 CGE with the IMPT plan versus 12.9 Gy with the IMRT plan. The mean dose to the right breast is 1.7 CGE with the IMPT plan versus 6.6 Gy with the IMRT plan. The mean dose to the stomach is 6.6 CGE with the IMPT plan versus 25.4 Gy with the IMRT plan. The mean dose to the right kidney is 0 with the IMPT plan versus 6.1 Gy with the IMRT plan. The mean dose to the left kidney is 6.5 CGE with the IMPT plan versus 20.6 Gy with the IMRT plan. The mean dose to the oral cavity is 4 CGE versus 12.5 Gy with the IMRT plan. The integral dose is 105 J with the IMPT plan versus 235.4 J with the IMRT plan.

FIGURE 20.8 Axial planes are shown for intensity-modulated proton therapy (IMPT) (left) and intensity-modulated radiation therapy (IMRT) (right) for a female patient with neck and mediastinal involvement with **Hodgkin lymphoma**. As apparent, the proton therapy plans expose a smaller volume of nontargeted tissue (particularly the heart, lung, spinal cord, stomach, left kidney, and right breast) to radiation than the IMRT plan. Integral dose with the IMPT plan was 105.1 J compared with 235.4 J with the IMRT plan. Mean heart dose is 10.4 Gy (RBE) with protons and 14.6 Gy with IMRT. The volume of lung receiving at least 5 Gy (V5 Gy) and 20 Gy (V20 Gy) are 42.4% and 18.8% with IMPT, respectively, compared with 69.1% and 24.8% with IMRT. Maximum dose to the spinal cord was 16.3 Gy (RBE) with IMPT compared with 21.5 Gy with the IMRT plan. Mean stomach dose was 6 Gy (RBE) with the IMPT plan compared with 25.4 Gy with the IMRT plan. Mean absolute dose to the left kidney was 6.5 Gy (RBE) with the proton plan compared with 20.6 Gy with the IMRT plan. Mean right breast dose is 1.7 Gy (RBE) with the IMPT plan compared to 6.6 Gy with the IMRT plan. RBE, relative biologic effectiveness.

The strong interest in PT for Hodgkin lymphoma relates to the high cure rate and longevity of its survivors, who unfortunately frequently succumb to secondary malignancy and heart disease. In a variety of settings in a single- and multi-institutional registry study, several studies reported minimal acute toxicity and excellent early disease control outcomes with PT in lymphoma.[171-176] Pinnix et al (MD Anderson Cancer Center) reported that small doses to large volumes of lung had the greatest influence on the risk of radiation pneumonitis in patients receiving IMRT for lymphoma[177]; thus, it is likely that the reductions in volumes of lung receiving low doses with PT, compared with IMRT, will result in lower rates of pulmonary injury. Several international cooperative groups have endorsed the usefulness of PT in lymphoma, including the International Lymphoma Radiation Oncology Group (ILROG)[178] and the PTCOG Lymphoma Subcommittee.[179] On behalf of the PTCOG Lymphoma Subcommittee and for ILROG, Patel et al reported a systematic review of the studies comparing PT with or without deep inspiration breath-hold (DIBH) techniques with IMRT with DIBH.[180] This review showed an advantage in lung and heart exposure with PT over IMRT, regardless of whether DIBH was used with PT. They also found that some studies showed a benefit for DIBH with PT over PT alone. Finally, in a study of secondary malignancies after radiation using the NCDB, Xiang et al reported an approximately 3-fold reduction in secondary malignancies after lymphoma radiation with protons compared to photons apparent at a median of 5 years after treatment.[23] Given the very long life expectancy of patients with most Hodgkin and many other lymphoma, this significant reduction in secondary malignancies is a compelling rationale for PT by itself.

Lung Cancers

Lung cancers are typically diagnosed at an advanced stage and often occur in patients with underlying lung damage. Consequently, concern for protecting unaffected lung tissue often mandates compromise in the tumor dose. Chun et al reporting secondary analyses from radiation therapy oncology group (RTOG) 0617 (a randomized trial of 60 Gy vs 74 Gy with concurrent chemotherapy using carboplatin and paclitaxel with or without cetuximab) showed that lung V20 was associated with increased ≥3 pneumonitis risk ($P = .026$) and that the cardiac V40 was associated with overall survival ($P < .05$).[181] In a retrospective study, Wang et al found significant associations between mean heart dose and symptomatic cardiac events in an analysis that accounted for World Health Organization/International Society of Hypertension scores and history of coronary artery disease.[182] The 2-year competing risk-adjusted event rates for patients with heart mean doses of <10, 10 to 20, and ≥20 Gy were 4%, 7%, and 21%, respectively. These studies set the stage for improved outcomes with protons in patients with more advanced lung cancer through cardiac and lung sparing.

The first application of PT was reported from Loma Linda University. It utilized a hypofractionated regimen and produced excellent results, which have been successfully replicated at many centers worldwide.[183] However, clinical results subsequently have been mixed. The first randomized trial directly comparing IMRT and PT (NCT00915005) had mixed results.[184] Passively scattered proton plans and IMRT plans were completed on patients prior to study enrollment; patients were eligible for study only if all dosimetry objectives could be met with the same tumor dose by both the proton and IMRT plans. Two dose levels were offered, with the higher dose level used only if both the IMRT and PSPT (passive scattering proton therapy) plans met all dosimetric objectives. It is likely that most patients who would have benefited from PT were thus not included in the study since the IMRT plans could meet the prescribed objectives. Not surprisingly, dosimetry comparison between the treatment arms showed improvements in cardiac dose with the proton plans, but not in esophageal or lung doses. At 12 months, there was no difference between the treatment arms for either pneumonitis or local disease control rates. In a secondary analysis,[184] the pneumonitis rate in the latter part of the study was significantly lower than in the initial part of the study for both the IMRT and proton arms but more significantly so for the proton arm, suggesting a steep learning curve in treatment planning and delivery in the proton arm. The combined event rate of local failure and pneumonitis for patients treated during the initial half of the study was 21.1% for IMRT versus 31% for PT,

and for the latter half of the study, 18.2% for IMRT versus 13.1% for PT. In another secondary analysis, there was no difference in local recurrence and particularly marginal failure between the arms, suggesting that the rapid dose falloff associated with proton plans outside the target volume was not a problem.[185] In a third secondary analysis, the volume of the lung receiving high doses was the best predictor of pneumonitis.[186] The authors speculated that IMPT might produce a better outcome than passive scatted PT by achieving the high-dose conformality of an IMRT but with a much lower integral dose to the rest of the lung. The ongoing trial RTOG 1308 (NCT01525446) randomizes patients with advanced non–small cell lung cancer to IMRT or PT and allows for IMPT or passively scattered PT. A consensus statement from the Thoracic Subcommittee of the PTCOG discusses the potential advantages in many scenarios in non–small cell lung cancer as well as the complexities of PT planning and delivery to the lung.[187]

Figure 20.9 shows IMPT and VMAT plans in a patient with stage III lung cancer. In this case, the volume of nontargeted lung tissue, breast, and heart exposed to radiation can be reduced with PT compared with IMRT. However, in some cases, there may be more or less of a benefit depending on the tumor's size and location and the treatment planner's expertise.

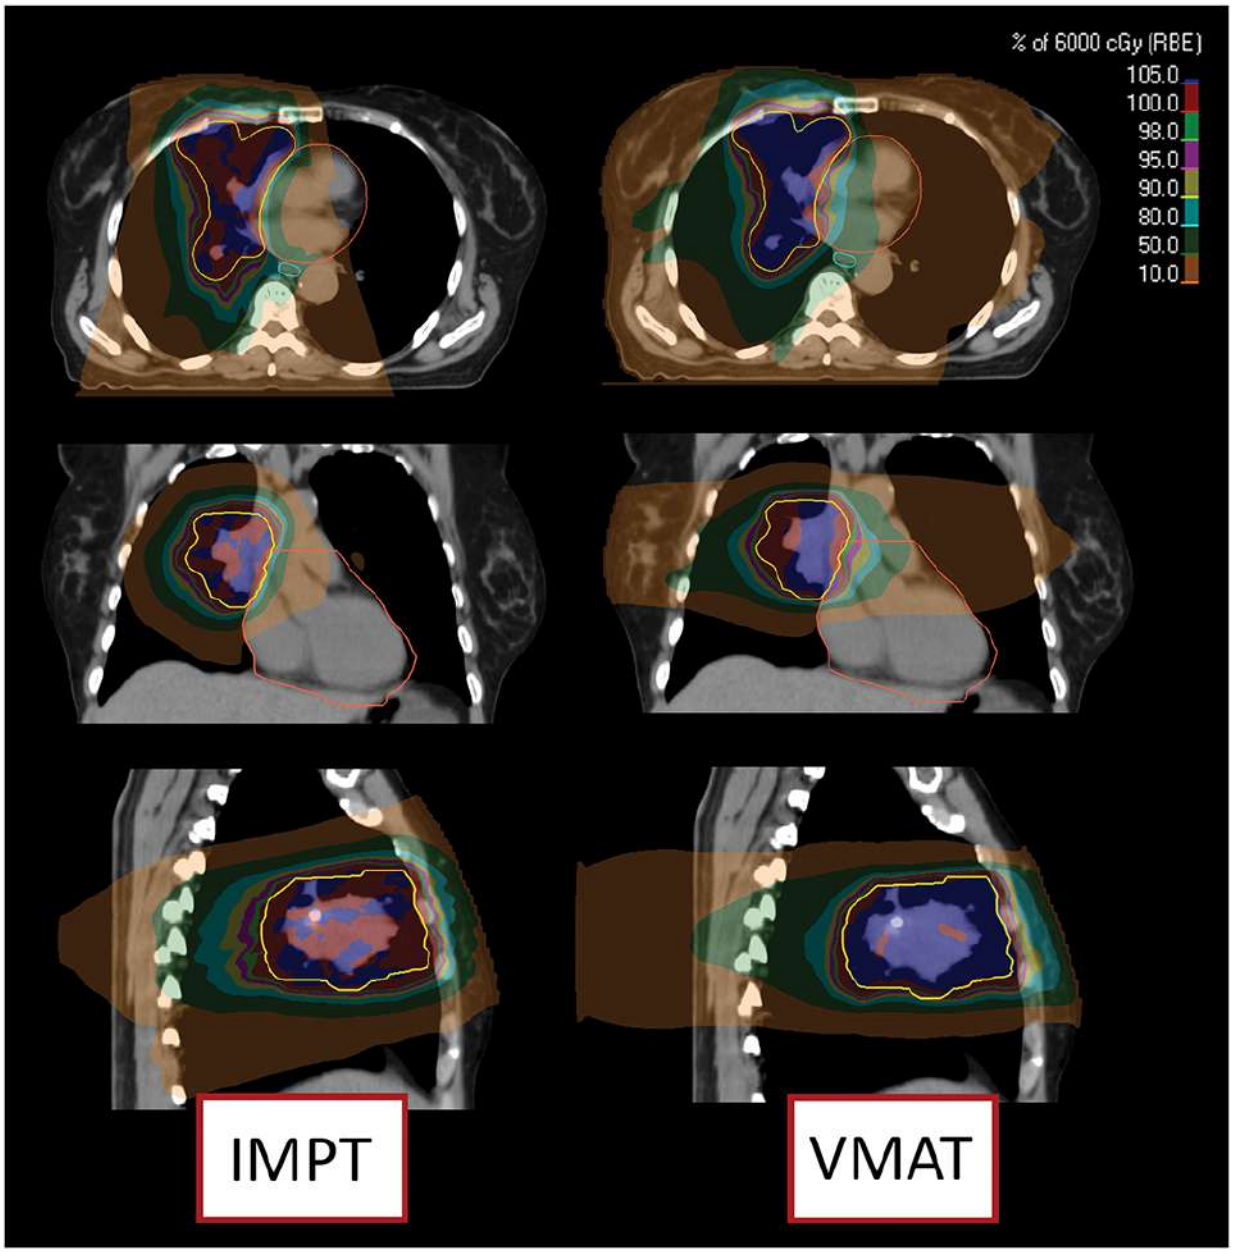

FIGURE 20.9 Axial, coronal, and sagittal planes are shown for intensity-modulated proton therapy (IMPT) (left) and volumetric modulated arc therapy (VMAT) (right) for a female patient with **lung cancer**. Integral doses for the IMPT and VMAT plans were 79.2 and 107.2 J, respectively. As apparent, the IMPT plan minimized the volumes of breast, lung, and heart exposed to radiation. The mean absolute doses with IMPT and VMAT to the lung were 13.8 Gy (RBE) and 15.1 Gy and to the heart were 6.9 Gy (RBE) and 12.9 Gy, respectively.

For other malignancies present in the lung, such as mesothelioma,[188] several studies have suggested that there may be fewer high-grade toxicities and shorter hospital stays with patients with esophageal cancer receiving PT compared with photon-based therapy.

Eye Malignancies

Passively scattered PT has been used for melanomas or other malignancies of the retina and optic structures for many years in Europe and the United States before the development of modern gantry-based proton facilities and more gantry-based scanning and/or PBS.[189-197] Given the lethality of ocular melanoma and the ability to preserve the globe and some vision with radiation strategies, most patients with ocular melanoma are treated with radiation

by either brachytherapy plaques with ruthenium, cobalt, or iridium or external beam radiation with PT or stereotactic body radiation therapy. In an excellent review of long-term visual outcomes, Jarczak et al described the various radiation strategies, including brachytherapy and PT, and the subsequent high incidence of visual deterioration, as well as potential strategies for mitigating visual deterioration.[198] Typically, the ophthalmologist identifies the target, and clips are placed behind the retina to guide tumor localization. Late visual effects have been associated with tumor size and dose to the macula or optic nerve. In recent years, efforts to improve the planning system and utilize magnetic resonance imaging in tumor identification will likely improve future PT applications in this rare tumor.

Pancreatic Cancers

Pancreatic cancers have extremely low survival rates with either conventional radiation alone or combined with surgery and chemotherapy. The disease is frequently localized for a window of time before spreading, providing a potential opportunity to improve the overall outcome by intensifying local therapy. Figure 20.10 shows IMPT and VMAT plans for a patient with cancer in the pancreatic head. As apparent, there is much less low-to-intermediate dose to the bowel, liver, kidney, and stomach with the IMPT plan. Integral doses with the IMPT and VMAT plans are 35.1 and 61.4 J, respectively. Mean doses with IMPT and VMAT are 5.7 Gy (RBE) and 15.1 Gy to the stomach and 14.3 Gy (RBE) and 9.4 Gy to the overall bowel space, respectively. The left kidney is also relatively spared with the proton plan, with a volume receiving 20 Gy of 0.2% with IMPT and 16.9% with the VMAT plan.

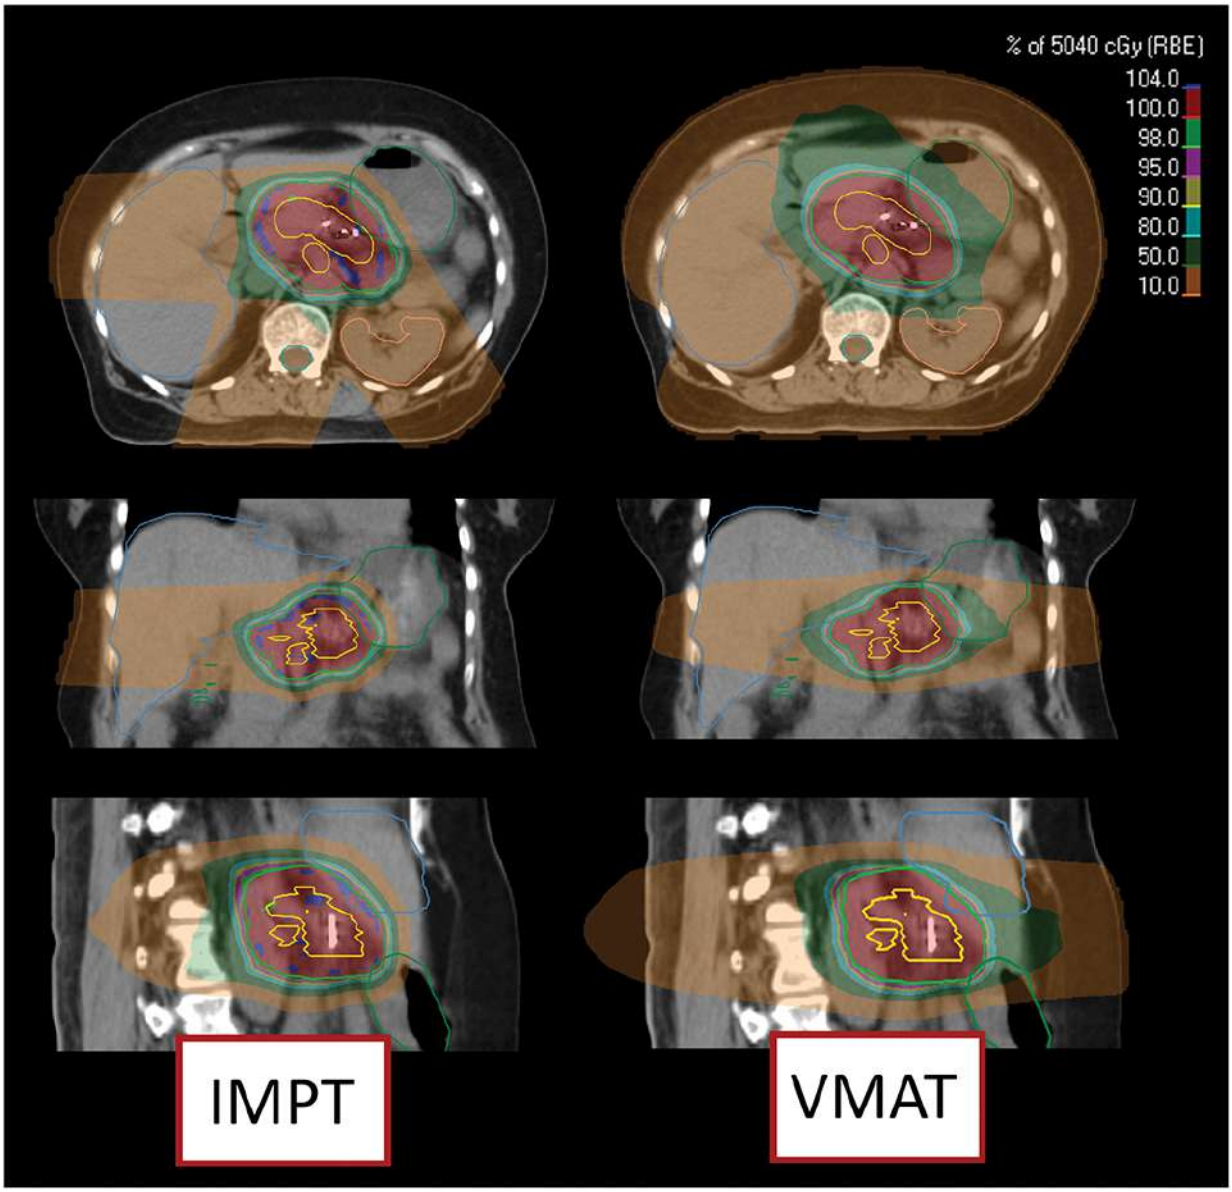

FIGURE 20.10 Axial, coronal, and sagittal planes of intensity-modulated proton therapy (IMPT) (left) and volumetric modulated arc therapy (VMAT) (right) plans for a **pancreatic head carcinoma**. As apparent, there is much less low-to-intermediate dose to the stomach, bowel, and kidney with the IMPT plan. Integral doses with the IMPT and VMAT plans are 35.1 and 61.4 J, respectively. Mean doses with IMPT and VMAT are 6.4 Gy (RBE) and 15.1 Gy to the stomach and 4.3 Gy (RBE) and 9.4 Gy to the overall bowel space, respectively. The left kidney is also relatively spared with the proton plan with the volume of lung receiving at least 20 Gy (V20 Gy) of 0.2% with IMPT and 16.9% with the VMAT plan. The lower doses to stomach and bowel may make combined modality therapy more easily tolerated and allow for dose escalation or intensification to the pancreas. RBE, relative biologic effectiveness.

Several clinical studies have documented the efficacy and safety of PT in treating pancreatic cancer, either as neoadjuvant, adjuvant, or definitive treatment.[199-205] Hong et al reported a phase I/II trial from Massachusetts General Hospital of neoadjuvant short-course PT with capecitabine followed by surgery and adjuvant gemcitabine for pancreatic carcinoma.[202] PT was delivered to the pancreas and draining lymphatics to 25 Gy (RBE) in 5 fractions. Surgery was performed in 37 of the 50 patients, with the findings of positive nodes in 81%, positive margins in 16%, and no pathologic complete responses. The median progression-free and overall survival times in the 37 patients who had surgery were 14.5 and 27 months, with 16% experiencing locoregional recurrence. The rate of grade 3 or higher toxicity was 4.1%. The same institution performed a separate phase I trial of photon-based stereotactic body radiation therapy using the same treatment volumes and dose fractionation regimen, but this

study was terminated early because of intraoperative toxicity.[206] The investigators concluded that preoperative PT was feasible, well tolerated, and did not delay surgical resection. Nichols et al reported on the University of Florida experience with 22 patients treated with concomitant capecitabine and passively scattered PT for resected (n = 5), marginally resectable (n = 5), and inoperable (n = 12) pancreatic and ampullary carcinomas.[203] Doses ranged from 50.4 to 59.4 Gy (RBE). No grade 3 or higher toxicity was observed. Median weight loss was 1.3 kg or 1.75% of the body weight, and 99% of the prescribed chemotherapy doses were given. Two of the 12 patients with inoperable disease achieved excellent radiographic responses, including one pathologically documented complete response. Despite the much higher radiation dose delivered in the University of Florida experience, the University of Florida experience confirmed the low rate of gastrointestinal toxicity with PT observed by Hong et al,[202] suggesting the potential for improvement in efficacy through dose escalation to accomplish complete pathologic responses. Neither proton experience delayed surgery or resulted in increased surgical complications, suggesting an additional potential value of PT in facilitating both surgical resection and chemotherapy intensification. Three excellent reviews of outcomes with particle therapy for pancreatic carcinoma have reported on the challenges of motion management, range uncertainties, and online volumetric imaging with early proton studies but offer promising results with respect to efficacy and toxicity.[207-209] With the availability of cone-beam CT on proton gantries, target location can be monitored easily, making IMPT feasible in most cases and further improving the dose distribution attainable with protons compared to photon-based treatment planning. More clinical data using modern PT planning and delivery and volumetric imaging are needed to determine the potential for PT to improve the therapeutic ratio in pancreatic cancer.

Esophageal Cancers

Many of the issues affecting the therapeutic ratio of radiation therapy in esophageal carcinoma in the esophagus are similar to issues in the lung, pancreas, breast, and oropharynx disease. Figure 20.11 shows comparative VMAT and proton plans. A meta-analysis of 45 studies by Zhou et al also confirmed a significant reduction in doses to OARs, toxicity, and improved prognosis for PT compared with IMRT in esophageal carcinoma.[210] A prospective randomized IIB trial of protons versus IMRT in locally advanced esophageal cancer demonstrated a significantly lower total toxicity burden with protons at a median follow-up of 44 months, meeting the criteria for early closure.[211] This study will be followed by another comparative trial conducted by the NRG-GI006.

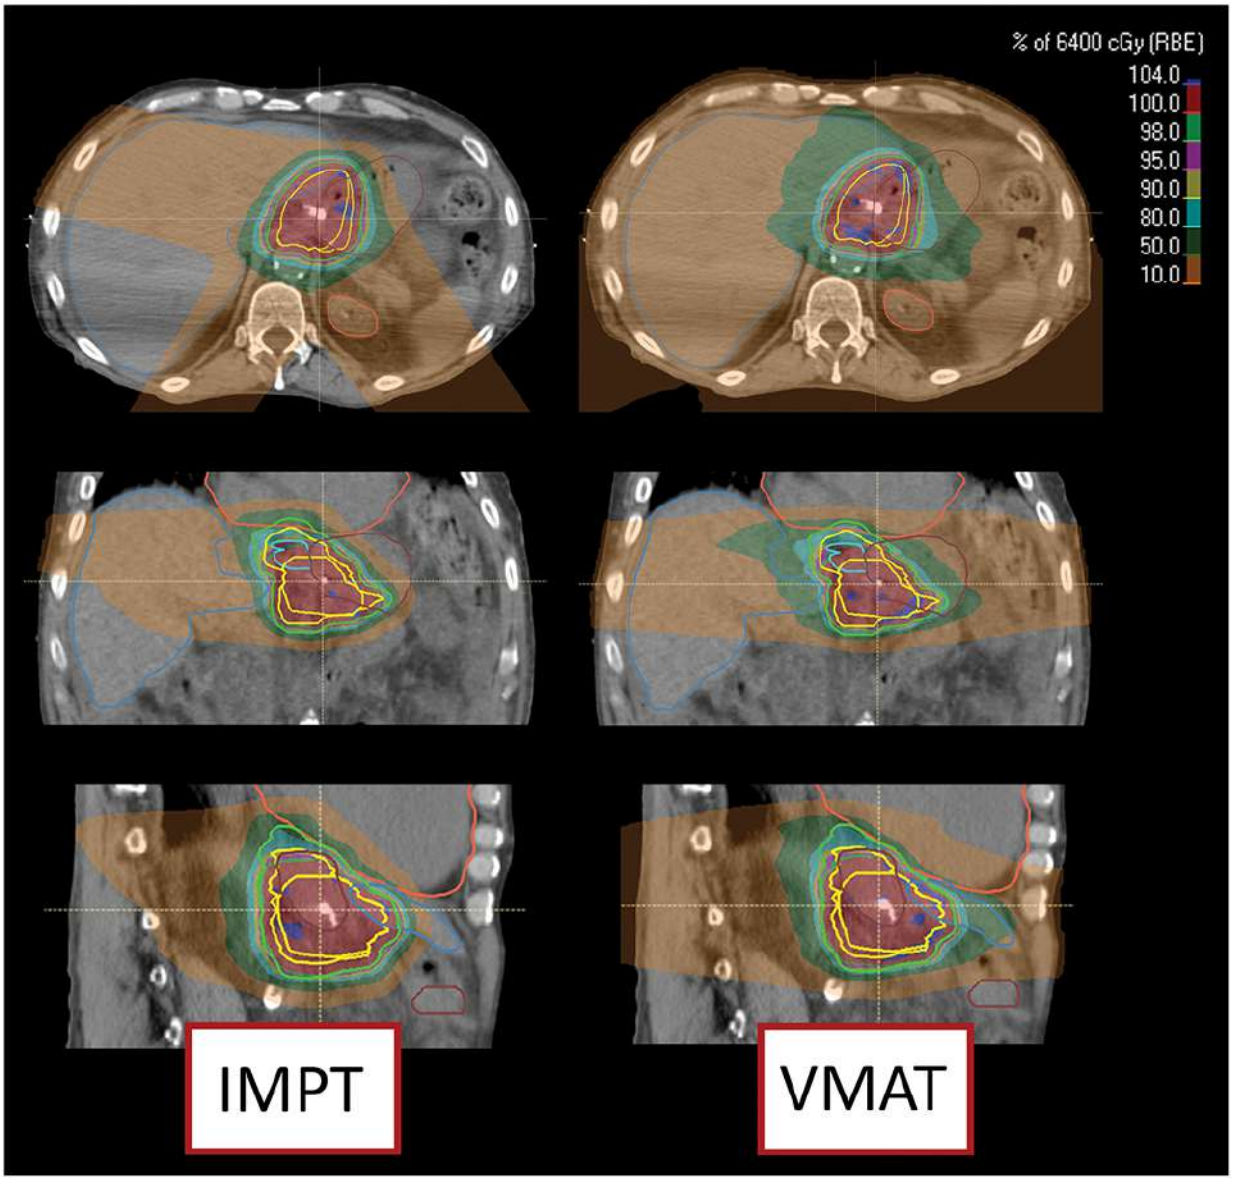

FIGURE 20.11 Axial, coronal, and sagittal planes of intensity-modulated proton therapy (IMPT) (left) and volumetric modulated arch therapy (VMAT) (right) plans for a patient with distal **esophageal carcinoma**. As apparent, there is much less low-to-intermediate dose to the heart, stomach, bowel, and liver with the IMPT plan compared to the VMAT plan. Integral dose was 57 J with the IMPT plan compared to 121.3 J with the VMAT plan. Mean absolute doses with the IMPT and VMAT to the heart were 2.6 Gy (RBE) with 5.7 Gy, to the liver were 8.3 Gy (RBE) and 16.7 Gy, to the kidneys were 6.7 Gy (RBE) and 9.3 Gy, and to the stomach were 25.07 Gy (RBE) and 35.45 Gy, respectively. The volume of nontargeted bowel receiving at least 20 Gy (V20 Gy) with the IMPT and VMAT plans were 7.2% and 49.5%, respectively. RBE, relative biologic effectiveness.

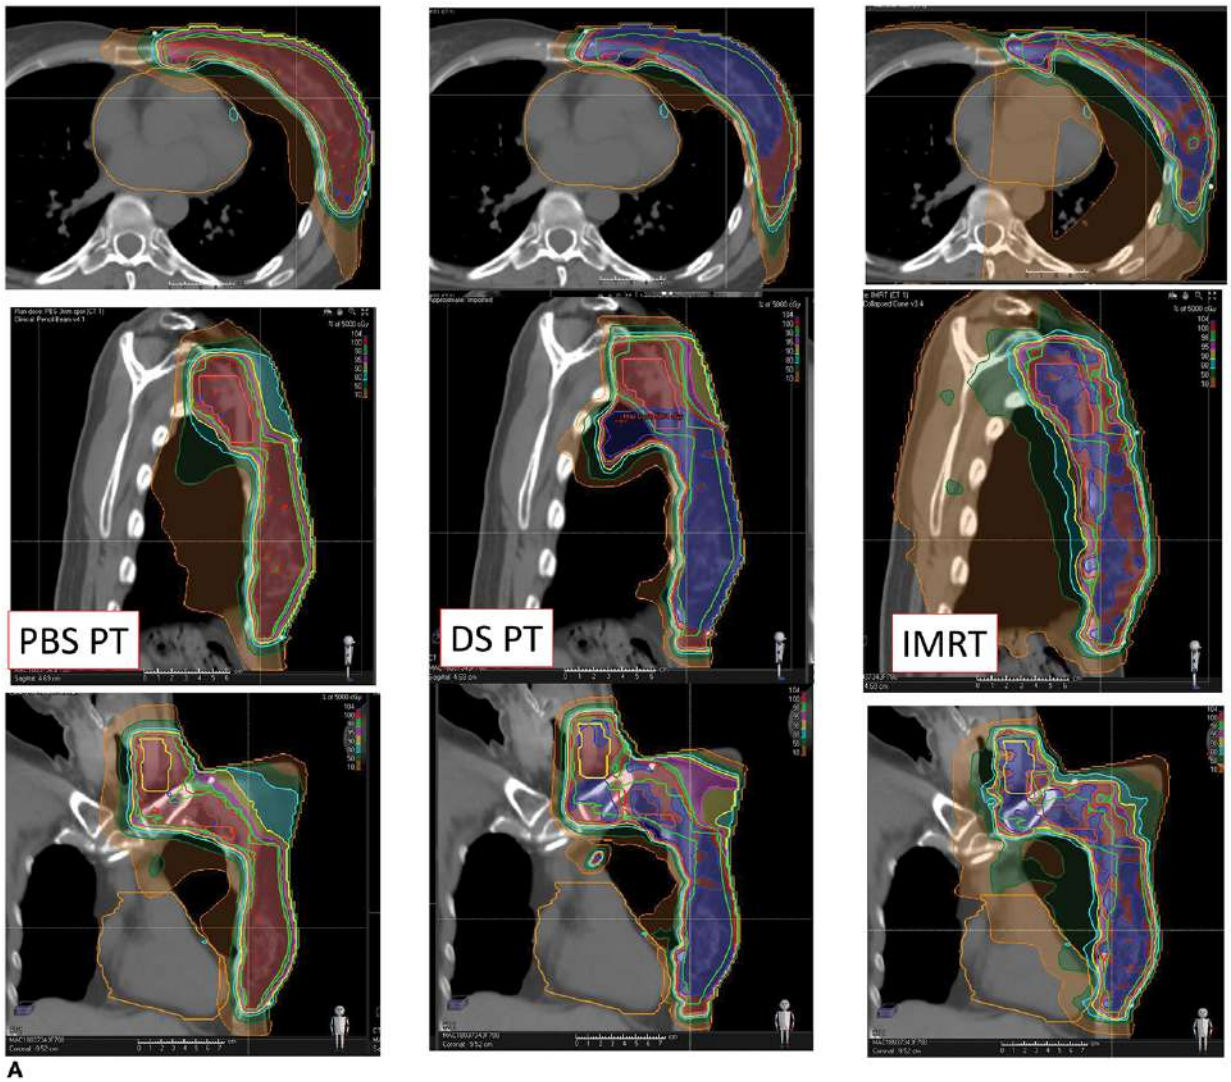
Breast Cancer

In patients with breast cancer, there is level I evidence for treating all regional nodes, including internal mammary nodes and axillary nodes, in patients at risk for residual disease after surgery because of positive axillary nodes, tumor size, and, in some cases, tumor location and grade.[212-220] There is also growing interest in minimizing dose to the heart and lung as increases in late cardiac and pulmonary morbidity and mortality continue to be documented.[212,213,215,221-224] The excess in cardiac disease has primarily been associated with patients with left-sided breast cancer, presumably because a greater volume of the heart is exposed to radiation with left-sided breast cancers compared with right-sided breast cancers.[213,221,222] More recently, evidence suggests that the risk of heart disease may be related to DVH parameters,[223] which has led to the goal of achieving as low as reasonably achievable doses to the heart and lung with dose constraint goals built into the guidelines for modern breast cancer

trials.[225,226] While it is widely accepted that patients with node-positive left-sided breast cancer generally benefit from heart and lung sparing with PT compared to photon-based alternatives, some patients with right-sided breast cancer have challenging anatomy, making target coverage and/or cardiac and lung sparing difficult.

Figure 20.12A shows comparative treatment plans for a patient with breast cancer receiving left-sided breast and regional node irradiation using IMRT, DS PT, and IMPT plans. Coverage of the axillary and supraclavicular nodes is similar among the plans, but coverage of the internal mammary nodes is inferior with IMRT (44 Gy) compared with both the DS PT and IMPT plans (50 Gy [RBE]). Striking differences are apparent among the IMPT, DS PT, and IMRT plans in heart V10 Gy at 3%, 2%, and 23%, respectively; mean heart doses, 1, <1, and 7; mean left anterior descending artery doses, 2, 2, and 14; and left lung V5 Gy, 38%, 27%, and 85%.



A

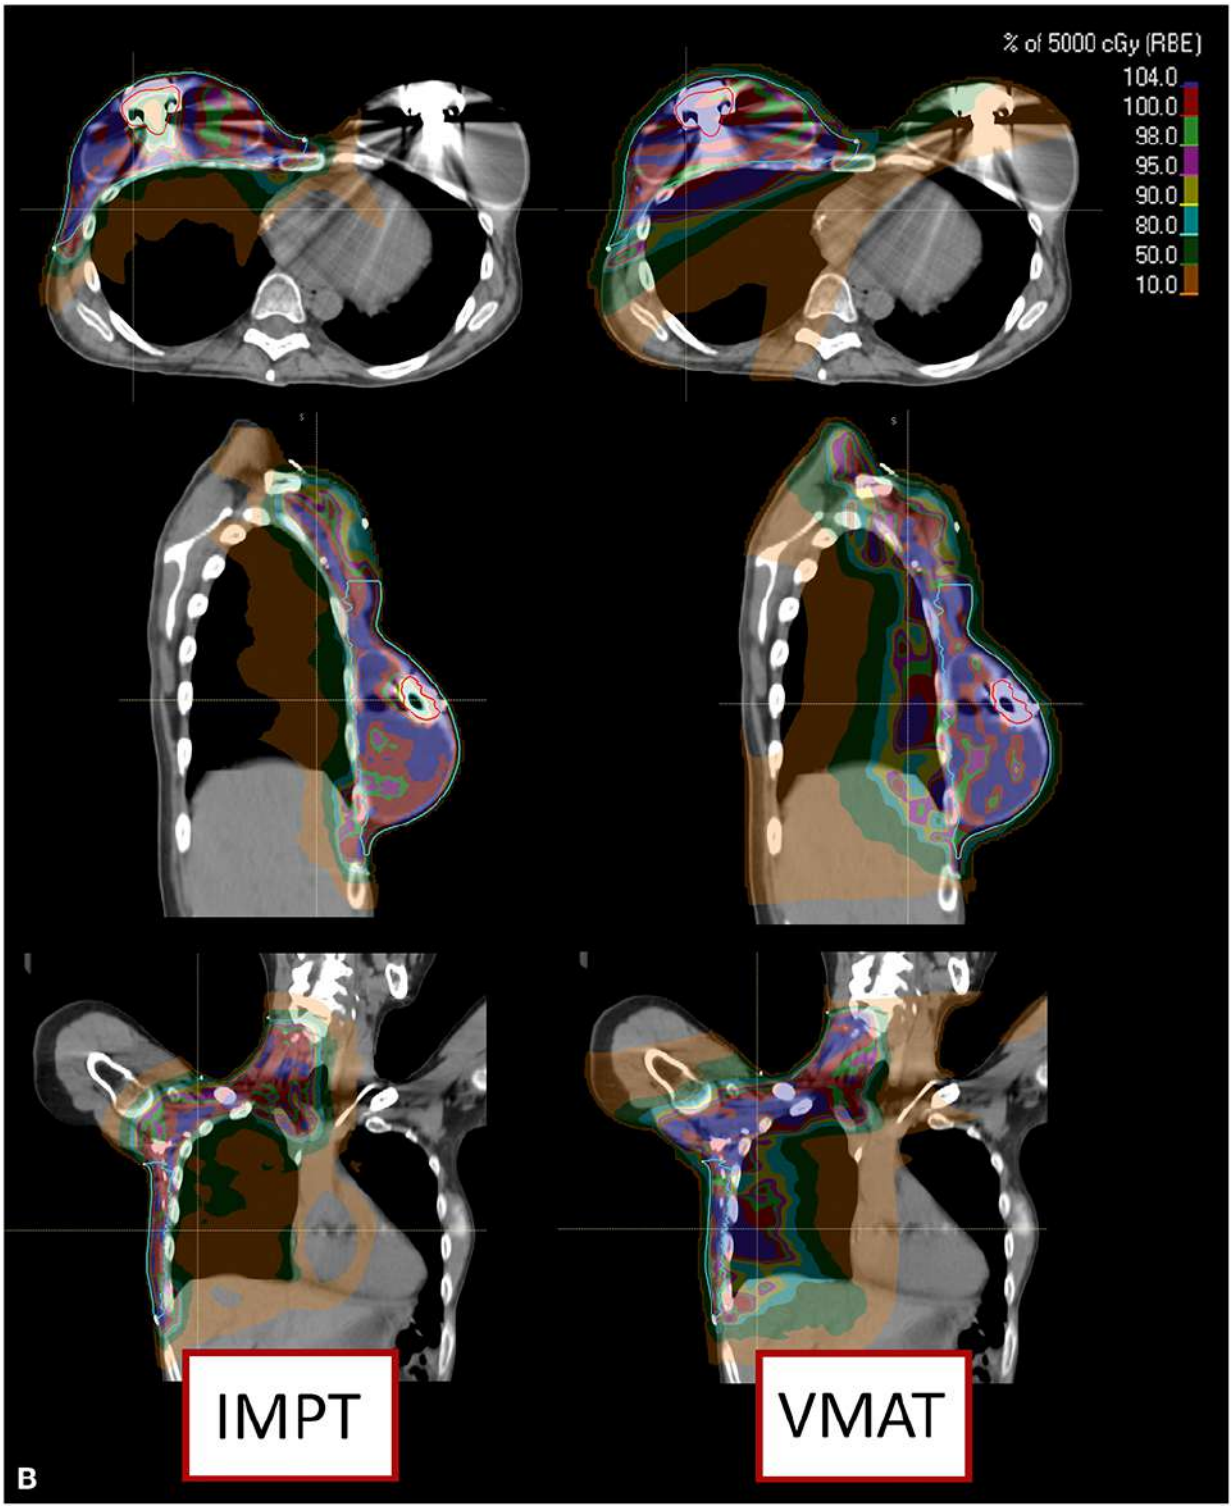


FIGURE 20.12 A. Intensity-modulated proton therapy (IMPT), double-scatter proton therapy (DS PT), and intensity-modulated radiation therapy (IMRT) plans for a woman with a **left-sided node-positive breast cancer**. Targets included the internal mammary nodes; levels I, II, and III axillary nodes; and supraclavicular nodal areas as well as the breast. The prescribed dose is 50 Gy to the breast planning target volume (PTV) and nodal PTV. Coverage of the internal mammary nodes is best with the IMPT plan compared to the DS PT and IMRT plans, with 95% of the internal mammary chain volume receiving 50 Gy (RBE) with both proton plans but only 44 Gy with the IMRT plan. The volume of heart receiving at least 10 Gy (V10 Gy) was 3%, 2%, and 23% with the IMPT, DS PT, and IMRT plans, respectively. Mean left anterior descending artery doses were 2 Gy (RBE), 2 Gy (RBE), and 14 Gy with the IMPT, DS PT, and IMRT plans, respectively. The volume of left lung receiving at least 5 Gy (V5 Gy) was 38%, 27%, and 85% with the IMPT, DS PT, and IMRT plans, respectively. Although

metrics appear similar or even better with DS PT compared with IMPT, skin reactions historically have been worse and daily setup is more difficult and time-consuming, so IMPT is the preferred proton delivery mode for breast cancer. B. It is generally accepted that protons produce more cardiac sparing and better internal mammary node coverage in patients with left-sided node-positive breast cancers, after either mastectomy or breast-conserving therapy. However, there is also a role for protons in some **right-sided breast cancers**. The figure below shows a woman who is postmastectomy for node-positive right-sided breast cancer and has had a reconstruction with temporary tissue expanders. With expanders or implants, the breast mound and attendant chest wall flap at risk for subclinical disease protrude anteriorly, making it difficult to cover with photon beams without exiting into the contralateral breast. The medial location of the internal mammary nodes may also be impossible to cover with photons without excessive exposure of the heart. In the case shown here, it was impossible to cover the right chest wall and regional nodal target without excess exposure of the ipsilateral lung, contralateral left breast, and heart. The volume of right lung receiving at least 20 Gy (V20 Gy) was 28.4% with IMPT and 46.2% with the IMRT plan. The mean absolute heart doses with IMPT and IMRT were 3 Gy (RBE) and 4.8 Gy, respectively. Integral doses with the IMPT plan and IMRT plans were 79.2 and 161 J, respectively. RBE, relative biologic effectiveness.

Figure 20.12B shows comparative plans for a 48-year-old female with node-positive right-sided lobular carcinoma s/p mastectomy with expander placement. The initial simulation revealed that an expander with a double port was used; the double port created substantial dose shadowing with proton planning and also created uncertainties with photon planning. The expander was replaced, but her anatomy made coverage of the internal mammary nodes and cardiac sparing impossible with a photon-based plan. The DVH comparison showed reduced doses to the lung and heart with IMPT compared to IMRT.

MacDonald et al from the Massachusetts General Hospital reported the acute toxicity and feasibility of PT in a prospective trial of 12 postmastectomy patients[227]; at a median follow-up of 6 months, there were no cases of pneumonitis, and maximum skin toxicity was grade 2. Bradley et al from the University of Florida reported a pilot study of PT for right- and left-sided cancers (stages IIA to IIIB) after either breast-conserving therapy or mastectomy.[228] The study included a treatment plan comparison of PT DS and conventional radiation plans, with the best treatment plan recommended to the patient. The proton plans were consistently better for coverage of the internal mammary nodes ($P = .0005$), minimization of cardiac V5 ($P < .0001$), and minimization of ipsilateral lung V5 and V20 ($P < .0001$). The only grade 3 toxicity was radiation dermatitis, observed in 22% of patients. An ongoing prospective randomized trial comparing IMRT and PT in patients who need internal mammary node irradiation should help define which groups of patients benefit most from PT in the future. Jimenez et al reported on a trial in patients with breast cancer requiring regional node irradiation, also showing excellent early disease control with minimal toxicity.[229]

There may be other indications in breast cancer where protons can be very useful when limiting the dose to OARs is important, such as bilateral breast cancer,[230] reirradiation for breast or chest wall recurrence or angiosarcoma,[231-233] radiation in patients with genetic mutations placing them at risk for radiation injury, men with challenging anatomy,[234] and women with reconstruction after mastectomy[235] and partial breast irradiation.[236] Much work is ongoing to determine the best treatment planning and delivery techniques to optimize PT results,[236] especially concerning rib fractures and skin reactions.[237-240] Mutter et al, on behalf of the PTCOG, published an excellent consensus analysis on the state of PT in breast cancer.[238] Holt et al published a systematic review and meta-analysis of clinical outcomes with PT in early breast cancer, concluding that while early results are promising, more clinical follow-up and randomized trials will be necessary.[241] An ongoing randomized trial comparing the outcomes of proton and IMRT patients who required internal mammary node irradiation will shed light on the ultimate clinical benefit of PT in breast cancer.[242]

Prostate Cancer

The ProtecT trial has underscored the importance of early definitive treatment for prostate cancer in men with a ≥10-year life expectancy to maximize freedom from distant metastases and documented increased toxicity with surgery compared to radiation therapy without an attendant increase in disease control rates.[243-245] Prostate cancer results with radiation therapy are generally excellent, and dose escalation trials indicate that increasing the dose to the prostate is associated with improved disease control rates.[246-249] However, dose escalation photon-based trials from the RTOG also show that increasing dose, dose per fraction, and the volume of the rectum exposed to a high radiation dose are associated with an increased risk of rectal toxicity.[250] Analysis of outcome data with PT indicates a similar correlation between the increasing volume of the rectal wall receiving high doses and the risk of gastrointestinal toxicity.[251] Hypofractionation of the treatment regimen is of great interest in prostate cancer, and while studies have demonstrated similar outcomes,[252,253] they also have sometimes reported more toxicity with hypofractionation,[254] so that attention given to the radiation exposure of OARs is critically important.[255] Most physician-reported gastrointestinal toxicity has been temporary rectal bleeding or ulceration.[251] However, rectal

urgency, frequency, and incontinence have been identified as problems that may occur later, persist, and significantly impact long-term patient-reported quality of life.[256-258] This symptom complex has been found to be related to reduced rectal elasticity and sphincter tone,[257,259] and these symptoms have been associated with the volumes of anus and rectum receiving 5 to 40 Gy.[247,255,260] Comparative IMRT and proton dosimetry studies have shown that with historical techniques for prostate stabilization, the volumes of the rectum and rectal wall receiving high radiation doses associated with rectal bleeding and ulceration are similar.[261,262] However, the volume of the rectum and rectal wall receiving low-to-moderate doses is significantly less with PT compared to IMRT. It is likely that strategies that create distance between the anterior rectal wall and posterior prostate have reduced the risk of rectal bleeding and/or ulceration in eligible patients receiving either photon- or proton-based radiation.[263,264] Thus, the main late gastrointestinal issue is rectal urgency and frequency. At this point, bladder and urethral toxicities with photon- and proton-based external beam radiation have not clearly been associated with dose-volume parameters; however, this may change with dose escalation or hypofractionation of treatment.

The most controversial indication for PT at this time is prostate cancer. The first experience came from Loma Linda University.[265] It is estimated that more than 30,000 men with prostate cancer have been treated with PT or a combination of PT and photon therapy with excellent results with both standard and moderately hypofractionated regimens. A consensus paper from the genitourinary subcommittee of the PTCOG has described the state of PT for prostate cancer.[266] Table 20.1 shows results from selected IMRT and PT experiences with long-term follow-up.[267-275] The longest follow-up for patients with prostate cancer treated with radiation therapy is in an IMRT experience from Memorial Sloan Kettering[275]; in this study of high dose (>80 Gy), the investigators report relapse-free survival rates of 76%, 65%, and 55% at 15 years for men with low-, intermediate-, and high-risk prostate cancers with rates of grade ≥3 genitourinary and gastrointestinal toxicity of 1% and 2%, respectively, and a secondary malignancy rates of 12.3%. Of note, the 5- and 10-year results from multiple PT experiences across two continents are strikingly consistent in disease control and toxicity rates. These disease control and toxicity rates with protons compare favorably with contemporaneous external beam photon experiences, but second malignancy rates have not been reported. A comparison of prospectively collected patient-reported quality of life data from cohorts of men treated with IMRT and PT has shown similar overall functional summary scores but significant differences in selected questions regarding bowel frequency and urgency that potentially reflect radiation injuries associated with the volume of the rectum receiving low-to-moderate doses, perhaps providing the first evidence of anticipated differences in functional outcomes related to PT and photon therapy reported directly by patients.[276] Importantly, a retrospective query of the NCDB by Xiang et al demonstrated a 3-fold increase in secondary malignancy in patients treated with photon-based therapy compared with PT[23]; within this study, the difference in secondary malignancy apparent at a median of 5 years in men with prostate cancer was 5-fold, making secondary malignancy risk a highly relevant concern. Two prospectively controlled clinical trials comparing outcomes between IMRT and protons for localized prostate cancer have completed enrollment. The first is a randomized comparison of IMRT and protons in 400 men with an end point of 2-year bowel summary score.[277] The second is a comparison of outcomes between prospective cohorts of 2,524 men treated with either IMRT or PT with the simultaneous end points of bowel frequency and urgency, rectal toxicity, and freedom from biochemical progression.[278] Early results from both trials should be available within the next few years, but assessment of important late outcomes such as disease control, long-term bowel function, and risk of secondary malignancy will require additional observational time.

TABLE 20.1 RECENT EXPERIENCES WITH IMRT AND PROTON THERAPY IN PROSTATE CANCER

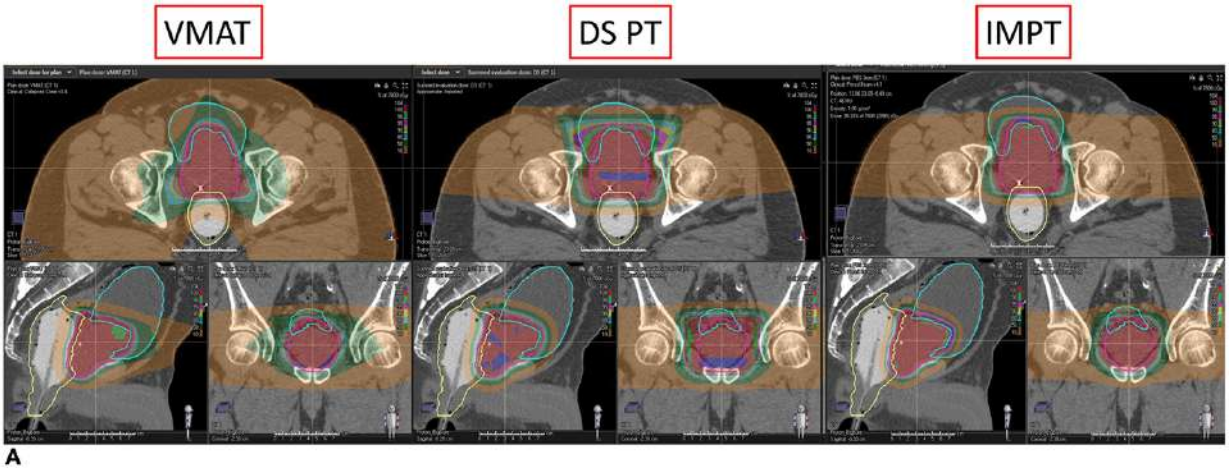
[a]Relapse-free survival rather than FFBP.

Figure 20.13A shows VMAT, DS PT, and IMPT plans for a patient with low-risk prostate cancer who has a large median lobe. As apparent, the rectal volumes receiving 25 and 45 Gy are generally lower with both proton plans than with the VMAT plan and lowest with the IMPT plan. Treatment planning is rapidly evolving for both VMAT and IMPT, and the relative value of high-dose conformality versus minimization of the integral dose in prostate cancer will require further investigation.



A

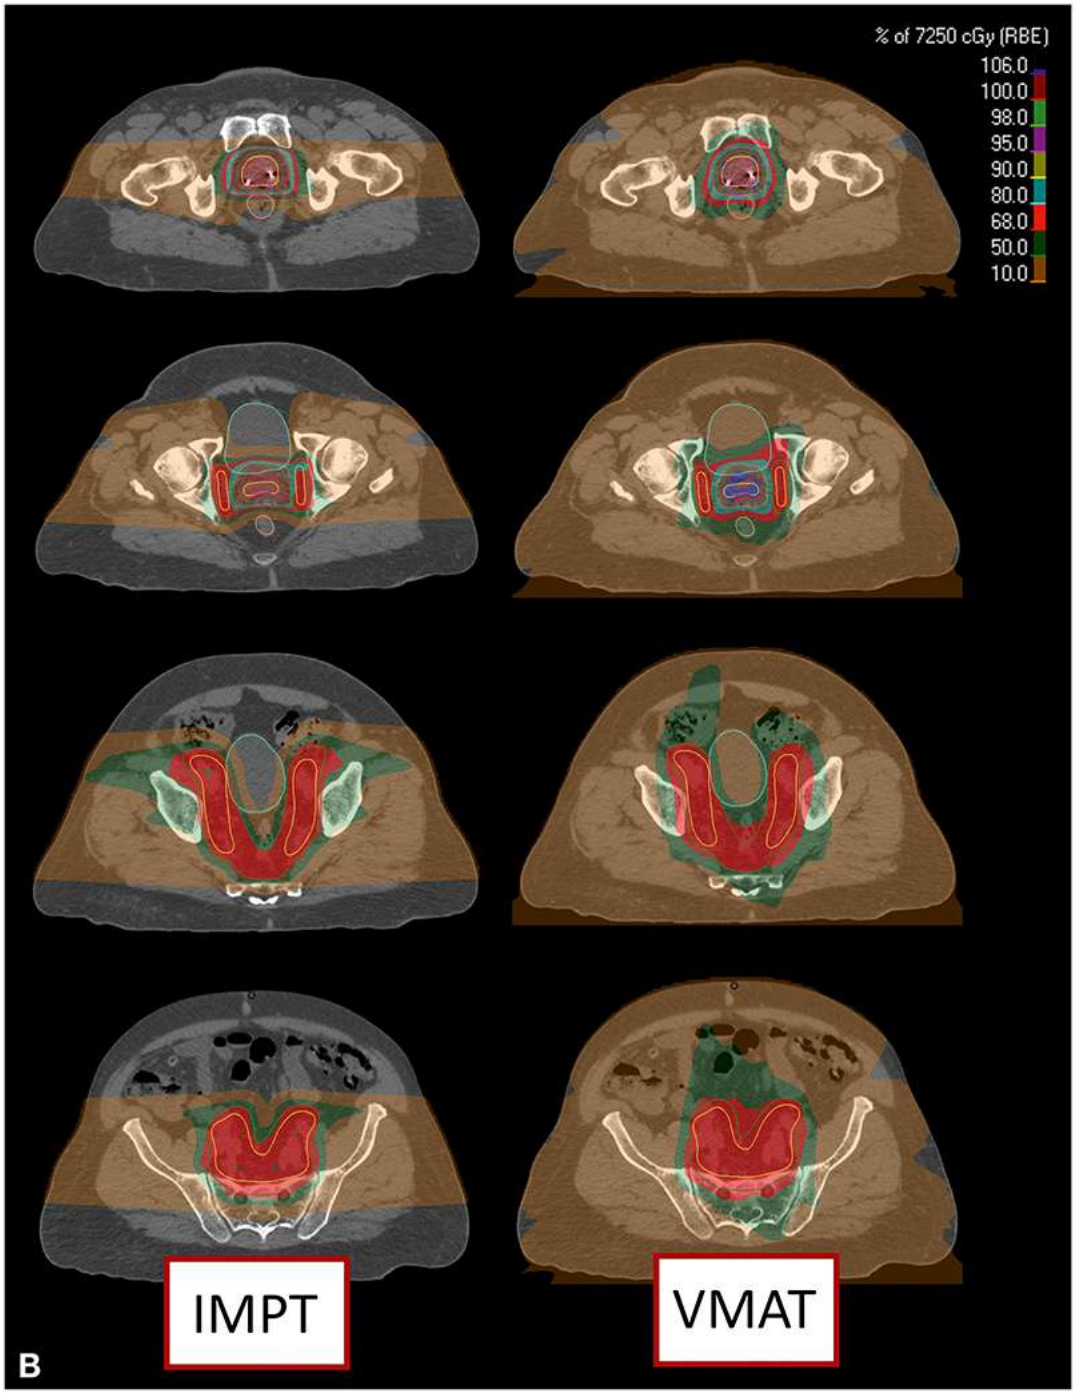


FIGURE 20.13 A. Axial, sagittal, and coronal planes of treatment plans with volumetric modulated arc therapy (VMAT), double-scatter proton therapy (DS PT), and intensity-modulated proton therapy (IMPT) for a patient with **prostate cancer** with a very large median lobe, which protruded into the bladder, making it difficult to meet dose constraints to the bladder wall. The target volume is shown in the heavy magenta line, the bladder is outlined in aqua, and the rectum is in yellow. A rectal balloon was used to stabilize the prostate and reduce the dose to the posterior portion of the rectum. As apparent, the VMAT plan delivered a low dose to a larger volume of nontargeted pelvic tissue, including the rectum. The target coverage goals were to deliver 100% of the prescribed dose to 95% of the planning target volume (PTV) and to deliver 95% of the prescribed dose to 100% of the PTV. As apparent, all plans met both target coverage goals with a high degree of dose homogeneity. The protection goals for the bladder wall, volume receiving at least 30 Gy less than 35 mL (V30 Gy <35 mL) and 80 Gy less than 8 mL (V80 Gy <8 mL), could not be met with the VMAT plan; the DS PT plan met the goal for the volume of bladder receiving 80 Gy, but not the volume receiving 30 Gy. The IMPT plan met all bladder protection goals. All plans met the relative rectal wall dose goals, but not the rectum absolute dose goals, though the IMPT plan came the closest to fulfilling this objective. A gel spacer may have helped in this case to meet the rectum dose constraint. B. Comparative plans for prostate, proximal seminal vesicle, and **pelvic node treatment in prostate cancer** using IMPT and photon-based VMAT treatment planning with a rectal spacer. Both plans achieved excellent

target coverage. The rectal spacer allowed both plans to minimize exposure of the anterior rectal wall to high doses (>59 Gy). The major difference is the substantial low- to moderate-dose bath covering the rectum and pelvic soft tissues in VMAT plans compared with the IMPT plan. With the IMPT and VMAT plans, the relative volumes of rectum exposed to 40 Gy (RBE) were 11.1% and 33.5%, to 30 Gy (RBE) were 18.3% and 59%, and to 20 Gy (RBE) were 28.7% and 68.5%, respectively. The volume of bowel space receiving 45 Gy (RBE) was 331.8 mL with the IMPT plan and 502.4 mL with the VMAT plan. Bladder exposure was similar between the two plans, but integral doses were 237.3 J for the IMPT plan and 442 J for the VMAT plan. RBE, relative biologic effectiveness.

Figure 20.13B shows VMAT and IMPT plans for a patient requiring prostate, proximal seminal vesicle, and elective pelvic node irradiation. The DVH comparison demonstrates substantial improvement in low-dose exposure to the rectum and bowel space with the VMAT plan. For example, the relative volume of rectum exposed to 25 Gy was 63.4% with the VMAT plan and 23.1% with the IMPT plan; the absolute volume of bowel space receiving 45 Gy was 502.4 cm^3 with the VMAT plan and 331.8 cm^3 with the IMPT plan. The overall integral dose with the VMAT and IMPT plans were 442 and 237.3 J, respectively.

COMPARATIVE EFFECTIVENESS OF PROTON AND PHOTON THERAPY

In medical interventions, level I evidence of comparative effectiveness is desirable but frequently difficult to generate: Fewer than 5% of adults currently participate in clinical trials in the United States. Among the reasons cited for low clinical trial participation are restrictive eligibility criteria, insurance coverage, distrust of physicians or the medical system, patient preference for either the “tried and true” or the “new” approach, physician equipoise, and institutional disincentives. In radiation therapy, randomized trials were not conducted to compare orthovoltage and cobalt, cobalt and x-rays, or 3DCRT with either SRT or IMRT before the general adoption of each of these technologies; each technology was adopted based on improved radiation dose distribution and the expectation of consequent improved clinical outcomes. However, many entities have called for comparative effectiveness evidence before adopting PT.

With respect to the design of comparative effectiveness studies in PT, the basic difference between protons and photons is the difference in beam entrance dose and exit dose that leads to significant differences in integral dose to nontargeted tissues. The essence of a randomized clinical trial of PT and photon-based therapy thus would be to test whether changes in integral dose result in clinical outcomes that can be measured, that is, toxicity or functional loss from injury to nontargeted tissue. Altruism, therefore, would be the primary motivation for patient participation if the informed consent process allowed for autonomy. It is unclear how willing patients would be to participate in such trials. Although there has been a significant increase in proton facilities in the United States and worldwide over recent years (Figure 20.14), only 44 operational proton facilities and no carbon ion facilities exist in the United States,[280] and particle therapy accounts for only 1% to 2% of radiation treatments delivered in the United States. Of note, the growth in the number of proton facilities in the United States mirrors the global growth. Unsurprisingly, no particle therapy facilities are located in nations deemed low- and middle-income countries by Research4Life due to being under-resourced.[281] Given the relatively few sites currently providing PT, some practical issues affecting comparative effectiveness research in protons also exist. For example, some patients would not be able to travel to receive PT, and others who might travel to receive PT might withdraw from a randomized study if assigned to receive conventional radiation therapy, which could be delivered more conveniently in their hometown. Insurance coverage with PT has continued to be unpredictable in patients without traditional Medicare coverage[282-284] and is often not verified in a time frame that would permit study participation. Finally, the number of patients and resources required for randomized controlled trials raise concerns regarding the best use of currently available PT treatment and research slots. Some investigators believe that more questions could be answered in the same time frame as a randomized controlled trial with a series of well-designed sequential studies to optimize PT through dose escalation and hypofractionation or comparative effectiveness cohort studies. As much is rapidly developing in treatment planning and delivery of PT, there are substantial risks to premature comparative trials, particularly in a multi-institutional design, because of the learning curve necessary to produce and deliver optimal PT.[285]

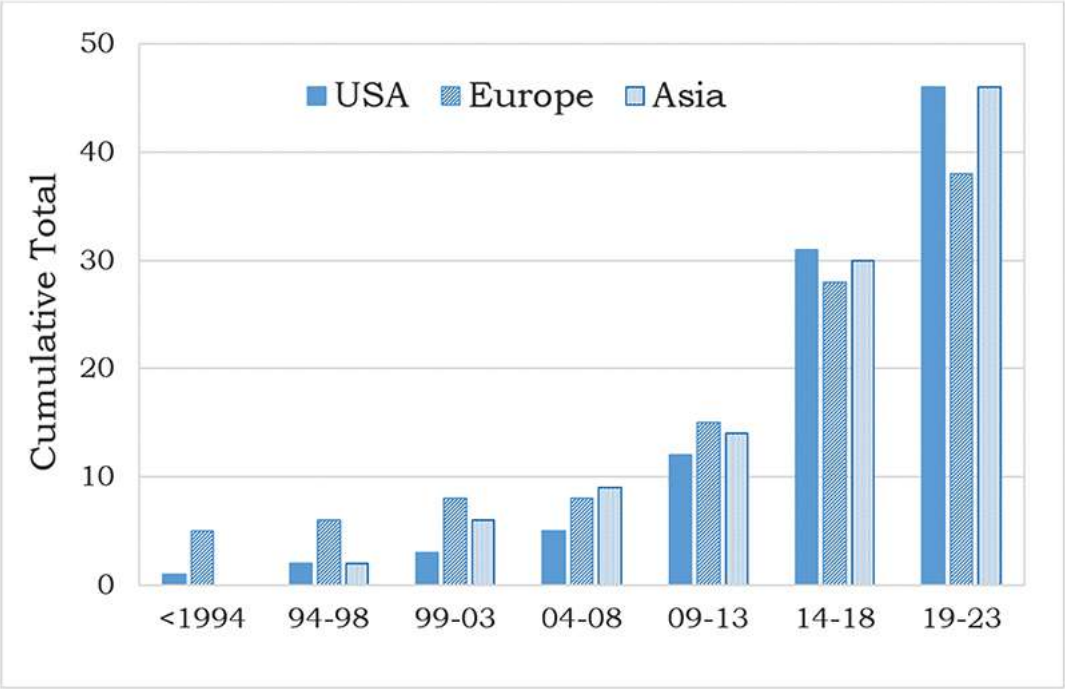

FIGURE 20.14 This graph depicts the cumulative number of particle therapy facilities over time in the United States, Europe, and Asia. All facilities before 1990 had "fixed" beams; Loma Linda University in California, which opened in 1990, was the first facility to have a rotational gantry. Of note, at the end of 2023, there were 130 operational particle therapy facilities across the world, including 14 carbon and 116 proton facilities. Whereas there was a similar slope for the growth in number of particle facilities in the United States, Europe, and Asia, there were no carbon facilities in the United States at the end of 2023. (In this graph, the Middle East is included in Asia and Russia and the Scandinavian countries are included in Europe.)

Despite these challenges, there are a few completed or ongoing randomized trials comparing photon- and proton-based therapy in lung cancer,[285-287] prostate cancer,[277] oropharyngeal carcinoma,[288] glioblastoma,[289] and breast cancer,[290] as well as trials comparing proton- and carbon-based therapy in skull base sarcomas,[102] glioblastoma,[291] and prostate cancer.[13,14]

In pediatric cancer survivors, increased risks of second malignancies and cardiovascular disease have been associated with radiation doses as low as 4 to 15 Gy.[292] In addition, elegant dose modeling studies at St Jude Children's Research Hospital have suggested no threshold dose for radiation injury in the childhood brain.[157] Thousands of children and many years of follow-up would be required to assess the results of a hypothetical controlled trial of PT and conventional radiation to determine whether the reduction in low-dose exposure to the brain and total body with PT would indeed result in a lower incidence of second malignancies or late cardiac injury. In the process, many children would intentionally be exposed to low-dose radiation in nontargeted tissues in the brain, likely resulting in permanent decreased neurocognitive function. Therefore, comparative trials will likely not be done in pediatric patients. Similar arguments may follow for Hodgkin lymphoma, another uncommon malignancy that affects relatively young patients with a high cure rate, long life expectancy, and substantial risks for second malignancy and late cardiac injury.

Comparative Cost-Effectiveness

Many factors must be accounted for in comparing the costliness and cost-effectiveness of different radiation technologies. These include facility and equipment costs, operating and maintenance costs, patient throughput, clinical outcomes, and the global and individual impact of those clinical outcomes.

Current PT equipment and facilities are up to 10-fold more expensive to construct than conventional radiation therapy facilities capable of treating a similar patient volume. In addition, operating costs are higher by 1- to 3-fold but vary significantly between countries[293] and even regions within the United States. Carbon facilities are 4-fold the cost of proton facilities with 2- to 3-fold the operational costs. Substantial differences exist between patient throughput in conventional radiation and proton facilities; however, that may offset differences in initial and

operating costs. Typically, conventional radiation equipment is used for a single daily work shift and is replaced every 7 to 10 years. Most PT facilities, however, operate two shifts a day, and equipment is expected to last 20 years or more. The Harvard Cyclotron was in use for over 40 years and closed primarily because of the availability of a new gantry-based clinical facility. The Loma Linda University synchrotron and most of its gantries have continuously operated for over 33 years. PT equipment appears to be substantially more durable than linear accelerators. Thus, the actual patient throughput (*for a given patient mix*) in a proton facility may be substantially higher than typical for a conventional radiation therapy facility, perhaps double the patients per day (because of double shifts) for 2 to 6 times as many years of operation, leading to a 4- to 12-fold increased throughput with proton facilities compared to photon facilities. PT throughput may be further enhanced if hypofractionation is more feasible with PT than with x-rays. Although the initial cost of the facilities and equipment is a known factor, ultimate throughput and clinical outcomes evolve over time so that the true cost-effectiveness of PT relative to conventional radiation will not be known until there are long-term facility performance and clinical outcome data. Different societies may interpret these data differently based on cultural values and prioritization of long-term cost-effectiveness for society or rapid return on investment for investors.

The impact of a particular clinical outcome may affect stakeholders differently. For example, if no intervention (cost) is associated with a radiation injury affecting a patient's quality of life, that particular clinical outcome may be valued differently by a patient and their insurer. Currently, there is no objective way to resolve such valuation differences. Meaningful cost-effectiveness analyses must account for a number of variables that are ill-defined and difficult to reduce to financial units. Regardless of the outcomes of cost and cost- effectiveness analyses, a shift to PT as a predominant radiation modality will likely require a paradigm shift in philosophy about both profit and daily operations.

CHALLENGES

The multiple challenges facing PT are complex and interrelated.

The first involves **technical developments** necessary to realize the full clinical outcome potential of PT, including the following:

- Improved treatment planning systems that better account for proton-stopping power and biologic effects of variations in LET and RBE along the beam path
- Online volumetric imaging and real-time range verification to ensure accuracy
- Real-time treatment plan adaptation to changes in tumor and/or normal tissue
- Increased delivery speed to minimize motion mitigation and improve operational workflow

The second challenge is generating reasonable evidence for the improved clinical outcomes anticipated with improved dose distributions. The development of reasonable evidence requires a critical mass of treatment facilities, a sufficient number of patients, sufficient technology maturation to reflect the modality's potential for outcome improvements, sufficient physician expertise to employ optimal techniques, and clinical trials that are scientifically credible, appealing to patients, nondisruptive to general clinical operations, and supported by funding agencies. The larger the anticipated clinical difference between treatment arms, the less likely a physician would have equipoise and a patient would consent to randomization, making accrual to a randomized study difficult. With smaller anticipated differences, accrual might be feasible, but larger numbers of patients would be required to assess the difference. A full assessment of clinical outcomes typically involves long follow-ups to document differences in late effects as well as early outcomes. Thus, comparative studies of PT and photon therapy will likely require large numbers of patients, possibly nonrandomized study designs, and long-term follow-up, making the funding of such studies challenging.

The third challenge is the development of **less expensive equipment** to lower the cost of participation in PT by patients, providers, hospitals, and payers. Despite the paucity of comparative effectiveness data for PT, the compelling dosimetric rationale drives increased capacity, although not as rapidly as commonly perceived. Although PT facilities have been described as increasing in number exponentially, studies by Miller et al and Waddle et al have shown minimal diffusion.[294,295] The primary barrier to more rapid diffusion has been the cost of facilities. Vendors' current solutions to lowering the cost of PT have converged on developing one-room facilities. Instead of installing a single large cyclotron or synchrotron that provides a proton beam for three to five treatment rooms, a smaller cyclotron could service only a single room, permitting access to the technology for 30% to 40%

of the cost of a full facility but with a commensurate reduction in capacity. True cost reduction will likely require significant technology development, which may only be driven by a significant increase in market demands.

Finally, the fourth challenge to progress in PT is attaining a **critical mass of facilities**. In 2005, just three proton facilities treated nonocular tumors in the United States. In 2015, just a decade later, there were 5 times as many facilities in operation in the United States, treating approximately 5,000 patients annually.[296] In 2017, there were only 26 centers in operation in the United States, and by 2024, this jumped to 47 proton facilities.[280] However, despite the 10-fold increase in proton facilities in the United States over the past 17 years, this pales compared to the over 4,000 conventional radiation facilities in operation. A critical mass of facilities, physicians, and physicists is necessary to collaborate with industry on technological developments, conduct sound clinical research, and drive significant market-driven cost reduction developments.

EMERGING TECHNOLOGIES IN PARTICLE THERAPY

Several new and emerging technologies are expected within the next several years. At the very top of this list is ultrahigh dose rate radiotherapy, known colloquially as FLASH. Preclinical studies have shown that radiation delivered in this manner, at dose rates higher than 40 to 100 Gy/s, can significantly improve the therapeutic ratio compared to radiation delivered at conventional dose rates of several Gray per minute.[297] The mechanism of the FLASH response is not entirely understood but is thought to be related to the instantaneous depletion of oxygen along the beam path, which leads to transient radioresistance in normal tissues. While early studies used modified electron beams and preclinical x-ray irradiators, commercial PT systems have garnered significant interest as the likely best option for near-term clinical implementation. “Shoot-through” FLASH, which utilizes the entrance region of the proton depth-dose curve, has already been used in the first known patient trial of FLASH radiotherapy. The FAST-01 study at the University of Cincinnati Cancer Center recently reported favorable outcomes in eight patients treated for bone metastases in the extremities, and a follow-up study, FAST-02, is currently enrolling up to 10 patients with bone metastases in the thorax.[298]

The shoot-through technique avoids beam losses in the degrader and beam transport system by utilizing the maximum energy produced by the cyclotron. In this way, it efficiently achieves FLASH dose rates without the need for significant modification of the PT system. The downside, of course, is the loss of the Bragg peak and its ability to limit dose beyond the target. Conformal FLASH is another technique currently under investigation that uses patient-specific ridge filters and range shifters to modulate the beam’s energy while also distally conforming it to the target. Ideally, conformal FLASH will further enhance the therapeutic ratio by combining the benefits of both conventional PT and the FLASH effect. While quite promising, considerable work is needed prior to the realization of this technique involving various aspects of dosimetry, beam monitoring and system design, quality assurance, and radiobiology.

Aside from FLASH, the other technological leap expected in the near future is proton arc therapy (PAT), a PBS technique that allows for the automated delivery of multiple proton beams either as a discrete set of gantry angles or in a dynamic, sweeping motion. Compared to IMPT, PAT is expected to improve dose conformity, delivery efficiency, and robustness and provide a more favorable LET distribution.[299-301] PAT is currently under development by multiple vendors and clinical programs working to establish the technology, treatment planning algorithms, quality assurance tools and methods, and the clinical implications of the technique.[302-304] A unique challenge to dynamic PAT is distributing the energy layers that must be delivered within specified windows and optimized to limit upward jumps that increase energy but take several seconds to complete. One proposed method is to assign spots to a single energy layer within a discretized segment of the larger arc. The weighting of the spots is then optimized along with energy layer sequencing that sorts energy layers from high to low along the arc’s path.[305] Tradeoffs exist between the number of spots, energy layers, arcs, and upward energy jumps, as well as parameters such as optimization time, plan quality, and delivery efficiency. While these tradeoffs and other similar questions posed by PAT are still being investigated, proponents of the method are rapidly establishing the framework for clinical implementation. Early adoption of PAT is forthcoming, with the potential for widespread clinical use once the benefits and limitations have clearly been defined.

CONCLUSIONS

Particle therapy offers the promise of reduced toxicity to patients compared with photon therapy—by reducing the radiation dose to nontargeted tissues—and possibly enhanced disease control through differential tumor effects and normal tissue biologic responses. Reduced toxicity may be leveraged to increase disease control through dose

escalation or intensification (hypofractionation). Hypofractionation may result in lower health care costs as well as increased disease control and reduced toxicity. Additional clinical research and technical development are needed to optimize treatment planning and delivery of particle therapy, to document and maximize its potential clinical benefits, and to understand its full impact on health care economics.

CHAPTER 21

Physics and Radiobiology of Brachytherapy

Zhe (Jay) Chen, Jeffrey F. Williamson, David J. Brenner, Emily Draeger, and Mark J. Rivard

Brachytherapy (BT) (*brachy* means short in Greek) consists of placing sealed radioactive sources very close to or within the target tissue. Because the absorbed dose falls off rapidly with increasing distance from the sources, high doses may be delivered safely to a localized target region over a short time. This chapter reviews the properties and applications of commonly used sealed radionuclides and sources, methods of source strength specification and dose calculation, principles of implant design and dose specification for interstitial and intracavitary BT, and the basic radiobiologic principles governing clinical response to BT.

BASIC TERMINOLOGY

BT source implantation techniques may be classified in terms of the geometric approach to irradiating the target volume (interstitial, intracavitary, transluminal, or surface applications); the means of controlling source delivery (temporary or permanent implants); the source loading technology (preloaded, manually afterloaded, or remotely afterloaded); and the dose rate (low, medium, or high).

Interstitial BT consists of surgically implanting small radioactive sources directly into the target tissues either temporarily or permanently. A *permanent* interstitial implant remains in place indefinitely and is not removed; the initial source strength is chosen so that the prescribed dose is fully delivered only when the implanted radioactivity has decayed to a negligible level. Low-energy photon-emitting sources are typically used.

Intracavitary BT consists of positioning applicators (bearing the radioactive sources) into a body cavity in proximity to or within the target tissue. Intracavitary BT is used most widely for the treatment of localized gynecologic malignancies and postoperative treatment in early-stage conservatively managed breast cancer. Intracavitary implants are mostly *temporary implants;* they are left in the patient for a specified time to deliver the prescribed dose. Some intracavitary implants place radioactive sources, such as GammaTiles, permanently into the surgical cavity. With a few exceptions for temporary implants, the patient must be confined to a controlled, if not shielded, area in the hospital to manage the radiation safety hazard posed by the large ambient exposure rates around implants using high-energy photon-emitting radionuclides.

Transluminal BT consists of inserting a single-line source into a body lumen to treat its surface and adjacent tissues. This is done most commonly for endobronchial, esophageal, biliary, and coronary artery treatments.

Surface BT (sometimes called plesiotherapy or mold therapy) uses an applicator permitting an array of radioactive sources or dwell positions, usually designed to deliver a

uniform dose distribution, that is placed on the skin or mucosal surface immediately adjacent to the target tissue.

Until the early 1960s, radioactive sources (needles or seeds for interstitial therapy or preloaded applicators for intracavitary therapy) were implanted directly into the patient. Radiation exposure to the radiation oncologist and operating room staff was reduced significantly with the advent of *afterloading* technology.[1,2] *Manual afterloading* consists of implanting nonradioactive tubes or intracavitary applicators into the patient. Following the transport of the patient to a dedicated room in the hospital, sources are manipulated into the applicators by means of forceps and other handheld tools. Exposure to staff responsible for source loading and the care of BT patients can be greatly reduced or eliminated by the use of a *remote afterloading system*, which consists of a motor-driven source transport system for robotically positioning radioactive material within the patient (see Chapters 23 and 24).

According to the International Commission on Radiation Units and Measurements (ICRU) Report 38,[3] *low-dose rate (LDR)* implants deliver doses at the rate of 40 to 200 cGy/hour (0.4-2 Gy/hour), requiring treatment times of 24 to 144 hours, during which the patient is confined to an inpatient treatment room. At the other extreme, *high-dose rate (HDR)* BT uses dose rates in excess of 0.2 Gy/min (12 Gy/hour). In fact, modern HDR iridium-192 (^{192}Ir) remote afterloaders deliver instantaneous dose rates as high as 0.12 Gy/s (440 Gy/hour) at a distance of 1 cm, resulting in treatment times of a few minutes. Such treatments must be delivered in shielded vaults using remote afterloading systems but allow fractionated BT to be delivered on an outpatient basis. Medium-dose rate delivery, defined as the 2 to 12 Gy/hour range, is rarely used today. Although not recognized by ICRU Report 38, the ultra-low dose rate (ULDR) range (0.01-0.3 Gy/hour) is also of great importance today as it is the dose rate domain used in permanent implants with ^{125}I, ^{103}Pd, and ^{131}Cs seeds.

PROPERTIES OF BRACHYTHERAPY SOURCES AND RADIONUCLIDES

The clinical utility of any radionuclide depends on practical properties, such as emission energies and radiation type, radioactive decay half-life, radiation output per unit of radioactivity, and the specific activity (radioactivity per unit mass; Ci/g). In addition, the methods of producing the radionuclide and its physical and chemical forms strongly influence cost-effectiveness, safety, and toxicity. Detailed properties of BT radionuclides are listed in Table 21.1.

TABLE 21.1 PHYSICAL PROPERTIES AND USES OF BRACHYTHERAPY RADIONUCLIDES

Element	Radionuclide	Average Energy (MeV)	Half-Life	HVL Lead (mm)	Exposure Rate Constant[a] ΓΔ	Source Form	Clinical Application
Obsolete sealed sources of historical significance							
Radium	^{226}Ra	0.83 (average)	1,620 y	16	8.25[b]	Tubes and needles	LDR intracavitary and interstitial

Element	Radionuclide	Average Energy (MeV)	Half-Life	HVL Lead (mm)	Exposure Rate Constant[a] ΓΔ	Source Form	Clinical Application
Radon	^{222}Rn	0.83 (average)	3.83 d	16	8.25[b]	Gas encapsulated in gold tubing	Permanent interstitial temporary molds
Currently used sealed sources

[b]0.5-mm platinum filtration; units of $R \cdot cm^2 \cdot mg^{-1} \cdot h^{-1}$.

Photon Spectrum and Dosimetric Characteristics of Brachytherapy Sources

The dose delivered by a BT procedure depends on the individual source strengths, source arrangement, and implant duration as well as the dosimetric characteristics of the implanted sources. These dosimetric characteristics are described by specifying the distribution of dose rates per unit strength about the source, often in terms of an "away-and-along" table[4] in Cartesian coordinates or in terms of the Task Group (TG) 43 protocol[5] described later in this chapter. The single-source dose distribution is of central importance to BT treatment planning because commercial computer planning systems estimate dose distribution from the spatial coordinates of the implanted sources using the principle of superposition. The source-superposition algorithm estimates the contributions of each source to each point of interest. These contributions are summed to estimate the total dose rate at each point. Often, total dose rates are calculated over a two-dimensional (2D) grid of points and are represented as isodose rate curves.

For conventional BT, for which the therapeutically relevant distance range is 2 to 20-mm, only photons (γ-rays or characteristic x-rays) with energies in excess of 15 keV contribute to the therapeutic effect. In general, four factors influence the single-source dose distribution for photon-emitting sources: (1) distance (inverse-square law); (2) radiation absorption and scattering in the source core and encapsulation; (3) photon attenuation; and (4) scattering in the surrounding medium (Figure 21.1). Encapsulation prevents radioactive material from leaking out of the source and absorbs nonpenetrating radiation (β-rays, α-particles, and low-energy photons) that would otherwise give rise to high surface doses while negligibly contributing dose to the target.

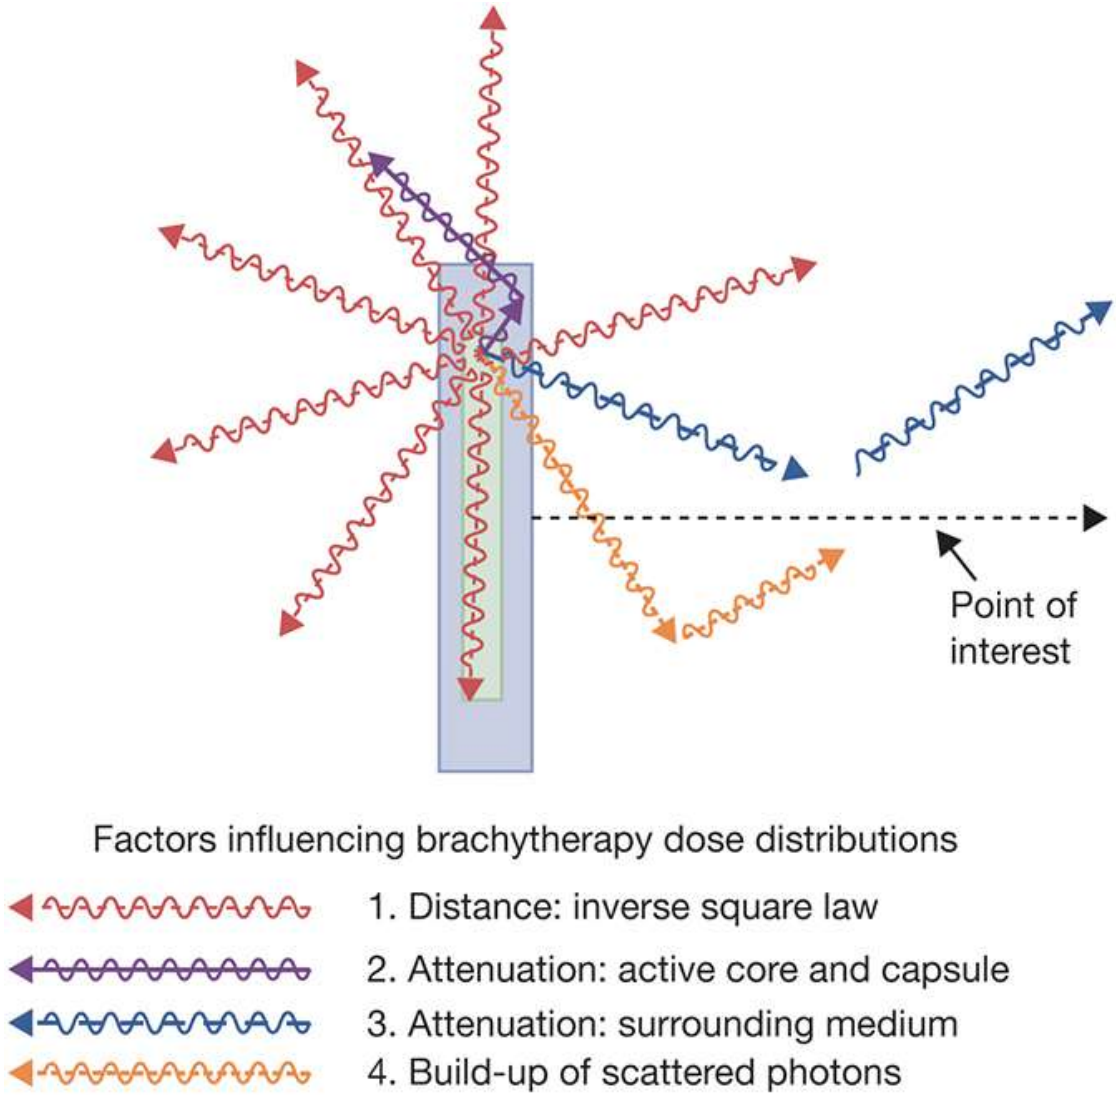

FIGURE 21.1 Typical cylindrical brachytherapy source, consisting of an active core (inner cylinder within which radioactivity is uniformly distributed) and the surrounding encapsulation (usually stainless steel or titanium for modern sources). The four principal factors influencing the relative dose distribution are (1) distance, (2) attenuation and scattering of photons by the source structure and two competing effects of the surrounding medium: attenuation of primary photons (3) and accumulation of scattered photons (4) originating throughout the medium.

Each voxel of radioactive core material shown in Figure 21.1 can be assumed to be an isotropic point source (Figure 21.2). Because of the straight line emission of photons with equal likelihood in all directions, photon intensity or fluence, $\Phi(r)$, at any point is proportional to the inverse square of its distance, r:

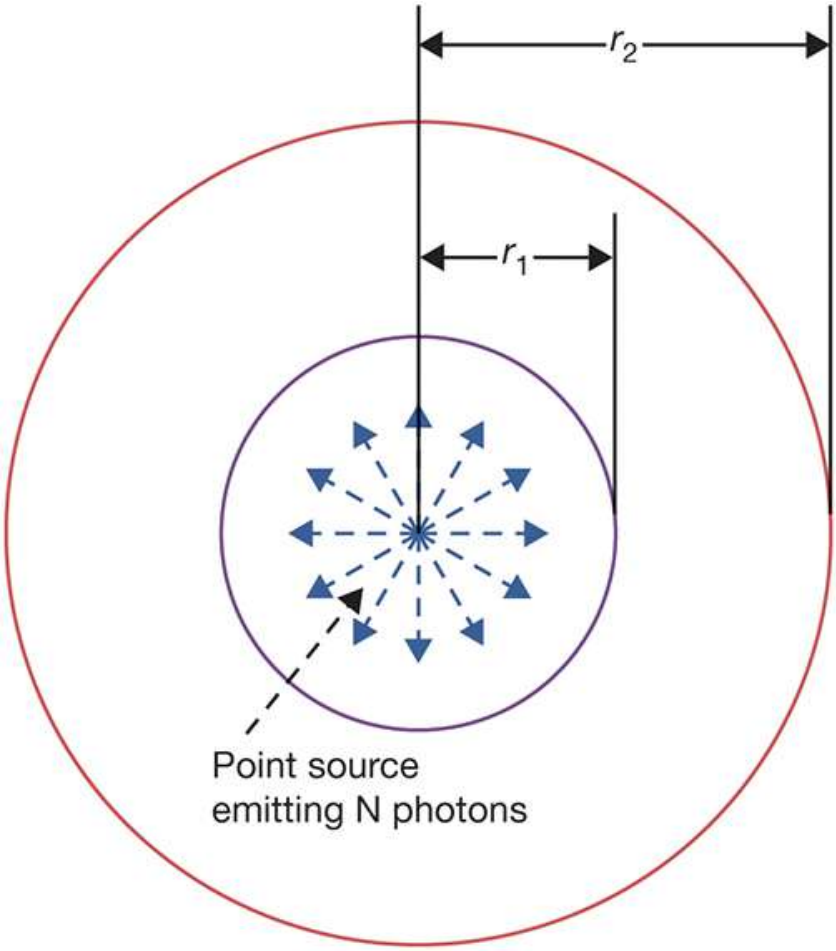

FIGURE 21.2 An *isotropic point source* of activity, *A*. To illustrate the derivation of inverse-square law, the source is surrounded by vacuum and placed at the center of two concentric spherical surfaces of radii r_1 and r_2. By definition, an *isotropic point source* has no extension and radiates photons with equal likelihood in all directions in straight line paths.

$$\Phi(r) = \frac{\text{No. incident photons}}{\text{Unit area irradiated}} = \frac{\text{No. photons emitted}}{4\pi r^2} \propto \text{Dose}(r) \propto \text{Exposure}(r) \tag{21.1}$$

assuming that attenuation and scattering can be neglected.

As a result of this purely geometric effect, the absorbed doses $D(r_1)$ and $D(r_2)$ at the two distances r_1 and r_2 (Figure 21.2) are related by:

$$\frac{D(r_1)}{D(r_2)} = \frac{\Phi(r_1)}{\Phi(r_2)} = \left(\frac{r_2}{r_1}\right)^2 \qquad (21.2)$$

This fundamental law applies exactly to each point of the radioactive core of the source shown in Figure 21.1, assuming that there is no attenuation and scattering of photons by the surrounding medium. However, Eq. 21.2 will not accurately describe the "collective" dose falloff arising from the combined action of the point sources distributed throughout the core, unless both r_1 and r_2 are large relative to the active source dimensions. Of the four factors influencing the dose distribution (see Figure 21.1), inverse-square law is by far the most important. For a pure isotropic point source, dose will decrease by more than a factor of 100 between 0.5 and 5 cm. The influence of the remaining factors over the same distance range rarely exceeds a factor of 2 or 3. Consequently, the dosimetric characteristics of implants (eg, the heterogeneous dose distribution within the target tissue and rapid fall off dose outside the implanted volume) can be accounted for by applying inverse-square law to each point-like element of radioactivity within the implant. Control of intersource spacing and positioning relative to the target and dose-limiting tissues is the most challenging issue in delivering BT.

Although the inverse-square law dominates BT dose distributions, the surrounding medium and the source structure significantly affect the dose distribution (see Figure 21.1). The source core and surrounding capsule reduce dose at the point of interest through absorption and scattering of primary photons. Primary photons contributing dose to points located near the longitudinal source axis (cylindrical axis of the source or axis of rotation) must traverse longer pathlengths of capsule and core material and, therefore, experience more attenuation than photons contributing dose to equidistant points on the transverse source axis (plane perpendicular to the longitudinal source axis that bisects its active core). For any fixed distance from the source center, doses near the longitudinal axis are usually smaller than on the transverse axis. This phenomenon is known as *oblique filtration* and is the main cause of dose *anisotropy* (variation of dose as a function of polar angle at each fixed distance relative to the source center) characteristic of BT sources. Because BT sources are cylindrically symmetric, the dose distribution will be equatorially isotropic (constancy of dose as a function of azimuthal angle for each fixed polar angle and distance).

The tissue equivalent medium surrounding the source affects the dose distribution in two competing ways (factors 3 and 4 described above and in Figure 21.1). At each point of interest, the intervening medium reduces the dose distribution by attenuating primary photons (deflecting them from their straight line trajectories). At the same time, photons are being emitted in all directions from the source and interacting with the medium by means of Compton scattering and photoelectric absorption. Thus, each volume element of tissue is effectively radiating scattered photons in all directions, many of which contribute to dose at the point of interest. This mechanism, known as scattered photon build-up, enhances the dose. The overall influence of the surrounding medium is the combined effect of these two

competing processes: photon attenuation and scattered photon build-up. In contrast to external beam radiotherapy (EBRT), in which the scattering volume is limited to a narrow cone, scattered photons dominate BT dose distributions at distances greater than 2 and 5 cm for low- and high-energy photon emitters, respectively. Photon scattering is the main source of complexity in BT dose measurement and algorithm development.

Figure 21.3 demonstrates that the relative dose versus distance from the source is nearly independent of its photon energy so long as the average photon energy is greater than 200 keV. In this energy range, dose deviates from inverse-square law by less than 5% over the 1- to 5 cm distance range. All of the "radium equivalent" radionuclides, including ^{60}Co, ^{137}Cs, ^{192}Ir, and ^{198}Au, fall into this energy range. This behavior greatly simplifies BT dosimetry and is the result of equilibrium between primary photon attenuation and build-up of scattered photons. Only for low-energy sources (eg, ^{103}Pd, ^{125}I, and ^{131}Cs) does the depth-dose curve significantly deviate from inverse-square law. Because photon absorption rather than Compton scattering dominates energy deposition below 40 keV, scatter build-up is unable to compensate for loss of dose resulting from attenuation.

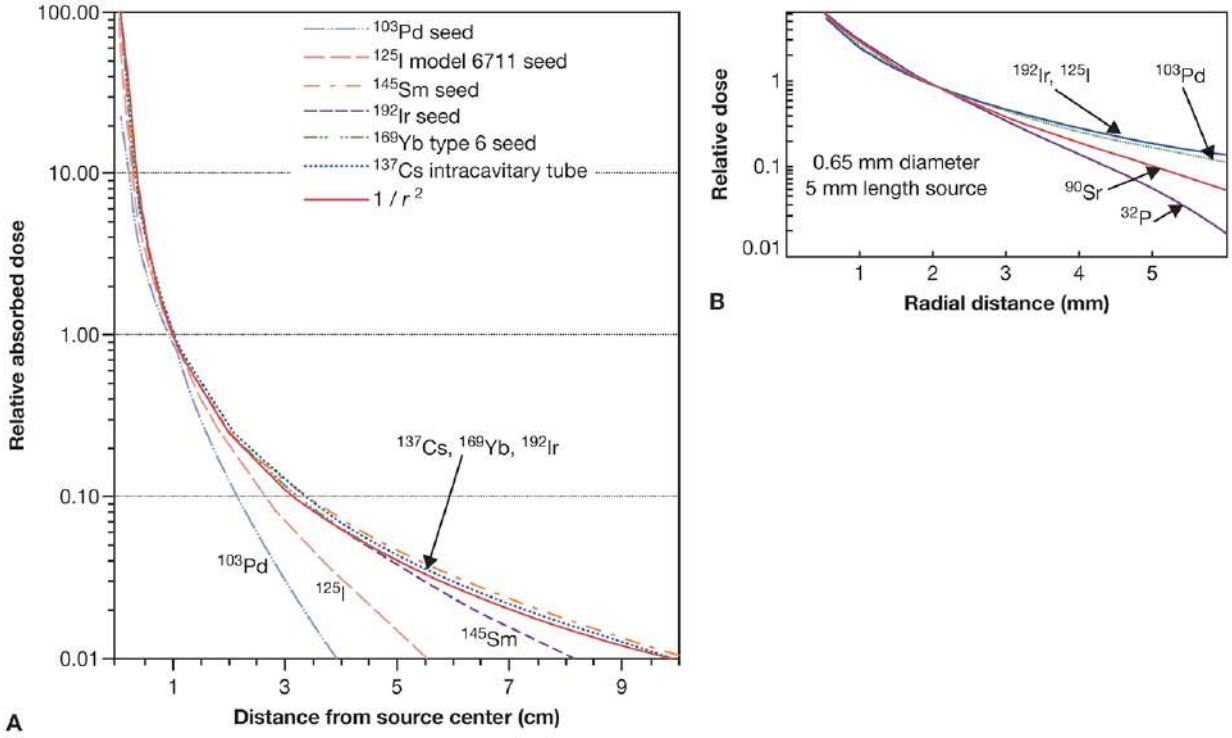

FIGURE 21.3 A. Variation of dose as a function of distance for point sources of ^{60}Co, ^{226}Ra, ^{137}Cs, ^{198}Au, ^{192}Ir, and ^{125}I. The results are normalized to 100% at 1 cm distance. The function ($1/r^2$) is plotted for comparison. B. Relative dose (normalized to 1.0 at 1 mm) versus distance for various cylindrical sources (0.65 mm diameter and 5 mm long) over the 1 to 5 mm distance range. (Reprinted from Amols HI, Zaider M, Weinberger J, Ennis R, Schiff PB, Reinstein LE. Dosimetric considerations for catheter-based beta and gamma emitters in the therapy of neointimal hyperplasia in human coronary arteries. *Int J Radiat Oncol Biol Phys*. 1996;36[4]:913-921. Copyright © 1996 Elsevier. With permission.)

For high-energy radionuclides, Figure 21.4A and B show that both absolute dose rates (cGy/hour to fat or water tissue per mgRaEq or unit air-kerma strength [S_K]) and relative dose distributions are nearly independent of energy and composition of the surrounding medium above 100 keV. Compton scattering, which dominates photon absorption and scattering above 100 keV, depends mainly on the electron density (electrons/g) of the medium, which is nearly constant for all biologic materials. Below this energy range, absolute and relative dose distributions vary significantly with energy and composition (atomic number) of the surrounding medium. Implanting a ^{125}I seed in fat medium (effective atomic number of Z_{eff} = 6) will deliver about half the absorbed dose at 1 cm, compared to the expected dose in water (Z_{eff} = 7.5). This is because energy absorption per unit mass from photoelectric interactions is proportional to the cube of the atomic number (Z_{eff}^3) of the medium. Despite the significant impact of tissue composition heterogeneities on low-energy seed BT dose delivery, only recently have treatment planning and dose measurement practices began to address tissue and applicator inhomogeneities.[6]

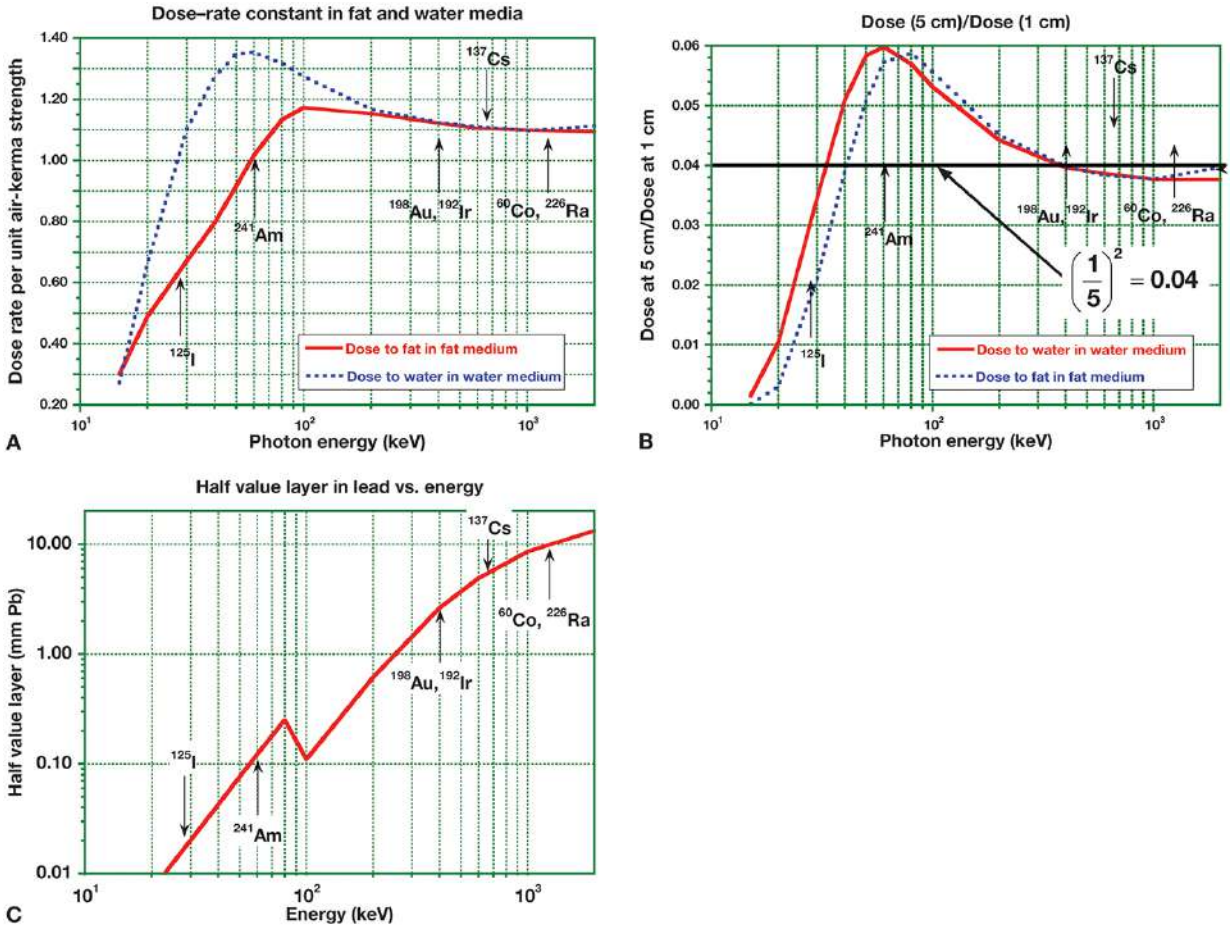

FIGURE 21.4 Variation of dosimetric properties of monoenergetic point sources as a function of photon energy. The location (in terms of average energy) of commonly used radionuclides is indicated by the labeled vertical arrows. A. Absolute dose rate per unit source strength in fat and water media at 1 cm distance. Source strength is specified in terms of output in air. B. Dose at 5 cm as a fraction of dose at 1 cm in fat and water media. The effect of inverse-square law, $(1/5)^2 = 0.04$, is shown for comparison as a broken line. C. Half-value layer in lead and the thickness (mm) in lead required to reduce primary dose by a factor of 2.

Figure 21.4B demonstrates that the inverse-square law actually underestimates relative dose at 5 cm by as much as a factor of 2 in the 60 to 100 keV energy range. In this narrow energy range, the photoelectric effect is negligible, whereas Compton scattering transfers most of the colliding primary photon energy to the scattered photon rather than to the Compton electron. As a result of this imbalance between energy absorption and photon scattering, build-up of scattered photons overcompensates for loss of dose as a result of primary photon attenuation out to distances of about 5 cm. Above the 100 keV threshold, the photon-energy spectrum is much less important to optimizing BT dose rate distributions than in EBRT.

Figure 21.4C demonstrates that although the high-energy photon spectrum is a relatively unimportant determinant of radium equivalent tissue dosimetry, it significantly influences the cost, weight, and thickness of shielding required to protect critical anatomic structures in the patient and personnel involved in patient care. The half-value layer (HVL) in lead

varies from 0.5 mm for a 100-keV source to 12 mm for ^{60}Co BT sources. Thus, for high-energy BT, a radionuclide with a mean energy of about 100 to 200 keV is optimal. The major benefit of low-energy sources is their ability to provide complete protection by thin lead foils (0.1-0.2 mm), greatly reducing exposure to physicians during the implant procedure and allowing permanent implant patients to be immediately released without posing a radiation safety hazard to the general public. There is interest in using radionuclides in the intermediate-energy range (60-120 keV).[7-9] Tissue dose distributions are still approximately radium equivalent in this energy range, and thin layers of lead provide significant sparing of dose-limiting normal tissues near the implanted volume.

Intracavitary Sources for Low-Dose Rate Gynecologic Brachytherapy

Since the 1930s, sources for classic LDR intracavitary BT have taken the form of "tubes" having a physical length of 2 to 2.5 cm and an external diameter of about 0.3 cm. For treatment systems influenced by the Manchester[10] and MD Anderson[11] treatment techniques, active lengths (ALs) of 1.3 to 1.5 cm are typical. Radionuclides for intracavitary applications should have a half-life long enough to support a +10-year working life without large variations in prescription dose rate so that the high cost of these reusable sources to be amortized over a large number of patient treatments. The average photon energy should be at least 60 keV, as the dose fall off for lower energy sources (eg, ^{125}I) is too rapid to adequately treat the target volume periphery (>2 cm from the applicator center) without overtreating mucosal tissues in contact with the applicator.

Radium-226 Sources

Radium-226 (^{226}Ra), a naturally occurring radionuclide, was the first radionuclide isolated, intensively investigated, and used in clinical BT. The unit of activity, the curie (Ci), originally was defined as the rate of disintegration within 1 g of ^{226}Ra. ^{226}Ra has a complex decay scheme, consisting of a cascade of transformations from one daughter product to another, ending with a stable isotope of lead, $^{206}_{82}\mathrm{Pb}$. ^{226}Ra decays to gaseous ^{222}Rn with a half-life of 1,600 years. Per disintegration, approximately 75 γ-rays are emitted by radium and its decay products, ranging in energy from about 0.05 to 2.4 MeV, giving an average energy of about 0.8 MeV. The maximum β-ray energy is about 3.3 MeV. The exposure-weighted average energy of ^{226}Ra is 1.25 MeV when its photon spectrum is filtered by 0.5 mm of platinum. Nearly all ^{226}Ra BT sources were filtered by at least 0.5 mm Pt, which reduces the surface dose contributed by β-particles to a negligible level.

Clinical ^{226}Ra sources consisted of discrete cells of radium salt (radium sulfate plus filler) placed in needles or tubes with platinum wall thicknesses of 0.5 and 1.0 mm, respectively. Intracavitary radium tubes were usually 22 mm long, containing 5 to 30 mg of radium (S_K = 30 to 200 μGy·m^2/hour), with ALs of 15 mm. For interstitial BT, the full-, half-, and quarter-intensity needles popularized by the Manchester LDR implant system typically contained 0.66, 0.33, or 0.165 mg of radium per centimeter of AL, respectively.

The clinical use of ^{226}Ra has disappeared and is now only of historic interest. The potential of damaged sources to leak radioactive salts or emit radon gas (^{222}Rn) is the major reason for its decline, and the exposure hazard to interstitial BT practitioners.[12] Also, the long half and disposal costs of spent ^{226}Ra sources present a significant financial liability. However, because of its many years of therapeutic use, several widely used quantities for source strength specification and prescription of intracavitary treatment are derived from the early experience with ^{226}Ra.

Cesium-137 Sources

Cesium-137 (^{137}Cs), a fission byproduct, was a popular radium substitute because of its 30-year half-life, dominating gynecologic intracavitary BT from 1970 to 2000. Its single γ-ray (0.66 MeV) is less penetrating (HVL_{Pb} = 0.65 cm) than the γ-rays from radium (HVL_{Pb} = 1.4 cm) or ^{60}Co (HVL_{Pb} = 1.1 cm). Because ^{137}Cs decays to solid ^{137}Ba, ^{137}Cs sources replaced ^{226}Ra in LDR gynecologic applications.

^{137}Cs BT sources were introduced in the early 1960s.[13,14] The most recent sources, for example, the Amersham model CDCS-J tube and 3M model 6500 intracavitary tube, consisted of radioactive cesium distributed within an insoluble glass or ceramic matrix,[4] which produced far less radiochemical hazard from ruptured sources than radon gas or cesium salts. ^{137}Cs sources were encapsulated in stainless steel sheaths with wall thicknesses of 0.5 to 1.0 mm, ALs of 13.5 to 15 mm, diameters of 2.6 to 3.1 mm, and total lengths of about 20 mm. In contrast, lightly filtered ^{137}Cs tubes produce nearly elliptical isodose curves. Consequently, vaginal applicator systems containing modern ^{137}Cs sources with their axes positioned perpendicular to the coronal patient plane (eg, the Fletcher colpostat) caused higher bladder and rectal doses than when loaded with ^{226}Ra tubes.[15] However, high-energy LDR BT has been largely abandoned in favor of high-energy HDR BT using high-intensity ^{192}Ir sources, with 85% of respondents in a survey reporting use of HDR or pulsed-dose rate (PDR) BT.[16] ^{137}Cs intracavitary tubes and other source configurations ceased to be commercially available in the United States after 2014, largely due to the National Nuclear Security Agency effort to remove ^{137}CsCl sources due to potential use as a radiologic dirty bomb.

Experimental Intracavitary Brachytherapy Radionuclides

Californium-252 (^{252}Cf) is a unique radionuclide with a 2.65-year half-life that decays by either α-particle emission (97%) or spontaneous fission (3%). Depending on the distance from the source, one-half to two-thirds of the total absorbed dose in tissue are the result of the neutron component. Assuming a relative biologic effectiveness (RBE) of 6 for the neutron component for LDR applications, approximately 90% of the biologically effective dose (BED) derives from the neutron component. The radiobiologic rationale for using ^{252}Cf, especially in treating bulky gynecologic malignancies, is that the high linear energy transfer (LET) neutron component more effectively depopulates the hypoxic core of a radioresistant tumor, thereby improving local control, while the rapid dose falloff maintains an acceptable level of late complications.[17] ^{252}Cf tube sources[18] required carefully designed

radiation protection and source handling procedures to reduce radiation exposure hazards to an acceptable level, due to the high neutron quality factor of 10 to 20 that is assumed by radiation protection standards.[19] Oak Ridge National Laboratory ceased fabrication of ^{252}Cf sources for medical use in 1997 and are currently not available elsewhere in the world. However, ^{252}Cf BT continues to be of clinical interest. Two groups using HDR ^{252}Cf BT remote afterloading systems have reported long-term clinical experiences[20,21] based on cohorts of locally advanced cervical cancer patients.

Ytterbium-169 (^{169}Yb)[8] and americium-241 (^{241}Am)[7] are examples of intermediate-energy photon emitters with average energies of 93 and 60 keV with half-lives of 32 days and 432 years, respectively. These radionuclides have been investigated as possible substitutes for ^{192}Ir.[22] Despite ^{169}Yb having an extremely high specific activity, none of these experimental prototype LDR sources[23] and HDR sources[9] have been commercially realized. Other promising intermediate-energy photon emitters include ^{57}Co,[24] ^{153}Gd,[25] and ^{101}Rh.[26]

Sources for Low-Dose Rate Temporary Interstitial Brachytherapy

The main additional requirement for radionuclides used in temporary interstitial BT is having a specific activity sufficient to support fabrication of miniaturized sources (less than 0.2 cm external diameter) so as to minimize trauma to the implanted tissues. Current interstitial implantation techniques favor disposable sources containing short-lived radionuclides that support afterloading and customization of AL.

Nonafterloading ("Preloaded") Sources: Radium and Cesium Needles

Radium-226 needles were the mainstay of interstitial BT until about 1970. These sources had external diameters of ~0.2 cm, ALs ranging from 0.3 to 4.5 cm, and Pt-Ir alloy encapsulation ranging from 0.5 to 0.65 mm in thickness. Because needle implantation can result in large exposures to the radiation oncologist's fingers, as well as whole-body exposure to operating room and implant imaging staff, interstitial implantation of ^{226}Ra or ^{137}Cs needles is no longer practiced.

Afterloading Interstitial Sources: ^{192}Ir Ribbons and Wires

Temporary interstitial BT experienced a renaissance in the 1960s because of the introduction of ^{192}Ir.[12] High specific activities can be achieved, and miniaturized interstitial sources can be fabricated relatively cheaply. The use of ^{192}Ir in BT was pioneered by Ulrich Henschke et al,[27] who developed a family of widely used afterloading techniques, and to Pierquin and Dutreix,[28] who developed the ^{192}Ir-based Paris interstitial system in the early 1960s.

^{192}Ir has a 73.8-day half-life and a complex decay scheme, not only dominated (95%) by β-decay to ^{192}Pt but also including electron capture (5%) to ^{192}O. Its photon spectrum includes characteristic x-rays and γ-rays ranging from 63 keV to 1.4 MeV and has an exposure-weighted average energy of 0.4 MeV. Compared with higher energy ^{137}Cs, the thicknesses of lead and concrete shielding can be reduced by 33% and 20%, respectively.[29]

More important advantages of ^{192}Ir sources are compatibility with afterloading techniques, technical flexibility, and patient comfort.

In the United States, LDR ^{192}Ir BT is still available (but rarely used) in the form of seeds, 0.05 cm in diameter and 0.3 cm long. The seeds are encapsulated in a 0.08-cm diameter nylon ribbon spaced at 0.5- to 1 cm center-to-center intervals and are available in strengths of 1 to 150 μGy·m^2/hour (0.1-20 mgRaEq). In Europe, ^{192}Ir was used in the form of a wire (0.03- or 0.06 cm outer diameter) consisting of an Ir-Pt core encased in a 0.01-cm Pt sheath. In addition to eliminating radiation exposure hazards in the operating room, ^{192}Ir ribbons and wires can be trimmed to the appropriate length for each catheter. Manual and remotely afterloading LDR interstitial BT utilization has declined in the developed world over the past two decades. A survey[30] indicated that in high-income European countries, only 11% of BT procedures performed in 2007 used LDR techniques compared to HDR (52%), PDR (10%), and permanent seed implants (21%).

Low-Energy Sources for Temporary Interstitial Brachytherapy

High-intensity ^{125}I sources[31] have been proposed for temporary interstitial implantation at classic dose rates. High-intensity ^{125}I seeds[32,33] now are used routinely as temporary interstitial sources for episcleral plaque treatment of ocular lesions.[34] By placing a 0.05-cm-thick Au shield over the episcleral plaque, tissues posterior to the eye are shielded, and radiation directed toward the tumor is partially collimated.[35] A disadvantage of high-intensity ^{125}I seed therapy is their higher cost relative to ^{192}Ir seeds. ^{103}Pd and ^{131}Cs sources have also been used as temporary interstitial sources in ocular plaque BT.[36]

Sources for Permanent Interstitial Brachytherapy

There are two basic approaches to permanent implantation. Classic LDR permanent BT originally used ^{222}Rn seeds and then ^{198}Au seeds, both of which have half-lives of a few days. To manage the radiation hazard resulting from their high-energy γ-rays, the patient must be confined to the hospital until the source strength decays to a safe level (2-3 half-lives or about 10 days). The contemporary approach to permanent implantation, ULDR BT, uses longer lived but low-energy photon emitters (eg, ^{103}Pd, ^{125}I, and ^{131}Cs). The patient tissue or a thin Pb foil is sufficient to limit ambient exposure rates to negligible levels, eliminating the need to hospitalize patients solely for radiation protection. During the implant procedure, low-energy photon sources markedly reduce radiation exposure to operating room personnel and to the radiation oncologist's hands.

Mathematics of Radioactive Decay

The phenomenon of exponential decay results in a reciprocal relationship between dose rate achieved and radionuclide half-life. The total activity, $A(t)$, present in the implant after an interval of time t has elapsed after source insertion, is given by Eq. 21.3, and exponential decay is demonstrated in Figure 21.5.

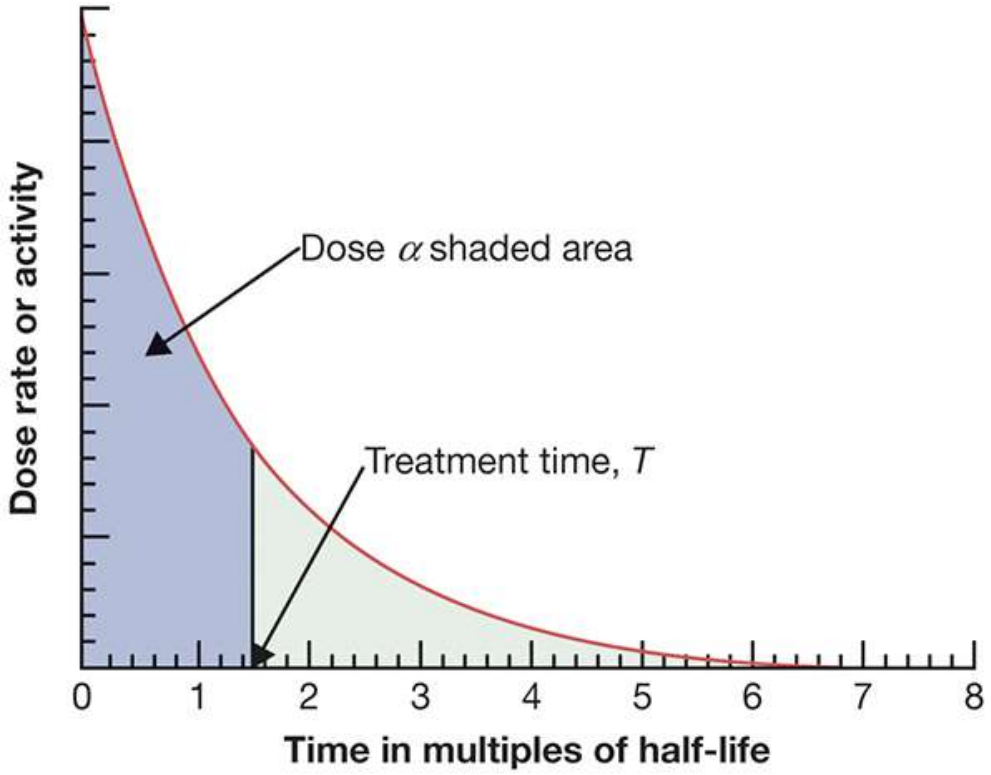

FIGURE 21.5 Illustration of exponential decay of source strength and dose rate. The area of the shaded region is the total dose administered to the patient over treatment time, *T*.

$$A(t) = A(0) \cdot e^{-\ln 2 \cdot t / T_{1/2}} \tag{21.3}$$

where $A(0)$ is the activity at the time of insertion, ln2 is the natural logarithm of 2 (equal to 0.693), and $T_{1/2}$ is the radionuclide half-life. The quantity $\ln 2/T_{1/2}$, represented by the symbol λ, is called the decay constant. Equation 21.3 is applicable to any measure of source strength (S_K, equivalent mass of radium, etc). Because dose rate, $\dot{D}(t)$, at time t is proportional to activity, that is, $\dot{D}(t) \propto A(t)$, we can write:

$$\dot{D}(t) = \dot{D}(0) \cdot e^{-t \cdot \ln 2 / T_{1/2}} \tag{21.4}$$

where $\dot{D}(0)$ is the dose rate at the time of source insertion. The total dose, $D(T)$, accumulated over time interval T after source insertion, is the shaded area under the curve of Figure 21.5 and can be obtained by integrating Eq. 21.4:

$$D(T) = \dot{D}(0) \cdot \int_0^T e^{-t \cdot \ln 2/T_{1/2}} \cdot dt$$
$$= \dot{D}(0) \cdot T_{1/2} \cdot 1.443 \cdot [1 - e^{-T \cdot 0.693/T_{1/2}}] \quad (21.5)$$

The product $T_a = 1.443 T_{1/2}$ is called the average life of the radionuclide and is the time required for all radioactive atoms to decay assuming the rate of decay remains fixed at its initial value, $A(0)$. Equation 21.5 should be used to calculate the total dose delivered by any implant when the treatment time, T, is more than 5% of the half-life. For shorter treatment times (less than 4 days for ^{192}Ir or less than 3 days for ^{125}I), the approximate expression

$$D(T) = \dot{D}(0) \cdot T \quad (21.6)$$

is accurate within 2% since decay during the implant is negligible.

For permanent implants, the total dose administered to the patient, D_{tot}, resulting from complete decay of the implant can be obtained from Eq. 21.5:

$$D_{tot} = \lim_{T \to \infty} D(T) = 1.443 \cdot T_{1/2} \cdot \dot{D}(0) = T_a \cdot \dot{D}(0) \quad (21.7)$$

This equation demonstrates that initial dose rate and radionuclide half-life are in reciprocal relationship with one another: The longer the half-life, the lower the initial dose rate will be. Typical initial dose rates and total doses are given in Table 21.2 for commonly used permanent implant sources. These sources fall into two categories: short-lived high-energy sources with initial dose rates within the classic LDR range and longer lived low-energy sources with initial dose rates below the classic range, that is, ULDR.

TABLE 21.2 TOTAL DOSE AND INITIAL DOSE RATES FOR PERMANENTLY IMPLANTED RADIONUCLIDES

Radionuclide	Mean Photon Energy	$T_{1/2}$ (days)	Typical Prescribed Dose (Gy)	Initial Dose Rate (cGy/hour)
^{222}Rn	1.2 MeV	3.83	100	75
^{198}Au	412 keV	2.7	100	107
^{131}Cs	31 keV	9.7	115	34.2[1]
^{125}I	28 keV	59.4	145	7.0

Radionuclide	Mean Photon Energy	$T_{1/2}$ (days)	Typical Prescribed Dose (Gy)	Initial Dose Rate (cGy/hour)
^{103}Pd	21 keV	17.0	125	21.2

Ultra-Low-Dose Rate and Low-Energy Permanent Implant Sources

An important development was the introduction of interstitial seeds using electron capture decay radionuclides, which have moderately long half-lives (10-60 days) and emit cascades of low-energy (20-40 keV) characteristic x- and γ-rays. The first practical K capture source, the Ti-encapsulated ^{125}I seed (half-life: 59.4 days, mean energy: 28 keV), was developed by Donald Lawrence[37] in the early 1960s and its clinical applications developed in the late 1960s by Basil Hilaris and his colleagues[38-40] at Memorial Sloan-Kettering Hospital. ^{125}I is produced by neutron activation in a specially equipped reactor designed to minimize activation of the contaminant radioisotope, ^{126}I. It decays by electron capture, producing a single 35-keV γ-ray. The captured K-shell electron produces a cascade of 27- to 32 keV characteristic x-rays. In addition, 93% of the γ-rays are internally converted, producing a second characteristic x-ray cascade. Thus, ^{125}I is an "x-ray emitter" because 95% of the useful primary photons are characteristic x-rays of atomic rather than nuclear origin.

Other important radionuclides are ^{103}Pd (17.0-day half-life and 20 keV mean energy), commercially realized in 1987, and ^{131}Cs (9.65-day half-life and 30 keV mean energy), which was initially proposed by Lawrence and Henschke[41] but became available as a commercial product in 2006.[42,43] The low-energy photons emitted by these radionuclides dramatically reduce external exposure hazards: An 8-cm thickness of tissue reduces exposure 10-fold. Thin (0.02 cm) Pb foils also produce almost complete shielding. Thus, there is usually no need to confine patients to the hospital solely for radiation safety reasons. The rapid growth trajectory of transperineal ultrasound (TRUS)-guided permanent seed BT[44,45] in the 1990s for definitive treatment of low- and intermediate-risk prostate cancer,[46,47] resulted in the introduction of approximately 25 different models of ^{125}I and ^{103}Pd to the market from 1997 to 2005. (See the American Association of Physicists in Medicine [AAPM] revised TG-43 reports[5,48,49] for a review of many of the available sources.) While BT remains a widely elected treatment modality for localized prostate cancer, its utilization has fallen from 24% in 2002 to 12% in 2010[50] and is even lower today. As a result, there has been consolidation in the low-energy seed market. The Brachytherapy Source Registry, managed jointly by the AAPM and the Imaging and Radiation Oncology Core (IROC) Houston QA Center (IROC-Houston, formerly the Radiological Physics Center),[51,52] lists all commercially available and clinically used orphan sources that meet the AAPM dosimetric prerequisites for use in clinical trials and everyday practice.[53] According to the Brachytherapy Source Registry, there are six ^{125}I, four ^{103}Pd, and one ^{131}Cs seed models that are commercially available.

Most low-energy interstitial seeds are encapsulated in thin (0.005-cm-thick) titanium tubing (exception: polymer-encapsulated CivaSheet and CivaString ^{103}Pd sources[54]) with external dimensions of 0.08 cm × 0.45 cm (Figure 21.6). Most of the available ^{125}I seed products are variations on the model 6711 seed[55] design, which was the only ^{125}I source

available from 1983 to 1998. It contained a 0.3-cm long Ag rod on which radioactive iodine was absorbed and was available in strengths of 0.5 to 13 $\mu Gy \cdot m^2$/hour (Figure 21.6A, top). The radio-opaque Ag rod enabled seeds to be visualized on orthogonal or stereo-shift radiographs as well as computed tomography (CT) imaging.

of Physicists in Medicine.) B. Isodose curves for a ^{198}Au seed (left half) and Model 6711 ^{125}I seed (right half) both with air-kerma strengths of 72 μGy·m^2/hour (equivalent to 35 mCi of ^{198}Au and 57 mCi of ^{125}I).

^{103}Pd decays by K-electron capture and emits characteristic x-rays of 21 keV. While needing a slightly thicker container to shield γ-rays exceeding 200 keV, it has all the radiation protection advantages of ^{125}I along with a significantly shorter half-life of 17 days. With this source, a monotherapy implant can deliver 112 Gy (90% of the prescribed dose) in approximately 8 weeks at an initial peripheral dose rate of 21 cGy/hour. The model 200 seed (Figure 21.6A middle) was the only commercially available ^{103}Pd seed from 1988 to 1999. The radioactive ^{103}Pd is distributed within a thin Pd metal coating of the two graphite pellets, which are encapsulated in Ti tubing of the same dimensions as ^{125}I seeds. The biologic rationale for using shorter lived ^{103}Pd and ^{131}Cs interstitial sources is discussed later in the "The Radiobiology of Brachytherapy" section.

Low-energy seed implantation poses a number of challenges. Their dose distributions are not radium equivalent (Figure 21.6B), falling off more rapidly with distance. Dose estimation is inherently more complex, depending significantly on photon energy and composition of the surrounding medium (see Figure 21.4),[56,57] and is more sensitive to the internal seed geometry.[58,59] ^{125}I and ^{103}Pd dosimetry has been uncertain and variable over most of the clinical life of these products because of shifts in calibration standards, large uncertainties in dose measurement, and questionable applicability of classic dose calculation model.[12] For example, between 1975 and 1999, the ^{125}I dose rate constant was revised downward, in several steps, by nearly 50%.[12] Only with development and validation of more sophisticated experimental and computation dosimetry techniques can we claim to know low-energy seed dose rate distributions with an uncertainty of 3% to 7%.[60] Because of the very LDRs used, permanent low-energy seed implantation is effectively a different therapeutic modality than classic LDR BT. In addition, 20 to 30 keV photons have a significantly higher LET, which results in an RBE for ^{125}I of 1.3 to 2.1 in in vitro systems compared with unity for high-energy photon spectra.[61-63] Thus, classic LDR clinical experience cannot be used to guide therapeutic decision- making for ^{125}I permanent implantation. Despite these limitations, low-energy source permanent implantation has been demonstrated to be a highly effective and convenient treatment for prostate cancer,[64,65] which produces tumor control rates and toxicity profiles comparable or superior to competing modalities.

Sources for High-Dose Rate Brachytherapy

Radionuclide Sources

In contrast to inpatient-based LDR BT, HDR BT uses high-intensity sources to deliver discrete fractions ranging from 3 to 10 Gy in an outpatient setting. As described in more detail in Chapters 23 and 24, a remote afterloading device must be used. Typically, a cable-mounted HDR source is sequentially inserted to each catheter (see Figure 21.7A), mechanically driven to its distal end, and retracted, stopping at each programmed dwell position for the programmed dwell time (typically 1-60 seconds). A radionuclide with high

specific activity is needed so that overall treatment dose rates of at least 12 Gy/hour can be achieved without sacrificing the level of miniaturization needed to support intracavitary and interstitial BT. A source no larger than 1 mm outer diameter by 4 mm long with an air-kerma rate of at least 1 cGy/s at 1 cm is required. Figure 21.7A and C illustrate typical PDR and HDR sources, respectively.

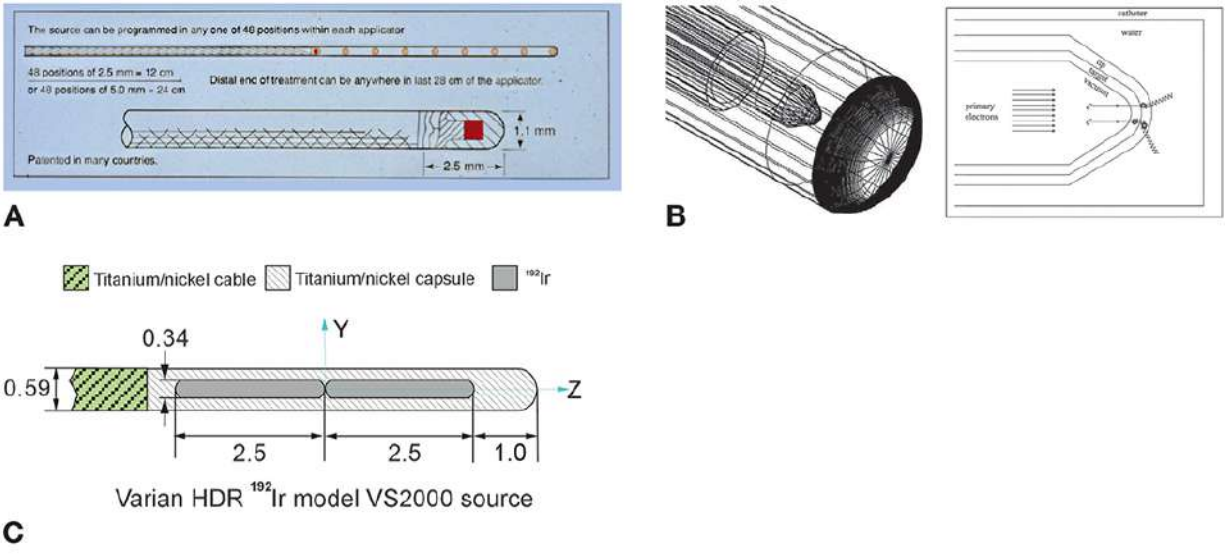

FIGURE 21.7 A. Top: a single-stepping source being withdrawn along the catheter axis from right to left illustrating the concepts of discrete dwell positions. Bottom: Geometry of the original pulsed-dose rate ^{192}Ir source introduced by Nucletron in 1993. B. Geometric model (left) of the Xoft electronic brachytherapy source consisting of an inner catheter terminated by a 0.07-μm-thick tungsten transmission target. Also illustrated is the oversized (5.3 mm OD) outer catheter needed to water cool the approximately 2.25-mm diameter by 15-mm-long x-ray tube (see right figure), which can support an air-kerma rate of 170,000 μGy·m^2/hour when operated at 50 kVp and 300 μA. (From Liu D, Poon E, Bazalova M, et al. Spectroscopic characterization of a novel electronic brachytherapy system. *Phys Med Biol*. 2008;53[1]:61-75. © Institute of Physics and Engineering in Medicine. The upper limit on specific activity of any substance, achieved when 100% of its atoms are radioactive, is a fundamental property that depends on its number of atoms per gram:

$$\text{Atoms/g} = \left[\frac{\text{Avogadro's no.}(6.023 \times 10^{23}\ \text{atoms/mole})}{\text{Atomic weight}}\right] \quad (21.8)$$

For radionuclides produced by neutron activation, competition with radioactive decay precludes activating 100% of the target atoms. The theoretically achievable maximum Ci/g (Table 21.3) depends on the neutron capture cross section of the target and the neutron flux in the reactor.[66] The extent to which this limit can be reached in practice depends on isotopic purity of the target, limits on reactor activation time, and the time required for shorter lived contaminant radionuclides to decay to a negligible level. Finally, the air-kerma rate achieved by a small source (eg, a 1 mm × 4 mm cylinder as shown in Table 21.3) depends on the chemical form (ie, relative mass of nonradioactive atoms) of the source, its density, dose rate constant of the source model, and photon self-absorption.

TABLE 21.3 SPECIFIC ACTIVITIES AND MAXIMUM EXPOSURE RATES ACHIEVABLE FOR DIFFERENT RADIONUCLIDES

Radionuclide	Maximum Ci/g Possible	Fraction Practicably Achievable (%)	Exposure Rate[a] (R/s) at 1 cm From 1 mm × 4 mm Seed (R·cm^2/s)
^{226}Ra	0.98	100	0.04
^{137}Cs	87	23	0.22
^{60}Co	1,020[b]	49	50
^{192}Ir	7,760[b]	35	248
^{169}Yb	33,700[b]	14	51

[a]Neglecting self-absorption.

[b]Reactor produced by neutron activation: a flux $\phi = 10^{14}$ $n \cdot cm^{-2} \cdot s^{-1}$ and 100% target purity are assumed.

Table 21.3 shows that ^{226}Ra cannot support HDR BT and that ^{137}Cs is, at best, a marginal choice. ^{60}Co (1,925-day half-life with 1.17 and 1.33 MeV γ-rays) has been widely used as an intracavitary HDR source in the form of small spherical pellets. Based solely on specific activity considerations, ^{192}Ir is the optimal choice for HDR BT and is the most widely used radionuclide for this application. Sources with external diameters as small as 0.6 mm (see Figure 21.7C) are now available for use in single-stepping source remote afterloading devices. In contrast to ^{60}Co, the lower energy ^{192}Ir photons are shielded effectively by the scatter and leakage barriers present in linear accelerator vaults. Because of their short half-lives, HDR ^{192}Ir sources are usually replaced at quarterly intervals. Because of the relative ease with which its low-energy photons can be shielded, ^{169}Yb sources have also been proposed for HDR intraoperative and intravascular BT.[9]

Electronic Brachytherapy Sources

Currently, there are two established BT delivery systems on the market that use miniaturized low kilovoltage x-ray tubes to eliminate radionuclide sources of radiation. The Zeiss IntraBeam system uses magnetic focusing and steering to transport externally accelerated 50 keV electrons down a long 3.2-mm diameter drift tube, which collides with a thin gold transmission target at the end of the implanted catheter.[67,68] In contrast, the Xoft Axxent electronic brachytherapy (eBT) system[69] is based upon miniaturizing the entire x-

ray tube (see Figure 21.7), which is placed in a somewhat larger diameter (5.4 mm) intracavitary catheter to allow system cooling. While the INTRABEAM system has been used for several tumor sites, including skin cancer,[70] the main application for both systems has been intraoperative accelerated partial breast irradiation (APBI). While the use of eBT for APBI is supported by a randomized, phase III prospective noninferiority trial,[71] its equivalence to ^{192}Ir-based APBI remains controversial.[72] However, due to its lower penetration and more rapid falloff compared to ^{192}Ir, for a fixed level of APBI planning target volume (PTV) coverage, eBT gives rise to larger $V_{150\%}$ and $V_{200\%}$ values.[73] A provocative debate[74] highlights many of the operational and physical differences between the two classes of HDR delivery systems.

BRACHYTHERAPY SOURCE STRENGTH SPECIFICATION AND DOSIMETRY

Two eras of BT dosimetry can be distinguished. The *classic era* (1940-1980) encompassed the maturation of the classic BT systems, the transition from ^{226}Ra to artificial radionuclide sources, and the rise of modern BT. It began with the successful application of Bragg-Gray cavity theory[75] to the calibration of ^{226}Ra and other high-energy sources in terms of exposure,[76] which allowed BT treatment intensity to be quantified using the same system of units and quantities as the external orthovoltage beam therapy of the day. Classic or semiempirical dose computation models are based on the dose distribution of an idealized point source. Dose rates around needle and tube sources were calculated by integrating the basic point-source model over their extended radioactivity distributions. Because of the technical difficulties in measuring the absorbed dose in the presence of steep dose gradients, BT treatment planning relied largely on calculated rather than measured dose distributions.

The modern or *quantitative* era of BT dosimetry began in the 1980s and continues to the present. Quantitative dosimetry relies on the measurement of source model–specific dose distributions by means of small thermoluminescent dosimeters (TLDs), radiochromic film (RCF), or silicon diode dosimeters.[77] Alternatively, radiation transport calculations in the form of 3D Monte Carlo simulations are accepted as an accurate and reliable source of clinically useful dosimetry data.[77] These technical developments were motivated by concerns that semiempirical dose calculation algorithms were not valid in the low-energy regime of ^{125}I and ^{103}Pd sources. To clinically utilize dose measurements and Monte Carlo calculations with an empirical dose calculation formalism, the AAPM TG-43 protocol[5] was developed. Both the classic and quantitative dosimetry methods are based on the principle that BT source strength should be specified in terms of air-kerma strength.

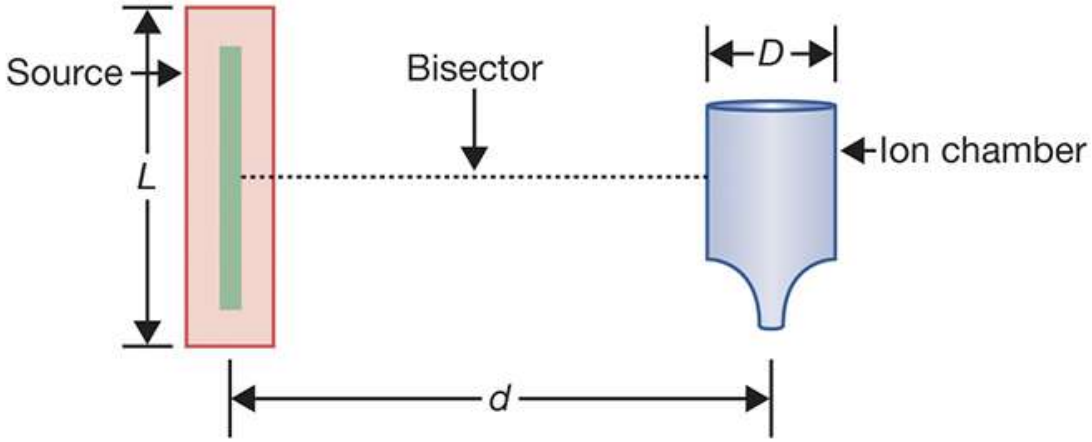
Source Strength Specification Quantities and Units

BT calibration is an unnecessarily confusing topic due to the multitude of quantities that have been used to specify source strength throughout its history. Many of the historically obsolete but still widely used quantities (eg, apparent activity and mgRaEq) were defined in terms of ^{226}Ra properties, the only BT radionuclide intensively studied until about 1940. Such quantities obscure the experimental origin of calibration measurements by describing output measurements in activity units. Finally, the BT literature has added to the lack of

conceptual clarity by obscuring the important distinction between quantities and units. A *quantity* is a property of nature that is directly or indirectly measurable (eg, kerma, equivalent mass of radium, length, time), whereas a *unit* is a selected sample of a quantity to which the magnitude unity (1.0) is assigned (eg, gray, mgRaEq, meter, second). A quantity such as absorbed dose can have many units (eg, cGy, Gy, J/kg).

Regardless of the units and quantity chosen to describe a calibration, all photon-emitting sealed BT sources are calibrated in terms of output (kerma rate, dose rate, or exposure rate) in air at a distance from the source on its transverse bisecting plane. Much like superficial x-ray beam calibration, a calibrated ion chamber (Figure 21.8) is used to measure the BT source output in a free-air geometry in which the source and chamber are suspended in air in a large room.

Output specification

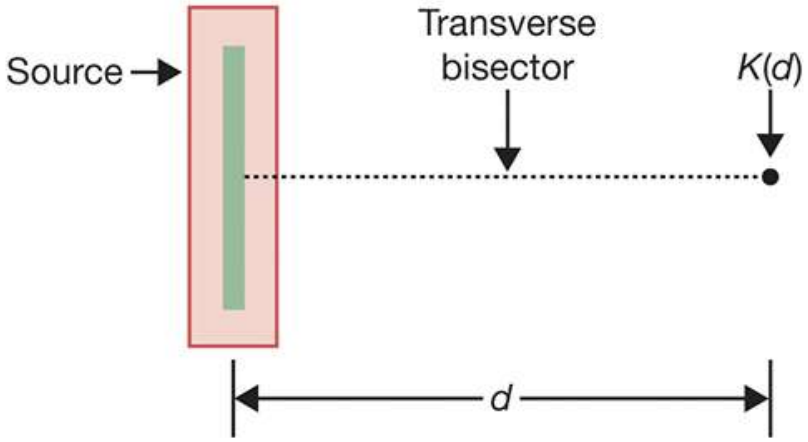


Conditions

1. Large distance *d*: $L << d$, $D << d$
2. Free in space
   - Measured in air
   - Corrected for air attenuation
   - Corrected for scattering from air, walls, etc.

A

Air-kerma strength: S_k



$S_k = K(d) \bullet d^2$

where $K(d)$ is air-kerma rate in free space on transverse bisector of source at large distance $d >> L$

B

Units: 1 μGy • m^2 • h^{-1} = 1 cGy • cm^2 • h^{-1} = 1 U

FIGURE 21.8 A. Illustration of a free-air geometry for measuring brachytherapy source strength in terms of a radiation output quantity such as air-kerma. In practice, the source and cavity chamber are suspended in air in a large room and separated by 20 to 100 cm (which must be large in relation to the detector and source dimensions). The measured air-kerma must be corrected for photon scattering from walls, floor, and ceiling and for photon scattering and attenuation by the intervening air. B. Definition of air-kerma strength. For an actual source, the air-kerma rate must be measured at a distance, d, which is large in relation to the source dimensions.

Air-Kerma Strength

In North America, photon-emitting source strength is specified in terms of air-kerma strength, denoted by S_K, a practice that was introduced by the AAPM in 1987.[78] The AAPM[5] currently defines S_K as the air-kerma rate, $\dot{K}_{\Delta,air}(d)$ at distance d, in vacuo and due to photons of energy greater than Δ, multiplied by the square of this distance, d^2.

$$S_K = \dot{K}_{\delta,air}(d) \cdot d^2 \qquad (21.9)$$

d is the distance from the source center to the point of air-kerma rate specification (usually but not necessarily the point of measurement), which must be on the transverse plane of the source (the plane normal to the long axis of the source that bisects its radioactivity distribution). S_K is independent of specification distance so long as d is large relative to the maximum linear dimension of the radioactivity distribution. $\dot{K}_{\Delta,air}(d)$ is usually inferred from transverse plane air-kerma rate measurements performed in a free-air geometry (see Figure 21.8) at distances large in relation to the maximum linear dimensions of the detector and source, typically of the order of 1 m. The "in vacuo" qualifier (equivalent in meaning to "in free space") means that $\dot{K}_{\Delta,air}(d)$ must be specified as if the source and small mass of air, producing ionization at distance d, were immersed in a vacuum of infinite extent. Air-kerma rate measurements must be corrected for photon attenuation and radiation scattering by the surrounding air as well as for scattering from nearby objects. The energy cutoff, Δ, is intended to exclude low-energy or contaminant photons (eg, characteristic x-rays originating in the outer layers of steel or titanium source cladding[79]) that increase $\dot{K}_{\Delta,air}(d)$ without contributing significantly to dose at distances greater than 0.1 cm in tissue. The value of Δ is typically 5 keV for low-energy photon-emitting BT sources. The unit of air-kerma strength is $\mu Gy \cdot m^2$/hour and is often denoted in the literature by the symbol "U," where 1 U = 1 $\mu Gy \cdot m^2$/hour.

Air-kerma strength is numerically (but not dimensionally) equal to the quantity reference air-kerma rate, $\dot{K}_{ref}$, a very similar quantity defined by the ICRU[3] and used outside North America. $\dot{K}_{ref}$ is defined as the air-kerma rate in free space at a reference distance, l (taken to be 1 m), on the transverse axis; it has units of μGy/hour at 1 m. Thus, $\dot{K}_{ref} = S_K/l^2$. The procedures for standardizing and measuring $\dot{K}_{ref}$ and S_K are identical.

The U.S. National Institute of Standards and Technology (NIST) maintains primary S_K standards for commercially available ^{137}Cs sources,[80] LDR ^{192}Ir seeds,[81] and all ^{103}Pd, ^{131}Cs, and ^{125}I seeds.[82] A *primary standard* is an instrument against which all other S_K measurement devices, called secondary or tertiary standards, must be intercompared. Primary standards are designed to permit inference of air-kerma values from the measured charge and instrument design using first principles. For ^{137}Cs and ^{192}Ir sources, the S_K standard is based on transverse-axis air-kerma measurements using spherical ion chambers with carbon walls[80,81]—the same instruments used to maintain the ^{60}Co teletherapy air-kerma standard. For low-energy interstitial seeds, a special free-air chamber,[82] called the wide-angle free-air chamber (WAFAC), is used. BT sources calibrated directly by the NIST standard or one of the AAPM-Accredited Dosimetry and Calibration Laboratories (ADCLs) are said to have *directly NIST-traceable calibrations*. Sources that are calibrated against sources or ion chambers, which themselves have directly traceable NIST calibrations, are said to have *indirectly NIST-traceable* calibrations. The Xoft eBT source has its own air-kerma standard based on the Lamperti free-air chamber for low-energy x-ray beams.[83] Because accurate estimation of the air attenuation correction for 50-kVp x-rays is conceptually and technically challenging, NIST chose to specify eBT source strength in terms of $\dot{K}_{air}$(50 cm), the air-kerma rate in air (rather than free space) at 50 cm source-to-detector distance, rather than S_K. For a more detailed description of air-kerma–based standards, measurement techniques, and traceability requirements, the reader is referred to a review by Sander.[84] The AAPM recommends[85] that individual clinics using BT sources maintain instrumentation able to make indirectly traceable calibration measurements for verification of vendor-supplied calibrations.

Kerma (kinetic energy released in the matter of interest), K_x, is the ratio $\Delta E_{tr}/\Delta m$, where ΔE_{tr} is the total kinetic energy transferred to charged particles by photon interactions with atoms in small mass, Δm, of medium x.[86] For photons, ΔE_{tr} includes the initial kinetic energies of any secondary charged particles (eg, Compton electrons, photoelectrons, and positrons) liberated by Compton, photoelectric, and pair production interactions. Kerma is defined only for indirectly ionizing radiation (eg, photons and neutrons) and quantifies the transfer of energy from these radiation fields to matter. It takes the same units (cGy and Gy) as the related quantity absorbed dose. Although kerma can be specified in any medium x, usually air medium (x = air) is assumed for radiation metrology. K_{air} replaces the obsolete quantity exposure and is closely related to absorbed dose, D, the ratio, $\Delta E_{ab}/\Delta m$, where ΔE_{ab} is the energy imparted to Δm by the radiation field. Because the secondary electrons released by photon collisions may travel a significant distance before depositing their energy and may convert some of their kinetic energy to bremsstrahlung radiation, D_{air} and K_{air} are not necessarily equal. When kerma remains relatively constant over the range of the secondary electrons, a special condition, secondary charged particle equilibrium (CPE), exists.[66,87] When the CPE is obtained, the rates of energy absorption and energy transfer are approximately equal so that kerma closely approximates absorbed dose:

$$D_{\text{air}} = X \cdot \left(\frac{W}{e}\right) = K_{\text{air}} \cdot (1 - g) \qquad (21.10)$$

where X represents the quantity exposure. The quantity (W/e) is the average energy imparted to air per ion pair created and is a constant, independent of photon energy: (W/e) = 33.97 eV/ion pair = 33.97 J/C = 0.876 cGy/R.[88] The factor g is the fraction of kinetic energy transferred to the medium converted back to radiant energy (photons) by the bremsstrahlung process; g is less than 0.001 at BT energies and is usually ignored, further simplifying Eq. 21.10. Most BT dose calculation algorithms and dosimetric analyses assume that CPE occurs and that dose, D_{med}, can be well approximated by kerma, K_{med}, everywhere. Although generally valid, CPE can be expected to break down in the presence of steep dose gradients near sources,[89] near metal-tissue interfaces,[90] and within the active elements of thin, bounded detectors.[91] The combination of CPE failure and β-ray transmission gives rise to $(D_{\text{med}}/K_{\text{med}})$ ratios that deviate from unity by 10% to 50% at 0.4 to 1.5 mm from the surface of lightly encapsulated HDR ^{192}Ir sources.[92]

Activity

The quantity activity, A, is defined as the rate of nuclear disintegration or transformation within a radioactive source. The contemporary unit of activity is the Becquerel (1 Bq = 1 disintegration/s). We will freely use the more traditional but obsolete unit, the curie (1 Ci = 3.7×10^{10} disintegrations/s = 3.7×10^{10} Bq). A more convenient multiple of the curie, the millicurie, is defined as 1 mCi = 10^{-3} Ci = 3.7×10^{7} disintegrations/s. Each disintegration represents the spontaneous transformation of an atom from one nuclear state to another. For most BT radionuclides, such transformations of nuclear state give rise to photons in the form of unconverted γ-rays, annihilation photons, characteristic x-rays, and bremsstrahlung photons. Activity is measured by counting the number of photons, β-particles, or other particles emitted by an unencapsulated point source of the radionuclide by means of scintillation or coincidence counters, from which its activity is inferred.[93] For sealed BT sources, A refers to activity contained inside the sealed source.

Contained activity, as defined in this strict sense, is no longer used in BT dosimetry. However, activity continues to serve as the basis for treatment specification and dosimetry of unsealed radiopharmaceuticals used for diagnosis and therapy and may play a future role in dosimetry of sealed β-emitting sources for intravascular BT and other clinical applications. NIST maintains contained activity standards for a wide variety of radionuclides in aqueous solution.[94]

The activity, A, of a radioactive nuclide–emitting photons and the air-kerma rate in free space, $\dot{K}_{\Delta}(r)$ (in Gy/s) at distance r (in meters) due to photons of energy greater than Δ, are related by a fundamental quantity, the air-kerma rate constant, $(\Gamma_{\Delta})_{K}$, defined as follows[86]:

$$\left(\Gamma_{\delta}\right)_{\mathrm{K}} = \frac{\dot{K}_{\delta}\left(r\right)\cdot r^{2}}{A}\ \text{air-kerma rate} \qquad (21.11)$$

$$\text{constant}\left(\mathrm{m}^{2}\cdot\mathrm{Gy}\cdot\mathrm{Bq}^{-1}\cdot\mathrm{s}^{-1}\right)$$

A closely related fundamental quantity, not used nowadays but of historical importance, is the exposure rate constant, $(\Gamma_{\Delta})_{\mathrm{X}}$,

$$\left(\Gamma_{\delta}\right)_{\mathrm{X}} = \frac{\dot{X}_{\square}\left(r\right)\cdot r^{2}}{A}\ \text{exposure rate} \qquad (21.12)$$

$$\text{constant}\ (\mathrm{cm}^{2}\cdot\mathrm{R}\cdot\mathrm{mCi}^{-1}\cdot\mathrm{h}^{-1})$$

$(\Gamma_{\Delta})_{\mathrm{X}}$, which equals to the exposure rate in *R*/hour at 1 cm from a 1-mCi point source, describes the rate at which air is ionized as a result of the emission of photons resulting from radioactive decay. The energy cutoff Δ eliminates low-energy bremsstrahlung and characteristic x-rays from consideration that are always absorbed within any practical source. The precise value of Δ depends on the application; it is usually assumed to be about 10 keV. Because $(\Gamma_{\Delta})_{\mathrm{X}}$ is defined in terms of an isotropic point source with exposure rates corrected for air attenuation and scattering, inverse-square law applies exactly. Thus, $(\Gamma_{\Delta})_{\mathrm{X}}$ is independent of the distance *r* used in Eq. 21.12.

$(\Gamma_{\Delta})_{\mathrm{X}}$ depends only on the number and energy of the photons emitted per disintegration. Suppose there are *N* different photons emitted per disintegration with energies E_1, E_2, …, E_{N} in units of MeV, and each nuclear decay emits P_{i} photons of energy E_{i}, where $i = 1, \ldots, N$, then $(\Gamma_{\Delta})_{\mathrm{x}}$ can be calculated by:

$$\left(\Gamma_{\square}\right)_{\mathrm{X}} = 193.7\cdot\sum_{i=1}^{N} P_{i}\cdot E_{i}\cdot\left(\mu_{\mathrm{en}}/\rho\right)_{i}^{\mathrm{air}} \qquad (21.13)$$

where $\left(\mu_{\mathrm{en}}/\rho\right)_{i}^{\mathrm{air}}$ is the mass-energy absorption coefficient (in units of cm^2/g) for air at energy *Ei*. A detailed derivation of this fundamental relationship is given elsewhere.[95,96] $(\Gamma_{\Delta})_{\mathrm{X}}$ and $(\Gamma_{\Delta})_{\mathrm{K}}$ are fundamental properties of the radionuclide's

unencapsulated photon spectrum that apply only to an ideal point source and neglect many significant properties of real sources, such as self-absorption, filtration, and extension.

Integrated Reference Air-Kerma

The ICRU[97] recommends total reference air-kerma (TRAK), which is defined in terms of air-kerma strength, as a prescription or reporting quantity. TRAK, symbolized by K_{ref} is given by:

$$K_{\text{ref}} = \sum_{i=1}^{N} \left(S_{\text{K},i} / l^2 \right) \cdot t_i \qquad (21.14)$$

where $S_{K,i}$ and t_i are the air-kerma strength and treatment time in hours, respectively, of the ith source, and l is the reference distance (taken to be 1 m or 1 cm). Thus, 1 unit of TRAK = 1 cGy at 1 cm = 1 μGy at 1 m. TRAK is related to obsolete quantities of milligram radium hour (mg-h) and milligram radium equivalent hour (mgRaEq-h):

$$K_{\text{ref}} = \begin{cases} \text{mg-h} \cdot 6.754 & \text{for filtration } t = 1 \text{ mm Pt} \\ \text{mgRaEq-h} \cdot 7.227 & \text{for filtration } t = 0.5 \text{ mm Pt} \end{cases} \qquad (21.15)$$

Intracavitary treatment systems[11] historically based on ^{226}Ra tubes (1-mm Pt encapsulation) typically use mg-h, whereas systems based on ^{137}Cs or other radium substitutes prescribe therapy in units of mgRaEq-h. Because of the difference in platinum filtration assumed by these 2 mg–based quantities, numerically identical prescriptions can deliver quantities of TRAK that differ by 7%. The use of TRAK as an integrated output reporting quantity eliminates this 7% ambiguity that has confused comparison of different implant systems since the appearance of radium-substitute sources for BT.

Classic Dose Calculation Formalism: Isotropic Point Source

Consider an unencapsulated point source as illustrated in Figure 21.9. Because this source has no extension, there is no attenuation of the emitted radiation by the source itself. Isotropy (see Figure 21.2) implies that photons are emitted with equal likelihood in all directions and travel in straight lines. In reality, actual BT sources are encapsulated, have finite dimensions, and are usually cylindrically rather than spherically symmetric. The dose rate, $\dot{D}(r)$ (cGy/hour), at distance r (cm) in the water equivalent medium surrounding the source is given by:

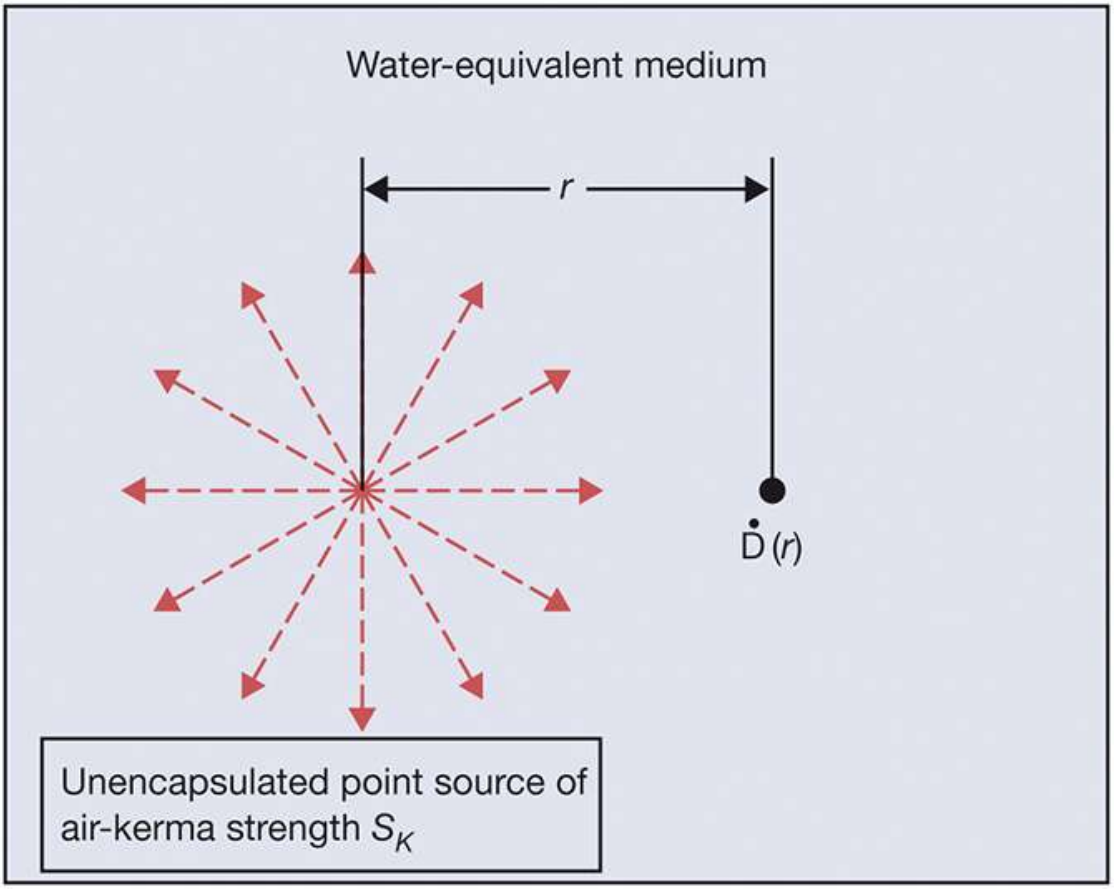


FIGURE 21.9 Unencapsulated point source of strength S_K immersed in an unbounded water equivalent medium.

$$\dot{D}_{med}(r) = S_K \cdot \frac{\overline{(\mu_{en}/\rho)}^{med}_{air}}{r^2} \cdot T(r) \qquad (21.16)$$

The inverse-square law term corrects for the difference in dose specification distance, r, and the 1-cm reference point is assumed by the units of air-kerma strength. The quantity $\overline{(\mu_{en}/\rho)}^{med}_{air}$ is the ratio of mass-energy absorption coefficients in medium to that in air averaged over the photon spectrum in free space. This correction, equal to $\dot{K}_{med}/\dot{K}_{air}$ in free space, is a consequence of the fundamental relationship between particle fluence and dose.[95,96] It corrects for the efficiency with which the medium extracts energy from the emitted photons compared with air. For all radionuclides emitting photons with energies greater than 200 keV, including all radium substitutes, $\overline{(\mu_{en}/\rho)}^{med}_{air}$ has the value 1.11 in water medium.

The last term of Eq. 21.16—the kerma-to-dose conversion factor, $T(r)$—describes the net influence of primary photon attenuation and build-up of scattered photons in the surrounding medium. Sometimes, this factor is termed the *effective attenuation factor* or the *scatter build-up factor*.

$$T(r) = \frac{\text{Dose in medium}}{\text{Medium} - \text{kerma in free space}} \qquad (21.17)$$

$$= \left.\frac{\text{Exposure in medium}}{\text{Exposure in air}}\right\} \begin{array}{l}\text{at distance } r \\ \text{from a point source}\end{array}$$

Figure 21.10 shows $T(r)$ for several high-energy radionuclides as well as for a few low-energy radionuclides. For high-energy radionuclides, $T(r)$ deviates less than 5% from unity (1.00) out to distances, r, of 5 cm. Numerous tabulations of $T(r)$ are available in the literature; those of Meisberger and colleagues,[98] Berger,[99] and Van Kleffens and Star[100] are among the best known. Most of these data are derived from theoretic photon transport calculations. The classic semiempirical model assumes that $T(r)$ is a function only of the radionuclide photon spectrum and that a single data set (eg, for ^{192}Ir) can be used for all ^{192}Ir source models, regardless of their construction.

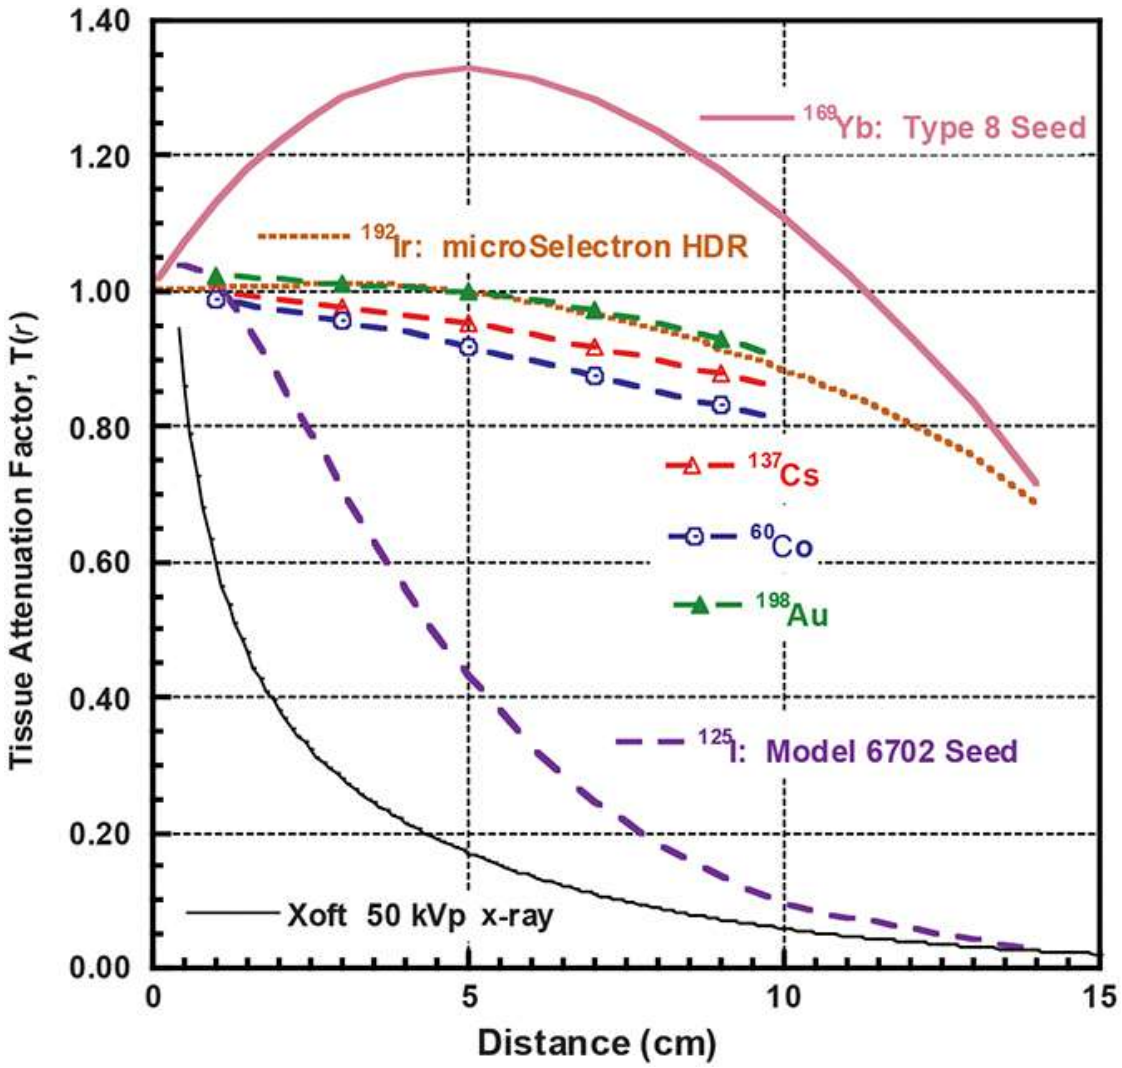

FIGURE 21.10 Photon attenuation and scatter factors, $T(r)$, for a number of brachytherapy radionuclides. The data for ^{137}Cs, ^{198}Au, and ^{60}Co are from the classic paper by Meisberger et al.[98] The high-dose rate (HDR) ^{192}Ir, Model 6702 ^{125}I, and Xoft 50=kVp x-ray $T(r)$ are from Daskalov et al,[394] Dolan et al,[136] and Hiatt et al.[395]

Modeling of Source Anisotropy: The Anisotropy Factor

Despite its simplicity, the classic isotropic point-source model (Eq. 21.16) accurately predicts the transverse-axis dose rate distributions of most actual radium-substitute sources. Simply by using an output quantity to calibrate the source, rather than contained activity, A, the influence of its internal structure (filtration and self-absorption) has been implicitly accounted for. Any uncertainties in $\{E_i, P_i\}_{i=1}^{N}$ (which are large for many radionuclides) and filtration corrections would directly degrade dose calculation accuracy. In addition, fundamental activity measurements are technically difficult for the high-intensity sources used in BT. For these reasons, contained activity does not play a role in photon BT dosimetry. In contrast, Eq. 21.16 infers dose rate from a quantity measured outside the source, which is not influenced significantly by knowledge of the unfiltered

photon spectrum. The required quantities, $\overline{(\mu_{\square\square}/\rho)}^{\text{med}}_{\text{air}}$ and $T(r)$, are ratios and are, therefore, insensitive to errors in the assumed spectrum.

Practically, all BT sources are cylindrical, giving rise to anisotropic dose distributions. In addition, some sources, especially those used in intracavitary BT, have ALs that are comparable to typical calculation distances. Thus, the dose rate, $\dot{D}(r, \theta)$, around a BT source depends on both distance r, and polar angle, θ (Figure 21.11). $\dot{D}(r, \theta)$ may deviate significantly from the transverse-axis dose rate, $\dot{D}(r, \pi/2)$, predicted by Eq. 21.16, especially near the long axis of the seed.

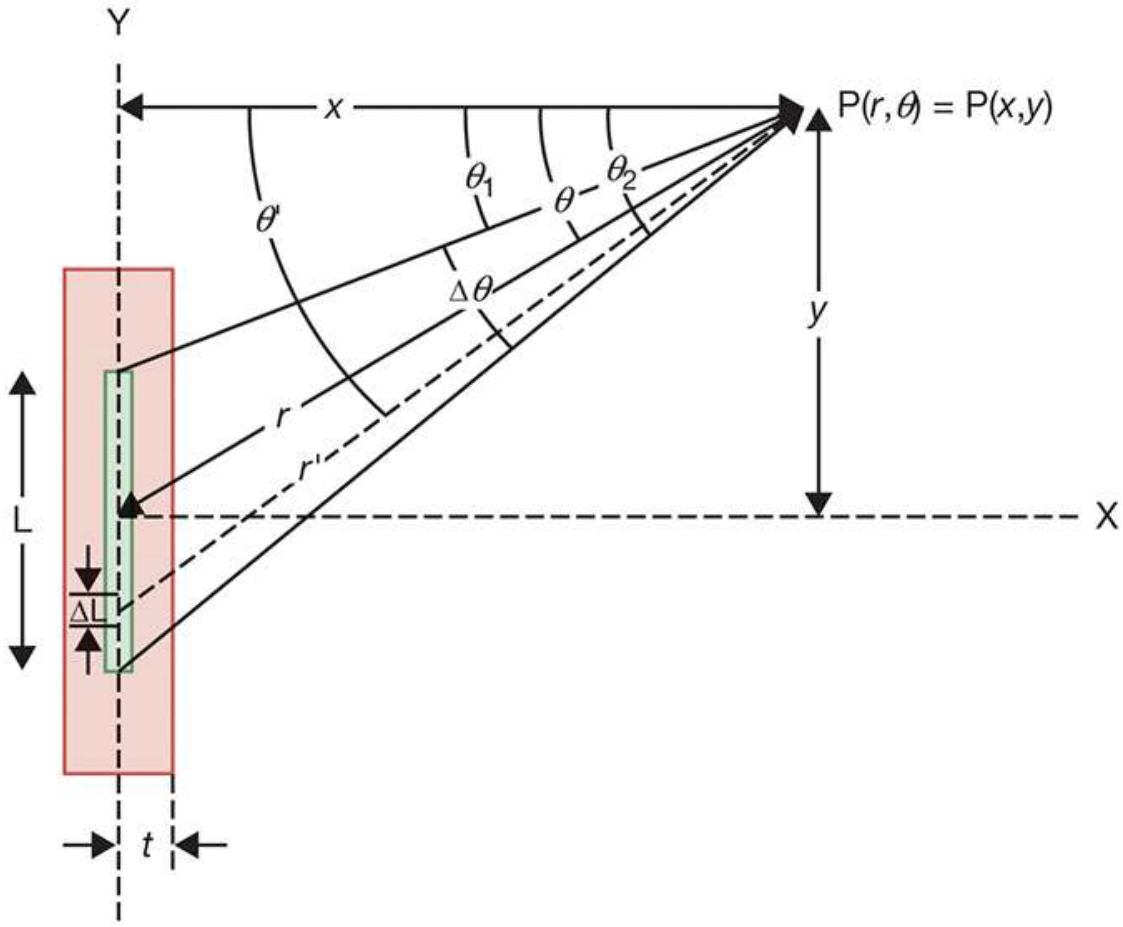

FIGURE 21.11 A typical encapsulated line source, illustrating calculation of dose rate at point P at (x, y) relative to the source center by the Sievert integral method. The active length and radial encapsulation thickness are denoted by L and t, respectively. The distances x and y are referred to as "distance away" and "distance along," respectively, in the literature.

In the case of implants consisting of many randomly oriented seeds with ALs less than the minimum distance of interest, Eq. 21.16 will accurately represent the multiple-seed dose distribution if an average correction for single-seed dose anisotropy is applied.[101] This

correction factor, which the TG-43 protocol refers to as the 1D anisotropy function, $\phi_{an}(r)$, is defined by averaging the dose at each fixed distance r with respect to solid angle, Ω:

$$\phi_{an}(r) = \frac{\text{Average dose at } r}{\text{Transverse-axis dose at } r} = \frac{\int_{4\pi} \dot{D}(r,\theta) \cdot d\Omega}{4\pi \dot{D}(r,\pi/2)} \cdot \qquad (21.18)$$

$$= \frac{\int_0^{\pi} \dot{D}(r,\theta) \cdot \sin\theta \cdot d\theta}{2 \cdot \dot{D}(r,\pi/2)}$$

Often, a distance-independent average value of $\phi_{an}(r)$, called the anisotropy constant, $\bar{\phi}_{an}$, is used. Incorporating this average correction into Eq. 21.16, leads to:

$$\dot{D}_{med}(r) = \frac{S_K \cdot \overline{(\mu_{en}/\rho)}_{air}^{med}}{r^2} \cdot T(r) \cdot \bar{\phi}_{an} \qquad (21.19)$$

For early radium-substitute sources, $\bar{\phi}_{an}$ was often evaluated by measuring relative photon fluence in air at relatively large distances (30-100 cm) using a NaI or GeLi scintillation detector.[55,102]

Equation 21.19 implies that source strength should be increased by a constant fraction ranging from 2% (^{192}Ir seeds) to 10% (^{103}Pd seeds) to correct for polar anisotropy effects. Lindsay et al[103] compared prostate implant 3D dose distributions derived from the isotropic point-source model, $\dot{D}(r)$, to those derived from the full 2D single-source dose calculation model, $\dot{D}(r, \theta)$. Based on voxel-by-voxel comparisons, they found that the isotropic point-source model introduced errors exceeding 10% of the D_{90} in 8% and 33% of the target volume for the model 6711 ^{125}I and model 200 ^{103}Pd sources, respectively. Corbett and colleagues[104] found that despite large local dose distribution differences, including 2D anisotropy effects did not alter the dose-volume histogram (DVH): Neither the V_{100} nor the margin between D_{100} and prostate boundary was altered significantly. For volume implants consisting of parallel arrays of ^{192}Ir seeds, a similar finding has been reported.[101]

Dose Calculation for Extended Sources: The Sievert Integral Model

Dose distributions around larger sources, such as intracavitary tubes and interstitial needles, are calculated by partitioning the extended source into a set of point sources to which corrections for distance, oblique filtration, attenuation, and scattering are applied separately. By summing these point-source contributions, the dose at point P can be estimated. This class of algorithms, first described by Rolf Sievert in 1921,[105] is known as the Sievert integral algorithm, or more generally, the 1D pathlength model.[95,106]

Assume that the source illustrated in Figure 21.11 has an air-kerma strength, S_K, and contained activity, A. The classic Sievert integral approximates the cylindrical active core by a line of radioactivity positioned along its axis. The axial length of the core is called the active length, L. Oblique filtration is modeled by assuming that the capsule reduces dose by exponential attenuation using an effective filtration coefficient, μ'. The dose rate $\Delta\dot{D}(x, y)$ at point (x, y) from the incremental source ΔL located at angle θ is

$$\Delta\dot{D}(x,y) = S_K \cdot \frac{\Delta L}{L} \cdot e^{\mu' \cdot t} \cdot \frac{\overline{(\mu_{en}/\rho)}^{med}_{air}}{(x/\cos\theta)^2} \cdot T(x/\cos\theta) \cdot e^{-\mu' \cdot t/\cos\theta} \quad (21.20)$$

By summing over all these incremental sources (ie, integrating with respect to θ') and transforming to polar coordinates, we obtain the Sievert integral:

$$\dot{D}(r,\theta) = \frac{S_K \cdot \overline{(\mu_{en}/\rho)}^{med}_{air} \cdot e^{\mu' \cdot t}}{L \cdot r \cdot \cos\theta} \cdot \int_{\theta_1}^{\theta_2} e^{-\mu' t \cdot \sec\theta} \cdot T(x \cdot \sec\theta) \cdot d\theta \quad (21.21)$$

The extra $e^{\mu' t}$ term outside the integral is needed to avoid global "double correction" for filtration.

Variants of Eq. 21.21 applicable to the regions near the source capsule ends are available. Numerous improvements to the basic model have been introduced over the years,[107,108] including modeling of photon absorption by the source core, extension to noncylindrical sources, generalization to radioactivity distributed over a volume,[4] extension to low-energy sources,[106] and treatment of applicator shielding and attenuation.[109,110]

The Sievert integral model was widely used to model 2D dose distributions around ^{137}Cs tubes and needles for clinical treatment planning prior to acceptance of the TG-43 table lookup method. Both experimental[111,112] and Monte Carlo studies[4,113] have demonstrated that it accurately predicts dose rate distributions in this energy range. When the filtration coefficient μ' is approximated[114] by the linear energy absorption coefficient, μ_{en} (0.023/mm for steel-clad ^{137}Cs sources), maximum errors are no larger than 8% and are much smaller (less than 3%) near the transverse axis. Published dose rate distributions derived from the Sievert model, tabulated in terms of distances away and along, are available for several

types of ^{137}Cs sources[4,115] and ^{226}Ra sources.[116] Williamson[106] showed that the classic Sievert integral gives rise to large errors (20%-37% maximum error, 7%-16% average error) when applied to lower energy sources of ^{192}Ir, ^{169}Yb, and ^{125}I. Although accuracy can be improved by modifying the basic model,[106] classic semiempirical models should be used cautiously at photon energies below ^{137}Cs (0.66 MeV). Tabulated dose rate distributions derived from direct measurement or Monte Carlo simulation are preferable for these sources.

If the encapsulation thickness is set to zero (t = 0) in Eq. 21.21, the Sievert integral reduces to a simple closed-form analytic expression:

$$\dot{D}(x,y) = S_K \cdot \overline{\left(\mu_{en} / \rho\right)}_{air}^{med} \cdot \frac{\Delta\theta}{L \cdot x} \qquad (21.22)$$

where $\Delta\theta$ is the angle, in radians, subtended by the active length, L, with respect to the point of interest (Figure 21.11). When the interest point lies on the transverse axis (y = 0), then $\Delta\theta = 2 \cdot \tan^{-1}(L/2x)$, where $\tan^{-1}$ denotes the inverse tangent or arctan function. Angles must be specified in units of radians rather than degrees (180° = π radians). This approximation is extremely useful as a manual calculation aid and is highly accurate near the transverse axis of lightly encapsulated ^{137}Cs sources.

Figure 21.12 shows that as the distance $r = \sqrt{(x^2 + y^2)}$ becomes large in relation to active length, L, Eq. 21.22 reduces to the point-source formula. For distances less than L (1.5 cm for intracavitary tubes), the use of Eq. 21.16 will yield errors of at least 10%. For distances greater than 1.5L (2.5 cm for gynecologic tubes), the point-source approximation is accurate within 5%.

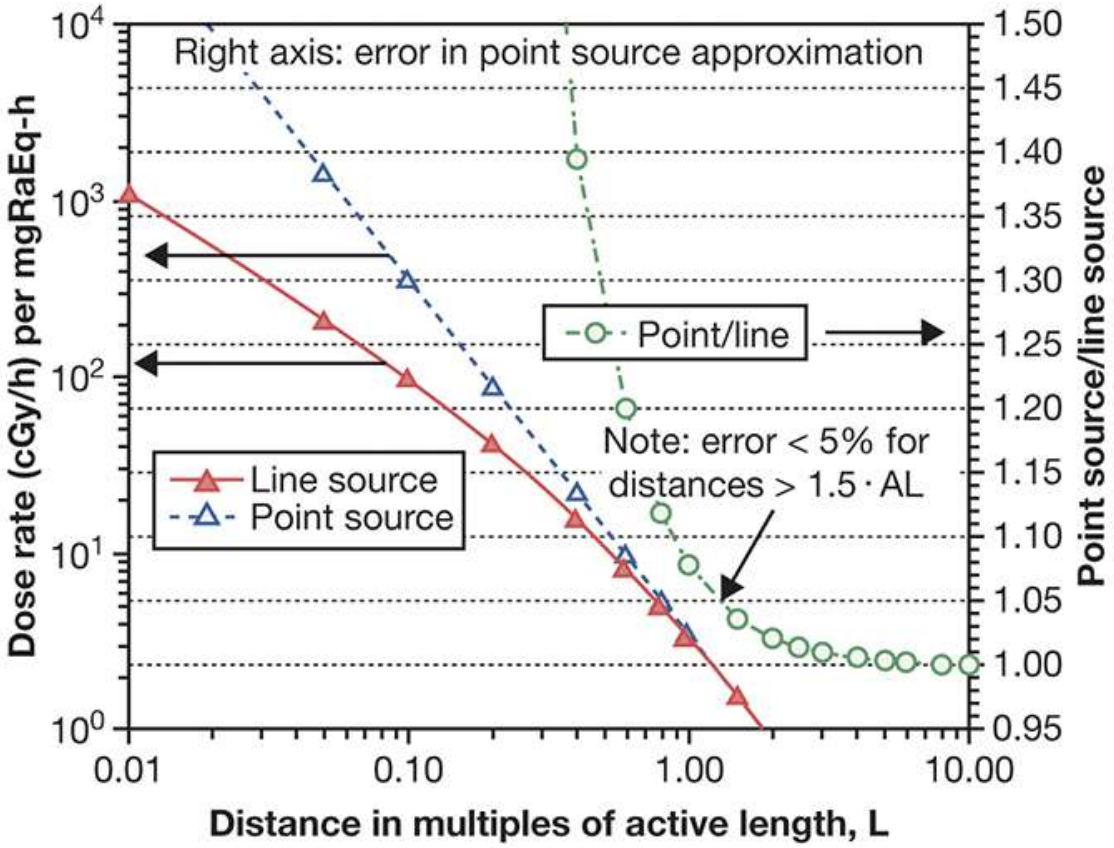

FIGURE 21.12 Error in the isotropic point source model relative to the line source model Eq. 21.22 as a function of transverse-axis distance expressed in multiples of active length (AL).

Source-Specific Dosimetric Characterization

The classic dose calculation models assume that the parameters $T(r)$ and $\overline{(\mu_{en}/\rho)}^{wat}_{air}$ depend only on the radionuclide used. This assumption began to break down with the introduction of ^{125}I interstitial seeds in the early 1970s, as this 30-keV x-ray emitter clearly fell outside the scope of validated analytic models.[12] While ^{125}I dose distributions derived from semiempirical models were published[117] and widely used, it was recognized[55] that internal seed structure could modulate the emitted photon spectrum and significantly alter the absorbed dose distribution. The growing use of ^{125}I and the introduction of a primary exposure standard in 1985[118] motivated investigations in the quantitative determination of source-geometry and source-construction-material–specific dosimetry parameters for each type of source. Currently, both experimental methods and sophisticated computational dosimetry approaches are routinely used to derive such source-specific parameters. Another characteristic of quantitative dose estimates is traceability to closely related primary standards, currently the air-kerma strength standards maintained by NIST. Finally, the total uncertainty[119] of the estimated dose, including both type A (random) and type B (systematic), typically less than 10%, must be well understood and validated.

Experimental Dosimetry Approaches

Direct use of measured dose rates in BT for treatment planning purposes is a relatively recent phenomenon, beginning in the mid-1980s. Historically, dose measurement was thought to be so difficult and intrinsically inaccurate that even simplistic theoretic models were more reliable. BT dose measurement does indeed place severe demands on detectors because the dose distributions are characterized by large dose gradients, a large range of dose rates, and relatively low photon energies. The most severe measurement artifact is the exquisite sensitivity of detector response to positioning errors; measurement of dose near a point source with 2% accuracy requires that the source-to-detector distance be specified with accuracy of 20, 50, 100, and 200 μm, respectively, at distances of 2, 5, 10, and 20 mm. Thus, a good detector system must have small size, high sensitivity, a stable and reproducible response, and reasonably flat energy response. Finally, a useful system should be sufficiently convenient that adequate spatial sampling of high-gradient dose distributions is feasible.

Commonly used single-element dose detectors include TLDs, small ion chambers, diode detectors, solid-state detectors, inorganic scintillators, and plastic scintillators. RCF[120-122] and plastic scintillator sheets[123] have been investigated as planar dose measurement systems. 3D dose measurement technologies under investigation include liquid scintillation cocktails[124] and polymer gel dosimetry[125,126] using either magnetic resonance imaging (MRI) or optical transmission tomography to quantify the detector signal. For various reasons, most of these approaches have not met with widespread acceptance by quantitative dosimetry investigators. In the case of the 2D/3D dosimetry media, the techniques have not been sufficiently developed that they can compete with the 5% total uncertainty supported by TLD-100. One consideration in selecting a detector for BT dosimetry is minimizing energy response artifacts, which arise from compositional differences between water and the detector and can result in variation of detector reading/unit dose in medium as the photon spectrum changes with position.

Silicon diodes have proven to be precise and accurate dosimeters for measuring relative dose distributions around low-energy sources, for example, ^{103}Pd and ^{125}I, as their sensitivity is nearly independent of the measurement point location.[127,128] However, for higher energy BT sources, variations in sensitivity with position in the phantom as large as 15% for ^{137}Cs and 75% for ^{192}Ir have been reported.[129] While plastic scintillation detectors have a well-established role in quantitative β-emitting eye plaque and applicator dosimetry,[130] the current focus of scintillation detector research is tertiary dose measurement applications, such as quality assurance (QA) and in vivo dosimetry, rather than reference quality dose measurement.[131]

LiF TLD, while hardly an ideal technology, has emerged as the best compromise between convenience and quantitative accuracy and is currently the de facto standard of practice[49]: All of the consensus data sets referenced by the AAPM TG-43 reports[5,48,49] rely on TLD-100. Quantitative TLD BT was developed and first validated by a 3-year (1987-1989) NCI-funded multi-institutional research effort, the Interstitial Collaborative Working Group (ICWG).[132] Using TLD-100 chips and powder capsules, embedded in machined solid-water phantoms to ensure positional accuracy, the ICWG developed the procedures used to this

day, including TLD dose calibration and energy response corrections, for making quantitative estimates of absolute dose rates in water. For the ^{125}I and ^{192}Ir sources then available, independent transverse-axis dose rate measurements showed excellent agreement among the three collaborating institutions, validating the TLD measurement methodology.[132] More complete 2D dose distributions about ^{125}I, ^{192}Ir, and ^{103}Pd BT sources[127,133,134] soon followed. While good agreement among the different measurements was observed, for ^{125}I seeds, there were substantial differences (10%-14%) between the measured dose rates and classically computed dose rates when normalized to the available air-kerma strength standard,[118] $S_{K,N85}$. However, good agreement between the classic and experimental approaches was observed for ^{192}Ir.

Estimation of the absorbed dose sensitivity, $S_{AD,med}(Q)$, has emerged over the past decade as the dominant source of uncertainty for TLD. For a given BT energy spectrum, Q, $S_{AD,med}(Q)$ is the TLD reading, $M(Q)$, per unit dose in medium, $D_{med}(_Q)$ at the TLD center in its absence:

$$S_{\mathrm{AD,med}}(Q)=\frac{M(Q)}{D_{\mathrm{med}}(Q)}=\left(\frac{M(Q)}{\overline{D_{\mathrm{TLD}}}(Q)}\right)\left(\frac{\overline{D_{\mathrm{TLD}}}(Q)}{D_{\mathrm{med}}(Q)}\right)=\frac{1}{k_{\mathrm{bq}}(Q)f(Q)} \quad (21.23)$$

where $\overline{D_{\mathrm{TLD}}}$ is the dose absorbed by the TLD medium averaged over its volume. As Eq. 21.23 shows, it can be factored into two components: the absorbed dose energy dependence, $f(Q)$, which is due to differences between energy deposition in the TLD material and the medium it displaces, and the intrinsic energy dependence, $k_{bq}(Q)$, which depends on the TLD signal formation process. $f(Q)$ can be calculated by Monte Carlo or cavity theory, but $k_{bq}(Q)$ can only be measured. Until recently, most TLD studies for ^{125}I and ^{103}Pd seeds adopted a generic absorbed dose-response factor of $S^{\mathrm{rel}}_{\mathrm{AD,med}}=1.41$ (relative to 4- or 6-MV x-rays used to calibrate TLDs) based upon old ICWG measurements,[135] which ignored the factorization above and many other subtleties by modern standards. Most Monte Carlo studies[136,137] neglected or otherwise assumed relative $k_{bq}(Q)$ = 1.0. Despite these uncertainties, the average agreement between TLD and Monte Carlo dose rates at 1 cm was 2% for 25 ^{125}I studies and 14% for ^{103}Pd studies.[77] However, subsequent measurements (see Table III in Reed et al[138] for a nice summary) over the past decade show that k_{bq}^{rel} values for ^{125}I to ^{103}Pd relative to megavoltage x-ray beams range from 0.93 to 0.87. Even for ^{192}Ir, $k^{\mathrm{rel}}_{\mathrm{bq}}\approx 0.95$ has been reported.[139] Rodriguez and Rogers[140] performed a rigorous Monte Carlo "reconstruction" of 24 published TLD-100 studies and found that universal k_{bq}^{rel} values of 0.931 and 0.922 for ^{125}I and ^{103}Pd, respectively, minimized the discrepancy between Monte Carlo and measured dose rates. Given the

possible dependence k_{bq}^{rel} on TLD structure and annealing/readout procedures, the most recent TG-43 guidance[49] states that additional research is needed before AAPM can take a position on whether or how to implement nonunity k_{bq}^{rel} into past and ongoing experimental consensus dosimetry studies. Thus, at minimum, a 5% (k = 1 corresponding to a 67% confidence interval) uncertainty must be included in uncertainty budgets for published experimental consensus data sets. This implies that with careful correction for TLD linearity, individual chip sensitivity, $f^{rel}(Q)$, and phantom corrections, absolute dose rate (cGy/hour in tissue per unit S_K) in water can be measured with a total uncertainty (k = 1) of 6%.[136,141] Should policies be put in place that reduce k_{bq}^{rel} uncertainty to 2%, TLD has the potential to achieve 3% uncertainties.[49]

Interest in RCF for BT dosimetry is growing, owing to its very high spatial resolution.[121] The need for improved (≈1 mm) spatial resolution is becoming more urgent as the field moves away from the determination of reference quality single-source distributions toward measurements in more complex geometries, including shielded applicators,[142] shielded eye plaques,[36] and, potentially, intensity-modulated BT. The value of RCF for quantitative dosimetry for HDR BT using higher energy photon sources[120] and β-emitting plaque therapy has long been appreciated.[143] The currently available EBT3 dosimetry media are much improved over their historical counterparts in terms of sensitivity, spatial uniformity, rapidity of film darkening, and flatness of energy response, making accurate HDR measurements more feasible (see §5.E[121] for a recent literature review). Low-energy seed RCF dosimetry is much more challenging. While doping the EBT3 active layer with alumina has been shown to diminish both intrinsic ($f_{bq}^{rel}(Q)$) and absorbed dose ($f^{rel}(Q)$) low-energy response artifacts, 20% to 30% variations in the 15 to 60 keV range continue to persist.[144,145] For example, 5% dose estimation accuracy about Xoft electronic source with EBT3 RCF was achieved, when energy-dependent dose-response curves were used to convert film readings into doses, which, in turn, required Monte Carlo simulations of the photon spectrum as a function of depth.[146]

Measured dose rate distributions using TLD are available for many common BT sources, including nearly all commercially available ^{125}I and ^{103}Pd sources (see the updated TG-43 report[5] and its supplements[49,147] for more comprehensive discussions). Measured dose rates are available for many ^{192}Ir LDR, HDR, and PDR sources as well as for many investigational sources.[148] For high-energy sources, the measurements are in close agreement with the classic semiempirical models: isotropic point-source and Sievert integral models.[4,95,106] For ^{125}I sources normalized to the $S_{K,N85}$ standard,[118] measured dose rates were found to be 10% to 20% lower than those predicted by Eq. 21.16.[149] A better agreement[77] was observed between classic models and measurements with calibrations traceable to the 1999 WAFAC standard ($S_{K,N99}$).[82] However, classic models such as the Sievert integral are not recommended for the low-energy source regime as they poorly predict low-energy source anisotropy and do not take into account modulation of the dose distribution by internal source geometry.[106]

Computational Dosimetry Methods: Monte Carlo Photon Transport Simulation

Concurrent with the above dosimetry developments, Monte Carlo photon transport techniques were being developed as tools for quantitative evaluation of single-source dose distributions. Based on an accurate and detailed geometric model of the internal source structure, photon histories can be generated and then evaluated to assess the absorbed dose. Monte Carlo techniques are now accepted as a reliable and probably the most accurate source of BT dosimetry data.[5,77] As illustrated in Figure 21.13, this theoretical method uses a digital computer to randomly select a small number (10^5-10^8) of photon trajectories or "histories." The geometric model must specify the location of all media boundaries and photon sources. By using probability distributions derived from total and differential cross sections, a photon is randomly constructed by following each photon from birth through successive scattering events and, eventually, to absorption or escape from the system. At each decision point, random sampling is used to decide the fate of the photon. The process of randomly constructing photon trajectories is equivalent to selecting photon histories from the set of all those possible by random sampling. To statistically estimate the dose rate at a specified point, the dose contributed by each simulated collision is estimated and then averaged over all collisions. Monte Carlo simulation techniques are reviewed in more detail elsewhere.[77] Because particle histories can be accurately and efficiently constructed even in the presence of complex 3D geometries, approximation free but statistically inexact solutions, derived from first principles, are possible for a wide range of geometrically complex but clinically relevant BT problems.

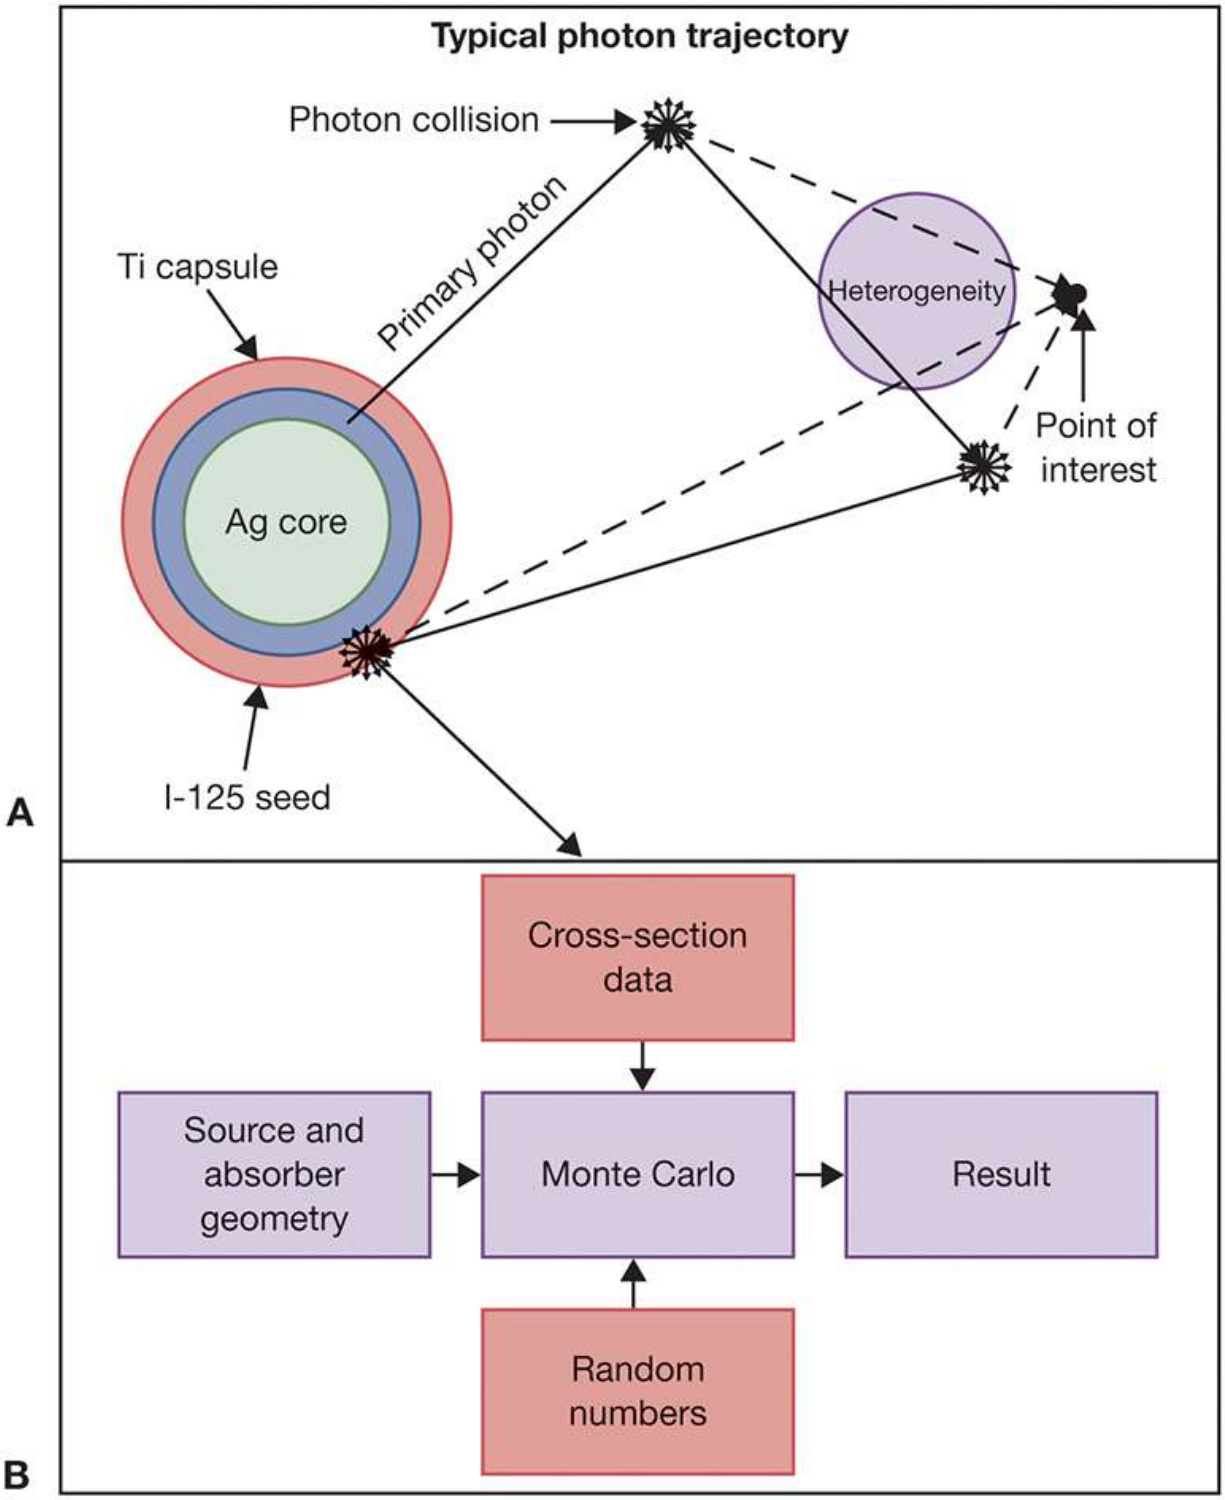

FIGURE 21.13 A. Two-dimensional representation of a typical photon history. The heavy solid lines illustrate the origin of the primary photon (randomly selected from the assumed distribution of radioactivity), and each successive collision, which is randomly selected from the competing collision mechanisms (photo effect, Compton scattering, and coherent scattering) is based on their relative probabilities. The dashed lines illustrate the problem of estimation (ie, calculating the probable contribution of each simulated collision to the point of interest). B. Functional diagram of a Monte Carlo code illustrating the required input data. Cross section data include total attenuation coefficients, total cross sections for each collision process, and differential cross

sections, which are used to randomly sample the distance between successive collisions, the interaction mechanism at each collision, and the angle and energy of the scattered photon leaving each collision, respectively. Sequences of random numbers are obtained from a "random number generator," a computer program designed to generate a pseudorandom sequence of numbers uniformly distributed between 0 and 1.

The dosimetric accuracy of Monte Carlo simulation has been confirmed across the entire energy spectrum from ^{103}Pd to ^{226}Ra. The agreement between Monte Carlo and TLD and precision diode measurements ranges from 2% to 6%, both in homogeneous medium and in the presence of tissue and applicator heterogeneities.[8,57,129,150,151] In contrast to experimental methods, Monte Carlo accuracy is not limited by dosimeter artifacts, such as energy response and volume averaging. Because the geometric relationship can be specified exactly, it is also free from detector positioning uncertainties. Recent analyses[60,48,136] have shown that the uncertainty (including all known systematic and random error sources) of Monte Carlo absolute dose rate estimates on the transverse axis of ^{125}I seeds is 2.5% to 5% over the 1 to 5 cm distance range. Unlike dose measurements, Monte Carlo dose calculations cannot account for unsuspected deviations from the design specifications of the problem (eg, a contaminant radionuclide in the source or an error in measuring its source strength).[152] The Rodriguez analysis,[140] described above, found average differences between measurement and calculation of 3.8% and 2.8% for ^{125}I and ^{103}Pd seeds, respectively, based upon treating TLD intrinsic energy response corrections as best fit parameters.

Historically, the most important role of Monte Carlo simulation was calculation of reference quality transverse-axis dose rate distributions and anisotropy functions for low- and medium-energy BT sources. In addition to Williamson's code PTRAN,[77] the most common public domain codes validated for this purpose are EGSnrc user codes,[153,154] Monte Carlo N-Particle (MCNP),[155,156] and GEANT4 user codes.[157,158] For all low-energy interstitial seed models used in routine clinical care, the AAPM recommends[53] that both experimental and Monte Carlo–based dosimetry studies that meet the AAPM's standards of rigor and completeness and are published in peer-reviewed journals being available. In addition, the vendor must supply secondarily traceable S_K calibrations. Finally, at annual intervals, S_K standards of the vendor, the ADCLs, and NIST must be intercompared. For stainless steel–encapsulated single-stepping ^{192}Ir sources, a published experimental dosimetry study is not necessary.[52] Commercially available sources that satisfy the AAPM-recommended prerequisites are posted on the Joint IROC-Houston/AAPM Source Registry.[51]

Monte Carlo simulation is useful in many other applications, such as characterizing the effects of applicator-shielding materials[8] and tissue heterogeneities[57] on BT dose distributions, validating heuristic dose calculation algorithms,[159] and optimizing new source and applicator designs.[160] Over the past 20 years, validating more approximate model-based dose calculation algorithms (MBDCAs) has emerged as one of the most important Monte Carlo applications. This is because Monte Carlo provides an unbiased but statistically imprecise partial solution of the Boltzmann Transport Equation (BTE), the fundamental integro-differential equation that completely describes the transport, absorption, and scattering of ionizing radiation in any system of media and sources in a 7D phase space.[115] As described in "Advanced Model-Based Dose Calculation Algorithms" section, the

MBDCAs commercially available to date are approximate deterministic BTE solutions that must be tuned and validated against the Monte Carlo benchmark for acceptable accuracy in each clinical problem domain.[161,162] This has helped spur the development of fast Monte Carlo codes capable of efficiently estimating 3D dose distributions in a high-resolution (1-2 mm) grid for complex analytically defined and voxel-based geometries. Two of the many 3D CT-based Monte Carlo codes developed in the past decade include PTRAN_CMC[163] and egs_brachy.[154] Both support high spatial resolution dose calculation times for clinical implants that are short enough for forward treatment planning.

American Association of Physicists in Medicine Task Group 43 Table-Based Dose Calculation Formalism

An important milestone in modern BT is the publication of the original AAPM TG-43 report in 1995[164] and a substantially revised and expanded version in 2004,[49] including two more recent supplements.[48,49] The TG-43 approach consists of using measured and Monte Carlo–generated dose rate distributions directly for clinical dose calculation aided by a standard table lookup formalism. For low-energy seeds, the revised TG-43 report and its supplements include the following:

1. A recommended table-based dose calculation formalism for representing 2D and 1D dose distributions around interstitial sources specifically designed to use a sparse matrix of Monte Carlo or measured dose rates as its input
2. A critically reviewed set of 2D dose distribution data for a total of 27 ^{125}I, ^{103}Pd, and ^{131}Cs seed models that satisfy the AAPM dosimetric prerequisites.[53] For each of these source types, a consensus dose distribution in TG-43 formalism format is recommended based upon "merging" published TG-43-compliant Monte Carlo and experimental dosimetry data sets.
3. A history of air-kerma strength primary standards,[82,118] which summarizes previous AAPM guidance,[165,166] including the impact of calibration shifts on the delivered-to-prescribed dose ratio[167]
4. Methodological recommendations for obtaining TG-43 dosimetry parameters from TLD measurements or Monte Carlo simulations, including uncertainty analyses
5. Guidance on clinical implementation of TG-43 report recommendations

The TG-43 report recommends that all treatment planning software systems utilize the TG-43 formalism as the basis of dose calculation or at least for data entry, allowing users to easily input the new data into their systems. With the introduction of the new WAFAC-based air-kerma strength standard by NIST and over 20 low-energy interstitial BT sources into the marketplace at various times, the radiotherapy community has embraced the TG-43 dose calculation formalism as well as many AAPM recommendations associated with its implementation. Most important among these are the AAPM dosimetric prerequisites for routine non–institutional review board (IRB)-approved BT procedures.[53] Only low-energy sources with NIST-traceable S_K calibrations supported by annual intercomparisons among NIST, the ADCLs, and the vendor[168] and two independent Monte Carlo and experimental

dosimetry studies published in the peer-reviewed literature will be posted on the Joint IROC-Houston/AAPM Registry website[51] or included in future TG-43 supplements. In 2012, a similar dosimetry validation process was introduced for higher energy sources.[148]

Because embracing new calibration standards and dosimetry parameters alters prescribed-to-delivered dose ratios, radiation oncologists must understand the implications for selection of prescribed dose, interpreting published outcome studies, and consistently reproducing their clinical experience through time. AAPM reports provide detailed discussions and recommendations on managing these changes. For example, in ^{125}I monotherapy for prostate cancer, the pre–TG-43 prescribed dose of 160 Gy is equivalent to 145 Gy using the TG-43 dosimetry parameters.[167] This document also addresses the management of up to 10% variations in prescribed-to-administered dose ratios due to the complex dosimetric history of ^{103}Pd monotherapy.

General Formalism for the Two-Dimensional Case

For a cylindrically symmetric source of strength S_K (Figure 21.14), dose rate, $\dot{D}(r, \theta)$, at the point (r, θ) is calculated in the TG-43 formalism as follows:

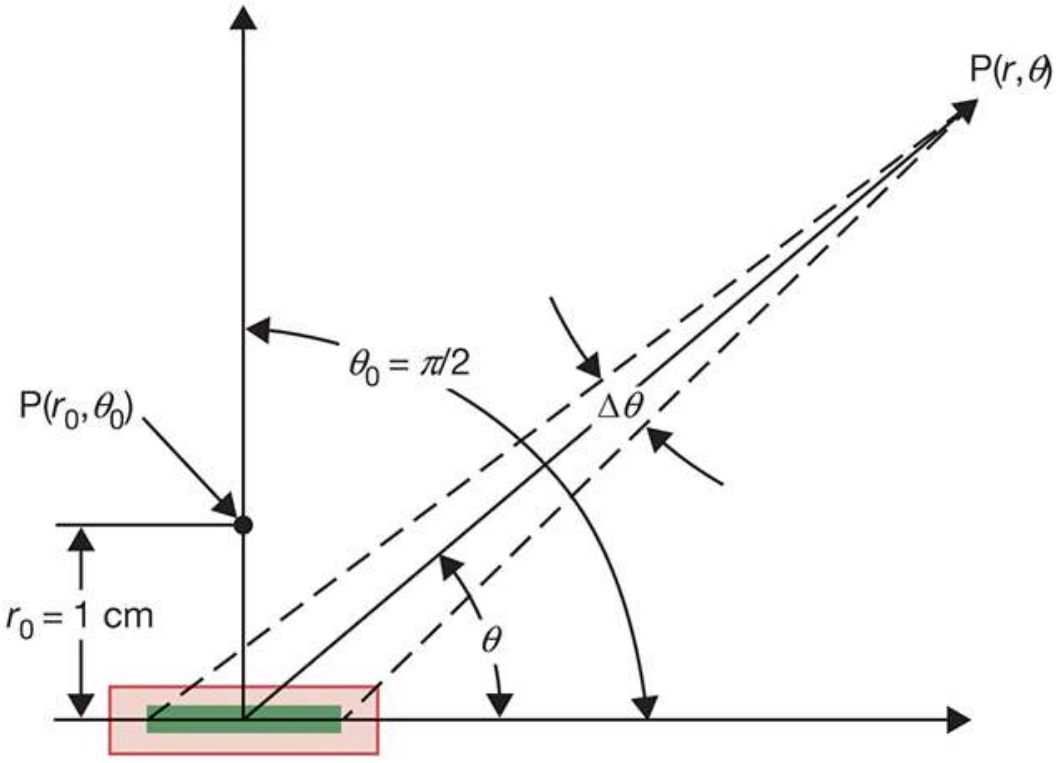

FIGURE 21.14 Illustration of Task Group 43 formalism for calculation of absorbed dose rate, $\dot{D}(r, \theta)$, at (r, θ), in a polar coordinate system centered about the source active core.

$$\dot{D}(r,\theta) = S_K \cdot \Lambda \cdot \frac{G_L(r,\theta)}{G_L(r_0,\theta_0)} \cdot g_L(r) \cdot F(r,\theta) \qquad (21.24)$$

where r denotes the distance (in cm) from the center of the active source to the point of interest, θ denotes the polar angle specifying the point of interest relative to the source longitudinal axis, r_0 denotes the reference distance (specified to be 1 cm), and θ_0 is the reference angle (90° or $\pi/2$ radians) that defines the source transverse plane. For ^{125}I and ^{103}Pd sources, AAPM Guidance[167] uses the symbols $S_{K,N99}$ and $S_{K,N85}$ to designate the 1999 WAFAC-based NIST standard[82] and the prior Loftus[118] free-air standard introduced in 1985. The other symbols in Eq. 21.24 denote the following quantities:

$G_L(r, \theta)$ is the line-source geometry function in units of cm^{-2}.

Λ is the dose rate constant of the source type in units of cGy/h·U^{-1}.

$F(r, \theta)$ is the dimensionless 2D anisotropy function that takes the value unity for θ_0 at all r.

$g(r)$ is the dimensionless radial dose function that takes the value unity at $r = r_0$.

The dose rate constant in liquid-water medium is defined by:

$$\Lambda = \frac{\dot{D}(r_0,\ \theta_0)}{S_K} = \frac{\dot{D}(1\,\text{cm},\ 90°)}{S_K} \qquad (21.25)$$

where $\dot{D}$ (r_0, θ_0) is the measured dose rate at the reference point. Λ includes the effects of source geometry, spatial distribution of radioactivity, encapsulation, self-filtration in the source, and attenuation and scattering of photons in the surrounding medium. It also depends on the standardization measurements to which the S_K calibration of the source is traceable.

For high-energy point sources, $\Lambda \approx \overline{(\mu_{en}/\rho)}^{med}_{air} \cdot T(r) \cdot G_L(1\,\text{cm}, \pi/2)$. Table 21.4 shows that during the $S_{K,N85}$ era (1984-1999), the classic point-source model overestimated absolute doses by as much as 15% for ^{125}I sources relative to TLD measurements and Monte Carlo calculations. In 1999, the WAFAC ($S_{K,N99}$) standard replaced $S_{K,N85}$, which required an upward adjustment of these Λ values, bringing the classic and quantitative values closer together. The old and new dose calculations are in close agreement for ^{192}Ir and other radium substitutes.

Model 6702 I-125	1.035	0.93	1.037	1.036	—
Model 200 Pd-103	—	0.74 $S_{K,T88}$	0.665	0.686	—
LDR/HDR sources Ir-192	1.12	1.12	1.12	1.12	1.109 (Elekta mHDR-v2) 1.100 (Varian VS2000) 1.117 (Gamma Med HDR+) 1.124 (Gamma Med PDR+) 1.110 (Best LDR seed) (AAPM HEBD Report 2012[148])

The purpose of the geometry function, $G_X(r, \theta)$—where the subscript X denotes point (P) or line source (L)—is to improve the accuracy with which dose rates can be estimated by interpolation from data tabulated at discrete points. Physically, $G_X(r, \theta)$ neglects scattering and attenuation and provides an effective inverse-square law correction based upon an *approximate model* of the spatial radioactivity distribution within the source. Because the geometry function is used only to interpolate between tabulated dose rate values at defined points, highly simplistic approximations yield sufficient accuracy for treatment planning.[5] To improve the accuracy of linear interpolation near the source, the AAPM protocol requires the use of (r, θ) for 2D calculations and prefers $G_L(r, \theta)$ to $G_P(r, \theta)$ for 1D calculations. For small cylindrical seeds, $G_X(r, \theta)$ is approximated by a line source.

$$G_{\mathrm{P}}(r,\theta) = r^{-2} \quad \text{point-source approximation}$$

$$G_{\mathrm{L}}(r,\theta) = \begin{cases} \dfrac{\Delta\beta}{Lr\sin\theta} & \text{if } \theta \neq 0^\circ \\ \left(r^2 - L^2/4\right)^{-1} & \text{if } \theta = 0^\circ \end{cases} \quad \text{line-source approximation} \tag{21.26}$$

where $\Delta\beta = \theta_2 - \theta_1$ is the angle subtended by the active source with respect to the point (r, θ). For sources where the radioactivity is distributed over or within a right cylindrical volume or annulus, L can be taken as the length of this cylinder. For sources containing uniformly spaced multiple radioactive components, L should be taken as the effective length, L_{eff}, given by, $L_{\mathrm{eff}} = \mathrm{DS} \times N$, where N represents the number of discrete pellets contained in the source with a nominal pellet center-to-center spacing, DS.

The 2D anisotropy function $F(r, \theta)$ gives the angular variation of dose about the source at each distance as a result of self-filtration, oblique filtration of primary photons through the encapsulating material, and photon attenuation and scattering in the surrounding medium.

$$F(r,\theta) = \frac{\dot{D}(r,\theta)}{\dot{D}(r,\theta_0)} \frac{G_{\mathrm{L}}(r,\theta_0)}{G_{\mathrm{L}}(r,\theta)} \tag{21.27}$$

where the dose rates, $\dot{D}(r, \theta)$, are obtained by measurement or Monte Carlo simulation. The line-source geometry function is used to suppress the influence of inverse-square law on the angular dose distribution at short distances. Thus, $F(r, \theta)$ need be tabulated only at a few distances, r, to facilitate accurate interpolation at all distances. Examples of anisotropy functions for various interstitial sources are illustrated in Figure 21.15 and in Table 21.6.

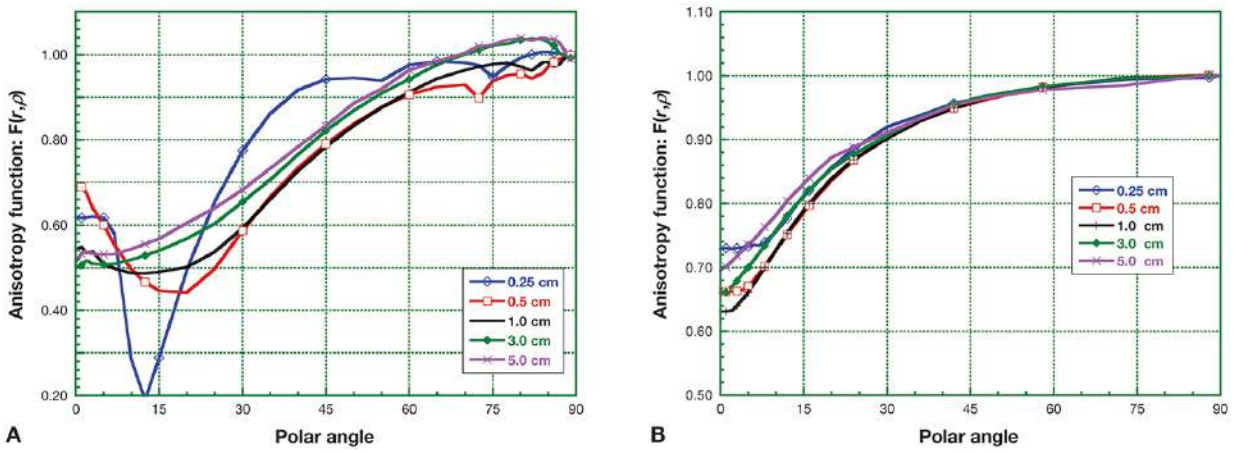

FIGURE 21.15 Examples of two-dimensional anisotropy functions evaluated for two different interstitial sources by the author's group. A. Theragenics Model 200 "light seed" ^{103}Pd source.[58] B. Nucletron/Elekta MicroSelectron Model V2 high-dose rate ^{192}Ir source.[394]

The radial dose function, $g_X(r)$, accounts for the falloff of dose along the transverse axis as a result of attenuation and scattering in the medium, capsule filtration, and self-absorption.

$$g_X(r) = \frac{\dot{D}(r,\theta_0)}{\dot{D}(r_0,\theta_0)} \frac{G_X(r_0\theta_0)}{G_X(r,\theta_0)} \tag{21.28}$$

$g_X(r)$ is normalized to unity at 1 cm distance and is illustrated by Table 21.5. For 2D dose calculations, TG-43 recommends that X = L.

One-Dimensional Isotropic Source Approximation

Most commercial treatment planning systems used for permanent implant dose computation support only 1D isotropic point-source calculations. Thus, the TG-43 formalism includes a 1D equation analogous to the classic isotropic point-source model (Eq. 21.19).

$$\dot{D}(r) = S_K \cdot \Lambda \cdot \frac{G_L(r,\theta_0)}{G_L(r_0,\theta_0)} \cdot g_L(r) \cdot \phi_{an}(r) \qquad (21.29)$$

where $\phi_{an}(r)$ is the 1D anisotropy function defined by Eq. 21.18 and illustrated in Table 21.6. Both the 1D and 2D TG-43 cases assume that each source implanted in the patient is positioned at the center of a large water sphere. The single-source superposition dose calculation algorithm found in all treatment planning systems thus ignores intersource attenuation effects (attention of one source by other sources), deviation of local tissue composition from that of water, and applicator attenuation effects. Avoiding these 2% to 50% dose calculation artifacts is the role of MBDCAs described in the next section.[6]

TABLE 21.6 EXAMPLE OF A TABULATED 2D ANISOTROPY FUNCTION, $F(R, \Theta)$ TABLE, ALONG WITH ITS ASSOCIATED 1D ANISOTROPY FUNCTION, $\Phi_{AN}(R)$, VALUES FOR THE THERAGENICS MODEL 200 ^{58}PD SOURCE.

Advanced Model-Based Dose Calculation Algorithms

The TG-43 source-superposition algorithm[5] assumes that patients consist of uniform liquid water, ignoring tissue composition inhomogeneities, seed-to-seed attenuation, and applicator-shielding effects. For ^{192}Ir BT, tissue composition heterogeneities introduce relatively small dose perturbations. However, both Monte Carlo and deterministic model-based dose calculations demonstrate skin contours (missing scatter volume), can reduce skin and rib doses by 4% to 8% for breast BT[169] while shielded vaginal applicators can reduce bladder and rectal doses by 8% to 25%.[170,171] In contrast, doses delivered by low-energy permanent seed BT and eBT are very sensitive to deviations of target tissues and organs at risk (OARs) from water equivalence, since photoelectric effect dominates energy deposition in this energy range. Using standard ICRP[172] bulk tissue compositions for prostate tissue, Carrier et al[173] found that TG-43 formalism underestimated D_{90} from ^{125}I seed implants by 9% relative to Monte Carlo studies, with 18/28 prostate cancer patients showing a 10% effect or more. Calcifications as small as 1% to 2% of the prostate mass

perturb DVH metrics by as much as 35%.[174] Even larger and highly variable (4%-50%) deviations of Monte Carlo D_{90} estimates from corresponding TG-43 estimates[163,175] was found for low-energy seed breast implants, because the breast tissue consists of a mixture of adipose and glandular tissues, which varies significantly from patient to patient. To address the potentially large impact of tissue and applicator heterogeneities on BT dose evaluation, sophisticated MBDCAs have been developed.[6]

Available Model-Based Dose Calculation Algorithms

Three major MBDCAs have been implemented in BT.[6,162] Monte Carlo simulation, as discussed earlier in source-specific dosimetry parameter determination, is the most widely investigated methodology. Because Monte Carlo simulation statistical uncertainty is proportional to the square root of computing time; the computing times (several hours or even days in the early development) associated with general-purpose codes used for dosimetry have limited Monte Carlo–based treatment planning[176] to the research setting. However, with advances in hardware and sophisticated variance reduction techniques,[177] this logistic barrier has been effectively overcome. As early as 2005 single-processor calculation times of the order of a minute for clinical prostate seed implants were reported.[174] Even faster specialized BT codes have been introduced, including a fast correlated sampling code[163] and an efficient EGSnrc-based planning code.[154]

Other groups have investigated deterministic transport solutions, mainly discrete ordinates codes[178] (also called "grid-based Boltzmann solvers" by some investigators) or heuristic 3D algorithms based on superposition/convolution of scatter dose point kernels.[159,179] Interestingly, planning software vendors have gravitated toward deterministic rather than Monte Carlo solutions. Varian Medical Systems has integrated a discrete ordinates dose calculation engine (ACUROS)[180,181] into its BrachyVision HDR planning system, the first commercially available BT dose calculation engine based on a rigorous radiation transport solution. Elekta BT (formerly Nucletron) has incorporated an Advanced Collapsed Cone (ACE) algorithm[159,182] into its planning system, which was adapted from the external beam collapsed cone scatter superposition/convolution algorithm.[183]

These advanced MBDCAs offer the possibility of departing from the TG-43 water-only geometries by modeling radiation transport in nonwater media (tissues, applicators, air-tissue interfaces), resulting in a much more physically accurate reconstruction of the dose distribution actually delivered to the patient. It also opens the possibility for innovative treatment modalities using novel applicators.[6,162]

Model-Based Dose Calculation Algorithm Commissioning and Clinical Implementation

To guide early clinical adopters of the emerging MBDCAs, the AAPM has published a major guidance document in 2012, the TG-186 report,[6] providing guidelines for clinical implementation and commissioning of MBDCAs in BT. The companion AAPM WGDCAB Report 372, published in 2023, further provided detailed workflow and data set of well-characterized test cases for commissioning commercially available MBDCAs (Varian

ACUROS and Elekta ACE) for ^{192}Ir-based afterloading BT.[162] The data set for the well-characterized test cases as well as step-by-step guides are available with open access in the Joint IROC-Houston/AAPM Brachytherapy Source Registry website.[162] The workflow outlined in these reports can be used to validate both the basic and advanced dose calculation features of commercial MBDCAs.

In addition to accurate commissioning, other issues associated with the use of MBDCAs, such as the choice of dose specification medium and voxel-by-voxel cross section assignment, could also affect their clinical implementation. MBDCA-calculated doses are sensitive to the dose specification medium. Energy-dependent differences exist between the dose calculated to water in a homogeneous water geometry (TG-43), dose calculated to the local medium in the heterogeneous medium, and dose calculated to a small volume of water in the heterogeneous medium (a theoretical construct).[6] The dose calculated to the local medium in the heterogeneous medium is a conceptually well-defined quantity and is recommended by the AAPM TG-186 for reporting when using MBDCAs. MBDCA-calculated doses are also sensitive to voxel-by-voxel interaction cross sections. Accurate geometrical descriptions of the patient and implanted applicators, including assignment of cross sections to all media, must be provided on a voxel-by-voxel or component-by-component basis in order to account for all sources of scatter and heterogeneities.[6] However, assigning voxel-by-voxel cross sections is challenging because the electron density information extracted from the conventional single-energy CT images cannot be used to distinguish between different materials that have the same density. AAPM TG-186 recommends the use of a number of standardized materials to maintain uniformity across institutions when using MBDCAs. Detailed discussions on these and other related issues can be found in the AAPM TG-186 report.[6]

INTERSTITIAL BRACHYTHERAPY

Interstitial BT typically uses multiple radioactive sources (or source dwell locations) to create extended dose distributions that are needed to cover clinical target volumes (CTVs) of various sizes and shapes. The classic implant systems (Manchester, Quimby, and Paris) that arose early in the 20th century were developed to guide the radiation oncologist in arranging and positioning radium needles within the surgically identified target volume. In contrast, most implant procedures today, such as the transperineal permanent implants of the prostate, use image guidance to position the sources. In place of classic system lookup tables and nomograms, 3D computerized planning is used to calculate and prescribe dose, as well as to optimize the implant geometry. Nonetheless, even the most sophisticated commercially available dwell-weight optimization software used with single-stepping source remote afterloaders (see Chapters 23 and 24) still requires the operator to specify the source and needle locations. In this regard, the concepts of the classic implant systems and their later variants can still offer some guidance in interstitial BT. This section reviews the relationship between implanted sources (strength, number, spatial arrangement, and implant duration) and the resultant spatial dose distributions and discusses the challenges in dose specification in interstitial BT.

Classic Implant Systems for Temporary Implants

The Manchester and Quimby systems were developed before the advent of computer-aided dosimetry in interstitial BT, whereas the Paris system is based on multiplanar isodose distributions. They all consist of the following components:

Source distribution rules: These rules specify how to distribute the radioactive sources and applicators in and around a given target volume.

Dose specification and implant-optimization criteria: At the heart of each system is a dose specification criterion (ie, a definition of prescribed dose). In the Manchester system, for example, the prescribed dose is the modal dose in the volume bounded by the peripheral sources. The distribution rules and dose specification criterion together often reflect a compromise between mutually exclusive goals such as dose homogeneity, normal tissue sparing, number of catheters implanted, dosimetric margins around the target, and the presence of high-dose regions outside the target.

Dose calculation aids: These devices are used to estimate the source strengths required to achieve the prescribed dose rate as defined by the system for source arrangements satisfying its distribution rules. The Manchester and Quimby systems use tables that give the dose delivered per mgRaEq-h (or TRAK in modern units) as a function of treatment volume or area. The Paris system makes extensive use of computerized treatment planning to relate the absorbed dose to source strength and treatment time.

The Manchester System

The Manchester system was developed by Ralston Paterson (radiation oncologist) and Herbert Parker (physicist) in the 1930s[184-187] and is often called the Paterson-Parker (P-P) system. Its distribution rules, anticipating the "peripheral loading technique," were designed to maximize dose homogeneity inside the implanted volume for volume implants and in the treatment plane (plane parallel to the needles at the treatment distance) for surface or planar implants (Figure 21.16). Its volume and area lookup tables remain useful as QA tools for optimized HDR volume implants.

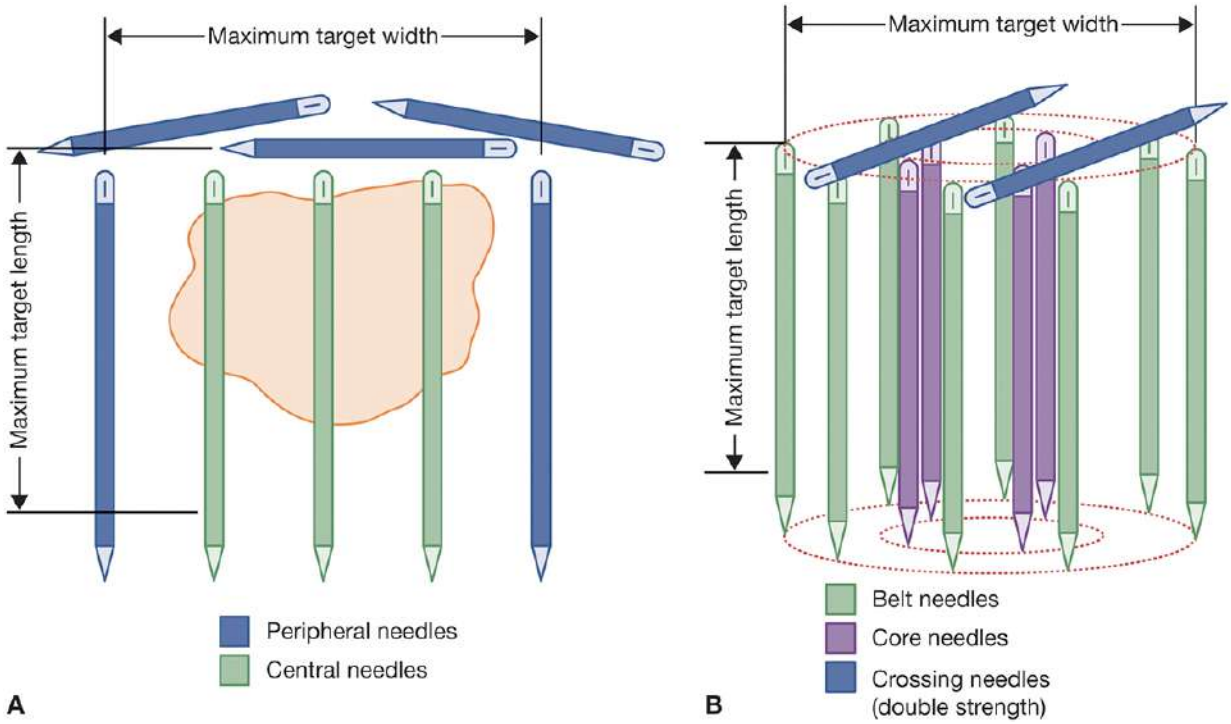

FIGURE 21.16 A. Relationship between target volume or area and peripheral needles (solid color active regions) and central needles (hatched active regions). Notice that peripheral needles always are placed on the boundary of the target region. B. For a cylindrical volume implant, the peripheral needles distributed on the cylindrical surface of the target are called *belt* needles, whereas those at right angles are called *end* or *crossing* needles. Because the inferior end of the implant is uncrossed, the target volume effectively treated is 7.5% shorter than the active length of the belt needles.

The P-P system rules preferentially concentrate radioactivity in the rind or periphery of the implant, compensating for the dose falloff characteristic of a uniform-density implant, thereby improving dose uniformity. After deriving the optimal fraction of radioactivity to be implanted in the rind and core (4:2 ratio) using a radioactive fluid model, Parker coalesced the continuous radioactivity distribution into several concentric cylindrical surfaces and then further discretized these surfaces into individual needles. A more detailed discussion of the mathematical derivation of the Manchester system is given by Anderson and Presser.[188] Table 21.7 lists the rules of the Manchester system, and Table 21.8 lists the stated dose per mgRaEq-h and per unit TRAK as a function of treated area or volume.

TABLE 21.7 MANCHESTER SYSTEM RULES

Feature	Paterson and Parker (Manchester System) Rules
Dose and dose rate	6,000-8,000 R in 6-8 days (1,000 R/day; 40 R/hour)
Dose specification criterion	Effective minimum dose is 10% above the absolute minimum dose in treatment plane or volume.
Dose gradient	Dose in treatment volume or plane varies by no more than ±10% from stated dose, except for localized hot spots.
	For double-plane implants with a separation greater than 1 cm, dose is specified on interior plane 0.5 cm from implanted plane resulting in 10%-30% midplane

Feature	Paterson and Parker (Manchester System) Rules					
	cold spot. Single-plane mgRaEq-h is multiplied by a separation factor to obtain total double-plane mgRaEq-h.					
Linear activity	Variable: 0.66 and 0.33 mgRaEq/cm					
Source strength distribution: planar	Area < 25 cm^2	2/3 periphery; 1/3 center				
	25 < area < 100 cm^2	1/2 periphery; 1/2 center				
	Area >100 cm^2	1/3 periphery; 2/3 center				
Source strength distribution: volume	Cylinder	Belt:core:end:end = 4:2:1:1				
	Sphere	Belt:core = 6:2				
	Cube	1/8 of the activity in each face				
		2/8 of the activity in the core				
Source implant pattern and spacing between sources	Constant uniform spacing: 1 cm separation between sources recommended. Smaller spacings must be used to satisfy distribution rules for small implants.					
Crossing needles	Perpendicular to and at the active ends of the parallel needles; if placed beyond the active ends of the needles, should be double strength. Crossing needles used when possible.					
	Planar implant: Target area effectively treated is reduced in length by 10% per uncrossed end.					
	Volume implant: Target volume effectively treated is reduced by 7.5% per uncrossed end.					
	1 uncrossed end:belt:core = 4:2:1					
	2 uncrossed end:belt:core = 4:2					
Elongation corrections	Long:short dimension	1.5:1	2:1	2.5:1	3:1	4:1
	Correction factors (applied to mgRaEq-h, not area or volume)					
	Planar	1.025	1.05	1.07	1.09	1.12
	Volume	1.03	1.06	1.10	1.15	1.23
Relation between implanted volume/area and treated (target) volume/area	Peripheral and crossing needles placed on the target volume boundaries. Active length determines target length.

[a]Original Manchester values from Paterson R, Parker HM. A dosage system for interstitial radium therapy. *Br J Radiol*. 1938;11:313-339.

[b]Modified from original values for Ir-192 assuming 860 cGy minimum peripheral dose per 1,000 "P-P" R and 7.227 μGy·m^2/mgRaEq-h.

The P-P rules are designed to yield the target area or volume dose distribution that deviates by no more than ±10% of the stated dose, excluding cold spots in the corners and local hot spots at distances less than 5 mm from the source centers. For planar implants, the target or treatment surface (Figure 21.16) is that area bounded by the peripheral needles, which is parallel to and 5 mm from the needle plane. For volume implants, the target volume is that region bounded by the peripheral sources. Fixed 1-cm needle spacing is recommended, with full-intensity sources placed on the periphery of the implants and partial strength needles used as central needles. For volume implants, these two groups of sources are called "belt" and "core" sources, respectively. The distribution rules assume that both planar and volume implants will be crossed at both ends by needles placed orthogonal to the predominant direction of insertion and at the level of the belt needle active tips. The stated or prescribed dose, the modal dose in the target region, is approximately 10% higher than the minimum peripheral dose (minimum dose to the implanted volume or area) and 10% below the effective maximum dose.

In effect, single-plane interstitial implants with crossed ends treat a 1-cm-thick target volume with an area equal to that bounded by the peripheral sources. Target volumes thicker than 1 cm must be treated by using two parallel planes of needles placed on the target volume boundaries (double-plane implant), with source strength arranged in each plane according to the single-plane rules. The mgRaEq-h is calculated from the 0.5-cm single-plane table, multiplied by the appropriate two-plane separation factor, and divided between the two planes. The dose actually is delivered to the inner plane 0.5 cm from each needle plane, resulting in midplane cold spots ranging from 10% to 30% for separations of 1.5 to 2.5 cm. Target volumes thicker than 2.5 cm must be treated by the volume implant system.

Volume implants can treat cylindrical, spherical, or cubic target volumes in which needles or seeds are arranged on concentric cylinders, concentric spheres, or parallel planes, using a 1-cm needle-to-needle spacing when possible. The target region is the volume encompassed by the peripheral sources. Regardless of implant size, 75% of the source

strength should be placed in the rind and 25% in the core, with more specific rules for cylinder implants.

To apply the P-P system, the relationship between target volume, implanted volume (region enclosed by peripheral sources), and treated volume (region receiving 90% of the stated dose) must be appreciated for crossed and uncrossed end cases. The treated volume may be larger than the target volume but always should contain the latter. The relationships between the AL required and target length (TL) for planar and volume implants with uncrossed end(s) are given below:

$$\begin{aligned}
&\text{Two crossed ends} && \text{AL} = \text{TL planar and volume} \\
&\text{One crossed end} && \text{AL} = \begin{cases} \text{TL} / 0.90 & \text{planar} \\ \text{TL} / 0.925 & \text{volume} \end{cases} \\
&\text{No crossed ends} && \text{AL} = \begin{cases} \text{TL} / 0.81 & \text{planar} \\ \text{TL} / 0.85 & \text{volume} \end{cases}
\end{aligned} \tag{21.30}$$

The area and volume used for looking up dose per mgRaEq-h from Table 21.8 should be calculated using the TL. For example, for a single-plane implant with two uncrossed ends, width W, and needles of active length AL, the area, A, used for table lookup is given by $A = W \times \text{AL} \times 0.81$.

To apply P-P tables to modern implants using ^{192}Ir wires or ribbons, several corrections must be applied. The 1938 P-P tables assumed a Γ value of 8.4, ignored attenuation and scattering, neglected oblique filtration, and specified treatment in terms of exposure rather than the absorbed dose. For ^{226}Ra needles, an average correction of 0.90[116] is needed to convert exposure in the original P-P tables to the absorbed dose. Applying these corrections for ^{137}Cs needles and ^{192}Ir seeds and adding an additional factor of 10% to convert from stated (modal target dose) to minimum target volume dose, we obtain the following equivalencies:

$$1\text{'}P\text{–}P\text{'}R = \left\{ \begin{array}{llll} 0.97 \cdot \dfrac{8.25}{8.4} & 0.98 & 0.98 & 0.90 \\ 0.97 \cdot \dfrac{8.25}{8.4} & 1.00 & 0.98 & 0.90 \\ 0.97 \cdot \dfrac{8.25}{8.4} & 1.00 & 1.00 & 0.90 \\ (cGy/R) \cdot \left(\dfrac{\Gamma_{new}}{\Gamma_{old}} \right) & \text{(filtration)} & \text{(attenuation / buildup)} & \left(\dfrac{\min}{\text{stated}} \text{ dose} \right) \end{array} \right\} = \left\{ \begin{array}{l} 0.82 \text{ cGy radium needles} \\ 0.84 \text{ cGy cesium needles} \\ 0.86 \text{ cGy iridium ribbons} \\ \left(\dfrac{\text{Modern cGy}}{\text{'P–P'R}} \right) \end{array} \right. \tag{21.31}$$

Using the 0.90 cGy/P-P R conversion factor, Stovall and Shalek[116] found excellent agreement between computer calculations and the P-P tables for a variety of planar and cylindrical implants following the Manchester distribution rules. For single-plane implants, 90% of the stated dose in cGy covers 94% to 99% of the target area. For cubic arrays of seeds using fixed 1-cm spacing, agreement between the tables and computer calculations is excellent for treatment volumes of more than 100 cm^3[189,190] but results in errors ranging from 10% to 40% for smaller arrays. These discrepancies probably result from deviations from the 4:2 activity ratio and use of a dose specification criterion incompatible with the Manchester system.

The classic implant systems are based on interstitial needles or ^{192}Ir wires consisting of continuous distributions of radioactivity (ie, line sources) with well-defined ALs. To apply the classic systems to modern interstitial sources consisting of discrete equispaced seeds or single-stepping source dwell positions, the dosimetric equivalence between linear arrays of discrete seed sources and line sources must be appreciated (Figure 21.17). An array consisting of N seeds with center-to-center separations, *S*, has a dose distribution that closely approximates that of a continuous line source of active length, AL, and strength $(S_K)_{line}$[101,191]:

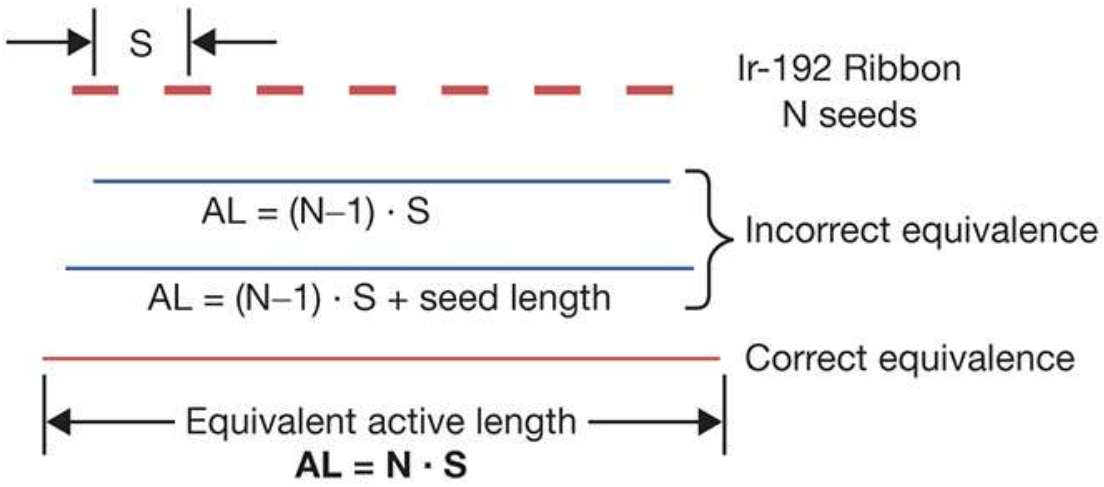

FIGURE 21.17 Relationship between a linear array of equally spaced discrete seeds and its dosimetrically equivalent line source. Both sources are assumed to have the same total strength. Common errors in defining this equivalence are illustrated. AL, active length.

$$\left.\begin{aligned} \mathrm{AL} &= N \cdot S \\ (S_K)_{line} &= N \cdot (S_K)_{seed} \end{aligned}\right\} \qquad (21.32)$$

This equivalence tends to break down at distances less than *S*/2: The cylindrical isodose curves break up into ellipsoidal shapes centered about each seed. In addition, the ribbon

isodose curves undulate significantly at distances comparable with or less than the gap, *S*, between adjacent seeds, although on average the equivalence remains accurate.

Because the P-P system uses 1-cm interneedle spacing, the fraction of sources in the core (vs periphery) increases as volume increases. Thus, using uniform strength ^{192}Ir ribbons and fixed spacing results in underloading the core for very small implants and overloading the core for very large implants, relative to the P-P distribution rules. In the latter case, the gap between minimum peripheral dose and central maximum dose widens. An alternative to the differential loading method is to vary the ribbon spacing with implant size, using smaller (less than 1 cm) spacing for very small implants and larger spacing (up to a limit of 1.5 cm) for larger implants so that the relative number of central ribbons complies approximately with the P-P rules, allowing uniform seed strengths to be used.

To use the Manchester tables for verification of computerized dose calculations requires a method for objectively identifying the computer-generated isodose surface that corresponds to the minimum peripheral dose rate predicted by the Manchester system. For volume implants, mean central dose (MCD), a quantity proposed by the ICRU Report 58 on dose specification in interstitial BT, is useful[192] (Figure 21.18). In the authors' experience, the maximum dose (110% of the stated dose) of the Manchester system is closely approximated by MCD. Minimum peripheral dose and stated dose are given by 80% and 89%, respectively, of MCD. For planar implants, the minimum dose/MCD ratio varies from 55% to 70%, depending on catheter spacing, and is of limited value.

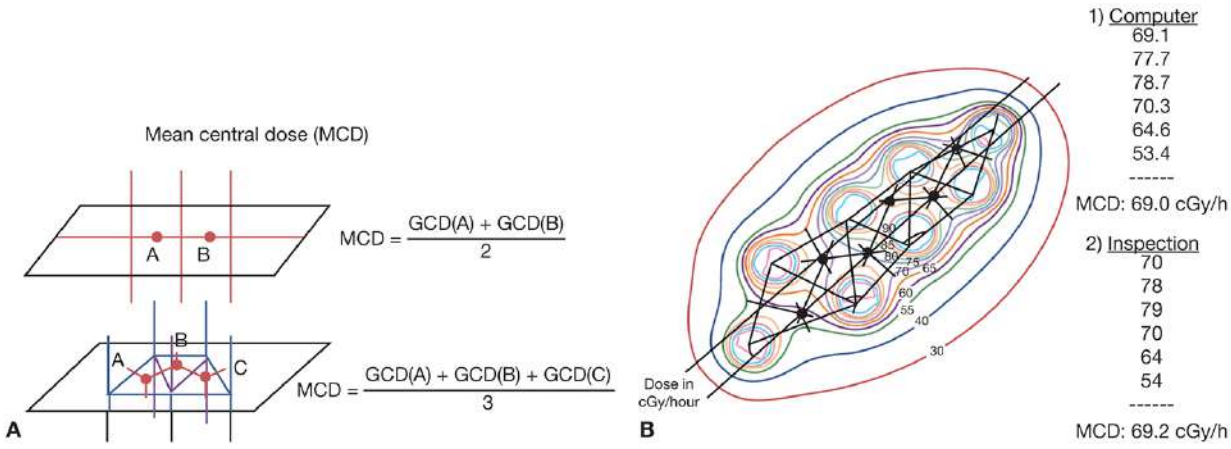

FIGURE 21.18 A. Calculation of mean central dose (MCD) as the arithmetic mean of the doses at mid-distance between each pair of adjacent sources for single-plane implants and the mean of the local minimum doses between each group of three adjacent sources in a multiple-plane implant. All local minimum doses are specified in the "central transverse" plane, which is normal to and bisects the source axes. B. Illustration of a practical specification of MCD for a computer plan.

The Quimby System

The Quimby system was developed by Edith Quimby and colleagues[193-195] at New York Memorial Hospital from 1920 to 1940. Unlike the Manchester system, equal linear intensity (mgRaEq/cm) needles are distributed uniformly (fixed spacing) in each implant. Like the

Manchester system, the associated Quimby tables give the mgRaEq-h needed to deliver a stated exposure of 1,000 R as a function of target volume or area.

The so-called planar implant tables were intended for surface molds; none of the early Memorial publications suggest that it was used for single-plane interstitial implants. In part because Quimby stated dose is the maximum dose in the treatment plane, Quimby planar implants deliver 30% to 40% less radiation (TRAK) per unit stated dose than an equivalent Manchester implant delivers. Rules for distributing radium needles (relationship to target area boundaries, crossed ends, spacing, etc) are not clearly described.

Volume implant needle arrangements are similar to their Manchester counterparts; both systems recommend crossed ends and placing peripheral needles on or beyond the target volume boundaries. However, Quimby allows the needle spacing to vary with implant size and specifies dose as the absolute minimum to the target volume. The physical and mathematical origins of the widely cited Quimby volume implant table are obscure; the tables published in the 1951 edition of *Physical Foundations of Radiology*[194] use 25% to 90% more mgRaEq-h per unit dose than P-P volume implants of similar size. Although vague on the subject, Quimby appears to specify a minimum dose at a point located 3 to 5 mm from the peripheral needles (and therefore outside the target volume) near their active tips.[195] This corresponds to a treatment volume (volume encompassed by prescription isodose surface) that is 6 to 10 mm larger than the implanted volume (used for table lookup) in each linear dimension. The Quimby planar and volume dose specification criteria are clearly inconsistent, and a detailed derivation of the associated tables is lacking. For these reasons, we do not recommend Quimby tables for clinical use.

The Paris System

The Paris system was developed in the early 1960s by Pierquin, Chassagne, Dutreix, and Marinello[196,197] and was motivated by the ^{192}Ir afterloading techniques developed by Henschke. Outside the United States, the Paris system is still widely used to guide definitive BT of localized lesions in the head and neck, breast, and many other sites. An up-to-date summary of the system has been published by Gillin and Mourtada.[198]

The starting point of the Paris system is the definition of the target volume, which is described in terms of thickness *T*, length *L*, and width *W*. The system provides rules for constructing implants, which, if followed, guarantee that the target volume is completely covered by the prescription isodose surface (Table 21.9). The prescription dose level, called the "reference dose," is a fixed percentage (85%) of the basal dose (see Figure 21.19), which closely resembles the more general concept of MCD in Figure 21.18. ^{192}Ir wire sources are arranged in parallel rectilinear arrays with their centers located in the central plane, which is perpendicular to the sources. Adjacent sources must be equidistant from one another, resulting in single-plane implants with equal spacing and double-plane implants with groups of adjacent sources arranged in equilateral triangles or squares in the central plane. The linear density (μGy·m2/h·cm) must be uniform and the same for all sources. Interneedle spacing scales with the thickness, *T*, of the target volume. The number of sources is determined largely by the relative shape of the target volume cross-sectional area,

$W \times T$. In contrast, the Manchester system uses fixed spacing and increases the number of sources as the cross-sectional area of the target volume increases.

TABLE 21.9 PARIS SYSTEM CHARACTERISTICS

Feature	Paris System Rules
Dose and dose rate	6,000-7,000 cGy in 3-11 days (25-90 cGy/hour)
Dose specification criterion	Reference dose (prescribed dose) is 85% of the basal dose and encompasses the target volume when distribution rules are followed. Basal dose is the average of the minimum doses between pairs or groups of adjacent sources in the central transverse plane.
Dose gradient	Fixed 15% gradient between reference dose and basal dose. The "hyperdose sleeve" (region receiving at least twice the reference dose) diameter should be less than 8-10 mm.
Linear activity	Constant (4-14 μGy·m2/h·cm) linear density ^{192}Ir wires used.
Source arrangement geometry for target volume of thickness, width, and length of $T \times W \times L$	Only single- and double-plane implants allowed. Spacing, S, and lateral margin (called "safety margin" for double-plane case), M, are fixed fractions of T and constant within a given implant. Active length, AL, is a fixed fraction of L, which varies with S.
	Single plane: T = 12 mm
	$S = 2 \times T$ (2 sources)
	$S = 1.67 \times T$ (3 sources)
	$M = 0.37 \times T$
	AL = (1.3 − 1.49) × T
	Double plane: (square pattern) (triangle pattern)
	$S = 0.62 \times T$ $S = 0.77 \times T$
	$M = 0.27 \times T$ $M = 0.15 \times T$
	AL = (1.37 − 1.62) × L AL = (1.33 − 1.49) × L
Source spacing, S, limits	Short sources (1-4 cm):
	Long sources (≤10 cm): 15 mm ≤ S ≤ 22 mm
Crossing needles	Generally not used; AL ~1.45 × L to compensate for uncrossed ends
	For oral cavity implants, hairpins are common, which approximate crossed ends.
Relation between target volume and implanted volume	W = distance between outermost sources + 2 × M L = (1.3 − 1.62) × L
	$T = \begin{cases} S/1.67 & \text{Single plane} \\ S + 2 \times M & \text{Double plane : squares} \\ S \times \cos 30^\circ + 2 \times M & \text{Double plane : triangles} \end{cases}$

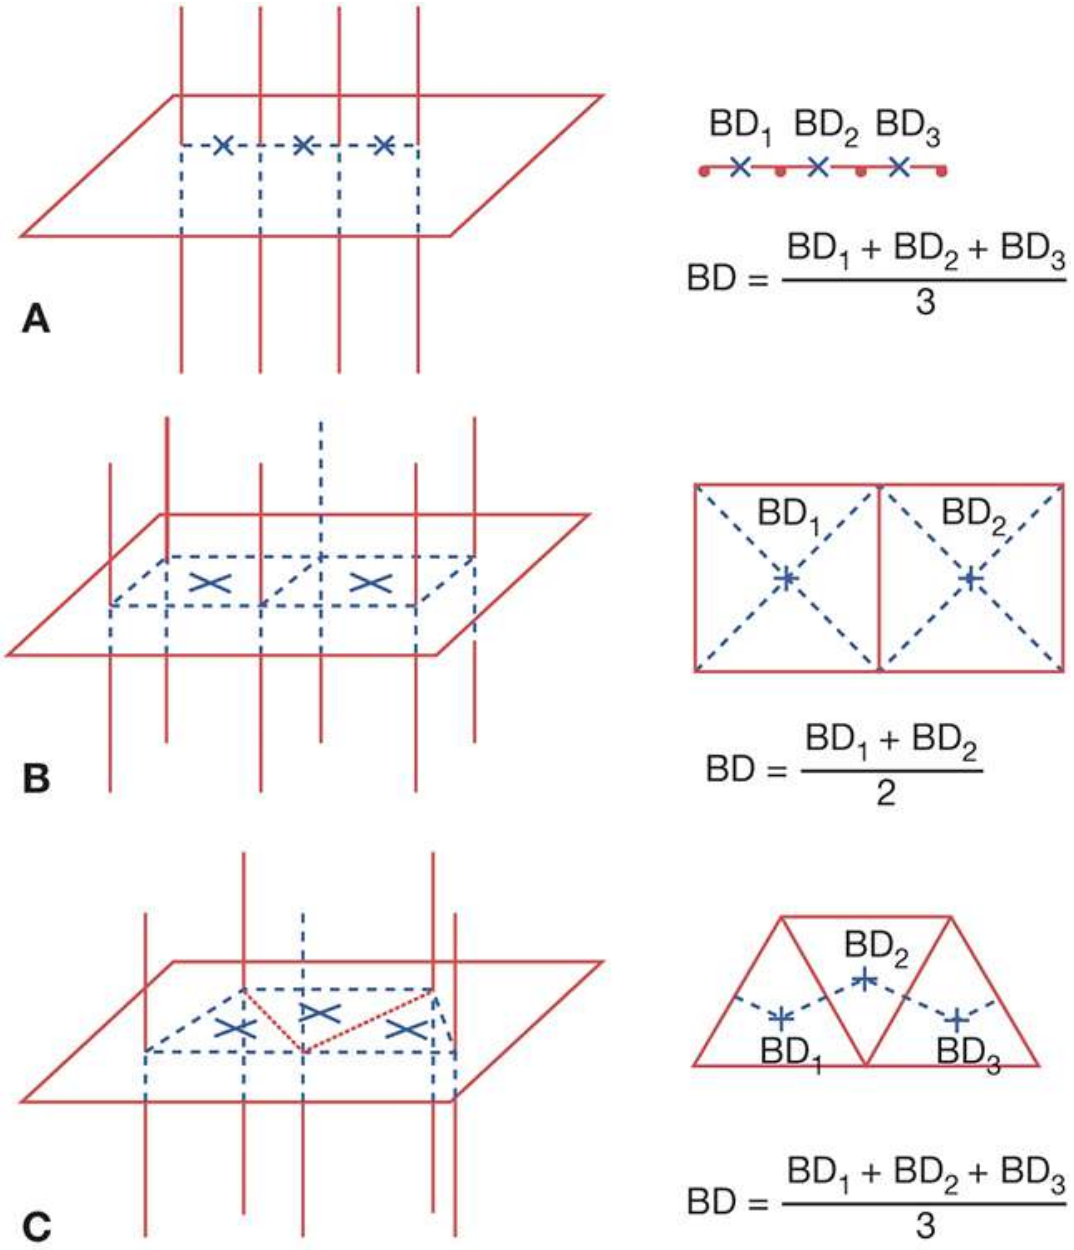

FIGURE 21.19 The three central plane configurations allowed by the Paris system: (A) single-plane implant, (B) double-plane implant using the pattern of squares, and (C) double-plane implant using the pattern of equilateral triangles. The calculation of basal dose (BD) rate at a point equidistant from each group of adjacent sources is illustrated for each configuration. (From Gillin MT, Albano KS, Erickson B. Classical systems II for planar and volume temporary interstitial implants: the Paris and other systems. In: Williamson JF, Thomadsen BR, Nath R, eds. *Brachytherapy Physics*. Medical Physics Publishing; 1995:232-343. Reprinted by permission of Medical Physics Publishing.)

Table 21.9 shows that the location of the peripheral sources relative to the treated volume (region encompassed by the reference isodose rate surface, as shown in Figure 21.20) differs from the Manchester system, which implants to the boundary of the treated tissue. In the transverse plane, the peripheral sources lie 2 to 4 mm (the lateral margin distance, *M*) inside the treatment surface, whereas longitudinally, the AL extends 15% to 20% beyond

the distal and proximal margins of the target volume. In practice, the margin, *M*, is treated as a safety margin, and the peripheral needles are implanted along the margins of the CTV. The maximum thickness, *T*, of a target volume treatable in the Paris system is about 2.5 cm. An example of a double-plane implant arranged in squares is shown in Figure 21.21.

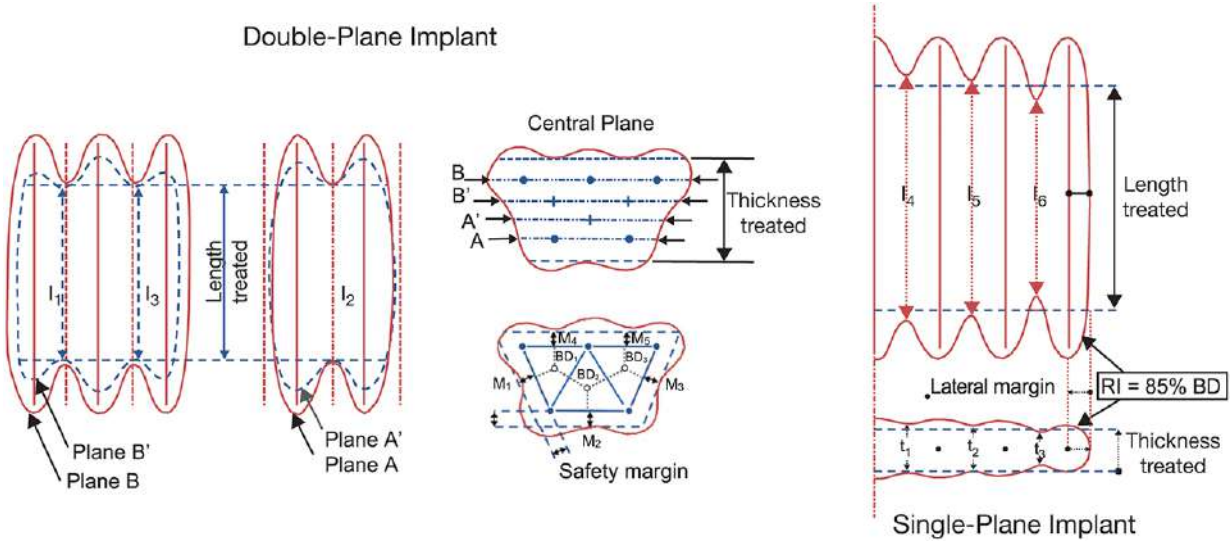

FIGURE 21.20 Relationship of the reference isodose (RI), source locations, and target volume dimensions for an illustrative a single-plane and a double-plane implant following the Paris system. The concept of safety margin (lateral margin), M, and location of basal dose (BD) points are illustrated. (Adapted from Thomadsen B, Miller R. Brachytherapy physics. In: Brahme A, ed. *Comprehensive Biomedical Physics*. Elsevier; 2014:315-381. *Radiation Therapy Physics and Treatment Optimization*; vol 9. Copyright © 2014 Elsevier. With permission.)

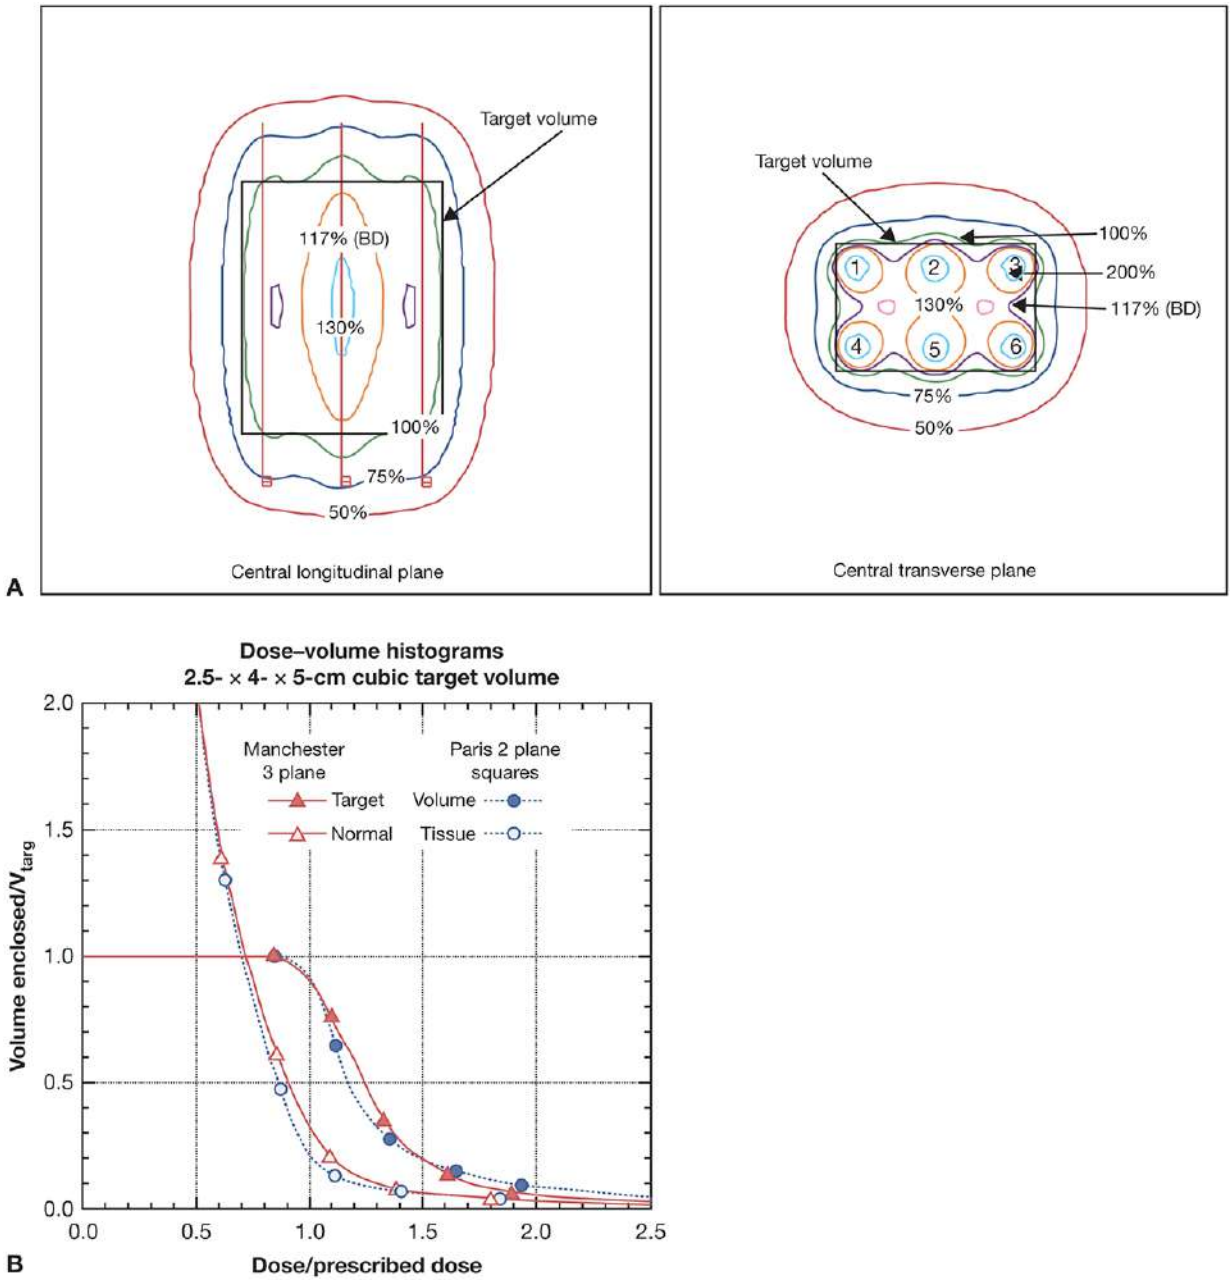

FIGURE 21.21 A. Isodose curves of a Paris system double-plane implant arranged "in squares" to treat a 2.5-cm × 4-cm × 5-cm target volume (heavy lines). The separation and active lengths of the ^{192}Ir wires are 1.6 and 7.3 cm, respectively. A linear strength of 6 μGy·m2/h·cm gives reference (100%) and basal (117%) dose (BD) rates of 60 and 70.6 cGy/hour, respectively. B. Comparison of dose-volume histograms calculated separately for the 2.5-cm × 4-cm × 5-cm target volume and the tissue outside the target for the Paris implant shown and a Manchester implant consisting of three planes, 15 ^{192}Ir ribbons with six seeds each, and 1.25-cm spacing between planes and ribbons. Each graph shows volume of tissue (in multiples of volume of the target) receiving at least the specified dose (in multiples of the prescribed dose). For the Paris and Manchester implants, respectively, the prescribed dose is calculated reference dose and minimum target dose predicted by the Paterson-Parker volume table. In both systems, the prescription isodose surface covers about 90% of the target. Surprisingly, both normal tissue sparing and dose homogeneity in the target are slightly better for the Paris implant.

To apply the Paris system, the target thickness *T* must be known, which defines the spacing and determines whether single- plane or double-plane geometry is required. The number of sources and selection of a square or triangular arrangement are defined by the relative cross-sectional shape of the target volume in the central plane perpendicular to the sources. Finally, the AL is calculated. The source tip and end coordinates are reconstructed from orthogonal radiographs, and the dose distribution and basal dose are calculated by computer for the actual implant geometry realized in the patient, not the idealized implant of clinical intention. This approach differs from the classic Manchester method, which bases dose prescription on the P-P table and, in general, ignores deviations of the actual implant geometry from the ideal. The Paris system addresses only single- and double-plane implants; large-volume implants for treating pelvic masses and brain tumors were not part of the original system. Extensions of Paris system principles to large-volume implants are discussed by Leung[199] and Gillin and coworkers.[200]

Modern Approaches for Temporary Implantation

A major development of the past three decades is a pronounced shift from LDR manual afterloading to HDR BT. Single-stepping HDR source remote afterloading (see Chapters 23 for a detailed treatment) allows the treatment time (dwell time) to be individually specified at each treatment (dwell) position in the catheter. This permits the use of dwell-weight optimization as a tool for improving dose uniformity and target coverage within implants. In contrast to the classic systems, which assume that ribbons and needles are of uniform linear density, dwell-weight optimization supports far more elaborate nonuniform source strength distributions than those envisioned by the Manchester system rules.

The published experience, confined largely to Paris-like double-plane breast implants, demonstrates that geometric optimization[201] preferentially increases the dwell times at dwell positions near the catheter ends. The most striking finding is that optimization allows the AL/TL ratio to be reduced from 1.33 to 1.5 and 1.1 to 1.25.[202-204] In the transverse plane, target coverage remains unchanged, whereas dose homogeneity is improved modestly, depending on the figure of merit (FOM) used to quantify this effect. When dose point optimization (specifying dose constraints at dose calculation points throughout the treatment volume) is used, acceptable dose homogeneity results with even smaller AL/TL ratios, even when all peripheral dwell positions are placed inside the target volume (AL/TL = 1.0)[205,206] for idealized volume implants and clinical volume implants.[203] These early efforts did not address the practical problem of how to distribute dose-constraint points in clinical volume implants with irregular catheter spacings and how to select dwell positions to be activated in each catheter. While dwell-weight optimization techniques have the potential to reduce AL/TL ratios to near unity with good conformal index (CI) and homogeneity index (HI), the selection of catheter direction and location relative to the target volume is still manual, with guidance drawn from the distribution rules of the classic systems or one's own clinical experience.

Three-Dimensional Imaging and Dosimetry

The use of 3D imaging to preplan implants or intraoperatively guide catheter or seed insertion is growing rapidly. The most widely practiced form of image-guided BT is use of intraoperative TRUS to guide transperineal insertion of needles used to implant the prostate gland with low-energy seeds.[44,45] However, image-guided implant methodologies have been developed for HDR interstitial implantation for prostate cancer[207] and HDR multicatheter interstitial[208] implants for accelerated APBI following lumpectomy. All of these approaches require delineation of the target volume and critical structure surfaces from 3D imaging studies. Then catheter or needle trajectories and, ultimately, seed or dwell position locations can be selected to improve target volume coverage while minimizing unnecessary dose to critical structures. The issues involved in utilizing image-guided and image-based BT in HDR interstitial BT, including treatment planning, selection of imaging modality, and impact on clinical workflow are covered in detail elsewhere.[209]

As practiced by most radiation oncologists, image-guided, intraoperatively planned implants continue to rely on the planner's judgment for selecting source locations. These decisions are guided by a "loading approach," or set of guidelines that specify margins, seed locations relative to the target boundary, spacings, and approximate periphery-to-core loading ratios.[210,211] Dose calculations and DVH quality indices are often used to guide manual source position adjustments to improve target volume coverage, improve dose homogeneity, and select source strengths (or dwell times) and the prescription isodose.

Anatomy-Based Optimization

An important advance upon standard dose point optimization is anatomy-based optimization in which constraints and treatment goals are defined in terms of doses to the CTV or normal tissues contoured from 3D imaging studies rather than surfaces defined relative to dwell positions. The simulated annealing HDR dwell-time optimization technique developed by Lessard and Pouliot[212] illustrates the general features of the various optimization approaches[213-216] that have been brought to bear on this problem (see Ezzell's[217] review for a highly readable introduction to BT optimization techniques). An objective function, consisting of penalty factors summed over the dose calculation points in the CTV, urethra, rectum, and other organs, is minimized. The penalty factors are used to penalize candidate dose distributions that deviate from the specified constraints and planning goals (see Ezzell's[217] review cited earlier). The inverse planning technique of Lessard and Pouliot[212] reduces CTV dose heterogeneity (V_{150} of 29% vs 50%) and urethral doses in clinical prostate implants compared to geometric optimization[218] and solves the problem of selecting active dwell positions and locations for dose-constraint points faced by the older dose point optimization algorithms. While anatomy-based inverse planning does not optimize catheter trajectories, its proponents argue[219] that it reduces the dependence of implant quality on the number and accurate positioning of the catheters relative to the CTV boundary. If true, inverse planning could reduce the dependence of implant quality on operator skill and reduce the need to follow system-based needle insertion rules.

Computerized dose calculation, dwell-weight optimization, and image-guided BT have made anatomy-based dose specification and meaningful implant optimization a reality in some clinical settings. However, as currently available, these innovations still require users

to conceptually plan implants in terms of specified source and needle distribution patterns, implant-target volume margins, and loading ratios. Specific rules borrowed from the classic systems (eg, AL/TL ratios) may require significant modification when adapted to these modern technologies.

Permanent Implantation

In contrast to temporary implantation, in which treatment time is varied to control the total dose delivered, the dose delivered by a permanent implant is determined by the initial geometric arrangement of sources and S_K per source: once the sources are implanted, neither the total dose delivered nor the relative distribution can be modified easily. Up through the mid-1980s, manual planning and dose calculation tools were used widely to estimate the number and density of sources needed to deliver the prescribed dose or to intraoperatively correct for deviations between the planned and actual source locations. While 3D treatment planning and dose calculation have replaced manual preplanning tools (see section "Modern Approaches"), manual aids can still be used for verifying the correctness of patient treatment plans.

Manual Approaches

For high-energy sources (eg, ^{198}Au), the Manchester, Laughlin et al,[189] or Shalek et al[190] tables and associated distribution rules have been used as manual planning aids. These manual planning aids for high-energy sources cannot be applied to low-energy seed (^{125}I, ^{103}Pd, and ^{131}Cs) implants because of the importance of tissue attenuation in this energy range. The influence of photon energy on the relationship between dose rate, $\dot{D}$, and implanted volume, V, is illustrated by Figure 21.22. Parker[184] recognized that this relationship can be described accurately by a power law formula, of the form

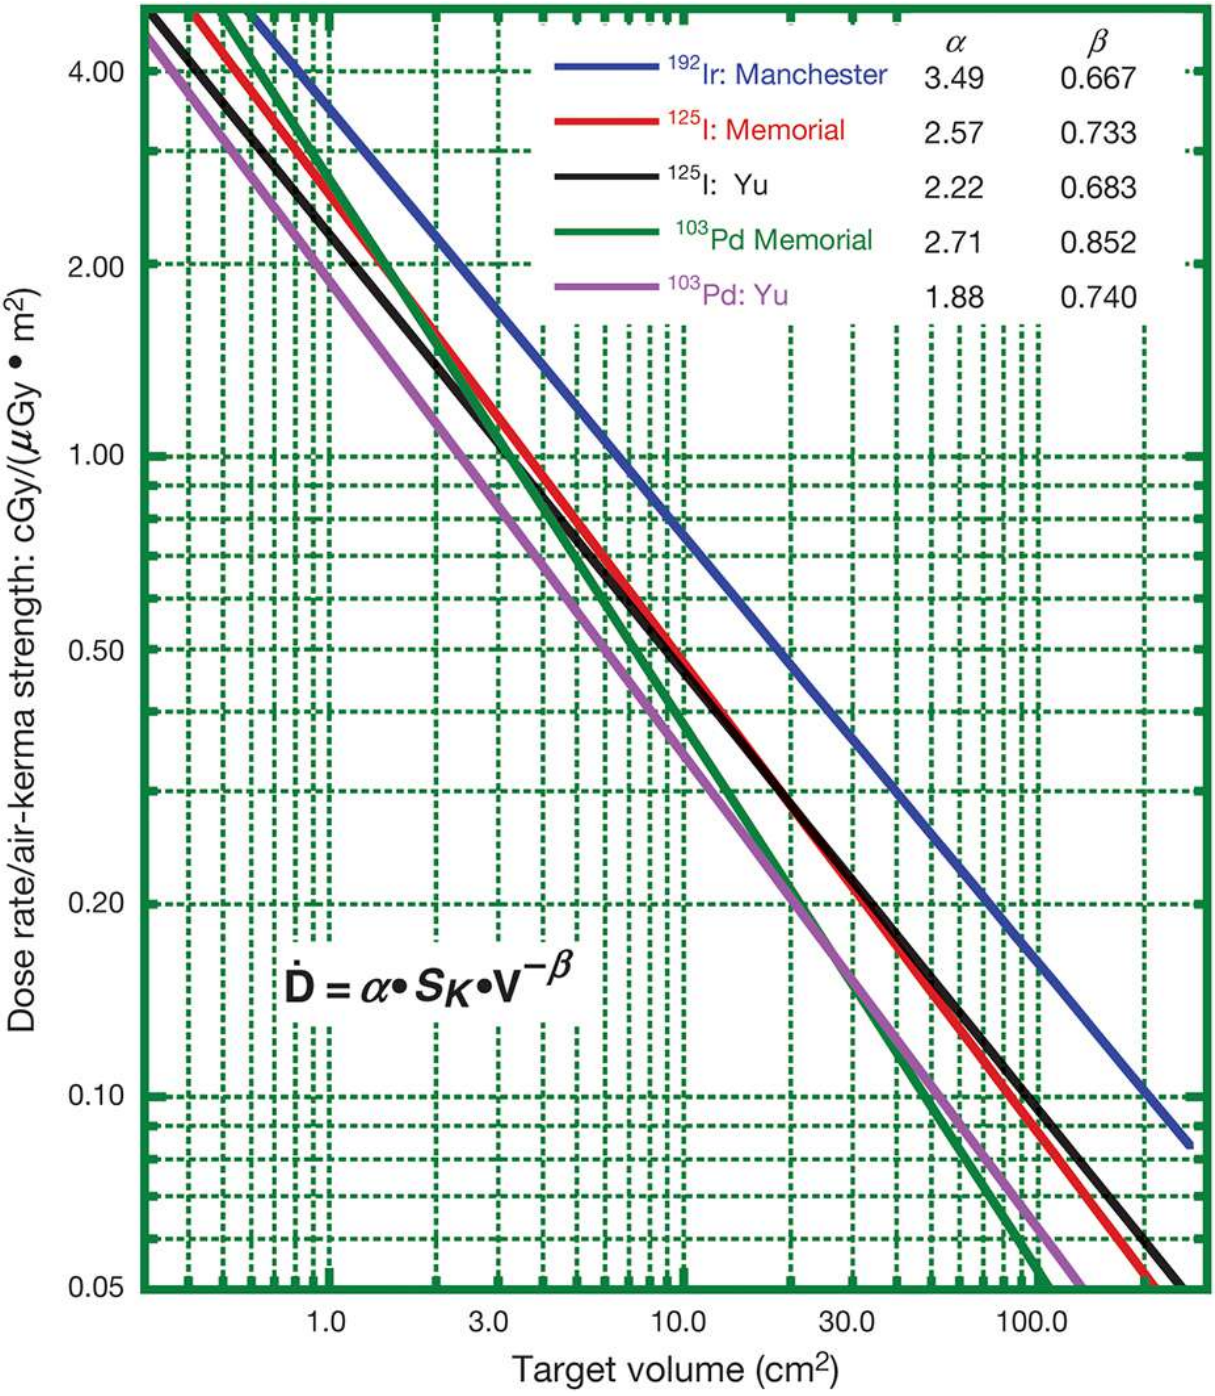

FIGURE 21.22 Comparison of reference dose rate per unit air-kerma strength versus volume of the target volume for Manchester volume implants and ^{103}Pd and ^{125}I permanent prostate implants. The inset gives the exponents and proportionality constants needed to describe these relationships in terms of a simple power law equation. The data in the figure are from Yu,[221] Memorial,[220] and Manchester.[184]

$$\dot{D} = \alpha \cdot S_{\mathrm{K}} \cdot V^{-\beta} \tag{21.33}$$

In fact, the original Manchester table (Table 21.8), converted to modern units and quantities, can be derived from equation 21.33 by setting $\alpha = 3.49$ and $\beta = 2/3$. While ^{103}Pd and ^{125}I volume implants also can be described by the power law formula, they have somewhat larger exponents, β, since dose rate falls off faster with increasing volume than for high- energy sources.[220,221] The proportionality constant, α, is substantially lower, indicating that low-energy seed implants require higher source strengths to achieve a stated dose rate. The author-to-author variations in α values for the same radionuclide are due, in part, to differences in dose specification and implant construction. Anderson's analysis,[220] based on the pre-TRUS era Memorial nomogram, assumes that dose is specified in terms of matched peripheral dose (MPD) and that all seeds are implanted 2 to 5 mm inside the target (prostate) boundary, whereas the Yu nomogram assumes[221] that peripheral seeds are implanted on or outside the boundary and that minimum target dose is specified. Before using a nomogram or lookup table for QA checks or preplanning, readers should carefully assess its consistency with dose calculation and planning methods used in their clinical practices.

The best known manual planning tool for permanent ^{125}I implantation is the Memorial dimension averaging method[220,222] and its associated nomogram. It was designed to guide direct implantation of seeds into the prostate following surgical exposure via the retropubic approach. The method name is derived from the fact that the mean of the three measured orthogonal dimensions of the prostate is the main input to the nomogram. By means of several juxtaposed logarithmic scales, the nomogram predicts the total apparent activity, the number of seeds, and the needle spacing. The seeds were implanted inside the prostate, such that peripheral needle-to-target boundary distance is less than 50% of the interneedle spacing.

The calculation method is designed to deliver an MPD of 160 Gy over the life of the implant when d_a is more than 3 cm.[220] MPD is defined as the dose level whose corresponding 3D isodose surface encompasses a volume, V_E, equal to that of an ellipsoid having the same orthogonal dimensions as the originally measured target volume ($V_E = \pi d_x d_y d_z/6$). For a given implant, MPD is derived from the corresponding cumulative DVH, $V(D)$, according to $V_E = V(\text{MPD})$. Note that the prescribed doses of 160 Gy delivered in the 1985-1999 era correspond to doses of 144 Gy when corrected for implementation of the WAFAC primary standard and TG-43 dosimetry parameters.[167] The MPD overestimates minimum target dose (mPD) because the prostate gland is rarely ellipsoidal and has small protrusions that may extend outside the MPD isodose surface. Likewise, small deviations of the peripheral seeds from their planned locations can alter dramatically the shape of the MPD isodose surface. One study[223] found that, on average, MPD was twice the D_{99} level (the dose ensuring 99% target coverage on postoperative CT imaging) and that only 69% to 89% of the target volume received a dose equal to or greater than MPD.

Modern Approaches

The most important advance in permanent implantation in the past four decades is the rise of image-based and image-guided techniques in prostate BT. The retropubic approach has

been abandoned in favor of the transperineal approach using intraoperative TRUS imaging,[44,224] which typically consists[209] of (a) preplanning using a TRUS examination, or "volume" study, obtained 2 to 3 weeks before the scheduled implant; (b) inserting the needles using interactive real-time TRUS imaging; and (c) followed by CT-based postprocedural planning 0 to 30 days after the procedure. During preplanning, the PTV is often defined as the contoured prostate gland plus a discretionary margin. Most radiation oncologists practice some form of peripheral loading to improve uniformity and reduce dose to the urethra. For example, the modified uniform loading as defined by Butler et al[210] distributes about 75% of the source activity in the periphery and emphasizes insertion of peripheral needles on or near the PTV boundary. Typically, needle locations and seed strengths are manipulated to achieve a prescribed minimum target dose (mPD or $D_{100\%}$) of 145 Gy for ^{125}I monotherapy. For ^{103}Pd monotherapy, the American Brachytherapy Society (ABS)[147] recommends retaining the prescribed dose of 125 Gy (compared to 115 Gy used before 2000) following implementation of the NIST $S_{K,N99}$ standard and recently revised TG-43 parameters based on the AAPM's most recent reconstruction[167] of historical ^{103}Pd prescribed-to-administered dose ratios. For ^{131}Cs monotherapy, a prescribed dose of 115 Gy prescription has been used.[225] More detailed discussion can be found in Chapters 22 and AAPM TG-137 report.[226]

Dose specification, for recording and reporting doses actually administered by a permanent prostate implant, is based on postimplant dose evaluation.[226,227] Following the implant procedure, a CT examination is obtained; the prostate gland, rectum, and bladder are contoured; and the seed locations are identified from the transverse images. The choice of dose specification parameter for this purpose has been the subject of intense investigation. Based on analysis of both idealized and actual implants, Yu and colleagues[221] found that the postimplant D_{100} was very sensitive to small random displacements of the seeds from their intended positions, which resulted in underdoses of 15% or more to small volumes in the target periphery. However, they found that the mPD of the idealized implant (no seed displacement) covered at least 90% of the target (ie, $D_{90} \geq$ mPD and $V_{100} \geq 90\%$), even in the face of 6-mm seed displacements. In a study of 60 consecutive implant patients, Merrick and associates[228] found mean V_{100} and D_{90} values of 94% of the CT prostate volume and 108% of the prescribed dose (mPD of the preplanned implant), respectively. Of these patients, 82% had a D_{90} exceeding the preplanned mPD and no patient had a D_{90} smaller than 90% of mPD. In contrast, D_{100} was only 68% of the prescribed mPD, on average. Two groups[229,230] have found a correlation between prostate-specific antigen (PSA) relapse-free survival at 4 years and D_{90}. In particular, Potters and colleagues[229] found a D_{90} dose-response cutoff of 90% of the prescribed dose but could find no statistically significant cutoffs for D_{100} and V_{100}.

An important contemporary development is "intraoperative planning"[209,231] in which TRUS-based planning (and postimplant dose evaluation as well, in some implementations) is performed during the procedure itself rather than on a volume study acquired weeks before. Intraoperative planning eliminates uncertainties due to differences in planning and

treatment anatomy due to probe positioning errors or impact of hormone ablation or external beam therapy. An extension of intraoperative planning is dose-guided implantation[209,232] or "dynamic dose planning,"[233] in which intraoperative planning is repeated 1 or more times during the implantation procedure, thereby allowing optimized insertion of needles yet to be implanted to overcome errors in previously inserted sources.

Dose Specification in Interstitial Brachytherapy

The ability to objectively compare different interstitial implant plans as to target volume coverage, normal tissue sparing, and dose homogeneity depends on dose specification. The term "dose specification" means objective identification of a spatial volume or location for evaluating absorbed dose for the purposes of prescription, for describing the quantity of radiation actually delivered to the patient, or for reporting. The "specified dose" sometimes is called "reference dose." The dose that an implant actually delivers to the patient, based on postimplant treatment planning, may differ significantly from the dose prescribed for a variety of reasons. For example, anatomic or technical constraints may preclude accurate positioning of sources at their intended locations, resulting in a partial geometric miss or underdose of the specified volume.

Because of the high-dose gradients near the peripheral sources or the target volume boundary, reproducible specification of dose and evaluation of implant quality is difficult. Small differences in dose specification criteria can lead to large differences in treatment time or in the geometric relationship between implanted and treated volume. Many of the differences between the Manchester, Paris, and Quimby systems can be attributed to fundamental differences in dose specification. Several divergent and rather abstract approaches to dose specification have been developed and promoted by various national and international advisory groups; no single approach to dose specification has been widely accepted within the BT community.

Minimum Dose to an Anatomically Defined Target Volume

The minimum dose to the anatomically defined target volume harboring malignant cells is conceptually attractive because it is based on the intuitively satisfying premise that local tumor control will be determined by the minimum dose received by tumor cells. The ABS[234] recommends that minimum dose should be identified as accurately as possible by the best means available and should be used for dose prescription, evaluation, and reporting.

In practice, minimum target dose specification is difficult to implement clinically for many implants. In the prostate BT literature,[227] minimum target dose is usually called "minimum peripheral dose," or mPD, when used for implant preplanning prescription and D_{100} (see discussion on dose-volume histograms) when used for postimplant dose evaluation. When imaging data showing the target volume in relation to the sources is not available, the ABS recommends approximate target localization by means of intraoperatively placed surgical clips, orthogonal planar imaging, or measurements relative to peripheral sources.

A clear disadvantage of minimum dose specification is that the target volume surface lies within the zone of largest dose gradient. This can result in large patient-to-patient fluctuations in the central-to-specified dose ratio because of small variations in the peripheral source locations relative to the apparent target boundary or uncertainties in delineating the target volume. As discussed earlier in the "Permanent Implantation" section, reviews of CT-based prostate implant dose evaluations showed that absolute minimum delivered doses (D_{100}) relative to the prescribed dose exhibited large patient-to-patient variabilities and average about 30% to 60%.[228,235] The minimum dose covering at least 99% (or 95%) of the target volume was found to be much less sensitive to small changes in the peripheral seed locations or uncertainties in the target volume surface location.

Minimum Implant Dose Relative to Sources

Historically, treatment planning utilized planar radiographs for 3D reconstruction of radioactive source positions, yielding accurate dose estimates relative to the sources, but not to an anatomic target volume.[95,209] Thus, it was natural to prescribe treatment to a point or surface that has a fixed relationship to the peripheral sources. The minimum implant dose (MID) is the minimum dose received by the "target" volume defined relative to the implanted volume, the smallest regular geometric shape circumscribing the peripheral sources. Often, this specification volume is taken to be that volume that is 2 to 5 mm larger in each linear dimension relative to the implanted volume, as in the Paris and Quimby systems. Prior to the acceptance of image-guided BT, MID was perhaps the most widely used specification approach and is the basis of the classic systems and the U.S. practice of selecting prescription isodose surfaces from 2D isodose curve plots.

However, MID yields information about tumor coverage only to the extent that the radiation oncologist has implanted peripheral sources at known distances from the anatomic target volume boundaries. In addition, MID lies in the zone of maximum dose gradient and can be difficult to evaluate objectively for an implant of irregular shape, again leading to large patient-to-patient variations and variations in the central-to-prescribed dose ratio. The Paris and Manchester systems eliminate the possibility of subjective isodose selection by rigidly specifying dose rate by means of basal dose rate and implant tables, respectively.

Mean Central Dose

The ICRU report on dose specification in interstitial BT[192] emphasizes reporting MCD (see Figure 21.18), although it recommends reporting the prescribed dose, the peripheral dose (minimum target dose), and a description of dose uniformity as well. MCD specifies dose in the low-gradient regions located between adjacent source locations in the central plane of the implant. Thus, MCD is relatively free of the variability inherent in minimum peripheral or target dose specification. It is a generalization of the Paris system basal dose.

As a reporting parameter, MCD can be reproducibly estimated from 2D central transverse plane isodoses and should be very useful for comparing implants performed using different clinical systems. However, for systems other than the Paris and Manchester systems (which rigidly specify how sources are to be arranged relative to the target volume), MCD does not

have a known relationship to minimum peripheral or target dose. Thus, its value as a prescription parameter is limited.

Dose-Volume Histogram Representations

DVHs are 1D plots that describe the distribution of tissue volumes, V, irradiated by the implant with respect to dose, D. DVHs can be presented in either differential, $\Delta V(D)/\Delta D$, or cumulative, $V(D)$, forms. Differential DVH computation involves calculating dose over a fine 3D grid over a defined volume, dividing the dose axis into small bins of width ΔD, and then counting the number of voxels falling into each dose interval. The cumulative DVH gives the volume of tissue, $V(D)$, receiving a dose of at least D.

DVHs can be evaluated for specific anatomic regions (eg, target and normal tissue as illustrated by Figure 21.21) or can be evaluated for tissue irradiated by the implant without regard to anatomic boundaries. For bounded volumes, $V(D)$ is flat below the minimum dose received by the volume. When evaluated over unbounded space, $V(D)$ steeply increases with decreasing dose and asymptotically approaches the central point-source DVH, $V_{\text{point}}(\dot{D}) = (4\pi/3)\cdot[S_K\cdot\Lambda/\dot{D}]^{3/2}$. The use of DVHs has enriched discussions of dose specification by focusing attention on describing the 3D dose distribution rather than on single parameters. However, in the absence of target volume and normal tissue geometry, DVHs in themselves do not solve the dose specification problem.

Because 3D anatomic models were often lacking until recently, several FOMs derived from DVHs have been proposed that do not require an anatomically defined target volume. Such FOMs may be useful for ranking the quality of competing implant geometries in terms of uniformity and normal tissue sparing or for optimally selecting a specification dose rate for a given implant geometry. An important contribution is the "natural" DVH introduced by Anderson.[236,237] The natural DVH is a plot of $\Delta V(u)/\Delta u$, where $u = D^{-3/2}$. The natural DVH plots as a horizontal line for a central point source. It suppresses r^{-2} effects, which dominate the conventional $V(D)$ plot, making its detailed implant geometry-specific structure more evident. Low and Williamson[206] introduced an alternative modified DVH, $R_p(D) = V_{\text{impl}}(D)/V_{\text{point}}(D)$. Both of these modified DVHs show a sharply defined peak centered about MCD, the width and height of which quantify the volume of tissue receiving an approximately uniform dose. Other useful quality measures include the uniformity index[238] and the dose nonuniformity ratio (DNR).[239] The DNR, usually plotted as a function of reference dose, D_r, is defined as the ratio of volume receiving a specified multiple of D_r (usually 1.25 or 1.5) to that receiving at least D_r.

Target volume–dependent DVH quality indices were introduced into BT by Saw and Suntharalingam.[240] For single- and double-plane implants designed to cover specified cubic target volumes, respectively, they defined three indices as a function of reference dose rate D_r. The coverage index, CI(D_r), is that fraction of the target tissue receiving a dose rate $\geq D_r$. The homogeneity index, HI(D_r), is the fraction of target volume receiving dose rates between D_r and 1.5 D_r. The external volume index, EI(D_r), is the volume of tissue outside the target volume, expressed in multiples of the target volume, receiving dose rates $\geq D_r$.

When these indices are plotted (Figure 21.23), the tradeoffs among these clinical end points are evident. If a prescription dose rate is selected to maximize dose homogeneity (ie, maximize HI), then 85% to 95% coverage of the target must be accepted. To minimize irradiation of tissue outside the target, both target coverage and dose homogeneity must be compromised. Low and Williamson[206] suggested ranking competing implant geometries by specifying the HI achieved for the maximum reference dose level that yields a CI of unity.

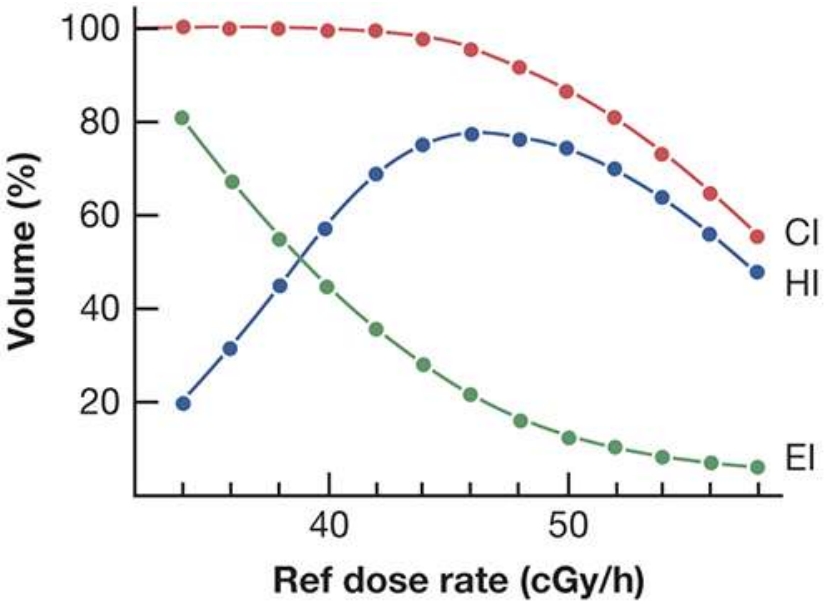

FIGURE 21.23 Plot of coverage index (CI), external index (EI), and homogeneity index (HI) as a function of reference dose rate for double-plane implant consisting of five ^{192}Ir ribbons with seven 1-mCi seeds in each plane and a 6-cm × 6-cm × 2.5-cm target volume. Ribbon and plane spacings of 1.5 cm were used. (From Saw CB, Suntharalingam N. Reference dose rates for single and double plane 192Ir implants. *Med Phys*. 1988;15[3]:391-396. Copyright © 1988 American Association of Physicists in Medicine. Reprinted by permission of John Wiley & Sons.)

For TRUS-guided prostate implantation, DVH metrics such as D_{100}, D_{99}, and D_{90}, denoting the minimum doses administered to the highest dose volumes covering 100%, 99%, and 90% of the contoured CTV or PTV, respectively, have become widely accepted as reporting parameters.[226,241] Volumetric indices, such as the V_{150}, V_{100}, and V_{90}, which denote the fraction of the CTV or PTV receiving at least 150%, 100%, and 90%, respectively, of the prescribed dose, are recommended to assess dose homogeneity and adequacy with which the prescription has been fulfilled.

INTRACAVITARY BRACHYTHERAPY

In contrast to the comparatively uniform dose distributions of interstitial BT, the unidirectional source arrangements used in intracavitary BT give rise to dose distributions that fall off rapidly with distance from the applicator surface. This produces large dose gradients across the target volume, making target volume–based dose specification difficult,

yielding a highly empirical treatment modality. Numerous parameters have been used to prescribe, constrain, or report intracavitary therapy applications. These include: mg-h, mgRaEq-h, reference point doses (points *A* and *B*), bladder and rectal reference point doses, vaginal surface dose, treatment time, the ICRU Report 38[3] 60-Gy reference volume, and, more recently, TRAK, rectovaginal reference point dose, and $D_{2\text{cm}^3}$ and $D_{0.1\text{cm}^3}$ for the bladder and rectum.[97] This section emphasizes the physical relationships among these parameters and their dependence on applicator characteristics. Systems for treating carcinoma of the cervix, the most intensively studied form of intracavitary therapy, are reviewed. Our focus is further restricted to applicator geometries and treatment systems derived from the Manchester system. This limited focus is justified by the fact that Manchester- or Fletcher-style applicators continue to be the dominant choice across the world for both HDR and LDR treatments.

The Manchester Family of Intracavitary Therapy Systems

The Manchester system, developed in 1938 by Tod and Meredith,[10] has heavily influenced intracavitary treatment practice patterns throughout the world, especially in North America. The widely used Fletcher-Suit applicator system, the Fletcher loadings, and point *A* and *B* reference points are all derived from the Manchester system. This system was the first to use applicators and loadings designed to satisfy specific dosimetric constraints.[10,242] It was also the first system to use a radiation field quantity, exposure at point *A*, rather than mg-h, to specify treatment.

The Classic Manchester System

The original Manchester applicator system consisted of a rubber intrauterine tandem and two vaginal "ovoids," whose ellipsoidal shape was designed to conform to the isodose curves arising from ^{226}Ra tubes placed along their long axes. The small, medium, and large ovoid minimum diameters were 2, 2.5, and 3 cm, respectively, and are the same as those used for the Fletcher colpostats.[243] The preloaded ovoids contained no shielding and relied on extensive anterior and posterior packing to spare bladder and rectal tissue.

The reference point *A* (Figure 21.24) was originally defined as the point "2 cm lateral to the center of the uterine canal and 2 cm from the mucous membrane of the lateral fornix in the plane of the uterus."[10] Point *A* was designed to represent average dose to the uterine vessels and ureters, an area termed "the paracervical triangle," which was believed to be the limiting factor in the treatment of cervical cancer. In current practice, point *A* dose is used to approximate the average or minimum dose to the tumor. Point *B*, defined to be 5 cm from the patient's midline at the same level as point *A*, was intended to quantify the dose delivered to the obturator lymph nodes.

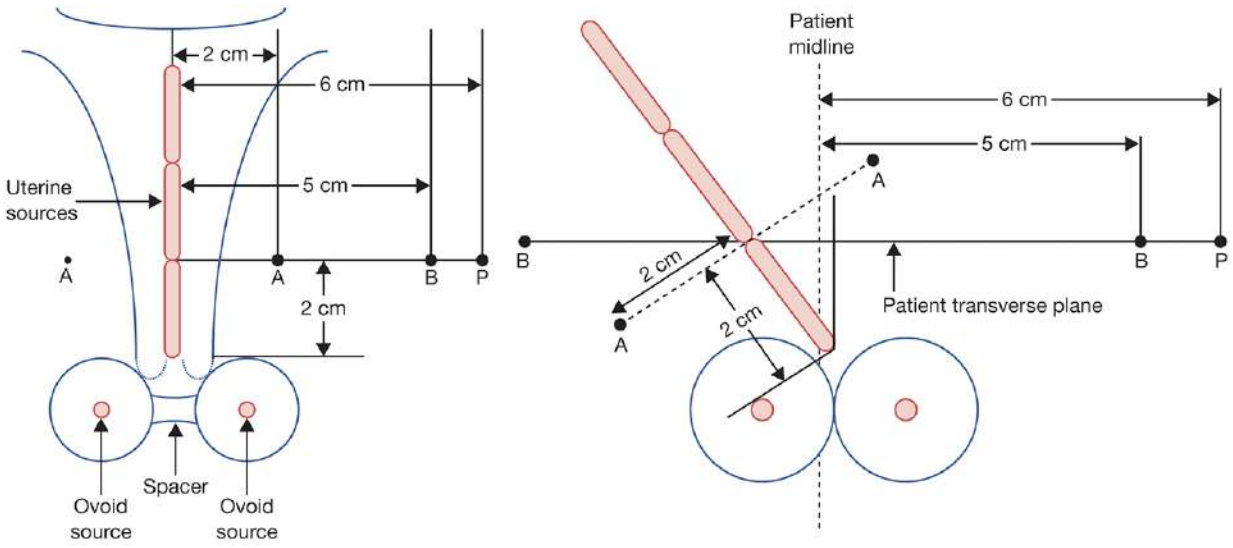

FIGURE 21.24 Definition of points *A* and *B* in an ideal application (left) and a distorted application (right), which is displaced to the left of the patient's midline, and a uterus, which is tilted toward the right. Note that point *A* is carried with the uterus, whereas points *B* and *P* are defined to be 5 and 6 cm, respectively, to the right and left of patient midline. Point *P* is used by the Mallinckrodt Institute of Radiology System to specify minimum dose to the pelvic lymph nodes. (Left: Adapted from Tod M, Meredith WJ. Treatment of cancer of the cervix uteri, a revised Manchester method. *Br J Radiol*. 1953;26(305):252-257. Contribution of image-guided adaptive brachytherapy to pelvic nodes treatment in locally advanced cervical cancer. *Brachytherapy*. 2017;16(2):366-372. Copyright © 2016 American Brachytherapy Society. With permission.)

The Manchester ovoid dimensions and applicator loadings were designed to ensure a constant point A dose rate (about 0.52 Gy/hour) for all allowed combinations. The design also ensured that the vaginal contribution to point *A* was limited to 40% of the total dose. Classic loading patterns included 17.5, 20, and 22.5 mg of radium for the small, medium, and large ovoids (to compensate for increased source-to-point *A* distance with increasing diameter), as well as 10 and 15 mg or 10, 10, and 15 mg sources for the medium (4 cm) and long (6 cm) tandems. These loadings satisfied the dosimetric constraints within 2%. The point *B* dose, determined largely by inverse-square law, is approximately 9 Gy for every 4,000 mg-h administered.

Without external beam treatment to the whole pelvis, a total point A dose of 72.8 Gy in 140 hours split between two applications was prescribed.[242] Regardless of applicator loading, delivery of a fixed point *A* dose amounts to using time, as the factor that terminates the treatment, compared to the Paris and Stockholm systems that prescribed a fixed number of mg-h (equivalent Manchester treatment regimens could deliver from 8,400 to 11,200 mg-h, a 33% variation).

As the size of an intracavitary application (ie, colpostat diameter and tandem length) increases, the penetration of the dose distribution increases. As colpostat diameter increases from 2 to 3 cm, the vaginal surface dose decreases by 35% relative to the dose 2 cm from the applicator surface; this is simply a consequence of increasing the source-to-surface distance. Similarly, increasing the tandem length increases the point *B* contribution relative to the uterine cavity surface dose; the radioactivity near the ends of the long tandem

contributes little to the surface dose (because of inverse-square law), whereas each tandem segment makes roughly equal contributions to points remote from the applicator. These physical principles underlie the practice of using the largest colpostats and longest tandem that the patient's anatomy can accommodate.[11,242]

Modern Fletcher-Suit Applicator Systems

The Fletcher applicator system (Figure 21.25A) adhered to the basic Manchester design while incorporating many improvements, including internal shielding. These shields are located on the medial aspects of the anterior and posterior colpostat faces (Figure 21.25B) and consist of 180° and 150° disk-shaped tungsten sectors 3- to 5-mm thick to shield the rectum and bladder, respectively.[243] The cylindrical colpostat body has a diameter of 2 cm that can be increased to 2.5 and 3 cm by the use of small and large slip-on plastic caps, thereby retaining the Manchester ovoid dimensions. Afterloading capability was added to the Fletcher applicator by Suit and coworkers.[2] The Fletcher loadings—15, 20, and 25 mg for small, medium, and large colpostats, respectively—are similar to those of the Manchester system, whereas tandem loadings are identical to their Manchester counterparts. Because of the similarity of Fletcher loadings to the Manchester loadings, point *A* dose rates are nearly independent of applicator dimensions.

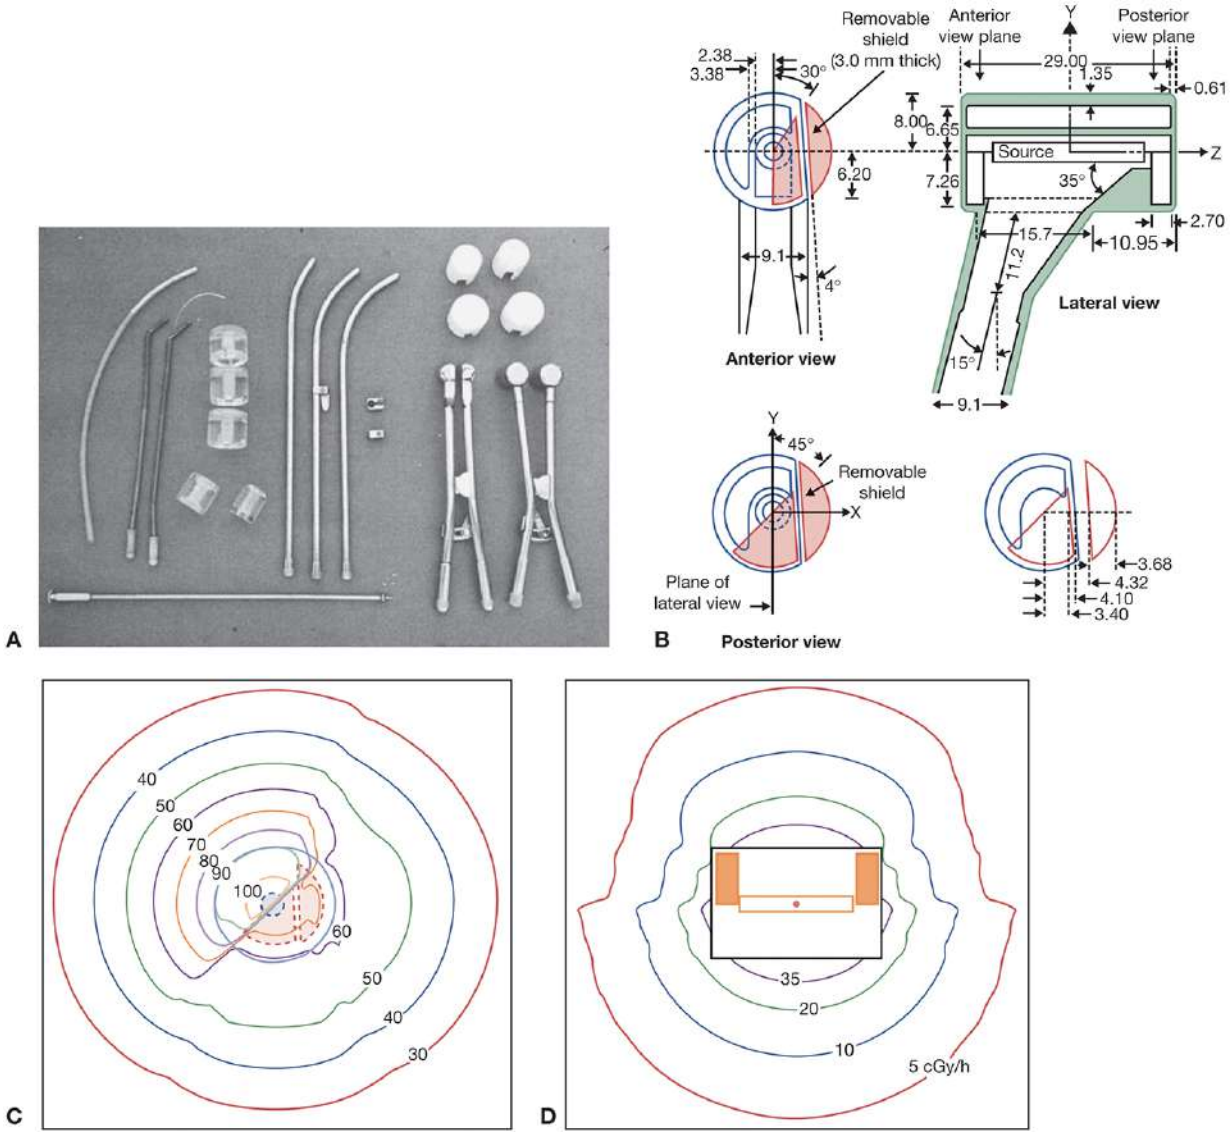

FIGURE 21.25 A. Fletcher-Suit applicator system. From left to right are tandem inserts loaded with dummy sources, colpostat source holders, vaginal cylinder sleeves, three curvatures of intrauterine tandems, cervical collars, Delclos mini-colpostats, and round handled Fletcher-Suit colpostats with small and medium caps. The tube-like instrument in the left foreground is a cervical localization seed implanter. (A. Reprinted with permission from Fletcher GH, Hamberger AD. Squamous cell carcinoma of the uterine cervix: treatment techniques according to size of the cervical lesion and extension. In: Fletcher GH, ed. *Textbook of Radiotherapy*. 3rd ed. Lea & Febiger; 1980;732-772.). B. Three orthogonal views of the 3M Fletcher-Suit Delclos colpostat consisting of a stainless steel body. The removable parts of the tungsten alloy shield, which allow conversion of the applicator to a shielded Delclos mini-colpostat, are inset into a nylon cap (not shown) with an outer diameter of 2 cm. Shown are isodose curves (C) in the coronal plane 10 mm from the posterior face of the applicator and (D) in the transverse plane of the colpostat for a 72 μGy·m^2/hour ^{137}Cs tube. (B-D. Reprinted from Williamson JF. Dose calculations about shielded gynecological colpostats. *Int J Radiat Oncol Biol Phys*. 1990;19[1]:167-178. Copyright © 1990 Elsevier. With permission.)

The shielded Fletcher colpostat was designed to reduce dose to the bladder trigone and the anterior rectal wall without decreasing irradiation to the uterosacral and broad ligaments, thereby reducing the need for the extensive vaginal packing characteristic of

Manchester insertions.[243] For a single colpostat (Figure 21.25B-D), the maximum dose reduction varies from 40% to 50%.[15,244,245] When the effects of the intrauterine tandem and the contralateral colpostat are included, applicator shielding reduces midline rectal and bladder doses by 21% to 34% relative to conventional treatment planning calculations, which ignore shielding and include only the effects of source encapsulation.[171] CT-based dose evaluation studies reveal that colpostat shielding modestly reduces rectal doses, reducing the rectal $D_{2\%}$ by 2% to 11%[246] and D_{2cc} by 10%.[247] Modern versions of the shielded Fletcher colpostat for LDR BT include the LDR 3M Fletcher-Suit Delclos (FSD)[15] and reproductions of the round handled Fletcher-Suit[244] colpostats. For HDR BT, the Fletcher-Williamson[248] applicator duplicates the original Fletcher shielding configuration. Weeks and Montana[249] have designed a CT-compatible version with afterloadable shields and an aluminum body having the same dimensions as the FSD applicator. Vendors of HDR remote afterloading systems and equipment also offer MRI- and CT-compatible variations of the Fletcher applicator.

Dose Specification in Intracavitary Brachytherapy

Point A Dose and Total Reference Air-Kerma

Two quantities are used widely to prescribe intracavitary BT: a product of source strength and treatment time (TRAK or, traditionally, mg-h) and point *A*. The first approach is mainly used in practices influenced by the MD Anderson Cancer Center system,[11,250,251] whereas some form of the Manchester point A dose specification is used by most other practitioners. Efforts to unify these two prescription practices by identifying a linear relationship between the two quantities are misguided[252] from the perspective of the Manchester system. A fixed point *A* dose will result in a range of TRAK due to source strength loading differences between the smallest and largest applicators, whereas a fixed TRAK delivery will result in large variations in treatment time and point *A* dose.

The proportionality of point *A* dose and treatment time applies only to the classic (Manchester) definition of point *A*. Many radiation oncologists use a revised definition of point *A* (Figure 21.26) that references its location to the cervical os (tandem collar, proximal aspect of the most caudal tandem source, or a gold seed implanted in the cervix) rather than to the lateral fornix. This practice obscures the relationship between point *A* and milligram-hour prescription philosophies. Potish and Gerbi's[252] study of 90 Fletcher applications demonstrates that the revised point *A* dose rates vary widely from patient to patient and are, on average, significantly higher than the classic Manchester value. Because point *A* is fixed to the tandem and the vertical tandem-to-colpostat displacement varies with each patient, the vaginal contribution to point *A* is highly variable. In contrast, classically defined point *A* dose rates are tightly grouped, independent of the loading, and in close agreement with the Tod-Meredith value. The vaginal contribution to classic point *A* is fixed by definition, whereas the intrauterine contribution is insensitive to colpostat-to-tandem displacement because of the parallel tandem isodose curves. Thus, the revised point *A* definition does not have the physical significance of the classic quantity. The use of revised point *A* dose to prescribe therapy for "free-floating" tandem and colpostat insertions may introduce large

patient-to-patient fluctuations in treatment times because of small, clinically insignificant variations in implant geometry. Significantly, the recent ICRU Report 89[97] on prescribing and reporting BT for cervical cancer has endorsed the classic point A definition.

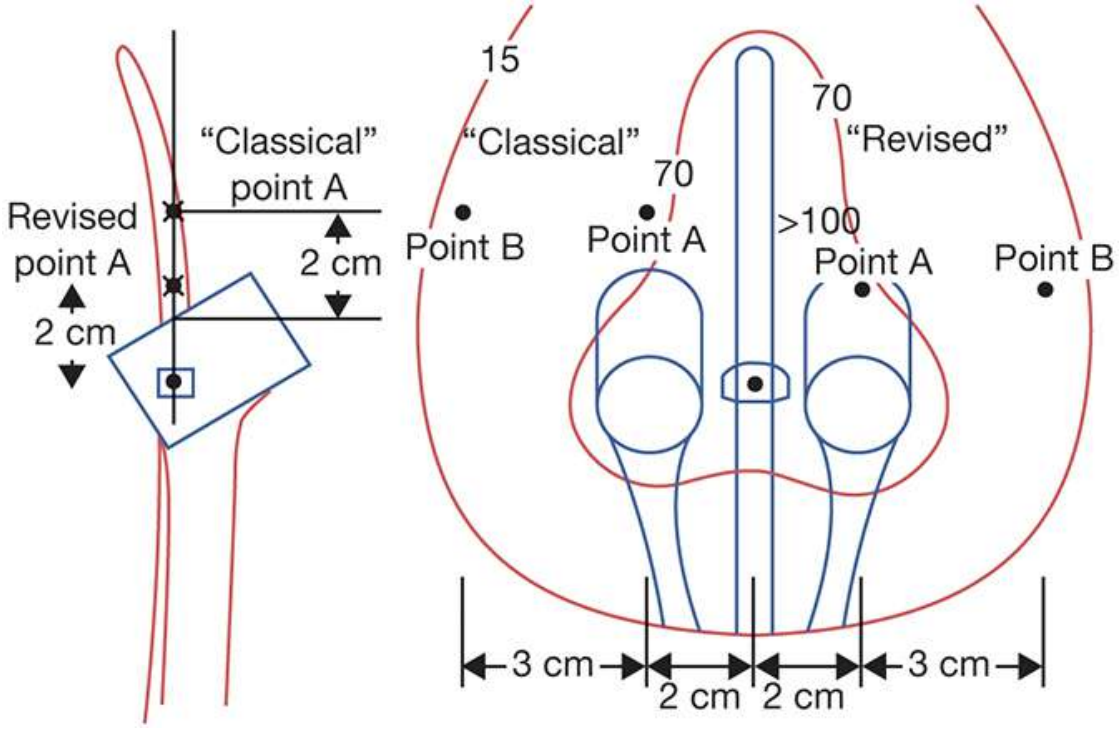

FIGURE 21.26 Radiographic definition of classic point *A* (2 cm above the cephalic-most aspect of the colpostat in the tilted coronal plane) and the revised point *A* (2 cm above the cervical collar top or center). Because the distance from caudal most intrauterine source tip to colpostat center (tandem-to-colpostat displacement) varies from patient to patient, the vaginal contribution to revised point *A* is highly variable. The revised definition was suggested by Tod and Meredith in their 1953 article.[242] (Used with permission of Radiological Society of North America from Potish RA, Gerbi BJ. Role of point A in the era of computerized dosimetry. *Radiology*. 1986;158[3]:827-831; permission conveyed through Copyright Clearance Center.)

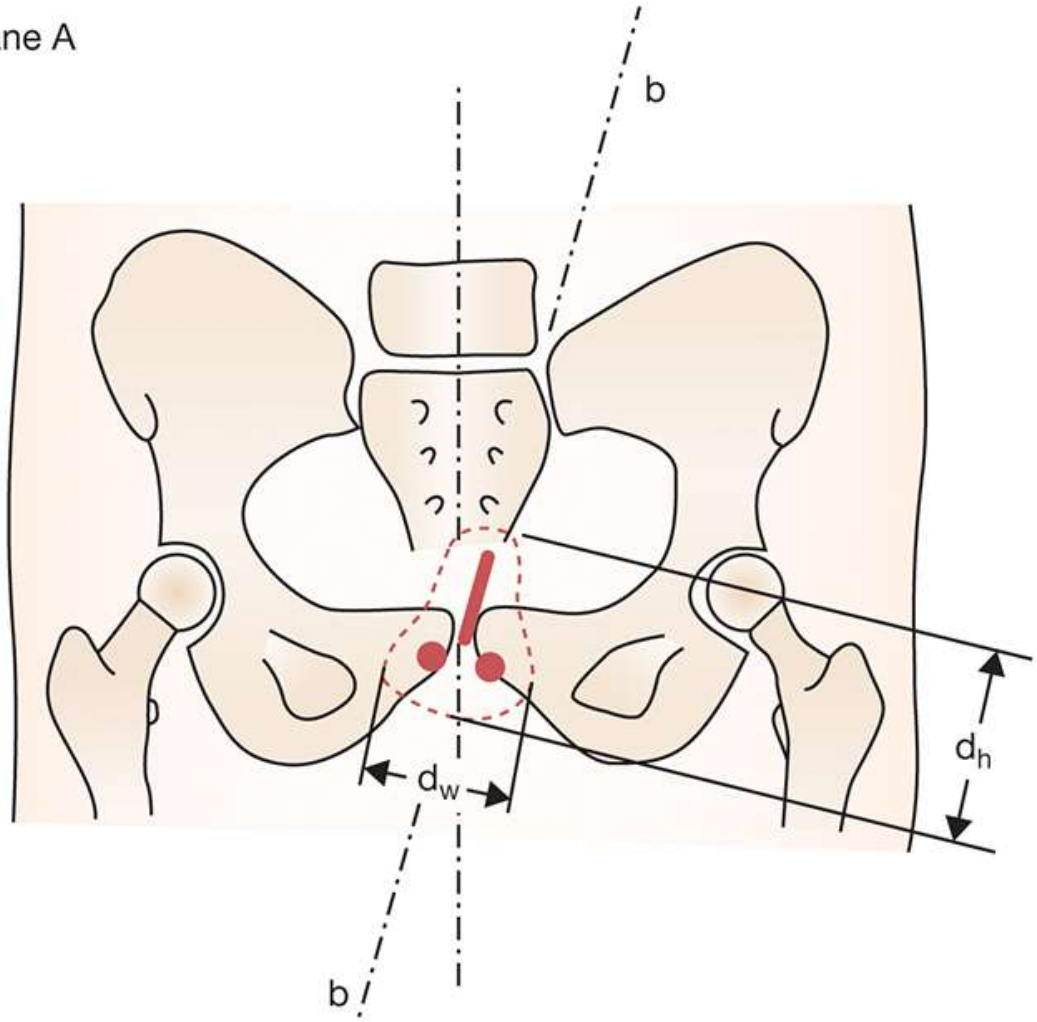
The previous discussion is applicable only to the Fletcher applicator system with relative loadings approximating those of the Manchester system. As the intrauterine to vaginal loading ratio (1:1 for the Manchester system) increases, the maximum width of the pear-shaped reference isodoses falls and the rectal dose increases.[253] Understanding how loading influences isodose shape and normal tissue doses is especially important in HDR BT, as well weight optimization can lead to deviations from the classical loading rules. Using judiciously placed dose points to control the relative dimensions of the point *A* isodose surface, Mai et al[254] were able to increase tapering near the cephalad aspect of the tandem, to reduce the vaginal surface dose, and to modestly reduce the rectal dose with only slight loss of the maximum width of the pear-shaped isodose. These considerations suggest that dose point–driven optimization of the dwell-weight distribution should be accompanied by a geometric analysis of the point *A* isodose surface so that changes to target coverage can be assessed at least approximately.

Other applicators in current use include the HDR tandem and ring applicator[255] and the LDR Henschke applicator.[1] The latter consists of hemispheric colpostats rigidly attached to the tandem with the vaginal source axes parallel to the intrauterine sources rather than transverse as in the Fletcher system. Henschke colpostats with internal shielding[256] are available. The vaginal ring applicator consists of a circular guide tube (usually 34 mm outer diameter) with its plane fixed rigidly normal to the tandem. It is placed up against the cervix and vaginal fornices with a donut-shaped cap attached, which increases the distance between the vaginal mucosa and the circular array of dwell positions (of which only the lateral dwell positions are activated) to 7 mm (compared to 10-15 mm for the Fletcher colpostat). Thus, the fraction of source strength loaded into the ring must be reduced to avoid overdosing the vaginal mucosa.[254,257] Although rectal and vaginal vault doses relative to the point *A* dose similar to that of the Fletcher system can be achieved through careful optimization, the lateral coverage, (ie, maximum coronal width of the point A isodose) is reduced.[254] Care must be taken in positioning the applicator system to avoid underdosing the gross tumor volume (GTV). Applicator geometry and loading practices should be changed only after extensive comparative evaluation of the old and new dose distributions to avoid dose distribution changes that would invalidate the evaluated clinical experience on which the radiation oncologist's knowledge of dose-response rests. Finally, for applicator systems that deviate from the classic Manchester geometry or relative loading rules, one cannot assume that point *A* dose is proportional to treatment time over all allowed variations of applicator sizes and loadings.

Volumetric Specification of Intracavitary Treatment: International Commission on Radiation Units and Measurements Report 38 Recommendations

While the recommendations in ICRU Report 38 have been superseded by ICRU Report 89, an overview of the Report 38 recommendations is included for completeness. The ICRU[3] introduced the concept of reference volume enclosed by the reference isodose surface for reporting and comparing intracavitary treatments performed in different centers, regardless of the applicator system, insertion technique, and method of treatment prescription used. For gynecologic BT, ICRU Report 38 recommended that the reference volume be taken as the 60-Gy isodose surface, including dose from external beam irradiation and intracavitary BT. The ICRU proposed that this pear-shaped reference volume (Figure 21.27) be described in terms of its three orthogonal maximal dimensions: height (d_h), width (d_w), and thickness (d_t), measured in the oblique coronal and sagittal planes containing the intrauterine sources. In addition to the 60-Gy volume, ICRU 38 also recommended reporting the dose to the bladder and rectal reference points, which are illustrated in Figure 21.28.

Plane A



Plane B

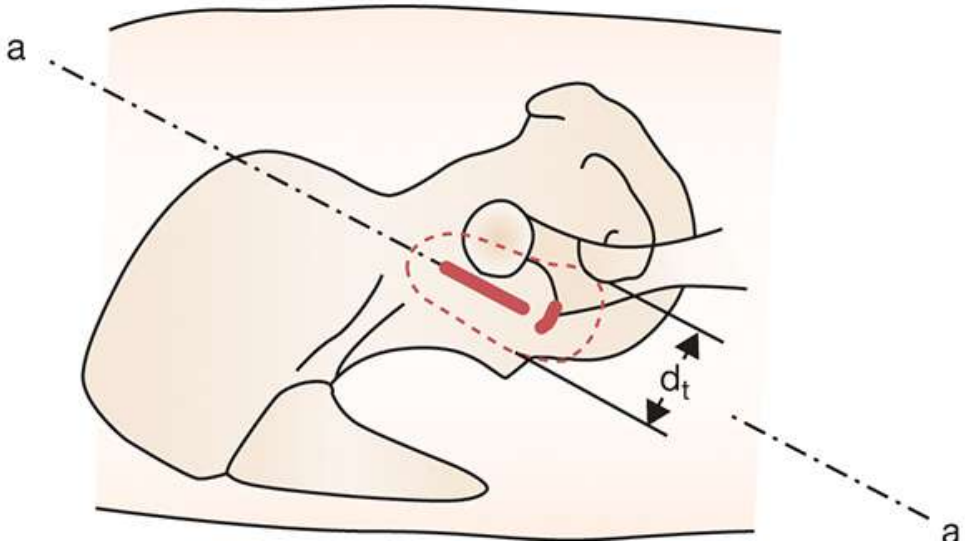


FIGURE 21.27 Geometry for measuring the three orthogonal dimensions of the pear-shaped International Commission on Radiation Units and Measurements reference isodose surface (broken line) in a typical treatment of cervix carcinoma using one rod-shaped uterine applicator and two vaginal applicators. Plane A is the "oblique" frontal plane that contains the intrauterine device. The oblique frontal plane is obtained by rotation of the frontal plane around a transverse axis. Plane B is the "oblique" sagittal plane that contains the intrauterine device. The oblique sagittal plane is obtained by rotation of the sagittal plane around the anteroposterior axis. The height (d_h) and the width (d_w) of the reference volume are measured in plane A as the maximal sizes parallel and perpendicular to the uterine applicator, respectively. The thickness (d_t) of the reference volume is measured in plane B as the maximal size perpendicular to the uterine applicator. In contrast to point *A* dose, the ICRU proposal is only a means of describing or reporting treatment. No guidance is given as to how to prescribe treatment, use these measurements to evaluate implant quality, or correlate reference volume dimensions with clinical outcome. The 60-Gy dose-level choice appears to have been motivated by the preoperative radiotherapy regimen popular at that time within the French school of radiotherapy.[258] The current ICRU Report 89[97] discards the concept of a reference isodose surface for a single

fixed total (external plus intracavitary) dose level, for example, the volume enclosed by the prescription isodose surfaces (typically 85 and 60 Gy) for the high- and intermediate-risk CTVs (CTVHR and CTVIR) (typically 85 and 60 Gy) to the high- and intermediate-risk CTVs (CTV_{HR} and CTV_{IR}). The ICRU 38 and 89 reference volume concepts appropriately emphasize that the volume of tissue irradiated, as well as dose, is an important predictor of clinical response to intracavitary irradiation. Wilkinson and Ramachandran[259] and Eisbruch et al[260] used DVHs to study the correlation between volume enclosed by intracavitary isodose surfaces and other prescription parameters. The latter analyzed the volumetric characteristics of 204 intracavitary insertions in 128 patients with carcinoma of the cervix and demonstrated that intracavitary implants delivering the same TRAK have nearly identical DVHs over the dose range of clinical interest despite significant differences in geometry and loadings. They also showed that the volume, $V(D, T)$, enclosed by isodose surfaces can be estimated accurately from a modified power law model requiring knowledge of only the intracavitary dose in cGy (D) and TRAK (T). The consequences of the findings above can be summarized as follows:

1. Volumetrically, an intracavitary implant behaves like a central point source: $V(D, M) \propto (M/D)^{3/2}$.
2. Describing an implant in terms of volume contained within its isodose curves carries no more information content than a statement of TRAK (historically mgRaEq-h).
3. The volume of tissue irradiated to a specified dose is closely related to total exposure given by the implant in terms of TRAK.

Consequence 2 suggests that the correlation between clinical outcome, in terms of tumor control and complications and isodose surface volume, should be no better or worse than the correlation between clinical outcome and TRAK for a fixed external pelvis dose. Consequence 3 suggests a new and fundamental physical interpretation of TRAK (a derivative of mgRaEq-h). Prescribing intracavitary BT by TRAK is equivalent to treating until each specified isodose surface achieves a fixed volume, independent of the underlying implant geometry. The use of TRAK to constrain intracavitary treatment, therefore, limits the volume of tissue irradiated to high doses. This observation may help explain the clinical utility of TRAK (and historically mgRaEq-h) as a dose specification parameter. Finally, the individual reference isodose dimensions, which are more strongly influenced by implant geometry than their product, clearly convey additional information about the spatial extension of the reference isodose surface in their respective planes and cannot be reduced to a statement of total exposure from the implant and may have additional prognostic significance.

Practical Systems for Intracavitary Prescription and Reporting

For Manchester-like loadings and applicators, if treatment were to be prescribed as a fixed TRAK without regard to the diameter and length of the applicators, the treatment times and total point A doses would differ by the ratio of total source strengths in the applications. Small applications would have unacceptably high point A and vaginal vault surface doses

and excessively long treatment times. Additionally, large applications treated to a fixed TRAK prescription would underdose these reference points. In contrast, the ICRU reference volume for fixed levels of whole-pelvic irradiation and TRAK would be independent of the loading because the TRAK is constant. Conversely, when the point *A* dose is held constant, the TRAK needed to deliver these doses will vary significantly, introducing corresponding variations in the volume of the ICRU reference isodose.

Physically, TRAK controls the volume of tissue treated to high doses, and parameters such as time, colpostat surface dose, and point *A* are used to control doses at points near the applicator to ensure that normal tissue tolerance is not exceeded and that the tumor is not undertreated. For each applicator combination and choice of external beam dose, a compromise between volume of tissue treated and dose delivered near the applicator must be reached. For example, the Fletcher system[11,261] specifies both a maximum treatment time and maximum milligram-hour constraint for each combination of external beam and intracavitary therapy (Table 21.10). Whichever constraint is reached first terminates the application. Small applications tend to be terminated by the maximum time constraint, which limits the milligram-hour and prevents tissues near the applicator from exceeding tolerance doses, whereas larger applications are terminated by the milligram-hour constraint, ensuring adequate dose to the tumor. Although the historical Fletcher system does not use the point *A* dose for either prescription or reporting, the total point *A* dose is constant within 12% for allowed tandem and colpostat loadings within each treatment scheme (A-E) of Table 21.10. The reader should note that the Fletcher system is a complex, highly individualized treatment system that resists formulation in terms of a few rules. Table 21.10 is a highly condensed and simplified summary derived from the literature, not from observation of current MD Anderson Cancer Center practice patterns.

TABLE 21.10 SIMPLIFIED FLETCHER SYSTEM PRESCRIPTIONS

Derived from Potish RA, Gerbi BJ. Cervical cancer: intracavitary dose specification and prescription. *Radiology*. 1987;165(2):555-560.

Manchester-like applicator loadings used for LDR applications yield an approximately constant point *A* dose rate of 65 cGy/hour. For HDR applications, the dwell weights are selected to duplicate the relative Manchester loadings and the TRAK per insertion is reduced to reflect the increased radiobiologic effectiveness of the HDR fractionation schedule relative to the LDR regimen. Classically defined point *A* doses are calculated for reporting purposes, although this quantity plays no role in prescribing therapy. Dose to the pelvic lymph nodes is calculated at point *P*, located 2 cm superior to the lateral fornix and 6 cm lateral to the patient's midline. The 2013 ICRU Report 89[97] continues to recommend the ICRU Report No. 38[3] bladder and rectal reference points for conventional 2D orthogonal film dosimetry.

Summary Principles: Intracavitary Brachytherapy Dose Specification

The most widely used intracavitary BT systems in North America are based on Manchester-type loadings and applicators, in which the point *A* dose rate is approximately constant and independent of loading, leading to a linear relationship between point A dose and time, not TRAK. Practical TRAK systems use various dose specification parameters to constrain and guide treatment and are far more Manchester like than the "strict" milligram-hour philosophy would suggest. These parameters have the following roles: (a) TRAK limits the volume of tissue treated to a high dose; (b) point *A* dose ensures that tumor periphery receives adequate dose; (c) vaginal surface dose ensures that dose to mucosal surfaces in contact with the applicator system remains within tolerance; and (d) treatment time ensures indirect control of point *A* dose.

Although the traditional treatment specification quantities have clear physical meanings and interrelationships, these concepts can be applied to patient treatment only within a clinical system supported by a base of evaluated clinical experience. In current practice, implant placement is guided by direct visualization and palpation, and treatment prescription is guided by the radiation oncologist's knowledge of treatment outcome averaged over groups of uniformly treated patients with similar tumor size and location and medical condition. This implies that the implant system must be applied as a whole: Mixing

dose specification methods, insertion techniques, and normal tissue dose-response relationships from different clinical systems are dangerous practices that can lead to suboptimal or indeterminate clinical outcomes. Second, because classic dose specification quantities incompletely describe the dose distribution, a radiation oncologist must be trained in all details of an intracavitary system to duplicate the results of its developers. Finally, for the clinical physicist, consistency of current dosimetric practice with past clinical experience may be more important than absolute dose computation accuracy or compliance with a practice standard external to the treatment system.

Image-Guided Intracavitary Brachytherapy

Classic intracavitary BT, with its empirically based rules, prescription practices, and feedback derived from patient follow-up to shape and position intracavitary dose distributions, demonstrates that even massive cervical cancers are potentially curable with concomitant chemoradiation therapy. In an effort to improve clinical outcomes in locally advanced cervical cancer and to reduce the significant incidence of local failure and late normal tissue toxicity, anatomy-based dose specification using 3D x-ray CT or MRI studies acquired with the applicator system in place has been intensively investigated. Early studies[262-264] consistently demonstrated that conventional orthogonal film-based reference points (2D planning) overestimate minimum doses to the cervix and underestimate maximum doses to critical structures by factors of 1.5 to 2.3 with large patient-to-patient variations. Because MRI has been shown to be far superior to CT for distinguishing tumor from normal cervical stroma[265] and for delineating surrounding critical structures, advisory groups[49,266] recommend using T2-weighted MRI studies acquired prior to initiating treatment and after each intracavitary insertion for BT planning and dose reconstruction. This has culminated in the publication of a revised ICRU Report 89[97] that provides detailed guidance for planning, prescribing, and reporting intracavitary BT in the MRI-guided era. An important innovation is a widely accepted target volume nomenclature (high-risk, intermediate-risk, and low-risk CTVs, denoted by CTV_{HR}, CTV_{IR}, and CTV_{LR}, respectively) and specific DVH parameters[267] for assessing the correlation between clinical outcome and the delivered dose distribution. The CTV_{HR} includes the entire cervix along with all palpable or presumed residual gross tumor volume (GTV_{res}) at the time of each intracavitary insertion. ICRU Report 89 recommends a dynamic adaptive treatment philosophy: The goal of each insertion is to deliver the prescribed D_{90} dose (roughly comparable to point *A* dose) to the "residual" CTV_{HR} for a total (external beam and BT) $D_{2Gy,90}$ dose (in 2-Gy fraction equivalents) of 85 to 90 Gy. The CTV_{IR} consists of the initial CTV_{HR} (based on the pretreatment GTV_{init} plus a margin for microscopic disease (typically 5 mm anterior-posteriorly and 10 mm elsewhere)). It typically receives a total D_{90} dose (D_{2Gy}) of 65 to 70 Gy for locally advanced disease. In addition to recommending tracking the classic dose specification quantities (TRAK and point *A*, bladder, and rectal reference doses), ICRU Report 89[97] recommends tracking D_{90} and D_{98} for CTV_{HR} and CTV_{IR} coverage and

$D_{2\text{cm}^3}$ and $D_{0.1\text{cm}^3}$ for assessing bladder and rectal doses. The report also provides a simplified linear-quadratic (LQ) model for converting LDR, HDR, and external beam doses into equivalent 2-Gy fractionated doses.

In addition to the ICRU, the Groupe Européen de Curithérapie European Society for Radiation Oncology (GEC-ESTRO) also offers consensus guidelines, drafted along with other national BT societies such as the ABS, the Indian Brachytherapy Society, and the Canadian Brachytherapy Group, pertaining to CT-based contouring for image-guided adaptive BT, target definition, and quality indicators for cervical cancers.[268-270]

Early reports of image-based conformal therapy in locally advanced cervical cancer are promising. For example, the use of intensity-modulated radiation therapy (IMRT) to replace traditional whole- and split-pelvis fields[271,272] suggests that grade III/IV late toxicity is significantly reduced relative to historical controls without increasing local recurrence. The most extensively reported experience with MRI-based intracavitary BT planning (156 patients at Medical University of Vienna) achieved excellent 3-year local control rates of 86% to 100% (International Federation of Gynecology and Obstetrics [FIGO] Ib-IIIb) with 3-year grade II/IV late toxicities of 4% or less[273] and demonstrated a robust dose-response relationship between CTV_{HR}, D_{90} and D_{100} for large tumors[274] and a good correlation between bladder and rectal DVH parameters, for example, $D_{2\text{cm}^3}$, and major late complications.[275]

The group at Aarhus University Hospital, in Aarhus, Denmark, reported on the use of MRI-guided adaptive radiotherapy for the treatment of cervical cancer in 2013.[276] For a cohort of 140 patients, they used MRI-guided adaptive radiotherapy, which included IMRT or volumetric modulated arc therapy (VMAT) treatment to 40 to 60 Gy (with 60 Gy used for simultaneous integrated boost to nodes), concurrent chemotherapy for 79% of patients, BT using a PDR source, and a tandem and ring applicator with a needle cap and plastic needles in cases needing hybrid intracavitary/interstitial treatment. They compared these results with previous results of a CT-based 3D conformal EBRT technique with BT boost planned using x-ray imaging. They found 3-year local control rates of 91%, compared to 63% in the previous study and a reduction in moderate and severe late morbidity of approximately 50%,[276] highlighting the improvements that can be obtained with image-guided adaptive BT.

The EMBRACE collaboration reported the results of their multicenter prospective study regarding MRI guidance in cervical cancer in 2021.[277] The aim of the EMBRACE-I trial was to evaluate the rates of morbidity and local control using MRI-based adaptive BT. The study included 24 centers from across Europe, Asia, and North America and included patients with biopsy-proven cancer of the uterine cervix, with FIGO stage IB to IVA disease and FIGO stage IVB disease restricted to node metastasis below the L1-L2 interspace. Treatment included chemoradiotherapy (cisplatin plus 3D conformal, IMRT, or VMAT EBRT), followed by MRI-based image-guided adaptive BT. They found that, at a median follow-up of 51 months, morbidity for genitourinary, gastrointestinal, vaginal, and fistulae events were all below 8.5%, and overall 5-year control was 92%,[277] illustrating the

effectiveness and long-term control offered by MRI-guided adaptive BT combined with chemoradiotherapy.

Challenges to image-guided intracavitary therapy include substantial soft tissue displacement and deformation due to applicator insertion and removal, tumor regression, and bladder and rectal filling variations (all ignored by clinical experiences cited above), making it difficult to meaningfully evaluate cumulative dose distributions. An important area of research is application of deformable image registration to account explicitly for the temporal sequence of deforming 3D anatomies needed to accurately characterize a multiple insertion course of intracavitary and external beam therapy.[278] Using dose summation over weekly MRI sets that had been contoured and nonrigidly registered, Lim et al[279] demonstrated that 5-mm PTV expansion of CTV_{IR} for the IMRT component of treatment was adequate for most patients, although large variations between planned and cumulative normal tissue doses was observed for some patients. As IMRT is used to create more conformal external beam dose distributions and to address peripheral CTV_{HR} underdoses by the intracavitary treatment components, the need to accurately account for local tissue deformation will become more acute.[280]

THE RADIOBIOLOGY OF BRACHYTHERAPY

The highly conformal dose distribution characteristic of BT sources significantly reduces the exposed volume, and often, the maximum dose in adjacent normal tissues, compared to EBRT.[12,281] Such dose sparing helps reduce both early- and late-responding normal tissue sequelae, making the short treatment times commonly used in temporary implant BT tolerable. This is in contrast to conventional EBRT where the risk of early-responding tissue sequelae requires treatment times to be prolonged for up to about 8 weeks, potentially reducing tumor control through tumor cell repopulation. Modern image-guided EBRT, such as stereotactic radiosurgery and stereotactic body radiotherapy, also takes advantage of the geometric dose sparing of adjacent normal tissues (via reduced PTV margin) to enable shortened overall treatment time (via hypofractionation). The short overall treatment times used in temporary implants confer both clinical and socioeconomic benefits for those tumor sites (eg, cervix, head and neck, and lung) where long overall treatment time is associated with reduced local control.

In addition to the dose-sparing advantages, the development of high-strength remote-afterloading stepping sources and low-energy permanently implantable sources has also resulted in clinical utilization of dose rates and dose-time- fractionation patterns that can differ radically from conventional LDR BT and EBRT. The interaction of such diverse temporal dose delivery patterns with the underlying cellular processes of the irradiated tumor and normal tissues could lead to different treatment responses for the same prescribed total dose.[282] A clear understanding of the radiobiologic implications of the spatial-temporal dose delivery patterns used in BT and combined EBRT and BT has become an essential clinical need.

Biophysical Modeling of Brachytherapy

The interactions of tissue biologic factors with BT dose delivery are complex and can be influenced by not only the total dose but also the dose rate, dose fractionation pattern, and photon energy emitted by the BT sources. Mathematical modeling of the radiobiologic interactions between relevant factors of the radiation field and the irradiated tissue has offered useful tools for elucidating the basic radiobiologic features of different BT techniques, comparing relative effects of different spatial-temporal dose delivery patterns, and designing iso-effective dose delivery schemes.

Most biophysical models use radiation-induced cell kill (or cell survival) as a surrogate for radiotherapeutic responses. Although not the sole determinant of biologic response, there is now a wealth of evidence that cell killing, that is, loss of reproductive integrity, is the dominant determinant of radiotherapeutic response, both for early- and late-responding endpoints.[283] Of the available cell survival models, the LQ model, which is based on mechanistic notions about how cells are killed by radiation and unequivocally distinguishes between early and late responses, is used most often in radiation oncology. After several decades of investigation and use, the basic ideas and parameters in the LQ model have been well supported by clinical experience and outcome data. The application of the LQ formalism to radiation therapy has been reviewed by Thames and Hendry,[283] Dale,[284] Fowler,[285] and many others.

The Linear-Quadratic Model

Central to the LQ approach is a biologic model of radiation action, which was spelled out in detail more than 70 years ago by Lea and Catcheside,[286,287] based on a mechanistic analysis of radiation-induced chromosomal aberration induction. In the most basic LQ approach, cellular survival, S, from dose D given in a single acute exposure or fraction, is written as

$$S(D) = \exp(-\alpha D - \beta D^2) \tag{21.34}$$

The mechanistic interpretation of Eq. 21.34 is that cell killing results from the interaction of two elementary damaged species, most often DNA double-strand breaks (DSBs), to produce species that cause cell lethality, such as dicentric chromosomal aberrations. The first term in Eq. 21.34, which is linear in dose, describes production of two DSBs by the same ionizing radiation quantum (usually a charged particle), while the second term, quadratic in dose, describes production of multiple DSBs by two independent quanta. Equation 21.34 for acute irradiation captures the intrinsic radiosensitivity of the irradiated cells but lacks explicit accounting of the cellular repair, repopulation, redistribution, and reoxygenation—the four "Rs" of radiobiology—that often dominate the radiobiologic responses.[288] Equation 21.34 can be extended to include these four "Rs," as described below, which is necessary for modeling the effects of different temporal dose delivery patterns used in BT.

Cellular Damage Repair

If the radiation is delivered over a protracted period rather than delivered acutely, two DSBs may be formed at different times. Therefore, it is possible that the first may be repaired before it has a chance to interact with the second. This will not affect the first term in Eq. 21.34, because the two DSBs are formed simultaneously from a single-particle track, but DSB repair during a prolonged exposure will result in a reduction of the second, quadratic term in Eq. 21.34, by a factor denoted by "G"[286,287]:

$$S(D) = \exp(-\alpha D - G \cdot \beta D^2) \qquad (21.35)$$

where, for acute exposures, $G \rightarrow 1$, and for very long exposures, $G \rightarrow 0$. In this context, "acute" and "long" are defined relative to the half-time (T_r) for DSB repair of sublethal damage. In general, G will depend on the detailed temporal distribution of dose delivery as well as on T_r. For many BT temporal dose delivery patterns, G can be expressed analytically in closed forms.[282] For example, LDR implants with dose delivered at a constant dose rate over an extended period T, $G = 2[\exp(-mT) + mT - 1]/(mT)^2$, where m ($=0.693/T_r$) is the sublethal damage repair rate. Formulae for G for many other schemes, such as fractionated, PDR, and permanent BT dose delivery, have been derived,[287,289] as has a general formalism for any possible protraction scheme.[290]

The LQ formalism, described by Eqs. 21.34 and 21.35, can be derived from a variety of underlying mechanistic models via first-order time-dependent perturbation theory when the dose or dose rate is not too high, a constraint that includes most clinically and experimentally relevant doses and dose rates.[291] For example, the theory of dual radiation action[292] is only one of several different approaches to describing radiobiology damage mechanistically. The approach devised by Lea and his coworkers[286,287] deals instead with the kinetics of damage development. Typical kinetic models track the temporal evolution of lesions as a cell gradually repairs or misrepairs the initial damage.[293-295] Many different molecular mechanisms have been studied kinetically, such as pairwise misrepair of DNA DSBs, direct one-hit induction of lethal lesions, and saturable repair pathways in which the repair enzyme system can be overloaded.

Cell Repopulation

For temporary implants or HDR, the effect of tumor cell repopulation is generally small over the treatment course, but this is not necessarily the case with longer permanent implants. Equation 21.35 can be simply modified to take into account repopulation, hence the effects of overall time. Following the original formulation by Travis and Tucker,[296] repopulation is taken into account by increasing the surviving fraction by a factor $\exp(gT)$, where T is the overall treatment time. One can also take into account delay in the onset of accelerated repopulation, by replacing T with $(T - T_D)$, where T_D is the delay after the

beginning of the treatment before tumor cell proliferation begins.[285] Then the surviving fraction is given by

$$S = \exp\left[-\alpha D - G \cdot \beta D^2 + \gamma\left(T - T_D\right)\right] \qquad (21.36)$$

The parameter g determines the rate of repopulation and is given by $\gamma = 0.693/T_P$, where T_P is the effective doubling time of cells in the tumor. When cell loss is negligible, T_P is the same as T_{POT}, which is the measurable[297] in vitro doubling time of the tumor cells.

Redistribution and Reoxygenation

The LQ model can be further extended to include redistribution of cell cycle progression and reoxygenation during irradiation by treating these two "Rs" as aspects of a single phenomenon, termed *resensitization*,[298] which occurs when a radiation exposure preferentially kills the more radiosensitive cells in a diverse population, leaving a cell population with decreased average radiosensitivity. Subsequent biologically driven changes tend to gradually restore the original population average radiosensitivity. The resultant linear-quadratic resensitization (LQR) model uses two additional adjustable parameters—an overall resensitization rate τ_S (analogous to sublethal damage repair rate) and overall resensitization amplitude $\frac{1}{2}\sigma^2$. The LQR model replaces the LQ Eq. 21.35 with:

$$S(D) = \exp(-\alpha D - G\beta D^2 + \tfrac{1}{2}\sigma^2 \hat{G}^2 D^2) \qquad (21.37)$$

The new term, $\frac{1}{2}\sigma^2\hat{G}D^2$, is the product of $\frac{1}{2}\sigma^2$ (representing the average of the dominant resensitization effects over the heterogeneous tumor), while the factor $\hat{G}$ models the influence of fractionation on resensitization. $\hat{G}$ is assumed to have exactly the same form as the sublethal damage repair function, G, except that μ is replaced by τ_S. In contrast to repair, resensitization tends to increase radiosensitivity as the overall time increases. For example, tumor cells in a resistant part of the cell cycle at the beginning of the treatment, and thus were spared preferentially, may move to a more sensitive part of the cell cycle as the treatment progresses. While mechanistically driven, LQR is sufficiently simple that it can be used for isoeffect calculations in radiation therapy and supporting reasonable fits to relevant experimental data.[298]

General Utility of the Linear Quadratic Model

The LQ model (Eqs. 21.34-21.37) can be used to elucidate the general radiobiologic properties of major BT delivery techniques by using G and $\hat{G}$ factors appropriate for their respective temporal dose delivery patterns.[282] We discuss some of the key radiobiologic

features of BT delineated by the LQ model in Section 6.3 (see section "Radiobiologic Features of Brachytherapy").

The LQ model can also be used as a convenient tool to compare the relative effectiveness of different BT dose delivery techniques or to design "equivalent" dose protraction protocols (ie, design a regimen with the same tumor response, or the same late complications, as a "tried-and-tested" regimen). To design a new dose protraction protocol (labeled "2"), which will have the same effect as a current protocol (labeled "1"), based on Eq. 21.35, we need to ensure the quantity ($aD + GbD^2$) is equal for the two protocols, that is,

$$D_1\left[1 + G_1 D_1 / (\alpha / \beta)\right] = D_2\left[1 + G_2 D_2 / (\alpha / \beta)\right] \qquad (21.38)$$

The quantity on either side of Eq. 21.38 is often called the biologically effective dose (BED),[285] that is,

$$\mathrm{BED} = D[1 + \mathrm{GD}/(\alpha/\beta)] \qquad (21.39)$$

Comparing the relative effectiveness of different BT protocols amounts to comparing their BED values, and generating a new "equivalent" regime amounts to matching BEDs for the old and new regimes.

When the new dose protraction protocol (the right-hand side of Eq. 21.38) is chosen as conventional EBRT delivered in 2-Gy per fraction, Eq. 21.38 can be used to determine the equivalent total dose, EQD2, which, when delivered in 2 Gy per fraction, will result in the same BED (ie, cell kill) of the current BT protocol, that is,

$$\mathrm{EQD2} = \mathrm{BED}/[1 + 2/(\alpha/\beta)] \qquad (21.40)$$

EQD2 is a more intuitive LQ-based biophysical index to use clinically as it is easily relatable to the clinical experiences of conventional EBRT given in 2-Gy fractions.

If tumor repopulation, reoxygenation, or redistribution are relevant, then, in order to design a new equivalent regimen, rather than comparing/match the quantity ($\alpha\, D + G \cdot \beta\, D^2$), we need to compare/match the quantity ($\alpha\, D + G \cdot \beta\, D^2 - \gamma\, [T - T_D]$) or

$\left(\alpha D + G \cdot \beta D^2 - \frac{1}{2}\sigma^2 \hat{G} D^2 - \gamma\left[T - T_D\right]\right)$. Equations 21.39 and 21.40 can be modified accordingly to take into account these cellular processes.

In addition, LQ model can be used as input to high-level models, such as tumor-control probabilities (TCPs) or normal tissue complication probabilities (NTCPs). To do so, we need additional models relating cellular survival (S) with TCP or NTCP. The simplest approach, originating with Munro and Gilbert,[299] equates TCP with the probability that after radiation treatment there are no remaining tumor stem cells capable of initiating tumor regrowth. Let us suppose that a dose, D, delivered in a given protraction pattern, produces a stem cell survival probability, S. Then, the probability that any given stem cell will be unable to initiate tumor regrowth is $(1 - S)$. Let K be the initial number of potential stem cells in the tumor. The TCP for the irradiated tumor is thus simply $(1 - S)^K$, which, for small values of S, can be approximated as

$$\mathrm{TCP} = \exp\left(-S \cdot K\right) \tag{21.41}$$

If cell survival, S, is described by Eq. 21.35, then

$$\begin{aligned}\mathrm{TCP}(D) &= \exp\left[-K \cdot \exp\left(-\alpha D - G \cdot \beta D^2\right)\right] \\ &= \exp\left[-\exp\left(\ln K - \alpha D - G \cdot \beta D^2\right)\right]\end{aligned} \tag{21.42}$$

Equation 21.42 may also be used to calculate NTCPs, except that now the parameter K does not refer to the number of tumor cells that need to be sterilized, but rather to the number of groups of cells in the normal tissue ("tissue-rescuing units"),[300] whose destruction would result in the late complication.

A problem with Eq. 21.42, or similar approaches to estimate clinical outcomes de novo, is that absolute values of TCP or NTCP are exquisitely sensitive to the parameter values, particularly the K parameter. In contrast, using the LQ model to compare competing protraction regimens or design equivalent dose protraction protocols (Eq. 21.38 and its extensions described above) makes no assumptions about the relationship between surviving fraction and clinical outcome and, therefore, is much less sensitive to the LQ parameter values.[301] The latter is a more robust application of the LQ model.

To improve the clinical utility of TCP or NTCP models, extensive efforts have been made to fit these models to clinical data, yielding tumor-/tissue-specific model parameters, for example, for head and neck tumors,[302,303] breast tumors,[304,305] prostate cancer,[306,307] brain

tumors,[308] rectal cancer,[309] and liver cancer.[310] In addition, empirical NTCP models such as Lyman-Kutcher-Burman (LKB) models were often used to model normal tissue complications.

Radiobiologic Features of Brachytherapy

Rationale for Low-Dose Rate Brachytherapy

It has long been known that lowering the dose rate generally reduces biologic damage[311] because of increased opportunity to repair the sublethal damages.[286,287] It also has been clear since the pioneering work of Coutard[312] that fractionating or protracting a radiotherapeutic exposure improves the "therapeutic ratio" (ratio of tumor control to complications). However, the exact link between these observations was not clearly made until the 1980s by Withers and colleagues.[313,314]

To understand their insight, consider the observed isoeffect curves shown in Figure 21.29 representing "equivalent" schemes for either early- or late-responding endpoints as a function of dose per fraction, a surrogate for dose rate. The generally steeper slopes of the solid line indicate that the late-responding tissues are more sensitive than early-responding tissues to changes in the protraction of a given radiation dose. For higher dose rates, the dose reduction needed to match late effects is larger than the dose reduction needed to match early effects, such as tumor control for typical tumors. For any selected dose, increasing the dose rate will increase late effects much more than it will increase tumor control. Conversely, decreasing the dose rate will decrease late effects much more than it will decrease tumor control. Thus, the therapeutic ratio increases as the dose rate decreases.

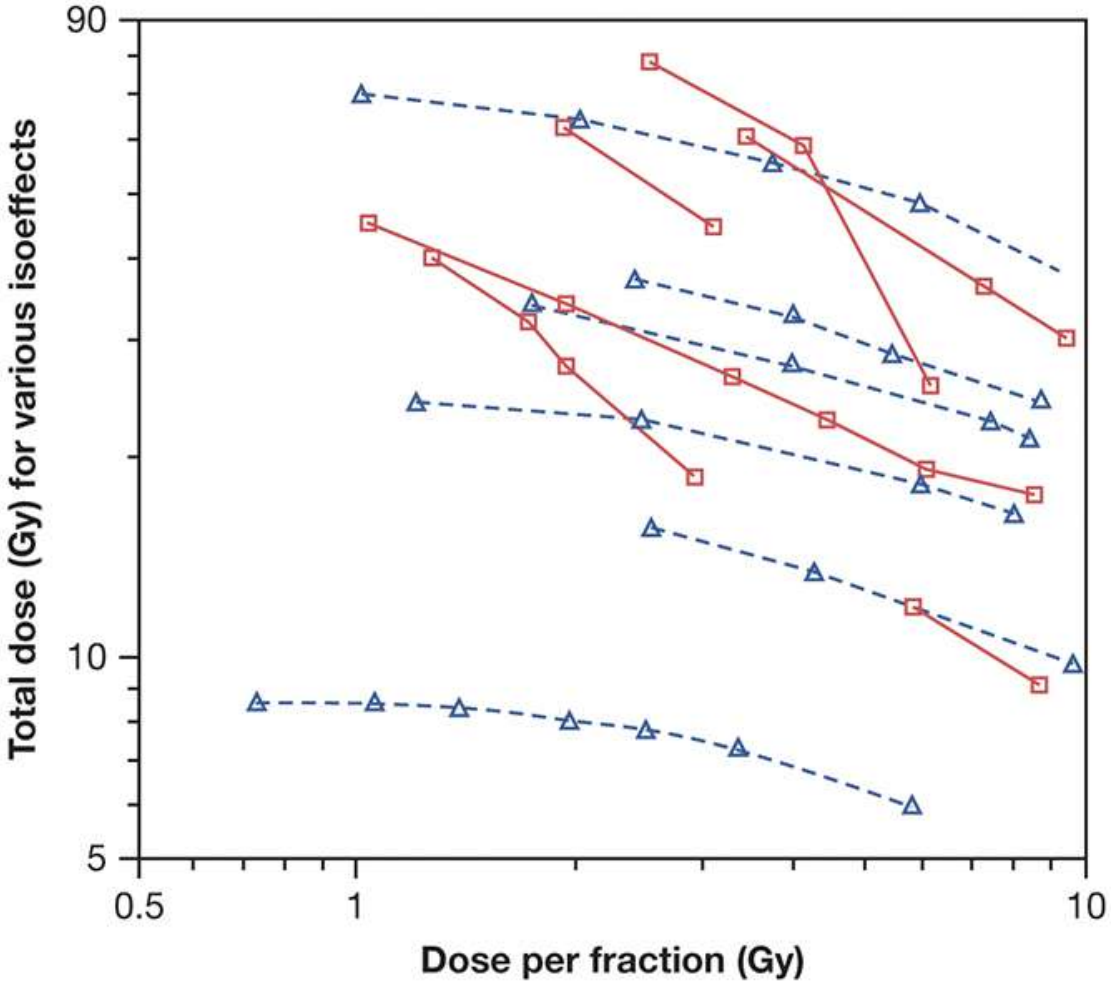

FIGURE 21.29 Isoeffect curves showing the total dose to produce a given end point, plotted against dose per fraction, a surrogate, in this context, for dose rate. The triangles, joined by dashed lines, refer to a variety of early-responding end points (of which tumor control is an example), whereas the squares, joined by solid lines, refer to a variety of late-responding sequelae. Note the generally steeper slopes of the solid lines, suggesting that late-responding tissues are more sensitive than early-responding tissues to changes in the protraction of a given radiation dose. (Adapted from Withers HR, Taylor JM, Maciejewski B. The hazard of accelerated tumor clonogen repopulation during radiotherapy. *Acta Oncol*. 1988;27[2]:131-146.[396])

These observations can be interpreted in terms of the α/β ratio[313] in the LQ Eq. 21.38. In terms of survival curves (Figure 21.30), the α/β ratio essentially describes the degree of "curviness" of the acute survival curve. A small value of α/β means that the β (dose squared) term dominates cell killing at radiotherapeutic doses, resulting in a curvy survival curve (Figure 21.30). A large value of α/β means that the linear in-dose α term dominates, resulting in a straighter semi-log survival curve. Now, as a first approximation, the dose-response relation for a fractionated (or LDR) regimen can be thought of as simply the result of multiple repeats of the initial part of the survival curve. It is clear that repeating the early part of a curvy survival curve many times will result in far more sparing than repeating the early part of a straighter survival curve.

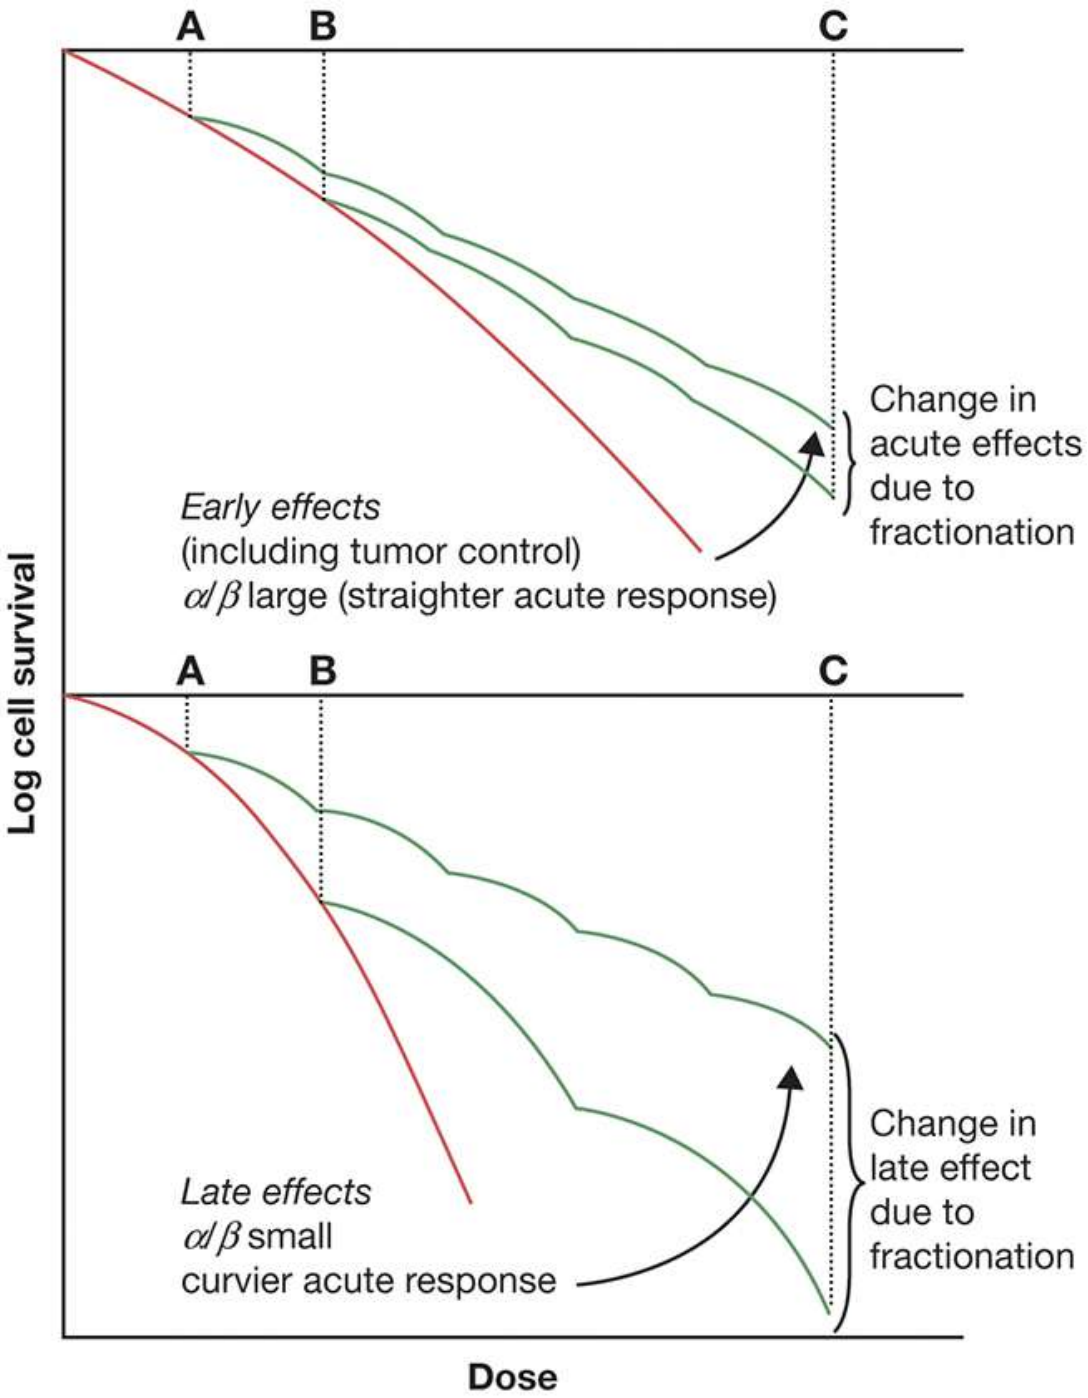

FIGURE 21.30 Illustration of the differing effects of protraction on early- and late-responding tissues, as elucidated by Thames and colleagues.[313] (Reprinted from Thames HD Jr, Withers HR, Peters LJ, Fletcher GH. Changes in early and late radiation responses with altered dose fractionation: implications for dose-survival relationships. *Int J Radiat Oncol Biol Phys*. 1982;8(2):219-226. Copyright © 1982 Elsevier. With permission.)

Thus, late effects, which are very sensitive to changes in fractionation, are characterized by small values of α/β (a typical value is 3 Gy), and early effects (tumor control or early-responding normal tissue sequelae) are characterized by large values of α/β, a typical value

for most tumors being about 10 Gy. As clinical data from which α/β ratios can be derived have accumulated, the dichotomy between α/β ratios for early and late effects has held up remarkably well. Consequently, when using the LQ model, it is essential to be clear about whether the calculation is designed to refer to early- or late-responding tissue and to then use the appropriate a/b value. From Eq. 21.38, it is clear that the use of different values of α/β will result in different predictions for the isoeffect dose.

High Dose Rate Intracavitary Brachytherapy for Cervical Cancer

There has been a trend moving toward increased use of fractionated HDR BT in many tumor sites, driven initially by the economic and logistical benefits of outpatient-based fractionated HDR BT. While in some situations, such as palliative or intraoperative BT, the therapeutic ratio between tumor control and late sequelae is not a primary consideration, in general for curative intent treatments, increasing the dose rate is likely to *decrease* the therapeutic advantage between tumor control and late sequelae as discussed in the previous section, unless significantly more fractions are used in the HDR regimens. However, there are two curative applications (intracavitary BT for cancer of the uterine cervix and interstitial BT for prostate cancer) where, for differing reasons, HDR BT is as effective, or potentially even more effective, compared to LDR BT.

The radiobiologic principles involved in converting LDR to HDR intracavitary BT are illustrated schematically in Figure 21.31, which shows typical dose-response relationships for early- and late-responding tissues. Suppose that we want to replace an LDR treatment delivering dose D by an HDR treatment that gives identical tumor control. As illustrated in the left panel of Figure 21.31, we need to reduce the dose by a dose reduction factor DRF. As discussed in the previous section, the dose-response relations for late effects are significantly "curvier" (smaller α/β ratio) than for early-responding tissues such as tumors that typically have larger α/β ratios. It can be seen, from the right panel of Figure 21.31, that this adjusted dose, DRF × D, will result in increased late effects compared to LDR. However, the LDR dose to OAR giving rise to the late effects is not the treatment dose D, but often at some lower dose value, $f \times D$, where $0 < f \leq 1$. This is the case for cervical BT because the bladder and rectum are generally some significant distance from the cervical implant. For example, if $f = ½$, that is, the OAR dose is half the treatment dose ($D/2$), we see, from the right-hand panel in Figure 21.31, that if HDR preserves the LDR level of dose sparing, that is, delivers dose DRF × D/2 to the OAR, where DRF matches tumor control, the late effects for HDR could be comparable to LDR because we are further up the survival curve for HDR late effects. Indeed, if the rectal dose were an even smaller fraction of the treatment dose (say $D/3$, in Figure 21.31), HDR would have even *less* late effects than the equivalent LDR regimen. In fact, if the cervical BT results in a dose to the bladder/rectum that is less than about ¾ of the treatment dose, the HDR late effects should not be worse than the LDR late effects when the HDR dose is reduced to give equal tumor control compared with LDR.[290,315]

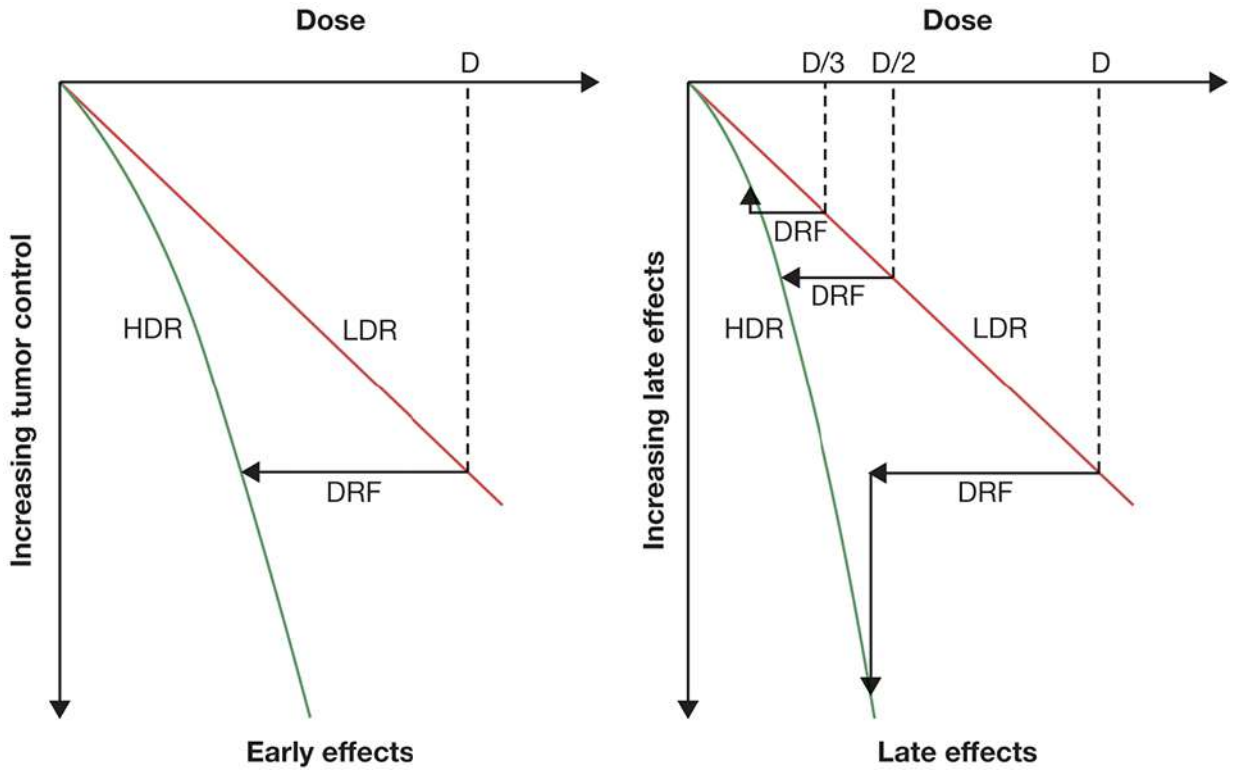

FIGURE 21.31 Illustration of the interplay between early and late effects for low-dose rate (LDR) and high-dose rate (HDR) brachytherapy for cervical cancer. DRF is the dose reduction factor that produces the same early effects (tumor control) for HDR as LDR. If *D* is the LDR giving rise to late effects, then reducing *D* by DRF for HDR will result in more late effects than at LDR. As the HDR dose to late-responding tissue is reduced by treatment planning, then reducing that dose by the factor DRF no longer produces worse late effects than at LDR.

There is another related factor to consider, that is, the short treatment time characteristic of HDR allows packing and retraction of the sensitive organs, which typically results in a 20% further decrease in the rectal/bladder dose compared to that achievable with LDR.[316] This gives an extra physically based advantage to HDR, in addition to the biologic factors discussed here.

The above radiobiologic consideration suggests that when the dose to the dose-limiting critical normal tissues (bladder/rectum) is less than about three-fourths of the prescribed dose, HDR (with at least about five fractions to ensure adequate tumor reoxygenation) results in comparable (or less) late effects than LDR—for the same level of tumor control for cervical cancer BT. These considerations are supported by a number of clinical studies.[317-323] These reports generally show that HDR and LDR for cervical BT produce similar local control and late complications.

As *BT* is often combined with pelvic *EBRT*, different time dose patterns of *EBRT* and intracavitary *BT* should be taken into account to calculate the combined effects to tumor and *OAR*s. The *EQD*2 from *EBRT* and *BT* may be summed up, assuming that the volumes and points of interest of *BT* receive the full *EBRT* dose. This estimate serves as a worst-case assumption for *OAR*s and is reasonable for the target volume of *BT*, which is often a boost

volume of the *PTV* of *EBRT*. A more appropriate calculation should consider highly heterogeneous dose of *BT* as discussed in the "Relative Biologic Effectiveness of Different Brachytherapy Sources" section.

High-Dose Rate Interstitial Brachytherapy for Prostate Cancer

As discussed earlier in the "Rationale for Low-Dose Rate Brachytherapy" section, one of the main reasons for protracting any radiotherapeutic exposure is that late sequelae are characterized by relatively low α/β ratios (3 Gy is typical) while tumors typically have higher α/β ratios (10 Gy is typical); lowering the dose rate generally spares late-responding tissues more than the tumor. The higher tumor α/β ratios are thought to be due to the larger proportion of cycling cells in tumors compared with normal tissues. However, because prostate tumors contain unusually small fractions of cycling cells,[297] it has been hypothesized that they may have α/β ratios and responses to protraction more typical of late-responding normal tissues.[306,324] If so, much of the rationale for LDR, or highly fractionated regimens would disappear.

A first estimate of α/β for prostate cancer was made in 1999,[306] by comparing results from EBRT with those from permanent seed ^{125}I BT. Consistent with the theoretical hypotheses (discussed above), the estimated value of α/β was 1.5 Gy [95% confidence interval: 0.8-2.2 Gy], indeed comparable to α/β values for late-responding normal tissues, and much smaller than those for most tumors. The problem with this α/β estimate, and almost all subsequent ones[307,325-329] is that they involved comparing or equating EBRT results with permanent implantation results. There are many pertinent differences between EBRT and BT (different dose distributions, different RBEs, different overall times, different institutions, different PSA distributions, hypoxia), any or all of which could bias the α/β estimate. Much debate has been centered on the significance of these biases and how to take them into account. For example, it has been reported that the consideration of hypoxia can significantly impact the α/β estimate.[330] Despite these problems, most of the analyses above support the hypothesis that the α/β value for prostate cancer is indeed quite low, probably in the 1 to 4 Gy range, which is similar to the values for most late-responding tissues.

One analysis[331] avoids many, though not all, of the potential biases involved in comparing EBRT and HDR BT: EBRT + two HDR boost fractions were compared with EBRT + three HDR boost fractions, all done with the same technique at the same institution. The resulting estimated α/β ratio for prostate cancer was 1.2 Gy [95% confidence interval: 0.03-4.1 Gy], again comparable with α/β values for late-responding normal tissues. A meta-analysis of four reports summarizing 21 studies yielded an estimated α/β ratio of 1.3 Gy.[332] A recent analysis of pooled multi-institutional data sets[333] led to $\alpha/\beta = 1.4$. A critical review of α/β ratio estimation methodologies and clinical analyses has been published by Oliveira et al.[334]

If the α/β value for prostate cancer is indeed similar to that for the surrounding late-responding normal tissue, HDR or hypofractionated external beam therapy regimens could be employed to match conventional fractionated regimens with respect to tumor control and late sequelae while reducing early urinary sequelae[335] and improving cost-effectiveness and patient convenience.

The arguments presented here really relate to the α/β value for prostate cancer in relation to the α/β value for the relevant late-responding normal tissue. Brenner reported an α/β value for radiation therapy oncology group (RTOG) grade ≥2 late rectal toxicity of 5.4 ±1.5 Gy based on an analysis of clinical data.[336] Another recent analysis of RTOG 94-06 data suggested that the α/β value for grade ≥2 late rectal toxicity was 4.8 Gy.[337] These α/β values, which are larger than that of most late-responding tissues, are higher than recent estimates of prostate tumor α/β ratio. This suggests that HDR prostate BT, as well as being logistically convenient, might actually improve the therapeutic outcome of prostate cancer BT.

HDR (or hypofractionation) in a curative setting, even when the dose is appropriately lowered, is a prima facie unsettling idea. However, there is now a significant body of clinical evidence suggesting that these approaches do not lead to increased early or late sequelae after prostate radiotherapy, either for EBRT or for BT, providing further evidence to support the underlying radiobiologic rationale. For EBRT, in those hypofractionation studies that have reported on potential late sequelae, there is to date little indication of any unexpected late sequelae after median follow-up periods of 21,[338] 31,[339] 48,[340] 59,[341] 66,[342] and 97 months.[343] HDR has been used in prostate BT as both a monotherapy[344,345] and, more commonly, a boost to EBRT.[346-349] In both cases, the results are promising with no evidence for excessive normal tissue complications.

However, mature long-term data on the effectiveness of tumor control are still needed for extremely hypofractionated *HDR* monotherapy for prostate cancer. In a single- fraction (19-Gy) *HDR* ^{192}Ir monotherapy trial, which included 441 patients with localized prostate cancer, the 3-year biochemical recurrence-free survival rate was 100% for low-risk patients, but dropped to 86% and 75%, respectively, for intermediate- and high-risk patients.[350] Importantly, the relapses after 19-Gy *HDR* BT monotherapy were mainly intraprostatic, predominantly associated with the site of initial disease.[351] While many factors could have contributed to the reported results, the loss of resensitization in single- fraction treatments and the increased sublethal damage repair during the prolonged dose delivery of large single-fraction dose[352] could also contributed to reduce the biologic effectiveness of the delivered dose.

Permanent Interstitial Brachytherapy for Prostate Cancer

Permanent interstitial BT delivers dose over the entire life of the implanted sources, making it necessary to consider cellular processes such as sublethal damage repair as well as tumor cell repopulation when examining its biologic effects. However, due to radioactive decay, the rate of dose deposition decreases exponentially over time. At certain point, the rate of cell kill produced by the implant will become equal to the rate of cell creation from repopulation, a time termed tactically as the effective treatment time, T_{eff}, by Dale.[353] Beyond T_{eff}, the dose delivered will not produce a net tumor cell reduction and the dose is considered “wasted.” The effective time is given by

$$T_{\text{eff}} = -\frac{1}{\lambda}\ln\left[\frac{0.693}{\alpha \dot{D}_0 T_{\text{p}}}\right] = -\frac{1}{\lambda}\ln\left[\frac{\gamma}{\alpha \dot{D}_0}\right] \qquad (21.43)$$

where λ is the radioactive decay constant of the particular nuclide used, and T_{p} is the potential doubling time of the tumor. At time T_{eff}, the dose that has been delivered is not the total dose, D, but rather a smaller effective dose, given by

$$D_{\text{eff}} = D\left(1 - \text{e}^{-\lambda T_{\text{eff}}}\right) \qquad (21.44)$$

As an example, using reasonable parameters for prostate tumors, the effective dose for a 145-Gy ^{125}I permanent seed implant is actually 139 Gy, which is the value that would be used in LQ-based calculations. The introduction of T_{eff} is necessary to avoid a conceptual difficulty encountered by the LQ-based model in handling permanent implants with proliferating tumors. The conceptual difficulty can be overcome using a more general TCP model introduced by Zaider and Minerbo.[354]

Many of the radiobiologic features of permanent prostate implant can still be elucidated using the LQ-based radiobiologic model (see AAPM TG-267 report for more details[282]). For example, the LQ model can be used to optimize the choice of radionuclide for a permanent implant.[355-357] The most common sources in current use are ^{125}I, ^{103}Pd, and ^{131}Cs (with half-lives of 59, 17, and 9.7 days, respectively). The optimal radionuclide for a given tumor depends on, among other factors, its growth rate, α/β value, radiosensitivity (α), and DSB repair rate. Generally speaking, short-lived radionuclides are more advantageous for treating fast-growing tumors, while longer lived radionuclides are more optimal for slow-growing tumors. However, short-lived radionuclides can effectively treat both fast- and slow-growing tumors[355,356] and, in addition, are less sensitive to the tumor properties and LQ parameter values assumed than is the case for long-lived radionuclides.

The discussions above assume that the geometric relationship between the implanted sources and the tissue remains unchanged. This assumption breaks down when the tumor shrinks over time[358,359] or when the implant volume expands and contracts in response to the surgical trauma of source implantation, such as the procedure-induced prostate edema.[235] The biologic effects of such intrairradiation tumor volume changes can be quantified using the LQ-based radiobiologic models.[358-360]

For tumor shrinkage during the implant, the reference surface to which dose is prescribed diminishes in size as the tumor shrinks, the physical dose rate and total dose delivered will increase as cells near the dose specification surface are moving closer to the implanted sources. Dale and colleagues reported[358,359] that, for permanent implants in tumors with long doubling times, tumor shrinkage may significantly enhance the clinical potential of longer

lived permanent implant radionuclides such as ^{125}I, but would have much less effect for short-lived radionuclides such as ^{103}Pd or ^{131}Cs, or for rapidly growing tumors. In fact, this is one argument against the use of long-lived nuclides for permanent implant BT, in that the outcome may depend on shrinkage parameters that are not easily predicted.

For procedure-induced prostate edema, on the other hand, the treatment volume and the location of the implanted sources expand initially followed by gradual edema resolution, making its biologic effect dependent on the interplay between the kinetics of edema resolution, the source radioactive decay, and the tumor cell sublethal damage repair and repopulation.[360] Chen and colleagues reported that, in general, the presence of prostate edema increases the cell survival and decreases the probability of local control.[360] The magnitude of edema-induced increase in cell survival and hence reduction in TCP increases with increasing edema severity, decreasing decay half-life, and decreasing photon energy. The magnitude of TCP reduction as a function of edema magnitude and resolution half-life was more rapid for implants using short-lived radionuclides, such as ^{103}Pd or ^{131}Cs. At the current level of dose prescription for prostate cancer, implants using ^{125}I sources are less affected by edema than those using ^{131}Cs or ^{103}Pd sources. Between ^{131}Cs and ^{103}Pd implants, the effect of edema on ^{103}Pd implant is slightly greater, even though the decay half-life of ^{103}Pd is longer than that of ^{131}Cs, because the advantage of the longer decay half-life of ^{103}Pd is negated by the lower effective energy of its emitted photons, making it more susceptible to source position variations.[360] The theoretical advantage of sources with shorter decay half-lives (eg, ^{131}Cs) discussed earlier could, therefore, be offset by their greater susceptibility to edema-induced dose reductions in LDR prostate BT.

Biologic Effects of Nonuniform Dose Distributions

Many implementations of the LQ and other radiobiologic models assume that an implant dose delivery can be approximated by a single uniformly administered prescribed dose, an assumption that ignores the highly nonuniform dose distributions produced by BT. The biologic effect of nonuniform dose could be estimated using the physical models derived from the LQ model based on cell survival.

A simple scalar metric for quantifying impact of such nonuniform dose is the equivalent uniform dose (EUD) concept proposed by Niemierko[361] or the corresponding equivalent uniform biologically effective dose (EUBED).[226,362-364] EUD is defined as the uniform dose which, if delivered with the same dose protraction regimen as the nonuniform dose distribution of interest, yields the same cell survival, hence the radiobiologic effect. The related concept, EUBED,[226,362,364] addresses both spatially nonuniform dose distributions and spatially variable temporal dose distributions, by replacing physical dose with BED. Suppose the dose distribution over an organ or tumor is described by a DVH, $\{D_i, v_i\}_{i=1}^{N}$, where v_i is the fractional volume of dose bin D_i. Then, EUBED is given by

$$\mathrm{EUBED} = -\frac{1}{\alpha}\ln\left(\sum_i v_i \mathrm{e}^{-\alpha\cdot \mathrm{BED}_i}\right) \tag{21.45}$$

where n_i is the fraction of the tumor target receiving the ith physical or biologically effective dose, D_i and BED_i.

Alternatively, dose inhomogeneity may be taken into account using other measures of cell survival, S, also weighted with the DVH[365-367]:

$$S = \sum_i v_i S(\mathrm{BED}_i)\cdot \tag{21.46}$$

This equation can also be used to estimate the overall TCP or to estimate equivalences between different treatments.[365-367]

To extend the concept of EUD to normal tissues, Niemierko (1999)[368] proposed a phenomenologic formula referred to as the generalized EUD or gEUD:

$$\mathrm{gEUD} = \left(\sum_i v_i D_i^a\right)^{1/a} \tag{21.47}$$

where v_i is the fractional organ volume receiving a dose D_i and a is a tissue-specific parameter that describes the volume effect. For $a \to -\infty$, gEUD approaches the minimum dose; thus, negative values of a are used for tumors. For $a \to +\infty$, gEUD approaches the maximum dose (serial organs). For $a = 1$, gEUD is equal to the arithmetic mean dose. For $a = 0$, gEUD is equal to the geometric mean dose. The original EUD concept has a more mechanistic interpretation than the empirical gEUD (described below). However, the gEUD is often used in plan comparison and optimization metric for EBRT and may be used for comparing different protraction schemes in BT because the same functional form can be applied to both targets and OARs with a single parameter capturing (it is hoped) the dosimetric "essence" of the biologic response. By replacing the physical dose DVH $\{D_i, v_i\}_{i=1}^N$ with biologically equivalent counterpart, $\{\mathrm{BED}_i, v_i\}_{i=1}^N$, the related metric, generalized EUBED (gEUBED),[281] is obtained.

The NTCP and TCP formalisms can also be generalized to accommodate nonuniform dose distributions. To compare different inhomogeneous dose distributions, TCP and NTCP can be computed by substituting equation Eq. 21.46 into the Poisson TCP model (Eq. 21.41), yielding

$$\mathrm{TCP}\left(\{D_i, v_i\}\right) = \exp\left(-K \cdot \sum_i v_i S(\mathrm{BED}_i)\right)$$
$$= \prod_i \left[\exp\left(-K \cdot S(\mathrm{BED}_i)\right)\right]^{vi} = \exp\left(-K \cdot \mathrm{e}^{-\alpha \cdot \mathrm{EUBED}}\right) \quad (21.48)$$

The second equation shows that inhomogeneous dose TCP, $\mathrm{TCP}\left(\{D_i, v_i\}\right)$, is the product of exponentially scaled (by volume fraction, v_i) TCPs, each describing uniform tumor irradiation by dose bin Di. The third equation shows that substituting the EUBED value derived from the DVH $\{D_i, v_i\}_{i=1}^{N}$ into the uniform dose TCP also reproduces $\mathrm{TCP}\left(\{D_i, v_i\}\right)$. Several authors[363,366,367] have extended this approach to spatial dose inhomogeneity to also include the possibility of inhomogeneous distributions of target cells within the tumor and radiosensitivities over the population of tumors.

Similar approaches for accounting for dose heterogeneity can also be applied to NTCP models[369] based on the survival of functional subunits (FSU). Many organs are best modeled by FSUs organized with a parallel architecture such that a complication results only when a sufficiently large number of FSUs are inactivated,[370] although serial architectures such as the spine can also be modeled.[366]

The literature suggests that dose nonuniformity can have a large impact on biophysical surrogates of clinical outcome. For example, for permanent seed prostate implants, Ling et al[364] demonstrated that doses between 100% and 130% of the D_{99} prescribed dose enhanced EUBED by 20% to 70% while Fatyga et al[281] found that dose inhomogeneity enhanced EUBED by 22% for HDR prostate implants. In a population of 423 patients with prostate cancer with minimum follow-up of 3 years and individual 3D dose distributions, Haworth et al[371] were able to identify a TCP cutpoint ($TCP > 0.62$) that was significantly correlated with freedom from biochemical failure at 5 and 8 years. In contrast, conventional D_{90} doses were not significantly correlated with outcomes in this population. Lindsay et al[372] found that α/β values derived by equating external beam and ^{125}I monotherapy TCPs ranged from

1.9 to 5.9 Gy when postimplant dose heterogeneity was accounted for compared to $\alpha/\beta \approx 1.5$ for assumed uniform BT dose distributions. However, they cautioned that in their spatially uniform clonogen density model, α/β estimates for individual patients were highly sensitive to peripheral cold spots.

While the above studies leave no doubt that BT dose heterogeneity can profoundly impact the results of biophysical model predictions, a major source of uncertainty is the sensitivity of TCP, NTCP, and EUBED calculations to the ubiquitous focal hot and cold spots characteristic of BT. Most applications of TCP and EUBED to 3D BT dose distributions assume a spatially uniform clonogen density and employ a cutoff (typically 110 Gy[373] or D_{99}[364]), which excludes low-dose voxels from the calculation, thereby avoiding unrealistically low estimates for clinical implant geometries. In a study of 613 postprocedural ^{125}I prostate implant dose distributions, Miksys et al[374] found that the mean EUBED ranged from 78 to 122 Gy for BED cutoffs ranging from 30 to 130 Gy (EUBED = 108 Gy for BED > 110 Gy). The corresponding range of mean TCP was 0.20 to 1.0 (TCP = 0.92 for BED > 110 Gy). In a study of 10 HDR prostate boost dose distributions, Fatyga et al[281] found that gEUBED for bladder and rectal tissue was highly sensitive to focal hot spots, requiring the use of a high BED cutoff taken to be the prescribed BED_{98}. Including higher dose focal hot spots for rectal complications was found to reverse the relative ranking of HDR and IMRT plans. This result is significant, since the gEUD formalism is equivalent to the DVH reduction scheme employed by the widely used LKB NTCP model.[375,376] In summary, straightforward application of EUBED and TCP to 3D dose calculations without arbitrary dose cutoffs requires patient-specific GTV and realistic spatially variant clonogen density models. Avoiding arbitrary high-dose cutoffs for normal tissue response modeling requires a yet-to-be-advanced model for predicting local injury saturation.

Relative Biologic Effectiveness of Different Brachytherapy Sources

As discussed earlier in this chapter, the mean photon energies of currently used BT radionuclides range from 21 keV (^{103}Pd) to 1,250 keV (^{60}Co). It is well established that biologic effectiveness varies with photon energy, as a result of different patterns of energy deposition produced by the different photon spectra.[63,377] It is possible, however, to estimate the RBE of these different isotopes directly from the energy deposition patterns—the subject matter of microdosimetry.[378] In this approach, the response per unit dose at LDRs (or low doses), R_i, to a particular radiation, i, can be written as[379]

$$R_i = \int w(y) \cdot \mathrm{d}_i(y) \cdot \mathrm{d}y \qquad (21.49)$$

where y is the stochastic quantity, lineal energy,[378] defined as the energy imparted to a cellular target arising from all ionizing radiation events caused by a single-photon track and

its secondary particles, divided by the target's mean chord length. The quantity $d_i(y)$ is the dose-weighted probability that a photon will deposit lineal energy y in the target volume of interest. The quantity $d_i(y)$ is often referred to as the microdosimetric single-event spectrum. It can be measured using a low-pressure proportional counter or calculated.[378] The quantity $w(y)$ describes the response of an individual cellular target to a lineal energy deposition, y. For sparsely ionizing radiations, for example, photons and electrons, it is reasonable to assume that $w(y)$ is proportional to y.[378] Thus, at LDRs

$$\mathrm{RBE}_i \propto \int y \cdot \mathrm{d}_i(y) \cdot \mathrm{d}y \qquad (21.50)$$

where $d_i(y)$ is the dose-averaged lineal energy.

Based on this approach, RBE values have been estimated from measured or calculated microdosimetric spectra.[63,380] For example, Wuu et al[63] report LDR RBE values relative to ^{60}Co of 1.3, 2.1, 2.1, and 2.3, respectively, for ^{192}Ir, ^{241}Am, ^{125}I, and ^{103}Pd. These values are comparable to those obtained experimentally. The approach outlined above is applicable only to LDR BT, but it can be generalized to HDR regimens.[379] Incorporating the LDR RBE into the LQ equations[381] requires a simple modification of the α term in Eq. 21.38 to $\alpha \cdot$RBE.

Use of Biophysical Models in Brachytherapy

The presentation above demonstrates that biophysical models, such as the basic LQ model, are very helpful in elucidating the radiobiologic properties of different BT regimes, with predictions consistent with the clinical experiences. More sophisticated TCP and NTCP models, while not sufficiently robust for use in clinical planning, are able to semiquantitatively account for the LDR and HDR BT clinical outcomes in several sites in terms of underlying descriptive radiobiologic mechanisms. Because of the simplistic nature of the models and the lack of tools for reliably determining patient-specific model parameters, these models are best used for comparing the relative effectiveness of different BT techniques, developing equivalent fractionation regimes, or optimizing therapeutic ratios in many clinical settings. Further guidance with regard to the use of biologic models in BT can be found in the recently published AAPM TG-267 report.[282]

CONCLUSIONS

This chapter has focused on several basic topics including the interplay between physical properties, source strength specification, single-source dosimetry, classic interstitial and intracavitary BT systems, dose specification, image guidance, computerized dosimetry and optimization, and biologic effects and clinical utility of BT sources. Many topics usually covered in an introductory survey have been omitted. For a review of radiographic imaging and localization of BT sources, the reader is referred to more specialized reviews.[382,383] For

discussions on QA of manual and remote afterloading BT and treatment planning, the reader is referred to Chapters 23 of this text as well as a number of excellent reviews,[384-388] including appropriate chapters from *Brachytherapy Physics*, 2nd edition,[389] and *Clinical Brachytherapy Physics*.[390] For useful reviews of the radiobiology of BT, the reader is referred to excellent reviews by Dale and Jones,[381] King,[391] Carlson et al,[392] and Chen et al.[282] For a discussion of BT licensing and regulatory issues, the review by Glasgow[393] is suggested.

CHAPTER 22

Clinical Applications of Brachytherapy: Low Dose Rate and Pulsed Dose Rate

Aspazia Spyrou, Sophie Otter, Caroline Holloway, Phillip M. Devlin, and Alexandra J. Stewart

HISTORY

Brachytherapy was the first form of conformal radiation therapy, using placement of radioactive sources within or very close to a tumor allowing high cancer to normal tissue dose ratios. After the isolation of radium, Henri Becquerel and Pierre Curie reported radium burns similar to those experienced by the early x-ray users. Radium was first used to treat skin lesions and superficial tumors, using boxes and tubes as applicators. From there, radium in metal needles or radon gas in glass seeds were placed in direct contact with tumors, using surface applicators, namely intracavitary and interstitial implants.[1] Source positioning within the tumor allowed high doses within the cancer, with small volumes of normal tissue irradiated and a sufficient dose at the margin between cancer and normal tissue to eradicate microscopic tumor foci. Early results were promising and they revolutionized cancer treatment.

In the 1950s, the use of brachytherapy was widespread; however, at that time, brachytherapy had several disadvantages. Classical radium needles were rigid and have a wide outer diameter ($\geq$1.5 mm^2). Brachytherapists had to have a high level of surgical skill to site the needles accurately, to achieve good dosimetry, and quickly, to minimize their own and others' exposure to radiation. Therefore, the emergence of teletherapy with the advantages of decreased staff exposure to radiation and radiation accessibility to more areas of the body with no dependency on surgical techniques led to a decrease in the use of brachytherapy.

However, brachytherapy has experienced a revival due to the emergence of newer artificial high-activity isotopes, afterloading systems, and

improved radiologic imaging with more sophisticated dose-planning techniques. Modern radiotherapy techniques have focused on escalating the dose to the target but decreasing the dose to normal tissues. Brachytherapy can meet both objectives in a highly conformal manner over a wide variety of disease sites.

Early texts describe the important principles of brachytherapy as uniformity in cross-section, uniformity in depth, and uniformity in opportunity (time).[2] These principles remain the cornerstone of modern brachytherapy practice, though modern techniques allow better assessment of them. Computerized tomography (CT) ultrasound and magnetic resonance imaging (MRI) scanning have enabled enhanced imaging in brachytherapy, allowing more accurate target definition, superior determination of applicator position, and improved evaluation of the position of normal tissues. In combination with computerized dosimetry, they have allowed better determination of the dosimetric coverage of a brachytherapy implant and an estimation of the subsequent risk of normal tissue toxicity.

DOSE RATE DEFINITIONS

Three categories of brachytherapy were defined in Report 38 of the International Commission on Radiation Units and Measurements[3]:

- low dose rate (LDR)—a range of 0.4 to 2 Gy/h. In clinical practice, the usual range is 0.4 to 1 Gy/h,
- medium dose rate (MDR)—a range of 2 to 12 Gy/h, and
- high dose rate (HDR)—over 12 Gy/h.

Pulsed dose rate (PDR) brachytherapy, first used in San Francisco in 1992, was developed in an effort to simulate the radiobiologic advantages and dosimetric properties of LDR, but with the advantages of computer optimization of dose, a stepping source, and remote afterloading usually achieved by HDR. The pathway of a single high-activity source through the implanted catheter can be accurately calculated by a computer with the dwell time adjusted as a function of its pathway within the implanted volume. PDR is a misnomer; in fact, the dose rate is often high, but the pulse intervals are short, so that the radiobiologic effect is similar to LDR.

PDR uses a single stepping ^{192}Iridium source of 15 to 37 GBq (0.5-1Ci), in the realm of one-tenth of HDR activity. Generally, the same total dose and total time as that of LDR are prescribed, but the radiation is administered in a large number of small fractions, usually a pulse every 1 to 4 hours. This produces treatment dose rates averaging 3 Gy/h. A typical pulse length is 10 minutes, which may increase to 30 minutes as the ^{192}Iridium source decays. It also has the advantage of a single afterloaded source compared to an inventory of LDR sources of different strengths, and all brachytherapy is feasible with one machine: intracavitary, interstitial, intraoperative, and intraluminal. This may become increasingly important as manufacture of traditional LDR sources ceases and disposal costs of existing LDR sources rise. Published series in a variety of tumor sites indicates that the clinical efficacy and the toxicity of PDR are similar to that of LDR/HDR.[4]

Permanent seed implants deliver a high total dose at a very low dose rate (vLDR), usually at <0.4 Gy/h. LDR sources can be placed directly into the body; however, with higher activity sources and large implants, this can result in exposure of the brachytherapist and operating room staff to a high radiation. To overcome this problem, afterloading techniques were developed. Initial techniques required applicator placement in the operating room and manual afterloading of sources in a shielded room at a later time. This has mainly been supplanted by remote afterloading techniques, where the patient has the applicators placed in the operating room and is later connected to a remote afterloading machine in a shielded room. The sources will only enter the patient when all personnel are at a safe distance from the patient; this can be used for LDR and is essential for PDR. During the course of an implant, careful monitoring of the sources must be maintained to detect applicator or source displacement. During a PDR implant, this may be done under direct vision or using radiologic confirmation. With both an LDR and a PDR implant, the patient should be safe to be left unsupervised for short periods of time to minimize staff exposure to radiation. This is where a PDR implant may have more advantage because those time periods will be briefer.

Table 22.1 demonstrates the advantages and disadvantages of LDR and PDR brachytherapy.

TABLE 22.1 THE ADVANTAGES AND DISADVANTAGES OF LDR AND PDR BRACHYTHERAPY

Advantages		Disadvantages	
LDR	**PDR**	**LDR**	**PDR**
>100 y of data	Source easily available	Often inpatient treatment with prolonged bed rest	One machine per patient used for 3-5 d
Standardized doses	Standard source strength	Radiation exposure to staff	More intense maintenance
Standardized treatment plans	Minimal staff exposure	Limited by available source strength	Requires more physician/physicist time in certain locations
Less source changes needed (depending on the isotope used)	Dose optimization of normal tissues	Many LDR sources no longer being manufactured	More expensive than LDR[5]
Less shielding needed during treatment	Radiation-free periods aid nursing care		Caution with conversion of dose from LDR to PDR, especially as intervals increase
	No source inventory required		May require prolonged bed rest depending on implant location
	With short pulse intervals, uses doses with known safety and efficacy		

CLINICAL USES OF BRACHYTHERAPY ISOTOPES

Brachytherapy uses radioactive isotopes to deliver therapeutic doses of radiation. The ideal radioisotope for brachytherapy should have a relatively short half-life to deliver the radiation in the shortest time possible and a high specific activity so that the source is small and, therefore, more versatile to implant. The emissions produced should have an adequate

penetration to deliver the dose to the desired depth, with rapid falloff to prevent damage to the surrounding normal tissue. Particular source characteristics such as half-life or specific activity can be tailored to the tumor and the surrounding organs at risk (OAR).

Temporary Implants

Traditional LDR sources such as iridium-192 and cesium-137 are no longer available in Europe and are becoming scarce in the rest of the world. Most radiation oncology departments wishing to continue using LDR-style dose and characteristics have switched to isotopes more suitable for remote afterloading, often using PDR techniques. Cobalt-60 (^{60}Co) is still used in afterloaders in the developing countries, with the advantage of decreased pressure on quality assurance and cost,[6,7] though more often using an HDR afterloader.[8,9]

Strontium-90 (^{90}Sr) is a pure β emitter and, therefore, is suitable for very superficial applications. It is commonly used for coronary brachytherapy and ophthalmic problems such as pterygium. It has a half-life of 28.1 years, so many departments are still using applicators purchased in the 1980s. Ruthenium-106 (^{106}Ru) is also a β emitter used in ophthalmic brachytherapy and has a much shorter half-life (1 year), making disposal concerns less and treatment delivery faster.

Permanent Implants

The artificial isotopes iodine-125 (^{125}I), palladium-103 (^{103}Pd), and cesium-131 (^{131}Cs) are all used in modern permanent vLDR implants. The isotope to be used can be chosen according to its individual characteristics, which may be desirable in different implants—for example, slower dose delivery may decrease normal tissue toxicity or a tumor with a higher α/β ratio may theoretically have more cells to kill using an isotope with a shorter half-life. All three isotopes are almost completely shielded with 0.2 cm of lead foil, making radiation protection easier.

CLINICAL SUITABILITY FOR BRACHYTHERAPY

Cancers with clinically and radiologically well-defined margins with a low risk of regional and metastatic spread are the most suitable for brachytherapy as a single modality. However, brachytherapy is becoming increasingly important when integrated with external beam radiation therapy (EBRT) to give a highly localized boost. EBRT is used to sterilize a larger area of possible microscopic or nodal spread, with brachytherapy used for areas of gross macroscopic or microscopic residual disease. This ensures that high doses are achieved within tumors, while normal tissues are not exposed to doses beyond recognized organ tolerance levels. It also has the potential for highly conformal localized dose escalation to areas at high risk of tumor recurrence.

In EBRT, the dosimetric goal is to achieve a homogeneous dose distribution, with doses ranging from 95% to 107% of the prescribed dose.[10] In contrast, brachytherapy has an extremely heterogeneous dose distribution, with isolated areas receiving more than 200% of the dose. The steep gradients are a consequence of the proximity of the clinical target volume (CTV) to the sources and decreasing dose with distance secondary to the inverse square law. As the dose falls off with distance, the normal tissues experience not only a reduced dose but also a reduced dose rate, which results in enhanced cell sparing. The sharp dose falloff with brachytherapy contrasts with the more gradual dose falloff seen with photon-based EBRT.

Brachytherapy can be used anywhere in the body that can be accessed for direct source placement. For many years, surface applicators and intracavitary gynecologic brachytherapy were the predominant modes of brachytherapy. However, with the advent of modern surgical techniques and interventional radiology, many more areas of the body are now accessible to the brachytherapist. Brachytherapy applicators can be placed within tubular organs in the body, either under direct vision (eg, cervix or vagina) or with the use of radiologic or endoscopic guidance (eg, bile ducts or esophagus). Interstitial implants can be placed with or without image guidance—for example, prostate implants using rectal ultrasound guidance and a template or a freehand extremity sarcoma implant. Interstitial implants can take the form of free seeds, or seeds within linked strands or catheters that will be afterloaded with the radioactive source. Of course, surface applicator

techniques are still used with the added benefits of modern imaging and dosimetry techniques to ensure target coverage.

TARGET DEFINITION

Many of the same definitions for delineation of treatment volumes in EBRT are used for brachytherapy.[10,11] There may be delineation of high-risk and low-risk areas if discrete areas of dose escalation are required within the CTV. The high-risk area has the highest risk of local recurrence, usually due to the presence of gross residual disease. An intermediate area may be defined as areas where there was macroscopic tumor during diagnosis that has regressed by the time of brachytherapy implant. The low-risk area includes potential microscopic spread—that is, the traditionally defined CTV. In EBRT, the planning target volume (PTV) traditionally consists of the CTV and a margin that will allow for physiologic movement and set-up uncertainty. Generally, in brachytherapy, these variations are minimized and, therefore, the PTV is usually the same as the CTV.

In a brachytherapy implant, there will be *high dose regions* around each source. Generally, the volume of the region receiving over 150% of dose is reported (V150).[3] *Low dose regions* are those within the CTV receiving <90% of the prescribed dose. Due to the heterogeneity of dose in brachytherapy, the average dose within the prescribed volume is usually far higher than the prescribed dose at the reference isodose point on the periphery of the implant. This is tolerated due to the volume-effect relationship: very small normal tissue volumes (eg, 1-2 cm^3) can tolerate very high radiation doses that larger volumes would not tolerate. The dose to OAR should be reported either as a total dose or as a ratio of volume. Parameters such as the minimum dose received by the most irradiated 2 cm^3 of tissue (D2 cm^3) or the volume receiving over 90% of the dose (V90) or dose received by 90% of the CTV (D90) are assessed.

RADIOBIOLOGIC CONSIDERATIONS

Radiobiologic principles are important in the daily clinical use of all forms of brachytherapy. Brachytherapy was initially developed empirically, with doses being determined by clinical effect. These correspond to many of the LDR and PDR dose schedules in current use. In the modern era,

radiobiologic modeling is used to predict the biologic effect of varying dose prescriptions. The importance of radiobiology and its use within brachytherapy was emphasized by the move from LDR treatment to PDR and fractionated HDR treatment. Of course, it must be remembered that applicator and source placement remains the single most important factor in brachytherapy such that, in an implant with poor geometry, changing radiobiologic parameters, such as fractionation or dose rate, will not improve the outcome.

Factors contributing to the response of tissues to radiotherapy have been labeled the "4 Rs of radiotherapy"[12]: repair, reassortment, repopulation, and reoxygenation. The way in which these radiobiologic characteristics relate clinically to the use of LDR and PDR either alone or in comparison to HDR is discussed in the following section.

Repair

Sublethally damaged cells are capable of repair if they are allowed sufficient time and if the cell contains all the necessary DNA repair proteins and enzymes. If sublethally damaged cells are exposed to further irradiation before repair occurs, the damage may become lethal. Late-reacting normal tissues seem more capable of repair than do tumor cells; therefore, at a given therapeutic dose, tumor is preferentially killed over normal tissue.

LDR or PDR treatment over several days allows time for sublethal damage repair in normal tissues. In contrast, the short treatment time of HDR treatment prohibits this repair during the actual irradiation. In PDR, generally the same total dose and total time as LDR are prescribed.

Dose rate is a key factor in determining the biologic effects of brachytherapy. In general, the effects of radiotherapy increase as the dose rate increases, predominantly due to a decrease in repair. It has been suggested that the total dose of LDR prescribed should be corrected for overall time of the implant,[13] though some investigators have found no difference in local control with the same total dose administered using a dose rate ranging from 0.05 to 0.167 Gy/min.[14] A randomized study in cervix carcinoma showed no difference in overall survival or local control for an LDR of 0.4 versus 0.8 Gy/h.[15,16] However, there was a significant increase in late complications in the higher dose rate group. A similar trend

has also been seen in LDR brachytherapy for breast cancer and head and neck carcinoma.[17,18] Therefore, it is recommended that the LDR (and PDR equivalence) should be in the range of 0.3 to 1 Gy/h due to the effects on late complications rather than local control. If the dose rate exceeds 1 Gy/h, a reduction in the total dose can be calculated using the biological effective dose (BED) equation.

Reassortment

In normal cells, proliferation occurs in a sequence of events termed the cell cycle.[19] There is a theoretical advantage of an improved effect on reassortment using LDR treatment since, during the overall treatment time, cells will pass out of the relatively radio-resistant cell cycle phases of late S and early G_2 into the more radiosensitive phases of late G_2 and M. This has been shown in vitro,[20] but in vivo, the effect of reassortment has not been shown to give a true advantage, possibly due to a disruption of the mechanisms of the cell cycle in cancer cells.[19]

Repopulation

In squamous cell carcinoma, studies have shown improved tumor control and increased survival when a radiotherapy course is given in the shortest overall time.[21-24] This may be because shorter treatment times allow less time for tumor cell repopulation or for accelerated repopulation to occur. The continuous administration of LDR and PDR probably prevents repopulation during treatment.

Reoxygenation

The response of cells to radiation is strongly dependent on oxygen. Radiation results in free radical formation within a tumor, and oxygen reacts with these free radicals to make DNA damage irreparable. The effect of hypoxia on tumor control has been well documented with decreased survival in certain patients with a low initial hemoglobin level.[25-27] When using LDR and PDR, transient hypoxia may correct during the treatment time,[28] which is not possible during the short duration of HDR

brachytherapy. If the brachytherapy is fractionated, tumor shrinkage and reoxygenation of areas of chronic hypoxia may occur between insertions.

MEASUREMENT OF BRACHYTHERAPY DOSE

Dosimetry systems aim to give the brachytherapist a set of guidelines to follow, which result in a prescribed dose being delivered to a patient in a predictable fashion. Initial brachytherapy dosimetry systems were developed for LDR implants using an empirical approach toward source placement and dose calculation. More modern techniques use computer programs to generate isodose distributions, which can then be analyzed in two dimensions, three dimensions, and volumetrically. To achieve the best ratio of cancer to normal tissue dose, the selection of an appropriate prescription point is essential. Applicator positioning is of primary importance, as differential loading cannot compensate for a poorly sited implant. Improved radiologic imaging has allowed a more accurate definition of the CTV and associated normal tissues, giving dose specification according to patient anatomy rather than to applicator position. This is more likely to correlate with patient outcome than previous dosimetry systems. This may result in not only better tumor control but also decreased risk of late complications.

LDR dosimetry is based on dosimetry systems originating in the 1930s with modifications over time, namely the Manchester, Quimby, and Paris rules (see Chapters 6). Where LDR uses fixed source positions and strengths to calculate the dose at the prescription point, afterloading machines and computerized dosimetry systems allow optimization of source dwell times to customize dose delivery to the patient's individual anatomy and tumor volume. PDR takes advantage of this dose optimization in a way that LDR cannot. Optimization results in nonuniform source loadings that give greater dose uniformity and CTV coverage that is often similar to those in an idealized Manchester dosimetry system implant.[29] The steep dose gradient around each wire/catheter needs to be accounted for, and widely spaced sources/applicators may form large high dose regions and increase the risk of necrosis. The maximum source separations and treatment thickness in the Paris system are useful rules to remember to decrease this risk. Traditionally, brachytherapy dose delivery was thought

not to be affected by alterations in the treatment position. While this may be true for dose delivery to the target volume, the position of OAR in relation to the brachytherapy implant may be altered, thereby increasing the dose delivered. For temporary implants, treatment should take place in the planning position to allow accurate determination of OAR dose.

CLINICAL SITES

There are areas where LDR techniques continue to predominate and areas where HDR techniques predominate. In some disease sites, the use of HDR and LDR was generally equal (eg, cervix cancer), but now HDR predominates, with a small but significant proportion of centers worldwide using PDR treatment. An overview of clinical uses for LDR and PDR is presented in the following section, with an emphasis on the brachytherapy dose rate rather than on the treatment technique. Individual indications will be described in the site-specific chapters.

Cervix

The use of LDR for cervix cancer treatment was first described with intracavitary implants in 1903 and with interstitial implants in 1913.[30] Brachytherapy has withstood technological innovations to remain an essential part of curative cervix cancer treatment[31,32] for all but the very earliest stages of the disease. The use of LDR has many years of safety and efficacy data, and physicians can be confident in their choice of brachytherapy dose. The four trials that compared LDR and HDR brachytherapy were all completed before the era of concurrent chemoradiation. They all concluded, however, that there are no differences between HDR and LDR in local control and survival, with HDR exhibiting a more favorable side effect profile, especially in regard to rectal complications[33] (Figure 22.1). A randomized controlled trial has shown that there is no significant difference between late rectal, bladder, and vaginal toxicity and survival when comparing PDR with HDR brachytherapy.[34] The American Brachytherapy Society guidelines for the use of LDR and PDR in cervix cancer[35] incorporate the volume-based dosimetry and updated quality control recommendations.

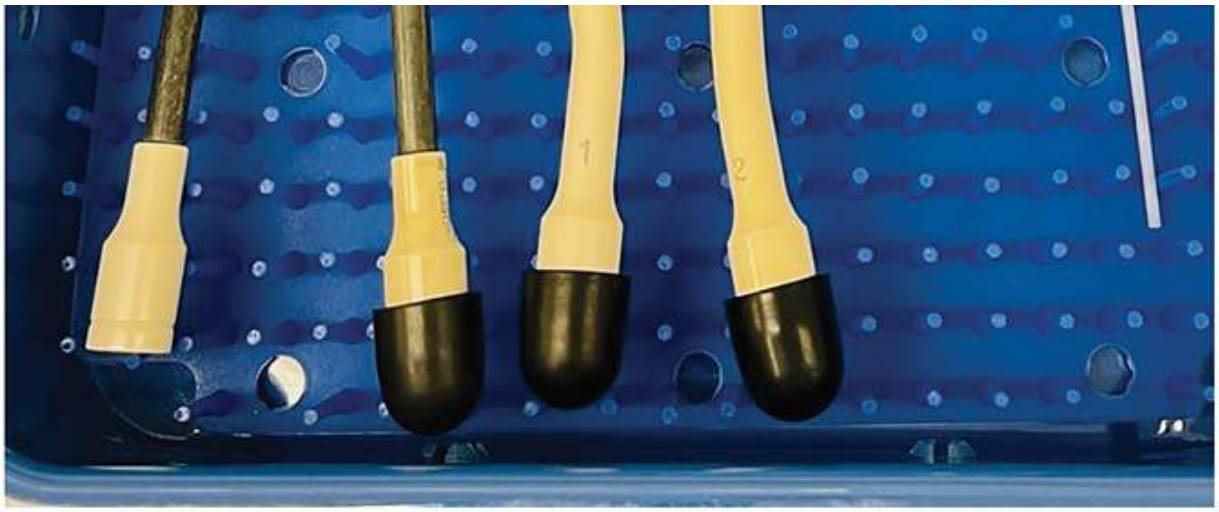

FIGURE 22.1 Tandem and ovoid kit. (Courtesy of Dr. Alexandra Stewart, St Luke's Cancer Center, Brachytherapy Department, Royal Surrey Hospital, Guildford, UK.)

With the use of CT- and MRI-based target volume and organ at risk definition, dose reporting in cervix cancer brachytherapy has changed from point based to volume based.[36-38] This means that tumor coverage is improved, and the doses to normal tissues can be decreased (Figure 22.2). This method relies on the use of dose optimization and thus has moved cervix brachytherapy away from LDR; therefore, PDR is the treatment of choice in those wishing to use a similar treatment modality.[39,40] The longer time taken to deliver one overall fraction of PDR than HDR is important when optimizing dose away from normal tissues, and it is important to recognize that the dose delivered to normal tissues over the whole treatment time may differ from that predicted, up to 33% more.[41] Rectal volume has been shown to increase during the course of delivery of PDR and, therefore, serial imaging and adaptive planning may be necessary as the cumulative rectal dose correlated with late rectal toxicity better than the planned dose.[42] A comprehensive description of this volume-based dosing is given in Chapters 23.

(Courtesy of Dr. Alexandra Stewart, St Luke's Cancer Center, Brachytherapy Department, Royal Surrey Hospital, Guildford, UK.)

PHRC Tridicol is a prospective French phase II study aiming to increase the dose delivered to the target volume during PDR brachytherapy for locally advanced cervical cancers.[43] Eight centers recruited 48 patients who were treated with concurrent chemo-radiotherapy followed by PDR brachytherapy. The 5-year local control rates were examined and were compared against the STIC PDR group and the retroEMBRACE cohort. The CTV dose delivered was below the target (85 Gy), which was thought to be due to low use of parametrial interstitial needles. The 5-year local control rate was improved compared to that of the STIC PDR group (78%) but lower than that of the retroEMBRACE cohort (89%). The complication rate was higher than that of the STIC PDR group but close to that of the retroEMBRACE cohort.

In cervical brachytherapy, the applicator is generally placed under operative conditions. The patient may require a general anesthetic, but

spinal anesthesia (Figure 22.3) has been shown to provide excellent analgesia, which can be maintained throughout the length of the implant by using a spinal catheter.[44] Spinal anesthesia does not affect tumor oxygenation during an HDR implant[45] and, thus, is not expected to during the whole duration of an LDR or PDR implant. When patients have the applicator in situ, they will remain lying flat, with prophylaxis against venous thromboembolism. Typically, agents are given to slow bowel motility. A urinary catheter is maintained throughout treatment. Prophylactic antibiotics are not routinely required but can be considered during interstitial implants. Pain and discomfort may be managed by epidural or intravenous patient-controlled analgesia. Use of a short-acting inhaled anesthetic agent for analgesia during episodes of acute pain such as toileting or applicator removal may improve the patient experience.[46]

FIGURE 22.3 Administration of a spinal anesthetic prior to a pelvic brachytherapy procedure.

Endometrium

Brachytherapy for the management of endometrial carcinoma was first described in 1935 by Heyman,[47] prior to the routine use of hysterectomy for

uterine cancer. Currently, the primary treatment for endometrial cancer is surgery with or without adjuvant radiotherapy and chemotherapy, based on the histology of the tumor and stage of presentation. As endometrial carcinoma is linked to obesity and hypertension, some patients have medical comorbidities that preclude surgery; for those patients, radiation therapy may be the definitive treatment of choice. In this group, treatment is delivered via intracavitary uterine brachytherapy, with or without EBRT.[48-50] With the decrease in LDR radioactive source availability, PDR has become the alternative modality to HDR. De Felice et al[51] give recommendations to manage the transition in modality.

For definitive treatment, packing the uterus with capsules allows excellent coverage of the entire endometrial cavity that can be adapted to every patient's individual anatomy,[52,53] but standardized applicators may provide more straightforward and reproducible dosimetry. Double channel applicators such as the Rotte applicator[54] can be used with CT planning, and computerized optimization with HDR delivers a dose very similar to the serosa[55]; this could be replicated with PDR (Figures 22.4 and 22.5). Various whole uterus prescription points have been described[56,57]; however, CT planning allows contouring of the outer contour of the uterus for volume-based dose prescriptions. A typical dose is 70 to 80 Gy (prescribed to the outer contour of the uterus alone), or 35 to 50 Gy in combination with 30 to 45 Gy EBRT.[58] GEC-ESTRO has published guidelines on converting LDR schedules to PDR schedules for all gynecologic cancers.[59]

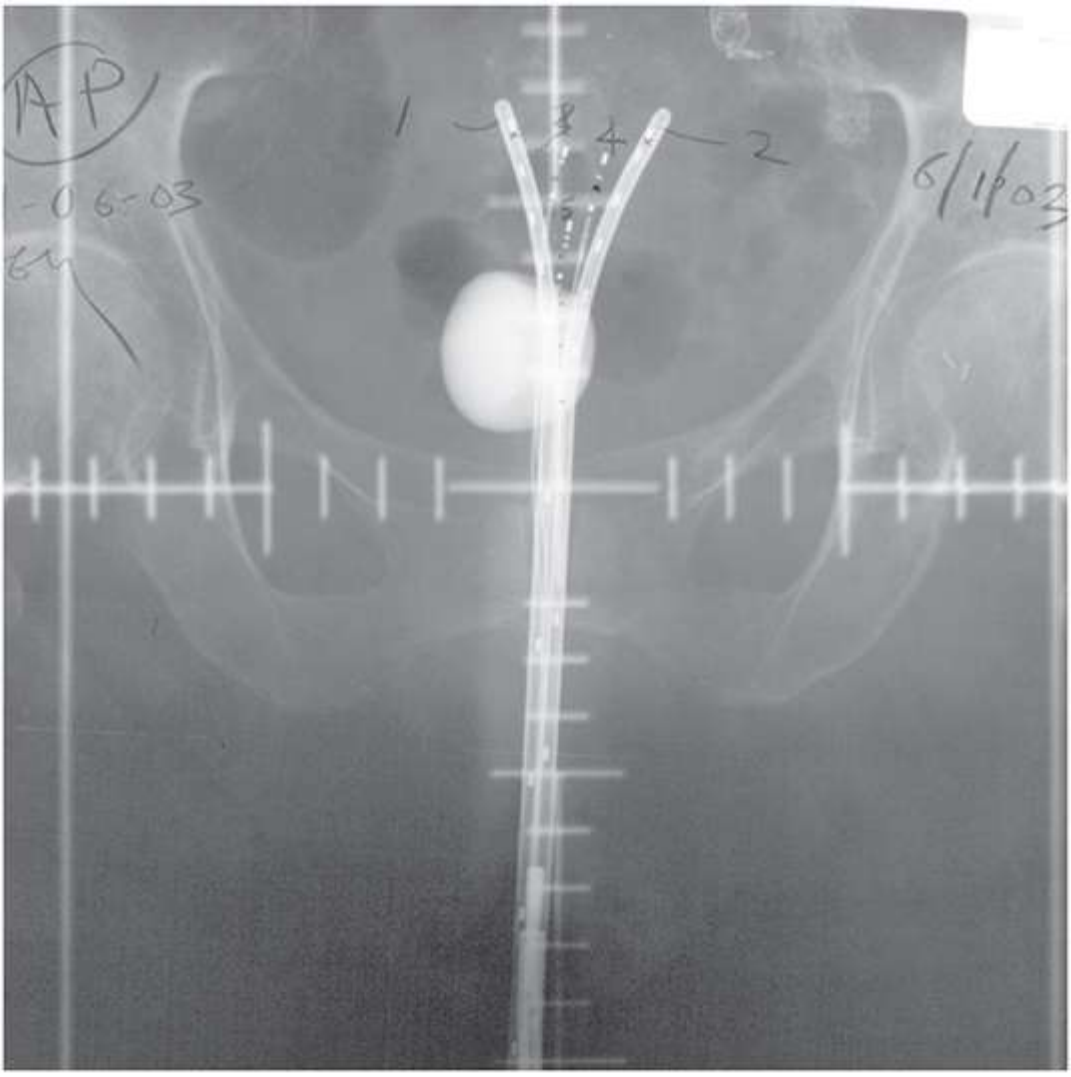

FIGURE 22.4 Double tandem Martinez applicator in place with three Heyman capsules placed within the uterus.

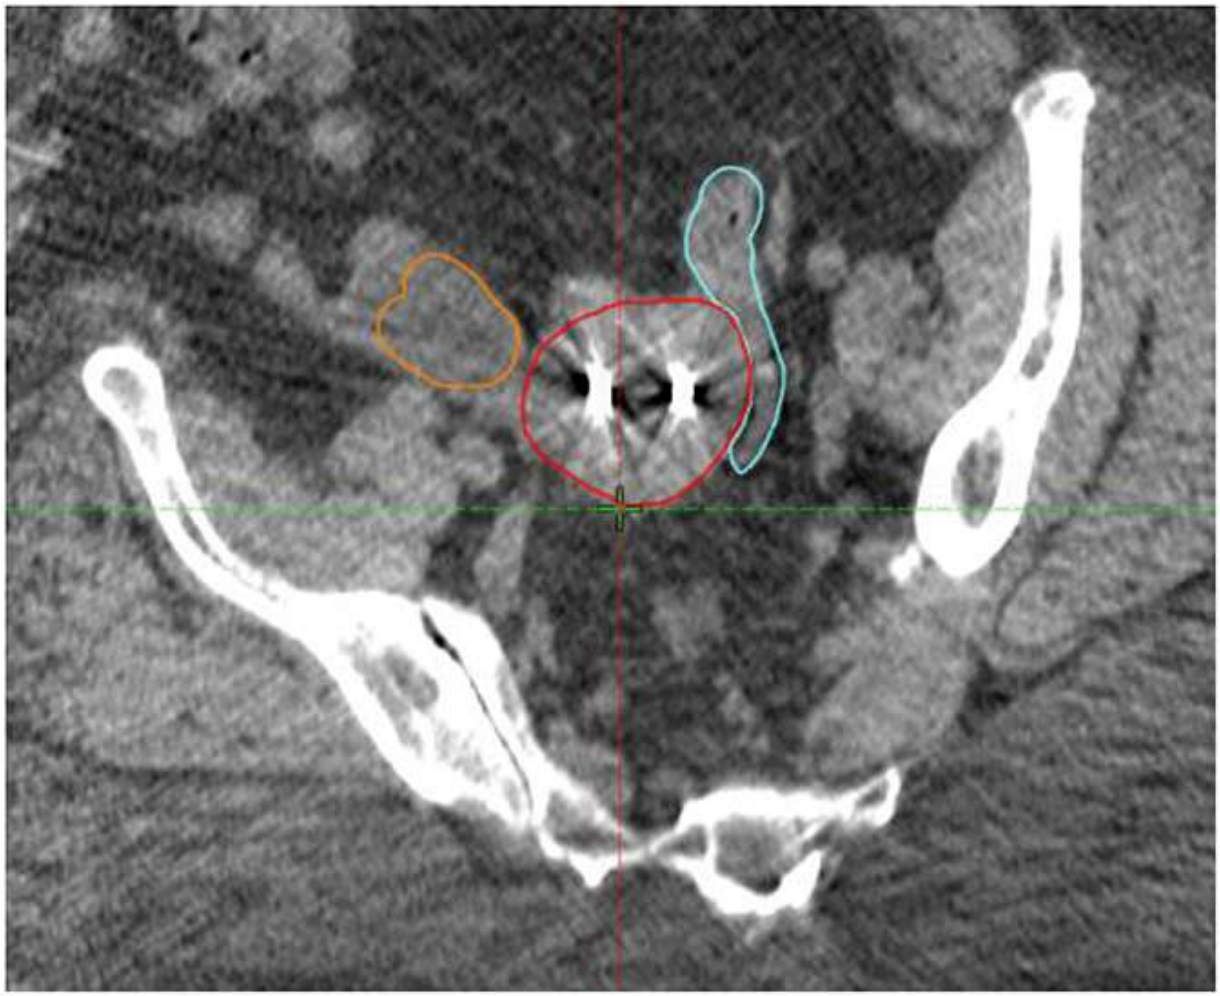

FIGURE 22.5 Axial CT slice demonstrating the Martinez applicator in situ. The high-risk CTV is outlined in red, sigmoid in blue, and bowel in orange.

Vaginal vault brachytherapy can be used in the adjuvant treatment of endometrial cancer and vaginal vault recurrence of endometrial carcinoma and also in other gynecologic malignancies such postoperative early-stage cervix cancer or early-stage vaginal cancer[60-63] (Figure 22.6). PDR vaginal vault brachytherapy is not frequently used as a boost to EBRT because the longer time of the application imposes the requirement for a urinary catheter. In addition, the side effects of thrombotic risk[64] and bowel dysfunction are not warranted for the low doses required in the adjuvant boost setting. The radiation dose received by the pelvic organs varies according to physiologic variations, for example, the bladder dose may vary according to the extent of bladder filling, which may also affect the amount

of small bowel in the field,[65,66] making the catheterization required for PDR less desirable.

Prostate

Prostate brachytherapy has become part of the treatment paradigm in prostate cancer for all stages of localized disease (see Table 22.2). It can be used as monotherapy or in combination with EBRT and/or hormone therapy for higher risk disease. A surveillance, epidemiology, and end results database (SEER) database analysis of men <60 years old has shown that prostate cancer-specific mortality was reduced in those treated with brachytherapy (±EBRT) compared to those treated with EBRT alone.[67] The most common prostate brachytherapy application has historically been LDR permanent seeds for monotherapy although more recently the use of single dose HDR as a boost is rising; however, LDR,[68] HDR,[69] and PDR[70,71] techniques can all be utilized.

TABLE 22.2 SELECTION CRITERIA FOR PROSTATE BRACHYTHERAPY[72,73]

Patient Factors
Life expectancy >5 y
IPSS <15
Prostate volume <60 mL No defect if previous TURP
Minimal pubic arch interference
Tumor Factors
Monotherapy: T1-T2b, Gleason ≤7, PSA ≤15[a]
Boost therapy: ≥T2c, Gleason ≥7, PSA ≥10

IPSS, International Prostate Symptom Score; PSA, XXX; TURP, transurethral resection of prostate.

[a]Gleason 7 and PSA >10 may be considered for either monotherapy or boost therapy.

Ash D, Flynn A, Battermann J, et al. ESTRO/EAU/EORTC recommendations on permanent seed implantation for localized prostate cancer. *Radiother Oncol*. 2000;57(3):315-321; Expert Panel on Radiation Oncology-Prostate, Frank SJ, Arterbery VE, et al. American College of Radiology Appropriateness Criteria permanent source brachytherapy for prostate cancer. *Brachytherapy* 2011;10(5):357-362.

Tumor criteria depend on whether monotherapy or boost therapy is planned. Typically, monotherapy is reserved for patients with the so-called favorable risk disease (eg, low- intermediate risk disease: T1-2b disease, Gleason <7, prostate specific antigen (PSA) <15 ng/mL). However, there is emerging evidence that some intermediate-risk disease may also be treated effectively with monotherapy[74]; therefore, boost therapy may be reserved for patients with unfavorable intermediate- risk and high-risk disease.[75,76]

In intermediate- to high-risk prostate cancer, brachytherapy in combination with EBRT has been evaluated in retrospective series with both LDR permanent seeds and HDR brachytherapy.[77-80] The ASCENDE-RT trial compared LDR brachytherapy (LDR-PB) with dose-escalated external beam boost (DE-EBRT), in patients with intermediate- and high-risk prostate cancers.[81] The DE-EBRT arm received an additional 32 Gy in 16 fractions, and the LDR-PB arm received an ^{125}I implant prescribed to a minimum peripheral dose of 115 Gy. Two hundred patients were randomized to the DE-EBRT arm and 198 to the LDR boost. The endpoint was biochemical progression-free survival. The distant relapse rate was 11% in the LDR-PB group and 14% in the DE-EBRT group. The 15-year metastasis-free survival (MFS) was 84% for LDR-PB and 79% for DE-EBRT. Six percent of patients in the LDR-PB arm and 9% in the DE-EBRT group died from prostate cancer. LDR brachytherapy demonstrated an advantage in biochemical progression-free survival, though this did come with a risk of toxicity.[82] At 5 years, the cumulative incidence of grade 3 genitourinary toxicity was 18% for LDR-PB versus 5% for DE-EBRT, and for grade 3 GI toxicity, it was 8% versus 3%. Conversely, LDR-PB allowed 45% of men to maintain similar erectile function compared to 37% after DE-EBRT. There was no significant difference detected in OS and MFS, though the authors note that the study was insufficiently powered to show a

survival difference. This is where the HDR brachytherapy could offer a dosimetric advantage over LDR. In a randomized phase III trial, Hoskin et al compared 106 patients receiving EBRT alone to 110 receiving EBRT combined with HDR brachytherapy boost (HDR-BTb).[83] At a median follow-up of 131 months, a median time to relapse of 137 months was seen in the HDR-BTb group compared to 82 months for the EBRT alone group ($p = 0.01$). There was 27% risk of recurrence with EBRT alone ($P = 0.001$), with a 21% improvement of the relapse free survival (RFS) at 12 years with the combination of EBRT+HDR-BTb. In this study, there was no difference in GU or GI toxicity with the addition of HDR-BTb. Consequently, the use of HDR as a boost modality is rising, and the use of LDR is falling. The same techniques used in HDR boost brachytherapy can be applied to PDR brachytherapy. PDR boost brachytherapy is not as extensively studied as HDR or permanent implants, but preliminary studies[84,71] show acceptable toxicity and tumor control with limited follow-up. In the study by Pieters et al, patients were treated with ≤1.2 Gy/pulse at short time intervals (≤2.2 hours). The doses in their study are relatively low with an EQD_2 between 68.8 and 74.4 Gy. They noted that tumor control at 5 years was comparable to many HDR studies and that there are large areas of prostate receiving >20% of the prescription dose because of the heterogeneous nature of brachytherapy. They recorded low rectal and urinary toxicity, and the International Prostate Symptom Score (IPSS) returned to baseline by 12 weeks post brachytherapy. Further dose escalation with PDR was felt to be worth pursuing because of the low rectal and urinary toxicity.

Cosset et al treated 675 patients with LDR monotherapy for low- and intermediate-risk prostate cancer.[85] Sixty-one percent retained sexual function within a 11-year follow-up period. The overall survival was 92% but for the intermediate-risk group, the RFS rate was only 71%. The side effect profile, specifically the likelihood of erectile dysfunction, was comparable to that of a series of 141 HDR monotherapy patients in the study by Behmueller et al. In this study, the RFS was 84% for intermediate-risk patients, though these comprised only 23% of the series.[86]

Prostate brachytherapy is also being investigated as salvage therapy after external beam radiation.[87,88] The International Delphi consensus study offers practical advice on salvage brachytherapy.[89] In a group of 30 international

experts, the majority agreed that HDR brachytherapy as a focal treatment or whole gland technique is appropriate. RTOG-0526, a phase 2 trial, investigated the option of salvage LDR brachytherapy for local recurrence after EBRT in 100 patients across 20 centers.[90] The median follow-up was 6.7 years with a median prior EBRT dose of 74 Gy. Androgen blockade treatment was combined with salvage brachytherapy (BT) in 16% of patients. The 10-year OS was 70% with 19 patients dying, five of those from prostate cancer. The 10-year failure rates were local 5%, distant 19%, and biochemical 46%. The 5-year freedom from biochemical failure was 68%, which was comparable to those reported for other salvage modalities. Although it is rare to have a repeat local failure (5%), the risk of biochemical failure was 46% by 10 years.

The role of EBRT and hormone therapy in combination with LDR brachytherapy is unclear and under investigation. Adjuvant androgen deprivation therapy (ADT) is used for prostatic cytoreduction in patients who do not have ideal prostatic geometry.[76,91] Cytoreduction may be achieved with use of lutenizing hormone-releasing hormone agonists and antiandrogens or antiandrogen in combination with 5α reductase-inhibitors.[91] ADT is also considered in patients thought to be at higher risk of prostate cancer recurrence; however, the benefit of ADT in this setting is not well defined.[92-95] The RTOG 0815 study investigated the benefit of dose-escalated RT alone (750 patients) versus RT combined with total androgen suppression (TAS, 742 patients) in patients with intermediate-risk prostate cancer. Early results reported at a median follow-up of 6.2 years show overall survival rates of 90% and 91%, respectively. More patients developed PSA failure and distant metastases in the RT alone group with statistically significant *P* values. In addition, more deaths relevant to prostate cancer were documented in the RT alone group compared to the combination treatment arm [HR 0.10 (0.01 − 0.80); $P = 0.007$]. This has shown that while TAS does not change the overall survival in men with intermediate-risk cancer, it may offer a significant decrease in the rates of biochemical failure and distant metastases.

A transrectal ultrasound-guided transperineal technique is the most popular technique for implanting the prostate. Axial images of the prostate from the base to the apex are taken and then used for brachytherapy planning (Figure 22.7). Other modalities incorporating MRI[96] and MRI

spectroscopy imaging have also been proposed.[97] The techniques for implanting ^{125}I and ^{103}Pd have been well described.[98-100] The patient criteria for selection include ability to undergo a general, spinal or less commonly local anesthetic,[101] prostate volume of <60 mL,[68] favorable anatomy (minimal or no pubic arch interference, median lobe), and minimal obstructive uropathy. However, Stock and Stone demonstrated that patients with larger prostate glands, ranging from 100 to 205 cm^3 (mean 126 cm^3), can also be treated successfully.[102] Thirty-four patients were assessed with a mean follow-up time of 6.7 years to document toxicities and biochemical freedom from failure rates (bFFF). The 10-year bFFF was 84.5%, with no differences in bFFF between PV100 and smaller glands (82.4% vs 84.5%, P = 0.71). Although urinary retention rates were higher, urinary toxicity scores were similar to those of patients with a prostate volume <100 cm^3.

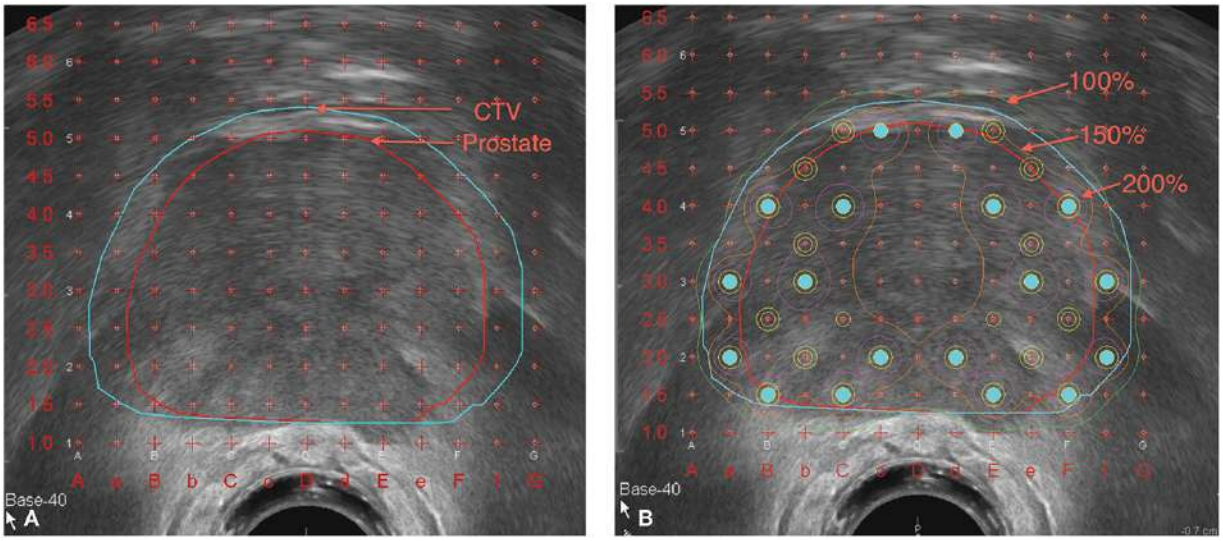

FIGURE 22.7 Prostate volume study with prostate and CTV defined (A), preplan with peripheral loading technique (B).

Current permanent LDR techniques involve implanting ^{125}I or ^{103}Pd seeds. ^{131}Cs is also approved for prostate brachytherapy and is used at some institutions. These isotopes have differing energies and half-life and, therefore, initial dose rates. Table 22.3 shows the various prescription doses for permanent LDR when used as monotherapy or as a boost in combination with 40 to 50 Gy of external beam radiotherapy. It had been postulated that ^{103}Pd compared with ^{125}I was more effective at treating

dedifferentiated tumors as the dose rate is higher; however, studies evaluating clinical outcomes for patients with prostate cancer have shown no difference.[103-105] Studies evaluating the toxicity to OAR (including the rectum and bladder) and sexual function have shown no difference in acute or long-term toxicity or difference in sexual function.[106-108] There is a difference in the time for the IPSS score to return to the preimplant baseline, with ^{103}Pd returning to baseline faster.[109] ^{131}Cs has not been studied as extensively. Commercially, ^{125}I and ^{103}Pd seeds are available as either loose or stranded seeds. Dosimetrically, the two are similar. The incidence of seed migration is decreased with stranded seeds as compared with that of loose seeds with the greatest difference being in migration to the lung and perineum.[110]

TABLE 22.3 PRESCRIPTION DOSE FOR PERMANENT LDR BRACHYTHERAPY WHEN USED AS MONOTHERAPY OR AS A BOOST COMBINED WITH 40 TO 50 GY EXTERNAL BEAM RADIATION THERAPY

	Monotherapy (Gy)	Boost (Gy)
^{125}I	145	110
^{103}Pd	125	100
^{131}Cs	115	85

The prescription dose for permanent LDR brachytherapy is dependent on the isotope and the indication for the implant, either monotherapy or as a boost. Table 22.3 describes the recommended doses for ^{125}I, ^{103}Pd, and ^{131}Cs when used as monotherapy or when combined with 40 to 50 Gy external beam radiation.[111-113] The prescription dose covers the entire prostate (CTV) and typically includes a margin. The dose for ^{131}Cs is still under investigation.

In the preoperative technique, the dose to the target volume as well as the OAR are evaluated. The source placement with ^{131}Cs is different to ^{125}I and ^{103}Pd, with needles placed further from the urethra and rectum.[112] Good pre-implantation dosimetry and toxicity levels correlate with a V100 >95% of CTV, D90 >100%, V150 ≤50% of CTV, rectum D2 cm^3 <reference prescription dose, D_{max} <150% of reference prescription dose, prostatic

urethra D10<150%, and D30 <130%.[114] Dose limits to structures such as the penile bulb and neurovascular bundles are under investigation.

Postimplant dose reporting in a structured quality assurance program is highly recommended and should include dose parameters to both the target and the OAR.[113,72] Timing of the post implant imaging varies at different centers but ideally should relate to the time at which edema is at a minimum. Evaluation at either day 0 or 30 is most common. Seed localization is crucial as is the contouring of the prostate and normal structures. CT/MRI fusion allows for identification of both the seeds and accurate definition of the prostate, particularly at the apex and base, which tend to be difficult to delineate on CT (Figure 22.8). Primary parameters to report and evaluate include the intended dose, D90, D100, V100, V150 to the prostate gland and rectal volume and dose and urethral doses. For patients with unacceptably cold implants, consideration for reimplantation should be given. There are no dosimetric parameters at present for penile bulb and neurovascular bundles.

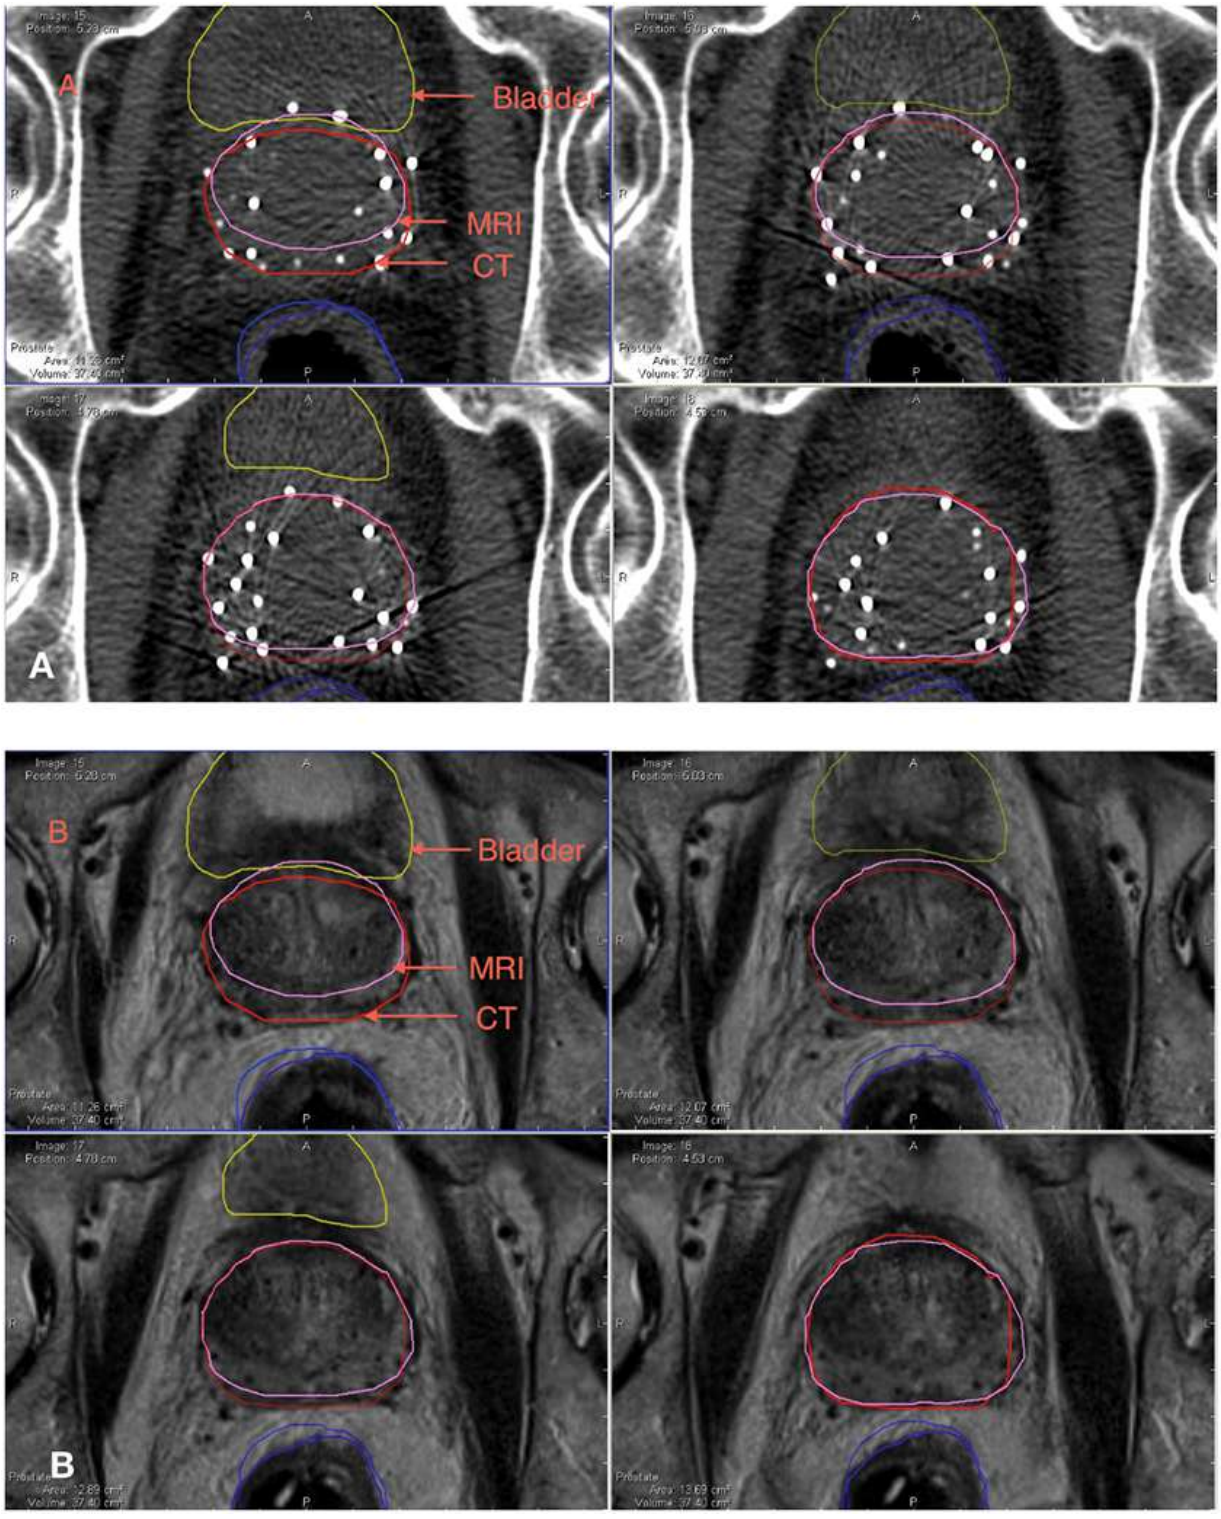

FIGURE 22.8 Prostate brachytherapy post plan with computed tomography and magnetic resonance (CT-MRI) fusion. The prostate volumes were drawn independently on the CT (A) and MRI (B) to show the difference in contours at the base of the prostate. The MRI images are better able to delineate the prostate, whereas the CT scan is better able to give information on the brachytherapy seed location.

Each hollow bore needle has a beveled edge and central stylet. Ultrasound images in both the axial and sagittal views (if available) guide the placement of the needle. Once the first needle is in the correct position (in three-dimensional coordinates), the retraction plane is set for positioning of the remaining needles. To drop the seeds within the prostate, the central stylet is held securely in place, and the outer needle is slowly pulled back along the stylet. On-demand fluoroscopy can be taken to check seed position relative to bony and organ anatomy. Additional seeds may be placed at the end of the procedure as required. Bladder irrigation and cystoscopy can be performed to evacuate migrated seeds in the bladder. Patients are conveniently discharged home the same day of the procedure; the majority of patients do not require a urinary catheter on discharge.

Penis

Penile cancer is rare in Western countries, representing only 1% of male malignancies. Squamous cell carcinoma is the predominant histology. Brachytherapy is used as an organ-sparing technique in T1, T2, and select T3 lesions (<4 cm) that do not involve the shaft of the penis.[115-117] When brachytherapy is compared with surgical treatment for the treatment of penile cancer, brachytherapy appears to be associated with better erectile function scores, and high quality-of-life scores with good satisfaction ratings in cosmetic appearance.[118] Both surface mold techniques (lesions <5 mm)[119,120] and interstitial techniques[121-125] (Figure 22.9) have been described. The 5-year local control with interstitial brachytherapy is 70% to 86% with penile preservation of 72% to 88%. Typical doses range from 50 to 65 Gy delivered in 4 to 7 days. Typically, at least two planes of catheters are required because it is difficult to assess the depth of disease. Crook et al[126] describe their implantation technique in detail for 75 cases implanted between 1989 and 2009 with both ^{192}Ir wire/seeds and PDR techniques. The implants are based on the Paris system using rigid templates with spacing between 12 and 18 mm. Computerized dosimetry mimics the Paris system and allows for visualization of dose to the target and OAR. They prescribed 60 Gy at a dose rate of 0.5 to 0.6 Gy/h with manually afterloaded ^{192}Ir or 0.5 to 0.6 Gy in hourly fractions when using PDR. Treatment takes approximately 5 days.[117] Penile preservation was 88% at 5 years and 67% at

10 years with actuarial survival of 59% at 10 years and cause-specific survival of 83.6%.[122] They reported a soft tissue necrosis rate of 12% and urethral stenosis rate of 9%. The soft tissue necrosis rate quoted in the literature ranges from 12% to 26% and increases with dose greater than 60 Gy, T3 disease, large volume implants (>30 mL), and more than two needle planes.[122-125,127] If conservative measures fail to manage soft tissue necrosis, hyperbaric oxygen therapy has shown success prior to resorting to surgical interventions such as debridement or amputation.[128] Urethral stenosis is reported in 10% to 45%[122-125,129] of cases and relates to the proximity of the needles to the urethra and the number of treatment planes. Achkar et al described PDR interstitial brachytherapy as an organ preservation approach.[130] Sixty-five patients with a median follow-up of 37 months received a median brachytherapy dose of 60 Gy and a median treated volume of 36 cm^3. The median reference dose rate and number of pulses were 0.42 Gy/pulse/h (0.4-0.5 Gy/pulse/h) and 150 pulses (87-175 pulses). Twelve patients (18.4%) relapsed locally (inguinal lymph nodes metastases), with a median time to local failure of 11 months. Six patients (9%) underwent partial surgery and four patients (6%) underwent total penectomy. The 3-year overall survival rate and 3-year disease-free survival (DFS) were 88.2% and 74.4%, respectively. Twelve patients (20%) experienced grade 2 painful ulceration resolving spontaneously, and 13 patients (21.5%) developed grade 2 meatal stenosis needing at least one meatal dilatation. The risk of meatal stenosis was strongly correlated with distal urethra D0.1 cm^3 (p = 0.0016) and D0.2 cm^3 (p = 0.0019) dose parameters in multivariate analysis. The optimal cutoff for these constraints were recommended as 82 and 78 Gy, respectively.

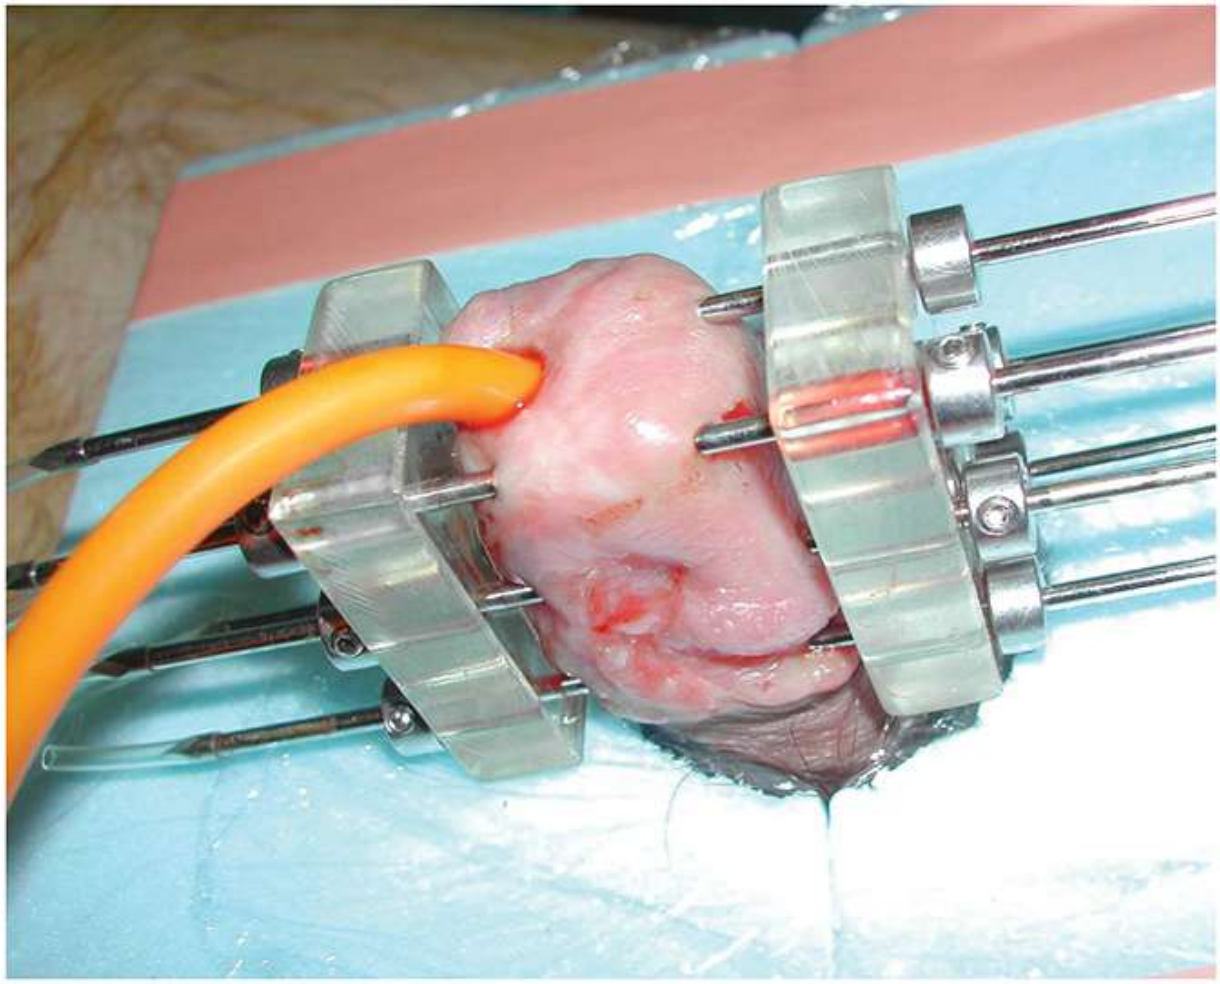

FIGURE 22.9 Low dose rate interstitial multiplane penile implant.

It is recommended that all men undergo circumcision prior to brachytherapy as this exposes the tumor, potentially removes disease allowing for a smaller implant, and decreases the risk of ulceration and necrosis to the foreskin.[124,126] Dose to the urethra and testes should be recorded. In men wishing to retain fertility, lead shielding can be placed around the testes.

Urethra

Brachytherapy may be used in the treatment of both male and female urethral cancers. Paraurethral cancers (PUC) are rare and aggressive, and account for less than 1% of genitourinary cancers. Intraluminal, intracavitary, and interstitial techniques have been described. Intraluminal

brachytherapy is limited to superficial lesions and involves a single catheter into the urethra.[131] Interstitial implants for the penile urethra are like penile implants. In treatment of the female urethra, an interstitial implant may be used in combination with a molded vaginal applicator[131] or alone (Figure 22.10). The dose with LDR as a monotherapy is 60 to 70 Gy in 3 to 5 days (0.5-1 Gy/h PDR) and 20 to 25 Gy, if used as a boost.

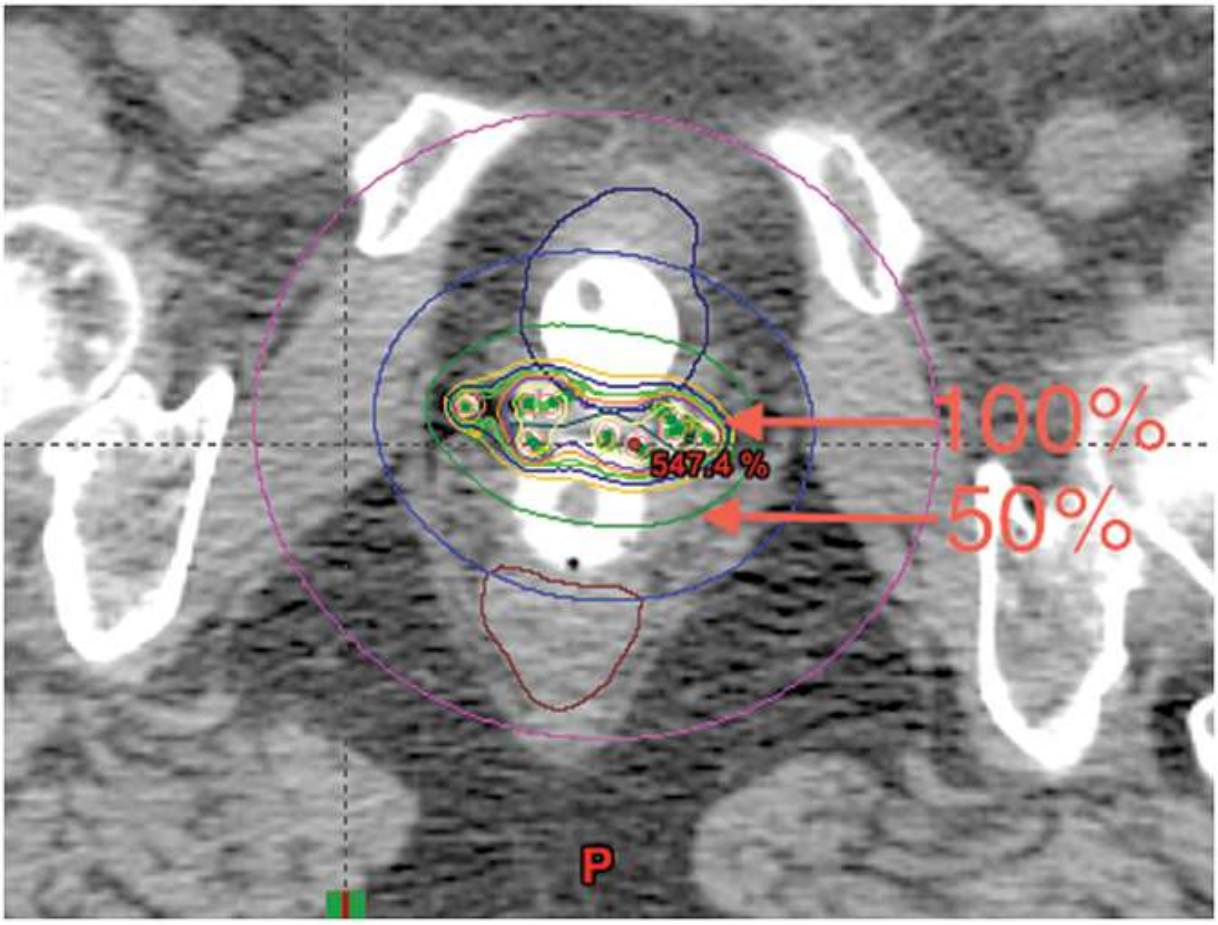

FIGURE 22.10 Low dose rate interstitial multiplanar urethral implant.

PUC may arise from the urethra directly, or from vaginal endometrial or cervical cancers. Andraud et al[132] conducted a retrospective review of 44 patients treated between 1990 and 2018. Of the total patients, 22 had primary PUC and 22 had a recurrence. Fifty percent arose from gynecologic sites (including cervix, uterus, and vulva) and 50% from the urethra. Prior to 2014, treatments were delivered using LDR brachytherapy. Thereafter, treatments were delivered using PDR. The median prescribed dose was 60

Gy for the 24 patients treated with BT alone and 20 Gy for the 20 patients treated with brachytherapy in conjunction with EBRT. Transperineal free-hand interstitial needles were implanted for patients with a tumor thickness of >7 mm. The median follow-up was 21.5 months during which six patients (17.5%) experienced local relapse. The 2 year overall survival probability was 63%. Milosevic et al[133] published their experience of 34 patients treated with radiation. Twenty of these patients received brachytherapy (five brachytherapy alone, 15 EBRT+brachytherapy). The tumors treated with brachytherapy tended to be ≤4 cm, involve the distal urethra, and did not invade adjacent organs. Most of the patients underwent volume implants. Patients who had brachytherapy as part of their treatment had better local control with 7-year local relapse-free rates of 77% versus 32% with EBRT alone. There was no difference in cause-specific survival, and the 7-year actuarial overall survival was 41%. The risk of vesico-vaginal fistula was reported as 15%.

Bladder

Bladder cancer can be treated with radical cystectomy or with chemoradiotherapy for an organ-preserving approach.[134,135] Several studies have shown good results with the addition of brachytherapy to EBRT.[136,137] Aluwini et al[136] reported on 192 patients with muscle invasive bladder cancer who were treated with EBRT followed by surgical exploration (with or without partial cystectomy) and interstitial brachytherapy (LDR or PDR). Salvage cystectomy-free survival at 5 and 10 years was 93% and 85%, respectively. The 5- and 10-year overall survival rates were 65% and 46%, whereas cancer-specific survival at 5 and 10 years was 75% and 67%. The distant metastases-free survival rate was 76% and 69% at 5 and 10 years. Multivariate analysis revealed no independent predictors of local recurrence-free survival. RTOG grade ≥3 late bladder and rectum toxicity were recorded in 11 patients (5.7%) and 2 patients (1%), respectively.

GEC-ESTRO guidelines have recently been published and recommend that EBRT and brachytherapy are reserved for patients with a solitary tumor of <5 cm, T2 to T3, no additional carcinoma in situ, and not located at the bladder neck or prostatic urethra.[138] Radiotherapy doses and schedules vary but a typical schedule is 40 Gy in 20 fractions EBRT followed by 25 to 30

Gy brachytherapy (HDR or PDR). The implant can be sited by open surgery (retropubic approach) or endoscopically (simultaneous laparoscopy and cystoscopy). The catheters are passed through the abdominal wall into the detrusor muscle and out to the opposite side of the abdominal wall.

Head and Neck

Brachytherapy can be used to treat head and neck cancers either as definitive treatment or as a boost following EBRT. Use of brachytherapy may avoid disfiguring or mutilating surgery and allow organ conservation. Brachytherapy can also be used as a method of reirradiation for localized recurrence.[139] There are many years of safety and efficacy data for LDR brachytherapy, and PDR appears to replicate these results.[140-144] Intensity modulated radiotherapy (IMRT) is becoming increasingly standard for head and neck cancer; however, there are indications that delivery of CT-planned optimized brachytherapy continues to deliver superior results over IMRT.[145,146] Plan quality aspects that are important for local control and risk of toxicity are similar to those of other interstitial implants.[147]

GEC-ESTRO have issued consensus recommendations for the use of head and neck brachytherapy[148,149] with a particular focus on dose, treatment selection, and quality assurance in the 2017 update. Data supports the use of both hourly pulses and two-hourly pulses, with a dose of 0.4 Gy per pulse (24 pulses per day) or 0.8 Gy per pulse (12 pulses per day). The overall dose is decreased slightly when using 12 pulses per day, for example, a monotherapy dose for a T1N0 cancer would be 70 Gy using 24 pulses per day and 60 Gy using 12 pulses per day. The ABS have recently updated guidelines for head and neck brachytherapy focusing on treatment selection in the era of advanced EBRT techniques.[150]

Patient selection is key for head and neck brachytherapy. Patients who are unfit for radical surgery may still be poor candidates for brachytherapy. PDR may allow the use of brachytherapy for patients with more complex nursing needs in whom LDR would have been contraindicated. It is important that the patient is fully assessed prior to brachytherapy. Dental assessment is essential, tooth extractions may be required, and for implants encompassing the oral cavity, customized leaded mandibular shields decrease the risk of osteo-radionecrosis. Feeding needs should be assessed

and where necessary, naso-gastric or percutaneous gastrostomy feeding tubes should be placed before the implant. For base of tongue implants, the patient should be prepared to have a tracheostomy, which can be reversed as soon as the postimplant edema subsides. The patient should be assessed regularly during the duration of the implant for displacement of the sources or applicators. Analgesia should be administered and mouthwashes are often helpful.

The majority of head and neck implants are placed in an operative procedure by freehand technique in a multiplane implant (Figures 22.11 and 22.12). These can be sited using a variety of techniques with use of afterloading catheters being preferred in the modern era for radiation safety reasons.[151] Standard applicators such as the Rotterdam applicator, which can be sited under local anesthetic without image guidance, are also available (Figures 22.13 and 22.14). Similar to other sites described later, interstitial ^{125}I seed implants can be used in cases of unresectable disease with favorable rates of control and toxicity.[152-155]

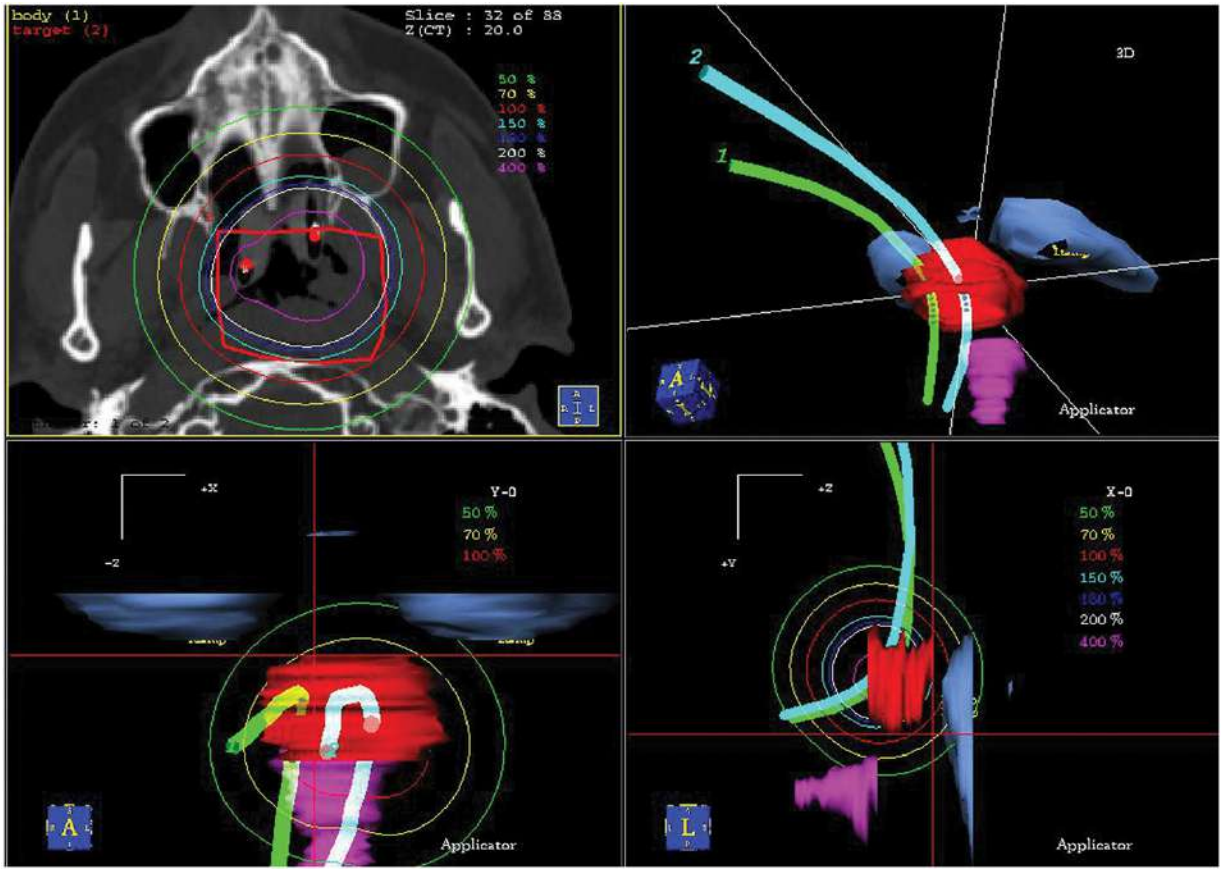

FIGURE 22.14 Three-dimensional dosimetry of the Rotterdam applicator, delivering computer-optimized brachytherapy.

Brachytherapy is indicated in most lip cancers, either as sole modality in tumors 0.5 to 5 cm or as a boost following EBRT in tumors >5 cm. For very superficial tumors, a surface applicator may be appropriate (Figure 22.15), thus preventing scars from puncture wounds. However, most tumors require the placement of two or three interstitial catheters across the tumor (Figure 22.16), which are placed freehand under local anesthetic. Typical doses are 45 to 75 Gy at the 85% reference isodose (higher doses for larger tumors, although at the risk of decreased cosmesis). Five-year local control rates with LDR are 90% to 95%[151,156] and 94% with PDR.[157,158]

FIGURE 22.15 Surface applicator technique used to deliver a boost dose to a lower lip sarcoma following external beam radiation therapy. The wax mouth bite was used to displace the tongue and could be placed for every pulse of the pulsed dose rate.

FIGURE 22.16 Multicatheter single-plane cheek implant. The metal gum shield can be placed for every pulse of the pulsed dose rate.

For oral tongue tumors, brachytherapy offers control rates similar to those of surgery with the benefit of organ and function preservation. Brachytherapy alone can be used for smaller lesions or as a boost for larger lesions. Interstitial implants are preferred, placed under general anesthetic using a metal trocar and threading the afterloading catheters through these. Looped catheters were popular when using ^{192}Ir ribbons, but with optimized PDR, it is difficult for the source to pass into the curved tube; therefore, individual button-ended catheters are preferred for source excursion (Figure 22.17). To prevent a cold spot on the tongue, an extra spacer can maintain the catheter above the tongue or dose optimization can be used, taking care not to cause a localized hot spot. Mandibular shielding is preferred. A dose of 65 Gy is typical as sole treatment and 20 to 25 Gy as a boost.[159] Local

control compares well to surgery with small superficial tumors showing local control rates >90%.[18] When combined with EBRT, a PDR boost for base of tongue tumors gives results at least equivalent to LDR with 5-year local control of 89%.[160]

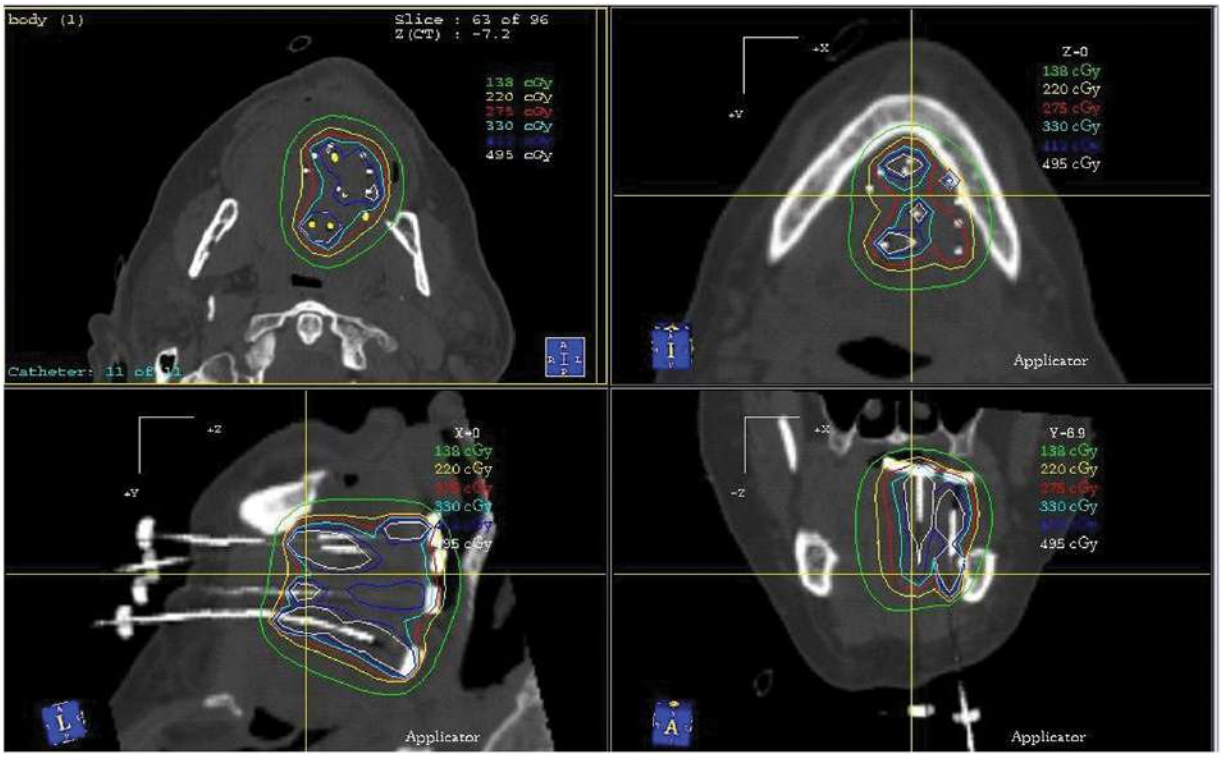

FIGURE 22.17 Three-dimensional computer-optimized dosimetry of a tongue implant using button-ended catheters.

Tumors on the floor of mouth are also best treated with interstitial implants with techniques similar to those of tongue implants. Distance to the mandible is critical to prevent osteo-radionecrosis. It may be preferable to perform surgery with reconstruction rather than risk late sequelae. Elective nodal dissection may be preferable to EBRT in advanced cases.[161] A dose of 65 Gy for sole treatment and 20 to 30 Gy boost is recommended, keeping overall treatment time as short as possible. Control rates range from 50% to 92% depending on tumor size, but bone necrosis is more common than other sites up to 30%.[151,161]

Mattei et al[162] recruited 79 patients with oral cavity squamous cell carcinomas, of whom 38 received LDR brachytherapy and 41 had PDR. All

patients underwent surgical resection of the primary tumor. The mean preoperative tumor size was 20 mm with brachytherapy indicated for patients at high risk of recurrence, who were not suitable for further resection. The median time interval between surgery and brachytherapy was 55 days. The median number of catheters used was four and the median total dose 55 Gy, with a median delivery time of 80 hours and a median dose rate of 0.7 Gy/h. The median follow-up period was 65.1 months. Totally, 15 patients (19%) experienced a local recurrence in the LDR group and 5 (12%) in the PDR group. The 1-, 3-, and 5-year local control rates for the study were 93%, 78%, and 76%, respectively. The 1-, 3-, and 5-year DFS rates were 86%, 63%, and 62%, respectively. Treatment modality had no significant impact on the DFS. In contrast, the presence of LVI (p = 0.055) and an excision margin less than 3 mm (p = 0.058) were approaching statistical significance, with positive excisional margins indicating a clear relevance (p = 0.007).

In a feasibility and safety study of 28 patients undergoing intratumor α radiation-based tumor ablation for oral squamous cell carcinoma termed Diffusing Alpha-emitters Radiation Therapy[163,164] 10 patients had oral squamous cell carcinoma (SCC) and 18 were diagnosed with cutaneous SCC, with a total of 31 lesions. They had a tumor size of ≤5 cm in the largest diameter. Treatment was delivered based on a CT-simulation pretreatment plan. Radium-224 (Ra-224) seeds were used, with each carrying a dose of 2 μCi and placed up to 5 mm apart. CT was used to confirm the position of the radioactive seeds. Two weeks after implantation, the seeds were removed, and 6 weeks after treatment, a CT scan was performed to assess the effect of treatment. Within 6 weeks after insertion of Ra-224 seeds, complete response was observed in 22 lesions (78.6%), and partial response in six lesions (21.4%). Five of the 22 complete response lesions relapsed at a median of 4.9 months. The 1-year local progression-free survival probability was 60%, and overall survival rate was 93% among complete responders.

Oropharyngeal cancers traditionally present at an advanced stage due to their location in an area that is not visible with few pain fibers. Surgery can be very debilitating; therefore, EBRT and localized boost techniques are favored. A boost of 20 to 30 Gy is delivered using an interstitial implant. The implant is performed under general anesthetic with nasal intubation,

and a covering tracheostomy is usually required. Hemorrhage may occur in implant removal, so it is important to remove the catheters under controlled conditions with wide bore venous access, suction, and surgical support.

Most nasopharyngeal tumors are inoperable due to their position at the base of the skull. However, the nasopharynx is easily accessible to brachytherapy catheters. These can be placed under topical anesthetic (eg, the Rotterdam applicator) or under direct vision using a Le Fort osteotomy. The main role of brachytherapy is as a localized boost or as a sole reirradiation technique, with typical doses of 12 to 20 Gy and 60 Gy, respectively. Local control is excellent even in reirradiation where control rates of at least 50% are reported.[151]

Brachytherapy is particularly suitable for reirradiation of head and neck cancer, administered with curative intent. A series of 104 patients with recurrent head and neck cancer were treated with brachytherapy alone (81) or with a brachytherapy boost (23), often with concomitant chemotherapy (56%) or hyperthermia (32%). At a median follow-up of 60 months, the 5-year local control was 82%, with acceptable rates of late toxicity, requiring surgery for toxicity in only 3% of cases.[165]

Thorax

Intraoperative permanent radioactive ^{125}I seed implantation can be used in the treatment of malignant thoracic tumors when resection margins are close or macroscopically or microscopically involved with tumor[166-181] or for palliation of inoperable disease.[182] The surgeon selects patients preoperatively when there is a concern of incomplete tumor resection or close or positive margins and refers to the brachytherapist. The patient consents in advance for a permanent implant to be placed intraoperatively, if required. Details of previous radiotherapy and chemotherapy treatment are carefully reviewed prior to surgery. The brachytherapy team is on call for the surgical procedure. Frozen section analysis of margins may be needed to assess whether an implant is needed. Seeds are placed directly into a tumor as a volume implant or woven in a grid pattern in a planar implant. Volume implants require the use of an applicator or preloaded needles to deliver the seeds directly to the tumor. A planar implant can be ordered readymade in advance (Figure 22.18) or custom made

intraoperatively[183] (Figure 22.19). I^{125} seeds set into Vicryl suture with 1-cm spacing between seeds can be woven into a mesh or sutured directly to the area at risk. The Vicryl suture and accompanying mesh degrade naturally after approximately 60 days; at this point, much of the dose has been delivered, and the seeds are often held in position by local fibrotic reactions. The mesh can be used in open surgery, thoracoscopically or utilizing a robotic system.[184] Seeds can be placed at equally spaced intervals into a layer of foam,[173,185] but this implant may be more difficult to suture in place, as the seeds are not easily visible and are therefore at risk of being displaced or damaged by the suture needle. Alternative seed-placement devices may aid seed placement such as the customized suture gun (Figure 22.20). Radiation exposure during the procedure to the implanting radiation oncologist and surgeon is very low[186] and well within occupational radiation exposure guidelines. When the implant has been sited, the operating room is surveyed for the presence of radiation. The patient is surveyed at the outer body surface over the implant, at 0.5 m and 1 m. In the immediate postoperative period, no change in patient care is required, subject to standard post-vLDR implant precautions of preventing exposure to children or pregnant women.[187]

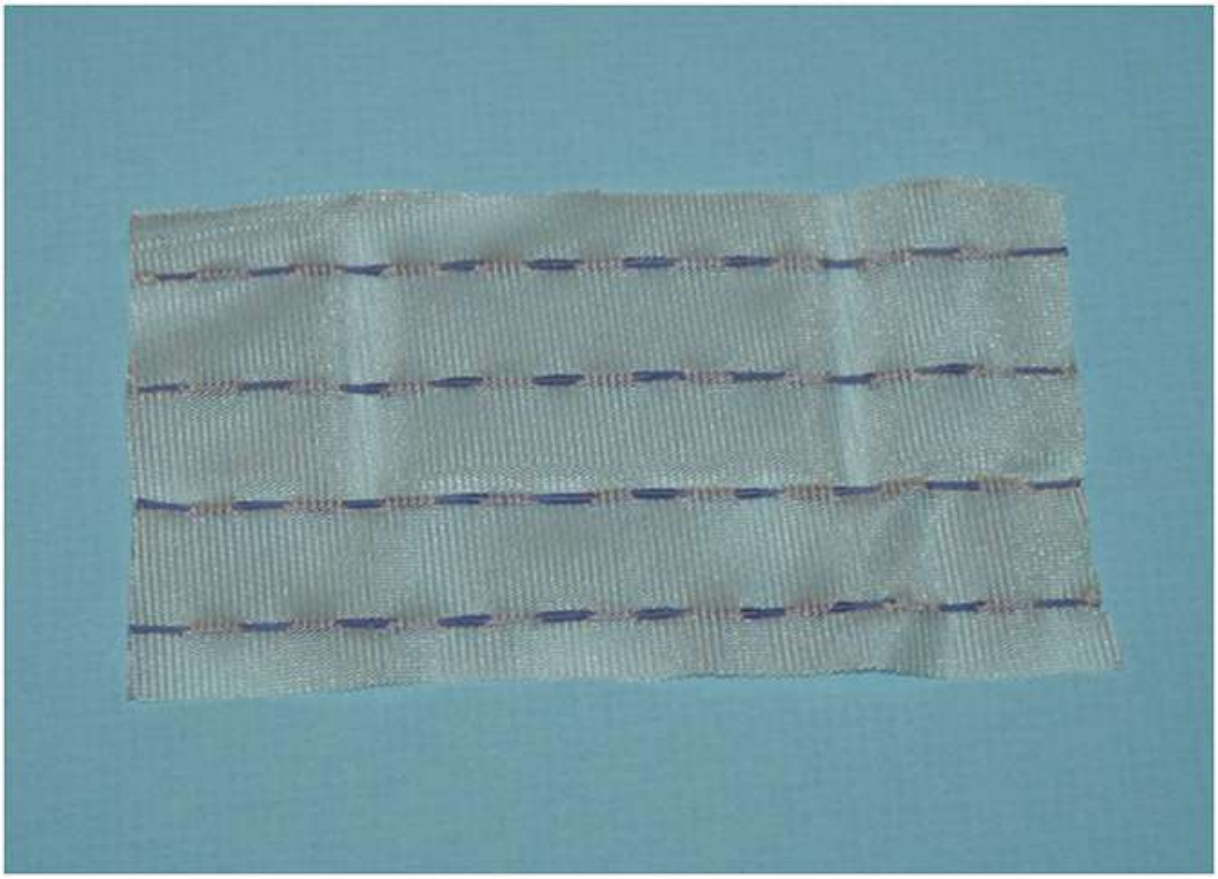

FIGURE 22.18 Premade seed mesh.

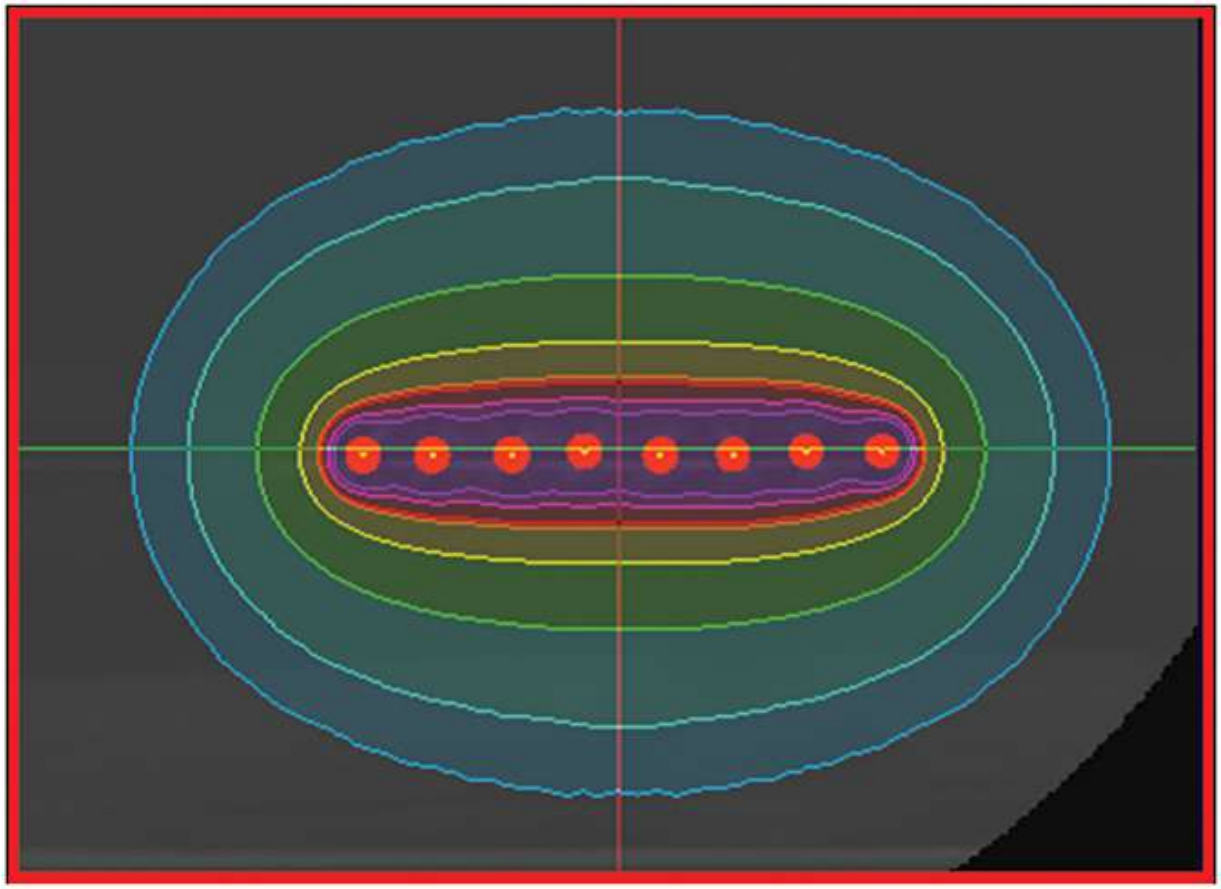
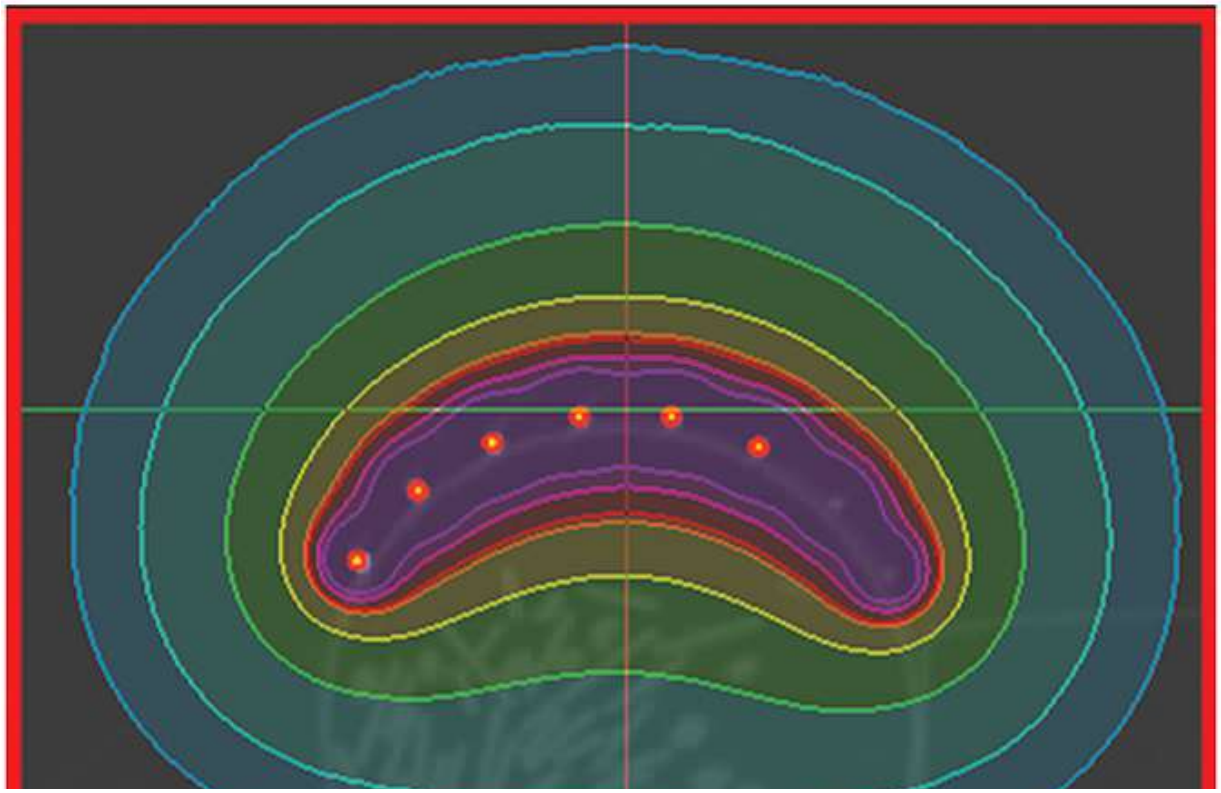
FIGURE 22.20 Seed staple gun.

For sublobar resection, the dose recommended is 100 Gy, at 5 mm from the mesh or 7 mm from the central axis of the implant. For incomplete resection of tumor/positive margins, the dose chosen will depend on many factors such as adjacent structures or previous radiation; the type of surgery performed must also be considered in case there is an increased risk of late

normal tissue toxicity.[188] The curvature of the implant should also be assessed because over a curved surface, dose penetration is asymmetric compared to a linear implant.[189] Isodoses on the concave side of a curvature are further from the implant surface potentially decreasing the dose delivered. The asymmetry increases with decreasing radii of curvature (Figure 22.21). Interestingly, in vitro studies have shown that selected human lung cancer cell lines show a sensitivity to ^{125}I seed brachytherapy greater than HDR irradiation, an effect that was further potentiated with the use of radiosensitizers.[190]





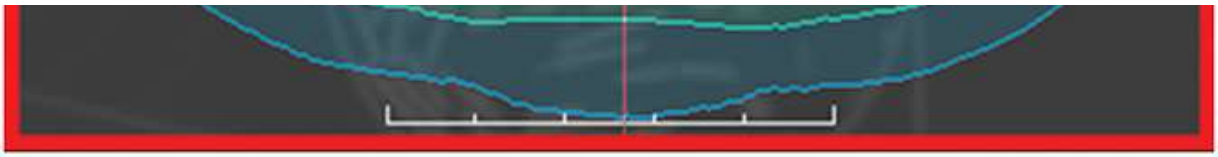


FIGURE 22.21 Effect of curvature on the dosimetry of a single planar mesh seed implant.

Lobectomy is the standard of care for patients with operable Stage I NSCLC; however, intraoperative ^{125}I seed placement has been used in conjunction with sublobar resection in patients with lung cancer who are medically unfit for lobar resection.[171,174,175,177-181] Retrospective studies showed that patients undergoing sublobar resection had similar rates of disease-free and overall survival but that patterns of relapse differed with higher rates of local recurrence in the sublobar resection group.[191] Thus, intraoperative permanent seed implant brachytherapy was evaluated in a multi- institution randomized phase III prospective trial by the American College of Surgeons Oncology Group (ACOSOG) Z4032.[192,193] This demonstrated that there was no difference in 5-year local recurrence with the addition of brachytherapy (17% with brachytherapy vs 14% without, $P = 0.59$). There was no difference in disease-free or overall survival. There was a trend toward favoring brachytherapy in patients with positive staple line cytology. Better than expected rates of negative margins were achieved, so the trial may have been underpowered to detect a small difference. Therefore, the ABS consensus recommendations do not recommend this outside the confines of a clinical trial.[194]

For intrathoracic tumors with incomplete resection or microscopic close margins, retrospective and prospective series have shown disease-free and overall survival rates, with the addition of an intraoperative permanent seed implant are improved over those that would be expected with incomplete resection alone[166-169,172] (Figure 22.22). Radioactive seed implantation (RSI)-BT can be used in early lung cancer in patients who cannot have surgery or tolerate EBRT or are unresectable (stages III/IV), with a PD between 100 and 120 Gy and local control rates between 80% and 100%.[195] The 1-year survival rates were documented as 90% to 95% and 2-year survival rates as 70% to 80%. Li et al treated 12 patients with RSI-BT in the inoperable setting and found that the local control rate achieved by RSI-BT was 97%, 67%, and 42% at 6, 12, and 24 months, respectively.[196] However, primary

image–guided RSI-BT is not routinely recommended for lung cancer patients unless there are no other treatment options, and more comparative data is required. For recurrent lung cancer after surgical resection, image-guided RSI-BT can be considered as palliation and may be applied in the majority of cases involving recurrent tumors in the chest, including lesions in the lung parenchyma and tumors that metastasize to the mediastinum, chest wall, vertebral body, and lymph nodes. Platinum-based chemotherapy with concurrent BT was investigated by Rezaei et al.[197] The use of conventional platinum-based drugs did not change the lung absorbed dose, while unconventional platinum-based drugs led to >2% dose changes when the platinum concentration exceeded 0.2 mg/g of lung tissue. This approach needs to be further investigated to clarify the usefulness of concurrent chemo-BT in lung cancer patients.

Breast

Breast-conserving surgery is a proven alternative to mastectomy in patients with early-stage breast cancer, offering equivalent disease-free and overall survival.[198-200] Adjuvant radiotherapy is required since it results in a significant reduction in the risk of death due to breast cancer; unfortunately, this is offset by an increase in deaths due to other causes.[200] In the nonirradiated breast, recurrences tend to occur in the tumor bed with an elsewhere recurrence rate of up to 3.5%.[198,199,201,202] Accelerated partial breast irradiation (APBI) has similar ipsilateral breast recurrence and survival rates to whole breast IMRT but lower acute and late toxicities and better cosmetic outcome.[203] APBI can be delivered with brachytherapy, localized radiotherapy, or intraoperatively with electrons[204] or photons.[205]

Postoperative APBI using brachytherapy was initially developed using interstitial implants. A number of needles or tubes are placed across the tumor bed usually under a general anesthetic, either using a template or freehand (Figures 22.23 and 22.24). The treatment volume is generally the tumor cavity and a 1- to 2-cm margin. The dose is custom-shaped to this treatment volume. The dose can be delivered using LDR or PDR brachytherapy, typically over 4 to 5 days. The large number of catheters in an interstitial implant allows more control over skin and chest wall doses than single catheter techniques, especially with PDR dose optimization. The dose within the tumor is more homogenous with lots of smaller hot-spots, compared to one large hot-spot with single catheter techniques.[206] Single catheter technique for left-sided tumors has also been shown to have a higher mean heart dose than deep inspiration breath hold whole breast radiotherapy,[207] whereas this is less likely to happen with multicatheter brachytherapy.

Interstitial implants have been in use for over 10 years. Phase 3 trials have shown that PDR or HDR APBI is noninferior to whole breast radiotherapy with respect to 5-year local control, disease-free, and overall survival in low-risk invasive or ductal carcinoma in situ.[208] Early toxicity was dramatically reduced in the brachytherapy APBI arm (86% vs 21%) for grades 1 to 2 early skin toxicity.[209] The 5-year toxicity and cosmetic outcomes were similar between the groups, although grade 2 to 3 late skin toxicity was significantly reduced in the brachytherapy arm.[210] APBI with LDR, PDR, or HDR brachytherapy after lumpectomy is also an option for patients with ipsilateral local recurrence with an overall survival rate equivalent to salvage mastectomy.[211]

Permanent interstitial seed implant has been described for APBI[212] (Figure 22.25). ^{103}Pd seeds were implanted using ultrasound guidance and a dose of 90 Gy prescribed to the tumor cavity and a 1.5-cm margin. In a group of 134 patients from 3 clinical trials, the observed local recurrence rate was 1.2% at 63 months, which is similar to the estimate for whole breast irradiation. Toxicity rates were acceptable. A radiobiologic dosimetric modeling study predicts that for APBI using brachytherapy, toxicity will be lower for a seed implant than for a multicatheter interstitial technique.[213]

Sarcoma

Soft tissue sarcomas (STSs) remain a challenge, given their rarity, multiple sites of origin, numerous histologies, and proximity to OARs. In the modern era, sarcoma surgery has become more refined moving away from disfiguring, disabling surgery and toward a multidisciplinary approach combining surgery and EBRT and, in certain tumors, chemotherapy.[214,215] Radiation therapy is an essential part of the treatment for most types of STSs. EBRT in the form of IMRT or volumetric modulated arc therapy

remains the main radiation technique for the treatment of STS. This can be given postoperatively or as a neo-adjuvant therapy with small fields required and lower doses. However, brachytherapy remains an important and versatile treatment option for STS of all organ sites. Temporary LDR implants were commonly used in the past; in general, these have been replaced by HDR and PDR. LDR interstitial implants have been described, and more recently, the use of a palladium-103 implant has shown promising results.[216] The American Brachytherapy Society recently updated their consensus recommendations for the use of brachytherapy in patients with STS.[217] Table 22.4 presents a summary of the general principles for STS brachytherapy. PDR BT can be used as monotherapy or a boost after EBRT. When delivered as monotherapy, the recommended dose is 45 to 50 Gy over 4 to 6 days, at 0.35 to 0.6 Gy/h. As a boost, the recommended LDR/PDR dose is 15 to 25 Gy, over 2 to 4 days, at 0.35 to 0.6 Gy/h. A brachytherapy boost can be considered in larger tumors, close surgical margins, and in high-risk cases such as local recurrence without previous radiotherapy, positive margins, challenging locations, and an inability to meet OAR constraints with EBRT alone. Brachytherapy catheters are usually placed at the time of initial resection using either a single-entry sealed-end catheter (Figure 22.26) or double-entry button-ended catheters and after-loaded 5 days postoperatively, enabling the whole STS treatment to be completed within 10 to 14 days. Placement under direct vision allows accurate coverage of the resection cavity. There may be less hypoxia immediately postoperatively, enabling the radiotherapy to be more effective. The catheter is secured with plastic buttons, which do not produce artifacts in CT or MRI scanning. The CTV is the tumor bed and a margin of 2 cm craniocaudally and 1 to 2 cm laterally.[218]

TABLE 22.4 GENERAL RECOMMENDATIONS FOR SOFT TISSUE SARCOMA BRACHYTHERAPY (INCORPORATING AMERICAN BRACHYTHERAPY SOCIETY GUIDELINES)[217,219]

- Discuss patient preoperatively in a multidisciplinary setting
- Determine CTV by radiographic, surgical, and pathologic findings
- Place catheters to encompass CTV, demarcate CTV with surgical clips, if possible
- Identify and demarcate normal structures that are at risk for complications
- Cover tenuous wounds with well-vascularized flaps

- Place microvascular anastomoses away from radiation target area
- Use drains over catheters to act as a spacer to increase the distance of the wound from the implant
- Use spacers (eg, Gelfoam) to increase the distance between catheters and critical normal structures
- Ensure catheters enter skin at least 1 cm from surgical incision
- Space catheters at 1- to 1.5-cm intervals in parallel arrays
- Secure catheters carefully, immobilizing extremity, if necessary
- Use CT to determine the CTV and organs at risk
- Do not load catheters until after the fifth day postoperatively

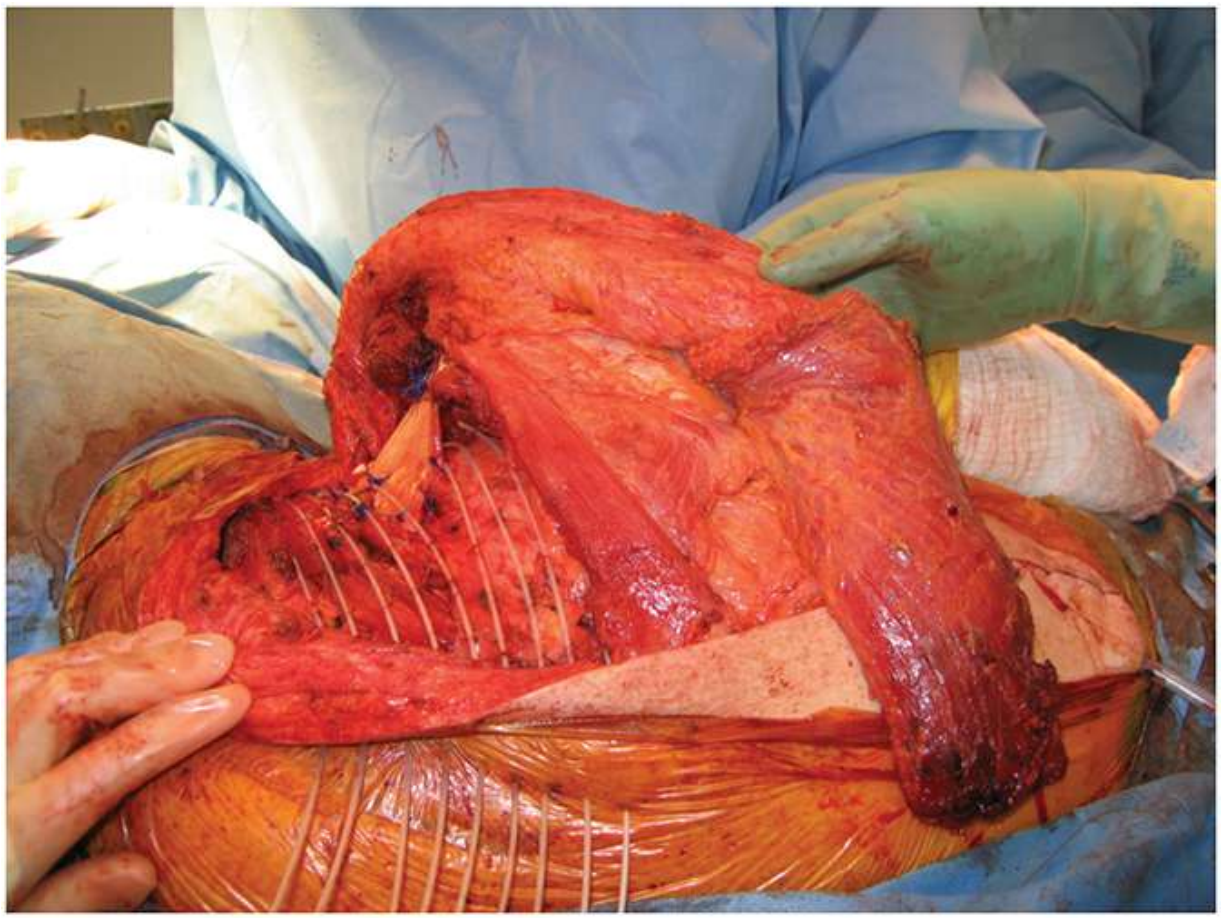

FIGURE 22.26 Intraoperative photograph of a multicatheter interstitial pulsed dose rate brachytherapy implant following excision of a sarcoma of the upper back.

Phase 2 trials showed the utility of LDR brachytherapy for postoperative STS treatment[169,220] and therefore, a randomized phase 3 trial was

conducted.[221] One hundred and seventeen patients were randomized to brachytherapy or no brachytherapy following R0 or R1 resection; patients were stratified by various factors including size and grade. The 5-year actuarial local control for all patients was 82% versus 69% (p = 0.04), but on subgroup analysis, no effect was seen in the patients with low grade tumors. With longer follow-up of the high-grade tumors only, local control was 89% versus 66% (p = 0.0025), but no effect was seen on distant metastases or overall survival. Functional parameters were well maintained post brachytherapy. PDR brachytherapy has been used in adults and children, either as a boost (for large tumors where compartmental surgery proved difficult) or as radical treatment.[222-224] Studies report excellent local control with good cosmetic results and acceptable toxicity, comparable to results achieved with LDR. However, a retrospective study of adjuvant LDR brachytherapy to pre- or postoperative IMRT in primary extremity sarcoma showed 5-year local control with IMRT to be better than brachytherapy (92% vs 81% P =.04). This is despite the fact that the IMRT group had significantly higher rates of adverse features (eg, tumors sized over 10 cm and with close or positive surgical margins).

Superficial Sites

Brachytherapy surface applicators can be used to treat a variety of superficial targets using LDR or PDR. For curved or irregular surfaces or thicker lesions, a customized mold can be constructed, often using an acrylic or thermoplastic cast (Figure 22.27) or a customized three-dimensional printed mold. The brachytherapy catheters can be laid directly onto the mold or used with a spacer to ensure uniform catheter distribution. When used with computerized optimization, this surface applicator technique has been shown to give dose distributions that are more homogeneous than conventional electron techniques.[225] A survey of members of ABS showed that many respondents preferred brachytherapy over EBRT due to shorter overall treatment times, conformality of treatment for irregularly shaped targets, and shallow dose deposition.[226] PDR carries the benefit of dose optimization, which allows the treatment depth to vary along different points of an individual catheter for lesions of varying thicknesses. Suitable superficial targets can also be treated with interstitial

implants, which can give greater penetration of dose beneath the skin surface.

FIGURE 22.27 Surface applicator mold used to administer brachytherapy to the dorsum of the foot following incomplete excision of an STS.

Surface applicator techniques have been used to treat primary tumors in both the radical and the palliative settings. A meta-analysis has shown that radiotherapy following surgery yields a lower keloid recurrence rate compared to radiotherapy alone and that brachytherapy had the lowest recurrence rate when comparing radiotherapy modalities (15% for brachytherapy compared to 23% for photons and 23% for electrons).[227] There does not appear to be a difference in recurrence rate between LDR and HDR.[228]

Surface applicator brachytherapy techniques have been used to treat locally recurrent breast cancer following previous chest wall irradiation. Using LDR ^{192}Ir implanted into flexible silicone sheets delivered in 2 to 3 fractions at monthly intervals to administer a total dose of 65 Gy 2 to 4 mm below the skin surface, Delanian et al[229] showed a complete regression of tumor in 9/11 patients. The two patients who did not respond died from pulmonary lymphangitis 4 and 5 months after brachytherapy. One patient developed a necrotic ulcer in the skin, which healed after 8 weeks of symptomatic treatment. One patient died from respiratory failure, which may have been related to cumulative pulmonary toxicity and must be considered as a treatment complication. Some patients also received interstitial implants in the chest wall, which would have increased the dose at depth to the previously irradiated tissue and to the underlying lung.

Harms et al used PDR brachytherapy and flexible rubber surface applicator molds in 58 patients with local recurrence of breast cancer who had received previous breast or chest wall EBRT. A median dose of 40 Gy to the skin surface in two fractions was administered at a median time interval of 31 days.[230] The local recurrence-free survival at 1 year was 96% for patients with microscopic disease at the time of brachytherapy and 89% for patients with macroscopic disease, 75% and 71%, respectively, at 3 years. Seven percentage of patients developed chronic ulcer, of whom two had undergone surgical treatment prior to reirradiation, and 50% of patients developed grade 3 telangiectasia in the treatment field. The skin toxicity was higher in this study, but this may have been a result of improved reporting of skin complications since the incidence of telangiectasia and fibrosis was not reported in the LDR study. A prospective cohort study recruited patients with unresectable malignant skin or soft tissue tumors.[231] Ten patients underwent DaRT to deliver a physical dose of 10 Gy to the

tumor (equivalent dose of 200 Cobalt Gy Equivalent). At 12 weeks following treatment, there was a 100% complete response rate. Nine of the 10 complete responses (90%) were confirmed by CT imaging. This suggests the feasibility of DaRT in unresectable skin and soft tissue cancers.

Eye

Ophthalmic brachytherapy applicators can be applied directly to the eye to deliver a highly localized dose with rapid falloff (Figure 22.28). These deliver dose to the conjunctiva of the eye, most commonly for malignant tumors of the conjunctiva such as squamous carcinoma, melanoma, and lymphoma or to prevent recurrence of pterygium following surgical excision. ^{125}I seeds are inserted into plaques formed of a silicone rubber inner seed holder with a gold exterior shield and are then sutured to the sclera. ^{90}Sr and ^{106}Ru are manufactured as curved applicators, and ^{90}Sr as a fixed-diameter applicator (typically 12 mm) (Figure 22.29), and ^{106}Ru in a range of diameters. The eye is anesthetized with installation of local anesthetic eye drops. The applicator is soaked in an antiseptic solution, followed by double-rinsing in sterile saline. Sterile lubricant is then applied to the active surface of the applicator to lessen trauma to the cornea and sclera. The applicator is then gently applied over the area of bare sclera, adjacent limbus, and affected cornea and held in place by the operator for short applications or sutured to the sclera for longer applications. Undue pressure must be avoided, as this increases trauma and reduces the distance from the applicator to the lens, which is the dose limiting normal tissue. If necessary, two treated fields can be overlapped if the area to be treated exceeds that of the active surface of the applicator—though this, inevitably, carries a risk of increased acute and chronic sequelae. After treatment, the patient wears an eye patch for 2 hours until the local anesthetic wears off. Some degree of conjunctivitis is common and, if mild, can be treated with antibiotic eye drops. If moderate to severe, a steroid-containing eye drop should be used. Long-term sequelae are unusual but more likely with a higher fraction size and a higher total dose. Scleral ulceration is the most common early complication in doses up to 52 Gy, with occasional development of symblepharon-fusion of the eyelid to the globe. Surgical trauma also plays a part in these sequelae. The most common late side

effect of ocular brachytherapy is the formation of cataracts.[232] The frequency ranges from 4.2% to 53.8% for ruthenium plaques and from 2% to 82% for iodine plaques. The incidence of radiation retinopathy and maculopathy is 10% to 63% and 13% to 52%, respectively, with a mean time of 25.6 months from treatment to maculopathy development. After treatment, tumor necrosis can cause retinal ischemia, leading to secondary neovascular glaucoma. The risk of this after iodine brachytherapy ranges from 4% to 45%, and the risk increases with time. Papillopathy secondary to optic nerve damage from ionizing radiation is rare with a documented range of 0% to 16%, and a median time to its occurrence is 22 months. Scleral necrosis is extremely rare (1%-2%). The main risk factors identified were location of the anterior tumor margin, tumor thickness >6 mm, and radiation dose >400 Gy to the external sclera.

FIGURE 22.29 Strontium ophthalmic applicator.

The Collaborative Ocular Melanoma Study (COMS) group conducted two randomized trials in North America, examining the use of ^{125}I for choroidal melanoma. The study examining the use of ^{125}I brachytherapy versus enucleation for tumors of 3- to 8-mm depth demonstrated no difference in survival and similar rates of toxicity[233,234] for the two techniques, thus supporting the use of ^{125}I. A SEER database analysis has shown similar survival outcomes for plaque brachytherapy compared to EBRT for choroidal melanoma.[235]

The use of palladium-103 and cesium-131 seeds has also been investigated with promising dosimetric results.[236,237] In fact, ^{103}Pd has efficacy similar to that of ^{125}I, but patients have an improved visual acuity following treatment with ^{103}Pd.[238] Modern dosimetry planning is being employed to investigate whether side effects may be lessened with optimal planning techniques.[237,239,240] Planning can be challenging, and rhuthenium-

106 plaques are MRI incompatible and create significant metal artifacts on conventional CT scans. Dual energy CT scans (DECT) may be used therefore to suppress these artifacts. A study by Detorakis et al[241] examined the possibility of creating fusion images from the preoperative MRI and postoperative (plaque in place) DECT scans, as a tool in confirming the anatomic placement of the plaque. They treated six patients with intraocular lesions, five with choroidal melanoma, and one with a retinal vasoproliferative lesion. The findings indicated that the elevation from the posterior plaque edge was slightly higher for anterior lesions, but overall the fusion images can be used to accurately confirm the plaque placement in relation to intraocular tumors in ophthalmic brachytherapy.

Strictly speaking, ^{90}Sr delivers HDR brachytherapy (a β emitter with a typical dose rate of 100 Gy/h compared to ^{125}I, a γ emitter with a dose rate of 0.5-1 Gy/h). Thus, ^{90}Sr delivers a single-fraction treatment dose over 2 to 3 hours, whereas ^{125}I delivers a treatment dose over 30 to 300 hours. The percentage depth dose in tissue falls from 100% at the surface to 4% at 4 mm, 1% at 6.5 mm, and 0.9% at 8 mm (corresponding to the anterior surface of the lens, equator, and posterior surface of the lens, respectively). Van Ginderdeuren et al[242] demonstrated a 90% 15-year-tumor control for sclera melanoma using an ^{90}Sr applicator with a proportion of the recurrences at the edges possibly due to the small applicator size, using doses of 450 to 800 Gy at the sclera. There was a 45% preservation of good vision, which was generally dependent on tumor position rather than on dose delivered. Ruthenium-106 eye plaques can also be used and may become the β emitter of choice, as ^{90}Sr eye plaques gradually decay beyond useful dose delivery. They deliver results similar to those of ^{90}Sr and have even been used with thermotherapy to deliver improved outcomes.[243,244]

Pterygium is a benign proliferation of the conjunctiva over the cornea, occurring most commonly in areas with high sun exposure. Surgery can be performed for irritative symptoms and effects on vision or cosmesis, but it carries a high recurrence rate. Locally applied ^{90}Sr has been used to decrease the rate of recurrence to as low as 0.5%,[245] using doses varying from 20 to 60 Gy in one to six fractions. The incidence of sclera complications is lower with fractionated treatment (4.5% vs 1%). However, alternative treatments such as topical chemotherapy and conjunctival autografting are replacing ophthalmic plaque brachytherapy.[246,247]

Brachytherapy should not be combined with topical chemotherapy due to the risk of scleral melting.

^{90}Sr has been used in the treatment of neovascular age- related macular degeneration (AMD), visual impairment caused by neovascularization beneath the retinal pigment of the retina. However, a phase 3 trial comparing patients with active AMD who were already on a vascular endothelial growth factor (VEGF) inhibitor to either vitrectomy followed by 24 Gy brachytherapy (and continuing prn anti-VEGF treatment) or to anti-VEGF treatment on an as-required basis alone showed that visual acuity and disease activity were actually better in the as-required anti-VEGF arm.[248]

Anus

Squamous cell carcinoma of the anus is a rare cancer usually treated with chemo-radiotherapy with good rates of sphincter preservation. The most common site of relapse is locally and, thus, methods of local dose escalation have been explored. EBRT, preferably with chemotherapy, is necessary to treat the tumor and wider nodal area and then the tumor boost can be delivered using brachytherapy.[249] Interstitial brachytherapy implants typically consist of a single plane catheter implant using a plastic perineal template curved around the anus. Catheter placement may be optimized by the use of advanced imaging techniques such as three-dimensional endoluminal ultrasound.[250,251] Papillon[252] described an LDR boost using ^{192}Ir to deliver 20 to 30 Gy in 221 patients two months after completing EBRT. Local control rates were comparable to surgical techniques, and 90% of the patients with no evidence of relapse remained colostomy-free. It has been suggested that when using a split course technique, if treatment time is extended over 80 days, a brachytherapy boost may provide better local control than EBRT.[253] PDR techniques have been described with rates of disease control and toxicity similar to those of LDR.[254-256]

Rectum

A retrospective analysis described 13 patients with colorectal cancer with pelvic or retroperitoneal recurrences, who underwent 18 minimally invasive CT-guided LDR brachytherapy implants—17 for pelvic recurrences and one

for a retrocaval nodal recurrence—with a median follow-up time of 17 months.[257] All patients were previously treated for either locally advanced (eight patients) or limited metastatic disease (five patients), four were treated for isolated pelvic recurrences, and 13 for oligo-progressive or oligorecurrent metastatic disease. Patients underwent dose calculation based on preimplantation CT imaging and contouring of gross tumor volume (GTV), followed by CT-guided percutaneous interstitial needle placement of either iodine-125 or palladium-103 permanent seed implants prescribed to the GTV. The median dose prescribed to the target volume was 80 Gy, with a median target volume of 5.0 cm^3 (range 0.6-25.5 cm^3). The 1-year estimated rates of overall survival and in-field control were 94.4% and 82.4%, respectively. All in-field failures occurred in targets above the median target volume of 5 mL. None of the patients experienced grade 2 or higher toxicities.

Esophagus

Esophageal brachytherapy is very useful in T1-T2 inoperable tumors, as palliation for dysphagia, as a boost prior to chemoradiotherapy, to achieve further downsizing post chemoradiotherapy, to control local relapse after primary chemoradiotherapy, and to avoid reobliteration of a stent. In general, HDR brachytherapy is the preferred modality. A phase 3 randomized trial of conventional stents versus stents loaded with ^{125}I seeds showed that median overall survival was increased in the irradiation stent arm compared to that in the conventional stent arm, but side effects were similar.[258]

Biliary Tract

Intraluminal biliary brachytherapy can be given with both curative and palliative intent. If the intention is curative, this is given after chemoradiotherapy to escalate the tumor dose.[259] The main indication in the palliative setting is to alleviate biliary obstruction. As with esophageal cancer, catheter-based HDR is the most used brachytherapy modality. When PDR is used in combination with EBRT, it is prescribed as a single dose of 20 or 40 Gy in two fractions. Stent insertion with insertion of I^{125} seeds for

malignant obstructive jaundice has been shown to increase the mean stent patency time (191 vs 88 days) and the median survival (241 vs 142 days).[260]

Central Nervous System

Although initial treatment for glioblastoma has improved over the past decade, most glioblastomas recur, with the majority of these were found within 2 cm of the original tumor cavity. Since most patients will have received 60 Gy to the tumor at the time of initial diagnosis, retreatment techniques may be limited; ^{125}I seeds can be used to deliver a conformal dose of reirradiation. At the time of recurrence, the surgeon will perform the maximal resection possible and implant ^{125}I seeds in the excision cavity at 0.5 to 1 cm intervals. This gives a highly localized boost, assuming the volume of disease residual is small since the dose falloff is rapid. The procedure appears to be well tolerated, and survival compares favorably to similar patients who did not receive brachytherapy.[238,261,262] The use of ^{125}I seeds at the time of initial radiotherapy has been investigated, but no difference was seen in randomized trials.[263,264] Thus, if a boost is required, this technique has generally been supplanted by stereotactic radiosurgery, which does not require a second invasive surgical procedure. Gliasite balloon brachytherapy (GBST) is a past technique no longer in use where a balloon is sited in the resection cavity and liquid ^{125}I is injected through a subcutaneous port for either primary or recurrent glioblastoma.[265] Results appear favorable.

^{125}I seed placement has also been described in patients with paraspinal tumors with a low rate of toxicity and good local control rates.[170,176] The procedure was well tolerated, and no myelitis was seen despite cumulative cord doses of up to 167 Gy.

Customized yttrium-90 dural plaques have been used intraoperatively in patients with spinal or paraspinal sarcomas to deliver a high localized dose to the dura while minimizing the dose delivered to the underlying spinal cord (Figure 22.30). Local control rates are promising, and there were no acute or late complications from brachytherapy.[266]

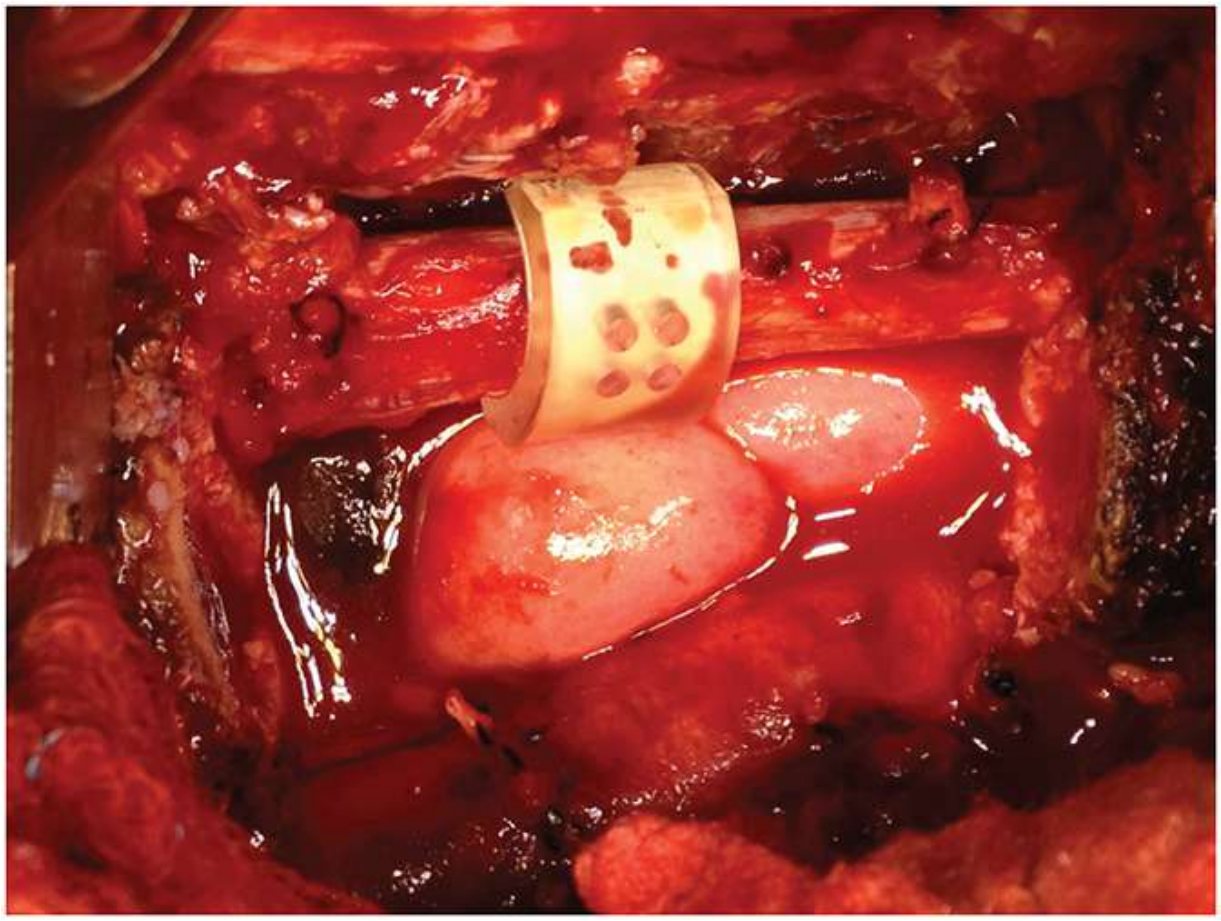

FIGURE 22.30 A dural plaque utilizes phosphorus-32 chemically bonded to a flexible polymeric film. The film is 0.5-mm thick and is backed by 4.5 mm of polycarbonate. Typical dose rates at time of treatment are in the 1.5- to 2.5-Gy/min range.

Cs-131 has gained a lot of interest in the brachytherapy treatment of newly diagnosed brain metastases as well as recurrent metastases of >3 cm.[267] It has a short half-life (9.6 days) and a higher dose rate (0.342 Gy/h) than I-125 (half-life 59.4 days and dose rate of 0.069 Gy/h). Cs-131 allows patients with brain metastases to start adjuvant systemic therapy as early as 1 month after resection. New studies are investigating Cs-131 in glioblastomas and anaplastic meningiomas. In addition, further studies will aim to evaluate the outcomes and effectiveness of Cs-131 brachytherapy with a special consideration for the implementation of the newer GammaTile technology. This newer technique has high activity Cs-131 seeds arranged geometrically in small Gelfoam tiles with unequal distance

to either surface for a more customizable coverage of brain tumor operative beds.

CONCLUSION

The dosimetry of LDR brachytherapy treatment planning has evolved from estimation of dose delivered to accurate image-guided computer-optimized determinations of dose. Exact knowledge of the position of OAR and that of the conformation of target volumes combined with dose optimization achievable with PDR computerized afterloading source delivery allows the brachytherapist to tailor dose delivery to highly specific ideals and deliver with great fidelity. This has allowed improved prediction of late toxicity and the possibility for dose escalation in areas with a high tumor burden.

Brachytherapy is particularly suited to subvolume dose escalation due to the ability to deliver a highly localized dose with rapid dose falloff in the surrounding tissue. This can allow increased dose to subvolumes within a CTV without a corresponding increase in dose to surrounding normal tissues. It is important with the advent of these new techniques that the accepted methods of practice are constantly reexamined to ensure that the patient receives the optimum treatment with the lowest risk of complications in the future.

Dosimetry remains critically important within modern brachytherapy practice. Knowledge of the established dosimetry systems is critical to prevent late complications resulting from suboptimal catheter placement, with reliance on computerized optimization to overcome this. Modern imaging techniques can provide three-dimensional information about a target volume and surrounding normal structures. It is important to generate methods of incorporating this new knowledge with existing practice.

LDR and PDR brachytherapy often require indwelling applicators or catheters that necessitate hospitalization for the duration of the brachytherapy course. Surgical procedures are often required to place the brachytherapy seeds and applicators. Special skill and training are required to perform brachytherapy, much of which is not generally a part of oncology training rotations. Fellowships in brachytherapy are valuable but rare.

LDR brachytherapy may result in radiation exposure to medical staff, although remote afterloaders and PDR techniques minimize this exposure. HDR techniques are more prevalent than PDR due in part to the ability to treat more patients each day with a single machine. However, PDR still appeals to many centers, especially those with a high throughput of interstitial brachytherapy cases. Such a highly localized treatment can result in little or no dose to adjacent areas at risk of tumor spread, risking marginal misses and tumor recurrence if case selection is not carefully considered.

Brachytherapy also requires a high initial capital outlay. The choice of brachytherapy as a radiotherapeutic modality must be made carefully with consideration of many factors; patient centered, tumor centered, and resource centered. As the "ultimate conformal therapy," the place of LDR and PDR brachytherapy (in addition to HDR) is firmly ensconced in the radiotherapy armamentarium and should not be overlooked.

CHAPTER 23

The Physics and Dosimetry of High-Dose Rate Brachytherapy

Bruce Thomadsen, Eric N. Carver, and Mark J. Rivard

NATURE OF HIGH-DOSE RATE BRACHYTHERAPY

Conventional brachytherapy was developed soon after the discovery of radium. The limited amount of radium that could be packaged into the needles and tubes dictated the use of many sources to treat the target volume. Even with many sources, treatment durations ranged from 1 day to 1 week. When new radionuclides became available, their source strengths were matched to extant radium sources to draw upon clinical experience gained through the decades of ^{226}Ra treatments. This treatment format describes low-dose rate (LDR) brachytherapy as discussed in greater detail within Chapters 21.

A new approach to brachytherapy developed around 1962. Using intense, smaller sources (usually ^{60}Co in the early machines and often three in number) on the ends of cables, a treatment unit would move the source through the intended treatment volume in a relatively short time (<1 hour). This rapid treatment delivery was designated as high-dose rate (HDR) brachytherapy. The original treatment units most often oscillated the source along a catheter's treatment length, a method in common use until the modern generation of units developed in the early 1980s. Treatments took so little time that the therapy proceeded on an outpatient basis; however, the treatment was divided into several fractions and was delivered over days or weeks. Modern HDR brachytherapy units move a single source through the treatment volume in a stepwise manner, moving at intervals determined by the machine design and the operator, to positions where the source pauses (dwell positions) for durations (dwell times) determined through the treatment planning process.

Advantages and Disadvantages

Advantages

In comparison to LDR brachytherapy, HDR brachytherapy has the following advantages:

1. *Dose uniformity*. LDR sources positioned along the length of a needle or catheter have dose cold spots between the sources due to the abutting encapsulations, and seeds are often spaced with 1.0-cm spacings. For HDR brachytherapy, a single source is moved along the same length with 0.5-cm dwell spaced commonly used, and possibilities for dwell spacings that are smaller than the physical length of the radionuclide distribution. Also with less dose anisotropy than LDR seeds, HDR brachytherapy is less subject to dose cold spots.
2. *Optimization*. The stepping-source design permits high spatial and temporal control of the source through the target volume. In most treatments, determination of the dwell times comes from inverse planning, that is, specifying the doses desired at various locations and using an algorithm to calculate the dwell times that best fit the dose optimization constraints. The dwell times and positions can be finely tailored to the geometry and needs of a particular patient because of the wide range of dwell times available. This process constitutes *optimization*. Optimization is not commonly used with LDR brachytherapy (permanent or temporary) as the source strengths are usually all the same and are inserted (and removed) at the same time.
3. *Immobilization and stability*. The comparatively short duration of HDR treatments allows better stability of many intracavitary treatment applicators during the treatment and thus higher precision to deliver dose to the target. In addition to diminishing time for applicator motion, the applicator and the patient can both be immobilized with respect to the treatment table over the treatment duration. Such fixation is not possible with LDR brachytherapy because the patient would not tolerate the immobility for long periods. Interstitial cases may or may not exhibit better stability. Needles often tend to slide outward over time for prostate or gynecologic implants, even with a template sutured to the patient that affixes the needles. In such a patient, the needles require

positional adjustment before each fraction yet move very little during treatment delivery. Performing the same treatment using temporary LDR brachytherapy would be subject to needle movement during the slower delivery and require larger margins around the clinical target volume (CTV). On the other hand, LDR head and neck implants with buttons anchoring the catheters at both ends may have little movement from the time of insertion through removal. Such cases would not find improved stability with HDR brachytherapy.

4. *Dose reduction to normal tissue*. Again, the short duration of HDR intracavitary treatments often allows displacement of normal tissue structure to a greater extent than with LDR treatments. This holds true for gynecologic and oral intracavitary cases, but not for intraluminal applications, such as endo-esophageal or endobronchial treatments. Most interstitial cases cannot make use of this feature because the needles or catheters fix all the tissues in place. Exceptions are mostly in the head, where the tongue sometimes can be moved away from the treatment site.
5. *Outpatient treatment*. Most HDR patients receive treatment as an outpatient. Exceptions include patients with indwelling needles such as prostate or gynecologic implants delivered in multiple fractions. Implants using plastic catheters that enter the patient on one end and exit the patient on the other (ie, not with sharp needle tips poking into flesh) almost always leave the hospital between treatment fractions. All intracavitary treatments are performed on an outpatient basis unless there are medical conditions that keep the patient in the hospital between fractions. Outpatient treatments present many advantages over the inpatient treatments characteristic of LDR brachytherapy:
    - *Patient comfort*. Patients confined to a room during LDR treatments often feel closed in. Compounding the claustrophobic effects, radiation safety considerations for high-energy sources limit the time nursing staff can spend with the patient, leading the patient to feel like a pariah.
    - *Patient health*. Many LDR brachytherapy applications require the patients to stay in bed, disturbing urination and bowel movements

and increasing the probability of thrombosis or bedsores. Although pneumatic socks greatly reduce the likelihood of thrombosis, aching muscles from immobility still create discomfort. In many cases, patients who could not tolerate protracted LDR treatments will be able to receive treatment using HDR techniques.

- *Economics*. The cost of staying in the hospital greatly exceeds that of outpatient treatment. Counterbalancing the cost of hospitalization, the costs of the HDR remote afterloading equipment far exceed those for LDR applications. However, the costs for HDR equipment quickly become amortized with a modest patient load, whereas the hospitalization costs remain constant, or continually increasing, for each LDR brachytherapy patient.

6. *Less discomfort due to small size*. Because the encapsulated HDR source is approximately 1 mm in diameter, the gynecologic intrauterine tandem need only be <3 mm in diameter compared with 7 mm for a standard LDR tandem. Another way of looking at this comparison is to recognize that the diameter of the HDR tandem equals the smallest size dilator used to stretch the cervical os to accept the LDR tandem. Much of the pain and discomfort from a cervical cancer treatment arises from the dilation. Eliminating that step eliminates much of the pain. Some facilities use only light sedation for the HDR tandem insertion rather than a general anesthetic as is common with LDR procedures.
7. *Elimination of delays*. When applications fail to follow a plan or when plans have to change because of a finding in the operating room during the procedure, HDR treatments can still proceed following localization with little, if any, delay. Permanent LDR treatments likely would require ordering new sources to match the new situation and a delay in treatment to await delivery. The HDR model eliminates extra charges accruing from multiple-source orders.
8. *Intraoperative procedures*. HDR brachytherapy allows treatment intraoperatively, with suitable shielding in the operating room. With the short duration for dose delivery, a surgeon can add placement of the applicator and treatment to the surgery with little additional time.

9. *Radiation safety*. HDR brachytherapy eliminates radiation exposure to personnel.

Disadvantages

Unfortunately, HDR brachytherapy has the following disadvantages in comparison to LDR brachytherapy:

1. *Radiobiology*. Compared with LDR brachytherapy, HDR treatments have worse therapeutic ratios, that is the amount of damage to tumor cells compared with damage to normal tissue cells for the same dose. Damage to both cell types per unit dose increases with dose rate, but the increase is greater for normal cells. Just as with external beam radiotherapy, which also is HDR delivery, fractionated treatments mitigate this effect. Although LDR therapy usually entails a single session or two, most curative HDR regimens use three or more fractions. The next section discusses the radiobiology in greater detail.
2. *Error hazard*. The increased complexity of HDR procedures and the compressed time frame of delivery increase the probability of treatment errors compared with LDR therapy.
3. *Potential for very high radiation doses to patients and unit operators following failure of the source to retract*. A new HDR source can deliver almost 10 Gy/min at 1 cm in the patient. If the source stops moving or separates from the drive cable, serious injury can occur in a short time.
4. *Resources*. HDR treatments demand more resources than LDR treatments:
    - *Personnel*. Because many HDR treatments proceed quickly from applicator placement to treatment delivery, all of the persons involved with the treatment must be available at the same time or in relatively quick succession. That means that the facility must have sufficient staffing to release these persons from other duties on demand for HDR brachytherapy cases.
    - *Economics*. HDR afterloading equipment comes with a large initial investment of about $1M (at the time of writing), not including the significant costs of shielding the treatment room.

High-Dose Rare Brachytherapy Fractionation

Due to the differing radiobiological characteristics between HDR and LDR treatments, careful consideration is required when planning the time course of the therapy regimen. When starting an HDR brachytherapy program, key questions often arise regarding the number of fractions and the appropriate dose per fraction. The larger the number of fractions, the better the therapeutic effect, measured as the ratio of the damage to tumor cells to the damage to normal tissue cells. This ratio improves with each additional fraction, but the amount by which the ratio increases will decrease with each added fraction. As an example, going from four to five fractions can improve the therapeutic ratio by 4.0%. Adding a sixth fraction improves the therapeutic ratio but only by another 3.5%. Each additional fraction carries with it costs in departmental resources (particularly the time of those persons involved) and inconvenience (and possibly discomfort) to the patient. Thus, selecting the number of fractions becomes a compromise. Most curative regimens use five or six fractions if applicator insertion procedures are involved, and 8 to 12 fractions if the applicator can be left in place and the patient simply treated. Small-volume applications, such as vaginal cuff or most endobronchial treatments, may require only three or four fractions. After establishing the number of fractions, determining the dose per fraction comes next. One method that uses the LDR experience sets the BED equal for the two modalities and then solves for the dose per fraction. However, the LDR situation is more complicated because repair takes place during the continual irradiation, reducing its effectiveness.

High-Dose Rate Devices

Remote Afterloaders

A remote afterloader (RAL) is a computer-driven system that transports the radioactive source from a shielded safe into the needle or applicator placed within the patient. On termination or interruption of the treatment, the source is driven back to its safe. A stepping-source RAL is a particular design of a treatment unit that consists of a source delivery cable that moves the source through applicators placed in the treated volume. The treatment unit can treat implants consisting of many needles or catheters in the patient. Multiple catheters are often required to cover the target with

uniform radiation doses. Each catheter or part of an applicator is connected to the RAL through a channel. The computer instructs the motor to drive the cable so the source moves from the safe through a given channel to the programmed dwell position for a specific dwell time. In any applicator, there may be many dwell positions. After treating all the positions in a given catheter (channel), the source is retracted to its safe and then driven to the next channel. There can be several dwell positions per centimeter in each channel, and the dwell time can vary from 0 to almost 1,000 seconds in 0.1-second increments, thereby giving a high level of flexibility of dose delivery. All currently available HDR RALs use the stepping-source design. Five models of HDR RALs are common. Three are marketed in the United States: Flexitron (Elekta Company, GA) and GammaMed and VariSource (both from Varian Medical Systems, Palo Alto, CA). The microSelectron (Elekta Company, GA) is no longer sold but is one of the most common units in clinical use. In Europe, the BEBIG MultiSource (Eckert & Ziegler BEBIG, Seneffe, Belgium) is also available. Figure 23.1 shows two of these units. Even though they may vary in details, all available HDR RALs consist of the same general components: shielded housing, radioactive source, source-drive mechanism (cable, reel stepper motor), channel indexer, transfer tube (all shown in Figure 23.2), and treatment control station and treatment control panel (not shown).

Sources

Whereas delivering HDR brachytherapy requires an intense source, passing the source through needles placed through a tumor requires one of a small size. The radioactive source in an HDR RAL is usually 3 to 10 mm in length and <1 mm in diameter, fixed at the end of a flexible steel delivery cable. The microSelectron source is placed in a stainless steel capsule and welded to the cable, whereas the Varian source is placed in a hole drilled into a nitinol cable and closed by welding. Figure 23.3 shows diagrams of the sources. While ^{192}Ir is most commonly used for HDR RALs, ^{60}Co is increasing in popularity outside the United States. ^{192}Ir emits many photon energies, mostly between 110 and 704 keV, with an effective energy of about 380 keV. A new HDR ^{192}Ir source has an activity near 0.4 TBq (12 Ci, 48 mGy m^2 h^{-1}). Because ^{192}Ir has a 74-day half-life, the source should be replaced at least 4 times annually to keep treatments in the HDR radiobiologic regimen (see later discussion). The potential advantage of using ^{60}Co is the 5.27-year half-life (26 times longer), extending the time between source changes to approximately 5 years. ^{60}Co γ-ray emissions are 1,173 and 1,332 keV[1] and require considerably more shielding than for devices using ^{192}Ir. A medical physicist calibrates HDR sources after each installation using a reentrant, well-type ionization chamber (as discussed later). The resulting source calibration is verified against the manufacturer' source- calibration certificate.

Applicators

Each vendor markets an array of applicators for different treatment sites with vendor-specific designs that can only be used with their system. Before an applicator is used clinically, tests should be performed to verify the functionality. An applicator should also be imaged with dummy sources to verify agreement with the vendor specifications. The length of each applicator, location of the dwell positions with respect to the applicator, and physical integrity should all be a part of a routine quality assurance (QA) program to ensure the safe and precise delivery of a radiation treatment plan. Figure 23.4 shows a comparison between LDR ^{137}Cs and HDR ^{192}Ir tandem and ovoid applicators. The newer applicators are magnetic resonance imaging (MRI) safe and can accommodate the thinner HDR ^{192}Ir source.

A

B

FIGURE 23.4 A comparison of tandem and ovoid applicators for low-dose rate (LDR) ^{137}Cs from the 1990s (A) and high-dose rate (HDR) ^{192}Ir from the 2020s (B). The differing tandems permit anatomic fitting for different uterine tilting, even for retroverted uteri. Both types allow selection of ovoid diameters. The modern HDR applicators are plastic and

compatible with both computed tomography and magnetic resonance imaging. Metal HDR applicators may be smaller in diameter with a higher risk of uterine perforation.

OPERATION

Personnel Roles

The American Association of Physicists in Medicine (AAPM) Task Group (TG)-59 Report discusses the roles of treatment team members for HDR brachytherapy.[2] For the most part, the personnel roles follow standard procedures for any brachytherapy, with the physician inserting the treatment appliance and prescribing the treatment, the nurse monitoring the patient's condition and welfare, therapists or radiographers performing the imaging for localization, a dosimetrist or physicist performing optimization and dose calculation, a physicist checking the plan for correctness and assuring the correct calibration of the source, and the physician and physicist evaluating the plan. Who performs some of the functional roles discussed in what follows varies by institution but needs clarification, so all persons involved understand the distribution of responsibilities.

Daily Quality Assurance

There are several required tests of the treatment unit at the beginning of the treatment day. The duty to perform these tests often falls to a trained radiation therapist or dosimetrist. The medical physicist reviews the results of the tests before treatments commence.

Treatment Planning Calculation

The TG-59 Report discusses options for entering patient data into the dose calculation computer and generating the treatment parameters (dwell positions and dwell times).[2] One model presented had a dosimetrist running the program and a physicist monitoring the input to correct any errors as they occur. Studies have shown that such supervision provides little protection against errors.[3] The other model presented has the physicist generate the treatment plan.

Quality Assurance on the Treatment Plan

Regardless of who generates the treatment plan, a medical physicist should review the plan for appropriateness and correctness. The reviewing medical physicist should not be the same person who generated the plan, so in facilities with only one medical physicist, a dosimetrist should perform HDR brachytherapy treatment planning.

Delivery of the Treatment

Several factors enter considerations of who should staff the control panel during the treatment. In a handful of states, regulations dictate that only therapists may deliver treatments and control treatment units. The regulations in the other states and from the U.S. Nuclear Regulatory Commission (NRC) are silent on this issue. At the time of writing, regulations uniformly require the attendance of a radiation oncologist and a medical physicist at the treatment (or within unamplified voice communication of the unit operator). As a result, many facilities have the medical physicist remain in the area of the control console during treatments. One important reason for this is that the radiation oncologist and medical physicist must be ready and willing to enter the room and take appropriate actions in case of any treatment delivery error. This would include reacting to the source getting stuck outside its shielded housing in the RAL (eg, potentially in an applicator within the patient).

Normal Procedures

When the afterloader receives a command from the treatment control panel to initiate a treatment, the source cable advances from the shielded safe through a Y-shaped tube (to accommodate either the dummy source or radioactive source), then an S-shaped tube guiding either source from the safe to the first channel in the RAL indexer, and then along a path constrained by transfer tubes to the first treated dwell position in the applicator (see Figure 23.2). The source dwells at that position for a predetermined duration. After completing that dwell, it goes to subsequent dwell positions. Some RAL units step as the source drives out (Flexitron, microSelectron, and GammaMed), stopping first at the dwell position most proximal to the afterloader, whereas in the other units (ie, VariSource), the source travels first to the most distal dwell (toward the applicator distal tip)

and then steps as the source returns toward the safe. Stepping on the outward drive obviates any concern about the effect of slack in the drive mechanism affecting the accuracy of the source position. The units that step on the way back toward the unit include correction for cable slack for the source location. Regardless of the stepping direction, upon completing treatment of the first channel, the source is retracted into the safe and redirected to travel to the second channel. The process is repeated for all the subsequent used channels. The programmed movement of the source is verified by means of an optical encoder or other device that compares the angular rotation of a stepper motor or cable length ejected or retracted with the number of pulses sent to the drive motor. These systems are capable of detecting a catheter obstruction or constriction as increased friction in the cable movement. Under certain fault conditions, such as the stepper motor failing to retract the source, a high-torque direct current emergency motor will retract the source.

Confirmation of the source exit from and return to the safe is carried out by an opto pair, consisting of a light-sensitive detector and an infrared light source to detect the cable when its tip obstructs the light path. All the currently marketed afterloaders are also equipped with check cables. The check cable is an exact duplicate of the radioactive source along with its cable, except that it is not radioactive. Before ejection of the radioactive source, the check cable is first ejected to check the integrity of the delivery path. After an uneventful evaluation by the check cable, the radioactive source is then ejected for treatment.

Emergency Procedures

Because HDR RALs are complicated devices containing very high activity radioactive sources, if the unit malfunctions, serious accidents can happen very quickly. This demands many safety features and operational interlocks to prevent erroneous dose to the patient or clinical staff. Each of the following safety features are equally important; however, some, like the emergency switch, have their own potential failure points, requiring additional fail safes.

Door Interlock

Interlock switches prevent initiation of a treatment with the treatment room door open. In the fast-paced clinical environment, ensuring that the door is shut before having radiation flood the room is important. In addition, if the door accidentally is opened during the treatment, this interlock ensures an immediate retraction of the radiation source to its safe in the RAL. The treatment can be resumed at the same point where it was interrupted by closing the door and pressing the start or the resume button at the control panel. This safety feature protects the medical personnel from radiation exposure in the event someone enters the treatment room without the knowledge of the operator.

Emergency Switches

Numerous emergency-off switches are located at places convenient for the operator(s) and are easily accessible in case a situation arises. One is located on the control panel of the HDR unit for quick retraction by the clinicians local to the HDR unit. If this switch does not retract the source and the physicist must enter the room, Vendors install two or more switches in the lower radiation areas of the treatment room. In addition, another one is located on the top of the RAL treatment unit. In the event a treatment is initiated with someone other than the patient in the treatment room, that person can stop the treatment and retract the source by pressing any of the emergency-off switches.

Emergency Crank

In the event of the failure of a source to retract normally and if none of the emergency switches work, all HDR RAL units have emergency cranks to retract the source cable. The operator must enter the room to use the crank.

Emergency Service Instruments

If the radioactive source fails to retract after termination or interruption, pushing the emergency switch, or cranking the stepper motor manually, the immediate priority is to remove the source from the patient. Because the source could be trapped in the applicator that is in contact (or within) the patient, it can cause severe injury in a very short time. However, radiation dose falloff is governed by the inverse square law; therefore, working at a

greater distance, it is unlikely that the operator will receive a dose exceeding the annual regulatory limit, let alone one that would cause health problems. Once the trapped source is located and moved >1 m from the patient and staff, actions can be taken to remove the patient from the room.

The safest approach to an unretractable source is to remove the applicator from the patient quickly and place the applicator containing the source in a lead-shielded storage container (ie, a lead pig). If it is clear that the source cable (ie, source) is caught in the transfer tube and not in the applicator, the applicator may be disconnected from the transfer tube and the patient removed from the treatment room. In some cases, this will be faster than extracting the applicator. The reason to avoid disconnecting the applicator from the transfer tube is that a source may stay in the applicator if the source encapsulation is compromised or separates from the cable. In that case, removing the applicator attached to the transfer tube contains the radioactivity, whereas disconnecting the two allows a potentially broken source to fall from the applicator into body cavities or crevices or roll onto the floor.

A situation might arise when the source needs to be detached manually from the treatment unit. Such a rare situation might occur if the unit with an unretractable source fell on a person and could not be moved by hand (perhaps by something else falling on the unit). The source could be close to the person, but not inside. In this situation, the source cable should be cut from the unit and the source placed in the shielded container that is always present in the room. In cutting the source cable, it must be clear that the cut is *not* through the source capsule. For units with the capsule welded on the cable, the cut must be through the braided cable as opposed to the smooth steel capsule. For sources imbedded within the cable, several centimeters of cable must be seen to ensure that the cut does not compromise the source. Thus, emergency tools that must be present in the treatment room and always readily accessible include a wire cutter, a pair of forceps, and a shielded storage container. The source should *never* be cut from the cable while the source is still in an applicator within the patient!

FACILITY DESIGN

Typically, an HDR ^{192}Ir source will have a maximum air kerma strength of approximately 48 mGy/m^2/h. According to the rules and regulations of the NRC, the annual limit for radiation exposure to the public is 1 mSv and the annual occupational limit is 5 mSv. The occupational exposure limit is 50 mSv/y, but following the principle of maintaining exposures as low as is reasonably achievable, the NRC usually holds licensees to limit exposure to one-tenth of the actual limit. In addition to the annual limit, NRC regulations require that in an unrestricted area, the dose equivalent rate should not be more than 0.02 mSv in any hour. Thus, the RAL unit needs to be housed in a room that has walls and a door of the proper thicknesses and materials to shield the surrounding areas from the high levels of radiation exiting the room. Since the radiation dose rate diminishes following the inverse square, larger rooms will need less shielding. In general, an adequately sized HDR ^{192}Ir room will require concrete walls of about 50 cm, 5 cm of lead, or an equivalent thickness dependent on a combination of materials. The tenth-value layer thicknesses for ^{192}Ir are 15 cm for concrete and 1.6 cm for lead. For details on the procedures for calculating barrier thicknesses for a particular facility, see a health physics text such as that by Cember and Johnson[4] or McGinley[5] or Report 151 from the National Council on Radiation Protection and Measurements.[6]

Imaging plays an important part in most brachytherapy, so consideration of required imaging modalities should enter into the room design. Having fluoroscopy and radiography in the treatment room can facilitate checking for applicator movement if moving the patient is required for computed tomography (CT) or MRI. It would be best to have the necessary imaging modalities in the procedure room. Having space and access for anesthesia in the room facilitates HDR brachytherapy for interstitial procedures, such as prostate and gynecologic procedures.

In a radiotherapy clinic, the HDR room may share a wall with a LINAC or other radiation treatment room. The complication arises when consideration of the nearby areas, since the annual radiation limits are known and strictly enforced, these situations require additional shielding. This circumstance complicates the shielding calculations, but properly dealing with this nuance is crucial to ensure proper radiation safety.

All HDR brachytherapy rooms must have video and audio communication for monitoring the patient. Radiation detectors are also

required for monitoring radiation levels in the room and indicating when the source is out of its safe.

QUALITY ASSURANCE OF A REMOTE AFTERLOADING UNIT

Several of the disadvantages of HDR brachytherapy concern the probability of failure, either human or mechanical. Both aspects require effective quality management. Reports from the AAPM discuss this topic.[2,7-13] Williamson et al summarized much of the important material.[14] For a comprehensive discussion, the reader is directed to Thomadsen.[15] Although many of these references are not recent, the QA tasks appropriate for these RAL units have not changed very much.[16] Many of these QA tasks are required by the local regulatory agency.

As for any piece of radiotherapy equipment, QA begins with acceptance testing and commissioning. Periodic QA includes tests performed with each new source (approximately quarterly for most centers) and at the beginning of each treatment day. Of all of these, the daily QA checks form the basic set of essential tests.

Daily Quality Assurance Checks

Although the following list of safety checks seems long, their evaluation need not consume a great deal of time (typically less than 15 minutes). Most of these items can be tested in numerous manners, but only one method is described here and individual units may differ in the exact methods. The procedure in the list often assumes the successful completion of all preceding items. Failure of any item requires evaluation by the physicist for the appropriateness to continue with patient treatments. Daily QA checks demonstrate that the system is operating safely, correctly, and as expected.

Safety Checks

The following items should be considered for safety checks:

Room monitoring. See that the television and intercom systems function.

Handheld radiation survey meter. The survey meter is to be carried into the treatment room any time after a source run. To test its functionality, place

the survey meter in a geometric reproducible manner such as in contact with the RAL unit or elsewhere for comparison to an expected reading.

Catheter attachment lock. Attach a transfer tube to one of the channels of the unit, but do not lock the transfer tube in place (often accomplished by the locking ring). Program the unit to send the source to a dwell position that would be in an applicator where one attached and initiate a source run. A program time for a single dwell of about 20 seconds would allow execution of the tests to follow. The unit should detect that the transfer tube has not been locked in place and prevent the source run. Were a treatment to take place in this condition, the source cable could push the transfer tube out of the unit and never enter the applicator.

Applicator attachment. Keeping the same program, lock the transfer tube in place but still do not attach an applicator to the transfer tube. Again, attempt to initiate a source run. The check cable run should detect the absence of an applicator and prevent sending out the source. Failure of the unit to detect this situation could lead to the source indicating that it treated a catheter when, in reality, the catheter was never attached. This test also checks that the unit will not send out a source if the pathway is blocked, because, for most transfer tubes, the applicators push aside a blockage of the tube when they lock in place.

Door interlock. Lock an applicator into the transfer tube. For future tests, it is convenient to use a needle or catheter in a well-type ionization chamber. Keeping the same program as in the previous tests and with the door to the room open, try to initiate a run. The unit should refuse to initiate the treatment and indicate that the door is open.

Source-out indicators. Close the door, and initiate the source run. Observe that the indication lamps operate on the control console. Most treatment rooms have three beam-on indicator lamps: one connected to a treatment unit microswitch that triggers when the source leaves its shielded housing, one that lights when the signal on the room radiation detector exceeds its threshold, and one from the Geiger counter in the RAL unit.

Door interrupt. With the source out, open the vault door and observe the RAL unit to retract the source. The retraction should take no longer than 6 seconds to return the source to its shielded location.

Emergency stop. Close the door and reinitiate the exposure. Once the source reaches the dwell position, press the emergency-off button. The unit must immediately retract the source and likely require a reset.

Treatment interrupt. Reinitiate the exposure, and once the source goes back to the dwell position, press the treatment interrupt button. Again, the unit must immediately retract the source.

Timer termination. Reinitiate the exposure and let it continue until the elapsed duration equals the time set on the timer. At that time, the unit stops the exposure and retracts the source.

Dosimetry Checks

The thrust of the dosimetry checks focuses on the delivery of the correct dose to the proper location.

Source Positioning Accuracy

Proper treatment requires that the source occupy the position along the catheter corresponding to that used in the treatment plan. The uncertainty of the determination of the dwell positions on the treatment plan is discussed elsewhere in this chapter. Here, the issue becomes duplicating the dwell locations on the treatment plan during execution. A usual criterion for coincidence with the planned treatment dwells is 2 mm, although the HDR units are able to place the source in a given location within 1 mm. Precision <0.5 mm begins to be less reproducible. To direct the source to correct locations corresponding to each dwell position, the source controller requires the distance along the catheter corresponding to the first dwell position. The distance may refer to the length from some part of the unit (such as the front face, the point of catheter insertion, or a microswitch that tells the unit when the source enters the catheter), or it may be from some fictitious point (similar in concept to the virtual source distance for electron beams). Verifying that the unit can place the center of the source at a specified distance becomes an important part of the daily QA practice.

The most expeditious method uses the ruler provided with the unit. Such a ruler provides a channel for the source to follow alongside a scale marked in the distance. Using any ruler requires a high-definition video monitoring system that can clearly distinguish the source capsule and resolve the ruler

markers. Lighting this ruler becomes an important variable. For one vendor's unit, a televised check of the source positions on an integrated ruler forms a routine part of any treatment. For another vendor, the ruler is an external part of the QA equipment and requires a separate video monitoring system, such as that used to monitor the patient. To perform the check, attach the ruler and program the source to the desired distance. Watch on the video monitor as the source moves into position. The source tip should be farther than the programmed distance. From the distance of the tip, subtract the known distance from the tip to the source center as shown in Figure 23.5. This check is performed with the source cable; for some units, the check cable does not go to the same distance as the source cable and would give an incorrect result.

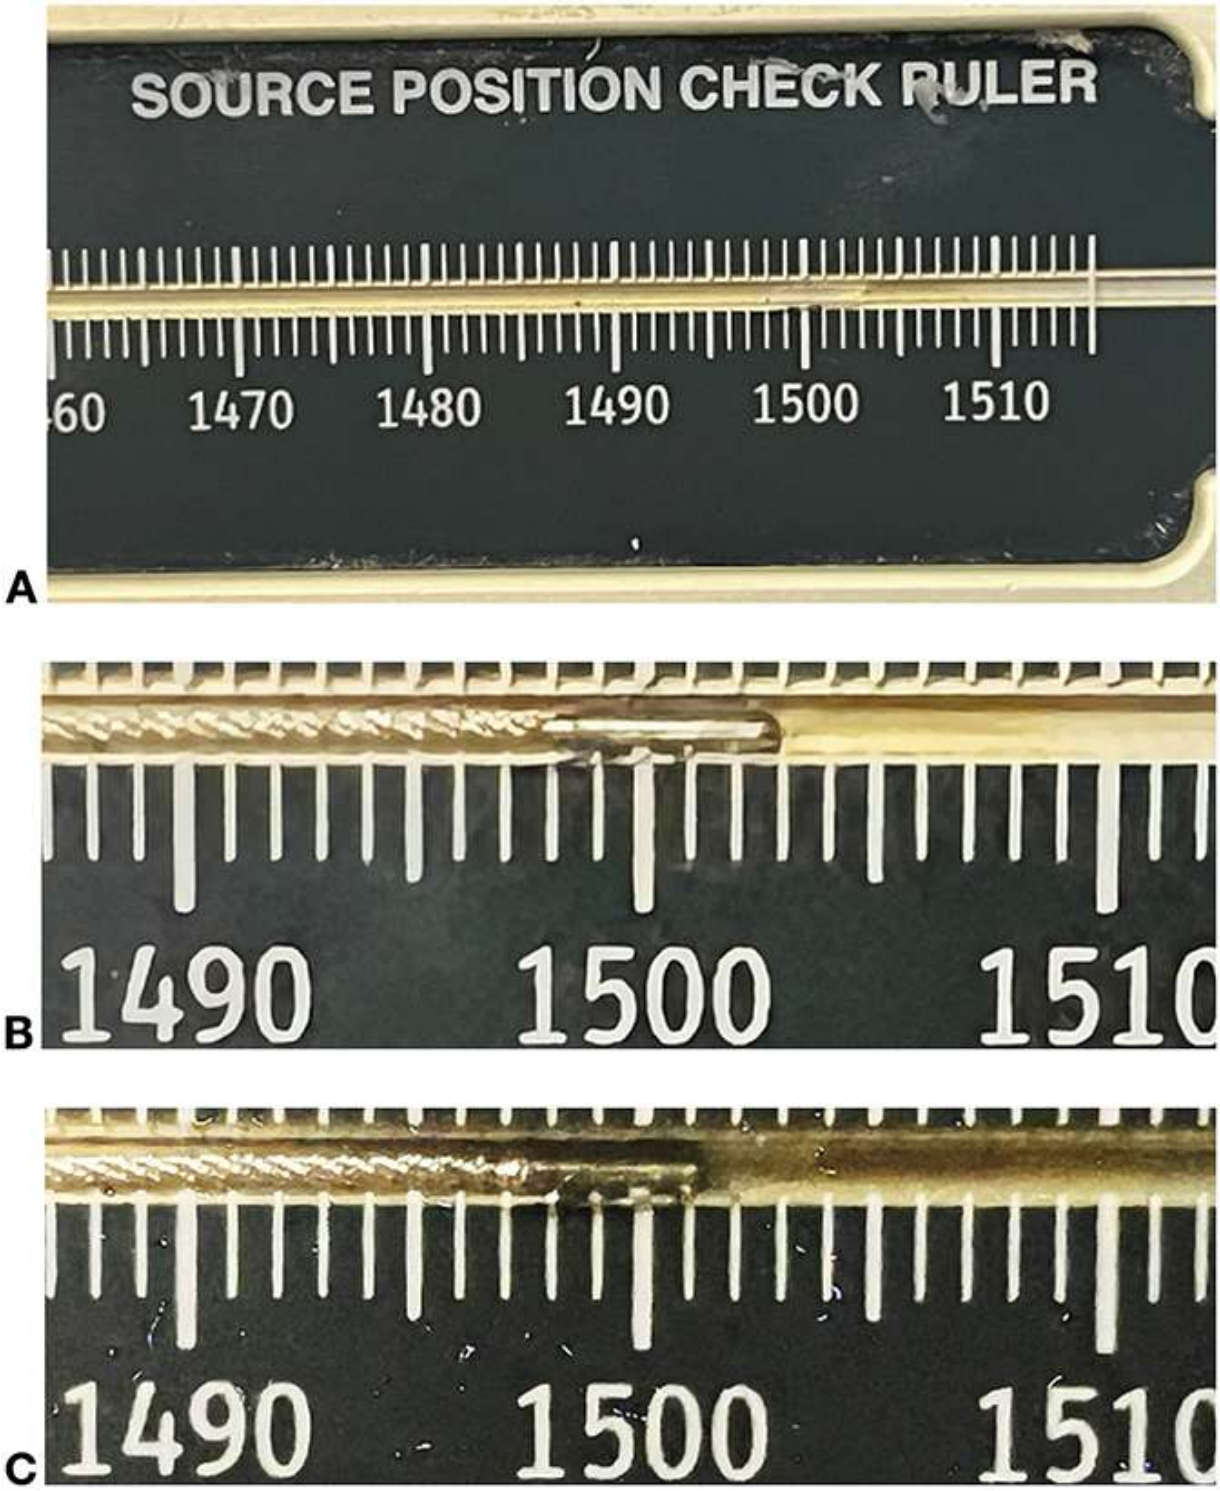

FIGURE 23.5 As part of a high-dose rate (HDR) brachytherapy quality management program, quality assurance (QA) positioning checks of the check source and HDR ^{192}Ir source can use the manufacturer source position check ruler. A. The source position check ruler showing darkening (accumulation of microscopic debris) ahead of the most distal position occupied by capsules of either the check source or HDR ^{192}Ir source. Friction has

cleaned elsewhere. B. Extension <1 mm of the check source beyond the HDR ^{192}Ir source as a safety measure to validate patency as required for some surface brachytherapy applicators is shown with the source tip at 1502.95 mm. Image resolution is 0.05 mm under these circumstances. Viewing perspective and divergence should be considered. C. The HDR ^{192}Ir source center is positioned at 1499.3 mm (0.7 mm proximal to the reference position) with a purposeful curvature of the source transfer tube imposed to validate that the source center remains within the 1 mm tolerance permitted by U.S. regulations. For QA purposes, localization uncertainties are minimized when identifying the distal edge of the source encapsulation instead of estimating the invisible center of the radionuclide distribution or considering variability when visualizing the cable:capsule weld. The picture also shows white electron artifacts in the camera speckle the image, resulting from proximity to the radioactive source.

A simple and more precise method of verifying source positioning follows the technique determined by DeWerd et a.[17] This method uses a well-type ionization with a special insert that includes lead attenuators and plastic transmission discs. The lead attenuators reduce the signal from the source to approximately one-third of its unshielded value, whereas the plastic discs have little effect. As the source passes through the needle centered in this insert, the measured signal peaks when the source is centered on the plastic discs, and the greatest gradient occurs when half the source is shielded and half is on the plastic. At these points, the signal depends critically on the precise position of the source, with the signal changing approximately 3.5%/mm. The signal at the plateau changes a little over 2 mm. Dividing the current signal at the high-gradient point by that at the plateau removes any variations in the reading due to source decay, timer miscalibration, or atmospheric density. Thus, the ratio of signals gives a sensitive indication of whether the unit accurately places the source to the correct location. Making measurements at two high-gradient points and the peak assesses not only the correct placement of the source at one point but also the correct interval between. The use of this method requires measurement of the signal profile as a function of distance along the axis of the well chamber after initial verification of the source position using one of the other methods. Once put in place, this approach takes <1 minute. If the insert is left in the well chamber, the needle can be used for the safety checks, and this test can follow the safety checks without requiring reentry into the room. Source position can also be checked using radiochromic film, marking the intended position of the source in a catheter using the

radiographic markers and then making an autoradiograph with the source. However, using film takes more time and carries a larger uncertainty than either of the two aforementioned methods.

Dose Consistency

Correct dose delivery hinges on the proper operation of the timer controlling the exposure. The proper operation does not depend on the timer accurately keeping true clock time. The only important features of the timer are that it operates linearly and that its operation remains consistent over time. The daily QA generally needs only check 2 times to evaluate timer consistency and linearity, compared with the tests performed during the source exchange. The uncertainty in the measurement should be on the order of a few tenths of a second in order to check the shorter times.

One technique for checking the timer observes the reading produced in a radiation detector as a function of the timer settings. To evaluate the timer, the measurement system must respond linearly to radiation dose and the setup provide a stable and reproducible geometry. A well chamber, such as that used for calibration, performs this function well. Such measurements in a well chamber include the effects of source decay and the source transit time. Source decay should not deviate from that expected based on half-life, but should still be checked because there have been sources with radio contaminants that produced anomalous decay. Because the reading varies directly with the set exposure time, these readings can form a timer check. The chamber reading needs a baseline, for example, a reading taken during source calibration. The expected reading can be tabulated as a function of days by correcting the initial reading by the decay factor, $e^{-0.693t/73.83}$ days, where t is the time in days since the initial reading for ^{192}Ir. The reading should remain within 1% of the projected reading, values that also could be in the decay table. Deviations from the projected values indicate changes in the timer operation (linearity or consistency), changes in the unit's transit time, or anomalous source decay. Further tests would be required to sort out the actual problem.

Source Strength Value

The value for the source strength at any time should be the same within 0.5% in the treatment delivery computer, treatment planning computer, independent dose calculation software, and decay table. The dates and times must also be correct to correctly account for source decay, and all systems should use the same value for the radionuclide half-life. The date format, American or European or ISO 8601, must be the same as that expected by the computer.

Initial Checks

Each source change requires a number of procedures in addition to the daily checks.

Safety Checks

The initial safety checks include the following:

Treatment unit backup batteries. In case of loss of power to the treatment unit, the RAL unit has backup batteries to retract the source and save the record of the treatment up to the time of retraction. Checking the batteries entails initiating a source run, pulling the circuit breaker for power to the unit, and verifying that the source retracts; the history is then saved, and the unit resumes the program where it left off when restarted after restoring the power.

In-room radiation monitor backup batteries. The in-room radiation monitor also has backup batteries allowing it to continue functioning in case of a power loss. Continued operation at such times becomes extremely important in case the source fails to retract. Verifying operation of these batteries simply requires unplugging the unit from the wall socket and performing the standard check.

Dosimetry Checks

The following are the initial dosimetry checks:

Calibration. The accepted method for calibration of an HDR source uses a well-type ionization chamber that has been calibrated in terms of HDR source strength per unit current. The calibration factor for the same

chamber will differ for LDR ^{192}Ir and HDR ^{192}Ir sources because of differences in source construction. The uncertainty (k = 1) in source strength calibrations using such chambers is about 2%. Brachytherapy source strength is in terms of air kerma strength, S_K, with units of μ Gy m^2 h^{-1}, often called U for convenience.[18] HDR source strengths range from 20,000 to 50,000 U. It is not recommended to use apparent activity anytime for brachytherapy sources; contained activity is used only for regulatory purposes, such as licensing and transportation.

Timer linearity. The verification for timer linearity uses several readings, R_i, for various increasing times, t_i, taken in the well chamber. The free-running reading rate, $R.$, can be defined as $R. = (R_{i+1} - R_i)/(t_{i+1} - t_i)$ and contains no effect from the source transit,[19] which cancels during the subtractions. Taking approximately five readings covering the range of dwell times common in treatments gives four values for the free-running reading rate using adjacent times. These values should differ by <0.5%.

The transit time from the unit to the dwell position is typically <1 second, but is hard to measure and is not important directly. What is important is that the transit time remains constant. An effective transit time can be defined as the time it would take to deliver the extra reading in the chamber because of the irradiation during the time the source moves into and then leaves the measurement dwell position, *if* the extra reading were delivered at the free-running reading rate.

Computer data entry. The new source strength must be entered into the treatment planning computer and the treatment unit computer. Special attention needs to be paid to selecting the units for the source strength, particularly if the system automatically defaults to given units.

Checks Preceding Treatment

Other than the check of the treatment plan just before treatment, connecting the patient also requires care and verification. For most gynecologic applicators, the three parts of a tandem and ovoid set, or the two parts for a tandem and ring, have mechanically keyed connectors that only allow for the correct transfer tubes to attach, and the transfer tubes also can only connect to the correct holes in the indexer. However, for implants with

needles or catheters, no interlocking prevents mismatches between channels and catheter or needle tracks. For large implants on older units, the treatments often require first connecting the number of catheters equal to the number of channels and delivering the part of treatment that uses those channels. Those channels are then disconnected, and the next set of catheters is then connected to the indexers starting again with channel number 1. One of the most likely errors would be connecting a channel during the second set to a catheter from the first or vice versa. Newer treatment units often have enough channels to accommodate implants needing many channels.

Also for interstitial implants, between fractions the catheters often move from the position they occupied during the imaging used for treatment planning. Immediately before treatment, the catheters must be returned to their original position, for example, by snugging the buttons on one side to the skin.

During the treatment, the operator needs to watch for movement by the patient that could affect the treatment and ensure that the source moves through its program.

Checks after Treatment

At the end of a treatment, the operator verifies complete source retraction by taking the following steps:

- Noting treatment completion as indicated by the control console
- Observing the room radiation monitor status
- Measuring the radiation levels at the patient with the radiation survey meter
- Measuring the radiation levels at the treatment unit with the radiation survey meter

DOSIMETRY AND TREATMENT PLANNING

Time Course of Procedures

As with LDR brachytherapy, treatment planning for HDR cases may follow different patterns based on the treatment approach. For example, cervical

cancer treatment using a tandem and ovoid usually has the physician place the treatment appliance followed by imaging and dose calculations. Less likely than with LDR approach, there can still be planning first based on an idealized application, such as a surface application using a standardized applicator and dose calculation method. Some HDR treatment planning may be interactive, such as with prostate implants where dosimetry following needle placement can direct subsequent needle placement in an adaptive manner. Despite this range of options, in most HDR cases, the treatment plan generation follows applicator placement and this model is assumed in the following discussion.

Differences between Low- and High-Dose Rate Brachytherapy Treatment Planning

HDR and LDR brachytherapy treatment planning differ in three ways. The first difference results from the treatment time course. For several sites, particularly gynecologic and prostate brachytherapy applications, the patient waits in the treatment position during the treatment plan generation. Most interstitial and intraluminal treatments differ little from the LDR approach, with treatment plan generation performed while the patient awaits. For those cases with the patient waiting in the treatment position, time becomes an important factor. If the plan generation takes too long, the patient will begin moving and the imaging data will not represent the treatment geometry to varying degrees. Additional problems with excessively long planning sessions include patient discomfort (other than leading to movement) and cost of support staff, such as anesthesiologists.

A second difference entails the quantities involved with the dose calculation. Temporary LDR brachytherapy applications often use source strength input by the user and calculate resulting dose rates based on the source configuration. The problem in many cases becomes selecting the dose rate isodose surface for which to base the treatment duration. The implant may require many sources, possibly of various strengths, but only a single implant duration for all sources. HDR brachytherapy has one source strength but with many different dwell times. In both cases, the dose calculation algorithm uses the product of the source strength and time at a given location as the basis for the resultant dose distribution.

The third difference concerns the role of input or output quantities. As noted earlier, LDR brachytherapy dose calculations most often input the source strengths and calculate the resultant dose rate distribution. Sometimes, the treatment duration is also specified to generate a dose distribution, but these are mostly permanent nowadays. HDR brachytherapy planning usually reverses the process, starting with the dose pattern desired and working backward to the dwell time distribution necessary to achieve that dose, a process termed *inverse planning*. A common part of inverse treatment planning is dose *optimization*, a process to achieve a treatment plan that satisfies some dosimetric criteria.

Optimization

For brachytherapy treatment planning, the term *optimization* implies the process to find the *best achievable* radiation treatment plan through quantitative iteration, given weighting of competing desires of delivering the therapeutic dose to the target region and ensuring minimal dose to surrounding healthy tissues. Many approaches actually only address finding a set of dwell times that deliver a specified dose to specified locations. Other approaches also try to control the dose distribution more finely and possibly limit the dose to specified organs at risk (OARs). The umbrella of optimization covers many disparate processes.

Optimization Approaches

Optimization in brachytherapy has taken many forms. The approaches fall into general categories, although considerable controversy surrounds the classifications. Ezzell[20] presents an excellent review of optimization. The discussion here can only brush the surface of the topic. The following sections outline popular optimization categories.

Stochastic approaches to optimization start with an initial generated time for each of the selected dwell positions. The starting dwell time distribution may be arbitrary, but knowledge-based information from similar cases can aid this optimization method and can reduce the time to generate a solution. Through the initial set of dwell times, the program calculates a value for an *objective function* (OF), which assigns a numerical value to the solution set that allows ranking the set according to quality. The OF may be as simple as

the difference between the value of dose calculated at a set of points and the dose desired. OFs often become more complicated, as in the following equation:

$$\mathrm{OF} = w_t\,(0.95D_{\mathrm{pre}} - D_{t,m})_{D_{t,m}<0.95D_{\mathrm{pre}}} + \sum_i w_{\mathrm{OAR},i}\,(\bar{D}_{\mathrm{OAR},i,\mathrm{calc}} - D_{\mathrm{OAR},i,\mathrm{limit}})^2_{\bar{D}_{\mathrm{OAR},i,\mathrm{calc}}>D_{\mathrm{OAR},i,\mathrm{limit}}} \quad (1)$$

In Equation 1, D_{pre} represents the prescription dose and $D_{t,m}$ stands for the minimum dose in the planning target volume. In this example, the person running the optimization wants to evaluate whether the dwell time set results in part of the target receiving <95% of the prescribed dose and, if so, to keep track of how much less. The second term considers the average doses ($\bar{D}$) to each of the OARs and determines for each the amount over some limiting dose assigned to that organ. The OF in this case is a penalty paid for the dwell time distribution. The first term would be omitted as long as the minimum target dose equaled or exceeded 95% of the prescription dose, and the term for any of the OARs would be zero as long as the dose remained below the limiting value. The exponential power of 2 allows some excess dose but imposes serious penalties for larger values. The weighting factors, *w*, allow a differentiation between the importance given to achieving the desired dose distribution and limiting the dose to a given OAR. In addition to the OF, the dwell time set might also be subject to *hard constraints* that would reject the set outright if the target dose fell to <90% of the prescribed dose or an OAR exceeded a different maximum limit. Because the OF value increases as the dose distribution gets worse, the program tries to minimize this function. Keep in mind that this equation only illustrates the concepts and is not intended to serve as a model of a good OF.

In *simulated annealing*,[21-24] random changes, often sizable, are made from an arbitrary initial solution for the dwell times of some or all of the dwell positions. After the changes and recalculation of the OF, the program holds on to the better of the two dwell time sets. New random changes are made

from the better set, and again the sets are compared using the OF. The randomness of the changes allows for greater variance throughout the iterative process, as a wider distribution of potential solutions is analyzed. As this process continues, the ideal area of the distribution is identified and investigation tightens to this local region, the allowed changes become smaller, and only direct improvements without random input over the previous iterations are accepted. As the process moves toward the solution, the OF improves and the optimal plan is the one with no further improvement in OF. If one properly creates the optimization parameters, the best OF should coincide with the best treatment plan.

The process as described can fall into a local minimum for the OF, where any small change will make the OF worse, a very different solution would be better. The small changes could not get to better solution. The methodology for finding the best set of dwell times differs among the stochastic approaches as each has its own method to avoid iteratively driving to a local minimum instead of the global minimum, which would result in a suboptimal plan approaches.

To avoid such traps, simulated annealing allows for the program periodically allowing for large jumps in the dwell times to investigate completely different regions of dwell times. If the new region does not seem promising because the OFs are worse, the program goes back to the better region.

Often, the value of the OF changes little with fairly large changes in individual dwell times in the neighborhood of the optimal solution. Going from a close dwell time set to the true optimum can require a considerable amount of computer time and often more than getting close in the first place. Most programs contain a criterion for stopping the process once the OF finds an adequate solution instead of continuing to the true optimum.

Other stochastic approaches, such as the *genetic algorithm*,[25] use different search mechanisms, but the overall procedures tend to be similar.

A nonstochastic approach, *geometric optimization*, solves for dwell times that would give the same doses to the vicinities around each of the dwell positions, based on several simplifying assumptions.[26] This approach recognizes that the dose near any dwell position results not only from the nearby dwell but also from the sum of the contributions from all the other sources. This method first calculates how much dose would be deposited to

a dwell position from all the other dwell positions and then weights the dwell time at that dwell position under consideration by the inverse of this dose. Thus, each dwell position needs only make up for the difference between the dose it already receives from the other positions and the dose desired. The first step sets the relative dwell weight, τ_i (the relative dwell time, normalized as described later), for dwell position *I*, based on the dose contributions of the other dwell positions. Using the point-source dose calculation formalism of AAPM TG-43,[27,28]

$$\tau_i = \left[\sum_{j \neq i} \frac{g\,(r_{i \leftarrow j})\ \varphi\,(r_{i \leftarrow j})}{r^2_{i \leftarrow j}} \right]^{-1}, \qquad (2)$$

where $r_{i \leftarrow j}$ is the distance between dwell positions *i* and *j*, $g(r_{i \leftarrow j})$ is the radial dose function, and $\varphi\,(r_{i \leftarrow j})$ is the one- dimensional (1D) anisotropy function. Commercial versions of this algorithm usually ignore the ^{192}Ir radial dose function, which remains within 2% of unity for $r < 5$ cm, and the 1D anisotropy function, which falls within 3.5% of 0.98 over that same radial range. Errors from these omissions and the point-source approximation (inherent in the inverse square relationship) remain smaller than errors that manifest later.

Determining the absolute dwell times then requires specifying the dose desired to a point or the average of several points. For the average dose to several points (indicated by *q*), the equation for the average dose to the points is

$$\bar{D}_{\text{initial pass}} = \frac{S_K \cdot \Lambda}{n} \sum_{q=n}^{1} \sum_{j=m}^{1} \frac{\tau_j \cdot g\,(r_{q \leftarrow j}) \cdot \varphi\,(r_{q \leftarrow j})}{r^2_{q \leftarrow i}}, \qquad (3)$$

where S_K is the air kerma strength in cGy cm^2 h^{-1}, Λ is the dose rate constant in cGy cm^2/unit source strength, n is the number of dose points in the average, m is the number of dwell positions, and t_j from Equation 2 serves as the initial estimate of the dwell time at position j.

Adjusting $\bar{D}_{\text{initial pass}}$ to become $D_{\text{prescribed}}$ requires scaling the dwell times. Letting each of the t_j be the time to deliver $D_{\text{prescribed}}$ and c be the scaling factor such that $t_j = c\tau_j$, then we have

$$C = \frac{\bar{D}_{\text{initial pass}}}{D_{\text{prescribed}}}. \tag{4}$$

This process calculated the doses to a dwell position assuming that all the dwell times were the same. That is not the case in Equation 3, which means that the calculated dwell times are not quite correct. The uniformity could be improved by iterating the process, at the sacrifice of its very high speed. The process also assumes that the implant, and particularly the dwell positions, matches the target volume.

Adjacent dwell positions along the same catheter track can produce the greatest effect on the dwell weights, resulting in isodose surfaces that tend to follow the catheters rather than conform to the shape of the implanted volume. This is especially the case if the separation between dwell positions along a catheter is much less than the separation between catheters. To reduce this effect, a version of the algorithm neglects all other dwell positions along the same catheter track when calculating the dwell weights in a given catheter. This variation is called *volume optimization* because it tends to spread the doses throughout the implanted volume. The original version, which includes the contributions of all other dwell positions for the calculation of any dwell weight, is called *distance optimization* because the isodose surfaces tend to follow a catheter at a constant distance.

The analytic approach, also known as *point optimization* or *point-dose optimization*, attempts to solve algebraically for the set of dwell times that produce the desired dose distribution, as represented by a set of points,

called *optimization points*, each with its own specified desired dose. In the most basic form, the specified doses and the dwell times establish a set of simultaneous equations of the form,[29,30]

$$D_i = \sum_{j=1}^{m} C_{i,j} \cdot t_j, \tag{5}$$

where D_i is the dose specified to point i, m is the number of dwell positions, t_j is the dwell time at position j, and the $C_{i,j}$ are factors that give the dose contribution at i because of the source at position j, with the sum over all sources. The source strength at each dwell position forms a variable (unknown), and each dose specification point yields an equation. Equal numbers of dwell times and dose points form a *determined* system with an exact solution. In more complex cases, there may be more optimization points than source positions, resulting in an *overdetermined* system (less variables than equations). This would be the situation in which optimization points were spread around a region of interest (ROI) contour and scattered through the volume. Faced with this situation, one can vary the dwell times to minimize the square of the differences between the desired and calculated doses at the optimization points. At the other extreme, a case may have more source positions than optimization points (more variables than equations), resulting in an *underdetermined* system. This situation most often happens with large implants and a minimum of optimization points or complicated gynecologic applicators with only a few dose control points. With this situation, the dwell times have no well-defined values; many solutions would possibly exist with the same value for the square of the difference between the doses desired and those calculated. Distinguishing between the solutions requires some other criteria. One is often a minimization of the total dwell time, under the assumption that such would also minimize the integral dose to the patient.

Determined and overdetermined systems can (and often do) generate solutions with negative dwell times. Simply truncating the negative dwell

times often results in an unsatisfactory dose distribution. Avoiding this nonphysical situation also requires an additional criterion. One possible criterion minimizes the differences between adjacent dwell times. For m dwell positions, this term becomes

$$\delta_i = \sum_{j=1}^{n-1} (t_j - t_{j+1})^2. \tag{6}$$

Including this term in the optimization limits time fluctuations between adjacent dwells. To deliver a dose to the target volume requires a net positive total dwell time, and so limiting the amount of difference between the dwell times eventually results in all positive times. An additional condition for underdetermined systems selects solutions that minimize the total radiation to the patient as a whole, which depends directly on the total dwell time. The final optimization becomes minimizing the chi-square value in

$$X^2 = \Sigma_{i=1}^{m} w_i \left(D_i - C_{ij} \sum_{j=1}^{n} t_j \right)^2 + v \sum_{j=1}^{n-1} (t_j - t_{j+1})^2 + u \sum_{j=1}^{n} t_j, \tag{7}$$

where, in addition to those quantities defined earlier, n is the number of dose points specified, w_i is the weighting given to the dose specification at point i (how much the operator wants the correct dose there), v represents the importance in minimizing the fluctuations between adjacent sources, and u represents the importance of minimizing the integral dose to the patient.

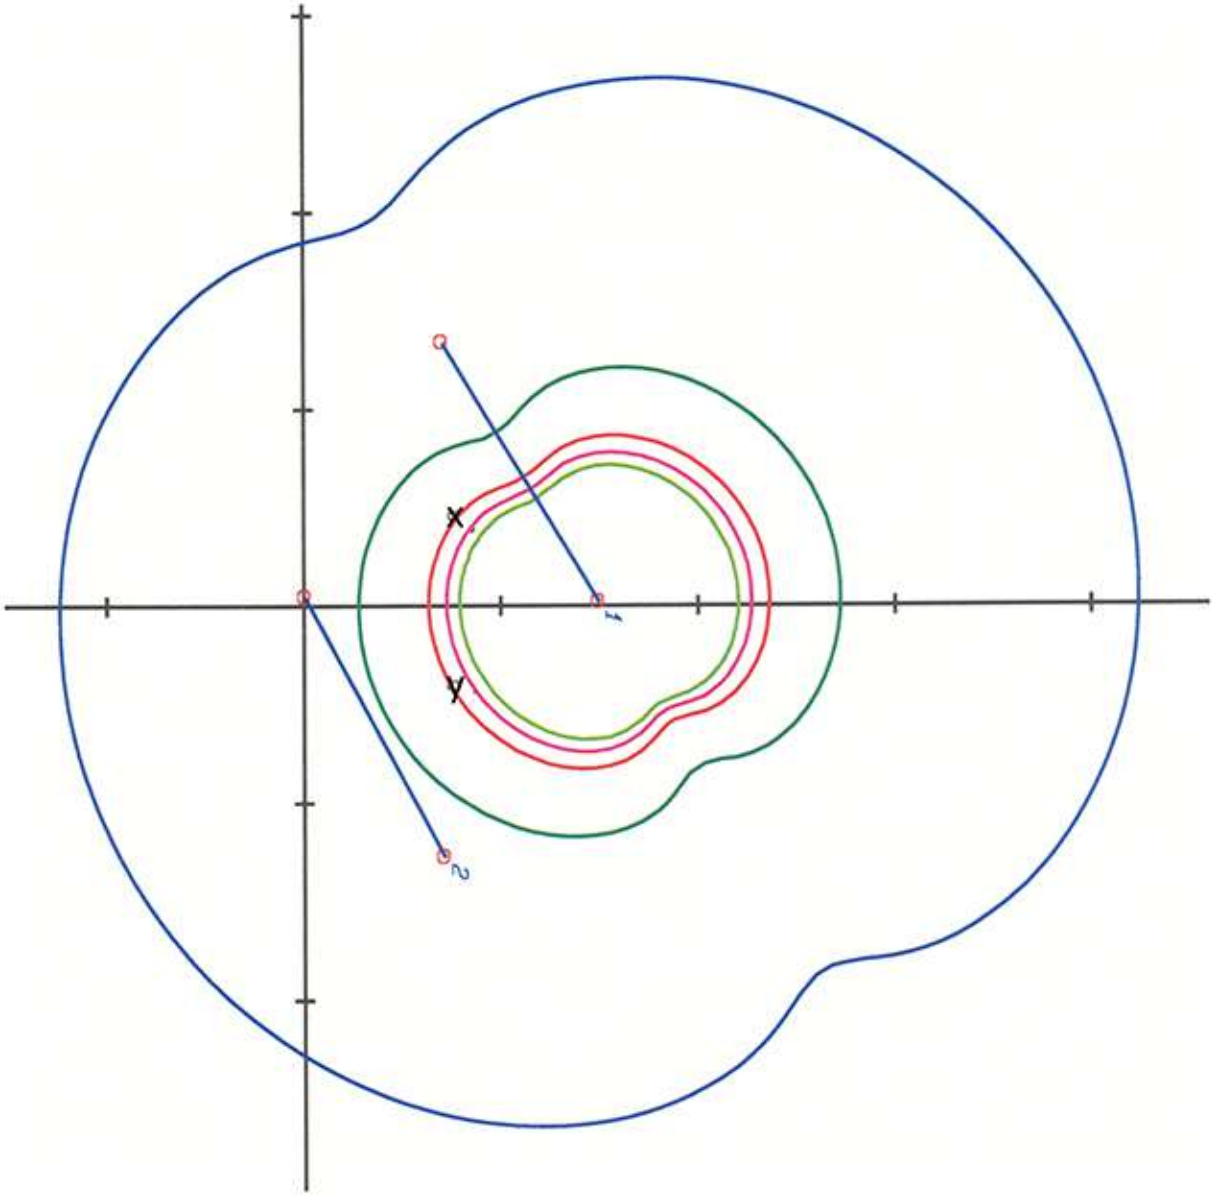
With a large number of optimization points or source positions, or both, the running of the program solving the equations becomes long, and approximations cut the calculation time greatly without significantly compromising the accuracy of the final dose distribution. By setting the dwell time

$$t_i = \sum_{k=1}^{p} a_k \cdot F_k\,(j-1), \tag{8}$$

where F is a fitting function, such as a polynomial or Fourier series of order p, and a_k is the coefficient for the kth element, and substituting that into the X^2 in Equation 7, the optimization now needs to solve only for the fitting coefficients, presumably a much smaller set of values. An alternative approach to solving the equation follows Newton's method.[31,32]

Obviously, the selection of the optimization points becomes very important. The number of points must adequately describe the shape of the dose distribution desired. The dose distributions may satisfy the specifications established for the optimization points but leave portions of the target without dose specification points untreated. However, the points should avoid regions of large dose gradients because specification there can produce unexpected and inappropriate results.

In general, lower values for v in Equation 7 allow better conformality of the dose distribution, and the optimum value often is that just sufficient to prevent negative dwell times. However, simply solving for the dose to specified points can produce an unwanted dose distribution, even when the approach seems to follow normal guidelines. Thomadsen et al[33] give an example similar to that in Figure 23.6. Here, the dose points mirror the basal dose points equidistant from the surrounding catheters. With a low value for v in the optimization equation, the simple solution places all of the dwell time in the center bottom needle—not at all what was really desired. The situation could be avoided by limiting the dwell time variations or using more dose points, particularly on the outside of the implant. Alternatively, performing a geometric optimization to obtain an approximate source distribution, followed by optimization on the points, also alleviates the problem.



x
y

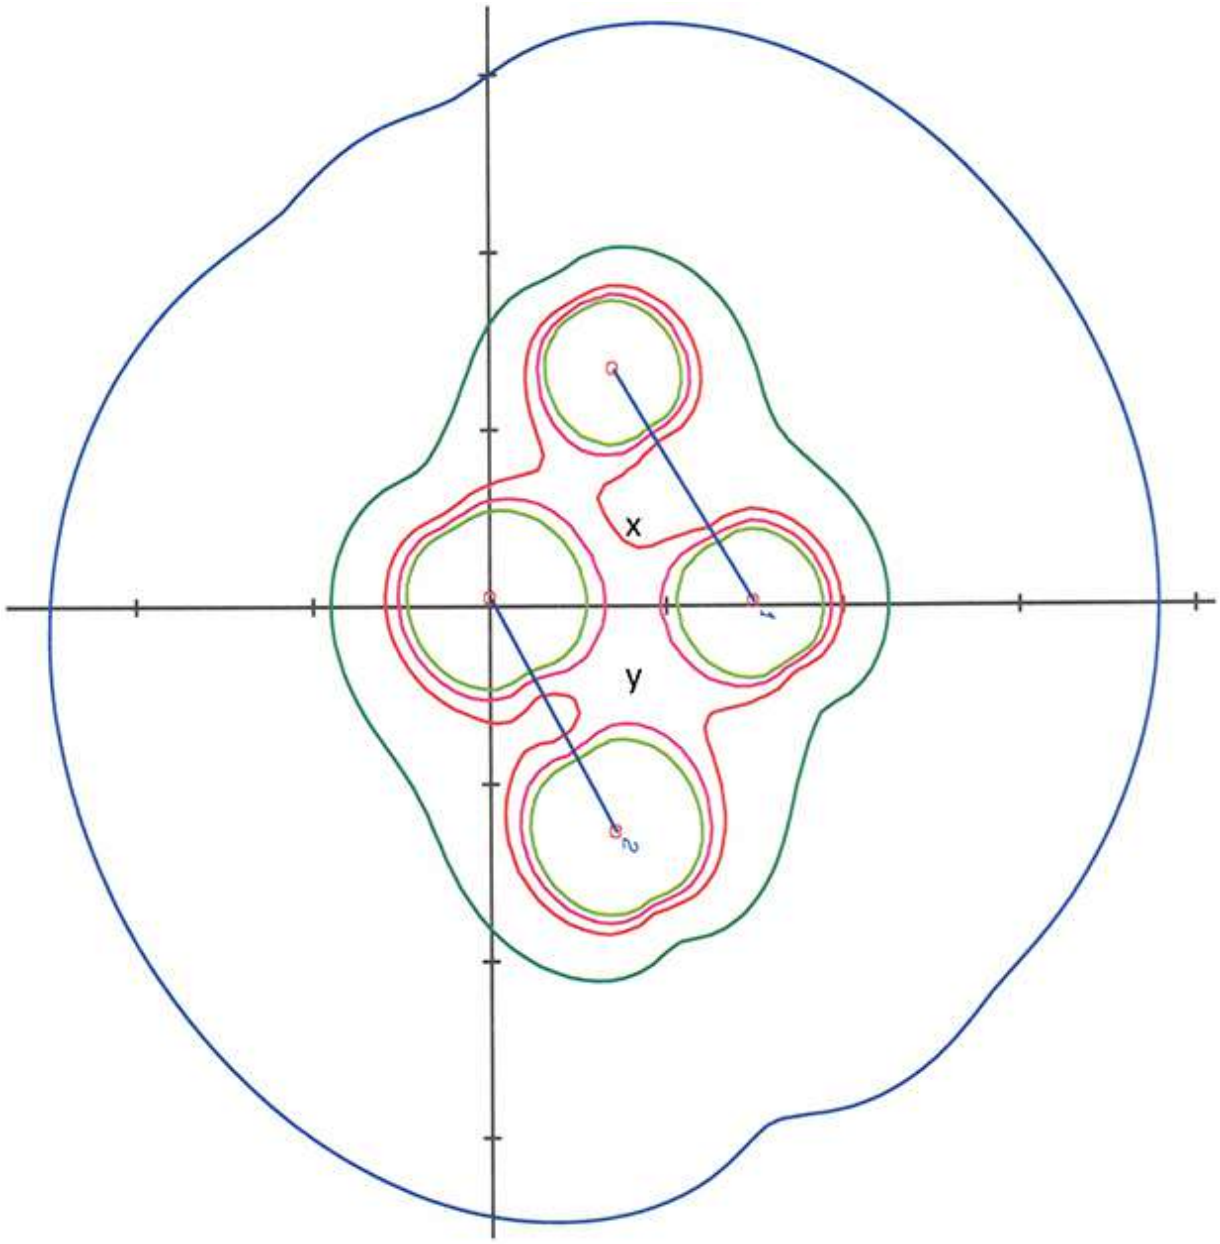


FIGURE 23.6 An example of potential optimization problem. Left: The criterion was that the two optimization points (X and Y) receive the same dose, which was satisfied by a single active dwell position. Right: Adding constraints on the dwell time variation solved the problem.

The output of any optimization approach may leave the operator wanting to make modifications. One method commercially available works on the computer screen display of the dose distribution and allows the operator to "grab" a dose line on the display with the cursor and move the line to a desired location. These fine adjustments make changes that would be

difficult to describe in the optimization routine's specifications. Most treatment planning systems (TPSs) allow adjustment of the dwell times over a range of spatial scales such as globally scaling the entire dose distribution, modifying weighting of individual needles, and as small as changing a single dwell time (affecting very local changes). However, even local changes will influence the dose distribution on image planes other than the one on which the change was made because the radiation extends beyond the immediate locale.

With 1-cm needle spacing and 0.5-cm dwells, it is more direct to adjust weighting along a needle instead of in a bisecting plane adjusting dwell times on multiple needles. Changes in the dose distribution to produce the desired modifications can also produce unintended changes. Of particular concern would be expanding the prescription isodose surface and inadvertently also expanding the higher dose surfaces, possibly into a significant volume. During any manipulation of the isodose surfaces, the display should also show the higher isodoses. Assuming that most of the manipulation occurs with the 100% surface, the 150% surface should also be on display.

Figure 23.7 shows some of the simpler optimization techniques. Usually, a single technique or a combination of two techniques can quickly produce the desired dose distribution. Geometric stability (patient anatomy and brachytherapy applicator or needles) should be considered to prevent high modulation of dwell times when reproducibility is suspect. A fixed approach to the entire treatment planning process should be established for each type of implant to provide a consistent and high standard of care.

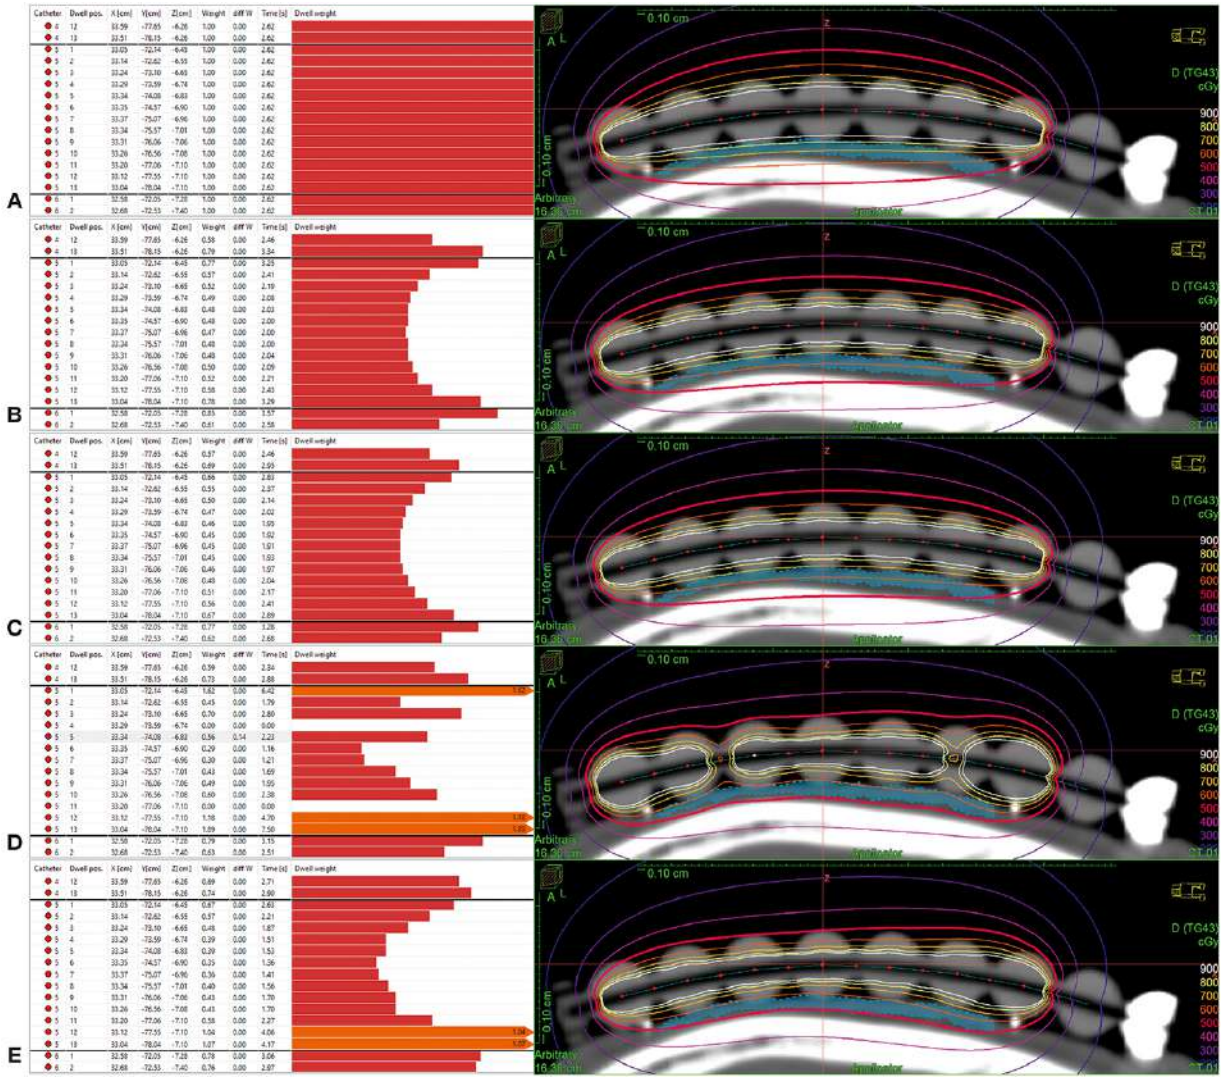

FIGURE 23.7 The aforementioned optimization approaches are shown graphically for a high-dose rate brachytherapy treatment plan of the scalp with a surface flap having dwell spacings of 0.5 cm and the catheter spacings and flap thickness being 1.0 cm. A. Equal dwell weightings are used throughout the implant. B. Geometric volume optimization. C. Geometric distance optimization. D. Geometric volume optimization refined with extreme graphical optimization. E. Geometric volume optimization refined with moderate graphical optimization. Dwell times for each optimization approach are shown on the left, while dose distributions are shown on the right for a plane through the central catheter of the flap. All plans were normalized to 98% clinical target volume coverage, yet the dose hotspots were 170%, 150%, 146%, 132%, and 138% of the prescription dose, respectively. A typical planning goal is <150% for dose hotspots and no intrusion of the prescription dose into healthy tissues such as the underlying bone. For implants with flexible geometry due to the applicator shape or the patient anatomy, extreme modulation of source dwell times is discouraged since the optimized approach may not be realized in clinical implementation.

Multicriteria optimization (MCO) delivers multiple Pareto optimized plans, one for each of the investigated criteria. Each of these plans possess one Pareto optimized condition, which means that the condition is fully optimized within the realm of the other conditions. The full set of Pareto optimized plans are presented to the planner as a Pareto front. The main advantage of this optimization method is that it allows the planner to quickly view the dosimetric effects resulting from each constraint.[34] Consequently, the planner can identify which constraints can be realistically met toward determining the ideal plan. At the time of writing, MCO is available only in a research setting.

Evaluation of Dose Distributions

Dose optimization calculates and sculpts relative dose distributions and requires only spatial dose information. After establishing the dose distribution shape, the entire distribution must be raised or lowered to give the correct absolute dose according to the prescriptive goals. This process requires evaluation of the dose distribution for prescriptive compliance. Other than visually examining the isodose distribution resulting from the optimization routine, there are tools that provide quantitative assessments of various aspects. Thomadsen provides a fuller discussion.[15]

Competing treatment plans may have quite different features. Some quantities that can help condense some characteristics into values include the following dose metrics. Some of these quantities originally applied to the dose distribution in the absence of any regions of interest but have been adapted to the modern situation in which volumetric imaging provides a context for assessment and evaluation. Unless indicated, the volumes are fractions of the whole ROI.

Coverage is usually specified in terms of the faction of the CTV raised to a required dose. As an example, if it were felt that all the CTV should receive at least 95% of the prescribed dose, this would be specified as $_{CTV}V_{95\%} = 100\%$. It might also be desirable that in a given fraction, 90% of the CTV receive at least 5 Gy, or $_{CTV}D_{90\%} = 5$ Gy.

High-dose volume (HDV)[35-37] is the volume of an ROI raised to a dose significantly higher than the target dose, often higher by a factor of 1.5. HDV = $_{ROI}V_{150\%}$.

Dose nonuniformity ratio (DNR)[37-39] is the ratio of the CTV HDV to that taken to at least the target dose. DNR = ${}_{CTV}V_{150\%}/{}_{CTV}V_{100\%}$.

Relative dose homogeneity index (DHI)[37,38] is the fraction of the target volume receiving a dose between the target dose and the high-dose level. DHI = ${}_{CTV}V_{150\%} - {}_{CTV}V_{100\%}$. Rarely are DNR and DHI used together.

Conformation number or *conformal index* (CN or COIN)[40,41] is a measure of how well the dose distribution fits the target. CN = $({}_{CTV}V_{100\%}/{}_{total}V_{100\%}) \times ({}_{CTV}V_{100\%}/{}_{CTV}V)$, where all the volumes are absolute such as in cm^3.

Each of these dose metrics tells a small part of the dose distribution's entire story. Each can help evaluate a dose distribution, and taken altogether gives a better picture. However, none of these—even together—captures the complexity and nuances of the total dose distribution. Inspection of the results of the optimization remains a necessity.

The *maximum significant dose* (MSD) refers to the highest level isodose surface that encompasses more than one needle track. The dose very close to a needle track becomes very high, but the body seems to tolerate these small local volumes. The MSD provides a convenient criterion for when the HDVs become "significant" and likely to produce biologic consequences. For most implants, the MSD should remain <150% of the prescription dose, assuming that the prescription dose encompasses the target volume. For vary large volumes (>30 cm^3), the limiting value should decrease to about 125% of the prescription dose.[42]

Evaluation of the treatment plan quality also entails assessing OAR doses.[43] This evaluation may use quantities such as ${}_{rectum}D_{2\ cc}$ as a review criterion. Limitations on the doses to normal tissue structures are discussed in detail in Chapters 12 and in most of the chapters on clinical applications.

Quality Control of Treatment Plan

The use of HDR brachytherapy in the definitive management of gynecologic cancer,[44] early-stage breast cancer,[45,46] and prostate cancer[47] has made the RAL unit a common treatment modality in most radiotherapy clinics. HDR TPSs integrate multimodality images (CT, MRI, and ultrasound [US]) and dose optimization software such as inverse planning or interactive graphical optimizers, which enable the planner to maximize

the dose uniformity while minimizing the implant volume needed to cover the target volume while reducing OAR doses. Such capability creates a challenge for the verification of optimized dose calculations with practical hand calculation techniques. With the time constraint following HDR treatment planning and the onset of treatment delivery, an efficient, precise, and easy method for checking complex computer calculation is necessary for quality control of the treatment plan. Every institution should have an established quality control program that takes only a few minutes yet provides a high probability of detecting significant errors, because the NRC considers a 20% difference between the administered dose and prescribed dose a reportable medical event.[48]

Simplistic models to verify TPS calculations quickly have drawbacks because applicators or interstitial implants used in HDR treatments are complex in design, and simple point-dose or linear source calculations tend to fall apart in most circumstances.[14,49,50] Because all TPS scan generate dose-volume histograms, it is logical that volume-based QA is preferred. Das et al[51,52] addressed this possibility and provided an easy and quick calculation check for most HDR interstitial and intracavitary implants.

DISEASE SITES COMMONLY TREATED WITH HIGH-DOSE RATE BRACHYTHERAPY

Several disease sites are especially amenable for treatment using HDR brachytherapy. This is due to a combination of favorable implant geometry and dose avoidance with respect to adjacent critical structures. Other chapters in this book discuss the therapeutic issues in greater detail.

Cervical Cancer Brachytherapy

Intracavitary brachytherapy has been a major part of the treatment for cervical cancer for almost 100 years, with most experience using HDR brachytherapy since the mid-1980s. Of the advantages of HDR over LDR brachytherapy given earlier, several apply directly to these treatments, particularly the small source size and the resultant smaller diameter of the intrauterine tandem, the greater stability of the treatment appliance and higher accuracy and relevance of the calculated dose distribution, and the ability to hold OARs more distant from the applicator and source path.

Imaging plays a major role in these modern treatments with the future likely seeing an increase in that role.[53] US can provide guidance during the placement of the intrauterine tandem, particularly to avoid fundus perforation or when the tumor obliterates the external cervical os. Fluoroscopy provides guidance during applicator placement, assisting in the assessment of applicator geometry (eg, evaluating the centering of the tandem with the ovoids in both the anteroposterior and lateral projections), correct applicator assembly and securement, and positions of the rectum and bladder.

The role of HDR gynecologic brachytherapy imaging is evolving. The European Society for Therapeutic Radiology and Oncology (Groupe Européen de Curiethérapie [GEC-ESTRO]),[54-58] the American Brachytherapy Society consensus guidelines for locally advanced cervical carcinoma,[59-61] and the International Commission on Radiation Units and Measurements (ICRU)[62] recommended moving toward image-based target prescriptions. At the time of writing, the AAPM TG-236 Report is under review and will issue recommendation on volume image–based treatment planning, dosimetry, and quality management for HDR intracavitary brachytherapy. Identifying the target (ie, tumor tissue in the uterus) requires MRI, the only form of imaging that also reliably differentiates the uterus from other pelvic tissues. GEC-ESTRO defines a high-risk clinical target volume (CTV_{HR}) as any tumor detectable by physical examination or imaging plus the entire cervix. Typically, 95% of the prescription dose should cover 95% of the CTV_{HR} volume. The formalism also defines an intermediate-risk clinical target volume (CTV_{IR}) based on disease extent at the time of diagnosis. Generally, the CTV_{IR} should receive about two-thirds of the dose to the CTV_{HR}. (The definition of the CTV_{IR} is actually more nuanced, and practitioners should study the references thoroughly before implementation.) The recommended integrated dose to the CTV_{HR} in 2-Gy per fraction radiobiologic equivalence (EQD_2) is 80 to 90 Gy, depending on tumor size and external beam radiation therapy dose contributions. To maintain a connection to historic experience while prescribing the dose to a target volume, ICRU 89 recommends also reporting dose to the conventional point A as defined per the ABS.[59]

Although only MRI identifies the target and the uterus, CT images the rectum and the bladder well. Although using CT localization does not permit as detailed target information as MRI, it does allow moderate target definition and facilitate determining the doses to the OAR when using conventional treatment prescriptions.[62] Dose calculations based on either CT or MRI often indicate that the maximum bladder dose is 2 to 4 cm superior to the conventional point indicated following ICRU 38 and may be 2 to 4 times the dose to the conventional point.[63] The ICRU-indicated rectal point differs less than the bladder point, with the true maximum falling between 1 and 3 cm superiorly and the true maximum dose being 1 to 3 times the conventional point. The GEC-ESTRO and the ICRU 89 formalism specify the dose of interest to OAR in terms of volumes rather than points. The locations of the highest dose to the rectum, bladder, and sigmoid are found, and these points locate the volumes of interest. For each OAR, the minimum doses in the most highly irradiated 2 and 0.1-cm^3 volumes are generally recorded.

The accuracy and precision of determining the dose matter much more in HDR intracavitary brachytherapy for the cervix than for LDR treatments for two reasons. The first is concerned for the precision of dose delivery. King et al[64] demonstrated that the typical LDR tandem and ovoids move an average of 2 cm over the course of treatment. HDR tandems and ovoids move a maximum of 0.3 cm when not moving the patient.[50] Thus, the added precision of volumetric, image-based dose calculations would be lost in the general positional uncertainty of LDR intracavitary brachytherapy. In the second place, HDR applications not only can use the dosimetric accuracy, but they may also require it. Because of the radiobiologic disadvantage of HDR brachytherapy, knowing the dose distribution with a high certainty is necessary to avoid complications.

Avoiding complications leads to several differences between HDR and LDR brachytherapy of cervical cancer. To prevent rectal complications, the dose to the rectum should remain <70% of the dose to the Manchester point A or the CTV_{HR}.[44,61] Treating with a rectal retractor in place usually accomplishes this goal. As noted under the advantages of HDR brachytherapy, patients would not tolerate such a practice over long durations with LDR applications. Adding distance to the bladder generally

uses copious packing anterior to the ovoids, taking care not to let the packing slip between the ovoid surface and the superior or lateral fornices. An unpublished 1988 review of LDR cervical cases at the University of Wisconsin found the beginning of late complications in the superior bowel (fistulae) at about 13 years after treatment and that the prevalence increased continually over time. That problem with LDR treatments generated concern that the situation might be worse with HDR treatments because of the unfavorable radiobiology. With HDR, unlike LDR, the dose to the superior bowel can be reduced by not loading the tandem as high into the uterus and making the dose distribution more square than the LDR applications.[44]

Prostate Brachytherapy

A radiobiologic parameter termed α/β characterizes the radiation sensitivity of specific cells like tumorous or healthy tissues and is discussed in detail in Chapters 21. Unlike most cancers, the radiobiologic α/β value for prostate cancer is low, possibly as low as 1.2 Gy and lower than that of most normal tissues.[65,66] The slow delivery of radiation with LDR treatments allows normal tissues to recover better than tumors, whereas HDR treatments cause a greater increase in the damage to the normal tissues than to tumors. When the relative size of the α/β inverts, as in prostate cancer, the advantages also invert. High doses per fraction cause a greater increase in damage to the tumor cells having an α/β value of 2 in comparison to normal tissue cells with an α/β value of 3. This situation makes HDR brachytherapy look attractive.[67,68]

Currently, the process for HDR prostate brachytherapy follows the LDR model fairly closely. US images provide guidance for the insertion of the catheters, although CT and MRI guidance has become more common.[69-71] Generally, catheter placement follows a pattern such as four around the urethra and then at 1.0- to 1.5-cm intervals around the gland periphery. The rectangular template grid complicates catheter placement at regular intervals, but the final dose distribution is relatively insensitive to the exact location of the catheters. Commercial software exists to guide the user for catheter placement, but those experienced in prostate implants probably perform as well without computer assistance.

After catheter placement, the optimization routine calculates dwell times to achieve the dosimetric criteria specified for the patient. The resultant dose distribution may still require small adjustment through graphical optimization. Following treatment plan approval, the operator connects the needles to the treatment unit using the transfer tubes. Because the needles have no inherent numbering, great care must be taken during this process to ensure the correct correlation between the needles in the patient and those in the treatment plan.

The location of the first dwell position in the needles would have been determined previously. Radiographing the needles with the x-ray markers in place forms one of the simplest methods. If the treatment unit does not seek the end of the needle to establish the first dwell position, all needles must be tested for uniformity of length.

Treating multiple fractions with the same insertion requires verification of the needle depth. Between fractions, the needles tend to slide outward and may need repositioning under US or fluoroscopic guidance. Marks on the needles where they enter the patient also can serve as indicators for possible repositioning.

Breast Brachytherapy

Accelerated partial-breast irradiation (APBI) for patients with breast cancer with HDR brachytherapy as monotherapy following lumpectomy has produced excellent local control rates and cosmesis.[51,72] Interstitial and intracavitary (catheter balloon) implants are used for this treatment modality. Usually within 8 weeks of lumpectomy and axillary nodal evaluation, the patient undergoes an interstitial implant with one of three methods: a prone stereotactic template method with digital mammographic guidance, a supine US-guided technique; or a supine template–guided CT technique. All three methods are performed under local anesthesia. Because of the perceived technical challenge of multicatheter interstitial implants, alternative intracavitary methods for APBI have been developed. One approach uses multiple catheters around the central catheter within a balloon that is placed within the lumpectomy cavity closed, often under US guidance, and inflated with saline or diluted contrast medium. Two such systems are the Contura (SenoRx, Bard Biopsy System, Tempe, AZ) and

multicatheter MammoSite (Hologic, Bedford, MA). An alternative is the SAVI device (Cienna Medical, Aliso Viejo, CA) that uses six to 10 struts in a configuration that looks similar to an egg whisk to hold the tylectomy cavity open instead of a balloon. The struts also serve as the paths for the source travel. Another device consisting of a double balloon (Best Industries, Springfield, VA) contains a single central treatment catheter and four peripheral treatment catheters that can be customized for radiation dosage coverage. The inner balloon can be filled with 7 to 30 cm^3 of saline to increase separation of the peripheral catheters, and an outer balloon can be filled with 35 to 110 cm^3 of saline to displace the breast tissue from the peripheral catheters. The multiple catheters for each of these devices allow some shaping of the dose distribution, but not comparable to that obtainable with multicatheter interstitial implants. Imaging of the balloon for its integrity, as well as rotation of the multiple catheter devices, should be performed before initiating each treatment.

ACKNOWLEDGMENTS

We thank Adam Uselmann, PhD, and Liyong Lin, PhD, for the artwork they contributed to this book chapter. This chapter represents an update and revision of previous chapters in this series, most recently by Rupak K. Das from the last edition. We are indebted to Rupak K. Das for their work and retain much of their prose in this current edition.

CHAPTER 24

Clinical Aspects and Applications of High-Dose-Rate Brachytherapy

Mustafa Al-Balushi, Ivan Buzurovic, Phillip M. Devlin, Peter Orio, and Martin T. King

High-dose-rate (HDR) brachytherapy (BT) is a standard-of-care treatment option for many disease sites in radiation oncology. This modality is capable of delivering an extremely high dose of radiation to the tumor while sparing critical surrounding organs-at-risk (OAR) due to rapid dose falloff. Radiation is delivered by a HDR radioactive source (≥12 Gy/hour),[1] which passes within hollow catheters placed in close proximity to the tumor. The position of the radioactive source is precisely controlled via cable by a remote afterloader.
