Table 5.26 Chromosomal disorders caused by aneuploidy (numerical abnormalities) (*Contd...*)

Chromosomal Disorder	Trisomy or Monosomy	Incidence	Clinical Manifestations	
Turner syndrome	Monosomy X (45, X)	1 in 2000–3000 live female births	▪ Streak ovaries ▪ Primary amenorrhea and infertility ▪ Webbed neck ▪ Short stature	▪ Broad chest ▪ Coarctation of aorta ▪ Absence of secondary sexual characters
XYY syndrome (Jacob syndrome)	Trisomy XYY (47, XYY)	1 in 1000 live male births	▪ Taller than average height ▪ Low muscular tone (hypotonia) ▪ Curved pinky finger (clinodactyly)	▪ Widely spaced eyes (hypertelorism) ▪ Cystic acne during adolescence
XXX syndrome	Trisomy XXX (47, XXX)	1 in 1000 live births	▪ Epicanthic folds ▪ Low muscular tone (hypotonia) ▪ Curved pinky finger (clinodactyly) ▪ Flat feet	▪ Abnormal shaped breastbone ▪ Seizures ▪ Kidney malformations

Nullisomy refers to loss of both homologous chromosomes (2n–2).

- Aneuploidy is defined as any deviation from the normal number of chromosomes in a cell nucleus arising from aberrations in cell division. Cell nucleus has too many (47) or too few (45) chromosomes instead of the usual 46 chromosomes.
- The most common aneuploid disorders that can result in live births are trisomies of sex chromosomes (Klinefelter syndrome, XXY syndrome; Jacob syndrome, XYY syndrome); **trisomies** of autosome chromosome (13, 18 and 21) associated with advanced maternal age; and monosomy X (Turner syndrome 45, X).
- The chromosomal abnormality may be present in some cells in a case, and is known as Turner syndrome with mosaicism.
- Aneuploidy is detected by prenatal screening. Ultrasonography is a screening test to evaluate aneuploid fetuses. However, invasive testing with chorionic villus sampling or amniocentesis is performed for establishing diagnosis.
- Nondisjunction of chromosome is the most common mechanism of aneuploidy. Failure of separation of pair of chromosomes or chromatids occurs during cell division (meiosis I, meiosis II and mitosis).
- Nonjunction of chromosome is defined as failure of a pair of homologous chromosomes to separate in meiosis I, failure of sister chromatids to separate during meiosis II, and failure of sister chromatids during mitosis. Nondisjunction results in daughter cells with abnormal chromosome numbers (aneuploidy).
- Trisomy and monosomy chromosomal abnormalities are shown in Fig. 5.21. Differences between trisomy and monosomy are given in Table 5.27.

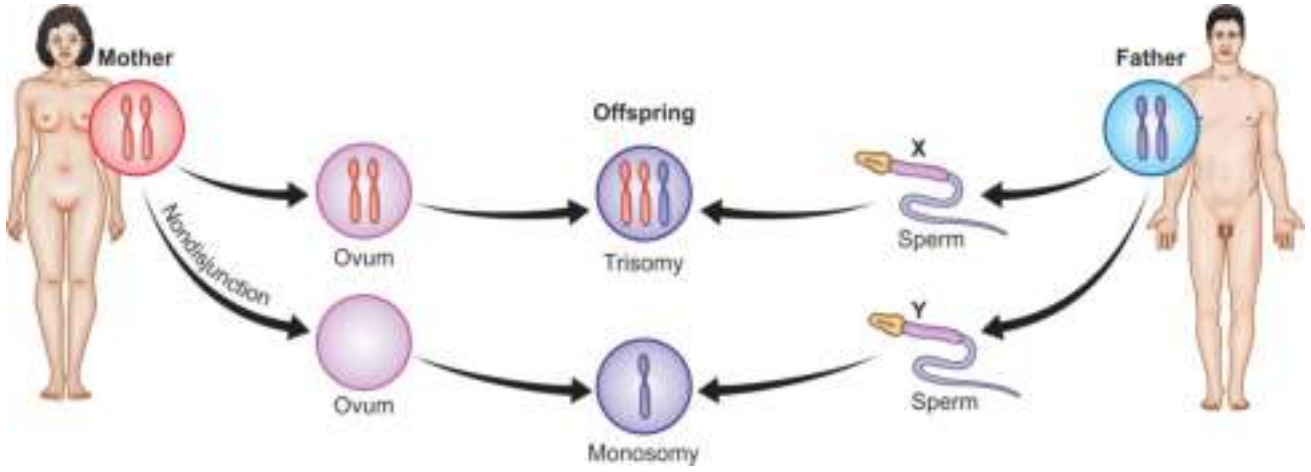

Fig. 5.21: Trisomy and monosomy chromosomal abnormalities. Trisomy is the presence of a third, extra copy of a chromosome, like in the case of Down syndrome. Monosomy is a form of aneuploidy with the presence of only one chromosome instead of the usual two chromosomes, like in the case of Turner syndrome.

Table 5.27 Differences between trisomy and monosomy

Characteristics	Trisomy	Monosomy
Definition	Trisomy refers to the condition of having an additional copy of a chromosome is present in the genome	Monosomy refers to the condition of having a diploid chromosome complement in which one chromosome lacks its homologous partner
Number of chromosomes	Presence of an additional chromosome	Presence of a single homologous chromosome in the homologous pair
Represented as	2n +1	2n –1
Example	Down syndrome (trisomy 21)	Turner syndrome (monosomy X) (45, X)

Polyploidy

Polyploidy is a term used to denote number of chromosomes multiple of haploid genome (23) such as triploidy (69 chromosomes) and tetraploidy (92 chromosomes). Polyploidy normally occurs in megakaryocytes and dividing hepatocytes. Polyploidy occurring in somatic cells of conception leads to spontaneous abortion.

ALTERATIONS IN AUTOSOME CHROMOSOME STRUCTURE

Alterations in chromosome structure occurs during cell division, which result from a break or breaks that disrupt the continuity of the chromosomes followed by reconstitution in an abnormal combination. Alterations in chromosome structure can occur by deletion of a section of chromosome, duplication of chromosome, translocation and inversion.

Deletion in Chromosome

Loss of chromosomal fragment ('p' short arm or 'q' long arm) or entire chromosome during cell division is termed deletion. Deletion of chromosome is shown in Fig. 5.22.

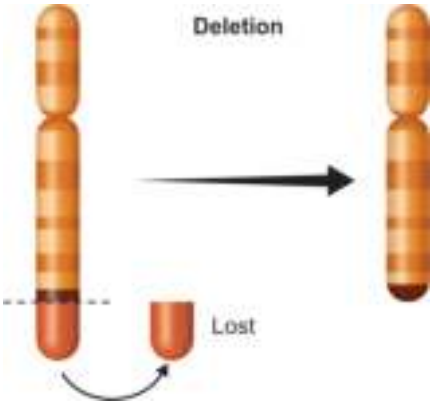

Fig. 5.22: Deletion of chromosome. Deletion of fragment of chromosome (long arm or short arm) during cell division leads to loss of genetic material and shortening of the chromosome. Deletion of the chromosome may occur in terminal or interstitial region. Deletions produce unbalanced meiotic products; thereby resulting in sterility.

- The severity of this lost genetic material depends upon the size of the deletion and the nature of the genetic material contained within it. Examples of chromosomal deletion syndromes include $5p^-$ deletion (cri-du-chat syndrome), $4p^-$ deletion (Wolf-Hirschhorn syndrome). Angelman syndrome and Prader-Willi syndrome.
- Smaller deletion in chromosome is detected by molecular techniques such as high-resolution banding, FISH and array comparative genome hybridization (array CGH).

Duplication of Chromosome

Chromosome duplication involves addition of chromosomal segment as a result of production of one or more copies of any piece of DNA or sometimes a gene or even an entire chromosome.

- A duplication of the chromosome is the opposite of a deletion. During a disease process, extra copies of the gene in the human genome can contribute to development of cancer.
- Genes can also duplicate in the evolution of human genome, where one copy of the original function and other copy of the gene produces new function. Duplication of whole chromosome causes disease.
- Chromosomal duplication happens during the crossing-over (recombination) between misaligned homologous chromosomes stage of meiosis. Duplication of chromosome results in trisomy (e.g. Down syndrome, XYY).
- Duplication of chromosome is detected by high-resolution banding, fluorescence *in situ* hybridization (FISH) and array comparative genome hybridization (array CGH).

Inversion of Chromosome

An inversion is a rearrangement in chromosome, in which a segment of a chromosome breaks at two regions is reversed end to end position in original chromosome after rotating by 180°. Inversion occurs when a single chromosome undergoes breakage and rearrangement within itself. As many as 1% of the newborn babies may carry an inversion that can be detected by G-banded

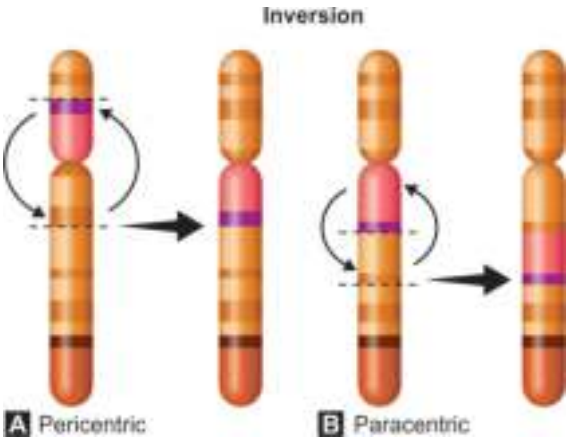

Fig. 5.23A and B: Inversion of chromosome. Inversion of chromosome requires two breaks in a single arm of chromosome. Inversions are of two types: pericentric (includes centromere) and paracentric (does not include centromere) turned through 180°.

chromosome karyotyping. Inversion produces unbalanced meiotic products; thereby resulting in sterility. There are two types of inversion: paracentric and pericentric. Inversion of chromosome is shown in Fig. 5.23A and B.

- **Differences between paracentric and pericentric inversions:** Paracentric inversion does not include the centromere and both breaks occur in one of the chromosomes. On the other hand, pericentric inversion includes the centromere and breaks occurs in both arms of chromosome. Differences and similarities between paracentric and pericentric inversions are given in Table 5.28.
- **Similarities between paracentric and pericentric inversions:** Both paracentric and pericentric inversions are large-scale chromosomal mutations occurring within a single chromosome. Both types of inversions do not cause a loss of genetic information. Both paracentric and pericentric inversions simply rearrange the linear gene sequence of a chromosome.

CHROMOSOMAL TRANSLOCATION

Chromosomal translocations involve breaks in two different nonhomologous chromosomes with exchange of chromosomal segments. Translocation may be balanced (reciprocal translocation in chronic myelogenous leukemia without loss of genetic material), or interstitial translocation (loss of segment of chromosome and reattaches to non-homologous chromosome).

Reciprocal or Balanced Chromosomal Translocation

A 'reciprocal' translocation occurs when there are break points in two chromosomes, with exchange of the fragments between two nonhomologous chromosomes, without loss of chromatin. Balanced translocation is often clinically silent. Philadelphia chromosome t(9; 22) discovered by Hugo de Vries in chronic myelogenous leukemia is an example of reciprocal translocation. Positivity of this Philadelphia chromosome t(9;22) indicates good prognosis in these patients. Reciprocal chromosomal translocation is shown in Fig. 5.24.

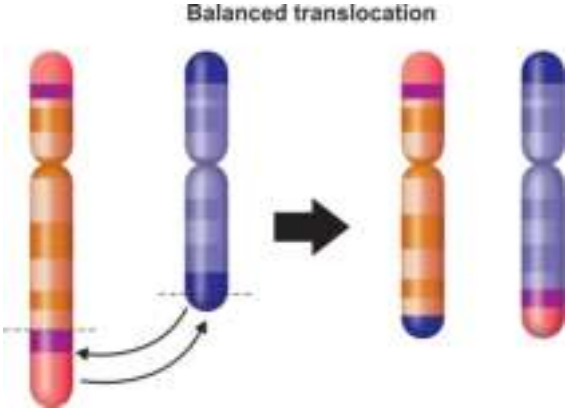

Fig. 5.24: Reciprocal chromosomal translocation. Reciprocal translocation is a chromosome rearrangement involving the exchange of chromosome segments between two chromosomes that do not belong to the same pair of chromosomes.

Table 5.28 Differences and similarities between paracentric and pericentric inversions

Parameters	Paracentric Inversion	Pericentric Inversion
Differences between paracentric and pericentric inversions		
Definition	Paracentric inversion is a type of chromosomal inversion in which a chromosomal segment that does not contain the centromere region rearranges in reverse orientation	Pericentric inversion is other type of inversion, in which a chromosomal segment containing the centromere segment containing the rearranges in reverse orientation
Breakpoint segment	Does not include a centromere	Centromere is included
Involvement of chromosome arms	Occurs in one arm of chromosome	Occurs in both arms of chromosome
Similarities between paracentric and pericentric inversions		
Mutation	Large scale mutation within same chromosome	Large scale mutation within same chromosome
Loss of genetic material	Nil	Nil

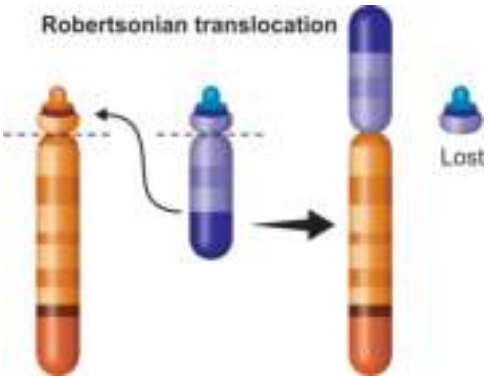

Fig. 5.25: Robertsonian translocation. In Robertsonian translocation, two nonhomologous acrocentric chromosomes break near centromeres, after which the long arms fuse to form one large metacentric chromosome. It is the most common type of chromosomal translocation in human beings.

Robertsonian Translocation

Robertsonian translocation is centric fusion of two acrocentric chromosomes resulting in the formation of one large metacentric chromosome and one small fragment. Robertsonian translocation is shown in Fig. 5.25.

- Acrosomal chromosomes with very short 'p' arms break very close to centromere leading to subsequent fusion of long 'q' arms. The human genome includes five acrocentric chromosomes: 13, 14, 15, 21, 22.
- The Y chromosome is also acrocentric chromosome. Robertsonian translocation predisposes to Down syndrome (14q;21q). Chromosome 21 is joined to a second acrocentric chromosome, commonly chromosome 14 or 22. The union of a gamete with this translocation with a gamete from an unaffected person can result in trisomy 21. There is high incidence of spontaneous abortion of fetuses.

Isochromosome

An isochromosome is an unbalanced structural abnormality created when the area surrounding the centromere in the pericentric region is divided transversely or perpendicular to the long axis of the chromosome. Isochromosome is shown in Fig. 5.26.

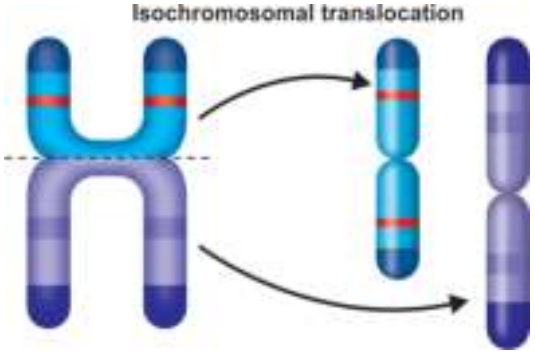

Fig. 5.26: Isochromosome arises from faulty centromere division, which leads to duplication of the long arm and deletion of the short arm, or the reverse.

- Isochromosome is formed by the duplication of one arm of a normal chromosome with deletion of the other arm. Both arms of the isochromosome are thus genetically identical.
- The chromosome consists of two copies of either the long (q) arm or the short (p) arm because isochromosome formation is equivalent to a simultaneous duplication and deletion of genetic material.
- As a result, there is partial trisomy of the genes present in the isochromosome and partial monosomy of the genes in the deleted arm. Example involving isochromosome (X chromosome) is observed in 15% cases of Turner's syndrome.

Ring Chromosome

Ring chromosome is formed by a break at both terminal (telomeric) ends of a chromosome followed by fragments and end to end fusion of fragments. The consequences depend on the amount of loss of genetic material as a result of break. Ring chromosome may form in cells following DNA damage by mutagens like radiation, but it may also arise spontaneously during development. Ring chromosome is shown in Fig. 5.27.

SOMATIC MOSAICISM

Somatic mosaicism is caused by an error (mutation) in the cell division very early in the development of the fetus, which occurs in two genetically distinct populations of cells with an individual derived a postzygotic mutation.

- In contrast to inherited mutations, somatic mutations can affect only a portion of the body and are not transmitted to the progeny. These mutations can affect varying genome size ranging from single nucleotide base pair to entire chromosome, which have been implicated in disease.
- Examples of mosaicism include mosaic Down syndrome, mosaic Klinefelter syndrome and mosaic Turner syndrome.

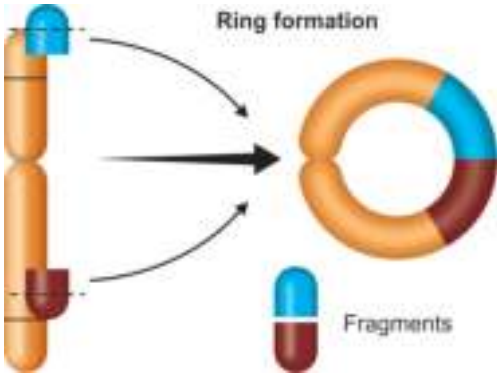

Fig. 5.27: Ring chromosome. A ring chromosome is an aberrant chromosome whose ends have fused together to form a ring as a result of DNA damage by mutagens or spontaneously during development.

Mosaic Down Syndrome

Persons with mosaic Down syndrome have a mixture of cells. Some cells have two copies, and some have three copies of chromosomes.

- A baby would be said to have mosaic Down syndrome if 5 of the 20 cells contain typical number of 46 chromosomes. The other 15 cells have a total of 47 chromosomes due to an extra chromosome 21.
- People with mosaic Down syndrome do not exhibit the physical features associated with Down syndrome individuals often go undiagnosed throughout their adulthood of this chromosome anomaly.

Mosaic Klinefelter Syndrome

Mosaic Klinefelter syndrome (46, XY/47, XXY) is not inherited, which results from random error during cell division early in the development of the fetus. As a result, there are two cell lines within the body. Some of the body's cells have usual one Y chromosome (46, XY), and other cells have an extra copy of the X chromosome (47, XXY). Persons with **mosaic Klinefelter syndrome** may have less severe signs and symptoms.

Mosaic Turner Syndrome

Mosaic Turner syndrome is also not inherited, which occurs as a random event during cell division in early fetal development. As a result, some of body's cells have the usual two sex chromosomes (46, XX) and other cells have only one copy of the X chromosome (45, X0).

- Girls and women with mosaic Turner syndrome tend to have fewer signs and health problems than those with typical Turner syndrome. It is because only some cells lack the second X chromosome in mosaic Turner syndrome.
- On the other hand, all cells in the body lack second X chromosome. The loss or change of the X chromosome happens very early in pregnancy by chance.

Confined Placental Mosaicism

Confined placental mosaicism (CPM) is defined as the presence of chromosomal abnormalities in the extraembryonic tissue (placenta), whereas cells in the fetus have normal karyotype. Therefore, placenta may be smaller in size than normal, which accounts for stillbirth or fetus growth retardation with normal karyotype. Conversely, a normal placental karyotype may allow longer survival of a fetus with abnormal karyotype. Confined placental mosaicism was first described by Kalousek and Dill in 1983.

MARKER CHROMOSOMES

Marker chromosomes are small additional chromosomes along with a normal set of chromosomes found during chromosome karyotyping that are usually derived from a structural rearrangement of chromosome X, 15, and 22. These are also referred to as supernumerary marker chromosome.

- Marker chromosomes may be in the form of ring or biosatellite chromosomes with or without centromeres. Marker chromosome with a centromere is relatively stable. However, marker chromosome without a centromere tends to be smaller with mitotic instability, which contain variable amount of heterochromatin or euchromatin.
- If marker chromosome arises *de novo*, then there is an increased risk for development of fetus mental retardation. However, if a parent has the marker as well, then it is familial and unlikely to be associated with mental retardation. Identification of the marker chromosome can be achieved by fluorescence *in situ* hybridization (FISH) or microarray chip assay.

DISORDERS OF AUTOSOMAL CHROMOSOME

Any chromosome except for the sex chromosome is known as autosome. Human beings have 44 autosomal chromosomes or autosomes. Chromosomal abnormalities usually happen due to one or more errors in cells: (a) errors during dividing of autosomes, (b) errors during dividing of sex cells, and (c) exposure to teratogenic substances resulting in birth defects.

DOWN SYNDROME (TRISOMY 21)

Down syndrome (trisomy 21) is a disorder, in which a person has an extra chromosome, i.e. three copies of a chromosome 21 instead of the usual two in every cell of the body as a result of error in cell division called 'nondisjunction' (failure of separation) of chromosome 21 in spermatozoa or ovum prior or at conception.

- The extra genetic material results in developmental changes and physical features of baby, as it grows during pregnancy and after birth. Baby is born with 46 chromosomes with extra copy of one of these chromosomes.
- Other common mechanisms that can give rise to Down syndrome include: Robertsonian translocation, isochromosome, or ring chromosome. Incidence of Down syndrome (trisomy 21) is 1 in every 1000 live births.
- There are three types of Down syndrome: (a) trisomy 21 (nondisjunction), (b) translocation type, and (c) mosaicism type. Schematic representation of Down syndrome (trisomy 21) is shown in Fig. 5.28.
  - **Down syndrome (trisomy 21):** Down syndrome (trisomy 21) accounts for 95% of all cases of Down syndrome, which occurs due to maternal meiotic nondisjunction of chromosomes. Patient has three copies of chromosome 21 rather than two copies

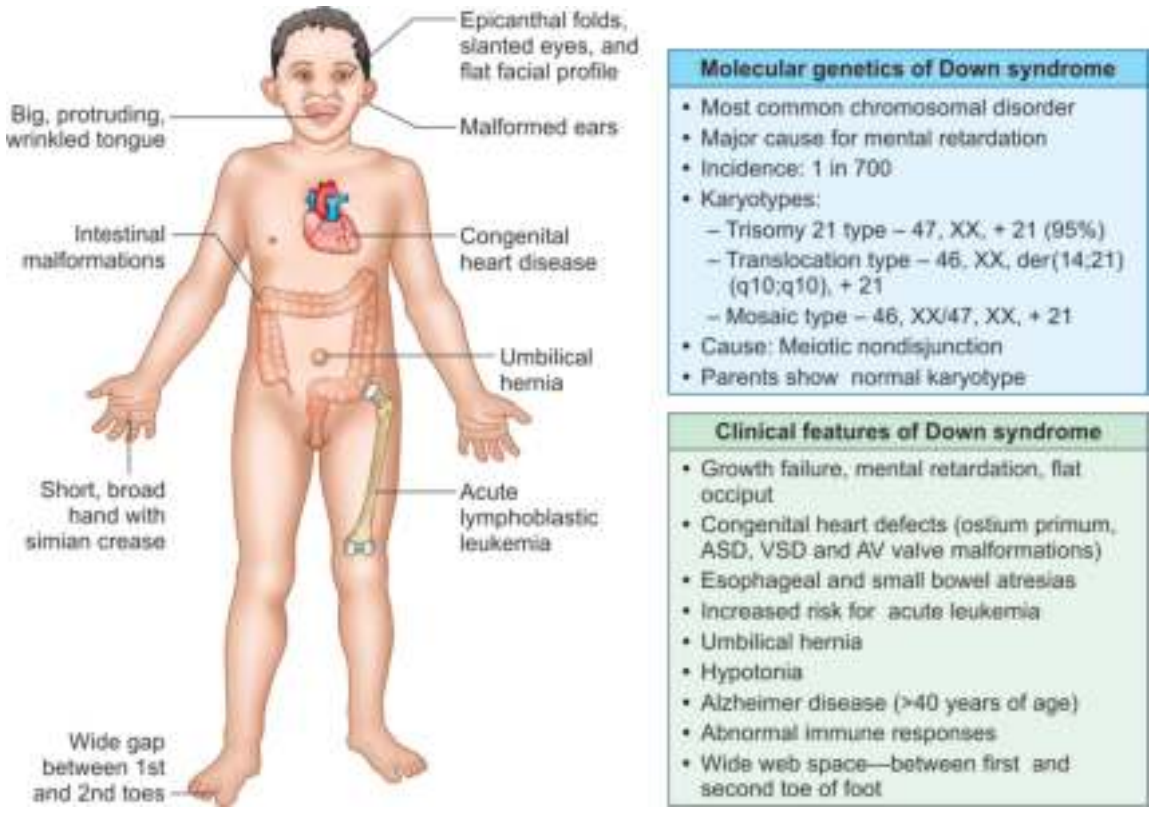

Fig. 5.28: Schematic representation of Down syndrome (trisomy 21). Patient with Down syndrome shows molecular genetic defects and clinical features.

of chromosome 21 in every cell of the body with chromosomal pattern 47, XX, +21. Incidence of Down syndrome increases with maternal age. When the cause is paternal nondisjunction, there is no relation to paternal age.

- **Down syndrome (chromosomal translocation type):** Down syndrome (chromosomal translocation type) accounts for 4% of all cases. Translocation of an extra-long arm of chromosome 21 to another acrocentric chromosome causes 46, XX, der(14; 21) (q10;q10), +21 pattern in the patient. There is no relation to maternal age. There is increased risk of Down syndrome in subsequent children.
- **Down syndrome (mosaic pattern type):** Persons with Down syndrome (mosaic pattern type) have a mixture of cells. Some of cells have extra copy of chromosome 21 and some cells lack extra copy of chromosome 21. People with Down syndrome (mosaic pattern type) do not exhibit the physical features of Down syndrome. These individuals often go undiagnosed throughout their adulthood.

Clinical Features

Patient suffering from Down syndrome presents with low intelligence quotient (IQ) ranging between 20 and 70, poor muscle tone, Mongolian idiocy (flat facial profile, oblique palpebral fissures and epicanthic folds), short neck with excess skin at the back of neck, large forehead, broad nasal bridge, wide-spaced upward slanting eyes often with a skin fold that comes out from the upper eyelid and covers the inner corner of the eye, large protruding tongue and small low-set ears.

- Small white spots are present at the periphery of iris known as Brushfield spots. Virtually all males are sterile but some females can reproduce.
- Musculoskeletal abnormalities in Down syndrome include short, broad hands with curvature of the fifth finger; simian crease, a single palmar crease; and an unusually wide space between the first and second toes. Clinical features and complications of Down syndrome are given in Table 5.29.

Maternal Screening

Maternal screening is performed by ultrasonography and hormonal assay. Ultrasonography reveals physical defects such as increased nuchal fold. The mother has high levels of serum human chorionic gonadotropin (hCG) and low levels of α-fetoprotein, and unconjugated estriol ('triple screen'). When mother has high levels of serum inhibin A, it is referred to as

Table 5.29 Clinical features and complications of Down syndrome (trisomy 21)

Body System	Physical Findings and Complications
Down syndrome: types	
Down syndrome (trisomy 21)	▪ Trisomy 21 (maternal meiotic nondisjunction of chromosome 21) ▪ Robertsonian translocation (14;21) ▪ Mosaic 21 (presence of two lines of cells)
Clinical features	
Intelligence quotient (IQ)	Low IQ ranging between 20 and 70
Facial features	▪ Mongolian idiocy (flat facial profile with large protruding tongue) ▪ Short neck with excess skin at the back of neck, large forehead and small low-set ears ▪ Wide-spaced upward slanting eyes often with a skin fold that comes out from the upper eyelid and covers the inner corner of the eye ▪ Oblique palpebral fissures and epicanthic folds broad nasal bridge ▪ Small white spots are present at the periphery of iris known as 'Brushfield spots'
Reproductive system	▪ Virtually all males are sterile ▪ Some females can reproduce
Musculocutaneous system	▪ Short, broad hands with curvature of the fifth finger; simian crease, a single palmar crease; and an unusually wide space between the first and second toes ▪ Poor muscle tone
Complications	
Congenital heart disease	▪ Atrial septal defect (ASD) ▪ Ventricular septal defect (VSD) ▪ Atrioventricular valve malformation (prolapse)
Gastrointestinal tract disorders	▪ Atresia of esophagus ▪ Atresia of small bowel ▪ Hirschsprung disease
Hematological disorder	▪ Acute lymphoblastic leukemia (ALL) ▪ Acute megakaryoblastic leukemia
Abdominal defects	Umbilical hernia
Central nervous system disorder	Alzheimer disease
Immune system disorder	Susceptibility to infection

Approximately 75% of fetuses with Down syndrome abort spontaneously. About 20% of patients die before the age of 10 years. Rest may have life expectancy of 60 years.

the 'quadruple' screen. There is also reduced levels of plasma protein A during pregnancy.

EDWARD SYNDROME (TRISOMY 18)

Edward syndrome (trisomy 18) is the second most common type of trisomy syndrome after Down syndrome (trisomy 21). Incidence of trisomy 18 is 1 in every 5,000 live births, which is more prevalent in female offspring. Karyotyping reveals trisomy 18 type (47, XX, +18) and mosaic type (46 XX, 47, XX, +18). Trisomy 18 is most often caused by extra copy of chromosome 18 in each cell in the body, instead of two copies. Edward syndrome (trisomy 18) is shown in Fig. 5.29.

Clinical Features

Patient suffering from Edward syndrome (trisomy 18) presents with mental retardation, prominent occiput, micrognathia (small lower jaw), low-set ears, rocker-bottom feet, flexion deformities of the fingers (index overlapping third and fourth), and congenital heart disease. Many babies cannot survive past the second or third trimester of pregnancy.

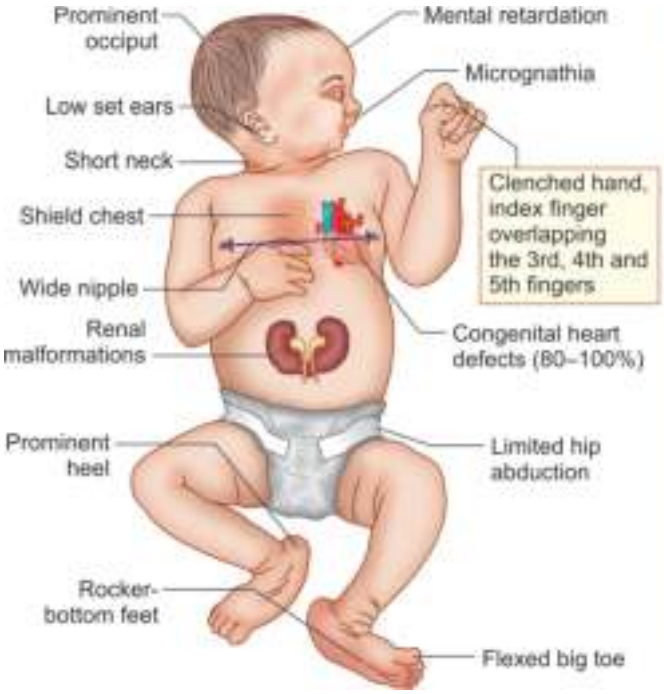
Laboratory Diagnosis

Ultrasonography is not accurate to diagnose Edward syndrome (trisomy 18) during pregnancy. More precise diagnostic methods include chorionic villus sampling and amniocentesis.

PATAU SYNDROME (TRISOMY 13)

Patau syndrome (trisomy 13) incidence is 1 in every 15,000 live births. Each cell in the body has three copies of chromosome 13, instead of the usual two in Patau syndrome.

- Most cases of Patau syndrome (trisomy 13) are not inherited. Patau syndrome results from errors in cell division, i.e. nondisjunction of chromosomes in cells with abnormal number of chromosomes.
- There are three types of Patau syndrome: (a) severe type trisomy 13 (nondisjunction, i.e. 47, XX, +13), (b) translocation (46, XX/47, XX, +13) and (c) mosaic type with some cells with extra copy of chromosome 13 (46, XX/47, XX, +13). Patau syndrome (trisomy 13) is shown in Fig. 5.30.



Edward syndrome (trisomy 18)

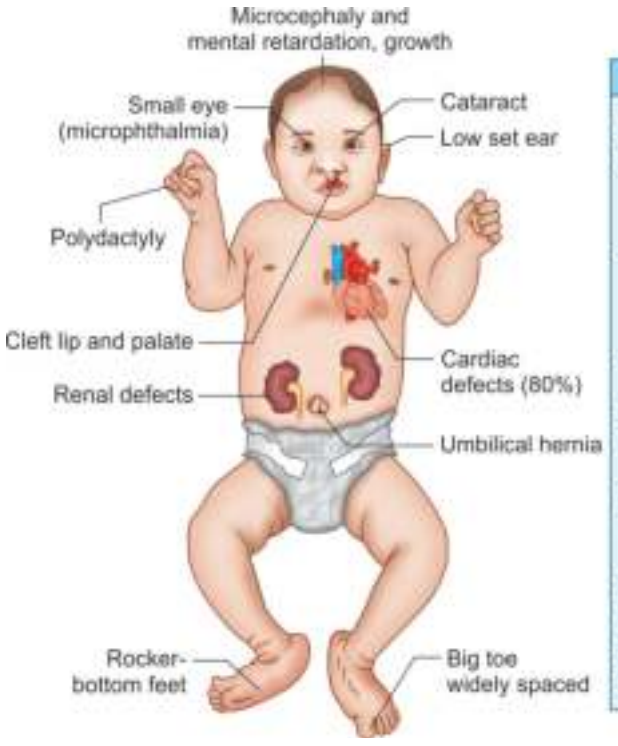
General considerations
- Incidence 1 in 8,000 births, higher in females
- Severe type (95%)
  - Trisomy 18 (47, XX, + 18)
- Mosaic type [less severe form (5%)]
  - 46, XX/47, XX, + 18
  - Some cells with two copies of chromosome 18
  - Some cells with three copies of chromosome 18

Cardiovascular disorders (80–100%)
- Ventricular septal defect
- Atrial septal defect
- Multivalvular disease
- Patent ductus arteriosus

Respiratory system disorders
- Upper airway obstruction
- Apnea

Gastrointestinal tract disorders
- Omphalocele
- Pyloric stenosis
- Tracheoesophageal fistula
- Imperforate anus

Fig. 5.29: Edward syndrome (trisomy 18) shows clinical features and genetic abnormalities.



Patau syndrome (trisomy 13)

General characteristics
- Incidence 1 in 15,000 births
- Severe type (trisomy 13.47 XX, + 13), infants die within one year of age
- Mosaic type: 46, XX/47, XX, +13 (some cells with two copies and some cells with three copies of chromosome)
- Translocation type (46, XX/47, XX, + 13)

Head and neck findings
- Microcephaly and mental retardation
- Broad flat face
- Slanting small eyes (microphthalmia)
- Short nose
- Cleft lip and palate
- Epicanthic eye folds
- Big wrinkled tongue
- Flat back

Upper limb findings
- Polydactyly (extra finger and toe)
- Overlapping of fingers over thumb
- Strange palm pattern (simian line)

Lower limb findings
- Prominent heel
- Deformed feet (rocker-bottom feet)
- Big toes widely spaced

Cardiac, renal and other defects
- Cardiac defects (80%)
- Renal defects
- Umbilical hernia

Fig. 5.30: Patau syndrome (trisomy 13) shows clinical features and genetic abnormalities.

Clinical Features

Patient suffering from Patau syndrome (trisomy 13) presents with mental retardation, microcephaly, microphthalmia, brain abnormalities, sloping forehead, cleft lip and cleft palate, low set ears, polydactyly, rocker-bottom feet, and congenital heart disease but with normal weight. It is difficult to predict the life expectancy of a baby with trisomy 13.

- Life span varies from one month, one year of 10 years.
- Ultrasonography is not 100% accurate to diagnose Patau syndrome (trisomy 13) during pregnancy.

Laboratory Diagnosis

Diagnosis of Patau syndrome (trisomy 21) can be confirmed prenatally with better than 99% accuracy through chorionic villus sampling and amniocentesis.

CRI-DU-CHAT (5p MINUS, CAT-CRY) SYNDROME

Cri-du-chat syndrome is also known as 5p– (5p minus) syndrome or cat-cry syndrome. It is a genetic disorder present since birth, that affecting both males (46, XY/5p minus) and females (46, XX/5p minus). Cri-du-chat syndrome is caused by the deletion of genetic material on the small arm (p arm) of chromosome 5.

- Infants with this disorder often has severe mental retardation, microcephaly, a high-pitched cry sounds that of a cat.
- On clinical examination, patient have low birth weight, round face, hypertelorism (wide-set eyes), low-set ears, and epicanthal folds. Clinical features of cri-du-chat syndrome in 80–90% of patients are given in Table 5.30.

DIGEORGE SYNDROME

DiGeorge syndrome is also known as microdeletion of 22q11 syndrome or velocardiofacial syndrome caused by the deletion of a small segment of chromosome 22q11.2.

- During intrauterine life, aberrant embryonic development of third and fourth branchial arches results in hypoplasia of thymus and parathyroid glands as well as anomalies of aortic arch, mandible and ear.
- Patient develops failure of maturation of T cell, but normal B cells functions resulting in recurrent infections. **CATCH-22 syndrome** also occurs due to microdeletion in chromosome 22q11.2.

Table 5.30 Clinical features of cri-du-chat syndrome in 80–90% of patients

Cri-du-chat syndrome is also known as 5p– (5p minus) syndrome or cat-cry syndrome
Epicanthus (prominent eye folds)
High-pitched voice
Intellectual disability (early severe mental retardation)
Low set posteriorly rotated eyes
Microcephaly (abnormally small skull, decreased circumference of cranium)
Microretrognathia (small protruded tongue)
Muscular hypotonia (low or poor muscular tone)
Round face
Severe global developmental delay
Wide nasal bridge

- Patient suffering from CATCH-22 syndrome presents with cardiac defects, abnormal facial features, thymic hypoplasia, cleft palate, hypoparathyroidism, hypocalcemia, tetany and recurrent infections. About 33% of cases develop behavior disorders and psychosis (bipolar disorder and schizophrenia) during adolescence.

SEX CHROMOSOME DEVIATION

Extreme karyotype deviations in the sex chromosomes are compatible with life; this is believed to be due to X chromosome inactivation (**lyonization**) and the relatively scanty genetic information carried by the Y chromosome.

Key Facts: Mary Lyon's Hypothesis of X Chromosome Inactivation

- Mary Lyon hypothesized that one of two X chromosomes in female cells derived from paternal or maternal is inactivated at random during early embryogenesis and that the inactive X chromosome is then maintained in a stable manner through all subsequent cell divisions. This inactivation of X chromosome is transmitted to all somatic cells except germ cells.
- Ovaries will always possess active chromosomes. In females, the inactive X chromosome in the somatic cells becomes condensed in the nucleus is called nuclear Barr bodies.
- Smears stained by scrapping of oral mucosa or circulating neutrophils demonstrate 'Barr bodies', which appear as drumstick appendage attached to one of the nuclear lobes.
- A minimum of 30% cells positive for sex chromatin (Barr body) indicates female genetic constitution.

BARR BODIES

Barr body is also known as sex chromatin, which appears as clumps of chromatin in the interphase nuclei of all somatic cells in females. Barr bodies are shown in Fig. 5.31.

- According to 'Lyon hypothesis', each Barr body represents one inactivated X chromosome. One Barr body is present in normal female cells (XX).
- Barr bodies are absent in males (XY). The number of Barr bodies is always one less than the number of X chromosomes.
- Barr body is absent in Turner syndrome with 45, XO karyotyping. One Barr body is present in Klinefelter syndrome with 47, XXY karyotyping. Two Barr bodies are demonstrated in 47, XXX (triple X) syndrome. Three Barr bodies are present in poly-X female with 48, XXXX karyotyping.
- Assessment of Barr bodies was considered as diagnostic tool in past. Now it has been supplanted by more definitive and sophisticated analytical

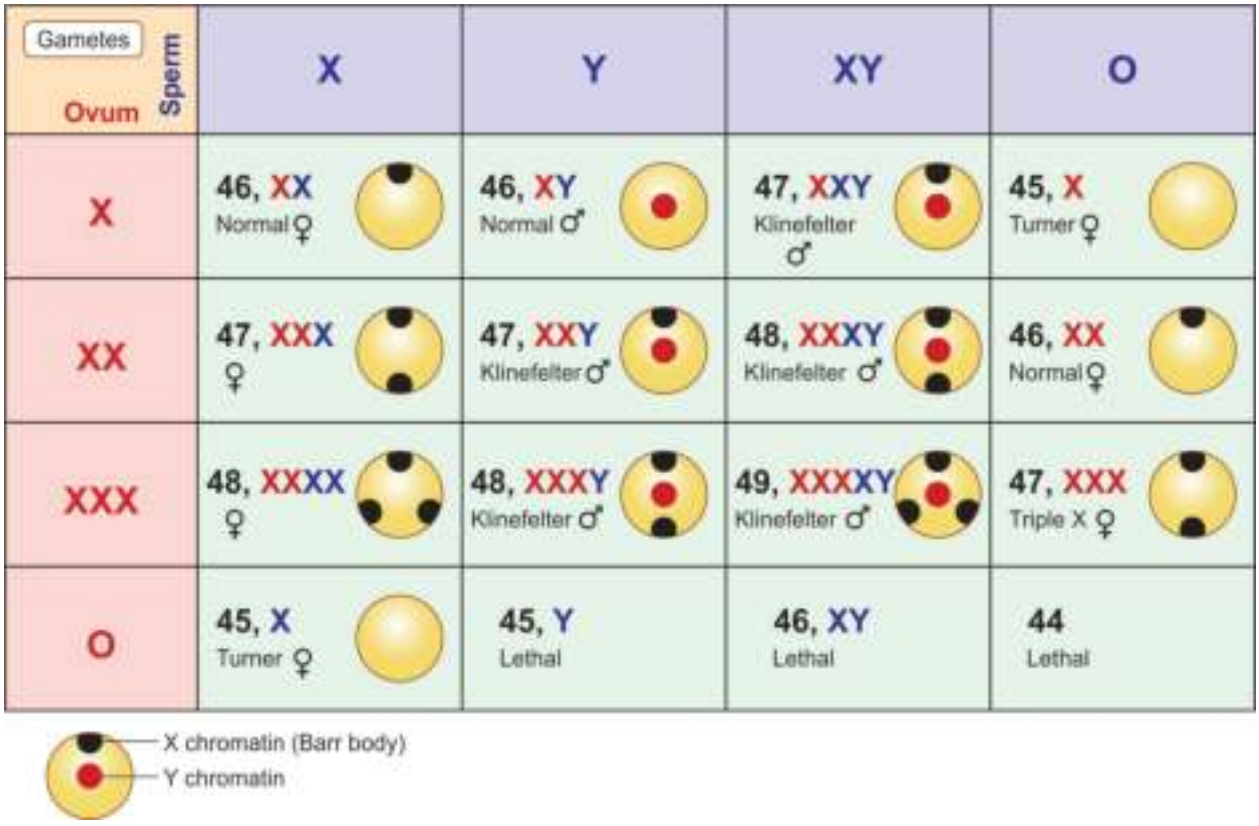


Fig. 5.31: Barr bodies. Barr body is a small, densely staining structure in the cell nuclei of females, consisting of a condensed, inactive X chromosome. It is regarded as diagnostic of genetic femaleness.

procedures. Number of different Barr bodies in human cells in different disorders related to sex chromosomes are given in Table 5.31.

X CHROMOSOME INACTIVATION

Females have two X chromosomes (XX), while males have only one X plus a Y chromosome. X chromosome inactivation is the process by which all X chromosomes except one are randomly inactivated at an early stage of embryonic development.

- X chromosome inactivation results in all normal females being mosaics, with two distinct cell lines, one with an active maternal X, and another with an active paternal X. It can be demonstrated if the female is heterozygous for an X-linked gene; if individuals demonstrate inheritable differences that distinguish the protein products of one X chromosome from the other, then members of the two cell lines can be identified.
- The X-inactive-specific transcript (Xist) is a large untranslated RNA molecule associated with 'coating' and inactivating of one of the two X chromosomes. All chromosomes except a single remaining X chromosome are inactivated. The phenotypic differences between XO, XX, and multiple X genotypes are thought to be caused by residual genes on the X chromosome that escape inactivation.

Table 5.31 Number of different Barr bodies in human cells in different disorders related to sex chromosomes

Sex Chromosomes	Disorder	Number of Barr Bodies
46, XX karyotyping in female	None	1
46, XY karyotyping in male	None	0
45, XO karyotyping	Turner syndrome	0
47, XXY karyotyping	Klinefelter syndrome	1
47, XXX karyotyping	Triple X syndrome	2
XXXX	Poly-X female	3

DISORDERS OF SEX CHROMOSOME

Classical disorders of sex chromosome are Klinefelter's syndrome, Turner syndrome, XYY syndrome, XXX syndrome (47, XXX), XY female gonadal dysgenesis (known as Swyer syndrome) with normal external genitalia; and other multi-X chromosome anomalies. Majority of disorders such as true hermaphroditism, mixed gonadal dysgenesis, and pure gonadal dysgenesis have abnormal sex chromosome.

KLINEFELTER SYNDROME (TRISOMY 47, XXY)

Klinefelter syndrome (trisomy 47, XXY) or testicular dysgenesis is the most common sex chromosome disorder in males in which an extra copy of the X chromosome is present, resulting in an XXY sex chromosome karyotype.

- The additional X chromosome(s) arises as a result of nondisjunction during gametogenesis. Incidence of this disorder is 1 in 1000 live births.
- Klinefelter syndrome is the most common genetic cause of male infertility, but many cases remain underdiagnosed because of substantial variations in Klinefelter syndrome such as 48, XXYY or 49, XXXXY or mosaic types. Klinefelter syndrome can shorten life expectancy up to two years. Schematic representation of Klinefelter's syndrome is shown in Fig. 5.32.

Clinical Features

Patient suffering from Klinefelter's syndrome presents with hypogonadism (atrophic testes), infertility and gynecomastia. Other manifestations include tall height, long arms, long legs, eunuchoid body status appearance, small penis, cryptorchidism, hypospadias, radioulnar synostosis, delayed puberty and lack of secondary male characteristics such as deep voice, beard, and male distribution of pubic hair.

Laboratory Diagnosis

Klinefelter syndrome may be suspected during a noninvasive prenatal screening blood test. Invasive prenatal amniocentesis and chorionic villi sampling are done to confirm the diagnosis.

- Blood or urine specimens can reveal abnormal hormone levels in Klinefelter syndrome. Plasma levels of hormones are elevated such as follicular

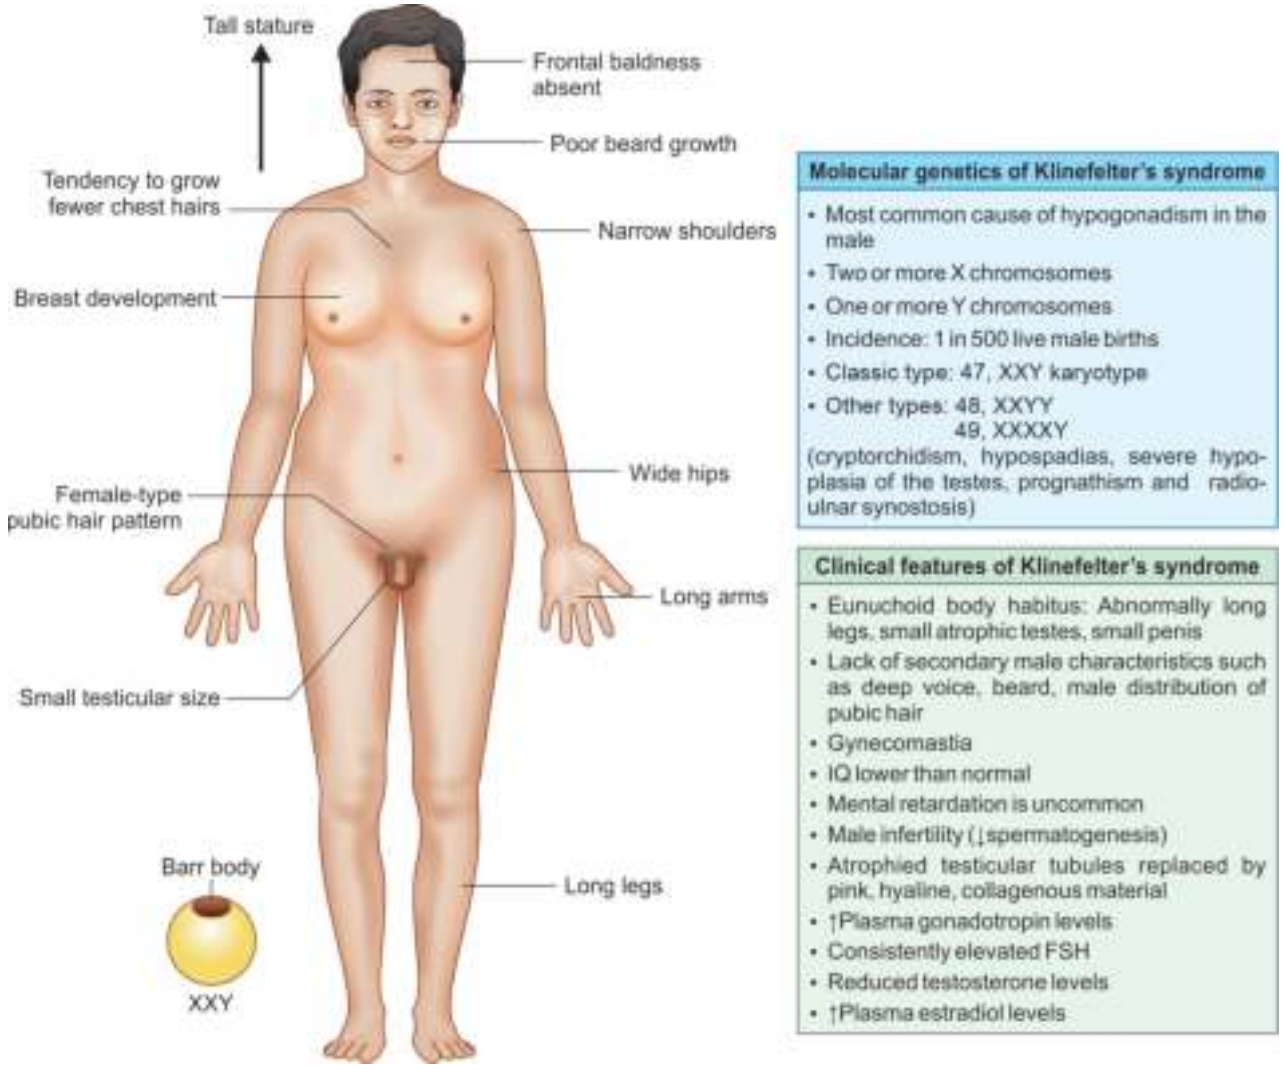

Fig. 5.32: Schematic representation of Klinefelter's syndrome. It shows molecular genetic abnormalities and clinical features such as short stature, pubertal delay and gynecomastia.

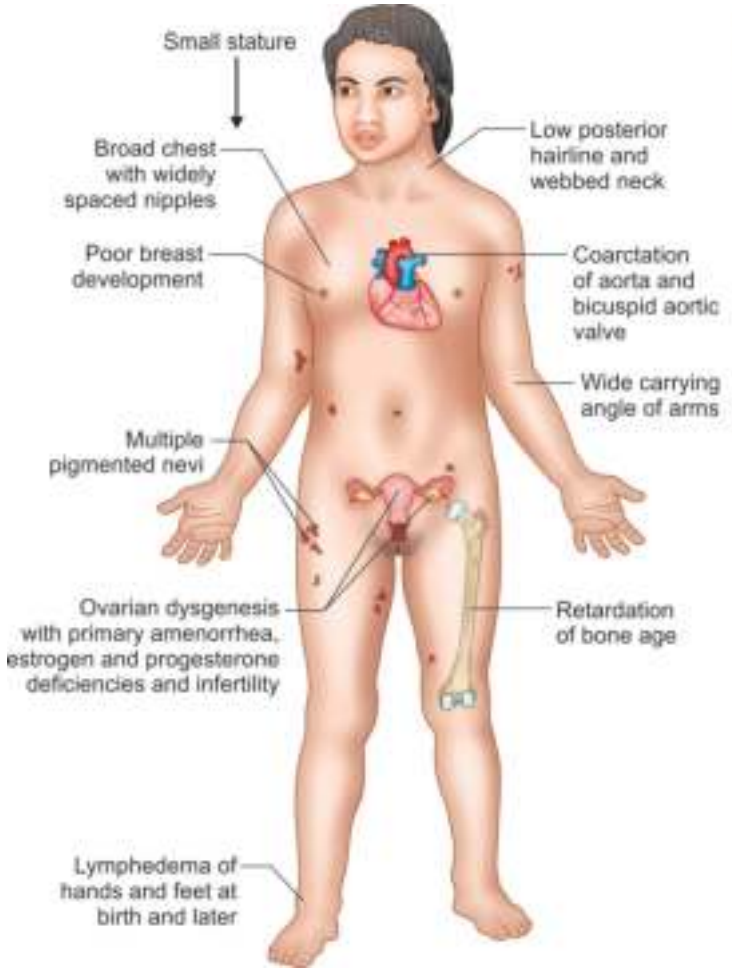
stimulating hormone (FSH), luteinizing hormone (LH), plasma pituitary gonadotropin and estradiol. Plasma testosterone level is markedly reduced due to loss of feedback inhibition in affected males.

- Karyotype analysis is done to confirm the diagnosis. Normal female (XX) has one Barr body. Normal male (XY) lacks Barr body. In **Klinefelter syndrome (XXY)**, patient shows **one Barr** body.

TURNER SYNDROME (MONOSOMY 45, X/XO)

Turner syndrome, also known as congenital ovarian hypoplasia syndrome or gonadal dysgenesis, is usually not inherited, but it is genetic chromosomal disorder in females called **monosomy** caused by a random error that leads to a complete or partial missing X chromosome in the sperm or ovum of a parent.

- Main clinical manifestations of Turner syndrome include infertility, rudimentary ovaries, early primary ovarian insufficiency, lack of menstrual cycle at menarche, short stature, lymphedema over dorsum of the hands, feet and nape of the neck, cardiovascular abnormalities and neurocognitive difficulties. **Infertility** is the most troubling problem of Turner syndrome. These females are unable to conceive even with years of estrogen replacement therapy. Turner syndrome is shown in Fig. 5.33.
- Turner syndrome demonstrates three patterns on karyotyping, classic pattern, mosaic pattern and structural pattern.
  - **Classic type of Turner syndrome:** There is complete or partial monosomy of the short arm of X chromosome (Xp), an XO karyotype (45, X) is characteristic in 57% of cases.
  - **Mosaic type of Turner syndrome:** A mosaic person has two lines of cells (one normal chromosome and another with monosomy single residual abnormal chromosome) for the affected chromosome pair due to anaphase lag. Turner's mosaicism is associated with 45, X/46, XX or 45, X/46, XY, 45, X/47, XXX, 45, X/46, X, i(X)(q10). A deletion of the SHOX gene can cause an identical phenotype and may be considered to be a variant of Turner syndrome.
  - **Structural abnormalities in second X chromosome of Turner syndrome:** These include 46, X, i(Xq) or 46, X, del(Xp), or 46, X, del(Xq) or 46, X, r(X) in 14% of cases.



Molecular genetics of Turner's syndrome

Incidence: 1 in 3000 female births

Karyotypes:

• Classic	45, X	(57%)
• Structural abnormalities in second X chromosome	46, X, i(Xq) 46, X, del(Xp) 46, X, del(Xq) 46, X, r(X)	(14%)
• Mosaic type:	45, X/46, XX 45, X/46, XY 45, X/47, XXX 45, X/46, X, i(X) (q10)	(29%)

Clinical features of Turner's syndrome

- During infancy (edema of the dorsum of the hand, foot, and nape of the neck)
- During puberty:
  - Failure to develop normal
  - Secondary sex characters: Infantile genitalia, breast development (inadequate, a little pubic hair)
- During adult life (short stature, amenorrhea)
  - Low posterior hairline
  - Bilateral neck webbing
  - Congenital heart disease (coarctation of aorta, bicuspid aortic valve)
  - Broad chest and widely spaced nipples
  - Cubitus valgus, streak ovaries, infertility
  - Pigmented nevi
  - Mental status: Normal/retardation
  - Hypothyroidism, glucose intolerance

Fig. 5.33: Turner syndrome shows molecular genetic abnormalities and clinical features such as amenorrhea, short stature, pubertal delay and obesity.

Clinical Features

Patient suffering from Turner syndrome presents with lymphedema on dorsum of the hands, feet and nape of the neck during infancy. At puberty, features include infantile genital organs, inadequate breast development, and little pubic hair.

- An adult female has short stature, webbed neck, shield-like chest with widely spaced nipples, bilateral neck webbing, and wide carrying angle of the arms, multiple nevi and cubitus valgus.
- Turner syndrome is also often associated with autoantibody-mediated hypothyroidism. Patient may have coarctation of the aorta and bicuspid valve congenital malformations.
- Most girls and women with Turner syndrome have normal intelligence. Most women with Turner syndrome cannot become pregnant naturally.

Laboratory Diagnosis

A diagnosis of Turner syndrome may be suspected when patient has physical features such as webbed neck, a broad chest and widely spaced nipples. Chromosomal composition of the female is analyzed by karyotyping technique. A standard 30-cell karyotype analysis is required for diagnosis of Turner syndrome, in order to exclude mosaicism. Diagnosis of Turner syndrome is confirmed by the presence of 45, X cell line or a cell line with deletion of the short arm of the X chromosome (Xp deletion).

JACOB SYNDROME (TRISOMY XYY)

Jacob syndrome (Trisomy XYY) is a rare sex chromosome disorder of a male infant born with an extra Y chromosome. Sex chromosome abnormality with XYY is also called Jacob syndrome. Incidence of this disorder is 1 per 1000 live births.

- Most cases are not inherited, and XYY syndrome occurs randomly in pregnancies of women from all ages and ethnic background. Normal female has two X chromosomes (XX), while normal male has one X chromosome and one Y chromosome (XY). However, male newborns with XYY syndrome have an extra Y chromosome in each cell of their body.
- Most of these cases occur due to a cell division error in the sperm prior to conception known as 'nondisjunction'(failure of separation). The exact cause of this nonjunction is not known.

Clinical Features

Male newborns suffering from Jacob syndrome (XYY syndrome) present with low-weight relative to tall height, large head dimensions, severe acne in adolescence, behavioral and emotional difficulties, learning disabilities, and delayed development of speech and language skills, delayed sitting and walking, hypotonia, hand tremors or motor tics, and slightly lower IQ than normal. Small percentage of cases of XYY syndrome have autistic spectrum of disease.

Complications

Patient with Jacob syndrome (XYY syndrome) experiences puberty at expected times, as well as normal development of sex organs and secondary sex characteristics. These cases may have decreased sperm quality with 'immature' spermatozoa often associated with male infertility.

Laboratory Diagnosis

Jacob syndrome (XYY) is usually diagnosed when prenatal karyotyping is done to detect Down syndrome by amniocentesis and chorionic villus sampling. A blood test can accurately diagnose Jacob syndrome (trisomy XYY).

TRIPLE X (47, XXX SYNDROME) AND OTHER MULTI-X CHROMOSOME ANOMALIES

Triple X (47, XXX syndrome) and other multi-X chromosome anomalies are usually unaccompanied by any clinical abnormalities, although they may be marked by menstrual irregularities. Additional X chromosomes beyond XXX are marked by progressively increasing mental deficiency, depending on the number of additional X chromosomes.

HUMAN GENE STRUCTURE AND MUTATIONS

GENE STRUCTURE

A gene is the basic physical and functional unit of heredity. Genes are made up of deoxyribonucleic acid. Each gene contains a 5′-regulatory or untranslated region (5′-UTR), where the transcription factors bind and initiate transcription of the primary transcript. Gene also contains three specific sequences of nucleotides: **exons** (coding sequence), intervening regions called **introns** (noncoding sequence) and regulatory sequences. Structure of human gene is shown in Fig. 5.34.

EXONS (CODING SEQUENCE) AND INTRONS (NONCODING SEQUENCE) IN GENE

Exons and **introns** are nucleotide sequences within a gene. An **exon** is the segment of a gene that encodes

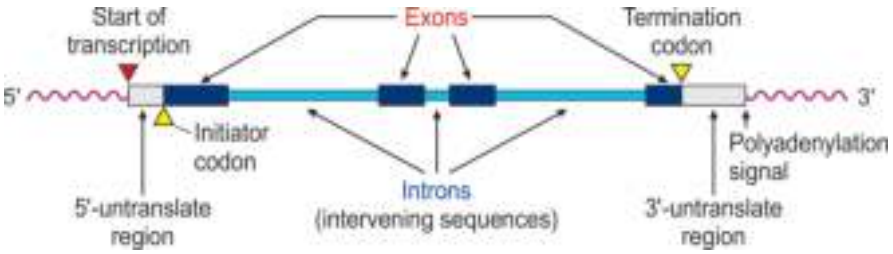


Fig. 5.34: Structure of human gene. Gene contains 5'→3'-untranslated regions, promoter, enhancer/silencer, exons (coding sequences), introns (noncoding sequences) and transcriptional and translational start and stop codon sites. Gene is composed of deoxyribonucleic acid (DNA).

the information for transcription and translation of sequence of amino acids to produce protein.

- Exons are separated by intervening sections of DNA known as introns that do not code for proteins.
- Following transcription, new immature strand of messenger RNA, called pre-mRNA. The pre-mRNA contains both exons and introns.
- The pre-mRNA molecule goes through modification process in the nucleus called **splicing** during which the noncoding introns are excised and only the coding exons remain with addition of 5′ cap and poly(A) tail.
- Splicing produces a mature messenger RNA molecule that is then translated into protein. Schematic representation of primary RNA transcript splicing and formation of messenger RNA is shown in Fig. 5.35.

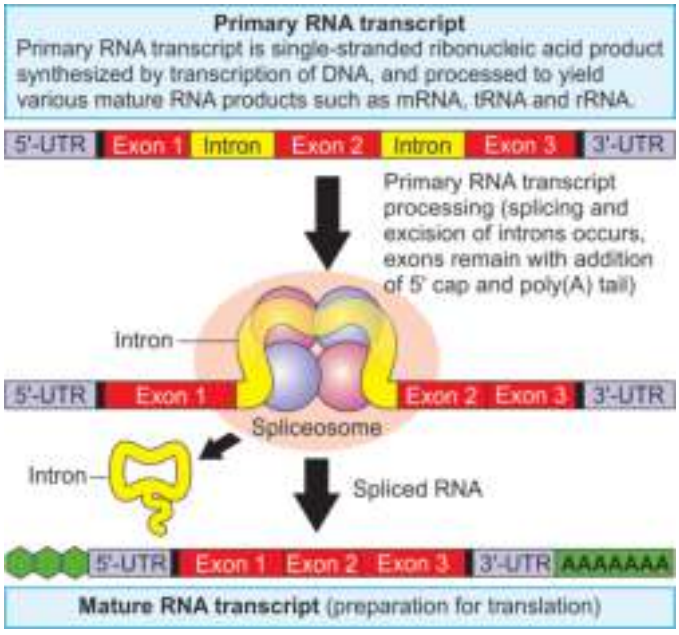

Fig. 5.35: Schematic representation of primary RNA transcript splicing and formation of messenger RNA. A primary transcript is the single-stranded ribonucleic acid product synthesized by transcription of DNA, and processed to yield various mature RNA products such as messenger RNA (mRNA), transfer RNA (tRNA) and ribosomal RNA (rRNA).

REGULATORY REGIONS IN DNA: PROMOTERS, ENHANCERS AND SILENCERS

A regulatory sequence is a segment of deoxyribonucleic acid molecule which is capable of increasing or decreasing the expression of specific genes within an organism. Regulation of gene expression is an essential feature of all organisms. Schematic representation of regulatory regions in DNA is shown in Fig. 5.36.

- **Human gene** contains 5′→3′ untranslated regions, promoters, enhancers and silencers.
  - **Promoters** are DNA regions of 1–2 kilobases (kb) of a gene transcription start site, they contain short regulatory elements (DNA motifs) necessary to assemble RNA polymerase transcriptional machinery.
  - Enhancers are found in the same region of a gene. An enhancer is a sequence of DNA that functions to enhance transcription.

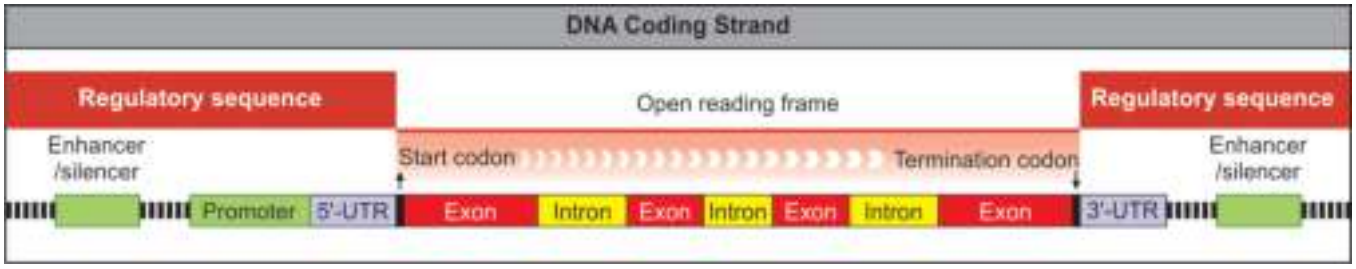

Fig. 5.36: Schematic representation of regulatory regions in DNA. Human gene is composed of deoxyribonucleic acid (DNA). The gene contains 5'→3'-untranslated regions, promoters, enhancers and silencers. Promoters are DNA regions within 1–2 kilobases (kb) of a gene transcription start site, they contain short regulatory elements (DNA motifs) necessary to assemble RNA polymerase transcriptional machinery. An enhancer is a sequence of DNA that functions to enhance transcription. A promoter has to be close to the gene that is being transcribed while an enhancer does not need to be close to the gene of interest.

- A promoter is a sequence of DNA that initiates the process of transcription. A promoter has to be close to the gene that is being transcribed while an enhancer does not need to be close to the gene of interest.

- Promoter and enhancer regions regulate the transcription of a gene into a pre-mRNA, which is modified to remove intervening introns and add a 5′ cap and poly(A) tail. It is the binding site for micro-RNAs (mRNAs).
- The mature messenger RNA (mRNA) 5′→3′-untranslated regions regulate translation into the final protein product. Each three-letter sequence of mRNA nucleotides corresponds to a specific amino acid, or to a stop codon. UGA, UAA and UAG are stop codons.
- Genetic code is universal. Silencers are noncoding regions, which can inhibit transcription.

Promoter Regulatory Region of DNA

A promoter is a regulatory region of DNA located upstream towards the 5′ region of a gene. A promoter contains specific DNA sequences that are recognized by proteins known as transcription factors (i.e. enhancers and silencers). A promoter regulates RNA polymerase, which binds and transcribes DNA to mRNA, which is ultimately translated into a functional protein.

Enhancer and Silencer Regulatory Region of DNA

Enhancer and silencer of regulatory region of DNA are located upstream towards 5′ region of a gene. Enhancer functions as a '**turn on**' **switch** in gene expression and activates the promoter region of a particular gene. Enhancer also functions with transcription factors to enhance the transcription of an associated gene. **Silencer** acts as the '**turn off**' **switch** in gene expression.

NONCODING REGULATORY RNA

A noncoding RNA (ncRNA) is a functional RNA molecule that is transcribed from DNA but not translated into proteins. Abundant and functionally important types of noncoding RNAs include transfer RNAs (tRNAs) and ribosomal RNAs (rRNAs), as well as small micro-RNAs such as micro-RNAs, siRNAs, piRNAs, snoRNAs, snRNAs, exRNAs, scaRNAs and the long ncRNAs such as Xist and HOTAIR. Schematic representation of noncoding regulatory RNAs is shown in Fig. 5.37.

MicroRNA (miRNA)

Human genome contains about 1000 microRNAs constituting 5% of total genome. MicroRNAs are mature oligomers of 22 nucleotides in length, which do not code for proteins. MicroRNAs participate in silencing

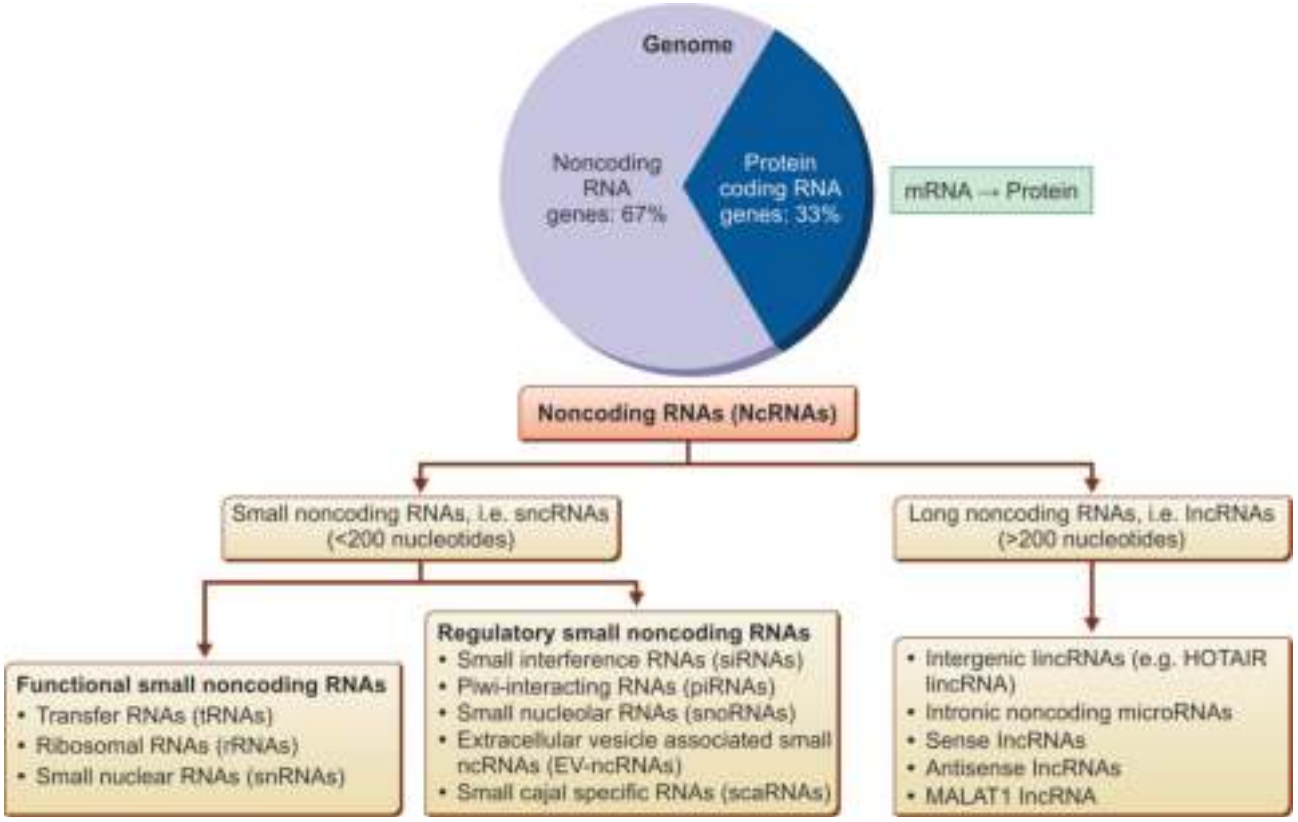

Fig. 5.37: Schematic representation of epigenetic-related small and long non-coding microRNAs(ncRNAs). Abundant and functionally important types of noncoding RNAs include transfer RNAs (tRNAs) and ribosomal RNAs (rRNAs), as well as small ncRNAs such as micro-RNAs, siRNAs, piRNAs, snoRNAs, snRNAs, exRNAs, scaRNAs and long lncRNAs (i.e.; intergenic, intronic (HOTAIR), sense, antisense and MALAT1)

post-transcriptional genes. All microRNAs comprise seed sequence in their 32 untranslated regions (UTR), which determine the specificity of miRNA binding and gene silencing.

Long Noncoding RNA (LncRNA)

Long noncoding RNA (LncRNA) participates in activation of gene, which inhibit gene transcription. Example of repressive function involves Xist (X inactive specific transcript). Xist inactivates X chromosomes resulting in Barr body formation. LncRNA stabilizes secondary or tertiary structure of protein that influence gene activity. It is linked to atherosclerosis and cancer.

START AND STOP CODONS

Cells decode mRNAs by reading their nucleotides in a group of three, called codons. Most codons specify an amino acid. Codons in an mRNA are read during translation, beginning with a start codon and continuing until stop codon is reached.

- Messenger RNA (mRNA) codons are read from 5′→3′, and these specify the order of amino acids in a protein from N-terminus (methionine) to C-terminus.
- The start codon marks the site at which translation into protein sequence begins, and the stop codon marks the site at which translation ends. The start codon is the first codon of a messenger RNA (mRNA) transcript translated by a ribosome, that initiates translation of the first amino acid in the polypeptide chain.
- The start codon always codes for methionine amino acid specified by one codon AUG. The three stop codons in messenger RNA are UAA, UAG, and UGA (U = uracil, A = adenine; G = guanine). The three **stop codons** mark the end of a protein, which are also called **termination codons** or **nonsense codons**. The genetic code is always universal.

GENE MUTATIONS

A gene mutation is a permanent structural alteration in the nucleotide sequence in genome DNA, which can be transmitted from a cell to its daughter cells. Somatic mutation is present in somatic tissues. Germline mutation is present in the gametes (eggs or sperms).

- Gene mutation results in abnormal transcribed DNA sequence (mRNA), abnormal translated proteins and lethal phenotype due to mutated RNA and protein. Gene mutations range in size, which can affect anywhere from a single DNA nucleotide base pair to a large segment of a chromosome that includes multiple genes.
- Gene mutations occur in two ways: spontaneous or induced by mutagens (ultraviolet radiation, ionizing radiation, chemical agents). Intercalating agents insert into the DNA molecule and cause single-nucleotide insertions and deletions. Oxidative reactions alter the chemical structures of nucleotide base pairs. Ionizing radiation alters nucleotide base pairs and breaking phosphodiester bonds. Ultraviolet produces light pyrimidine dimers, which block DNA replication.
- The DNA sequence of a gene can be altered in a number of ways. Gene mutations alter the function of essential proteins, which adversely affect the health of individuals. The types of gene mutations include: nonsense, missense, insertion, deletion, duplication, frameshift mutations and trinucleotide repeat expansion. Characteristics of different types of gene mutations are given in Table 5.32.

Table 5.32 Characteristics of different types of gene mutations

Gene Mutation	Comments
Mutations	Mutations are heritable changes in genetic information, which mutations include the mispairing of base in DNA replication and spontaneous depurination and deamination. Alkylating agents, deaminating chemical and hydroxylamine result in mutations by modifying the chemical structure of bases
Mutation rate	Mutation rate is the frequency with which a particular mutation arises, which is influenced by genetic and environmental factors. Some mutations occur spontaneously
Mutagenic agents	Intercalating agents insert into the DNA molecule and cause single-nucleotide insertions and deletions. Oxidative reactions alter the chemical structures of nucleotide bases. Ionizing radiation alters base structures and breaking phosphodiester bonds. Ultraviolet light produces light pyrimidine dimers, which block DNA replication
Somatic mutations	Somatic mutations occur in somatic cells
Germline mutations	Germline mutations occur in the cells that give rise to gametes (sperms or ova)
Base substitution mutation	Base substitution mutation changes the base of a single DNA nucleotide

Contd...

Table 5.32 Characteristics of different types of gene mutations (*Contd...*)

Gene Mutation	Comments
Transition	Base substitution in which a purine replaces a purine or a pyrimidine replaces a pyrimidine
Transversion	Base substitution in which a purine replaces a pyrimidine or a pyrimidine replaces a purine
Insertion	Addition of one or more nucleotides alters the number of DNA bases in a gene by adding a piece of DNA resulting in protein made by the gene, that may not function proper. Insertion can arise from strand slippage in DNA replication or from unequal crossing over. Insertion of intercalating agents into DNA molecule causes single-nucleotide insertion
Deletion	Deletion of one or more nucleotides alters number of DNA bases as well as the function of the resulting protein(s). Small deletion removes one or few base pairs within a gene, while large deletion removes an entire gene or several neighboring genes. Deletion can arise from strand slippage in DNA replication or from unequal crossing over. Insertion of intercalating agents into DNA molecule causes single-nucleotide deletion
Frameshift mutation	Insertion or deletion that alters the reading frame of a gene resulting in production of nonfunctional protein. Reading frame consists of groups of three bases that each code for one amino acid. Insertion, deletions and duplications can frameshift mutations
Inframe deletion or insertion	Deletion or insertion of a multiple of three nucleotides that does not alter the reading frame
Duplication mutation	A piece of DNA is abnormally copied one or more times resulting in alteration in function of protein
Expanding nucleotide repeats	Expanding nucleotide repeats are short DNA sequences that are repeated a number of times, in which the number of copies of the sequence increases
Forward mutation	Changes the wild-type phenotype to a mutant phenotype
Reverse mutation	Changes a mutant phenotype back to the wild-type phenotype
Silent mutation	A silent mutation produces a sense codon into a synonymous codon, that encodes the same amino acid; there is no change in amino acid sequence of the protein
Nonsense mutation	A nonsense mutation changes a sense codon into a nonsense codon, which alters DNA sequence causing premature termination of translation; but there is no substitution of one amino acid for another
Missense mutation	A missense mutation alters the coding sequence (i.e. sense codon changes into different codon), so one amino acid is substituted for another amino acid in the protein made by a gene
Neutral mutation	A neutral mutation changes alters the amino acid sequence of a protein but does not change the function of the protein
Loss-of-function mutation	Loss-of-function mutation results in complete or partial loss of function
Gain-of-function mutation	Gain-of-function mutation causes the appearance of a new trait or function or causes the appearance of a trait in inappropriate tissue or at an inappropriate time
Lethal mutation	Lethal mutation causes premature death
Suppressor mutation	Suppressor mutation suppresses the effect of an earlier mutation at a different site
Intragenic suppressor mutation	Intragenic suppressor mutation suppresses the effect of an earlier mutation within the same gene
Intergenic suppressor mutation	Intergenic suppressor mutation suppresses the effect of an earlier mutation in another gene

POINT MUTATION (SUBSTITUTION IN SINGLE NUCLEOTIDE BASE PAIR) WITHIN CODING SEQUENCES

Single nucleotide base substitution is called point mutation. Substitution is a type of gene mutation involving replacement or substitution of a single nucleotide base with another in DNA or RNA mole-cule (i.e. a change in single chemical letter such as switching an A to a G). Such substitution can change a codon that encodes a different amino acid leading to a small change in the protein produced. Schematic representation of point mutation is shown in Fig. 5.38.

Single Nucleotide Base Substitution and Gene Mutation

Single nucleotide base substitution is most common type of mutation, that occurs by two ways: (a) transition occurs when a purine is substituted with another purine or when pyrimidine is substituted with another pyrimidine in DNA or RNA molecule, and (b) transversion occurs, when a purine is substituted for a pyrimidine or a pyrimidine replaces a purine in

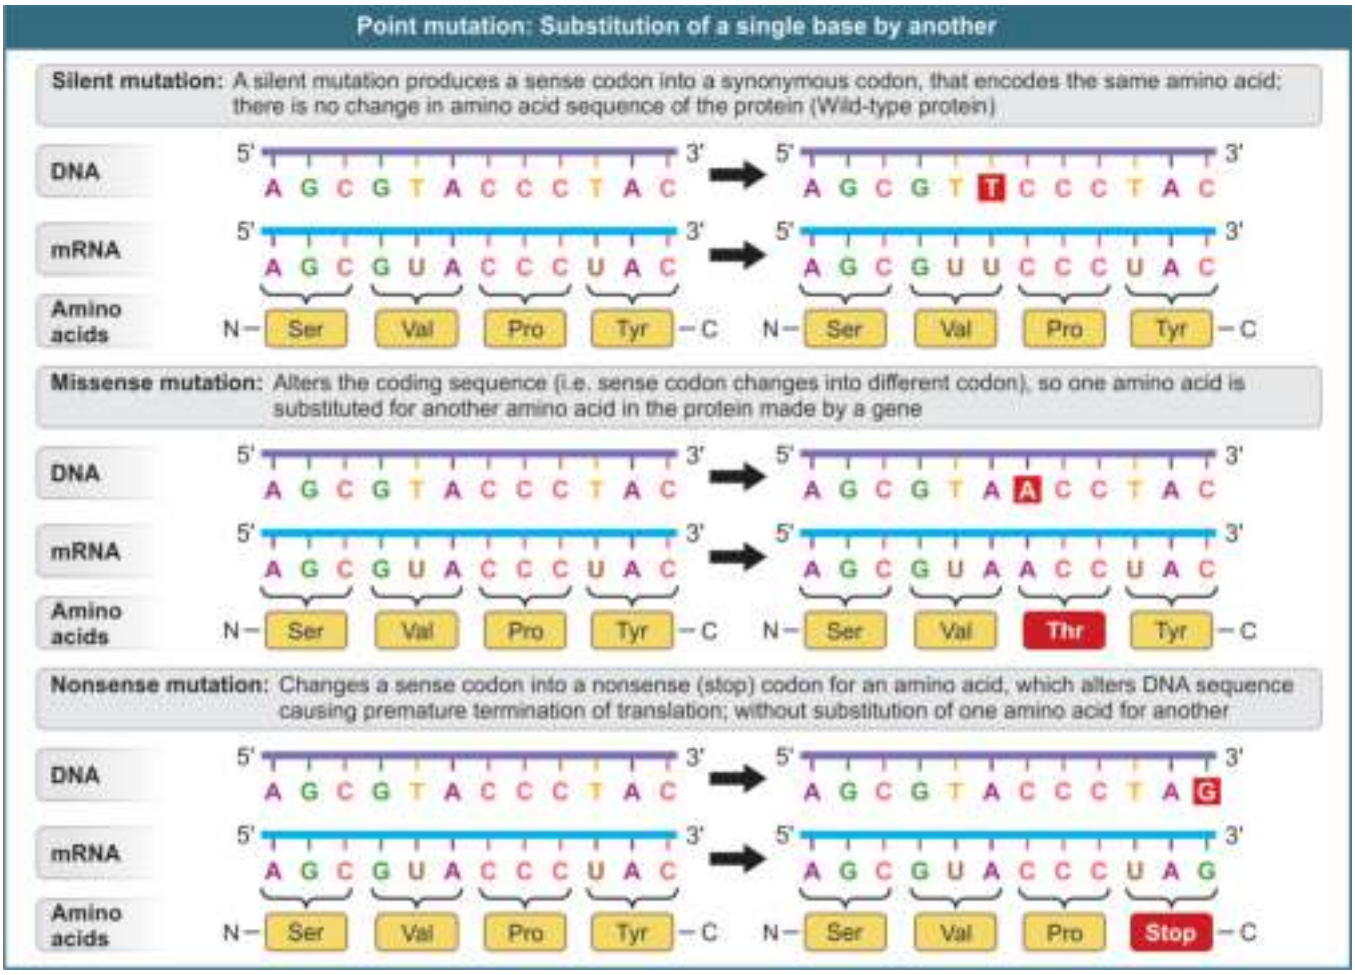

Fig. 5.38: Schematic representation of point mutation. Point mutation refers to substitution of a single base by another, that occurs by silent, missense and nonsense mutations.

DNA or RNA molecule. Comparison of transitions and transversions is given in Table 5.33.

Single Nucleotide Base Substitution and Types of Mutations

Single nucleotide base substitution induces three kinds of mutations: (a) silent mutation does not affect the sequence of amino acids during translation, (b) nonsense mutation occurs when a premature nonsense or stop codon is introduced in the DNA sequences resulting in early termination of translation, i.e. production of amino acid and protein; and (c) missense mutation changes the amino acid specified by a codon.

- It is worth remembering that frameshift mutation could allow for a partially functional protein to be made, whereas a nonsense mutation does not produce protein at all; and a missense mutation only affects a single amino acid production specified by a codon.
- Single nucleotide base substitution can cause silent, nonsense and missense point mutations at DNA, mRNA and protein level.

Silent Mutation

A silent mutation is a change in the nucleotide sequence of a gene that does not alter amino acid sequence of the encoded protein, when messenger RNA (mRNA) is translated. Thus, it has no measurable effect on the genome. For example, if the codon AAA is altered to become AAG, the same amino acid-lysine will be incorporated into the peptide chain.

Nonsense Mutation

A nonsense mutation is a genetic mutation in a DNA sequence that prematurely stops the translation (reading) of messenger RNA (mRNA) resulting in a polypeptide chain that ends prematurely and the unfinished protein product is incomplete and nonfunctional.

- DNA is a chain of many smaller molecules called nucleotide base pairs. There are three nonsense codons called amber (UAG), ochre (UAA) and opal (UGA) in the genetic code (mRNA), which do not code for an amino acid and instead signal the end of polypeptide chain during translation.

Table 5.33 Comparison of transitions and transversions

Characteristics	Transitions	Transversions
Nucleotide base replacement	▪ Purine to purine • Adenine (A) to guanine (G) • Guanine (G) to adenine (A) ▪ Pyrimidine to pyrimidine • Thymine (T) to cytosine (C) • Cytosine (C) to thymine (T)	▪ Purine to pyrimidine • Adenine (A) to thymine (T) • Adenine (A) to cytosine (C) • Guanine (G) to cytosine (C) • Guanine (G) to thymine (T) ▪ Pyrimidine to purine • Thymine (T) to adenine (A) • Thymine (T) to guanine (G) • Cytosine (C) to guanine (G) • Cytosine (C) to adenine (A)
Time of change during	DNA replication	DNA replication
DNA breakage	Not involved	Not involved
Frequency	High	Low
Effect on the nucleotide base	Yield normal nucleotide base	Yield abnormal nucleotide base
Detection of change	Both ways as above	Both ways as above
Causes	▪ Misincorporation ▪ Misreplication	▪ Misincorporation ▪ Misreplication
Reading frame of codon	Not changed	Not changed

- During protein synthesis, stop codons cause the release of the new polypeptide chain from the ribosomes.
- Examples of nonsense mutations include cystic fibrosis caused by the G542X mutation in the cystic fibrosis transmembrane conductance regulator (CFTR), β-thalassemia, Hurler syndrome and Dravet syndrome.

Missense Mutation

Missense mutation is a point mutation in which a single nucleotide change results in a codon that codes for different amino acids. If the properties of amino acid remain the same, the mutation is called '**conservative**', in which case the protein function is not altered. On the other hand, the mutation is called 'nonconservative', in which case the protein function is altered resulting in disease.

INSERTIONS AND DELETIONS WITHIN CODING SEQUENCES

Insertion, deletions and duplications can cause frameshift mutations. Insertions and deletions involve adding or subtracting a pair of nucleotide bases respectively. Insertions and deletions can alter a gene so that its message is no longer correctly analyzed. These changes are called frameshifts. Schematic representation of frameshift mutation is shown in Fig. 5.39.

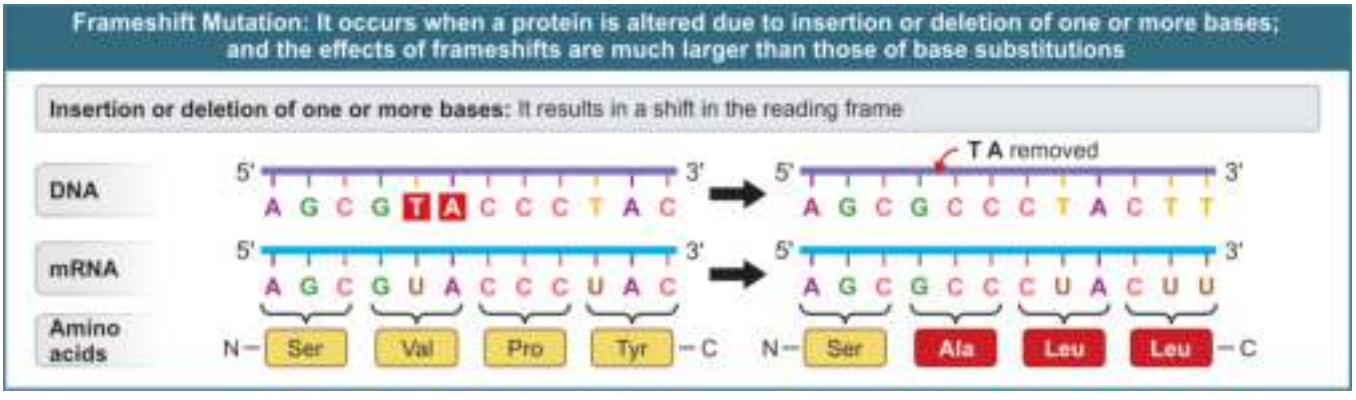

Fig. 5.39: Schematic representation of frameshift mutation. It occurs when a protein is altered due to insertion or deletion of one or more bases; and the effects of frameshifts are much larger than those of base substitutions.

- An insertion is a point mutation in one or more nucleotide base pairs is/are added to a DNA sequence. Deletion is a point mutation in which one or more base pairs is/are removed from a DNA sequence. Because the genetic code is read in codons (three nucleotide base pairs at a time), insertions and deletions may change the 'reading frame' of DNA sequence. These mutations are called frameshift mutations.
- Insertion and deletion result in a frameshift mutation that alter the reading of subsequent group of mRNA codons and, therefore, change the entire amino acid sequence that follows the mutation resulting in synthesis of abnormal translated protein. A codon is a group of three nucleotides that corresponds with a specific amino acid.
- Insertions and deletions that are multiple of three nucleotides will not cause frameshift mutations.
- Insertion and deletion are usually more harmful than a substitution in which a single amino acid is altered. Frameshift mutations occur when the number of deleted or inserted nucleotide base pairs is a multiple of three base pairs, which results in a change in only a few amino acids; it may be possible for the gene product (protein) to function, even though its sequence may be slightly different. Examples of frameshift mutations associated disorders are given in Table 5.34.

Table 5.34 Examples of frameshift mutations associated disorders

Frameshift Mutation	Cancer
BRCA1 frameshift mutation	Breast cancer, ovarian cancer
HEXA frameshift mutation	Tay-Sachs disease
CFTR frameshift mutation	Cystic fibrosis
NFKB1 frameshift mutation	Ulcerative colitis
MEN1 frameshift mutation	Multiple endocrine neoplasia 1 (MEN1)

TRINUCLEOTIDE REPEAT MUTATIONS

DNA (deoxyribonucleic acid) is a molecule that makes up our genes. Trinucleotide repeats in DNA molecule have eight copies of a CAG repeat. Two strands of DNA separate and replicate.

- In the course of DNA replication, a hairpin forms on the newly synthesized DNA strand, causing part of the template strand to be replicated twice and increasing the number of nucleotides repeat on the newly synthesized DNA strand. The two strands of the new DNA molecule separate and the strand with extra CAG copies serves as a template for DNA replication.
- When the number of trinucleotide repeats increases to a larger than normal number of copies, that alters the DNA. Each gene affected by trinucleotide repeat expansion has a different number of trinucleotide repeats that results in manifestation of disease.
- Examples of trinucleotide repeats genetic disorders include X-linked spinal and bulbar muscular atrophy, fragile X syndrome of mental retardation, Jacobsen syndrome, spinocerebellar ataxia (several types), autosomal dominant spinocerebellar ataxia, myotonic dystrophy, Huntington's disease, Friedreich ataxia, dentatorubral-pallidoluysian atrophy, myoclonus epilepsy of the Unverricht-Lundborg type and amyotrophic lateral sclerosis.
- There are many genetic disorders caused by repeat expansion to four (tetranucleotide), five (pentanucleotide) or 10 (dodecanucleotide) in length. The trinucleotide repeat genetic disorders are divided into three categories determined by the type of trinucleotide repeat. Disorders of trinucleotide repeat expansion mutation are given in Table 5.35.

Table 5.35 Disorders of trinucleotide repeat expansion mutation

Disorder	Trinucleotide Repeat Expansion	Disease Range	Normal Range
X-linked spinal and bulbar muscular atrophy	CAG	40–62	11–33
Fragile X syndrome with mental retardation	CGG	50–1500	6–54
Jacobsen syndrome	CGG	100–1000	11
Spinocerebellar ataxia (several type)	CAG	21–130	4–44
Autosomal dominant spinocerebellar ataxia	CAG	37–220	7–19
Myotonic dystrophy	CTG	40–3000	5–37
Huntington's disease	CAG	37–121	9–37
Friedreich ataxia (expansion of frataxin gene)	GAA	200–900	6–29
Dentatorubral-pallidoluysian atrophy	CAG	49–75	7–26
Myoclonus epilepsy of the Unverricht-Lundborg type	CCCCGCCCCGCG	12–13	2–3
Amyotrophic lateral sclerosis	GGGGCC	700–1600	2–23

Polyglutamic (PolyQ) Disorders

The most common trinucleotide repeat is CAG, when it is present in the coding region of a gene, which codes for amino acid glutamine (Q). Therefore, these genetic disorders are called polyglutamine (polyQ) disorders.

Nonpolyglutamic Disorders

Trinucleotide repeats do not involve the CAG in the coding region of the gene. Hence, trinucleotide repeat disorders are referred to as nonpolyglutamic disorders. Trinucleotide repeats are present in the promoter region of the affected gene, with the 5′-untranslated regions (5′-UTR) within introns, or within the 3′-UTR.

Polyalanine (Poly-Ala) Tract Disorders

Trinucleotide repeat expansion consists of genetic disorders associated with expansion of a polyalanine tract, or alterations in genes harboring a polyalanine tract, that may cause protein folding and aggregation.

- Polyalanine (poly-Ala) tract expansions are linked to nine inherited human diseases, in which about 500 genes encoding proteins, that harbor stretches of consecutive alanine residues ranging from 4 to 2000 amino acids in length.
- Key feature of the polyalanine repeat is due to imperfect repeat consisting of the nucleotides GCN, where N designates any nucleotide.

MUTATIONS WITHIN NONCODING SEQUENCES (INTRONS)

Most human genes contain segments of coding sequences (exons) interrupted by noncoding sequences (introns). Both exons and introns are transcribed to yield a long primary RNA transcript. The introns are then removed in order for the messenger RNA (mRNA) to encode a protein with the right sequence. Noncoding sequences (introns) in DNA do not provide instructions for making proteins.

Introns

The introns are noncoding sequences, that may affect a gene function/expression, which bind additional transcriptional enhancers or silencers; so, mutation in these regions can affect transcription. Introns can also be important in a process called alternate splicing, which can produce multiple types of small regulatory RNAs (miRNAs, incRNAs) from a single-gene.

Regulatory Noncoding RNAs

Regulatory RNAs are noncoding RNA molecules, that play a role in cellular processes such as activation or inhibition processes.

Table 5.36 Summary of direct and indirect intron functions

Direct Intron Functions
▪ Introns regulate alternate splicing
▪ Intron sequences control mRNA transport or chromatin assembly
▪ Introns in the 5'→3'-UTR (untranslated regions) affects nonsense-mediated decay of gene product
Indirect Intron Functions
▪ Different ordinal position of introns within a gene may have different functional role
▪ Introns length matters in the efficiency of natural selection
▪ Introns can provide a source of new genes
▪ Traits associated-SNPs (single nucleotide polymorphism) are enriched in introns
▪ Introns harbor several kinds of noncoding functional RNA genes

- When the mutations change the processing or sequence of these regulatory RNAs, which can alter the quantity produced of gene product.
- Mutations in the introns can lead to differentially truncated or spliced gene products, that may not be functional or even have more or less different functions.
- Finally, mutations in introns in the 5′→ 3′-UTR (untranslated regions) may affect the amount of protein produced. Summary of direct and indirect intron functions is given in Table 5.36.

SOMATIC MUTATIONS

Genes and chromosomes can undergo mutation either in somatic tissue (nongerm cell) or germline tissue (i.e. sperm and ovum), and these changes are called somatic or germline mutations respectively.

- Somatic mutations differ from the germline genetic alterations that occur in the germ cells (i.e. sperm and ovum) and can be passed onto offspring in every cell in the entire body.
- Somatic mutations are acquired mutations and frequently caused by environmental factors such as exposure to ultraviolet radiation or to certain chemical agents.
- Somatic mutations can be passed to the progeny of the mutated cell in the course of cell division, which accumulate in the cells despite proficient DNA repair mechanisms. Somatic genetic alterations can cause cancer or other diseases.
- **Somatic mutations** can be identified from parallel DNA sequencing by directly comparing the DNA sequence from the tumor tissue samples with their normal counterparts.

HUMAN GENETIC DISORDERS

Many human disorders have a genetic component, which can be caused by a mutation in one gene (monogenic disorder), by a combination of gene mutations and environmental factors, or by damage to chromosomes (changes in the number or structure of entire chromosomes, the structures that carry genes).

DISORDERS RELATED TO SINGLE-GENE MUTATION

Single-gene mutation disorders are caused by DNA changes in one particular gene, and often have predictable inheritance patterns. Most common single-gene mutation disorders include cystic fibrosis, primary hemochromatosis, sickle cell disease, fragile X syndrome, Duchenne muscular dystrophy, Huntington disease, phenylketonuria, color blindness, familial hypercholesterolemia and Tay-Sachs disease. Single gene mutation disorders induced due to various defects are given in Table 5.37. Single-gene mutation disorders and inheritance pattern are given in Table 5.38.

- Even though diseases are primarily caused by a single-gene mutation or different gene mutations can cause same disease, but with varying degrees of severity and phenotype. For example, other genes have been shown to modify the clinical course of cystic fibrosis in children, who carry the same CFTR gene mutation. In addition, for some disorders such as galactosemia, mutations in different genes can result in similar phenotype.
- Genetic testing is now available for many single-gene mutation disorders; however, the clinical examination is very important in the differential diagnosis particularly with no family history.
- Neonatal screening is useful in management of these disorders. Despite advancements in the understanding of genetic etiology and improved diagnostic techniques, treatments are not available to prevent the onset and progression of single-gene mutation disorders.
- There are a number of inheritance patterns of single-gene mutation disorders that are predictable such as autosomal dominant, autosomal recessive and X-linked recessive disorders.

Table 5.37 Single-gene mutation disorders induced due to various defects

Enzyme Defect
Phenylketonuria (accumulation of substrate, lack of product, failure to inactivate a protein which causes damage)
Receptor/Transport of Protein Defect
Familial hypercholesterolemia
Structural Protein Defects
▪ Marfan's syndrome ▪ Ehlers-Danlos syndrome
Enzyme Defect that Increases Drug Susceptibility
G6PD deficiency

COMPLETE MUTAGENIC DISORDERS

Human genome contains DNA molecule that encodes genetic makeup of the cell. DNA is subjected to several extrinsic and intrinsic insults (mutagens such as radioactive substances, X-rays, ultraviolet radiation, certain chemical and biological agents) and renders incorporation of faulty base pairing among the nucleotides.

- Mutagenesis is defined as the change in the genetic information of an organism in a stable manner, that may occur spontaneously in nature or as a result of exposure to mutagens.
- Researchers also use a number of techniques to create mutations including transposon mutagenesis to generate random gene knockouts at random position, and site-directed mutagenesis, which utilizes the polymerase chain reaction to introduce specific mutations.

Table 5.38 Single-gene mutation disorders and inheritance pattern

Disorder	Gene (Chromosome Location)	Inheritance Pattern
Familial hypercholesterolemia	LDL receptor (19p13)	Autosomal dominant disorder
Huntington disease	Huntington (4p16)	Autosomal dominant disorder
Sickle cell anemia	Beta-globin (11p15)	Autosomal recessive disorder
Cystic fibrosis	CFTR (7q31)	Autosomal recessive disorder
Primary hemochromatosis	HFE (6p21)	Autosomal recessive disorder
Tay-Sachs disease	Hexosaminidase A (15q23)	Autosomal recessive disorder
Congenital deafness (nonsyndromic)	Connexin 26 gene (13q11)	Autosomal recessive disorder
Duchenne muscular dystrophy	Dystrophin (Xq21)	X-linked recessive disorder

RANDOM MUTAGENESIS

Random mutagenesis is a powerful technique for generating enzymes, proteins, entire metabolic pathways, or even entire genomes with desired or improved properties. In this technique, point mutations are introduced at random positions in a gene of interest through polymerase chain reaction employing an error-prone DNA polymerase. Randomized sequences are then cloned into a suitable expression vector and the resultant mutant libraries can be screened to detect mutants with altered properties.

SITE-DIRECTED MUTAGENESIS

Site-directed mutagenesis is a technique for altering a gene or vector sequence at a selected location. Point mutations, insertions, or deletions are introduced by incorporating primers containing the desired modification with a DNA polymerase in an amplification reaction.

MENDELIAN (MONOGENIC) DISORDERS (SINGLE-GENE MUTATION)

Gene mutation is a permanent change in the DNA sequence that makes up a gene. Mutations range in size from one DNA nucleotide base to a whole chromosome change. Single-gene mutation follows laws of inheritance described by Gregor Mendel in 1856.

- Mutation of a gene leads to synthesis of abnormal protein. Therefore, disorders caused by single-gene mutation are known as Mendelian disorders. In single-gene mutation disorders, an error occurs at a single-gene site on the DNA strand.
- An error may occur in the copying and transcribing of a single codon through additions, deletions, or excessive repetitions. Some disorders of single-gene mutation and their significance are given in Table 5.39.

Table 5.39 Some disorders of single-gene mutation and their significance

Disorder	Clinical Manifestations
Autosomal dominant inheritance	
Adult polycystic kidney disease	Numerous cysts replacing kidneys
Familial hypercholesterolemia	Premature atherosclerosis
Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome)	Recurrent hemorrhage from skin and mucous membrane telangiectasia
Hereditary spherocytosis	Hemolytic anemia
Marfan's syndrome	Abnormal elastic tissue—skeletal, cardiovascular and ocular disease
Ehlers-Danlos syndromes	▪ Abnormal collagen—skin, joint and vascular effects ▪ Ehlers-Danlos syndromes may show autosomal or sex-linked recessive inheritance
Neurofibromatosis I	Multiple nerve sheath tumors
Neurofibromatosis II	Acoustic neuroma
Huntington's chorea (chromosome 4 mutant allele)	Progressive neuronal degeneration of brain tissue in middle age
Familial polyposis coli	Multiple colonic adenomas with malignant potential
Tuberous sclerosis	Multiple hamartomas within brain face, and kidneys (rhabdomyoma of heart, and subependymal giant cell astrocytoma
von Hippel-Lindau disease	Autosomal dominant disorder characterized by retinal hemangioma, cerebellar hemangioblastoma, adenomas or cysts in liver, kidney, pancreas, and renal clear cell carcinoma (sporadic or familial)
Achondroplasia	Dwarfism
Myotonic dystrophy	Muscle weakness and wasting. These neurological syndromes are known to be the result of inserts of multiple triple repeats
Osteogenesis imperfecta	Brittle bones, fracturing with minimal trauma

Contd...

Table 5.39 Some disorders of single-gene mutation and their significance (*Contd…*)

Disorder	Clinical Manifestations
Autosomal codominant inheritance	
ABO blood group antigens	Blood group disorders
α_1-Antitrypsin deficiency	Inhibitor of trypsin responsible for emphysema
HLA antigens	HLA associated disorders
Autosomal recessive inheritance	
Cystic fibrosis	Abnormal ion-transport protein
Sickle cell anemia	Abnormal hemoglobin
Thalassemia	Decreased synthesis of chain hemoglobin
Glycogen storage disease	Enzyme deficiency: Anderson disease (branching enzyme), McArdle disease (phosphorylase V), Hers disease (phosphorylase VI), Forbes-Cori disease (debranching enzyme), Pompe disease (lysosomal acid maltase) and von Gierke disease (glucose-6-phosphatase)
Mucopolysaccharidoses	Enzyme deficiency involving liver, spleen, bone marrow, lymph nodes
Lipidoses	Enzyme deficiency
Phenylketonuria	Deficiency of phenylalanine hydroxylase and impaired brain development
Albinism	Enzyme deficiency
Wilson's disease	Copper accumulation
X-linked recessive inheritance	
Hemophilia A	Bleeding tendency due to factor VIII deficiency
Hemophilia B	Bleeding tendency due to factor IX deficiency
Hunter syndrome	Hepatosplenomegaly, joint stiffness, mild mental retardation, retinal degeneration and cardiac lesions
G6PD deficiency	Hemolytic anemia occurs with certain drugs
Duchenne muscular dystrophy	Progressive muscle weakness due to dystrophin deficiency
Becker muscular dystrophy	Relative dystrophin deficiency
Fabry disease	Deficiency of α-galactosidase resulting in accumulation of ceramide trihexoside in skin over the lower trunk, febrile episodes, severe burning pain in the extremities, and cardiovascular and cerebrovascular involvement
X-linked Bruton agammaglobulinemia	Decreased gamma globulins due to B cell maturation
X-linked ichthyosis	Permanently thick scaly skin due to steroid sulphatase deficiency
Fragile X syndrome	Intellectual disability
X-linked dominant inheritance	
X-linked dominant hypophosphatemic rickets	Mutation in PHEX gene located on X chromosome, resistant to vitamin D supplementation
Rett syndrome	Mutation in MECP2 located on X chromosome in 95% of cases among females
Alport syndrome (most cases)	Mutation in COL4A5 collagen gene coding collagen protein located on X chromosome
Incontinentia pigmenti	More common in females than males
Giuffré-Tsukahara syndrome	Also known as radioulnar synostosis-microcephaly-scoliosis syndrome
Goltz syndrome	Also known as facial dermal hypoplasia
X-linked dominant protoporphyria	ALAS2 gene on X chromosome affecting males
Fragile X-linked dominant syndrome	Caused by an expansion of the CGG triplet repeat with the FMR1 (fragile X mental retardation 1) gene located on the X chromosome

MODES OF INHERITANCE OF MENDELIAN DISORDERS

Five basic modes of inheritance for single-gene diseases include autosomal dominant, autosomal recessive, X-linked recessive, X-linked dominant, and mitochondrial inheritance.

- In autosomal dominant disorders, affected parents transmit the phenotype to their children (sons and daughters) with 50% chance of inheritance in each generation of the pedigree.
- Autosomal recessive disorders appear in their children (sons and daughters with 25% chance of being affected, 50% chance of being carrier and 25% without being suffering) of unaffected parents.
- In sex-linked recessive disorders, genes for the traits are X chromosome (not on Y chromosome), hence these disorders always affect males whether X-linked recessive or dominant disorders because they have only one X chromosome.
- Mitochondria contain their own DNA (mtDNA), which is quite different from the chromosome in the nucleus. Unlike nuclear DNA (nDNA), mitochondrial DNA is maternally inherited and present as multiple copies per cell. Mitochondrial inheritance is uniparental. The paternal mitochondria are lost before sperm enters or fuses with the ovum. In others, the paternal cytoplasm is excluded from the ovum upon fertilization.

AUTOSOMAL DOMINANT INHERITANCE

Autosomal dominant inheritance that a person only requires one copy of the changed gene (genetic difference) in order to have the genetic disorder.

- Usually, the changed gene is inherited from a parent, who also suffers from the genetic disorder and every generation in the family members may suffer from the disorder.
- There are some instances in which an individual has single-gene mutation that causes the genetic disorder, but is asymptomatic; but still pass the mutated gene to his or her children.
- A person, who carries a mutated gene for an autosomal dominant inheritance has a 50% chance of passing the mutated gene to each child.

AUTOSOMAL RECESSIVE INHERITANCE

Autosomal recessive inheritance means that it is essential to have two copies of the changed gene to have the genetic disorder. Each parent contributes one changed copy of the gene to the child, who has the genetic disorder.

- The parents are called carriers of the genetic disorder, because they have only one normal copy of the gene and one changed copy of the gene, but parents do not show symptoms of the genetic disorder.
- When both parents are carriers of the changed gene, each of their children has a 25% chance of having the genetic disorder, a 50% chance of being a carrier of the genetic disorder (like their parents), and a 25% chance of neither a carrier nor having the genetic disorder. These risks remain the same for each pregnancy.
- When there is more than one person in the family suffering from the genetic disorder, these persons are most often in the same generation.

X-LINKED RECESSIVE INHERITANCE

X-linked recessive inheritance is usually seen in males, which is more common than X-linked dominant inheritance. Person with X-linked recessive inheritance lacks any normal copy of the gene. X-linked (sex-linked) recessive disorders are given in Table 5.40.

- Male child only has one X chromosome, so if a male inherits a changed gene on the X chromosome (which is always inherited from the mother), then male child lacks another copy of the working gene to compensate.
- Female child with one copy of a changed gene on X-chromosome is called carrier of X-linked inheritance. It is rare for a female child to have the changed gene on both her X chromosomes.
- In most cases, females, who are carriers do not show symptoms because the working of gene compensates for the non-working copy of the gene.
- Carrier females have 25% chance of having a son with the X-linked recessive disorder, 25% chance of having a son without the genetic order, 25% chance of having a carrier daughter and 25% chance of having a daughter, who is not carrier.
- Males with X-linked recessive disorder cannot pass the genetic disorder to their sons, but 100% of their daughters will be carrier.

Table 5.40 X-linked (sex-linked) recessive disorders

Duchenne muscular dystrophy
Hemophilia A and B
Fragile X syndrome
X-linked Bruton agammaglobulinemia
Wiskott-Aldrich syndrome
Lesch-Nyhan syndrome
Glucose-6-phosphate dehydrogenase (G6PD) deficiency
Hunter syndrome

X-LINKED DOMINANT INHERITANCE

X-linked dominant inheritance follows an inheritance pattern similar to autosomal dominant inheritance except that females are more affected than males. However, X-linked dominant inheritance is rare.

MITOCHONDRIAL INHERITANCE

Mitochondrial inheritance results from the expression of mitochondrial DNA. Mitochondrial inheritance does not follow Mendelian pattern since it involves mitochondrial genome expression.

- Conditions caused by a mutation in the mitochondrial DNA have unusual patterns: (a) both males and females are affected, (b) the condition is transmitted through the female to her offspring, and (c) if a male has the trait and his spouse does not, their offspring would not have the trait.
- Mitochondrial disorders include mitochondrial myopathy, diabetes mellitus and deafness (DAD), Leber hereditary optic neuropathy (LHON), Leigh syndrome, subacute sclerosing encephalopathy; neuropathy, ataxia, retinitis pigmentosa and ptosis (NARP) and myoneurogenic encephalopathy (MNGIE).

CODOMINANT INHERITANCE

Codominant inheritance is a type of inheritance wherein the alleles of a gene pair in heterozygotes are fully expressed. As a result, the phenotype of the offspring is a combination of the phenotype of the parents. Thus, the final trait is neither dominant nor recessive. An example in human is the **ABO blood group**, where both A and B alleles are expressed. Therefore, if an individual inherits allele A from mother and allele B from mother, such individual has **blood group AB type**.

MENDELIAN TRAITS

Mendelian traits are dominant, recessive or codominant. Codominant inheritance is characterized by complete expression of both alleles in a heterozygote as seen in ABO blood group inheritance.

- For unknown reasons, on autosomes, one allele may be more influential than another in determining a specific trait. The more powerful, or dominant gene is more likely to be expressed in the offspring than recessive gene.
- Offspring will express a dominant allele when one or both chromosomes in a pair carry it. A recessive allele will not be expressed unless both chromosomes carry identical copies of the allele.

AUTOSOMAL DOMINANT DISORDERS

In single-gene disorders, an error occurs at a single-gene site on the DNA strand. An error may occur in the copying and transcribing of a single codon through additions, deletions, or excessive repetitions.

- Autosomal dominant disorder transmission most often affects male and female offspring equally. Affected males and females appear in each generation of the pedigree.
- Affected mothers and fathers transmit the phenotype to both sons and daughters. Selected autosomal dominant disorders are given in Table 5.41. Some autosomal dominant disorders of single-gene mutation and their significance are given in Table 5.42.

Table 5.41 Selected autosomal dominant disorders

Neurological Disorders
Huntington disease
Musculoskeletal Disorders
▪ Marfan's syndrome (fibrillin 1 protein involved) ▪ Ehlers-Danlos syndrome ▪ Osteogenesis imperfecta ▪ Achondroplasia ▪ Myotonic dystrophy
Hematopoietic Disorders
▪ Hereditary spherocytosis (ankyrin, spectrin, band 4.1, band 3 proteins involved) ▪ von Willebrand disease
Renal Disorders
Adult polycystic kidney disease
Metabolic Disorders
Familial hypercholesterolemia (LDL receptor protein involved)
Tumor Syndromes
▪ Neurofibromatosis type 1, also called von Recklinghausen disease (neurofibromin protein involved) ▪ Neurofibromatosis type 2, also called bilateral acoustic neurofibromatosis (merlin protein involved) ▪ Familial adenomatous polyposis coli (APC protein involved) ▪ Wilm's tumor ▪ Li-Fraumeni syndrome (i.e. early breast carcinoma associated with sarcoma and other tumors) ▪ Retinoblastoma ▪ Tuberous sclerosis (hamartin, tuberin proteins involved) ▪ von Hippel-Lindau disease
Other Autosomal Dominant Disorder
Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome)

Table 5.42 Some autosomal dominant disorders of single-gene mutation and their significance

Disorder	Clinical Manifestations
Adult polycystic kidney disease	Numerous cysts replacing both kidneys
Familial hypercholesterolemia	Premature atherosclerosis
Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome)	Recurrent hemorrhage from skin and mucous membrane telangiectasia
Hereditary spherocytosis	Hemolytic anemia
Marfan's syndrome	Abnormal elastic tissue—skeletal, cardiovascular and ocular disease
Ehlers-Danlos syndrome (autosomal or sex-linked recessive inheritance)	Abnormal collagen—skin, joint and blood vessels
Neurofibromatosis I	Multiple nerve sheath tumors
Neurofibromatosis II	Acoustic neuroma
Huntington's chorea (chromosome 4 mutant allele)	Progressive neuronal degeneration of brain tissue in middle age
Familial polyposis coli	Multiple colonic adenomas with malignant potential
Tuberous sclerosis	Multiple hamartomas within brain, face, and kidneys (rhabdomyoma of heart, and subependymal giant cell astrocytoma)
von Hippel-Lindau disease	Autosomal dominant disorder characterized by retinal hemangioma, cerebellar hemangioblastoma, adenomas or cysts in liver, kidney, pancreas, and renal clear cell carcinoma (sporadic or familial)
Achondroplasia	Dwarfism
Myotonic dystrophy	Muscle weakness and wasting. These neurological syndromes are known to be the result of inserts of multiple triple repeats
Osteogenesis imperfecta	Brittle bones, fracturing with minimal trauma

ADULT POLYCYSTIC KIDNEY DISEASE

Adult polycystic kidney disease (APKD) is an autosomal dominant disorder. Though the genetic defect is present at birth, yet it manifests between 15 and 30 years of age. APKD is most often associated with berry aneurysm of the circle of Willis resulting in subarachnoid hemorrhage.

- Patient develops numerous bilateral renal cysts that replace and ultimately destroy the renal parenchyma resulting in enlargement. Most cases are caused by mutations in the polycystic kidney disease 1 (PKD1) gene, which encodes polycystin.
- The kidneys are enlarged up to 3 or 4 kg or more. The affected kidney contains large fluid-filled cysts with areas of organized hemorrhage.
- Patient presents with sense of heaviness in the loins, bilateral flank and palpable renal masses, hypertension, blood clots in the urine (**hematuria**), progression to end-stage renal failure over a period of several years. Secondary polycythemia may occur.

FAMILIAL HYPERCHOLESTEROLEMIA

Familial hypercholesterolemia is an autosomal dominant disorder caused by mutations of the gene coding for LDL receptors.

- The gene defect affects the uptake of LDL in the liver, causing hypercholesterolemia. It leads to high levels of low-density lipoproteins in blood.
- Clinically, the disease presents with xanthomas characterized by raised yellow lesions filled with lipid-laden macrophages, in the skin and tendons. Patient develops marked atherosclerosis, ischemic heart disease and peripheral vascular disease.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome) is a rare autosomal dominant disorder that leads to abnormal blood vessel formation in the skin, mucous membranes, lungs, liver and brain resulting to recurrent hemorrhage from these lesions.

- A person with hereditary hemorrhagic telangiectasia (**HHT**) may form blood vessels lacking capillaries, hence, blood passes from arteries directly into the vein. HHT type 1 is caused by mutations in the ENG gene.
- HHT type 2 is caused by mutation in the ACVRL1 gene. Juvenile polyposis/HHT syndrome occurs due the mutation in the SMAD4 gene. Incidence is more in certain populations, such as in Mormon families of Utah. Pulmonary lesions are at risk of rupture and life-threatening.

HEREDITARY SPHEROCYTOSIS

The normal membrane cytoskeleton of RBCs is composed of spectrin, ankyrin, actin, protein 4.1 and protein 3, which maintain the normal biconcave shape of RBCs.

- Hereditary spherocytosis (**HS**) is an autosomal dominant disorder associated with inherited defects of erythrocyte membrane-associated cytoskeleton proteins such as spectrin, ankyrin, actin, protein 4.1 and protein 3.
- Mutation of the ankyrin gene is the most common finding, accounting for most cases of hereditary spherocytosis. Protein 4.2 deficiency is common in Japan. Patient develops hereditary spherocytosis. The spheroidal erythrocytes are sequestered and destroyed in the spleen, producing hemolytic anemia.

Clinical Features

Signs and symptoms can range from mild to severe anemia, jaundice, cholelithiasis and/or splenomegaly. Osmotic fragility is increased. Spleen is firm, deep red tissue with thin capsule, but Malpighian follicles are grossly not identifiable. Histologic examination of spleen shows marked congestion in the cords, empty sinuses containing ghost cells, prominent endothelial lined sinuses, hemosiderin deposition and erythrophagocytosis. Splenectomy prolongs the life of red blood cells, although these still have genetic defects.

MARFAN'S SYNDROME

Marfan's syndrome is an autosomal dominant systemic connective tissue disorder, that affects many parts of the body such as skeleton, eyes and cardiovascular system.

- The diagnosis of Marfan's syndrome is established with new diagnostic criteria, known as Ghent nosology, based on major and minor clinical manifestations in various organ systems and the family history.
- Aortic root aneurysm, prolapse of mitral valve and ectopia lentis (dislocated lenses) are the cardinal features. Skeletal muscle, fat, skin, fascia and respiratory tract may be affected. Major and minor diagnostic criteria of Marfan syndrome are given in Table 5.43.

Pathogenesis

Exact pathogenesis of Marfan's syndrome has not been fully elucidated. The disorder is caused by missense mutations of the fibrillin gene 1 (**FGN1**) on chromosome 15. Fibrillin is a family of connective tissue proteins analogous to the collagens.

Clinical Features

Clinical manifestations of Marfan's syndrome may include tall and slender built, disproportionate long arms, legs and fingers; deformity of the thoracic cage, striae atrophicae, mitral valve prolapse, a mid- and nonprogressive dilatation of the aortic root. Clinical manifestations of Marfan syndrome are given in Table 5.44 and schematic representation of Marfan's syndrome is shown in Fig. 5.40.

Table 5.43 Major and minor diagnostic criteria of Marfan syndrome

Major Diagnostic Criteria
▪ Enlarged aorta
▪ Tear in aorta
▪ Dislocation of ocular lens (ectopia lentis)
▪ Family history of Marfan syndrome
▪ Dural ectasia (enlargement of lining that surrounds part of the spinal cord)
Minor Diagnostic Criteria
▪ Short-sightedness (myopia)
▪ Unexplained stretch mark
▪ Loose joints

Patient has at least four of the skeletal problems such as very tall height and thin built, long arms and legs, long slender spider-like fingers (arachnodactyly), hyperextensible joints (especially thumb), anterior chest deformity (pectus excavatum) and scoliosis and lordosis.

Laboratory Diagnosis

Marfan syndrome is usually diagnosed in young persons associated with poor prognosis. Laboratory tests for Marfan syndrome can include echocardiogram, electrocardiogram, cardiac magnetic resonance imaging or computed tomography and DNA test to confirm the genetic defect.

Table 5.44 Clinical manifestations of Marfan syndrome

Skeletal Defects
▪ Vey tall height and thin built
▪ Long arms and legs
▪ Long slender spider-like fingers (arachnodactyly)
▪ Hyperextensible joints (especially thumb)
▪ Anterior chest deformity (pectus excavatum)
▪ Scoliosis and lordosis
Cardiovascular Defects
▪ Mitral valve prolapse resulting in mitral regurgitation
▪ Cystic medial degeneration of aorta causing dilatation of aortic valve and aortic regurgitation and later dissecting aortic hematoma
Ocular Defects
▪ Bilateral dislocation (subluxation) of the ocular lens (ectopia lentis)

Cause of death in Marfan syndrome is aortic dissection. Hence, hypertension should be treated at the earliest.

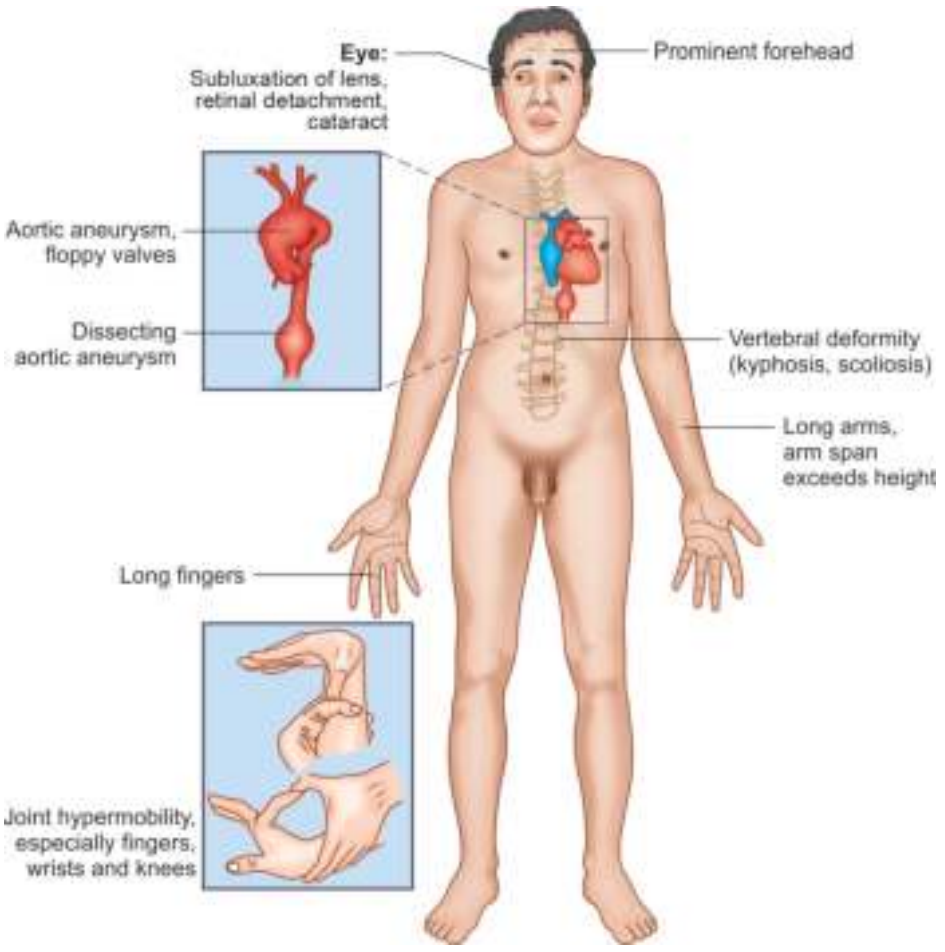

Fig. 5.40: Schematic representation of Marfan's syndrome. Marfan's syndrome shows clinical manifestations.

EHLERS-DANLOS SYNDROME

Ehlers-Danlos syndrome is rare autosomal dominant disorder of collagen fibers. Autosomal recessive and X-linked recessive varieties are also known. There is generalized defect in collagen fibers, molecular structure, synthesis, secretion, and degradation. Ehlers-Danlos syndrome is characterized by joint hypermobility, abnormalities in skin texture elasticity, vascular fragility in blood vessels and viscera.

Clinical Features

Skin, ligaments and joints of person suffering from Ehlers-Danlos syndrome are commonly affected. Generalized defects in collagen fibers lead to hyperelasticity of skin (stretching of skin to many centimeters). Bleeding diathesis occurs as a result of fragile skin. Dehiscence of surgical incisions is common because sutures do not hold well. Hypermobility of joints (unusual extension and flexion) is common finding. Clinical manifestations of Ehlers-Danlos syndrome are given in Table 5.45.

Table 5.45 Clinical manifestations of Ehlers-Danlos syndrome

Site Involved	Cardinal Features	Primary Consequences	Secondary Consequences
Joints	Hypermobility	Arthralgia, joint dislocation	Instability of joints and soft tissue trauma
Skeleton	Osteoporosis	Scoliosis, fracture	Skeletal deformities
Skin	Hyperextensibility	Thinning of skin, striae atrophicae	Bruising and hematoma, violaceous papyraceous scars, subcutaneous spheroids
Vasculature	Mitral valve involvement in type 4 of Ehlers-Danlos syndrome	Prolapse mitral valve	Subacute bacterial endocarditis
Skeletal muscles	Skeletal muscles at various regions	Hernia, urinary bladder and rectal diverticula	Rectal prolapse, uterine prolapse and neuromyopathy

Laboratory Diagnosis

Laboratory tests for Ehlers-Danlos syndrome include genetic tests, skin biopsy, and echocardiogram.

NEUROFIBROMATOSIS TYPE 1

Neurofibromatosis type 1, an autosomal disorder, is also known as von Recklinghausen disease caused by mutation of NF1 gene, a tumor suppressor gene located on chromosome 17q11.2. NF1 gene coding for abnormal protein product neurofibromin is expressed in many tissues. Neurofibromin belongs to family of GTPase-activating proteins (GAPs) that facilitates the conversion of active RAS-GTP to inactive RAS-GDP. Loss of GAP activity in cells acquiring a second hit mutation in NF1 gene permits uncontrolled RAS p21 protein activation, an effect that predisposes to the formation of benign neurofibromas. Diagnostic criteria of neurofibromatosis type 1 are given in Table 5.46.

Clinical Features

Patient suffering from neurofibromatosis type 1 presents with disfiguring neurofibromas in skin, skin pigmentation (café au lait spots), pigmented dome-shaped lesions on the surface of iris (known as Lisch nodules), meningioma, optic glioma, pheochromocytoma, Wilm's tumor, rhabdomyosarcoma, and leukemia. Approximately 3–5% of patients, benign neurofibromas can become malignant.

NEUROFIBROMATOSIS TYPE 2

Neurofibromatosis type 2 is an autosomal dominant disorder caused by mutation in NF2 tumor suppressor gene on chromosome 22q.12, which encodes abnormal **merlin**, and characterized by bilateral acoustic neuroma/vestibular schwannomas. Symptoms become apparent during childhood, adolescence, early adulthood or later in adult life. Diagnostic criteria of neurofibromatosis type 2 are given in Table 5.47.

Table 5.46 Diagnostic criteria of neurofibromatosis type 1

Patient must have at least two or more features as mentioned:
Two or more neurofibromas
One plexiform neurofibroma
Six or more café au lait macules >5 mm (pubertal) or >15 mm (post-pubertal)
Ocular iris hamartomas
Sphenoid bone dysplasia
First degree relative suffering from neurofibromatosis type 1

Table 5.47 Diagnostic criteria of neurofibromatosis type 2

- **Patient with NF2 disease should have features as mentioned:** Bilateral vestibular schwannomas
- **Family history of neurofibromatosis type 2 in first degree relative:**
  - Unilateral vestibular schwannoma in below 30 years of age
  - Any two of the lesions, i.e. meningioma, schwannoma, glioma, posterior subcapsular lenticular opacities/juvenile cortical cataract.

Clinical Features

Depending on the exact size and location of the tumor in the vestibulocochlear nerve, patient with neurofibromatosis type 2 experiences problems with balance and gait, dizziness, headache, tinnitus, and/or progressive hearing loss. Some persons may have additional abnormalities such as meningioma, astrocytoma, juvenile posterior subcapsular lens opacities.

TUBEROUS SCLEROSIS COMPLEX

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder with variable expression, and also known as Epiloia disease or Bourneville-Pringle disease. Disorder is caused by mutations in either the TSC1 or TSC2 genes, which code for the inhibitors of the central cell growth control the mechanistic target of rapamycin (mTOR) pathway most often result in early-life refractory epilepsy and autism spectrum disorder. Patient is associated with multiple hamartomas within brain (cortical tubers and subependymal hamartomas), renal angiomyolipoma (80%), cardiac rhabdomyoma, subependymal giant cell astrocytoma and hypomelanotic macules.

VON HIPPEL-LINDAU DISEASE

von Hippel-Lindau disease is an autosomal dominant disorder with high penetrance and variable phenotypic expression.

- von Hippel-Lindau disease is caused by mutation in vHL, a tumor suppressor gene located on chromosome 3p (3p12 to 3p26). vHL gene mutation occurs by loss of sequences on chromosome 3p, imbalanced translocation (3; 6, 3; 8, 3; 11) and hypermethylation (80%). Mutation of one allele of vHL gene is seen in 98% of sporadic and 2% of familial renal cell carcinomas.
- von Hippel-Lindau disease is most often associated with vascular tumors (e.g. retinal hemangioma, cerebellar hemangioblastoma, spinal cord hemangioblastoma), and less frequently, pancreatic cystic neoplasm, pancreatic neuroendocrine tumor, clear cell carcinoma of the kidney, endolymphatic sac

tumor, pheochromocytoma, paraganglioma, and liver cysts or liver adenoma.

AUTOSOMAL RECESSIVE DISORDERS

Autosomal recessive inheritance usually affects male and female offspring equally. If both parents are affected, all their offspring will be affected. If one parent is affected and the other is a carrier, 50% of their children will be affected. Autosomal recessive disorders may occur when there is no family history of the disease.

Table 5.48 Selected autosomal recessive disorders

Metabolic Disorders

- Cystic fibrosis (abnormal ion-transport protein)
- Hemochromatosis
- Lysosomal storage diseases
- Glycogen storage diseases
- Mucopolysaccharidoses
- Galactosemia
- Phenylketonuria (amino acid metabolic disorder)
- Albinism (enzyme deficiency)
- Wilsons' disease (copper accumulation)

Hematopoietic Disorders

- Sickle cell anemia (abnormal hemoglobin)
- Thalassemia (decreased synthesis of hemoglobin)

Neuromuscular Disorders

- Friedreich ataxia
- Muscular dystrophy (some forms)

Endocrinal Disorders

- Congenital adrenal hyperplasia (21-hydroxylase deficiency)

Selected autosomal recessive disorders are given in Tables 5.48 and 5.49.

SICKLE CELL DISEASE

Sickle cell disease is an autosomal recessive disorder of the hemoglobin, that affects red blood cells. Sickle cell anemia is the name of a special form of sickle cell disease, in which there are two sickle cell genes.

- Sickle cell trait is the inheritance of one sickle cell gene. Homozygous genotypes contain abnormal hemoglobin HbS/HbS (sickle cell disease). Heterozygous genotypes contain abnormal hemoglobin HbA/HbS (sickle cell trait).
- The mutant hemoglobin molecule undergoes polymerization under low oxygen tension causing the change in the shape of the RBC from biconcave to elongated sickle-like structure resulting in excessive destruction of RBCs.
- The life span of RBCs is reduced 10–20 days (normal RBCs life span is 100–120 days). Patients suffer from chronic hemolytic anemia and other clinical manifestations. Schematic representation of sickle cell anemia is shown in Fig. 5.41.

Pathophysiology

Mutant allele chromosome 11 causes substitution of valine for glutamine at the 6th codon in β-chain of globin molecule of hemoglobin due to the single base substitution at the 6th codon of the β-globin gene from GAG to GUG and synthesize abnormal HbS resulting in sickle cell anemia.

Table 5.49 Selected autosomal recessive disorders and enzyme defects

Disorder	Enzyme Deficiency	Accumulation in Tissues
Tay-Sachs disease	Hexosaminidase A (Hexa gene mutation on 15)	GM2 ganglioside
Gaucher's disease A and B	Glucocerebrosidase	Glucocerebroside
Niemann-Pick disease	Sphingomyelinase	Sphingomyelin
Hurler's syndrome	α-L-iduronidase (IDUA gene mutation on 4p16.3)	Heparan sulfate, dermatan sulfate
von Gierke disease (type 1 glycogenosis)	Glucose-6-phosphatase	Glycogen
Pompe disease (type 2 glycogenosis)	α-1,4-Glucosidase	Glycogen
Cori disease (type 3 glycogenosis)	Amylo-1,6-glucosidase	Glycogen
McArdle syndrome (type 4 glycogenosis)	Muscle phosphorylase	Glycogen
Galactosemia	Galactose-1-phosphate uridyltransferase	Galactose-1-phosphate
Phenylketonuria	Phenylalanine hydroxylase	Phenylalanine and its degradation products
Alkaptonuria	Homogentisic oxidase	Homogentisic acid
Hereditary hemochromatosis	Human homeostatic iron regulator (HFE protein)	Iron
Wilson disease	ATP-dependent Cu^{2+} transporter	Copper
Maple syrup urine disease	Branched-chain α-keto acid dehydrogenase complex	Branched-chain amino acids including leucine, isoleucine, and valine
Hunter disease	Iduronate-2-sulfatase	Heparan sulfate, dermatan sulfate

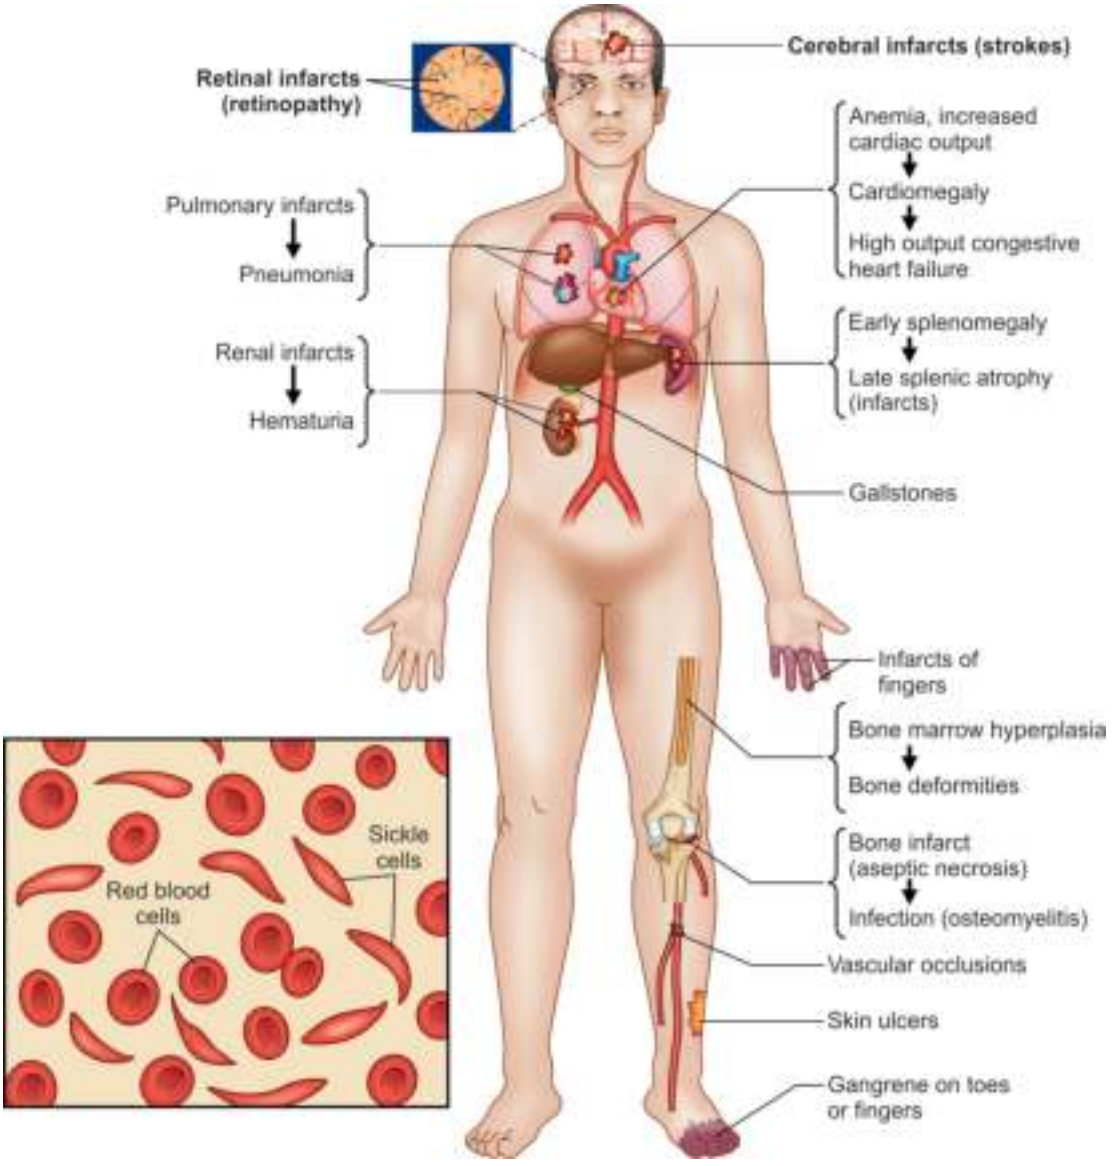

Fig. 5.41: Schematic representation of sickle cell anemia. Clinical and pathological findings, peripheral blood smear shows sickled RBCs. Sickled red cell appears in peripheral blood specimens only in patients with sickle cell disease because all of their hemoglobin is hemoglobin S. Red cells with any amount of hemoglobin S, however, can be induced to sickle as part of a laboratory test for the presence of hemoglobin S.

- As a result, red blood cells sickle in low oxygen states causing occlusion of the small blood vessels circulating through the tissues of the body.
- Impaired circulation and lack of oxygen result in tissue damage/organs and severe disability. The sickle-shaped red blood cells are prematurely removed from the circulation resulting in a chronic hemolytic anemia.

Clinical Features

Patient with sickle cell anemia develops episodes of intermittent 'crises' of variable frequency and severity depending on the degree of organ involvement. Major symptoms of sickle cell anemia include fatigue, anemia, pain, sickle cell crises (e.g. vaso-occlusive most common, sequestration, aplastic, hemolytic and bone pain crises), dactylitis (swelling and inflammation of the hands and/or feet), arthritis, sudden pooling of blood in the spleen and liver (congestion), bacterial infections, leg ulcers, aseptic necrosis of bone, heart and lung injury, renal papillary necrosis and retinopathy.

Treatment

With newborn screening and early management, the death rate among the children with sickle cell disease has declined.

- Current treatment of sickle cell anemia is directed primarily toward managing the individual

manifestations of the illness, as they occur. Blood transfusion is indicated for symptomatic anemia to prevent cerebral stroke and for acute chest syndrome. Repeated blood transfusion increases risk for excess deposition of iron in various tissues.

- In addition, due to differences in RBCs antigens between donors and recipients, these patients are at increased risk for development of RBC alloantibodies, which can complicate further blood transfusion. It is therefore, essential of prevent alloimmunization by transfusing leukoreducted red blood cells that match the patient for the C, E, and Ki antigens.
- Transplantation of human progenitor cells obtained from bone marrow, peripheral blood or umbilical cord can cure sickle cell disease.

CYSTIC FIBROSIS

Cystic fibrosis is an autosomal recessive life-threatening disorder that affects lungs and exocrine glands. Both parents carry the mutated CFTR gene located on long arm of chromosome 7, that encodes an abnormal transmembrane conductance regulator protein and transmit to their children.

- Normally, CFTR protein participates in the movement of chloride and other ions across the membranes. Genetic defect of chromosome 7 allele causes failure of chloride ions transport resulting in accumulation of chloride in sweat and tears.
- Defective CFTR protein results in production of thick and sticky mucus secretion that clog the lungs and obstructs the pancreas. Cystic fibrosis is a lethal disease among White population. Patient with cystic fibrosis exhibiting clinical manifestations is shown in Fig. 5.42.

Clinical Features

Patient of cystic fibrosis develops recurrent pulmonary infections and dysfunction of both gastrointestinal tract and accessory glands; warning sign of cystic fibrosis in a newborn is intestinal obstruction caused by thick viscous meconium known as 'meconium ileus'.

- Cystic fibrosis affects sweat glands in the skin resulting in abnormally thick salty perspiration. There is increased risk of heat stroke and salts depletion especially in infants.
- Almost all men with cystic fibrosis are **infertile** but not sterile due to defective development of the vas deferens, epididymis and seminal vesicles. Women with cystic fibrosis often have normal reproductive system and can have successful pregnancies. Systemic manifestations of cystic fibrosis are given in Table 5.50.

Laboratory Diagnosis

Sweat chloride test is an important diagnostic tool of cystic fibrosis. Secretion by sweat glands of chloride and sodium is normal, but their reabsorption by sweat

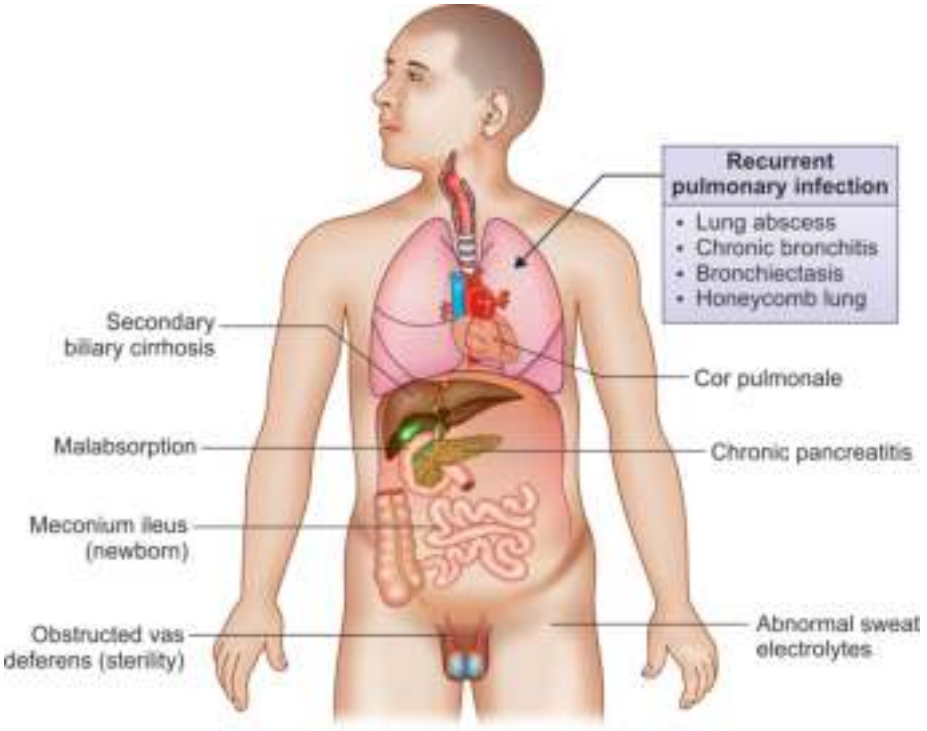

Fig. 5.42: Schematic representation of cystic fibrosis. Patient with cystic fibrosis shows clinical manifestations.

Table 5.50 Systemic manifestations of cystic fibrosis

Organs	Secondary Effects	
Skin	▪ Salty sweat results in hyponatremia ▪ Acrodermatitis	▪ Dilation of eccrine and apocrine glands
Gastrointestinal lower tract	▪ Meconium ileus warning sign in newborn resulting in obstruction, perforation, peritonitis	▪ Rectal prolapse
Pancreas	▪ Pancreatic duct obstruction causes pancreatic insufficiency (steatorrhea) ▪ Chronic pancreatitis	▪ Failure to thrive ▪ Diabetes mellitus
Liver	▪ Hepatic duct obstruction causes biliary cirrhosis resulting in esophageal varices	▪ Sclerosing cholangitis
Gallbladder	Cholecystitis	
Kidney	▪ Nephrolithiasis ▪ Diabetic glomerulopathy	▪ Immune complex-mediated glomerulonephritis
Respiratory system	▪ Bronchiectasis ▪ Recurrent infections ▪ Atelectasis	▪ Allergic bronchopneumonia ▪ Aspergillosis
Heart	▪ Cor pulmonale ▪ Left ventricular fibrosis	▪ Carotid bodies enlarged
Male genital system	Male infertility (obstructive aspermia due to vas deferens atresia in 6% and male infertility in 1–2%)	
Female genital system	▪ Multiple ovarian follicular cysts ▪ Cervicitis	▪ Reduced fertility
Musculoskeletal system	▪ Osteoporosis ▪ Muscle wasting	▪ Hypertrophic pulmonary arthropathy ▪ Clubbing of fingers
General manifestations	▪ Malnutrition ▪ Vitamin deficiencies (vitamin B_{12}, vitamin K*)	▪ Amyloidosis

**Vitamin K deficiency at birth may lead to bleeding.*

ducts is impaired. Molecular testing of CFTR gene mutation is another diagnostic tool. Screening done by using immunoreactive trypsinogen (IrT) assay shows elevated levels in infants with cystic fibrosis.

Treatment

The patient with cystic fibrosis disease is treated by inhaler bronchodilators to reduce resistance in respiratory airways. Inhaled mucolytic agents and saline help in dissolving mucus. Antibiotics are administered to cover infection.

GLYCOGEN STORAGE DISEASES

Glycogen storage diseases (**GSDs**) are the result of deficiency of lysosomal enzymes that cause the alteration of glycogen metabolism (glycogen synthesis or glycolysis) in the liver and skeletal muscle.

- The liver forms of glycogen storage diseases (types 1, 3, 4 and 6) are marked by inability to convert glycogen to glucose.
- The skeletal muscle forms of glycogen storage diseases (types 2, 3A, 5 and 7) have mild symptoms appearing during strenuous exercise owing to inability to provide energy for skeletal muscle contraction. Glycogen storage diseases are given in Table 5.51.

Glycogen Storage Disease Type 0

Glycogen storage disease type 0 (GSD type 0) is an inherited autosomal recessive lysosomal storage disorder caused due to mutation in glycogen synthase 2 (GYS2) gene that encodes abnormal glycogen synthase enzyme.

- GSD type 0 is inherited within families in an autosomal recessive fashion. Normally, glycogen synthase participates in the generate glycogen, that is stored in the liver.
- Glycogen synthase deficiency leads to low amount of glycogen in the liver resulting in hypoglycemia and hyperketonemia.

Clinical Features

Early in infancy, children usually have no symptoms. Any child with a history of needing frequent meals and with hypoglycemia and presence of ketone bodies in the urine is suggestive of GSD type 0.

Table 5.51 Glycogen storage diseases

Type	Defective Enzyme	Organ Affected	Glycogen in the Affected Organ	Clinical Features
Type 1 GSD (von Gierke disease)	Glucose-6-phosphatase or transport system	▪ Liver ▪ Kidney	Increased amount of normal structure	▪ Massive hepatomegaly, failure to thrive ▪ Severe hypoglycemia ▪ Ketosis ▪ Hyperuricemia ▪ Hyperlipidemia
Type 2 GSD (Pompe disease)	Alpha-1,4-glucosidase (lysosome)	All organs (liver, kidney, skeletal muscle)	Massive increase in amount, normal structure	▪ Hypotonia (floppy baby) ▪ Hypertrophic hypertrophy ▪ Cardiorespiratory failure causes death usually before age of two years
Type 3 GSD (Cori disease)	Amylo-1,6-glucosidase (debranching enzyme)	▪ Skeletal muscles ▪ Liver	Increased amount; short outer branch	Like type 1, but milder form
Type 4 GSD (Anderson disease)	Branching enzyme (α-1,4 $\rightarrow$ α-1, 6)	Liver and spleen	Normal amount; very long outer branches	▪ Progressive liver cirrhosis with fatal outcome before age of two years ▪ Hepatocellular failure with fatal outcome before age of two years
Type 5 GSD (McArdle disease)	Phosphatase	Skeletal muscles	Moderately increased amount; normal structure	▪ Limited ability to perform strenuous exercise due to painful muscle cramps ▪ Otherwise, patient is well-developed and normal
Type 6 GSD (Hers disease)	Phosphorylase	Liver	Increased amount	Like type 1, but milder course
Type 7 GSD	Phosphofructokinase	Skeletal muscles	Increased amount, normal structure	Like type V
Type 8 GSD	Phosphorylase kinase	Liver	Increased amount, normal structure	Mild hepatomegaly, mild hypoglycemia

Type 1 through type 7 are inherited disorder, and type 8 is sex-linked disorder.

Laboratory Diagnosis

Genetic testing on blood sample is now available. Aim of treatment for type 0 glycogen storage disease is to prevent low blood sugar (hypoglycemia) by avoiding fasting. Frequent meals and snacks should be given every 3–4 hours during the day.

von Gierke's Disease (GSD Type 1)

von Gierke disease is most common autosomal recessive lysosomal storage disorder caused due to deficiency of glucose-6-phosphatase, in which body cannot break glycogen stored in the liver and skeletal muscle. Normally, glycogen stored in the liver and skeletal muscle is broken down to glucose by glucose-6-phosphatase to generate energy. von Gierke disease is also called glycogen storage disease type 1 (**GSD 1**).

Clinical Features

Patient with GSD-1 presents with severe hypoglycemia that coincides with ketonuria, metabolic acidosis and elevated lactate (due to excessive glycolysis) and alanine. Building up of glycogen in liver results in hepatomegaly.

- Decreased glucose causes lipolysis resulting in hyperlipidemia. Uricemia is caused by competitive inhibition by lactate of renal tubular urate secretion and increased uric acid production.
- Patient has growth retardation. Epinephrine and glucagon cannot produce hyperglycemia but result in lipolysis and increased lactate concentration.

Laboratory Diagnosis and Treatment

GSD-1 disorder is diagnosed by liver biopsy and DNA testing. Patients are treated by cornstarch, allopurinol and granulocytes colony stimulating factor (**GCSF**).

Pompe Disease (GSD Type 2)

Glycogen storage disease type 2, also called Pompe disease, is an autosomal recessive lysosomal storage disorder, which damages skeletal muscle, cardiac muscle, liver and nerves throughout the body. Pompe disease occurs due to deficiency of lysosomal enzymes, α_4-glucosidase enzyme and α_4-glucosidase resulting in accumulation of glycogen in the lysosomes.

Clinical Features

Patient of Pompe disease (GSD-2) develops intractable hypoglycemia, muscle weakness and cardiomegaly with normal liver functions. Pompe disease is of two types: (a) infantile type and (b) delayed onset type (childhood and juvenile/adult types).

- Infantile type is most severe form of Pompe disease. Infants are normal at birth, and manifest within the first two to three months with rapidly progressive skeletal muscle weakness, diminished skeletal muscle tone, respiratory problems, feeding problems, hypertrophic cardiomyopathy progressing to cardiorespiratory failure before 3 years of age.
- Delayed onset childhood and juvenile/adult type of Pompe disease manifests during infancy or early childhood with delayed motor milestones. Juvenile/adult form of Pompe disease presents during in second and seventh decades of life with muscle weakness.

Laboratory Diagnosis and Treatment

Patients of Pompe disease are diagnosed by skeletal muscle biopsy, liver biopsy, lysosomal acid maltase assay and DNA testing. Patients are treated by lysosomal acid maltase replacement.

Cori Disease (GSD Type 3)

Cori disease is an autosomal recessive lysosomal storage disorder caused due to deficiency of glycogen debranching enzymes (amylo-1,6-glucosidase) resulting in storage of abnormal form of glycogen in the liver, heart, or skeletal muscle.

Clinical Features

Patient with Cori disease (GSD-3) presents with stunted growth, hepatomegaly, and hypoglycemia. Glycogen storage disease is divided into types 3A, 3B, 3C and 3D, which are distinguished by the pattern of signs and symptoms.

- GSD types 3A and 3C mainly affects the liver (hepatomegaly) and skeletal muscles (muscle weakness).
- GSD types 3B and 3D affect only the liver (hepatomegaly). GSD types 3A and 3B are the most common forms of Cori disease.

Laboratory Diagnosis and Clinical Course

Beginning in infancy, any type of GSD 3 is characterized by low blood sugar (hypoglycemia), hyperlipidemia and elevated blood concentration of liver transaminases and creatinine kinase.

- As the infant gets older, the child develops hepatomegaly. Liver size returns to normal during adolescence.
- Some affected persons develop cirrhosis, hepatocellular failure and liver adenoma in life.

Anderson Disease (GSD Type 4)

Anderson disease is an autosomal recessive trait lysosomal storage disorder caused by deficient activity of the glycogen-branching enzyme resulting in accumulation of abnormal glycogen in the liver, muscle, and/or other tissues. Synonyms of GSD type 4 are Anderson disease or glycogenosis, amylopectinosis, branching enzyme deficiency and glycogenosis type 4.

Clinical Features

Infant with Anderson disease (GSD-4) presents with failure to thrive and hepatosplenomegaly followed by cirrhosis progressing to portal hypertension and hepatocellular failure. Death occurs from heart or liver failure before 5 years of age. In addition, several neuromuscular variants of Anderson disease have been described that may be evident at birth, in late childhood or adulthood.

- Patient develops isolated skeletal muscle involvement with skeletal myopathy and/or dilated cardiomyopathy leading to muscle weakness, fatigue, exercise intolerance, shortness of breath with exertion, edema and cardiac arrhythmias.
- Neuromuscular variant of GSD type 4 in adults, known as polyglucosan body disease is characterized by dysfunction of the central nervous system (brain and spinal cord) and peripheral nervous system (motor, sensory and autonomic nervous system).

Laboratory Diagnosis and Treatment

Diagnosis of Anderson disease (GSD-4) is established by clinical evaluation, history and physical examination. Biopsy obtained from liver, skeletal muscle, heart, skin or peripheral nerve and examined under light microscope demonstrates abnormal deposition of amylopectin-like material. Patients are diagnosed by liver biopsy and DNA testing. Patients are treated by liver transplantation.

McArdle Disease (GSD Type 5)

McArdle disease (GSD-5) is the most common metabolic autosomal recessive lysosomal storage disorder of skeletal muscle carbohydrate metabolism and one of the most frequent genetic myopathies.

- McArdle disease is caused by mutations in PYGM gene (muscle glycogen phosphorylase form), located on chromosome 11q13 that codes for the phosphorylase enzyme.
- Deficiency of muscle phosphorylase results in accumulation of glycogen in skeletal muscle. Synonyms of GSD type 5 are McArdle disease, glycogenosis type 5, myophosphorylase deficiency or muscle glycogen phosphorylase deficiency.

Clinical Features

McArdle disease (GSD-5) manifests during second or third decade of life with skeletal muscle cramps, muscle stiffness and muscle weakness after strenuous exercise, hypoglycemic seizures or cardiomegaly; increased blood concentration of creatine kinase, myoglobinuria (dark burgundy-colored urine due to presence of myoglobin, a protein found in heart and skeletal muscles), exaggerated increase in ammonia and diminished activity of muscle phosphorylase. Patient is advised to take sucrose prior to strenuous activity. Patients are diagnosed by skeletal muscle enzyme assay and DNA testing.

Hers Disease (GSD Type 6)

Hers disease (GSD-6) is an autosomal recessive disorder caused by a deficiency of hepatic phosphorylase enzyme resulting in excessive accumulation of glycogen in the liver. Hepatic phosphorylase enzyme is essential to break down glycogen stored in the liver and skeletal muscle and used for energy.

Clinical Features

Infant or child suffering from Hers disease presents with failure to thrive, hypotonia, hepatomegaly, ketotic hypoglycemia, elevated hepatic transaminases, hyperlipidemia and low prealbumin level.

- Most common complications of Hers disease (GSD-6) include short stature, delayed puberty, osteopenia and osteoporosis. Liver fibrosis commonly develops in GSD-6, but cirrhosis and hypertrophic cardiomyopathy rarely develop.
- Clinical and biochemical alterations may decline with age, but ketosis and hypoglycemia can continue to occur.

Laboratory Diagnosis

Diagnosis of Hers disease (GSD-6) is established by clinical evaluation, history and physical examination; and molecular testing of PYG1 gene mutation.

Taruis' Disease (GSD Type 7)

Taruis' disease (GSD-7) is an autosomal recessive lysosomal storage disorder. It is more often in individuals of Japanese and Ashkenazi Jewish descent equally affecting males and females. Disease is caused by mutations in the muscle phosphofructokinase gene that encodes phosphofructokinase enzyme resulting in deficiency of phosphofructokinase enzyme in skeletal muscle and erythrocytes. Phosphofructokinase enzyme deficiency leads to reduced amount of energy available to skeletal muscles during exercise.

Clinical Features

Taruis' disease (GSD-7) usually begins in childhood. Patient presents with weakness, pain, stiffness of skeletal muscles during exercise; sometimes associated with nausea, vomiting and dark burgundy-colored urine due to the presence of myoglobin (myoglobinuria). GSD type 7 can rarely affect infants and adults.

Laboratory Diagnosis and Treatment

Taruis' disease is diagnosed by a **skeletal muscle biopsy** for the measurement of phosphofructokinase enzyme level or analysis of phosphofructokinase enzyme in red blood cells.

- Molecular genetic testing for mutation in phosphofructokinase gene encoding phosphofructokinase enzyme in Japanese and Ashkenazi Jewish descent.
- The patients should be advised to avoid strenuous exercise for prevention of skeletal muscle pain and cramps. Consumption of carbohydrates should be avoided. Genetic counseling is recommended for affected individuals and their families.

Glycogen Storage Disease (GSD Type 9)

Glycogen storage disease type 9 is an autosomal recessive lysosomal storage disorder. Disorder is caused by the inability to breakdown glycogen by phosphorylase enzyme in the liver. The signs and symptoms such as hepatomegaly and slow growth begin in the early childhood.

Clinical Features

Affected children may have delayed development of milestones (sitting, standing, walking) and mild skeletal muscle weakness. Adolescents may have delayed puberty and liver fibrosis, that can rarely progress to cirrhosis.

- During prolonged periods of fasting, patient develops hypoglycemia or elevated levels of ketone bodies in the blood (ketosis). Ketones are molecules produced during lipolysis, which occurs when stored sugars are not available.
- GSD-9 can affect skeletal muscle tissue in children and adults. Patient experiences fatigue, skeletal muscle weakness, skeletal muscle pain, and cramps during strenuous exercise.

Laboratory Diagnosis

GSD-9 can cause breakdown of skeletal muscle resulting in release of myoglobin and its excretion in the urine. Myoglobinuria can cause the **urine** to be red or brown. In a small number of patients with GSD type 9, both liver and skeletal muscles are affected, however skeletal muscle problems are usually mild.

Glycogen Storage Disease (GSD Type 10)

Glycogen storage disease type 10 is an autosomal recessive lysosomal storage disorder of glycogen metabolism. Disease is caused by mutation in the **PGAM2 gene** encoding skeletal muscle phosphoglycerate mutase enzyme.

- GSD-10 primarily affects skeletal muscles. Patient presents with muscle cramps following strenuous physical activity, recurrent episodes of myoglobinuria as a result of breakdown of skeletal muscle.
- Untreated cases of myoglobinuria can result in renal failure. In some cases of GSD type 10, microscopic tube-shaped structures called tubular aggregates are demonstrated in skeletal muscle fibers. It is not clear how tubular aggregates are associated with the signs and symptoms of the disorder.

GALACTOSEMIA

Galactosemia is an autosomal recessive disorder of carbohydrate metabolism that affects the body's ability to convert galactose (a sugar contained in milk, including human mother's milk) to glucose.

- The cause of classic galactosemia is deficiency of galactose-1-phosphate uridyltransferase, with resultant accumulation of galactose-1-phosphate in many tissues.
- Patient suffering from galactosemia presents with failure to thrive, infantile cataracts, mental retardation, and progressive hepatocellular failure leading to cirrhosis and death. Most of these changes can be prevented by early removal of galactose from the diet.
- Galactosemia due to galactokinase deficiency is much less frequent than classic galactosemia. The disorder is often marked only by **infantile cataracts**.

MUCOPOLYSACCHARIDE STORAGE DISEASES (MUCOPOLYSACCHARIDOSIS TYPE 2)

Mucopolysaccharide storage (MPS) diseases are autosomal recessive disorders and caused by disturbances of the normal breakdown of carbohydrate complex known as mucopolysaccharides. Examples of mucopolysaccharide storage diseases are Hurler syndrome, Hunter syndrome, Sanfilippo syndrome, Maroteaux-Lamy disease, Sly disease and Morquio disease.

- MPS diseases have certain common characteristics of osteoarthritis, which include deformities of the bones and weight-bearing large joints that interfere with mobility.
- All MPS diseases except Sanfilippo disease interfere with growth development, causing short stature.

Hurler Syndrome (MPS Type 1 Disease)

Hurler syndrome, the most severe form of mucopolysaccharidosis is an autosomal recessive lysosomal storage disorder. Disorder is caused by mutations in the IDUA gene located on 4p16.3, that encodes **α**-L-iduronidase enzyme resulting in accumulation of mucopolysaccharides in lysosomes, such as dermatan sulphate and heparan sulphate in the heart, brain, liver and other organs. Affected patient inherits one mutated copy of the gene from each parent, who is referred to a carrier.

Clinical Features

Patient of Hurler syndrome presents with skeletal abnormalities (abnormal bones in the spine, claw hands, stubby fingers, joint stiffness, dwarfism, growth retardation), progressive mental retardation, cognitive impairment, intellectual disability getting worse overtime, respiratory problems, cardiac valve deformities, characteristic facies, corneal clouding, deafness, hepatosplenomegaly and reduced life expectancy.

Laboratory Diagnosis and Treatment

A urine analysis is only one of first steps in diagnosing Hurler syndrome (mucopolysaccharidosis I). Definite diagnosis requires a test to measure α-L-iduronidase enzyme activity levels in the blood or skin cells. Mucopolysaccharidosis I is a progressive, debilitating, and often life-threatening disease. In severe cases, death occurs by the age of ten years. Some patients may have a normal life span with enzyme replacement therapy.

Sanfilippo Syndrome (MPS Type 3 Disease)

Sanfilippo syndrome also known as mucopolysaccharidosis type 3 (MPS type 3 disease) is an autosomal recessive lysosomal storage disorder in which large sugar molecules called glycosaminoglycans build up and accumulated in lysosomes in various tissues especially brain and spinal cord.

Clinical Features

Patient suffering from Sanfilippo syndrome presents with growth retardation, intellectual disability overtime, abnormal bones in spine, claw hand, delay speech, headache, respiratory tract infections, deafness, cardiac valves problems, joint disease, chronic diarrhea and sleeping problems.

Laboratory Diagnosis

Urine analysis reveals excretion of large amounts of mucopolysaccharide (heparan sulfate). Blood culture is done to grow microorganisms and their sensitivity to therapeutic agents.

Morquio Syndrome (MPS Type 4 Disease)

Morquio syndrome also known as mucopolysaccharidosis type 4 (MPS type 4 disease) is an autosomal recessive lysosomal storage disorder in which body cannot process certain types of sugar molecules called glycosaminoglycans resulting in accumulation in lysosomes in bones, joints, cartilage, skin and other tissues.

- The disorder can lead to a number of potential complications. MPS type 4 equally affects males and females.
- Patient suffering from Morquio syndrome presents with short stature with very short trunk, bell-shaped chest with ribs flared at the bottom, abnormal bone and spine development including scoliosis.

Scheie Syndrome (MPS Type V Disease)

Scheie syndrome is an autosomal recessive lysosomal storage disorder caused by deficiency of iduronidase enzyme resulting in building of glycosaminoglycans in the body. Disorder is the mild-subtype of MPS type 1 disease and the most severe type of MPS type 1 disease. Symptoms appear by the age of five years.

Clinical Features

Patient presents with mild coarsening of the facial features (large head, mouth, tongue and thick lips), hydrocephalus, large vocal cords, upper respiratory tract infections, nasal secretion, neurosensorial hearing loss, hepatomegaly, stiff joints, mild skeletal changes and carpal tunnel syndrome, umbilical hernia and inguinal hernia.

Laboratory Diagnosis

Urine analysis reveals high levels of glycosaminoglycans (GAGs). Aortic valve involvement may be present. A definite diagnosis requires molecular testing to measure enzyme activity in the blood or skin cells. Enzyme replacement therapy with iduronidase enzyme and surgery may be essential.

Maroteaux-Lamy Disease (MPS Type 6 Disease)

Maroteaux-Lamy disease is an autosomal recessive trait lysosomal storage disorder caused by ARSB gene (5q13-q14) encoding N-acetylgalactosamine-4-sulfatase (arylsulfatase B).

- Under physiologic state, N-acetylgalactosamine-4-sulfatase (arylsulfatase B) participates in breakdown of large sugar molecules called glycosaminoglycans (GAGs). GAGs are usually linked to proteins to form proteoglycans and include chondroid 4-sulfate, chondroid 6-sulfate, heparan sulphate, dermatan sulfate, keratan sulfate and hyaluronic acid.
- Deficiency of N-acetylgalactosamine-4-sulfatase (arylsulfatase B) results in accumulation of glycosaminoglycans in lysosomes of connective tissue and organs.

Clinical Features

Patient suffering from Maroteaux-Lamy disease presents with somatic features such as skeletal abnormality, including short stature and joint deformities but not by mental retardation. Other clinical findings include hepatosplenomegaly, decreased pulmonary function, cardiac valve deformities, reduced pulmonary function, otitis media, hearing loss, sinusitis, cloudy cornea, carpal tunnel syndrome, sleep apnea and umbilical or inguinal hernia.

Laboratory Diagnosis

A diagnosis of Maroteaux-Lamy disease is based on clinical features, family history, increased excretion of dermatan sulfate in urine, blood sample for enzyme of arylsulfatase, skin biopsy for arylsulfatase B and molecular testing for ARSB gene mutation.

Sly Syndrome (MPS Type 7 Disease)

Sly syndrome, also known as mucopolysaccharidosis type 7 (MPS type 7 disease), is an autosomal recessive lysosomal storage disorder caused by deficiency of the β-glucuronidase enzyme. Normally, β-glucuronidase enzyme is responsible for degradation of large sugar molecules called glycosaminoglycans. Deficiency of β-glucuronidase enzyme results in accumulation of glycosaminoglycans in skeletal, joints, brain, spinal cord, heart, spleen and liver.

Clinical Features

The most severe cases of Sly syndrome (MPS 7) are characterized by hydrops fetalis as a result of excessive accumulation of fluid in the body before birth, which can result in stillborn or death after birth. Neonatal jaundice or yellow discoloration of skin may occur. In MPS 7 disease, children present with short stature, macrocephaly, short neck, unusual short trunk and multiple bone deformities such as prominent breast bone (pectum carinatum), flared ribs, frequent hip dislocations, 'frozen' joints (contractures), club foot, and/or an inward curve of the knees and outward bowing of the ankles (genu valgum).

GAUCHER'S DISEASE

Gaucher's disease is most common autosomal recessive lysosomal storage disorder in European (Ashkenazi) Jewish lineage. Disorder is caused by a deficiency of the lysosomal glucocerebrosidase enzyme (lysosomal acid β-glucosidase), which leads to an accumulation of its substrate, glucosylceramide (membrane

glycosphingolipids) derived from the catabolism of senescent leukocytes, in the lysosomes of macrophages.

Diagnostic Hallmark

The hallmark of Gaucher's disease is the presence of '**Gaucher's cells**' with a distinctive fibrillary cigarette paper-like cytoplasmic appearance and eccentric nuclei, which are lipid-laden macrophages present in the red pulp of the spleen, liver sinusoids (Kupffer cells), lymph nodes, lungs (alveolar macrophages), and bone marrow. Bone marrow aspiration reveals numerous Gaucher's cells, but specific enzymes (chitotriosidase and angiotensin-converting enzyme markers of macrophage proliferation) assay is required to confirm the diagnosis. Mutations in the GBA1 gene can be demonstrated in these cases.

Clinical Features

Clinical features of Gaucher's disease are variable depending on three distinct variants of Gaucher's disease types 1, 2 and 3 based on the presence or absence of neurological complications. Gaucher's disease type 1 lacks neurological complications. Neurological complications are present in Gaucher's disease in types 2 and type 3. Comparison of three variants (types 1, 2 and 3) of Gaucher's disease is given in Table 5.52.

- **Type 1 or adult Gaucher's disease:** Gaucher's disease type 1 accounts for >90% of cases in Europe and USA. Patient presents with marked hepatosplenomegaly, bone pain and fracture due to erosion of femoral head and other long bones. Mild anemia and thrombocytopenia (easy bruising) are also present. Patient may live a normal life span. Gaucher's cells are demonstrated in the bone marrow, liver, spleen, and lymph nodes.
- **Type 2 or infantile Gaucher's disease:** Gaucher's disease type 2 occurs in newborns and infants present with neurological complications such as involuntary skeletal muscle spasm, difficulty is swallowing and loss of previously motor skills with fatal outcome before 1 year of age.
- **Type 3 or juvenile Gaucher's disease:** Gaucher's disease type 3 occurs during first decade of life and presents with neurological complications such as mental retardation, inability to coordinate voluntary movements and skeletal muscle spasms of the extremities or entire body; and visceral involvement. It is less severe than type 2 Gaucher's disease.

Morphology: Gaucher's Disease

Light Microscopy

- Gaucher's cells are demonstrated spleen, liver, bone marrow, CNS, tonsil, thymus, Peyer's patches, and lungs.
- Cytoplasm is fibrillary and crumpled (tissue paper-like).
- Histologic examination of liver biopsy shows Gaucher's cells with a distinctive cigarette paper-like cytoplasmic appearance and eccentric nuclei, which are lipid-laden macrophages present liver sinusoids (Kupffer cells). Histology of Gaucher's disease is shown in Fig. 5.43.

Treatment

The patients with Gaucher disease are treated by administration of enzyme replacement therapy by

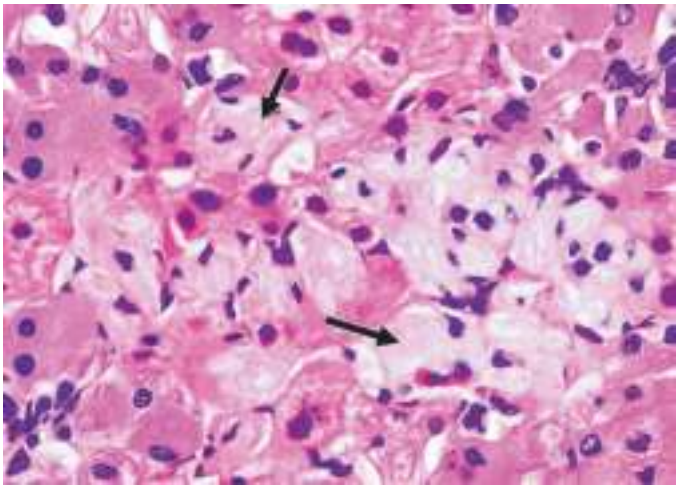

Fig. 5.43: Histology of Gaucher's disease. Gaucher's disease shows Gaucher's cells containing cigarette paper-like cytoplasmic appearance and eccentric nuclei, which are lipid-laden macrophages (arrows) (400X).

Table 5.52 Comparison of three variants (types 1, 2 and 3) of Gaucher's disease

Parameters	Gaucher's Disease Type 1	Gaucher's Disease Type 2	Gaucher's Disease Type 3
Age group	Adults (>90% in Europe and USA)	Infants	Early childhood
Frequency	>90% most common	Uncommon	Uncommon
Organs involved	Liver, spleen, bone marrow, lymph nodes	Liver, spleen, bone marrow and central nervous system	Central nervous system and viscera
Clinical features	Splenomegaly, hepatomegaly, cytopenia, fracture of femoral head	Failure to thrive and neurological impairment	Myoclonic convulsions
Prognosis	Normal life span	Fatal by one year of age	Less severe disorder

intravenous route (imiglucerase, velaglucerase, or taliglucerase). Orally administered inhibitors (miglustat of eliglustat) of glucosylceramide biosynthesis can be used.

NIEMANN-PICK DISEASE

Niemann-Pick disease is an autosomal recessive lysosomal storage disorder, which occurs due to SMPD1 gene mutation encoding protein resulting in accumulation of sphingomyelin in the lysosomes of phagocytes especially in type A and type B Niemann-Pick disease.

Diagnostic Criteria

Diagnostic hallmark of Niemann-Pick disease is presence of foamy histiocytes known as 'Niemann-Pick cells' containing sphingomyelin in liver, spleen, lymph nodes, skin, bone marrow, tonsil, GIT, and lungs.

- On light microscopy, Niemann-Pick cells are large cells 25–100 µm in size with eccentric nuclei and foamy cytoplasm. Foam cells show positivity with oil red O and Sudan black B.
- Electron microscopy of skin, rectal neurons, liver, or brain may demonstrate polymorphous cytoplasmic bodies. Niemann-Pick disorder is shown in Fig. 5.44.

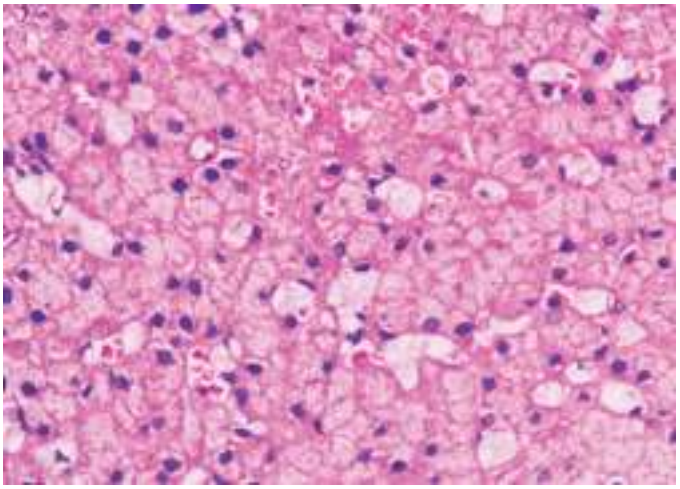

Fig. 5.44: Niemann-Pick disorder. Kupffer cells of liver show foamy histiocytes' containing sphingomyelin (400X).

Niemann-Pick Disease Variants

There are three variants of Niemann-Pick disease: types A, B and C. Comparison of three types (A, B, C) of Niemann-Pick disease is given in Table 5.53.

- **Niemann-Pick disease (type A):** It is a severe disease affecting infants within six months of life. Infant has extensive involvement of nervous system, liver and spleen. Patient presents with hepatosplenomegaly, lymphadenopathy, anemia, fever, a cherry red spot inside the macula of eye similar to that of Tay-Sachs disease, difficulty in feeding and neurologic manifestations with fatal outcome by three years of age.
- **Niemann-Pick disease (type B):** It is less severe disease, which does not involve central nervous system and organs. Patient presents with hepatomegaly, splenomegaly, pulmonary insufficiency and central nervous system manifestations with relatively better prognosis. Patient survives till adulthood.
- **Niemann-Pick disease (type C):** It occurs due to mutations in NCP1 and NCP2 genes, which encode cholesterol transport protein leading to accumulation of cholesterol within phagocytes of organs. Patient presents with hepatomegaly, splenomegaly, pulmonary insufficiency and central nervous system manifestations with relatively better prognosis. Patient survives up to adulthood.

Table 5.53 Comparison of three types (A, B, C) of Niemann-Pick disease

Parameters	Type A Niemann-Pick Disease (Classic Infantile Type)	Type B Niemann-Pick Disease (Visceral Type)	Type C Niemann-Pick Disease (Visceral Type)
Age group	Infants (severe disease)	Adults (less severe)	10 and 25 years
Basic defect	SMPD1 gene mutation encoding acid sphingomyelinase (ASM) protein resulting in accumulation of sphingomyelin in the lysosomes of phagocytes	SMPD1 gene mutation encoding acid sphingomyelinase (ASM) protein resulting in accumulation of sphingomyelin in the lysosomes of phagocytes	NPC1 or NCP2 gene mutations resulting in accumulation of sphingomyelin in the lysosomes of phagocytes
Clinical features	Hepatomegaly, splenomegaly, anemia, fever, profound neurologic manifestations and cherry red spots inside eye, difficulty in feeding	Hepatomegaly, splenomegaly, pulmonary insufficiency and central nervous system manifestations	Hepatomegaly, splenomegaly, central nervous system manifestations
Prognosis	Fatal outcome by three years of age (rarely survival beyond three years of age)	Survival in adulthood	Sometimes fatal outcome

- The diagnosis of Niemann-Pick disease type C (visceral type) should be considered in persons presenting with clinical manifestations: (a) fetal ascites or neonatal liver disease accompanied by prolonged jaundice and pulmonary infiltrates, (b) infantile hypotonia without evidence of progression for months to years, (c) vertical supranuclear gaze palsy followed by progressive ataxia, dystonia, dysarthria and seizures, (d) psychiatric presentations mimicking depression or schizophrenia, and (e) hepatomegaly or splenomegaly particularly, in early childhood.
- Molecular genetic testing is necessary to confirm the diagnosis in all persons with suspected Niemann-Pick disease.

ASPARTYLGLUCOSAMINURIA

Aspartylglucosaminuria (AGU) is an autosomal recessive lysosomal storage disorder. AGU is caused by mutation in AGU gene located on chromosome 4q34.3 encoding abnormal N-aspartylglucosaminidase enzyme, that cleaves N-acetylglycosamine-asparagine bond found into many glycopeptides and N-glycosylated proteins, and causes excessive accumulation of glycoasparagine in the body tissues and its excretion in urine. Low activity of N-aspartylglucosaminidase enzyme is demonstrated in lymphocytes, fibroblasts and trophoblasts. AGU is exceptionally found **outside of Finland**.

Clinical Features

Clinical manifestations of aspartylglucosaminuria appear several months after birth involving central nervous system and skeletal system. Clinical signs of AGU include slowly developing mental retardation, beginning of clumsiness (poor coordination of movements), delayed speech, mild gradual facial dysmorphism (coarsening), hyperkinesis, slight kyphoscoliosis and macroglossia. Hepatosplenomegaly is rare and reported in patients outside Finland.

BATTEN DISEASE

Batten disease is an autosomal recessive lysosomal storage disorder, that begins in childhood between five and ten years of age. Disorder is characterized by the accumulation of lipopigment in the brain as well as other tissues that lack nerve cells resulting in death of neurons in the brain, retina and central nervous system.

- Patient develops rapidly progressive neurological disturbances (e.g. deterioration of both intellect and neurological functions) and vision failure (optic atrophy). The life expectancy is between eight to ten years of age.
- No definite treatment is available to cure Batten disease. The seizures can be controlled with anti-seizures drugs.

GM2 GANGLIOSIDOSIS

GM2 gangliosidosis disease is a rare autosomal recessive lysosomal storage disorder that includes two disorders (e.g. Tay-Sachs disease and Sandhoff disease). It is caused by inherited deficiency in hexosaminidase A, B, and AB. The disorder progressively destroys nerve cells in the brain and spinal cord.

GM2 Gangliosidosis Type 1 (Tay-Sachs Disease)

GM2 gangliosidosis type 1 (Tay-Sachs disease) is a rare autosomal recessive trait lysosomal storage disorder seen in Ashkenazi (central European origin) Jewish descent.

- Tay-Sachs disease is caused by mutation in the HEXA gene located on chromosome 15 encoding the α-N-hexosaminidase enzyme resulting in accumulation of GM2 ganglioside in the neurons of brain and spinal cord, that progressively destroys neurons in brain and spinal cord.
- On average, half of the offsprings are expected to be heterozygotes and silent carriers of the gene mutation. Tay-Sachs disease is also known as amaurotic familial idiocy, which exists in two forms: infantile and the late-onset Tay-Sachs disease.

Clinical Features

Patient suffering from infantile type of Tay-Sachs disease presents with severe mental and motor deterioration, feeding problems, generalized weakness and an exaggerated startle reflex (sudden shock) in response to sudden loud noises, central nervous system degeneration, loss of motor skills (turning over, sitting and crawling), cherry red spot in the ocular macula and blindness between three to six months of age. Children die before 4 years of age. Late-onset of Tay-Sachs disease may become apparent anytime from adolescence through the mid of third decade, that progresses more slowly than the infantile Tay-Sachs disease.

GM2 Gangliosidosis Type 2 (Sandhoff Disease)

GM2 gangliosidosis type 2 (Sandhoff disease) is an autosomal recessive lysosomal storage disorder caused by mutation in gene encoding abnormal β-subunit of the hexosaminidase B enzyme resulting in accumulation of GM2 gangliosides in the lysosomes of neurons of brain and spinal cord and hence progressive loss of neurological function. Disorder occurs in two forms: infantile and juvenile/adult Sandhoff disease.

Clinical Features

Patient suffering from GM2 gangliosidosis type 2 (infantile Sandhoff disease) presents with clinical manifestations between the age of three to six months such as feeding problems, general weakness, an exaggerated startle reflex (sudden shock) in response to sudden loud noises, development of cherry red spots in the back of the eyes, splenomegaly, cardiac murmurs, progressive motor weakness and seizures. Juvenile/adult forms of Sandhoff disease are more variable in the age of onset and severity of symptoms.

METACHROMATIC LEUKODYSTROPHY

Metachromatic leukodystrophy (MLD) is an autosomal recessive lysosomal storage disorder characterized by accumulation of fats called sulfatides in myelin resulting in destruction of the myelin sheath surrounding the nerves in both central nervous system and the peripheral nervous system.

- When biopsy is examined under light microscope, sulfatide accumulation in cells appear as granules that are colored differently than other cellular material (metachromatic).
- There are three types of MLD based on the clinical manifestations: late-infantile, juvenile and adult forms. Patient initially presents with vague signs and symptoms followed by developmental delay, unsteadiness when walking, marked spasticity, seizures and profound mental retardation.

SCHINDLER DISEASE

Schindler disease is an autosomal recessive lysosomal storage disorder caused by mutation in the NAGA gene located in chromosome 22q13.2 encoding abnormal enzyme α-N-acetylgalactosaminidase **A and B** in lysosomes resulting in deficient activity of enzyme. There are two forms of Schindler disease: **type 1** infantile and **type 2** adult forms.

- Schindler disease type 1 appears during infancy until approximately one year of age and presents with loss of previously acquired skills that require coordination of physical and mental activities.
- Schindler disease type 2 affects adults and presents with development of wart-like discoloration on the skin, relative coarsening of facial features and mild intellectual impairment. The dilation of small lymphatic channels may lead to swelling.

MUCOLIPIDOSIS

Mucolipidosis is a group of inherited metabolic disorders that affect the body's ability to perform the normal turnover of various materials within cells. In this disorder, abnormal amounts of carbohydrate and lipids accumulate in the cells resulting in symptoms that range from mild learning disabilities to severe intellectual impairment, vision problems and skeletal abnormalities. Mucolipidosis occurs in types 1, 2, 3 and 4.

Mucolipidosis Type 1

Mucolipidosis type 1 is an autosomal recessive lysosomal storage disorder caused by a deficiency of the neuraminidase enzyme and accumulation of sialidated glycopeptides and oligosaccharides. Excessive swelling throughout the body is observed at birth. Newborn has coarse facial features such as flat nasal bridge, puffy eyelids, enlargement of gums, macroglossia, hypotonia, failure to thrive, skeletal malformations such as hip dislocation, sudden involuntary muscle contractions (called myoclonus), cherry red spots (macules) in their eyes, impaired intellect and respiratory infections with fatal outcome before the age of one year.

Mucolipidosis Type 2

Mucolipidosis type 2 is a slowly progressive autosomal recessive lysosomal storage disorder, that may begin during infancy or later. This disorder is characterized by growth retardation, visual disturbances, is mild coarse features, mild mental retardation, skeletal abnormalities (abnormalities of skull and face), facial dysmorphism, stiff skin, developmental delay and cardiomegaly.

Mucolipidosis Type 3

Mucolipidosis type 3 is a slowly progressive autosomal recessive lysosomal storage disorder, that affects many parts of the body. Signs and symptoms of disease typically appear around three years of age. Patient presents with short stature, cardiac valve abnormalities, mild clouding of cornea, stiffness of the hands and shoulders with later development of carpal tunnel syndrome, deterioration of hip joints and scoliosis.

Mucolipidosis Type 4

Mucolipidosis type 4 is an autosomal recessive lysosomal storage disorder, caused by mutation in ML4 gene mapped on chromosome 19q13. It is characterized by severe neurological manifestations (delayed psychomotor development) and ophthalmological abnormalities (corneal opacities and strabismus).

CYSTINOSIS

Cystinosis is an autosomal recessive lysosomal storage disorder caused by mutation in the CTNS gene located on chromosome 17p13, which results in an abnormal accumulation of the amine acid cystine within lysosomes due to lack of a cystine-specific transporter protein. Infantile cystinosis is most common severe

form of disease. Cystine accumulation occurs in cells throughout the body and causes progressive damage to multiple organs such as kidneys, eyes, skeletal muscles, pancreas, and brain. The clinical signs appear between three and six months of age.

Clinical Features

Patient suffering from cystinosis presents with polyuria, polydipsia, anorexia, vomiting, constipation and marked growth retardation secondary to impairment of proximal reabsorption capacity with severe fluid–electrolyte alterations (termed Fanconi syndrome).

- Skeletal bone deformities are observed secondary to hypophosphatemia rickets. Ocular changes due to cystine deposits in the cornea and conjunctiva result in photophobia after three years of age.
- Cystine deposition in various organs (pancreas, gonads, liver, spleen, skeletal muscles, cerebrum, cerebellum and kidneys) progressively lead to insulin-dependent diabetes mellitus, hypothyroidism, hypogonadism, male infertility, hepatosplenomegaly, skeletal muscle weakness, hypotonia, oropharyngeal dysfunction and end stage renal failure before the age of ten years.

AMINO ACID METABOLISM DISORDERS

Amino acids are 'building blocks' that join together to form protein. Amino acid metabolism disorders include phenylketonuria, alkaptonuria including ochronosis and maple syrup urine disease.

Phenylketonuria (PKT)

Normally, phenylalanine hydroxylase coverts phenylalanine to tyrosine in the liver. Gene mutation encoding abnormal **phenylalanine hydroxylase** results in failure of conversion of phenylalanine to tyrosine in the liver.

- **Clinical features:** High serum concentrations of phenylalanine are neurotoxic and enter cerebrospinal fluid resulting in progressive cerebral demyelination, mental deterioration and seizures by the age of one year.
  - Phenylalanine is catabolized into phenyl pyruvic acid and phenylacetic acid and excreted in urine in large amounts. Other manifestations include decreased pigmentation of hair, eyes, skin and musty body odor from phenylacetic acid in urine and sweat.
- **Screening test:** The concentration of phenylalanine in affected infants is usually normal at birth and increases rapidly during the first days of life. False-negative results are common immediately after birth. Blood sample for phenylketonuria is usually taken from the infant's heel within 2–3 days after birth.
- **Treatment:** Successful treatment is a phenylalanine-free diet. If affected mother is not controlled, the infant is at high risk of development of congenital heart disease, growth retardation, microcephaly, and mental retardation due to phenylketonuria.

Alkaptonuria

Due to deficiency of homogentisic oxidase enzyme causes incomplete metabolism of phenylalanine and tyrosine resulting in accumulation and urinary excretion of homogentisic acid (black pigment). Clinically, this disorder manifests alkaptonuria and ochronosis. The term alkaptonuria refers to urinary excretion of unmetabolized homogentisic acid imparting a dark color to urine on standing.

Pathology Pearls: Ochronosis

- The term ochronosis refers to pigment deposition in multiple tissues, most prominently in cartilage and connective tissue. Homogentisic acid (dark pigment) is deposited in the articular cartilage of vertebral column and later hips, knees and shoulder joints. Cartilage of nose, ears, larynx and bronchi is also affected.
- Larger joints may be distended by effusions, which is usually noninflammatory and synovium is hypertrophied.
- Cardiac valves, prostate, and sweat glands may also be involved.
- Light microscopy of the lesion shows granular pigment in chondrocytes and matrix is diffusely stained. Synovium shows evidence of acute or chronic inflammation.

Maple Syrup Urine Disease

Maple syrup urine disease is a rare inborn error of metabolism. It means the body is unable to process certain amino acids (the 'building blocks' of protein) causing a harmful build up of substances in the blood and urine. Normally, body breaks down protein foods such as meat and fish into amino acids. Defects in proteins forming branched-chain keto acid dehydrogenase (keto acid decarboxylase) complex results in maple syrup urine disease. Urine contains high levels of keto acids of leucine, isoleucine, and valine giving maple syrup odor.

- Newborns are treated with protein-modified diets. Patient presents with retardation of physical and mental health along with feeding problems.
- Untreated newborn may develop mental and physical disabilities with fatal outcome.

X-LINKED RECESSIVE DISORDERS

Genes for these traits are located only on the X chromosome (not on the Y chromosome). X-linked alleles always show up in males whether dominant or recessive because males have only one X chromosome. Selected

Table 5.54 Selected X-linked recessive disorders

Hematological Disorders	
▪ Glucose-6-phosphatase (G6PD) deficiency ▪ Hemophilia A (deficiency of factor VIII) ▪ Hemophilia B (deficiency of factor IX)	
Immunodeficiency Disorders	
▪ X-linked Bruton agammaglobulinemia ▪ Chronic granulomatous disease ▪ Wiskott-Aldrich syndrome	
Storage Disorders	
▪ Fabry's disease	▪ Hunter's disease
Skeletal Muscle Disorders	
▪ Duchenne's muscular dystrophy (absolute dystrophin gene mutation)	▪ Becker's muscular dystrophy (relative dystrophin gene mutation)
Metabolic Disorders	
▪ Diabetes insipidus	▪ Lesch-Nyhan syndrome
Other Disorders	
▪ Red-green color blindness ▪ Fragile X syndrome ▪ X-linked ichthyosis	▪ Menkes 'kinki hair' syndrome (inability to transport copper into the cells)

X-linked recessive disorders are given in Table 5.54 and selected X-linked recessive disorders due to enzyme deficiency are given in Table 5.55.

CLASSIC HEMOPHILIA

Classic hemophilia is common X-linked recessive disorder. X and Y chromosomes are called sex chromosomes. Mutation in factor VIII gene located on the tip long arm of X chromosome encodes deficient clotting factor VIII, that does not produce sufficient thrombin in the intrinsic pathway of the coagulation cascade resulting in bleeding.

Molecular Genetic Alterations

The gene for hemophilia is located on the tip of the long arm of X chromosome.

- Females inherit two X chromosomes, one from their mother and one from their father (XX).
- Males inherit an X chromosome from their mother and a Y chromosome from their father (XY). It means that if a son inherits an X chromosome from a carrier mother, will suffer from hemophilia, meaning thereby father cannot transmit hemophilia to his sons.
- Because daughter has two X chromosomes, even if she inherits hemophilia gene from the mother and healthy X chromosome from her father, does not suffer from hemophilia.
- A daughter who inherits an X chromosome that contains the gene for hemophilia is called a carrier. She can transmit the hemophilia gene onto her children. Hemophilia can occur in daughters, but is rare.
- Heterozygous females are carriers, which transmit the disease to the male progeny. The family pedigree of Queen Victoria shows a number of hemophilic descendants as she was a carrier of the disease. In females, the other normal X chromosome corrects the abnormality, but females can be asymptomatic carriers. In males, the disease is expressed because there is no normal X chromosome to correct the abnormality.

Clinical Features

Classification of hemophilia A according to plasma procoagulant factor VIII levels is as follows: (a) severe hemophilia A with plasma factor VIII levels less than 1% of normal levels (<0.01 IU/ml), (b) moderate hemophilia A with plasma factor VIII levels between 1 and 5% of normal levels (0.01–0.05 IU/ml), and (c) mild hemophilia A with more than 5% but less than 40% of normal (<0.05 to 0.40 IU/ml). Classification of hemophilia A according to plasma procoagulant factor VIII levels is given in Table 5.56. Clinical manifestations of hemophilia are shown in Fig. 5.45.

- **Severe hemophilia A:** Person presents with bleeding following tissue injury and spontaneous bleeding episodes into the joints and skeletal muscles. Recurrent hemarthroses can lead to progressive crippling deformities. Bleeding in gastrocnemius muscle results in 'equine gait'.

Table 5.55 Selected X-linked recessive disorders due to enzyme deficiency

Disorder	Enzyme Deficiency	Accumulation
Hunter's syndrome	L-Iduronosulphate sulphatase	Heparan sulfate, dermatan sulfate
Fabry's disease	Alpha-galactosidase A	Ceramide trihexoside
G6PD deficiency	Glucose-6-phosphate dehydrogenase	Red blood cells hemolysis without any accumulation
Classic hemophilia (factor VIII deficiency)	Factor VIII	Without any accumulation
Lesch-Nyhan syndrome	Hypoxanthine-guanine phosphoribosyltransferase (HGPRT)	Uric acid
Duchenne muscular dystrophy	Dystrophin	Without any accumulation

Table 5.56 Classification of hemophilia A according to plasma procoagulant factor VIII levels

Severity of Hemophilia A	Plasma Factor VIII Levels Percentage	Frequency
Severe hemophilia A	Less than 1% of normal (<0.01 IU/ml)	60%
Moderate hemophilia A	1–5% of normal (0.01–0.05/ml)	15%
Mild hemophilia A	More than 5% but less than 40% of normal (>0.05 to <0.40 IU/ml)	25%

Classification of hemophilia A according to plasma procoagulant factor VIII levels is also applicable to factor IX deficiency (Christmas disease)

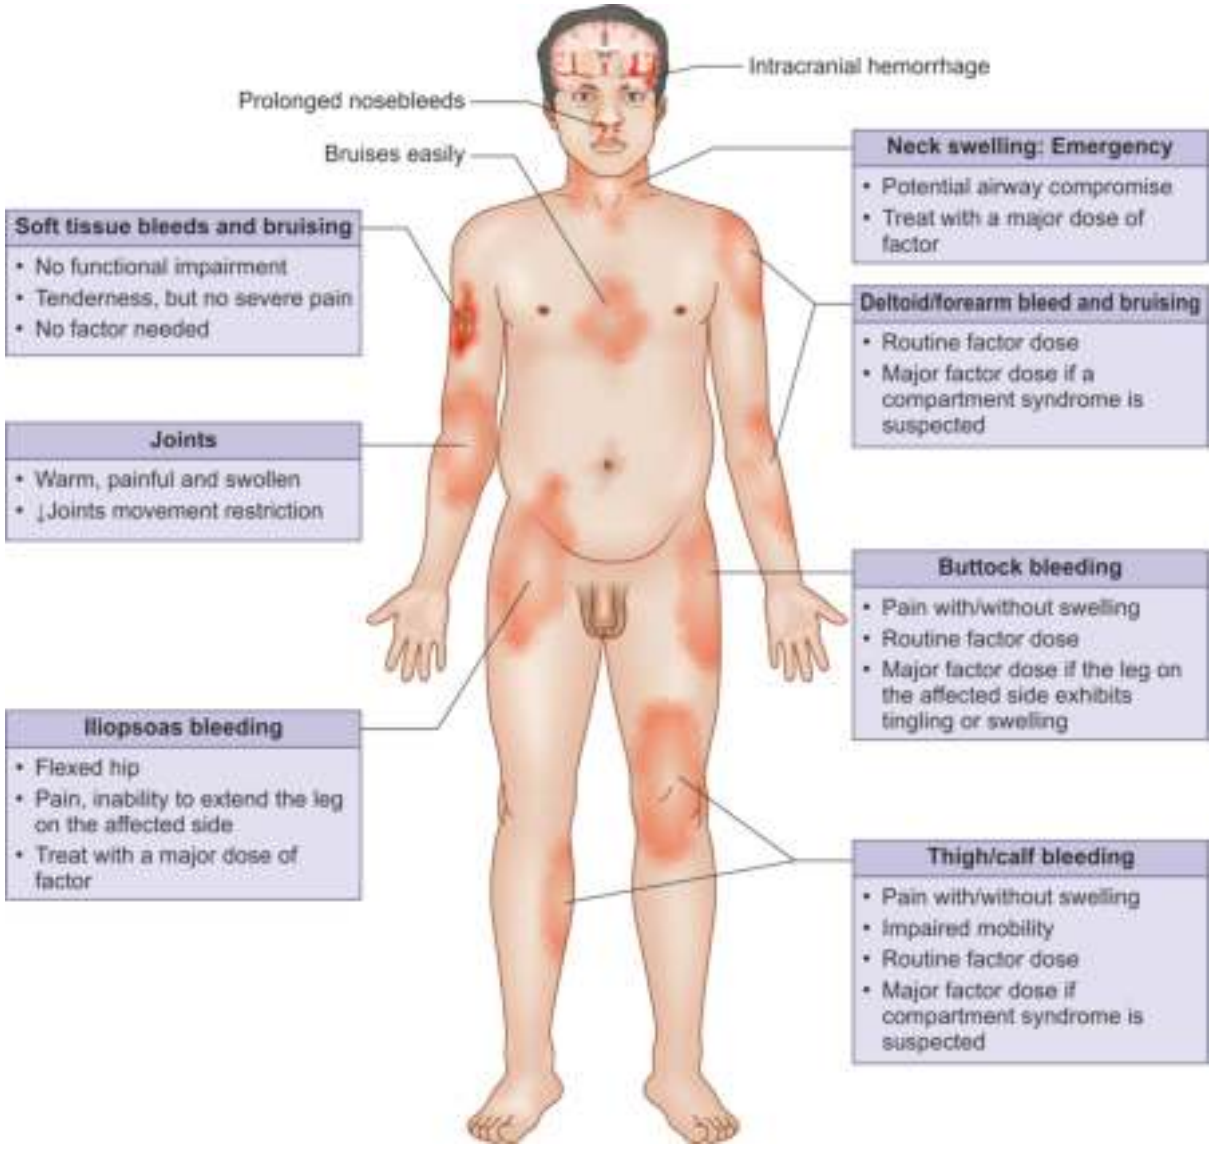

Fig. 5.45: Clinical manifestations of hemophilia.

- **Moderate hemophilia A:** Patient presents with bleeding episodes following injuries. Bleeding that occurs without obvious cause is called spontaneous bleeding episodes.
- **Mild hemophilia A:** Patient presents with bleeding only after severe injury, trauma or surgical procedures.

In many cases, mild hemophilia A is not diagnosed until an injury, surgery or tooth extraction results in prolonged bleeding. The first bleeding episode may not occur until adulthood. Women with mild hemophilia often experience menorrhagia, heavy menstrual periods, and can postpartum hemorrhage.

Laboratory Diagnosis

Hemophilia A is diagnosed primarily by reviewing a patient's family history as it is an inherited disorder. Physical examination and blood tests help in determination of the extent and severity of the disorder. Persons with known family history of the disorder can have tests done during pregnancy to determine if the fetus has inherited the disorder. Hemophilia cases are generally diagnosed between 0 and 2 years after birth with the mean age for diagnosis being nine months.

Treatment

Hemophilia A patient with bleeding manifestations is treated by infusion of concentrated FVIII clotting factor in fresh frozen plasma.

- The Medical and Scientific Advisory Council (MASAC) of the National Hemophilia Foundation encourages the use of recombinant FVIII product prepared from human-derived donor plasma by DNA technology.
- DDAVP (desmopressin acetate) is the synthetic version of vasopressin, a natural antidiuretic hormone that helps to stop bleeding. DDAVP can be administered in patients with mild hemophilia for bleeding in mucous membranes of the mouth and nose, joints and skeletal muscle before and after surgical procedures.
- Antifibrinolytic agents (e.g. aminocaproic acid and tranexamic acid) prevent the breakdown of blood clots in hemophilic patients, hence, it is recommended before dental procedures and to treat bleeding in nose and mouth.

DUCHENNE MUSCULAR DYSTROPHY

Duchenne muscular dystrophy is X-linked genetic disorder is the most common and severe variety of the disease due to deletion of one or many exons in the dystrophin gene (**DMD gene**) located on the short arm of the X chromosome (Xp21).

- Normally, dystrophin links the subsarcolemmal cytoskeleton to the exterior of the cell through a transmembrane complex of proteins. Boys with disorder cannot produce dystrophin at all.
- Dystrophin deficient skeletal muscles of pelvic and shoulder girdles predispose to death of myocytes during contraction. Serum levels of creatine kinase are markedly increased.

Clinical Features

Children fail to walk by 18 months of age due to weakness in the proximal muscles of the extremities, progressing to muscle necrosis, wasting, muscle contracture with fatal outcome in their teens. They develop pneumonia due to weakness of respiratory muscles. More than 90% of afflicted boys are wheelchair bound by the age of 10 years and bedridden by age 15 years.

Complications

The most common causes of death are complications of respiratory insufficiency caused by muscular weakness or cardiac arrhythmia due to myocardial involvement.

BECKER MUSCULAR DYSTROPHY

Becker muscular dystrophy is an X-linked recessive disorder caused by mutations in dystrophin gene, which encodes abnormal protein dystrophin in the muscle cell membrane. It is less common and less severe disorder than Duchenne muscular dystrophy.

- In Duchenne muscular dystrophy, dystrophin gene mutation results in the severe deficiency of protein dystrophin (<5%) in the muscle cell membrane.
- But in Becker muscular dystrophy, the mutation results in production of abnormal dystrophin or insufficient dystrophin protein in the muscle cell membrane.

Clinical Features

Becker muscular dystrophy is characterized by slowly progressive muscle weakness of the legs and pelvis in boys. Patient experiences difficulty in sports, climbing stairs and lifting heavy loads. Patient has calf muscles that look bigger than normal, even though these are weaker.

HUNTER SYNDROME (MPS TYPE 2 DISEASE)

Hunter syndrome is X-linked recessive disease and also known as mucopolysaccharidosis type 2 (MPS type 2 disease) in which deficiency of iduronate-2-sulfatase results in accumulation of large sugar molecules called glycosaminoglycans such as heparan sulfate and dermatan sulfate in the lysosomes in various tissues. Disease is transmitted from one generation to the next in a specific way. Hunter syndrome is less severe disease than Hurler syndrome.

Clinical Features

Patient suffering from Hunter syndrome presents with joint stiffness (immobile joints), skeletal muscle weakness, difficulty in walking, numbness, weakness and tingling sensations in hands; hepatosplenomegaly, upper respiratory tract infections, breathing problems at night, hearing loss, mild mental retardation, optic nerve edema, uveal effusion, retinal degeneration, visual field defects and cardiac lesions.

LESCH-NYHAN SYNDROME

Lesch-Nyhan syndrome is X-linked recessive disorder caused by deficiency of hypoxanthine-guanine phosphoribosyl transferase (hGPrT), resulting in impaired purine metabolism and excess production of uric acid. Patient presents with gout, mental retardation, choreoathetosis (abnormal involuntary muscle movements), spasticity, self-mutilation, and aggressive behavior.

GLYCOGEN STORAGE DISEASE (GSD) TYPE 8

Glycogen storage disease type 8 is X-linked recessive hepatic glycogen disorder resulting from lack of expression of phosphorylase-β-kinase activity. This is a regulatory enzyme in the activation cascade of glycogenolysis. GSD type 8 is mildest form of glycogenoses and characterized by hepatomegaly, increased glycogen in liver, growth retardation and decreased leukocyte phosphorylase, elevation of glutamate-pyruvate transaminase and glutamate oxaloacetate transaminase, hypercholesterolemia and hyperglyceridemia. Liver shrinkage occurs in response to glucagon.

FABRY DISEASE

Fabry disease is X-linked lysosomal storage disorder and also known as 'angiokeratoma corporis diffusum universale'. It occurs due to mutation in GLA gene encoding abnormal α-galactosidase A enzyme in lysosomes resulting in accumulation of ceramide trihexoside in body tissues such as skin, eyes, gastrointestinal system, kidney, heart and nervous system. Clinical manifestations are apparent until second or third decade of life.

Clinical Features

Patient suffering from Fabry disease presents episodes of fever, severe pain and burning sensations in hands and feet, decrease in sweat production, discomfort in warm temperatures and reddish to dark blue colored flat or raised skin rashes (angiokeratoma) in the lower trunk and area between the hips and knees; and cardiovascular and cerebrovascular involvement. Fabry disease is diagnosed by measuring the amount of α-galactosidase A enzyme activity. Patient dies of renal failure in early adult life.

X-LINKED DOMINANT DISORDERS

X-linked dominant inheritance refers to genetic disorders associated with mutations in one gene on X chromosome. A single copy of gene mutation is sufficient to cause disorder in males as well as females. If the trait is dominant, one of the parents must have the trait. X-linked dominant disorder can be passed down through families. In X-linked recessive traits, males are much more affected than females. X-linked dominant disorders are given in Table 5.57.

Table 5.57 X-linked dominant disorders

X-linked dominant hypophosphatemic rickets
Rett syndrome (95% of cases due to sporadic mutations)
Alport syndrome (most cases)
Incontinentia pigmenti
Giuffre-Tsukahara syndrome
Goltz syndrome
X-linked dominant protoporphyria
Fragile X-linked dominant syndrome

X-LINKED DOMINANT HYPOPHOSPHATEMIC RICKETS

X-linked dominant hypophosphatemic rickets can have several patterns of inheritance. Disorder results from mutation in the PHEX gene located on X chromosome. X-linked dominant hypophosphatemic rickets is characterized by inability of the kidneys to activate vitamin D and keep phosphate out of the urine and in the blood stream. Disease differs from most cases of rickets in that vitamin D supplementation does not cure the disease. Patient develops bone deformity, short stature, genu varum (bowing of legs), bone pains and severe dental problems.

RETT SYNDROME

Rett syndrome is an X-linked dominant disorder caused by mutation in MECP2 gene located on X chromosome in 95% of cases among females.

- After a short period of initial normal development, patient experiences neurological problems such as loss of speech and purposeful hand use, stereotypic hand movements and gait abnormalities.
- Additional clinical features include deceleration of head growth, seizures, autistic features and breathing abnormalities. Disease can also affect male infants. Most of them die before birth or early in infancy.

ALPORT SYNDROME

Alport syndrome is an inherited X-linked dominant disorder caused by mutation in **COL4A5 collagen gene** located on X chromosome, which codes for abnormal collagen protein. Collagen is important to the normal structure and function of the kidneys. Changes in collagen also results in ears and eyes problems. Disease

is characterized by progressive kidney disease (hematuria, proteinuria), hearing loss and eye abnormalities.

INCONTINENTIA PIGMENTI

Incontinentia pigmenti (IP) is a rare X-linked dominant genetic disorder, which occurs more common in females than males. Disease affects skin, teeth, nails and central nervous system. Patient presents with skin lesions blistering rash followed by wart-like lesions and brown hyperpigmented patches, and later hypopigmentation on arms and legs; small teeth, vision loss, intellectual disability and seizures.

GIUFFRÈ-TSUKAHARA SYNDROME

Giuffrè-Tsukahara syndrome, also known as radioulnar synostosis-microcephaly-scoliosis syndrome, is an X-linked dominant disorder. Disease is characterized by radioulnar synostosis with microcephaly, scoliosis, short stature, clinodactyly of the fifth fingers, partial webbing and intellectual disability.

GOLTZ SYNDROME

Goltz syndrome, also known as facial dermal hypoplasia, is an X-linked dominant multisystem disorder, that involves skin, skeletal system (hands, feet), face, eyes, cardiovascular system, central nervous system, urinary system and gastrointestinal system. In Goltz syndrome, ectodermal dysplasia affects normal development of hair, skin, nails and glands. Affected infant has thin skin, areas of missing skin, soft, yellow pink fat nodules in skin, and pigmentary changes.

X-LINKED DOMINANT PROTOPORPHYRIA

X-linked dominant protoporphyria is caused by mutation in ALAS2 gene located on X chromosome. Males usually develop the severe form of the disorder, while females remain asymptomatic.

- **Clinical features:** Patient presents with cutaneous photosensitivity since infancy that results in tingling, burning pain, and itching without blisters within minutes of exposure to sunlight, which persist for hours or days. Photosensitivity is lifelong. The photosensitivity and subsequent pain can be reduced by administration of α-melanocyte stimulating hormone analog.
- **Laboratory diagnosis:** The diagnosis of X-linked dominant protoporphyria is confirmed in a male with markedly elevated free erythrocyte protoporphyrin and zinc-chelated erythrocyte protoporphyrin by identification of hemizygous pathogenic gain of function in **ALAS2 gene** on molecular testing. Same molecular testing is performed to establish diagnosis in heterozygous female.

FRAGILE X SYNDROME

Fragile X syndrome has an X-linked dominant inheritance, which is caused by an expansion of the CGG triplet repeat with the FMR1 (fragile X mental retardation 1) gene located on the X chromosome.

- Disease is expressed in both sexes and characterized by moderate intellectual disability in affected males and mild intellectual disability in affected females.
- Males can develop large head, long face, prominent forehead and chin, ears, loose joints and large testes after puberty. Behavioral abnormalities including autistic behavior are common.

MITOCHONDRIAL DNA MUTATIONS ASSOCIATED DISORDERS

Mitochondrial inheritance is mediated through maternal lines (cytoplasmic mitochondrial genes), as mitochondria in the embryo are derived from **ovum**. Mitochondrial genes code for enzymes involved in oxidative phosphorylation.

- Only female parent transmits the trait to her children. Transmission of abnormal mitochondrial genes by female parent affects enzymes involved in oxidative phosphorylation. If an affected male has children, his progeny is unaffected.
- A mixture of genetically normal and abnormal mitochondria in tissues is termed 'heteroplasmy'. Disorders associated with mitochondrial DNA mutations are given in Table 5.58.

CHRONIC PROGRESSIVE EXTERNAL OPHTHALMOPLEGIA

Chronic progressive external ophthalmoplegia (CPEO) is a mitochondrial disorder that mainly involves extraocular of the eyes. Patient presents with slowly progressive symmetrical bilateral limitation of eye movements, eyebrows and ptosis. Mitochondrial DNA mutations are being recognized as the etiology of this disorder.

MITOCHONDRIAL DEAFNESS

Mitochondrial deafness is caused by pathogenic variants in mitochondrial DNA (mtDNA) and transmitted by maternal inheritance. The mother of a proband (usually) has the mtDNA pathogenic variant and may or may not have hearing loss.

KEARNS-SAYRE SYNDROME

Kearns-Sayre syndrome is a rare inborn error of metabolism and characterized by progressive external

Table 5.58 Disorders associated with mitochondrial DNA mutations

Mitochondrial Disorders	System Involved	Clinical Manifestations
Chronic progressive external ophthalmoplegia	Eye	Progressive weakness of extraocular muscles
Mitochondrial deafness	Ear	Progressive sensorineural deafness often associated with aminoglycoside antibiotics
Kearns-Sayre syndrome	▪ Eyes ▪ Heart	▪ Progressive weakness of extraocular muscles of early onset, retinal pigmentation ▪ Heart block
Leber hereditary optic neuropathy	Eyes	Painless, subacute visual loss, with central blind spots (scotomata) and abnormal color vision
Leigh disease	▪ Nervous system ▪ Eyes	▪ Proximal muscle weakness, sensory neuropathy, developmental delay, ataxia, seizures, dementia ▪ Visual pigment degeneration
MELAS (mitochondrial encephalopathy, lactic acidosis and stroke-like episodes)	Nervous system	Mitochondrial encephalomyopathy (cerebral structural changes), lactic acidosis, and stroke-like syndrome, other clinical and laboratory abnormalities; may manifest as diabetes mellitus
MERRF (myoclonic epilepsy with ragged-red fibers) syndrome	Nervous system and muscles	Myoclonic epilepsy, ragged-red fibers in muscle, ataxia, sensorineural muscle weakness and fatigue

ophthalmoplegia (impairment of eye movements and ptosis), pigmentary retinitis and an onset before the age of 20 years.

- Common additional features of Kearns-Sayre syndrome include deafness, cerebral ataxia, muscle weakness, kidney problems, dementia, and cardiac conductance defects.
- When muscle cells of affected persons are stained and viewed under a light microscope, which usually appear abnormal. The abnormal muscle cells contain an excess of structures called mitochondria, which are known as ragged-red muscle fibers.

LEBER'S HEREDITARY OPTIC NEUROPATHY

Leber's hereditary optic neuropathy (LHON) is a mitochondrial inherited disorder optic nerve disease caused by mutation in genetic code of the mitochondria, which are small subunits that reside within the cell. Disease is transmitted from mother to predominantly male offspring. Patient resents with sudden, painless central vision loss caused by degeneration of retinal ganglion cells and their exons during adult life.

LEIGH DISEASE

Leigh syndrome is a severe neurodegenerative disorder that usually becomes apparent in the first year of life. Disorder follows a mitochondrial inheritance pattern, also called maternal mitochondrial inheritance.

- Initially, infant has poor sucking ability, loss of head control and motor skills, loss of appetite, vomiting, and seizures.
- As the disease progresses, symptoms may include weakness, lack of muscle tone, spasticity, movement disorders, cerebellar ataxia and peripheral neuropathy.
- Complications can lead to impaired functions of respiration, heart and kidney. Death occurs within two to three years due to respiratory failure.

MITOCHONDRIAL ENCEPHALOPATHY, LACTIC ACIDOSIS AND STROKE-LIKE EPISODES

Mitochondrial encephalopathy, lactic acidosis and stroke-like episodes (MELAS) is the most common maternally inherited mitochondrial disorder. More than 80% of MELAS cases have a common mutation A→G in the mitochondrial tRNA at 3243 of mitochondrial DNA.

- Neuroimaging reveals transient nature of the stroke-like episode abnormalities. The cardinal laboratory abnormalities include elevated serum lactate during the acute episodes and respiratory enzyme defects in skeletal muscle.
- Skeletal muscle biopsy also helps confirm the diagnosis by identification of abnormal proliferation of mitochondria. Current treatment options for MELAS are largely supportive.

MYOCLONIC EPILEPSY WITH RAGGED-RED FIBERS (MERRF) SYNDROME

Myoclonic epilepsy with ragged-red fibers (MERRF) syndrome is mitochondrial inheritance disorder, also called maternal mitochondrial inheritance.

- MERRF syndrome is a multisystem disorder involving skeletal muscle and nervous system. Patient presents with generalized epilepsy, ataxia, skeletal muscle weakness and dementia during childhood and adolescence.
- Diagnosis of MERRF syndrome is based on clinical features and skeletal muscle biopsy finding of ragged-red fibers. In over 80% of cases, MERRF syndrome occurs due to mutations in the mitochondrial gene called MT-TK.

BALANCED POLYMORPHISM

Genetic polymorphism refers to the occurrence of two or more clearly different phenotypes exist in the same population of species.

- Balanced polymorphism occurs in a population when two alleles are maintained in stable equilibrium. Heterozygous person (with one allele) survives longer than homozyous person (with two alleles).
- This variability allows an organism to adapt rapidly in the face of changing environmental conditions. Summary of the genetic disorder and infectious diseases pairings is given in Table 5.59.

GENETIC DISORDERS CONFERRING RESISTANCE TO INFECTIOUS DISEASES

Some genetic disorders can confer resistance to specific infectious diseases. These genotypes are maintained in the population regularly exposed to certain highly virulent infectious agents.

- Understanding, how human genetic disorders influence infectious disease susceptibility offers the opportunity for new insights into pathogenesis, genetic mechanisms of resistance, developing novel potential drug targets, risk stratification, response to therapy, vaccination and improving current therapies.
- Genetic disorder—infectious disease pairings include: (a) hemoglobinopathies—resistance to malaria, (b) cystic fibrosis—resistance to cholera, (c) Tay-Sachs disease—resistance to tuberculosis, (d) phenylketonuria low-risk of miscarriages, (e) Niemann-Pick type C1 disease—resistance to flaviviruses, (f) myasthenia gravis—resistance to rabies and (g) congenital disorder of glycosylation 2B and resistance to viral infections. Out of these first four (a, b, c, d pairs) of the resistance-associated pairings appear to be a result of selection pressures in geographic regions in which the specific pathogen is endemic.
- Additional disorders are also being discussed here, which include enzymopathies—infectious disease (G6PD deficiency—resistance to malaria, pyruvate kinase deficiency—resistance to malaria and hemosiderosis) and hemosiderosis—hypersusceptibility to typhoid fever.

HEMOGLOBINOPATHIES AND RESISTANCE TO MALARIA

Normal persons (HbA) are more susceptible to malaria. The genetic resistance to malaria infection, particularly *Plasmodium falciparum* is associated with hemoglobinopathies. Plasmodium has a life cycle that includes alternating hosts: (a) sexual cycle in the female Anopheles mosquito insect vector and, (b) human cycle that includes a liver stage and an erythrocytic stage. Malaria causes cycles of fever and chills.

Sickle Cell Anemia and Resistance to Malaria

The best-defined hemoglobinopathy showing protection against malarial parasite is sickle cell disease, which illustrates balanced polymorphism because carriers are resistant to malarial parasite (*Plasmodium falciparum*). Malaria causes cycles of fever and chills.

Table 5.59 Summary of the genetic disorder and infectious diseases pairings

Genetic Disorder	Genetic Basis of Disorder	Protection Against Infectious Disease
Sickle cell heterozygotes (HbA/HbS)	Mutations encoding hemoglobin or enzymes vital to RBCs metabolism	Malarial parasite and pneumococcal pneumonia
Cystic fibrosis	Mutations in gene encoding a chloride channel (CFTR)	Cholera
Phenylketonuria	Mutations in the gene encoding phenylalanine hydroxylase	Miscarriage in pregnant women
Congenital disorder of N-linked glycosylation and resistance to viral infections	Glycosidase 1 deficiency	Viral infections

- Sickle cell anemia is an autosomal recessive disorder caused by a point mutation in the β-chain of hemoglobin located on chromosome 11 causing the hydrophilic amino acid glutamic acid to be replaced within hydrophobic amino acid valine at the sixth position, that results into sickle-shaped red blood cells.
- Sickle-shaped red blood cells are fragile and clog the small blood vessels thus causing damage to the organs, severe anemia, joint pain, splenomegaly, recurrent infections and heart failure.
- Heterozygous persons (HbS/HbA) with one normal allele and one allele of the disease are relatively resistant to *Plasmodium falciparum* malaria.
- Homozygous persons (HbS/HbS) with copy of two alleles have greater number of red blood cells containing abnormal hemoglobin (HbS).
- About 10–20% population in Africa carries at least one sickle cell allele. Therefore, sickle cell trait shows a case of balanced polymorphism where sickle cell heterozygotes have advantage over sickle cell homozygotes in a population.

Thalassemia and Resistance to Malaria

Thalassemias are disorders involving alterations in the globin chains that make up the hemoglobin molecule.

- The disease is classified as α- or β-thalassemia depending on whether α- or β-hemoglobin chain harbors a mutation.
- Four genes, two from each parent, are required to produce enough α- or β-chains: α- or β-thalassemia trait occurs if one or two of the four genes are missing or altered.
- Researchers observed that β-thalassemia provides a high degree of protection against malaria, whereas α-thalassemia cases are more susceptible to malaria.

ENZYMOPATHIES AND RESISTANCE TO MALARIA

Both G6PD and pyruvate kinase deficiency are linked to resistance to malarial parasite. These enzymopathies have been recognized as important drug targets against *Plasmodium falciparum*.

Glucose-6-Phosphate Dehydrogenase Enzyme Deficiency

G6PD deficiency is an X-linked disorder that leads to increased oxidative stress in red blood cells due to food (fava beans), drugs (e.g. antimalarial or sulphonamide therapeutic agents) and various chemical agents. The disorder most commonly affects persons of Asian, African, Mediterranean of Middle Eastern descent.

- Patient presents with anemia, tiredness, jaundice and splenomegaly. The heterozygous who possesses G6PD deficiency has some protection against malaria. Red blood cells with low G6PD activity offer a hostile environment to malarial parasite growth and thus an advantage to G6PD carriers. The invasion of malarial parasite exacerbates G6PD deficiency disease, making red blood cells highly susceptible to phagocytosis. Infected G6PD deficient red blood cells are morphologically different compared to noninfected ones and are thus hypersusceptible to phagocytosis.
- In this instance, selection working both positively and negatively clearly represents a manifestation of the balance implied by the term balanced polymorphism.
- In addition to G6PD deficiency, other examples of balanced polymorphism include heterozygotes persons with β-thalassemia and ovalocytosis, which provide some protection against malaria.

Pyruvate Kinase Enzyme Deficiency

Pyruvate kinase enzyme is responsible for the final step of glycolysis in which phosphoenolpyruvate is converted to pyruvate with the production of ATP.

- Deficiency of pyruvate kinase leads to altered membrane rigidity of red blood cells, thus preventing entry of malarial parasite.
- Moreover, pyruvate kinase deficiency significantly reduces the intracellular concentration of glucose, a vital source of energy for the intracellular life of cycles of malarial parasite.

RED BLOOD CELL-ASSOCIATED ANTIGENIC POLYMORPHISM AND RESISTANCE TO MALARIA

Duffy blood group antigens serve as receptor for *Plasmodium vivax* invasion into red blood cells, which are determined by polymorphisms of the Duffy antigen receptor for chemokines (DARC), which a chemokine receptor as well as the receptor for *Plasmodium* species. A point mutation in the Duffy gene leads to lack of expression of the encoded receptor and thus negates attachment of *Plasmodium vivax* infection on the surface of red blood cells and thus provides protection against **malaria**.

CYSTIC FIBROSIS AND RESISTANCE TO CHOLERA

Cystic fibrosis is an autosomal recessive disorder caused by a mutation in the both copies of the cystic fibrosis transmembrane conductance regulator (CFTR) gene in the person resulting in defective chloride channel.

- The disorder most commonly affects Caucasian population. The body produces thick and sticky mucus that can clog the lungs, gastrointestinal tract and pancreatic duct system resulting in impaired functions.

- Heterozygous individuals with mutation if CFTR gene and less functioning chloride channels demonstrate balanced polymorphism and provide protection against the fatal diarrheal disease 'cholera'.
- Cholera is caused by toxin secreted by the bacterium *Vibrio cholerae* in the small intestine. The toxin acts through intracellular guanine nucleotide binding protein, which causes the release of cAMP, which in turn induces chloride ion movement through chloride channel into the lumen of the gastrointestinal tract leading to osmosis, loss of sodium ion and water into the lumen of gastrointestinal tract resulting in watery diarrhea.

TAY-SACHS DISEASE AND RESISTANCE TO TUBERCULOSIS

Tay-Sachs disease is an autosomal recessive disorder caused by mutation in **HEXA gene** located on chromosome 15 that codes for abnormal hexosaminidase A enzyme leading to accumulation of GM2 ganglioside in nerve cells in brain and spinal cord thus causes damage to the nerve cells resulting in deterioration of mental and physical abilities with fatal outcome by the age of four and five years.

- The disorder is more prevalent in Eastern European people of Jewish descent (Ashkenazi Jews).
- Symptoms of Tay-Sachs disease include deafness, progressive blindness, decreased muscle strength, paralysis, muscle stiffness, delayed mile stones, failure to thrive and red spots on the macula (an oval-shaped region near the center of the retina in the eyes).
- Heterozygous persons are protected against *Mycobacterium tuberculosis*, thus showing balanced polymorphism.

PHENYLKETONURIA AND LOWER RISK FOR MISCARRIAGES

Phenylketonuria (PKU) is a rare inherited inborn error of metabolism disorder that results in building of phenylalanine amino acid in the body due to non-functional hepatic enzyme, phenylalanine hydroxylase.

- Patient presents with intellectual disability, seizures, behavioral problems, mental disorders, musty smell and lighter skin.
- Researchers observed that heterozygotes women with phenylketonuria had a much lower risk of miscarriages due to protective effect of a gene against some factor causing fetal death, when compared to wild-type homozygous women.
- Phenylketonuria is an example of balanced polymorphism. Researchers also suggested that decrease in fetal mortality is mediated by the higher concentration of phenylalanine in the heterozygous pregnant women's blood.
- Phenylketonuria is most prevalent in Scotland, where the consistent damp climate promotes growth of *Aspergillus* species on grains and beans.
- *Aspergillus* species produce mycotoxin known as ochratoxin A, which is nephrotoxic, hepatotoxic and teratogenic.
- In pregnant women, ochratoxin A can cross placenta and cause spontaneous miscarriages. The ochratoxin A being an N-acetyl derivative of phenylalanine is a competitive inhibitor of phenylalanine. Inhibition of phenylalanine hydroxylase and other enzymes that use phenylalanine as a substrate is based on this structural homology.
- High frequency of the phenylketonuria gene present in women may help to protect against sudden miscarriages, thus ensuring normal pregnancy.

NIEMANN-PICK TYPE C DISEASE AND RESISTANCE TO FLAVIVIRUSES SUCH AS EBOLA AND MARBURG VIRUSES

Niemann-Pick type C (NPC) disease is an autosomal recessive lipid storage disorder caused by mutations in NPC1 gene in 95% of cases and NPC2 gene in 5% of cases.

- The disorder is characterized by accumulation of cholesterol within lysosomes due to shortage of NPC1 protein that normally transports cholesterol out of the lysosomes.
- Patients with classic childhood onset—Niemann-Pick type C usually appears normal in first two years of life and later presents with gradual-onset of neurologic symptoms such as ataxia, seizures, myoclonic jerks and loss of previously learned speech. Niemann-Pick type C demonstrates resistance to flaviviruses such as Ebola virus and Marburg virus.

MYASTHENIA GRAVIS AND RESISTANCE TO RABIES VIRUS

Myasthenia gravis is a neuromuscular autoimmune disorder that involves the destruction of acetylcholine receptors by autoantibodies, and inhibit neuronal transmission at the neuromuscular junction by accelerated degradation of acetylcholine receptors, blocking acetyl-binding sites, and degradation and simplification of synaptic folds.

- Loss of acetylcholine receptors at neuromuscular junction leads to pronounced muscle weakness and fatigue involving ocular muscles or multiple groups of muscles. Patient may present with muscles

weakness and drooping of eyes (ptosis), double vision, dysphonia, dysphagia, dysarthria, proximal limb weakness and life-threatening respiratory failure. Patients have low-risk of rabies infection.

- Rabies is a neurotropic rhabdovirus that causes viral encephalitis in warm-blooded mammals. The disease is transmitted through the bite of a rabid animal via direct contact with saliva through broken skin or mucous membranes in the eyes, nose or mouth; or nervous system tissue of an infected animal.
  - Rabies may enter the central nervous system through several routes.
  - The virus enters through the neuromuscular junctions of both the intrafusal and extrafusal muscles.
  - Virus binds to nicotinic acetylcholine receptors and gains entrance into the skeletal muscles via receptor-mediated endocytosis.
  - Following initial infection, rabies virus enters the peripheral nervous system where it undergoes replication in the dorsal root ganglion and then travels to the central nervous system through retrograde transport mechanism.
- Myasthenia gravis exerts its effects on musculature by either occupying or attacking acetylcholine receptors. It indicates that myasthenia gravis patients show diminished likelihood of rabies infection due to delay in the spread of the rabies virus in peripheral nervous system, immune clearance and additional medical intervention.
- Further research on the different mechanisms behind nicotinic acetylcholine receptors degradation in myasthenia gravis patients may offer new insights into new medications to better prevent rabies virus pathogenicity.

CONGENITAL DISORDER OF N-LINKED GLYCOSYLATION (GLYCOSIDASE 1 DEFICIENCY) AND RESISTANCE TO VIRAL INFECTIONS

Congenital disorder of N-linked glycosylation is caused by defects in the synthesis and processing of the asparagine-linked oligosaccharides of glycoproteins.

- Patient suffering from congenital disorder of N-linked glycosylation (CDG) presents with severe developmental delay, muscular hypotonia, recurrent edema, seizures, retrognathia, high arched palate and overlapping fingers.
- Congenital disorder of N-linked glycosylation has been linked to resistance to glycosylation-dependent viral infections (e.g. HIV-1, hepatitis C, dengue virus, herpes simplex 2 and influenzae) resulting from hinderane of viral entry and replication in cells.

SICKLE CELL ANEMIA AND SUSCEPTIBILITY TO PNEUMOCOCCAL INFECTIONS

While sickle cell anemia confers resistance to malaria, and also renders the patient to susceptible to invasive bacterial infections such as *Streptococcus pneumoniae*, *Haemophilus influenzae* type B and *Salmonella* non-*typhi*. In sickle cell anemia, the respiratory endothelium becomes hyperactive and overexpresses the receptor for platelet activating factor (PAF), which is a docking site for *Streptococcus pneumoniae*. Thus, overexpression of platelet-activating factor (PAF) receptor provides ample sites for the infection by bacteria.

HEMOSIDEROSIS AND SUSCEPTIBILITY TO TYPHOID FEVER

Hemosiderosis is a term used for excessive accumulation of iron such as hemosiderin in the tissues/organs. The lungs and kidneys are often sites of hemosiderosis. *Salmonella enterica* pathogen causes systemic infection designated typhoid fever.

- Hemosiderosis increases the susceptibility to Salmonella infection. The siderophore receptor protein (**SRP**) is important for the growth and survival of Salmonella. SRP is required for the activation of iron-dependent metabolic and virulence proteins as part of Salmonella physiology.
- The anti-Salmonella SRP vaccine blocks the iron transport through the SRP. The iron depletion ultimately results in the elemination of Salmonella pathogen.

POLYGENIC AND MULTIFACTORIAL DISORDERS

Polygenic disorders are more common than monogenic disorders. Polygenetic disorders are caused by abnormalities of two or more genes regulating their protein products. Environmental factors modulate polygenic disorders. Common polygenic disorders include ischemic heart disease, diabetes mellitus type 2, essential hypertension, gout, schizophrenia, bipolar disorder, hip dysplasia and neural tube defects.

DIABETES MELLITUS TYPE 2

Diabetes mellitus type 2 is a polygenic disorder, which has complex defects in both insulin secretion and its action resulting in metabolic derangements.

- The pathophysiology of diabetes mellitus type 2 is the result of a combination of polygene defects and environmental factors, characterized by

hyperglycemia as a result of peripheral insulin resistance (most common), impaired regulation of hepatic glucose production and declining β cell function, eventually leading to β cell failure in pancreas.

- Patient presents with polyuria, polydipsia, polyphagia, unexplained weight loss, sudden vision changes, tingling sensations in the hands and feet, tiredness and dry skin. Uncontrolled blood sugar in these patients leads to numerous complications such as cardiovascular disorder, neuropathy, nephropathy, retinopathy, foot damage, hearing impairment and Alzheimer disease.

ESSENTIAL HYPERTENSION

Essential hypertension is a multifactorial disease involving interactions among polygene, environmental, demographic, vascular and neuroendocrine factors. No single-genetic variant has emerged from linkage or association analyses as constantly related to blood pressure level in every sample in population. Essential hypertension can lead to morbidity and mortality. The discovery of genes, known as quantitative trait loci (QTLs), contributing to blood pressure control is considered the most direct means of achieving this objective.

NEURAL TUBE DEFECTS

Neural tube defects occur in the brain (anencephaly) or spine or spinal cord (spina bifida) in the newborns. These happen in the first month of pregnancy, often before a woman even knows that she is pregnant.

- Neural tube defects are caused by a combination of multiple genes and environmental factors such as folic acid deficiency, maternal insulin dependent diabetes mellitus and maternal use of certain anticonvulsant medications. Incidence of neural tube defects is 1 or 2 per 1000 of pregnancies.
- Ultrasonography can detect neural tube defects in fetus around 18–20 weeks pregnancy in 95% of cases.
- Patient develops paralysis, urinary and bowel control problems, blindness, deafness, intellectual disability, lack of consciousness and even fatal outcome.
- There is no permanent cure of neural tube defects. Treatment is focused to relieve pain and prevent further damage. Babies who have **spina bifida** may require **surgery** to correct the defect.

DEVELOPMENTAL DYSPLASIA OF THE HIP

Developmental dysplasia of the hip (DDH) is a disorder where the ball and socket; **joint** of the **hips** does not function properly in babies and young children. It is also called congenital dislocation of the hip.

- In a normal hip joint, the ball at the upper end of femur fits firmly into the socket, which is the part of the pelvis bone. DDH is caused by a combination of genetic, environmental and mechanical risk factors.
- Mechanical risk factors for DDH include high birth weight of the newborn, breech presentation, oligohydramnios, primiparity, intrauterine malposition, swaddling and laxity of ligaments.
- DDH is not associated with Marfan syndrome and Ehlers-Danlos syndrome, in which laxity of ligaments occur.
- Patient develops pain, unstable hip joint, limping when walking and unequal leg length.
- Mild DDH is managed by conservative treatment such as relieving pain, weight loss, lifestyle modification, joint injections and physiotherapy. Developmental dysplasia of the hip can be treated by periacetabular osteotomy procedure, that involves a series of cuts to the bone to reorient the acetabulum over the femoral head in order to restore a more normal anatomy.

GENETIC POLYMORPHISM

Genetic polymorphism is a difference in DNA sequence among persons, groups, or populations. Example of genetic polymorphism is blood groups. It is amazing to know that around 99.99% of the individual's genome among individuals are alike, and only 0.1% of genome differs in chromosomes.

- Genetic and environmental factors make human phenotype variations. When the genome DNA sequences on equivalent chromosomes of any two individuals are compared, there is substantial variation in the sequence at many points throughout the genome.
- Presently, the geneticists use the term 'genetic polymorphism' to describe functionally silent differences in DNA sequences that make each human genome unique among persons.
- In order to understand the phenomenon of genetic polymorphism, an emphasis has been done on the structures and functions of nucleotides, genes and nucleic acids including their relationship with polymorphism.
- **Genetic polymorphism** can be caused due to permanent transmissible change in the DNA sequence.

Table 5.60 Comparison of mutation and genetic polymorphism

Parameters	Gene Mutation	Genetic Polymorphism
Gene	Gene directly leads to disorder	Gene confers an increased risk, but does not directly cause disorder
Inheritance	Mendelian pattern of inheritance	Inheritance pattern not clear
Population affected	Rare	Common in population

Mutations can involve somatic and germline; and the length of the nucleotide sequences in genes and chromosomes.

- Genetic variation is of three types: single nucleotide polymorphism (SNP), copy number variations (CNVs) and repeat length polymorphism. Various types of genetic polymorphisms include; single nucleotide polymorphisms (SNPs), small scale insertions/deletions, polymorphic repetitive elements, microsatellite variation and haplotype. Comparison of mutation and genetic polymorphism is given in Table 5.60.

SINGLE NUCLEOTIDE POLYMORPHISM

Single nucleotide polymorphisms (SNPs) represent as variations in DNA sequences and can have a major impact on how human beings respond to the disease, pathogens, chemical agents, drugs and other therapies. Genetic polymorphism is studied by PCR-based diagnostic techniques involving DNA markers.

- Two persons possess exactly same DNA sequence in 99.99% of their DNA. Therefore, two persons vary in the remaining 01% of DNA. Single nucleotide polymorphism (SNP) is the most common type of genetic polymorphism among people.
- Each SNP represents an alteration in single DNA block called nucleotide (adenine, thymine, cytosine, or guanine) in every 1000 base pairs in the genome sequence in at least 1% of the population.
- Human genome comprises more than 6 million SNPs. Most commonly, SNP variations are found in the DNA between the genes in the regions of exons and introns. Less than 1% of SNPs occur in the coding regions. SNPs can be detected by polymerase chain reaction (PCR) and TaqMan assay protocol.

COPY NUMBER VARIATIONS

Human genome contains 5–24 million nucleotide base pair of copy number variations (CNVs), which represent large number of contiguous stretches of DNA from 1000 to millions nucleotide base pairs. About 50% persons have CNVs in the coding regions. CNVs range in size from one kilobase to several megabases that differ among individuals due to insertion, deletion, invasion, duplication or complex recombination, which are the basis of phenotype diversity. Recent evidence shows that the gene copy number can be elevated in cancer cells.

REPETITIVE DNA SEQUENCE CAUSING POLYMORPHISM

The term "repetitive DNA sequences" refers to homologous DNA fragments that are present in the genome. DNA sequences that are repeated in the genome do not code for protein. Repetitive DNA sequence can be divided into two classes: the tandem repetitive sequences (known as satellite DNA) and the interspersed repeats along the single stretch. The term satellite is used to describe DNA sequences that comprise short head-to-tail tandem repeats incorporating specific motifs. Satellite DNA is of two types: microsatellites and minisatellites. Satellite DNA types are given in Table 5.61.

Table 5.61 Satellite DNA types

Microsatellite DNA	Minisatellite DNA
Short tandem repeats that consist of 1–9 nucleotide base pairs monomer repeating sequences	Short tandem repeats that consist of 10–100 nucleotide base pairs monomer repeating sequences
Rich with adenine (A) and thymine (T) nucleotide base pairs	Rich with guanine (G) and cytosine (C) nucleotide base pairs
Also known as simple sequence repeats (SSR) or short tandem repeats (STR)	Also known as variable number tandem repeats (VNTR)

DISORDERS OF SEXUAL DIFFERENTIATION

Disorders of sexual development (DSD) occur when a baby is born with both male and female reproductive organs, atypical chromosomes or atypical anatomical appearances to their genitals.

- Presence of significant overlap in genital anatomy makes it difficult differentiate between sex of the baby. If newborn has disorders of sexual development, the sex chromosomes may still be male (XY) or female (XX). At the same time, newborn's reproductive organs and genitals may be of opposite sex.
- Physical examination provides important information about the degree of virilization of the external genitalia and the presence or absence of palpable gonads. Exact cause of disorder of sexual development is not known. In DSD, the tissue that eventually turns into testes or ovaries is present early in fetal development.
- Development of sexual organs is influenced by chromosomes, hormones and environmental factors.
  - Congenital adrenal hyperplasia due to 21-hydroxylase deficiency is the most common cause of DSD resulting in virilization of a child with 46, XX. In the past, disorders of sexual differentiation were given names such as intersex or hermaphroditism.
  - Different types of DSD in children include: 46, XX karyotype testicular disorder of sexual differentiation, female with ambiguous or male genitals (46, XX DSD), 46, XY female DSD, mixed genitals and sex organs (46, XX ovotesticular), sex chromosome DSD, and Mayer-Rokitansky-Küster-Hauser syndrome.

46, XX KARYOTYPE TESTICULAR DISORDER OF SEXUAL DEVELOPMENT

46, XX karyotype testicular disorder of sexual development (DSD) is characterized by external genitalia ranging from normal to atypical with testosterone deficiency. Incidence is 1 in 15000 of live births. The disorder is caused by translocation of a small Y chromosome fragment including SRY (sex determining region of Y chromosome) gene to X chromosome or another chromosome. In SRY gene negative cases, copy of recurrent NR5A1, copy number variations, involving regulatory genes (SOX3, SOX9) and common recurrent NR5A1 have been reported.

- **Clinical features:** SRY positive cases (80–90%) develop normal male to atypical external genitalia, undescended testes with absent Müllerian structures and infertility, and after puberty with short stature, normal pubic hair, normal penis size, small testes, gynecomastia and azoospermia-related sterility. Undescended testes and hypospadias are also reported in literature.
  - On the other hand, SRY negative newborn cases (10–20%) present with penoscrotal hypospadias and undescended testes.
  - Long-term complications due to male hypogonadism include: low libido, erectile dysfunction of penis, decreased secondary characteristics, osteopenia and depression.
- Diagnosis of 46, XX karyotype testicular disorder of sexual development (DSD) is based on clinical signs and cytogenetic or molecular testing (SNP) array confirming an XX genome. SRY gene mutation is detected by fluorescence *in situ* (FISH) or polymerase chain reaction (PCR).
- Genetic counseling is essential for the affected persons and their families. Recurrence risk depends on the type of genetic alterations found. SRY positive cases are generally not inherited. Inheritance pattern in SRY negative cases depends on the genetic cause.
- Testosterone replacement therapy is given to correct hormonal imbalance. Reduction mammoplasty may be considered in some cases. The affected persons are sterile.

46, XX KARYOTYPE FEMALE WITH NORMAL OVARIES AND UTERUS BUT MALE OR AMBIGUOUS GENITALIA

A newborn with this disorder of sexual development (DSD) has 46, XX the female chromosomes (XX karyotype) with normal ovaries and uterus, but male or ambiguous external genitalia.

- Patient has enlarged clitoris that resembles like a penis, with closed lower section of vagina.
  - Congenital adrenal hyperplasia (CAH) due to 21-hydroxylase deficiency is the most common cause of DSD resulting in virilization of a child with 46, XX.
  - Newborn with 21-hydroxylase deficiency fails to synthesize cortisol and aldosterone, hence body produces more androgens in female baby.
- Exposure to excessive androgens during fetal life results in male or ambiguous external genitalia. Newborn with 21-hydroxylase deficiency can cause life-threatening salt losing nephropathy.

46, XY DISORDER OF SEXUAL DIFFERENTIATION

A normal male has one X chromosome and one Y chromosome in each cell (XY, karyotype).

- In XY, female disorder of sexual development, some female children have similar chromosomal pattern, i.e. one X chromosome and one Y chromosome in each cell (XY, karyotype), but their external genitals may not clearly indicate male or female.
- Some male infants have underdeveloped testes or absence of testes with reduced or no sperm production; and penoscrotal hypospadias.
- Female infants have underdeveloped female reproductive system or absence of female reproductive system (uterus and fallopian tubes).
- Androgen insensitivity syndrome (AIS) is one of the causes of this disorder, in which body is not sensitive to androgens. Individuals with 46, XY DSD are treated by surgery and hormonal replacement therapy.
- These patients are at great risk of development for gonadal tumors and benefit from regular surveillance or surgery to remove abnormally developed gonads.

MIXED GENITALIA AND SEX ORGANS (46, XX OVOTESTICULAR DISORDER OF SEXUAL DIFFERENTIATION)

Synonyms of 46, XX ovotesticular disorder of sexual differentiation are true gonadal intersex or true hermaphroditism.

- Infant is born with the internal reproductive organs (gonads) of both sexes (ovaries and testes).
  - Gonads can be any combination of ovary, testes or combined ovary and testes (ovotestes).
  - The external genitalia are usually ambiguous but can range from normal male to normal female. Infant has abnormal vagina and hypoplastic uterus.
- Infant has undescended testes (cryptorchidism) and hypospadias in penis. Upon reaching puberty, feminization, breast development and menstruation may occur.
- Most affected persons are infertile but spermatogenesis or ovulation is possible. Tumors of testes or ovaries have been reported but are very rare.
- Children with this type of DSD have female chromosomal pattern (XX). Exact cause of this disorder is not known; however, some cases have been linked to genetic material normally found on the Y chromosome that is misplaced and translocated on the X chromosome or another chromosome.
- Small number of cases have genetic variations of other genes such as deletions in DMRT1 gene, mutation in SRY gene, mutation in MAP3K1 gene, mutation in NR5A1 gene, mutation in RSPO1 gene and duplication of SOX9 gene.

SEX CHROMOSOME DISORDER OF SEXUAL DIFFERENTIATION [CHILDREN MAY HAVE EITHER ONE X CHROMOSOME (X0) OR AN EXTRA CHROMOSOME (XXY)]

Some children have neither male (XY) nor female (XX) chromosomes. Instead, these children may have either one X chromosome (X0) or an extra chromosome (XXY). Reproductive organs are normally formed in these children as seen in normal individuals, which may not go through normal sexual development at puberty. Children with female sex organs may not start having menstrual periods, and may have small breasts.

MAYER-ROKITANSKY-KÜSTER-HAUSER (MRKH) SYNDROME

Müllerian agenesis, also known as Mayer-Rokitansky-Küster-Hauser syndrome or vaginal agenesis, is a congenital malformation characterized by a failure to development of Müllerian duct, resulting in absence of uterus and variable degrees of vaginal hypoplasia of its upper portion.

- However, ovaries and vulva are still present. Females still develop breasts and pubic hair at puberty. Exact cause of this disorder is not known. Females have normal XX chromosomal pattern.
- The first sign of Mayer-Rokitansky-Küster-Hauser syndrome is that a girl does not have menstrual periods. Sexual intercourse may be difficult because the vagina is shorter than normal. It is sometimes possible to obtain ova from these females to make a surrogate pregnant.

PSEUDOHERMAPHRODITE

Pseudohermaphrodite has gonads of only one sex, but the appearance of the external genitalia does not correspond to the gonads present.

MALE PSEUDOHERMAPHRODITE

Male pseudohermaphrodite is congenital disorder also known as testicular feminization syndrome, which occurs due to a congenital deficiency of the androgen receptor.

- The cause may be tissue resistance to androgens (testicular feminization), defects in testosterone synthesis, or hormones administered to the mother during pregnancy.
- Patient has cryptorchid testes, but the external genital organs appear feminine or ambiguously female, with signs of virilization. The condition has also been linked to chromosomal anomalies, such as 46, XY/45, X mosaicism.

FEMALE PSEUDOHERMAPHRODITE

In female pseudohermaphrodite, the gonads are always ovaries, but the external genitalia are not clearly female. Disorder is most often caused by increased androgenic hormones from congenital adrenal hyperplasia, an androgen-secreting adrenal or ovarian tumor in the mother, or hormones administered to the mother during pregnancy. Patient shows 46, XX genotypically normal female.

GENOME IMPRINTING DISORDERS

Each person inherits two copies of every autosomal gene, one copy of gene from mother and one copy of gene from father. Both copies of autosomal genes are functional for the majority of these genes.

- However, in a small subset, one copy of the gene is 'turned off' (silenced) through DNA methylation in a parent-of-origin dependent manner. The repressed allele is methylated, while the active allele is unmethylated.
- These genes are termed 'imprinted genes' because one copy of the gene was epigenetically marked or imprinted in either the sperm or ovum. Thus, the allelic expression of an imprinted gene depends upon whether it resided in a male or female of the previous generation. Imprinted expression can also vary between tissues, developmental stages and species.
- Genome imprinting is a normal process, when genome imprinting combined with genome mutations can result in diseases.
- Genomic imprinting disorders are a group of congenital diseases characterized by overlapping clinical features affecting growth, development and metabolism; and common molecular disturbances affecting genomic imprinted chromosomal regions and genes.
- Many of inherited diseases and human development violates Mendelian law of inheritance, this way of inheriting is studied by epigenetics. Prader-Willi syndrome and Angelman syndrome have same cytogenetic deletion (15) (q11q13) resulting in differing phenotypes in progeny depending on whether the cytogenetic deletions were transmitted by the mother or the father.

PRADER-WILLI SYNDROME

Prader-Willi syndrome (PWS) is a disorder caused by the loss of expression of the paternal active genes in a particular region of chromosome 15 between 15q11 and 15q15. Incidence is 1 in 12,000 to 15,000 per live births.

- Prader-Willi syndrome can cause a wide range of symptoms, and affect the child's physical, psychological and behavioral development.
- Patient presents with hypogonadism, hypotonia, mental retardation, short stature, small hands and feet, strabismus, behavior problems, and uncontrolled appetite leading to obesity and diabetes mellitus.
- Men who suffer from Prader-Willi syndrome may have small sex organs, deep voice and loss of facial hair. These patients are not able to have children.

ANGELMAN SYNDROME

Angelman syndrome is a genetic disorder caused due to UBE3A gene mutation located on maternal chromosome 15 or by paternal uniparental disomy.

- Uniparental disomy occurs when two copies of a chromosome or part of chromosome are inherited from one parent and nothing comes from the other parent.
- These cytogenetic changes occur as random events during the formation of sperm or ovum or in early development.
- This disorder was once known as 'happy puppet syndrome' because of the child's sunny outlook and jerky movements. Incidence is 1 in 12,000 to 20,000 per live births.
- Normally, people inherit one copy of the gene from each parent, and both copies of the gene become active in many areas of the body.
- Angelman syndrome occurs when only one copy of the UBE3A gene in certain areas of the brain. Patient presents with delayed development, intellectual disability, severe impairment of speech, inappropriate laughter, ataxia, epilepsy and small head size.

DIAGNOSTIC APPROACH OF GENETIC DISORDERS

Genetic disorders are the leading causes of morbidity and mortality in human beings. The prevalence of genetic disorders varies widely in different clusters depending on their organization, ethnic origin and socioeconomical factors.

- Genetic disorders are caused by mutations in single-gene (monogenic), polygenic (combination of genes); chromosomal (whole or part) abnormalities and multifactorial diseases.
- Genetic disorders are diagnosed by history, physical examination, pedigree construction, genetic testing such as cytogenetic testing, biochemical testing and molecular testing.
- Cytogenetic and molecular techniques are being widely used to detect alterations in genes and chromosomes. Barr bodies and Y chromatin are also analyzed.

HISTORY AND PHYSICAL EXAMINATION

Diagnostic approach of genetic disorders requires a comprehensive clinical examination composed of three major elements: (a) physical examination, (b) detailed medical family history; and (c) clinical and laboratory testing reports, if appropriate and available.

- **Physical examination:** Distinctive facial features can suggest the diagnosis of a genetic disorder. Physical examination includes measurement of head circumference, distance between the eyes and length of the arms and legs. Neurological examination and fundoscopy of eyes should be performed.
- **Personal medical history:** Detailed information about a patient's health, often going back to birth, can provide clues to a genetic diagnosis. A personal medical history includes past health problems, hospitalizations, surgeries, allergies, medications, and the results of any medical or genetic testing that has already been performed.
- **Family medical history:** Because genetic disorders often run-in families, information about the health of family members can be a critical information for diagnosing these disorders. The geneticist must ask about health conditions in a patient's parents, siblings, children, and possibly more distant relatives. This information can give clues about the diagnosis and inheritance pattern of a genetic disorder in a family.
- **Laboratory tests, including genetic testing:** Imaging studies including X-rays, computerized tomography (CT) scans and magnetic resonance imaging (MRI) are done to analyze structures inside the body. Molecular, chromosomal, and biochemical genetic testing are performed to diagnose genetic disorders. Other laboratory tests that measure the levels of certain substances in blood and urine can also help suggest a diagnosis.

PEDIGREE CONSTRUCTION

A pedigree is a diagram that shows the history of a trait as it is passed from one generation to the next. Study of pedigree construction helps in determining the mode of inheritance of genetic disorder, i.e. autosomal domonant, autosomal recessive or sex-linked. It is useful to identify carriers of genetic disorders and genetic counseling. Schematic representation of family pedigree is shown in Fig. 5.46A to C.

Pathology Pearls: Inheritance Pattern Analysis by Pedigree Construction

- **Autosomal dominant inheritance:** In autosomal dominant inheritance, one parent carries a gene and other parent is normal. Only one copy of the abnormal gene needs to be inherited resulting to expression in both homozygous or heterozygous state in 50% of cases. Children of both sex are affected.
- **Autosomal recessive inheritance:** In autosomal recessive inheritance, both the parents carrying abnormal gene are inherited for the disorder resulting to **homozygous state** affected children of both sex. In **heterozygous state**, person is a silent career.
- **X-linked recessive inheritance:** In X-linked recessive inheritance, one of the X chromosomes carrying mutant gene in female is transmitted to male resulting to hemophilia. Because affected males do not have normal X chromosome to correct the abnormality, hence, suffer from hemophilia. Heterozygous female is an asymptomatic carrier.
- **X-linked dominant inheritance:** X-linked dominant inheritance is a rare variant of X-linked inheritance. Hemizygous males as well as heterozygous females phenotypically manifest the disorder.
- **Mitochondrial inheritance:** Mitochondrial inheritance is mediated through maternal lines (cytoplasmic mitochondrial genes), as mitochondria in the embryo are derived from ovum.
  - Mitochondrial genes code for enzymes of oxidative phosphorylation. Only female parent transmits the trait to all of their children.
  - Transmission of abnormal mitochondrial genes by female parent affects enzymes of oxidative phosphorylation. If an affected male has children, his progeny is unaffected.
  - A mixture of genetically normal and abnormal mitochondria in tissues is termed '**heteroplasmy**'.

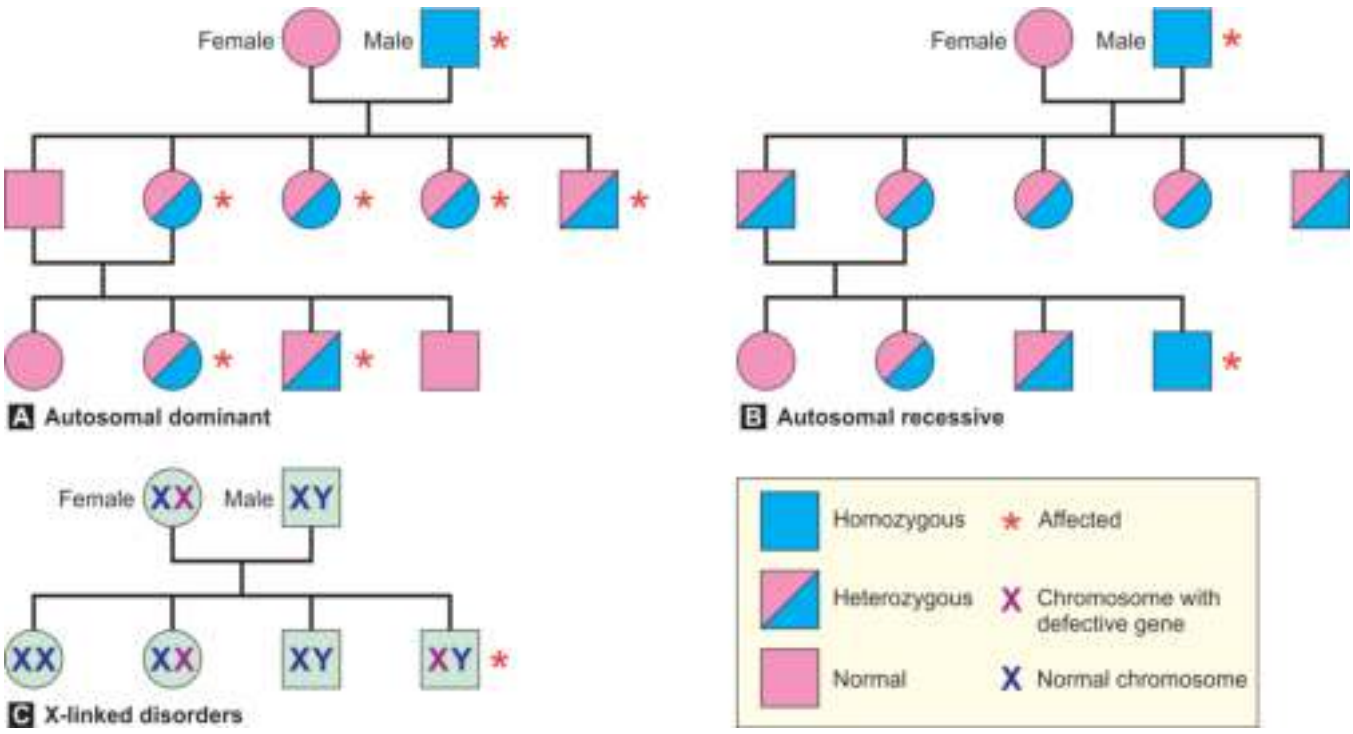

Fig. 5.46: Schematic representation of family pedigree. Family pedigrees are used to determine patterns of inheritance: (A) autosomal dominant, (B) autosomal recessive, (C) X-linked disorders and individual genotypes.

Table 5.62 Uses of genetic tests in clinical practice

Newborn screening
Carrier testing
Prenatal testing
Pre-implantation testing
Diagnostic testing
Prognostic testing
Predictive/predispositional testing

GENETIC TESTING

Genetic testing plays a vital role in determining the risk of developing certain genetic disorders as well as screening and sometimes medical treatment. Different types of genetic testing can be performed for many different purposes. Uses of genetic tests in clinical practice are given in Table 5.62.

Pathology Pearls: Genetic Testing uses

- **Prenatal testing:** Prenatal testing is performed to detect changes in a fetus's genes or chromosomes, which helps the couples to be aware of increased risk of having a baby with a genetic disorder. Down syndrome (trisomy 21) and Edward syndrome (trisomy 18) patients are often screened. A tissue sample for genetic testing can be obtained through amniocentesis or chorionic villus sampling.
- **Newborn screening:** Newborn screening is the most type common of genetic testing. Early detection of genetic disorders can lead to interventions to prevent the onset of symptoms or minimize the severity of the disorder. This type of genetic testing is important because if results show there is a genetic disorder such as congenital hypothyroidism, sickle cell disease or phenylketonuria (PKU) care and treatment can start right way.
- **Pre-implantation testing:** Pre-implantation testing is performed when attempt is made to conceive a child through *in vitro* fertilization. The embryos are screened for genetic abnormalities. Embryos without abnormalities are implanted in the uterus in hopes of achieving pregnancy.
- **Carrier genetic testing:** Carrier genetic testing can be performed in individuals, who have a history of genetic disorder and to help the couples about risk of genetic disorder passing to their children such as cystic fibrosis, sickle cell disease or Tay-Sachs disease.
- **Genetic testing of couple:** Genetic testing of couple can provide information about a couple's chance of having a child with a specific genetic disorder.
- **Diagnostic genetic testing:** Diagnostic genetic testing is performed to confirm a diagnosis in a symptomatic person such as cystic fibrosis or Huntington's disease or used to monitor prognosis of a disease or response to treatment.
- **Pharmacogenetic testing:** Pharmacogenetic testing performed to determine what medication and dosage will be most effective and beneficial for the patient.

- **Predictive or predispositional testing:** Predictive or predispositional testing can detect persons at risk of getting a disease prior to the onset of symptoms, which is useful if a person has a family history of a specific genetic disorder and an intervention is available to prevent the onset of disease or minimize severity of the disorder. Predictive testing can detect gene mutations that increase a person's risk of developing conditions with a genetic basis of certain type of cancer. Early detection of genetic disorders can lead to interventions to prevent the onset of symptoms.

TYPES OF GENETIC TESTING

Several different methods are currently performed in genetic testing laboratories. The type of genetic test depends on the type of abnormality being analyzed. In general, three major types of genetic testing are available, which include: cytogenetic (chromosomal), biochemical and molecular methods.

CYTOGENETIC TESTING

Cytogenetic testing involves the examination of chromosomes to identify structural abnormalities under microscope.

- Chromosomes of a dividing human cell can be analyzed clearly in white blood cells, specifically T cells, which are easily collected from blood. Cells from other tissues such as bone marrow, amniotic fluid, and placenta can also be cultured for cytogenetic analysis.
- Following several days of cell culture, chromosomes are fixed, spread on microscope slides, and stained. The staining methods for routine analysis allow each of the chromosomes to be individually identified.
- The distinct bands of each chromosome revealed by staining allow for analysis of the chromosomal structure.

Karyotyping

Karyotyping is a technique to examine pairing and ordering of chromosomes in genome, thus providing a genome-wide photographs of an individual chromosome. It is performed in a sample of cells such as amniotic fluid (amniocentesis), blood (lymphocytes), bone marrow biopsy and placental tissue. Schematic representation of amniocentesis is shown in Fig. 5.47.

- The sample is put into a special dish or tube and allowed to grow in the laboratory for several days. Karyotypes are prepared from mitotic cells that have

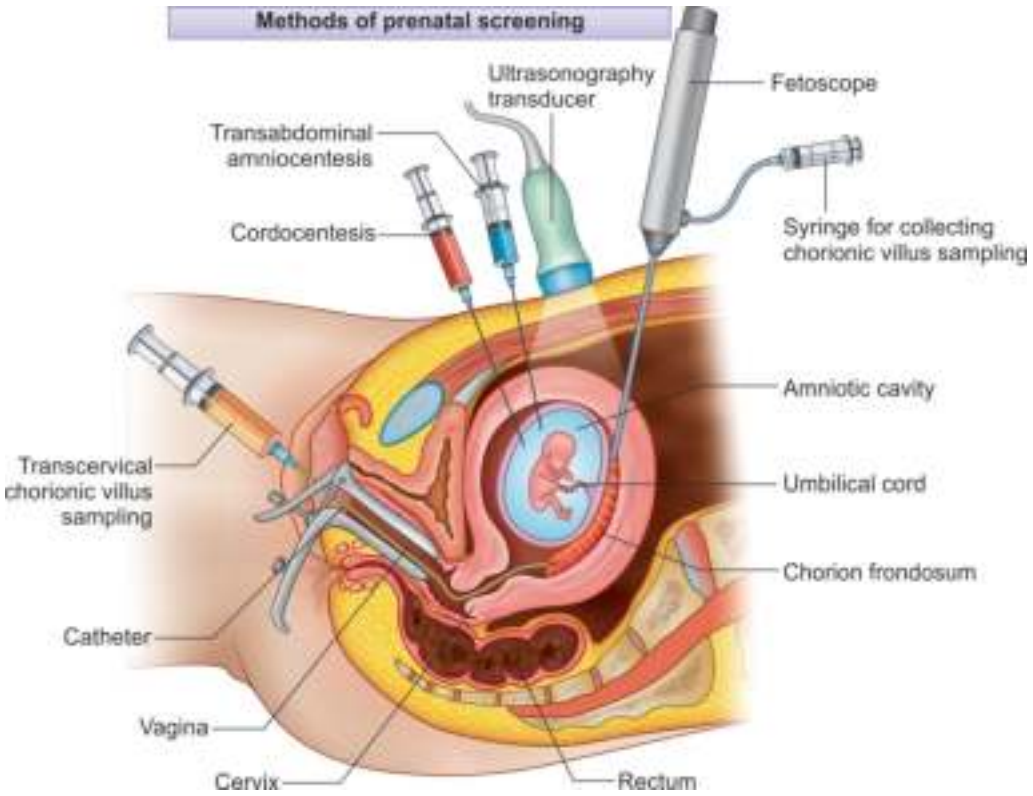

Fig. 5.47: Schematic representation of amniocentesis. In amniocentesis, a syringe is used to collect amniotic fluid. Ultrasound imaging is used to guide the tip of the syringe to prevent damage to the placenta and fetus. Fetal cells in the collected amniotic fluid can then be chemically tested or used to produce a karyotype of the developing baby.

Table 5.63 Chromosomal banding techniques

Technique	Staining Employed
G-banding technique	Giemsa stain to analyze condensed chromosome
R-banding technique	Reverse Giemsa stain after incubation in hot phosphate buffer
C-banding technique	Analysis of centromeres involves acid treatment of metaphase chromosomes, followed by incubation in alkali (e.g. barium hydroxide) and then staining with Giemsa dye
Q-banding technique	Quinacrine fluorescence stain to obtain bright and dull regions produced along the chromosome

been arrested in the metaphase or prometaphase of the cell cycle by colchicine, when chromosomes assume their most condensed conformations.

- Cells are spread on the slides, stained with Giemsa stain, examined under microscope, and photographed that reveal characteristic structural features for individual chromosome such as size, shape, number, arrangement of chromosomes and location of centromere in the cell sample.
- Chromosomes contain thousands of genes that are stored in the DNA, the basic genetic material. According to Denver classification based on the length, chromosomes are classified into seven groups: A to G. Grouping and characteristics of chromosomes are given in Table 5.63.

Pathology Pearls: Clinical Significance of Karyotyping

Karyotyping can be performed to detect for prenatal or postnatal diagnosis of many genetic disorders such as premature ovarian failure and Philadelphia chromosome in chronic myelogenous leukemia (CML).

- **Prenatal diagnosis:** Sonography, first trimester screening, quad screening, amniocentesis, chorionic villi biopsy sampling, and percutaneous umbilical cord blood sampling (PUBS) are important procedures that allow prenatal diagnosis. Karyotype analysis of chromosomes is usually performed either for prenatal congenital abnormalities.
- **Postnatal diagnosis:** In postnatal diagnosis, cells are derived from blood lymphocytes, or from biopsy of skin to obtain fibroblasts. Karyotype analysis of chromosomes is usually performed for postnatal diagnosis of pediatric disorders such as mental or growth retardation, failure of sexual development at puberty; obstetric disorders such as infertility, recurrent abortions, pregnancy in older women; and solid tumors including leukemias.

Pathology Pearls: Chromosome Banding Techniques

Chromosome banding techniques are either based on staining chromosome with a dye. The most common methods of dye-based chromosome techniques are G (Giemsa) banding, R (reverse) banding, C (centromere) banding and Q (quinacrine) banding. Chromosomal banding techniques are given in Table 5.63.

- **G (Giemsa) banding:** G-banding is a technique used in cytogenetics to produce a visible karyotype by staining condensed chromosomes and showing dark and light regions banding patterns along chromosome.
- **R (reverse) banding:** R-banding is a technique used in cytogenetics to produce the reverse of the G-band stain on chromosomes. R-(reverse) banding is obtained by incubating the slides in hot phosphate buffer, then a subsequent treatment with Giemsa stain.
- **C (centromere) banding:** C-banding (synonym: constitutive heterochromatin or centromere banding) has been used to analyze the centromeres. This technique involves acid treatment of metaphase chromosomes, followed by incubation in alkali (e.g. barium hydroxide) and then staining with Giemsa dye.
- **Q (Quinacrine) banding:** Q-banding is the first chromosome banding pattern reported. The resulting pattern is similar to the G (Giemsa) banding pattern in a way that the bright and dull regions produced along the chromosome correspond to the dark and light regions in G (Giemsa) banding patterns respectively.

Y Chromosome

Smears are prepared from oral mucosa to analyze Y chromosome. Long arm of Y chromosome exhibits intense fluorescence with quinacrine dye. Under ultraviolet light, Y chromatin appears as a bright dot. Multiple numerical aberration of sex chromosome can be demonstrated by immunofluorescence study.

Pathology Pearls: Lyon Hypothesis

- In females, during embryogenesis, inactivation of one of two X chromosomes derived from maternal or paternal is known as Lyon hypothesis.
- Inactivation of one of two X chromosomes is transmitted to all somatic cells except germ cells. Ovaries will always possess active chromosomes.
- Inactive X chromosome in the somatic cells becomes condensed in the nucleus is called nuclear sexing.

Barr Bodies (Sex Chromatin)

Barr bodies are also known as sex chromatin, which appear as clumps of chromatin in the interphase nuclei of all somatic cells in females. According to the Lyon hypothesis, each Barr body represents inactivated X chromosome.

- **One Barr body** is present in normal female cells (XX). Barr bodies are absent in males (XY). The number of Barr bodies is always one less than the number of X chromosomes.
- Barr body is absent in Turner syndrome with 45, XO karyotyping. One Barr body is present in Klinefelter syndrome with 47, XXY karyotyping.
- Triple X syndrome with 47, XXX karyotyping demonstrates two Barr bodies. Three Barr bodies are present in poly-X female with 48, XXXX karyotyping.
- Assessment of Barr bodies was considered as diagnostic tool in past. It has now been supplanted by more definitive and sophisticated analytic procedures. Smears stained by scrapping of oral mucosa or circulating neutrophils demonstrates 'Barr bodies', which appear as drumstick appendage attached to one of the nuclear lobes. A minimum of 30% cells positive for sex chromatin indicates female genetic constitution.

BIOCHEMICAL GENETIC TESTING

Biochemical genetic testing is the study of different proteins in the body that may be unusual in some way. These studies can be performed to analyze enzyme defect or mutation in gene from the samples obtained such as blood, urine, amniotic fluid, cerebrospinal fluid, or tissue.

- Normally, different types of proteins are required in biochemical reactions in the cells. Several classes of proteins such as enzymes, transporters, structural proteins, hormones and receptors perform multiple functions. Inborn errors of metabolism are inherited disorders in which the body cannot properly turn food into energy.
- Genetic disorders are usually caused by defects in specific proteins (enzymes) that participate in breakdown of food constituents. Newborn screening is done around 24–48 hours after birth.
- Since proteins are less stable than DNA and can degrade quickly, the sample must be collected, stored properly and transmitted promptly according to the laboratory's specifications. Types of protein changes resulting in altered function are given in Table 5.64.

Table 5.64 Types of protein changes resulting in altered function

No protein made
Too much or too little protein made
Misfolded protein made
Altered active site or another critical region
Incorrectly localized protein (buildpu of protein)
Incorrectly assembled protein

MOLECULAR GENETIC TESTING

Molecular genetic testing (DNA testing) is done to study single-gene or short lengths of DNA to identify variations or mutations that lead to a genetic disorder. Diagnostic molecular methods for evaluation of gene expression are given in Table 5.65.

Table 5.65 Diagnostic molecular methods for evaluation of gene expression

Method	Principle	Requirement and Comments
Immunohistochemistry	Recognizes variably molecule-specific epitopes with antibody	▪ Frozen or formalin fixed paraffin-embedded tissue section ▪ Specific monoclonal antibody
SDS-PAGE and Western blot	Sorting of proteins by molecular weight masses, electrotransfer onto membrane and probing of the membrane with antibody	▪ Fresh or frozen possibly alcohol fixed ▪ Specific antibody required ▪ Technique confirms the presence of immune-reactive protein of the expected molecular weight ▪ Tissue topography lost
mRNA *in situ* hybridization	Technique demonstrated specific transcripts on tissue sections	▪ Fresh, frozen possibly formalin fixed tissue ▪ Specific probe required
RT-PCR (reverse transcriptase-polymerase chain reaction)	Reverse transcription to cDNA, followed by PCR amplification, preferably quantitatively	▪ Fresh or frozen tissue ▪ Thermal cycler, or quantitative PCR system) light cycler/ real-time PCR ▪ No topography correlation
cDNA microarray analysis	Hybridization of tumor cDNA onto the filters or slides and simultaneously screens potentially thousands of transcripts	▪ Specially prepared filters/slides with probes, hybridization, and filter reader are required ▪ No topography correlation

- Direct DNA analysis is applicable when the gene sequence of interest is known. DNA is extracted from the cells obtained from blood, bone marrow, amniotic fluid (amniocentesis), buccal mucosa and analyzed.
- Some genetic diseases can be caused by numerous different mutations, making molecular testing challenging. For example, more than 1000 gene mutations in the cystic fibrosis conductance regulator (CFTR) gene can cause cystic fibrosis. It is not possible to examine the entire sequence of the CFTR gene routinely to identify the causative gene mutation because the CFTR gene is quite large.
- Majority of cystic fibrosis cases are caused by about 30 mutations; hence these cystic fibrosis cases are tested before more comprehensive molecular genetic testing is performed.

MOLECULAR GENETIC TESTING: METHODOLOGY

Cytogenetics is the study of structure and number of chromosomes using a microscope, whereas molecular cytogenetics is the study of chromosomes and DNA at the molecular level using DNA technology.

- As the number of genetic tests has expanded rapidly over the last decade, so have the different types of genetic testing methodologies used.
- The type of genetic test employed depends on the type of abnormality being measured. In general, three categories of genetic testing—cytogenetic, biochemical, and molecular—are available to detect abnormalities in chromosome structure, protein function, and DNA sequence, respectively.
- Direct DNA analysis is applicable when the gene sequence of interest is known. For small DNA mutations, direct DNA testing is typically the most effective method, particularly if the function of the protein is unknown and a biochemical test cannot be developed.
- A DNA test can be performed on any tissue sample and requires very small amounts of sample. Several different molecular technologies, including direct sequencing, polymerase chain reaction-based assays, and hybridization, can be used to perform testing.
- Polymerase chain reaction (**PCR**) is a common procedure used to amplify targeted segments of DNA through repeated cycles of denaturation (heat-induced separation of double-stranded DNA), annealing (binding of specific primers of the target segment to parent DNA strand), and elongation (extension of the primer sequences to form a new copy of the target sequence). The amplified product can then be further tested.
- For some genetic disorders, many different mutations can occur in the same gene and result in the disease, making molecular testing challenging. However, if the majority of cases of a particular genetic disorder are caused by a few mutations, this group of mutations is first tested before more comprehensive testing such as sequencing is performed.
- Comparative genome hybridization (**CGH**) or chromosomal microarray analysis (**CMA**) is a molecular cytogenetic method for analyzing gains or losses in DNA that are not detectable with routine chromosome analysis. The CGH method is based on the proportion of fluorescently-labeled patient DNA to normal reference DNA, which can detect small deletions and duplications, but not structural chromosomal changes such as balanced reciprocal translocations or inversions or changes in chromosomal copy number.
- DNA microarray analysis, also referred to as gene, genome, or DNA chip analysis, is a tool for determining gene expression. Molecules of mRNA bind, or hybridize, specifically to a DNA template, typically a gene or portion of a gene, from which it originated. When an array contains many DNA microarray templates, the expression level of hundreds to thousands of genes from an individual patient sample can be measured using a computer to detect the amount of mRNA bound to each site on the array.
- Protein microarray analysis is used to quantify the amount of protein present in **biological samples**. Similar to chromosome and DNA microarray analysis, the hybridization of labeled target proteins in a patient sample is measured against a reference sample. Also referred to as a biomarker, the presence, absence, increase, or decrease of a particular protein can be an indicator of disease in a person. For example, analysis of the cerebrospinal fluid of a patient for amyloid β or τ proteins may be used to diagnose Alzheimer's disease.

FLUORESCENCE *IN SITU* HYBRIDIZATION

Fluorescence *in situ* hybridization (FISH) is a molecular cytogenetic technique that uses fluorescent probes and that binds to genes on chromosomes visualized by fluorescence microscopy. FISH technique is used for rapid diagnosis of chromosomal abnormalities such as trisomies, monosomies, microdeletions, translocations.

- FISH technique is used to identify chromosomal abnormalities such as insertions, deletions (e.g. DiGeorge syndrome del22), translocations (9 and 22 in chronic myeloid leukemia) and copy number aberrations.
- The basic elements of FISH technique include a DNA probe and target sequence. Before hybridization, these DNA probes are labelled directly (right panel) or indirectly (left panel).
  - For indirect labeling, DNA probes are labeled with modified nucleotides that contain a hapten, whereas direct labeling uses nucleotides that have been modified to contain a fluorophore, which are consequently detected by fluorescent antibodies and finally visualized under the fluorescence microscope. FISH technique is faster with directly labeled probes.
  - FISH technique with indirectly labeled probe offers the advantage of signal amplification by using several antibodies, and production of a signal that is brighter compared with background levels.
- FISH technique has gained recognition worldwide as a physical mapping technique and support for large-scale mapping the chromosomes related to the human genome project. Three FISH probes are used to detect the chromosomal alterations. Refer to FISH technique in Chapter 14: Molecular Diagnostic Techniques in Clinical Practice, Section II.

COMPARATIVE GENOME HYBRIDIZATION

Comparative genome hybridization (CGH) is a special FISH technique used to detect all genome imbalances (i.e. chromosomal copy number changes bypassing cell culturing) occurring in human beings.

- Fundamental of CGH is to compare total genome DNA of the given abnormal (patient) sample and total genome DNA of the normal (person) cells sample. Both genome DNA samples of patient and normal person are labeled with two different fluorescent dyes. The final mixture is added, hybridized and observed under fluorescence microscopy and the results are compared with green to red fluorescence ratio along chromosomal axis, which represents loss or gain of genetic material in the tumor at that specific locus.
- Drawback of conventional CGH is that it cannot detect the structural chromosomal aberrations without copy number changes such as mosaicism, balanced chromosomal translocations, inversions and the ring chromosomes. CGH can only detect gains or losses relative to the ploidy level. Refer to comparative genome hybridization (CGH) in Chapter 14: Cellular–Molecular Diagnostic Techniques in Clinical Practice, Section II.

QUALITATIVE FLUORESCENCE POLYMERASE CHAIN REACTION

Qualitative fluorescence polymerase chain reaction (QF-PCR) is a rapid molecular technique for detection of the chromosome copy number by amplification of repeat sequences at chromosome-specific polymorphic loci. QF-PCR is performed to prenatal diagnosis of aneuploidy in fetus in mid-pregnancy for cost effective and rapid diagnosis.

MULTIPLEX LIGATION-DEPENDENT PROBE AMPLIFICATION

Multiplex ligation-dependent probe amplification (MLPA) method works under PCR-based technology, that utilizes up to 40–50 probes, each specific for a different DNA sequence (mainly exons of a specific gene of interest) to evaluate the relative copy number changes of each DNA sequence in a single PCR reaction.

- MLPA can also be used to analyze the subtelomeric regions of chromosomes or multiple regions of specific chromosomes to detect aneuploidy. Software programs are used for analysis.
- MLPA is performed to detect familial adenomatous polyposis, breast cancer (BRCA1 and BRCA2), ovarian cancer, Duchenne muscular dystrophy, hereditary neuropathy with liability to pressure palsies, spinal muscular atrophy and Charcot-Marie-Tooth disease.

WHOLE-EXOME SEQUENCING

Exome sequencing (synonym whole-exome sequencing, i.e. WES) is a genome technique used for sequencing all of the protein coding regions of genes in a genome (known as exome).

- The exome refers to the sequence encompassing all exons of protein coding genes in the human genome. Exome sequencing differs from whole genome sequencing. Whole genome sequencing involves sequencing all coding regions (exons), noncoding regions (intron), nuclear DNA and mitochondrial DNA.
- However, ALL protein coding genes are found in the exome. Whole exome sequencing (WES) has four basic steps: (a) library preparation, (b) cluster generation, (c) sequencing, and (d) data analysis and interpretation of the results.

BIOCHEMICAL GENETIC TESTING: METHODOLOGY

Biochemical genetic testing is the study of enzymes or proteins instead of a gene, that may be unusual in some way in the body. Many biochemical genetic diseases are known as 'inborn errors of metabolism' in children, because they are present at birth and disrupt a key metabolic pathway.

- Biochemical genetic testing measures enzyme or protein activity, level of metabolites and protein structure in samples such as blood, urine, cerebrospinal fluid and amniotic fluid. Because gene products are relatively unstable than DNA or RNA, that can degrade quickly, hence the sample must be collected, stored properly, and transported immediately according to the laboratory's specifications.
- Biochemical genetic testing can be done by various diagnostic tools such as high-performance liquid chromatography, gas chromatography/mass spectroscopy and tandem spectrometry metabolites.
- Biochemical genetic testing techniques estimate both qualitative and quantitative determination of metabolites. In addition, bioassays may employ fluorometric, radioisotopes or thin layer chromatography methods.

CHAPTER 6

Neoplasia

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

NEOPLASIA: GENERAL CONSIDERATIONS

- Human deoxyribonucleic acid (DNA) and cancer
  - Deoxyribonucleic acid (DNA) packaging
  - Gene expression: DNA replication, transcription and translation
- Four classes of normal cellular regulatory genes
  - Proto-oncogenes, oncogenes and viral oncogenes
  - Tumor suppressor genes
  - Apoptosis regulatory genes
  - DNA repair genes
- Molecular/cytogenetic alterations in human cancers
  - Genomic instability linked to human cancers
  - Epigenetic alterations
  - Cancer stem cell properties
- Histogenesis of neoplasms
  - Intraepithelial neoplasia
  - Dysplasia in mesenchymal tissues
- Kinetics of tumor growth and angiogenesis
- Tumor invasion and metastasis
- Tumor metastatic cascade

NOMENCLATURE AND CLASSIFICATION OF TUMORS

- Tumor nomenclature
  - Histogenesis of tumors
- Tumor classification hierarchy
  - Benign epithelial tumors
  - Benign mesenchymal tumors
  - Borderline tumors
  - Malignant epithelial tumors
  - Malignant mesenchymal tumors
  - Locally malignant tumors
  - Mixed benign and malignant tumors
  - Germ cell tumors
  - Primitive neuroectodermal tumors (PNETs)
  - Neuroendocrine tumors
  - Hematolymphoid malignancies
  - Miscellaneous terminology related to neoplasms

FEATURES USED TO DISTINGUISH BENIGN TUMORS FROM MALIGNANT TUMORS

- Distinguishing features of benign and malignant tumors
  - Two basic cellular components in tumors
  - Degree of differentiation in tumors
  - Nucleocytoplasmic features in tumors
  - Growth rate in tumors
  - Cellularity and cell polarity in tumors
  - Mitotic figures in tumors
  - Tumor monoclonal properties: analysis techniques
  - Telomerase activity in tumors
  - Tumor angiogenesis
  - Tumor invasion and metastasis

NORMAL PROCESSES THAT REGULATE CELLS AND INHIBIT CARCINOGENESIS

- Cell cycle and cell division
  - Cell cycle and cell division: phases
  - Cell cycle checkpoints
  - Cell cycle regulators
- DNA repair protects cellular genomes from genotoxic stresses
  - DNA repair pathways
- Telomeres and senescence
- Apoptosis inhibits tumor growth

EPIDEMIOLOGY OF CANCER

- Global impact of cancer
  - Cancer epidemiology and prevention strategies
  - Immunodeficiency states in cancer epidemiology
  - Acquired premalignant diseases
  - Interactions between genetic and environmental factors linked to inherited cancer syndromes

PREFERENTIAL ROUTES OF METASTASIS OF TUMORS

- Local invasion: first step metastasis
- Lymphatic route of metastasis
- Hematogenous route of metastasis
  - Liver metastasis
  - Pulmonary metastasis
  - Bone metastasis
  - Brain metastasis
  - Adrenal gland metastasis
- Seeding of cancer stem cells and transcoelomic route of metastasis
  - Peritoneal cavity seeding
  - Pleural cavity seeding
- Perineural and leptomeningeal routes of metastasis
- Intraepithelial route of metastasis
- Iatrogenic malignant tumor implantation during surgery

MOLECULAR BASIS OF CANCER

- Chromosomal abnormalities and dysregulation of genes: mechanisms
  - Numerical alterations in chromosomes
  - Structural alterations in chromosomes
  - Genes dysregulation and carcinogenesis
- Cellular and molecular hallmarks of cancer
  - Growth signal autonomy (unrestricted cell proliferation)
  - Insensitivity to growth inhibitory (suppressor) signals (inactivation/biallelic loss of tumor suppressor genes)
  - Evasion of apoptosis (programmed cell death)
  - Enabling replicative potential (immortality)
  - Induction and sustained tumor angiogenesis
  - Activating tissue invasion and metastasis
  - Reprogramming energy metabolism (Warburg effect)
  - Evasion of immune destruction
  - Genomic instability (mutated phenotype)
  - Tumor-promoting inflammation
  - Phenotypic plasticity and disrupted differentiation
  - Nonmutational epigenetic reprogramming in cancer stem cells
  - Polymorphic microbiomes and cancer

CARCINOGENIC AGENTS: CELLULAR INTERACTION AND CARCINOGENESIS

- Chemical carcinogenesis
  - Multistep carcinogenesis: mechanisms
  - Chemical carcinogenic agents: classification
- Radiation-induced carcinogenesis
  - Ultraviolet radiation-induced carcinogenesis
  - Ionizing radiation-induced carcinogenesis

- Viral carcinogenesis
  - Oncogenic RNA viruses associated cancers
  - Oncogenic DNA viruses associated cancers
- Bacterial carcinogenesis
  - *Helicobacter pylori*-induced gastric carcinogenesis
  - *Borrelia burgdorferi*-induced breast carcinogenesis
  - *Campylobacter jejuni*-induced colorectal carcinogenesis
- Parasite-induced carcinogenesis
- Hormonal carcinogenesis
  - Role of hormones in breast carcinoma
  - Hormonal replacement therapy in pregnant women linked to clear cell carcinoma of vagina in their daughters
  - Role of hormones, obesity and leptin in endometrial carcinoma
  - Role of hormones in prostatic adenocarcinoma

ROLE OF ONCOGENES AND TUMOR SUPPRESSOR GENES IN CARCINOGENESIS

- Cell signaling
  - Growth factors
  - Cell surface receptors
  - GTP-binding proteins (G proteins)
  - Signal transduction proteins
  - Transcription factors
  - Chromatin remodeler proteins
  - Cell cycle regulatory proteins
  - Apoptosis regulatory proteins
  - DNA repair proteins maintaining genome integrity
- Proto-oncogenes, oncogenes and viral oncogenes
  - Proto-oncogenes function during physiologic and pathologic state
- Tumor suppressor genes
  - Tumor suppressor gatekeeper genes
  - Tumor suppressor caretaker genes
  - Tumor suppressor genes function as inhibitors of Wnt/β-catenin mitogenic signaling activator pathway
  - Tumor suppressor genes function to inhibit cell cycle progression
  - Tumor suppressor genes function to inhibit tumor angiogenesis
  - Tumor suppressor genes: genomic stability enabler (most important)
  - Tumor suppressor genes function DNA repair system
  - Tumor suppressor genes function by various mechanisms
- Epigenetics in cancer
- Tumor invasion and metastasis: molecular mechanisms
  - Epithelial–mesenchymal transition in development of malignant tumor and its clinical significance
  - Tumor microenvironment
  - Metastasis multi-step process

CLINICAL ONCOLOGY

- Local effects of tumors on the host
- Non-metastatic systemic effects of cancer on the host
  - Cancer-associated cachexia
  - Paraneoplastic syndromes
- Host defense against cancer
  - Cancer immunosurveillance and immunoediting
  - Cancer stem cells evasion of immune response
- Tumor markers: diagnostics in clinical practice
  - Molecular basis of tumor markers
  - Tumor markers: detection methods
  - Tumor markers: classification and uses
  - Recommendations for advising tumor marker tests
- Diagnostic approach of cancer
  - Clinical history
  - Past medical history
  - Lifestyle, social history and environmental factors
  - Systemic evaluation of the body systems
  - Blood tests
  - Urine analysis
  - Imaging techniques
  - Cytologic examination
  - Surgical pathology
- Treatment modalities for treating cancer
  - Surgical treatment
  - Radiation therapy
  - Hormonal therapy
  - Chemotherapy
  - Immunotherapy
- Prognosis of solid cancers
- Prevention modalities of cancers

MOLECULAR DIAGNOSTICS IN ONCOLOGY

- Purpose to analyze cancer biomarkers
- Specimen requirements for molecular diagnostics in cancer
- Molecular diagnostics uses in oncology
- Molecular techniques: methodologies
  - Liquid biopsy: cell-free DNA technology
  - Targeted mutation analysis methods
  - Whole genome sequencing analysis
  - Ribonucleic acid (RNA) biomarkers
  - Proteins as biomarkers
  - Chromosomes analysis (karyotyping test)

NEOPLASIA: GENERAL CONSIDERATIONS

Cancer is the most common cause of mortality across world. Knowledge of the non-neoplastic cell proliferation is helpful in understanding neoplasia. Some non-neoplastic cellular proliferations include hyperplasia (increase in number of cells in the tissue or organ), metaplasia (change from one type of differentiated tissue to another type, usually in response to an irritating stimulus), and **dysplasia** (disordered development of cells with nuclear features of malignancy, i.e. an alteration in their size, shape and organization). Anaplasia refers to lack of differentiation (almost always indicative of malignancy, that exhibits pleomorphism, numerous atypical mitoses, abnormal nuclear morphology and cellular disorganization, i.e. loss of polarity). Oncogenesis (neoplasia) is a process of development of benign or malignant tumor.

- **Neoplasia** is defined as autonomous, purposeless, excessive, progressive, and disorganized cell proliferation, and monoclonal growth with irreversible permanent genetic alteration in cells that persists in the same excessive manner after cessation of the initiating injurious stimuli, which has evoked the change (Ancient Greek, *neo*—new and *plasia*—creation). Neoplasia term can be applied to any tumor mass, benign or malignant. **Oncology** (Greek *onkos*—tumor + logia) is the study of neoplasms (tumors), including the etiology and pathogenesis.
- **Neoplasm (new growth)**, synonymous with tumor, is composed of cells that deviate from normal programme of cell division and differentiation. Depending on the biological behavior, tumors are classified as benign (slow-growing, non-invasive without metastasis), borderline low-malignant potential and malignant (rapid growth, invasive and metastasis), which may arise from epithelial tissue, mesenchymal tissue, neuroectodermal tissue, hematolymphoid tissue and germ cells.
  - The most common tumors originate from tissues of rapid turnover of cells, i.e. epithelium of mucous membranes, skin, breast and reproductive organs and hematolymphoid tissues, which are exposed to environmental mutagens. **Carcinoma** is a

malignant tumor of epithelial origin (skin, prostate, lung, colon). **Sarcoma** is a malignant tumor of mesenchymal origin (soft tissue and bone).
  - In clinical practice, some malignant tumors (e.g. basal cell carcinoma) may grow locally and invade normal tissues but never metastasize. Some malignant tumors produce distant metastases only after a very considerable time, while at the other end of spectrum, some malignant tumors metastasize very early to distant organs.
  - Familial cancer syndrome refers to an inherited susceptibility to malignancy, typically involving a mutation either in an oncogene (autosomal dominant inheritance) or tumor suppressor gene (autosomal recessive inheritance).
- Neoplasia results from mutations that '**turn on**' oncogenes and '**turn off**' tumor suppressor gene (inactivation/biallelic loss). Malignant tumors most often have both activation of oncogenes and inactivation/biallelic loss of tumor suppressor genes. Degree of vascularization is the important determinant of tumor growth potential. Cancer stem cells (CSCs) can bind to laminin and fibronectin in connective tissue, and secrete tissue degrading matrix metalloproteinases (MMPs), i.e. collagenases and proteases, and then invade surrounding tissues and disseminate to distant organ(s). Cancer stem cells may attain 'immortality' or the ability to keep dividing indefinitely.
- **Carcinogenesis** results from accumulation of complementary gene mutations in a stepwise manner overtime. During carcinogenesis, transformation of normal cell to cancer stem cell (CSC) must follow several steps involving disruption of key cellular processes: acquire self-sufficiency in growth signals, ignore growth inhibitory signals, evade apoptosis, acquire defects in DNA repair, acquire ability to undergo uncontrolled cell division (i.e. cell cycle regulation, cell cycle progression, apoptosis and senescence), clonal expansion, accumulate oncogenic mutations, promote angiogenesis for providing oxygen and blood supply to tumor, tumor heterogeneity, invade basement membrane and surrounding tissue, and metastasize to distant organ(s). Immune system fails to recognize and respond to eliminate cancer stem cells.
  - Most of malignant tumors are caused by combined interaction of genetic factors, lifestyle and environmental mutagens. Three major environmental factors, which induce tumorigenesis include chemical carcinogens, radiation and viruses. Gene mutations that contribute to the evolution of malignant phenotype are referred to driver mutations. Along with driver gene mutations, passenger mutations are present in genome of cancer stem cells, because they often occur during somatic cell division and have no functional consequences.
  - Most carcinomas are initiated by inactivation/biallelic loss of tumor suppressor genes. Malignant tumors most often have both activation of oncogenes and inactivation/biallelic loss of tumor suppressor genes. Mutation in single gene is not sufficient to cause cancer. Subsequent progression to malignant phenotype involves additional gene mutations such as gain-of-function ('dominant') mutations occur in proto-oncogenes and loss-of-function ('recessive') mutations due to inactivation/biallelic loss of tumor suppressor genes in all types of malignant tumors. The genetic alterations persist in the progeny of the initial cancer stem cell (CSC).
  - Malignant tumors occur due to uncontrolled proliferation of cancer stem cells (CSCs), which are monoclonal. For example, clonal plasma cells produce the same type of immunoglobulin including the same light chain. On contrary, inflammatory polyclonal plasma cells produce various immunoglobulins with heavy and light chains. Some of the cancer stem cells undergo further gene mutations, which are passed to their progeny, that is called '**clonal evolution**' or progression to malignant phenotype. Some of the subclones grow more rapidly and disseminate more readily to distant organ(s), while other subclones are so abnormal, that proliferation of subclones does not take place and undergo programmed cell death (apoptosis). Aneuploidy indicates irregular increase in the cellular DNA content.
- Typically, a long-time pass between the initiated event and onset of malignant disease by multistep carcinogenesis, i.e. initiation, promotion and progression. Cancer stem cells continue to grow and replicate each time undergoing successive changes and further undergo gene mutations. Eradication of the malignant tumor requires removal of the cancer stem cells, which possess protein product encoded by BMI1 gene that inhibits normally functional negative regulators of the cell cycle.
- Primary malignant tumor growth and available blood supply determine the cell cycle duration. Epithelial tissue cells have a shorter cell cycle duration than connective tissue cells, hence carcinomas derived from epithelial tissue grow more rapidly than do sarcomas derived from connective tissue. Malignant tumors require an available blood supply to provide nutrients and oxygen that promote tumor growth from

one-to-two (1–2 mm) millimeter in size to large-size malignant tumor. Cellular components of malignant tumor microenvironment secrete angiogenic factors, which stimulate tumor angiogenesis to meet the demand of the malignant tumor.

- Cancer stem cells also produce their own growth factors, which bind to numerous growth factor receptors present on the cell membranes of rapidly growing cancer stem cells. Increase in growth factor receptors, in conjunction with the changes in the cell membranes, further enhance uncontrolled proliferation of cancer stem cells.
- The immune surveillance system includes CD8+ cytotoxic T cells, natural killer cells (NK cells), and macrophages, which recognize tumor-associated neoantigens presented by major histocompatibility complex (MHC) class molecules on antigen-presenting cells (APCs). The equilibrium between signals from the tumor microenvironment and immune system shifts, which fails to eliminate cancer stem cells.
  - In this chapter, we will discuss the basic terms associated with tumors, features used to distinguish benign tumors from malignant tumors, epidemiology and etiology of tumors, effects of tumors including paraneoplastic syndromes, molecular carcinogenesis, proto-oncogenes and tumor suppressor genes, diagnostics, tumor markers and immunohistochemistry, and tumor grading and staging.

Pathology Pearls: Carcinogenic Agents Linked to Cancer

- Chemical carcinogens (asbestos, nickel, cadmium, vinyl chloride, benzene, tobacco, processed meat)
- Physical carcinogens (ultraviolet X-rays, ionizing radiation, i.e. atomic bomb explosion, and nuclear power plant accidents)
- Viral carcinogens (HPV, HBV, HCV, EBV, HTLV-1, herpesvirus 8)
- Microbial carcinogens (*Helicobacter pylori*)
- Fungus derived carcinogens (aflatoxin of *Aspergillus flavus* fungus)
- Parasitic carcinogens (*Schistosoma haematobium*, *Opisthorchis viverrini*, *Clonorchis sinensis*)
- Oncogenes (RAS, ABL, Myc, HER2/neu, cyclin D1, cyclin E, β-catenin gene mutations, chromosomal translocation, gene arrangements, nucleotide base pair aberrations, gene amplification and gene overexpression)
- Inactivation/biallelic loss of tumor suppressor genes (RB, TP53, APC, WT1, NF1, NF2, BRCA1 BRCA2 genes)
- Defective DNA repair system
- Chromosomal/genomic instability (xeroderma pigmentosum, ataxia-telangiectasia, Fanconi anemia, Bloom syndrome)

HUMAN DEOXYRIBONUCLEIC ACID (DNA) AND CANCER

Genetic changes that cause cancer can be either inherited or somatic (acquired) that arise from exposure to certain environmental mutagens (carcinogens), i.e. chemical agents, tobacco smoke, solar ultraviolet-rays, ionizing radiation and human papillomavirus (HPV). Genetic changes can also happen because of random mistakes in deoxyribonucleic acid (DNA) that occur during cell division and germline mutations. Genes are segments of DNA that carry instructions to make a specific protein or several proteins.

- At the simplest level, chromatin is a double-stranded helical structure of deoxyribonucleic acid (DNA) that winds around each other like a twisted ladder. DNA is made up of nitrogenous base pairs, and sugar phosphate backbone. Each DNA strand is made of three billion nucleotide base pairs: adenine (A), thymine (T), guanine (G) and cytosine (C).
- A linear sequence of deoxyribonucleotides is linked together by 3′–5′ phosphodiester linkages. The informational content of DNA resides in the sequence in which monomers—purines and pyrimidine deoxyribonucleotides are ordered. The polymer deoxyribonucleotides possess a polarity; one end has a 5′-hydroxyl or phosphate terminal, while other has a 3′-phosphate or hydroxyl terminal.
- Double helical deoxyribonucleic acid (DNA) molecule has two strands. Each DNA strand possesses a polarity, and antiparallel, i.e. one DNA strand runs in the 5′–3′ direction and the other DNA stand in the 3′–5′ direction. Sugar phosphate backbone joins together nucleotides in a DNA sequence. DNA nucleotide base pairs are linked by covalent bonds, formed between the deoxyribose sugar of one nucleotide base and the phosphate group of the subsequent nucleotide base. This arrangement makes and alternating chain of deoxyribose sugar and phosphate groups in the DNA polymer, a structure known as 'sugar-phosphate backbone'.
- Both strands of double helical deoxyribonucleic acid (DNA) molecule are stabilized by hydrogen bonds between nucleotide base pairs, i.e. two hydrogen bonds between adenine (A): thymine (T) nucleotide base pairs, while three hydrogen bonds between cytosine (C): guanine (G) nucleotide base pairs, and store the same biological information of DNA replication. In Watson and Crick's model, the two strands of DNA twist around each other to form a right-handed helix. The nucleotide base residues in double helix deoxyribonucleic acid (DNA) molecule form a spiral in clockwise direction.

- In double-stranded DNA molecule, genetic information is stored in the sequence of nucleotide base pairs on template DNA strand, that is copied during ribonucleic acid (RNA) synthesis. The opposite noncoding DNA strand constitutes more than 98% of DNA that lacks protein sequences.
- Major and minor grooves wind along the DNA molecule parallel to the phosphodiester backbones, in which proteins can interact with specifically exposed atoms of the nucleotide base pairs via specific hydrophobic and ionic interactions without disrupting the nucleotide base pairs of double-helical DNA molecule.
- Mitochondria have their own DNA, which is circular and does not utilize histones. Mitochondrial DNA is passed almost exclusively from the mother to offspring through the ovum. Mitochondrial DNA test talks about maternal ancestors of offspring.

DEOXYRIBONUCLEIC ACID (DNA) PACKAGING

Deoxyribonucleic acid (DNA) exists in the condensed to form chromosomes to fit into the nucleus. As DNA is replicated during S phase of the cell cycle, histone octamer core proteins are synthesized in the cytosol by ribosomes in parallel, and imported to the nucleus, where they are assembled into core particles and incorporated into the growing chromatin strand, as nucleosomes ('beads on string'). DNA methylation changes the expression of a DNA segment without changing the nucleotide base sequences. It is worth mentioning that mitochondria have their own DNA, which is circular and does not utilize histones. Human double-stranded deoxyribonucleic acid (DNA) molecule packaging is shown in Fig. 6.1.

Deoxyribonucleic Acid (DNA) Supercoiling

DNA supercoiling reduces the space and allows for much more DNA to be packaged.

- Negative supercoiling is the left-handed coiling of DNA in counterclockwise direction and also known as 'underwinding of DNA'.
- Positive supercoiling is the right-handed coiling of DNA; thus, winding occurs in the clockwise direction and also known as the 'overwinding of DNA'.
- Certain DNA topoisomerase enzymes are able to change supercoiled DNA topology to facilitate several essential functions such as DNA replication, transcription and recombination.

Histone Octamer Core Proteins

Since DNA is negatively charged in nature because of sugar phosphate backbone, it is wrapped around the positively charged histone octamer core proteins, and found in nuclei that package and order the DNA into the basic fundamental structural unit of chromatin called 'nucleosome'.

- Histone octamer core proteins contain two pairs of H2A, H2B, H3 and H4 proteins. Histone linker protein is highly basic and rich in **proline** and **lysine**. Histone linker protein H1 binds the nucleosome at the starting and ending sites of the DNA, thus locking the DNA into place and help in the formation of high order structure and thereby stabilizing the chromatin fiber. Phosphate group gives a negative charge. Lysine and arginine give histone octamers a positive charge. Histone octamer core proteins play an important role in the maintenance of gene expression.
- Recent studies revealed that deletion of the four histone octamer core proteins (e.g. H2A, H2B, H3 and H4) lack the N-terminal tail, that affect the histone–DNA interactions and decreased nucleosome stability. Histone octamer proteins work with nonhistone proteins to stabilize the structure of DNA.
- Histone octamer core proteins form nucleosomes that are basic units of chromatin. The presence of nonhistone proteins is essential for the packaging of chromatin at higher level, i.e. chromatin fibers and chromosomes essential for function of histone proteins. Histone octamer core proteins play an important role in the maintenance of gene expression. Nonhistone proteins play a key role in regulation of gene expression.
- Histone tails are flexible structures that flank both ends of the histone fold and protrude from the nucleosome. Post-translational modifications of histone tails modulate DNA accessibility within the nucleosome, which are essential for stable folding of oligonucleosome arrays into condensed chromatin fiber-to-fiber interactions, involved in higher-order chromatin architecture. Histone tails also play an important role in providing structural stability to nucleosomal core particle itself, gene transcription and expression in the nucleosome.
- Histone methylation mostly makes DNA inactive by changing the expression of DNA segment without changing the nucleotide base sequences. Histone methylation usually causes reversible transcriptional suppression, but can also cause activation on location of methyl groups. On contrary, histone acetylation relaxes DNA coiling, allowing for transcription and making DNA active.

Nucleosomes

Nucleosome is the fundamental unit of chromosome, which consists of 146 nucleotide base pairs of the DNA wrapped tightly around a positively-charged histone octamer, forming 'beads on a string' joined with linker DNA into coiled chromatin.

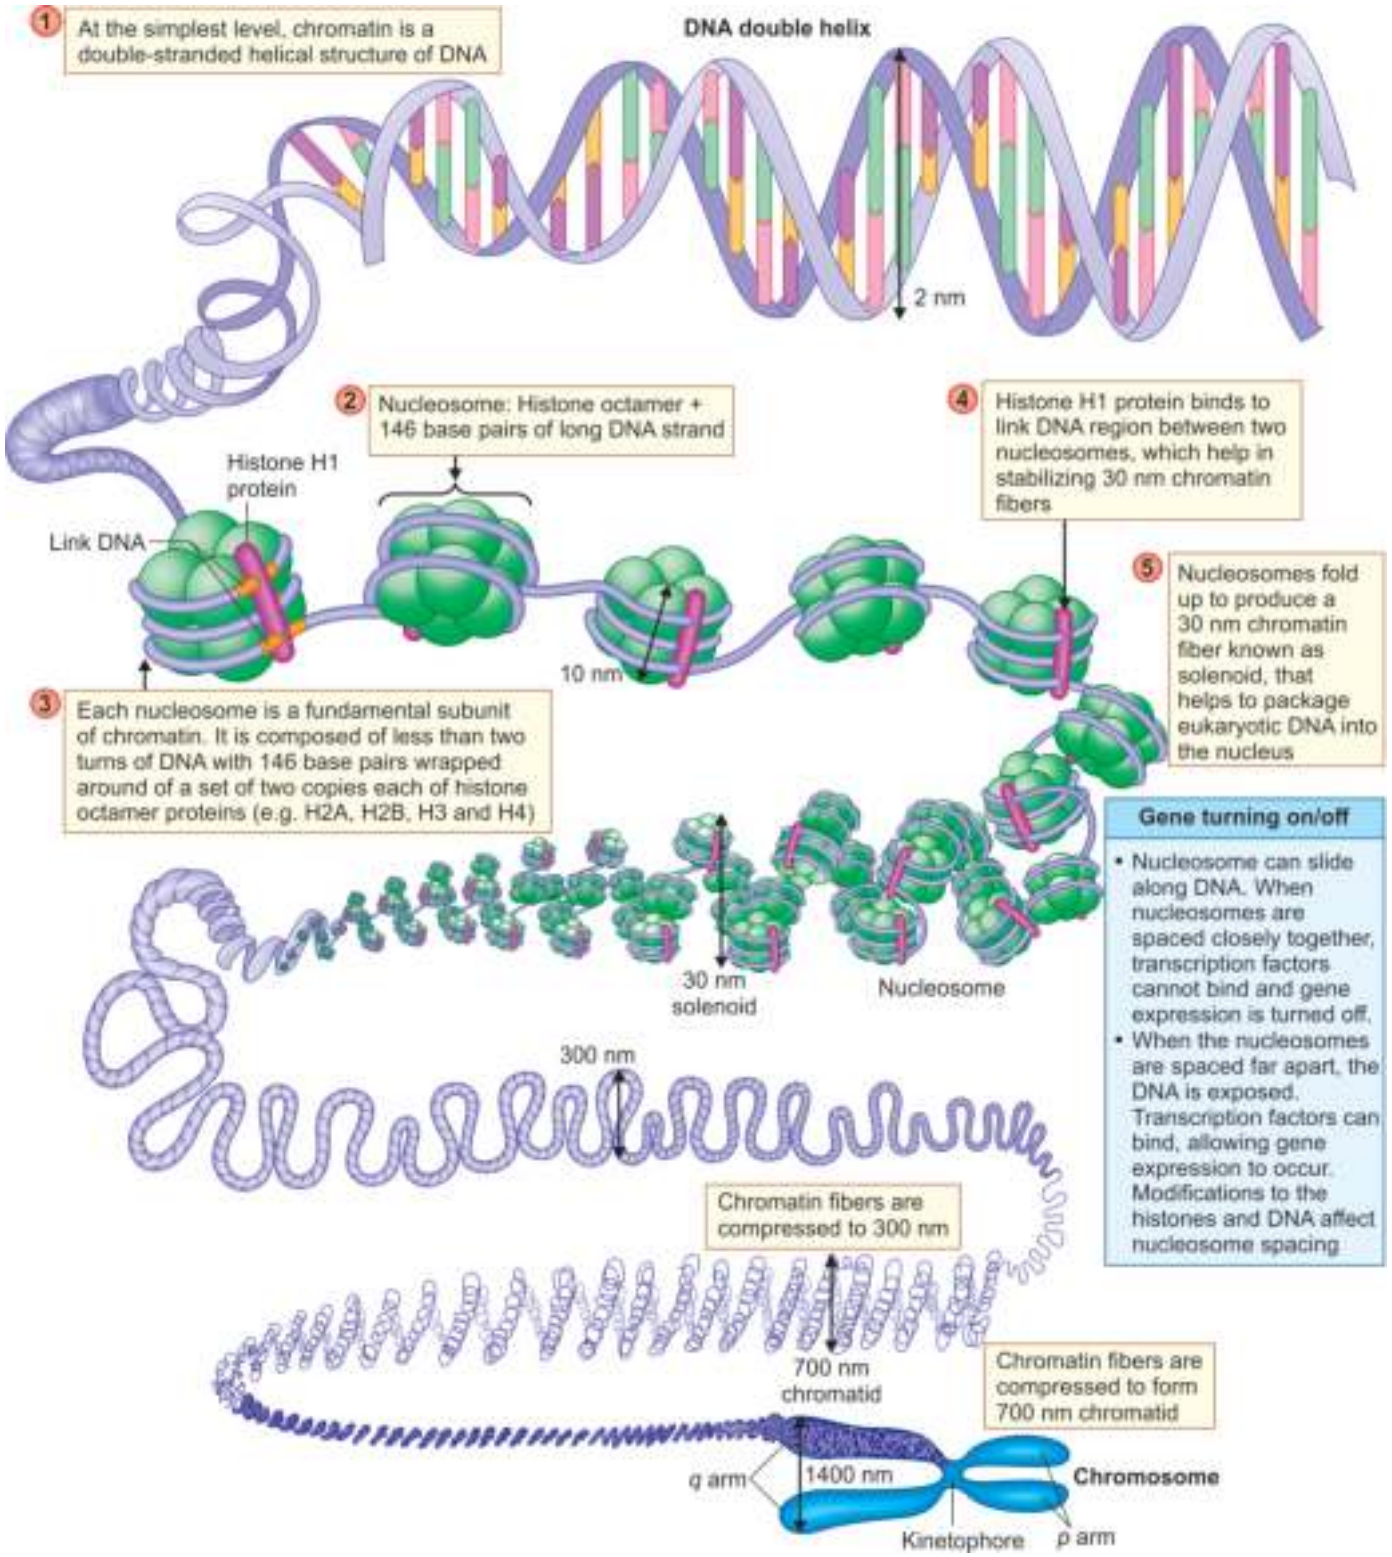

Fig. 6.1: Human double-stranded deoxyribonucleic acid (DNA) molecule packaging. DNA molecule is composed of two linear strands that run opposite to each other and twist together. DNA is wrapped around positively charged histone octamer. composed of amino acids (i.e. lysine and arginine), found in nuclei that package and order the DNA into structural units called nucleosome. The end result is compression of chromatin into chromosome. The nucleosome is fundamental unit of chromatin consists of 146 nucleotide base pairs of the DNA around a histone octamer and play a role in gene regulation. Switching gene 'turning on' or 'turning off' gene occurs due to nucleosomal spacing along DNA. Nucleosomes can slide along DNA. When nucleosomes are spaced closely together, the transcription factors cannot bind and gene expression is turned off. When the nucleosomes are widely spaced far apart, the DNA is exposed, and the transcription factors can bind, which cause allowing gene expression ('turning on') to occur. Modifications to the histones and DNA affect nucleosome spacing.

- Both histone proteins and nonhistone proteins are involved in the formation of the chromatin structure of DNA and providing structural support to the DNA. The basic difference between histone proteins and nonhistone proteins is in the structure they provide. Histone proteins become core protein molecules to form nucleosomes that are basic units of chromatin. The presence of nonhistone proteins is essential for the function of histone proteins.
- Nucleosomes play a key role in compaction of chromatin structure and gene regulation, which can slide along DNA. When nucleosomes are closely spaced together, transcription factors cannot bind and thus gene expression is 'turned off'. When the nucleosomes are spaced far apart, the DNA is exposed to transcription factors, which can bind to exposed DNA and thus gene expression is '**turned on**'. Modifications to the histone octamers and DNA affect nucleosome spacing.

Solenoid and Chromatin Condensation

Nucleosomes are packaged into a condensed thread-like chromatin fiber that helps to package eukaryotic DNA into the nucleus, sometimes described as 'beads on a string'. The end result is formation of chromatin fibers (30 nm), which are condensed into chromatid (700 nm), which is further compressed to chromosome (1400 nm), i.e. forming two strands of a replicated chromosome during mitotic cell division and visible under electron microscope. Chromatids are connected by a centromere called 'sister chromatids'. Nonhistone proteins are additional set of proteins required for packaging of chromatin at higher level, i.e. chromatin fibers and chromosomes.

Chromatin Fibers

The architecture of the chromatin dictates whether it permits or inhibits transcription and other DNA-template processes, i.e. DNA replication, DNA repair and recombination. Changes in the chromatin structure are central to transcriptional regulation. One main pathway to alter chromatin structure involves covalent modifications of the histone tails.

Chromosome

Each chromosome has two sister chromatids with two short arms (p arms), two long arms (q arms), and a centromere holding it together at the center. Human beings have 23 pairs of chromosomes (46 in total): one set comes from mother and one set comes from father. Of these 23 pairs, one pair is sex chromosomes so depending on whether one is male (XY) or female (XX). The other 22 pairs are autosomes (non-sex chromosomes), that look same for both males and females.

Deoxyribonucleic acid (DNA) making up each of our chromosomes contains thousands of genes. At the ends of each of chromosome is repetitive nucleotide TTAGG sequence of DNA containing 15000 nucleotide base pairs are called telomeres. Telomeres serve critical role of preserving genomic sequence by protecting the genome from degradation and inhibiting chromosomal fusion and recombination during DNA replication. Sister chromatids and centromere of chromosomes are also involved in chromosome organization within nucleus.

Heterochromatin and Euchromatin Regions in Chromosomes

Deoxyribonucleic acid (DNA) is tightly bound with histone octamer core proteins and condensed, that appears darker region on chromosome known as 'heterochromatin'. DNA is unfolded to form a beaded structure, that appears transcriptionally, accessible lighter region on the chromosome known as 'euchromatin'. Cell division occurs by two processes: mitosis and meiosis. The critical difference between mitosis and meiosis is that mitosis produces two genetically identical daughter cells, whereas meiosis produces four genetically different daughter cells.

Genes in Human Genome

Approximately, 20,000–25,000 genes located on 23 pairs of chromosomes are packed into the human genome. Gene is the unit of DNA made up of nitrogenous nucleotide base pairs, and sugar phosphate backbone, which carries the instructions for making specific set of protein(s). Gene expression is the process by which information from a gene is used in the synthesis of a functional gene product, i.e. protein. Gene directs the production of an average three proteins with the assistance of enzymes and messenger molecules. Structure of human gene is shown in Fig. 6.2.

- **Gene structure:** Gene contains 5'–3' untranslated regions: (a) promoter region near to gene (start site transcription), (b) enhancer region far away (enhancer site of transcription which does not specify amino acids), (c) exons (coding sequences, which specify a sequence of amino acids), (d) introns (noncoding sequences), (e) transcriptional and (f) translational start and stop codon sites. Regulatory sequences play a role in determining when and where the protein is produced.
- **Gene 'turning on' and 'turning off':** Many proteins such as transcription factors and complex of mediator proteins 'turn on' the gene and help RNA polymerase to read the gene, which creates copies called pre-messenger RNAs (**pre-mRNAs**), which transmit the instructions for building the desired protein. The pre-messenger RNAs (pre-mRNAs) get cleaned

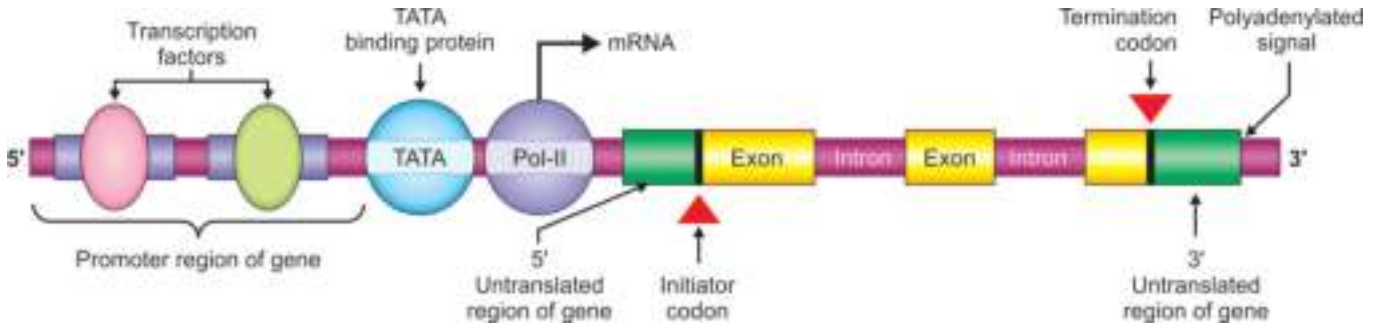

Fig. 6.2: Structure of human gene. Gene consists of 5'–3' untranslated regions, promoter, enhancer/silencer, coding sequences (exons, which specify a sequence of amino acids), noncoding sequences (introns, which do not specify amino acids) and regulatory sequences that play a role in determining when and where the protein is produced (transcriptional and translational start and stop codon sites). Transcription factors and mediator proteins complex 'turn on' the gene and help RNA polymerase to read the gene.

up a little and introns are excised, then mature mRNAs leave the nucleus via nuclear pore and enter the cytoplasm resulting in production of desired protein with the help of transfer RNAs (tRNAs) and ribosomal RNA (rRNA) unit.

GENE EXPRESSION: DNA REPLICATION, TRANSCRIPTION AND TRANSLATION

Histone octamer core proteins play an important role in the maintenance of gene expression. On contrary, nonhistone proteins play a key role in regulation of gene expression, which involves DNA replication, transcription and translation. The Central Dogma of Molecular Biology states that genetic information flows only in one direction from DNA→RNA→protein, i.e. polypeptide (chain of polypeptide). Gene expression involves three processes: DNA replication, transcription and translation. Gene expression involving DNA replication, transcription and translation is shown in Figs 6.3 and 6.4.

DNA Replication

DNA replication is the process by which the genome's double-stranded molecule of DNA is copied with its own complete identical helices of DNA in the cell before cell division through mitosis or meiosis. DNA must be replicated in order to ensure that each new daughter cell receives the correct number of chromosomes. Enzymes that participate in DNA replication process include DNA helicase, DNA primase, DNA polymerases, topoisomerase (DNA gyrase), exonuclease and DNA ligase.

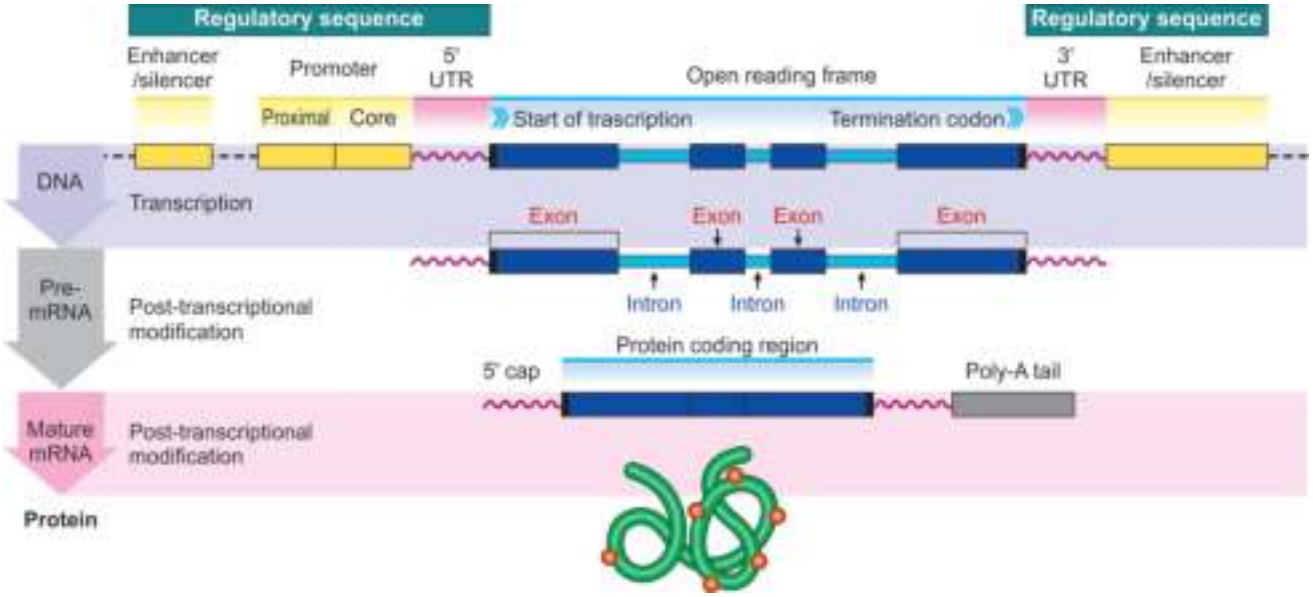

Fig. 6.3: Gene expression involving DNA replication, transcription and translation. Genetic information is transcribed from DNA into primary RNA transcript (pe-messenger RNA) that becomes a messenger RNA (mRNA) after processing, that can be translated into the proteins, noncoding regions (introns) must be removed and protein-coding regions (exons) joined by RNA splicing to produce mature messenger RNA products (mRNA, tRNA and rRNA).

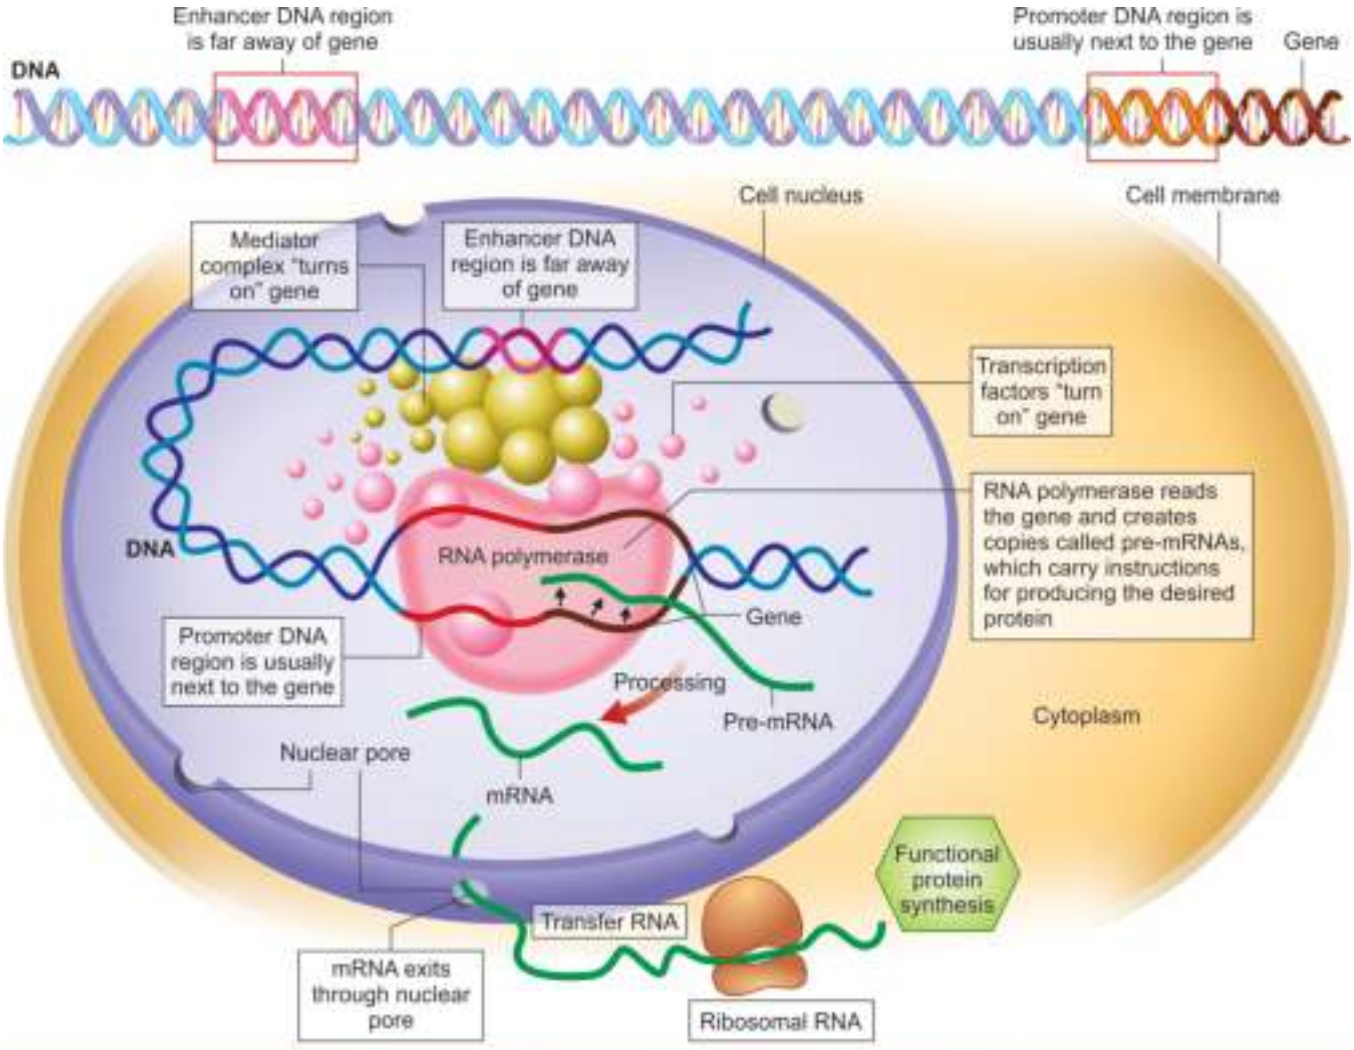

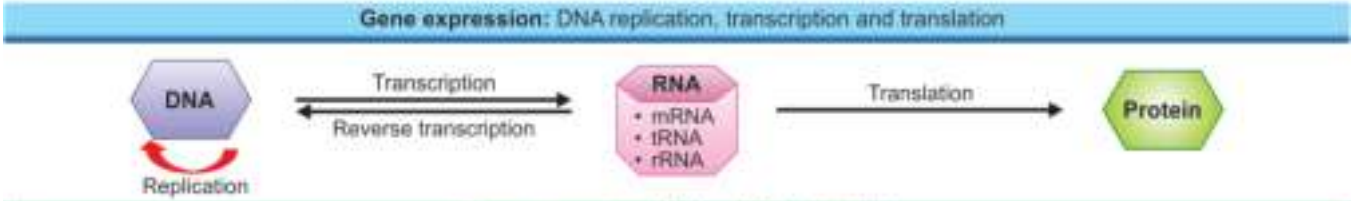

Gene expression (DNA→RNA→Protein)	
• DNA replication	DNA→DNA copy occurs in nucleus.
• Transcription	DNA→mRNA occurs in nucleus, then mRNA moves on to ribosomes into the cytoplasm for translation.
• Translation	Protein synthesis occurs in cytoplasm (mRNA transcript is decoded into protein with the help of a ribosome and tRNA).
Human genome contains around 30,000 genes, each gene codes for one protein.	

Fig. 6.4: Gene expression involving DNA replication, transcription and translation. Gene expression is the process by which information from a gene is used in the synthesis of a functional gene product such as protein. Transcription is the process of making messenger RNA (mRNA) from a DNA template by RNA polymerase. Transcription factor is a protein that binds to DNA and regulates gene expression by promoting or suppressing transcription. Transcription factor and mediator proteins complex 'turn on' the gene and help RNA polymerase to read the gene.

Transcription

Transcription is the process of making messenger RNA (mRNA) from a deoxyribonucleic acid (DNA) template strand by RNA polymerase. Transcription process yields a primary RNA transcript that gets a cap added to the 5′ end and undergoes polyadenylation and splicing to produce messenger RNA (mRNA).

- Transcription factor is a protein that binds to DNA and regulates gene expression by promoting or suppressing transcription. Transcription factor and

mediator proteins complex 'turn on gene' and help RNA polymerase to read the gene.

- Transcription is regulated by controlling the rate of gene expression by helping or hindering RNA polymerase binding to DNA. Increase in the rate of gene expression is termed upregulation, activation or promotion. Decrease in rate of gene expression is termed downregulation, repression or suppression. Coactivator is a protein that works with transcription factors to increase the rate of gene expression. Corepressor is protein that works with transcription factors to decrease the rate of gene expression.

Translation

Following transport of mRNA to the cytoplasm, mature messenger RNA (mRNA) is translated in the cytosol to specific amino acid sequence of polypeptide molecule onto ribosome. Each set of three nucleotide base pairs is translated into specific sequence of single amino acid in a polypeptide chain. Like DNA transcription, translation has three stages: initiation, elongation and termination.

- **Primary RNA transcript splicing and messenger RNA formation:** A primary transcript is the single-stranded ribonucleic acid (RNA) protein product synthesized by transcription of DNA, and processed to yield various mature RNA products such as messenger RNA (mRNA), transfer RNA (tRNAs) and ribosomal RNA (rRNA).
- **Protein synthesis:** Specifically, messenger RNA (mRNA) copies the information in a gene in DNA. The messenger RNA (mRNA) moves out of the cell nucleus and into the ribosomal machinery called ribosome located in cell's cytoplasm, and the information is used to link together small molecules called amino acids in the right order to make a specific protein (e.g. immunoglobulins, enzymes, messenger proteins, structural component proteins and transport/storage proteins). Depending on their size and the sequence of amino acids, proteins can fold or coil into certain shapes, which then perform nearly all cellular functions.

FOUR CLASSES OF NORMAL CELLULAR REGULATORY GENES

Four classes of normal cellular regulatory genes include growth-promoting proto-oncogenes, growth-inhibiting tumor suppressor genes, genes involved in programmed cell death (apoptosis) and DNA repair genes, which are the principal targets of mutations causing malignant phenotype. Broad categories of genes are given in Table 6.1. Molecular carcinogenesis is shown in Fig. 6.5.

Table 6.1 Broad categories of genes

Proto-oncogenes

- HER2/neu (ERBB2) proto-oncogene
- RAS family proto-oncogenes
- Myc proto-oncogene
- SRC family of receptor tyrosine kinase proto-oncogenes
- hTERT gene (encodes telomerase reverse transcriptase)
- BCL-2 (B cell lymphoma) proto-oncogene
- EGFR proto-oncogene
- CCND1 proto-oncogene (encodes cyclin D protein)

Tumor Suppressor Genes

- Tumor suppressor caretaker genes
  - BRCA1 and BRCA2 genes
  - DNA mismatch repair genes (MLH1, MSH2, MSH3, MSH6, PMS1, PMS2)
  - Fanconi anemia DNA repair genes (FANCA, FANCB, FANCC, FANCD-1, FANCD-2, FANCE, FANCF, and FANCG)
  - DNA nucleotide excision repair genes (XPA, XPB, XPC, XPD, XPE, XPF, XPG, and XPV)
- Tumor suppressor gatekeeper genes
  - TP53, RB1, APC, BRCA, and APC/β-catenin genes
- Tumor suppressor genes function to inhibit Wnt/β-catenin mitogenic signaling activator pathway
  - APC, NF1, NF2, PTCH, SMAD2, SMAD4, and PTEN genes
- Tumor suppressor genes function to inhibit cell cycle progression
  - CDKN2A, and RB genes
- Tumor suppressor genes function to inhibit angiogenesis
  - vHL (von Hippel-Lindau), SDHA, SDHB, SDHC, SDHD, and STK11 genes
- Tumor suppressor gene functions as genomic stability enabler (most important)
  - TP53 gene
- Tumor suppressor genes function by various mechanisms
  - WT1, MEN1/SMAD4/DPC4, ATM, CHEK2, TGF-β, and p16 genes

DNA repair genes function to repair damaged DNA

- DNA mismatch repair genes (MLH1, MSH2, MSH3, MSH6, PMS1, and PMS2)
- Fanconi anemia DNA repair gene (FANCA, FANCB, FANCC, FANCD-1, FANCD-2, FANCE, FANCF, and FANCG)
- DNA nucleotide excision repair genes (XPA, XPB, XPC, XPD, XPE, XPF, XPG, and XPV)

Apoptosis regulatory genes function to inhibit cell cycle and promote apoptosis

- TP53, BAX, and c-Myc pro-apoptotic genes
- BCL-2 anti-apoptotic gene

- **Proto-oncogenes** are normal genes coding for a number of proteins, which stimulate cell division during G0 to G1 phase of cell cycle. Tumor suppressor genes are normal genes, which inhibit cell division during G1 phase of cell cycle. Apoptosis regulatory

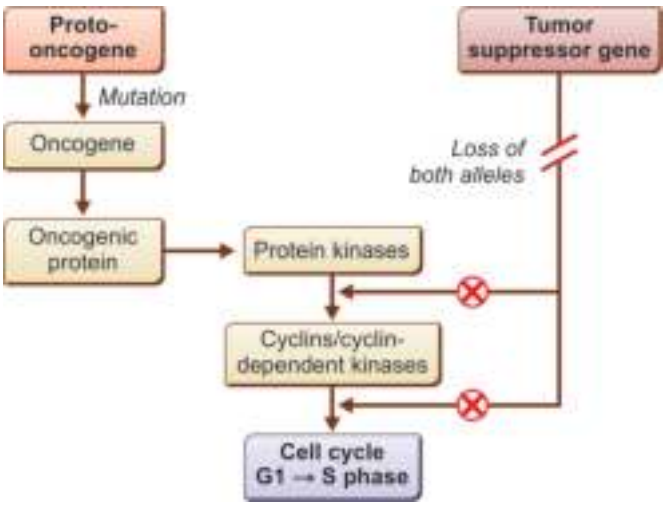

Fig. 6.5: Molecular carcinogenesis. Neoplasia can either results from mutations that 'turn on' the oncogenes or both alleles loss of tumor suppressor gene. Gain-of-function ('dominant') mutations occur in proto-oncogenes, which become activated and called oncogenes. Loss-of-function ('recessive') mutations in tumor suppressor gene leads to inactivation, or both alleles loss resulting in loss-of-function of the decoded protein.

genes eliminate damaged cells by activation of cysteine caspases and maintain tissue homeostasis, which include TP53 tumor suppressor gene, anti-apoptotic BCL-2 gene and the pro-apoptotic gene BAX. Normal wild type TP53 gene can limit cell proliferation after DNA damage by two mechanisms: (a) arresting cell division and (b) activating apoptosis. DNA mismatch repair is regulated by DNA repair genes, which is a highly conserved biological pathway that plays a key role in maintaining genome stability.

- Normal controls are defective in cancer stem cells, so that the balance between factors stimulating and inhibiting cell growth is permanently lost resulting in uncontrolled cell division. In the cancer stem cells, proto-oncogenes are permanently mutated to become oncogenes, which cause uncontrolled cell proliferation.
- Activity of the oncogenes is complex and is activated by many ways, i.e. gene amplification (Myc gene in neuroblastoma or increased mRNA transcription due to chromosomal translocation 8 and 14 in Burkitt lymphoma). Activated oncogenes can either produce excess of proteins or abnormal functional proteins. Only one copy a given oncogene needs to be activated to cause uncontrolled cell proliferation. On contrary, when tumor suppressor gene is mutated due to inactivation/biallelic loss that results in loss or reduction in its function, thus normal cell can progress to cancer stem cell (CSC), usually in combination with other genetic changes. Characteristics of oncogenes (mutated form of proto-oncogenes) and tumor suppressor gene mutation are given in Table 6.2.

PROTO-ONCOGENES, ONCOGENES AND VIRAL ONCOGENES

Proto-oncogenes

Proto-oncogenes are normal growth-promoting genes. Each proto-oncogene encodes specific growth factor, growth factor receptor and intracellular regulatory proteins responsible for providing positive signals leading to cell growth, cell division, apoptosis and maintenance of normal cell. In general, extracellular growth factor binds to growth factor receptor, which activates intracellular downstream signal transducers. The signaling pathway initiates DNA transcription of genes involved in cell growth, which involves binding of transcription factors to DNA regulatory proteins and recruiting chromatin remodelers to carry out gene transcription.

Oncogenes

Oncogenes are mutated forms of proto-oncogenes (normal cellular genes), which occur as a result of point mutation, gene amplification, balanced

Table 6.2 Characteristics of oncogenes (mutated form of proto-oncogenes) and tumor suppressor gene mutation

Characteristics	Oncogenes	Tumor Suppressor Gene Mutation
Number of gene mutation events required to contribute to tumorigenesis	One allele loss	Two alleles loss
Function of the mutant allele	Dominant (gain-of-function)	Recessive (loss-of-function)
Activity demonstrated in gene transfer assays	Yes	Yes
Associated with hereditary syndromes (inheritance of germline mutations)	Seldom (c-RET proto-oncogene)	Often
Somatic gene mutations contribute to cancer development	Yes	Yes
Tissue specificity of mutational event	Somatic mutation in specific tissue cell	In inherited cases, there is often a tissue preference

chromosome translocation (without genetic loss), deletion, overexpression, chromosomal rearrangement and insertional mutagenesis. Balanced chromosome translocations contribute to molecular carcinogenesis due to overexpression of oncogenes or generation of novel fusion-proteins with altered functions and generally involved in promoting unrestricted cell growth and cell division.

- Oncoproteins are the products of oncogenes, which are formed when a gene is transcribed and translated to RNA and manufacturing the proteins. Oncogene gets permanently 'turned on', which is known as 'gain-of-function', i.e. dominant gene mutation. This means that only one copy of proto-oncogene needs to be mutated in order to induce carcinogenesis. In general, most soft tissue sarcomas and blood cancers are initiated by activation of an oncogene.
- Genomic sequencing has demonstrated numerous small deletions and insertions, as well as chromothripsis (chromosomal shattering), in which a chromosome is shattered and then reassembled in a disorganized way.

Viral Oncogenes

Viral oncogenes are responsible for oncogenesis resulting from persistent virus infection when integrated into host genome. Virus-encoded oncoproteins that activate growth factor receptors can also induce human cancers.

TUMOR SUPPRESSOR GENES

A tumor suppressor gene encodes gene product involved in cell cycle arrest and prevents carcinogenesis. Tumor suppressor genes regulate diverse cellular processes, i.e. cell cycle checkpoint responses, detection and repair of DNA damage, protein ubiquitination and degradation, mitogenic signaling, cell specification, cell differentiation and migration and tumor angiogenesis.

- Caretaker tumor suppressor genes encode proteins that engage in maintaining the genome stability and DNA repair thus prevent cancer. Examples of caretaker tumor suppressor genes are BRCA1, BRCA2, DNA mismatch repair (MLH1, MSH2, MSH3, MSH6, PMS1, PMS2), Fanconi anemia DNA repair, and DNA nucleotide base pairs excision repair genes. In contrast, gatekeeper tumor suppressor genes regulate cell cycle.
- Gatekeeper tumor suppressor genes encode proteins, which either stimulate cell proliferation and differentiation or apoptosis. Loss-of-function of gatekeeper tumor suppressor genes allows enhanced cell proliferation and transmission of mutated genes. Mutation in tumor suppressor genes results in loss-of-function (recessive gene mutation). Examples of gatekeeper tumor suppressor gene include TP53, RB1, APC, BRCA, APC/β-catenin genes. TP53 gene has been called the 'guardian of genome'. TP53 gene mutations have been demonstrated in many human cancers. Germline mutation of TP53 gene is a feature of Li-Fraumeni syndrome. Dysregulation of tumor suppressor genes is linked to carcinogenesis.
- Mitogenic signaling tumor suppressor genes encode protein, that engage in inhibition of mitogenic signaling. Examples of mitogenic signaling inhibitor genes include APC, NF1, NF2, PTCH, SMAD2, SMAD4, and PTEN. Mitogenic signaling normally activates RAS, GTPase, that then activates the rest of the MAPK signaling pathways, ultimately expressing proteins that stimulate cell cycle progression. It is likely that most cancers have some mutation in the RAS/RAF/mitogen-activated protein kinase (MAPK) signaling pathway most commonly in RAS.
- Cell cycle progression tumor suppressor genes encode proteins that inhibit cell cycle progression. Examples of cell cycle progression tumor suppressor genes include CDKN2A and RB.
- Tumor angiogenesis and tumor suppressor genes encode proteins that inhibit tumor angiogenesis. Examples of tumor angiogenesis and tumor suppressor genes include vHL (von Hippel-Lindau), SDHA, SDHB, SDHC, SDHD, and STK11. Tumor angiogenesis is the formation of new blood vessels that tumors need to grow. Angiogenesis is caused by the release of angiogenic factors by the tumor and host cells near tumor microenvironment.
- Genomic stability enabler TP53 tumor suppressor gene encodes p53 protein, that acts as guardian of the genome. TP53 gene is the most frequently mutated in >50% of human cancers.
- Tumor suppressor genes function by various mechanisms include WT1, MEN1, SMAD4/DPC4, ATM, CHEK2, TGF-β, and p16.

Pathology Pearls: Li-Fraumeni Syndrome (TP53 Gene Mutation) Linked to Human Cancers

- TP53 tumor suppressor gene mapped on chromosome 17 is the guardian of the genome, which normally serves to arrest the cell cycle and induce apoptosis under condition of DNA damage. When TP53 gene undergoes mutation, apoptosis function is lost and cells with DNA damage will continue to divide and proliferate, possibly acquiring mutations which confer malignant behavior.
- Germline mutation in TP53 gene (aberrant p53) in Li-Fraumeni syndrome is linked to many cancers (i.e. breast carcinoma, osteosarcoma, soft tissue sarcomas, brain tumors, acute leukemia and adrenocortical carcinoma) including cancers of gastrointestinal tract, lung, kidney, thyroid gland, skin, ovary,

testes and prostate. It is important to note that not every person with mutation in TP53 gene will necessarily develop cancer, but the risks are substantially higher than the general population.

- Li-Fraumeni syndrome involves TP53 tumor suppressor gene, with the 'Knudson' two-hit hypothesis. A person inherits mutated one allele of TP53 gene (**first hit**), but still has another functional allele of TP53 gene. Loss of both alleles of TP53 gene (second hit) leads to cell growth control loss, allowing clonal expansion of neoplastic cell.
- Familial cancers often involve more than one organ in patients with Li-Fraumeni syndrome, which include breast carcinoma, osteosarcoma and soft tissue sarcomas. Female at birth, who has Li-Fraumeni syndrome has 100% chance of developing breast cancer.
- Affected persons with germline mutation in TP53 tumor suppressor gene can develop cancers in multiple organs. However, it must be noted that TP53 gene mutations are most commonly observed in sporadic cancers. A primary sporadic cancer may be treated by surgery, radiation and chemotherapy.
- Diagnosis of Li-Fraumeni syndrome depends on clinical manifestations and/or genetic testing for mutation in the TP53 gene. Molecular genetic testing is performed for early detection of cancer in these patients.

APOPTOSIS REGULATORY GENES

Apoptosis regulatory genes are involved in extrinsic death receptor pathway and intrinsic mitochondrial pathway. Apoptosis is programed cell death mechanism characterized by nuclear condensation, cell shrinkage, membrane blebbing, DNA fragmentation, formation and phagocytosis of apoptotic bodies. Caspases, a family of cysteine proteases, are the central regulators of apoptosis. For example, BCL-2 oncogene produces aberrant protein associated with the cell membrane that prevents programed cell death (apoptosis). Oncogenes may also synthesize oncoproteins that reduce apoptosis leading to survival of the cells. Dysregulation of apoptosis regulatory genes evades apoptosis and survival of cancer stem cells leading to malignant phenotype.

DNA REPAIR GENES

During DNA repair, DNA glycosylases remove the damaged nucleotide base pairs by cutting them out of the DNA strand through the cleavage of the covalent bonds between the nucleotide base pairs and the sugar phosphate backbone. The resulting gap is then filled by a specialized DNA repair polymerase and sealed by ligase. XPA is DNA repair protein that initiates recognizing damaged DNA and forming complexes with other proteins such as XPB and XPD involved in DNA repair process. XPB and XPD proteins act as helicases that unwind the damaged DNA. Dysregulation of DNA repair genes is linked to carcinogenesis.

MOLECULAR/CYTOGENETIC ALTERATIONS IN HUMAN CANCERS

Recently, human cancers may be viewed as a genetic disease with various chromosomal and nucleotide base pair aberrations, which include chromosomal translocations, gene mutations, gene deletions, gene amplifications, gene arrangements during the transformation of a normal cell to cancer stem cell (CSC).

- Most forms of localized DNA damage occur by various mechanisms: (a) single-stranded DNA breaks, (b) double-stranded DNA breaks, (c) DNA adducts, (d) nucleotide base pair insertions and deletions, and (e) mismatch of nucleotide base pairs.
- Single-stranded DNA break is repaired by nucleotide base pair excision mechanism. Double-stranded DNA break is repaired by non-homologous end-joining (NHEJ) or homologous recombination (HR). DNA adduct is repaired by nucleotide base pair excision.
- Failure to DNA repair system results in xeroderma pigmentosum, an autosomal recessive disorder linked to skin cancers. Mismatch nucleotide base pair is repaired by insertion of correct nucleotide base pair. Failure to DNA repair is linked to development of colorectal carcinoma, pancreatic carcinoma, breast carcinoma and ovarian carcinoma.

GENOMIC INSTABILITY LINKED TO HUMAN CANCERS

Genetics is the study of heredity (biological process) whereby parents pass certain genes onto their children. Every child inherits genes from both of his/her biological parents, and in turn, child expresses specific traits.

- Genes are present within the chromosomes, which carry instructions to make proteins involved in regulation of cellular functions especially how cells grow and divide. Mutation in gene can affect how it functions. Gene mutations can be present either acquired in somatic tissues or inherited in germ cells (egg or sperm).
- Most human cancers are caused by somatic (acquired) gene mutations in 75–80% cases, because there is no identified germline gene mutation involved. On contrary, inherited cancers account for 20–25% of cancers due to germline gene mutations. Many of the targeted therapies used to treat human cancers are designated to address changes in cell growth caused by particular gene mutations.
- Carcinogenesis is an evolutionary process whereby cells accumulate numerous permanent gene mutations in the nucleotide base pair sequences. Genomic instability and high rates of gene mutation cause

malignant tumor to acquire additional numerous mutations and chromosomal alterations during its evolution, most are termed 'passenger mutations' because they do not confer malignant phenotypes. Driver gene mutations cause transformation of normal cells to cancer stem cells (CSCs) and subsequent clonal expansion and progression to malignant tumor growth.

Pathology Pearls: Terminology of Gene Alleles and Mutations

- **Driver gene mutation:** Genetic alteration in driver gene that facilitates tumorigenesis and survival.
- **Passenger gene mutation:** Genetic alteration in passenger gene that is not essential for tumorigenesis.
- **Gene mutation with gain-of-function:** Gene mutation that increases a gene aberrant product's activity or results in a new function. Dominant gene mutations act to oppose normal gene function.
- **Gene mutation with loss-of-function:** Gene mutation that decreases the gene product's function. Loss-of-function gene mutation partially disrupts normal function.
- **Haploinsufficiency:** Haploinsufficiency occurs when one functional copy (allele) of a gene is inactivated or deleted and the remaining **wild-type copy (allele)** of the gene is not sufficient to produce the needed gene product to preserve normal function.
- **Gatekeeper tumor suppressor genes:** Gatekeeper tumor suppressor genes encode protein products that restrain cell growth and their loss-of-function allows enhanced cell proliferation and transmission of gene mutations.
- **Caretaker tumor suppressor genes:** Caretaker tumor suppressor genes encode protein products that maintain genomic stability involved in deoxyribose nucleic acid (DNA) repair.
- **Landscape genes:** Landscape gene mutations encode aberrant products that contribute to the abnormal neoplastic growth of cells by fostering a microenvironment conductive to unregulated cell proliferation.
- **Gradualism:** The gradual and stepwise accumulation of tumorigenic gene mutations occur overtime.
- **Chromothripsis:** The nearby simultaneous acquisition of multiple gene mutations in a tumor via catastrophic shattering and then reassembly of chromosomes.
- **Genetic modifiers:** Genetic modifiers are defined when the effects of one gene and modified by single or multiple genes.
- **Gene interactions:** The gene interactions can be defined as genetic enhancers or suppressors, dominant/recessive (interaction between alleles of the same gene), or epistatic/hypostatic (phenotype suppression).

Somatic (Acquired) Gene Mutations Linked to Cancers

Somatic (acquired) gene mutations occur in the particular parent cells after birth and cannot be transmitted to the offspring. Such persons lack family history of cancer or inherited changes in their DNA, that would increase risk for developing that cancer. Somatic gene mutations are much more common than germline mutations.

- **Causes of somatic gene mutations:** Somatic gene mutations can be induced by environmental mutagens (chemical agents, ultraviolet radiation, ionizing radiation and biologic agents) encountered throughout life in somatic cells leading to uncontrolled cell proliferation and development of cancers (e.g. breast, ovary, lung, colon, kidney, urinary bladder and prostate gland) in 90% of cases. Intercalating agents insert into the DNA molecule and cause single-nucleotide insertions and deletions. Oxidative reactions alter the chemical structures of nucleotide base pairs. Ionizing radiation alters nucleotide base pairs and breaks phosphodiester bonds. Ultraviolet radiation induces production of pyrimidine dimers, which cause distortion in the double helix DNA molecule resulting in inhibition of DNA replication and transcription.
  - Many of the mutated genes that contribute to development of cancer fall into three broad categories: oncogenes (RAS family of genes, HER2/neu, cyclin D1, cyclin E, β-catenin), tumor suppressor genes (BRCA1, BRCA2, TP53, RB), and DNA repair genes. Mutations in the growth promoting genes have usually autosomal dominant inheritance, because a mutation in a single copy of the proto-oncogene is usually sufficient to produce stimulatory effect. Dominant acting growth promoting genes that cause cancer are termed oncogenes.
  - Targeted therapies are now available for many gene mutations found in human cancers that can control the growth of cancer at least for a period of time. Few examples of genomic changes in cancer include: (a) EGFR mutations, ALK rearrangements, ROS1 rearrangements, MET and RET mutations in lung cancer, and (b) BRAF mutations in melanoma and some lung cancers.
- **Mechanisms of somatic gene mutations:** Gene mutations most often occurs by substitutions, in which a single nucleotide base is changed into different nucleotide base. Other gene mutations result in the loss (deletion) or addition (insertion) of one/more nucleotide base pairs. Nucleotide substitutions occur by two mechanisms: transition or transversion. In transposition, a purine nucleotide is replaced with a purine nucleotide, or a pyrimidine nucleotide is replaced with a pyrimidine nucleotide of the same class. In transversion, there is change in the class of the nucleotides, i.e. a purine nucleotide is replaced with a pyrimidine nucleotide, or pyrimidine nucleotide is replaced with a purine nucleotide.

- **Consequence of somatic gene mutations:** Gene mutation results in abnormal transcribed DNA sequence (mRNA), abnormal translated proteins and lethal phenotype due to mutated RNA and protein. Mutations range in size, which can affect anywhere from a single DNA nucleotide base pair to a large segment of a chromosome that includes multiple genes. Gene mutations alter the function of essential proteins, which adversely affect the health of individuals. Gene mutations occur by various mechanisms, which include nonsense, missense, insertion, deletion, duplication, frameshift mutations and trinucleotide repeat expansion.
- **Somatic gene mutations and cancer:** Cancer is an abnormal growth of cells, which tend to proliferate in an uncontrolled manner, that can disseminate via lymphatic route to draining lymph nodes, via hematogenous route to distant organ(s) and via transcoelomic route to peritoneum. During process of carcinogenesis, pre-malignant cells accumulate genetic mutations until a fully malignant phenotype develops. Although, cancer has a genetic basis, yet it is not necessarily hereditary. Most human cancers arise from somatic gene mutations instead of inherited (germline) gene mutations. Two main groups of genes are implicated in development of cancer: activation of oncogenes and inactivation/biallelic loss of tumor suppressor genes.

Germline (Inherited) Gene Mutations Linked to Cancers

Germline gene mutations are present at birth and exist in all cells of the body. It is not certain that all cases with germline gene mutations develop cancer. Family members develop site-specific cancers in more than one site. Germline gene mutations related human cancers may have either autosomal dominant inheritance with mutation in proto-oncogenes or autosomal recessive inheritance with mutation in tumor suppressor genes. Germline gene mutations in BRCA1/BRCA2 tumor suppressor genes increase the risk of breast cancer and ovarian cancer in women. Germline mutation in TP53 gene (aberrant p53) in **Li-Fraumeni syndrome** is linked to many cancers. Screening of family members is recommended at a younger by genetic testing on blood or saliva to detect germline gene mutations. Survivors of inherited cancer syndrome have limited treatment options except follow-up care.

Familial Cancer Syndromes

Familial cancer syndromes are inherited susceptibility to malignancy, typically involving a mutation in either an oncogene (autosomal dominant) or tumor suppressor gene (autosomal recessive). Most inherited cancer syndromes follow autosomal-dominant inheritance, in which the patient's first-degree relatives (parents, children and siblings) have a 50% risk of carrying the causative gene mutation themselves. Extensive clinical history of screening of early development of cancers is required in the management of these patients developing colorectal cancer, breast carcinoma, Wilms' tumor, or renal cell carcinoma. Molecular genetic testing is done to detect inherited cancers-causing gene in cancer stem cells as well as tissues of family members.

- **Heterozygous inheritance:** In these cases, one faulty allele has to be present for an individual to have a predisposition to cancer. Individuals with one normal allele and one faulty allele are known as heterozygous inheritance. The detrimental effects of recessive cancer gene are less common within population as compared to their dominant cancer gene counterparts. Familial adenomatous polyposis coli is an example of familial cancer syndrome.
- **Homozygous inheritance:** Homozygous inheritance of these recessive cancer genes does not cause cancer directly, but rather, the loss-of-functional protein that they encode results in genomic instability, which provides an ideal environment for oncogenic mutations and predisposes the affected person to cancer.

EPIGENETIC ALTERATIONS

Epigenetic alterations are commonly demonstrated in human cancers. Epigenetic alterations are genetic modifications that impact gene activity such as 'turning on'/'turning off' without changing the nucleotide base sequences of DNA building blocks. A common type of epigenetic alteration is called DNA methylation that involves the attachment of methyl groups to DNA building blocks. When methyl groups are present on a gene, that gene is turned off or silenced, and no protein is produced from that gene.

- Another common epigenetic change is 'histone octamer modification'. Histones are structural proteins in the cell nucleus. Deoxyribonucleic acid (DNA) wraps around histones, giving chromosomes and their shape. Histones can be modified by the addition or removal of chemical methyl groups or acetyl groups, which determine how tightly DNA is wrapped around histone octamer proteins and affect whether a gene can be 'turned on' or 'turned off'.
- Errors in the epigenetic process, such as modification of the wrong gene or failure to add a chemical group to a particular gene or histone octamer proteins, can lead to altered gene activity or inactivity. Malignant tumors often have hypomethylation of the cell genome (increases gene expression and overall, for

increased metabolic activity) with hypermethylation of the cell genome (silences tumor suppressor genes that control cell growth).

CANCER STEM CELL PROPERTIES

Cancer stem cells (CSCs) are relatively/absolutely autonomous, and monoclonal in nature, which undergo uncontrolled proliferation in disorganized manner, and become unresponsive to extracellular growth factors and regulatory mechanisms operating inside normal cells/tissues.

- Cancer stem cells proliferate, invade surrounding tissues, and disseminate via lymphatic route to lymph nodes, via hematogenous route to distant organ(s), and via transcoelomic route to peritoneum. Cancer stem cells synthesize angiogenic factors, and growth factors, which promote angiogenesis and tumor growth. Cancer stem cells have ability to escape immune surveillance resulting in development of clinical cancers.
- Proprieties of transformed cancer stem cells (CSCs) include: (a) loss of cell-to-cell contact (continue to grow over one other, piling up into dense aggregates), (b) altered cell morphology (rounded shape, refractile in phase contrast microscope), (c) reduced requirement for mitogenic growth factors by cancer stem cells, (d) increased transport of glucose in the CSCs, and (e) inability to halt cell proliferative response to deprivation of growth factors. Transformation of normal cell to cancer stem cell is associated with genetic instability, immortalization, aberrant growth control and tumorigenicity. General characteristics of transformed cancer stem cells are given in Table 6.3.

Pathology Pearls: Anchor-independent Cancer Stem Cell Growth on Culture Dish

- Each of cancer stem cell large colonies may contain several hundred cells in anchor-independent growth.
- Ability to grow without attachment to solid substrate (anchorage independence) is analyzed by suspending cells in semi-solid medium such as agarose or methylcellulose, to prevent their attachment to a solid substrate, specifically, the bottom of the Petri dish.
- The ability of cancer stem cells to proliferate while held in suspension, the phenotype of anchor independence is usually a good predictor of their ability to form tumors *in vivo*.

Table 6.3 General characteristics of transformed cancer stem cells

Genetic Characteristics
▪ Aneuploidy (abnormal number of chromosomes) ▪ Heteroploidy ▪ Increased spontaneous gene mutation ▪ Mutated proto-oncogenes (i.e. oncogenes get 'turned on' hence autosomal dominant inheritance) ▪ Inactivation or deletion of both copies of tumor suppressor genes (which get 'turned off', hence results in autosomal recessive inheritance disorder)
Structural Changes
▪ Cytoskeleton protein alterations in cancer stem cells ▪ Extracellular matrix (ECM) alterations ▪ Cell adhesion molecules (CAMs) alterations ▪ Cancer stem cell polarity disruption
Growth Characteristics
▪ Ability of cancer stem cells to proliferate indefinitely (cell immortalization) ▪ Loss of contact inhibition among cancer stem cells (ability to grow over another) ▪ Ability of cancer stem cells to grow without attachment to solid substrate (anchorage independence growth—good predictor of their ability to form tumors *in vivo*) ▪ Density limitation of growth reduction ▪ Reduced requirement of mitogenic growth factors of cancer stem cells (growth factor-independent) ▪ Shortening of doubling time of cancer stem cells population ▪ Increased transport of glucose in cancer stem cells ▪ High saturation of density (ability to accumulate large number of cancer stem cells in culture dish)
Neoplastic Characteristics
▪ Tumorigenesis ▪ Tumor angiogenesis ▪ Increased protease secretion by cancer stem cells, and causing degradation of extracellular matrix (ECM) ▪ Invasion of cancer stem cells in the surrounding tissue ▪ Metastasis of cancer stem cells to distant organ(s)

HISTOGENESIS OF NEOPLASMS

Histogenesis is a method of classifying neoplasms on the basis of the tissue cell of origin. Most human organs (except for nervous system) are composed of epithelial or connective tissue cells or both. Benign tumors refer to those tumors incapable of metastasis associated with good prognosis. Borderline tumors of low-malignant potential lack stromal invasion. Malignant tumors are capable of invasion and/or metastasis, often fatal if not treated effectively. Metastasis refers to spread of a malignant tumor from one site to another site via lymphatic, hematogenous and transcoelomic routes.

INTRAEPITHELIAL NEOPLASIA

Intraepithelial neoplasia represents an intermediate stage in the production of malignant tumor. All the cytomorphological features are present such as disordered squamous epithelial growth marked by

the loss of polarity and presence of nuclear hyperchromasia, but the cells have not evaded the surrounding tissues.

- Intraepithelial neoplasia is frequently observed in the cervix uteri at the junction of ectocervix and endocervix.
- The concept of progressive premalignant cell proliferation applies in other organs such as breast, stomach, colorectal region, esophagus, bronchus, prostate, urinary bladder, oral cavity and vulva.
- Low-grade intraepithelial neoplasia does not involve whole thickness of epithelium, which is reversible if the irritant is removed. On the other hand, severe dysplasia/carcinoma *in situ* refers to epithelial malignancies confined to the epithelium without invasion through the basement membrane. Comparison of dysplasia and anaplasia is given in Table 6.4.

Cervical Intraepithelial Neoplasia

Cervical intraepithelial neoplasia (CIN) is graded as CIN I (mild dysplasia, involving lower third of epithelium and usually reversible), CIN II (moderate dysplasia, involving up to middle third of epithelium and usually reversible) and CIN III (severe dysplasia, involving entire thickness of epithelium up to surface layer). Carcinoma *in situ* in cervical epithelium is synonymous with CIN III and involves severe dysplastic changes extending through the entire thickness of the epithelium up to surface layer but not invading the basement membrane, i.e. carcinoma *in situ*, which shares similar molecular and genetic alterations with squamous cell carcinoma. Increased expression of TP53 is demonstrated in moderate and severe dysplasia (carcinoma *in situ*).

- **Pathophysiology:** Squamous cell carcinoma of cervix arises from the ectocervix, and adenocarcinoma originates from endocervix. Epidemiologic risk factors for cervical carcinoma are early sexual activity, multiple sexual partners and cigarette smoking.
  - Human papillomavirus (HPV) 16, 18, 31 and 33 is frequently associated with cervical squamous cell carcinoma. HPV-DNA sequences are often integrated into the genome of dysplastic or malignant cervical epithelial cells.
  - HPV viral E6 protein binds and inactivates the gene product of TP53 tumor suppressor gene, and HPV viral E7 protein binds and inactivates the gene product of RB tumor suppressor gene, thus allowing the cervical epithelial cells to accumulate and causes DNA damage leading to cell cycle progression.
  - Extracellular HPV viral E7 protein affects endothelial cells by increasing production of IL-6 and IL-8, promoting progression to invasive cervical carcinoma. Development of cervical intraepithelial neoplasia (CIN I, CIN II, CIN III) and invasive cervical carcinoma is shown in Fig. 6.6.
- **Diagnostics:** Gold standard to evaluate of cervical intraepithelial neoplasia, i.e. dysplasia is still on routine histologic examination. Thus, there is a natural history from metaplasia-to-dysplasia-to-invasive carcinoma. This is best evidenced in development of the uterine cervix and respiratory tract neoplasms.

DYSPLASIA IN MESENCHYMAL TISSUES

Osteofibrous dysplasia of bone is non-inherited developmental disorder and characterized by fibrous stroma with trabeculae of immature woven bone reflecting defective bone maturation as a result of post-zygotic mutation in GNAS1 gene, which encodes G protein-coupled receptor activating adenyl cyclase resulting in excessive production of adenosine monophosphate that derives cellular proliferation.

- Osteofibrous dysplasia variants include monostatic (70–75%) and polyostotic (25–30%). Polyostotic fibrous dysplasia may be associated with McCune-Albright syndrome (precocious puberty and skin pigmentation) or Mazabraud syndrome (hyperplasia

Table 6.4 Comparison of dysplasia and anaplasia

Characteristics	Dysplasia	Anaplasia
Greek word	Greek word dysplasia means *dys* (bad) and *plasis* (formation)	Greek word anaplasia means *ana* (backward) and *plasis* (formation)
Definition	Dysplasia describes abnormal arrangement of cells, when mature cells partially lose their morphological features	Anaplasia describes cells that have lost the distinct characters which define them as particular tissue type
Pathology	Less advanced lesion	More advanced lesion
Examples	Cervical intraepithelial neoplasia (CIN), bronchial dysplasia, pituitary dysplasia, hip dysplasia, cemento-osseous dysplasia, dentin dysplasia, osteochondral dysplasia, osteofibrous dysplasia and myelodysplastic syndrome	Poorly differentiated carcinoma

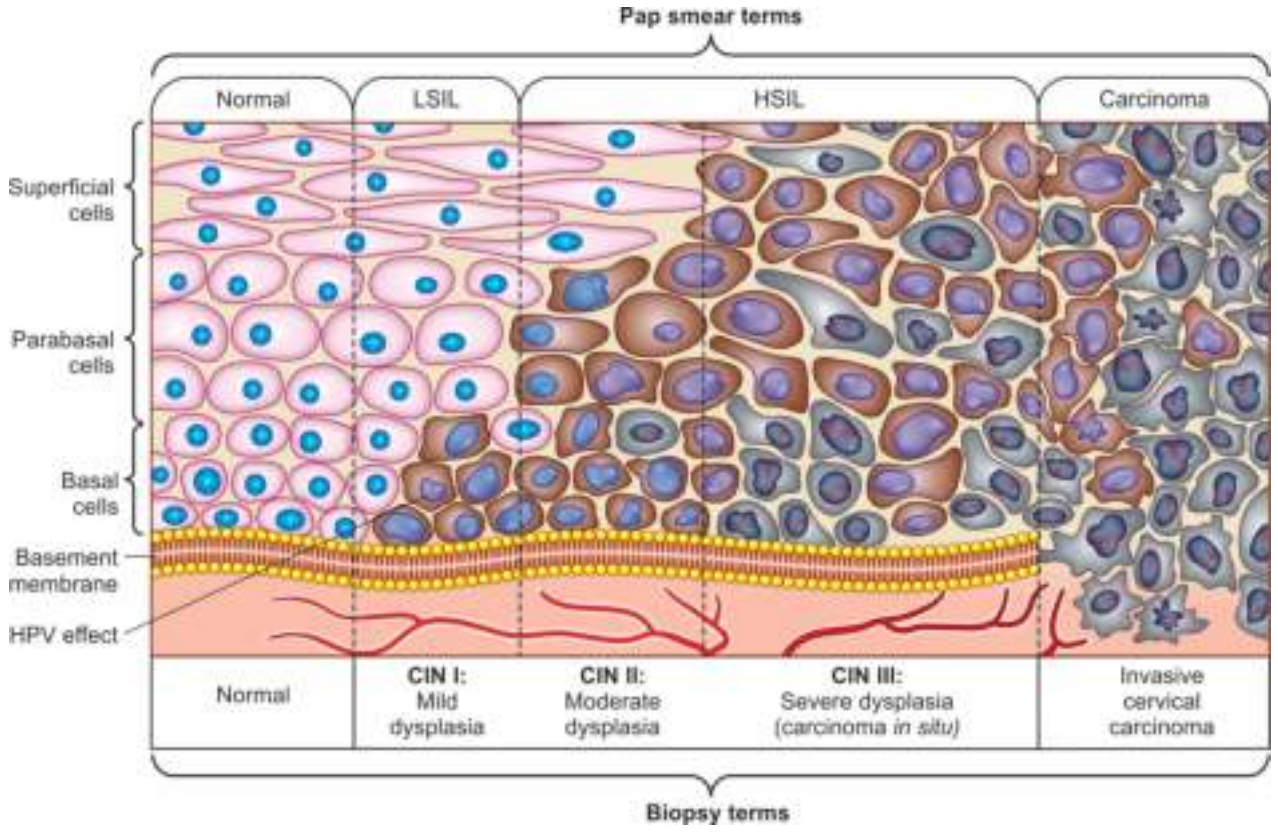

Fig. 6.6: Development of cervical intraepithelial neoplasia (CIN I, CIN II, CIN III) and invasive cervical carcinoma. Cervical intraepithelial neoplasia-I (CIN I) shows moderate dysplastic cervical epithelium in the lower one-third. Cervical intraepithelial neoplasia-II (CIN II) shows moderate dysplastic cervical epithelium in the lower two-thirds. Cervical intraepithelial neoplasia-III (CIN III) involves full thickness of cervical epithelium that does not invade the basement membrane and shows severe dysplastic cells. About 25% of untreated cases of cervical intraepithelial neoplasia may progress to cervical carcinoma. So, involved cervis must be excised with conization to prevent development of carcinoma. LSIL denotes low-grade intraepithelial lesion. HSIL denotes high-grade intraepithelial lesion.

of endocrinal glands and skin pigmentation). Radiograph shows well-circumscribed lesion with sclerotic rim of variable density giving 'ground glass appearance'.

- Osteofibrous dysplasia can undergo malignant phenotype in less than 1% of cases in polyostotic osteofibrous dysplasia or in patients with McCune-Albright syndrome.

KINETICS OF TUMOR GROWTH AND ANGIOGENESIS

Tumor growth depends on the activity of specific cell membrane receptors which regulate signaling pathways within the cell. Cell signal transduction involves the communication process where signals from outside the cell are transferred to the nucleus inside the cells.

- **Growth factors:** Several important growth factors have been identified, which bind to their cognate receptors, which include epidermal growth factor receptor (EGFR) family, platelet-derived growth factor receptor (PDGFR), BCR-ABL, KIT, vascular endothelial growth factor (VEGF), transforming growth factor (TGF), and fibroblast growth factor (FGF).
- **Receptor tyrosine kinases:** Receptor tyrosine kinases (RTKs) are a subgroup of growth factor receptors involved in the signal transduction process. RTKs play an important role in various cellular processes such as cell growth, proliferation, migration, differentiation and survival. Normally functioning growth factor receptors emit cytoplasmic signals in response to binding ligand. However, mutations in the genes encoding aberrant growth factor receptor molecules can cause subtle alterations in protein structure, such as amino acid substitutions, that cause ligand-independent fire leading to human cancer. Alterations in receptor structure including truncation of the ectodomain, may also yield such deregulated signaling. Receptor proteins are overexpressed in many human cancers.
- **Tumor angiogenesis:** Degree of vascularization is the important determinant of tumor growth potential. Tumor angiogenesis plays vital role in tumor growth, invasion and metastasis. In cancer, an '**angiogenic switch**' is almost always activated and remains

'turning on', causing existing normally quiescent vasculature networks near the tumor to continually sprout new blood vessels in the malignant tumor.

TUMOR INVASION AND METASTASIS

Invasion and metastasis constitute important hallmarks of cancer. CSCs proliferate leading to increase in size of malignant tumor that eventually penetrates basement membrane and then invades the surrounding extracellular matrix environment involves several steps. Microinvasion is spread of epithelial malignancies just beyond the point of origin through the basement membrane. Ductal carcinoma *in situ* (DCIS) with microinvasion is a pathologic diagnosis defined by the presence of 1 mm of invasive carcinoma in a background of ductal carcinoma *in situ* in female breasts.

- Microinvasive carcinoma of breast is usually detected by mammography due to abnormal calcifications in associated with DCIS. Cure rate of microinvasive carcinoma is close to 100% following surgical excision. Prognosis may depend on features of ductal carcinoma *in situ*.
- Cancer stem cells first acquire the ability to bind to components of the extracellular matrix (ECM). Tumor–ECM interactions are mediated by the expression of numerous adhesion molecules.
- The tumor undergoes epithelial–mesenchymal transition (EMT). ECM is degraded by proteolytic (MMPs) enzymes released from CSCs.
- After moving through the extracellular matrix environment, the cancer stem cells penetrate or lymphatic channels and venous tributaries by same mechanisms.
- After survival of CSCs in blood circulation from immune system evasion, the CSCs exit the vascular system. CSCs establish micrometastases at the site where it leaves the vasculature.
- These micrometastases grow into grossly evident metastases in organ(s).

TUMOR METASTATIC CASCADE

Tumor metastasis is a process, in which CSCs break away from original (primary) cancer, invade directly in surrounding tissue, travel through lymphatic route to draining lymph nodes, and via hematogenous route disseminate to a new location and establishes a secondary (metastatic) tumor in the new environment of distant organ(s). Most metastatic cancers are manageable, but not curable. Treatment can relieve symptoms, slow cancer growth and improve quality of life. Outline of operational steps is involved in metastases mediated by tumor–host interactions is shown in Fig. 6.7. Tumor development, invasion and metastasis are given in Table 6.5.

- **Metastasis pathways of malignant tumors:** Malignant tumors disseminate by one of five following pathways: tissue invasion, metastasis via lymphatic route to lymph nodes, via hematogenous route to distant organ(s), via transcoelomic route to peritoneum, and surgical implantation.
  - Carcinomas most often metastasize by lymphatic route involving regional lymph nodes, and later via hematogenous route to distant organ(s).
  - Sarcomas disseminate via hematogenous route to distant organ(s). It must be noted that in the lymph nodes, communication between the lymphatic channels and venous tributaries allows cancer stem cells access to the systemic circulation.
  - Virchow node is left (usually) supraclavicular lymph node metastasis from an abdominal malignancy.
- **Metastasis steps:** The five key steps of metastasis include: CSCs invasion, intravasation, circulation, extravasation, and colonization in distant organs. Metastatic cascade is the consequence of chromosomal instability that is caused by continuous errors in chromosome segregation. Metastatic process requires regulation of both metastasis-promoting genes and metastatic suppressor genes.
  - **Metastasis-promoting genes:** Hundreds of genes have been reported to determine invasive potential suggesting that CSCs in primary malignant tumor exhibit metastasis-promoting genes. Most notable genes are the DCC, ABCA13, IAM2, CREBBP, BCL6B and ZNF185 genes, mainly mutated exclusively in metastases and highly likely driver genes of metastatic progression.
  - **Metastasis-suppressor genes:** Metastatic suppressor genes are molecules that inhibit metastatic cascade at a secondary site without affecting the growth of primary tumor. Their specific regulation in the metastatic cascade is critical for the understanding of tumor metastasis. Metastatic-suppressor genes target various signaling pathways at multiple points in the cascade involving RAF/MEK/ERK mitogen-activated protein kinase (MAPK) signaling pathway, G protein-coupled receptor, cell adhesion, cytoskeleton, transcriptional regulation and metastatic susceptibility. A greater understanding of common signaling pathways/molecules targeted by metastasis suppressor could improve metastasis treatment strategies. Metastatic suppressor genes and their mechanism of actions are given in Table 6.6.

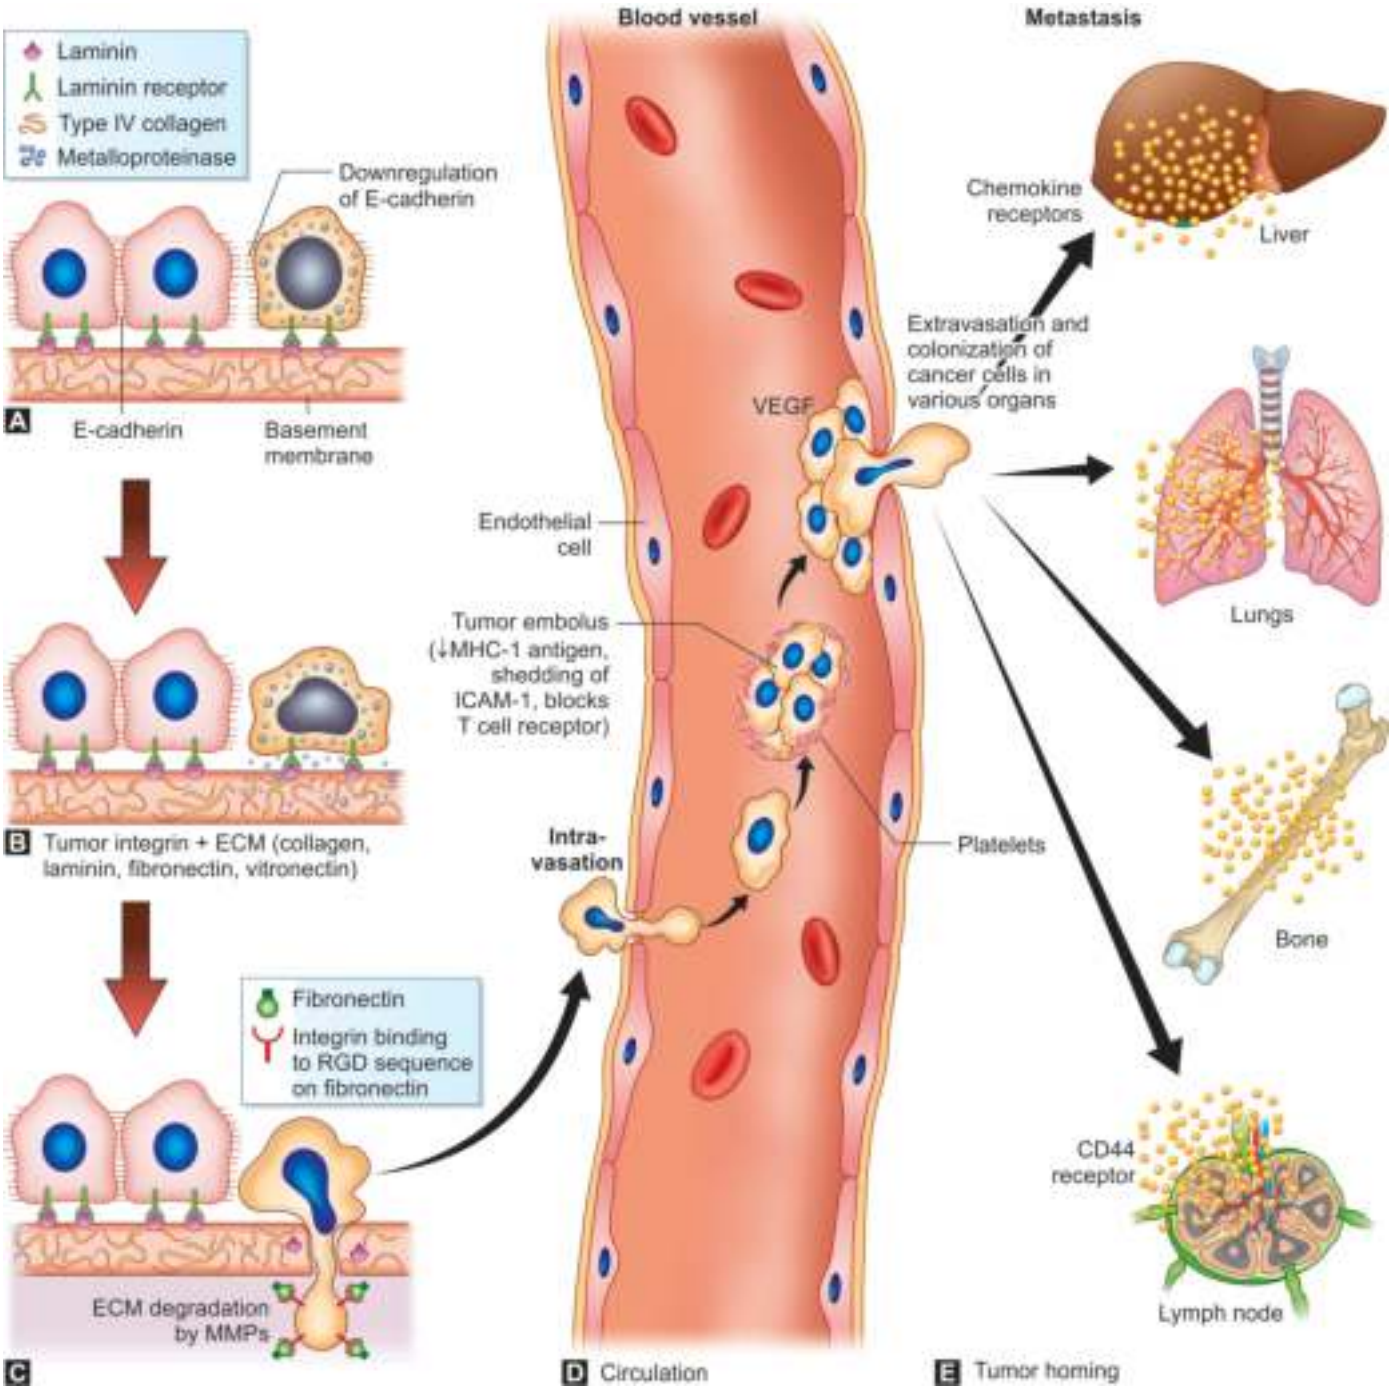

Fig. 6.7: Outline of operational steps involved in metastases mediated by tumor–host interactions. (A) Penetration through basement membranes by tumor cells is preceded by adhesion to basement membrane components. CSCs express receptors for the basement membrane protein laminin and their ligand receptor interaction between laminin and its receptor on CSCs is an important mechanism mediating binding, (B and C) binding of CSCs to connective tissue matrix proteins is followed by proteolytic breakdown of these matrices and detachment of CSCs, which then move through the breaches created by matrix protein-breakdown, (D) intravasation of CSCs, (E) extravasation of cancer stem cells and dissemination to distant organ(s).

- **Metastasis in distant organs:** A number of factors may produce minute clinically inapparent, metastatic foci of cancer stem cells (CSCs) to enter G0 phase of cell cycle, but may be reactivated to enter the cell cycle and form a clinically grossly evident macrometastasis. Micrometastases may also entail a balance between cell proliferation and apoptosis. If this equilibrium is disturbed in favor of tumor cell proliferation, the result may be a grossly evident macrometastasis. **TNM staging** is used to describe most cancers, i.e. (T) tumor size, (N) lymph node involvement and (M) metastasis.

Table 6.5 Tumor development, invasion and metastasis

Tumor Metastasis-promoting and Suppressor Genes	
▪ Tumor metastasis-promoting genes	▪ Tumor metastasis-suppressor genes
Expansive Growth and Invasion of Basement Membrane into the Surrounding Tissue	
▪ Enhanced protease activity (e.g. matrix metalloproteinases—MMPs) ▪ Decreased integrity/strength of the cell-cell contacts (E-cadherin)	▪ Enhanced cell motility interaction with surrounding tissue/ extracellular matrix/stromal cells
Angiogenesis, Intravasation and Transport Cancer Stem Cells (CSCs) within Blood Vessels	
▪ Migration interaction through extracellular membrane (ECM) ▪ Interaction of CSCs with vascular endothelial cells ▪ Interaction of CSCs with cavity mesothelial cells during transcoelomic metastasis	▪ Invasion of CSCs into the blood vessels ▪ Survival of cancer stem cells in circulation from immune system evasion
Arrest and Extravasation of Cancer Stem Cells near Secondary Tissues/Organs	
▪ Interaction of CSCs with vascular endothelial cells ▪ Invasion of CSCs into secondary tissues/organs	▪ Interaction with cavity mesothelial cells during transcoelomic metastasis
Formation of Micrometastasis and Macrometastasis in Secondary Tissues/Organs	
▪ Invasion and migration of CSCs into secondary tissues/organs ▪ Interaction and adaptation to tissue microenvironment	▪ Establishment of new vasculature ▪ Secondary tumor establishment or dormancy

Table 6.6 Metastatic tumor suppressor gene mutations and associated cancers

Functional Categories	Metastatic Tumor Suppressor Gene Mutations	Associated Cancers
Cell adhesion proteins	▪ E-cadherin 1 (CDH1 gene) ▪ DCC (i.e. netrin receptor DCC gene mutation)	▪ Breast carcinoma, gastric carcinoma, colorectal carcinoma, thyroid carcinoma and ovarian carcinoma ▪ Colorectal carcinoma
Apoptosis	▪ Caspase 8 gene ▪ GAS1 (growth arrest specific gene 1) ▪ KAI1 (CD82) gene mutation	▪ Head and neck squamous cell carcinoma ▪ Colorectal carcinoma ▪ Prostatic carcinoma
Cytoskeleton proteins	▪ Gelsolin (actin depolymerization) ▪ RhO/ROCK pathway ▪ DL1	▪ Breast carcinoma ▪ Diffuse gastric carcinoma (linitis plastica) ▪ Lung carcinoma
Tumor dormancy maintenance	KISS1/KISS1R g	Metastatic melanoma
MAPK signaling pathways	▪ MAP2K4 ▪ MKK4 ▪ MAK7 ▪ NM23	▪ Colorectal carcinoma, non-small cell lung carcinoma, melanoma, ovarian carcinoma ▪ Prostatic carcinoma, ovarian carcinoma ▪ Colon carcinoma ▪ Breast carcinoma, melanoma
Transcription regulation	▪ BRMS1 ▪ KLF17 (Krueppel-like factor 17) negative regulator of EMT	▪ Lung adenocarcinoma, breast carcinoma ▪ Metastatic breast carcinoma
Angiogenesis	DRG1	Lung adenocarcinoma
Other metastatic suppressor genes and microRNAs	▪ PTEN upregulation ▪ TXNIP (redox regulation) ▪ CD44 (hyaluronic acid receptor) upregulation ▪ LSD1 (chromatin remodeling) gene ▪ MicroRNA-335 ▪ MicroRNA-126	▪ Prostatic carcinoma, uterine cancer and some brain tumors ▪ Breast carcinoma invasion and metastasis ▪ Molecular marker of CSCs ▪ Breast carcinoma invasion and metastasis of luminal cancer stem cells ▪ Melanoma and nasopharyngeal carcinoma invasion and metastasis ▪ Lung adenocarcinoma

MicroRNA-335 and 126 cause suppression of SOX4 transcription factor, MERTK encoding receptor tyrosine kinase, PTPN2 encoding protein tyrosine phosphatase non-receptor type 2, TNC gene encoding tenascin C.

NOMENCLATURE AND CLASSIFICATION OF TUMORS

TUMOR NOMENCLATURE

Human body is composed of two major classes of tissue: parenchymal tissue and mesenchymal tissue (connective tissue, muscle, bone and blood vessels). The term 'neoplasm' means new growth—synonymous with tumor does not imply benign or malignant, which correlate to the clinical course of the tumor. Tumors are autonomous, progressive (continue to grow in the absence of external stimuli), purposeless and parasitic nature (continue to derive nourishment from host).

- The term 'dysplasia' is a reversible process in a cell or tissue, where nuclear features of malignancy (anisocytosis, poikilocytosis, hyperchromatic nuclei, disorderly arranged unusual number of cells, with prominent nucleoli and abnormal mitotic figures, and cell disorganization—loss of polarity) are observed but general architectural features are benign lesions that regress spontaneously or may transform into malignancy in some cases.
- The term neoplasia refers to the process of tumor growth. Benign tumors of most tissues are usually designated by the suffix-oma. The term 'cancer' refers to malignant tumor. Malignant tumors of the parenchyma are designated as **carcinomas**, while malignant tumors of mesenchymal tissues are designated as sarcomas.
- Anaplastic tumor is poorly-differentiated tumor that exhibits pleomorphism, numerous atypical tripolar or quadripolar mitoses, abnormal nuclear morphology and cell disorganization (loss of polarity).

HISTOGENESIS OF TUMORS

Histogenesis is a method of classifying neoplasms on the basis of the tissue cell of origin and lineage of differentiation, and whether the tumor is benign, borderline (low-malignant potential without stromal invasion) or malignant (*in situ* or invasive carcinoma) based according to their morphological appearance and clinical behavior.

- Tumors are further described by appearance, embryonic tissue of origin (i.e. ectoderm, mesoderm and endoderm), and differentiation. Ectoderm gives rise to skin and nervous tissue. Mesoderm gives rise to muscle, bone and blood-forming cells. Endoderm gives rise to intestine derived pouchings, bronchial tissue, lung, liver and pancreas.
- Tumor is composed of neoplastic element and non-neoplastic supporting connective tissue stroma. Benign tumors are usually well-differentiated and localized, which neither invade surrounding tissues nor metastasize to distant organs(s). Borderline tumors are of low-malignant potential without stromal invasion. Cells that initiate and sustain a malignant neoplasm are called CSCs. Malignant tumors can exhibit a range of differentiation, invade surrounding tissues and metastasize to distant organs(s). There are four main routes of metastasis of malignant tumors—local invasion, lymphatic route, hematogenous route and transcoelomic route.

Benign Tumors

Benign tumors are derived from epithelial and mesenchymal tissues, which stay localized in one place. Benign tumors are slow-growing, well-encapsulated or well-circumscribed, resembling the tissue of origin and localized to the site of origin without invading surrounding tissues, and not metastasizing to distant organ(s).

- In general, cells of benign tumors are well-differentiated, which mimic the structure of their parent tissue of origin, exhibit uniformity in size, shape and nuclear configuration and have relatively infrequent normal type of bipolar mitotic figures.
- In general, benign tumors of most tissues are designated by the 'suffix-oma'. It is worth mentioning that some malignant tumors are also ending with 'suffix-oma', which include melanoma, seminoma (germ cell tumor of testis), dysgerminoma (germ cell tumor of ovary) and mesothelioma (mesothelial cell tumor).
- It is worth mentioning that some non-neoplastic lesions also end with 'suffix-oma' (i.e. hematoma, granuloma, or hamartoma.
- Following surgical excision, some benign tumors (e.g. uterine leiomyoma, pleomorphic adenoma of salivary gland and atrial myxoma) may disseminate to distant organ(s).

Benign Epithelial Tumors

Benign epithelial tumors are essential of two types, i.e. papilloma and adenoma. Papilloma originates from surface epithelium, as the epithelium proliferates, it is thrown into visible finger-like projections, which become complex, which is accompanied by a corresponding growth of supporting connective tissue and blood vessels. Adenoma is derived from the ducts and acini of glands, and proliferation of gland leads to formation of tubules, which ramify and become compound.

Benign Mesenchymal Tumors

Benign mesenchymal tumors are composed of mature connective tissue, i.e. adipose tissue, smooth muscle,

skeletal muscle, lymphatic channel, blood vessel, cartilage, and bone, which include lipoma, leiomyoma, rhabdomyoma, lymphangioma, hemangioma, chondroma and osteoma respectively, which tend to form encapsulated, lobulated masses and compress the surrounding tissues.

Borderline Tumors of Low Malignant Potential

Borderline tumors are of low malignant potential, defined histologically by atypical proliferation of surface epithelial cells, without stromal invasion, e.g. serous, mucinous and endometrioid borderline tumors of ovary, which account for 15% of all primary ovarian neoplasms in women of 20–40 years.

Malignant Tumors

Malignant tumors are derived from any of the three germinal layers (ectoderm, mesoderm and endoderm) and from epithelial tissue (carcinoma derived from squamous, glandular and transitional epithelium lining the organs) and mesenchymal tissue (sarcoma derived from cartilage, bone, smooth muscle, skeletal muscle and blood vessels). Other malignant tumors include neuroectodermal tumors, neuroendocrine tumors, germ cell tumors, hematolymphoid tumors and melanoma.

- **Genetic alterations and cancer:** Mutations may cause gain- or loss-of-function of genes. Malignant tumors occur either due to gain-of-function of oncogenes or inactivation/biallelic loss of tumor suppressor genes. Dominant mutations result from a gain-of-function, some novel characteristics of the protein product. Recessive mutations occur due to loss of function by the polypeptide product.
- **Normal cell is transformed to CSC:** Malignant tumor begins as a single mutated cell. About 30 divisions (doubling time) of transformed CSC take place before the patients develop earliest symptoms. Each division of CSC leads to additional gene mutations. Cancers that are detected late, and tend to have poor prognosis.
- **Rate of tumor growth:** Malignant tumors are rapidly growing, poorly-circumscribed mass, which obtain nourishment from the body and not related to the physiologic needs of the body.
- **Indicators of malignancy:** CSCs possess several unique capabilities such as self-renewal, invasion and metastasis to distant organs(s). Invasion and metastasis are the most important defining indicators of malignancy.
  - Many malignant tumors invade surrounding tissue and metastasize via lymphatic route to lymph nodes (e.g. carcinomas), via hematogenous route (e.g. carcinomas and sarcomas) to distant organ(s) anywhere in the body most commonly in the liver, lungs, brain and bone, and via transcoelomic route to peritoneum (Krukenberg tumor of ovary from metastatic breast carcinoma, gastric carcinoma and colon carcinoma).
  - When malignant tumor metastasizes to distant organ(s), the tissue from which tumor originated is not always apparent from its morphologic properties. In such cases, electron microscopy and immunohistochemistry may aid in detection of correct origin of the tumor.
- **Electron microscopy:** Electron microscopic examination demonstrates desmosomes or special junctional complexes in carcinomas, and melanosomes in melanomas, and membrane-bound granules with dense core in endocrine neoplasms. Electron microscopy remains an invaluable diagnostic adjunct revealing certain subcellular features that indicate a specific line of differentiation in pleomorphic sarcomas of soft tissues (e.g. high-grade fibrosarcoma, pleomorphic liposarcoma and pleomorphic rhabdomyosarcoma).
- **Immunohistochemistry:** Immunohistochemistry technique is an important application of monoclonal antibodies widely used for diagnosis of malignant tumors; as specific tumor antigens are expressed de novo or upregulated in certain human cancers.
  - Immunohistochemistry technique plays an important role in diagnostic and research laboratories to predict prognosis of malignant tumors by detection of enzymes, tumor-specific oncogenes, tumor suppressor genes and proliferation of CSCs.
  - Immunohistochemistry technique is performed to diagnose primary malignant tumor of uncertain origin and metastatic tumor from unknown primary cancer by using a panel of antibodies to resolve diagnostic problem cases.
  - The selection of monoclonal antibodies being made is based on clinical history, morphologic features and results other relevant laboratory investigations. Immunohistochemical stains for intermediate filaments are expressed by CSCs (i.e. cytokeratin, vimentin, desmin, neurofilaments and glial fibrillary acidic proteins).
- **Eradication of malignancy:** Most of the patients with malignant tumors have fatal outcome, whereas benign tumors usually remain localized without morality. Debulking of malignant tumor in stage I done by surgery may result in successful remission. Eradication of the malignant tumor requires removal of the CSCs, which must have the **BMI-1 gene** encoding BMI-1 gene products, which inhibit

tumor suppressors $p16^{INK4A}$ and $p14^{ARF}$. It is worth mentioning that $p16^{INK4A}$ and $p14^{ARF}$ normally function to inhibit the cell cycle.

- **Prediction of therapeutic response to therapy:** Immunohistochemistry technique is widely used to predict therapeutic response in both breast carcinoma and prostatic carcinoma.
  - Growth of breast carcinoma and prostatic carcinoma is under hormone estrogen and androgen respectively. The specific receptors for these growth regulating hormones are located on target CSCs.
  - Tumors expressing high-level of receptor positivity would respond favorably for removal of the source of such hormones, therefore hormonal therapy is administered to lower their levels.
  - Tamoxifen is administered to treat hormone estrogen receptor-positive breast carcinoma. Men have higher levels of androgens, i.e. testosterone and dihydrotestosterone (DHT). Hormonal therapy for prostatic carcinoma can reduce production of androgens by testicles or blocking the action of androgens throughout the body.
- **Screening of cancers:** Goals of screening of cancer is to detect intraepithelial neoplasia (severe dysplasia/carcinoma *in situ*) before it becomes carcinoma, before clinical symptoms appear. Common screening methods for detection of cancers include Papanicolaou smear (cervical carcinoma) and mammography; and prostate-specific antigen analysis and digital rectal examination (prostatic carcinoma); occult blood and colonoscopy (colorectal carcinoma) before it spreads to distant organ(s).

Malignant Epithelial Tumors

Carcinomas, which develop from squamous epithelium or glandular epithelium lining organs that form nests of epithelial cells supported by non-neoplastic stroma. Terminology related to histologic appearance of epithelial tissue-derived malignant tumors includes differentiation, anaplasia, dysplasia (mild/moderate and carcinoma *in situ*/severe dysplasia), and invasive carcinoma.

- Squamous cell carcinoma most often occurs on skin, especially on exposed surfaces, but also develops in other sites covered by stratified squamous epithelium, e.g. lips, tongue, pharynx, esophagus and vagina. In addition, squamous cell carcinoma may occur on surfaces covered by glandular type epithelium through metaplastic transformation as seen in bronchus, uterine cervix and gallbladder.
- Adenocarcinoma may take origin from gland duct, acini or the glandular epithelium of mucous surfaces. On mucosal epithelial surfaces, adenocarcinoma may start as a polypoidal growth, and in compound glands, e.g. the female breast, adenocarcinoma forms an irregular penetrating mass, which exhibits crab-like appearance.
- Transitional cell carcinoma begins in urothelial cells that line urethra, urinary bladder, ureters and renal pelvis. Urothelial cells can change shape and stretch without breaking apart.

Malignant Mesenchymal Tumors

Malignant mesenchymal tissue tumors are referred to as sarcomas, which take origin in soft tissue, bone, cartilage, smooth muscle, skeletal muscle, blood vessels and rarely in viscera. Sarcomas are composed of neoplastic cells intermixed with the connective tissue stroma. Sarcomas are far less common than carcinomas, Unlike the ill-defined growth of invasive carcinomas, sarcomas are well-defined fleshy tumors.

Malignant Tumors Lacking Benign Counterpart

In nomenclature of tumors, many life-threatening malignant tumors lack benign counterpart despite ending in 'suffix-oma'.

- 'Blastomas' with immature embryonic cells resembling fetal analogue occur due to failure of proper differentiation into their intended cell types before birth during embryogenesis or during infancy and early childhood, which include neuroblastoma, retinoblastoma, hepatoblastoma, nephroblastoma (Wilms' tumor), medulloblastoma, ameloblastoma of maxilla, pancreatoblastoma, pleuropulmonary blastoma, gonadoblastoma and glioblastoma multiforme.
- Some malignant tumors ending with 'suffix-oma' include seminoma, dysgerminoma, germinoma, mesothelioma, melanoma, non-Hodgkin's lymphoma and hepatoma.
- Malignant tumors called disease include leukemias, Paget's disease of breast.
- Malignant tumors nominated by scientists' name include Hodgkin's disease, Ewing sarcoma.

Pathology Pearls: Blastomas-derived from Immature Embryonic Cells Resembling Fetal Analogue

- Neuroblastoma
- Retinoblastoma
- Hepatoblastoma
- Nephroblastoma (Wilms' tumor)
- Medulloblastoma
- Ameloblastoma of maxilla
- Pancreatoblastoma
- Pleuropulmonary blastoma
- Gonadoblastoma
- Glioblastoma multiforme

TUMOR CLASSIFICATION HIERARCHY

Tumors may be classified in two ways based on: (a) clinical behavior (i.e. benign, borderline of low malignant potential without stromal invasion and malignant) and (b) histologic origin (i.e. epithelial tissue, mesenchymal tissue, neuroectoderm, neuroendocrine, germ cells and hematolymphoid cells). In clinical practice, there is a spectrum of malignant tumors. Some malignant tumors may grow locally and invade normal surrounding tissues, but never metastasize to distant organs(s). Other malignant tumors produce metastases only after a very considerable time, while some of the malignant tumors metastasize very early in their development. The commonest tumors originate from tissues, which have rapid turnover of cells, and which are exposed to environmental mutagens, e.g. epithelium of mucous membranes, skin, breast, reproductive organs and hematolymphoid tissue. Differences between normal tissue cell and CSC are given in Table 6.7. Tumor classification hierarchy is given in Table 6.8. Principal characteristics of benign and malignant tumors are given in Table 6.9. Classification of common benign and malignant tumors according to their origin are given in Table 6.10. Principal characteristics of carcinoma and sarcoma are given in Table 6.11.

- **Normal cells versus CSCs:** CSCs differ from normal cells in many respects: tumor growth *in vivo*, lack of differentiation (anaplasia), and pleomorphism. Malignant tumors exhibit clonal expansion of cancer stem cells, pleomorphism (varying size and shape), hyperchromatic nuclei, prominent nucleoli,

Table 6.7 Differences between normal tissue cell and cancer stem cell

Characteristics	Normal Tissue Cell	Cancer Stem Cell
Morphologic features		
Differentiation	Well-differentiation	Well-moderate-poor differentiation
Nuclear polarity	Basal polarity	Loss of basal polarity
Nuclear morphology	Normal morphology	Pleomorphic morphology
Nuclear to cytoplasmic (N/C) ratio	Low N/C ratio	High N/C ratio
Nuclear chromatin	Normal chromatin	Hyperchromatism
Nucleolus	Normal	Prominent
Mitotic figures	Bipolar mitoses	Tripolar or quadripolar mitoses
Giant cells	Giant cells absent in normal tissue	Tumor giant cells present in cancers
Molecular features		
Regulation	Normal regulation	Autonomous regulation (uncontrolled cell proliferation)
Genetic stability	Stable	Unstable
Growth factor dependence	Growth factor dependent	Growth factor independent
Density dependent	High	Low
Anchorage dependence	High	Low
Cell-to-cell adhesion	High	Low
Cell-to-cell communication	High	Low
Cell life span	Limited	Unlimited
Antigen expression on cell surface	Absent	Tumor antigen may be present (e.g. carcino-embryonic antigen)
Substance (i.e. protease, hormone) production	Normal	Ectopic production substances
Cytoskeleton composition and arrangement	Normal	Abnormal
Mitochondria number	Numerous mitochondria	Few mitochondria
Rough endoplasmic reticulum (RER) and ribosomes	▪ More prominent ▪ Numerous ribosomes attached to the rough endoplasmic reticulum	▪ Less prominent ▪ Ribosomes dissociated and scattered in the cytoplasm
Chromosomes	Diploidy	DNA polyploidy

Table 6.8 Tumor classification hierarchy

Differentiation of Tumors
▪ Epithelial tumors ▪ Nonepithelial tumors ▪ Mixed tumors (e.g. fibroadenoma of breast, carcinosarcoma, teratocarcinoma, malignant mixed Müllerian tumors of uterus, adenosquamous carcinoma and metaplastic carcinoma)
Embryonic Origin of Tumors
▪ Tumors originate from ectoderm-derived structures, e.g. skin, keratinocytes, sweat glands, breast, salivary glands and nervous system (neuroectoderm) ▪ Tumors originate from mesoderm-derived structures (e.g. bone, cartilage, smooth muscle, fibroblasts, adipocytes, endothelial cells, kidney, testis, endometrium, and blood forming cells) ▪ Tumors originating from endoderm-derived structures, e.g. stomach, small intestine, colon, lung, pancreas, thyroid gland, liver, urinary bladder and prostate gland
Biological Behavior of Tumors
▪ Benign epithelial and mesenchymal tumors are associated with good prognosis ▪ Borderline tumors of ovary (serous cystadenoma, mucinous cystadenoma) have low malignant potential ▪ Malignant epithelial and mesenchymal tumors include carcinoma and sarcoma associated with poor prognosis

atypical tripolar or quadripolar mitotic figures, and chromosomal abnormalities, both structural (e.g. Philadelphia chromosome in chronic myelogenous leukemia) and numerical (e.g. aneuploidy).
  - In contrast to the normal cells, CSCs exhibit loss of functions, simplified cytoplasmic architecture and synthesis of oncofetal proteins such as α-fetoprotein (AFP) and carcinoembryonic antigen (CEA).
- **Benign versus malignant tumors:** Benign tumors are well-differentiated, which resemble the structure of parent tissue and show a remarkable uniformity in size, shape and nuclear configuration, and relatively infrequent bipolar mitotic figures.
  - Malignant tumors tend to be less well-differentiated than those of benign tumors, which show generally haphazard arrangement of tumor cells, variation in size, shape and nuclear configuration, reflecting an increase in chromosomal number and DNA content (aneuploidy) and atypical tripolar or quadripolar mitotic figures.
  - There is a wide spectrum within malignant tumors, from slow-growing and well-differentiated tumors to rapidly growing and highly malignant undifferentiated tumors.
  - Benign tumors do not invade or metastasize to distant organs, whereas primary malignant

Table 6.9 Principal characteristics of benign and malignant tumors

Characteristics	Benign Tumors	Malignant Tumors
General features		
Origin of tumors	▪ Epithelial tissue-derived benign tumors (adenoma, polyp, papilloma) ▪ Mesenchymal tissue-derived (osteoma, fibroma, chondroma)	▪ Epithelial tissue-derived malignant tumors (squamous cell carcinoma, adenocarcinoma, transitional cell carcinoma) ▪ Mesenchymal tissue-derived tumors (osteosarcoma, chondrosarcoma, liposarcoma, fibrosarcoma, rhabdomyosarcoma)
Differentiation	Well-differentiated tumor	Well, moderately and poorly differentiated tumor
Growth rate	Slow-growing tumor remains localized	Rapidly growing tumor usually invades adjacent tissues
Behavior	Expansile sessile or papillary growth growing locally	Fungating, ulcerated or annular tumors invading surrounding tissue
Direction of epithelial growth on skin or mucosal surfaces	Exophytic growth (most often)	Endophytic growth (most often)
Invasion of tumor	Absent (benign tumor grows as a cohesive mass encapsulated by dense connective tissue)	Most often present (malignant tumor destroys surrounding tissue and lacks a well-defined capsule)
Metastases of tumor	Benign tumors most often do not metastasize except tumors metastasize after surgical excision (uterine leiomyoma, cardiac myxoma and pleomorphic adenoma of salivary glands)	Malignant tumor most often metastasizes to distant organ(s), except basal cell carcinoma and glioma of central nervous system

Contd...

Table 6.9 Principal characteristics of benign and malignant tumors (*Contd...*)

Characteristics	Benign Tumors	Malignant Tumors
Effect on host	Slight harmful (can be harmful if, located in brain and airways)	Significant harmful due to invasion and metastasis to distant sites
Gross morphology		
Tumor border	Often well-circumscribed or encapsulated tumor	Irregular poorly-defined or irregular tumor growth and lacks capsule and clear demarcation
Cut surface of tumor	Homogenous cut surface of tumor	Heterogenous cut surface of tumor
Hemorrhage and necrosis on cut surface	Hemorrhage and necrosis rare	Hemorrhage and necrosis common
Ulceration of tumor	Ulceration rare	Ulceration common on skin or mucosal surfaces
Histologic features		
Histologic resemblance to normal tissue	Benign tumor resembles cell of origin (well-differentiated tumors)	Malignant tumor often shows failure of cellular differentiation (may be well-differentiated or moderately-differentiated tumors)
Cells morphology	Cells are uniform throughout the tumor	Pleomorphic cells vary in shape and size in the tumor
Nucleus polarity	Basal nuclear polarity	Loss of basal nuclear polarity
Nuclear morphology	Often normal nuclear morphology	Pleomorphic nucleus morphology with irregular outlines, multiple nucleoli
Nucleocytoplasmic ratio	Nucleocytoplasmic ratio low (1:4 or 6)	Nucleocytoplasmic ratio high (1:1)
Chromatin pattern	Nucleus with normal chromatin	Nucleus with hyperchromatism
Nucleolus	Inconspicuous nucleolus	Prominent nucleolus
Mitotic rate	Low-mitotic rate	High-mitotic rate
Mitotic figures	Bipolar mitoses	Atypical tripolar or quadripolar mitoses
Giant cells	Benign giant cells can be observed in some benign tumors	Bizarre tumor giant cells present in malignant tumors
Tumor ploidy	Chromosomal abnormality without aneuploidy	Usually, aneuploidy

tumors invade the basement membrane of tissues through the action of matrix metalloproteinase (MMP) enzymes, detach from neighboring cells, metastasize via lymphatic route to lymph nodes, via hematogenous route to distant organ(s), or transcoelomic routes to peritoneum to form secondary tumors.

- **Diagnostic significance of classification of tumors:** Distinction between benign and malignant tumors of great importance in diagnosis, treatment, and prognosis. A clear understanding of the histologic classification of tumors is essential for the study of tumors. However, the entire spectrum of tumors arising in various tissues and organs has been difficult to follow a single classification scheme that is either purely morphologic basis or molecular basis. Malignant tumors can exhibit a range of differentiation (well, moderate and poor/undifferentiation).
- **Clinical significance of classification of tumors:** Histologic features of tumors together with information about their respective cell tissue-of-origin, differentiation states and the biologic behaviors (benign versus malignant tumors) are taken into consideration to develop a taxonomy of human tumors that has proven useful for the diagnosis and clinical management of most tumors. Malignant tumors are capable of invasion surrounding tissues and metastasize to distant organ(s). This distinction between benign and malignant tumors is important in clinical practice because metastatic disease is associated with significant morbidity and mortality.

BENIGN EPITHELIAL TUMORS

Benign epithelial tumors are slow-growing, well-circumscribed, encapsulated, resembling to tissue of origin, and most often confined to their site of origin, which neither invade surrounding tissues nor metastasize to distant organ(s). It is worth mentioning that following surgical intervention, tumor cells from

Table 6.10 Classification of common benign and malignant tumors according to their origin

Tissue of Origin	Benign Tumors	Malignant Tumors
Epithelial origin tumors		
Stratified squamous epithelium	Squamous cell papilloma	Squamous cell carcinoma
Basal cell of skin	None	Basal cell carcinoma
Epithelial lining of ducts and glands (glandular epithelium)	▪ Adenoma ▪ Papilloma	▪ Adenocarcinoma ▪ Papillary carcinoma
Respiratory passages	Bronchial adenoma	Bronchogenic carcinoma
Renal epithelium	Renal tubular adenoma	Renal cell carcinoma
Liver cell (hepatocyte)	Hepatocellular adenoma	Hepatocellular carcinoma
Ovarian surface epithelium	▪ Serous cystadenoma ▪ Mucinous cystadenoma	▪ Serous cystadenocarcinoma ▪ Mucinous cystadenocarcinoma
Neuroectoderm (melanocytes)	Benign nevus	Malignant melanoma
Urinary tract surface epithelium	Transitional cell papilloma	Transitional cell carcinoma
Placental epithelium	Hydatidiform mole	Choriocarcinoma
Germ cell of gonads	Benign cystic teratoma (ovary) and extra-gonadal germ cell neoplasms (mediastinum)	Germinoma/seminoma/dysgerminoma, teratomas, embryonal carcinoma, yolk sac tumor and choriocarcinoma
Connective tissue origin tumors		
Fibrous tissue	Fibroma	Fibrosarcoma
Adipose tissue	Lipoma	Liposarcoma
Cartilage	Chondroma	Chondrosarcoma
Bone	Osteoma	Osteosarcoma
Smooth and skeletal muscle tissue origin tumors		
Smooth muscle	Leiomyoma	Leiomyosarcoma
Striated muscle	Rhabdomyoma	Rhabdomyosarcoma
Blood vessels origin tumors		
Lymphatic channels	Lymphangioma	Lymphangiosarcoma
Blood vessels	Hemangioma	Angiosarcoma
Surface covering origin tumors		
Synovium	None	Synovial sarcoma
Mesothelium	Benign fibrous tumor	Malignant mesothelioma
Brain coverings	Meningioma	Invasive meningioma
Hematopoietic myeloid cells, lymphoid cells, histiocytes and primitive cells origin tumors		
Hematopoietic myeloid cells	None	▪ Acute myelogenous leukemia ▪ Chronic myelogenous leukemia
Lymphoid cells	None	▪ Hodgkin's disease ▪ Non-Hodgkin's lymphoma ▪ Malignant thymoma ▪ Multiple myeloma ▪ Acute lymphoblastic leukemia (ALL) ▪ Chronic lymphocytic leukemia (CLL)
Histiocytes	None	Histiocytosis X
Primitive mesenchyme	None	Ewing sarcoma

Contd...

Table 6.10 Classification of common benign and malignant tumors according to their origin (*Contd...*)

Tissue of Origin	Benign Tumors	Malignant Tumors
Tumors with various components usually derived from one germ layer		
Salivary gland	Pleomorphic adenoma	Malignant mixed tumor of salivary gland
Renal analogue	None	Wilms' tumor
Totipotent cells	Benign cystic teratoma ovary	Teratocarcinoma
Nervous system origin tumors		
Primitive neuroectodermal cells	▪ Oligodendroglioma (adults) ▪ Ependymoma (adults) ▪ Meningioma	▪ Astrocytoma ▪ Glioblastoma multiforme ▪ Medulloblastoma ▪ Neuroblastoma (children) ▪ Retinoblastoma
Nerve sheaths	Neurilemmoma	Neurofibrosarcoma
Embryonic tissue origin tumors		
Kidney	None	Wilms' tumor
Liver	None	Hepatoblastoma
Secondary tumors		
Tumors metastasizing to distant sites	None	▪ Carcinoma derived from epithelial tissue ▪ Sarcoma derived from mesenchymal tissue

Tumors eponyms are applied to malignant tumors that cannot be properly classified (e.g. Hodgkin's disease, Wilms' tumor, Ewing sarcoma, Kaposi sarcoma, mesothelioma, melanoma, seminoma, dysgerminoma, chordoma and Burkitt's lymphoma).

Table 6.11 Principal characteristics of carcinoma and sarcoma

Parameters	Carcinoma	Sarcoma
Origin	Epithelial tissue	Mesenchymal tissue
Examples of malignant tumors	Squamous cell carcinoma, basal cell carcinoma, adenocarcinoma, transitional cell carcinoma	Osteosarcoma, chondrosarcoma, fibrosarcoma, rhabdomyosarcoma, leiomyosarcoma, liposarcoma, angiosarcoma, Kaposi sarcoma
Behavior	Malignant behavior	Malignant behavior
Frequency	Common	Relatively rare
Growth rate	Slow growth	Rapid growth
Preferential routes of metastases	Lymphatic route (except renal cell carcinoma, follicular thyroid carcinoma)	Hematogenous route
In situ phase	*In situ* phase present	*In situ* phase absent
Age group	>50 years (most often)	<50 years (most often)
Neoangiogenesis (new blood vessels formed)	Neoangiogenesis confined to the malignant tumor (carcinoma) hence tumor is relatively less vascular	Neoangiogenesis extending from the malignant tumor (sarcoma) into the surrounding tissue hence tumor is more vascular
Histologic examination	Group of cells are separated by connective tissue	Individual cell is separated from adjacent cell by connective tissue
Electron microscopy	Cells express desmosomes and specialized junctional complexes	Cells do not express desmosomes and specialized junctional complexes
Immunohistochemistry	Cytokeratins, epithelial cell membrane (EMA), Ber-Ep4, B72.3, carcinoembryonic antigen (CEA)	Vimentin, desmin, muscle specific actin (SMA), CD99
Prognosis	Relatively good	Poor

Carcinomas often exhibit desmosomes and specialized junctional complexes, which are structures that are not typical of sarcomas or lymphomas.

pleomorphic adenoma of salivary gland may enter circulation and reach distant sites. Benign epithelial tumors can compress surrounding structures resulting in clinical manifestations. Benign epithelial tumors are essentially of two types: papilloma and adenoma, which originate from ectoderm and endoderm. The tumors can be sessile, papillary and polypoid growth on the surface of the skin, larynx, paranasal sinuses, tongue or urinary bladder. Tumors are usually ovoid or rounded in shape. Cut surface of solid and cystic areas but are lacking hemorrhage and necrosis.

Papilloma in Various Organs

Papilloma originates from epithelial lining of skin, larynx, paranasal sinuses, tongue, lactiferous ducts of female breast or urinary bladder. As the epithelium proliferates, it is thrown into visible finger-like projections, which become increasingly complex. The epithelial cell proliferation is accompanied by a corresponding growth of supporting fibrovascular core containing blood vessels.

Breast Intraductal Papilloma

Papilloma may also originate within ducts in the breast, which becomes compressed and exhibits complex structure, which can be located in central and peripheral regions of breast in young women. Peripheral breast papilloma tends to be even smaller in size than a central papilloma. Multiple papillomas can occur in bilateral breasts.

- **Clinical features:** Signs and symptoms depend on location of papilloma in the breast. Females can present with serous discharge in nipple. Some intraductal papillomas containing abnormal cells and multiple intraductal papillomas may have a slightly higher risk of developing breast cancer.
- **Gross morphology:** Tumor is tan-pink, friable, and usually <1 cm in size.
- **Histologic examination:** In general, papilloma consists of fibrovascular core with delicate finger-like projections lined by epithelial cells. Intraductal papilloma is lined by cuboidal to columnar cells toward lumen and outer layer of myoepithelial cells. Histology of intraductal papilloma in female breast is shown in Fig. 6.8.
- **Treatment:** If there is nipple discharge in solitary papilloma, the duct is excised by surgery.

Adenomas in Various Organs

Adenoma is benign tumor derived from the ducts and acini of glands. Proliferation of ducts and acini of glands leads to formation of tubules, which ramify and become compound. The original communication with the parent gland or acinus tends to become lost.

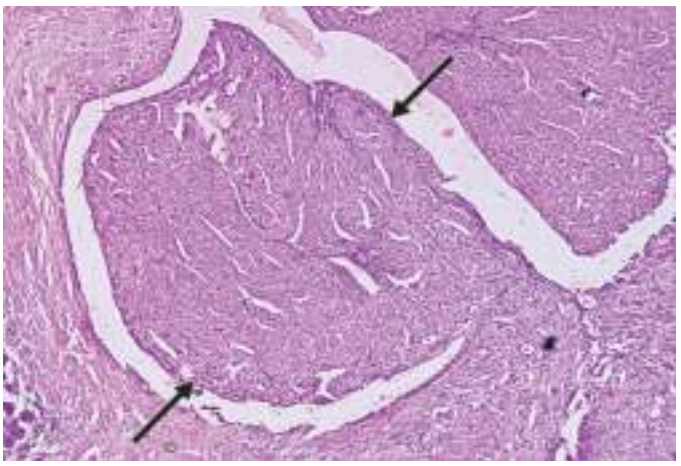

Fig. 6.8: Histology of intraductal papilloma in female breast. Tumor shows multiple branching papillae composed of thin fibrovascular core lined by cuboidal to columnar ductal cells toward lumen and outer myoepithelial cells (arrows) (200X).

- Adenoma is usually pushed upwards into the lumen of the viscus. Most common sites of adenomas include large intestine, salivary glands, thyroid gland, parathyroid glands, pituitary gland and breast.
- In cases, in which retention of secretion results in cyst formation and such tumor is called cystadenoma (ovarian serous, mucinous and endometrioid cystadenomas), which may reach size of 30–40 cm in diameter in the ovary, particularly mucinous cystadenoma is associated with excellent prognosis.

Colorectal Adenomas

Tubular adenoma, villous adenoma, and tubulovillous adenoma arise in the right colon especially in sigmoid colon (40%), left colon (40%) and rectum (20%). Risk of malignant transformation is more in >2 cm sized villous adenoma in rectosigmoid region. Majority of cases have chromosomal instability and demonstrate TP53 gene mutations.

- **Clinical features:** Villous adenoma in the colorectal region can occasionally manifest as a syndrome of severe diarrhea with massive fluid and electrolyte loss. In most cases, colonic/colorectal adenomas are asymptomatic and detected on routine colonoscopy procedure to rule out colon carcinoma. However, some patients can present with blood in the stool or rectal bleeding, abdominal pain, iron deficiency anemia, diarrhea or constipation of more than one week.
- **Gross morphology:** Colorectal adenoma is soft, irregular, red-tan to white mucosal fragments. Specimen is received in 10% formalin. Surgical specimen of tubular adenoma of colon is shown in Fig. 6.9.

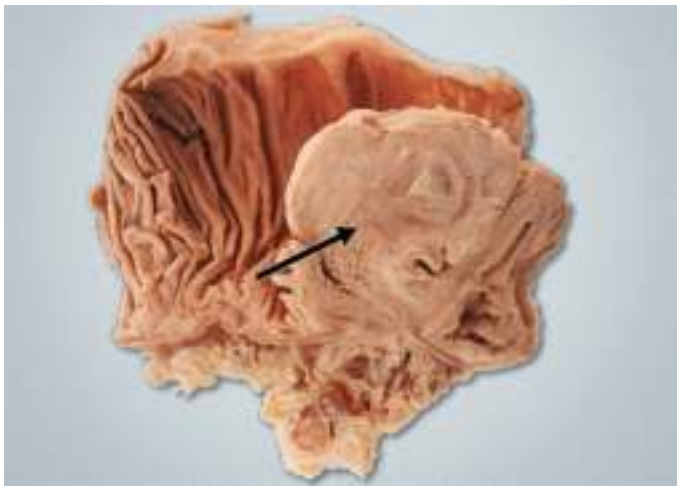

Fig. 6.9: Surgical specimen of tubular adenoma of colon. Tubular adenoma originates in the descending colon (90%) and rectum (50%) compared with other polyps. Tumor has pedunculated polyp (arrow). (*Courtesy:* Dr. Sujata Kanetkar, Professor and Head, Department of Pathology, Krishna Institute of Medical Sciences, Karad, Maharashtra.)

- **Histologic examination:** Colorectal adenomas are categorized based on how they grow: (a) tubular adenoma grows in a round or oval shape, (b) villous adenoma grows in a shaggy, cauliflower-like pattern, and (c) tubulovillous adenoma is a mixture of the two growth patterns such as tubular adenoma and villous adenoma. Villous component architecture resembles small intestinal villi. Histology of tubular adenoma of colon is shown in Fig. 6.10.
- **Treatment:** Endoscopic resection of the colorectal adenoma cures the patient.

Pleomorphic Adenoma of Salivary Gland

Pleomorphic adenoma is most common benign triphasic salivary gland tumor in children and adults. Diagnosis can be rendered on preoperative fine needle aspiration cytology (FNAC) and biopsy, showing metachromatic fibrillary stroma on cytologis examination or triphasic growth pattern on histologic examination of biopsy. Tumor is composed of epithelial (ductal) cells, myoepithelial cells and chondromyxoid stroma.

- **Clinical features:** Pleomorphic adenoma originates from major salivary glands, i.e. parotid gland (85%), submandibular gland, sublingual gland, and minor salivary glands of upper aerodigestive tract. Patient presents with slow-growing, painless and well-circumscribed mass involving major/minor salivary gland.
- **Gross morphology:** Pleomorphic adenoma of salivary gland is well-demarcated, bosselated and gray-white myxoid mass. Recurrent tumor after surgical excision shows numerous myxoid to fibrotic nodules of variable size, giving a shotgun appearance.
- **Histologic examination:** Pleomorphic adenoma of salivary gland has three components: (a) epithelial (ductal) component is forming the inner layer of tubules and cysts, (b) myoepithelial cells are lining the outer layer of tubules and cysts and scattered within the myxoid stroma, which can be spindle shape, stellate shape, epithelioid or clear morphology, and (c) stromal component is typically myxoid, chondroid or myxochondroid, hyalinized or fibrotic.
  - **Metaplastic changes** can be observed, i.e. adipose metaplasia, osseous metaplasia, squamous metaplasia (sometimes with keratinization), sebaceous metaplasia and mucinous metaplasia.
  - **Intravascular permeation** has been reported in small percentage of cases following surgical intervention. Histology of pleomorphic adenoma of salivary gland is shown in Fig. 6.11.

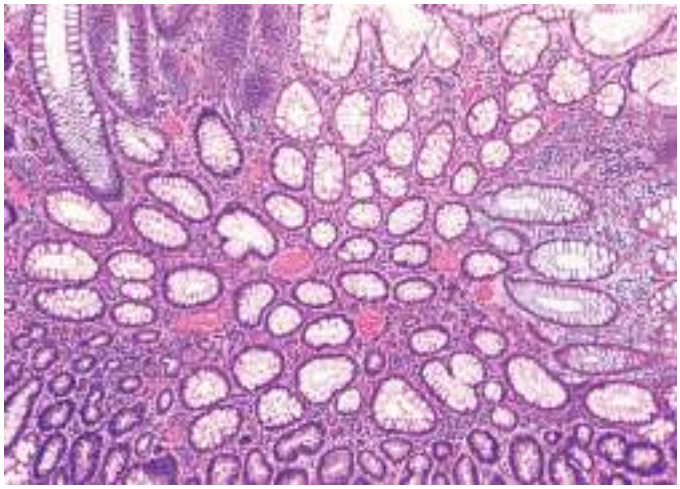

Fig. 6.10: Histology of tubular adenoma of colon. It shows closely packed tubular glands lined by mucus-secreting columnar epithelium (100X).

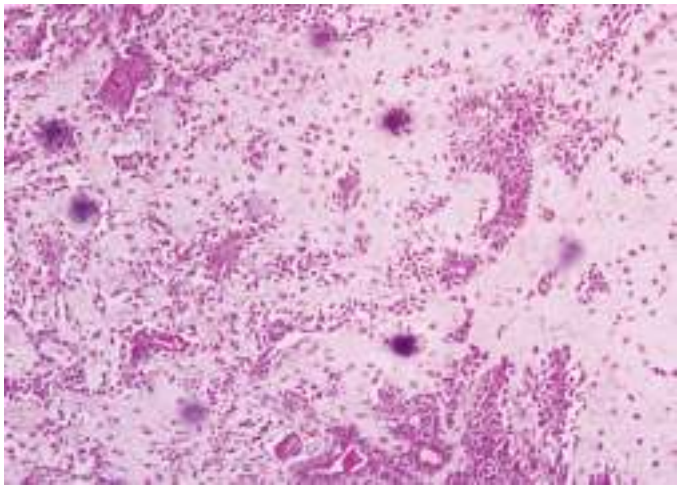

Fig. 6.11: Histology of pleomorphic adenoma of salivary gland. Tumor is composed of gland-like epithelial component surrounded by a myxomatous stroma often containing foci of bone or cartilage (100X).

- **Treatment:** Complete surgical resection of pleomorphic adenoma of salivary gland with negative margin is considered curative. Recurrences are common after incomplete surgical excision. Rarely, on surgical intervention, pleomorphic adenoma may metastasize to distant organs such as bone, sphenoid bone, central nervous system, kidney, liver, lung, lymph node, maxilla, pharynx, and skin. Tumor has benign morphology in primary site as well as metastatic site.

Follicular Thyroid Adenoma

Follicular thyroid adenoma is benign tumor that shows evidence of follicular differentiation, but lacks features of malignancy, and without capsular and vascular invasion.

- **Clinical features:** Patient presents with long-standing solitary thyroid nodule. Patient is most often euthyroid.
- **Gross morphology:** Tumor is solitary, encapsulated and variable size (1–10 cm) with solid fleshy, tan or light brown on cut surface. It is important to exclude malignancy because thyroid carcinoma mimics adenoma.
- **Histologic examination:** Tumor is completely encapsulated by thin capsule and architecturally and cytologically different from surrounding thyroid gland tissue and shows signs of compression. Tumor is composed of closely packed thyroid follicles. Tumor can demonstrate normofollicular, macrofollicular, microfollicular or trabecular/solid sheet patterns.
- **Treatment:** Surgical excision of follicular thyroid adenoma cures the patients.

Parathyroid Adenoma

Most cases of parathyroid adenoma are sporadic. Predisposing factors include radiation exposure and long-term lithium therapy. Parathyroid adenoma may be associated with multiple endocrine neoplasia [MEN-1 (most common), MEN-2A and MEN-2B] and hyperparathyroidism jaw tumor syndrome (HRPT2 gene germline mutation).

- **Clinical features:** Patient presents with symptoms related to hypercalcemia such as nephrolithiasis, osteopenia, osteitis fibrosa cystica, weakness, fatigue and psychiatric disturbances. Blood tests should be done to check the levels of parathormone, calcium, phosphorus and vitamin D. Ultrasonography, CT, MRI and technetium 99 sestamibi scintigraphy (99mTc) are performed to detect parathyroid adenoma.
- **Gross morphology:** Tumor size varies from few mm to more than 10 cm. Cut surface of tumor is solid yellow/tan, and well-circumscribed ovoid nodule without invasion into adjacent structures.
- **Histologic examination:** On histologic examination, tumor is composed of chief cells with round nucleus and granular cytoplasm.
- **Treatment:** Surgical excision of parathyroid adenoma cures the patients.

Pituitary Adenoma

Pituitary adenomas are benign tumors located in the anterior lobe of pituitary gland (i.e. pituitary cell lineage—somatotroph, lactotroph, thyrotroph, corticotroph, gonadotroph and null cell). Abnormal levels of certain hormones may indicate a specific pituitary gland-related syndrome.

- **Clinical features:** Some pituitary adenomas secrete one or more hormones in excess that affect body functions. The symptoms of pituitary adenoma may include headache, vision disturbances, weight gain, easy bleeding/bruising, change in bone structure in the face and hands, menstrual irregularity, lactation and erectile dysfunction.
- **Histologic examination:** Pituitary adenoma is composed of cells with moderate dense or granular cytoplasm, uniform nucleus with stippled chromatin and inconspicuous nucleoli.
- **Biochemical assays:** Blood and urine tests detect abnormal levels of hormones such as growth hormone (GF), prolactin (PRL), insulin-like growth factor 1 (IGF-1), free thyroxine, cortisol and testosterone.
- **Treatment:** Surgical excision of lactating pituitary adenoma cures the patients.

Lactating Adenoma of Breast

Lactating adenoma is well-circumscribed mass in breast in pregnant women and during postpartum period. Tumor may develop in ectopic breast tissue along milk-line extending from axilla to vulva.

- **Clinical features:** Patient presents with slow-growing, painless, soft and mobile discrete. Infarction may lead to pain, tenderness and rapid enlargement.
- **Gross morphology:** Tumor is well-circumscribed, lobulated, solitary or multiple that lacks a true capsule. Cut surface reveals firm/rubbery, gray tan mass usually <5 mm in size.
- **Histologic examination:** Lactating adenoma is composed of cuboidal cells or hobnail-shaped cells with small round nuclei and clear to granular vacuolated cytoplasm, and actively secreting closely packed glands and myoepithelial cell layers separated by thin, delicate connective tissue.
- **Treatment:** Surgical excision of lactating adenoma cures the patients.

Ovarian Cystadenomas

Ovarian cystadenomas are benign epithelial tumors, which vary in size and carry an excellent prognosis.

Ovarian serous and mucinous cystadenomas are most frequent types, whereas endometrioid, clear cell and seromucinous cystadenomas are rare. Despite advances in imaging studies (pelvic ultrasonography, computed tomography, magnetic resonance tomography), definite diagnosis of ovarian cystadenoma is established by histologic examination of surgical specimens.

- **Gross morphology: Serous cystadenoma** ranges in size from 1–30 cm, has smooth external surface and contains thin-walled unilocular/multilocular cysts filled with clear watery fluid. **Mucinous cystadenoma** has smooth external surface and contains thin-walled multilocular cysts filled with mucinous fluid. **Endometrioid cystadenoma** ranges in size from 1–15 cm and is filled with dark brown chocolate hemorrhagic fluid. **Clear cell cystadenoma** ranges in size from 3–15 cm, and has smooth, lobulated external surface. **Seromucinous cystadenoma** is a unilocular cyst with a smooth external surface and may contain serous or mucinous fluid.
- **Histologic examination:** Ovarian cystadenomas are benign tumors lined by epithelial cells with/without minimal cytologic atypia, which carry excellent prognosis. Histologic variants of ovarian cystadenomas include serous cystadenoma, mucinous, endometrioid cystadenoma, clear cell cystadenoma and seromucinous cystadenoma.
- **Treatment:** The management of ovarian cystadenomas depends on symptoms, size of the cystadenoma, age of the patients, clinical history, menopausal status of patient. Unilateral salpingo-oophorectomy or ovarian cystectomy is the adequate treatment of ovarian cystadenomas.

BENIGN MESENCHYMAL TUMORS

Benign mesenchymal tumors are derived from mesoderm and named based on their tissue of origin (e.g. lipoma, fibroma, leiomyoma, benign vascular tumors, rhabdomyoma, chondroma, and osteoma). They are slow-growing, well-circumscribed, encapsulated, resembling to tissue of origin, and most often confined to their site of origin, which neither invade surrounding tissues nor metastasize to distant organ(s). It is worth mentioning that following surgical intervention, tumor cells from leiomyoma and cardiac myxoma may enter blood circulation and reach distant sites. Benign mesenchymal tumors are composed of mature connective tissues, which tend to compress surrounding tissues resulting in clinical manifestations.

Lipoma

Lipomas are most common benign mesenchymal tumors derived from adipocytes that present as soft painless subcutaneous nodules anywhere in the body, i.e. subcutaneous, shoulders, buttocks, proximal extremities, abdominal region, and deep-seated region (intramuscular, parosteal, visceral), where normal adipocytes are present. Subcutaneous lipomas are not usually fixed to the underlying fascia. That is why the fibrous capsule should be surgically removed completely to prevent its recurrence. Lipomas very rarely arise from the viscera.

- **Predisposing factors:** Multiple lipomas are present in 5–10% of affected patients in the settings of familial lipomatosis or genetic disorders (e.g. familial multiple lipomatosis, Gardner syndrome, multiple endocrine neoplasia type 1, Cowden syndrome, Bannayan-Riley-Ruvalcaba syndrome, benign symmetric lipomatosis, Proteus syndrome, and Dercum disease).
- **Gross morphology:** Tumor is well-circumscribed, and rounded/lobulated mass that compresses the surrounding tissues. Cut surface reveals homogenous and yellow appearance of <5 cm in size. Surgical specimen of lipoma is shown in Fig. 6.12.
- **Histologic examination:** Tumor is composed of mature, normal-appearing adipocytes with a small eccentric nucleus intermixed among thin fibrous septa containing blood vessels. Lipoma must be carefully distinguished from low-grade liposarcoma. Histology of lipoma is shown in Fig. 6.13.
- **Treatment:** Most lipomas are removed by surgical excision. Recurrences after removal of lipomas are uncommon. Liposuction treatment uses a syringe and needle to remove the fatty tissue.

Uterine Leiomyoma

Leiomyoma (fibroid) is the most common benign tumor of the uterus, usually arising in women of reproductive age. Tumor originates from smooth muscle cells of

Fig. 6.12: Surgical specimen of lipoma. Tumor is encapsulated varying in size. Cut surface shows yellow and translucent adipose tissue.

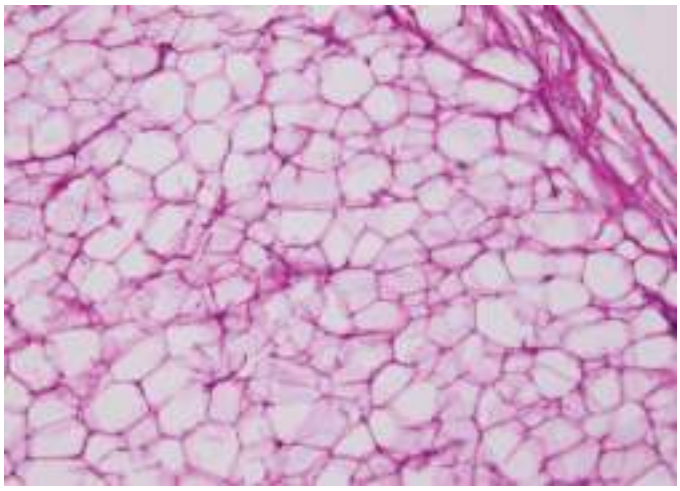

Fig. 6.13: Histology of lipoma Tumor is indistinguishable from normal adipose tissue. Tumor is composed of lobules of well-differentiated unremarkable adipocytes with inconspicuous eccentrically located nuclei intermixed among thin fibrous septa containing blood vessels (400X).

Fig. 6.14: Surgical specimen of uterine leiomyomas. Leiomyoma is a benign mesenchymal tumor derived from smooth muscle and located in the uterus: intramural, submucosal and subserosal. Tumors are most often multiple, well-circumscribed and nonencapsulated. Cut surface of leiomyomas in uterus reveals white or tan-white whorled, firm and bulging above surface.

the myometrium in the uterine corpus (intramural, submucous and subserous regions), cervix and uterine ligaments. Tumor can cause painful menstruation and infertility. Majority of leiomyomas are present within wall (intramural), but some are pedunculated and present in submucosal and subserosal region.

- **Pathogenesis:** Ovarian steroid hormones play key role in the pathogenesis of uterine leiomyomas. Estradiol and progesterone induce mature smooth muscle cells to release mitogenic factors, which stimulate adjacent immature smooth cells leading to uterine leiomyoma with undifferentiated cells that support neoplastic process. Tumor most often regresses after the menopause as a result of decreased estrogens.
- **Molecular/cytogenetic alterations:** Leiomyoma shows chromosomal abnormalities of 12q, 7q and 6p resulting in rearrangement of genes.
- **Clinical features:** Symptoms depend on the size and location of leiomyoma. Patient can present with heavy menstrual bleeding, pelvic pain, frequency of micturition, difficulty in emptying urinary bladder infertility, and backache.
- **Gross morphology:** Tumors are discrete, firm, pale gray, sharply circumscribed and varying in size without encapsulation. Cut section of leiomyoma reveals whorled pattern reflecting the fact that tumor is composed of smooth muscle bundles. Secondary changes in large leiomyomas include yellow-brown to red softening (red cystic degeneration), atrophy, hyaline degeneration, cystic degeneration, fatty change, dystrophic calcification, and chondroid/osteoid metaplasia. Surgical specimen of uterine leiomyomas is shown in Fig. 6.14.
- **Histologic examination:** Tumor is composed of smooth muscle cells arranged in whorled fashion, that resembles the uninvolved myometrium. Individual smooth muscle cells are uniform in size and shape containing oval nucleus and long slender bipolar cytoplasmic processes. Bipolar mitotic figures are sparse in leiomyoma. Histologic examination of uterine leiomyoma is shown in Fig. 6.15.
- **Histologic variants:** Histologic variants of leiomyoma include cellular leiomyoma, leiomyoma with bizarre nuclei, mitotically active leiomyoma, hydropic leiomyoma, apoplectic leiomyoma, lipomatous

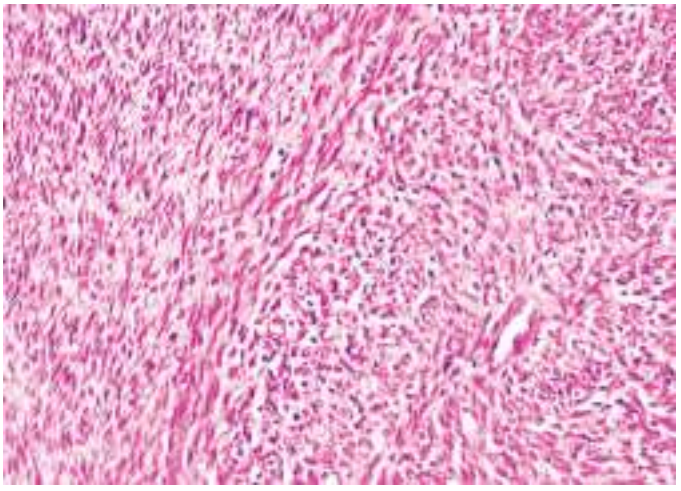

Fig. 6.15: Histology of uterine leiomyoma. Normal myometrium is at the left, and the neoplasm is well-differentiated so that the leiomyoma at the right hardly appears different. Bundles of smooth muscle are interlacing in the tumor mass (400X).

leiomyoma (lipolieomyoma), epithelioid leiomyoma, myxoid leiomyoma, dissecting (cotyledon-like) leiomyoma, diffuse leiomyomatosis leiomyoma, intravenous leiomyoma and metastasizing leiomyoma.

- **Immunohistochemistry:** Neoplastic cells of leiomyoma are immunoreactive with smooth muscle actin (SMA), desmin, muscle specific actin (MSA), h-caldesmon, smooth muscle myosin heavy chain (SMMHC) and estrogen/progesterone receptors.
- **Treatment:** Treatment options for uterine leiomyoma are uterine artery embolization, radiofrequency ablation, laparoscopic or robotic myomectomy, and hysteroscopic myomectomy.

Vascular Tumors

Benign vascular tumors are composed of circumscribed proliferation of predominantly small capillary-sized blood vessels. These are most common tumors of childhood and infancy located in the superficial region of head and neck. Hemangioma most often occurs in infants. Tumors are rare in deep visceral and skeletal regions. Recent studies revealed that benign vascular tumors result from endothelial proliferation with uncontrolled angiogenesis and abnormal function of downstream HIF1A,VEGF and PI3K/AKT signal transduction pathways.

- **Clinical features:** Symptoms and signs depend on size of tumor and its anatomic site. Tumor may compress surrounding structures and cause symptoms in patients. Hemangioblastoma in the brain may cause balance problems, headache, nausea or vomiting. Spinal hemangioblastoma may cause constipation, bowel and urinary incontinence, numbness and muscle weakness.
- **Gross morphology:** Deep-seated vascular tumors are well circumscribed and solid to cystic with dilated blood vessels with/without thrombus formation. Tumor may be polypoid with a stalk. Hemangioblastoma is well-circumscribed, lobulated, gray to brown and solid and cystic mass surrounded by a pseudocapsule.
- **Histologic examination: Capillary hemangioma** consists of capillary-sized vascular channels filled with blood/thrombi separated by scant connective tissue stroma, and lined by single layer of flattened endothelial cells. Histology of capillary hemangioma is shown in Fig. 6.16.
  - Cavernous hemangioma shows predominantly ectatic vascular channels in the dermis and subdermis in pediatric age group during first year of life.
  - Glomeruloid hemangioma resembles glomerular capillaries.

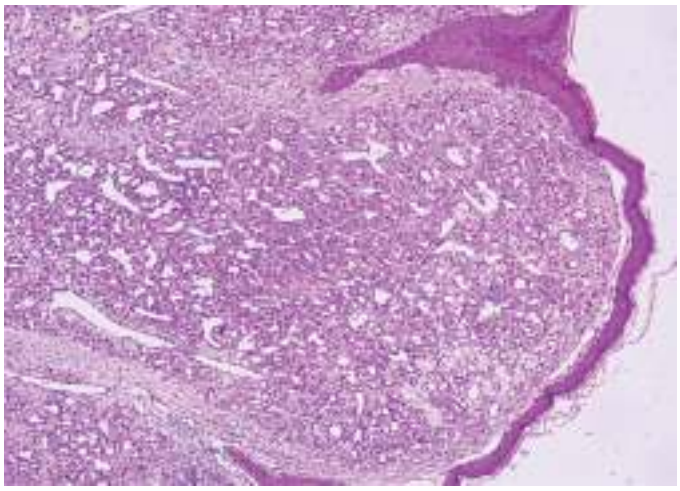

Fig. 6.16: Histology of capillary hemangioma. Capillary hemangioma is composed of closely packed aggregated of thin-walled capillaries filled with blood and lined by single layer of bland endothelial cells (400X).

  - Hemangioblastoma originates from the cells in the lining of the blood vessels of cerebellum, brainstem, spinal cord or retina of adults. Tumor occurring in the setting of von-Hippel-Lindau (vHL) disease in 20–25% of cases is composed of neoplastic stromal cells with mild nuclear pleomorphism, clear cytoplasm and lipid containing vacuoles arranged between numerous thin-walled small blood vessels.
- **Immunohistochemistry:** Immunohistochemical markers for vascular differentiation include CD31, CD34, D2–40 (podoplanin), factor VIII and vWF, *Ulex europaeus*, CD141 and Fli-1.
- **Treatment:** Microsurgical excision of benign vascular tumor using a surgical microscope and fine operating tools cures the patients.

Chondroma

A chondroma is benign tumor of mature hyaline cartilage within medullary cavity, periosteum and soft tissue. Chondroma arises in the region of metaphysis within medullary cavity of the tubular bones of hands and feet, which grows slowly, causes gradual expansion of the bone and can induce pain and pathologic fracture. Less commonly, parosteal chondroma can occur in the long bones, i.e. humerus and femur in children and adults. Rarely, multiple enchondromas occur in the settings of Ollier disease or Maffucci syndrome in children and associated with deformity.

- **Gross morphology:** Tumor has pale blue and glassy appearance due to presence of hyaline cartilage.
- **Histologic examination:** Tumor is lobulated and hypocellular and composed of mononuclear chondrocytes with inconspicuous small nuclei, and arranged in clusters with abundant intercellular

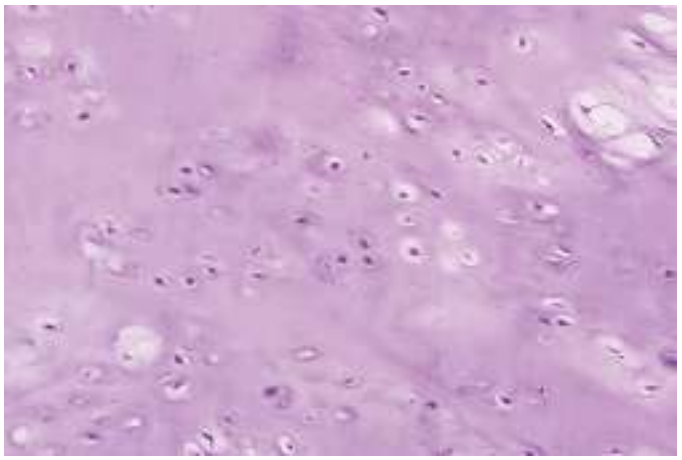

Fig. 6.17: Histologic examination of chondroma. Tumors are composed of well-differentiated hyaline cartilage. Chondrocytes contain small round nuclei with condensed chromatin. These are situated within sharp-edged lacunar spaces (100X).

hyaline cartilaginous matrix. Histologic examination of chondroma is shown in Fig. 6.17.

- **Treatment:** Surgical excision of chondroma cures the patients.

Osteoma

Osteoma is a benign bone forming tumor and composed of mature cortical type or less frequently, trabecular bone. Tumor occurs on the surface of craniofacial skeleton (i.e. paranasal sinuses, orbit, nasal cavity, jaw bones, cranial vault), and rarely it may occur in the long bones. Osteoma is relatively of small size but may produce severe symptoms because of its situation.

- **Gross morphology:** Gross examination reveals well-circumscribed solitary, oval, round or polypoid tumor attached to the underlying bone and cut surface with dense compact bone or trabecular bone.
- **Histologic examination:** Tumor consists of admixture or mature and woven bone patterns with Haversian-like canals with typical cortical type bone architecture that lacks cellular atypia.
- **Treatment:** Surgical excision of osteoma cures the patients.

BORDERLINE TUMORS

Borderline tumors of ovary have low-malignant potential defined histologically by atypical proliferation of cells without stromal invasion in 20–40 years old women, which account for 14–15% of all primary ovarian neoplasms. Examples of borderline ovarian neoplasms include serous tumor (K-RAS mutation), mucinous tumor (K-RAS mutation), endometrioid tumor (β-catenin, PTEN mutation), clear cell tumor and transitional cell tumor (Brenner tumor). Gene mutations in borderline ovarian tumors are given in Table 6.12.

Table 6.12 Gene mutations in borderline ovarian tumors

Histologic Variants	Gene Mutations
Borderline serous ovarian tumor	▪ RAS gene (67%) ▪ BRAF gene (67%)
Borderline mucinous ovarian tumor	RAS gene (>60%)
Borderline endometrioid ovarian tumor	▪ β-catenin (>50%), loss of heterozygosity ▪ PTEN gene (20%) ▪ Microsatellite instability (13%)
Borderline clear cell ovarian tumor	▪ K-RAS gene (5–16%) ▪ Microsatellite instability (13–50%)

- **Serous borderline tumor of ovary:** Borderline serous tumor of ovary most often affects women of 20–50 years of age. It is associated with regional lymphadenopathy and peritoneal 'implants' reflecting 'multifocal origin' rather than metastasis. Tumor shows nuclear atypia and increased mitotic activity and confined to the ovary without stromal invasion. Tumor cells are positive for S-100 calcium binding protein. Prognosis is excellent after surgical excision. Histology of serous borderline tumor of ovary is shown in Fig. 6.18.
- **Mucinous borderline tumor of ovary:** Borderline mucinous tumor of ovary most often affects younger women (mean age 45 years). Tumor is associated with implants (invasive in some cases) in abdomen or pelvic region. K-RAS gene mutation is observed in 60% of cases. It is important to establish a diagnosis by exclusion of metastatic adenocarcinoma of gastrointestinal tract by immunohistochemistry technique using a cytokeratin panel.

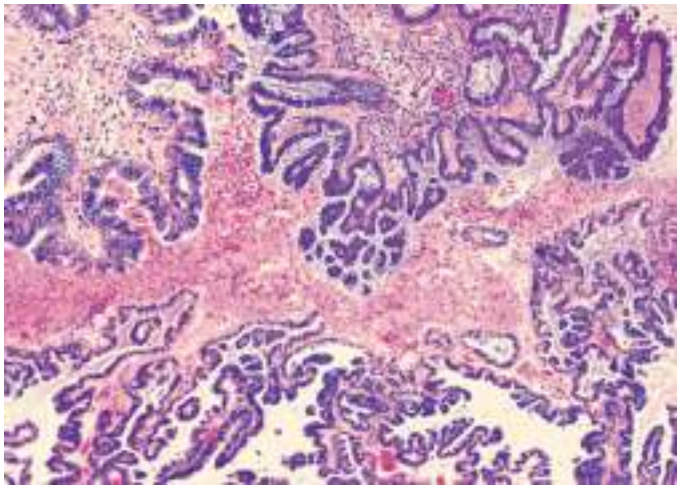

Fig. 6.18: Histology of serous borderline tumor of ovary. Tumor shows varying degree of nuclear atypia and increased mitotic activity confined to epithelium. There is no invasion of stroma by tumor cells (100X).

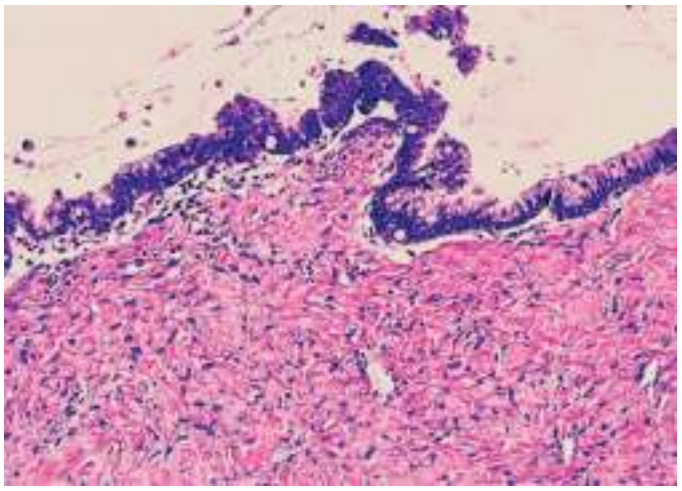

Fig. 6.19: Histology of mucinous borderline tumor of ovary. Tumor shows varying degree of nuclear atypia and increased mitotic activity confined to epithelium. There is no invasion of stroma by tumor cells (100X).

- **Histologic variants:** Borderline mucinous tumor of ovary has distinct histologic variants: intestinal (90%) and endocervical (10%) subtypes. Intestinal subtype coexists with pseudomyxoma peritonei in 70% of cases. The Müllerian subtype—mucinous borderline tumor of ovary is bilateral in up to 40% of cases and may coexist with ipsilateral ovarian or pelvic endometriosis in 20–30% of cases.
- **Histologic examination:** Borderline mucinous tumor of ovary has complex architecture with tufting and villus histology that shows low-grade dysplasia, and mitosis without stromal invasion. Histology of mucinous borderline tumor of ovary is shown in Fig. 6.19.

- **Endometrioid borderline tumor of ovary:** Borderline endometrioid tumor of ovary is characterized by mutations involving the β-catenin gene (50%), PTEN gene (20%) and microsatellite instability (up to 50%). The tumor has potential to progress to low-grade invasive endometrioid carcinoma. Endometriosis and endometrioid adenofibroma serve as precursors of borderline endometrioid ovarian tumor.

MALIGNANT EPITHELIAL TUMORS

Like benign epithelial tumors, carcinomas can arise from squamous epithelium (skin, mouth, esophagus and vagina, as well regions of squamous metaplasia in bronchi or squamocolumnar junction of the uterine cervix) or glandular epithelium (ducts, acini), epithelium (e.g. stomach, colon, lung, breast, endometrium, ovary, pancreas, and prostate), and transitional epithelium (renal pelvis, ureter and urinary bladder). Adenocarcinoma may exhibit acinar, solid, papillary, micropapillary, lepidic with preserved alveolar structure and mucin-secreting (mucinous) patterns. Carcinomas can be further subclassified according to their ability to invade, clinical behavior based on histologic grading of cellular differentiation. Tissue sites of more common histologic types of carcinomas are given in Table 6.13.

- **Rate of growth of malignant epithelial tumors.** Benign epithelial tumors tend to grow slower, whereas malignant epithelial tumors tend to grow more quickly, most often at a rate corresponding to their degree of anaplasia. Growth fraction refers to the proportion of CSCs in the proliferative phase. At the point when most malignant tumors are clinically detected, the growth fraction is less than

Table 6.13 Tissue sites of more common histologic types of carcinomas

Squamous Cell Carcinoma in Tissue Sites
▪ Squamous cell carcinoma of skin
▪ Squamous cell carcinoma of nasal cavity
▪ Squamous cell carcinoma in oropharynx
▪ Squamous cell carcinoma in larynx
▪ Squamous cell lung carcinoma
▪ Squamous cell carcinoma of esophagus
▪ Squamous cell carcinoma of cervix
Adenocarcinoma in Tissue Sites
▪ Breast adenocarcinoma
▪ Esophageal adenocarcinoma in the setting of Barrett's esophagus
▪ Gastric adenocarcinoma
▪ Colorectal adenocarcinoma
▪ Pancreatic adenocarcinoma
▪ Prostatic adenocarcinoma
▪ Endometrial adenocarcinoma
▪ Ovarian adenocarcinoma
▪ Lung adenocarcinoma
Transitional Cell Carcinoma
▪ Transitional cell carcinoma of renal pelvis
▪ Transitional cell carcinoma of ureter
▪ Transitional cell carcinoma of urinary bladder
▪ Transitional cell carcinoma of urethra
Clear Cell carcinoma
▪ Renal cell carcinoma, clear cell variant
▪ Clear cell carcinoma of vagina in daughter [associated with diethylstilbestrol (DES) administration to mother]
Other Type of Carcinomas
▪ Small cell lung carcinoma
▪ Large cell lung carcinoma
▪ Hepatocellular carcinoma
▪ Gastric signet cell carcinoma (linitis plastica)

The epithelia of the body are derived from all three germ cell layers: ectoderm, mesoderm and endoderm. Squamous cell carcinoma of skin arises from ectoderm. Gastrointestinal adenocarcinoma arises endoderm. Renal cell carcinoma and connective tissue sarcoma originates from mesoderm.

20% (i.e. most malignant tumors have their most rapid rate of growth prior to detection).

- **Tumor invasion and metastasis:** Histologic features and rate of growth alone cannot distinguish between benign and malignant tumors. Invasion and metastasis to distant organs are indicators of malignancy, which can distinguish malignant tumors from benign tumors. Malignant tumors are rapidly growing, poorly circumscribed, and invade and destroy surrounding normal tissues, grow quickly and metastasize via lymphatic route to draining lymph nodes, via hematogenous route to distant organ(s) and via transcoelomic route to peritoneum. The metastases spawned by malignant tumors are responsible for almost all deaths from cancer.
  - **Preferential routes of metastasis:** Carcinomas usually metastasize via lymphatic route to draining lymph nodes and via hematogenous route to distant organs (i.e. liver, lungs, bones, brain and adrenal glands).
  - **Rarely metastasizing tumors:** Few organs such as heart, skeletal muscle and spleen do not allow tumor metastasis to grow due to anatomical consideration. Basal cell carcinoma of skin rarely metastasizes.
  - **Non-metastatic malignant tumors:** Some malignant tumors do not metastasize (e.g. gliomas and basal cell carcinoma of skin), but they do invade. Overall, 30% of malignant solid tumors have metastases to distant organ(s) at the time they are clinically detected.
  - **Metastases of solid tumors:** Approximately 30% of newly diagnosed patients with solid tumors (except squamous cell carcinoma of skin and melanoma) most often present with clinically evident metastases. An additional 20% of cases have occult (hidden) metastases at the time of diagnosis.
- **Clinical features:** Malignant epithelial tumors can cause bleeding from ulcerated growth, tissue destruction, obstruction of blood flow in vital organs, and cachexia (severe weight loss and reduction in skeletal muscle mass) and production of tumor specific products/hormones. Poor prognostic factors for carcinomas include large tumor size, deep invasion, perineural invasion, lymphovascular invasion, poor differentiation and immunosuppression.
- **Gross morphologic features:** Desmoplasia refers to the proliferation of non-neoplastic connective tissue in malignant tumor that gives the tumor a firm, fibrous with 'scirrhous appearance' in the settings of infiltrating duct carcinoma of breast (scirrhous type), diffuse type gastric carcinoma (linitis plastica), pancreatic adenocarcinoma and prostatic adenocarcinoma.
  - **Tumor stroma:** Malignant epithelial tumors synthesize growth factors that induce formation of stromal supporting architecture upon which tumors can grow.
  - **Tumor angiogenesis:** Vascularity in malignant epithelial tumors results from elaboration of angiogenic factors that promote angiogenesis. Malignant epithelial tumors must establish a blood supply for their growth. Blood vessels are leaky hence cut surface of malignant epithelial tumor may reveal areas of hemorrhage.
  - **Tumor necrosis:** Necrosis is common in malignant epithelial tumors because CSCs function poorly and cannot maintain their architecture or blood supply or metabolic demands. Necrosis becomes more likely as the size of malignant epithelial tumor increases in size and undergoes dedifferentiation.
- **Tumor invasion assessment on histologic examination:** *Dysplasia* is disordered growth of epithelium with loss of cellular uniformity and architectural orientation that covers the spectrum of changes short of invasive carcinoma in some cases: mild dysplasia, moderate dysplasia and severe dysplasia/carcinoma *in situ*. Dysplasia can be reversible, if inciting agent is removed.
  - Carcinoma *in situ* (intraepithelial neoplasia) involves full-thickness severe dysplasia of the epithelium without invading through the basement membrane. It is frequently observed in the cervix uteri at the junction of ectocervix and endocervix.
  - Microinvasive carcinoma refers to stromal invasion <5 mm beneath the basement membrane without evidence of lymphatic or vascular involvement.
  - Early invasive carcinoma refers to invasion through the basement membrane and surrounding tissue through the action of proteolytic enzymes and detachment of CSCs resulting from lack of surface adhesion molecules such as E-cadherin.
  - Advanced invasive carcinoma disseminates via lymphatic route to draining lymph nodes, blood vessels via hematogenous route (liver, lungs, brain and bone) and via transcoelomic route within peritoneal cavity (Krukenberg tumor of ovary from breast carcinoma, gastric carcinoma and colon carcinoma).
- **Cytomorphologic features:** Histologic features of malignant epithelial tumors include: pleomorphism (variation in nuclear and cytoplasmic shape between cells), increased abnormal tripolar or quadripolar mitotic figures, hyperchromasia (increased nuclear basophilia) and hypercellularity, with loss of normal polarity.

- **Differentiation:** Differentiation is defined how histologically a malignant epithelial tumor closely resembles the structure of normal tissue. Differentiation is used for histologic grading system, which is different for each type of malignant epithelial tumor such as well-moderate-poor differentiation (anaplasia).
- **Pleomorphism:** CSCs often exhibit pleomorphism (i.e. variation in size and shape). Anaplastic tumors contain multinucleated giant tumor cells. Some tumor giant cells contain a single huge polymorphic hyperchromatic nucleus, while other tumor giant cells contain two or more bizarre nuclei.
- **Abnormal nuclear morphology:** Malignant epithelial cells (i.e. CSCs) generally have nuclei, prominent and increased nucleocytoplasmic ratio that approaches 1:1 instead of the normal 1:4 or 1:6.
- **Hypercellularity and loss of polarity:** Normal cells are anchored and oriented to the basement membrane. On contrary, anaplastic cells lose this uniform orientation and grow in a disorganized fashion.
- **Hyperchromasia:** CSCs exhibit hyperchromatism and increased basophilia of the nucleus. Chromatin condensation occurs during the G2/S phase of the cell cycle.

- **Anaplasia:** Anaplasia refers to dedifferentiation (i.e. loss of structural and functional differentiation) of cells during carcinogenesis that is considered a molecular hallmark of cancer.
  - Anaplastic cells appear primitive (undifferentiated) and lack specialization along with a particular tissue cell line of origin.
  - Anaplastic tumor is composed of pleomorphic cells with bizarre hyperchromatic nuclei, abnormal nuclear contours, prominent nucleoli with nucleus to cytoplasmic ratio approaching 1:1, cellular dyspolarity, tumor giant cells with two or more bizarre nuclei. Numerous bizarre tripolar or quadripolar mitotic figures are indicative of proliferative activity in parenchymal cells with increase in number of chromosomes and DNA content (aneuploidy). Anaplastic cells exhibit dark staining on light microscopy in hematoxylin and eosin-stained tissue sections.
  - It is worth mentioning that nuclei in the normal epithelial cells are oriented along the basement membrane, whereas nuclei in anaplastic cells exhibit loss of polarity of nuclei away from basement membrane growing in an anarchic disorganized fashion.
  - Anaplastic tumors are rapidly growing, invading and destroying surrounding normal tissue and metastasizing to distant organ(s). However, extent of metastasis of tumor is used for clinical staging.
- **Atypical mitotic figures:** Atypical mitotic figure (tripolar or quadripolar) count is an important microscopic parameter in tumor classification and prognosis in several human malignancies. Chromatin condensation occurs during the G2/S phase of the cell cycle. Bipolar mitotic figures are demonstrated in proliferating cells in normal bone marrow, intestinal cells, hepatocytes; certain benign tumors and some low-grade malignant tumors, and non-neoplastic proliferations. Counting mitotic figures in hematoxylin and eosin-stained histologic sections are an integral part of the grading system for assessment of prognosis and clinical decisions.
- **Immunohistochemistry:** Panel of immunohistochemical markers are used to diagnose epithelial tissue-derived carcinomas. Immunohistochemical markers on such epithelial-derived malignant tumors can yield conflicting results.
- **Electron microscopy:** Carcinomas exhibit reduced adhesion molecules, free ribosomes, simplification of rough endoplasmic reticulum, pleomorphic mitochondria, and disruption of cytoskeleton (microfilaments, microtubules and intermediate filaments).
  - Classification of pleomorphic malignancies is frequently difficult and important with regard to treatment.
  - Their histologic differential diagnosis is usually wide including sarcomatoid carcinoma, melanoma, anaplastic lymphoma and sarcomas with overlapping histologic appearances (e.g. high-grade fibrosarcoma, myxofibrosarcoma, pleomorphic sarcoma, pleomorphic leiomyosarcoma, pleomorphic rhabdomyosarcoma).
  - In such cases, electron microscopy provides valuable diagnostic subcellular features that indicate a specific line of differentiation.
- **Grading system:** Grading of tumors is based on degree of differentiation, nuclear pleomorphism, size of nucleoli and mitotic activity (atypical tripolar or quadripolar). Well-differentiated carcinoma looks very similar to normal tissue. Moderately-differentiated carcinoma looks something like normal tissue. Poorly-differentiated carcinoma (anaplasia) virtually has no resemblance to normal tissues.
- **Staging system:** Size and spread of malignant tumors determine the stage. *In situ* carcinoma refers to epithelium-derived malignant tumors confined to just the epithelium without invading the basement membrane.
  - **Microinvasion:** Microinvasion refers to spread of malignant epithelial tumor just beyond the point of origin through the basement membrane.

- **Local invasion:** Local invasion refers to spread of malignant epithelial tumor within the organ of origin or contiguous structures.
- **Local spread:** Local spread refers to non-contiguous spread of the malignant epithelial tumor via lymphatic route to draining lymph nodes.
- **Distant metastasis:** Distant metastasis refers to spread of malignant epithelial tumor to distant organ(s) via hematogenous route far away from draining lymph nodes.

Squamous Cell Carcinoma in Various Tissues

Squamous cell carcinoma is a malignant epithelial tumor that begins in the thin and flat squamous epithelium in the tissues. Squamous epithelium forms the surface of the skin, the lining of the hollow organs of the body, and the lining of the respiratory tract (nasal cavity, larynx, lung) and digestive tracts (oropharynx, esophagus), and uterine cervix.

Majority of the squamous cell carcinoma cases occur in various anatomic sites: skin, digestive tract (oropharynx, esophagus), respiratory tract (nasal cavity, lung) and uterine cervix.

Squamous Cell Carcinoma of Skin

Squamous cell carcinoma of skin most often occurs in sun-exposed anatomic sites (e.g. scalp, ear, lip, nose, eyelid) that displays variable degrees of differentiation and cytological features. Well-differentiated squamous cell carcinoma grows slowly. In contrast, poorly-differentiated squamous cell carcinoma spreads early via lymphatic route to draining lymph nodes.

- **Predisposing factors:** Predisposing factors for squamous cell carcinoma of skin are ultraviolet radiation, tobacco smoking, chewing tobacco, marijuana, betel nuts and pan (India), actinic keratosis, xeroderma pigmentosum, chronic skin ulcer, and discharging sinus tract. Epstein-Barr virus is demonstrated in all oral cancers.
- **Pathogenesis:** Cutaneous squamous cell carcinoma develops through a multistep process. Ultraviolet radiation, gene mutations (TP53, CDKN2A, TERT, EGFR, NOTCH1, NOTCH2) and molecular pathways (RAS/RAF/MEK/ERK and PI3K/AKT/mTOR) play important role in its pathogenesis.
- **Gross morphology:** Tumor is most often hyperkeratotic scaly plaque, that may exhibit induration, ulceration and hemorrhage.
- **Histologic examination:** Tumor is composed of cells arranged in irregular strands and columns. CSCs invade basement membrane and underlying connective tissue. Grading of the tumor is based on degree of differentiation and keratinization.
  - Well-differentiated squamous cell carcinoma of skin is slow growing tumor that looks very similar to normal tissue and composed of solid nests of polygonal-shaped cells with distinct borders, intercellular bridges, and pink keratinized cytoplasm. Histology of well-differentiated squamous cell carcinoma of skin is shown in Fig. 6.20.
  - Moderately-differentiated squamous cell carcinoma of skin is composed of uniform cells with indistinct borders arranged in irregular nests, cords and sheets, focal keratinization and atypical mitotic figures.
  - Poorly-differentiated carcinoma (anaplastic carcinoma) of skin virtually has no resemblance to normal tissues. Tumor is composed of small cells with scanty cytoplasm and hyperchromatic nuclei arranged in small nests, cords, sheets and single cells, rare or lack of keratinization and brisk atypical mitotic figures.

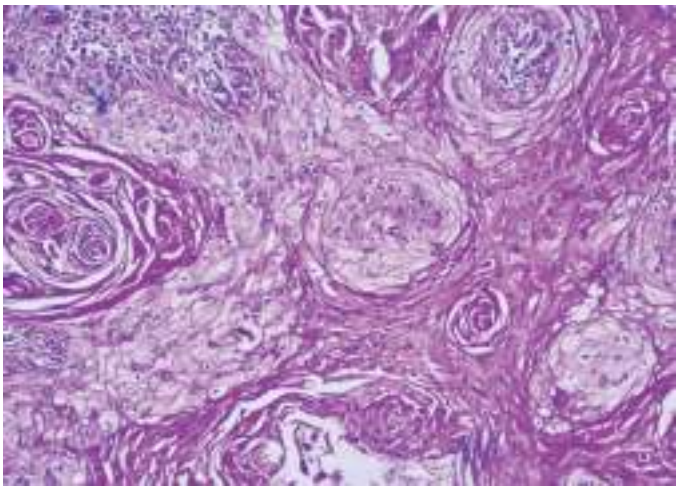

Fig. 6.20: Histology of well-differentiated squamous cell carcinoma of skin. Tumor is composed of solid nests of polygonal-shaped cells with distinct borders, intercellular bridges, pink keratinized cytoplasm and keratin formation (400X).

- **Immunohistochemistry:** Immunohistochemistry technique is usually essential to confirm the diagnosis and exclude melanoma, sarcoma, poorly-differentiated and undifferentiated squamous cell carcinoma. Immunohistochemical markers for squamous epithelial tissue differentiation include cytokeratins, i.e. CK9, CK10, CK11, CK16, CK17 (HMWCK), and epithelial membrane antigen (EMA).
- **Treatment:** Treatment options for high-risk squamous cell carcinoma of skin are Mohs surgery, surgical excision with adequate margins, curettage, electrodessication, radiation therapy; and immunotherapy if inoperable.

Squamous Cell Carcinoma of Oral Cavity and Tongue

About 95% of oral cavity cancers are squamous cell carcinoma. Tumor most often occurs in the floor of mouth, tongue, hard palate, base of tongue.

- **Predisposing factors:** Predisposing factors for squamous cell carcinoma in the region of oral cavity include alcohol consumption, tobacco smoking, tobacco chewing, marijuana, betel nuts and pan (India), Epstein-Barr virus and HPV 6, 8, 11 (10%).
- **Clinical features:** Patient presents with leukoplakia or mass with necrosis, ulcer and rolled border and induration specific for invasive tumor. Tumor spreads locally and via hematogenous route metastasizes to lung, liver, bone and mediastinum.
- **Histologic examination:** Histologic examination reveals verrucoid growth pattern but moderate/marked atypia at base, irregular and infiltrative stromal invasion.

Squamous Cell Carcinoma of Cervix

Squamous cell carcinoma of cervix is most common neoplasm in 40–55 years old women associated with high-risk human papillomavirus (HPV 16, 18), which arises from a precursor lesion at the squamous-columnar junction of the cervix. Grading of cervical squamous cell carcinoma is based on degree of differentiation, nuclear pleomorphism, size of nucleoli, mitotic activity and necrosis and does not correlate with prognosis. Lymphovascular invasion may be present.

- **Predisposing factors:** Predisposing factors are sexual activity with multiple partners, sexual contact with human papillomavirus 16, 18, 31,33 or 45, tobacco smoking, oral contraceptive use and immunosuppression. Steps in evolution of cervical squamous cell carcinoma include: cervical intraepithelial neoplasia (CIN-I, -II, -III), microinvasion, early invasion and advanced invasion stage.
- **Pathogenesis:** Human papillomavirus (HPV 16, 18, 31) encodes E6 and E7 oncoproteins, which bind to p53 and pRB respectively and interfere with normal functions of the tumor suppressors. HPV-E6 oncoprotein induces proteolytic degradation of p53 protein via ubiquitination pathway leading to deregulation of cell cycle, unrestricted cell proliferation and cervical carcinoma. HPV-E7 oncoprotein induces inactivation of pRB that results in overexpression of p16 tumor suppressor protein involved in cell cycle regulation by inhibiting cyclin-dependent kinases (CDKs). The p16 is a surrogative immunomarker for high-risk HPV infection.
- **Clinical features:** Patient in advanced disease presents with abnormal persistent bleeding or spotting between menstrual cycles or postcoital bleeding and pain, pelvic pain, foul smelling vaginal discharge (saprophytic infection), vaginal leakage of stool or urine from a fistula, anorexia, cachexia, weight loss and anemia.
- **Gross morphology:** Tumor is red, friable, indurated, or ulcerated lesion in early stage. Later, tumor is exophytic, nodular, papillary, polypoidal or ulcerated or invasive mass invading into surrounding structures.
- **Histologic examination:** Squamous cell carcinoma of cervix accounts for 80–90% of cases. Grading is based on degree of differentiation and keratinization. Tumor can be well-, moderately-, poorly-differentiated. Tumor is composed of mature atypical squamous cells with abundant keratin pearls, occasional well-developed intercellular bridges, minimal pleomorphism, minimal mitotic activity. Histology of well-differentiated squamous cell carcinoma of cervix is shown in Fig. 6.21. Histologic variants of cervical carcinoma are keratinizing, nonkeratinizing, papillary, basaloid, warty, verrucous, squamotransitional, lymphoepithelial-like and spindled/sarcomatoid.
- **Immunohistochemistry:** Immunohistochemistry technique is usually essential to confirm the diagnosis of poorly differentiated and undifferentiated squamous cell carcinoma. Immunohistochemical markers for cervical carcinoma include HPV, p16, Ki-67, pankeratin (CK5/CK6), AE1/AE3, CEA, p63, CD10, CD146, inhibin and β-hCG.
- **Treatment:** Cervical carcinoma is treated by radical hysterectomy and removal of pelvic lymph nodes with or without radiation to the pelvis, plus chemotherapy.

Squamous Cell Lung Carcinoma

Squamous cell lung carcinoma (SCLC) often occurs in the central region of the lung in the left or right bronchus. Staging is based on CT scan images according to the TNM (tumor-node-metastasis) staging system.

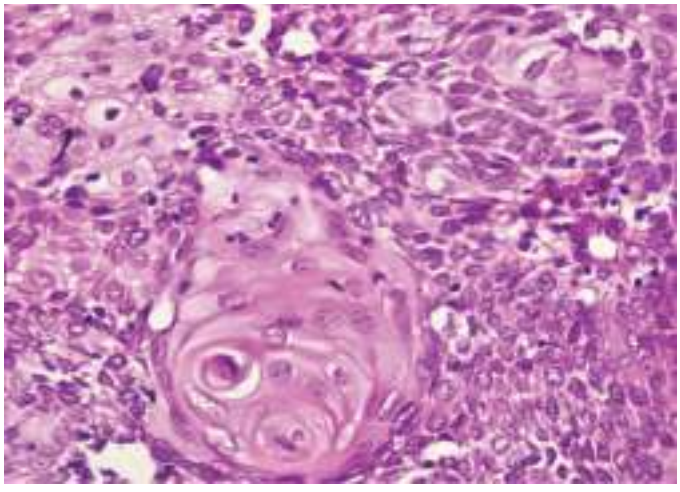

Fig. 6.21: Histology of well-differentiated squamous cell carcinoma of cervix. Tumor is composed of mature squamous cells with abundant keratin pearls, occasional well-developed intercellular bridges, minimal pleomorphism, minimal mitotic activity (400X).

- **Predisposing factors:** Predisposing factors of SCLC are tobacco smoking, exposure to radon gas, asbestos, uranium, arsenic, vinyl chloride, nickel chromates, coal products, mustard gas, chloromethyl ethers, gasoline and diesel exhaust.
- **Clinical features:** Symptoms of SCLC are related to extent of disease, i.e. cough, chest pain, shortness of breath, hemoptysis, wheezing, hoarseness, recurring chest infections, loss of appetite, weight loss, and weakness. Tumor invades adjoining structures, metastasizes via lymphatic route to regional lymph nodes and via hematogenous route to distant organ(s) because of constant flow of lymph and blood through the lungs. Advanced disease can cause bone pain, spinal cord impingement and neurological symptoms (i.e. headache, weakness or numbness of limbs, dizziness, seizures).
- **Gross morphology:** Bronchus exhibits fungating growth towards lumen extending in adjacent structures. Surgical specimen of squamous cell lung carcinoma is shown in Fig. 6.22.
- **Histologic examination:** Squamous cell lung carcinoma is categorized into well, moderately and poorly differentiated, based on amount of keratinization present in predominant component. Histology of well-differentiated squamous cell lung carcinoma is shown in Fig. 6.23.
- **Immunohistochemistry:** Tumor cells in SCLC are positive for p63, CK5/CK6 (85–100%), epithelial membrane antigen (EMA) and thrombomodulin (85–100%). Other variably expressed immunomarkers are CD15, carcinoembryonic antigen (CEA), HPV, p53, p40, S-100 and mesothelin.

Fig. 6.22: Surgical specimen of squamous cell lung carcinoma. Patient presents with six months history of dysphagia to solids, nausea, weight loss, recent hemoptysis and onset of hoarseness of voice. He has history of chronic cigarette smoking. Chest auscultation reveals diminished breath sounds over right lung fields. Chest radiograph reveals a 8 cm hilar mass on the right. Laboratory studies show serum calcium 15 mg/dl (normal 8.5–10.5 mg/dl).

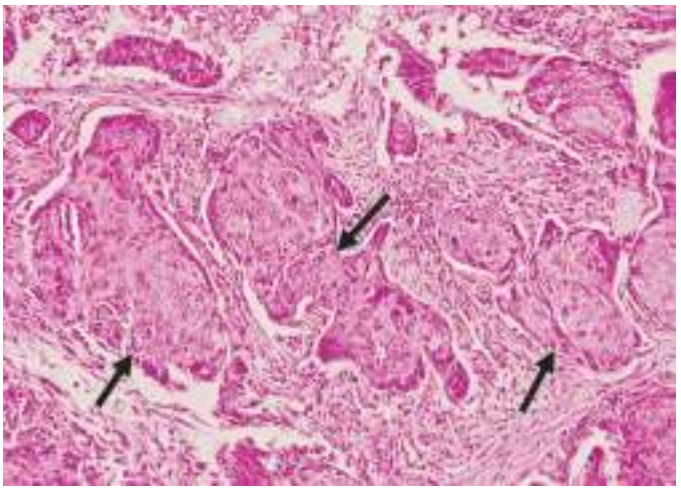

Fig. 6.23: Histology of well-differentiated squamous cell lung carcinoma. Tumor is composed of polygonal tumor cells with pink cytoplasm with distinct cell borders, intercellular bridges, hyperchromatic angular nuclei and many abnormal mitoses (arrows) (400X).

- **Laboratory diagnosis:** Diagnostic modalities for squamous cell lung carcinoma include bronchoscopy, imaging techniques, fine needle aspiration cytology, histologic examination, immunohistochemistry, and molecular testing (PD-L1, EGFR, ALK fusion oncogene and gene mutations).
- **Treatment:** Approved treatment options for squamous cell lung carcinoma include surgery, radiation therapy, chemotherapy, angiogenesis inhibitors and immunotherapy.

Adenocarcinoma in Various Tissues

Adenocarcinoma is a malignant epithelial tumor that begins in the glandular tissue, which lines certain internal organs and makes and releases substances in the body such as mucus, digestive juices and other fluids. Most adenocarcinomas occur in various anatomic sites, i.e. breast, esophagus (in the setting of Barrett's esophagus), stomach, colon, rectum, pancreas, lung, prostate, ovary (surface epithelium-derived) and uterine endometrium.

Breast Ductal Adenocarcinoma

Breast ductal adenocarcinoma arises from epithelial component cells of breast in terminal duct lobular unit (TDLU) or in axilla accessory breast tissue. *In situ* ductal carcinoma of breast does not invade the normal breast tissue, however has significant potential to become invasive carcinoma, that is the reason, *in situ* ductal carcinoma must be adequately treated to prevent the patient from developing invasive ductal adenocarcinoma of breast. CSCs of invasive ductal adenocarcinoma invade tissues outside the normal breast lobules and ducts to grow into underline connective tissue, which has potential to metastasize to draining

lymph nodes and distant organ(s). About 75–80% of breast carcinomas are invasive ductal adenocarcinoma, followed by invasive lobular carcinomas, which account for 10–15% of cases.

- **Predisposing factors:** Most studies have revealed that hormones, reproductive factors, dietary factors and genetic factors increase risk of development of breast carcinoma, which include: (a) prolonged exposure to estrogen in the settings of early menarche, late menopause, nulliparity, post-menopausal women with obesity and estrogen producing ovarian tumors, hormonal replacement therapy, (b) genetic risk factors include familial clustering of breast cancer (BRCA1/BRCA2 germline mutations), Li-Fraumeni syndrome, Cowden disease, heterogenous career for ataxia-telangiectasia, (c) environmental risk factors include obesity, alcohol consumption, and lack of exercise, and (d) other risk factors include atypical proliferative breast disease, carcinoma of endometrium and opposite breast and increased mammographic density.
- **Clinical features:** Patient may present with unifocal palpable lump in the upper outer quadrant of breast, change in the size or shape of the breast, nipple retraction, nipple discharge, change in the color or texture of the skin. In screened populations, mammography reveals as a spiculated mass, architectural distortion with or without calcifications.
- **Gross morphology:** Gross examination may reveal evident tumor nodular mass with an irregular stellate outline/poorly circumscribed mass, firm to hard in consistency on cut surface. On cut surface, tumor may show streaks of chalky white elastic stroma penetrating surrounding stroma (crab-like) and calcification. Large tumor shows areas of hemorrhage and necrosis.
- **Histologic examination:** Histologic grading of breast ductal adenocarcinoma is based on the Nottingham/modified Bloom & Richardson Score: tubule formation, i.e. >75% (1 point), 10–75% (2 points), <10% (3 points); nuclear pleomorphism, i.e. small nuclei similar to normal ductal epithelial cells (1 point), moderate increase in nuclei (2 points), large pleomorphic nuclei (2 points), and mitotic count (1 to 3 points) depending on microscopic field area. Total score is calculated by adding points for tubule formation, nuclear pleomorphism and mitotic count: grade 1 (3–5 points), grade 2 (6–7 points), and grade 3 (8–9 points).
  - Histologic features of breast ductal carcinoma, not otherwise specified vary considerably from case to case. Architecture of tumor varies from sheets, nests, cords, individual cells, clusters with abundant eosinophilic, clear, foamy, granular cytoplasm and uniform to pleomorphic nuclei, but lacks cytomorphologic features of invasive lobular carcinoma of breast.
  - Tubule formations are prominent in well-differentiated breast ductal adenocarcinoma, but absent in poorly differentiated tumors.
  - Mitotic figures are variable from virtually absent to extensive in these tumors. Calcification with variable necrosis is demonstrated in 60% of cases. Perineural invasion is demonstrated in 28% of cases. Histology of breast invasive ductal adenocarcinoma is shown in Fig. 6.24.
- **Laboratory diagnosis:** Screening of patients is done by imaging techniques (mammography, targeted ultrasonography, magnetic resonance imaging), clinical history, clinical examination, fine needle aspiration cytology, surgical specimen examination (gross morphological features, histologic examination and immunohistochemistry), flow cytometry (DNA ploidy), serum tumor markers (CA 15-3, CA 27-29, BRCA, mammaglobin, gross cystic fluid protein 15) and fluorescence *in situ* hybridization technique.
- **Immunohistochemistry:** Breast ductal adenocarcinoma shows positivity for ER/PR (50%), GCDFP (50), mammaglobin (50%), HER2/neu (50%), Ki-67, p53 (poor prognostic marker), CK7 and GATA3.
- **Treatment:** Breast ductal adenocarcinoma is treated by surgical excision, i.e. breast conserving surgery (lumpectomy), mastectomy, with or without axillary lymph node dissection. Patient is given local radiotherapy after lumpectomy or chest wall after mastectomy to reduce local recurrence risk. Systemic chemotherapeutic drugs can be administered in these patients. Selection of treatment is based on tumor size, histologic grade, stage, biomarker status

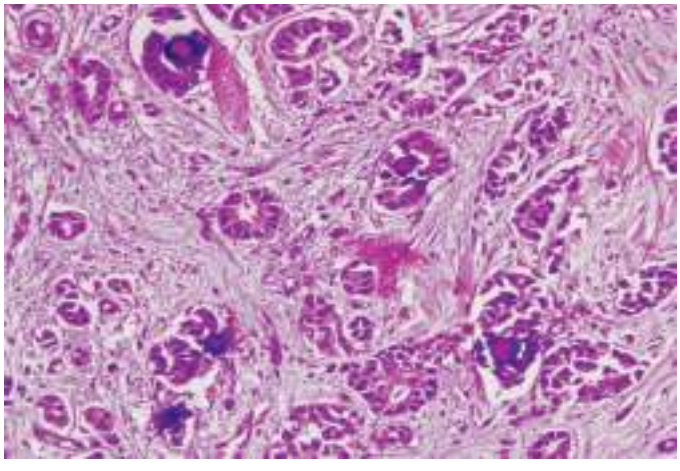

Fig. 6.24: Histology of breast invasive ductal adenocarcinoma. Tumor is composed of atypical pleomorphic cells with hyperchromatic nuclei and arranged in glandular structures, clusters, and sheets invading surrounding connective tissue stroma of breast (400X).

(estrogen receptor, progesterone receptor, HER2/neu status), results of genomic risk assessment (e.g. oncotype DX recurrence Score®, anatomic location, patient's age and heritable breast cancer risk (e.g. BRCA status), prior exposure to chemotherapy or radiation therapy, cosmetic outcome and patient's preference.

Colorectal Adenocarcinoma

More than 90% of colorectal carcinomas are originating from the epithelial cells of the colorectal mucosa of sigmoid colon, ascending colon, transverse colon, descending colon, and cecum. Tumor is detected on colonoscopy and confirmed on histologic examination.

- **Predisposing factors:** Predisposing factors of colorectal adenocarcinoma include inherited polyposis syndromes, Lynch syndrome also known as hereditary nonpolyposis colorectal cancer (HNPCC), inflammatory bowel disease, low-fiber and high-fat diet, red meat consumption, tobacco smoking and radiation therapy applied at abdomen.
- **Molecular genetic alterations:** Colorectal adenocarcinoma arises through chromosomal instability pathway (70–80%) or microsatellite instability pathway (10%). Most commonly mutated genes are APC, TP53 and K-RAS in colorectal adenocarcinoma. Tumor can be screened for microsatellite instability by immunohistochemistry technique to analyze MLH1, MSH2, MSH6 and PMS2. Stage of the disease is the most important prognostic factor.
- **Clinical features:** Right-sided colorectal adenocarcinoma causes rectal bleeding, anemia, weakness, constipation, unexplained weight loss and fatigue. Left-sided colorectal adenocarcinoma causes persistent change in bowel habits (constipation or diarrhea). Poor prognostic factors are positive margins of tumor, advanced stage, higher grade, lymphovascular and perineural invasion, CDX2 loss and high stromal content.
- **Gross morphology:** Tumor in the right colon appears polypoid or fungating or cauliflower-like mass. On the contrary, tumor in rectosigmoid region shows annular lesion that produces "napkin-ring" appearance. Surgical specimen of colon carcinoma is shown in Fig. 6.25.
- **Histologic examination:** Colorectal adenocarcinoma is usually well-differentiated (15–20%) or moderately differentiated (60–70%) or poorly differentiated. Neoplastic glands are often cribriform and filled with necrotic debris in both primary and metastatic sites. Marked desmoplasia is present at the edge of the tumor.
  - Well-differentiated tumor is composed of well-formed glandular structures with uniform, basally oriented nuclei that resemble adenomatous epithelium.
  - Moderately-differentiated tumor is composed of simple or slightly irregular glandular structures.
  - Poorly-differentiated tumor consists of sheets of cells without formation of glandular structures usually in right-sided. Histology of colorectal adenocarcinoma is shown in Fig. 6.26.
- **Immunohistochemistry:** Colorectal adenocarcinoma is positive for immunohistochemical markers CK20, CDX2, CEA, villin, CDX2 and β-catenin.
- **Poor prognostic factors:** Poor prognostic factors of colorectal carcinoma include tumor with positive margins, advanced stage, higher-grade, lymphovascular and perineural invasion, CDX2 loss and high stromal component.

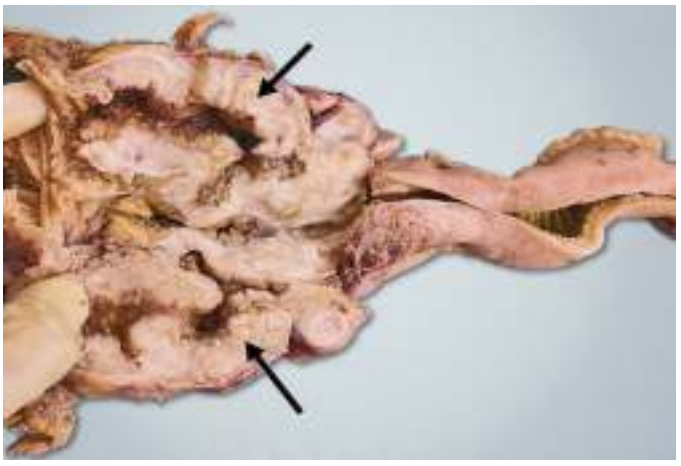

Fig. 6.25: Surgical specimen of colon carcinoma. Cut opened caecum shows fungating and ulcerated growth within lumen. Tumor is gray white firm with areas of hemorrhage and necrosis (arrows). (*Courtesy:* Dr. Sujata Kanetkar, Professor and Head, Department of Pathology, Krishna Institute of Medical Sciences, Krar, Maharashtra.)

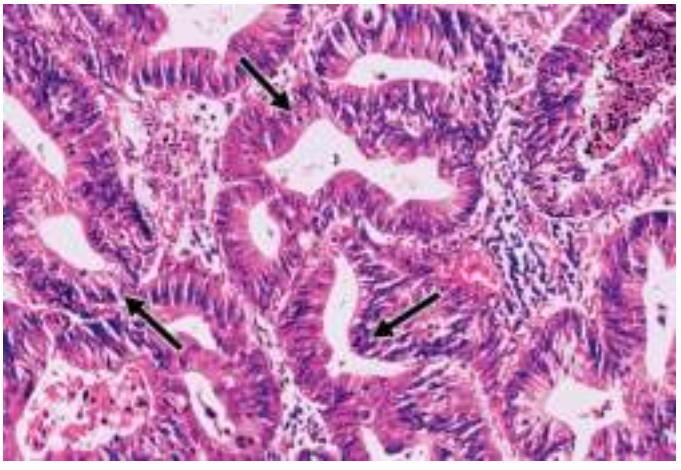

Fig. 6.26: Histology of colorectal adenocarcinoma. Tumor is composed of irregularly distributed tubular cribriform structures with abundant intracytoplasmic pool of mucin in 50% of the tumor area, and intraluminal necrosis in a desmoplastic stroma (arrows) (400X).

- **Treatment:** Patients are treated by combination of surgery, radiation therapy, which can be used to slow the spread of disease.

Intestinal Type of Gastric Adenocarcinoma

Intestinal type of gastric adenocarcinoma is a bulky tumor that can be divided into early and advanced gastric carcinoma. Early intestinal type of gastric adenocarcinoma is defined as invasive gastric adenocarcinoma confined to mucosa and/or submucosa, with or without lymph node metastases irrespective of the tumor size. Tumor can be unifocal in majority of cases or multifocal in some cases. Advanced gastric adenocarcinoma invades the muscular coat or beyond and metastasizes to liver and lung and are associated with poor prognosis.

- **Predisposing factors:** Predisposing factors for intestinal type of gastric adenocarcinoma include *Helicobacter pylori* infection, mucosa-associated lymphoid tissue (MALT) lymphoma, adenomatous gastric polyps, previous partial gastrectomy, pernicious anemia, atrophic gastritis, intestinal metaplasia, exposure to nitrosamines from smoked foods, tobacco smoking and family history of cancer.
- **Clinical features:** Patient presents with epigastric fullness, vomiting and weight loss in advanced stage of gastric adenocarcinoma. Diagnosis is confirmed by esophagogastroduodenoscopy and biopsy. Imaging studies and laparoscopy aid in determining the caner stage. Consequently, staging system dictates the management approach.
- **Gross morphology:** Tumor is large, bulky or ulcerated with raised margins that preferentially involves the lesser curvature of stomach.
- **Histologic examination:** Tumor can demonstrate different histologic patterns such as tubular (grossly polypoidal/fungating growth), papillary (metastases in lymph nodes and liver), and mucinous (signet-ring cells floating in the abundant extracellular mucin pools, which constitute at least 50% of the tumor). Neoplastic intestinal glands resemble colonic adenocarcinoma, which contain apical mucin vacuoles. Tumor can be well-differentiated consisting of tubules with branching and anastomosing structures or poorly differentiated with solid sheets of neoplastic cells.
- **Treatment:** Stage II and III intestinal types of gastric adenocarcinoma are treated by total or subtotal gastrectomy followed by radiation therapy and chemotherapy.

Lung Adenocarcinoma

Lung adenocarcinoma is a type of non-small cell lung carcinoma, which most often occurs in non-smokers. Tumor shows glandular differentiation, mucin production or pneumocyte immunomarker expression. Tumor usually involves lungs (upper lobe > lower lobe, central > peripheral regions. Tumor invades surrounding tissues and metastasizes to brain, bone, liver and adrenal glands in decreased frequency.

- **Molecular/cytogenetic alterations:** Molecular/cytogenetic alterations in lung adenocarcinoma are EGFR mutation, ALK rearrangement, ROS1 gene fusions, RET fusion, HER2/neu amplification, BRAF mutation, NTRK mutation and SMARCA4 mutation.
- **Clinical features:** Patient presents productive cough, hemoptysis, dyspnea, weight loss and chest pain.
- **Gross morphology:** Tumor is well-defined but unencapsulated. Cut surface reveals tan-white that may have central scarring or necrosis.
- **Histologic examination:** Invasive lung adenocarcinoma has main two histologic patterns: mucinous (i.e. acinus, papillary, micropapillary, lepidic, solid) and non-mucinous. Tumor with mucinous histology is composed of glandular differentiation lined by columnar cells with abundant mucin. Tumor-grade is dependent on combination of histologic patterns.
- **Immunohistochemistry:** Neoplastic cells of lung adenocarcinoma are positive for immunohistochemical markers, cytokeratin 7, epithelial membrane antigen (EMA), napsin A, TTF-1, CEA, B72.3, Ber-Ep4 and CD15 (Leu).
- **Electron microscopy:** Tumor cells have short microvilli and reprogrammed cytoskeleton network that aids in the progression, survival, growth, invasion and dissemination to various organs.
- **Treatment:** Treatment of lung adenocarcinoma depends on stage. Tumor without invasion is treated by surgical resection and adjuvant radiation therapy. Inoperable invasive or metastatic tumor is molecular dependent chemotherapy and radiation.

Transitional Cell Carcinoma in Tissues

Transitional cell carcinoma is a malignant tumor derived from urothelial cells (also called transitional cells) that line urethra, urinary bladder, and renal pelvis. Urothelial cells can change shape and stretch without breaking apart.

Transitional Cell Carcinoma of Urinary Bladder

Transitional cell carcinoma (urothelial carcinoma) of urinary bladder arises from transitional epithelium of the urinary tract (e.g. renal pelvis, ureter, urinary bladder).

- **Predisposing factors:** Predisposing factors include tobacco smoking, occupational exposure to β-naphthylamine, *Schistosoma haematobium* infestation, cyclophosphamide and analgesics, radiation

therapy done for cancers of cervix, prostate, or colorectal region, and exstrophy of the urinary bladder (absence of the anterior part of the urinary bladder and abdominal wall).

- **Molecular/cytogenetic alterations:** Mutations of TP53, PIK3CA, RB1 and FGF3 genes involved in cell cycle progression are demonstrated in transitional cell carcinoma of urinary bladder. Aneuploidy in chromosomes 3, 7 and 17 and loss of 9p21 locus is detected by fluorescent *in situ* hybridization (FISH) in majority of cases. Nuclear matric proteins (NMP22) and urinary bladder tumor antigen (BTA) produced by cancer cells are analyzed for surveillance and detection of transitional cell carcinoma of urinary bladder in majority of cases.
- **Clinical features:** Patient presents with hematuria, painful micturition, back pain, unexplained weight loss, and extreme fatigue.
- **Gross morphology:** Tumor ranges from subtle urinary bladder wall thickening, infiltrative, sessile to obvious exophytic fungating or ulcerated mass. Surgical specimen of urothelial carcinoma of urinary bladder is shown in Fig. 6.27.
- **Histologic examination:** Histologic characterization and depth of invasion are the most important factors for determining prognosis. Neoplastic cells are arranged in irregular nests or single cells invading the lamina propria and muscularis propria. High-grade urothelial carcinoma exhibits nuclear pleomorphism, hyperchromasia, high nuclear–cytoplasmic ratio with frequent atypical tripolar or quadripolar mitotic figures. Vascular invasion by cancer stem cells can be demonstrated. Histology of micropapillary urothelial carcinoma with vascular invasion of urinary bladder is shown in Fig. 6.28.
- **Immunohistochemistry:** Positive immunohistochemical markers for transitional cell carcinoma (urothelial carcinoma) are GATA (most sensitive marker), p63, thrombomodulin, uroplakin III, CK7 and CK20.
- **Treatment:** Transitional cell carcinoma of urinary bladder is treated by surgery, intravesical and systemic chemotherapy, radiation therapy, immunotherapy and targeted therapy.

Fig. 6.27: Surgical specimen of urothelial carcinoma of urinary bladder. Cut-opened specimen of urinary bladder shows exophytic, cauliflower-like, fungating growth that fills cavity with areas of hemorrhage (arrows). Macroscopic appearances range from subtle urinary bladder wall thickening to obvious exophytic mass. (*Courtesy:* Senior Professor and Head, Department of Pathology, Govt. Medical College, Srinagar, J&K.)

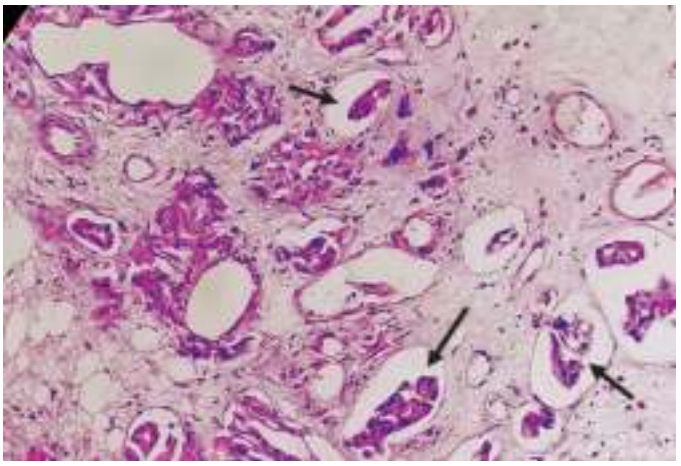

Fig. 6.28: Histology of micropapillary urothelial carcinoma with vascular invasion of urinary bladder. Tumor is composed of neoplastic cells arranged in nests with back-to-back pattern invading blood vessels (arrows) (400X) (*Courtesy:* Senior Professor and Head, Department of Pathology, Govt. Medical College, Srinagar, J&K.)

Clear Cell Carcinoma in Various Anatomic Sites

Clear cell carcinoma occurs most often in the kidney and female reproductive organs (e.g. vagina). Tumor is composed of clear cells when viewed under light microscope.

Renal Cell Carcinoma—Clear Cell Variant

Renal cell carcinoma—clear cell variant is solitary cortical mass that arises in the epithelial cells lining the proximal convoluted tubule in the renal cortex in sporadic tumor. Snake-like masses of tumor may involve the portal vein (35–80%), hepatic vein (20%) or inferior vena cava (similar to small cell lung carcinoma).

- **Predisposing factors:** Predisposing factors include cigarette smoking, obesity, hypertension, long-term hemodialysis and acquired adult cystic kidney disease.
- **Molecular/cytogenetic alterations:** Loss of the vHL protein function usually occurs by deletion or unbalanced transcription, resulting in chromosomal loss of 3p12–26. Second allele of vHL undergoes somatic mutation or epigenetic inactivation through hypermethylation. vHL protein loss

results in accumulation of hypoxia-inducible factor 1α (HIF-1α) that drives transcription of hypoxia-associated genes, including VEGF, PDGFB, GLUT1, TGF-α, erythropoietin and matrix metalloproteinases.

- **Clinical features:** Patient presents with anemia, gross hematuria, flank pain, abdominal mass, weight loss and fever. Classic triad of flank mass, pain and hematuria are present in <10% of cases.
- **Gross morphology:** Tumor is well-circumscribed, expansile in the renal cortex at poles. Cut surface shows golden yellow color due to high lipid content, variegated appearance (i.e. solid and cystic), fibrosis, hemorrhage and necrosis.
- **Histologic examination:** Tumor is composed of compact nests and sheets of cells with clear cytoplasm and distinct membrane arranged in solid, alveolar, acinar or microcystic patterns within delicate stroma. High-grade tumors demonstrate homogenous granular eosinophilic cytoplasm, eccentric nucleus and globular eosinophilic intracytoplasmic inclusions. Histology of renal cell carcinoma—clear cell variant is shown in Fig. 6.29.
- **Immunohistochemistry:** Renal cell carcinoma—clear cell variant is positive for immunomarkers CAIX, PAX8, PAX2, EMA, cytokeratin and vimentin.
- **Treatment:** Patients are managed by surgical resection, immunotherapy with checkpoint inhibitors, monoclonal antibodies against PD1, PDL1 and CTLA4; inhibitors of mammalian target of rapamycin (mTOR) pathways, and tyrosine kinase inhibitors targeting PDGFR and VEGFR.

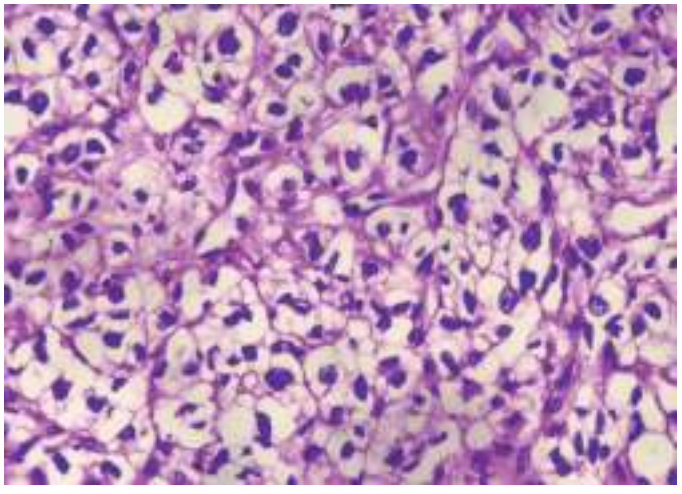

Fig. 6.29: Histology of renal cell carcinoma—clear cell variant. Tumor is composed of cells with clear cytoplasm and distinct membrane with clear to granular eosinophilic cytoplasm arranged in solid nests and sheets, alveolar, microcystic or occasional macrocystic architectural patterns. Presence of network of arborizing small thin-walled blood vessels is important diagnostic feature for cases with granular eosinophilic cytoplasm (400X). (*Courtesy:* Dr. Neha Kumari and Dr. Tushar Kalonia.)

Clear Cell Adenocarcinoma of Vagina

Clear cell adenocarcinoma of vagina develops in daughter due to maternal use of diethylstilbestrol (DES) during pregnancy. Tumor most often involves anterior vaginal wall. About 15–25% of patients remain asymptomatic. Lymphovascular spread involves lymph nodes, lung, peritoneum, omentum, ovary, liver and brain.

- **Pathogenesis:** Diethylstilbestrol (DES) causes persistence of Müllerian epithelium while inducing contact between epithelium and vaginal mesenchyme. Unopposed estrogen and obesity cause increase in the peripheral conversion of steroid hormones to estrone by the aromatase enzyme resulting in hyperestrogenic state.
- **Clinical features:** Patient presents with abnormal vaginal bleeding, malignant pericardial effusion and cardiac tamponade. Per vaginal examination reveals polypoidal and exophytic mass that originated from the anterior wall involving upper two-thirds of the vagina.
- **Gross morphology:** Tumor is superficially located as exophytic polypoidal mass that arises from the anterior wall involving upper two-thirds of vagina.
- **Histologic examination:** Tumor is composed of cuboidal cells with round to irregular hyperchromatic nuclei and conspicuous nucleoli arranged in cystic, tubular, papillary, glandular, and solid patterns. Sometimes, tumor cells contain hobnail type of nuclei protruding into the lumen.
- **Treatment:** Surgery is primary management for low-stage vaginal clear cell adenocarcinomas. Small tumors are managed by local excision, evaluation of retroperitoneal lymph nodes followed by local irradiation to the bed of tumor. Large tumors are treated by neoadjuvant chemotherapy and radiotherapy.

Other Histologic Types of Carcinomas

Other histologic types of carcinomas include diffuse gastric adenocarcinoma (linitis plastica) and conventional hepatocellular carcinoma (HCC).

Diffuse Gastric Carcinoma (Linitis Plastica)

Diffuse gastric adenocarcinoma is an aggressive tumor associated with poor prognosis. Tumor has signet-clear cell morphology, marked desmoplasia, rapid lymphovascular invasion, metastasis involving peritoneum and distant organ(s), and chemoresistance. Tumor can be seen in sporadic and familial (germline mutation in CDH1 gene encoding E-cadherin).

- **Molecular/cytogenetic alterations:** E-cadherin is a calcium-dependent adhesion molecule that

interacts with β-catenin to maintain the structure of epithelium. Germline mutation in E-cadherin gene (CDH1) results in familial diffuse gastric carcinoma (linitis plastica) at an early age.

- **Clinical features:** Patient presents with indigestion, nausea or vomiting, dysphagia, postprandial fullness, loss of appetite, melena, hematemesis and weight loss. Serum carcinoembryonic antigen (CEA) and CA 19-9 levels are elevated in many cases.
- **Gross morphology:** Prophylactic gastrectomy in early-stage disease may not demonstrate any visible lesion. Advanced stage tumor may present as thickening, ulceration or just rigid, leather-like stomach (linitis plastica) due to extensive infiltration by CSCs; that may cause pyloric obstruction. Endoscopy shows flat or depressed lesions with ill-defined border. It is worth mentioning that desmoplasia occurs in the settings of infiltrating duct carcinoma of breast (scirrhous type), diffuse type gastric carcinoma (linitis plastica), pancreatic adenocarcinoma and prostatic adenocarcinoma.
- **Histologic examination:** Tumor is composed of poorly-cohesive cells without well-formed glands that can be either signet-ring cells with a central optically clear, global droplet of cytoplasmic mucin with an eccentrically placed nuclei or differentiated cells, present as scattered individual cells or clusters. Histology of diffuse gastric carcinoma (linitis plastica) is shown in Fig. 6.30.
- **Treatment:** Treatment depends on the extent of the disease, which include surgery, chemotherapy, radiation therapy, chemoradiation, and targeted therapy.

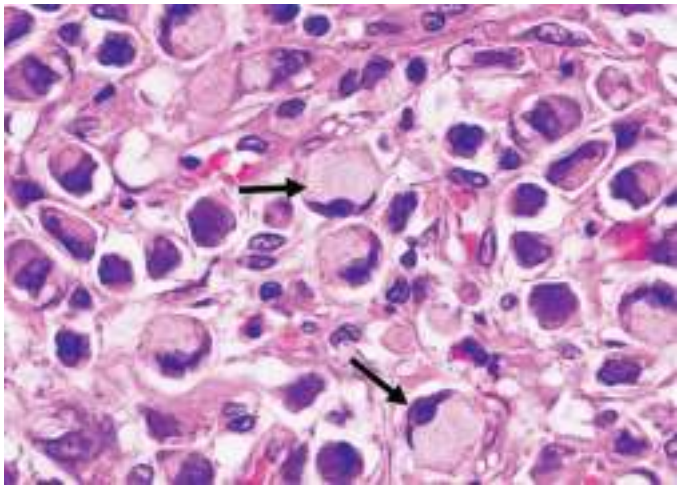

Fig. 6.30: Histology of diffuse gastric carcinoma (linitis plastica). Tumor is composed of poorly-cohesive cells without well-formed glands that can be either signet-ring cells with a central optically clear, global droplet of cytoplasmic mucin with an eccentrically placed nuclei or differentiated cells, present as scattered individual cells or clusters (arrows) (400X).

Conventional Hepatocellular Carcinoma

Conventional hepatocellular carcinoma (HCC) most common occurs in persons with liver disease due to HBV and HCV infection. Stepwise process of hepatocellular carcinoma (low-grade dysplastic nodule → high-grade nodule → early hepatocellular carcinoma → progressive hepatocellular carcinoma) is accompanied by accumulation of molecular alterations such as telomere shortening, TERT activation, cell cycle checkpoint inhibitor inactivation. TERT promoter mutation is a salient event in progression of hepatocellular carcinoma.

- **Predisposing factors:** Predisposing factors include chronic alcohol consumption, HBV and HCV infection, cirrhosis, diabetes mellitus or obesity-related nonalcoholic steatohepatitis (NASH). Other less prevalent risk factors include cirrhosis resulting from primary biliary cholangitis, hemochromatosis, α_1-antitrypsin deficiency and aflatoxin B1 produced by *Aspergillus flavus*. Aflatoxin B1 reacts with DNA to form mutagenic adducts, leading to codon 249 mutation of TP53 gene.
- **Clinical features:** Patient presents with abdominal pain, weight loss, jaundice, ascites, hepatomegaly and splenomegaly. Most metastatic sites in decreasing frequency include lung, portal vein, lymph nodes involvement in portal and abdominal regions.
- **Gross morphology:** Gross examination reveals well-circumscribed solitary mass or multiple discrete nodules that exhibits tan-yellow to green with areas of hemorrhage and necrosis. Background liver is usually cirrhotic.
- **Histologic examination:** Tumor is composed of polygonal cells with nuclear atypia, thick nuclear membrane, prominent nuclei, atypical tripolar or quadripolar mitoses, intracytoplasmic globular hyaline inclusions (Mallory-Denk bodies), and lack of portal triad. Tumor cells are arranged in trabecular (sinusoidal, plate-like) pattern with ≥3 cells much wider than normal liver plate thickness of two cells thick. Presence of sinusoidal vessels surrounding tumor cells is an important diagnostic factor. The reticulin framework is generally reduced or absent. Reticulin stain highlights the thickened hepatocyte plates (≥3 cells). Histology of conventional hepatocellular carcinoma is shown in Fig. 6.31.
- **Immunohistochemistry:** Conventional hepatocellular carcinoma is positive for immunohistochemical stains such as arginase 1, Hep Par 1 (hepatocyte paraffin 1), glypican 3, α_1-antitrypsin, AFP (α-fetoprotein), CEA (carcinoembryonic antigen) polyclonal, CAM 5.2 (CD8/CD18), des-gamma carboxyprothrombin (DCP protein induced by vitamin K absence or antagonist II/PIVKA-2), and TTF-1.

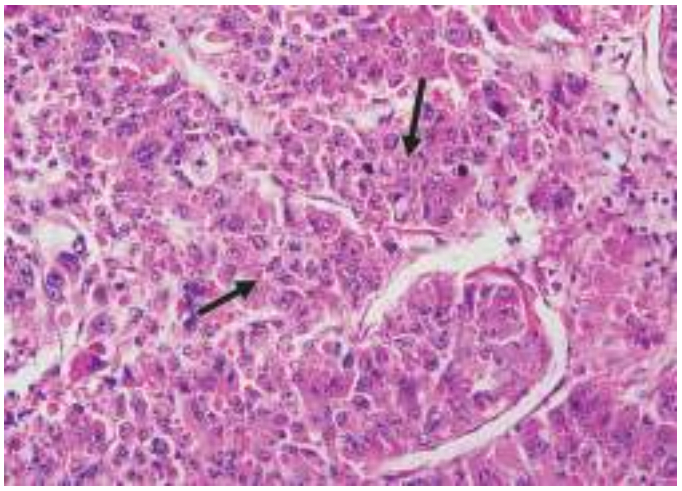

Fig.6.31: Histology of conventional hepatocellular carcinoma. Tumor is composed of liver cords that are much wider than the normal liver plate that is two cells thick. Tumor cells are arranged in trabeculae. There is no discernible normal lobular architecture, though vascular structures are present. It is associated with elevated α-fetoprotein (arrows) (400X).

- **Treatment:** Multiple treatment options are available for conventional hepatocellular carcinoma including curative surgical resection, liver transplantation, radiofrequency ablation, transarterial chemoembolization and systemic chemotherapy (i.e. sorafenib).

MALIGNANT MESENCHYMAL TUMORS

Sarcomas are malignant tumors derived from mesenchymal tissue (adipocyte, fibrous tissue cell, cartilage, bone, fascia, smooth muscle, skeletal muscle, blood vessels and mesothelium). Sarcomas are far less common than carcinomas. Tumors are composed of pleomorphic spindle-shaped cells admixed with supporting mesenchymal stroma and many large thin-walled blood vessels, which are easily invaded by mesenchymal CSCs. Blood-borne metastases to lung are common. In contrast, lymph node involvement is rare in most types of sarcoma. Many highly malignant sarcomas are so poorly differentiated that their specific histologic type cannot be determined. Immunohistochemistry technique, electron microscopy and cytogenetic analysis are helpful in establishing diagnosis by conventional histology alone. Malignant tumors arising from mesenchymal tissue are given in Table 6.14.

Table 6.14 Malignant tumors arising from mesenchymal tissue

Cell Lineage Forming Sarcoma	Malignant Tumor
Smooth muscle cell	Leiomyosarcoma
Striated/skeletal muscle cell	Rhabdomyosarcoma
Cartilage	Chondrosarcoma
Bone osteoblast	Osteosarcoma
Adipose tissue adipocytes	Liposarcoma
Fibrous tissue cell	Fibrosarcoma
Blood vessel endothelial cell	Angiosarcoma and Kaposi sarcoma

Conventional Osteosarcoma

Conventional intramedullary osteosarcoma is primary malignant tumor of bone in 10–20 years of age. Tumor involves long bones near proliferative plates around knee joint (distal end of femur or proximal end of tibia in 60%), hip bones (15%), proximal femur (10%), mandible (8%). Multifocal osteosarcoma may occur in the settings of Paget disease of the bone. Serum alkaline phosphatase is increased two- to three-fold.

- **Predisposing factors:** Predisposing factors for conventional osteosarcoma are giant cell tumor of bone, Li-Fraumeni syndrome (germline TP53 gene mutation), Diamond-Blackfan anemia, Werner syndrome, osteoblastoma, chondroblastoma, metallic and polyethylene implants, osteogenesis imperfecta, familial retinoblastoma, Ollier disease (enchondromatosis), Maffucci syndrome (enchondromatosis associated with hemangiomas), Rothmund-Thomson syndrome and occupational exposure to radium used in watch-dial.
- **Clinical features:** Patient presents with bone pain, swelling and tenderness near the affected region, pathological fracture, fatigue and unexplained weight loss.
- **Radiologic examination:** Tumor has intramedullary permeative growth that replaces medullary spaces and erodes native trabeculae, fills haversian systems, destroys cortex, and invades soft tissue. Serum alkaline phosphatase is increased two- to three-fold. Radiograph shows intramedullary invasive, destructive and blastic intraosseous mass, mineralization, periosteal reactions (sunburst appearance and Codman triangle), cortical permeation, and soft tissue invasion.
- **Gross morphology:** Tumor usually occurs in metaphysis with cortical permeation and soft tissue component that raises the periosteum. Cut surface reveals gritty and mineralized (hard), hemorrhage, necrosis and cystic areas that depends on histologic variant of tumor. Gross morphology of conventional intramedullary osteosarcoma of upper tibia is shown in Fig. 6.32.
- **Histologic examination:** Tumor is composed of pleomorphic neoplastic cells with hyperchromatic nuclei, mitotic figures, formation of variable amount of osteoid, collagen and mineralized bone matrix

Fig. 6.32: Surgical specimen of conventional intramedullary osteosarcoma. Cut section of the specimen shows intramedullary mass arising from the metaphyseal region of upper tibia, which is permeating within medullary region and surrounding soft tissues (arrows).

in lace-like disorganized woven bone intimately associated with neoplastic cells and broad sheets of bone. Histology of conventional intramedullary osteosarcoma of upper tibia is shown in Fig. 6.33.

- **Histologic variants:** Histologic variants of intramedullary osteosarcomas include: osteoblastic, chondroblastic, fibroblastic, giant cell rich, small cell-rich, clear cell, chondroblastoma-like, malignant fibrohistiocytoma-like and telangiectatic osteosarcoma. Peripheral osteosarcomas occur in parosteal and periosteal region of long bones, and jaw.
- **Treatment:** Conventional treatment for osteosarcoma consists of combination of neoadjuvant and adjuvant chemotherapy and surgery.

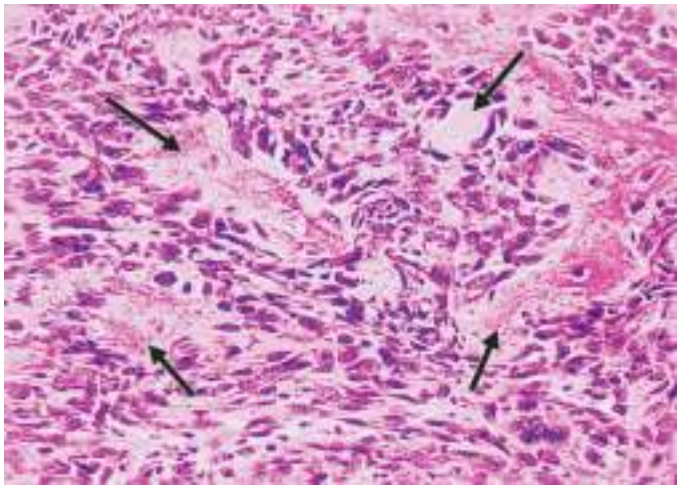

Fig. 6.33: Histology of conventional intramedullary osteosarcoma. Tumor is composed of bone formation by malignant pleomorphic neoplastic cells with hyperchromatic nuclei, numerous mitoses; and formation of 'lace-like' osteoid and calcified bone spicules (arrows) and islands of reactive new woven bone by tumor cells (400X).

Chondrosarcoma

Chondrosarcoma is second most common primary malignant bone tumor characterized by formation of cartilaginous matrix that constitutes 15% of all primary malignant bone tumors. Tumor most often originates in the medulla of flat bones such as pelvic girdle (25%), shoulder girdle (scapula), ribs, and vertebral column.

- **Clinical features:** Patient presents with enlarging lump, pain, and swelling. Skull base tumors induce neurological symptoms. Change in the size and clinical symptoms might be an indicator of malignant transformation in enchondromas and osteochondromas.
- **Radiologic examination:** Radiograph shows popcorn-like calcifications, osteolytic lesions, endosteal scalloping, thickened cortex, cortical erosion or destruction, soft tissue involvement. Cortical destruction and soft tissue extension of pre-existing enchondromas might be indicators of secondary central chondrosarcoma. Thick cartilaginous cap (1.5–2 cm) is demonstrated in secondary peripheral chondrosarcoma. Multilobular appearance is seen in periosteal chondrosarcoma. CT scan and MRI are helpful in showing extent of the tumor.
- **Gross examination:** Tumor has atypical neoplastic hyaline cartilage. Cut surface reveals lobulated appearance, gray-tan, and cystic, myxoid or mucoid material. Mineralization shows chalky calcium deposits. Cortical erosion and soft tissue extension can be seen. Secondary peripheral chondrosarcoma shows thick cartilaginous cap (1.5–2 cm). Periosteal chondrosarcoma appears as a large, lobular mass attached to the surface of bone.
- **Histologic examination:** Tumor is composed of atypical chondroblasts within cartilaginous lacunae. There is increased cellularity showing >2 cells with hyperchromatic nuclei per lacunae. Features of malignancy especially mitoses are best demonstrated at the edge of the tumor. Histology of chondrosarcoma is shown in Fig. 6.34.
- **Treatment:** Conventional treatment for chondrosarcoma consists of surgery, radiation therapy and chemotherapy.

Liposarcoma

Liposarcomas are malignant tumors with differentiation towards adipose tissue that consist of five different

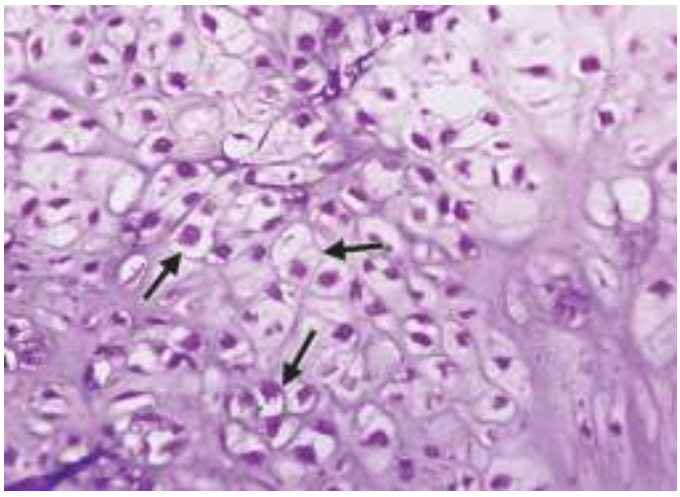

Fig. 6.34: Histology of chondrosarcoma. Tumor is moderately cellular and well-differentiated tumor. It is composed of atypical uniform chondrocytes. Cartilaginous lacunae contain >2 cells with hyperchromatic nuclei. Five-year survival rate is seen in >80% of cases (arrows).

histologic subtypes: well-differentiated, myxoid, round cell, pleomorphic and undifferentiated. Well-differentiated liposarcoma rarely metastasizes and has a good prognosis. Pleomorphic and round cell liposarcomas are highly aggressive tumors, which metastasize early. Primitive adipocyte (lipoblast) is hallmark of liposarcomas. Diagnosis is made with a biopsy showing immature lipoblasts with various cellular atypias depending on the subtype of liposarcomas.

- **Locations:** Liposarcomas are typically seen in patients 50–80 years of age, who present with slow-growing painless mass deep to fascia in lower extremities, upper extremities and retroperitoneum.
- **Clinical features:** Patient presents with a new lump anywhere, or an existing lump that grows persistently, and history of pain in the lump.
- **Molecular/cytogenetic alteration:** Amplification of MDM2 gene and ring chromosome 12 is demonstrated in well-differentiated liposarcoma. Myxoid liposarcoma demonstrates chromosomal translocation t(12;16).
- **Gross morphology:** Tumor is usually large and relatively well-circumscribed. Cut surface may be yellow, fatty, or firm and white with interspersed fibrous septae. Areas of hemorrhage and necrosis may be seen in high-grade tumor.
- **Histologic examination:** Histologic variants of liposarcoma are well-differentiated (low-grade tumor), myxoid (low-to-intermediate grade), round cell (high-grade) and dedifferentiated (low-grade and high-grade) tumors.
  - **Well-differentiated liposarcoma:** Tumor is a low-grade with minimal cellular located in central or retroperitoneal regions. Tumor is composed of atypical lipoblasts in the background mature lipoblasts. Histology of well-differentiated liposarcoma is shown in Fig. 6.35.
  - **Myxoid liposarcoma:** Tumor is low-to-intermediate grade composed of proliferating lipoblasts upon a myxoid stroma matrix.
  - **Round cell liposarcoma:** Tumor is high-grade poorly-differentiated composed small blue cells.
  - **Pleomorphic liposarcoma:** It is high-grade tumor composed of giant lipoblasts with bizarre nuclei.
  - **Dedifferentiated liposarcoma:** Tumor has two histologic variants: low-grade and high-grade dedifferentiated liposarcoma. High-grade dedifferentiated liposarcoma is composed of dedifferentiated mesenchymal heterogenous components such as neural tissue, angioblastic tissue, skeletal muscle, smooth muscle, bone and cartilage. Rhabdomyoblastic differentiation has been associated with poor prognosis.
- **Treatment:** Patients with well-differentiated liposarcoma are treated by marginal surgical excision. Wide surgical resection and radiation is indicated for intermediate and high-grade liposarcomas.

Malignant Vascular Tumors

Malignant vascular tumors have an infiltrative growth and varying degrees of vasoformative features in adults older than 20 years of age. Most common sites are extremities, head and neck region. Immunohistochemical markers for vascular differentiation include CD31, CD34, D2–40 (podopolin), factor VIII and vWF, ulex europaeus, CD141 and Fli-1.

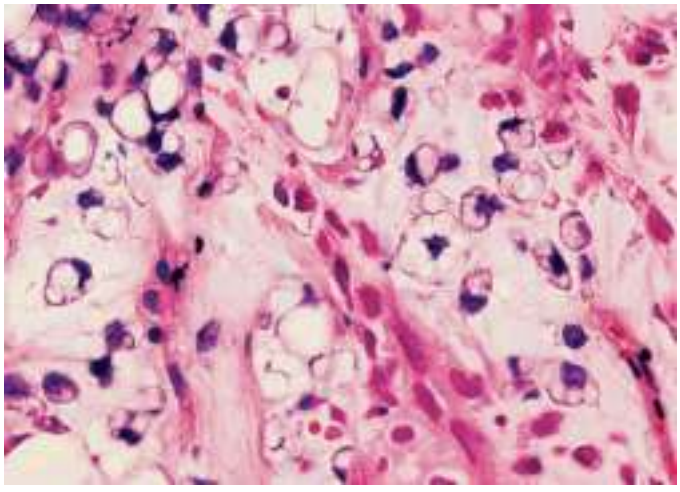

Fig. 6.35: Histology of well-differentiated liposarcoma. Tumor is composed of mature adipocytes of variable size and shape associated with nuclear atypia in adipocytes or spindle cells in the tumor. Spindle cells containing hyperchromatic nuclei tend to be more numerous within fibrous septa. There is presence of varying number of monovacuolated or multivacuolated lipoblasts. It is worth mentioning that mere presence of lipoblasts is not essential to establish the diagnosis (400X).

Epithelioid Hemangioendothelioma

Epithelioid hemangioendothelioma is locally aggressive malignant tumor with metastatic potential involving lymph nodes, soft tissue, bone, liver, lung, and skin. Diagnostic workup includes radiology, histology (biopsy or tumor resection), immunohistochemistry and molecular analysis.

- **Clinical features:** Clinical presentation depends on tumor location. Patient presents with pain, edema or thrombophlebitis due to vascular occlusion, and recurrence after surgery. Tumor may metastasize to lymph nodes and lungs.
- **Gross morphology:** Tumor is poorly circumscribed. Cut surface reveals firm and white-tan mass of variable size up to 18 cm.
- **Histologic examination:** Tumor has histologic variants: (a) WWTR1-CAMTA1 rearranged epithelioid hemangioendothelioma is composed of large atypical endothelial cells with abundant eosinophilic cytoplasm arranged in cords and small nests embedded in a myxohyaline stroma, and (b) YAP1-TFE3 rearranged epithelioid hemangioendothelioma is composed of solid nests or pseudoalveolar formations of epithelioid cells enmeshed in a fibrous stroma.
- **Immunohistochemistry:** Epithelioid hemangioendothelioma is positive for immunohistochemical stains such as CD31, ERG, podoplanin (D2–40), Fli-1, von Willebrand factor, CD34 (can be negative) and CAMTA1 (in WWTR1-CAMTA1 rearranged tumor).
- **Treatment:** Tumor needs wide surgical excision.

Angiosarcoma

Angiosarcoma is a malignant tumor derived from the endothelium of blood vessels and lymphatic channels. It can occur in the skin (face, scalp), breast, liver, spleen and deep tissues. Clinical examination and imaging studies determine size and location of tumor.

- **Locations:** Most common sites of angiosarcoma are skin of the head and neck (60%), extremities, soft tissues, visceral organs, bone and retroperitoneum in adults. Tumor is highly-aggressive with involvement of lymph nodes and distant organ(s).
- **Clinical features:** Patient presents with rapidly growing blue or purple macular, nodular or plaque-like lesion. Advanced disease can show hemorrhage and necrosis. Cervical lymphadenopathy is observed in 10% of cases at the time of presentation.
- **Histologic examination:** Tumor is composed of irregularly shaped anastomosing vascular channels lined by multilayered endothelial cells with nuclear atypia, numerous atypical mitoses and necrosis.
- **Immunohistochemistry:** Tumor is positive for vascular immunohistochemical markers such as CD31, CD34, VEGF, ERG, factor VIII and vWF.
- **Treatment:** Surgical excision is the most common treatment of angiosarcoma.

Kaposi Sarcoma

Classic Kaposi sarcoma and HIV-associated Kaposi sarcoma can involve skin, oral cavity, gastrointestinal tract, lymph nodes, leg, feet, lungs, liver, and spleen. Human herpesvirus-8 (HHV-8) is observed in Kaposi sarcoma patients.

- **Predisposing factors:** Predisposing factors are human immunodeficiency virus (HIV) infection or immunosuppressive drugs administered after organ transplant. Tumor is composed of numerous spindle cells, vascular slits and vascular structures with a predominance of endothelial cells. Some spindle cells can demonstrate nuclear pleomorphism. Extravasated erythrocytes and hemosiderin-laden macrophages are evident.
- **Kaposi sarcoma variants:** Classic Kaposi sarcoma is found most often in elderly men of Eastern European Jewish origin or Italian origin. Patient presents with slow-growing tumor over legs and feet. Epidemic Kaposi sarcoma (HIV-associated Kaposi sarcoma) can involve any part of body such as skin, oral cavity, gastrointestinal tract, lymph nodes, lungs, liver and spleen.
- **Histologic features:** On histologic examination, Kaposi sarcoma demonstrates increased number of spindle cells with vascular slits and vascular structures with a predominance of endothelial cells. Extravasated erythrocytes and hemosiderin-laden macrophages are evident. Some spindle cells can demonstrate nuclear pleomorphism.
- **Treatment:** Classic Kaposi sarcoma is treated by surgery and radiation therapy.

Fibrosarcoma

Fibrosarcoma is a malignant tumor of fibroblasts with herringbone architecture and variable collagen fibers. Tumor can affect both adults and infants. Adult fibrosarcoma involves deep soft tissue of extremities or trunk. Infantile fibrosarcoma occurs before 2 years of age in extremities associated with rapid growth. Tumor can metastasize to lung and bones. Treatment options are surgical excision, irradiation and chemotherapy.

- **Gross morphology:** Adult fibrosarcoma tumor is well-circumscribed but unencapsulated. Cut surface reveals fleshy and white-tan appearance with areas of hemorrhage and necrosis. Infantile fibrosarcoma tumor is poorly-circumscribed and lobulated mass with areas of hemorrhage and necrosis.

- **Histologic examination:** Tumor is composed of numerous small to large fibroblasts arranged in fascicles or herringbone architecture. Tumor cells contain scant cytoplasm, and tapering elongated atypical nuclei with increased granular chromatin, variable nucleoli and numerous abnormal mitotic figures.
- **Histochemistry:** Reticulin stain demonstrates reticulin fibers surrounding each cell. Phosphotungstic acid-hematoxylin (PTAH) demonstrates abundant cytoplasmic fibrils.
- **Immunohistochemistry:** Fibrosarcoma is positive for immunohistochemical stains such as vimentin, type 1 collagen, p53 and high Ki-67.
- **Electron microscopy:** Electron microscopy reveals fibroblasts with prominent rough endoplasmic reticulum but lack myofilaments, external lamina, and distinct myofibroblast.
- **Treatment:** Tumor is treated by surgical excision, irradiation and chemotherapy. Tumor recurs after surgical excision in 50% of cases. Tumor can metastasize to lung and bone. Prognosis is better if tumor is superficial and better differentiated.

Leiomyosarcoma

Leiomyosarcoma is malignant tumor of smooth muscle cell origin *de novo*, and unrelated to pre-existing leiomyoma. Tumor can originate in various anatomic sites, i.e. uterus, soft tissue, blood vessels, retroperitoneum, and skin/subcutaneous tissue.

- **Clinical features:** Patient presents with postmenopausal bleeding, pressure symptoms, pain in pelvis, abnormal vaginal discharge, and a change in urinary bladder or bowel habits.
- **Gross morphology:** Tumor is bulky, fleshy tumor invading into myometrial wall or polypoid tumor projecting into lumen. Cut section reveals tumor is not bulging above the surface. Tumor is invasive and infiltrative growth. Areas of hemorrhage necrosis are present.
- **Histologic examination:** Tumor is composed of spindled/fascicular cells resembling smooth muscle with moderate to marked pleomorphism. Histologic diagnostic criteria include the following features on light microscopy: (a) 10 or more mitoses per 10 HPFs; (b) 5 or more mitoses per 10 HPFs, with nuclear atypia and necrosis; and (c) myxoid and epithelioid leiomyosarcomas with 5 or more mitoses per 10 HPFs.
- **Immunohistochemistry:** Leiomyosarcoma is positive for immunohistochemical stains such as smooth muscle actin (SMA), desmin, muscle specific actin (MSA), h-caldesmon, smooth muscle myosin heavy chain (SMMHC), calponin and ER/PR.
- **Treatment:** Tumor is treated by surgical excision, irradiation and chemotherapy.

Rhabdomyosarcoma

Rhabdomyosarcomas are malignant mesenchymal tumors with skeletal differentiation involving head and neck, uterus, vagina, and urinary bladder, and extremities. Tumors can metastasize via hematogenous route to distant sites. Tumors rarely metastasize to regional lymph nodes.

- **Molecular/cytogenetic alterations:** Chromosomal translocation t(2;13) (q25;q14) is observed in the majority of alveolar rhabdomyosarcoma, and t(1;13) (p36;q14) is found in a smaller subset. The congenital/infantile form of sclerosing/spindle cell rhabdosarcomas demonstrate gene fusions involving VGLL2 and NCOA2 or CITED2 genes.
- **Clinical features:** Although, rhabdomyosarcoma can originate anywhere in the body, tumor is more likely to arise in head and neck region, urinary bladder, reproductive system (i.e. vagina, uterus and testes) and extremities. Signs and symptoms depend on location of tumor.
- **Gross morphology:** Tumor can be well-circumscribed or multinodular with infiltrative borders. Cut surface reveals glistening, gelatinous or gray-white or pink-tan fleshy and bulging appearance. Areas of cyst formation, hemorrhage or necrosis may be present.
- **Histologic examination:** Histologic variants of rhabdomyosarcoma include embryonal rhabdomyosarcoma (botryoid rhabdosarcoma), alveolar rhabdomyosarcoma, pleomorphic rhabdomyosarcoma and spindle cell/sclerosing rhabdomyosarcoma. Tumor cells in rhabdomyosarcoma range from small primitive hyperchromatic round/spindle/stellate cells, and large differentiated ribbon, strap, tadpole, racket-shaped cells with abundant eosinophilic cytoplasm and cross-striations (rhabdomyoblasts), which contain large, round and vesicular nuclei with a prominent nucleolus.
- **Immunohistochemistry:** Immunohistochemical markers for skeletal muscle differentiation include muscle specific actin (MSA), MyoD1 (transcription factor-specific marker), myogenin (transcription factor), desmin, and myoglobin.
- **Treatment:** Patients are treated with surgery and chemotherapy with or without radiation therapy. The histologic type and location of rhabdomyosarcoma influence the survival. The botryoid rhabdomyosarcoma, a variant of embryonal rhabdomyosarcoma has the best prognosis, while pleomorphic rhabdomyosarcoma is most often fatal.

Synovial Sarcoma

Synovial sarcoma is malignant tumor of uncertain lineage of young persons in extremities, and pleuropulmonary parenchyma (10%). It is a misnomer as the tumor does not originate from synovium.

- **Clinical features:** Patient presents with lump in extremities or pleuropulmonary region and related pain in the region.
- **Molecular/cytogenetic alterations:** Chromosomal translocation t(X;18) (p11; q11) with SS18-SSX1 (67%), SS18-SSX2 (33%) fusion gene product is present in more than 95% of cases.
- **Gross examination:** Tumor is large well-circumscribed/lobulated tan-white with subtle invasive growth. Cut surface reveals soft to rubbery with areas of hemorrhage and necrosis. Cystic degeneration and gelatinous areas may be present.
- **Histologic examination:** Synovial sarcoma has three histologic variants: monophasic, biphasic, and poorly differentiated tumors.
  - **Monophasic synovial sarcoma:** Tumor is composed of monomorphic spindled cells with nuclear monotony arranged in fascicular/herringbone growth pattern, atypical mitotic figures, necrosis, hemangiocytoma-like vascular pattern, hyalinized collagen and calcifications.
  - **Biphasic synovial sarcoma:** Tumor is composed of monomorphic spindled cells and epithelial-lineage cells admixed in variable proportions. Epithelial-lineage cells can form glandular structures or solid nests and cords, seldom show squamous metaplasia or granular cell change. Histology of synovial sarcoma is shown in Fig. 6.36.

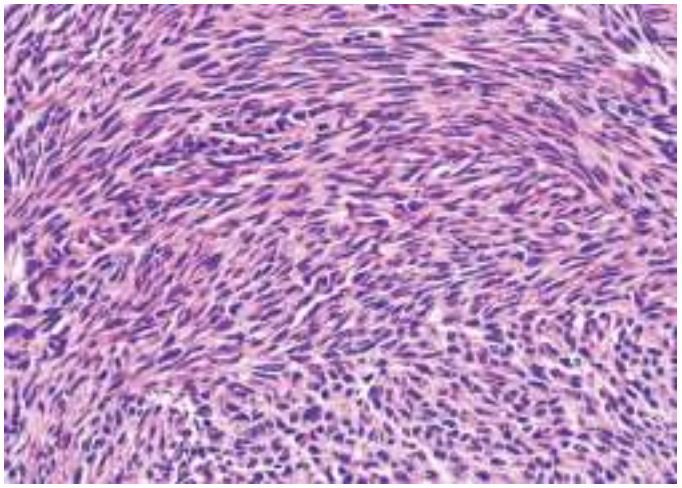

Fig. 6.36: Histology of synovial sarcoma. Tumor shows two histologic patterns depending on the presence of epithelial and spindle cell components in varying proportions: (a) monophasic variant (containing spindle cell component without epithelial differentiation) and (b) biphasic (containing both epithelial and spindle cell components). Biphasic synovial sarcoma usually shows areas of calcification and ossification (400X).

  - **Poorly-differentiated synovial sarcoma:** Tumor is composed of primitive round cells, epithelioid cells or high-grade spindled cells, atypical mitotic figures, frequent rhabdoid change and necrosis.
- **Immunohistochemistry:** Positive immunohistochemical markers for biphasic synovial sarcomas are TLE1, CD99, cytokeratins and epithelial membrane antigen (EMA).
- **Molecular genetic testing:** Chromosomal translocation t(X;18) (p11; q11) with SS18-SSX1 (67%), SS18-SSX2 (33%) fusion gene product is present in more than 95% of cases. Definitive diagnosis of synovial sarcoma often requires molecular genetic testing (RT-PCR and FISH) on small biopsies.
- **Treatment:** Synovial sarcoma is treated by wide surgical excision. A tumor-free margin of 1–3 cm is recommended.

Alveolar Soft Part Sarcoma

Alveolar soft part sarcoma is a malignant tumor of uncertain lineage composed of large polygonal cells with round vesicular nucleus, prominent nucleolus, abundant eosinophilic cytoplasm arranged in pseudoalveolar pattern and PAS diastase resistant positive intracytoplasmic rhomboid- or rod-shaped crystals.

- **Locations:** Tumor predominantly affects the deep soft tissues of the extremities (thigh and buttock), trunk, and internal organs in young adults with female predominance, and head and neck region (tongue and orbit) in young children.
- **Molecular/cytogenetic alterations:** Definitive diagnosis is confirmed by analyzing chromosomal translocation t(X;17) (p11.2; q25) with ASPSCR1-TFE3 fusion gene product. TFE3 nuclear expression is analyzed by immunohistochemistry.
- **Clinical features:** Patient presents with slow growing and painless mass in the region or proptosis in orbital tumor. Tumor is localized in the initial stage. Later, tumor can involve regional lymph nodes and metastasize to distant organ(s).
- **Gross morphology:** Tumor is solid, partially circumscribed mass with fleshy nodules and fibrotic bands with mean 6.5 cm. Cut surface reveals yellow to gray to white-tan tumor with median 6.5 cm size and presence of large blood vessels at the periphery of tumor.
- **Histologic examination:** Tumor is composed of large polygonal cells with round vesicular nucleus, prominent nucleolus, abundant eosinophilic cytoplasm, arranged in pseudoalveolar pattern and PAS diastase resistant positive intracytoplasmic rhomboid- or rod-shaped crystals. Tumor is divided into lobules by thick fibrous septa and rich capillary

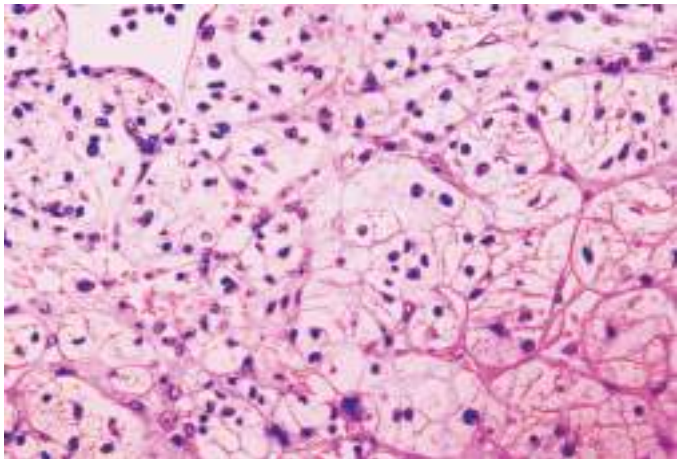

Fig. 6.37: Histology of alveolar soft part sarcoma. Tumor is composed of large uniform epithelioid cells with well-defined borders, centrally placed bland nuclei and abundant eosinophilic cytoplasm somewhat granular and rod-shaped intracytoplasmic inclusions. Neoplastic cells are arranged in solid nests and/or alveolar structures and separated by delicate fibrovascular septa. Loss of cellular cohesion and necrosis of the neoplastic cells in the central region of nests of tumor cells gives pseudoalveolar pattern (400X).

vascular network, dilated veins at the periphery of the tumor. Vascular invasion is common by tumor cells. Histology of alveolar soft part sarcoma is shown in Fig. 6.37.

- **Treatment:** Radical surgical resection of tumor is the treatment of choice. Radiation may reduce the risk of recurrence. Adjuvant chemotherapy does not seem to be effective.

LOCALLY MALIGNANT TUMORS

Groups of slow-growing malignant tumors that spread only by direct invasion in surrounding tissues without dissemination to distant organs. Tumor cells show features of malignancy. Examples of locally-malignant tumors include basal cell carcinoma of skin, dermatofibrosarcoma protuberans, giant cell tumor of bone (osteoclastoma), adamantinoma (tibia or fibula), craniopharyngioma of pituitary gland and carcinoid tumor.

Basal Cell Carcinoma of Skin

Basal cell carcinoma (BCC) is the most common slow-growing locally aggressive malignant epithelial tumor arising from sun-exposed skin on the face near the eyes and nose and trunk regions. Tumor starts as flattened papillary growth which slowly increases in size over months to two years. The surface of tumor breaks down and a shallow, ragged ulcer with pearly edges is formed.

- **Predisposing factors:** Predisposing factors for basal cell carcinoma include ultraviolet radiation, arsenic exposure, blue basal nevus (Gorlin syndrome), xeroderma pigmentosum, oculocutaneous albinism, Bazex-Dupre-Choristol syndrome, Muir Torre syndrome and nevus sebaceous.
- **Clinical features:** Patient with nodular variant of basal cell carcinoma in facial region presents with pearly pink, flesh colored papule or nodule with arborizing and branching blood vessels. Tumor with ulceration has rolled borders. Superficial variant of tumor on trunk region presents with scaly macules, or plaques with erythematous surface.
- **Gross morphology:** Tumor forms nodule, which may extend into subcutaneous tissues. Cartilaginous invasion is unusual.
- **Histologic examination:** Tumor is composed of nests of basaloid cells resembling those of the basal layer of skin with peripheral palisading containing basophilic nuclei, scanty cytoplasm and scattered atypical mitotic figures at the periphery in haphazard arrangement, associated with a fibromyxoid stroma. Histology of basal cell carcinoma of skin is shown in Fig. 6.38.
- **Immunohistochemistry:** Positive immunomarkers are cytokeratins and BerEP4.
- **Treatment:** Treatment options for basal cell carcinoma are surgery, Mohs micrographic surgery, curettage and electrodesiccation, radiation therapy, topical treatment (6-fluorescent, imiquimod), and systemic therapy (Hedgehog pathway inhibitors).

Giant Cell Tumor of Bone

Giant cell tumor of bone (i.e. osteoclastoma) is potentially low-grade rarely metastasizing malignant

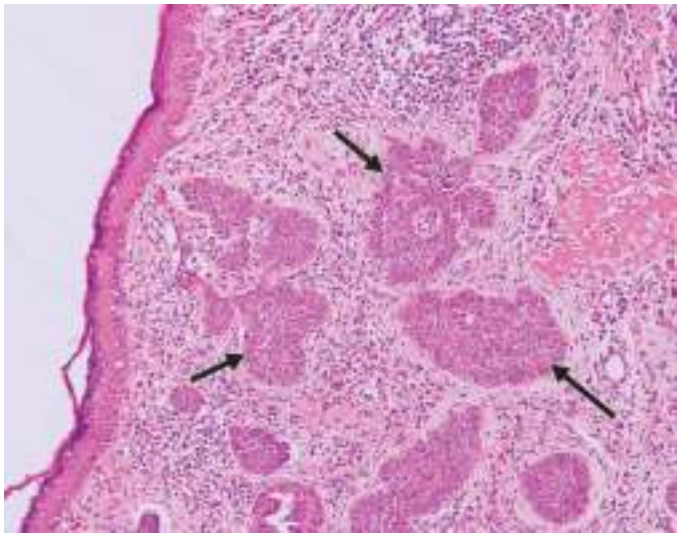

Fig. 6.38: Histology of basal cell carcinoma of skin. Tumor is composed of infiltrative deeply basophilic epithelial (basaloid) cells with narrow rims of cytoplasm arranged in clusters, which are attached to the epidermis and protruding into the subjacent papillary dermis. Nuclei in the periphery of the clustered cells are arranged in palisading manner. Mitotic figures are absent (arrows) (400X).

tumor of monocyte-macrophage lineage that affects 20–45 years of age.

- **Locations:** Locations of giant cell tumor are epiphysis of long bones around knee joint (lower end of femur or upper end of tibia). Tumor can also occur in wrist, upper end of femur, upper end of humerus, spine and pelvis. Local recurrence after curettage is associated with pulmonary metastasis in 2% of cases.
- **Clinical features:** Patient presents with bony mass, pathological fracture, limited movement in the nearest joint, and pain.
- **Molecular alterations:** Giant cell tumor of bone related clonal aberrations occur in a background of epigenetic modifications especially G34W mutation of H3F3A gene.
  - Neoplastic mononuclear stromal cells in the tumor express receptor activator of NF-κB ligands (RANKLs), chemokines and cytokines associated with monocyte recruitment and reactive multinucleated giant cells (osteoclastogenesis).
  - Activation of Wnt/β-catenin pathway, clonal telomeric association and therapeutic radiation are linked to giant cell tumor of bone. Mutations in TP53 gene and H-RAS gene have been demonstrated in malignant giant cell tumor of bone not associated with prior radiation.
- **Radiologic examination:** Conventional radiograph examination shows well-circumscribed osteolytic lesion on epiphyseal region of a long bone in eccentric location giving 'soap bubble appearance'.
- **Gross examination:** Tumor is soft, friable, slightly brownish or red-tan, somewhat poorly defined in the ends of long bone. Surrounding cortex is thinned out and may be destroyed completely. Destructive tumor may extend into the soft tissue. Cut surface of malignant change in giant cell tumor of bone is typically firm and fleshy in consistency. Surgical specimen of giant cell tumor of bone is shown in Fig. 6.39.
- **Histologic examination:** Tumor consists of round to oval and spindled mononuclear neoplastic cells with pale eosinophilic cytoplasm, nuclei with dispersed chromatin and small nucleoli and numerous mitoses, macrophages and uniformly distributed multinucleated giant cells. Numerous mitotic figures are commonly present. Presence of atypical tripolar or quadripolar mitoses should raise suspicion for malignant change in giant cell tumor. Necrosis is present in the setting of pathologic fracture. Histology of giant cell tumor of bone is shown in Fig. 6.40.
- **Treatment:** Without treatment, giant cell tumor of bone will continue to grow and destroy the surrounding bone, so treatment is always essential. Aim of treatment is to excise the tumor, prevent damage to bone and avoid recurrence of the tumor. Surgical treatment is preferred for giant cell tumor of bone. Radiotherapy, tumor embolization and chemotherapy are nonsurgical treatment modalities. Local recurrence after curettage is associated with pulmonary metastasis in ≤2% of cases.

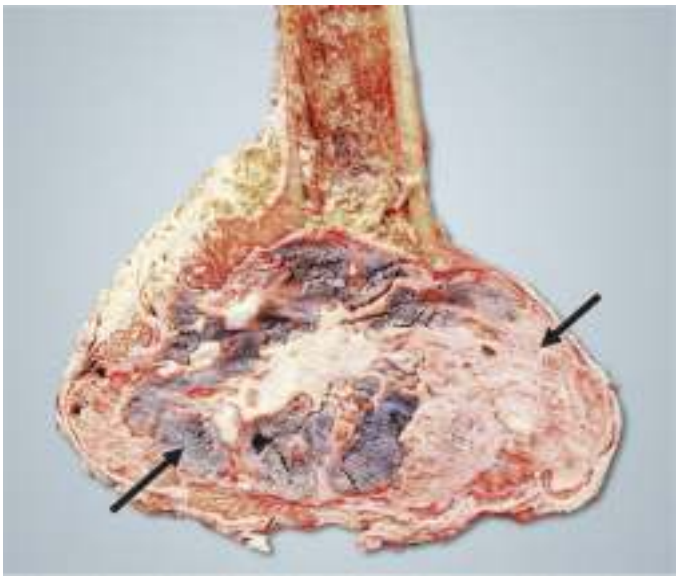

Fig. 6.39: Surgical specimen of giant cell tumor of bone. Tumor is large red brown, fleshy well-demarcated mass. Cut surface shows yellow and/or cystic areas. Areas of hemorrhage and necrosis are common. Hemosiderin deposition and reactive bone formation are demonstrated in the tumor (arrows). (*Courtesy:* Dr. Sujata Kanetkar, Professor and Head, Department of Pathology, Krishna Institute of Medical Sciences, Karad, Maharashtra.)

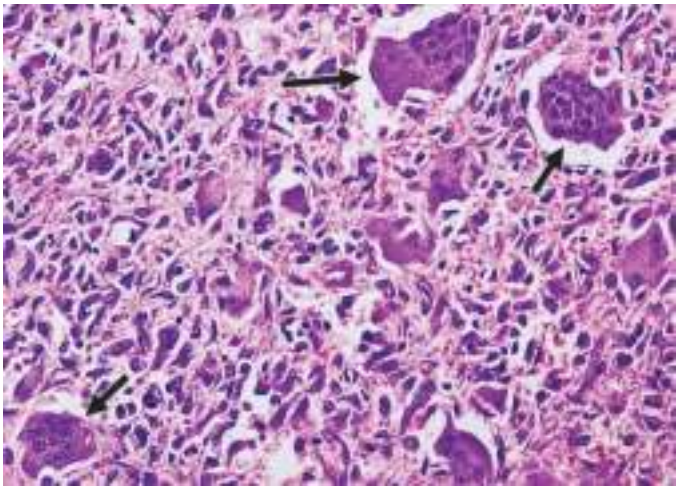

Fig. 6.40: Histology of giant cell tumor of bone. Tumor is composed of ovoid mononuclear cells with indistinct cellular outlines growing in the form syncytium; interspersed with numerous osteoclast-like multinucleated giant cells containing >100 nuclei scattered among mononuclear cells. Mitotic figures are common in mononuclear cells. Morphology of nuclei of stromal mononuclear cells and osteoclast-like multinucleated giant cells are identical (arrows) (400X).

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) is locally aggressive mesenchymal neoplasm with fibroblastic differentiation located in skin/cutis. COL1A1-PDGFB fusion gene products are demonstrated by molecular testing in all cases. Tumor demonstrates positivity for immunohistochemical marker CD34.

- **Clinical features:** Patient presents with slow-growing exophytic and nodular cutaneous mass that may progress to fibrosarcomatous transformation.
- **Gross examination:** Tumor may be plaque-like dermal/subcutaneous thickening initially progressing to raised firm multinodular mass of 0.5 to more than 10 cm. Cut surface reveals gray-white, firm-to-myxoid and gelatinous appearance.
- **Histologic examination:** Tumor is composed of monomorphic spindle cells and ovoid to elongated cells with abundant eosinophilic cytoplasm with variable mitotic activity arranged in storiform or whorled pattern; and collagenous or myxoid stroma. Adnexal structures are typically spared. Fibrosarcomatous transformation denotes those with cellular spindle cell fascicles or 'herringbone pattern', greater atypical mitotic figures and positive expression of CD34.
- **Treatment:** Wide local excision is treatment option for localized disease. Advanced disease requires chemotherapy.

Adamantinoma

Adamantinoma is primary biphasic fibro-osseous of bone that involves middle third of diaphysis of tibia or fibula. Multifocal involvement of the tibia is frequently present. Tumor has been reported in the ulna, femur, humerus, radius, ribs, tarsal and metatarsal bones, as well as extraskeletal pretibial soft tissue. Definite diagnosis is established by histologic examination.

- **Clinical features:** Symptoms depend on location and extent of the disease. Patient presents with indolent and nonspecific symptoms as well as slow-growing mass.
- **Gross examination:** Tumor is yellow-gray or gray-white. Cut surface reveals fleshy or firm in consistency. Some tumors may demonstrate straw colored fluid on cut surface.
- **Histologic examination:** Classic biphasic adamantinoma is composed of epithelial and osteofibrous components intermixed with each other in various proportions. Epithelial component is composed of mildly atypical epithelial cells within osteofibrous dysplasia-like stroma forming solid basaloid cells arranged in nest with palisading pattern or less often tubular structures, keratinized squamous nests or spindle cell bundles.
- **Immunohistochemistry:** Positive immunohistochemical stains are cytokeratins (AE1/AE3, CK5, CK14, CK19), vimentin, epithelial membrane antigen (EMA), p63 and podoplanin (D2–40).
- **Treatment:** Tumor is treated by wide local surgical excision. Long-term follow-up is essential due to possibility of late complications.

Craniopharyngioma

Craniopharyngioma is a benign cystic epithelial tumor (WHO grade 1) in suprasellar region, that frequently extends into surrounding structures. Tumor possibly originates from neoplastic transformation of ectodermal-derived epithelial remnant of Rathke's pouch and craniopharyngeal duct.

- **Molecular/cytogenetic alteration:** CTNNB1 (β-catenin) gene mutations and aberrant nuclear expression of β-catenin is demonstrated in up to 95% of cases.
- **Clinical features:** Patient presents with visual disturbances, endocrine deficiencies, failure to thrive, diabetes insipidus, headache, cognitive impairment and personality changes.
- **Radiologic examination:** Preoperative imaging has best diagnostic tool. Radiograph demonstrates multilobulated and multicystic tumor of variable size in extra-axial and suprasellar region. CT scan demonstrates areas of calcifications within tumor.
- **Gross examination:** Tumor is lobular and cystic with calcifications. Cysts contain dark fluid composed of cholesterol and hemorrhage. Tumor can interface with adjacent brain or densely adherent to brain.
- **Histologic examination:** Tumor is composed of well-differentiated squamous epithelium bordered by palisading epithelium, and peripheral loose plumed cells called stellate reticulum, keratin associated with surrounding gliosis and Rosenthal fibers.
- **Immunohistochemistry:** Positive immunomarkers are CK7, CK8, CK9, EMA and β-catenin.
- **Treatment:** Patient is treated with total or partial surgical excision followed by radiation therapy.

Pathology Pearls: Locally Malignant Tumors

- Basal cell carcinoma of skin
- Dermatofibrosarcoma protuberans
- Giant cell tumor of bone (osteoclastoma)
- Adamantinoma
- Craniopharyngioma
- Carcinoid tumor

MIXED BENIGN AND MALIGNANT TUMORS

Mixed benign and malignant tumors have two different morphologic patterns that are derived from the same germ cell layer, which may be benign (e.g. pleomorphic adenoma of salivary gland and fibroadenoma of breast) or malignant (e.g. carcinosarcoma also called malignant mixed Müllerian tumors of uterus), metaplastic carcinoma, mixed germ cell tumor and adenosquamous carcinoma.

Pathology Pearls: Mixed Benign and Malignant Tumors

- Fibroadenoma of breast
- Carcinosarcoma (malignant mixed Müllerian tumors of uterus)
- Metaplastic carcinoma
- Mixed germ cell tumors of gonads
- Adenosquamous carcinoma

Fibroadenoma of Breast

Fibroadenoma is a painless, unilateral, well circumscribed, solid, benign tumor in adolescents and young women within breast or accessory breast tissue in axilla with pushing borders that does not infiltrate the adjacent breast parenchyma. Tumor is composed of proliferation of both glandular epithelial and stromal components of the terminal duct lobular unit (TDLU). Juvenile fibroadenoma generally occurs in younger and adolescent women less than 20 years of age. Complex fibroadenoma affects older women. Myxoid fibroadenoma is associated with Carney complex. Cyclosporin immunosuppression increases risk of fibroadenoma of breast.

- **Clinical features:** Patient most often presents with painless, firm, slow-growing, solitary mobile lump usually <3 cm in diameter, which can be multiple and bilateral in breast or accessory breast tissue in axilla.
- **Gross morphology:** Tumor is well-circumscribed, unencapsulated firm, ovoid mass with bosselated and lobulated bulging above the cut surface with slit-like spaces. Cut surface may be mucoid, and fibrotic appearance. Tumor may undergo calcification.
- **Histologic examination:** Fibroadenoma of breast is a biphasic benign tumor composed of both glandular epithelial and interlobular stromal components of the terminal duct lobular unit (TDLU). Tumor is composed of proliferation of both glandular epithelial and stromal components of the terminal duct lobular unit. Glandular component has two growth patterns: (a) intracanalicular pattern consists of glands compressed into linear branching structures by proliferating stroma, and (b) pericanalicular pattern consists of glands retained open lumens by separated by expanded stroma. Glandular components have intact myoepithelial cells. Stromal component consists of collagen and spindle-shaped cells with elongated or ovoid nuclei. Histology of breast fibroadenoma is shown in Fig. 6.41.
- **Treatment:** Treatment options are conservative management, local surgical excision and follow-up.

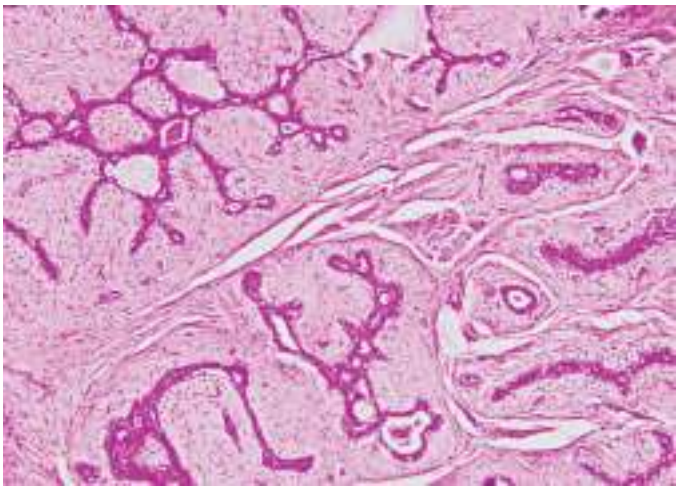

Fig. 6.41: Histology of breast fibroadenoma. Tumor shows intracanalicular and pericanalicular patterns. Glands compressed by stroma result in slit-like spaces known as intracanalicular pattern. Ducts not compressed by stroma have round shape known as pericanalicular pattern (100X).

Carcinosarcoma (Malignant Mixed Müllerian Tumor)

Carcinosarcoma (malignant mixed Müllerian tumor) is biphasic high-grade malignant tumor epithelial and mesenchymal (homologous or heterologous) components. Sarcomatous component is derived from the carcinomatous component as a result of metaplasia/transdifferentiation (EMT: epithelial to mesenchymal transition). Terminology used for carcinosarcoma are mixed Müllerian tumor, malignant mesodermal mixed tumor or metaplastic carcinoma. Tumor is sporadic that almost affects postmenopausal woman (mean age: 65 years).

- **Locations:** Tumor most frequently occurs in the uterine corpus, cervix, ovaries, fallopian tubes, vagina, peritoneum and extragenital sites.
- **Pathogenesis:** Carcinomatous components of tumor convert themselves to sarcomatous components of tumor via epithelial–mesenchymal transition (EMT). This theory is supported by EMT gene signature scores as a result of epigenetic changes at microRNA promoters and mutations and amplification of histone octamer genes.
- **Predisposing factors:** Predisposing factors for malignant mixed Müllerian tumor include tamoxifen use, pelvic radiation therapy, prolonged estrogen exposure, nulliparity, obesity and diabetes mellitus.
- **Clinical features:** Patient presents with vaginal bleeding, abdominal lump and pelvic pain, extrauterine metastasis (≤45%) and distant metastasis (10%).

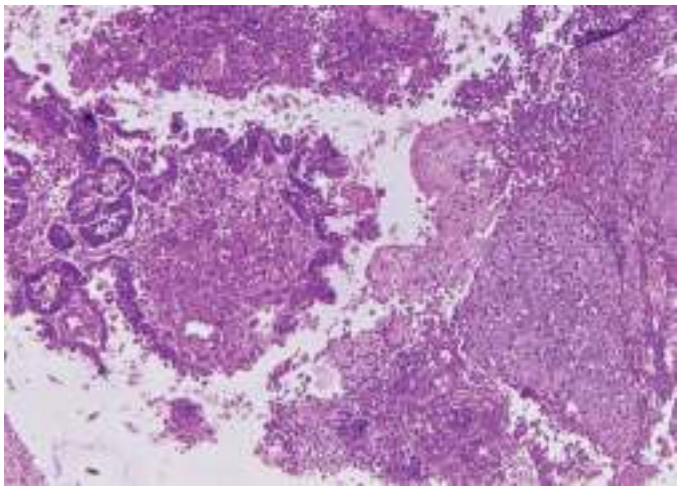

Fig. 6.42: Histology of malignant mixed Müllerian tumor with heterogenous differentiation. Endometrial curettings from 68 years postmenopausal female shows malignant Müllerian tumor composed of juxtaposed areas of adenocarcinoma and chondrosarcoma components (400X).

- **Prognostic factors:** Stage of disease is the most consistent independent predictor of outcome. Five-year survival for stage 1 disease is over 80%. Presence of heterogenous elements is poor prognostic factor in early-stage disease. Carcinomatous component tends to spread via lymphatic route. Sarcomatous component spreads via hematogenous route to lungs.
- **Gross examination:** Polypoidal tumor with extensive invasion into muscle and extension beyond organ is observed in the surgical specimen. Cut surface reveals fleshy, bulky and friable with hemorrhage and necrosis.
- **Histologic examination:** Tumor is biphasic malignant tumor composed of juxtaposed carcinomatous and sarcomatous components. Histology of malignant mixed Müllerian tumor with heterogenous differentiation is shown in Fig. 6.42.
  - **Carcinomatous component:** Carcinomatous component is most often either endometrioid carcinoma, or high-grade serous carcinoma (50–70%) or hybrid morphology tumor. Lymphovascular invasion is more common in carcinomatous element.
  - **Sarcomatous component:** Sarcomatous element is most often spindle and pleomorphic that consists of heterologous elements (i.e. rhabdomyosarcoma, chondrosarcoma, liposarcoma, osteosarcoma, angiosarcoma). Other types of sarcomatous element are less common.
- **Immunohistochemistry:** Immunohistochemistry technique can be used to demonstrate heterologous elements in carcinosarcoma. Positive immunohistochemical markers for carcinomatous component of tumor are PAX8, EMA and cytokeratins. Aberrant p53 is expressed in both serous and high-grade endometrioid carcinomas. Endometrioid component of tumor shows ER and PR positivity. Sarcomatous component of tumor shows aberrant p53 expression. Rhabdomyosarcoma component expresses desmin and myogenin. Chondrosarcoma and liposarcoma components show S-100 protein positivity.
- **Treatment:** Treatment consists of total abdominal hysterectomy and bilateral salpingo-oophorectomy with pelvic lymphadenectomy, radiation therapy and chemotherapy.

Metaplastic Carcinoma of Breast

Metaplastic carcinoma of breast is characterized by the histologic presence of two or more cellular components, commonly a mixture of epithelial and mesenchymal components including but not restricted to spindle, chondroid and osseous cells and other cells. When breast carcinoma lacks features of ductal carcinoma *in situ* or invasive ductal carcinoma, a panel of immunohistochemical markers (cytokeratins and p63) are required to confirm the presence of epithelial differentiation.

- **Clinical features:** Patient presents with large-sized breast lump with low-to-high grade biological behavior.
- **Gross examination:** Tumor is well circumscribed, solid and firm with mean 4 cm in diameter. Cut section reveals gray-white and glistening surface in areas of squamous and chondroid differentiation.
- **Histologic examination:** Tumor is composed of heterogenous elements: (a) epithelial component (low-to-high grade adenosquamous carcinoma), and (b) heterogenous mesenchymal components (i.e. chondroid or osseous-derived malignant element). Histology of breast metaplastic carcinoma is shown in Fig. 6.43.

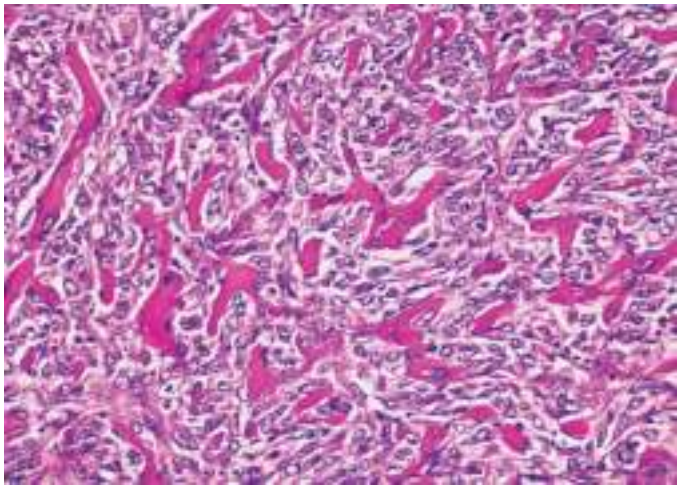

Fig. 6.43: Metaplastic carcinoma of breast. Tumor is composed of heterogenous malignant mesenchymal components such as osseous element and spindle cells (400X).

- **Immunohistochemistry:** Positive immunohistochemical markers include broad spectrum cytokeratin (AE1/AE3, CAM 5.2, OSCAR:75–90%), high-molecular-weight cytokeratin (CK5/CK6, CK14:70–75%), and low-molecular-weight cytokeratin (CK8/CK18, CK19:35–60%).
- **Treatment:** Metaplastic carcinoma of breast is treated by mastectomy with or without radiation therapy and chemotherapy. Tumor has poor response to neoadjuvant systemic therapy. Complete response to neoadjuvant systemic therapy is seen in 10–15% of cases.

Adenosquamous Carcinoma in Various Organs

Adenosquamous carcinoma is defined as tumor in which both glandular and squamous elements are clearly recognizable histologically malignant. Tumor can occur in lung, cervix, endometrium, breast, esophagus, colon and gallbladder, salivary gland and pancreas. Tumor disseminates via lymphatic, perineural and hematogenous routes. Clinical features depend on location of tumor and extent of invasion and metastasis. Adenosquamous carcinoma of cervix is composed of glandular and squamous components. Histology of adenosquamous carcinoma of cervix is shown in Fig. 6.44.

Mixed Germ Cell Tumors of Gonads

Mixed germ cell tumors contain more than one germ cell component. The most frequent combinations are embryonal carcinoma with seminoma, teratoma, or yolk sac tumor. However, any combination can be seen.

- Common combinations include: (a) teratoma + embryonal carcinoma + endodermal sinus tumor (yolk sac tumor), (b) seminoma + embryonal carcinoma, and (c) teratoma + embryonal carcinoma.

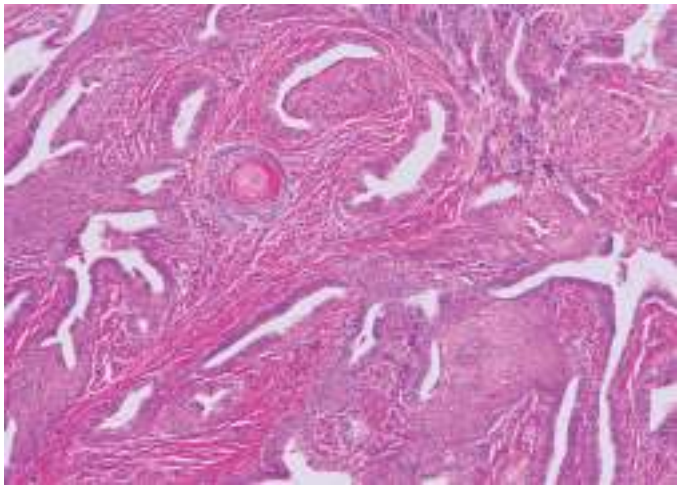

Fig. 6.44. Histology of adenosquamous carcinoma of cervix. Tumor arises from reserve cells in cervix with favorable prognosis. Tumor is composed of glandular and squamous components (400X).

- Tumor contains more than two components. It may be noted that seminoma with syncytiotrophoblastic cells is not a mixed germ cell tumor and is classified as a seminoma. Even though, tumor contains more than one component because its biologic behavior is similar to seminoma. Mixed germ cell tumor is heterogenous, multinodular solid tumor with foci of hemorrhage and necrosis.

GERM CELL TUMORS

Germ cell tumors are broadly divided in two classes: seminomatous (germinoma in pineal gland, suprasellar region, seminoma in testis, dysgerminoma in ovary) and nonseminomatous germ cell tumors (teratoma, yolk sac tumor, embryonal carcinoma, and choriocarcinoma).

- Germinoma is an intracranial counterpart of seminoma in testis and dysgerminoma in ovary.
- Mixed germ cell tumors have two or more than two different germ cell components.
- Patients with gonadal germ cell tumors have better prognosis than those with extragonadal mediastinal germ cell tumors, and survival exceeds 90% in localized tumors.
- Treatment options for germ cell tumors include surgical removal of the tumor, chemotherapy with drugs and radiation therapy. Seminoma in testes, dysgerminoma in ovary, intracranial germinoma and other extragonadal tissues are highly radiation sensitive tumors associated with good prognosis.

Germinoma/Seminoma/Dysgerminoma

Germinoma is an intracranial counterpart of seminoma in testis and dysgerminoma in ovary. Seminoma can occur in anterior mediastinum, and retroperitoneum. Presence of syncytiotrophoblast giant cells is associated with elevated hCG levels in some cases.

Teratomas

Teratomas contain tissues from the three germ cell layers: ectoderm, mesoderm and endoderm. Teratomas can be located in ovary, testis and extragonadal sites mainly in the midline structures, e.g. brain (pineal gland, suprasellar region), nose, beneath tongue, neck region, mediastinum, retroperitoneal region and sacrococcygeal region. Mediastinal teratoma may present with cough, dyspnea or cyanosis. Benign cystic teratoma (also known as dermoid cyst) is a benign tumor of ovary, which consists of well-differentiated derivatives of germ cell layers (i.e. ectoderm, mesoderm and endoderm) developing as hair, muscle, teeth or bone. Prepubertal and post-pubertal testicular mature and immature teratomas have malignant behavior. As there is great risk of torsion of benign cystic teratoma, hence,

Fig. 6.45: Surgical specimen of benign (mature) cystic teratoma of the ovary. Cut surface shows cyst filled with hair, teeth and adipose tissue (arrows).

it should be surgically excised. Surgical specimen of benign (mature) cystic teratoma of the ovary is shown in Fig. 6.45. Histology of benign (mature) cystic teratoma of the ovary is shown in Fig. 6.46.

Yolk Sac Tumor

Yolk sac tumor is malignant primitive germ cell tumors of ovary, testis and extragonadal tissues such as retroperitoneum, mediastinum and pineal as well as more exotic locations. Elevated serum α-fetoprotein (AFP) should raise the suspicion for a yolk sac component. Tumor may occur in as pure yolk sac tumor or mixed with another germ cell tumor (e.g. teratoma and embryonal carcinoma) in pediatric age group.

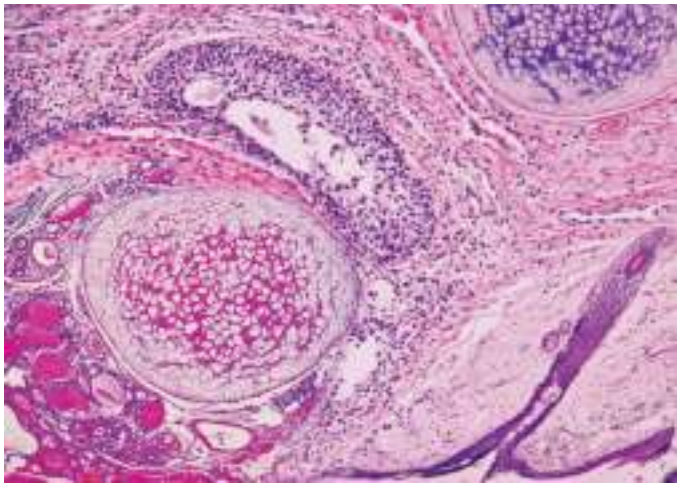

Fig. 6.46: Histology of benign (mature) cystic teratoma of the ovary. Outer surface of mature cystic teratoma of ovary is composed of ovarian hyalinized stroma. The cavity is lined by skin, and cutaneous structures. The skin is composed of keratinized squamous epithelium and contains sebaceous and eccrine glands associated with adipose tissue. Some tumors may demonstrate lipogranulomatous, fat necrosis-like, sieve-like pattern. Cyst contains hair and other dermal appendages (400X).

Embryonal Carcinoma

Embryonal carcinoma is a germ cell tumor that occurs in the ovary and testis in young age group. Pure embryonal carcinoma is extremely rare and most often found as a part of a mixed germ cell tumor. Serum levels of β-hCG and α-fetoprotein can be elevated. OCT4 immunohistochemical stain is positive in embryonal carcinoma and negative in yolk sac tumor, hence OCT4 is the best discriminatory stain.

Choriocarcinoma

Choriocarcinoma is highly malignant germ cell tumor characterized by the presence of syncytiotrophoblastic and cytotrophoblastic elements, and biochemically by the production of the human chorionic gonadotropin (hCG). Tumor originates in the testis or ovary, uterus or midline structures with pluripotent germ cells. Women may develop choriocarcinoma following hydatidiform mole, normal pregnancy or spontaneous abortion. Tumor metastasizes to lungs, vulvovaginal region, brain and liver. Tumor occurs in young boys associated with elevated hCG, and impotence associated with poor prognosis.

PRIMITIVE NEUROECTODERMAL TUMORS

Primitive neuroectodermal tumors are a group of highly-malignant tumors composed of small round cells of neuroectodermal origin that arise in central nervous system, autonomic nervous system and outside central and autonomic nervous systems. Primitive neuroectodermal tumors (PNETs) include glioblastoma multiforme, astrocytoma, epen dymoma, medulloblastoma (rosettes in 33% cases), oligodendroglioma, retinoblastoma, neuroblastoma and Ewing sarcoma. PNETs exhibit great diversity in their clinical manifestations and pathologic similarities with other small cell tumors. Neuroectodermal neoplasms are given in Table 6.15.

Neuroblastoma

Neuroblastoma is a primitive neoplasm of neuroectodermal origin. Tumor occurs anywhere in distribution of neuroendocrine system (adrenal medulla, sympathetic ganglia) followed by soft tissue, retroperitoneum, and mediastinum. Tumor most often affects children under 5 years with peak incidence in the first 3 years of life. Tumor secretes catecholamines, hence urine analysis reveals high levels of catecholamines or their metabolites (dopamine, vanillylmandelic acid, homovanillic acid).

- **Clinical features:** Clinical features depend on location and extent of tumor. Deteriorating health, malnourishment and pain indicate metastatic disease. Patient often presents with a large abdominal

Table 6.15 Neuroectodermal neoplasms

Tumor	Cell of Origin	Comments
Astrocytoma	Astrocyte (type of glial cell)	Astrocytes normally provide support to neurons in central nervous system and tumor arising from astrocyte is called astrocytoma
Glioblastoma multiforme	Astrocyte (type of glial cell)	Highly aggressive astrocytoma
Medulloblastoma	Granular cells of cerebellum	Granular cells are present at the lower level of cerebellar cortex
Ependymoma	Cells lining the ventricles of the brain	Ventricles are fluid-filled cavities of brain, tumor arising from cells lining the ventricles is called ependymoma
Oligodendroglioma	Oligodendrocytes covering axons	Oligodendrocytes are similar to Schwann cells that construct insulating myelin sheath around axons in the brain
Meningioma	Arachnoid cells of meninges	Meninges cover the brain, tumor arising from arachnoid cells is called meningioma
Schwannoma	Schwann cells around axons	Schwann cells around axons construct insulating myelin sheath in the peripheral nervous system
Retinoblastoma	Cone cell in the retina	Photosensor for color vision during day-light
Neuroblastoma	Cells of the peripheral nervous system	Neuroblastoma arises from cells of the sympathetic nervous system

mass, malaise, fever, pallor and loss of weight. Neuroblastoma spreads to the liver, bones in skull, orbit, scalp, lymph nodes, subcutaneous tissue, intraspinal extension or kidney. Bone metastases are multiple and sometimes symmetric.

- Hutchinson's type of neuroblastoma is characterized by left side primary tumor and spreading upward by lymphatic route and metastases in the orbit and skull.
- Pepper type of neuroblastoma is characterized by primary tumor as well as secondaries especially liver metastases on right side of body.

- **Radiologic examination:** Abdominal contrast enhanced CT scan demonstrates irregular-shaped lobulated and heterogenous mass, calcification, hemorrhage and necrosis.
- **Gross examination:** Tumor is well-circumscribed ovoid to multilobated. Cut surface reveals areas of hemorrhage with vague and bulging lobules.
- **Histologic examination:** Tumor is composed of small, round blue tumor cells (neuroblasts) with '**salt and pepper chromatin**', inconspicuous nucleoli, and minimal cytoplasm, forming characteristic rosette-like structures (Homer-Wright pseudorosettes) around small vessels. Histology of neuroblastoma is shown in Fig. 6.47.
- **Immunohistochemistry:** Tumor cells of neuroblastoma show positivity for immunohistochemical markers neuron-specific enolase (NSE), neurofilament, chromogranin A, and synaptophysin.
- **Treatment:** Several types of treatment can be used for neuroblastoma which include surgery, chemotherapy, radiation therapy, high-dose chemotherapy and stem cell transplant, and immunotherapy.

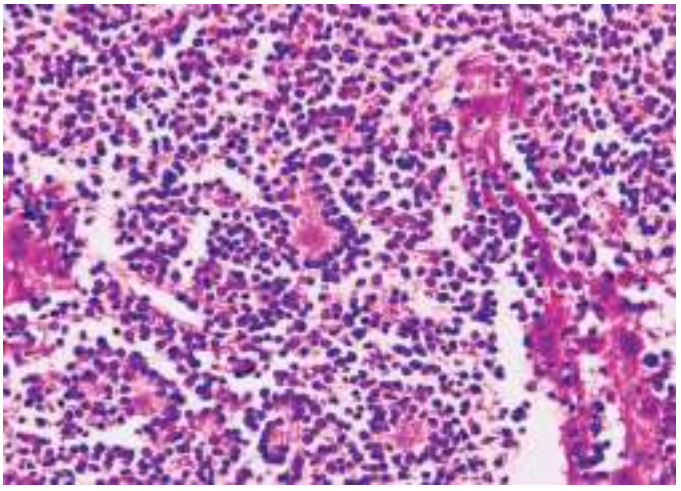

Fig. 6.47: Histology of neuroblastoma. Tumor is composed of small round blue cells (neuroblasts) and Homer-Wright pseudorosettes. Tumor cells contain round to oval nuclei with stippled salt and pepper chromatic and scanty cytoplasm (400X).

Retinoblastoma

Retinoblastoma is the most common intraocular malignancy in children caused by mutational inactivation of both alleles of RB1 gene, which maps to chromosome 13q14 and encodes retinoblastoma protein (pRB) that acts a tumor suppressor. Normally, RB1 gene is essential for the normal differentiation and growth of retinal stem cells. Tumor arises from the nuclear layer of the retina, with different growth patterns: endophytic, exophytic and mixed.

- **Clinical features:** Signs of retinoblastoma include white pupil, called leukocoria, strabismus, painful blind eye and loss of vision.

- **Radiologic examination:** Mineralization is common within human retinoblastoma, that can be diagnosed by ultrasound, CT scan and MRI scan. Exposure to radiation is not preferred especially in patients with RB1 germline mutation predisposed to second malignancy.
- **Gross morphology:** Cut surface of tumor reveals white, brain-like appearance with chalky areas of dystrophic calcification and yellow necrotic areas. Choroid and optic nerve extension can often be observed on gross examination.
- **Histologic examination:** Tumor is composed of small round blue cells with hyperchromatic nuclei, scant cytoplasm, high nuclear to cytoplasmic ratio, variable necrosis and calcifications. Tumor differentiation can be determined by the presence of rosettes. Well-differentiated retinoblastoma shows 'Homer-Wright rosettes'. Less-differentiated retinoblastoma shows 'Flexner-Wintersteiner rosettes' and fleurettes. Poorly-differentiated retinoblastoma comprises anaplastic cells without rosettes or fleurette formation with nuclear pleomorphism and atypical mitotic figures.
- **Treatment:** Several types of treatment for retinoblastoma are surgery (enucleation), radiation therapy, laser therapy (photocoagulation or thermotherapy), cryotherapy, and chemotherapy.

NEUROENDOCRINE TUMORS

Neuroendocrine tumors may synthesize a number of hormones. Selected examples of neuroendocrine tumors are carcinoid tumors, medullary thyroid carcinoma, pheochromocytoma, Merkel cell carcinoma, small cell lung carcinoma and large cell neuroendocrine tumor of lung. Recent 2022 WHO classification of neuroendocrine tumors is given in Table 6.16.

- **Tumor markers:** Many tumor markers are used for diagnosis and follow-up of neuroendocrine tumors such as serum calcitonin in medullary thyroid carcinoma, serum catecholamines, and urinary 5-hydroxyindoleacetic acid (5-HIAA) in carcinoid tumor, serum insulin in insulinoma, gastrin, pancreatic polypeptide and glucagon specific to one subtype of exocrine neuroendocrine tumor of pancreas. Tumor markers

Table 6.16 Recent 2022 WHO classification of neuroendocrine tumors

Neuroendocrine Neoplasm	Classification	Diagnostic Criteria
Gastrointestinal and panreatobiliary tract		
Well-differentiated neuroendocrine tumor (NET)	▪ NET grade 1 ▪ NET grade 2 ▪ NET grade 3	▪ Mitoses (<2/2 mm²) and/or Ki-67 (<3%) ▪ Mitoses (2–20/2 mm²) and/or Ki-67 (3–20) ▪ Mitoses (>20/2 mm²) and/or Ki-67 (>20)
Poorly-differentiated neuroendocrine tumor (NET)	▪ Small cell NET ▪ Large cell NET	▪ Mitoses (>20/2 mm²) and/or Ki-67 (>20) ▪ Mitoses (>10/2 mm²) and/or Ki-67 (>20, often >70) and large cell morphology
Upper aerodigestive tract and salivary glands		
Well-differentiated neuroendocrine carcinoma (NEC)	▪ NET grade 1 ▪ NET grade 2 ▪ NET grade 3	▪ Mitoses (<2/2 mm²) and/or necrosis, Ki-67 (<20) ▪ Mitoses (2–10/2 mm²) and/or Ki-67 (<20) ▪ Mitoses (>10/2 mm²) and/or Ki-67 (>20)
Poorly-differentiated neuroendocrine carcinoma (NEC)	▪ Small cell NET ▪ Large cell NET	▪ Mitoses (>10/2 mm²) small cell morphology and/or Ki-67 (>20) ▪ Mitoses (>10/2 mm²) larger cell morphology and/or Ki-67 (>20)
Lung and thymus gland		
Well-differentiated neuroendocrine tumor (NET)	▪ Typical carcinoid/NET grade 1 ▪ Atypical carcinoid/NET grade 2 ▪ Carcinoids/NETs with elevated mitotic counts and/or Ki-67 proliferative index	▪ Mitoses (<2/2 mm²) and lack of necrosis ▪ Mitoses (2–10/2 mm²) and/or necrosis (usually punctate) ▪ Mitoses (>10/2 mm²) and/or Ki-67 (>30)
Poorly-differentiated neuroendocrine carcinoma (NEC)	Small cell lung carcinoma	▪ Mitoses (>10/2 mm²) often necrosis and small cell morphology ▪ Mitoses (>10/2 mm²) and virtually presence of necrosis and large cell morphology
Thyroid gland		
Medullary thyroid carcinoma (MTC)	▪ Low-grade MTC ▪ High-grade MTC	▪ Mitoses (<5/2 mm²) and lack of necrosis and/or Ki-67 (<5) ▪ At least one of the following features: Mitoses (≥5/2 mm²), Ki-67 (≥5), necrosis

Table 6.17 Tumor markers in neuroendocrine tumors in clinical oncology

Neuroendocrine Tumor	Serum and Urine Markers
Carcinoid tumor	▪ Serum chromogranin A ▪ Urinary 5-hydroxyindoleacetic acid (5-HIAA)
Nonfunctional carcinoid tumor	▪ Serum chromogranin A ▪ Serum neuron-specific enolase (NSE)
Small cell lung carcinoma	▪ Serum chromogranin A ▪ Serum synaptophysin ▪ Serum neuron-specific enolase (NSE)
Medullary thyroid carcinoma	▪ Calcitonin ▪ Serum chromogranin A ▪ Carcinoembryonic antigen (CEA)
Insulinoma	▪ Serum insulin ▪ Serum C-peptide ▪ Serum proinsulin ▪ Serum neuron-specific enolase (NSE) ▪ Serum chromogranin A
Nonfunctional pancreatic neuroendocrine tumor	▪ Serum pancreatic polypeptide ▪ Serum neuron-specific enolase ▪ Serum chromogranin A
Gastrinoma	▪ Serum gastrin ▪ Serum chromogranin A
Pheochromocytoma	▪ Urinary metanephrine ▪ Serum neuron-specific enolase ▪ Serum chromogranin A

in neuroendocrine tumors in clinical oncology are given in Table 6.17.

- **Immunohistochemistry:** General immunohistochemical markers for various neuroendocrine tumor subtypes include chromogranin A, synaptophysin and neuron-specific enolase (NSE).

Carcinoid Tumor

Carcinoid tumor is slow-growing neuroendocrine tumor originating in gastrointestinal tract (70%), i.e. stomach, appendix, small intestine, colon, rectum, respiratory tract (25%), i.e. bronchopulmonary region, and rarely ovaries, testicle and kidneys. Carcinoid tumors are classified based on embryonic site of origin: (a) carcinoid tumors in foregut with trabecular pattern (stomach, respiratory tract), (b) carcinoid tumors in midgut with polygonal cells arranged in sheets (small intestine, appendix), and (c) carcinoid tumors in hindgut (distal colon, rectum, genitourinary tract) with similar morphologic pattern and demonstrated by silver staining.

- **Clinical features:** In normal persons, biologically active polypeptides and biogenic amines (5-hydroxytryptamine, 5-hydroxyindoleacetic acid, dopamine, histamine), polypeptides (chromogranin A, neurotensin, vasoactive amines, motilin, somatostatin, substance P), tachykinins (kallikrein, neuropeptide) and prostaglandins are normally inactivated in the liver. Most patients become symptomatic due to increased level of serotonin. Serotonin is an end product of tryptophan metabolism. Serotonin undergoes oxidative reactions that lead to the formation of 5-hydroxyindoleacetic acid (5-HIAA) with the help of aldehyde dehydrogenase, which is then excreted in the urine.
  - **Midgut carcinoid tumor:** Midgut carcinoid tumor secretes bioactive products, which causes carcinoid syndrome in patient with liver metastasis. Active bioactive products, i.e. biogenic amines, polypeptides (tachykinins, serotonin, histamine, kallikrein and prostaglandins) directly enter the systemic circulation, escaping the first-pass metabolism of the liver as these bioactive products are not inactivated due to deranged liver function. Patient presents with carcinoid syndrome characterized by flushing over face, neck and upper trunk (85%), wheezing (10–20%), diarrhea (80%), malabsorption, pellagra (secondary to niacin), tricuspid valvular disease (60–70%), and fatigue. Midgut carcinoid tumors are frequently multiple exhibiting multicentricity associated with mechanical obstruction of the small intestine as a result of extensive mesenteric fibrosis.
  - **Foregut and hindgut carcinoid tumors:** Carcinoid tumors of the foregut and lungs lack the enzyme aromatic L-amino acid decarboxylase, which is essential for metabolism of 5-hydroxytryptophan to serotonin. Foregut and hindgut carcinoid tumors do not produce and bioactive products hence they rarely cause carcinoid syndrome. However, lung carcinoid tumor secretes histamine, which can cause flushing and pruritus.
- **Diagnostic modalities:** Diagnostic modalities for carcinoid tumors include testing for biochemical markers followed by localization of tumors with radiologic and endoscopic studies: 24-hour urine for 5-hydroxyindoleacetic acid (5-HIAA), immunomarker chromogranin A, radiographic imaging and histologic examination of bronchoscopy biopsy.
- **Gross examination:** Tumor is well circumscribed but not encapsulated. Cut surface reveals white or pale-yellow tan and very firm due to marked desmoplastic reaction.
  - Gastric carcinoid tumor is usually large and solitary.

- Appendiceal carcinoid tumor is discovered as incidental finding.
- Bronchopulmonary carcinoid tumor originates from Kulchitsky cells of bronchopulmonary mucosa, which is well-circumscribed tan-colored, sessile or pedunculated with partial or complete obstruction.

- **Histologic examination: Typical carcinoid tumor** is well-differentiated with size >5 mm and composed of cytologically uniform bland cells with polygonal shape, round to oval nuclei with 'salt and pepper chromatin' and inconspicuous nucleoli arranged in nests, trabecular and pseudoglandular pattern, that exhibit minor cellular atypia and <2 mitoses/2 mm^2 and absence of necrosis. Pathologic diagnostic criteria of atypical bronchopulmonary carcinoid tumor depend on the presence of morphology and at least one of the following: (a) necrosis or (b) 2–10 mitoses per 10 high power fields. Histology of carcinoid tumor of ileum is shown in Fig. 6.48.
- **Immunohistochemistry:** Chromogranin A, synaptophysin, CD56 and neuron-specific enolase (NSE) are diffusely and strongly positive in carcinoid tumors. Ki-67 proliferative index is useful to discriminate between typical and atypical carcinoid, and high-grade small or large cell neuroendocrine tumor. TTF-1 and RB are useful immunomarkers of bronchopulmonary carcinoid tumors.
- **Treatment:** Surgical approach is the primary therapy for localized and locoregional resectable disease.

Small Cell Lung Carcinoma

Small cell lung carcinoma (SCLC) is high-grade neuroendocrine tumor in tobacco smokers associated with invasion and metastasis via lymphatic route to lymph nodes, and via hematogenous route to liver, adrenal glands, bone marrow and brain. Snake-like masses of tumor may involve the portal vein (35–80%), hepatic vein (20%) or inferior vena cava (similar to renal cell carcinoma). Tumor is treated by combined chemotherapy and radiotherapy.

- **Clinical features:** Patient presents with cough, dyspnea, weight loss and paraneoplastic syndromes like Cushing syndrome (ACTH secretion), syndrome of inappropriate antidiuretic hormone secretion (SIADH), Lambert-Eaton syndrome, peripheral neuropathy, cerebellar degeneration, gynecomastia and testicular atrophy (gonadotropin-like hormone).
- **Gross morphology:** Tumor is centrally located in the hilar along peribronchial region. Gross examination reveals white-tan, soft, friable and necrotic tumor with fleshy appearance on cut surface.
- **Histologic examination:** Tumor is composed of round/oval blue cells with minimal cytoplasm, usually small- to medium-sized with finely dispersed chromatin, molding, smudging and high mitotic rate but without distinct nucleoli. Tumor cells are arranged in sheets, clusters, ribbons, and rosettes. Thin, scant and delicate fibrovascular stroma present. 'Azzopardi phenomenon' can be demonstrated as basophilic nuclear material lining blood vessel walls.
- **Electron microscopy:** Electron microscopy of tumor reveals neurosecretory granules, which are present in cytoplasm with perinuclear hallo.
- **Immunohistochemistry:** SCLC is positive for immunohistochemical markers such as synaptophysin and chromogranin A (90–100%). Other immunomarkers such as CD56, CD57, neuron specific enolase (NSE), TTF-1, and napsin.

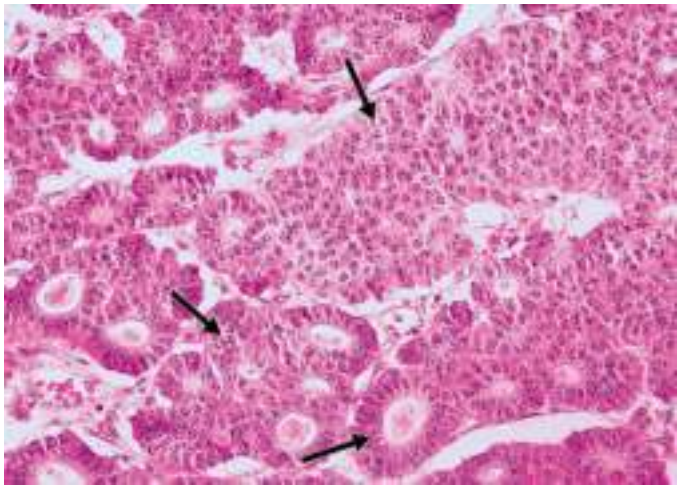

Fig. 6.48: Histology of carcinoid tumor of ileum. Tumor is composed of uniform cells with stippled chromatin (arrows) (400X).

Medullary Thyroid Carcinoma

Medullary thyroid carcinoma is neuroendocrine tumor derived from C cells of ultimobranchial body of neural crest, which secretes calcitonin. Tumor can be either sporadic (70%) or familial (germline mutation of RET gene in 30%) in the settings of multiple endocrine neoplasia 2A or 2B (MEN-2A or 2B), familial medullary thyroid carcinoma, von Hippel-Lindau disease or neurofibromatosis (NF).

- **Clinical features:** Patient presents with painless thyroid mass, and/or lymph node involvement (75%). Serum calcitonin level is correlated with tumor burden. Patient with metastasis may present with severe diarrhea and flushing. Tumor may secrete ACTH or corticotropic releasing hormone leading to Cushing syndrome.

- **Gross examination:** Sporadic medullary thyroid carcinoma is well-circumscribed and unencapsulated, gray-tan and firm mass. Familial medullary thyroid carcinoma is generally bilateral and multifocal. Cut surface of large tumor shows areas of hemorrhage and necrosis.
- **Histologic examination:** Tumor is composed of round, polygonal, plasmacytoid with round nuclei and fine to coarse chromatin, arranged in nests, cords and follicles. Tumor stroma demonstrates amyloid deposits from calcitonin, prominent vasculature and calcifications.
- **Histochemical stain:** Congo red stain demonstrates amyloid in tumor stroma of medullary thyroid carcinoma.
- **Immunohistochemistry:** Medullary thyroid carcinoma is positive for immunohistochemical markers such as calcitonin, carcinoembryonic antigen (CEA), PAX8, calcitonin gene-related peptide, ACTH, somatostatin, gastrin releasing peptide, neurotensin, chromogranin A, synaptophysin, and neuron-specific enolase (NSE).
- **Biochemical modalities:** High serum calcitonin and CEA levels are demonstrated in untreated patients with medullary thyroid carcinoma. Patients are monitored to analyze their levels.
- **Treatment:** Surgical thyroidectomy with neck dissection is performed base on serum calcitonin. Total thyroidectomy with cervical lymphadenectomy is done for lymph node positive patients.

Pheochromocytoma

Pheochromocytoma is a neuroendocrine tumor, which originates from chromaffin cells of the adrenal medulla that affects fourth- and fifth-decade persons. The tumor cells have traits of both hormone-producing endocrine cells (catecholamines, i.e. adrenaline and noradrenaline during stress), and nerve cells.

- **Pathogenesis:** Tumor is most often sporadic, associated with hereditary syndromes (30%) in the settings of von Hippel-Lindau syndrome, multiple endocrine neoplasia 2 (MEN2), neurofibromatosis type 1 (NF1) and familial paraganglioma. Malignant pheochromocytoma occurs in 10% of cases. Uncontrolled surges of extra catecholamines (adrenaline and noradrenaline) released by pheochromocytoma increase blood pressure and heart rate. Hormonal surges can still lead to life-threatening complications, i.e. cerebral stroke, myocardial infarction or sudden cardiac death.
- **Clinical features:** Patient presents with classic triad of episodic headaches, sweating and increased heart rate in 30% of cases. Other clinical manifestations are palpitations, postural hypotension and paroxysmal hypertension. Subclinical pheochromocytoma remains asymptomatic.
- **Gross examination:** Tumor is well-circumscribed and unencapsulated mass. Cut surface reveals solid, white to red-brown and hemorrhagic tumor with a mean weight of 150 g. Malignant tumor weighs 280 g.
- **Histologic examination:** Tumor is composed of large, polygonal, uniform or extensively vacuolated cells with abundant fine granular red-purple cytoplasm, round to oval nuclei, prominent nucleoli and arranged in nests, solid sheets or trabecular pattern.
- **Immunohistochemistry:** Positive immunohistochemical stains for pheochromocytoma are synaptophysin, chromogranin A, S-100, GATA3, CD10, and vimentin. SDHB is usually positive unless in SDHB deficient tumor.
- **Diagnostic modalities:** Tumor secretes catecholamines (i.e. noradrenaline and adrenaline or dopamine) or their metabolites. Catecholamines and their metabolic products are detected in the blood or urine via high performance chromatography or tandem mass spectroscopy. Chromogranin A secreted by chromaffin cells is detected in serum in 90 of cases. Computed tomography (CT) imaging can detect lesion 5 mm. Magnetic resonance imaging (MRI) is done to evaluate metastatic disease.
- **Treatment:** Surgical resection of pheochromocytoma tumor is done via total adrenalectomy unless bilateral tumors. Chemotherapy is administered in unresectable malignant tumor.

Pathology Pearls: Paraganglioma (Neuroendocrine Tumor)

- Paraganglioma is a slow-growing neuroendocrine tumor that can originate in the abdomen (most common), along sympathetic nervous system or parasympathetic nerves in the head and neck, carotid artery, chest, pelvis and urinary bladder. Tumor remains localized (60%) and metastasizes (40%) to distant organs.
- Like pheochromocytoma, sympathetic paraganglioma almost always secretes catecholamines. Sympathetic nervous system regulates body's responses to stress and activity.
- Parasympathetic paraganglioma occurs in the head and neck regions, which usually does not produce catecholamines. Parasympathetic nervous system regulates the body functions during rest.

Merkel Cell Carcinoma

Merkel cell carcinoma is highly aggressive primary neuroendocrine carcinoma of skin affecting elderly and immunocompromised persons. Tumor occurs in the

settings of polyomavirus (most often), and exposure to sun ultraviolet radiation (head and neck > extremities > trunk).

- **Gross examination:** Tumor is fleshy to tan-brown with expansile, nodular or diffusely infiltrative growth with variable ulceration within dermis and variably in subcutis.
- **Histologic examination:** Tumor is composed of small round cells with round to oval nuclei, nuclear molding, finely dispersed chromatin with **salt** and **pepper appearance,** scant cytoplasm, atypical mitotic figures arranged in sheets and trabeculae.
- **Immunohistochemistry:** Merkel cell carcinoma is positive for immunohistochemical markers such as cytokeratins (CAM 5.2, AE1/AE3, CK20), chromogranin, synaptophysin, neuron-specific enolase (NSE), and CD556. MCPyV is positive nuclear immunostain. Tumor can express PAXA5, BCL-2, CD99, Fli-1 and TdT.
- **Treatment:** Treatment consists of wide local excision in negative sentinel lymph node patient with or without adjuvant radiotherapy. Advanced tumor is treated by immune checkpoint blockade therapy, targeting PDL1/P1 signaling pathway. Chemotherapy is ineffective and reserved for palliation.

HEMATOLYMPHOID MALIGNANCIES

The hematopoietic cells are derived from the embryonic mesoderm. Hematolymphoid malignancies have no benign counterparts, which include leukemias, multiple myeloma, Hodgkin's disease and non-Hodgkin's lymphoma.

Leukemias

Leukemia is a heterogenous group of hematologic malignancies that originate from dysfunctional proliferation of developing leukocytes in the bone marrow. It can be classified by either acute myelogenous leukemia (AML-M0-to-AML-M7) or acute lymphoblastic leukemia (ALL-L1, ALL-L2, ALL-L3), or chronic myelogenous leukemia (CML) and chronic lymphocytic leukemia (CLL). Leukemic cells can infiltrate liver, spleen, lymph nodes, central nervous system, testes and other organs.

- **Acute myelogenous/lymphoblastic leukemias:** According to revised 2016 WHO classification of acute leukemias (acute myelogenous leukemia and acute lymphoblastic leukemia), diagnostic criteria are the presence of ≥20% blast cells as the cut off percentage in bone marrow and peripheral blood. Patient suffering from acute leukemias presents with weakness, lethargy, fatigue, dyspnea, fever, weight loss or easy bruising or bleeding. Blasts may also infiltrate lymph nodes and organs resulting in lymphadenopathy and hepatosplenomegaly. Bone marrow infiltration with blasts can result in bone pain.
- **Chronic myelogenous/lymphocytic leukemias:** CML is pluripotent hematopoietic stem cell disorder with chromosomal translocation t(9,22) (q34.1;q12.2) and formation of the Philadelphia (Ph) chromosome, containing the BCR-ABL1 fusion gene. CML occurs in three different phases: chronic phase (bone marrow, blood and spleen), accelerated phase and blast phase (spleen, liver, lymph nodes, skin and soft tissue). CLL is a malignant disorder of mature B cells with characteristic immunophenotype showing peripheral lymphocytosis ($\geq 5 \times 10^9$/L) with or without lymph node or extranodal manifestations.

Multiple Myeloma

Multiple myeloma is a neoplastic proliferation of plasma cell that can commonly result in multiple skeletal lesions, hypercalcemia, renal insufficiency, anemia and immunosuppression.

- **Diagnostic criteria:** Diagnostic criteria of multiple myeloma include: presence of plasma cells ≥10% in trephine bone marrow biopsy or biopsy proven bony/extramedullary plasmacytoma and ≥1 of the CRAB features and multiple myeloma defining events. CRAB features of end-organ damage include: high calcium level (C), renal insufficiency, anemia (A), bone pain (B) and ≥1 osteolytic lesion on radiograph, CT scan or PET/CT scan.
- **Treatment:** Treatment is usually chemotherapy and radiation. Surgery management is indicated for associated pathologic fractures.

Lymphomas

Lymphomas are malignancies that develop from lymphocyte (i.e. Hodgkin's disease and non-Hodgkin's lymphoma), which mainly involve the lymph nodes. WHO categorizes Hodgkin's disease into two subtypes: (a) classical Hodgkin's disease (i.e. nodular sclerosis, mixed cellularity, lymphocytic depletion and lymphocytic rich), and (b) nodular lymphocytic-predominance.

- **Diagnostic criteria:** Hodgkin's disease is marked by the presence of neoplastic Reed-Sternberg cells (RS cells), whereas Reed-Sternberg cells are absent in non-Hodgkin's's lymphoma.
  - Reed-Sternberg cells in Hodgkin's disease (HD) include classical Reed-Sternberg cells (mixed cellularity HD), mononuclear Reed-Sternberg cells (mixed cellularity HD), pleomorphic Reed-Sternberg cells (lymphocytic depletion HD), lacunar Reed-Sternberg cells (nodular sclerosis HD), and lymphocytic–histiocytic (popcorn) Reed-Sternberg cells (nodular lymphocytic predominance HD).

- Reed-Sternberg cells are CD30 and CD15 positive except in the Hodgkin's disease (nodular lymphocytic predominance). Nodular lymphocytic predominance Hodgkin's diseases are positive for CD20 and CD45.

- **Lymph nodes involved:** Hodgkin's disease most often involves lymph nodes in neck, axillary region and chest. In contrast, non-Hodgkin's lymphoma involves lymph nodes throughout the body.

MISCELLANEOUS TERMINOLOGY RELATED TO NEOPLASMS

Miscellaneous terminology related to neoplasms is used by pathologists such as congenital melanocytic nevus, hamartomas, choristomas and polyps in various organs. Hamartoma is not a neoplasm, which consists of a disorganized collection of tissue, normally found in the organ. Choristoma is not a neoplasm, which is composed of ectopic fairly normal tissue located at a site where it normally is not present. **Polyp** refers to mass projecting from a mucosal surface, which may or may not be a neoplasm.

Hamartoma

Hamartoma (from Greek *hamartia* meaning '**fault defect**' and *oma*, denoting a tumor) is benign appearing non-neoplastic tissue composed of mature but disorganized cells of tissues indigenous to the particular organ, where growth occurs. It is considered a developmental error and can occur at a number of sites. Hamartoma contains varying combinations of mature cartilage, ducts or bronchi, connective tissue, blood vessels, and lymphoid tissue. Developmental remnants may be considered hamartomatous if they form discrete tumor-like masses. Hamartomatous syndromes are given in Table 6.18.

- **Congenital melanocytic nevus:** Congenital melanocytic nevus represents an aggregate of pigment cells since birth over trunk and limbs, that are normally dispersed in the skin. Nevus can be flat or raised or thickened that shows tan to black discoloration. Excessive hair growth can occur within the nevus.
- **Hamartomas in Peutz-Jeghers syndrome:** Peutz-Jeghers syndrome is an autosomal dominant disorder due to LKB1/STK11 gene in young children 10–15 years of age. Patient presents with multiple hamartomatous polyps in small intestine (most common), stomach, and colon in decreasing frequency; melanotic pigmented macules (1–5 mm) on lips, perioral skin, hands and genitalia. Peutz-Jeghers syndrome is linked to increased risk for cancers of gastrointestinal tract, thyroid, breast, lung, pancreas, gonads and urinary bladder.
- **Pulmonary hamartoma:** Pulmonary hamartoma presents as a nodule composed of cartilage, bronchial epithelium, and smooth muscle cells. It occurs in adults over 40 years of age, with a peak incidence

Table 6.18 Hamartomatous syndromes

Syndrome	Gene Locus	Clinical Features	Predisposition to Cancers
Juvenile polyposis	▪ SMAD4 (18q21.1) ▪ BMPRIA (10q22.3)	Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu) especially with SMAD4 gene mutation	▪ Colorectal carcinoma ▪ Gastric carcinoma ▪ Pancreatic carcinoma
Peutz-Jeghers syndrome	STK11 (18p13.3)	▪ Small intestinal hamartomas that may obstruct or bleed ▪ Hyperpigmented macules mouth, buccal mucosa, eyes, nostrils, perianal regions	▪ Thyroid carcinoma ▪ Ovarian carcinoma ▪ Lung carcinoma ▪ Pancreatic carcinoma ▪ Breast carcinoma
Cowden's syndrome (PTEN hamartoma syndrome)	PTEN (10q23.31)	▪ Mucocutaneous features in ≤80% ▪ Macrocephaly ▪ Mixed colonic polyposis	▪ Thyroid carcinoma ▪ Breast carcinoma ▪ Endometrial carcinoma ▪ Brain cancer ▪ Renal cell carcinoma
PTEN-hamartoma syndrome (Bannayan-Riley-Ruvalcaba syndrome)	PTEN (10q23.31)	▪ Microcephaly ▪ Lipomatosis ▪ Pigmented macules of the glans penis	▪ Thyroid carcinoma ▪ Breast carcinoma ▪ Endometrial carcinoma ▪ Brain cancer ▪ Renal cell carcinoma
Hereditary mixed polyposis syndrome	▪ BMPRIA (10q22.3) ▪ GREM1	▪ Atypical polyposis with juvenile polyps, adenomas ▪ Hyperplastic and inflammatory adenomas	Colorectal carcinoma

in the sixth decade of life. It constitutes 10% of coin lesions in lungs with popcorn pattern of calcification, discovered as incidental finding on chest radiograph. Immunohistochemistry technique demonstrates expression of smooth muscle actin and S-100 in spindle cells. In males, the epithelial cells express ER, PR and androgen receptors. Histology of pulmonary hamartoma is shown in Fig. 6.49.

- **Bile duct hamartoma:** Bile duct hamartoma is asymptomatic lesion also known as von Meyenburg complex that shows irregularly dilated bile ducts. It is important to distinguish this disorder from multiple hepatic metastases. Women are more affected than men. Histologic examination of the hamartomatous nodule shows proliferations of bile ducts. Histology of bile duct hamartoma is shown in Fig. 6.50.

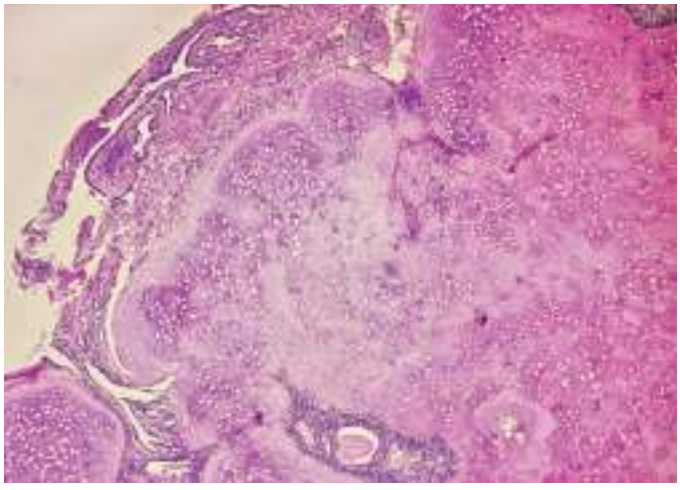

Fig. 6.49: Histology of pulmonary hamartoma. Tumor is composed of cartilage, bronchial epithelium, and smooth muscle cells (100X).

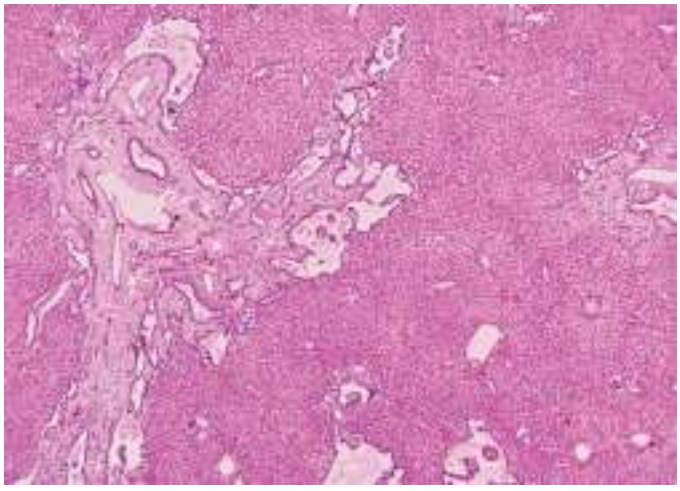

Fig. 6.50: Histology of bile duct hamartoma. Multiple bile duct hamartomas are also known as von Meyenburg complex. Bile duct hamartoma is composed of small disorganized clusters of dilated cystic bile ducts lined by columnar cells enclosed within fibrocollagenous stroma (100X).

Table 6.19 Selected examples of choristomas

Microscopic Tissue	Located in Organs
Pancreatic tissue	Stomach intestine, liver
Gastric mucosa	Meckel's diverticulum
Adrenal rest	Beneath renal capsule
Ectopic brain tissue	Nasal cavity
Splenic tissue	Peritoneal cavity

Choristoma

Choristoma is ectopic islands of normal mature tissue derived from germ cell layers misplaced within another organ, e.g. pancreatic tissue within the wall of the stomach.

- About 85% of osseous and cartilaginous choristomas occur on tongue (dorsal posterior third near foramen cecum) especially in adults. Presence of ectopic islands of normal mature tissue derived from germ cell layer in an organ in a disorganized mass is called choristoma. Selected examples of choristoma are given in Table 6.19.
- Patient presents with firm, exophytic, symptomatic nodule covered by intact oral mucosa. Base of the lesion may be sessile or pedunculated. Glial choristoma of palate has been reported in one-month infant. Buccal choristoma has been reported in a five-year old child. Surgical resection remains the best treatment to prevent recurrence of choristoma.

Surgical Pathology: Choristoma

Gross Morphology

- Choristoma is firm mass covered by oral mucosa with smooth contour usually measuring less than 1 cm. Careful histologic examination of choristoma of >2 cm size is essential.
- Oral choristomas can be classified according to types of tissues they constitute: salivary gland choristoma, cartilaginous choristoma, osseous choristoma, lingual thyroid choristoma, lingual sebaceous choristoma, glial choristoma, gastric mucosal choristoma and respiratory mucosal choristoma.
- Cartilaginous choristoma is composed of mature hyaline cartilage in fibrous tissue that resembles perichondrium; usually multilobulated chondrocytes lacking atypia.
- Osseous choristoma is composed of dense mature bone with compact osteocytes.

Histologic Examination

- Choristoma should be differentiated from cartilaginous metaplasia beneath ill-fitted denture and pleomorphic adenoma of thyroid gland.

- Pancreatic tissue can be located in wall of gastric, intestine and liver.
- Gastric tissue is demonstrated in Meckel's diverticulum.
- Adrenal rest may be located beneath renal capsule.
- Splenic tissue may be located in the peritoneum.

Polyps in Various Organs

Polyp is a mass that projects above a mucosal surface to form a macroscopically visible structure. A polyp is a descriptive term; the mass causing the polyp may or may not be a neoplasm. Polyps are distinguished by their growth patterns (i.e. sessile or pedunculated). Sessile polyps are flat and they grow directly out of the surrounding tissue. Pedunculated polyps have a stalk, that is attached to the mucosa. Polyps occur on surface lining of nasal cavity, gastric region, large intestine and uterine endometrium.

Nasal Polyps

Nasal polyps are soft painless, benign growths on the lining of nasal passages or paranasal sinuses. They hang down like grapes, and frequently occur in childhood. Nasal polyps arise from wall of maxillary antrum, extending through maxillary ostium into nasal cavity. These may project into choanae or nasopharynx.

- **Predisposing factors:** Predisposing factors for nasal polyps include chronic inflammation, bronchial asthma, allergic rhinitis, sensitivity to nonsteroidal anti-inflammatory drugs (NSAIDs), cystic fibrosis and Churg-Strauss syndrome or immune system disorders.
- **Clinical features:** Patient presents with sensation of nasal block, breathing through mouth, running nose, postnasal drip, nasal congestion, snoring, and headache.
- **Gross morphology:** Nasal polyp has long narrow stalk with firm fibrous body.
- **Histologic examination:** Nasal polyp is composed of thin surface, stroma with stellate cells, less edema and fewer glands, prominent blood vessels and numerous eosinophils.
- **Treatment:** Nasal polyps may recur after surgery.

Endometrial Polyps

Endometrial polyps are hyperplastic overgrowth of endometrial tissue that forms a localized projection as polypoidal or pedunculated mass into the endometrial cavity. Polyp originates from anywhere in the endometrium in the posterior surface of uterine cavity, followed by anterior, lateral and uterotubal junction.

- **Predisposing factors:** Predisposing factors for endometrial polyps include increased endogenous estrogen and exogenous estrogen administration.
- **Clinical features:** Patient can present with irregular or heavy periods, bleeding or spotting between menstrual periods or abnormal vaginal bleeding after menopause in 25% of patients.
- **Gross morphology:** Endometrial polyp is usually solitary, 0.3–12 cm size, smooth surface, sessile or broad base, pedunculated or attached to the endometrium by thin stalk. Cut surface reveals soft, cystic, firm, and fibrous appearance.
- **Histologic examination:** Endometrial polyp is composed of glandular architecture out of menstrual cycle phase with the background endometrium and supporting fibrous stroma rich in collagen with abundant extracellular connective tissue that contains thick-walled blood vessels secondary to complex interaction of leuteinizing hormone, follicle-stimulating hormone, estrogen and progesterone hormones.
- **Treatment:** Postmenopausal polypectomy of hysterectomy is performed for symptomatic polyp(s).

Gastric Polyps

Gastric polyps are arising from epithelium include fundic gland polyps, hyperplastic polyps and adenomatous polyps. Fundic gland polyps are small and smooth flat benign lesions detected on endoscopy.

- **Hyperplastic gastric polyps:** Hyperplastic gastric polyps are strongly linked to chronic gastritis, *Helicobacter pylori*-induced gastritis and pernicious anemia, and which may undergo malignant change.
- **Adenomatous gastric polyps:** Adenomatous gastric polyps are the most common neoplastic polyps found in the gastric antrum, which may transform to malignant phenotype.

Colonic/colorectal Polyps

Colonic/colorectal polyps are growths that appear on the mucosal surface of the colon varying in size and number. Polyps are distributed throughout the large intestine, i.e. right colon (40%), left colon (40%) and rectosigmoid region (20%). Colonic/colorectal neoplastic polyps include: (a) benign hyperplastic colonic polyps without undergoing malignant change, (b) adenomatous polyps in the colon greater than 2 cm in size may be precursor of colon carcinoma, and (c) malignant colonic polyps are diagnosed by histologic examination.

FEATURES USED TO DISTINGUISH BENIGN TUMORS FROM MALIGNANT TUMORS

DISTINGUISHING FEATURES OF BENIGN AND MALIGNANT TUMORS

Benign tumors tend to grow slower; and malignant tumors tend to grow more quickly, often at a rate corresponding to their degree of anaplasia. Histologic features are reliable indicators of malignancy in many organs, which do not always distinguish benign tumors from malignant tumors in the endocrine glands.

- Benign tumors are well-circumscribed with distinct borders and smoothzz on cut surface. On the other hand, gross appearance of cancers is highly variable, consistent with the diversity of their origin, size, and biological behavior. Cut surface of malignant tumors may be firm, hard (scirrhous)/soft in consistency, homogeneous/heterogeneous texture, solid/cystic appearance, pale/dark color, and discolored by endogenous pigments, and hemorrhage and/or necrosis. Overall, 30% of malignant solid tumors have metastases in organ(s) at the time clinical presentation. Invasion and metastasis are indicators of malignancy associated with poor prognosis.
- In the biology of malignant tumors, cancer stem cells (CSCs) differ from normal cells in their biological properties in many aspects in respect of (a) tumor growth *in vivo*, (b) tumor structure, (c) tumor degree of differentiation, (d) tumor nucleocytoplasmic features, (e) tumor growth rate, (f) tumor cellularity and cell polarity, (g) tumor atypical mitotic figures, (h) monoclonal expansion of CSCs, (i) telomerase activity, (j) tumor angiogenesis, and (k) tumor invasion of basement membrane of tissues, through the action of matrix-metalloproteinase enzymes, detachment of CSCs from neighboring cells due to lack of surface adhesion molecules such as E-cadherin, and (l) tumor metastasis via lymphatic route to draining lymph nodes, hematogenous route to distant organs (lung, liver, bones and brain), and transcoelomic route to ovary (Krukenberg tumor).
- Cancer stem cells (CSCs) also differ from normal cells in many aspects in respect of tumor growth *in vitro*: (a) lack of contact inhibition, (b) exhibition of anchorage-independent growth in soft agar, and (c) exhibition of growth factor-independent tumor growth (autocrine stimulation).
- The term '**anaplasia**' refers, which implies dedifferentiation (loss of the structural and functional differentiation) of normal cells during tumorigenesis, which is almost always indicative of malignancy. Anaplastic cells exhibit pleomorphism, hyperchromatic nuclei, prominent nucleoli, nucleocytoplasmic ratio approaching 1:1, atypical mitotic figures (tripolar, quadripolar), chromosomal structural abnormalities (Philadelphia chromosome in chronic myelogenous leukemia/acute lymphoblastic leukemia), and chromosomal numerical abnormalities (aneuploidy).

TWO BASIC CELLULAR COMPONENTS IN TUMORS

Majority of benign and malignant tumors have two basic components: (a) proliferating neoplastic cells that constitute their parenchyma; and (b) supportive stroma made up of connective tissue and blood vessels. Parenchymal cells have the ability to divide, however supporting connective tissue stroma contains blood vessels, which provide nutrition to the parenchymal cells. Hematopoietic lineage-derived tumors lack supporting connective tissue stroma.

Benign Tumors: Two Basic Components

Benign tumors consist of two distinct components: parenchyma neoplastic (neoplastic cells), and non-neoplastic supporting connective tissue stromal components. They lack invasion in surrounding tissues metastasis. Benign tumors are well-differentiated, which resemble to their normal tissue of origin.

Malignant Tumors: Two Basic Components in Solid Organs

Most solid malignant tumors consist of two distinct components: parenchyma neoplastic (neoplastic cells) and non-neoplastic supporting connective tissue stromal components.

- **Tumor parenchyma:** Tumor parenchyma is made up of neoplastic cells that determines the biologic behavior of the tumor. The stromal cells work in conjunction with the parenchymal cells. The tumor parenchymal cells are responsible for the progression and invasiveness of malignant tumor.
- **Tumor non-neoplastic supporting connective tissue stroma:** Non-malignant and extracellular matrix (ECM) constitute the stroma in the tumor. Tumor connective tissue stroma is induced by the CSCs that contains newly formed blood vessels (tumor angiogenesis induced by angiogenic growth factors), that provide nutritional support and remove waste products. Tumor stroma is made up of two types of cells: (a) resident cells (cancer-associated fibroblasts, endothelial cells, pericytes, CSCs, mesenchymal cells), and (b) non-resident cells (T cells, B cells,

natural killer cells, myeloid-derived suppressor cells (MDSCs) and tumor-associated macrophages). In case of leukemias, blood serves as stroma, although an additional stromal response, i.e. angiogenesis may develop in the bone marrow.

Pathology Pearls: Stromal Desmoplasia in Solid Malignant Tumors

- Most infiltrating carcinomas (i.e. invasive ductal adenocarcinoma, i.e. scirrhous carcinoma of female breast, desmoplastic melanoma, cholangiocarcinoma, pancreatic carcinoma and diffuse gastric carcinoma—linitis plastica) induce production of a dense fibrous stroma (desmoplasia) composed of fibroblasts, vascular channels, immature cells and extracellular matrix (ECM) in varying proportions and minimal cellular infiltrate. Desmoplasia in patients with malignancy has long been associated with a poor clinical outcome.
- Stromal desmoplasia has been considered to be a response of invasive cancer stem cells (CSCs) in supporting stroma of the malignant tumor.
- Recent studies revealed that desmoplasia is the result of coordinated changes in several stromal cells under the control of CD36 gene product, whose expression results in a decrease in accumulation of adipocytes, and increase in dedifferentiation of cancer stem cells (CSCs) into fibroblasts, which themselves synthesize more collagen fibers leading to increased deposition of extracellular matrix (ECM) within malignant tumor
- Presence of desmoplasia in breast cancer detected in the form of mammographic density is one of the strongest risk factors for infiltrating duct carcinoma of female breast. On the other hand, medullary carcinoma of female breast lacks desmoplasia and hence exhibits soft consistency.

DEGREE OF DIFFERENTIATION IN TUMORS

During embryonic development, cells become more differentiated and specialized that reflect their specific functions. Differentiation is a term used to describe the extent to which appearance of tumor resembles corresponding their normal parenchymal tissue of origin. Cancer stem cells (CSCs) lose the ability to differentiate and enter a state called anaplasia.

Degree of Differentiation in Benign Tumors

All benign tumors tend to grow slowly and remain localized at the site of origin. Many benign tumors are enclosed by a capsule consisting of connective tissue derived from the structures immediately surrounding the tumor. Well-encapsulated tumors are not anchored to their surrounding tissues. Benign tumors are well-differentiated, which closely resemble to the tissue of origin on histologic examination.

Degree of Differentiation in Malignant Tumors

Malignant tumors are often poorly differentiated/undifferentiated (loss of resemblance to corresponding original parenchymal tissue, called anaplastic tumors), grow rapidly with many atypical mitoses (tripolar or quadripolar mitotic figures), which exhibit invasive growth without capsule and frequently metastasize via lymphatic route to draining lymph nodes and via hematogenous route to distant organ(s).

- On histologic examination, some malignant tumors can exhibit well-differentiation (close resemblance to their tissue of origin), moderate differentiation (intermediate resemblance to their tissue of origin) and poor differentiation. Invasion and malignancy are reliable indicators of malignancy.
- Histologic differentiation is used in grading system of malignant tumors. Differentiation often predicts responsiveness to certain therapies such as estrogen receptor inhibitor such as tamoxifen drug in treatment of infiltrating ductal carcinoma of breast.
  - Keratin pearl is a characteristic feature of a well-differentiated squamous cell carcinoma originating from skin, mouth, upper respiratory tract, and lungs. Squamous cell lung carcinoma synthesizes various ectopic hormones such as ACTH, parathyroid-like hormone, insulin and glucagon.
  - Well-differentiated and moderately-differentiated adenocarcinoma show glandular histology. If malignant tumors outgrow their blood supply, these may undergo necrosis on cut surface.

NUCLEOCYTOPLASMIC FEATURES IN TUMORS

Normal cell contains cell membrane, nucleus and cytoplasm. The cell nucleus contains the majority of the cell's genetic material in the form of multiple linear DNA molecules organized into structures called chromosomes. The nuclear pore complex is the only known gateway between the cell nucleus and the cytoplasm.

Nucleocytoplasmic Features in Benign Tumors

Benign tumors exhibit nucleocytoplasmic ratio close to the normal cells 1:4 or 1:6 and normal bipolar mitotic spindles (bipolar mitoses). On contrary, malignant tumors are composed of pleomorphic cells with hyperchromatic nuclei due to abundant DNA content, prominent nucleoli with high nucleocytoplasmic ratio 1:1, atypical mitotic figures (tripolar or quadripolar) and loss of polarity (disturbed orientation and tendency to form anarchic disorganized growth).

Nucleocytoplasmic Features in Malignant Tumors

In the pathology laboratory, surgical specimens are scrutinized by pathologist to observe nucleocytoplasmic

features to distinguish benign tumors from malignant tumors. Malignant tumors exhibit nucleocytoplasmic ratio 1:1, irregular nuclear membrane, atypical mitotic spindles (tripolar or quadripolar mitoses), and abnormal distribution of chromatin.

- Cytomorphologic nuclear abnormalities in cancer stem cells (CSCs) occur resulting from gene mutations, abnormal expression of genes, dysregulation of signal transduction pathways, alterations in nuclear envelope proteins and abnormal distribution of chromatin, and aneuploidy. Nuclear morphologic abnormalities are analyzed by examination of body fluids, fine needle cytology aspirates and biopsies.
- Cytomorphologic features are important in evaluation of tissue biopsies, where nuclear morphologic features are assessed in conjunction with architectural features such as growth pattern of CSCs in conjunction with desmoplastic stromal response.
- Intranuclear inclusions are important diagnostic features of many benign and malignant tumors (e.g. adrenal cortical adenoma, papillary thyroid carcinoma, melanoma, meningioma, hepatocellular carcinoma, pancreatoblastoma, pulmonary blastoma, fetal type adenocarcinoma, lobular carcinoma of breast and ovarian serous carcinoma). Intranuclear pseudoinclusions represent invaginations of cytoplasm into the nucleus, which are appreciated in cytologic preparations than in frozen sections or paraffin-embedded hematoxylin and eosin-stained tissue sections under light microscope thus forming an important cytological feature.

GROWTH RATE IN TUMORS

Benign tumors tend to grow at slower rate and stay in their primary locations without invading other sites of the body. In contrast, malignant tumors tend to grow rapidly, most often at a rate corresponding to their degree of anaplasia, which destroy surrounding normal tissues and metastasize via lymphatic route to lymph nodes, via hematogenous route to distant organs (liver, lungs, brain and bone) and via transcoelomic route. Growth rate of tumors depends on cell cycle, blood supply and hormones. As the epithelial cells have a shorter cell cycle than connective tissue cells, thus tumors of epithelial origin grow more rapidly than do tumors of connective tissue origin.

Growth Rate in Benign Tumors

Tumor develops when cells in the body divide and grow at an excessive rate. A tumor is a heterogenous mass of cells derived from a single ancestor cell.

- Most benign tumors have slow growth rate.
- A few benign tumors have variable growth rate (e.g. uterine leiomyoma, pituitary adenoma).
- Uterine leiomyoma has variable growth rate depending on circulating estrogen levels. Increased estrogen levels increase the size of leiomyoma, while decreased estrogen levels after menopause leads to decrease in size of leiomyoma.
- Pituitary gland adenoma shrinks in size due to compression of blood vessels by progressive enlargement of tumor in sella turcica.

Growth Rate in Malignant Tumors

Growth fraction refers to the proportion of CSCs in the proliferative phase. At the point, when most malignant tumors are clinically detected, growth fraction is less than 20% (i.e. most malignant tumors have their most rapid growth rate prior to detection).

- At least 30 doubling times of cancer stem cell (CSC) are essential for a malignant tumor to be clinically evident. Exposure to carcinogens result in the transformation of a normal cell to malignant phenotype. Malignant tumors continue to grow with further mutations, only if available nutrients, oxygen, and blood supply are adequate and the immune system fails to recognize or respond to CSCs.
- Growth rate is variable and dependent on differentiation of malignant tumors. Anaplastic cancers have marked increase in growth rate. Growth rate is faster in leukemias, non-Hodgkin's lymphoma and lung carcinoma than breast carcinoma and colon carcinoma.
- CSCs in tumors synthesize their own growth factors, which act in autocrine fashion. There is increased expression of growth factor receptors on the cell membrane of these rapidly growing CSCs. Increased growth factor and growth factor receptors further enhance proliferation of CSCs.
- Chemotherapy is targeted on rapidly proliferating CSCs. Debulking of malignant tumor is done by surgery or radiotherapy. Human cancers synthesizing growth factors with autocrine actions are given in Table 6.20.

CELLULARITY AND CELL POLARITY IN TUMORS

Cell divisions are controlled by internal and external positive and negative signals. In the **asymmetric** division, a stem cell produces one differentiated cell and one stem cell. In the **symmetric division,** a stem cell produces two differentiated cells or two stem cells, which plays an important role in development and homeostasis. Pathologists play important role in molecular diagnostics beyond identification of correct cells for analysis. Accurate cellularity not only ensures

Table 6.20 Human cancers synthesizing growth factors with autocrine actions

Ligand (Growth Factor)	Receptor	Human Cancer Type
HGF	Met	Miscellaneous endocrine tumors, breast carcinoma, lung carcinoma, osteosarcoma
IGF2	IGF-1R	Colorectal carcinoma
IL-6	IL-6R	Multiple myeloma, hereditary nonpolyposis colon cancer (HNPCC)
IL-8	IL-8R	Urinary bladder carcinoma
NRG	ErbB2α/ErbB3	Ovarian carcinoma
PDGF-BB	PDGFRA, B	Osteosarcoma, glioma
PDGF-C	PDFGRA, B	Ewing sarcoma
PRL	PRLR	Breast carcinoma
SCF	KIT	Ewing sarcoma, small cell lung carcinoma
VEGF-A	VEGFR (FLT-1)	Neuroblastoma, prostatic carcinoma, Kaposi sarcoma
TGF-α	EGFR	Squamous cell lung carcinoma, breast carcinoma, prostatic carcinoma, pancreatic carcinoma, mesothelioma
GRP	GRPR	Small cell lung carcinoma

sufficient material for required analytic sensitivity, but also provides a quality assurance of the molecular assays.

Cellularity in Tumors

Normal cells are anchored and oriented to the basement membrane; and CSCs lose this uniform orientation, which grow in a disorganized fashion. Histologic cellularity assessment of residual tumors in post-surgical tissues is used to analyze a malignant tumor's response to a therapy. Correct cellularity assessment of malignant tumors increases the chances of getting an appropriate treatment and facilitates patient's survival.

Cell Polarity in Tumors

Cell polarity is characterized by differences in structure, composition and function between at least two poles of a cell.

- **Physiologic state:** The correct establishment and maintenance of cell polarity in epithelial cells are crucial for normal cell physiology and tissue homeostasis. Apical-basal cell polarity and cell-to-cell adhesion are tightly interconnected. Functionally, **apical-basal polarity** has two fundamental roles in epithelial cells that are intimately linked to tumor suppression. Cell-to-cell adhesion and apical-basal cell polarity are tightly interconnected.
- **Pathologic state:** Loss of cell-to-cell adhesion and apical-basal cell polarity in epithelial cells, tissue disorganization and excessive cell growth are commonly observed in malignant epithelial tumors and correlates with their migration into adjacent tissue surrounding by epithelial–mesenchymal transition (EMT), and metastasis to distant organ(s).
  - Asymmetric cell division has recently emerged as a major regulatory mechanism that regulates stem cell numbers and differentiation.
  - **Front-to-back** polarity exists in migrating cells, which allow cells to adhere and detach from extracellular matrix (ECM) and migrate as isolated cells as well as in clusters during tumorigenesis.

MITOTIC FIGURES IN TUMORS

In normal eukaryotic cells, mitotic cell division typically occurs in a bipolar fashion resulting in two daughter cells with identical nuclear genomes. This restricted polarity is based on tight control of the centrosome cycle so that no more than two chromosomes are concurrently active during mitosis.

- Normally, bipolar mitoses are seen in rapidly proliferating cells in normal bone marrow, intestinal cells, hepatocytes.
- The centrosome is the main microtubules (MT)-organizing center in eukaryotic cells, which plays important roles in polarity, migration and cell division. During the cell cycle, centrosomes duplicate only once during synthetic (S) phase to ensure that at mitotic onset a cell carries two centrosomes, which serve as main microtubule-organizing centers to form mitotic spindle cell at the poles in distinct eukaryotic cell lineages.

- Mitotic activity is a measure of how fast tumor cells are dividing and growing. Careful scrutiny of mitotic figures is important in evaluation of proliferative activity as the counting methodology.

Landscape of Centrosome Abnormalities in Benign Tumors

Increased mitotic activity occurs in myometrial smooth muscle and intramural leiomyoma (up to 15 bipolar mitoses/10 high power fields) over the course of menstrual cycle. Leiomyoma with increased mitotic activity must not have any significant atypia or tumor necrosis. Mitotic activity should be reported as an average over per 10 high power field by using the 40X objective on conventionally figured light microscopes.

Landscape of Centrosome Abnormalities in Malignant Tumors

The centrosome plays an important role in polarity, migration and cell division. Centrosomal defects in human cancers can be classified as structural or numerical aberrations. It is worth mentioning that pyknotic nuclei in smooth muscle can be mistaken as mitoses by an inexperienced pathologist. Ki-67 is a proliferative marker that has some prognostic significance in leiomyosarcoma. Ki-67 immunohistochemical marker is helpful in exclusion of pyknotic nuclei and diagnosing malignancy.

Structural Aberrations in Centrosome and Human Cancers

Structural defects in centrosome can be divided into two groups: (a) defects in centriole structure, and (b) defects in the amount of pericentriolar material (PCM). A centrosome consists of two centrioles embedded in a matrix of proteins known as the pericentriolar material (PCM), which serves as a platform for protein complexes that regulate organelle trafficking, protein degradation and spindle assembly. The origin of centriole structural defects in human cancer is still not clear.

Numerical Aberrations in Centrosome and Human Cancers

Centrosome amplification is hallmark of cancer and has been associated with high-grade tumors and poor prognosis. A number of mechanisms can lead to centrosome amplification, including cytokinesis failure, mitotic slippage, cell–cell fusion, overduplication of centrioles and *de novo* centriole assembly.

- The number of underlying mechanisms may explain the diversity of proteins encoded by oncogenes and tumor suppressor genes and centrosome amplification in human solid malignant tumors breast, prostate, urinary bladder, colon, ovary and pancreas and hematolymphoid neoplasms (Hodgkin's disease, non-Hodgkin's lymphoma, multiple myeloma and leukemias).
- Similarly, loss of the tumor suppressor BRCA1 gene leads to centrosome amplification via increasing the levels of the pericentriolar material (PCM) and γ-tubulin. In urothelial cancers, centrosome amplification is a strong predictor of tumor recurrence, highlighting its potential as a biomarker for advanced disease.
- In cancers of breast, prostate and head and neck, centrosome amplification is correlated with lymph node and distant metastases, further reinforcing its association with disease progression.
- Counting abnormal mitotic figures (tripolar, quadripolar) in hematoxylin and eosin-stained tissue sections are an integral part of evaluation and grading system of malignant tumors by pathologists for assessment of prognosis and clinical decisions. An elevated mitotic index indicates rapidly dividing cells, which is an important prognostic factor predicting both overall survival and response to chemotherapy in most malignant tumors.
- Anaplastic tumors display abnormal mitotic figures (i.e. tripolar, quadripolar, and multipolar spindles). Atypical tripolar mitosis in high-grade carcinoma is shown in Fig. 6.51.

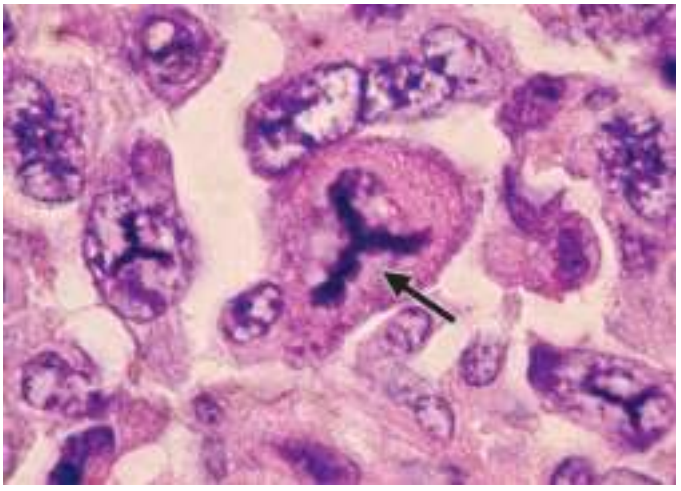

Fig. 6.51: Atypical tripolar mitosis in high-grade carcinoma. Tumor is composed of pleomorphic cells with hyperchromatic large nuclei and high nuclear to cytoplasmic ratio, and atypical tripolar mitotic figure (400X) (arrow).

TUMOR MONOCLONAL PROPERTIES: ANALYSIS TECHNIQUES

Heterogenous malignant tumors invariably develop from the clonal expansion of one genetically damaged precursor cell (clonal progeny), i.e. malignant tumors

are monoclonal rather than polyclonal. Polyclonal cell proliferation is always non-neoplastic in nature. Transformation of a clonal cell population to a malignant tumor is usually a multistep process. Monoclonal properties of malignant neoplasms are shown in Fig. 6.52.

- Successive proliferation of transformed cells leads to form subclones harboring additional different driver and passenger gene mutations with high proliferative potential, which differ from the original normal precursor cell. Eventually, some clonally expanded cells acquire a fully malignant tumor to produce an invasive malignant phenotype. This type of clonal evolution continues in established malignant tumor so that not all cells in a malignant tumor are genetically identifiable, e.g. different growth patterns, and different expression of proteins.
- Evolution of different clonal and subclonal cell properties during carcinogenesis often leads to development of more clinically aggressive malignant tumor. Heterogenous malignant tumor is formed via genetic and epigenetic changes. Similarly, therapeutic maneuvers such as chemotherapy and radiation therapy may be selected for malignant tumor subclones that are resistant to these therapeutic treatment options. For example, patients with estrogen positive breast cancer respond differently to tamoxifen anti-estrogen therapy.
- In addition to monoclonal CSCs, all solid malignant tumors consist of stromal component that provides a supporting extracellular matrix and blood vessels that are essential for malignant tumor growth beyond microscopic 1–2 mm size.
- Growth factors and cytokines secreted by CSCs stimulate stromal component resulting in characteristic histologic appearance called tumor desmoplasia. This type of stromal reaction is characteristic features of most invasive malignant tumors.
- Stromal and vascular cells are not directly derived from CSCs. Malignant tumor-associated vasculature is abnormal and leaky. In some situations, different properties of malignant tumor-associated vasculature may provide therapeutic targets (e.g. blocking tumor angiogenesis).

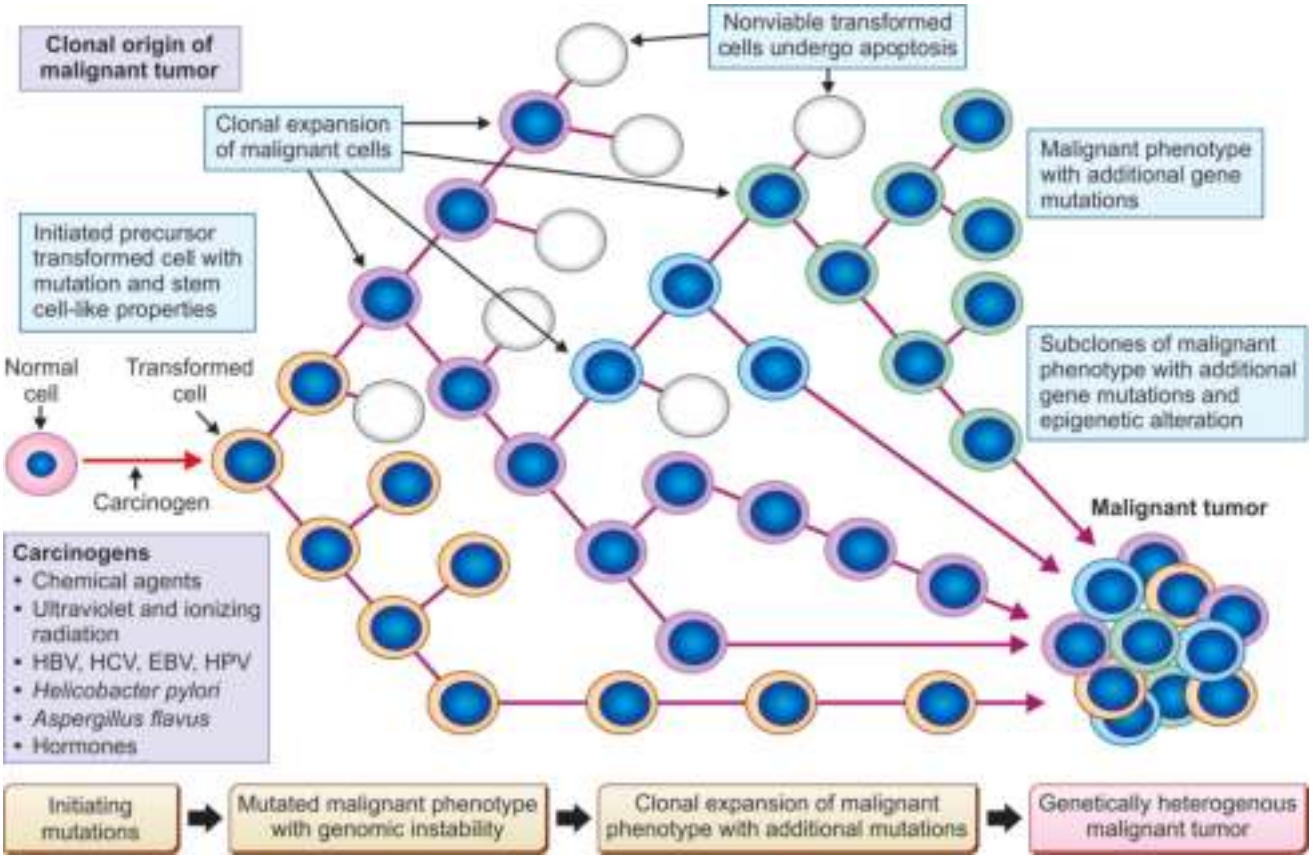

Fig. 6.52: Monoclonal properties of malignant neoplasms. Exposure to carcinogenic stimulus, single aberrant cell undergoing malignant transformation reproduces itself into a monoclonal heterogenous population of tumor cells harboring different mutations with high proliferative potential forming malignant tumor. Some of transformed cells undergo apoptosis. As the tumor grows, it becomes a complex population of clonal cells, each clone with different behavior. With time, it becomes difficult to eliminate transformed cells with chemotherapeutic agents (e.g. tamoxifen for breast carcinoma), because different patients respond differently to the treatment.

- The clonal property of tumors is important to understand carcinogenesis and discovery of new important genes such as retinoblastoma (RB) tumor suppressor gene model. Further research into clonal property of malignant tumors will provide new insights into malignant tumor development and growth as well provide clonal markers relevant to the clinical diagnosis and follow-up of individual cases. Three major approaches to assess monoclonality of malignent tumors include X chromosome inactivation, lymphocyte analysis and somatic mutation in genes.

G6PD Isoenzyme (A or B) Analysis Technique in Tumors

Monoclonal property is assessed by studying glucose-6-phosphate dehydrogenase in selected benign and malignant tumors. Some women are heterozygous for having two alleles of glucose-6-phosphate dehydrogenase (G6PD) on the long arm of the X chromosome, which possess differing sensitivities to heat inactivation. Early in the developing embryo, one X chromosome inherited from mother or one from father are in active state. Normal ratio of active isoforms of G6PD in cells of any tissue is 1:1, as 50% of cells exhibit G6PD-A and other 50% of cells demonstrate G6PD-B.

- **X-inactivation (also called lyonization):** X-inactivation (also called lyonization) is a process by which one of the two X chromosomes is inactivated in every cell and appears as a '**Barr body**' attached to the nuclear membrane in females during development.
  - Such X chromosome inactivation silences expression of almost all the genes on that chromosome related to differential methylation of cytosine in the DNA.
  - As a result, the tissues are having mosaic cells that express either A or B isoenzyme of G6PD. Only one isoform is present in tumor, which is monoclonal. G6PD isoenzyme monoclonality analysis is based on females heterozygous for a particular X-linked polymorphism.
- **G6PD isoenzyme (A or B) in uterus during pregnancy and leiomyoma:** During pregnancy, some uterine smooth muscle cells express G6PD-A isoenzyme, while rest of smooth muscle cells display G6PD-B isoenzyme indicating polyclonal origin. Uterine leiomyoma arising from a single cell shows either G6PD-A isoenzyme or G6PD-B isoenzyme. This finding demonstrates the monoclonal origin of the uterine leiomyoma. However, polyclonal tumor can have both G6PD-A isoenzyme and G6PD-B isoenzyme phenotype.

G6PD Isoenzyme (A or B) Analysis to Assess Monoclonal Properties in Human Cancers

The majority of human cancers analyzed by this technique have demonstrated monoclonal property.

- Monoclonality is demonstrated in many human cancers (e.g. breast carcinoma, colon carcinoma and cervical carcinoma).
- G6PD enzyme analysis is useful in the diagnosis of chronic myelogenous leukemia (CML). Cytogenetic analysis in CML is obtained from white blood cells (WBCs), which contain nuclei, while red blood cells (RBCs) and platelets lack nuclei.
- Some cases of colon carcinoma, breast carcinoma and hepatocellular carcinoma demonstrate double G6PD enzyme phenotypes.

G6PD Isoenzyme (A or B) Analysis to Assess Polyclonal Properties in Some Human Neoplasms

Polyclonal composition of these tumors is presumably related to the different time course and mechanism of tumorigenesis.

- Similarly, a polyclonal origin of colorectal adenomas in Gardner's syndrome (familial adenomatous polyposis syndrome) has been proposed based on assessment of G6PD mosaicism.
- These divergent results might be due to use of recombinant techniques and contaminating non-neoplastic cells, removed from the benign tumors by histologic examination of cryostat sections.

Restriction Fragment Length Polymorphism Technique to Assess Monoclonal Properties of Tumors

In molecular biology, restriction fragment length polymorphism (RFLP) technique detects variations in homologous DNA sequences, known as polymorphism. RPFL technique detects the locations of genes within DNA sequence, which can distinguish individuals, populations, or species. Molecular probes used for X-linked polymorphic genes now make it possible to detect clonal markers in tumor cells in same manner analogous to the G6PD isoenzyme studies. Active and inactive copies of polymorphic X-chromosome genes can be differentiated through differences in patterns of methylation of the genes.

- Diagnostic approach has widened the scope of clonality analysis to include all females in whom suitable X-linked polymorphism is present. Both normal and tumor DNA are first disgusted with appropriate restriction endonuclease to differentiate the paternal and maternal copies of the gene through X-linked RFLP. A second endonuclease sensitive to methylation of cysteine residues in its recognition

sequence differentiates active from inactive copies of the gene through changes in the DNA methylation pattern.

- X-linked gene polymorphism useful for studies include RFLPs of the hypoxanthine phosphoribosyltransferase gene and the phosphoglycerate kinase gene. Molecular probes for X-linked polymorphic genes are used to analyze clonality in acute leukemia, chronic leukemia, uterine leiomyoma, Wilms' tumor and parathyroid adenomas.

Lymphocyte Analysis Technique to Assess Monoclonal Properties of Tumors

Lymphocyte analysis is done to study monoclonality of B cell- or T cell-derived neoplasms. B cell-derived neoplasms are studied by immunoglobulin light chain analysis. On the contrary, immunoglobulin and TCR gene analysis are done to analyze monoclonality of T cell-derived neoplasms.

Immunoglobulin Light Chain Analysis Technique to Assess Monoclonal Properties of Tumors

Clonality of B lymphocyte is determined by immunoglobulin (Ig) light chain phenotype. immunoglobulin (Ig) is composed of heavy chains and light chains. Each B cell expresses light chain that is either κ or λ.

- Normal ratio of κ to λ light chain is 3:1. Ratio of κ and λ light chain increases to >6:1 or reverses to 1:3 in lymphoma after treatment. This ratio of κ and λ light chain is maintained in cell hyperplasia, which is polyclonal.
- One of the standard methods for analyzing monoclonal property of B cell neoplasms is the demonstration of immunoglobulin molecules in serum and immunoglobulin light chain rearrangement on the surface of atypical B cell in chronic lymphocytic leukemia (**CLL**) and some cases of non-Hodgkin's lymphomas.
- There is no analogous system of surface markers on T cells indicating monoclonality in T-cell derived neoplasms. However, monoclonal antibodies, which are specific for family of related variable regions, which use the same variable region genes can act as indicators of the monoclonality of some T cell populations.

Immunoglobulin and TCR Gene Analysis Technique to Assess Monoclonal Properties of Tumors

The more recent use of molecular probes to detect immunoglobulin and TCR gene rearrangements overcomes many of the limitations of immunoglobulin light chain analysis. This technique is applied to all lymphoid malignancies. Immunoglobulin and TCR gene rearrangements give rise to DNA markers unique to each individual lymphoid cell and its progeny. Monoclonal population of cells have the same genetic rearrangement, which can be detected by Southern blotting technique. In a polyclonal lymphoid proliferation, these rearrangements are not detectable by Southern blotting technique.

- **Immunoglobulin and TCR rearrangements analysis:** Immunoglobulin and TCR rearrangements also provide information about the cell-lineage of lymphoid neoplasms, whereas TCR rearrangements are regularly demonstrated in T cell-derived leukemias/non-Hodgkin's lymphomas. Using these techniques, it is possible to prove monoclonality of B cell origin of hairy cell leukemia and T cell-derived mycosis fungoides.
- **Southern blotting technique:** Southern blotting technique is unable to detect gene rearrangements at much below the level of 5%. Now polymerase chain reaction (PCR) technique overcomes the limitation of Southern blotting technique, and is used to detect clonal markers at much lower level by amplification of immunoglobulin and TCR gene rearrangement in the study of 'minimal residual disease' in T cell-derived leukemias/non-Hodgkin's lymphoma. It is worth mentioning that immunoglobulin gene rearrangements are not consistently stable clonal markers since these are subject to cause variability as a result of ongoing somatic gene mutations. Clonal property of lymphoid cell proliferation is given in Table 6.21.

Human Androgen Receptor Gene Analysis Technique to Assess Monoclonal Properties of Tumors

Human androgen receptor gene (HUMARA) analysis to assess monoclonality has been used to determine the clonal origin of malignant tumors. HUMARA analysis

Table 6.21 Clonal property of lymphoid cell proliferation

Cell Type	Benign Lymphoid Cells	Malignant Lymphoid Cells
B cells	Ig light chain heterogeneity	Ig κ and λ only
Plasma cells	Ig light chain heterogeneity on electrophoresis	Monoclonal Ig spike on electrophoresis
T cells	Heterogeneous variable regions	Homogenous variable regions

is based on using X chromosome inactivation analysis on the different methylation patterns of active and inactive alleles of gene called HUMARA mapped on Xq13 chromosome in multiple population. Recently, a polymerase chain reaction-based androgen receptor gene analysis method has been developed.

Somatic Mutations Analysis Technique to Assess Monoclonal Properties of Tumors

Somatic mutation refers to an alteration that occurs after conception in any of the cells of the body except the germ cells (sperm and ovum) and therefore are not transmitted to children. These somatic alterations in DNA can cause cancer or other disorders in some persons. Somatic mutations can be analyzed by cytogenetic and molecular studies.

Cytogenetic Analysis Technique to Assess Monoclonal Properties of Tumors

Many human cancers demonstrate consistent, nonrandom chromosome abnormalities, which demonstrate as clonal markers. Philadelphia chromosome analysis in chronic myclogenous leukemia (CML) detects clonal markers and provides information relevant for diagnosis, classification and prognosis. Limitation of cytogenetic analysis is that cells can be studied in mitosis only. This limitation is overcome in study of clonal chromosomal abnormalities in acute leukemias by a new technique using the detection of lineage-specific antigens in dividing leukemic cells by monoclonal antibodies.

Chromosomal Losses Detected by Molecular Probes Technique to Assess Monoclonal Properties of Tumors

The loss of chromosomal material is one of the most important alterations in malignant tumors. Homologous DNA sequence analysis depends on the ability to distinguish the two chromosomal homologues by the detection by restriction fragment length polymorphism (RFLP) technique.

- The DNA analysis is informative if constitutional DNA displays heterozygosity for a particular type of restriction fragment length polymorphism (RFLP). The loss of DNA sequences in tumor DNA indicates chromosomal loss in malignant tumors. The use of molecular probes to detect polymorphisms due to variable number of tandem repeats (VNTRs) makes this method feasible in majority of cases on account of their high heterozygosity rates.
- Molecular probes are small DNA or RNA segments that recognize complementary sequences in DNA or RNA molecules that allow detection and isolation of specific sequences. Comparative genomic *in situ* hybridization (CGS) uses a fluorescent reporter attached to a DNA probe to detect the presence of specific DNA sequences in chromosomes by molecular hybridization. Labeled genomic test DNA prepared from tumor specimens is mixed differently labeled control DNA prepared from normal cells with chromosome complements and analyzed.

Chromosomal Translocation Detected by Breakpoint Cluster Region Probes Technique to Assess Monoclonal Properties of Tumors

Chromosomal translocations can be detected to assess monoclonal property in certain human malignant tumors by DNA analysis. DNA probe is used, which hybridizes to the region of the breakpoint on one of the chromosomes involved in the translocation. Breakpoints must be clustered within a defined DNA sequence.

- Analysis of 'Philadelphia chromosome' illustrates variable breakpoints on chromosome 9 and clustered breakpoints on chromosome 22 in majority of cases over a region of 5.8 kilobases, known as 'breakpoint cluster region'. DNA probes are used, which hybridize to the 'breakpoint cluster region' on chromosome 22 detect most cases of Philadelphia chromosome positive chronic myelogenous leukemia.
- The prognosis of chronic myelogenous leukemia (CML) has changed radically due to the development of novel drugs able to target the enhanced tyrosine kinase activity of the BCR-ABL.
- Other chromosomal translocations can be detected directly by 'Southern blotting technique', which include t(11;14) in some B cell lymphomas t(14;18) in follicular lymphoma and t(8;14) in Burkitt's lymphoma. These chromosomal translocations present at low concentration in cells are detected by polymerase chain reaction (PCR), provided the breakpoints on the chromosomes are clustered within defined regions.

Point Mutations in Genes Analysis Technique to Assess Monoclonal Properties of Tumors

The RAS gene family consists of three small G proteins such as K-RAS, H-RAS and N-RAS, that play a central role in cell signaling relating to the cell proliferation, survival, adhesion, and motility. Mutations in RAS proteins are one of the most common genetic alterations observed in malignant tumors.

- *In vivo*, oncogenic RAS mutations have been shown to occur at exons 12, 13 and 16, resulting in any 1 of 19 possible point mutations in a given tumor for a specific RAS isoform. RAS mutations can be detected by polymerase chain reaction (PCR)/restriction fragment length polymorphism (RPFL) analysis.
- K-RAS mutation demonstrated at exon 12 in adenoma progressing to colon carcinoma has been associated

with a poor survival. Oncogenic N-RAS mutations at exon 12 in hematopoietic pluripotent stem cells cause RAS-associated myelofibrosis.

DNA Fingerprinting Analysis Technique to Assess Monoclonal Properties of Tumors

DNA fingerprinting is a technique used to detect lots of minisatellites (highly variable nucleotide DNA) in the human genome from a sample of DNA unique in an individual especially lacking an obvious cytogenetic abnormality. Comparative DNA fingerprint analysis of a patient's malignant tumor and constitutional DNA represents a new method for analyzing clonal markers. The feasibility of this technique depends on the properties of the minisatellite DNA probes, which detect a large number of variable number of tandem repeats (VNTRs) scattered throughout the human genome. Use of three minisatellite DNA probes have demonstrated differences between the tumor DNA and constitutional DNA (peripheral blood or mucosa) in gastrointestinal tumors.

Viral Integration Analysis to Assess Monoclonal Properties of Tumors

Molecular analysis of tumors containing viruses offers a novel diagnostic technique of clonality. Hepatitis B virus (HBV) infection is one of the leading causes of cirrhosis, hepatocellular failure and hepatocellular carcinoma. Polymerase chain reaction (PCR) technique is used to detect hepatitis B virus (HBV) integration in peripheral blood mononuclear cells in chronic hepatitis B infection. The monoclonality of cell populations within the hematopoietic system can be analyzed with specific probes by Southern blot hybridization of DNA technique.

TELOMERASE ACTIVITY IN TUMORS

Telomerase enzyme adds repetitive nucleotide sequences to maintain the length of the telomeres by preventing gene loss at the ends of chromosomes after multiple cell divisions. With each round of somatic cell replication, the telomere shortens. The length of telomeres acts as a molecular clock, which governs the life span of replicating germ cells to preserve species. Somatic cells do not normally express telomerase. Telomerase enzyme activity is increased in certain human malignancies. Activation of telomerase activity in malignancy does not lose genetic material after multiple cell divisions.

TUMOR ANGIOGENESIS

Tumor angiogenesis denotes formation of new blood vessels. It is a requirement for the continued growth and survival of malignant tumors, whether primary or metastatic. Newly formed blood vessels are essential for the inflow of nutrients and oxygen into the malignant tumor. In the absence of new vessels, malignant tumors do not grow larger than 1–2 mm in diameter. Hypoxia is most important driving force for angiogenesis by inducing hypoxia inducible factor-α (HIF-α) transcriptional factor. Tumor angiogenesis is a balancing act between proangiogenic and antiangiogenic factors.

Proangiogenic Factors in Tumor Angiogenesis

Proangiogenic factors synthesized by malignant tumors and inflammatory cells include: VEGF, FGF, TGF-β, HGV, PDGF, angiogenin, angiotensin II, angiopoietin, platelet activating factor (PAF), TNF-α, G-CSF, placental growth factor, proliferin, leptin, IL-6 and erythropoietin. Vascular endothelial growth factor (VEGF) is important angiogenic factor in the proliferation of blood vessels in a growing malignant tumor, in which new blood vessels become torturous, irregular, and leaky blood vessels. Eventually, the tumor outgrows its blood supply, and induces tumor necrosis resulting in slower tumor growth.

Anti-angiogenic Factors in Tumor Angiogenesis

Various anti-angiogenic factors such as angiostatin, endostatin, vasculostatin, and thrombospondin 1 are also synthesized, which inhibit development of cancers. Extracellular matrix (ECM) derived anti-angiogenic factors include endostatin, thrombospondin (I, II), chondromodulin I anastellin, fibulin, tumstatin and canstatin. Non-matrix derived anti-angiogenic factors include angiostatin, vasculostatin, antithrombin III, vasostatin, platelet factor 4, interferon-α and interleukins (IL-1, IL-12, IL-18).

TUMOR INVASION AND METASTASIS

Histologic features and rate of growth alone cannot distinguish between benign and malignant tumors. Invasion and metastasis are the most reliable feature of malignancy that distinguishes malignant tumors from benign tumors.

- Cancer stem cells invade basement membrane and surrounding tissues, and metastasize via lymphatic route, hematogenous route and transcoelomic route to distant organs of the body. Metastasis consists of multiple steps (i.e. invasion, intravasation and transport of CSCs, and extravasation), which are collectively called '**metastatic cascade**'. Invasion and metastatic cascade of malignant tumor is shown in Fig. 6.53.
- Approximately 30% of newly diagnosed solid malignant tumors present with clinically evident metastases. **Occult (hidden) metastases** are seen in 20% of patients at the time of diagnosis. Approximately 30% of newly diagnosed solid malignant tumors

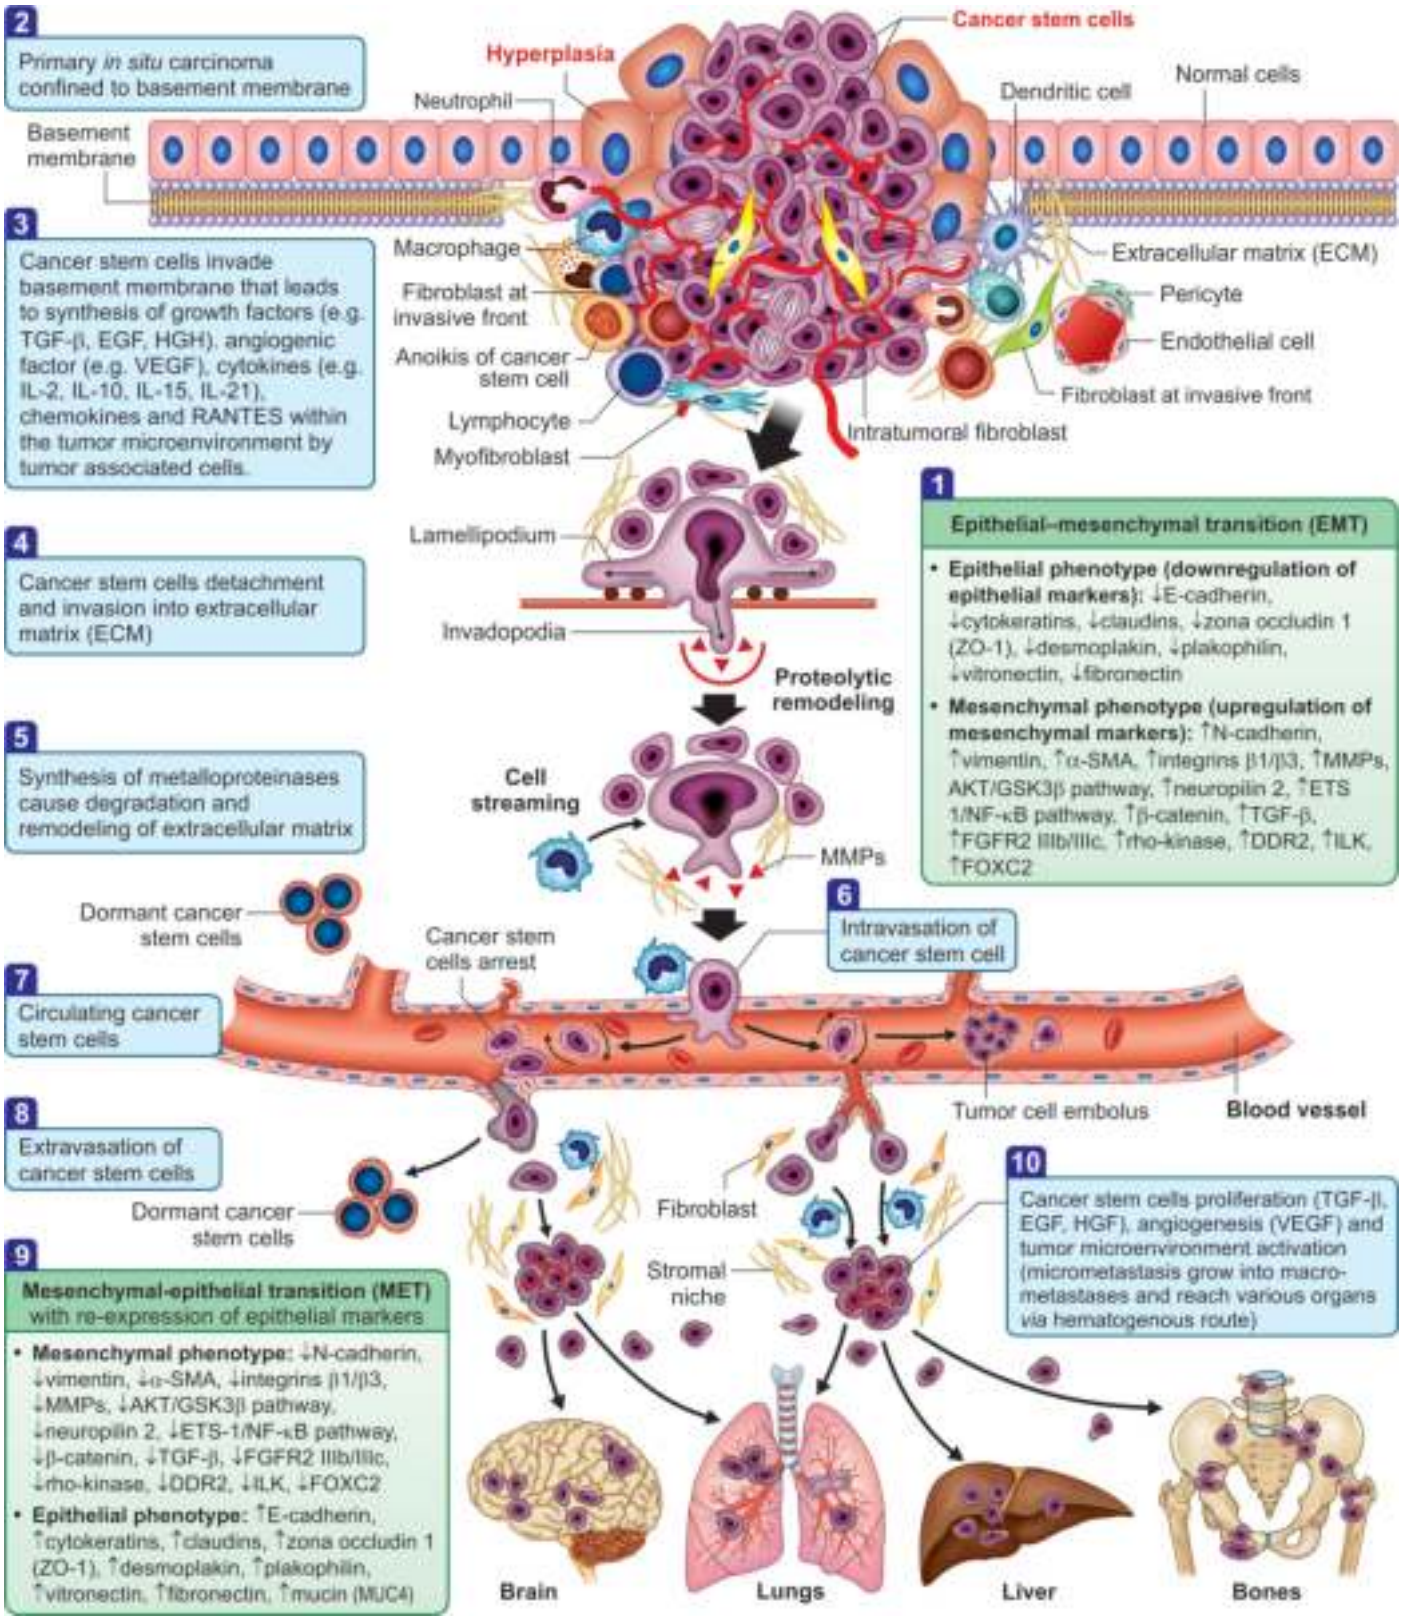

Fig. 6.53: Invasion and metastatic cascade of malignant tumor. Detachment of cancer stem cells from an epithelial-derived primary malignant tumor and its migration to reach a blood vessel or lymphatic vessel for dissemination to a secondary site is very complex process that includes alterations in the expression of multiple genes involved in the cell adhesion, chemoattractant and growth factors.

present with clinically evident metastases. The majority of deaths occur due to metastasis, which is the important hallmark of cancer, and associated with poor prognosis.

- Invasion and metastasis are triggered by genetic and epigenetic factors that are induced by environmental stimuli (e.g. aging and circadian disruption); adhesive signals from extracellular matrix (ECM) components (e.g. collagen); ECM mechanical pressures, including compression and tension; cell–cell interactions; soluble signals (e.g. growth factors, cytokines) and the intratumoral microbiota.

NORMAL PROCESSES THAT REGULATE CELLS AND INHIBIT CARCINOGENESIS

Cellular processes, such as transcription, DNA replication, and DNA repair involve interactions between multiple proteins: (a) extracellular signals (i.e. growth factors, and their cellular receptors), and (b) intracellular regulatory genes (i.e. proto-oncogenes and tumor suppressor genes). Normal cell growth requires a balance between the activity of proto-oncogenes and tumor suppressor genes, which produce proteins that act as 'on' and 'off'' switches of cell cycle.

- Mutations in regulatory genes result in loss of control over normal cell growth termed 'autonomy' resulting in transformation of normal cell to CSC, which differ from normal cell in terms of cell size, differentiation, function and ability to metastasize to distant tissues and organ system.
- Oncogenesis is the process through which healthy cell is transformed to CSC that occurs by a series of cellular changes and genetic alterations including activation of oncogenes (mutated proto-oncogene) or inactivation/biallelic loss of tumor suppressor genes, that lead to cell division in an uncontrolled manner. Several critical cellular processes provide protection and prevent tumor development, which are closely related, and intertwined, cell cycle regulation, DNA repair and telomerase activity.

Pathology Pearls: Regenerating Capacity of Cells

Cell proliferation is defined as an increase in cell number leading to cell growth and cell division. In cellular biology, regenerative capacity of cells allows them to be classified into three groups: labile, stable and permanent cells.

- Labile cells never go to G0 phase (quiescent phase) of cell cycle and continuously multiply and divide with a short G1 phase to reproduce new stem cells and replace functional cells that are lost in the body throughout life (e.g. hematopoietic stem cells in bone marrow, skin, hair follicles, gut epithelium, epithelia of ducts and germ cells). It is worth mentioning that labile cells are affected by chemotherapy.
- Stable cells remain in quiescent state but after stimulation, they may enter G1 phase of cell cycle to divide and regenerate when needed (e.g. hepatocytes, proximal convoluted cells of kidney, smooth muscle cells and periosteal cells).
- Permanent cells are terminally differentiated cells, which have lost the capacity to regenerate and enter cell cycle to divide (e.g. neurons skeletal muscle, cardiac muscle, red blood cells and cells in lens of eye). Permanent cells remain in G0 phase of cell cycle.

CELL CYCLE AND CELL DIVISION

Cell cycle refers to series of events that takes place in a cell as it grows and divides. Cell cycle (i.e. cell division) is divided into major two events: interphase and mitosis (M) phase. Interphase consists of G1 phase (centrosome duplication), S phase (chromosome replication), and G2 phase (assembly of mitotic spindles composed of microtubules). Mitosis phase refers to cell division to form two identical daughter cells. Quiescent cells are in the G0 phase (resting or inactive state) that have not entered the cell cycle (i.e. outside cell cycle), where cell has stopped division.

- During interphase of cell cycle, the cell grows and prepares for cell division. Cell division occurs during mitosis (M) phase, which consists of cell mitosis and cytokinesis. Cell division (mitosis and cytokinesis) consists of equal division of chromosomes and cytoplasmic components (termed cytokinesis), i.e. cell membrane, cytoplasm and organelles between two daughter cells with identical genomes. Mitotic activity remains restricted to somatic stem cells in the following circumstances: cell growth, and cell replacement during tissue repair and regeneration. G0, G1, G2, S and M phases of cell cycle are shown in Fig. 6.54 and given in Table 6.22.
- Meiosis occurs where a germ cell is divided to produce haploid cells containing half the number of chromosomes of the parent germ cell (gametes, i.e. spermatozoa in males and egg in females).

CELL CYCLE AND CELL DIVISION: PHASES

Cell cycle is divided into four phases: G1 (centrosome duplication), S (chromosome replication), G2 (assembly of mitotic spindles composed of microtubules)

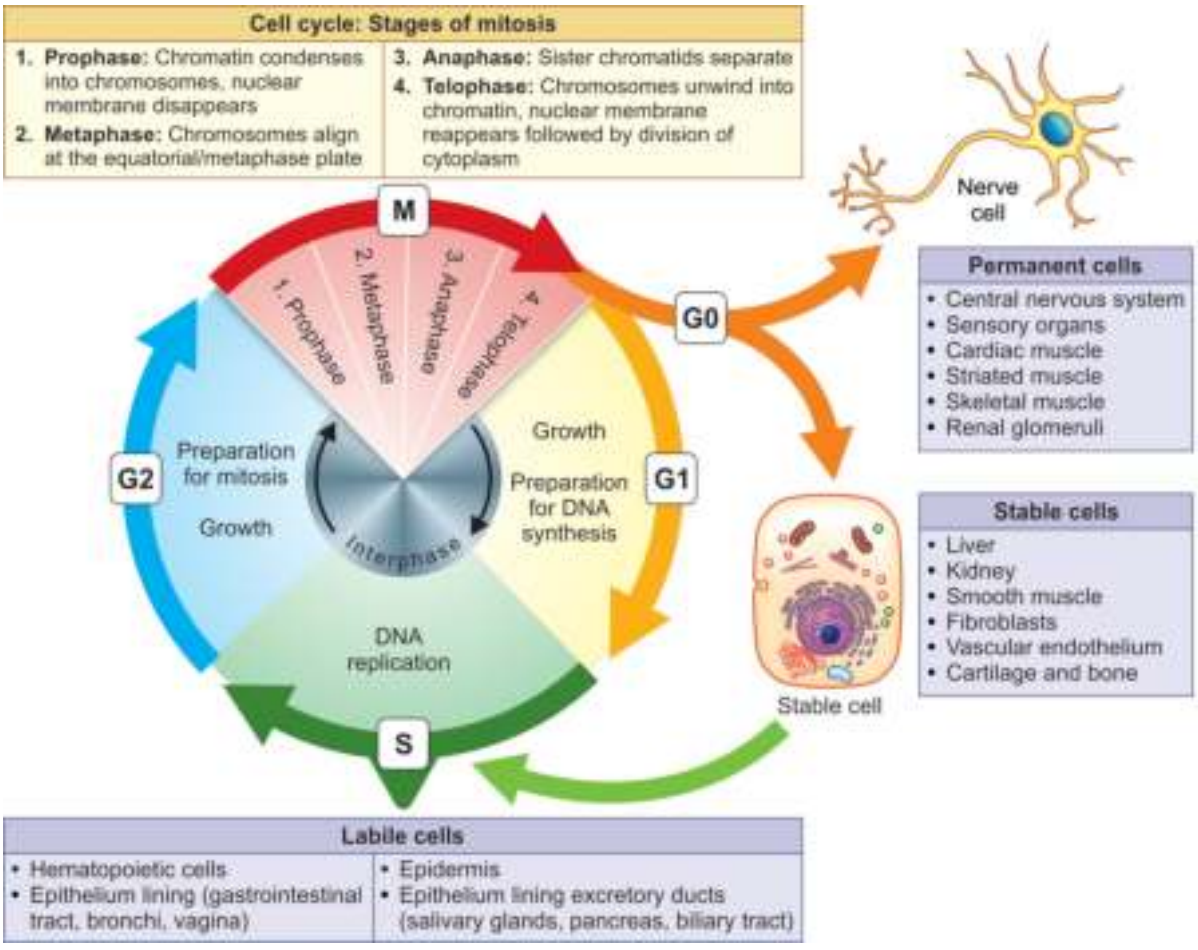

Fig. 6.54: G0, G1, G2, S and M phases of cell cycle. Location of the G1 is the restriction point. G1/S and G2/M are checkpoints of cell cycle. Cells from labile tissues such as bone marrow, epidermis, epithelial lining gastrointestinal tract, bronchi and vagina may cycle continuously.

Table 6.22 G0, G1, G2, S and M phases of cell cycle

Cell Cycle Stage (Phase)	Major Features
Resting phase	
G0 phase	Stable, nondividing period of variable length
Interphase	
G1 phase	Growth and development of the cell; G1/S checkpoint
S phase	Synthesis of DNA
G2 phase	Preparation for cell division; G2/M checkpoint
M phase	
Prophase	Chromosomes condense and formation of mitotic spindle
Prometaphase	Nuclear envelope disintegrates, and spindle microtubules anchor to kinetophores
Metaphase	Chromosomes align on the metaphase plate; spindle-assembly checkpoint
Anaphase	Sister chromatids separate, becoming individual chromosomes that migrate toward spindle poles
Telophase	Chromosomes arrive at spindle poles; the nuclear envelope re-forms and the condensed chromosomes relax leading to create two daughter cells with identical genomes

Note: Meiosis consists of two distinct processes; meiosis I and meiosis II. Meiosis includes the reduction division, in which homologous chromosomes separate and chromosome number is reduced by half. In meiosis II (equational division), sister chromatids separate.

and M (cell division to form two daughter cells). After completion of cell cycle, cell either starts the process of cell division from G phase or exists through G0 phase.

G0 Phase (Resting or Quiescent Phase)

G0 phase is a form of the resting state, or quiescent state outside the cell cycle, in which cell resides until it receives appropriate growth signals from growth factors (mitogens). Growth factors stimulate cell to enter and progress through the cell cycle. Terminally differentiated cells also remain in resting phase, or quiescent phase. Significance of G0 phase is that these cells cannot divide and undergo replication. On contrary, CSCs continue to divide as a result of deregulated cell cycle. The CSCs cannot be put into G0 phase until the environment becomes favorable for cell division.

Interphase: First Stage of Cell Cycle

Interphase is also known as **resting phase** of the cell cycle, in which the cell prepares for cell division (mitosis) by increasing cell growth. Interphase occupies around 95% of time of the overall cell cycle. The interphase is divided into three phases: G1, S and G2. Interphase aneuploidy results in increased cell proliferation.

G1 (Pre-synthetic) Phase of Cell Cycle

G1 phase is a period of cell growth and preparation for DNA synthesis (S phase). During the G1 phase (G1/S transition), the cell continues to grow as a result of synthesis of cytoplasmic organelles, RNA, and proteins, but lacks DNA replication. Growth factor (mitogen) is only required in the early G1 phase of cell cycle, while late G1 phase of cell cycle remains mitogen-independent.

- During early G1 phase, growth factors (EGF, HGF, PDGF, IGF1, IGF2, TGF-α, insulin) bind to cognate tyrosine kinase receptors on cell surface, which provide the stimulatory signal to proceed forward leading to cell growth as a result of synthesis of cytoplasmic organelles, RNA, and proteins. Cell differentiation, maturation and stimulation of cell division occurs via activation of proto-oncogenes. Once the cell progresses past the restriction point (R point), mitogens are no longer required for cell cycle progression. Length of G1 phase determines how slow or rapid, cell division takes place.
- **Restriction point (R point)** is the '**point of no return**' where the cell is committed to undergo progression to the next phase (i.e. G1 phase to S phase), that has been temporarily mapped at 2–3 hours prior to the onset of DNA synthesis.
- Phosphorylation of RB protein restricts cell cycle in mid-G1 phase by inhibiting E2F-mediated S phase transcription factors. At G1/S transition controlled by cyclin-dependent kinase 2 (CDK2), the cell checks whether internal or external conditions such as nutrients, molecular signals and DNA integrity are sufficient for cell division. DNA damage may result in DNA repair system pathways or apoptosis (programmed cell death).

S (Synthetic) Phase of Cell Cycle

Synthesis (S) phase of cell cycle refers to synthesis of DNA. During S phase of cell cycle, cell undergoes DNA replication with production of identical replicates of DNA. Synthetic phase also induces duplication of microtubule-organizing structure called '**centrosome**' that helps in separation of DNA during mitosis (M) phase. G1/S transition allows checking the DNA integrity before cell DNA is replicated.

- In early synthetic phase, S phase genes are activated as a result of cyclin A replacing cyclin E to form cyclin A-CDK2 complexes in early synthetic phase. In late synthetic phase, cyclin A-CDK1 complex is formed. Upon completion of synthetic phase, cyclin A-CDK2 phosphorylates E2F-DP heterodimers, thus terminating E2F's activity.
- After completion of synthetic phase, cyclin B replaces cyclin A, forming cyclin B-CDK1 complexes, which move the cell into the second gap phase of the cell cycle G2 phase and into mitosis.

G2 (Pre-mitotic) Phase of Cell Cycle

G2 phase (pre-mitotic phase) refers to preparation of cell for cell division. After synthetic phase of DNA replication, cell enters S phase that ensures everything (i.e. DNA replication, RNA, proteins and other macromolecules required for mitotic division) is ready to enter the mitosis (M) phase for cell division. G2 phase features synthesis of tubulin, which is required for formation of mitotic spindle essential for cell division.

- TP53 gene product (p53 protein) is an important regulator of cell cycle at G1/S and G2/M transition. TP53 gene product (p53 protein) can stop the cell cycle for DNA repair or induce apoptosis, if the DNA damage is beyond repair.

Mitosis: Second Stage of Cell Cycle

Mitosis is the process by which a cell replicates its chromosomes and then segregates them, with division of nucleus and followed by cytokinesis (division of cytoplasm) resulting in production of two new identical daughter cells. Mitosis is subdivided into four phases in strict sequential order and cytokinesis: prophase, metaphase, anaphase and telophase. Before cell division, a cell must double its mass and content that occurs during the growth phase, called interphase. Before cell division, a cell must double its mass and content that occurs during the growth phase, called interphase.

Prophase

Prophase is the first phase of mitosis, in which chromosomes coil and shorten, and centrioles move apart and dissolution of nuclear membrane. Each chromosome is made up of a pair of strands called chromatids, which are connected by a spindle of fibers called 'centromere'.

Metaphase

During metaphase, the centromere divides and pulls the chromosome apart, which line up along the metaphase or equatorial plate. The centromeres align themselves in the middle of the spindle.

Anaphase

During anaphase, the centromere and sister chromatids begin to separate and pull the newly replicated chromosomes toward opposite poles of the cell and cleavage furrow begins to develop. Centromere defect and chromosome misaggregation result in abnormal mitotic tripolar and quadrangular figures in malignant tumors.

Telophase

Telophase is the terminal phase of mitosis and characterized by cytokinesis, reconstruction of nucleus and nuclear envelope disappearance of mitotic spindle fibers, and unwinding of 46 chromosomes into chromatin. Mitotic cell division leads to production of two identical new daughter cells. Mitosis occurs actively in the bone marrow and epidermis to replace cells, which have limited life span. Mitotic spindle defects lead to aberrant cellular divisions. Acquisition of successive chromosome mutations initiates carcinogenesis.

CELL CYCLE CHECKPOINTS

Checkpoints control transitions occur between various phases of cell cycle. This process is regulated by cyclins, cyclin-dependent kinases (CDKs) and tumor suppressor genes.

- M phase is the shortest phase of cell cycle, which includes mitosis (prophase, prometaphase, metaphase, anaphase, telophase) and cytokinesis (cytoplasm splits into two). G1 and G0 phases of cell cycle are of variable duration.
- Growth factors bind to cognate surface tyrosine kinase receptors on the cell; and then transmembrane proteins relay information to the cell by signal transduction. Growth factors stimulate cell division. On the contrary, growth-inhibiting factors inhibit cell division.
- Normal cells divide only when growth factor and growth-inhibiting factor in balanced proportions favor cell division. CSCs divide without constraint.
- Cancer is primarily caused by mutations in growth factor genes and growth factor inhibiting tumor suppressor genes, and signaling pathways, that inhibit the normal sequence of events associated with apoptosis. Genomic instability (failures in checkpoints and apoptosis system) results in cell proliferation and aberrant chromosomes division.

Cell Cycle Checkpoints: Phases

Cell cycle checkpoints (i.e. transition between phases of the cell cycle) monitor each phase of mitosis to maintain genomic integrity. Checkpoint is a stage in the eukaryotic cell cycle at which the cell examines internal and external stress to DNA and decides whether or not to move forward with cell division. Positive cell cycle regulator molecules allow cell cycle to advance to the next stage. Negative cell cycle regulator molecules monitor cellular conditions, and halt the cell cycle until specific requirements are made.

- Important internal checkpoints of cell cycle include: (a) G1 checkpoint at G1/S transition to analyze integrity of the DNA, (b) G2 checkpoint at G2/M transition to analyze proper chromosome duplication, and (c) M checkpoint (spindle checkpoint) at the transition from metaphase to anaphase to analyze chromosome attachment to spindle at metaphase. G1, G2 and M checkpoints of cell cycle are shown in Fig. 6.55.

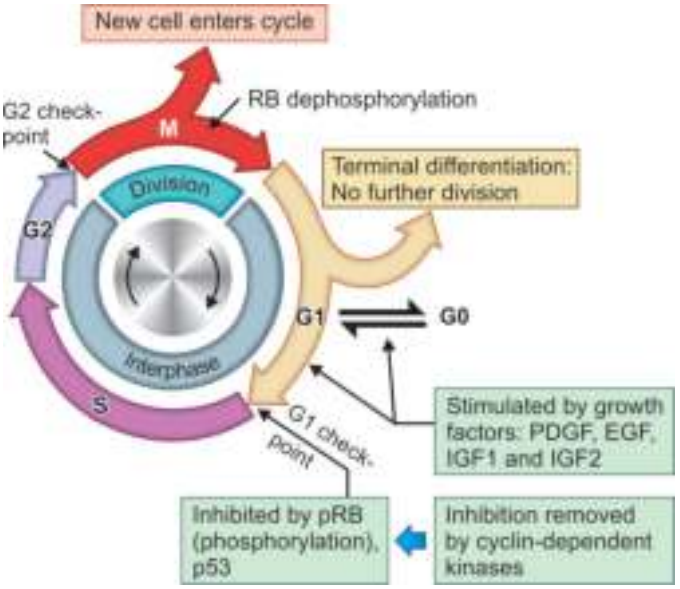

Fig. 6.55: G1, G2 and M checkpoints of cell cycle. The cell cycle consists of two phases: interphase (G1, S and G2) and mitotic phase. G1 phase is the first growth period of the cell cycle during interphase, in which the cell grows and cytoplasmic organelles are replicated. DNA replication is the biological process of producing two identical replicates of DNA during synthetic phase (S phase) of cell cycle. G2 phase allows replicated DNA to be checked before mitosis at the G2/M transition. DNA replication and duplication occur during the four phases of mitosis during mitotic phase.

- RB gene (pRB), TP53 gene (p53 protein) and p21 protein act the G1 checkpoint. It has been studied that RB protein is responsible for a major G1/S transition, blocking S phase entry and cell growth.
- Tumor suppressor TP53 gene product (p53 protein) is a multifunctional protein that plays a critical role in growth arrest, recruitment of enzymes to repair damaged DNA and apoptosis. The growth arrest inhibits the progression of cell cycle and thus prevents replication of damaged DNA. Failure to repair the cellular DNA damage, TP53 (p53 protein) can trigger apoptosis to prevent duplication of damaged chromosomes. Increased concentration of TP53 (p53) protein level triggers production of p21 protein that binds and inhibits the activity of the cyclin–CDK complex, and thus prevents cell cycle progression.

G1 Checkpoint at G1/S Transition to Analyze Integrity of the DNA

G1 checkpoint (restriction checkpoint) determines whether all conditions are favorable for cell division to proceed. The G1/S transition is checkpoint, also called 'restriction checkpoint' (R checkpoint). At restriction checkpoint phosphorylation of RB by cyclin-dependent kinases (CDKs) causes the release of transcriptional activator E2F that forms E2F/DP1/RB complex (positive regulator of cell cycle) in the nucleus.

- G1 checkpoint is the main decision-making point for a cell to choose whether or not to divide. Once the cell passes the G1 checkpoint, cell enters synthetic phase (S phase), and the cell becomes irreversibly committed to divide by barring unexpected replication errors in DNA.
- G1 checkpoint, the cell checks whether internal or external conditions such as nutrients, molecular signals and DNA integrity are right for cell division. If the cell does not get the go-ahead cues, it needs at the G1/S transition, cell may leave the cell cycle and enter a resting state called G0 phase.
- Some cells stay permanently in G0 phase, while other cells resume cell division if conditions improve. Failure of DNA repair leads to either apoptosis or accumulation of mutations responsible for transformation of normal cell to CSC. Defect in the G1 checkpoint is the most important cause of human cancers.

G2 Checkpoint at G2/M Transition to Analyze Proper Chromosome Duplication

The cell has an additional G2 checkpoint before M phase of cell cycle, that ensures smooth cell division with healthy DNA to maintain genomic integrity. At this stage, the cell checks DNA integrity, whether there are any replication errors in DNA. However, most important role of G2 checkpoint is to ensure that all the chromosomes have been replicated, and the replicated DNA is not damaged. G2 checkpoint is most important checkpoint in cells exposed to ionizing radiation.

- Chromosomal abnormality occurs due to defects in G2 checkpoint that initiates carcinogenesis. If the G2 checkpoint detects errors in DNA, the cell cycle halts, and the cell tries to repair DNA damage. If the cell is unable to repair DNA damage, it may undergo apoptosis (programmed cell death).
- Excessive DNA damage activates BAX pro-apoptotic gene that inhibits BCL-2 antiapoptotic gene resulting in release of 'cytochrome c' from the mitochondria and apoptosis of the cell. Apoptosis ensures that damaged DNA is not passed to the daughter cells during cell division resulting in inhibition of transformation of normal cell to CSC.

M (Mitosis) Checkpoint (Spindle Checkpoint) at the End of Metaphase Stage of Karyokinesis

M (mitosis) checkpoint, also known as the '**spindle checkpoint**', occurs near the end of the metaphase stage of karyokinesis to examine whether all the sister chromatids are correctly attached to the spindle microtubules. Because the separation of the sister chromatids during anaphase is an irreversible step, the cell cycle does not proceed until all the chromosomes are firmly attached to at least two spindle fibers from opposite poles of the cells. The cell does not scan the metaphase plate to confirm that all the chromosomes are there, instead, the cell looks for 'straggler (stray) chromosomes' that are in the wrong place. If a chromosome is misplaced, the cell mitosis halts, and allows time for the spindle to capture the stray chromosome.

CELL CYCLE REGULATORS

Cell cycle regulators control transition from G1/S transition in normal tissues. Cell cycle is controlled by regulatory molecules that either promote the process of cell cycle or inhibit progression of cell cycle.

- Positive cell cycle regulators drive cell cycle progression, which includes cyclins (A, B, D, E) and cyclin-dependent kinases (CDKs) and other molecules.
- Negative regulators of cell cycle include as pRB, TP53 (p53 protein), INK family of CDK inhibitory proteins (p16, p15, p18, p19) and CIP/KIP (CDK interacting protein/kinase inhibitory proteins, i.e. p27, p21, p57) which inhibit cyclin-dependent kinases thus block cell cycle progression within G1 phase. Hence, these negative regulators of cell cycle provide protection against development of cancers.

- Mutation in cell cycle regulators results in uncontrolled cell division via disruption of signaling pathways, which initiate carcinogenesis. If negative regulatory proteins are not produced or become nonfunctional, then these resulting in uncontrolled cell division initiation of carcinogenesis. Aberrant expression of cell cycle regulatory proteins analyzed by immunohistochemistry technique is valuable in diagnosis of some tumors as well as predicting prognosis in a number of tumors.
- Positive and negative regulators of cell cycle are given in Table 6.23. Cell cycle of positive and negative regulators are shown in Fig. 6.56. Regulation of the cell cycle is shown in Fig. 6.57.

Cell Cycle: Positive Regulators

The cell cycle starts when a growth factor acts on a quiescent cell to provoke the cell to divide. Cell is triggered to go from G0 to G1 by binding of growth factors such as EGF, HGF, PDGF, IGF1, IGF2, TGF-α to cognate tyrosine kinase receptors on cell to promote cell differentiation, maturation and stimulation of cell division via activation of proto-oncogenes. Once, the cell progresses past the restriction point, mitogens are no longer required for cell cycle progression in late phase of G1 (mitogen-independent). Growth factors stimulate the production of two types of cell cycle regulators: (a) positive regulators of the cell cycle, and (b) negative regulators of the cell cycle. Cyclins and cyclin-dependent kinases (CDKs) are key positive regulators of the cell cycle.

Cyclin Family of Proteins: Positive Regulators of Cell Cycle

Cyclin family of proteins regulate the progression of a cell through the cell cycle by tightly binding and activating CDK enzymes. To be fully active, cyclin/cyclin-dependent kinase complex must be phosphorylated in specific locations to coordinate cell cycle progression.

- Binding of S cyclin to CDK results in DNA replication. M cyclin participates in chromosome condensation and breakdown of nuclear envelope during mitosis phase of cell cycle.
- Concentration of cyclin proteins fluctuate throughout three major cell cycle checkpoints in a predictable cycle. There is sharp decline of cyclin levels following each checkpoint (i.e. transition between phases of the cell cycle), as cyclin is degraded by cytoplasmic enzymes.

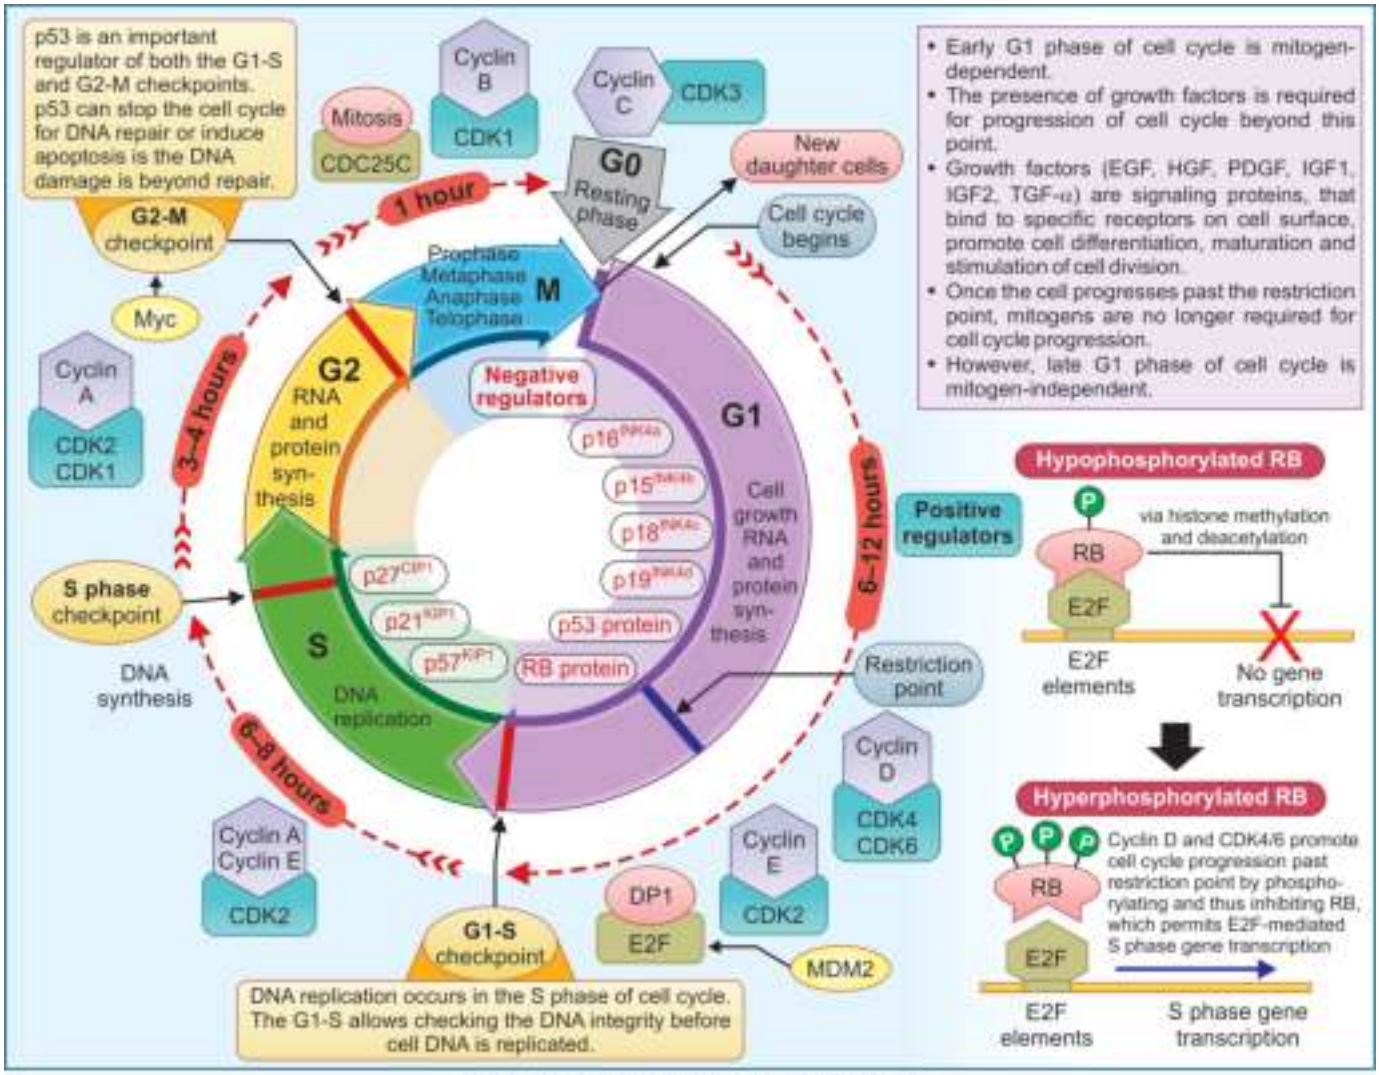
Cyclin-dependent Family of Serine/Threonine Kinases (CDKs): Positive Regulators of Cell Cycle

Cyclin-dependent kinases family of serine/threonine kinases interact with cyclins, and participate in regulation of cell cycle through regulation of cell cycle checkpoints, transcription response to extracellular and intracellular signals as well as communication, metabolism and apoptosis. The CDK activities are regulated by their association with partner with cyclins and without their corresponding cyclin subunit, the CDK is less active that fails to induce functional response.

- Binding of cyclin to CDK forms cyclin–CDK complex, that can phosphorylate specific target molecule. The attached phosphate group acts like a switch, making the target protein more or less active. Binding of cyclin to CDK results in breakdown of nuclear membrane at G1/S transition. Binding of cyclin-D to CDK results in phosphorylation of retinoblastoma protein (pRB) at G1/S transition. CDK-cyclin E complex in G1 phase and CDK-cyclin A complex in S phase mediate the G2/M transition. Binding of CDK1 to cyclin B results in G2/M transition.
- Dysregulation of CDKs is a hallmark of cancers, and inhibition of specific member is considered an attractive target in cancer therapy. Dual CDK4/CDK6 inhibitors are used for the treatment of

Table 6.23 Positive and negative regulators of cell cycle

Cell Cycle Phase	Positive Cell Cycle Regulators	Negative Cell Cycle Regulators
G0	Cyclin C+ CDK3	CDK inhibitor (no role)
G1 (6–12 hours)	▪ Cyclin D (D1, D2, D3) ▪ Cyclin E + CDKs (4,2,6)	▪ RB gene (pRB) ▪ TP53 gene (p53 protein) ▪ INK family of CDK inhibitory proteins (p16, p15, p18, p19)
S phase (6–8 hours)	▪ Cyclin A + CDK2 ▪ Cyclin E + CDK2	CIP/KIP (CDK interacting protein/kinase inhibitory proteins, i.e. p27, p21, p57)
G2 phase (3–4 hours)	Cyclin A + CDKs (2,1)	CDK inhibitor (no role)
M phase (1 hour)	Cyclin B + CDK1	CDK inhibitor (no role)



Cell cycle positive and negative regulators

Cell cycle	Positive regulators			Negative regulators	
Phase	Cyclins	Cyclin-dependent kinases (CDKs)	Other positive regulators include	Cyclin-dependent kinase inhibitors	Other negative regulators include
G0 phase	**Cyclin C**	**CDK3**	–	–	–
G1 phase (6–12 hours)	**Cyclin D (D1, D2, D3) Cyclin E**	**CDK4, CDK2, CDK6**	**MDM2**	**INK family of proteins** ($p16^{INK4a}$, $p15^{INK4b}$, $p18^{INK4c}$, $p19^{INK4d}$) **RB protein, p53 protein**	**BRCA1, BRCA2, MSH2, MLH1, PMS1, PMS2, ATM proteins**
S phase (6–8 hours)	**Cyclin A Cyclin E**	**CDK2**	–	**CIP/KIP family of proteins** ($p27^{CIP1}$, $p21^{KIP1}$, $p57^{KIP1}$)	–
G2 phase (3–4 hours)	**Cyclin A**	**CDK2, CDK1**	**MYC**	**p53 protein**	–
M phase (1 hour)	**Cyclin B**	**CDK1**	–	–	–

Concept: *Cell cycle is tightly controlled by positive and negative regulators. Dysregulation of cell cycle is a hallmark of all malignancies. Metastatic breast disease is treated by cyclin-dependent kinase inhibitor (e.g. palbociclib, CDK4/CDK6 inhibitor) that can cross blood–brain barrier.*

Fig. 6.56: Cell cycle of positive and negative regulators. Positive cell regulators such as cyclins and cyclin-dependent kinase (CDK) enzymes regulate DNA replication and apoptosis. Cell cycle negative regulators are tumor suppressors such as RB (pRb), TP53 (p53 protein), INK family of proteins and CIP/KIP family of proteins, which restrict the ability to a cell to progress from G1 to S phase in the cell cycle.

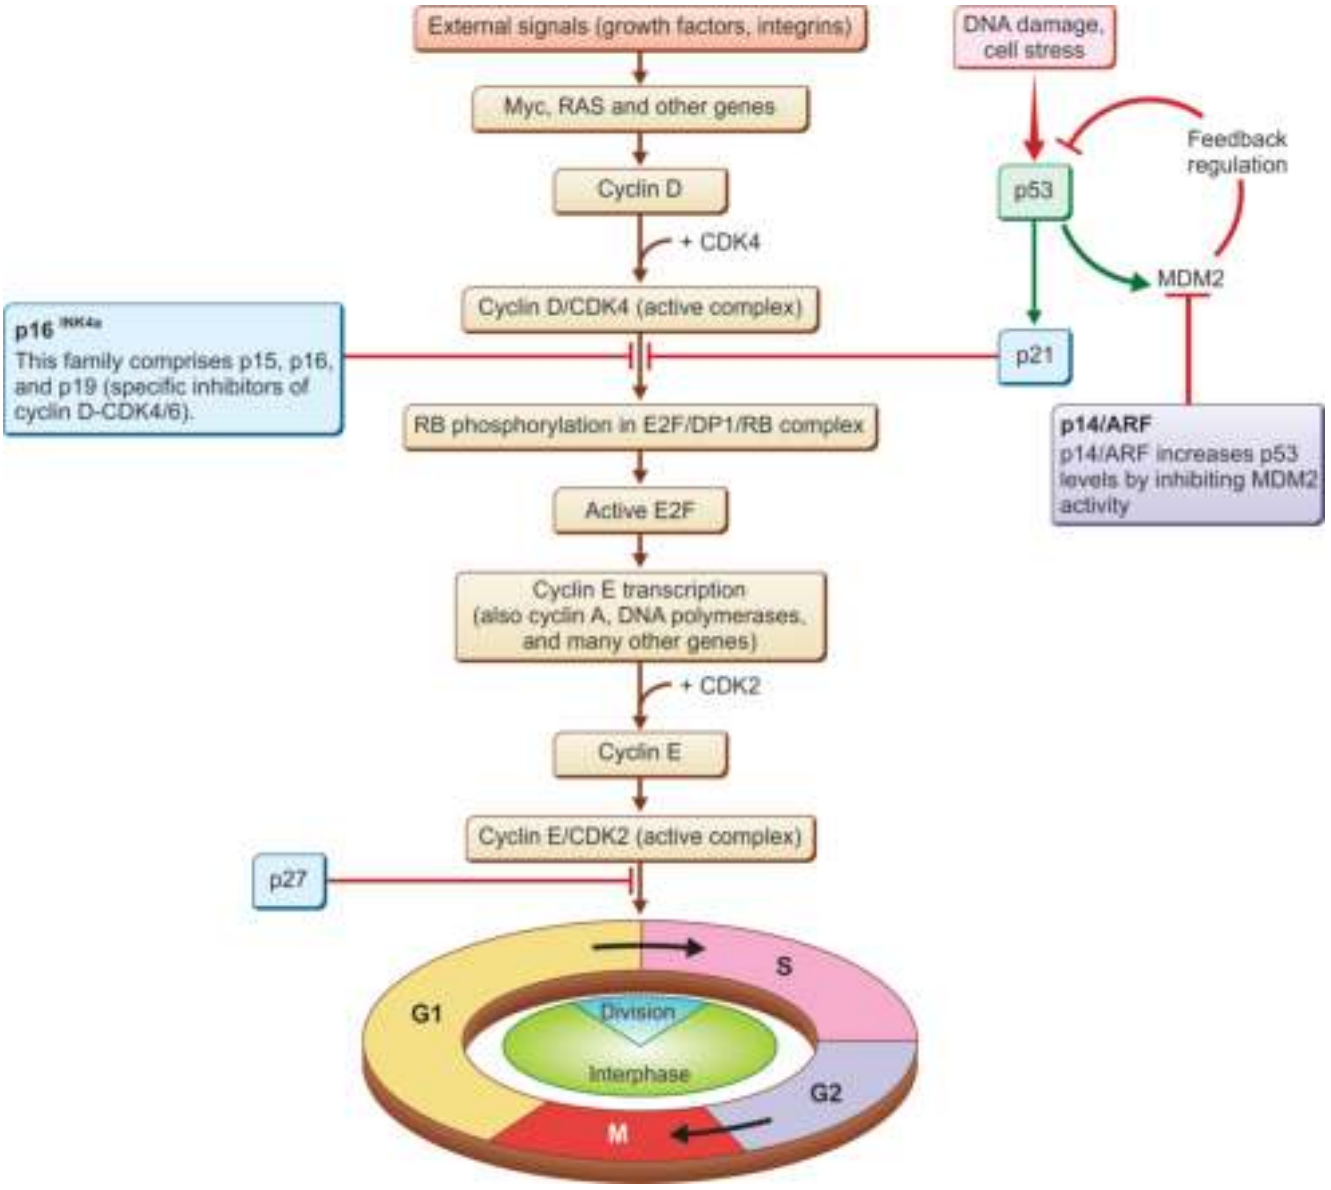


Fig. 6.57: Regulation of the cell cycle. Cells are triggered to go from G1 to G0 by growth factors and cytokines via activation of proto-oncogene. A significant time in the movement of cells from G1 to S phase is the restriction point R. An important regulatory event in this process is the phosphorylation of RB by cyclin-dependent kinases (CDKs), which causes the release of transcriptional activator E2F that forms E2F/DP1/RB complex in the nucleus. CDKs are suppressed by cyclin-dependent kinase inhibitors (CKIs) that are regulated by p53 protein. Tumor suppressor proteins block cell cycle progression within G1.

estrogen-positive (ER+)/human epidermal growth factor 2 negative (HER2/neu negative) breast cancer. Dysregulation of cyclins and cyclin-dependent kinase associated human cancers is given in Table 6.24.

Maturation/Mitosis Promoting Factor (MPF): Positive Regulators of Cell Cycle

Maturation/mitosis promoting factor is the universal master regulator of mitosis (M phase) of cell cycle

Table 6.24 Dysregulation of cyclins and cyclin-dependent kinase associated human cancers

Cyclin 1 Dysregulation and Human Cancers		
▪ Breast carcinoma	▪ Esophageal carcinoma	▪ Mantle cell lymphoma
▪ Multiple myeloma	▪ Hepatocellular carcinoma	
Cyclin-dependent Kinase 4 (CDK4) Dysregulation and Human Cancers		
▪ Glioblastoma multiforme	▪ Melanoma	▪ Sarcoma

from G2 phase by phosphorylating several different proteins involved in breakdown of nuclear envelope and chromosome condensation needed for mitosis. MPF is activated at the end of G2 phase, which removes an inhibitory phosphate group added earlier.

E3 Ubiquitin Ligase Anaphase-promoting Complex/ Cyclosome: Positive Regulators of Cell Cycle

E3 ubiquitin ligase anaphase-promoting complex/ cyclosome regulates ordered cell cycle, that ensures accurate chromosome segregation during mitosis, thus contributing to maintenance of genomic stability.

- Anaphase-promoting complex/cyclosome is a multi-subunit of E3 ubiquitin ligase, that causes degradation of cell cycle regulatory proteins and thus pushes the cell out of mitosis allowing the new daughter cells to enter G1 phase of the cell cycle.
- Dysregulation of E3 ubiquitin ligase anaphase-promoting complex/cyclosome can trigger the abnormal accumulation of its substrates, thus, leading to genomic instability and human cancers.

E2F Transcription Factor/DP1 Protein Complex: Positive/Negative Regulators of Cell Cycle

E2F regulates the expression of number of cellular genes involved in DNA replication and progression through G1/S transition of cell cycle either by activating or repressing their transcription. It is worth mentioning E2F can function as tumor promoter and tumor suppressor. The activity of E2F is dependent on its binding partners, i.e. dimerization protein 1 (DP-1) and RB tumor suppressor protein (pRB). During cell cycle progression, cyclin-dependent kinases (CDKs) phosphorylate RB tumor suppressor protein releasing E2F, which is then available to promote the expression of genes involved in S phase entry, DNA synthesis and mitosis.

MDM2 (Murine Double Minute 2) Protein: Positive Regulator of Cell Cycle

MDM2 (murine double minute 2) protein is an important negative regulator of p53 tumor suppressor protein. MDM2 protein functions as an E3 ubiquitin ligase to degrade unphosphorylated p53 tumor suppressor protein.

- MDM2 protein also binds to another ARF transcription factor that facilitates sequestration of MDM2 protein in the nucleolus thus promotes activation of p53 tumor suppressor protein and thus causes cell cycle arrest.
- Dysregulation of MDM2 proto-oncogene has significant impact on the p53 tumor suppressor functions and in turn leading to tumorigenesis. Considering the key role of MDM2 in the development of human cancers, a better understanding of the regulation of MDM2 will help to develop targeted chemotherapeutic agents against MDM2 protein with an aim to activate p53 tumor suppressor protein in the cells.

Myc Proteins: Positive Regulators of Cell Cycle

Myc proteins (c-Myc, L-Myc, N-Myc, S-Myc family of transcription factors) stimulate cell cycle progression and cellular proliferation through the regulation of genes related to cell cycle control. Myc protein induces positive regulators of cell cycle such as cyclins, cyclin-dependent kinases (CDKs) and E2F transcription factors involved in cell cycle progression at G2/S transition.

Cell Cycle: Negative Regulators

In cell cycle regulation, active positive regulatory molecules such as cyclin/CDK complexes induce cell cycle progression. Negative cell cycle regulators inhibit cell cycle progression and hence provide protection against tumor development, which include retinoblastoma protein (pRB), p53, INK family of proteins (p15, p16, p18, p19), CIP/KIP family of proteins (p21, p27), and p57, which inhibit CDKs thus block cell cycle progression within G1. If negative regulatory proteins are not produced or become non-functional then these induce uncontrolled cell proliferation leading to development of malignant tumor.

Retinoblastoma Tumor Suppressor Protein

Retinoblastoma (RB) gene is a tumor suppressor gene mapped on long arm of chromosome 13p14 that codes for nuclear pRB protein, master brake on cell cycle. Normal people have two alleles of the RB tumor suppressor gene that inhibits the cell cycle progression at G1/S transition. Normal people have two alleles of the RB tumor suppressor gene that inhibits the cell cycle progression at G1/S transition. Role of RB gene as a cell cycle regulator is shown in Fig. 6.58.

- Two opposing enzymatic reactions regulate the activity of retinoblastoma tumor suppressor protein (pRB). Phosphorylated RB releases E2F transcription factor, which binds to DNA and '**turns on**' gene expression, thus inducing cell cycle progression, whereas dephosphorylated pRB is unable to bind to DNA and '**turns off**' gene and thus inhibits cell division at G1/S transition.
- Mutation of RB gene (deletion and nonsense) causes loss of regulation of cell cycle activation through sequestration of transcriptional factors. Germline and somatic mutations of RB tumor suppressor gene are linked to human cancers.

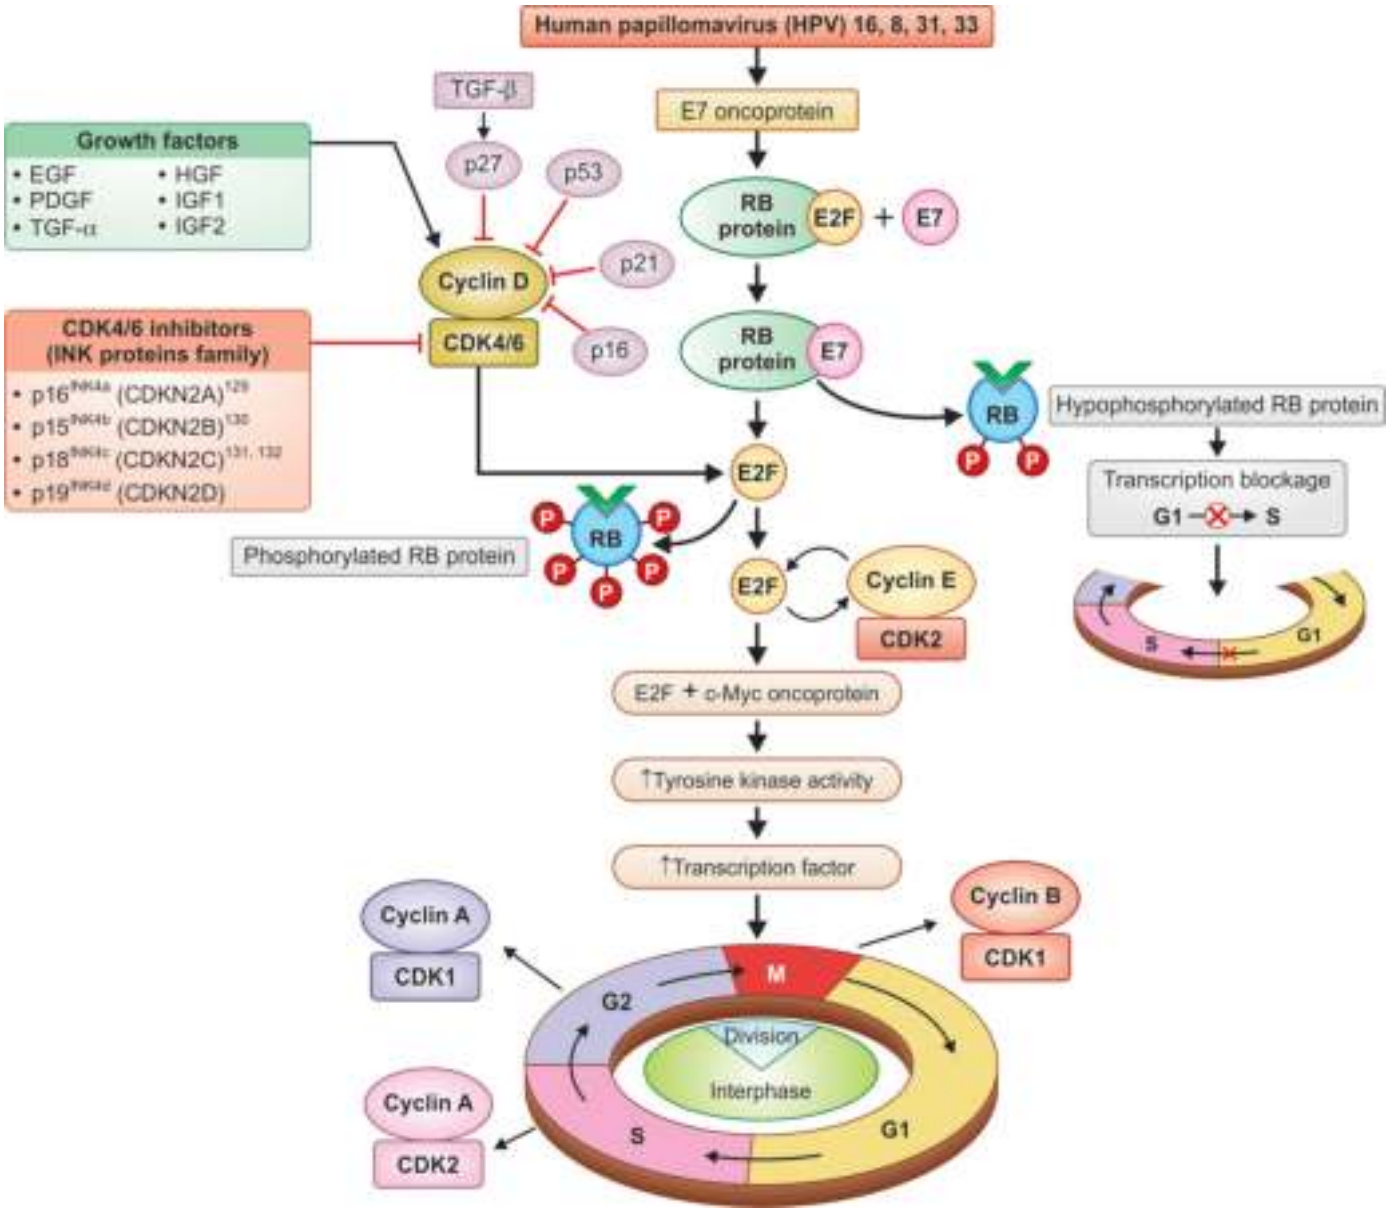

Fig. 6.58: Role of RB gene as a cell-cycle regulator. Various growth factors promote the formation of the cyclin D to CDK4 complex. This complex transforms active hyperphosphorylated RB to hypophosphorylated inactive state. RB inactivation allows the cell to pass the G1 checkpoint at G1/S transition. Virtually all cancers show dysregulation of the cell cycle.

- **Germline mutations in RB gene:** According to the '**Knudson two-hit hypothesis**', both alleles of the RB1 gene must be lost for development of cancer. Germline mutations in both alleles of the RB gene predispose to retinoblastoma and osteosarcoma.
- **Somatic mutation in RB gene:** Somatic mutation in RB gene can cause retinoblastoma (unilateral and unifocal in 1–2 years of age group) including other cancers such as osteosarcoma, breast carcinoma, colon carcinoma, prostatic carcinoma, urinary bladder carcinoma, glioblastoma, pancreatic carcinoma and small cell lung carcinoma.

Pathology Pearls: RB Gene Germline and Somatic Mutations Associated with Familial and Sporadic Cancers

RB Germline Mutations and Familial Tumors

- Retinoblastoma (B/L and multifocal before the age of one year)
- Osteosarcoma

RB Somatic Mutations and Sporadic Tumors

- Retinoblastoma (unilateral and unifocal)
- Osteosarcoma
- Breast carcinoma
- Colon carcinoma
- Prostatic carcinoma
- Urinary bladder carcinoma
- Lung carcinoma

TP53 (p53 Protein) Tumor Suppressor Gene in the Cell Cycle

TP53 tumor suppressor gene is mapped on chromosome on 17p13, that encodes nuclear transcription factor p53 multifunctional protein. TP53 is **guardian** of **genome**. The p53 protein level is low in healthy cells. DNA damage and other stress signals may trigger the increase in level of p53 protein in the cells.

- TP53 tumor suppressor gene product (p53) performs many functions: (a) inhibits G1/S and G2/M transitions of cell cycle, (b) promotes apoptosis interacting with numerous proapoptotic and antiapoptotic proteins, (c) repairs damaged DNA by recruitment of enzymes, (d) activates autophagy, and (e) regulates many metabolic pathways of glucose, lipid and amino acid.
- MDM2 (murine double minute 2) protein is an important negative regulator of p53 tumor suppressor protein, which functions as an E3 ubiquitin ligase to degrade unphosphorylated p53 tumor suppressor protein. Phosphorylated p53 protein is not degraded by MDM2. MDM2 protein also binds to another ARF transcription factor that facilitates sequestration of MDM2 protein in the nucleolus, thus promotes activation of p53 tumor suppressor protein and thus causes cell cycle arrest.
- TP53 gene mutation has been demonstrated in familial and sporadic cancers in more than 50% of patients.
  - **Germline mutations** in **TP53 gene:** Germline mutations in TP53 gene can result in unrestrained cell division and cause Li-Fraumeni syndrome (e.g. breast carcinoma, brain tumors, soft tissue sarcoma, leukemia, and adrenocortical carcinoma). Similar to retinoblastoma, the two-hit hypothesis also applies to Li-Fraumeni syndrome as well. One allele of TP53 is lost in the germline and second allele is lost somatically.
  - **Somatic mutations** in **TP53 gene:** Somatic mutations in TP53 gene are demonstrated in 50% of sporadic cancers such as breast carcinoma (20–40%), colorectal carcinoma, brain cancers (several types), urinary bladder carcinoma, small cell lung carcinoma, cholangiocarcinoma, hepatoblastoma and squamous cell carcinoma in head and neck region.

Pathology Pearls: TP53 Gene Mutation Associated with Familial and Sporadic Cancers

Familial Tumors (Li-Fraumeni Syndrome Associated with Cancers in Children and Young Adults)

- Breast carcinoma
- Osteosarcoma
- Brain tumors
- Soft tissue sarcoma
- Leukemias
- Adrenocortical carcinoma

Sporadic Tumors

- Breast carcinoma (20–40%)
- Colorectal carcinoma
- Brain cancers (several types)
- Urinary bladder carcinoma
- Small cell lung carcinoma
- Cholangiocarcinoma
- Hepatoblastoma
- Squamous cell carcinoma of head and neck region

Cyclin-dependent Kinase (CDK) Inhibitor Proteins

CDKN1A is tumor suppressor gene mapped on chromosome 6p21.2 that encodes two families of cyclin-dependent kinase inhibitors: CIP/KIP family of proteins (p21, p27 and p57) and INK family of proteins (p15, p16, p18 and p19). Cyclin-dependent kinases (CDKs) are positive regulators of cell cycle. CIP/KIP and INK family of proteins inhibit the activity of cyclin-dependent kinases (CDKs).

- **CIP/KIP family of proteins:** CIP/KIP family of proteins include p21, p27 and p57, which possess a wider spectrum of inhibitory activity of cyclin/CDK complexes (cyclin/CDK4/CDK6, cyclin E/CDK2, and cyclin A/CDK2) at G1 phase and S phase of cell cycle.
  - **The p21 protein:** The p21 protein plays a significant role in modulating DNA repair process, which inhibits activity of cyclin-dependent kinases (CDKs, e.g. CDK2, CDK1, CDK4/6) and thus halts cell cycle progression at G1/S transition, and allows DNA repair to proceed while inhibiting apoptosis. Cytoplasmic expression of p21 can be significantly correlated with lymph node metastasis, distant metastasis, advanced TNM stage and overall poor survival.
  - **The p27 protein:** The p27 protein is found in cells and tissues throughout the body. Within cells, p27 protein is located primarily in the nucleus, where it plays an important role in controlling cell growth and division. TGF-β induces p27 protein production that mediates G1 phase cell cycle arrest. Loss or reduced expression of p27 protein is associated with poor prognosis in cancers of breast, prostate, lung, stomach and colorectal region.
  - **The p57 protein:** The p57 is a tumor suppressor multifunctional protein, that inhibits cyclin to CDK complexes and halts cell cycle at G1 phase. Due to its role in cell cycle control, p57 is involved in the many cellular processes such as embryogenesis and tissue differentiation. Loss-of-function of p57 protein is linked to development of **Wilms' tumor** and **hepatoblastoma** during childhood in cases of **Beckwith-Wiedemann syndrome** (BWS). Loss-of-function of p57 protein is also linked to complete hydatidiform mole.

- **INK family of proteins:** INK family of proteins include p15, p16, p18 and p19, which possess a wider spectrum of inhibitory activity of cyclin to CDK complexes (cyclin D to CDK4/6 complex).
  - **The p16 protein:** The p16 is a tumor suppressor protein that plays an important role in regulating the cell cycle. The p16 inhibits cell cycle progression at G1/S transition by inactivating CDKs 4 and 6, that phosphorylates RB tumor suppressor protein, which regulates the cell cycle.
  - **The p15 protein:** The p15 protein is present in the cytoplasm and nucleus and interacts strongly with cyclin-dependent kinases (CDK4 and CDK6) and inhibits their activities leading to cell cycle arrest. The p15 protein is a critical tumor suppressor in the absence of p16.
  - **The p18 protein:** The p18 protein interacts strongly with CDK6, and weakly with CDK4. It inhibits cell growth and cell cycle progression at G1/S transition with a correlated dependence on endogenous RB tumor suppressor protein.
  - **The p19 protein:** The p19 protein inhibits cell growth and cell cycle progression at G1/S transition. The $p19^{INK4D}$ protein is also involved in the cellular senescence mechanism contributing to heterochromatin formation.

DNA REPAIR PROTECTS CELLULAR GENOMES FROM GENOTOXIC STRESSES

Deoxyribonucleic acid (DNA) is an organic chemical that stores information and instructions for protein synthesis. These instructions are stored inside cells and distributed among 46 chromosomes, which are made of numerous short segments of DNA, called genes. DNA damage denotes alterations in the chemical structure of DNA such as a break in DNA strand, nucleotide base pair missing from the backbone of DNA, and a chemical alteration in the nucleotide base pair. DNA damage can be recognized by DNA repair enzymes and correctly get repaired.

- **Causes of DNA damage:** DNA damage can be caused by errors during DNA replication, alkylating agents, reactive oxygen species (ROS) during normal cellular respiration and other biochemical pathways, and physical mutagens (ultraviolet rays, X-rays and γ-radiation). DNA damage leads to genome instability, increased cancer risk, accelerated aging process and neurodegenerative disorders. Damage to DNA can occur by cellular metabolic or hydrolytic processes (deamination and depurination).
- **DNA damage at various levels:** Most forms of localized DNA damage occur at various regions, which include single-strand breaks, double-strand breaks, DNA adducts, nucleotide base insertions or deletions, and nucleotide base pair mismatches. Dysfunction of the mismatch repair system is linked to human cancers. Comet assay or single-cell gel electrophoresis assay is a convenient diagnostic tool for measuring universal DNA damage in individual's cells.

DNA REPAIR PATHWAYS

DNA repair mechanisms depend on the presence of two strands of DNA because nucleotide base pairs in the damaged region are removed and replaced by mismatch nucleotide base pair repair, nucleotide base-excision repair and nucleotide-excision repair. Poly-ADP-ribosyl-polymerase (PARP) plays a central role in nucleotide-excision repair (NER) and base-excision repair (BER) and enables repair of DNA damage caused by alkylating agents and chemotherapeutic agents. PARP is also involved in many other cellular processes including transcription and modulation of chromatin structure. DNA repair mechanisms occur by using a common four-step pathway.

- **Detection of damaged DNA:** Damaged region of the DNA is recognized.
- **Excision of damaged DNA:** Endonuclease gives a small cut to the sugar-phosphate backbone on either one or both sides of the DNA damage to remove one or more nucleotides.
- **Polymerization of damaged DNA:** DNA polymerase enzyme adds nucleotides to the newly exposed 3'OH group by using the other strand of DNA as a template and replacing damaged nucleotide base pairs as well as some undamaged nucleotides in base-excision, mismatch and nucleotide repair mechanisms.
- **Ligation and sealing of damaged DNA:** DNA ligase seals and fills in the small gaps produced by the excision and removal of the damaged nucleotides base pairs in the sugar-phosphate backbone in all three base-excision, mismatch and nucleotide base repair mechanisms.

Pathology Pearls: Microsatellite Instability—Indicators of Defective Mismatch Repair

- Microsatellite instability is an important indicator of defective mismatch repair. Microsatellite instability is short repeated sequences of nucleotide base pairs in genomic DNA.
- Microsatellite mutations are usually recognized and repaired by mismatch repair enzymes. Mediators of mismatch repair system include various mismatch gene products.
- DNA single nucleotide base pair mismatch is detected by MSH2 and MSH6 proteins, which recruit a group of mismatch repair enzymes, which correct the defective sequence.
  - If the mismatch pairing occurs as a result of small insertion or deletion, a second group of mismatch repair enzymes (i.e. MSH2 and MSH3) detect the defective sequence and restore the correct sequence.

- Failure to repair microsatellite mutations in germline or somatic cells is linked to human cancers.

- Human beings, who possess mutations in mismatch-repair genes often exhibit upregulated somatic mutation rates and are frequently susceptible to colon cancer.

Pathology Hallmarks: DNA Repair Mechanisms

- Base excision repair (BER) mechanism
- Direct reversal of DNA damage mechanism
- Repair of DNA protein crosslinks mechanism
- Nucleotide excision repair (NER) mechanism
- Mismatch excision repair (MMR) mechanism
- Double DNA break repair mechanism
- Homologous recombination mechanism
- Nonhomologous end-joining mechanism
- DNA replication fork repair mechanism

Direct DNA Damage Reversal

Direct DNA damage reversal system acts directly on damaged single nucleotide base pair chain, that restores the DNA genome to its normal original state in a single-reaction step. But only a few damaged nucleotides can be repaired directly. Pyrimidine dimers are repaired by a light-dependent direct system called **photoreactivation**.

Mismatch Repair Mechanism

DNA mismatch repair is a mechanism of repairing errors in DNA during DNA replication by the removal of mismatched nucleotide base pairs via mismatch repair (MMR) proteins. DNA replication is extremely accurate in healthy cells.

- DNA mismatch repair (MMR) recognizes and repairs erroneous insertion, deletion and misincorporation of nucleotide base pairs that can arise during DNA replication and recombination, and repair some forms of DNA damage.
- DNA mismatch repair plays an important role in maintaining genomic stability and cellular homeostasis. Most of the errors that initially arise during DNA replication are corrected and never becomes permanent mutations.
  - Some of these errors in nucleotide base pairs are corrected during proofreading by polymerases. During proofreading, some of the incorrect nucleotide base pairs are inserted to the newly synthesized strand of DNA.
  - Mismatched nucleotide base pairs and other DNA errors are corrected by mismatch repair mechanism by inhibiting DNA replication at the G2/M checkpoint, correct errors and then allow DNA replication to continue.
  - Exonucleases remove nucleotide base pairs on the newly synthesized strand of DNA between the GATC sequence and the mismatch.
  - DNA polymerase replaces the nucleotide base pairs, correcting the mismatch, and DNA ligase seals the nick in the sugar-phosphate backbone.
- Examples of mismatch gene products include MLH1 gene (3p21), MSH2 gene (2p15), MSH3 gene (5q11.12), MSH4 gene (1p31.1), MSH5 gene (6p21.33), MSH6 gene (2p16), MLH3 gene (14q24.3), PMS1 gene (2p32.2), PMS2 gene (7p22.1), and HFM1 gene (1p22.2). Defective mismatch repair may be inherited (germline) or acquired (somatic). Acquired defects in mismatch repair may reflect either mutations that develop overtime in somatic cells or epigenetic silencing of component of mismatch repair system.

Excision Repair Mechanism

Excision repair mechanism involves excision of a segment of the polynucleotide containing a damage site followed by synthesis of the correct nucleotide sequence by DNA polymerase enzyme and then ligation. Excision repair occurs by two mechanisms: base excision repair and nucleotide excision repair.

Nucleotide Base Excision Repair Mechanism

Nucleotide base excision repair refers to repair of damage to a single-nucleotide base caused by oxidation, alkylation, hydrolysis or deamination. The damaged nucleotide base pair is removed by DNA glycosylase enzyme, synthesis by DNA polymerase enzymes, and sealing by DNA ligase enzyme.

Nucleotide Excision Repair Mechanism

Damage to the DNA distorts the configuration of the molecule. An enzyme complex recognizes the distortion of DNA resulting from damage. DNA strand becomes separate. Single-strand binding proteins stabilize the single strand. An enzyme cleaves the damaged strand on both sides of the damage. Part of the damaged strand is removed, and the gap is filled in by DNA polymerase and sealed by gyrase.

Recombination Repair Mechanisms of Single- and Double-Strand Breaks of DNA

Ionization, certain chemical agents and ROS can produce both single-strand breaks (SSBs) and double strand breaks (DSBs) in the DNA backbone. Breaks in single-strand of the DNA molecule are repaired using the same enzyme systems that are used in base excision repair. The damaged nucleotide base pair is removed by DNA glycosylase enzyme, synthesis by DNA polymerase enzymes, and sealing by DNA ligase enzyme. DSB inhibits DNA replication and may lead to chromosomal rearrangements such as deletions, inversions, duplication, and translocations. Two major pathways for repairing DSBs include homologous recombination and nonhomologous end joining.

Homologous Recombination Repair Mechanism

Homologous recombination (HR) repairs a broken DNA molecule by using the identical or nearly identical genetic information contained in another DNA molecule, usually a sister chromatid or homologous chromosome.

- The process homologous recombination is responsible for crossing over of chromosomes that results in creation of new combinations of DNA sequences in each chromosome.
- The breast cancer tumor suppressor BRCA1 and BRCA2 genes are essential for the maintenance of genomic integrity in human cells through their role in DNA repair by homologous recombination. Inherited (germline) mutations of these genes predispose women to breast and ovarian cancers.

Nonhomologous End-joining Mechanism

Nonhomologous end joining (NHEJ) repairs double-strand breaks without using a homologous template. This pathway is most often used when the cell is in G1 phase of cell cycle and a sister chromatid is not available for repair through homologous recombination.

- Nonhomologous end joining uses proteins that recognize the broken ends of DNA molecule, bind to the ends and then join together. NHEJ is more prone to errors such as deletions, insertions and translocations than homologous recombination.
- Errors in nonhomologous end joining may be associated in translocation in various cancers such as Burkitt's lymphoma, Philadelphia chromosome in chronic myelogenous leukemia (CML) and B cell non-Hodgkin's lymphoma.

TELOMERES AND SENESCENCE

Healthy cells can divide a limited of times before becoming senescent. Cell senescence process is regulated by the shortening of telomeres after each cell cycle division.

- Once the telomeres shorten to certain threshold, DNA repair gene products of TP53 gene and RB gene, the abnormal telomere length induce cell cycle arrest, thereby stopping further DNA replication of the senescent cell. If p53 protein is lost, a special type of DNA repair occurs, called **nonhomologous end joining**. The ends of the random chromosomes are joined together, forming dicentric chromosomes (with two centromeres).
- Continuation of mitosis would result in mitotic catastrophe with breakage of the chromosomes because of the pulling apart of aberrantly located centromeres and resulting in cell death.
- In tumor cells, telomerase enzyme present in self-regenerating stem cells allows lengthening of telomerases after each cell division. The tumor cell evades senescence and can continue replicating despite accumulation of DNA damage.

APOPTOSIS INHIBITS TUMOR GROWTH

Apoptosis is way of eliminating a cell without eliciting a major host inflammatory and/or immune response. Apoptosis is essential for development, tumor suppression, immune function and maintenance of homeostasis. The accumulation of DNA damage usually triggers the intrinsic pathway to induce apoptosis of cells.

- The loss of apoptotic control allows CSCs to survive longer and gives more time for the accumulations of gene mutations, which induce tumorigenesis, angiogenesis, invasion and metastasis to distant organ(s).
- BCL-2, an antiapoptotic protein, is usually upregulated in human cancers to protect against apoptosis. TP53 gene product is usually downregulated in cancers to evade apoptosis, even in the face of irreparable DNA damage.

EPIDEMIOLOGY OF CANCER

Many human cancers are related to lifestyle factors and specific environmental carcinogenic agents, which can act either as an initiator or promoter or both in the process of carcinogenesis. Cancer arises from the transformation of normal cell to cancer stem cell in a multi-step process due to interaction between a person's genetic factors and environmental carcinogenic agents such as physical carcinogens (e.g. ultraviolet radiation and ionizing radiation), chemical carcinogens (e.g. asbestos exposure, cigarette smoke, alcohol consumption, food contaminant aflatoxin B1 produced by *Aspergillus flavus* in stored agriculture crops such as maize, peanuts, tree nuts and cotton seed in warm and humid regions), and biological carcinogens (e.g. bacteria, viruses and parasites).

- Cancer begins as a single mutated transformed CSC. Approximately, 30 cell divisions form 1–2 mm tumor size before the earliest clinical symptoms appear in the host. Each cell division (doubling time) results in increased gene mutations. Cancers that do not produce symptoms until late in the course of disease, which would have undergone unrestricted cell proliferation, and hence, additional gene mutations

occur. Cancers that are detected late tend to invade surrounding tissues, metastasize to distant organ(s) associated with poor prognosis.

- Goal of cancer screening is to detect severe dysplasia (carcinoma *in situ*) before it becomes invasive carcinoma, before patients have clinical symptoms. Papanicolaou smear (named after George Nicholas Papanicolaou) detects cervical intraepithelial neoplasia III (CIN-III) before it becomes invasive cervical carcinoma. Mammography detects ductal carcinoma *in situ* of breast (DCIS) before it becomes palpable invasive ductal carcinoma, that invades surrounding tissues and metastasizes to distant organ(s). Prostate-specific antigen (PSA) and digital rectal examination can detect prostatic adenoma before it transforms to prostatic adenocarcinoma.

GLOBAL IMPACT OF CANCER

Cancer is a leading cause of death worldwide due to breast carcinoma, lung carcinoma, colon carcinoma and prostatic carcinoma. About 33% of cancer patients population have fatal outcome due to tobacco smoking, tobacco chewing, high-body index, alcohol consumption, low-fiber vegetable consumption, low-intake of fruits and lack of physical activity. About 33% patients develop malignancy due to human papillomavirus (HPV 16, 18), hepatitis B virus (HBV) and hepatitis C virus (HCV) infections. Many cancers can be cured, if detected early and treated effectively by surgery, radiotherapy and chemotherapy. As malignant tumors obtain nutrients from the host, they can alter normal cellular biological processes and cause cachexia.

CANCER EPIDEMIOLOGY AND PREVENTION STRATEGIES

Cancer epidemiology is the study of the distribution, determinants and frequency in specific populations. Its main objective is to define etiologic factors to formulate preventive strategies for controlling the cancer disease. The main epidemiological parameters used in the study of human cancers are sex predilection, age, ethnicity, geography, style factors and specific environmental carcinogenic agents, which can act either as an initiator or promoter or both in the process of carcinogenesis. Epidemiologic assessment provides the clinician with a quantification of cancer risk, outlines the basis for screening modalities for high-risk populations and determines the efficacy of a preventive intervention.

Incidence of Cancers in Men and Women

Incidence of cancer varies from country to country and region to region across world. Many cancers are related to specific environmental and lifestyle factors that predispose a person to develop cancer. Incidence of cancers in women and men is shown in Fig. 6.59.

- In Western countries (USA and Europe), men are most often affected by prostatic carcinoma (32%), lung carcinoma (16%), colorectal carcinoma (12%), urinary bladder carcinoma (9%) and melanoma (4%). On the other hand, women develop breast carcinoma (32%), colorectal carcinoma (13%), lung carcinoma (12%), urinary bladder carcinoma (4%) and ovarian carcinoma (4%).
- In Indian population, men most often develop cancers of oral cavity, pharynx and lung, and women are most often affected by cervical carcinoma and breast carcinoma. Incidence of cervical carcinoma is declining due to early detection by exfoliative cytology stained by Papanicolaou stain. Incidence of oropharyngeal carcinoma is more prevalent in North Indian population, while gastric carcinoma in South Indian population.

Age Group and Cancers

The incidence of many human cancers increases with age. Few cancers are found in children, and the incidence of cancer correlates directly to increasing age, which indicates that numerous cumulative events are essential for the initial gene mutation to continue, eventually forming a malignant tumor. Children ≥15 years suffer from lethal cancers like acute lymphoblastic leukemia (ALL), Burkitt's lymphoma, Wilms' tumor, hepatoblastoma, cerebellar astrocytoma, retinoblastoma, neuroblastoma, testicular germ cell tumors, botryoid rhabdomyosarcoma and osteosarcoma. Most frequent types of cancers in children from birth to childhood are given in Table 6.25.

Sex Predilection and Cancer

Certain cancers are more prevalent in women, and others in men. Sex hormones influence development of breast carcinoma, endometrial carcinoma and prostatic carcinoma. Researchers believe that sex hormones sensitize the cell to initial precipitating factor, thus promoting carcinogenesis.

- **Male predominance** has been observed in prostatic carcinoma, lung carcinoma, colorectal carcinoma, esophageal carcinoma, renal cell carcinoma, urinary bladder carcinoma, squamous cell carcinoma of skin, pancreatic carcinoma, and hematolymphoid malignancies (leukemias/lymphomas).
- **Female predominance** has been observed in breast carcinoma, cervical carcinoma, endometrial carcinoma, leiomyosarcoma of uterus, lung carcinoma, colorectal carcinoma, cutaneous squamous cell carcinoma, pancreatic carcinoma and lymphomas.

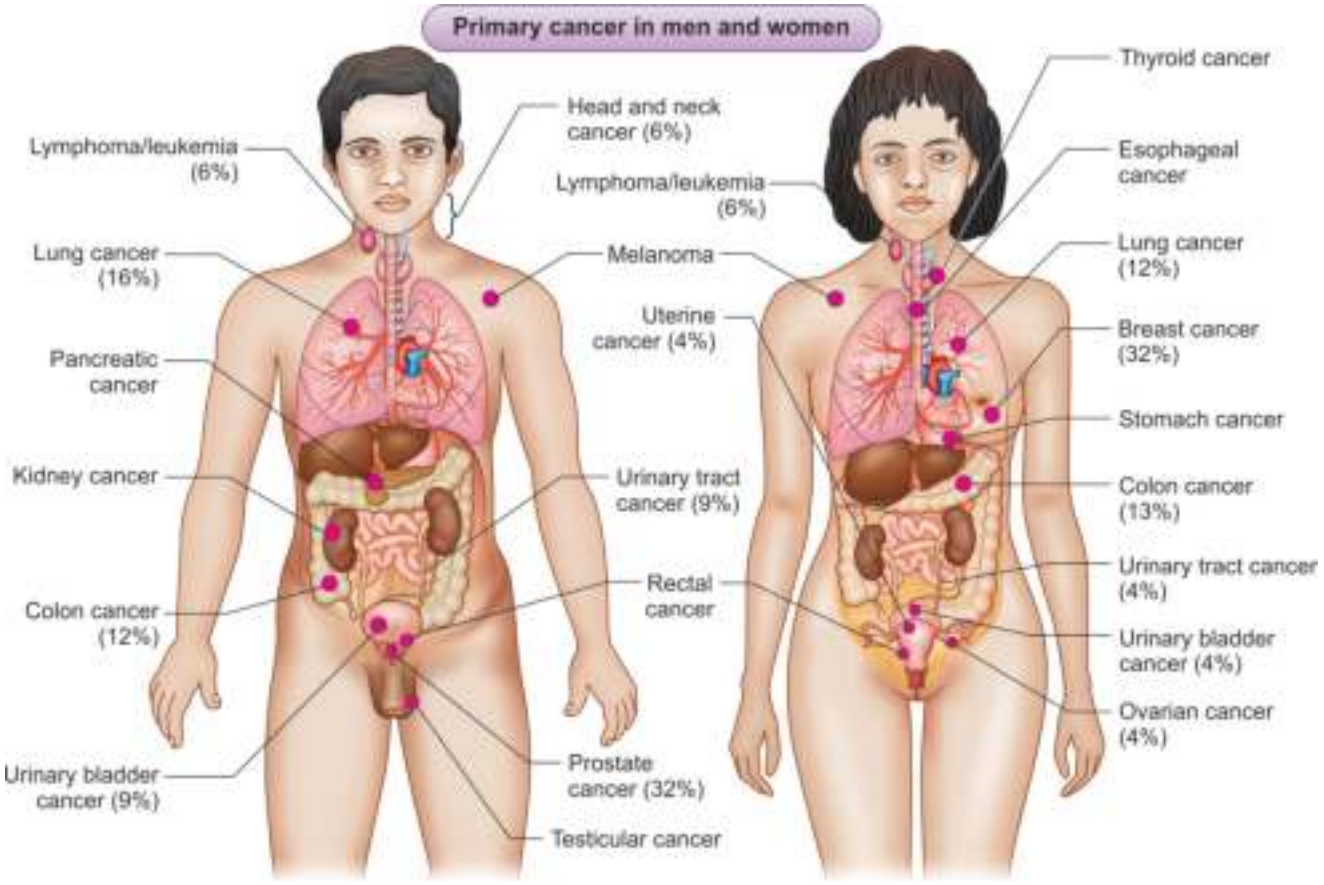

Fig. 6.59: Incidence of cancers in women and men. In men, excluding skin cancers, other cancers account for 75% cases. In women, excluding skin cancers, other cancers account for 80% cases. Most common locations for cancer in men include skin, prostate, lung and colon. Most common locations for cancer in women include skin, breast, lung, colon and uterus. Most common cancers in young children include acute myelogenous leukemia (AML), acute lymphoblastic leukemia (ALL), neuroblastoma, retinoblastoma and botryoid rhabdomyosarcoma.

Table 6.25 Most frequent types of cancers in children from birth to childhood

Nomenclature of Tumors	Malignancies	
Hematolymphoid malignancies	▪ Acute myelogenous leukemia ▪ Acute lymphoblastic leukemia	▪ Hodgkin's disease ▪ Burkitt's lymphoma
Primitive neuroectodermal tumors (PNETs)	▪ Astrocytoma ▪ Primitive neuroectodermal tumors ▪ Brain stem gliomas	▪ Cerebellar astrocytoma ▪ Ependymomas
Germ cell tumors	▪ Yolk sac tumor of the testis	
Bone tumors	▪ Osteosarcoma	▪ Ewing sarcoma
Soft tissue tumors	▪ Alveolar rhabdomyosarcoma	▪ Embryonal rhabdomyosarcoma (e.g. botryoid rhabdomyosarcoma)
Blastomas	▪ Retinoblastoma ▪ Neuroblastoma	▪ Nephroblastoma (Wilms' tumor) ▪ Hepatoblastoma

Geographic and Racial/Ethnic Disparities in Epidemiology and Genomics in Cancer

Geographic and racial/ethnic disparities in rates of incidence, mortality, survival, prevention, early detection and genomics of many cancers are well documented and often associated with socioeconomic status in particular population and subpopulation resulting from exposure to environmental carcinogens.

Geographic and racial/ethnic differences in cancer epidemiology are given in Table 6.26.

- System level and health care professional-related issues likely to contribute to specific racial and ethnic health disparities have been reviewed to provide possible suggestions for future strategies to reduce the disproportionate burden of many specific cancers.
- Although, carcinogenesis is a multifactorial process driven by environmental exposures to carcinogens, genetic variations, and accumulation of somatic genetic events, which appear to have racial and ethnic disparities, that in turn impact the observed epidemiological differences in rates, incidence, mortality and survival.
- Incidence of breast cancer is higher in Japanese women, as compared to American women. Incidence of gastric carcinoma is higher in Japan and Iceland persons, as compared with the USA. Incidence of hematologic malignancy is higher in sub-Saharan African persons, as compared with persons in USA. Prostatic carcinoma is more prevalent in the Black population, than White population in USA. Skin cancer is more prevalent in patients with fair skin and light hair.
- The genomic diversity of oncogenes and tumor-suppressor genes across racial and ethnic groups poses unique but important challenges for therapeutic opportunities to provide personalized medical care. Molecular genomic profiling for specific alterations is essential to identify patients likely to benefit from targeted therapy.

Alcohol Consumption and Tobacco Products Linked to Cancer

Excessive alcohol consumption is linked to cirrhosis leading to hepatocellular carcinoma in some cases. Patient can also develop breast carcinoma and colorectal carcinoma. Heavy use of alcohol and cigarette smoking

Table 6.26 Geographic and racial/ethnic differences in cancer epidemiology

Cancers	Higher Cancer and Geographical Distribution
Malignant melanoma	Australia (Queensland)
Oral carcinoma	Indian population (consumption of oral betel nut and tobacco chewing), and France population (consumption of cider-based liquors)
Lip carcinoma	Canada
Breast carcinoma	United States of America and Northern Europe, persons with BRCA gene mutation (less prevalent in Japanese women)
Esophageal carcinoma	South Africa, belt from Turkey to Eastern China
Gastric carcinoma	Japan (consumption of smoked fish), Chile, persons with blood group A (incidence low in United States of America)
Nasopharyngeal carcinoma	China (Epstein-Barr virus), Hong Kong, Singapore
Hepatocellular carcinoma	Sub-Sharan African nations (incidence low in United States of America)
Lung carcinoma	United States (Louisiana African American), Eastern Europe (male)
Cervical carcinoma	Brazil, Eastern Europe
Ovarian carcinoma	New Zealand (Polynesian)
Colon carcinoma	Australia, New Zealand (male)
Pancreatic carcinoma	United States (Los Angeles—Korean Americans)
Burkitt's lymphoma	African population (Epstein-Barr virus)
Kaposi sarcoma	African population (human herpesvirus 8)
Hepatocellular carcinoma	South East Asia (hepatitis B virus and aflatoxin produced by *Aspergillus flavus*), China (Shanghai)
Cutaneous squamous cell carcinoma	Northern Australia, South Western of United States, persons with fair skin, light hair and blue eyes, xeroderma pigmentosum, Kashmiri population carries a basket with burning charcoal (*Khangri*) held close to abdomen to keep them warm during winter season, and develops skin carcinoma on the abdominal region (low incidence in dark skin persons)
Penile carcinoma	United States of America, Brazil, persons with balanitis (incidence low in Muslims and Jews, who undergo circumcision of prepuce. It may be probably smegma that acts as a solvent for environment carcinogens)
Prostatic carcinoma	United States of America Black population (incidence low in White population in USA)
Choriocarcinoma	Asia pacific region near the Western Pacific Ocean

synergistically increase the incidence of cancers of the mouth, larynx, pharynx, and esophagus. It is likely that alcohol acts as a solvent for the carcinogenic agents in tobacco smoke, thus enhancing their absorption. Cigarette smoke comprises neutral and acidic fractions. Neutral fraction contains polycyclic hydrocarbons, which bind to nuclear DNA and exert mutagenic effect. Acidic fraction of tobacco smoke contains a number of tumor-promoting agents. Tobacco smoking increases risk of lung carcinoma.

Dietary Factors and Lifestyle Factors Linked to Cancers

High consumption of smoked foods (salted fish or meats), and dietary nitrites are linked to gastric carcinoma. Consumption of red meat increases risk of lung carcinoma (i.e. squamous cell lung carcinoma, lung adenocarcinoma), esophageal carcinoma, colorectal carcinoma, prostatic carcinoma, and ER therapy-induced breast carcinoma. Aflatoxin B1 synthesized by *Aspergillus flavus* in stored food grains increases risk of hepatocellular carcinoma. High body mass index (BMI) increases risk for various cancers. Exercise and soy food consumption decrease risk of breast carcinoma.

Sexual Factors Linked to Cancer

Cervical carcinoma is one of the most common cancers affecting women worldwide. It is readily detected and treated at precursor stage, i.e. 'carcinoma *in situ*'. Cervical carcinoma associated with high-risk human papillomavirus (HPV 16, 18) infection transmitted via sexual route develop primarily at the '**transformation zone**', region, where metaplastic squamous epithelial cells are detected in otherwise columnar epithelium lined endocervical glands. HPV 16, 18 infection can result in cervical carcinoma 5–30 years after the initial infection.

- Woman is at high-risk of HPV infection linked to cervical carcinoma, who has sex without the use of condoms with multiple sexual partners. Enabling woman to successfully negotiates condom use with her sexual partners may therefore decrease the risk for cervical carcinoma.
- Early age at first sexual intercourse increases the risk for cervical carcinoma as damage might be caused to the cervix at a time, when it is developing. The risk of getting HPV infection and cervical carcinoma in woman is more, who has sexual course around 15 years of age.

Reproductive Hormones Linked to Cancers

Steroid hormones, i.e. estrogen, progesterone, and testosterone have been implicated as promoters of breast carcinoma, endometrial carcinoma, ovarian carcinoma, or prostatic carcinoma. Researchers believe that the hormone sensitizes the cells to the initial precipitating factor, thus promoting carcinogenesis. Breast carcinoma is more common in women than men, probably due to the greater mammary epithelial volume and to the promoting effects of circulating estrogens.

Environmental Pollutants Linked to Cancer

Many outdoor air pollutants such as arsenic, benzene, hydrocarbons, polyvinyl chloride, and other industrial emissions as well as vehicle exhaust have carcinogenic properties. Chloromethyl ether is a potent carcinogen causing small cell lung carcinoma. Combustion of coal and other fossils releases polycyclic aromatic hydrocarbons (benzopyrene), which increase risk for lung carcinoma.

Occupational Workers Exposed to Carcinogens Linked to Cancers

Exposure to various carcinogens, occupational workers may develop cancers. Occupational workers involved in the production of aniline dyes, textiles, rubber and paint, exposure to β-naphthylamine increases risk for urothelial carcinoma.

- Mesothelioma (pleura, peritoneum), lung adenocarcinoma and gastrointestinal cancers are more prevalent in pipe fitter and ship builder occupational workers exposed to asbestos mineral dust.
- Nickel exposure in mine workers is associated with cancers in occupational works of nasal cavity and lungs. Arsenic exposure may cause squamous cell carcinoma of skin, lung carcinoma, and liver angiosarcoma. Beryllium exposure may cause bronchogenic carcinoma. Cadmium used in batteries and metal paintings is implicated in prostatic carcinoma. Chromium used in paints, pigments and preservatives is linked to lung carcinoma. Occupational workers exposure to carcinogens and associated cancers are given in Table 6.27.

Radiation Exposure Linked to Cancers

Exposure to ultraviolet solar radiation, causes genetic mutation in TP53 gene. Ultraviolet radiation is a direct cause of melanoma, basal cell carcinoma of skin and squamous cell carcinoma of skin. Ionizing radiation may cause lung carcinoma. Japanese are at high risk of lung carcinoma (squamous cell lung carcinoma, adenocarcinoma and small cell lung carcinoma) after atom bomb explosion in Hiroshima and Nagasaki. Prolonged exposure to X-ray radiation is linked to acute leukemia, thyroid carcinoma, breast carcinoma, gastric carcinoma, colon carcinoma, urinary bladder carcinoma, and multiple myeloma. Low doses of X-ray radiation can cause DNA mutations and chromosomal alterations which play important role in carcinogenesis.

Table 6.27 Occupational workers exposure to carcinogens and associated cancers

Heavy Metals and Inorganic Chemical Agents	Occurrence and Type of use	Associated Cancers
Arsenic compounds	Component of alloys, preparation of electrical and semiconductor device, medications, fungicides and herbicides	Squamous cell carcinoma of skin, basal cell carcinoma of skin, lung carcinoma and hepatic angiosarcoma
Asbestos	Used as material in building construction	Lung carcinoma, esophageal carcinoma, gastric carcinoma, and mesothelioma (pleura and peritoneum)
Benzene	Used in printing, paint, rubber, dry cleaning, detergents, adhesives	Acute myelogenous leukemia (AML)
Uranium	Mine workers	Lung carcinoma
Nickel compounds	Used in nickel plating ceramics, ferrous alloys, batteries and stainless steel welding	Lung carcinoma and oropharyngeal carcinoma
Chromium compounds	Component of metal alloys, paints, pigments and preservatives	Lung carcinoma
Beryllium compounds	Used in missile fuel, nuclear reactors, aerospace application and light weight alloys	Lung carcinoma
Cadmium compounds	Used in batteries and metal paintings	Lung carcinoma and prostatic carcinoma
Vinyl chloride	Used to make polyvinyl chloride (PVC) pipes, plastic kitchenware, wire coatings, pesticides, dyes, drugs and synthetic polymers	Hepatic angiosarcoma

Genetic Factors Linked to Cancers

Genotype of an individual plays a role in determining susceptibility to malignant disease as a result of chromosomal alterations related to various genetic syndromes or single gene abnormalities.

- Three chromosomal disorders are prone to develop cancers. Down's syndrome is prone to develop acute lymphoblastic leukemia (ALL) or acute myelogenous leukemia (AML). There is increased risk for breast carcinoma in males with Klinefelter's syndrome. **Gonadal dysgenesis** with male genotype is more likely to develop tumors of gonads.
- Person with xeroderma pigmentosum is prone to develop squamous cell carcinoma of skin and basal cell carcinoma of skin. Familial adenomatous polyposis coli predisposes to colorectal carcinoma. Women with BRCA1 gene mutation have high-risk for breast carcinoma.

IMMUNODEFICIENCY STATES IN CANCER EPIDEMIOLOGY

Transformation of normal cell to CSC and their subsequent successful clonal expansion and progression to development of clinically apparent solid malignant tumors and hematologic malignancies is a complex multifactorial process due to genetic, immunologic, microbial and environmental constituents.

- Immune system is composed of highly specialized cells, tissues, organs, and soluble factors that interact in a complex way to ensure immune defense. Patients, who are deficient in T cell immunity are at high-risk to develop malignancies especially caused by oncogenic viruses.
- Primary immunodeficiency disorders are characterized by impaired humoral and/or cell-mediated immunity in persons, which include common variable immunodeficiency (CVID), hyper-IgE syndrome (Job syndrome), familial hemophagocytic lymphohistiocytosis, selective IgA deficiency, DNA repair disorders (e.g. ataxia-telangiectasia, Wiskott-Aldrich syndrome, Nijmegen breakage syndrome), severe congenital neutropenia (SCN), and severe combined immunodeficiency disease (SCID). The patients suffering from primary immunodeficiency disorders are linked malignancies.

Common Variable Immunodeficiency Disease

The hallmark of CVID disease is hypogammaglobulinemia due to impaired B cell differentiation. Patient presents with recurrent sinopulmonary recurrent infections, autoimmune disorders and granulomatous disease, who have increased risk of developing B cell non-Hodgkin's lymphomas in extranodal sites (especially in brain), gastric carcinoma, breast carcinoma, urinary bladder carcinoma, and cervical carcinoma. Defective immune system fails to eliminate transformed cancer stem cells. Immune dysregulation and oncogenic Epstein-Barr virus (EBV) infection probably are linked to B cell non-Hodgkin's lymphoma.

Hyper-IgE Syndrome (Job Syndrome)

Hyper-IgE syndrome (Job syndrome) is characterized by occurrence of recurrent boils, eczema, and pneumonitis in those patients, who have very high level of serum IgE. A mutation in the signal transducer and the activator of the transcription 3 (STAT3) gene has been detected in the majority of cases. These patients are at high risk for B cell non-Hodgkin's lymphoma due to abnormalities in STAT3/IL-21-dependent differentiation of B cells into plasma cells with possible involvement of CD4+ helper T cells in the lymphoid follicles. Defective B cells play important role in the carcinogenesis, invasion and metastases of many cancers such as lung carcinoma and melanoma. Viral infection in these patients is associated with increased risk for cancer.

Familial Hemophagocytic Lymphohistiocytosis

Familial hemophagocytic lymphohistiocytosis (FHL) occurs due to defects in natural killer cells, and CD8+ cytotoxic T cells due to mutation in PRF1 gene resulting in a multisystem inflammatory disease with persistent fever and hepatosplenomegaly, pancytopenia and metabolic alterations. Mutations in PRF1 gene leads to reduced ability of immune cells to perform essential immunosurveillance roles against development of B cell non-Hodgkin's lymphoma in these patients.

Selective IgA Deficiency

Selective IgA deficiency is asymptomatic in many patients, who present with gastrointestinal system and respiratory system infections, atopy, autoimmune disorders, and later in life developing abdominal lymphoid and gastrointestinal malignancies. Recently, primary cutaneous marginal lymphoma with subsequent development of nodal marginal lymphoma has been reported in patients with selective IgA deficiency.

Ataxia-Telangiectasia

Ataxia-telangiectasia is an autosomal recessive disorder with DNA repair defect and characterized by progressive cerebellar ataxia, oculocutaneous telangiectasia and dysarthria. Cells have reduced ability to activate cell cycle checkpoints following exposure to γ-radiation due to mutation in ATM gene. Normally, ATM protein acts as sensor of double-stranded DNA breakage. Mutations in ATM gene predisposes to leukemia, lymphoma and breast carcinoma, thought to be related to excessive production of DNA translocation.

Nijmegen Breakage Syndrome

Nijmegen breakage syndrome (NBS) is an autosomal recessive disorder with DNA repair defect closely related to ataxia-telangiectasia seen across world. The defective NBS gene is a component within the same pathway as ATM gene. Both NBS and ATM gene products are part of a multi-subunit complex involved in correcting γ-radiation induced chromosomal aberrations and repair of double-strand DNA breaks.

- Patients with Nijmegen breakage syndrome have severe immunodeficiency of both humoral (i.e. agammaglobulinemia, IgA, IgG2 deficiency) and cellular immunity (lymphopenia, decreased CD4+ helper T cells). Physical examination reveals microcephaly, short stature and bird-like face.
- Nijmegen breakage syndrome is linked to immune dysfunction and high-risk of developing non-Hodgkin's lymphoma (NHL), acute lymphoblastic leukemia (ALL), breast carcinoma and prostatic carcinoma.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome is an X-linked primary immunodeficiency disorder with DNA repair defect due to mutation in Wiskott-Aldrich syndrome (WAS) gene located on short arm of X chromosome encoding WASp only expressed in hematopoietic cells. Patient presents with recurrent infections, microthrombocytopenia, eczema and increased incidence of autoimmune disorders, acute myelogenous leukemia (AML) and myelodysplastic syndrome (MDS).

Severe Congenital Neutropenia

Severe congenital neutropenia (SCN) occurs due to the arrest of myelopoiesis maturation at the promyelocyte/myelocyte stage, resulting in neutropenia with systemic neutrophil blood counts $<0.5 \times 10^9$/L. There is increased risk of developing myelodysplastic syndrome (MDS), acute myelogenous leukemia (AML), chronic myelomonocytic leukemia (CMML).

Molecular/Cytogenetic Mutations

Mutation in elastase 2 gene has been detected in 50–60% of severe congenital neutropenia cases. In addition, other gene mutations have been detected in severe congenital neutropenia, which include HAX1 gene encoding hematopoietic cell-specific Lyn substrate 1 (HCLS1), glucose-6-phosphatase, catalytic 3 (G6PC3), GATA2 gene and granulocyte colony-stimulating factor 3 receptor (G-CSF3R) gene.

- Heterozygous mutations in GATA2 gene causes disorders of hematopoiesis, lymphatics, and immune system.
- Normally, GATA2 is a zinc finger transcription factor, which is essential for differentiation of hematopoietic precursor cells, and regulation of phagocytosis by alveolar macrophages. Upregulation of GATA2 gene in alveolar macrophages increases phagocytic activity up to threefold.

Clinical Features

Patient with severe congenital neutropenia presents with **recurrent severe infections** due to HPV, Epstein-Barr virus (EBV), mycobacteria, invasive fungi infection and persistent neutropenia. Daily administration of granulocytic colony-stimulating factor (**G-CSF**) results in elevation of blood neutrophil counts to prevent recurrent severe infections. Patient can also develop human papillomavirus (HPV) positive malignant tumors (cervical carcinoma, vaginal carcinoma, penile carcinoma, anal carcinoma and oropharynx) and Epstein-Barr virus (**EBV**) positive tumors such as Burkitt's lymphoma, immunoblastic lymphoma, nasopharyngeal carcinoma, and gastric carcinoma.

ACQUIRED PREMALIGNANT DISEASES

Acquired premalignant diseases are associated with an increased risk for cancer resulting from persistent focal cell regeneration, atypical hyperplasia, metaplasia and dysplasia in different anatomic sites. Premalignant diseases linked to increased risk of development of cancer are given in Table 6.28.

- Acquired premalignant disease is a pathologic state in different anatomic sites, i.e. skin, gastrointestinal tract, hepatobiliary system, respiratory system, female genital system, skeletal system, urinary system, and thyroid gland, that progresses directly to cancer disease without a known intermediate step that can help in providing detail about the dynamic carcinogenesis process, before development of clinical cancer disease.
- Although the cell-of-origin of cancer is difficult to pinpoint cancer clones, which harbor information about their clonal ancestries. In an effort to detect premalignant cells before they evolve into life-threatening cancer disease, clinicians currently diagnose premalignant diseases at frequencies that substantially exceed those of clinical cancers.
- Cancer risk prediction relies on our ability to distinguish between premalignant diseases and cancer malignant tumors show marked heterogeneity in their cellular morphology and clonal architecture, e.g. adenoma-carcinoma paradigm in colorectal carcinoma progression, and Barrett's metaplasia-dysplasia-carcinoma sequence.
- It is difficult to obtain tissue sampling, detect and diagnose precursor lesions in ovary and pancreas. Premalignant diseases do not invariably progress to malignant phenotype, because some premalignant lesions are detected on screening procedure, which are treated, thereby decreasing risk of developing malignant tumor. This is one of the rationales behind the screening programmes.

Acquired Precursor Lesions Linked to Cancer

Term 'acquired precursor lesions' encompasses several entities that are linked to cancer, which include persistent regeneration of cells, atypical epithelial hyperplasia, metaplasia and dysplasia in various anatomic sites.

Table 6.28 Premalignant diseases linked to increased risk of development of cancer

Conditions	Premalignant Conditions	Human Cancers
Persistent focal regeneration of epithelial cells and fibrosis	Cirrhosis	Hepatocellular carcinoma
Atypical hyperplasia of epithelial cells	▪ Atypical hyperplasia of epithelial cells lining fistulous tract in anal region ▪ Atypical endometrial hyperplasia ▪ Atypical ductal/lobular hyperplasia	▪ Squamous cell carcinoma of skin ▪ Endometrial carcinoma ▪ Ductal/lobular carcinoma of breast
Metaplasia of epithelial cells	Barrett's esophagus	Esophageal adenocarcinoma
Dysplastic change in epithelial cells	▪ Cervical intraepithelial neoplasia III (CIN-III) ▪ Dysplastic nevus ▪ Bronchial dysplasia ▪ Pancreatic intraepithelial neoplasia	▪ Squamous cell carcinoma of cervix ▪ Malignant melanoma ▪ Bronchogenic carcinoma ▪ Pancreatic adenocarcinoma
Chronic inflammation	▪ Atrophic gastritis ▪ Ulcerative colitis ▪ *Opisthorchis viverrini*-induced cholangitis ▪ Cholelithiasis ▪ *Helicobacter pylori*-induced chronic gastritis ▪ HBV and HCV-induced hepatitis ▪ Discharging sinuses of skin	▪ Gastric adenocarcinoma ▪ Colonic adenocarcinoma ▪ Cholangiocarcinoma ▪ Gallbladder adenocarcinoma ▪ Gastric carcinoma and mucosa-associated lymphoid tissue (MALT) lymphoma ▪ Hepatocellular carcinoma ▪ Squamous cell carcinoma of skin

Persistent Regeneration of Cells in Organ(s) Linked to Cancer

In Crohn's disease, a fistula develops when characteristic inflammation occurs in the gastrointestinal tract so that an ulcer forms, that spreads through the intestinal wall and then bores a hole through muscle and skin near the anus. Persistent regeneration of cells results in development of squamous cell carcinoma in the margins of a chronic skin fistula or in delayed skin wound healing. Persistent regeneration of hepatocytes in cirrhosis can result in hepatocellular carcinoma.

Atypical Epithelial Hyperplasia Linked to Various Cancers in Females

Atypical ductal hyperplasia is a relatively common lesion demonstrated in 5–20% of breast biopsies. It is classified as a high-risk precursor lesion due to its association with progression to ductal carcinoma *in situ* and invasive ductal carcinoma of breast.

- Endometrial atypical hyperplasia thickens the epithelial lining of uterus with resultant increase in gland to stroma ratio, causing dysfunctional bleeding. Excessive circulating estrogens (exogenous administration or ovarian granulosa cell tumor and thecoma) may induce endometrial atypical hyperplasia (precursor lesion) leading to development of endometrial carcinoma. Histologic examination of endometrial atypical hyperplasia reveals closely packed endometrial glands of variable sizes, irregular luminal contours with glands to stroma >3:1 ratio.
- Excess diethylstilbestrol intake by pregnant mother can cause vaginal adenosis (precursor lesion) in the daughter, who has great risk of developing vaginal adenocarcinoma.

Metaplasia in Organ(s) Linked to Cancers

Many acquired precursor lesions arising in the settings of chronic inflammation can progress to malignancies of esophagus, stomach and lung. Acquired precursor lesions can be recognized by the presence of glandular metaplasia of distal esophagus in Barrett's esophagus in response to gastroesophageal reflux disease (GERD), *Helicobacter pylori*-induced gastric glandular metaplasia due to chronic atrophic gastritis, squamous metaplasia in bronchi in tobacco smokers, and squamous metaplasia in the urinary bladder due to *Schistosoma haematobium* infection.

Dysplasia in Organ(s) Linked to Cancers

Dysplasia is a term used to describe the presence of cytologically abnormal cells confined within their original basement membrane, which can be mild, moderate or severe, depending on how abnormal the cells look under a light microscope and how much of the tissue or organ is affected. Squamous severe dysplasia/carcinoma *in situ* of oropharynx, larynx, and uterine cervix may undergo squamous cell carcinoma. Bronchogenic carcinoma develops in the dysplastic bronchial mucosa in chronic cigarette smokers. Patients with dysplastic nevus may develop malignant melanoma.

Benign Tumors Undergoing Malignant Transformation

Colorectal adenomatous polyps (e.g. tubular adenoma, villous adenoma or tubulovillous adenoma), and familial adenomatous polyposis (**FAP**) are linked to **colorectal carcinoma**. Mortality can be prevented by performing colonoscopy or virtual colonoscopy for several years to eliminate adenomatous polyps in order to reduce risk of colorectal carcinoma and its consequences.

Chronic Inflammation Linked to Cancers

In chronic inflammation, chemical mediators exert pleiotropic effects in the development of cancer. Chronic inflammation in the microenvironment surrounding premalignant (precursor) lesion favors carcinogenesis, transformation of normal cell to cancer stem cell, tumor growth, invasion and metastasis to distant organ(s). Microenvironment surrounding precursor lesion is composed of immune cells, myoepithelial cells, fibroblasts, blood vessels, and extracellular matrix (ECM). Chronic inflammation can stimulate immune system that might limit carcinogenesis. Chronic inflammation and their related cancers in various anatomic sites are given in Table 6.29.

Table 6.29 Chronic inflammation and their related cancers in various anatomic sites

Premalignant Conditions or Lesions	Development of Cancer
Skin disorder linked malignancies	
Acinic (solar) keratosis	Squamous cell carcinoma of skin
Chronic irritation at sinus orifice	Squamous cell carcinoma of skin
Third degree burns	Squamous cell carcinoma of skin
Dysplastic nevus	Malignant melanoma of skin
Xeroderma pigmentosum	Squamous cell carcinoma and basal cell carcinoma of skin

Contd...

Table 6.29 Chronic inflammation and their related cancers in various anatomic sites (*Contd...*)

Premalignant Conditions or Lesions	Development of Cancer
Head and neck including oral cavity disorder linked malignancies	
Leukoplakia oral cavity	Squamous cell carcinoma of oral cavity
Proliferative verrucous leukoplakia	Squamous cell carcinoma of oral cavity
Oral submucosal fibrosis	Squamous cell carcinoma of oral cavity
Lichen planus oral cavity	Squamous cell carcinoma of oral cavity
Thyroid gland disorder linked malignancies	
Autoimmune disorders (Hashimoto's thyroiditis or Sjögren syndrome)	Mucosa-associated lymphoid tissue (MALT) lymphoma
Hashimoto's thyroiditis	Papillary thyroid carcinoma
Gastrointestinal tract disorder linked malignancies	
Leukoplakia oral cavity (caused by ingestion of tobacco products)	Squamous cell carcinoma of oral cavity
Dysplasia of oropharynx	Squamous cell carcinoma of oropharynx
High-grade dysplasia (chronic atrophic gastritis)	Gastric adenocarcinoma
Barrett's esophagus (glandular metaplasia of esophagus induced by reflux esophagitis: high-grade dysplasia)	Esophageal adenocarcinoma
Plummer-Vinson syndrome	Esophageal carcinoma
Helicobacter pylori-induced chronic atrophic gastritis	Gastric adenocarcinoma (distal-half region), mucosa-associated lymphoid tissue (MALT) lymphoma and carcinoid tumors
Inflammatory bowel disease by gut pathogens (ulcerative colitis/ Crohn's disease: adenoma—high-grade dysplasia)	Colorectal carcinoma and bile ductal adenocarcinoma
Villous and tubulovillus adenoma	Colon carcinoma
Exocrine pancreas disorder linked malignancies	
Pancreatitis (induced by chronic alcoholism)	Pancreatic adenocarcinoma
Pancreatic intraepithelial neoplasia (alcoholism and germline mutation in trypsinogen gene)	Pancreatic adenocarcinoma
Hepatobiliary system disorder linked malignancies	
Persistent regeneration and repair forming nodule in liver	Hepatocellular carcinoma
Cirrhosis	Hepatocellular carcinoma
Hepatotropic viruses (HBV, HCV) infection	Hepatocellular carcinoma
Chronic cholecystitis with cholelithiasis (bile duct bacteria and cholelithiasis)	Gallbladder carcinoma
Opisthorchis cholangitis (liver fluke)	Cholangiocarcinoma and colon carcinoma
Respiratory system disorder linked malignancies	
Squamous dysplasia of larynx and bronchi	Squamous cell carcinoma of larynx and squamous cell lung carcinoma
Chronic bronchitis induced by tobacco smoke	Lung carcinoma
Atypical ductal hyperplasia	Lung carcinoma
Asbestosis	Mesothelioma and lung carcinoma
Female genital system disorder linked malignancies	
Vaginal adenosis in daughter (diethylstilbestrol intake by pregnant mother)	Vaginal adenocarcinoma (in the daughter)
Lichen sclerosus of vulva	Vulvar squamous cell carcinoma
Severe dysplasia, i.e. cervical intraepithelial neoplasia III (CIN-III) induced by human papillomavirus (HPV 16, 18)	Cervical carcinoma
Endometrial hyperplasia (estrogen induced)	Endometrial adenocarcinoma
Endometriosis in ovary	Ovarian endometrioid carcinoma
Hydatidiform mole	Choriocarcinoma

Contd...

Table 6.29 Chronic inflammation and their related cancers in various anatomic sites (*Contd...*)

Premalignant Conditions or Lesions	Development of Cancer
Female breast disorder linked malignancies	
Atypical ductal hyperplasia of breast	Breast carcinoma
Sclerosing adenosis of breast	Breast carcinoma
Small duct papilloma of breast	Breast carcinoma
Skeletal system infection linked malignancies	
Chronic bacterial osteomyelitis discharging sinuses	Squamous cell carcinoma in regions of draining sinuses
Urinary bladder disorder linked malignancies	
Chronic cystitis (*Schistosoma haematobium* infection)	Urinary bladder carcinoma
Hematological disorder linked malignancies	
Myelodysplastic syndrome (MDS)	Acute leukemia
Monoclonal gammopathy of unknown significance (MGUS)	Multiple myeloma
Autoimmune disorders (Sjögren syndrome)	MALT lymphoma

Metaplastic and hyperplastic cells become dysplastic before progressing to cancer

- **Initiation of tumorigenesis:** In the initial phase of tumorigenesis, chemical mediators of chronic inflammation such as cytokines (e.g. IL-1, IL-6, TNF, PGSH-2), reactive oxygen species (ROS) and reactive nitrogen intermediates (RNI) derived from immune cells in precursor lesion microenvironment induce epigenetic alterations, which silence tumor suppressor genes. Self-sufficiency in growth signals and insensitivity to tumor suppressor gene signals induce genomic instability in precursor lesion parenchymal cells. Limitless replicative potential and evading apoptosis contribute to sustained proliferation and survival of premalignant cells.
  - Chronic inflammation induces production of transcription factors such as nuclear factor kappa-B (**NF-κB**), STAT-3, and hypoxia-inducible factor 1 (HIF-1) and accumulation of tumor-promoting factors modulated by chemical mediators in the microenvironment surrounding precursor lesions. NF-κB and STAT-3 interact at multiple levels leading to carcinogenesis.
  - Nuclear factor kappa-B (NF-κB) is a transcription factor, that regulates inflammation-related genes, such as inducible nitric oxide synthase (**iNOS**) and cyclooxygenase-2 (**COX-2**) leading to production of proinflammatory cytokines in the premalignant tissue environment resulting in proliferation and survival of precursor cells. Nuclear factor kappa-B (**NF-κB**) also induces production of chemokines that attract additional immune cells/inflammatory cells to sustain tissue microenvironment-associated inflammation.
- **Promotion of tumorigenesis:** During tumor promotion, immune cells secrete cytokines and chemokines, that act to stimulate proliferation of transformed cells and their survival. The '**angiogenic switch**' is essential for an adequate supply of nutrients, oxygen and survival factors to transformed cells. Angiogenesis induces alterations in the cells essential for invasion and metastasis. Angiogenesis, localized immunosuppression, and favorable microenvironment lead to proliferation and survival of transformed cells, and accumulation of additional gene mutations and epigenetic modifications. Eventually, chronic inflammation also promotes metastatic dissemination to organ(s).
- **Progression of tumorigenesis:** During tumor progression and metastasis, CSCs and immune cells of tumor microenvironment secrete cytokines and chemokines leading to an increase in cell survival, motility and invasiveness. Epithelial–mesenchymal transition (EMT) and mesenchymal–epithelial transition (MET) are crucial processes involved in tumor invasiveness and metastasis to distant organs(s).

Cervical Intraepithelial Neoplasia III (CIN-III) Linked to Cervical Carcinoma

Human papillomavirus (HPV 16 or HPV 18) is the most common viral infection of the reproductive tract transmitted through sexual contact, that plays important role in cervical carcinogenesis. Protein products (E6 and E7) of the HPV viral genome inhibit the function of two important suppressors; retinoblastoma protein (pRB) and TP53 (p53) protein.

- Cervical intraepithelial neoplasia (CIN) has a proliferating epithelium, which has three grades: (a) CIN-I (mild dysplasia), (b) CIN-II (moderate dysplasia), and (c) CIN-III (severe dysplasia/carcinoma *in situ*). Morphologic features of cervical epithelial neoplasia III (CIN-III) include abnormal pleomorphic hyperchromatic nuclei, loss of nuclear polarity and differentiation, and numerous mitotic figures indicating extensive cell proliferation. Screening of cervical intraepithelial neoplasia and its treatment can prevent development of cervical carcinoma.
- With reference to the development of cervical carcinoma, cervical intraepithelial neoplasia precursor lesions can be detected by cytologic sampling (cervical smears/scrapes or liquid-based cytology stained with Papanicolaou stain), and treated effectively, preventing progression to invasive cervical carcinoma—as a part of cervical screening programmes.
- The basis of successful cervical carcinoma prevention programmes is excision or destruction of the transforming zone of the the cervix, where almost all cervical carcinomas arise after histologic confirmation of precursor lesion.

Barrett's Esophagus Linked to Esophageal Adenocarcinoma

Development of esophageal adenocarcinoma in Barrett's esophagus occurs as a result of metaplastic change in lining epithelium of distal esophagus. Metaplasia is provoked by gastroesophageal reflux disease (GERD), i.e. chronic acid reflux from the stomach can become a precursor lesion to an ulcerated esophageal adenocarcinoma. In Barrett's esophagus, the squamous cells that normally line the residual squamous mucosa of esophagus are replaced by secretory cells that migrate from the lining of the stomach.

Leukoplakia and Erythroplakia of the Oral Mucosa Linked to Oropharyngeal Carcinoma

Leukoplakia (dysplastic white patch in mouth) and erythroplakia (dysplastic red region in the oropharynx that bleeds easily) are the two most common potentially malignant disorders of the oral mucosa in persons due to tobacco smoking and consumption of chewing tobacco. The acquired precursor lesions can also develop in badly fitting dentures that constantly rub gums or the inside of mouth or tongue. The prognosis and overall survival of patients with oral carcinoma is dependent on the early detection of precursor lesion that might identify high-risk patients before development of metastatic disease.

INTERACTIONS BETWEEN GENETIC AND ENVIRONMENTAL FACTORS LINKED TO INHERITED CANCER SYNDROMES

Mounting evidence supports the concept that inherited cancer syndromes are largely attributable to environmental factors or acquired pre-malignant diseases. Most inherited cancer syndromes are associated with a 'germline mutation' in tumor suppressor genes, which have entered the zygote via the egg or spermatozoa and is consequently present in every cell of the human body.

- Every person has two copies of tumor suppressor genes, i.e. one from each parent (father and mother). Most individuals are born with two normal copies of each gene. When a person inherits a copy of the faulty gene from the mother or father, cell contains one functional copy and one mutated copy of tumor suppressor gene, and the cell still works.
- According to 'Knudson' two-hit hypothesis, two-hit mutations within the genome are essential for a malignant phenotype to develop. Since one-hit mutation is already present in every cell from germline mutation in tumor suppressor gene since birth, and only one additional hit to the remaining functional copy (allele) of the tumor suppressor genes is necessary to develop malignant phenotype. On the contrary, two-hit mutations in two copies of tumor suppressor gene occurs within a single somatic cell after birth. Cancers have a tendency to demonstrate karyotypic abnormalities such as chromosomal translocation, deletions and gene amplifications.
- The inherited cancer syndromes fall into two categories: autosomal dominant and autosomal recessive disorders.
- Most inherited cancer syndromes follow autosomal-dominant inheritance, in which the patient's first-degree relatives (parents, children and siblings) have a 50% risk of carrying the causative gene mutation themselves. In these cases, one faulty allele of gene has to be present for an individual to have a predisposition to cancer.
- Individuals with one normal allele and one faulty allele of the gene are known as **heterozygous**. The detrimental effects of recessive cancer gene are less common within population as compared to their dominant cancer gene counterparts.
- Homozygous inheritance of these recessive cancer genes does not cause cancer directly, but rather, the loss of functional protein that gene encodes causing genomic instability, which provides an environment ideal for oncogenic mutations and predisposes the affected person to cancer.

Table 6.30 Comparison of inherited and acquired (sporadic) cancers

Characteristics	Inherited Cancers with Germline Mutations	Acquired (Sporadic) Cancers
Incidence of cancers (%)	Incidence—10%	Incidence—90%
Gene mutation	Born with germline gene mutations (first hit) in all the cells; and second hit in gene copy in hereditary tumor	During lifetime acquired gene mutation and both hits in sporadic tumor but none in the blood
Family tree inheritance pattern	Present	Absent
Human cancers	Multiple cancers in same individual	Solitary sporadic cancer
Age group affected with cancer	Younger persons	Elderly persons

Table 6.31 Inherited cancer syndromes

Inherited Cancer Syndromes	Comments
Mendelian hereditary cancer syndrome	▪ Autosomal dominant disorder (adult) ▪ Autosomal recessive disorder (children)
Defective DNA repair-linked hereditary cancer syndrome	▪ Autosomal dominant disorder ▪ Autosomal recessive disorder
Familial cancers	▪ Relative at cancer risk (breast, ovary, prostate) ▪ Transmission unclear ▪ Genetic testing

- Extensive clinical history of screening of early development of cancers is required in the management of these patients developing colorectal cancer, breast carcinoma, Wilms' tumor, or renal cell carcinoma. Molecular genetic testing is done to detect inherited cancer-causing gene in CSCs as well as tissues of family members. Comparison of inherited and acquired (sporadic) cancers is given in Table 6.30. Inherited cancer syndromes are given in Table 6.31.

Pathology Pearls: Medical Genetics

- All diseases have a genetic component, which do not require a medical genetic consultation.
- **Germline mutations** affect egg cells or spermatozoa and are transmitted via mitosis to the daughter cells.
- **Somatic mutations** occur in individual body cells, but not in germ cells, and therefore, somatic mutations are not transmitted to progeny.
- **Autosomal dominant inheritance** occurs when a single copy of a gene mutation on an autosomal chromosome is sufficient to cause disease that can be passed down through families to their 50% of children.
- **Autosomal recessive inheritance** has a risk of mutations for 25% of siblings.
- **Penetrance** is defined as the proportion of mutation carriers who harbor any manifestations of a disease.
- **Single gene mutation** in inherited cancer syndrome has high but incomplete penetration.
- **Mutation carriers** are at high risk of developing malignancies. Some mutation carriers do not develop malignancy.
- All persons with a gene mutation will not develop the same manifestations. For example, BRCA1 gene mutation in mother patient develops ovarian carcinoma and daughter develops breast carcinoma. Von Hippel-Lindau (**vHL**) syndrome has variety of systemic manifestations, but all patients will not have same organ involvement.
- **Down syndrome** child has increased risk of developing acute lymphoblastic leukemia (**ALL**) and acute myeloblastic leukemia (**AML**). **Klinefelter syndrome** patient presents with male sterility, who has increased risk for developing breast carcinoma. **Gonadal dysgenesis** with male genotype is more likely to develop tumors of gonads.

Clinical Pearls: Genomic Instability Linked to Inherited Cancer Syndromes

- Usually, multiple ≥2 family members suffer from same type of cancer or cancers are related to hereditary cancer syndromes.
- Multiple generations of related affected family members include mother, daughter and aunt.
- Family members develop cancer at younger age than sporadic cancers developing in elderly persons. Rarely, males may also develop cancer (breast cancer) related to hereditary cancer syndrome.
- Multiple primary cancers can occur in the same individual (i.e. breast and ovarian cancers in the same women).
- Physical findings that may suggest a hereditary syndrome, e.g. Peutz-Jeghers syndrome is characterized by excessive melanin pigment deposits on the skin around oral cavity, and gastrointestinal hamartomatous polyps.

Autosomal Dominant Inheritance Linked to Inherited Cancer Syndromes

Most inherited cancer syndromes follow autosomal dominant inheritance in which the patient's first-degree relatives (parents, children and siblings) have a 50% risk of carrying the causative mutations themselves. These cancers are caused by '**germline mutation**' which has entered the zygote via the egg or spermatozoa and is consequently present in every cell of the human body later. Autosomal dominant inherited cancer syndromes are given in Table 6.32.

BRCA1 and BRCA2 Gene Mutations and Associated Inherited Breast and Ovarian Cancers

BRCA1 and BRCA2 genes are highly penetrant breast cancer susceptibility genes linked to high-risk of

Table 6.32 Autosomal dominant inherited cancer syndromes

Inherited Cancer syndrome(s)	Mutated Tumor Suppressor Gene(s)	Associated Tumors
Inherited cancer syndromes involving breast and ovaries		
Breast and ovarian cancer syndrome	BRCA1 gene (17q21) and BRCA2 gene (13q12) encode DNA repair proteins and regulation of cell division	Breast carcinoma, ovarian carcinoma, prostatic carcinoma, fallopian tube carcinoma
Site-specific breast and ovarian cancer syndrome	BRCA2 gene (13q12) (encoding DNA repair proteins)	Breast carcinoma, ovarian carcinoma, prostatic carcinoma, pancreatic carcinoma
Breast carcinoma	PALB2 gene (partner and localization of BRCA1 gene)	Breast carcinoma, pancreatic carcinoma, ovarian carcinoma
Inherited cancer syndromes involving nervous system		
Hereditary retinoblastoma	RB gene (13q14.2) encodes pRB that regulate cell cycle pathway	Retinoblastoma (most often bilateral), osteosarcoma
Inherited cancer syndromes involving gastrointestinal tract		
Familial adenomatous polyposis (FAP) with >100 polyps in colon	APC gene (5q21)	Colon carcinoma, Gardner's syndrome (multiple adenomatous polyposis + desmoid tumors), Turcot syndrome (multiple polyps + primary CNS tumors (medulloblastoma, astrocytoma and ependymoma)
Hereditary nonpolyposis colorectal cancer (HNPCC)	DNA mismatch repair and cell cycle regulation genes such as MLH1 gene (3p21), MSH2 gene (2p15), MSH3 gene (5q11.12), MSH6 gene (2p16), PMS1 gene (2p32), PMS2 gene (7p22)	Colon carcinoma, endometrial carcinoma, gastric carcinoma, urothelial carcinoma
Juvenile polyposis coli (multiple polyps in colorectal region)	DPC4/SMAD4 gene, BMPR1A gene	Colorectal carcinoma, other gastrointestinal cancers
Hereditary diffuse gastric cancer	CDH1 gene encodes proteins regulating cell adhesion pathway	Gastric carcinoma
Hereditary gastrointestinal stromal tumors	KIT gene (4q12)	Gastrointestinal stromal tumors (GISTs)
Peutz-Jeghers syndrome	LKB1/STK11 gene (19p13.3)	Hamartomatous polyps in stomach and intestine, adenocarcinoma gut
Oligodontia-colorectal cancer syndrome	AXIN2 gene (17q23-24)	▪ Gastrointestinal polyposis ▪ Early-onset colorectal cancer and/or breast cancer ▪ Medulloblastoma
Inherited cancer syndromes involving skeletal system		
Hereditary multiple osteochondromas (previously called hereditary multiple exostoses)	▪ EXT1 gene (8q24.1) ▪ EXT2 gene (11p11–13) ▪ EXT3 gene (19p)	Osteochondroma can transform to osteochondrosarcoma

Contd...

Table 6.32 Autosomal dominant inherited cancer syndromes (*Contd...*)

Inherited Cancer syndrome(s)	Mutated Tumor Suppressor Gene(s)	Associated Tumors
Hyperparathyroidism jaw-tumor syndrome	HRPT2 gene also called CDC73 (1q25–q31)	Parathyroid adenoma, parathyroid carcinoma, ossifying fibroma of the maxilla and mandible, renal tumors, uterus tumors
Inherited cancer syndromes involving kidney		
Hereditary papillary renal cell carcinoma (HPRCC)	MET gene (4q12)	Hereditary papillary renal cell carcinoma
Familial Wilms' tumor	WT (11p13) regulate cell cycle and transcription	Wilms' tumor (nephroblastoma)
Von Hippel-Lindau (vHL) disease	vHL gene (3p25) encodes multifunctional protein involved in hypoxia response	Hemangioblastoma (brain, spinal cord and retina), pheochromocytoma, multiple cysts in kidney, pancreatic endocrine tumors, reproductive tract, renal cell carcinoma arising in renal cyst
WAGR, Denys-Drash syndrome, Frasier syndrome and non-syndromic hereditary Wilms' tumor	WT1 gene (11p13)	Wilms' tumor (nephroblastoma)
Hereditary leiomyomatosis and renal cell carcinoma (HLRCC)	FH (fumarate hydratase) gene (1q43)	Leiomyoma (skin, uterus), renal cell carcinoma
Inherited cancer syndromes involving endocrine system		
Hereditary paraganglioma-pheochromocytoma syndrome	SDHA gene (5p15), SDHB gene (1p35–36.1), SDHC gene (1q21–23), SDHD (11q23) gene	Multiple bilateral paragangliomas arising from neuroendocrine tissues along the spine from the base of the skull to the pelvis; pheochromocytoma (paraganglioma) confined to adrenal gland
Multiple endocrine neoplasia 1 (MEN1)	MEN1 gene (11q13) encodes 'Menin' protein	Pancreatic islet neoplasms (glucagonoma and VIPoma), pituitary adenomas (e.g. prolactinoma and growth hormone producing adenoma, parathyroid hyperplasia/adenoma)
Multiple endocrine neoplasia 2 (MEN2A, MEN2B and familial medullary thyroid carcinoma)	RET gene (10q11.2) encodes RET receptor tyrosine kinase	Medullary carcinoma of thyroid, pheochromocytoma (germline mutation), parathyroid hyperplasia
Inherited cancer syndromes involving skin		
Familial melanoma	CDKN2A gene (p16/INK4A, p14/ARF) on 8p21.3, CDK4 gene (4q12), TERT gene (5p15.32), POT1 gene (7q31.33)	Cutaneous malignant melanoma
Xeroderma pigmentosum	Xp group of genes	Squamous cell carcinoma of skin, malignant melanoma
Familial atypical multiple mole melanoma	CDNK2A (p16/INK4A, p14/ARF) on 8p21.3	Cutaneous melanoma, pancreatic carcinoma
Basal cell nevus syndrome (also called Gorlin-Goltz syndrome)	PTCH1 gene (9q22.3), PTCH2 gene (1p34.1), SUFU gene (10q24.32)	Multiple nevoid basal cell carcinomas
Inherited cancer syndromes involving multiple sites		
Li-Fraumeni syndrome	TP53 gene (17p13.1) encodes p53 protein that regulate cell cycle pathway	Breast carcinoma, osteosarcoma, soft tissue sarcoma, brain tumors, acute leukemia
Carney complex type 1	PRKARIA gene (17q24.2)	Skin myxoma, cardiac myxoma, breast myxoma, testicular neoplasms, thyroid carcinoma

Contd...

Table 6.32 Autosomal dominant inherited cancer syndromes (*Contd...*)

Inherited Cancer syndrome(s)	Mutated Tumor Suppressor Gene(s)	Associated Tumors
Cowden syndrome part of PTEN hamartomatous syndrome (features overlap with Bannayan-Riley-Ruvalcaba syndrome)	PTEN gene (10q23) encodes protein (P13K antagonist)	Colorectal carcinoma, breast carcinoma, thyroid carcinoma, squamous cell carcinoma of skin, endometrial carcinoma, renal cell carcinoma, melanoma
Werner syndrome	WRN	Soft tissue sarcoma, thyroid carcinoma, melanoma of skin, osteosarcoma
Ataxia-telangiectasia	ATM	Lymphoma, leukemia, breast carcinoma
Brooke-Spiegler syndrome (familial cylindromatosis)	CYLD gene (16q12)	Skin adnexal tumors, salivary gland benign/malignant tumors, colon polyps, colon carcinoma
Birt-Hogg-Dube syndrome	FLCN/BHD gene (17p11.2)	▪ Diverse renal tumors (chromophobe oncocytoma hybrid renal cell carcinoma) ▪ Skin fibrofolliculoma ▪ Pulmonary cysts
Inherited cancer syndromes involving skin and nervous system		
Neurofibromatosis type 1 (can be associated with Noonan syndrome and Watson syndrome)	NF1 gene (15q13) encodes neurofibromin is a negative regulator of RAS protein	Malignant peripheral nerve sheath tumor (neurofibrosarcoma), astrocytoma, malignant melanoma, neurofibroma, optic nerve glioma
Neurofibromatosis type 2	NF2 gene (22q12.2) encodes cytoskeleton protein	Bilateral vestibular schwannoma, meningioma
Tuberous sclerosis and lymphangioleiomyomatosis (LAM)	▪ TSC1 gene (9q34.13) encodes hamartin ▪ TSC2 gene (16p13.3) encodes tuberin (both TSC1 and TCS2 form mTOR-inhibiting complex, which is disrupted by mutation)	CNS cortical hamartomas, skin subungual keratomas, renal angiomyolipoma

hereditary breast cancer (female or male) and ovarian cancer (HBOC) in women in an autosomal dominant inheritance pattern including cancers of fallopian tube and peritoneum, and to a lesser extent other cancers of prostate, pancreas and melanoma.

- Mammography, breast self-examination, regular clinical examinations and annual mammography and magnetic resonance imaging (MRI) help in early detection of breast cancer.
- Annual transvaginal ultrasonography and blood CA-125 levels may be considered for ovarian cancer screening. Molecular genetic testing of BRCA1 and/or BRCA2 genes is performed to for breast cancer screening in women. Women with BRCA1 and/or BRCA2 gene mutations could consider prophylactic bilateral mastectomy or oophorectomy as a primary surgical management due to high rate of ipsilateral and contralateral breast cancer.

Phosphatase and Tensin Homolog Linked to Hamartomatous Syndrome

Patients with phosphatase and tensin homolog (**PTEN**), a tumor suppressor gene mutation (10q23) has increased risk of breast carcinoma, thyroid carcinoma, endometrial carcinoma, colorectal carcinoma, renal cell carcinoma and melanoma.

Li-Fraumeni Syndrome

Germline mutation in TP53 gene (aberrant p53) in Li-Fraumeni syndrome (LFS) is linked to diverse spectrum of childhood and adult-onset malignancies, i.e. breast carcinoma, osteosarcoma, soft tissue sarcoma, brain tumors, acute leukemia, adrenocortical carcinoma, gastrointestinal cancers, lung carcinoma, renal cell carcinoma, thyroid carcinoma, ovarian carcinoma, testicular carcinoma, prostatic carcinoma, and skin cancer.

- It is important to note that not every person with mutation in TP53 gene will necessarily develop cancer, but the risks are substantially higher than the general population.
- The lifetime of cancer risk in persons with Li-Fraumeni syndrome is ≥70% for men and ≥90% for women. Diagnosis of Li-Fraumeni syndrome depends on clinical manifestations and/or genetic testing for mutation in the TP53 gene. Molecular genetic testing of germline mutation in TP53 tumor suppressor gene is performed for early detection of cancer in these patients.

Hereditary Retinoblastoma

Hereditary retinoblastoma is an autosomal dominant disorder caused by germline mutation in RB1 tumor suppressor gene mapped on chromosome 13q14.2 with

subsequent somatic inactivation of the other allele of RB1 gene. Tumor has incomplete penetrance in 90% of cases. Patient presents with multifocal and/or bilateral retinoblastoma with an anticipation of the mean age of diagnosis within the first year of life of child. Patient presents with white pupillary reflexes (leukocoria) in one or both eyes or strabismus, glaucoma, inflammation and poor visual tracking. Molecular genetic testing of germline mutation in RB tumor suppressor gene is performed for early detection of retinoblastoma in these patients.

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) is an autosomal dominant disorder caused by germline mutation in APC tumor suppressor gene mapped on chromosome 5q21 that encodes aberrant APC protein in cells of colon. Both copies of the APC gene are mutated in 80% of sporadic colorectal tumors.

- Patients with FAP develop numerous potentially precancerous tubular adenomas (>100–1000 polyps) in the rectosigmoid region during second decade of life (50%) and by 35 years (90%) of life.
- Patients can later develop adenomatous polyps in the periampullary region of duodenum, which can progress to colorectal cancers within 10–20 years.
- About 10% have a family history of polyps and/or colorectal carcinoma at younger age. Nonspecific symptoms such as unexplained rectal bleeding (hematochezia), diarrhea and abdominal pain in young patients may be suggestive of familial adenomatous polyposis.
- Preventive surgery is the standard treatment of FAP. Until the colon is surgically excised, these noncancerous polyps will become malignant. Surgical specimen of familial adenomatous polyposis coli is shown in Fig. 6.60.

Fig. 6.60: Surgical specimen of FAP. FAP coli is an autosomal dominant disorder in which numerous adenomatous polyps (>100–1000 in number) form mainly in the epithelium of the large intestine.

Attenuated Familial Adenomatous Polyposis

Attenuated familial adenomatous polyposis (AFAP) is an autosomal dominant disorder due to germline mutation in APC tumor suppressor gene located on chromosome 5q21 that encodes aberrant protein in every cell in their colon. Patient develops multiple adenomatous polyposis (<100 polyps) in colon, upper gastrointestinal tract (fundus, duodenum), colorectal carcinoma (70% risk), hepatoblastoma, gastric carcinoma and breast carcinoma.

Polymerase Proofreading-associated Polyposis

Polymerase proofreading-associated polyposis (PRAP) is an autosomal dominant disorder caused due to germline mutations in POLE (12q24.3) and POLD1 (19q13.33) genes, that encode aberrant proteins leading to mismatch DNA repair. Germline mutations in POLE and POLD1 genes are linked to multiple adenomatous polyposis in colon (number of polyps unknown), colorectal carcinoma, ovarian carcinoma, endometrial carcinoma, pancreatic carcinoma and brain malignancies.

Hereditary Nonpolyposis Colorectal Cancer

Hereditary nonpolyposis colorectal cancer (HNPCC), also known as Lynch syndrome (described by Dr. Henry Lynch) is an autosomal dominant disorder, that is associated with high-risk HNPCC in the region proximal to splenic flexure in 70–85% of cases, which is most often preceded by serrated adenomas (pedunculated with broad-based polypoid pattern of growth), rather than tubular adenomas as seen in the traditional–APC carcinoma pathway within three years due to germline mutations versus 8–10 years for sporadic adenoma-carcinoma sequence.

- **Molecular genetic testing** in hereditary nonpolyposis colorectal cancer reveals mutation in one of the mismatch repair genes such as MLH1 gene (3p21), MSH2 gene (2p15), MSH3 gene (5q11–12), MSH6 gene (2p16), PMS1 gene (2p32) and PMS2 gene (7p22). Immunohistochemical analysis can help to pinpoint the affected mismatch repair gene.
- Hereditary nonpolyposis colorectal cancer (HNPCC) associated additional malignancies include colon carcinoma (most common), endometrial carcinoma (40–60%), ovarian carcinoma (12–15%), gastric carcinoma, pancreatic carcinoma, hepatobiliary carcinoma, urothelial carcinoma of renal pelvis and ureter, brain tumors and Muir-Torre syndrome (e.g. sebaceous adenomas, carcinoma and multiple keratoacanthoma) and visceral malignancy due to alterations in microsatellite nucleotide sequences.
- Hereditary nonpolyposis colorectal cancer is treated by surgical interventions such as subtotal colectomy

Table 6.33 Cardinal features of hereditary nonpolyposis colon carcinoma (HNPCC) are also called Lynch syndrome

Parameters	Features
Mode of inheritance	Autosomal dominant inheritance
Colorectal carcinoma (mean age)	45 years
Progression period from adenoma to colorectal carcinoma	About three years due to germline mutations (versus 8–10 years for sporadic adenoma-carcinoma)
Colorectal carcinoma site	70–85% proximal to splenic flexure
Risk of development of additional colorectal carcinoma since subtotal colectomy	25–30% develop colorectal carcinoma within 10 years since subtotal colectomy
Development of additional extracolonic malignant tumors	Endometrial carcinoma (40–60%), ovarian carcinoma (12–15%), gastric carcinoma, pancreatic carcinoma, hepatobiliary carcinoma, renal pelvis and ureter carcinoma, brain tumors (Turcot syndrome), skin tumors, i.e. Muir-Torre syndrome (e.g. sebaceous adenomas, carcinoma and multiple keratoacanthoma)
Histologic features	Poorly-differentiated colorectal carcinoma with excess of mucinous and signet ring cell type carcinoma; excess of tumor infiltrating lymphocytes
Conformation of diagnosis	Identification of germline mutation in one of the mismatch repair genes, e.g. (MSH2 (2p15), MLH1 (3p21), PMS1 (2p32) and PMS2 (7p22)

with ileorectal anastomosis or total colectomy with ileoanal pull-through (pouch procedure). Cardinal features of hereditary nonpolyposis colon carcinoma (HNPCC), also called Lynch syndrome, are given in Table 6.33.

Juvenile Polyposis Syndrome

Juvenile polyposis syndrome (JPS) is an autosomal dominant disorder due to germline mutations in two different genes (SMAD4 and BMPR1A), characterized by multiple benign polyps on lining epithelium of gastrointestinal tract anywhere from stomach to the rectum before 20 years of age even in multiple family members of same family. There is risk of developing gastrointestinal carcinomas. Patient presents with gastrointestinal bleeding, abdominal pain and diarrhea. About 15% of patients may have abnormalities such as intestinal malrotation, cardiac or brain abnormalities, cleft palate, polydactyly and urogenital abnormalities.

Hereditary Diffuse Gastric Carcinoma

Hereditary diffuse gastric carcinoma (HDGC) is an autosomal dominant disorder caused due to germline mutation in one copy (allele) of CHD1 gene, that shows a diffuse gastric carcinoma without a solid growth.

- Patient presents with abdominal pain in gastric region, nausea, vomiting, dysphagia, anorexia and weight loss as well as symptoms related to organs involved (e.g. hepatomegaly, pathological bone fractures, ascites).
- Prophylactic gastrectomy is performed to prevent developing and spreading of HDGC. When surgery is not possible, chemotherapy is administered to treat in such HDGC cases.

Oligodontia-Colorectal Cancer Syndrome

Oligodontia-colorectal cancer syndrome is an autosomal dominant disorder due to nonsense germline mutation in AXIN2 gene located on chromosome 17q23–24, that encodes aberrant AXIN2 related protein.

- Patient presents with congenital severe permanent tooth agenesis of six or more permanent teeth (excluding the third molars), and risk of developing gastrointestinal polyposis to early-onset colorectal cancer and/or breast cancer and medulloblastoma.
- There may be associated ectodermal dysplasia (sparse hair and/or eyebrows). Molecular genetic testing of family members is done to detect carrier before the age of 16–18 years.

Brooke-Spiegler Syndrome (Familial Cylindromatosis)

Birt-Hogg-Dubé (BHD) syndrome is an autosomal dominant disorder due to germline mutation in FLCN/BHD tumor suppressor gene located on chromosome 17p11.2, that encodes aberrant '**folliculin**' **protein**. Patient presents with multiple benign skin tumors over face, neck and upper chest, associated with increased risk of benign or malignant tumors of kidney, and cysts in the lungs that cause pneumothorax and lung collapse.

Hereditary Leiomyomatosis and Renal Cell Carcinoma

Hereditary leiomyomatosis and renal cell carcinoma (HLRCC) is an autosomal dominant disorder caused due to germline mutation in fumarate hydratase (FH) gene mapped on chromosome 1q43 encodes an aberrant FH protein that inactivates enzyme leading to alteration of tricarboxylic acid (TCA/Krebs) cycle.

- Patient develops cutaneous (e.g. on trunk, arms, legs and occasionally over face) and uterine leiomyomas and associated with increased risk of papillary renal cell carcinoma that presents with triad (low back pain, hematuria and palpable flank mass) and manifestations related to paraneoplastic syndrome and disseminated disease.
- Molecular genetic testing of family members is done to detect carrier from the age of 16–18 years of age.

Multiple Endocrine Neoplasia Type 2

Multiple endocrine neoplasia 2 (MEN 2) is an autosomal dominant disorder due to germline mutation in RET tumor suppressor gene located on 10q11.2, that encodes aberrant 'RET receptor tyrosine kinase'.

- There are two types of MEN2 syndromes: (a) MEN2A (Sipple syndrome) is characterized by medullary thyroid carcinoma, pheochromocytoma or parathyroid adenoma/hyperplasia (inducing primary hyperparathyroidism, and (b) MEN2B (Gorlin syndrome) is characterized by familial medullary thyroid carcinoma.
- Prophylactic thyroidectomy should be performed in patients with germline mutation in RET proto-oncogene. Medullary thyroid carcinoma is treated by surgical excision and tyrosine kinase inhibitor therapy. Annual analysis of serum calcitonin concentration is done to detect residual or recurrent medullary thyroid carcinoma after thyroidectomy.

Neurofibromatosis Type 1

Neurofibromatosis type 1 (NF1) is an autosomal dominant genetic disorder caused due to germline mutation in NF1 tumor suppressor gene located on chromosome 15q13, that encodes an aberrant 'neurofibromin' protein, which is normally a negative regulator of RAS protein.

- Patient presents with skin pigmentation (multiple café-au-lait spots), and growth of tumors along nerves in the skin (neurofibromas), brain (optic neuroma affecting vision) and nerves near the spinal cord or along nerves elsewhere in the body in adults.
- In some patients, neurofibroma can undergo transformation to malignant peripheral nerve sheath tumor. NF1 can be associated with other autosomal dominant disorders such as Noonan syndrome and Watson syndrome.
- Molecular genetic testing is performed to detect mutations in NF1 gene prior to development of clinical manifestations.

Neurofibromatosis Type 2

Neurofibromatosis type 2 (NF2) is an autosomal dominant disorder caused due to **germline mutation** in **NF2 tumor suppressor gene** mapped on chromosome 22q12.2, that encodes aberrant 'merlin' (also known as schwannomin) cytoskeleton protein.

- Patient develops benign bilateral tumors of auditory nerves (vestibular schwannomas/acoustic neuroma) and meningiomas (brain or spinal cord) and/or ependymomas.
- Molecular genetic testing can be done to analyze NF2 gene mutation to establish diagnosis. Surgery is the primary treatment for most peripheral nerve tumors.

Von Hippel-Lindau Disease

Von Hippel-Lindau (vHL) disease is an autosomal dominant disorder caused due to **germline mutation** in **vHL tumor suppressor gene** located on chromosome 3p25, that encodes aberrant vHL protein.

- Clinical hallmarks of vHL disease are development of tumor and/or cysts in multiple organs (e.g. brain, spinal cord, eyes, kidneys, pancreas, adrenal glands, inner ears, reproductive tract, liver and lung).
- Hemangioblastoma occurs in brain (cerebellum), spinal cord and retina that have subsequent potential for malignant change.
- Pheochromocytoma results in high blood pressure. Pheochromocytoma should be diagnosed by biochemical catecholamine analysis and CT/MRI scanning of abdomen.

Hereditary Papillary Renal Cell Carcinoma

Hereditary papillary renal cell carcinoma (HPRCC) is an autosomal dominant disorder due to germline mutation in MET gene mapped on chromosome 4q12, that encodes aberrant receptor for hepatocyte growth factor (HGF) protein affecting many cell types. Diagnosis of HPRCC is suspected on the basis of a family history of papillary renal cell carcinomas and can be confirmed by molecular genetic testing to detect germline mutation in the MET exons 15–21, which encodes aberrant cytoplasmic domain of the receptor.

Nevoid Basal Cell Carcinoma Syndrome (Gorlin-Goltz Syndrome)

Nevoid basal cell carcinoma syndrome (also called Gorlin-Goltz syndrome) is an autosomal dominant disorder due to germline mutations in **PTCH1** (9q22.3), **PTCH2** (1p34.1) and **SUFU** (10q24.32) tumor suppressor genes, which encode aberrant patched-receptor proteins. Patient can develop benign tumors (e.g. ovarian fibroma, myocardial fibroma, medulloblastoma, meningioma, rhabdomyoma and lymphomesenteric cysts), ocular defects (colobomas, cataracts, glaucoma) and cleft lip and palate.

Familial Paraganglioma-Pheochromocytoma Syndrome

Familial paraganglioma-pheochromocytoma syndrome is an autosomal dominant disorder due to germline mutation genes such as **SDHA gene** (5p15), **SDHB** (1p35–36.1), **SDHC** (1q21–23), and **SDHD** (11q23), which encode aberrant succinate dehydrogenase (**SDH**) protein complex, which links the tricarboxylic acid cycle with the electron transport chain.

- Familial paraganglioma-pheochromocytoma syndrome is characterized by the presence of tumors: (a) paraganglioma (sympathetic/parasympathetic) arising from neuroendocrine tissues symmetrically distributed along the spine from the base of the skull to the pelvis, and (b) pheochromocytoma.
- Molecular genetic testing is done to establish diagnosis by detecting mutations in SDHA, SDHB, SDHD, SDHAF2 and MAX genes.

WAGR Syndrome, Denys-Drash Syndrome, and Nonsyndromic Hereditary Wilms' Tumor

WAGR syndrome, Denys-Drash syndrome, and non-syndromic hereditary Wilms' tumor are autosomal dominant disorders caused due to germline mutations in WT1 gene located on chromosome 11p13, that encodes an aberrant zinc finger-containing protein.

- WAGR syndrome (also called as WAGR complex or Wilms tumor-aniridia syndrome) is occurs due to germline mutation in WT1 tumor suppressor gene along with PAX6 gene and characterized by development of Wilms' tumor, aniridia (absence of iris due to PXA6 gene mutation) and genitourinary anomalies. Most cases of WAGR syndrome are not inherited.
- Denys-Drash syndrome (DDS) consists of a triad of intersex, Wilms' tumor and nephrotic syndrome (diffuse mesangial sclerosis) associated with progressive renal failure.
- Nonsyndromic hereditary Wilms' tumor can be inherited (10%) or sporadic (90%) forms in children caused due to mutations in WT1 tumor suppressor gene mapped on chromosome 11p13. Nearly all cases of Wilms' tumor are diagnosed before the age of 10 years with two-thirds being found before age of 5 years.

Familial Melanoma

Familial melanoma is an autosomal dominant disorder caused due to germline mutation in CDK4 gene (4q12), CDKN2A gene (8p21.3), TERT gene (5p15.32) and POT1 gene (7q31.33) encode aberrant proteins linked to familial malignant melanoma. High and intermediate penetrance genes involved in familial melanoma susceptibility are given in Table 6.34.

Familial Atypical Multiple Mole Melanoma Syndrome

Familial atypical multiple mole melanoma syndrome (FAMMM syndrome) is an autosomal dominant disorder caused due to germline mutations in CDNK2A gene located on chromosome 8p21.3, that encodes aberrant $p16^{INK4A}$ and $p14^{ARF}$ proteins. Patient presents with multiple melanocytic nevi (often >50) with atypical appearance (different shades of tan, brown, black or red on back, chest, buttocks, breasts and scalp). There is a family history of melanoma in 80% of patients. Early diagnosis and treatment of melanoma is associated with better prognosis.

Table 6.34 High and intermediate penetrance genes involved in familial melanoma susceptibility

Gene	Encoded Protein	Function	Gene Mutation Prevalence in Families
High penetrance genes linked to familial melanoma susceptibility			
CDKN2A (cyclin-dependent kinase 2A) gene (8p21.3)	▪ p16 INK4A protein ▪ p14ARF protein	▪ Cell cycle regulator ▪ Cell cycle regulator	▪ 20–40% ▪ 1%
CDK4 (cyclin-dependent kinase 4) gene (4q12)	CDK protein	Cell cycle regulator	17%
TERT (telomere reverse transcriptase) gene (5p15.32)	Catalytic subunit of telomere protein	Telomere elongation	2%
POT1 (protection of telomere) gene (7q31.33)	POT1 protein	Telomere maintenance	14%
Intermediate penetrance genes linked to familial melanoma susceptibility			
MC1R (melanocortin 1 receptor) gene (16q24.3)	MC1R protein	Melanocyte synthesis and their proliferation	Not applicable
MITF (microphthalmia-associated transcription factor) gene (3p12–p14.1)	MITF protein	Melanocyte development and differentiation	Not applicable

Autosomal Recessive Inheritance Linked to Inherited Cancer Syndromes

Detrimental effects of autosomal recessive cancer gene are observed less often within the population as compared to their autosomal dominant counterparts. In autosomal recessive inheritance, two copies of the recessive allele of gene must be inherited, one from each parent (mother and father), in order for the mutation to have effect on individual's phenotype. Homozygous inheritance of these recessive cancer genes does not cause human cancer directly. However, loss of functional protein results in genomic instability in autosomal recessive homozygous inheritance. This genomic instability fosters an ideal environment for oncogenic mutations and predisposes the affected individual to cancer. Autosomal recessive inheritance linked to inherited cancer syndromes are given in Table 6.35.

NTHL1-Associated Polyposis Disorder

NTHL1-associated polyposis (NAP) is an autosomal recessive disorder caused due to **germline mutation NTHL1 gene** in mapped on chromosome on 16p13.3, that encodes aberrant DNA N-glycosylase of the endonuclease III family. DNA N-glycosylase catalyzes the first step in base excision repair (BER) of oxidative DNA damage. Patient presents with attenuated adenomatous polyposis and colorectal carcinoma(s) and extracolonic malignancies (e.g. endometrial carcinoma, duodenal carcinoma, breast carcinoma and pancreatic carcinoma).

Ataxia-Telangiectasia

Ataxia-telangiectasia is an autosomal recessive disorder caused due to **germline mutation** in **ATM gene** mapped on chromosome 11q22.3, that encodes aberrant ATM

Table 6.35 Autosomal recessive inheritance linked to inherited cancer syndromes

Inherited Cancer Syndrome	Gene and Locus	Associated Tumors
Attenuated polyposis known as MUTYH-associated polyposis (MAP)	Base pair excision repair (BER) MUTYH gene (1p34.1)	▪ Multiple adenomatous polyposis in colon ▪ Colon carcinoma
NTHL1-associated polyposis (NAP)	NTHL1 gene (16p13.3)	▪ Multiple adenomatous polyposis in colon ▪ Colorectal carcinoma
Polymerase proofreading-associated polyposis (PRAP)	▪ POLE (12q24.3) ▪ POLD1 (19q13.33)	▪ Multiple adenomatous polyposis in colon ▪ Colorectal carcinoma ▪ Ovarian carcinoma ▪ Endometrial carcinoma ▪ Pancreatic carcinoma ▪ Brain malignancies
Ataxia-telangiectasia	ATM gene (11q22.3)	▪ Leukemia ▪ Non-Hodgkin's lymphoma
Fanconi anemia	Fanconi anemia DNA repair genes	▪ Acute myelogenous leukemia ▪ Liver tumors ▪ Squamous cell carcinoma (oropharyngeal and anogenital regions)
Bloom syndrome	BLM gene (15q26)	▪ Leukemia ▪ Non-Hodgkin's lymphoma ▪ Gastrointestinal stromal tumors
Rothmund-Thompson syndrome	RECQLA gene (8q24.3)	Osteosarcoma (early onset)
Werner's syndrome	WRN gene (8p12)	▪ Meningioma ▪ Soft tissue sarcoma
Nijmegen breakage syndrome	NBSI gene (8q21)	▪ Leukemia ▪ Non-Hodgkin's lymphoma
Familial medulloblastoma	SUFU gene (10q24.32)	Medulloblastoma
Xeroderma pigmentosum	Xeroderma pigmentosum genes	▪ Squamous cell carcinoma of skin ▪ Basal cell carcinoma of skin

protein that is unable to repair damaged DNA and thus genomic instability.

- Patient presents with progressive cerebellar degeneration (ataxia, abnormal eye movements and postural instability), telangiectasia on ocular region and skin, immunodeficiency (sinopulmonary infection), radiation sensitivity and cancer susceptibility (e.g. leukemia and non-Hodgkin's lymphoma, urinary bladder carcinoma, breast carcinoma, melanoma, lung carcinoma and ovarian carcinoma).
- Diagnosis of ataxia-telangiectasia is made based on a detailed patient history, a thorough clinical evaluation, identification of clinical manifestations and a wide variety of specialized tests include blood tests, magnetic resonance imaging and karyotyping.

Fanconi Anemia

Fanconi anemia (FA) is an autosomal recessive disorder caused due to germline mutations in Fanconi anemia DNA repair genes that encodes aberrant proteins. Genomic instability is linked to bone marrow failure and Fanconi anemia-associated with acute myelogenous leukemia (AML), hepatocellular malignancy, and squamous cell carcinoma in oropharyngeal and anogenital regions. Fanconi anemia is most often diagnosed in children between 3 and 14 years of age.

Bloom Syndrome (Congenital Telangiectasia Erythema)

Bloom syndrome is an autosomal recessive disorder caused due to germline mutation in BLM gene mapped on chromosome 15q26, that encodes aberrant one of the five RECQ DNA helicases.

- Bloom syndrome is seen in persons of multiple ethnic backgrounds but highest prevalence within Ashkenazi Jewish population.
- Patient presents with short stature, prominent nose and ears, ultraviolet radiation sensitivity and occasionally mental retardation. Patient is at risk of development of leukemia, non-Hodgkin's lymphoma and gastrointestinal tumors.

Rothmund-Thomson Syndrome

Rothmund-Thomson syndrome is an autosomal recessive disorder due to **germline mutation** in **RECQLA gene** mapped on chromosome 8q24.3, that encodes aberrant RECQLA protein. Patient presents with poikiloderma, juvenile cataracts, growth retardation, chronic diarrhea, skeletal dysplasia, sparse scalp hair, hypogonadism (25%) and increased susceptibility to early onset of osteosarcoma and skin cancers (basal cell carcinoma of skin and squamous cell carcinoma of skin).

Nijmegen Breakage Syndrome

Nijmegen breakage syndrome (NBS) is an autosomal recessive disorder caused due to germline mutation in NBSI gene mapped on chromosome 8q21, that encodes aberrant NBS1 (nibrin) protein leading to chromosomal instability. Patient presents with radiosensitivity, cancer predisposition (e.g. leukemia and non-Hodgkin's lymphoma), progressive microcephaly (bird-like facial appearance), growth retardation and immunodeficiency.

Werner's Syndrome

Werner's syndrome is an autosomal recessive disorder due to germline mutations in WRN gene located on chromosome 8p12, that encodes aberrant Werner protein. Normal Werner (WRN) protein is involved in repairing damaged DNA. Patient presents with premature aging, graying and thinning of hair, wrinkling and ulceration of skin, atherosclerosis, osteoporosis and cataracts. In addition, patient exhibits an increased incidence of diabetes mellitus type 2, hypertension and susceptibility to development of benign and malignant neoplasms (meningiomas and soft tissue sarcoma).

Familial Medulloblastoma

Familial medulloblastoma is an autosomal recessive disorder caused due to germline mutation in SUFU gene located on chromosome 10q24.32, that encodes aberrant protein domain suppressor of fused protein (SUFU). Clinical neurologic manifestations of familial cerebral medulloblastoma depend on the extent of tumor.

Xeroderma Pigmentosum

Xeroderma pigmentosum is an autosomal recessive disorder due to germline mutations in xeroderma pigmentosum genes encode aberrant proteins. Patient presents with photosensitivity, hyperpigmentation of skin, premature skin aging and increased risk of malignancies (e.g. squamous cell carcinoma and basal cell carcinoma) due to ultraviolet radiation induced defect in DNA repair.

X-linked Inheritance Disorders Linked to Inherited Cancer Syndromes

X-linked recessive inheritance refers to genetic disorders passed from parent to the child associated with mutations in genes on the X chromosome.

- As males have only one chromosome, mutation in the copy of the gene on the single X chromosome causes the X-linked recessive genetic disorders. Females, who have two X chromosomes must have a mutation

on both X chromosomes in order to be affected with the genetic disorder.

- If only the father or the mother has the mutated X-linked genes, the daughters are usually not affected and are called '**carriers**' because one of their X chromosomes has the mutation but the other X chromosome is normal. Sons will be affected if they inherit the mutated X-linked gene from their mother. Father cannot pass X-linked genetic orders to their sons.
- Loss of X-linked gene expression has been observed in 20% of cancers, including breast carcinoma and ovarian carcinoma. Loss of heterozygosity (LOH) at the X chromosome is also associated with sporadic colorectal carcinoma, renal cell carcinoma, melanoma and neuroendocrine tumor.
- Recent whole genome-wide scan analysis has provided substantial information regarding single-hit inactivation of X-linked cancer-related tumor suppressor gene involved in development of cancers in breast, colorectal region and skin.
  - Single-hit inactivation of X-linked cancer-related tumor suppressor genes (FLNA, PFC, PRPS1, TAF, KLH4, MAGEE1) have been observed in breast carcinoma.
  - Single-hit inactivation of X-linked cancer-related tumor suppressor genes (FLNA, TBX22, KIAA2022, IRS4, PCDH11X, GPR112 and F8) has been found in colorectal carcinoma.
  - Single-hit inactivation of tumor suppressor genes (ZNF280C, PNMA3, IL3RA, NHS and FGD1) has been observed in melanoma.

Simpson-Golabi-Behmel Syndrome

Simpson-Golabi-Behmel syndrome is an X-linked recessive disorder due to germline mutations in GPC3 gene mapped on chromosome Xq26, that encodes aberrant glypican protein. There is increased risk for development of benign and malignant tumors (e.g. Wilms' tumor, neuroblastoma and hepatoblastoma) in 10% of cases.

Unknown Mode(s) of Inheritance Inherited Cancer Syndromes

Unknown mode(s) of inheritance inherited cancer syndromes include familial carcinoid syndrome, familial Hodgkin's disease, familial pancreatic carcinoma and familial testicular germ cell tumors.

Familial Carcinoid Syndrome

Carcinoid syndromes (neuroendocrine tumors) are capable of secreting vasoactive substances such as serotonin, histamine and bradykinin. Patients harbor sporadic slow-growing carcinoids (neuroendocrine tumors) in gastrointestinal tract (98%) and familial (1–2%). A newly discovered condition called familial small intestinal neuroendocrine tumor occurs due to mutation of IPMK gene.

Familial Hodgkin's Disease

Genetic susceptibility plays a role in the pathogenesis of familial Hodgkin's disease. Approximately 1% of patients with Hodgkin's disease have a family history of the disease. Siblings of an affected person are at higher risk for development of familial Hodgkin's disease in younger age.

Familial Pancreatic Carcinoma

Familial pancreatic carcinoma (FPC) is defined by the presence of pancreatic cancer in two or more first-degree relatives in younger age group. Tobacco smoking represents a significant risk factor for familial pancreatic carcinoma arising from the exocrine pancreas (95%) especially in head of pancreas [arise from the exocrine (95%)] or endocrine portions of the pancreas.

- Patient presents with pain in the upper abdomen, that radiates to the back, loss of appetite, significant weight loss and painless jaundice due to bile duct obstruction. As the clinical course is silent, and FPC goes undetected until advanced stages of the disease.
- In more than 80% of cases, familial pancreatic carcinoma is either locally advanced or disseminated disease at the time of diagnosis that can metastasize to regional lymph nodes and via hematogenous route to distant organs (liver, peritoneum and lungs).

Familial Testicular Germ Cell Tumors

Familial testicular germ cell tumors (FTGCT) occur in more than one blood relative of the same family. Testicular germ cells arise from the primordial germ cells that are blocked in maturation. This process is thought to be initiated during fetal development and can be caused by both genetic and environmental factors. A noninvasive stage (intratubular germ cell neoplasia unclassified or carcinoma *in situ*) precedes progression to testicular germ cell tumor. There is increased risk of testicular germ cell tumors in the setting of cryptorchidism, infertility and microlithiasis.

Familial Cancers in Various Organs

Certain common cancers of breast, ovary, prostate and colon may occur in more than one member of the same family, but are not thought to be hereditary. Multiple family members may be diagnosed with the same cancer, but usually the cancer occurs at later ages and

does not follow the same patterns that are observed in hereditary cancers.

- Familial cancers are not caused by mutation in specific gene. Instead, family cancers are caused by combination of mutations in several genes and other environmental factors such as diet and exercise. Family members may need earlier frequent cancer screening.
- Family cancers should be suspected on following criteria: clustering of cancer in one family, onset of adult type of carcinoma at an early age, multiple independent carcinomas arising in individual, bilateral cancer in paired organs, presence of a rare cancer and presence of the same or associated cancers that comprise a syndrome.

PREFERENTIAL ROUTES OF METASTASIS OF TUMORS

Preferential routes of metastasis vary with specific neoplasms. Carcinomas most often tend to metastasize via lymphatic route, while sarcomas tend to metastasize via hematogenous route to distant organ(s). Notable exceptions include renal cell carcinoma and hepatocellular carcinoma, which most often metastasize via hematogenous route to distant organ(s).

- Malignant epithelial tumors (carcinomas) most commonly metastasize to via lymphatic route to draining lymph nodes, and later via hematogenous route to distant organs (e.g. lungs, liver, bones, brain and adrenal glands). Malignant mesenchymal tumors (sarcomas) metastasize via hematogenous route to lungs, which rarely metastasize to skeletal muscles and spleen.
- Metastasize to liver often arises in patients with colon carcinoma. The portal vein drains blood from the colon into the liver, which provides a route of metastasis of colon carcinoma directly to the liver. Breast carcinoma often metastasizes to brain. Ovarian carcinoma most often involves peritoneum. Rarely metastasizing tumors include basal cell carcinoma of skin and gliomas.
- Tumor progression is characterized by the accumulation of successive molecular/cytogenetic alterations. For example, progression of changes in normal colonic epithelium to colon carcinoma to dissemination occur with parallel successive molecular/cytogenetic alterations in APC, K-RAS, DCC, TP53 and other genes. Individual cancer stem cells within a malignant tumor may possess varying metastatic potential. Malignant tumors disseminate by one of five pathways. Local invasion and metastasis of various cancers via various routes are shown in Fig. 6.61. Routes of metastasis of primary lung carcinoma are shown in Fig. 6.62.

LOCAL INVASION: FIRST STEP IN METASTASIS

Local invasion of malignant tumor is the first step in metastasis, which follows line of least resistance. The proliferating CSCs break through normal barrier, invade, permeate surrounding tissues, and exert mechanical pressure on the surrounding tissues. Lytic enzymes (collagenases) secreted by CSCs invade basement membrane. CSCs lack cell adhesion molecules, e.g. E-cadherin, hence become less adhesive, thus via increased amoeboid movements invade vasculature and metastasize to distant organs.

- Cancer stem cells (CSCs) may stimulate the production of new collagen fibers which are sometimes converted into excess dense fibrous tissue that contracts and fixes the growth into surrounding structures. Breast carcinoma causes nipple retraction and fixation of tumor to underlying skeletal muscle of involved breast.
- Cancer stem cells (CSCs) invade, compress nerve and cause loss-of-function. Brain astrocytoma spreads by direct extension into surrounding tissue.
- Lung carcinoma invades surrounding lung parenchyma via local spread and produces bronchopleural fistula. Cervical carcinoma invades surrounding tissues and produces vesicovaginal fistula. Pancreatic carcinoma invades celiac plexus resulting in severe pain. Ovarian carcinoma may involve peritoneum.

LYMPHATIC ROUTE OF METASTASIS

Lymphatic route is the commonest mechanism of dissemination of carcinomas and melanomas, but rarely of sarcomas. Cancer stem cells (CSCs) easily invade lymphatic channels of tissue spaces.

- Group of CSCs detach to form clusters, which are carried in the form of tumor emboli and trapped in the first draining lymph node, it encounters. Tumor emboli appear first in the subcapsular sinus, penetrate its efferent channels, proliferate, metastasize and destroy chain of lymph node structure. Invaded lymph nodes become enlarged, firm and white. Localized immune reaction to the CSCs may limit their further spread.
- Mesenteric lymph node invaded by CSCs of abdominal malignancies may invade cisterna chyli and eventually reach the venous blood circulation via

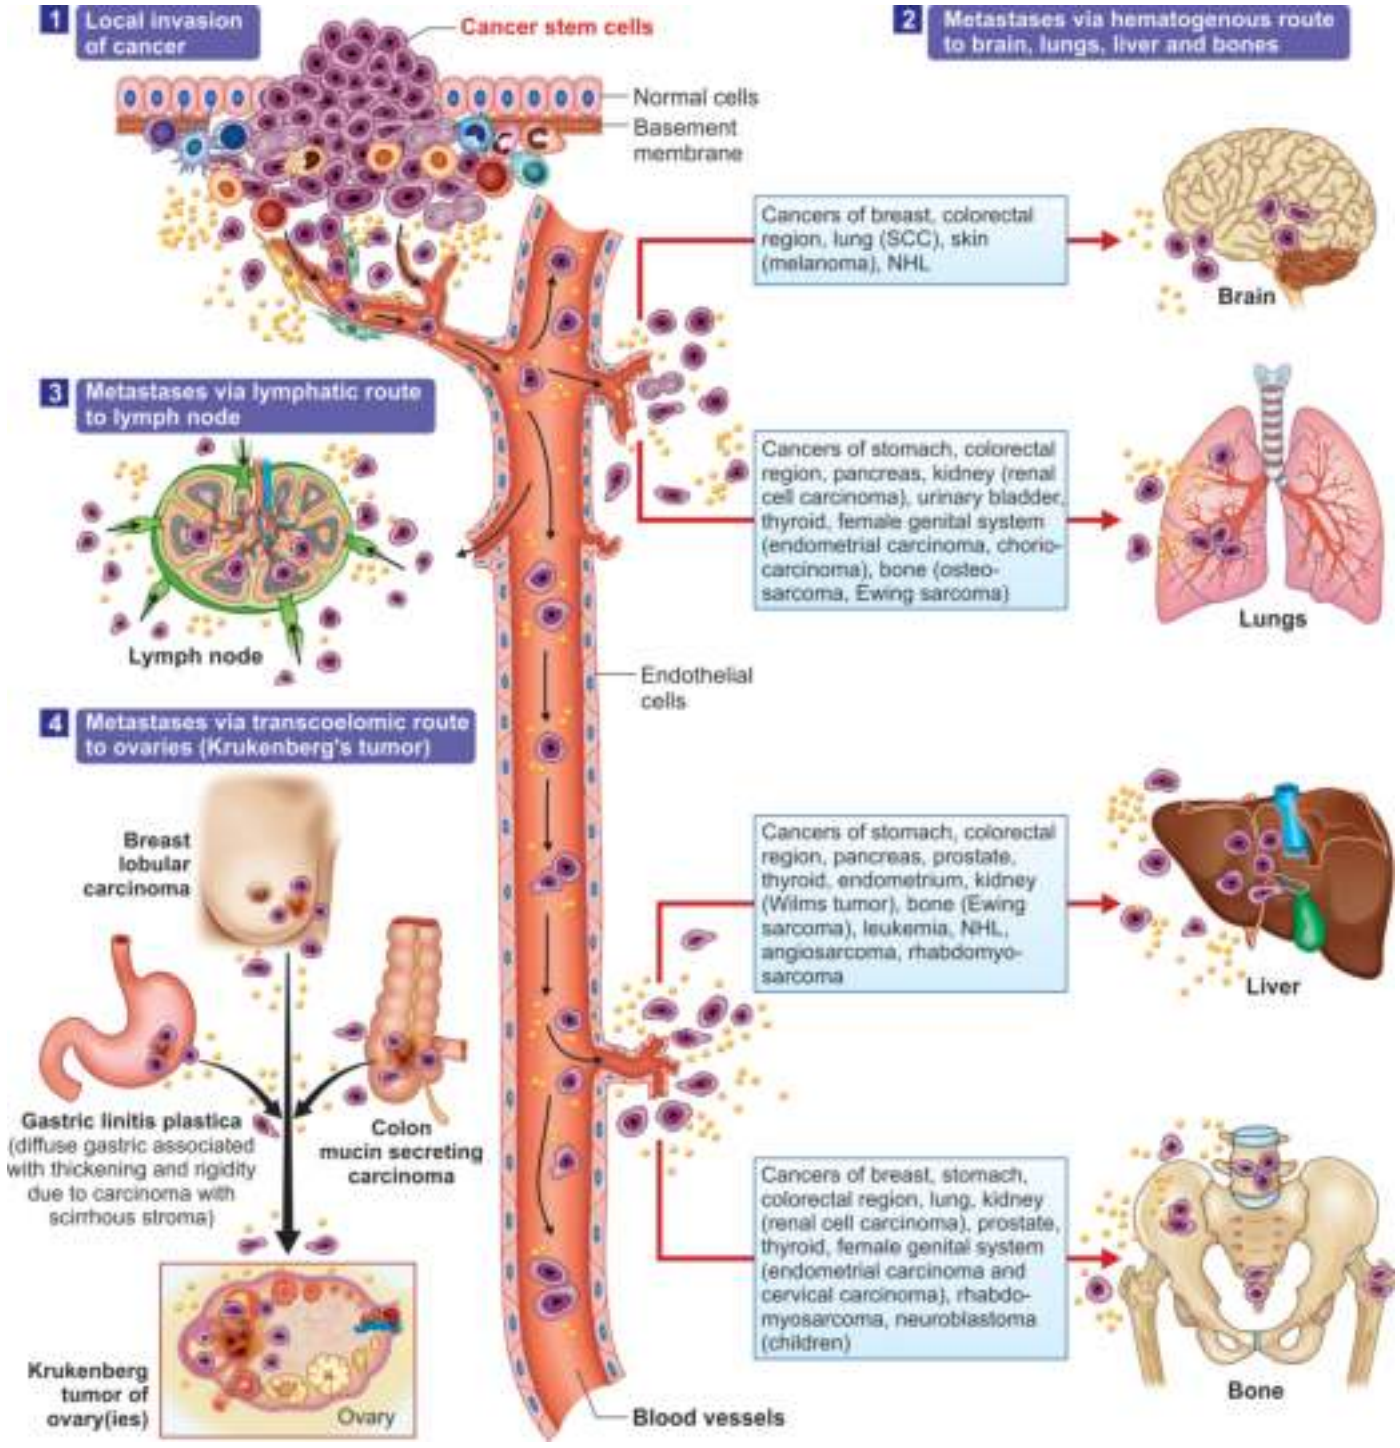

Fig. 6.61: Local invasion and metastasis of various cancers via various routes. Metastatic cascade represents a multistep process which includes CSC invasion, entry into the vasculature followed by the exit of cancer stem cells from the circulation and colonization in the distant organs.

thoracic duct. CSCs can enter the blood circulation from the lymphatic circulation through plentiful connections between the lymphatic and venous systems.

- Breast carcinoma in the outer quadrant involves axillary lymph nodes, whereas breast carcinoma present in the inner quadrant metastasizes to internal mammary lymph nodes. The first lymph node involved in a regional lymphatic drainage is called 'sentinel lymph node'. Histologic examination of sentinel lymph node is performed to select the patients, who require 'extensive lymph node dissection' particularly in breast carcinoma, colon carcinoma and melanoma. Breast carcinoma metastasis in

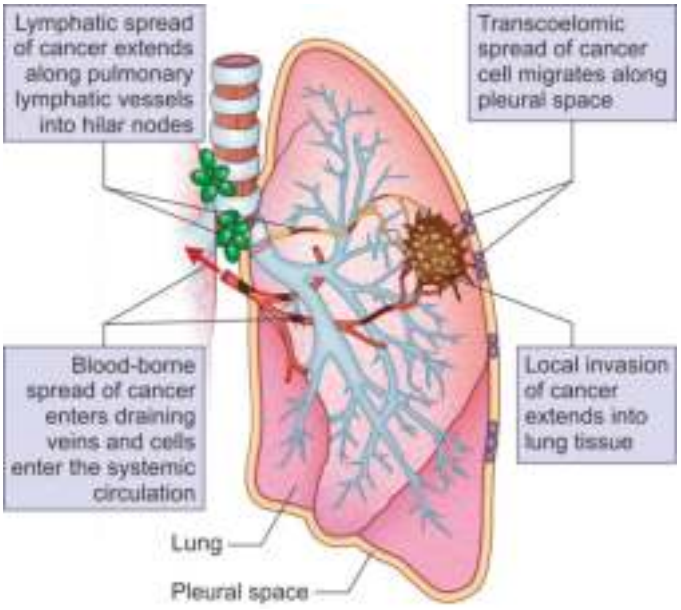

Fig. 6.62: Routes of metastasis of primary lung carcinoma. Routes of metastasis of primary lung carcinoma include local invasion, lymphatic, hematogenous and transcoelomic routes.

lymph nodes is shown in Fig. 6.63. Melanoma of skin metastasis in lymph nodes is shown in Fig. 6.64.

- Lung carcinoma metastasizes to perihilar tracheobronchial, and mediastinal lymph nodes. Colorectal carcinomas metastasize first to the mesenteric lymph nodes.
- Local chemotherapy and immunotherapy can sterilize a lymph node laden with CSCs. Histologic examination of sentinel lymph node is increasingly carried out to select the patients who require extensive lymph node dissection.

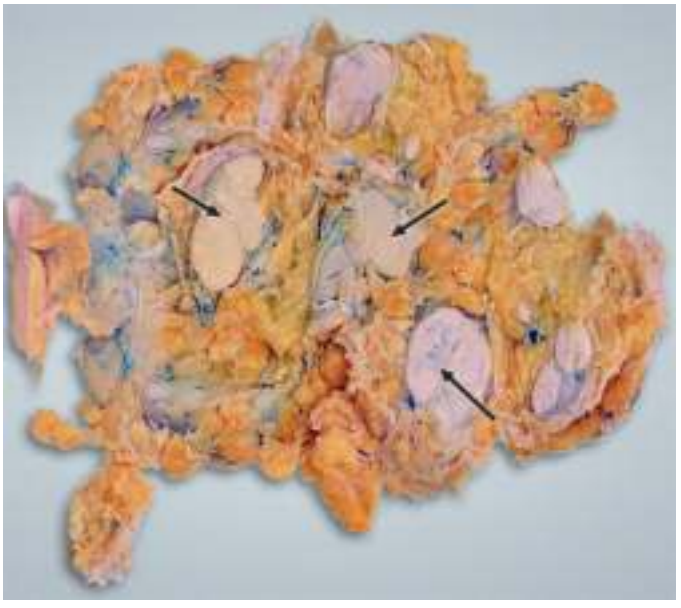

Fig. 6.63: Breast carcinoma metastasis in lymph nodes. Regional metastatic breast carcinoma refers to original tumor has spread to nearby lymph nodes most often axillary lymph nodes and sometimes internal mammary lymph nodes and supraclavicular lymph nodes (arrows).

Fig. 6.64: Melanoma of skin metastasis in lymph nodes. Melanoma can grow extremely quickly and can become life-threatening within six weeks and associated with poor survival. (*Courtesy:* Dr. Sujata Kanetkar, Senior Professor and Head, Department of Pathology, Krishna Institute of Medical Sciences, Karad Maharashtra.)

Pathology Pearls: Lymph Node Metastasis

Tumor deposits measuring 0.2–2 mm are classified as micrometastases in lymph nodes, whereas tumor deposits measuring ≥2 mm is classified as macrometastases in lymph nodes.

Tumors Spreading Lymph Node Metastasis Against Lymphatic Flow

Tumors spreading against the lymph flow in lymphatic channels may cause metastases at unusual sites. For example, prostatic carcinoma metastasizes to the supraclavicular lymph nodes.

Sentinel Lymph Node

- The first lymph node involved in a regional lymphatic drainage is called sentinel lymph node, which can be identified by injecting blue dye. Sentinel lymph node mapping is done in breast carcinoma and colon carcinoma. If the sentinel lymph node is involved, the patient needs 'extensive lymph node dissection' surgery.
- In breast carcinoma, the sentinel lymph node is usually located in the axillary region under the armpit. In most cases, there is involvement of 1–5 sentinel nodes, and all are surgically excised and sent for histologic examination for signs of metastases.

Sinus Histiocytosis

- Necrotic products of the malignant tumor often evoke reactive changes in the lymph nodes such as enlargement and hyperplasia of the lymphoid follicles, proliferation of macrophages in the subcapsular sinuses, known as sinus histiocytosis.
- Sinus histiocytosis can also occur due to infections, immunodeficiency state, autoimmunity and Rosai-Dorfman disease.

Skipped Metastases

- Metastases to the regional draining lymph nodes may be bypassed (skipped metastases) due to involvement of lymphatic-venous anastomoses by inflammation or irradiation resulting in obliteration of these channels.
- For examples, carcinomas in the abdominal cavity may be first detected as enlarged supraclavicular lymph node.

HEMATOGENOUS ROUTE OF METASTASIS

Both malignant epithelial tumors (carcinomas) and malignant mesenchymal tumors (sarcomas) spread via hematogenous route to distant organ(s). Direct invasion of CSCs in arteries and arteriolar lumens is very rare due to the physical barrier provided by their thick muscular and elastic walls.

- Cancer stem cells (CSCs) invade the thin walls of venules, circulate as tumor emboli in lymphatic channels through thoracic duct enter blood circulation and via hematogenous route, metastasize to distant sites (e.g. liver, lung, bones, brain, adrenal glands). Conversely, rhabdomyosarcomas, although rich in capillaries, are rare site of secondary deposits via hematogenous route.
- Malignant mesenchymal tumors (sarcomas) usually metastasize via hematogenous route to distant organs(s). However, some carcinomas such as renal cell carcinoma, hepatocellular carcinoma, follicular thyroid carcinoma, prostatic carcinoma may also metastasize via hematogenous route. Renal cell carcinoma often invades the renal vein to grow in a snake-like fashion in the inferior vena cava sometimes reaches the right side of the heart.
- Cancer stem cells (CSCs) synthesize thromboplastin that may induce thrombosis of distant veins (thrombophlebitis migrans).
- Metastases irrespective of anatomic localization of the malignant tumors and natural pathways of venous drainage occurs by the following ways. Prostatic carcinoma preferentially spreads to bone. Bronchogenic carcinoma involves the adrenal glands and the brain. Neuroblastoma most often metastasizes to the liver and bones.
- Destination of tumor emboli depends on the anatomical drainage of the invaded blood vessel. CSCs reaching venous tributaries of the inferior vena cava flow to the right side of the heart and reach the lungs, whereas CSCs of colon carcinoma via portal vein drainage metastasize to the liver. Tumor emboli in lungs occur when solid malignant tumors seed the systemic circulation with individual CSCs, cluster of CSCs, or large tumor fragments. Tumor emboli pass to left-sided heart and systemic circulation.
- As in lymphatic channels, growth of tumor emboli within a vein causing 'reversal of blood flow' is called retrograde venous spread of tumor emboli. In addition, reversal of blood flow occurs in regions of the body where presence of rich plexus of veins are deficient in valves, e.g. in the pelvis and around vertebrae. Changes in intra-abdominal and intrathoracic pressures easily induce alterations in blood flow in these veins due to this reason, secondary tumors are relatively common in **vertebral bodies**.
- The distribution of tumor emboli is determined by anatomy and surface properties of the CSCs, e.g. increased expression of integrins and their receptors present on the endothelial cells of blood vessels at the metastatic site. Variations in immune response play important role in seeding of malignant tumor emboli.

LIVER METASTASIS

The liver is one of the most common site for malignant tumor metastasis accounting for nearly 25% of cases. A variety of malignant tumors may be the source for hepatic metastasis in adults and children, which include: (a) carcinomas of breast, lung, stomach, colorectal region, pancreas, kidney, prostate, endometrium, thyroid, (b) sarcomas of blood vessel, skeletal muscle, (c) melanoma (melanocyte), (d) round cell tumors (e.g. Wilms' tumor, neuroblastoma, Ewing sarcoma, bronchial carcinoid), and (e) hematolymphoid malignancies (e.g. leukemias, non-Hodgkin's lymphoma). Colorectal carcinoma metastasizes to liver via portal vein in 50% of diagnosed patients. Metastases in liver are shown in Fig. 6.65. Metastasis from invasive ductal adenocarcinoma of breast in liver is shown in Fig. 6.66.

PULMONARY METASTASIS

Pulmonary metastases are more common than primary lung carcinomas. In one-third cases, lung metastases are evident at autopsy. Blood-borne metastases from breast carcinoma (most common), renal cell carcinoma, colon carcinoma, thyroid carcinoma, osteosarcoma and testicular malignancies reach the lungs via systemic venous circulation to the right side of heart. Other malignant tumors from larynx, salivary glands, thyroid gland, uterus, ovaries, urinary bladder, prostate and skin (melanoma) may metastasize to the lungs. Metastasis from osteosarcoma in lung is shown in Fig. 6.67.

- On imaging study (X-ray chest, CT scan, positron emission tomography—PET scan), pulmonary

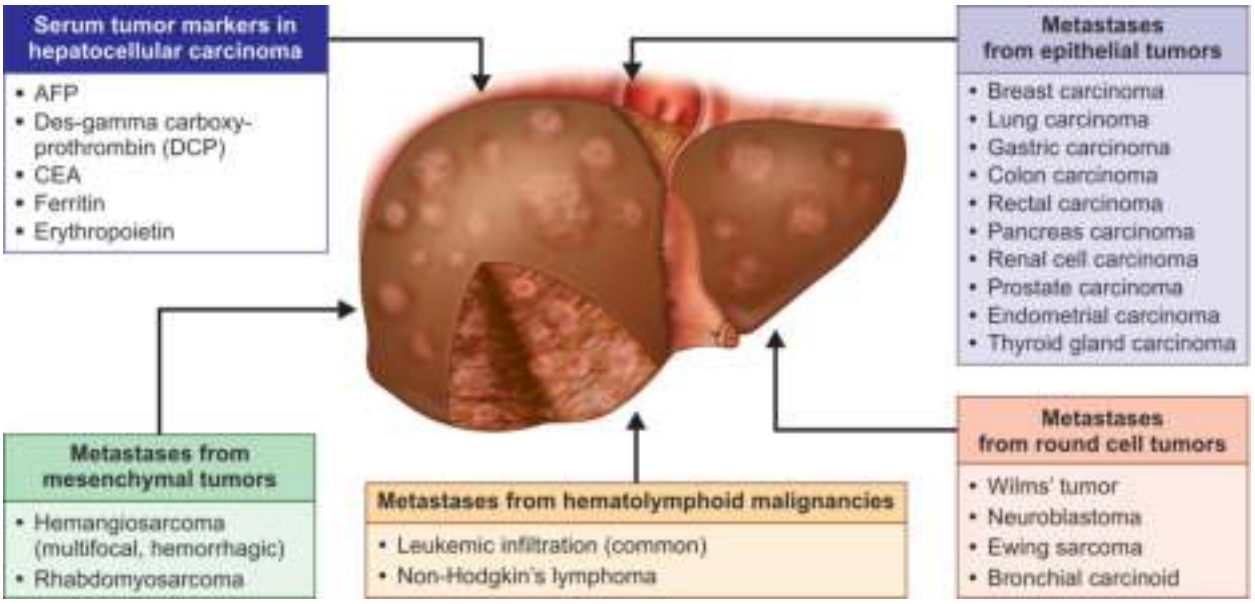

Fig. 6.65: Metastases in liver. Malignant tumors derived from epithelial, mesenchymal and hematolymphoid tissues can metastasize to liver.

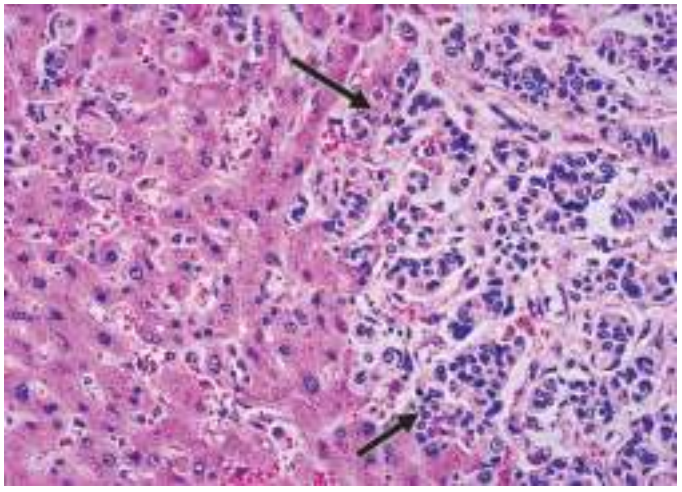

Fig. 6.66: Metastasis from invasive ductal adenocarcinoma of breast in liver. Histologic examination reveals metastatic infiltrating ductal carcinoma from breast is seen on the right side and normal liver parenchyma on the left side (arrows) (400X).

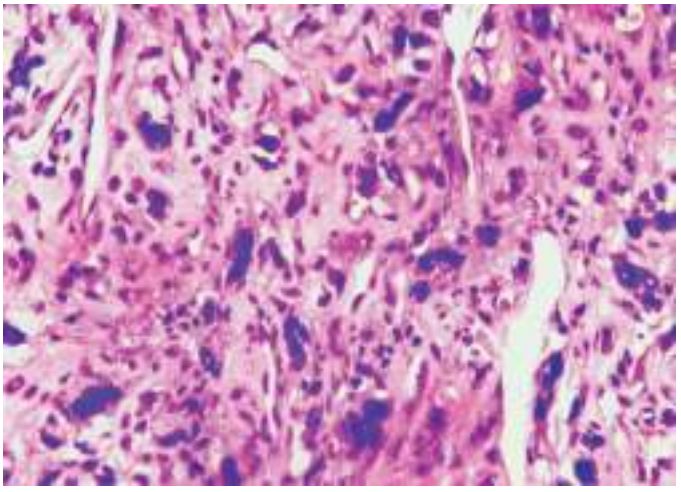

Fig. 6.67: Metastasis from osteosarcoma in lung. Osteosarcoma in lung is the most common mesenchymal bone tumor. Osteosarcoma metastasis in lung at diagnosis has a significantly poor prognosis, even when patient is treated with surgery and chemotherapy. Histologic examination shows pleomorphic atypical cells with hyperchromatic nuclei, numerous atypical mitotic figures and lace-like osteoid and calcified spicules produced by atypical cells in the pulmonary parenchyma (400X). (*Courtesy*: Dr. Tushar Kalonia)

metastases are most often multiple, and sharply circumscribed lacking cavitation in the lung. Calcification is unusual in the lungs except metastases from osteosarcoma and chondrosarcoma.

- Biopsy is obtained by bronchoscopy, transthoracic needle aspiration, and surgery and studied by histologic examination and immunohistochemistry.
- Chemotherapy is most common treatment for pulmonary metastases, which is administered to shrinkage of malignant tumors. Chemotherapy is sometimes induce along with surgical excision and targeted therapy to treat pulmonary metastases.

BONE METASTASIS

Batsons' paravertebral venous plexus has connection with the vena cava and vertebral venous system. Vertebral venous system is extensive and valveless, and has constant connection to breast, thyroid, lung, and prostate. In addition, the venous plexuses are connected to dural sinuses and vasa vasorum of humerus and femur. There are numerous interconnections

between vascular and lymphatic system. CSCs in blood circulation usually arrive in the bone via hematogenous route. Metastasis to bone occurs irrespective of anatomic localization of the tumor and natural pathways of venous drainage. It is important to know the major malignant tumors that metastasize to bone via hematogenous route, which include malignant epithelial tumors of the bronchus, breast, thyroid gland, kidney and prostate gland.

Age Group Distribution of Bone Metastasis

Metastatic carcinoma is the most common tumor of bone after 40 years of age. Most common malignant tumors metastasizing to the bones in male adults include prostatic carcinoma, small cell lung carcinoma, lung adenocarcinoma, gastric carcinoma, colorectal carcinoma, pancreatic carcinoma, renal cell carcinoma and transitional cell carcinoma of urinary bladder.

- Most common malignant tumors metastasizing to bones in female adults include breast carcinoma, thyroid carcinoma, renal cell carcinoma, endometrial carcinoma, uterine cervical carcinoma and uterine leiomyosarcoma.
- In children, metastatic tumors of bone include neuroblastoma, embryonal rhabdomyosarcoma, and retinoblastoma.
- Patient with metastatic bone disease presents with pain, swelling, deformity, encroachment of hemopoietic tissue in the bone marrow, compression of spinal cord or nerve roots and pathologic fractures. Bone metastases in adults and children are given in Table 6.36.

Sites, Solitary and Multifocal Metastases in Bones

Vertebral column is the most common site of metastases in hematopoietic bone marrow; followed by pelvis, ribs, skull and proximal long bones (femur humerus).

Table 6.36 Bone metastases in adults and children

Age Group	Tumors Metastasizing to Bones	
Male adults	▪ Prostatic carcinoma ▪ Small cell lung carcinoma ▪ Lung adenocarcinoma ▪ Gastric carcinoma ▪ Colorectal carcinoma	▪ Pancreatic carcinoma ▪ Renal cell carcinoma ▪ Transitional cell carcinoma of urinary bladder
Female adults	▪ Breast carcinoma ▪ Thyroid carcinoma ▪ Renal cell carcinoma	▪ Endometrial carcinoma ▪ Cervical carcinoma ▪ Leiomyosarcoma
Children	▪ Retinoblastoma ▪ Clear cell sarcoma of kidney	▪ Neuroblastoma ▪ Embryonal rhabdomyosarcoma

Skeletal metastases are uncommon below knee or elbow joints. Basal cell carcinoma of skin, gliomas, and soft tissue sarcomas (except embryonal rhabdomyosarcoma) rarely metastasize to bone.

- Patient may present with bone pain, swelling, deformity, pathological fracture, encroachment of hemopoietic tissue in the bone marrow, compression of spinal cord or nerve roots, urinary incontinence, bowel incontinence, weakness in arms and legs, and hypercalcemia-induced nausea.
- Metastatic deposits in hematopoietic bone marrow in descending order are given in Table 6.37. Solitary and multifocal bone metastatic disease is given in Table 6.38.

Type of Bone Lesions seen on Imaging Techniques

Bone metastases can be evaluated using radionuclide bone scanning, except in multiple myeloma where a skeletal survey is required. Osteolytic lesions are most often detected through radiographic examination, and are also known as X-rays.

- The use of modern imaging techniques such as bone scintigraphy, positron emission tomography (PET) and whole-body magnetic resonance imaging (MRI) to determine the extent of bone metastasis and its character, i.e. osteolytic or osteoblastic lesions.

Table 6.37 Metastatic deposits in hematopoietic bone marrow in descending order

Vertebral column (most common site)
Pelvis
Ribs
Skill
Humerus—proximal end
Femur—proximal end

Skeletal metastases are uncommon below knee or elbow joints. Tumors rarely metastasizing to bones include basal cell carcinoma, gliomas and soft tissue sarcomas except embryonal rhabdomyosarcoma.

Solitary Lesion in Metastatic Bone Disease
▪ Lung carcinoma
▪ Renal cell carcinoma
▪ Well-differentiated thyroid carcinoma
Multifocal Lesion in Metastatic Bone Disease
▪ Breast adenocarcinoma
▪ Gastric adenocarcinoma
▪ Colorectal adenocarcinoma
▪ Neuroblastoma

Table 6.39 Osteolytic or osteoblastic lesions on radiograph in metastatic bone disease

Radiograph Findings	Tumors Metastasizing to Bone	Comments
Osteolytic lesions	▪ Renal cell carcinoma ▪ Well-differentiated follicular thyroid carcinoma ▪ Gastric adenocarcinoma ▪ Colorectal adenocarcinoma ▪ Malignant melanoma ▪ Non-Hodgkin's lymphoma ▪ Neuroblastoma	▪ Increased serum calcium (hypercalcemia) ▪ Increased excretion of calcium in urine (calciuria) ▪ Increased excretion of hydroxyproline containing peptide in urine indicates bone matrix destruction
Osteoblastic lesions	▪ Prostatic adenocarcinoma ▪ Ductal adenocarcinoma of female breast ▪ Hodgkin's disease	▪ Increased serum alkaline phosphatase ▪ Decreased serum calcium level
Osteolytic/osteoblastic lesions	▪ Small cell lung carcinoma ▪ Ductal carcinoma in female breast	Serum and urinary findings depend on type of lesion

- Breast carcinoma and small cell lung carcinoma may produce either osteolytic or osteoblastic lesion. Osteolytic or osteoblastic lesion on radiograph in metastatic bone disease is given in Table 6.39.

Laboratory Diagnosis of Bone Metastasis

A high level of blood alkaline phosphatase could suggest that patient has bone metastasis. An elevation of blood calcium can alert clinician to possible bone metastasis. Radiologic examination (radiograph, CT scan, MRI) and histologic examination of bone marrow aspiration and biopsies establish the diagnosis of bone metastasis.

- **CT/MRI-guided bone biopsies:** A biopsy needle retrieves a sample of bone and sent for histologic examination to determine the cause of bone pain and tenderness, and to distinguish between benign and malignant primary/secondary bone tumors including other bone abnormalities.
- **Liquid biopsies in bone tumors:** Liquid biopsies are done to analyze ctDNA, CTCs and EVs and detect tumor-specific DNA mutations in primary (osteosarcoma, Ewing sarcoma) and bone metastases (breast lung, prostate), which provide new avenues in early detection and monitoring treatment of disease.

BRAIN METASTASIS

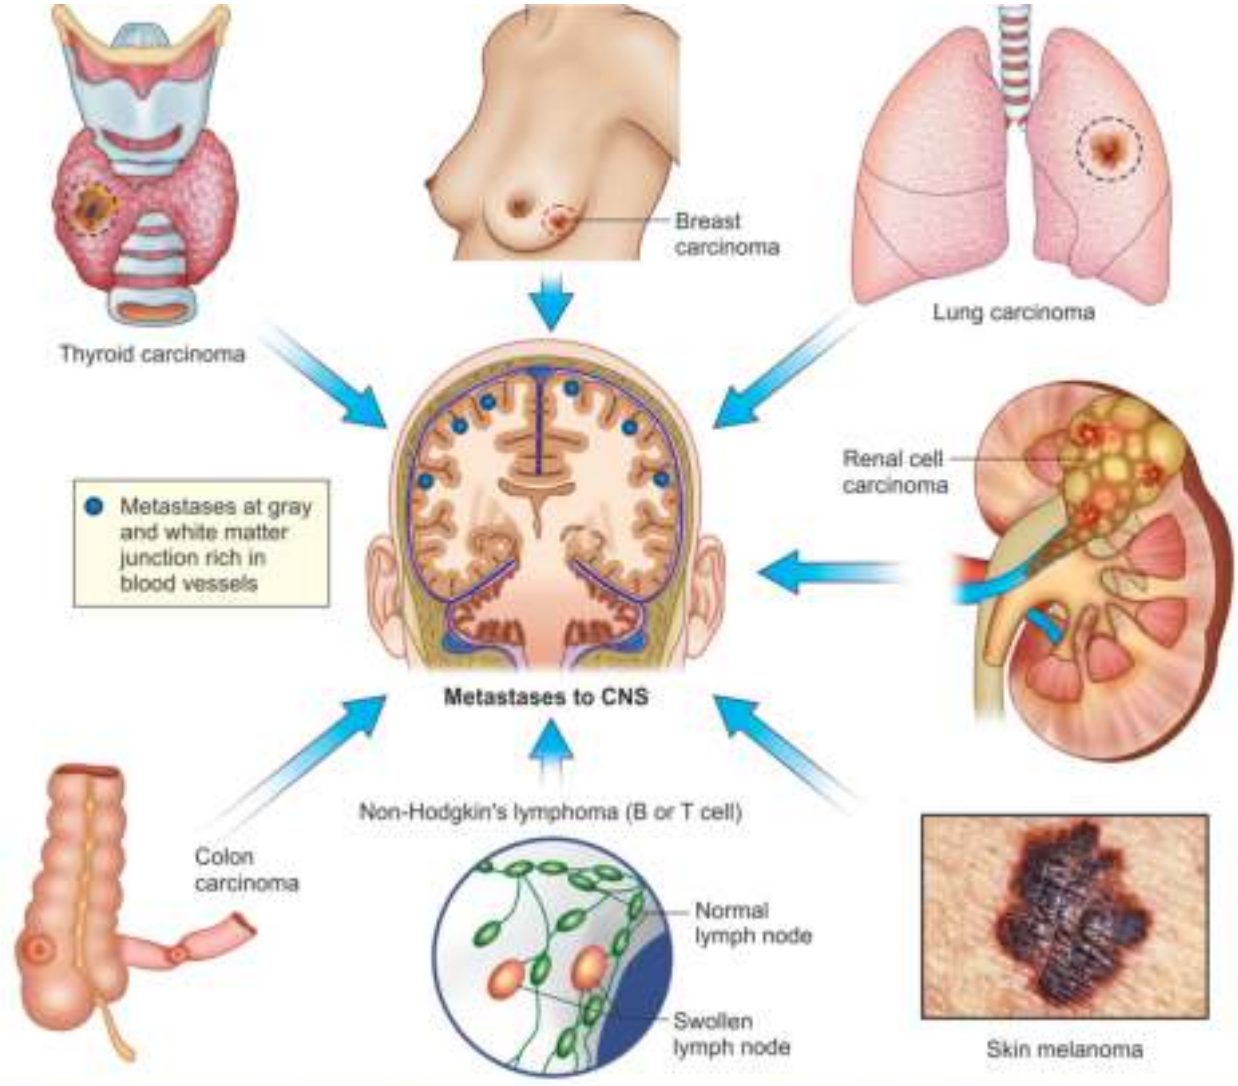
Metastatic tumors are more common than primary intracranial tumors of central nervous system. Certain malignant tumors metastasizing to the brain in the region at the junction of gray and white matter rich in blood vessels include thyroid carcinoma, breast carcinoma, lung carcinoma, renal cell carcinoma, colon carcinoma, non-Hodgkin's lymphoma, and melanoma in 30% of adults. Common brain metastases in adults are shown in Fig. 6.68.

- Brain metastasis occurs in 6–10% children from osteosarcoma, rhabdomyosarcoma, acute lymphoblastic leukemia (ALL) and testicular germ cell tumors. As the metastatic brain tumor grows, it creates pressure on surrounding brain tissue and disrupt functions. Brain metastases can cause many signs and symptoms.
- Pathologic patterns of brain metastases include dural metastasis, leptomeningeal carcinomatosis, miliary metastasis, intravascular metastases, and tumor-to-tumor metastasis in which CSCs from primary malignant tumor metastasize via hematogenous route to another malignant tumor. For example, primary renal cell carcinoma metastasis into a pancreatic neuroendocrine tumor exhibiting a tumor-to-tumor metastasis has been reported. Immunohistochemical markers can be useful to separate metastatic tumors from primary brain tumors.

ADRENAL GLAND METASTASIS

Metastatic spread to bilateral adrenal glands occurs mainly by hematogenous route, involving bilateral adrenal glands. Primary malignant tumors metastasizing to the adrenal glands include renal cell carcinoma, lung carcinoma, colon carcinoma, melanoma and non-Hodgkin's lymphoma. Adrenal gland metastases from ovarian carcinomas are extremely rare.

- Most patients with adrenal gland metastases are asymptomatic. Adrenal gland metastases have been primarily detected on autopsy.
- Computed tomography (CT) scan, magnetic resonance imaging (MRI), and positron emission tomography (PET) scan are done in diagnosing, staging and follow up. Adrenal gland metastases are increasingly detected as incidental finding. Occasionally, patients may present with back pain or abdominal pain due



Primary cancer metastases to central nervous system	Immunohistochemistry
• Thyroid carcinoma	Thyroglobulin, CA 125 cell surface glycoprotein demonstrated by monoclonal antibody OC-125 and TTF1
• Breast carcinoma	ER, PR, HER2/neu, CK7, GCDFP-15 and mammoglobulin
• Lung carcinoma (squamous cell carcinoma)	EMA, CK7, TTF1, p63
• Renal cell carcinoma	Cytokeratin, vimentin
• Skin melanoma	HMB-45, melan-A (MART-1), CAM 5.2, S-100
• NHL (B cell type)	CD10, CD19, CD20
• NHL (T cell type)	CD3
• Colon carcinoma	CK20, CDX2 and β-catenin

Fig. 6.68: Common brain metastases in adults from thyroid, breast, lung, kidney, colon, skin melanoma and NHL.

to rapidly growing metastatic tumor in adrenal gland and causing adrenal insufficiency.

- The best treatment for metastatic adrenal gland tumor is chemotherapy. Adrenalectomy may be recommended, when the primary disease is well controlled and adrenal gland metastatic disease. On gross pathology, arenal gland metastases are gray-white or black colored, solitary or multiple, firm heterogenous masses with occasional area of hemorrhage and necrosis.
- Cytologic and histologic examination of involved adrenal gland demonstrates features of metastatic disease.
- Immunohistochemical markers could be useful to separate metastatic tumors from primary adrenocortical tumors.

SEEDING OF CANCER STEM CELLS AND TRANSCOELOMIC ROUTE OF METASTASIS

Transcoelomic (meaning 'across the peritoneal cavity) metastasis route refers to the dissemination of malignant tumors throughout the surfaces and organs of the abdominal cavity and pelvic cavity covered by peritoneum.

- Cancer stem cells (CSCs) originating in organs (i.e. stomach, colon, breast, endometrium, appendix, pancreas and ovary) can invade into the peritoneal cavity.
- The omentum is the most common site of ovarian carcinoma metastasis via the transcoelomic and hematogenous routes.
- Advanced breast carcinoma can invade peritoneum via the lymphatic and hematogenous routes.
- Surgical resection of colorectal carcinoma can cause intraperitoneal seeding.
- As the CSCs from various malignant tumors of breast, gastrointestinal tract and lung sink within the peritoneal cavity. They settle in various sites, and cause inflammatory reaction with fibrin formation, malignant effusion and adhesion of organs. There can be seeding of CSCs in the pleural and pericardial sacs.

PERITONEAL CAVITY SEEDING

Primary carcinomas of stomach, colon, breast, endometrium, appendix and pancreas may involve the peritoneum and ovaries. Krukenberg tumor, which refers to bilateral ovarian neoplasms and is composed of atypical, mucin containing signet-ring cells. Malignant tumors can spread to the ovary by several mechanisms: direct, transcoelomic spread, and lymphovascular routes.

- **Clinical features:** Peritoneal seeding is common in patients with ovarian serous or mucinous cystadenocarcinomas. Mucinous cystadenocarcinoma secretes large amount of mucinous material and filling the abdominal cavity is known as 'pseudomyxoma peritonei'.
  - Woman with Krukenberg tumor presents with bilateral ovarian enlargement.
  - Final diagnosis of Krukenberg tumor is established by histologic examination and immunohistochemistry. Patients are treated by debulking surgery with or without chemotherapy.
- **Gross morphology:** Gross morphologic examination of 'Krukenberg tumor' reveals most often bilateral ovarian involvement <10 cm in size with multiple small nodules on ovarian surface and extensive intra-abdominal spread. Hematogenous spread of primary malignant tumor to ovary most often involves hilar region of the ovary. Gross morphology of Krukenberg tumor is shown in Fig. 6.69.
- **Histologic examination:** Histologic examination of 'Krukenberg tumor' shows multinodular growth pattern with intervening normal ovarian parenchyma, multiple vascular emboli, specific pattern favoring metastasis such as signet cell carcinoma, pseudomyxoma peritonei, colloid carcinoma, infiltrative pattern of small glands with desmoplastic reaction and single cell infiltration. Histology of Krukenberg tumor is shown in Fig. 6.70.
- **Immunohistochemistry:** Gastric and colon carcinoma metastasis to ovaries are positive for immunohistochemical markers (CK7, CK20, CDX2, SATB to MUC), and breast carcinoma is positive for GCDFP-15.

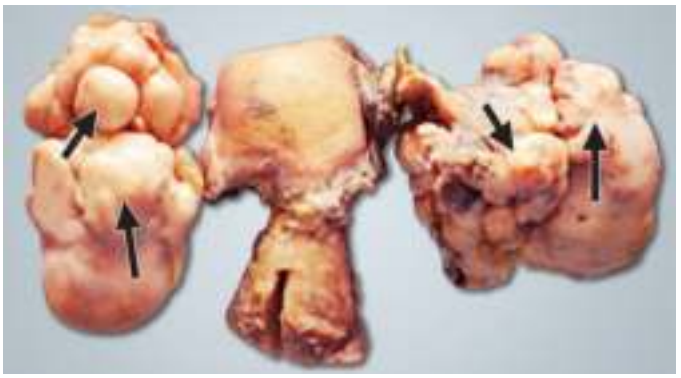


Fig. 6.69: Krukenberg's tumor gross morphology: Both ovaries show involvement as a result of metastases from primary cancers of stomach or colon or breast (arrows).

PLEURAL CAVITY SEEDING

Malignant pleural effusion refers to the presence of CSCs in the pleural cavity associated with significant morbidity and an overall poor prognosis. The most

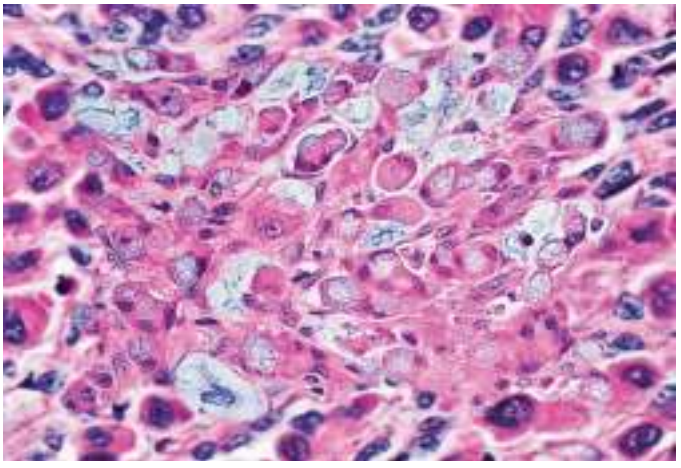

Fig. 6.70: Krukenberg's tumor histology. Tumor is composed of nests of mucin-filled "signet ring" epithelial cells with eccentric nuclei within a cellular stroma derived from the ovary (400X).

common etiologies of malignant pleural effusion are lung carcinoma, breast carcinoma, non-Hodgkin's lymphoma, ovarian carcinoma, gastric carcinoma and mesothelioma in decreasing frequency.

- **Pathogenesis:** Malignant pleural effusion occurs as a result of loss of cell adhesion molecules, detachment of CSCs from the primary tumor invades surrounding tissue. CSCs penetration in venules, migration through the pleura, production of autocrine growth factors induce angiogenesis.
- **Clinical features:** Patient presents with progressive dyspnea, chest pain, cough, constitutional symptoms including weight loss, malaise and anorexia. Severity of symptoms depends on the rate of fluid accumulation in the pleural cavity rather than on the total quality of fluid that might have accumulated over a prolonged time period. Clinical history and physical examination assist in further investigations.
- **Physical examination:** Physical examination may demonstrate stony dullness on percussion, decreased vocal resonance, and tactile fremitus and decreased intensity of breath sounds over the affected region.
- **Diagnostic modalities:** Pleural effusion can be detected by radiograph, ultrasonography, computed tomography (CT) scan and magnetic resonance imaging (MRI). Therapeutic thoracentesis should be completed prior to any definitive pleural procedure to ensure the patient benefits from aspiration of pleural fluid. Pleural fluid aspiration is performed for diagnostic and combined with a therapeutic procedure to relieve symptoms.
  - Cancer stem cells (CSCs) may be demonstrated in pleural fluid on cytological examination.
  - Malignant pleural effusions are generally exudates and lymphocytic predominant. Pleural biopsy is obtained and sent for histologic examination, which should be directed to look for primary tumor.
- **Treatment:** The primary malignant tumor cell type will predict responsiveness to chemotherapy or radiation in the setting of malignant pleural effusion. An indwelling catheter may be inserted into the pleural cavity, which allows intermittent drainage with a vacuum bottle.

PERINEURAL AND LEPTOMENINGEAL ROUTES OF METASTASIS

Cancers that spread by perineural and leptomeningeal routes rely on the nervous system.

- **Perineural spread of cancers:** CSCs may also grow along perineural spaces leading to compression of nerves causing pain and loss of function. Observations reveal that perineural spread is detected in the prostatic carcinoma, colorectal carcinoma and head and neck cancers, where these sites are heavily innervated.
- **Leptomeningeal route of metastasis:** In contrast to perineural spread of cancers, leptomeningeal spread refers to the spread of malignant tumors by the cerebrospinal fluid involving leptomeninges overlying brain parenchyma, and spinal cord; and subarachnoid space. Glioblastoma multiforme, medulloblastoma and ependymoma follow leptomeningeal route originate in the brain, but not all. Non-Hodgkin's lymphoma, breast carcinoma and lung carcinoma especially small cell lung carcinoma are associated with the greatest predilection to metastasize to the subarachnoid space via leptomeningeal route.
  - Leptomeningeal route of metastasis consists of metastatic CSCs growing either attached to the pia mater of brain, and spinal cord or floating in the cerebrospinal fluid (CSF) in the subarachnoid space, that provides favorable environment for the growth of metastatic tumor. Rich vascular supply of meninges provides hematogenous metastatic access to the subarachnoid space.
  - Cerebrospinal fluid has high content of glucose and oxygen to support metastatic CSCs with high metabolic activity that is the reason that metastatic CSCs escape angiogenesis.
  - Patient with leptomeningeal metastasis has overall median survival of 2–4 months. There are many new approaches to the diagnosis and treatment of leptomeningeal meningitis, that promise to extend life and prevent disability.
  - Leptomeningeal meningitis is diagnosed by molecular techniques. Patients are treated by drugs available for intrathecal administration, using systemic chemotherapy; and applying strategies such as gene therapy and immunotoxins to the management of leptomeningeal metastases.

INTRAEPITHELIAL ROUTE OF METASTASIS

Intraepithelial route of metastasis can occur, where malignant epithelial tumor originates from duct in the breast. Patient presents with eczematous, scaling, pruritic eruption of the skin that clinically mimicks inflammatory dermatoses. Paget's disease of the female breast is shown in Fig. 6.71.

- Paget's disease of the female breast involving nipple and areola originates by intraepidermal migration of CSCs from *in situ* carcinoma or invasive ductal carcinoma of breast through the lactiferous ducts to the surface epithelium of the nipple and areola.

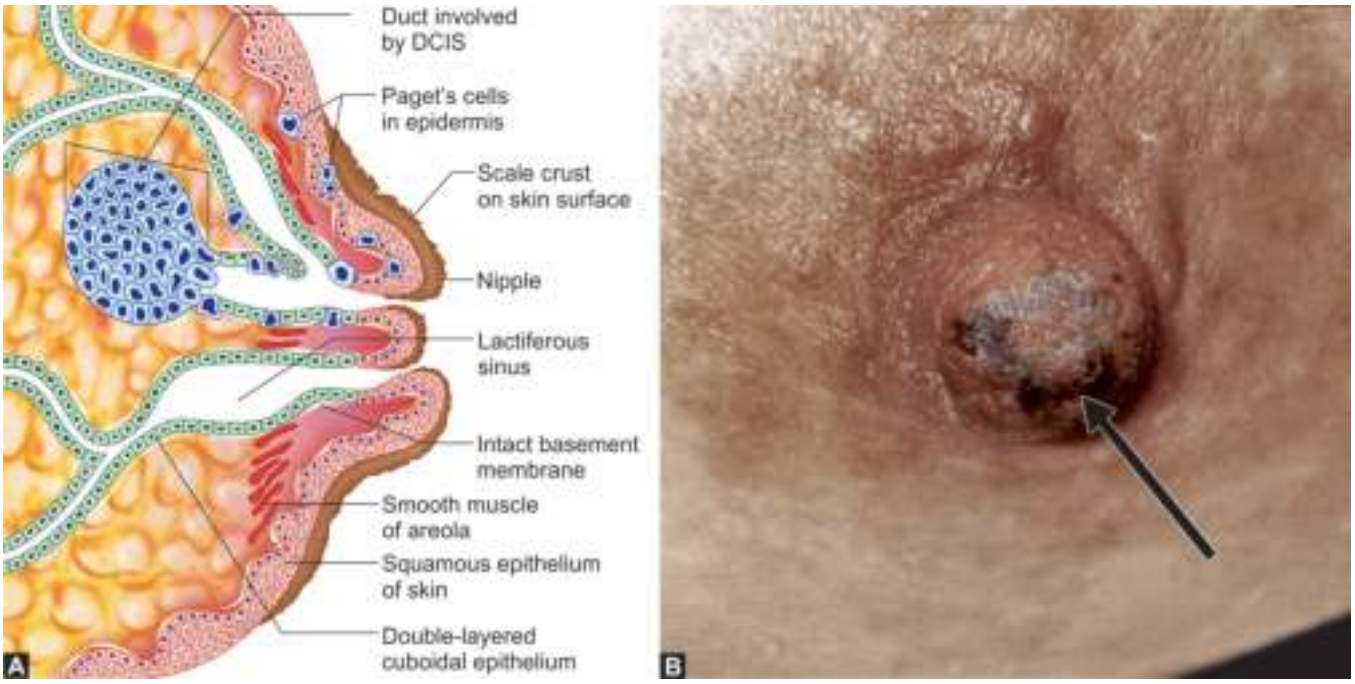

Fig. 6.71: Paget's disease of the female breast. It is ductal carcinoma that affects skin of the nipple, which sometimes is accompanied by more invasive breast carcinoma. Patient presents with crusting of the skin and areola and discharge mimicking eczematous lesion (arrow).

- Paget cells infiltrate the entire thickness of epidermis singly or in nests and laterally in the surface epithelium with clear or pale eosinophilic cytoplasm, vesicular nuclei, prominent nucleoli, and increased mitotic activity. Glandular and acinar structures and signet ring cells with intracytoplasmic mucin may be present.
- Paget cells are positive for immunohistochemical markers such as LMWCK (CAM 5.2, CK7), AE1/AE3, epithelial membrane antigen (EMA), HER2/neu, and GATA3.

IATROGENIC MALIGNANT TUMOR IMPLANTATION DURING SURGERY

Iatrogenic malignant tumor implantation results from various medical or surgical procedures used for diagnosis and treatment of a malignancy. It involves accidental spillage of CSCs by direct contact during surgical procedures. It is significant potential hazard during malignant tumor surgery. Dissemination of CSCs can result in local recurrence or distant metastasis from the tumor under treatment.

MOLECULAR BASIS OF CANCER

Cell division occurs by two processes: (a) mitosis in somatic cells and (b) meiosis in gametes (ova and sperms). Mitotic activity is restricted to somatic cells that eventually repair injuries, and the committed stem cells have the ability continuously to regenerate new cells and differentiate for maintenance of hemostasis. **Cell division** is the process by which a parent somatic cell divides and duplicates accurately the vast amount of deoxyribonucleic acid (DNA) into the chromosomes and then segregate the copies precisely into two genetically identical daughter cells.

- **Cell cycle–cell division major activities:** Normal cell cycle consists of two major activities: interphase (G1, S, and G2 phases) and mitotic phase (M phase). During interphase, cells are metabolically active, which accumulate nutrients needed for mitosis and duplicating its DNA in somatic cells. Mitotic (**M**) phase consists of prophase, metaphase, anaphase, and telophase.
  - Cell division is tightly regulated by two sets of opposite functioning genes, i.e. proto-oncogenes (growth-promoting), and tumor suppressor (growth-inhibiting) genes.
  - Apoptosis regulatory genes, and DNA repair genes also play important role in cell division.
  - Activation of proto-oncogenes (oncogenes), and inactivation/biallelic loss of tumor suppressor

genes leads to unrestricted cell proliferation and carcinogenesis to produce malignant tumors.

- **Cell cycle regulation:** Cell cycle is tightly regulated by positive regulators (i.e. cyclins and cyclin-dependent kinases), and negative regulators, i.e. RB, TP53, INK family of proteins ($p16^{INK}$, $p15^{INK}$, $p18^{INK}$, $p19^{INK}$), CIP/KIP family of proteins ($p27^{KIP}$, $p\ 21^{KIP}$, $p57^{KIP}$), and BRCA1 and BRCA2 acting at various phases of the cell cycle.
  - Extracellular regulation of cell cycle is controlled by mitogens (growth factors), growth factor receptors, and survival factors. A lone cyclin or cyclin-dependent kinase (CDK) exists in inactive state until cyclin binds to CDK.
  - Binding of cyclin to CDK results in formation of cyclin–CDK complex, that gets phosphorylated by receiving phosphate protein by kinase. Activated cyclin–CDK complex phosphorylates target functional proteins in the genome and activate the cell cycle.
- **Cell cycle–cell division dysregulation and cancer:** Cell cycle dysregulation is a hallmark of cancer. Following DNA damage, the ability of normal cells to undergo cell cycle arrest is crucial for the maintenance of genome integrity.
  - The biochemical pathways that inhibit the cell cycle response to cellular stressors are called checkpoints. Defective checkpoint function leads to acquisition of genetic alterations (chromosome mutations), genomic instability that contribute to carcinogenesis, development of malignant tumor and chemoresistance.
  - Transformation of normal cell to CSC involves disruption of key processes such as cell cycle regulation, growth factor-induced cell cycle progression, apoptosis and senescence.
  - Loss of function of tumor suppressor genes (TP53, SMAD4, p14, p16, CDKN2A, and p27), and gain of function of oncogenes (i.e. K-RAS, HER2/neu, MDM2, cyclin D-CDK4 complex) are linked to human cancers.
  - Cancer stem cells (CSCs) can alter growth factor signaling to unrestricted cell proliferation by following mechanisms, which include: (a) CSCs may synthesize growth factors to stimulate self-growth in an autocrine fashion, (b) CSCs may also harbor growth factor receptor mutations that make the receptor constitutive active, i.e. active without having a growth factor bound to it, which permits continuous stimulatory signal to proliferate malignant neoplastic cells, i.e. CSCs, and (c) CSCs may overexpress growth factor receptors resulting in increased signaling. For example, a type of epidermal growth factor (EGF) receptor, known as HER2/neu, is overexpressed in breast carcinoma (HER2/neu-positive). Trastuzumab (**Herceptin**) is a monoclonal antibody directed against HER2 receptor that is used to treat HER2/neu-positive breast cancers. Oncology is a branch of medicine that specializes in the diagnosis and treatment of cancer.
- **Genes most commonly involved in the process of carcinogenesis:** Several regulatory genes regulate the normal cell growth in human body, which include: proto-oncogenes, tumor suppressor genes, apoptosis regulatory genes, and DNA repair genes. Dysregulation of regulatory genes is linked to carcinogenesis and development of malignant tumor.
  - Proto-oncogenes are growth-promoting genes (HER2/neu, RAS, Myc, SRC, hTERT, BCL-2, and EGFR), which code for proteins that promote cell division, growth and development. The viruses have appropriated their oncogenes from normal cellular DNA by genetic recombination. Retrovirus associated oncogenes that have been discovered in altered form in human cancers are given in Table 6.40.
  - Tumor suppressor genes (**growth-inhibitory genes**) code for tumor suppressor proteins that inhibit cell division. Caretaker tumor suppressor genes code for proteins that engage in maintaining the genome stability and DNA repair thus prevent carcinogenesis. Examples of caretaker tumor suppressor genes are BRCA1, BRCA2, DNA mismatch repair (MLH1, MSH2, MSH3, MSH6, PMS1, PMS2), Fanconi anemia, DNA repair and DNA nucleotide base pairs excision repair genes. In contrast, gatekeeper tumor suppressor genes regulate cell cycle. Gatekeeper tumor suppressor genes (TP53 guardian of the genome, RB1, APC, BRCA, APC/β-catenin genes) code for proteins, which regulate cell cycle. Dysregulation of tumor suppressor genes is linked to carcinogenesis.
  - Apoptosis regulatory genes include pro-apoptotic genes (TP53, BAX, c-Myc) and anti-apoptotic B cell lymphoma (BCL-2) family of genes. Apoptosis is a programmed cell death. There are two primary pathways that lead to apoptosis: extrinsic (death receptor-mediated) pathway and intrinsic (mitochondrial-mediated) pathway. Both apoptosis pathways result in the activation of caspases, which are final effectors of apoptosis and cleave several proteins leading to programmed cell death.
  - DNA mismatch repair genes include BRCA1, BRCA2, ATM, CHEK2, MLH1, MSH1, MSH3, MSH6, PMS1, PMS2, XP, MLM, and TERT, Fanconi anemia genes and DNA nucleotide excision repair genes, which encode DNA repair proteins.

Table 6.40 Retrovirus associated oncogenes that have been discovered in altered form in human cancers

Name of the Virus	Virus Present in Species	Viral Oncogene	Oncoprotein	Homologous Oncogene Observed in Human Cancers
Rouse sarcoma	Chicken	v-Src	Nonreceptor tyrosine kinase	Colon carcinoma, breast carcinoma
Abelson murine leukemia virus	Mouse	v-Abl	Nonreceptor tyrosine kinase	Precursor B cell lymphoid blast crisis of chronic myelogenous leukemia (CML)
Avian erythroblastosis	Mouse	v-Erb2	Receptor tyrosine kinase (RTK), also known as epidermal growth factor receptor (EGFR)	Gastric carcinoma, lung carcinoma, breast carcinoma (receptor for EGF, related erbB2/HER2/neu protein overexpressed in breast carcinoma)
McDonough feline sarcoma	Cat	v-Fms	Receptor tyrosine kinase (RTK)	Acute myelogenous leukemia (Fms receptor for colony stimulating factor 1 found in few cases of AMLs)
H-Z feline	Cat	v-Kit	Receptor tyrosine kinase (RTK) for stem cell factor	Gastrointestinal tract stromal tumors
Murine sarcoma 3611	Mouse	v-Raf	Serine threonine kinase (B-Raf mutation in melanoma)	Urinary bladder carcinoma
Simian sarcoma	Monkey	v-Sis	Platelet-derived growth factor (PDGF)	Many human cancers
Harvey sarcoma	Mouse/rat	H-RAS (mutant H-RAS in human cancers)	Small GTP proteins	Urinary bladder carcinoma
Kirsten sarcoma	Mouse/rat	K-RAS (mutant H-RAS in human cancers)	Small GTP proteins	Many human cancers
Avian erythroblastosis	Chicken	v-erbA	Nuclear receptor (receptor for thyroid hormones)	Hepatocellular carcinoma, renal cell carcinoma, pituitary tumors
Acute myeloblastosis E26	Chicken	v-ets	Transcription factor	Leukemias
Avian myelocytoma	Chicken	v-Fos, v-Jun, v-Myc (related N-Myc gene in pediatric neuroblastoma)	Transcription factor	Many human cancers, e.g. osteosarcoma and fibrosarcoma
Reticuloendotheliosis	Turkey	rel (constitutes NF-κB transcription factor)	Transcription factor	Lymphoma

- **Carcinogenesis:** Malignant tumors most often have both activation of oncogenes and inactivation/biallelic loss of tumor suppressor genes. Transformation of normal cell to CSC results from accumulation of successive somatic nonlethal gene mutations, so that cell can survive and undergo unrestricted cell division and thus propagate multiple gene mutations and expression of mutant forms of growth factors, growth factor receptors, signal transducing proteins, transcription factors, DNA repair proteins, chromatin remodelers, regulatory proteins of apoptosis, positive and negative regulatory proteins of the cell cycle, generally give rise to dominantly active oncogenes resulting in carcinogenesis and development of malignant tumor. Conversion of one of the two alleles of proto-oncogene to an oncogene, is sufficient for initiation, promotion and progression of malignant tumor. However, it requires inactivation/biallelic loss of tumor suppressor genes to promote malignant tumor growth. Transformed CSC acquires self-sufficiency in sustained growth signals, inactivation/biallelic loss of tumor suppressor signaling, evasion of apoptosis, defective DNA repair mechanisms, uncontrolled cell division, angiogenesis, escape immune destruction of CSCs, invasion into surrounding tissues, and metastasis to distant organ(s) through stepwise acquisition of complementary gene mutations.

- **Initiation, promotion and progression to malignant phenotype:** Genetic alterations of cellular proto-oncogenes (i.e. oncogenes) lead to initiation of transformation of normal cell to CSC. Activation of a proto-oncogene into an oncogene occurs due to several different mechanisms: numerical and/or structural alterations in chromosomes, chromothripsis, gene amplification, gene overexpression, gene deletion, and point mutation. Promotion occurs due to mutations in tumor suppressor genes, which induce cell growth through activation of cell cycle and propagation of gene mutations induced by initiator oncoproteins. Both initiator and promoter oncoproteins must act together to transform normal cell to CSC. Activation of oncogenes promote progression of malignant tumor, i.e. angiogenesis, invasion, metastasis to distant organs(s) and immunologic tolerance. Tumor angiogenesis is the process of new blood vessels formation from pre-existing blood vessels. Tumor invasion is the mechanism by which CSCs invade and expand into nearby environments. Tumor invasion is the process by which malignant neoplastic cells, i.e. CSCs in malignant epithelial tumor (carcinoma invade basement membrane and then surrounding tissues. Tumor metastasis is the process by which malignant tumor spreads from its origin to another site of the body via lymphatic, hematogenous and transcoelomic routes.
- **Gain-of-function (dominant) versus loss-of-function (recessive) mutations:** Gain-of-function ('dominant') mutation in proto-oncogene encodes oncoprotein. Inactivation/biallelic loss of tumor suppressor genes (recessive mutations) results in unrestricted cell cycle progression and malignant phenotype.
- **Oncogenic driver versus passenger mutations in cancer evolution:** Multistep carcinogenesis results from accumulation of successive driver and passenger mutations in genes. Driver gene mutations perturb regulatory or metabolic signaling pathways that promote unrestricted CSC proliferation, and progression to form malignant epithelial tumor. Numerous additional gene mutations taking place in malignant tumor are called 'passenger gene mutations', which confer malignant phenotype.
- **Genetic and epigenetic alterations and cancer:** Genetic and epigenetic alterations in DNA contribute to abnormal gene expression and genomic instability in cells and development of malignant tumors. The link between the genetic and epigenetic alterations in cancer is demonstrated by the existence of aberrant cellular metabolism and biochemical pathways in CSCs. Genetic alterations in proto-oncogenes, tumor suppressor genes, apoptosis regulatory genes and DNA repair genes are induced by aging process, mutagenic chemical agents, physical carcinogens (ultraviolet rays, ionizing radiation, i.e. X-rays, and γ-radiation), oxygen-derived species (ROS), ethanol metabolic product acetaldehyde, tobacco smoke and incomplete combustion of organic substances. Epigenetic alterations occur due to advancing age and chronic inflammation in the settings of biological carcinogens (HBV, HCV, EBV, HPV, *Helicobacter pylori, Schistosoma haematobium, Opisthorchis viverrini, Clonorchis sinensis, Aspergillus flavus*). Epigenetic alterations such as DNA methylation, histone modifications, nucleosome remodeling and microRNAs dysregulate gene expression leading to development of malignant tumors.
- **Targeting therapy in cancers:** Debulking of malignant tumor performed by surgery is one of the strategies in the management of human cancers. Targeted therapy is the foundation of precision medicine to treat human cancers with medications that disrupt cellular mechanisms, which induce unrestricted proliferation of CSCs and promotion of malignant tumor growth. Targeted therapy does not directly kill CSCs, but alter their biological composition and thus inhibit their growth.
  - Basic aim of targeted therapy is to antagonize specific hallmark of cancer. As researchers learn more about changes in DNA and aberrant proteins involved in driving malignant phenotype, they are in a position to design promising treatments that target aberrant proteins.
  - Most targeted therapies are either small molecule inhibitors or monoclonal antibodies. Small molecule inhibitors are minute organic compounds that attach to the surface of CSC, then enter the CSCs and interfere with their activity. Monoclonal antibodies are laboratory-manufactured cancer-specific antibodies which attach to the surface of CSCs and activate the immune system to induce destruction of CSCs.

CHROMOSOMAL ABNORMALITIES AND DYSREGULATION OF GENES: MECHANISMS

Normal gene expression is the process by which a gene gets '**turned on**' in a cell to make RNA and proteins essential for cellular processes. Four classes of normal

cellular regulatory genes include proto-oncogenes (growth-promoting), tumor suppressor (growth-inhibiting) genes, apoptosis regulatory genes and DNA repair genes, which are the principal targets of mutations causing malignant phenotype. Deregulated function of proto-oncogenes and tumor suppressor genes leads to transformation of normal cell to CSC and tumorigenesis.

- **Proto-oncogenes:** Proto-oncogenes are normal growth-promoting genes, which include HER2/neu (ERBB2), RAS family of genes, Myc, SRC family of tyrosine kinase, hTERT gene (codes for telomerase reverse transcriptase), BCL-2 (B cell lymphoma), EGFR and CCND1 proto-oncogene (codes for cyclin D protein).
  - Each proto-oncogene codes for specific growth factor, growth factor receptor and intracellular regulatory protein responsible for providing positive signals that lead to cell growth, cell division, apoptosis and maintenance of hemostasis.
  - In general, extracellular growth factor binds with growth factor receptor, which activate intracellular downstream signal transducers. The signaling pathway initiates DNA transcription of genes involved in cell growth, which involves binding of transcription factors to DNA regulatory proteins and recruiting chromatin remodelers to carry out gene transcription.
- **Oncogenes:** Oncogenes are mutated forms of normal cellular proto-oncogenes generally involved in promoting cell growth and unrestricted CSC proliferation.
  - Oncoproteins are the products of oncogenes formed when a gene is transcribed and translated to RNA and synthesis of aberrant proteins.
  - Oncogene gets permanently 'turned on', which is known as 'gain-of-function', i.e. dominant gene mutation. This means that only one copy of gene needs to be mutated to induce carcinogenesis.
  - Malignant tumors most often have both activation of oncogenes and inactivation/biallelic loss of tumor suppressor genes, which can invade basement membrane, surrounding tissues and metastasize to distant organ(s).
  - Most malignant tumors occur due to somatic (acquired) rather than germline gene mutations.
- **Viral oncogenes:** Viral oncogenes are responsible for oncogenesis resulting from persistent viral infection when integrated into host genome. Virus-encoded oncoproteins that activate growth factor receptors can induce human cancers. Although different human viruses express different viral oncogenes that induce different tumors, their oncoproteins most often target similar sets of cellular tumor suppressors or signal pathways to immortalize and/or transform infected cells to become CSCs.
- **Proto-oncogene conversion into oncogene—mechanisms:** Activation of a proto-oncogene into an oncogene occurs due to several different mechanisms: numerical alterations in chromosomes, structural alterations in chromosomes, chromothripsis, gene amplification, gene overexpression, gene deletion, and point mutation. Chromosomal rearrangements can be either balanced or imbalanced. Balanced chromosomal rearrangements occur in an even exchange of chromosome material (segment) between two chromosomes without genetic information extra or missing genes, and ideally fully functional. In imbalanced chromosomal rearrangements occur where the exchange of chromosome material is unequal resulting in extra or missing genes.
  - **Numerical alterations in chromosomes:** Numerical alterations in chromosomes (aneuploidy and polyploidy) occur due to segregation errors during mitosis. There may be gain or loss of chromosome. Notability, approximately 90% of human cancers have lost or gained at least one chromosome, e.g. trisomy 12 in chronic lymphocytic leukemia (CLL), trisomy 8 in AML, monosomy 7 in MDS/AML, and monosomy 17 in breast carcinoma.
  - **Structural alterations in chromosomes:** A chromosome's structure can be altered in several ways: translocations (e.g. reciprocal and Robertsonian), deletion, duplications, inversion and ring chromosome. Chromosomal rearrangements can lead to cancer by forming a hybrid gene or by causing dysregulation of a gene. Philadelphia chromosome, which is formed due to rearrangement (reciprocal chromosomal translocation to a transcriptionally active site) that creates the hybrid BCR-ABL fusion gene. The aberrant protein encoded by the hybrid gene accelerates cell division and is associated with chronic myelogenous leukemia (**CML**). Both reciprocal and Robertsonian translocations are one of the most common balanced structural chromosomal abnormalities in the general population accounting for 0.2–4%.

Pathology Pearls: Proto-oncogene Conversion to Oncogene by Imbalanced Chromosomal Rearrangements

- **Chromosomal deletion:** Chromosomal deletion can involve the loss of any number of nucleotides from a single nucleotide to an entire segment of a chromosome.
- **Chromosomal duplication:** Chromosomal duplication simply means that a segment of a chromosome is duplicated, or present in two copies. This results in having extra genetic material, even though total number of chromosomes is usually normally.

- **Chromosomal inversion:** Chromosomal inversion refers to portion of chromosome is broken off, turned upside down, and reattached resulting in inversion of genetic material.
- **Chromosomal insertion:** Chromosomal insertion is a type of mutation that involves the addition of one or more nucleotides into segment of DNA.
- **Ring chromosome:** Ring chromosome can result when a chromosome undergoes two breaks and the broken ends fuse into a circular/ring fashion with or without loss of genetic material.
- **Isochromosome:** An isochromosome is formed when an arm of the chromosome is missing and the remaining arm undergoes duplication.
- **Chromothripsis:** Chromothripsis is a mutational phenomenon characterized by massive clustered genomic rearrangements that are often generated in a single catastrophic event and localized to isolated chromosomal regions leading to cancers and other diseases.
- **Point mutation in proto-oncogene:** Point mutation in proto-oncogene brings a growth-regulatory gene under the control of a different promoter and causes inappropriate expression of the gene. Point mutation in RAS proto-oncogene is linked to lung carcinoma, colon carcinoma and pancreatic carcinoma.
- **Gene amplification of proto-oncogene:** Gene amplification of proto-oncogene is a localized reduplication of a DNA segment, i.e. additional copies of a proto-oncogene.
- **Overexpression of proto-oncogene:** Proto-oncogene is not mutated but overexpressed. For example, HER2/neu proto-oncogene is overexpressed in breast carcinoma.

- **Oncogenes hyperactivate signaling pathways:** Oncogenes can cause hyperactivation of signaling pathways leading to unrestricted cell proliferation, whereas inactivation/biallelic loss of tumor suppressors (p53, pRB, cyclin-dependent kinase inhibitors such as $p16^{INK4A}$, $p15^{INK4B}$, $p21^{CIP1}$) eliminate critical negative regulators of cellular signaling pathways. During the course of tumor progression, CSCs acquire genetic and epigenetic alterations resulting in invasion, angiogenesis, metastasis, evasion of apoptosis. Many of the oncoproteins currently under investigation as possible targets for targeted therapy.

NUMERICAL ALTERATIONS IN CHROMOSOMES

Haploid cells contain only one set of chromosomes. Gametes (ovum and sperm) are most common type of haploid cells produced through meiosis. Haploid cells are vital and important for genetic diversity and sexual reproduction. When the haploid cells from both male and female gametes fuse together during fertilization, it results in formation of diploid cells, which are vital for growth and development.

- Chromosomes are thread-like structures in which DNA is tightly packaged many times around associated histone octamer proteins within the nucleus, that carries genetic information.
- Human beings have 23 pairs of chromosomes for a total of 46 chromosomes in diploid cell.
  - Each cell contains 22 pairs of chromosomes called autosomes and one pair of sex chromosomes (gametes): female has XX pattern and male has XY pattern.
  - In diploid cells, one set of chromosomes is inherited from the individual's father, while the second set of chromosomes is inherited from mother.
  - The total number of chromosomes in diploid cells is described (2n), which is twice the number of chromosomes in a haploid cell (n).
- Numerical alterations in chromosomes (aneuploidy or polyploidy) occur due to errors in segregation of chromosomes during mitosis resulting in **genomic instability** due to gain or loss of chromosome. Notability, approximately 90% of human cancers have lost or gained at least one chromosome.
- The chances of spontaneous gene mutations are higher in somatic diploid cells (2n) than haploid cells (n).
  - Numerical alteration in chromosomes means an individual is either missing one of the chromosomes from a pair or has more than two chromosomes instead of a pair.
  - Numerical alterations in chromosomes result from errors in segregation of chromosomes.
  - Trisomy, monosomy and polyploidy are among the major causes of spontaneous abortions. Trisomies are compatible with survival that often result in multiple defects. Trisomies, monosomies and segmental aneuploidies have impact on chromosomal stability.
  - Aneuploidy and chromosomal instability are commonly found in human cancers.
  - Chromosomal instability leads to karyotype heterogeneity in malignant tumors and is associated with chemoresistance, metastasis and poor prognosis.

Aneuploidy

Alterations in chromosomes involving addition or loss of chromosome in a cell leading to unbalanced chromosome component is termed aneuploidy. Human cell has 47 or 45 chromosomes instead of 46. Trisomy and monosomy are examples of aneuploidy.

- Specific aneuploidy has been observed in various non-cancer genetic orders such as **Down syndrome** (trisomy 21), **Patau syndrome** (trisomy 13) associated with advanced maternal age, **Edwards syndrome**

(trisomy 18, **Klinefelter syndrome** (trisomy XXY), Jacob syndrome (trisomy XYY), and XXY syndrome; and Turner syndrome (monosomy 45X, i.e. absence of one X chromosome). While, clonal aneuploidy is detected in some human cancers, i.e. chronic lymphocytic leukemia (trisomy 12 in CLL) and acute myelogenous leukemia (trisomy 8 in AML).

- Complete loss of chromosome 17 (monosomy 17) has been detected in breast carcinoma. Complete or partial loss of chromosome 7 (monosomy 7) is linked to pediatric acute myelogenous leukemia (AML).
- Aneuploidy can later induce carcinogenesis, which is considered a hallmark of cancer. If extra copies of chromosome containing an oncogene are present, more of the protein may be produced. Alternatively, loss of chromosomes that code for tumor suppressor proteins will lead to less expression of tumor suppressor proteins resulting in carcinogenesis.
- Aneuploidy is demonstrated by fluorescence *in situ* hybridization (**FISH**) in many human cancers, i.e. trisomy 21 in chronic lymphocytic leukemia (**CLL**) and trisomy 8 in acute myelogenous leukemia (**AML**) in 8.5% of cases.

Polyploidy

Polyploidy refers to increase in number of chromosomes (a whole set of chromosomes) more than as in diploid cell (2n), which occurs due to failure of cytokinesis after telophase stage of cell division. Polyploidy is rarely compatible with life, and usually results in spontaneous abortion. Triploidy (3X) is three times the haploid number; tetraploidy (4X) is four times the haploid number and so on.

STRUCTURAL ALTERATIONS IN CHROMOSOMES

Structural alterations in chromosomes occur by relocation of a gene into incorrect promoter region of the gene to a new chromosomal site that results in the higher expression of abnormal proteins/chimeric proteins leading to increased oncogenic potential and thus inducing disruption in normal cell regulation.

- Structural alterations in chromosomes arise during DNA replication of the chromosomes just prior to cell division, which can occur in several ways: (a) deletion of a section of chromosome, (b) duplication of chromosome, (c) chromosomal rearrangement and creation of chimeric (fusion gene) and chromosomal rearrangement to a transcriptionally active site, (d)Robertsonian translocation, (e) chromosome inversion, and (f) formation of ring chromosome.
- Philadelphia chromosome in chronic myelogenous leukemia (CML) and acute lymphoblastic leukemia (ALL) is an example of reciprocal chromosomal translocation t(9;22). Philadelphia chromosome is a t(9;22) that juxtaposes the BCR gene on chromosome 22 with the c-ABL proto-oncogene on chromosome 9. The **BCR-ABL fusion** creates a constitutively active tyrosine kinase product that promotes unrestricted cell proliferation independent of extrinsic regulation.
- Chromosomal translocation to a transcriptionally active site involves c-Myc gene mapped on 8q24 and IgH locus mapped on 14q32 that results in fusion of BCL-2 gene located near to IgH locus leading to over expression of BCL-2 anti-apoptotic protein in the settings of B cell lymphoid malignancies, e.g. Burkitt's lymphoma (90%), diffuse large B cell lymphoma (DLBCL) and acute lymphoblastic leukemia (ALL).
- Structural alterations in chromosomes and exchange of sister chromatids give rise to structural abnormalities that can be easily marked by employing various chromosomal banding techniques used as biomarkers for human cancers. Further, homogenously stained regions (HSR) and double minute chromosomes (small fragments of extrachromosomal DNA) are frequently associated with gene amplification in breast carcinoma, lung carcinoma, ovarian carcinoma, colon carcinoma and neuroblastoma.

Balanced Chromosomal Rearrangement

In genetics, balanced chromosomal rearrangement is a phenomenon that results in unusual rearrangement of chromosomes that can lead to solid and lymphoid malignancies either by creating hybrid gene or dysregulation of gene (i.e. activation of proto-oncogene or inactivation/biallelic loss of tumor suppressor gene). Common balanced chromosomal rearrangements in human malignancies are given in Table 6.41.

- Balanced chromosomal rearrangement is defined as the genomic abnormality resulting from either breaking of the whole chromosome or breaking of a portion of chromosome that reattaches to a different chromosome. Depending on the location of chromosome breaks, balanced chromosomal rearrangement may lead to formation of fusion gene, or may disrupt gene or its regulatory sequences, and in this way may cause dysregulation of gene. Balanced chromosomal rearrangement contributes to molecular **carcinogenesis** by overexpression of oncogenes or generation of novel fusion proteins with altered functions.
- Balanced chromosomal rearrangement can be detected by karyotyping of the CSCs. Cancer therapeutics may cause chromosome translocations that generate secondary therapy-induced cancers.

Table 6.41 Common balanced chromosomal rearrangement in human malignancies

Cancer	Molecular Mutations and Fusion Gene Product	Chromosomal Rearrangements
Hematolymphoid malignant tumors		
CML (chronic myelogenous leukemia)	BCR-ABL	t(9;22)
ALL (acute lymphoblastic leukemia)	▪ BCR-ABL ▪ MLL-AF4 ▪ ELA-PBX ▪ TEL (ETV6)-AML1 (CBFA2) ▪ Myc-IgH	▪ t(9;22) ▪ t(4;11) ▪ t(1;19) ▪ t(12;21) ▪ t(12;14)
AML-M2 (FAB)	ETO-AML1	t(8;21)
AML-M3 (FAB), i.e. acute prolymphocytic leukemia	PML-RARA	t(15;17)
AML-M4	CBFB-MYH11	t(16;16) inversion
Plasma cell myeloma	▪ FGFR3-IGH ▪ c-MAF-IGH ▪ c-MAF-IGL	▪ t(4;14) ▪ t(4;16) ▪ t(4;22)
Burkitt's lymphoma	IgH-Myc	t(8;14)
Follicular lymphoma	BCL-2-IgH	t(14;18)
Mantle cell lymphoma	BCL-1-IgH	t(11:14)
Diffuse large cell B cell lymphoma (DLBCL)	▪ BCL-2-IgH ▪ BCL-6-IgH ▪ ALK-clathrin	▪ t(14;18) ▪ t(3;14) ▪ t(2;17)
Marginal zone lymphoma	▪ ALP-12-MLT ▪ BCR-10-IGH	▪ t(11;18) ▪ t(11;14)
Small cell lymphocytic lymphoma/CLL	BCL-3-IGH	t(14;19)
Mesenchymal tissue-derived malignant tumors		
Fibrosarcoma	ETV6-NTRK3	t(12;15)
Alveolar rhabdomyosarcomas	▪ PAX3-FKHR ▪ PAX27-FKHR	t(2;13) t(1;13)
Clear cell sarcoma	EWS-ATF1	t(12;22)
Dermatofibrosarcoma protuberans	COL1A1-PDGF	t(17;22)
Desmoplastic small round cell tumor	EWS-WT1	t(11;22)
Extraskeletal myxoid chondrosarcoma	EWSR1-CHN	t(9;22)
Synovial sarcoma	SYT-SSX1 or SYT-SSX2	t(X;18)
Epithelial tissue-derived malignant tumors		
Follicular thyroid carcinoma	PPARG-PAX8	t (2;3)
Papillary thyroid carcinoma	RET-PTC	Rearrangement on 10q11.2
Primitive neuroendocrine tumor (PNET)		
Ewing sarcoma	▪ EWSR1-FLT1 ▪ EWSR1-ERG ▪ EWSR1-ETV1 ▪ EWSR1-ETV4 ▪ EWSR1-FEV ▪ FUS-ERG	▪ t(11;22) ▪ t(21;22) ▪ t(7;22) ▪ t(17;22) ▪ t(2;22) ▪ t(16;21)

BCR-ABL Fusion Gene Positive Chronic Myelogenous Leukemia

The best-known example of an acquired chromosomal translocation in a human cancer is the 'Philadelphia chromosome', which is found in 95% of patients with chronic myelogenous leukemia (**CML**) and some patients with acute lymphoblastic leukemia (ALL). Schematic representation of Philadelphia chromosome in chronic myelogenous leukemia is shown in Fig. 6.72.

- Reciprocal translocation between human chromosomes 9 and 22, which carries ABL (Abelson mouse leukemia) proto-oncogene on chromosome 9 and BCR gene on chromosome 22, result in the fusion and creation of BCR-ABL hybrid genes, that code for hybrid BCR-ABL proteins commonly observed in 95% cases of CML. BCR-ABL fusion protein product provides a growth factor by virtue of increased nonreceptor protein kinase, that cannot '**turn off**' and codes for abnormal fusion protein, that results in cell growth, unrestricted leukemic cell proliferation and progression in unregulated manner independent of extrinsic regulation.
- 'Philadelphia chromosome' is the hallmark of CML and also occurs in about 5% of children and 20% of adults with ALL. Philadelphia-positivity in ALL is associated with aggressive disease and has been associated with poor prognosis, especially in children.
- Philadelphia chromosome can be detected by cytogenetic analysis and polymerase chain reaction (PCR) to analyze DNA sequence and detect BCR-ABL fusion gene. PCR testing may be used to monitor a patient's clinical course.
- Patients with CML are treated by chemotherapeutic agent 'imatinib', that inhibits the activity of BCR-ABL fusion protein, thus prevents cell growth, progression and metastasis.

Myc-IgH Fusion Gene Positive Burkitt's Lymphoma

In Burkitt's lymphoma, reciprocal translocation t(8;14) (q24;q32), which involves the c-Myc gene (8q24) and immunoglobulin heavy-chain (IgH) gene locus (14q32). Burkitt's lymphoma is characterized by a high-turnover rate of malignant B cells and the c-Myc gene deregulation. Schematic representation of chromosomal translocation (14;18) (q32.q21) in Burkitt's lymphoma is shown in Fig. 6.73.

- The immunoglobulin heavy-chain (IgH) gene acts as a promoter for the c-Myc gene. Myc is a transcription factor that is aberrantly activated in Burkitt's lymphoma. Balanced chromosomal rearrangement is the basis of malignant transformation of lymphocyte in Burkitt's lymphoma. Patients can develop Burkitt's lymphoma in the jaw region or in the mouth region that interfere with the ability to eat.
- Cytological analysis is performed on bone marrow and blood samples in these patients. Most Burkitt's lymphoma cases demonstrate t(8;14) (q24;q32) with Myc-IGH fusion gene product, and less commonly t(8;22) (q24;q11) or t(2;8)(p12;24). The Myc breakpoints are diverse and distributed over 2Mb region. High quality metaphases are required to detect t(8;14) and t(8;22). Fluorescence *in situ* hybridization (FISH) technique cannot detect all Myc rearrangements.

BCL-2-IgH Fusion Gene Positive Follicular Lymphoma

Chromosome translocation (14;18) (q32.q21) is the hallmark of follicular lymphoma. Translocation of chromosomes 14 and 18 places potent antiapoptotic

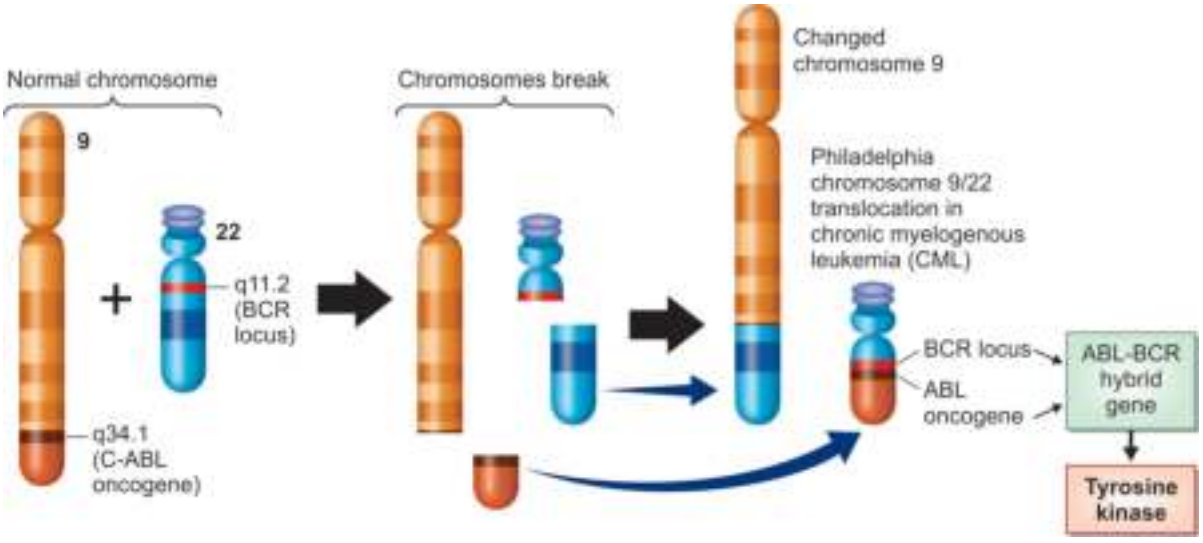

Fig. 6.72: Schematic representation of Philadelphia chromosome in chronic myelogenous leukemia. Reciprocal chromosomal translocation t(9;22) of ABL (Abelson mouse leukemia on chromosome 9) into the BCR site on chromosome 22 creates the 'BCR-ABL fusion protein product' in 90% cases of chronic myelogenous leukemia.

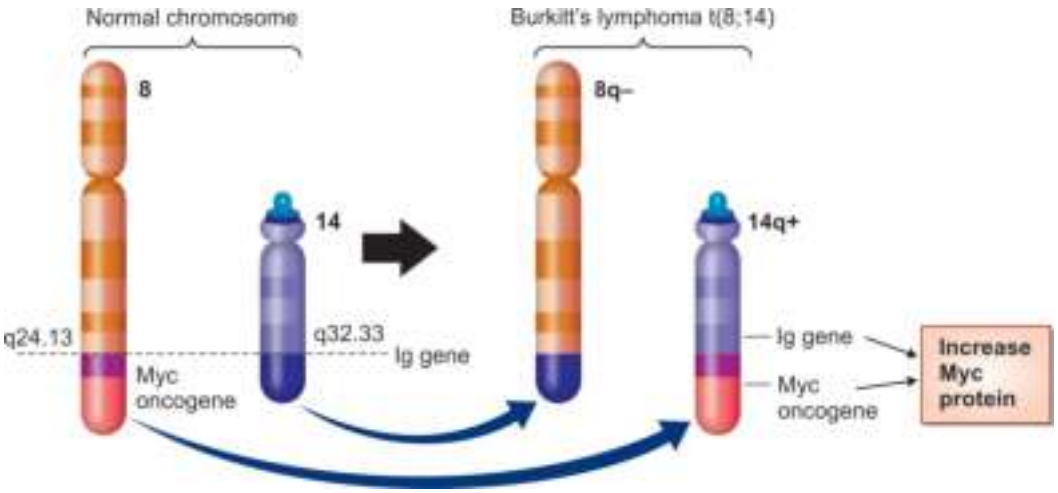

Fig. 6.73: Schematic representation of chromosomal translocation (14;18) (q32.q21) in Burkitt's lymphoma. Translocation of c-Myc oncogene from chromosome 8 to an immunoglobulin heavy gene locus on chromosome 14 results in expression of c-Myc gene.

BCL-2 gene, next to the promoter region of immunoglobulin heavy-chain (IgH) gene leading to development of B cell-derived **follicular lymphoma**. B cell-derived follicular lymphoma evades apoptosis by overexpression of antiapoptotic BCL-2 protein.

EWSR1/FLT1 Fusion Gene Positive Ewing Sarcoma/PNET

Approximately 20% cases of Ewing sarcoma show features of neural differentiation. Diagnostic criteria of Ewing sarcoma/peripheral primitive neuroectodermal tumor (PNET) includes (≥2 major features of neural differentiation): (a) Homer Wright rosettes, (b) MIC2 expression, (c) vimentin expression, (d) expression of neuron-specific enolase (NSE), synaptophysin and chromogranin.

- In Ewing sarcoma/PNET, reciprocal recurrent chromosomal between chromosome 11 and 22 results in fusion of the amino terminus of EWSR1 gene to the FLT1 gene, which codes for a nuclear transcription factor leading to unrestricted CSC proliferation in 100% of cases.
- Approximately 5–15% of these tumors have chromosomal translocation q22; q12. Occasionally chromosomal translocation (21; 22) may also be observed in these patients.
- Ancillary laboratory tests, i.e. conventional cytogenetic analysis, fluorescence *in situ* hybridization (FISH) and polymerase chain reaction (PCR) are performed to analyze EWSR1/FLT1 and EWSR1/ERG fusion gene.

AML1/ETO Fusion Gene Positive Acute Myelogenous Leukemia (AML2-FAB)

Acute myelogenous leukemia (AML2-FAB) is most common childhood hematologic malignancy, and the cases with the chromosome t(8;21) (q22,q22) aberration stand for a subset with the biological and clinical features. AML1/ETO fusion represents one of the first fusion genes employed in monitoring of minimal residual disease (MRD).

- AML1 gene mapped on chromosome 21 is involved in several leukemias. In acute myelogenous leukemia (AML2) with chromosomal translocation t(8;21) (q22,q22), AML1 gene is juxtaposed to the ETO gene mapped on chromosome 8 generating AML1/ETO fusion protein leading to cell proliferation, differentiation and the viability of leukemia cells. Both AML1/ETO and AML1 proteins recognize the same consensus DNA-binding motif (TGT/CGCT), which is found in the promoter regions of several genes involved in hematopoiesis.
- Acute myelogenous leukemia (AML2-FAB) can be diagnosed by cytogenetic analysis by G-binding technique and fluorescence *in situ* hybridization (**FISH**) technique. Detection of AML1/ETO fusion gene can be detected by reverse transcriptase polymerase chain reaction (**RT-PCR**).

RARA-PML Fusion Gene Positive Acute Promyelocytic Leukemia (AML3-FAB)

Acute promyelocytic leukemia (APL) is a unique subtype of acute myelogenous leukemia (AML3-FAB) characterized by abnormal proliferation of promyelocytes, life-threatening coagulopathy due to chromosomal translocation t(15;17) (q24:q21) resulting in the RARA-PML fusion gene, that codes for an oncoprotein responsible for disruption of myeloid distinction.

- Rapid molecular testing is performed for fluorescence *in situ* hybridization (FISH) to detect RARA-PML fusion gene in acute promyelocytic leukemia (AML3).

- Acute promyelocytic leukemia patients are treated by all-*trans* retinoic acid (ATRA) and arsenic trioxide (ATO) therapy.

IgH-CCND1 Fusion Gene Positive Hematolymphoid Malignancies

Chromosomal translocation juxtaposes the CCND1 gene mapped on chromosome 11q13 with the IgH gene mapped on chromosome 14q32 results in creation of IgH-CCND1 fusion gene chiefly found in B cell-derived mantle cell lymphoma, and less commonly in multiple myeloma, plasma cell leukemia, splenic lymphoma with villous morphology, B-prolymphocytic leukemia and chronic lymphocytic leukemia (CLL). Molecular testing strategy for mantle cell lymphoma includes immunohistochemistry (strong cyclin D1 positivity on formalin-fixed paraffin-embedded tissue), cytogenetic analysis/fluorescence *in situ* hybridization technique (IgH-CCND1 fusion gene, t(11;14) on fresh tissue), flow cytometry for leukemia/lymphoma phenotyping (bright CD20, monoclonal light chains, CD5+, CD10–, CD23–), and bone marrow analysis for staging and monitoring disease.

ETV6/RUNX1 Fusion Gene Positive Pediatric Acute Lymphoblastic Leukemia

In pediatric B cell acute lymphoblastic leukemia (ALL), the chromosome translocation t(12;21) (p13;q22) results in ETV6/RUNX1 (also called TEL/AML1) chimeric fusion gene that codes for creation of ETV6/RUNX1 chimeric fusion transcript. This structural alteration in chromosome occurs in 25% of pediatric acute lymphoblastic leukemia cases between 2 and 10 years of age group, with a median of 4 years.

- ETV6/RUNX1-positive pediatric ALL is a 'two-hit' disease for molecular carcinogenesis, i.e. first hit (ETV6/RUNX1) and second hit (ETV6 deletion, RUNX1 gain, CDK2NA, PAX5).
- **Conventional molecular cytogenetic analysis** is performed to detect ETV6 and RUNX1 related chromosomal abnormalities. Recently, t(12;21) and other related abnormalities are analyzed by using fluorescence *in situ* hybridization (**FISH**) technique and real-time polymerase chain reaction.

SYT-SSX1/SSX2 Fusion Gene Positive Synovial Sarcoma

Synovial sarcoma is a highly malignant mesenchymal tumor. Tumor originates in the region of a joint rather within joint cavity. Demonstration of chromosomal translocation t(X;18) (p11, q11) is characteristic finding in synovial sarcoma in 95% of cases. SYT gene from chromosome 18 is fused to SSX1 and SSX2 gene mapped on X chromosome. There is possible ectopic expression of SSX1 and SSX2 gene products in the patients.

PRCC-TFE3 Fusion Gene Positive Pediatric Renal Cell Carcinoma

Pediatric renal cell carcinoma is characterized by various chromosomal translocations involving Xp11.2, all resulting in creation of gene fusion involving the transcription factor E3 (TFE3) gene recognized by World Health Organization. While TFE3 translocations involving a multitude of various partners have been reported, i.e. chromosome 17 [t(X;17) (p11.2; q25), ASPL-TFE3], and chromosome 1 [t(X;1) (p11.2; q21), PRCC-TFE3 fusion] in the patients.

ASPSCR1-TFE3 Fusion Gene Positive Alveolar Soft Part Sarcoma

Alveolar soft part sarcoma is a rare slow-growing malignant tumor of young adults. Tumor is defined by a specific chromosomal alteration, der(17) t(X;17) (p11;q25) resulting in fusion of transcription factor E3 (TFE3) with alveolar soft part sarcoma critical region 1 (ASPSCR1) at 17q25 leading to creation of ASPSCR1 TFE3 fusion protein and unrestricted proliferation of CSCs.

Robertsonian Translocation

Robertsonian translocation is centric fusion of two acrocentric chromosomes resulting in the formation of one large metacentric chromosome and one small fragment. Robertsonian translocation is linked to Down syndrome (trisomy 21) and Patau's syndrome (trisomy 13). Robertsonian translocation is shown in Fig. 6.74.

- Acrosomal chromosomes with very short p arms break very close to centromere leading to subsequent fusion of long q arms. The human genome includes five acrocentric chromosomes: 13, 14, 15, 21, 22.
- The Y chromosome is also acrocentric chromosome. Robertsonian translocation predisposes to Down syndrome (14q;21q).
  - Chromosome 21 is joined to a second acrocentric chromosome, commonly chromosome 14 or 22.

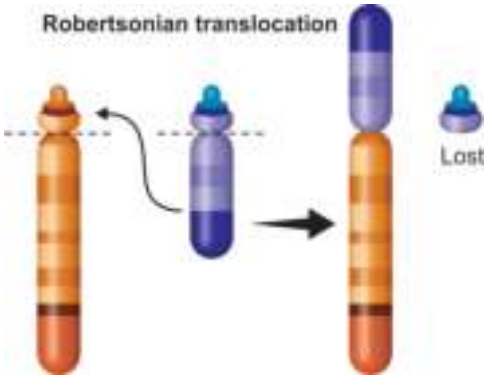

Fig. 6.74: Robertsonian translocation. In Robertsonian translocation, two nonhomologous acrocentric chromosomes break near centromeres, after which the long arms fuse to form one large metacentric chromosome. It is the most common type of chromosomal translocation in human beings.

- The union of a gamete with this translocation with a gamete from an unaffected person can result in trisomy 21. There is high incidence of spontaneous abortion of fetuses.
- Robertsonian translocation confers a high-risk of childhood leukemia, non-Hodgkin's leukemia, and breast cancer with Robertsonian translocation (13;14).

Imbalanced Chromosomal Rearrangements

Imbalanced chromosomal rearrangements occur, where the exchange of chromosome material (segment) is unequal resulting in extra or missing genes by various mechanisms: deletion, duplication, insertion, ring chromosome and isochrome creation.

Chromosome Deletion

In genetics, loss of chromosomal fragment containing numerous genes ('p' short arm or 'q' long arm) or entire chromosome during DNA replication just prior to cell division is termed 'chromosome deletion'.

- Any number of nucleotide base pair(s) can be deleted ranging from single nucleotide base pair to an entire piece of chromosome involving tumor suppressor genes. Examples of chromosomal deletion syndromes include 5p– deletion (**cri-du-chat syndrome**), 4p– deletion (**Wolf-Hirschhorn syndrome)**.
- Chromosome deletion appears to be the earliest as well as the most frequent somatic (acquired) genetic alteration during carcinogenesis, which occurs by three mechanisms: (a) loss of heterozygosity (**LOH**) as proposed in the Knudson' two-hit hypothesis (inactivation of both alleles of RB tumor suppressor gene resulting in retinoblastoma), (b) haploinsufficiency through quantitative deletion and associated with loss of expression, and (c) truncating of the genome by homozygous deletions. Chromosomes 1p and 16q are commonly lost in solid malignant tumor.

Pathology Pearls: Chromosome Deletion Mechanisms

Loss of Heterozygosity

Loss of heterozygosity (LOH) is defined as the loss of one copy of a segment of DNA (second allele) assuming the knocking out of the first allele. Haploinsufficiency refers to poorly functional second allele assuming the knocking out of the first allele of tumor suppressor gene. Human cells have two copies of any genomic segment-one from each parent, so in the case of loss of heterozygosity, only one copy would still be present.

- Loss of heterozygosity is a common form of allelic imbalance of essential genes by which a heterozygous somatic cell becomes homozygous because one of the two alleles gets lost.
  - Loss of heterozygosity (LOH) causes chromosomal instability resulting to potential cancer vulnerabilities.
  - When tumor suppressor genes are absent or nonfunctional due to loss of heterozygosity, normal cell may begin to divide abnormally and becomes cancer stem cell (CSC).
  - The classical example of loss of heterozygosity is the loss or inactivation of both alleles of the retinoblastoma (RB) gene in retinoblastoma. The pRB protein is inactivated either by somatic or germline mutations leading to the pediatric tumor of the eye 'retinoblastoma'.
- Knudson initially proposed that retinoblastoma was initiated by inactivation of putative RB1 tumor suppressor gene. Knudson' two-hit hypothesis was subsequently confirmed by demonstration of loss of heterozygosity (LOH) at chromosome 13q14 in retinoblastoma gene and the cloning of the first RB1 tumor suppressor gene. Retinoblastoma is virtually always fatal due to metastasis.

Haploinsufficiency

Haploinsufficiency of tumor suppressor genes (TSGs) occurs when single copy of the **wild-type** allele in the tumor suppressor gene at a genomic locus is **inactivated** or **deleted** and the remaining functional copy of the gene is not adequate to produce the needed gene product to execute normal cellular functions, and thus contributing to development of malignant tumor.

Truncating the Genome by Homozygous Deletions

Homozygous deletion is defined as the loss of both alleles of the gene at given locus. A deletion changes the DNA sequence by removing at least one nucleotide base pair in a gene. Deletion of chromosomal material is the most common feature of cancer genomes. The landscape of somatic homozygous deletions in CSCs is shaped by positive and negative selection. Recurrent deletions of chromosomal material typically target tumor suppressor genes resulting in positive selection. Simultaneously, loss of a nearby essential gene can lead to negative selection, and introduce latent vulnerabilities specific to CSCs.

- **Chromosome 8p deletion:** The short arm of chromosome 8 (8p) is one of the most recurrently deleted genomic regions in the majority of advanced epithelial cancers, i.e. urinary bladder carcinoma, colorectal carcinoma, prostatic carcinoma, lung carcinoma, and hepatocellular carcinoma.
- **Chromosome 5p deletion:** Multiple early genetic events on chromosome 5p deletion have been identified in the progression of nonsmall cell lung carcinomas (e.g. squamous cell lung carcinoma and lung adenocarcinoma). Lung carcinoma is most widely diagnosed malignancy in the world. Using a high-resolution chromosome 5p– specific genome array, which contains a tilting patch of DNA segments for comparative genomic hybridization, nine novel minimal regions of loss and gain have been demonstrated in bronchial carcinoma *in situ* specimens.
- **Chromosome 1p32 deletion:** Chromosome 1p32 is the largest human chromosome, spanning about 249 million DNA building blocks (nucleotide base pairs) and representing approximately 8% of the total DNA in cells.

- Chromosome 1p32 contains 2,000 to 2,100 genes that provide instructions for making proteins, which perform a variety of different biological functions in the body.
- **TAL1 gene** is mapped on short arm of chromosome 1p32 that codes for a hematopoietic transcription factor essential for normal hematopoiesis. Disruption of TAL1 via chromosomal translocation of a site-specific deletion has been reported in 30–50% of T cell acute lymphoblastic leukemia (**T-ALL**).
- Chromosome 1p32 deletion can be detected by conventional cytogenetics, fluorescence *in situ* hybridization, southern blot analysis and real-time polymerase chain reaction (RT-PCR).

Chromosome Duplication

The term 'chromosome duplication' means duplication of chromosomal segment resulting in extra genetic material, even though the total number of chromosomes is usually normal. Chromosome duplication is the opposite of deletion.

- During a disease process, extra copies of the gene in the human genome can contribute to carcinogenesis. Genes can also duplicate in the evolution of human genome, where one copy of the original gene function and other copy of the gene produces new function. Duplication of whole chromosome induces disease.
- Chromosome duplication happens during the crossing-over (recombination) between misaligned homologous chromosomes stage of meiosis.
- Duplication of chromosome results in trisomy (e.g. Down syndrome, trisomy 21) and Pallister-Killian syndrome (#12). Duplication of chromosome is detected by high-resolution banding, fluorescence *in situ* hybridization (FISH) and array comparative genomic hybridization (array CGH).

Chromosome Inversion

An inversion is a rearrangement in chromosome, in which a segment of a chromosome breaks at two regions is reversed end to end position in original chromosome after rotating by 180°. Inversion occurs when a single chromosome undergoes breakage and rearrangement within itself.

- As many as 1% of the newborn babies may carry an inversion in chromosome that can be detected by G-banding chromosome karyotyping. Chromosome inversion produces unbalanced meiotic products; thereby resulting in sterility.
- Chromosome inversion leading to the formation of the **EML4-ALK fusion oncogene** is most commonly present in lung adenocarcinoma. EML4-ALK fusion oncogene is also demonstrated in **breast carcinoma** and **colorectal carcinoma**. There are two types of inversion: paracentric and pericentric.
  - **Differences between paracentric and pericentric inversion:** Paracentric inversion does not include the centromere and both breaks occur in one of the chromosomes. On the contrary, pericentric inversion includes the centromere and breaks occurs in both arms of chromosome.
  - **Similarities between paracentric and pericentric inversion:** Both paracentric and pericentric inversions are large-scale chromosomal mutations occurring within a single chromosome. Both types of inversion do not cause a loss of genetic information. They simply rearrange the linear gene sequence in the chromosome.
- Researcher reported a related chromosome 16 inversion in acute myelomonocytic leukemia (AMML), i.e. AML-M4 (FAB), that is defined with differentiation along with both myeloid and monocytic lines in bone marrow and high number of circulating monocytes.
  - Bone marrow contains myeloblasts and monoblasts constitute 20%.
  - Monoblasts must be <80% of total nucleated cells. Cytogenetic analysis detects chromosome 16 inversion. Flow cytometry is performed to confirm the diagnosis. In general, myeloblasts are moderate CD45 positive, low SSC and express CD34, CD13, CD33, CD117 and HLA-DR.
  - Monoblasts and promonocytes are CD45 positive bright and SSC slightly higher than myeloblasts; and these cells express CD11b, CD11c, CD13, CD14, CD64 and HLA-DR.

Chromothripsis (Shattering of Chromosomes)

Chromothripsis means shattering of chromosomes into small fragments that leads to remarkable gene rearrangements in localized regions. During mitosis, chromosomes undergo condensation, and focal DNA damage can be induced by exogenous (radiation) or endogenous factors such as microhomology-mediated break-induced replication (MMIR) or chromosome lagging, micronuclei formation, and pulverization as a result of inappropriate chromosome segregation.

- After chromosome shattering, DNA fragments are joined by nonhomologous end joining (NHEJ) within chromosomal regions. Repaired chromosomes contain chromosomal rearrangements such as deletions, head-to-head and tail-to-tail inversions, and tandem duplications.
- With exit of mitosis, shattering of chromosome (chromothripsis can be incorporated into the nucleus. Lack of DNA damage checkpoints, such as TP53 (p53 protein), facilitates the survival of cells during the chromothripsis process.
- As a result, chromothripsis can induce activation of oncogene by chromosome translocations or duplications as well as inactivation/biallelic loss of tumor

suppressor genes by deletions or locus disruptions, thus facilitating progression of human cancers (e.g. **osteosarcoma** and **glioma**).

GENES DYSREGULATION AND CARCINOGENESIS

Carcinogenesis is the multistep process involving genetic alterations (e.g. gene amplification, point mutation, frameshift mutations and insertion) in proto-oncogenes, and tumor suppressor genes, that regulate normal functions and leading to transformation of healthy cell into CSCs.

Gene Amplification

Gene amplification refers to an increase in additional copies of the same proto-oncogene without a proportional increase in other genes within the genome that leads to increase in production of the associated protein and then self-sufficiency in growth signals may be achieved. Gene amplification can result from duplication of a region of DNA, that contains a gene through errors in DNA replication and repair machinery as well as through insertion of oncogenic retroviruses. Gene overexpression occurs due to gene amplification, activating gene mutation or epigenetic activation.

- Oncogenes such as ERBB2, CCND1, c-Met, N-Myc, EGFR, and MDM2 are amplified in human cancers and can be associated with increased expression of their respective aberrant proteins. Amplification of N-Myc oncogene is linked to neuroblastoma. Amplification of HER2/neu is linked to breast carcinoma. Gene amplification and associated human cancers are given in Table 6.42.

Table 6.42 Gene amplification and associated human cancers

Name of Oncogene	Oncoprotein	Human Cancers
K-RAS gene	Small GTP proteins	Lung carcinoma, ovarian carcinoma, colorectal carcinoma, urinary bladder carcinoma (20%)
N-RAS gene	Small GTP proteins	Head and neck cancers
H-RAS gene	Small GTP proteins	Colorectal carcinoma (30%)
ERBB1/EGFR gene	Receptor tyrosine kinase (RTK)	Glioblastoma multiforme (50%), squamous cell carcinoma of skin (10–20%), melanoma, breast carcinoma, colorectal carcinoma, gastric carcinoma, lung adenocarcinoma
ERBB2 (HER2/neu) gene	Receptor tyrosine kinase	Breast carcinoma (20%), ovarian carcinoma, lung adenocarcinoma, squamous cell carcinoma of skin, salivary gland carcinoma
ERBB3 gene	Receptor tyrosine kinase	Breast carcinoma, prostatic carcinoma, urothelial carcinoma
FGF-R1	Receptor tyrosine kinase	Breast carcinoma (10%)
MDM2 gene	p53 inhibitor	Soft tissue sarcomas, osteosarcoma, breast carcinoma
AKT-1 gene	Serine/threonine kinase	Gastric carcinoma (20%)
AKT2 gene	Serine/threonine kinase	Pancreatic carcinoma, ovarian carcinomas (30%)
CCND1 gene	Cyclin D1 protein	Breast ductal carcinoma, breast lobular carcinoma, urinary bladder carcinoma, lung adenocarcinoma, squamous cell carcinoma of larynx (25–50%)
CDK4 gene	Cyclin-dependent kinase	Sarcomas (10–30%), squamous cell carcinoma in head and neck region (40%), B cell lymphomas (25%)
CDK6 gene	Cyclin-dependent kinase	Gliomas (5%)
Cyclin E gene	Cyclin	Gastric carcinomas (15%)
PIK3CA gene	Phosphoinositide 3-kinase	Squamous cell lung carcinoma, ovarian carcinoma, breast carcinoma
c-Met gene	Receptor tyrosine kinase	Gastric carcinoma (20%), esophageal carcinoma, lung carcinoma, colorectal carcinoma
K-SAM gene	Receptor tyrosine kinase	Gastric carcinoma (10–20%), breast carcinoma (10–20%)
AIB1/BTAK gene	Receptor coactivator	Breast carcinoma (15%)
c-Myc gene	Transcription factor	Leukemias, carcinomas (10–50%)

Contd...

Table 6.42 Gene amplification and associated human cancers (*Contd...*)

Name of Oncogene	Oncoprotein	Human Cancers
L-Myc/DDX1 gene	Transcription factor	Lung carcinoma (10%)
N-Myc gene	Transcription factor	Neuroblastoma (25–30%), lung carcinoma (30%), retinoblastoma, rhabdomyosarcoma, breast carcinoma
GLI gene	Transcription factor	Glioblastoma multiforme
ETS-1 gene	Transcription factor	Lymphomas
MYB gene	Transcription factor	Colon carcinoma (5–20%), leukemias

Table 6.43 Reagents and equipment required for the polymerase chain reaction (PCR)

Reagents and Equipment	Purpose
PCR target or 'template'	The segment of the nucleic acids (DNA or RNA) that is to be amplified
Nucleotides	Building blocks from which nucleic acids are constructed; adenine, guanine, cytosine and uracil
Primer	A short sequence of nucleotides complimentary to, and binding (annealing) to, known sequences of the target nucleic acid; essential for 'priming' the amplification reaction
Taq DNA polymerase	A heat-stable enzyme that makes a new copy of the target nucleic acid by adding nucleotides to annealed primer
Reverse transcriptase	An enzyme that converts RNA into a complimentary DNA sequence (used in reverse transcription PCR)
Thermocycler	The equipment in which PCR reactions occur, it is able to change rapidly to the different temperatures required for repeated PCR cycles

- Gene amplification indicates aggressive behavior of malignant tumors. Gene amplification is linked to chemotherapy resistance. Amplification of c-Myc gene is observed in small cell lung carcinoma associated with clinically aggressive malignant tumor.
- Polymerase chain reaction (PCR) is widely used method to analyze gene amplification. Reagents and equipment required for the polymerase chain reaction (PCR) are given in Table 6.43.
- Cytological analysis of gene amplification reveals homogenous staining regions (HSRs) and abnormal banding regions on chromosomes stained with special stains, and double minutes recognized as small, paired cytoplasmic bodies.

ERBB2 (HER2/neu) Gene Amplification

ERBB2 (or HER2/neu) gene amplification is most commonly detected in oncology. Upwards of 20 copies of ERBB2 genes may be demonstrated in breast carcinoma, ovarian carcinoma, lung adenocarcinoma, and squamous cell lung carcinoma, which help to drive progression of disease and associated with poor prognosis.

- ERBB2 (HER2/neu) gene encodes a member of the epidermal growth factor (EGF) receptor family of receptor tyrosine kinase, that regulates outgrowths and stabilization of peripheral microtubules. ERBB2 gene amplification activates downstream signaling pathways (mitogen-activated protein kinase (MAPK) and phosphatidylinositol 3-kinase) leading to unrestricted CSCs and malignant tumor growth.
- It must be noted that sometimes, proto-oncogenes only need to be overexpressed (not mutated) become oncogenes, which drive cell proliferation and render the cell unresponsive to normal growth inhibitory signals, ultimately resulting in malignant tumor growth. For example, ERBB2 (HER2/neu) gene is overexpressed in HER2/neu-positive breast carcinoma.

CCND1 Gene Amplification

The protein encoded by CCND1 belongs to the cyclin family, whose members are characterized by a dramatic periodicity in protein abundance throughout cell cycle. Cyclins function as regulators of CDK kinases. CCND1 gene amplification is linked to invasive ductal/lobular breast carcinoma, urinary bladder carcinoma and lung adenocarcinoma.

The c-Met Gene Amplification

The 'c-Met' is a receptor tyrosine kinase belonging to the Met family and expressed on the surface of various cells. Hepatocyte growth factor (HGF) is a ligand for c-Met tyrosine kinase receptor.

- The binding of HGF to c-Met initiates a series of intracellular signals, that mediate embryogenesis and wound healing in normal cells. The c-Met gene amplification is linked to gastric carcinoma, esophageal carcinoma, lung carcinoma, and colorectal carcinoma.
- In CSCs, aberrant HGF/c-Met axis activation as a result of c-Met amplification promotes tumor development and progression by stimulating the PI3K/AKT, RAS/MAPK, JAK/STAT, SRC, Wnt/β-catenin and other signaling pathways. Thus, c-Met and its associated signaling pathways are clinically important therapeutic targets.

N-Myc Gene Amplification

N-Myc gene coding for protein normally functions in brain development before birth. N-Myc gene amplification is linked to **neuroblastoma** associated with poor prognosis.

EGFR Gene Amplification

Normal function of epidermal growth factor receptor (EGFR) is to regulate epithelial tissue development and homeostasis. Amplification of EGFR gene is linked to lung carcinoma, breast carcinoma, glioblastoma multiforme, gastric carcinoma, colon carcinoma, and esophageal squamous cell carcinoma.

Mouse Double Minute 2 (MDM2) Homolog Gene Amplification

Mouse double minute 2 (MDM2) homolog gene encodes E3 ubiquitin-protein ligase. MDM2 gene is important negative regulator of the TP53 (p53) tumor suppressor gene. Amplification of MDM2 gene is linked to soft tissue sarcomas, osteosarcomas and breast carcinoma.

Point Mutation in Proto-oncogene

Point mutation occurs in the genome when single nucleotide base pair in a gene sequence is substituted (altered), added, deleted. Point mutation is less serious than chromosomal alteration. Point mutation can occur during DNA replication or due to environmental mutagens, i.e. X-rays, ultraviolet rays, extreme heat or certain chemical agent (i.e. benzene).

- DNA is made up of many nucleotide base pairs (cytosine, guanine, adenine and thymine). **Codon** is a sequence of three nucleotide base pairs that codes for a certain amino acid, or to start (start codon) or stop (stop codon) the production of an amino acid chain. Point mutation changes the codon UUU to the codon UCU.
- Point mutation in proto-oncogene occurs by various mechanisms: (a) silent mutation (formation of same amino acid), (b) missense (formation of different codon but lacking stop codon) mutation, (c) nonsense mutation, i.e. substitution (formation of a stop codon but lacking codon coding for an amino acid), (d) insertion (addition of extra nucleotide base to a sequence) and (e) deletion (deletion of nucleotide base pair from a sequence). The effects of point mutations depend on how they change the genetic code. Point mutation types, examples and effects are given in Table 6.44.
- While most point mutations are benign, e.g. cystic fibrosis (deletion of three nucleotides in the cystic fibrosis transmembrane conductance regulator (CFTR) gene associated with thick mucus in lungs, salty sweat and short life expectancy), sickle cell disease (deletion of single nucleotide base pair point mutation of amino acid valine for glutamic acid in the seventh codon of β-globulin chain on chromosome 11p15) and Tay-Sachs disease (point mutation in HEXA gene associated with nerve involvement and fatal outcome before the age of four). Patients can also have functional consequences such as gene expression or alterations in encoded proteins. However, point mutation of C-RAS oncogene is linked to human cancer.

Frameshift Mutations

A frameshift mutation in a gene refers to the deletion or insertion of one or more nucleotide base pairs in numbers that are not multiple of three that changes the reading frame of the DNA sequence. Deletions remove nucleotide base pairs, and insertions add nucleotide base pairs.

- Genetic code is read in triplet nucleotides called codons. Each of these 'triplet codons' corresponds to one of 20 different amino acids used to build a

Table 6.44 Point mutation types, description, examples and effects

Point Mutation Types	Description	Point Mutation Examples	Point Mutation Effects
Silent mutation	Mutated codon codes for the same amino acid	CAA (glutamine) → CAG (glutamine)	None
Missense mutation	Mutated codon codes for a different amino acid	CAA (glutamine) → CCA (proline)	Variable effects
Nonsense mutation	Mutated codon is a remature stop codon	CAA (glutamine) → UAA (stop) usually	Serious effects

protein. Each coding sequence has three possible reading frames.
- Frameshift mutations show that genetic code is read triplets from a fixed starting point. If gene mutation disrupts the normal reading frame, then the entire gene sequence following the mutation will be incorrectly read. This can result in the addition of the wrong amino acids to the protein and/or the creation of a codon that stops the protein from growing longer leading to the synthesis of truncated proteins, that have lost their function, accelerating progression of malignant tumor.

Insertional Mutagenesis

In molecular biology, insertional mutagenesis is the creation of mutations by addition of one or more nucleotide base pairs.
- Such insertional mutagenesis can occur naturally, mediated by viruses or transposons (group of mobile genetic elements that are defined as a DNA sequence), or can be artificially created for research purposes in the laboratory to identify novel genes involved in the pathogenesis of human cancers.
- Insertional mutagenesis induces dysregulation of oncogenes or tumor suppressor genes, which can cause transformation of normal cell to CSC.
- Hepatitis B virus-related insertional mutagenesis in chronic hepatitis B patients is an early drastic genetic change leading to hepatocarcinogenesis.

CELLULAR AND MOLECULAR HALLMARKS OF CANCER

A cell is defined as the fundamental, structural and functional unit of all living organisms, which divides by two process: mitosis (somatic cell) and meiosis (gametes) and are tightly regulated by positive and negative regulators of cell cycle. Dysregulation of cell cycle is linked to human cancers of breast, colon, rectum, prostate, skin and stomach. Many cancers can be cured, if detected early by screening the patients (HPV testing and exfoliative cytology for cervical carcinoma, mammography for breast carcinoma, and colonoscopy for colon carcinoma), and treated effectively by surgery, radiotherapy and/or systemic therapy (chemotherapy, hormonal treatments, targeted biological therapies).
- The cellular and molecular hallmarks of cancer are the distinctive biologic capabilities acquired during multistep carcinogenesis by transformation of normal cell to cancer stem cell (CSC) leading to development of malignant tumor growth, invasion and distant metastasis to organ(s). Basic objective is to understand how cellular and molecular hallmarks of cancer can distinguish between normal cell and CSC.
- In early 2000, researchers Professor Hanahan and Professor Weinberg proposed that when normal cells progress towards a malignant phenotype and acquire distinctive capabilities, these have been termed '**hallmarks of cancer**', and characterized by distinctive biologic capabilities acquired by cells during multistep process of transformation of normal cell to CSC leading to tumor growth, invasion and metastasis to distant organs.
  - Writing about the complexity of the scientific literature in cancer in 2000, Professor Hanahan and Professor Weinberg brought a conceptual shift leading to the enumerate of '**six-core rules**' that orchestrate the multiple processes involved in transformation of normal cell to CSC.
  - Basic six 'Hallmarks of cancer' capabilities in the year 2000 include: (1) growth signal autonomy (unrestricted cell proliferation, (2) insensitivity to growth inhibitory (suppressor) signals, (3) evasion of apoptosis and survival CSCs even after substantial DNA damage resulting from downregulation of pro-apoptotic genes and upregulation of antiapoptotic genes), (4) enabling limitless replicative potential not limited by telomeres (immortalization), (5) induction and sustained tumor angiogenesis, and (6) activating invasion and metastasis.
  - Later in the year 2011, Professor Hanahan and Professor Weinberg included other four molecular hallmarks of cancer such as (7) reprogramming of energy metabolism (Warburg effect), (8) evasion of immune destruction, (9) genomic instability (mutated phenotype), and (10) tumor-promoting inflammation.
  - New dimensions expanding the frontiers of cancer biology in the year 2022 have been described by additional emerging hallmarks of cancer to the roster of functionally important cell types in the tumor microenvironment, which include: (11) phenotype plasticity and disrupted differentiation, (12) nonmutational epigenetic reprogramming, and (13) polymorphic microbiome. Cellular and molecular hallmarks of cancer are shown in Fig. 6.75 and given in Table 6.45.
- Cancer is caused by oncogenes resulting from activation ('**turning on**') of proto-oncogenes and/or inactivation/biallelic loss ('**turning off**') of tumor suppressor genes. Cellular and molecular hallmarks of cancer reflect alterations in cellular signaling pathways that drive cancer progression, that is achieved due to gene mutations that lead to activation of growth promoting oncogenes, inactivation/biallelic loss of tumor suppressor genes, evasion

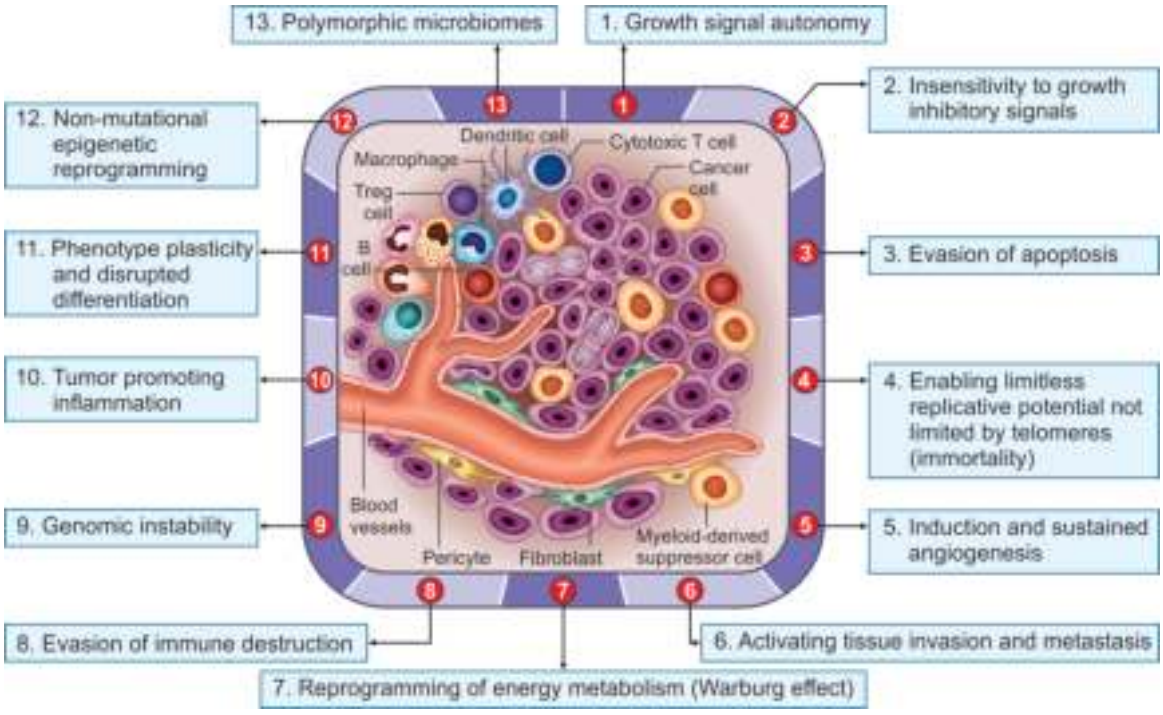

Fig. 6.75: Cellular and molecular hallmarks of cancer. These are the distinctive biologic capabilities acquired by cancer stem cells during multistep process of transformation of normal cell to cancer stem cell leading to tumor growth, invasion and metastatic dissemination.

Table 6.45 Cellular and molecular hallmarks of cancer and oncogenic activities

Oncogenic Driver Functions
▪ Growth signal autonomy (self-sufficiency of growth signal)
▪ Insensitivity to growth inhibitory signals
▪ Reprogramming of energy metabolism (Warburg effect)
Oncogenic Decreased Cell Attrition
▪ Cancer stem cells evade apoptosis
▪ Evasion of cellular senescence
▪ Cancer stem cells evade immune destruction
Oncogenic Invasion of Cancer Stem Cells
▪ Disruption of cell adhesion and cell polarity
▪ Cancer stem cells acquire motility property
▪ Extracellular matrix (ECM) degradation by matrix metalloproteinases (MMPs)
Oncogenic Fostering Functions
▪ Defective DNA repair and maintenance → Genomic instability
▪ Recruitment of normal immune cells and moulding of the tumor microenvironment → inflammation, angiogenesis and fibrosis

Pathology Pearls: Cellular and Molecular Hallmarks of Cancer

The Original Hallmarks of Cancer (2000) Proposed by Hanahan and Weinberg

1. Growth signal autonomy (self-sufficiency of growth signal)
2. Insensitivity to growth inhibitory (suppressor) signals
3. Evasion of apoptosis in cancer
4. Enabling limitless replicative potential not limited by telomeres (immortalization)
5. Induction and sustained angiogenesis
6. Activating tissue invasion and metastasis

The Next Generation (2011) updated by Hanahan and Weinberg

7. Reprogramming of energy metabolism (Warburg effect)
8. Evasion of immune destruction
9. Genomic instability
10. Tumor promoting inflammation

New Dimensions: Expanding the Frontier of Cancer Biology (2022)

11. Phenotype plasticity and disrupted differentiation
12. Non-mutational epigenetic reprogramming
13. Polymorphic microbiomes

of apoptosis and impaired DNA repair system. Genetic and epigenetic alterations are linked to carcinogenesis. Each major molecular hallmarks of cancer are antagonized by multiple tumor suppressor gene protein products.

GROWTH SIGNAL AUTONOMY (UNRESTRICTED CELL PROLIFERATION)

Normal cell remains in quiescent state (G0 phase) until stimulated by mitogenic growth signals from other cells, which enter into an active proliferative state resulting in

cell division tightly regulated by two sets of opposing functioning genes in normal cells: (a) proto-oncogenes (growth-promoting genes) and (b) tumor suppressor (growth inhibitory) genes.

- Mutated proto-oncogenes (i.e. oncogenes) can be classified according to the function of their oncoprotein products: growth factors (e.g. EGF, PDGF, VEGF, TGF-α, TGF-β, FGF, IGF, HGF, PGF, TNF-α, G-CSF, KGF, BMP), growth factor receptors (e.g. ERBB2/HER2 related to epidermal growth factor), GTP binding proteins (e.g. K-RAS, N-RAS), and nuclear binding proteins (e.g. Myc). EGFR inhibitors are therapeutic targets of this signaling pathway. Deregulated function of genes, i.e. activation of proto-oncogenes (i.e. oncogenes) and inactivation/biallelic loss of tumor suppressor genes leads to unrestricted cell division and carcinogenesis.
- Normal cell proliferation depends on external growth signals. Oncogenes are mutated form of proto-oncogenes, which code for oncoproteins (growth factors, growth factor receptors, GTP-binding proteins and transcription factor molecules), which positively regulate cell growth and differentiation. Oncogene activation results in sustained proliferation of CSCs, which can generate most of the oncogenic growth signals by themselves and induce unrestricted proliferation of CSCs.
- Oncoproteins can be produced in abnormally large quantity due to oncogene amplification (e.g. Myc oncogene in neuroblastoma) or increased transcription (Philadelphia chromosome 9/22 translocation in chronic myelogenous leukemia). Oncogenes, their mode of activation and associated cancers are given in Table 6.46.

Cell Cycle–Cell Division under Physiologic State

Cell cycle is a four-phase process: interphase (G1, S, G2) and mitotic phase (M phase). Cell cycle is tightly regulated by cell cycle positive regulators, i.e. cyclins/cyclin-dependent kinases (CDKs) and cell cycle negative regulators, i.e. RB protein, TP53 (p53 protein), INK family of CDK inhibitory proteins (p16, p15, p18, p19), and CIP/KIP (CDK interacting protein/kinase inhibitory proteins, i.e. p27, p21, p57).

Table 6.46 Oncogenes, their mode of activation and associated cancers

Proto-oncogene	Mode of Activation	Associated Malignancies
GTP-binding proteins (GTPase) involved in signal-transduction with oncogenic potential		
K-RAS (12p12.1)	Point mutation	▪ Colon carcinoma ▪ Lung carcinoma ▪ Pancreatic carcinoma
H-RAS (11p15)	Point mutation	▪ Renal cell carcinoma ▪ Urinary bladder carcinoma
N-RAS (1p13)	Point mutation	▪ Melanomas ▪ Hematologic malignancies
GNAO (16p13)	Point mutation	Uveal melanoma
GNAS (20q13)	Point mutation	▪ Pituitary adenoma ▪ Other endocrine tumors
Nonreceptor tyrosine kinase involved in signal-transduction with oncogenic potential		
ABL (Abelson mouse leukemia) (9q34.1)	▪ Translocation (9:22) ▪ Point mutation	▪ Chronic myelogenous leukemia (CML) ▪ Acute lymphoblastic leukemia (ALL)
RAS signal-transduction involved in signal-transduction with oncogenic potential		
BRAF (7q34)	Point mutation/translocation	▪ Hairy cell leukemia (100%) ▪ Melanoma (60%) ▪ Colon carcinoma ▪ Dendritic cell tumor ▪ Benign nevi
NOTCH signal-transduction involved in signal-transduction with oncogenic potential		
NOTCH1 (9q34.3)	Point mutation/translocation/gene rearrangement	▪ Leukemias ▪ Lymphomas ▪ Breast carcinoma
JAK/STAT signal transduction involved in signal-transduction with oncogenic potential		
JAK2 (Janus kinase 2) (9p24.1)	Translocation	▪ Myeloproliferative disorders ▪ Acute lymphoblastic leukemia (ALL)

- Extracellular mitogenic growth signals are transmitted to the normal cell through transmembrane tyrosine kinase receptors (RTKs) that bind to a specific class of cytoplasmic signaling transducing molecules such as additional cytoplasmic proteins and second messenger molecules, and initiate signaling transduction to the nucleus.
- The signaling pathway initiates DNA transcription of genes involved in cell growth, by binding of transcription factors to DNA regulatory proteins and recruiting chromatin remodelers to carry out gene transcription leading to cell cycle progression and cell division. In this way, mitogenic growth signals maintain cellular and tissue homeostasis. On the contrary, disruption in signaling pathways results in unrestricted cell division leading to carcinogenesis and development of malignant tumor.

Cell Cycle Deregulation and Unrestricted Proliferation of Cancer Stem Cells

Cell cycle is disrupted in human malignancies. Cancer stem cells generate their own growth signaling molecules (e.g. EGF/EFGR) and thereby reducing their dependence on external stimulation.

- CSCs respond by autocrine and paracrine mechanisms. Sustained CSC proliferative signaling occurs due to defect in negative feedback mechanisms such as insensitivity to growth inhibitory (tumor suppressor) signals, evasion of apoptosis (CSC survival even after substantial DNA damage), enabling limitless replicative potential not limited by telomeres (immortality), and genomic instability.
- Sustained proliferative signaling occurs by various mechanisms: (a) alterations in extracellular growth factor signals, (b) alterations of transmembrane receptor's growth signals, (c) alteration in GTP binding proteins, (d) aberrant signal transduction proteins, (e) aberrant nuclear transcription factors, and (f) alterations in intracellular circuits that translate those growth signals into action.

Pathology Pearls: Molecular Techniques to Assess Cell Proliferation

- Cell proliferation can be used to analyze health of normal cell, responses to toxic insult, and assess prognostic and diagnostic tool in several human cancers. The available markers typically look at the level of DNA synthesis, cellular metabolism and synthesis of specific proteins involved in cell division. A number of methods exist to assess cell proliferation and they vary in regard to which phase of cellular growth and cell division.
- The principal approaches are being used to assess cell proliferation, based on three aspects of cell division: (a) nucleoside analog (b) incorporation during DNA synthesis, and (c) cell cycle associated proteins and cytoplasmic proliferation dyes.
  - **Ki-67**, a marker of cell proliferation, is a nonhistone nuclear protein expressed throughout the active phase of cell cycle, except G0 and early G1 and used to asses cell proliferation in formalin-fixed paraffin-embedded tissue sections. It has become an important and reliable predictive marker in breast ductal carcinoma.
  - **Minichromosomal maintenance 2 (MCM2)** is also used to assess cell proliferation as a prognostic marker in certain human cancers.
  - Edu (5-Ethylene-3 deoxyuridine) is the preferred marker of choice to assess cell proliferation. DNA synthesis is the most reliable and accurate method to assess cell proliferation.
- Living cells are incubated with thymidine analogs (compounds) capable of being incorporated into newly synthesized DNA during replication and then assessed. It is important to be aware that thymidine analogs can induce gene mutations and DNA damage in some instances and thereby affect the cell cycle. Thus, method is suitable for immunohistochemistry (**IHC**), enzyme-linked immunosorbent assay (**ELISA**), flow cytometry and some multiplex assays.
- Cell proliferation can be assessed by measuring the cellular metabolic activity in culture via tetrazolium salts, which form a dye present in a metabolic active environment. The resulting color change of the media can be quantified in a spectrophotometer, giving an indication of the extent of cell proliferation. Molecular techniques to assess cell proliferation are given in Table 6.47.

INSENSITIVITY TO GROWTH INHIBITORY (SUPPRESSOR) SIGNALS (INACTIVATION/BIALLELIC LOSS OF TUMOR SUPPRESSOR GENES)

Multiple growth inhibitory (suppressor) signals maintain homeostasis in normal tissues by pushing cells out of cell cycle into temporary quiescent state, or sending them into their terminal, most differentiation state. Due to genomic instability, most cancer stem cells (CSCs) evade cleverly normal growth inhibitory (suppressor) signals in the G1 checkpoint of cell cycle by subverting the mechanisms that control cell cycle progression e.g. by disrupting TP53 (p53) and pRB signaling pathways, and over-expressing growth-stimulatory factors such as c-Myc. If carcinogenesis is to be successful, these endogenous tumor suppressors must be evaded or inactivated. Another important molecular hallmark of cancer is the lack of cell-cell contact inhibition. On contrary, in normal self-regulatory process, cells stop proliferating once cell-to-cell contact is established.

Table 6.47 Molecular techniques to assess cell proliferation

Assay Analysis	Cell Cycle Phase	Major Equipment	Recommended Applications
Nucleoside-analogues (DNA synthesis) analysis—molecular diagnostic technique			
Tritiated thymidine to label DNA	S phase	Liquid scintillation counter	Cell culture, mixed lymphocyte reactions
BrdU (5-bromo-2'-deoxy-uridine) to label DNA	S phase	▪ Flow cytometry ▪ Light microscopy ▪ Fluorescence microscopy	*In vivo* for the assessment of cell proliferation over time
Idu (idoxuridine) to label DNA	DNA replication fork progression rates, stability or origin of firing	Immunohistochemical analysis of formalin-fixed paraffin-embedded sections	Histology
Edu (5-ethylene-3 deoxy-uridine) to label DNA	G1/S and G2/M	Immunohistochemical analysis of formalin-fixed/paraffin-embedded sections	Histology
Cell cycle-associated proteins analysis—molecular diagnostic technique			
Ki-67 proliferative marker	G1, S, G2, M phases	▪ Flow cytometry ▪ Light microscopy ▪ Fluorescence microscopy	Histology
Phosphorylated-histone H3 marker analysis	M phase	▪ Flow cytometry ▪ Light microscopy ▪ Fluorescence microscopy	Histology
Proliferating cell nuclear antigen marker	S phase	▪ Flow cytometry ▪ Light microscopy ▪ Fluorescence microscopy	Histology
Cytoplasmic proliferation dye analysis—molecular diagnostic technique			
Carboxyfluorescein diacetate succinimidyl ester fluorescent dye for cell labeling	Cytokinesis	Flow cytometry	*In vivo* proliferation monitoring of transferred stained cells, mixed lymphocyte reactions
Cell trace violet for cell labeling	Cytokinesis	Flow cytometry with a 405-nm laser	*In vivo* proliferation monitoring of transferred stained cells, mixed lymphocyte reactions

Tumor Suppressor Genes Coding for Growth Inhibitory (Suppressor) Signals in Normal Cells

Within normal cells, multiple growth-inhibitory (suppressor) signals transmitted by tumor suppressor genes operate to maintain cellular quiescence and tissue homeostasis. Tumor suppressor genes code for proteins, that act to restrain inappropriate cell growth and cell division, as well as to stimulate apoptosis, before they can travel down the road to development of malignant tumor. Some of the tumor suppressor genes are involved in DNA repair processes. Inactivation/biallelic loss of these tumor suppressor genes can be disastrous.

- Binding of soluble growth inhibitory (suppressor) molecules to cell surface receptors are coupled to intracellular signaling circuits. Numerous growth inhibitory (suppressor) signals maintain the homeostasis in normal cells by pushing cells out of cell cycle into a temporary quiescent state (G0 phase), or sending normal cells into their terminal post-mitotic differentiation state.
- TP53 and RB1 tumor suppressor genes code for p53 protein and retinoblastoma protein (pRB) respectively. The p53 protein functions as a **central regulator of cell cycle**, that arrests the cell cycle upon detection of DNA damage. Retinoblastoma protein (pRB) inhibits the normal cells' passage through the restriction point in the G1 phase. The pRB protein integrates signals from diverse extracellular and intracellular sources and in response, decides whether or not a cell should proceed through its cell growth and cell division.
- Survival of normal cells is dependent on signals from extracellular growth factors, attachment of cells to solid surface, contact with other cells, and limited number of cell division before entering senescence.

Survival of Normal Cells Dependent on Signals from Extracellular Growth Factors

Survival of normal cells is dependent on signals from extracellular growth factors. On contrary, CSCs are able to survive in the absence of growth factors required by their normal counterparts. In normal cells, TGF-β

initially inhibits cell progression through G1 phase of cell cycle. However, at later stage in many cancers, TGF-β signaling is redirected away from suppression to activation of a cellular programme termed 'epithelial–mesenchymal transition' (**EMT**), which plays pivotal role in development of malignant tumor progression, invasion and metastasis to distant organ(s).

Epithelial–mesenchymal transition process is associated with reduction in the epithelial-like features of CSCs, and acquisition of mesenchymal-like features that are essential to mediate effective invasion and migration. EMT mechanism is regulated by transcription factors (i.e. SNAIL, ZEB, TWIST).

Anchorage-dependent Normal Cell Proliferation

Normal cells must be attached to a solid surface to divide, which require interaction of transmembrane proteins (integrins) with the components of extracellular matrix (ECM). Epithelial cells and connective tissue cells are anchorage-dependent cells. On the contrary, blood cells and CSCs are anchorage-independent cells. Moreover, anchor-dependent cells are mainly used in the manufacture of viral vaccines, while anchorage independent cells are required in cancer research studies. Comparison of anchorage-dependent and anchorage-independent cell proliferation is given in Table 6.48.

Cell-to-Cell Contact Inhibition

Cell-to-cell contact inhibition is defined as cessation of cellular movement, growth and cell division upon contact with other cells. When a normal cell loses cell-to-cell ability, it starts unrestricted cell division leading to development of malignant tumor. Cell-to-cell contact is mediated by transmembrane proteins called **E-cadherin**. Two mechanisms have been proposed to explain that E-cadherin maintains contact inhibition.

- **NF2 tumor suppressor gene (merlin)-mediated mechanism:** NF2 tumor suppressor gene mapped on chromosome 22 codes for '**merlin**' protein, that acts downstream of E-cadherin in signaling pathway involved in maintenance of cell-to-cell contact inhibition. NF2 gene mutation fails to maintain cell-to-cell contact inhibition. Homozygous loss of NF2 gene is linked to neural tumors. Germline mutation in NF2 gene is associated with hereditary neurofibromatosis type 2.
- **Adenomatous polyposis coli (APC) tumor suppressor gene E-cadherin/β-catenin interaction mechanism:** E-cadherin regulates cell-to-cell contact by involving its binding to β-catenin signaling protein, which is a key component of Wnt signaling pathway, that regulates the morphology and organization of epithelial cells lining the large intestine. APC gene exists in equilibrium with E-cadherin and β-catenin.
  - **Normal adenomatous polyposis coli (APC) tumor suppressor gene function:** APC gene mapped on chromosome 5 encodes APC protein, that degrades β-catenin. In addition, APC protein binding to E-cadherin, β-catenin is key component of Wnt signaling pathway involved in cell–cell adhesion.
  - **Adenomatous polyposis coli (APC) tumor suppressor gene mutation:** APC gene mutation encodes aberrant APC protein, that is linked to adenomatous polyposis coli, in which patient develops numerous adenomatous polyps in the colon, which later may undergo malignant transformation (i.e. colon carcinoma). APC gene mutation prevents β-catenin degradation that leads to sustained activation of Wnt signaling pathway, even in the absence of transcriptional factors. The β-catenin translocates and accumulates into nucleus of colonic epithelium, where it acts as a transcription activator of growth-promoting genes (i.e. cyclin D1, Myc) as well as transcriptional regulator genes (TWIST, SLUG), which repress E-cadherin expression.

Normal Somatic Cells with Limited Proliferative Activity

Normal somatic cells have a limited number of cell divisions before entering senescence. As the cells differentiate, their rate of proliferation decreases, and thus most adult normal cells are arrested in the G0 phase of the cell cycle. Some differentiated permanent

Table 6.48 Comparison of anchorage-dependent and anchorage-independent cells

Characteristics	Anchorage-Dependent Cells	Anchorage-Independent Cells
Definition	Anchorage-dependent cell survives when attached to inert surface	Anchorage-independent cell has lost the requirement of attachment to a surface
Examples of anchorage dependent/independent cells	Epithelial cells and mesenchymal cells	White blood cells and CSCs
Clinical usage	Manufacture of viral vaccines	Cancer research studies purpose
Industrial usage	Anchorage-dependent cell are used for industrial purpose in large quantities	Anchorage-dependent cells are not used for industrial purpose

cells in nervous system never divide again. Stable cells resume proliferation to replace cells that have been lost as a result of cell injury or cell death.

- Hematopoietic cells in bone marrow, and epithelial cells lining skin and digestive tract have short life span and must be replaced by continuous hematopoietic stem cell (HSC) proliferation in adult tissues/organs throughout life. Cell proliferation is thus carefully balanced with programmed cell death to maintain a constant number of cells in adult tissues and organs. On the contrary, CSCs have unlimited capacity to proliferate, which induce malignant tumors of breast, brain, lung, prostate, esophagus and colon.

Mutated Tumor Suppressors (Growth Inhibitory Signals) Linked to Human Cancers

Without functional tumor suppressor genes, there is a high-risk of dysregulated cell growth, that can result in development of malignant tumors. Mutations in tumor suppressor genes have been detected in many human cancers of ovary, breast, lung, colorectal region, pancreas, head and neck, uterus and urinary bladder. Several familial cancer syndromes including Li-Fraumeni syndrome are associated with mutations in TP53 tumor suppressor genes. Insensitivity to growth inhibitory (suppressor) signals in human cancers is given in Table 6.49.

Table 6.49 Insensitivity to growth inhibitory (suppressor) signals in human cancers

Key Marker	Gene Locus	Gene Product	Gene Function	Gene Mutations and Human Cancers
RB1 gene	13	pRB	Cell division, DNA replication and apoptosis	Biallelic loss of RB1 gene results in retinoblastoma
TP53 gene	17	p53	'Guardian of the genome' involved in cell division, DNA replication and apoptosis	TP53 gene mutation linked to several cancers including Li-Fraumeni syndrome (e.g. breast, bone, soft tissue, brain, adrenal cortex)
APC (adenomatous polyposis coli) gene	5	APC protein	APC gene is a component of Wnt/β-catenin signaling pathway	APC gene mutation linked to familial adenomatous polyposis coli that may progress to colon carcinoma
BRCA1 gene	17	BRCA1 protein	DNA repair and cell cycle	BRCA1 gene mutation linked to triple negative breast cancer (e.g. ER/PR/HER2/neu)
BRCA2 gene	13	BRCA2 protein	DNA repair and cell cycle	BRCA2 gene mutation linked to estrogen positive breast cancer
Phosphatase and tensin homolog (PTEN) gene	10	PTEN protein	PTEN gene is a component of PI3K-AKT-mTOR signaling pathway that regulates cell division	PTEN gene mutation linked to glioblastoma multiforme, lung carcinoma, breast carcinoma, prostatic carcinoma
CDKN2A (Cyclin-dependent kinase inhibitor 2A) gene	9	p16 and p14 proteins	Cell division, apoptosis	CDKN2A (INK4A) mutation linked to melanoma and many different cancers
WT1 gene	11	WT1 transcription factor	Cell division, cell survival, and angiogenesis	WT1 gene mutation linked to familial Wilms tumor
WT2 gene	11	WT1 transcription factor	Cell division, cell survival	WT2 gene mutation linked to Beckwith-Wiedemann syndrome
NF1 gene	17	Neurofibromin	RAS signaling pathway and cell division in nervous system	NF1 gene mutation linked to malignant peripheral nerve sheath tumor (MPNST), brain cancer, breast carcinoma
NF2 gene	22	Merlin or schwannomin	Cell shape, cell growth and cell-to-cell adhesion	NF2 gene mutation linked to bilateral vestibular schwannomas (acoustic neuroma) and several additional both benign and malignant tumors

Loss of Heterozygosity (LOH)

Mutant one allele of tumor suppressor gene behaves as a recessive, that is, as long as the gene contains one normal allele, which has adequate tumor suppressor activity that is known as **heterozygous state**. Inactivation/biallelic loss of tumor suppressor gene is linked to cancer, and is known as '**loss of heterozygosity**'. Retinoblastoma develops due to mutations in both alleles of RB gene. On the contrary, when one mutant allele of oncogene leads to malignant tumor formation, and it is known as **homozygous state**.

Tumor Suppressor Gene Mutations and Cancer

Caretaker tumor suppressor genes (BRCA1, BRCA2, MLH1, MSH2, MSH6, PMS2, FAMC, and Xp) maintain the integrity of the genome by repairing DNA damage. Gatekeeper genes (TP53 gene, RB and APC) inhibit the cell proliferation with damaged DNA, and also promote apoptosis of cells with DNA damage.

- Some examples of caretaker and gatekeeper tumor suppressor gene mutations associated with human cancers include: retinoblastoma (RB gene mutation), Li-Fraumeni syndrome (TP53 gene mutation), breast carcinoma and ovarian carcinoma (BRCA1 BRCA2 gene mutations), familial adenomatous polyposis/colon carcinoma (APC gene mutations), breast carcinoma (BRCA1/BRCA2, PTEN gene mutation), and hereditary nonpolyposis colon carcinoma (HNPCC) are called Lynch syndrome (MLH1, MSH2, MSH3, MSH6, PMS1, PMS2 gene mutations).

Pathology Pearls: Key Players in Cell Growth Suppression

- Key players in cell growth suppression include: (a) **TP53 gene** senses the need to inhibit cell progression and trigger apoptosis, and (b) **RB gene** is gatekeeper of cell cycle progression.
- TP53 tumor suppressor gene mutations are demonstrated in more than 50% of human cancers. **Li-Fraumeni syndrome** is genetic disorder due to germline mutation in TP53 gene that increases risk of family members to develop cancers. Females at birth, who have Li-Fraumeni syndrome have a nearly 100% risk for breast cancer.

Haploinsufficiency Susceptivity Genes: Model of Dominant Gene Actions

Haploinsufficiency in genetics describes a model of dominant gene action in diploid organisms in which a single copy of the standard **wild-type gene** is **inactivated** or **deleted**, and the remaining functional copy of the gene is not adequate to produce the needed particular gene protein product to preserve normal cell function. It is one of the major causes of certain dominant inherited diseases, as heterozygosity or hemizygosity elicits significant phenotypic impacts. Haploinsufficiency susceptibility gene mutation and associated syndromes are given in Table 6.50.

Table 6.50 Haploinsufficiency susceptibility gene mutation and associated syndromes

Haploinsufficiency Susceptibility Gene	Gene Mutation and Associated Syndrome
Deregulation of translation function	
PTEN gene	Cowden syndrome (multiple hamartomas)
LKB1 gene	Peutz-Jeghers syndrome
PTCH1 gene	Nevoid basal cell syndrome
Deregulation of cell proliferation function	
NF1 gene	Neurofibromatosis type 1 syndrome
APC gene	Familial adenomatous polyposis (FAP)
Deregulation of genetic integrity and apoptosis function	
BLM gene	Bloom syndrome
TP53 gene	Li-Fraumeni syndrome (100% risk for breast cancer)

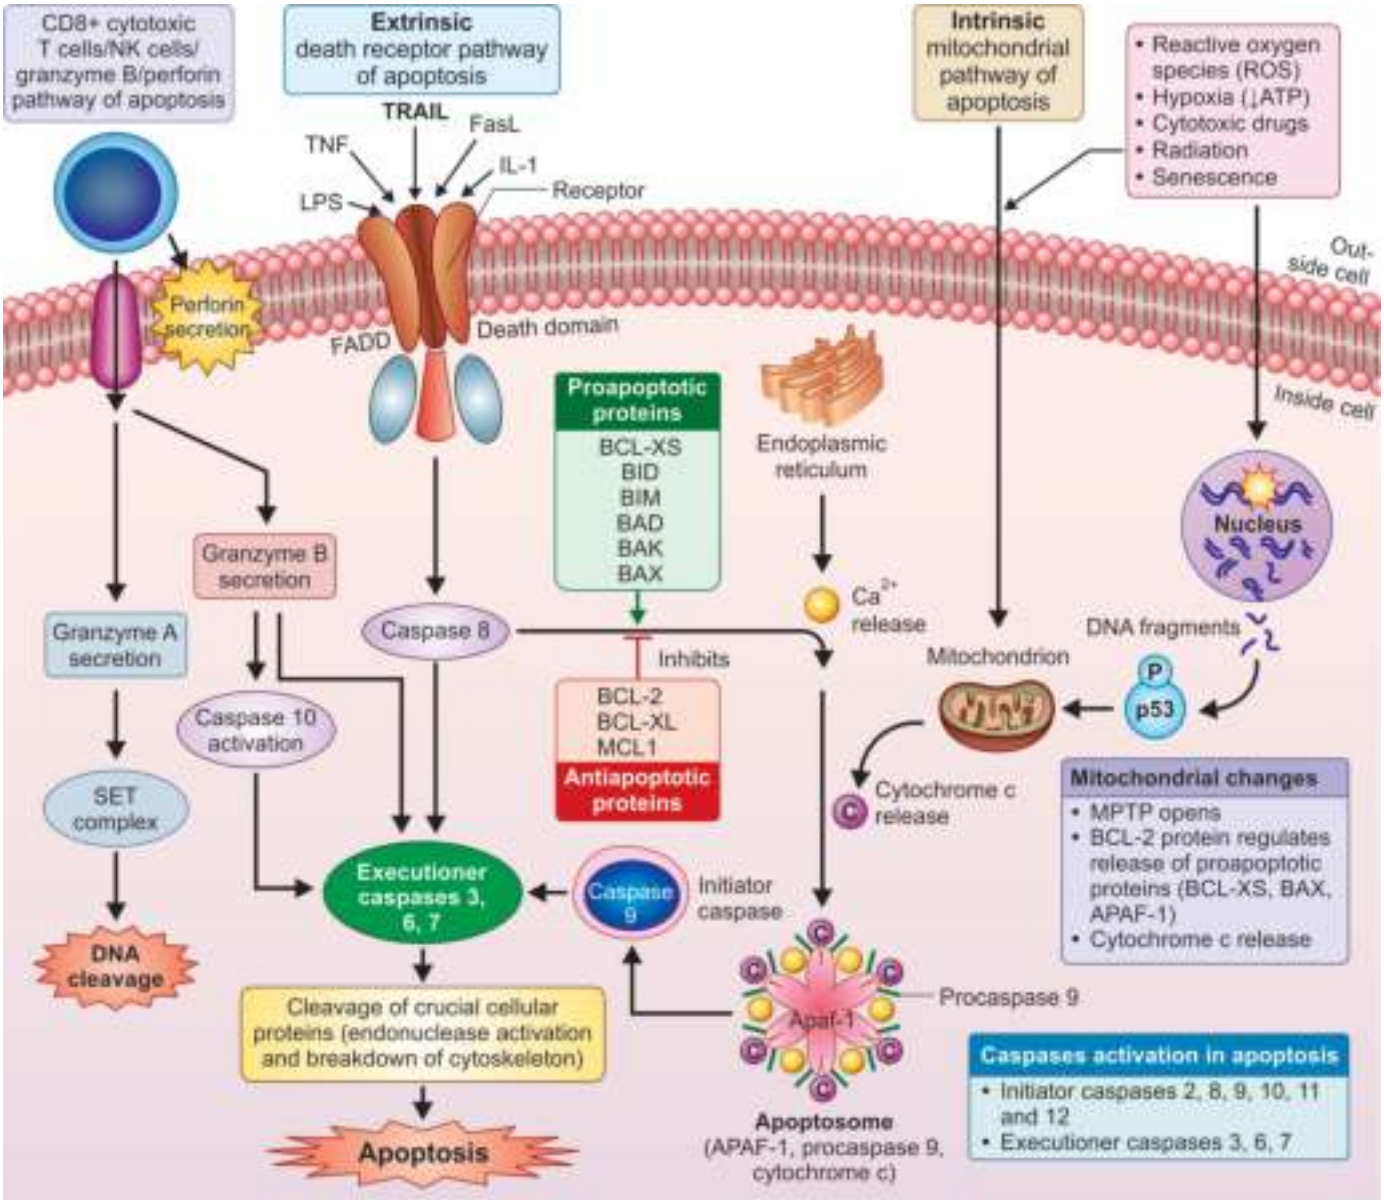
EVASION OF APOPTOSIS (PROGRAMMED CELL DEATH)

Apoptosis is the process of programmed cell death that maintains tissue homeostasis during embryogenesis to eliminate unwanted cells between fingers of developing hands. In adults, apoptosis is used to get rid of damaged cells beyond repair. Apoptosis also plays a role in preventing cancer.

- Apoptosis occurs by extrinsic (death receptor) and intrinsic (mitochondrial) pathways mediated by a family of proteases, called caspases. Both extrinsic and intrinsic pathways can flow independently until the last step of DNA degradation by **executioner caspases 3, 6** and **7**. The caspases cause proteolysis of specific substrates resulting in various morphologic and biochemical characteristics in apoptotic cells.
  - The extrinsic pathway can be engaged by activation of death receptors of the tumor necrosis factor (TNF) superfamily such as Fas (Apo/CD95) TNF receptor 1 (TNFR-1). TNF-related apoptosis inducible ligand (TRAIL) receptors and others located on the cell surface, by binding with their ligands.
  - On the contrary, intrinsic pathway of apoptosis is primarily regulated by the B cell lymphoma (BCL-2) family of proteins, that is activated by internal stress sensors in response to cellular stresses like nutrient deprivation, DNA damage and hypoxia.
  - It must be noted that perforin/granzyme apoptotic pathway is the primary signaling pathways used in activation of CD8+ cytotoxic T cells, which eliminate virus-infected and/or transformed CSCs.
- Detachment of CSCs from extracellular matrix (ECM) can also induce a form of apoptotic cell death called '**anoikis**', which acts to control the growth and attachment of detached CSCs to a different

ECM. Resistance to anoikis is an attribute of CSCs with metastatic potential. Anoikis can engage both extrinsic and intrinsic pathways of apoptosis.

- Schematic representation of apoptosis mediated by extrinsic (death receptor) and intrinsic (mitochondrial) pathways are shown in Fig. 6.76.



Morphologic changes	Apoptosis is characterized by cell shrinkage, chromatin condensation, nuclear fragmentation, plasma membrane blebbing without loss of cell integrity, organelles in the plasma membrane blebs, generation of apoptotic bodies.
Clearance	Degradation of apoptotic bodies by phagocytes (macrophages and surrounding cells).
Laboratory diagnosis	Techniques for detection of apoptotic cells include: (a) cytomorphologic changes, (b) DNA discontinuous fragmentation ladder assay on agarose gel electrophoresis, (c) TUNEL assay, executioner caspase 3 and annexin V (IHC), (d) p53, executioner caspase 3 activation, FasR, TNF-α, and TRAIL (IHC, RT-PCR, Western blot, ELISA), and (e) cytochrome c release (ELISA).

Fig. 6.76: Schematic representation of apoptosis mediated by extrinsic (death receptor) and intrinsic (mitochondrial) pathways. Both extrinsic (death receptor-mediated) and intrinsic (mitochondrial-mediated) pathways can flow independently induced by initiator caspases (2, 8, 9, 10, 11, 12) until the last step of DNA degradation by executioner caspases 3, 6, 7. The execution pathway of apoptosis results in characteristic cytomorphological features, i.e. cell shrinkage, chromatin condensation, nuclear fragmentation by endonuclease, plasma membrane blebbing, intact and preserved cytoplasmic organelles, generation and phagocytosis of apoptotic bodies by macrophages and surrounding epithelial cells and lack of inflammation. Perforin/granzyme apoptotic pathway is the primary signaling pathways used in activation of CD8+ cytotoxic T cells to eliminate virus-infected cells and/or transformed CSCs.

Pathology Pearls: Morphologic Changes in Apoptosis and Diagnostic Techniques

Cytomorphological Changes in Apoptotic Cells

- Apoptosis is characterized by several cytomorphologic features such as cell shrinkage, cell membrane blebbing, cytoplasmic organelles intact and preserved, apart from some swelling of the endoplasmic reticulum, chromosome condensation (**pyknosis**), nuclear fragmentation (karyorrhexis), DNA laddering and the eventual engulfment of the cell apoptotic bodies by phagosomes (i.e. macrophages and surrounding tissue cells).
- Phagocytic cell synthesizes cytokines (TGF-β, IL-10), which inhibit inflammation, and the apoptotic bodies are then phagocytosed by macrophages and surrounding tissue cells within an hour, rendering their appearance very transient. Kindly refer apoptosis in details in Chapter 1 'Cellular Pathology and Biology of Aging'.

Diagnostic Techniques to Detect Apoptotic Cells

- There are many diagnostic techniques available for the detection of apoptotic cells; based on cytomorphologic changes and biochemical events in apoptosis.
- Apoptosis is diagnosed to detect DNA fragmentation (DNA ladder assay, TUNNEL assay and Comet assay), phosphatidylserine (Annexin V, flow cytometric analysis), BID, p53 (RT-PCR technique, Western blot technique, ELISA analysis, flow cytometric analysis, immunohistochemistry), caspase activation (Western blot, ELISA, flow cytometric analysis), FAS, TNF, TRAIL (RT-PCR, Western blot, immunohistochemistry), and 'cytochrome c' release ELISA analysis.

Cancer Stem Cells Evade Apoptosis

Cancer stem cells (CSCs) are resistant to apoptosis, which acquire the overwhelming ability to evade apoptosis, thereby the genetically mutated CSCs become immortalized leading to carcinogenesis.

- Evasion of apoptosis allows CSCs to survive even with sustained DNA damage; resulting from various mechanisms: (a) loss of TP53 gene (p53 protein) leads to reduced function of pro-apoptotic proteins (e.g. BAX, BAK, BCL-Xs, BIK, BIM, BID, BAD), (b) reduced egress of 'cytochrome c' from mitochondria as a result of upregulation of anti-apoptotic proteins (e.g. BCL-2, BCL-XL, MCL-1), (c) loss of apoptotic peptidase activating factor 1 (APAF1), (d) upregulation of inhibitors of apoptosis, (e) reduced CD95 level in hepatocellular carcinoma, (f) inactivation of death-induced signaling complex Fas associated death domain (FADD). Mechanisms contributing to evasion of apoptosis in human cancers are shown in Fig. 6.77 and Table 6.51.
- Some cancers have high-level of anti-apoptotic proteins (e.g. BCL-2) that bind to death-inducing signaling complex Fas associated death domain (FADD) and thus, prevent the activation of caspase 8. BCL-2 activation inhibits apoptosis (programmed cell death) of atypical lymphocytes in Burkitt's lymphoma, which accumulate in the lymph nodes, bone marrow, and spill over in the blood circulation.
- Intrinsic (mitochondrial) apoptotic pathway is most often disabled in human cancers. Capspase 8, BCL-2 gene and TP53 gene products are among key apoptotic signaling proteins, that are known to be mutated in many human malignancies of breast, lung, kidney (renal cell carcinoma), ovary, endometrium, head and neck, melanoma, and hematopoietic tissue (leukemia and Burkitt's lymphoma).
- Cancer stem cells (CSCs) also evade apoptosis resulting from upregulation of phosphoinositide 3-kinase (PI3K)/AKT/mTOR signaling pathway and nonsignaling decoy receptor for Fas ligand.

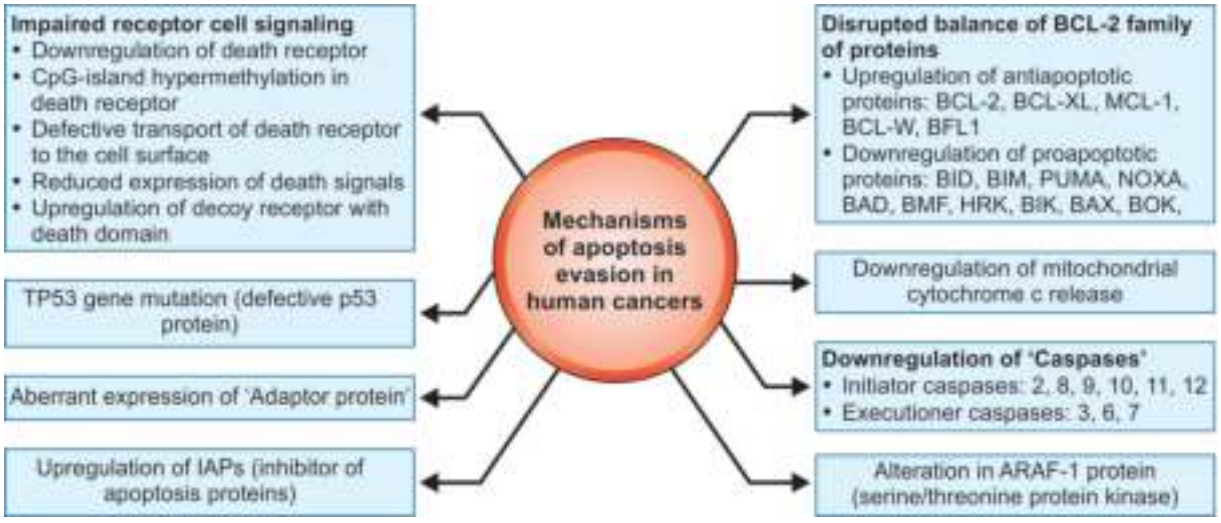


Fig. 6.77: Mechanisms contributing to evasion of apoptosis in human cancers. CSCs may escape apoptosis by downregulation of proapoptotic genes, upregulation of antiapoptotic genes respectively.

Table 6.51 Mechanisms contributing to evasion of apoptosis in human cancers

Disrupted Balance of BCL-2 Family of Proteins and Evasion of Apoptosis
▪ ↑Antiapoptotic proteins (BCL-2, BCL-XL, MCL-1, BCL-W, A1/BF1, BCLB/BCL-2-L10)
▪ ↓Proapoptotic proteins (BID, BIM, PUMA, NOXA, BAD, BMF, HRK, BIK, BAX, BOK)
Impaired Receptor Cell Signaling and Evasion of Apoptosis
▪ ↓Death cell surface receptor
▪ ↓Defective transport of death receptor ligand to the cell surface
▪ ↓Death receptor signaling
▪ ↑Decoy receptor with death domain
Dysregulation of Key Molecules and Evasion of Apoptosis
▪ ↑Inhibitor of apoptosis proteins (IAPs)
▪ Aberrant expression adaptor protein
▪ Inactivation of death-induced signaling complex FADD (Fas associated via death domain).
▪ Inactivation/biallelic loss in TP53 gene leads to reduced function of proapoptotic factors (e.g. BAX, BAK, BCL-Xs, BIK, BIM, BID, BAD)
▪ ↓Caspases expression
▪ ↓Apoptotic peptidase activating factor 1 (APAF1)
▪ ↓Egress of cytochrome C release from mitochondria resulting from upregulation of antiapoptotic factors (e.g. BCL-2, BCL-XL, MCL-1)
▪ ↓CD95 level in hepatocellular carcinoma
▪ ARAF-1 (A-RAF-1) serine/threonine-kinase protein alterations
▪ CpG-island hypermethylation in death receptors

Mutation in TP53 Tumor Suppressor Gene and Cancer Stem Cells Evading Apoptosis

Evasion of apoptosis can be acquired by the CSCs using a variety of strategies. TP53 tumor suppressor gene mapped on chromosome 17p13 codes for p53 protein, that acts as a 'guardian of cellular DNA'. The p53 protein either repairs damaged DNA before cell division by inducing cell cycle arrest at G1/S transition to allow time for DNA repair or force the cell to undergo apoptosis via activation of BAX gene and downregulation of BCL-2 antiapoptotic gene, and thus suppresses development of malignant tumor growth.

- Pathway of apoptosis-induced by normal TP53 gene involves: TP53 gene (p53 protein) phosphorylation → activation of BAX, PUMA and NOXA → cytochrome c release, and activation of apoptosome formation (α_1-apoptotic peptidase activating factor 1, cytochrome c, procaspase) → activation of caspase 9 → activation of caspase 3, 6, 7 → induction of apoptosis.
- Cancer stem cells (CSCs) evade apoptosis due to inactivation/ biallelic loss of TP53 tumor suppressor gene. Loss of apoptotic peptidase activating factor 1, and increased inhibitors of apoptosis (IAP) promote immortalization of CSCs. Upregulation of MCL-1 (BCL-2 member) prevents apoptosis of CSCs that leads to immortalization of chemoresistance.
- The p53 immunomarker may be useful as serum tumor marker, that differentiates p53 positive malignant tumors (carcinoma *in situ* and invasive carcinoma) from p53 negative reactive/metaplastic processes. The p53 immunomarker can distinguish p53 positive serous endometrial carcinoma from negative endometrioid carcinoma in formalin fixed paraffin-embedded tissue sections.

Disruption of Phosphoinositide 3-Kinase/AKT/mTOR Signaling Pathway and Cancer Stem Cells Evading Apoptosis

The phosphoinositide 3-kinase (PI3K)/AKT/mTOR signaling pathway is frequently activated in human cancers and represents an attractive target therapies based on small molecule inhibitors. PI3K isoforms play pivotal role in the signal transduction events activated by cell surface receptors, i.e. receptor tyrosine kinases (RTKs) and G protein-coupled receptors (GPCRs). PI3K/AKT/mTOR signaling pathway is found to be upregulated either by extracellular factors such as GF-1 and IL-3, or by intracellular signals involving RAS protein, thus resulting in escape of CSCs from apoptosis.

Disruption of Nonsignaling Decoy Receptor for FAS Ligand and Cancer Stem Cells Evading Apoptosis

Recently, activation of nonsignaling decoy receptor for Fas ligand evades apoptosis of CSCs in lung carcinoma and colon carcinoma, by decreasing the intensity of death inducible signal and moving most of it away from Fas death receptor CSCs. It can also lead to the identification of novel targeted therapeutic agents. Purpose of chemotherapeutic agents is to induce apoptosis of CSCs. Development of multidrug chemoresistance in CSCs has been attributed to apoptosis resistance. It is therefore mandatory to understand the biologic pathways involved in imparting apoptosis resistance and to overcome of multidrug resistance development in treating cancers.

Pathology Pearls: Cell Surface Nucleolin and Evasion of Apoptosis by CSCs

- Multifunctional RNA-binding '**nucleolin**' protein encoded by NCL gene, that is primarily distributed in the nucleolus (90%), cytoplasm, and cell membrane.
- Cell surface nucleolin can bind to various ligands to affect many physiologic functions including ribosomal biogenesis, processing of ribosomal RNA (rRNA), messenger RNA

stability, downstream target of several regulation of signal transcriptional pathways and cell proliferation. Nucleolin interacts with DNA repair proteins to maintain **genomic stability** via stability of apoptosis-related mRNAs by binding to nucleolin RNA-binding domain (RBD) to the 5' and 3' UTR of mRNA and inhibit apoptosis.

- The expression and localization of nucleolin is often abnormal in human cancers, as the differential distribution of nucleolin can influence carcinogenesis, CSC proliferation, survival, angiogenesis, invasion and metastasis to distant organ(s). Thus, nucleolin may be a novel and promising target for anticancer treatment.
- Cell-surface nucleolin can bind to Fas and block the interaction of Fas/FasI, which prevents CSCs from entering Fas-induced apoptosis. The interaction of cell-surface nucleolin with ERB1 and RAS also favors unrestricted cell proliferation. Therefore, cell-surface nucleolin can facilitate anti-apoptotic phenotype and induce initiation and survival of CSCs.
- Upregulation of nucleolin can also elevate levels of anti-apoptotic BCL-2 protein in CSCs. Nucleolin binds to BCL-2, thereby increasing half-life of BCL-2. The anti-apoptotic BCL-2 protein is overexpressed in a variety of human cancers, particularly leukemias. Nucleolin also interacts with microRNAs 15, 6 which are negative regulators of BCL-2 expression.

ENABLING REPLICATIVE POTENTIAL (IMMORTALITY)

Enabling replicative potential (immortalization) of CSCs is one of the key hallmarks of cancer. CSCs have limitless replicative potential, that permit malignant neoplastic cells to avoid cellular senescence and mitotic catastrophe.

- Normal cells possess finite life span and limited number of successive **60–70 cell divisions**, which self-limit their replication at some point due to TP53 tumor suppressor gene (p53 protein), and RB tumor suppressor gene (pRB protein) dependent cell cycle arrest at the G1/S and G2/M checkpoints. This replicative limit is termed '**Hayflick limit**' after its discoverer Leonard Hayflick. Once cells go into 'cellular senescence' (G1 phase of cell cycle), and it is an irreversible change; although cells fail to grow and divide, hence the cells remain alive. Cellular senescence process occurs as a result of shortening of telomeres at the end of chromosome after each mitotic division.
- However, CSCs differ from normal cells, because they can exceed 'Hayflick limit' continue to undergo cell divisions (mitosis) to become immortal that avoid cellular senescence and mitotic catastrophe.
  - Telomeres are located at the ends of a chromosome; which have a specific sequence of nucleotide base pairs; shorten after each mitotic cell division in cell cycle process.
  - Cancer stem cells rely on the '**telomerase enzyme**' to maintain the length of telomeres at chromosomal ends above a critical threshold that allows them to undergo cell division by inhibiting cellular senescence and apoptosis. Telomerase inhibitors are therapeutic targets of this signaling pathway.
- The Wnt/β-catenin signaling pathway regulates pluripotency self-renewal of stem cells and differentiation. Abnormal activation of Wnt/β-catenin signaling pathway promotes CSCs progression and metastasis. The Hippo signaling pathway disruption is responsible for development of malignant tumor. Therefore, it is important to administer targeted therapy to maintain telomere machinery and disrupt abnormal action of Wnt/β-catenin and Hippo signaling pathways.

Telomeres

Telomeres are regions of repetitive TTAGGG sequence of DNA capping and protecting the ends of chromosome from degrading or fusing with another chromosome. Each time the cell undergoes division, telomeres become slightly shorter. Eventually, telomeres become so short that cell can no longer divide successfully, and the cell dies. This sequence occurs when the tumor suppressors p53 protein and pRB protein are intact. Progressive telomere shortening activates p53 protein and pRB protein, which leads to cell cycle arrest at the G1/S and G2/M checkpoints.

- Without telomeres, each time, the cell undergoes division, human genome progressively loses information because the chromosomes would keep on shortening. With every cell replication, 50–100 nucleotide base pairs of DNA in telomeres is lost, thus eventually causes the telomeres to lose their ability to protect the ends of chromosomal DNA.
- Left unprotected by telomeres, the exposed ends of chromosomes become damaged. The DNA damage response results in cell cycle arrest and senescence. When chromosomal ends fuse with each other, thus irreversible DNA damage results in cell crisis and apoptosis.

Pathology Pearls: Telomere Shortening → Genomic Instability

- Consequent replicative senescence triggers cell death.
- Sequence of events of senescence triggered cell death include: chromosome with capped telomeres → progressive cell mitoses → shortening of telomeres → activation of tumor suppressor p53 protein and pRB proteins → cell cycle arrest at the G1/S and G2/M checkpoints → replicative senescence → cell death.

- Nonhomologous end joining (NHEJ) DNA repair defects, homologous recombination repair of double-stranded DNA defects, DNA damage checkpoint defects and telomere dysfunction lead to double-stranded breaks (DSBs) and telomere uncapping.
- Intact p53 protein causes apoptosis of cells. Deficient p53 protein leads to genomic instability, cell survival and transformation of normal cell to CSCs.

Telomere/Telomerase Complex and Unlimited Replicative Potential Linked to Cancer

The telomere/telomerase complex is the key element that determines unlimited replicative potential, one of the hallmarks of cancer. Normal cells undergo apoptosis after 60–70 cell divisions. Telomere/telomerase complex and enabling limitless replicative potential of CSCs (immortalization) are shown in Fig. 6.78 and Table 6.52.

- Normal cells shorten their telomeres during each round of DNA replication. On the contrary, in cancer stem cells (CSCs), telomere length is stabilized by reactivation of human telomerase reverse transcriptase (hTERT) enzyme, and a multiprotein complex is called '**shelterin**'. The hTERT enzyme has a diminished capacity to repair DNA double-strands break.

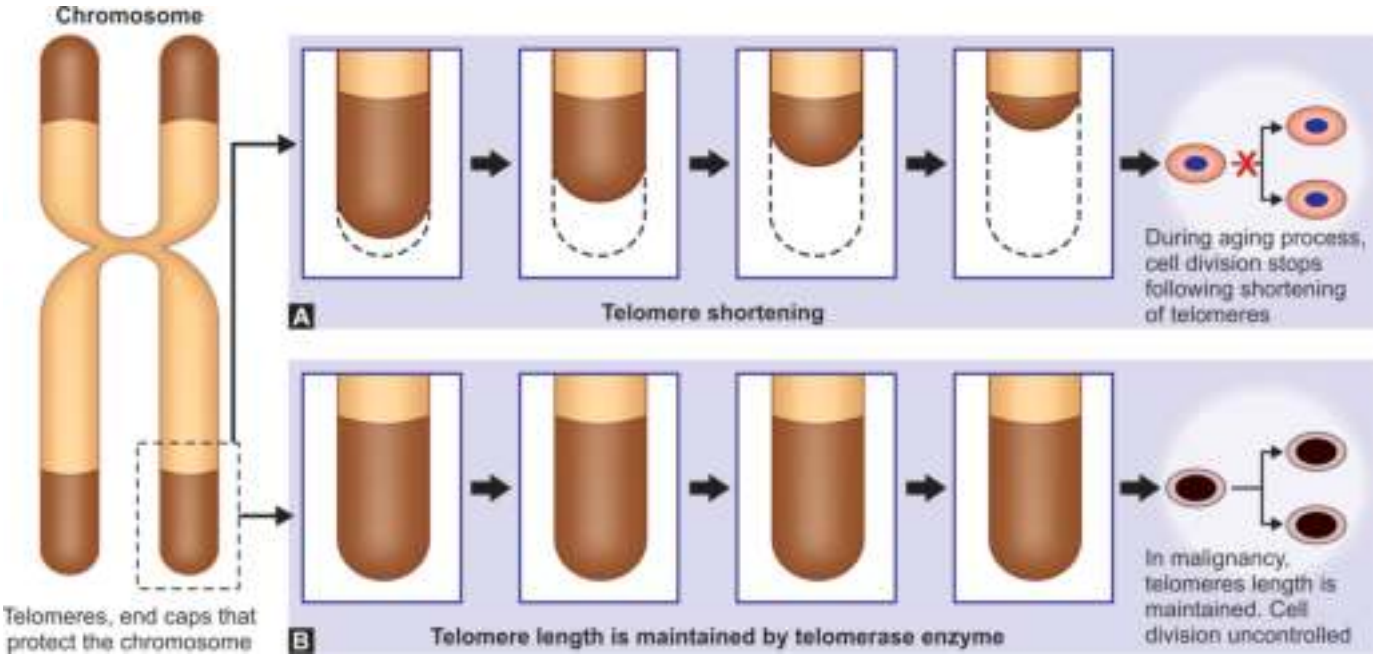

Fig. 6.78: Telomere and telomere/telomerase complex and enabling limitless replicative potential of cancer stem cells (immortality). Telomeres are the caps at the end of chromosomes that shorten as aging process continues. (A) During aging process, cell division stops following shortening of telomeres, (B) in malignancy, length of the telomeres is maintained by telomerase enzyme. Uncontrolled cell division takes place in cancers.

Table 6.52 Telomere and telomere/telomerase complex and enabling limitless replicative potential of cancer stem cells (immortalization)

Key Marker	Function
Telomere maintenance and regulation	
hTRET	▪ hTRET is the major component of telomerase activity ▪ Telomerase has been identified as a diagnostic marker for various human malignancies
TRF1/TRF2/POT1/TIN2/RAP1/TPP1 (Shelterin complex)	TRF1/TRF2/POT1/TIN2/RAP1/TPP1 (Shelterin complex) is a core of six proteins integral for telomere function
TP53 (p53) signaling pathway	
TP53 gene (p53 protein)	TP53 gene (p53 protein) is tumor suppressor gene and called 'guardian of the genome' and key regulator of gene expression
MDM2 gene	MDM2 is a proto-oncogene that inhibits transcriptional activation of TP53 gene (p53 protein)
$p14^{ARF}$ gene	$p14^{ARF}$ is a tumor suppressor gene that binds to MDM2-TP53 (p53) complex and prevents degradation of TP53 (p53)
E2F-1 transcription factor	E2F-1 is the transcription factor of p53 signaling pathway that regulates via initiating transcription of $p14^{ARF}$

- On the contrary, CSCs escape replicative limit, which undergo unrestricted cell divisions leading to carcinogenesis, invasion and metastasis.
  - CSCs become immortal and contain damaged chromosomes. The immortalization of CSCs due to maintenance of telomere length and structure by telomerase enzyme represents essential step in tumorigenesis and progression.
  - Telomerase enzyme activity is maximum in germ cells. However, somatic cells lack telomerase activity. Telomerase activity is increased in 90% of human cancers.
- Genetic and epigenetic alterations increase activity of telomerase enzyme that maintains length and structure of telomeres in chromosomes, hence germ cells limitless proliferative potential leads to initiation and progression of malignant tumors, thus making telomere/telomerase complex as an attractive therapeutic target.

INDUCTION AND SUSTAINED TUMOR ANGIOGENESIS

Angiogenesis is the formation of network of new functional blood vessels from preexisting neighboring venules, which occurs as a result of an intricate balance between endogenous proangiogenic factors and anti-angiogenic factors. '**Angiogenic switch**' involves sprouting, splitting and remodeling of the existing blood vessels. Endogenous proangiogenic factors involved in promoting angiogenesis are shown in Table 6.53. Endogenous antiangiogenic factors involved in inhibiting angiogenesis are shown in Table 6.54.

- One specific and promoter of angiogenesis is vascular endothelial growth factor (**VEGF**) in both normal and tumor angiogenesis.
  - Binding of VEGF to two structurally related membrane receptor tyrosine kinases '**switches on**' multiple signaling pathways leading to vascular endothelial cell growth, proliferation and survival.
  - Angiopoietin 1 (**Ang1**) binding to vascular endothelial cells recruits pericytes and supports cells around endothelial cells. Maturation and stabilization with remodeling of the newly formed blood vessels occurs under the influence of angiopoietin 2 (**Ang2**) and local growth factors.
- Angiogenesis plays important role in injured tissue healing, placenta formation after fertilization in the uterus in female populations, embryonic development, body growth, organ regeneration and cancers.

Table 6.53 Endogenous proangiogenic factors involved in promoting angiogenesis

Categories	Angiogenic Growth Factors
Proteins	VEGF, TGF-α, TGF-β, FGF acidic/basic, TNF-α, PDGF (A, B, C, D, EGF, PlGF, HGF, angiogenin, scatter factor, G-CSF, interleukins (IL-1, IL-6, IL-8), proliferin, leptin, angiopoietins (Ang1, Ang4), HIF-1,-2,-3
Small molecules	Adenosine, nicotinamide, 1-butyryl glycerol, prostaglandins E1 and E2
Trace element	Cu (copper)
Protease	Cathepsins, gelatinase A and B, stromelysin, urokinase (plasminogen activator)
Oncogenic proteins	c-Myc, RAS in VEGF-mediated angiogenesis, c-Src, V-Raf, c-Jun

VEGF (vascular endothelial growth factor), TGF-β (transforming growth factor-β), FGF (fibroblastic growth factor), TNF-α (tumor necrosis factor-α), PDGF-A,-B,-C,-D (platelet-derived growth factor-A,-B,-C,-D), EGF (epidermal growth factor), PlGF (placental growth factor), HGF (hepatocyte growth factor), G-CSF (granulocyte colony-stimulating factor), interleukins (IL-1, IL-6, IL-8), Ang1, Ang4 (angiopoietins) and HIF-1, 2, 3 (hypoxia-inducible factors 1, 2, 3)

Table 6.54 Endogenous anti-angiogenic factors involved in inhibiting angiogenesis

Categories	Anti-angiogenic Factors
Extracellular matrix (ECM)-derived angiogenic inhibitors	Angiostatin, endostatin, thrombospondin 1 and 2, anastellin, endorepellin, fibulin, tumastatin, canstatin, arresten
Nonmatrix-derived angiogenic inhibitors	Angiopoietins (Ang2, Ang3), angiostatin 2, vasculostatin, vasostatin, PF-4 (platelet factor 4), caveolin I and II
Protease inhibitors	TIMP-1,-2,-3 (tissue inhibitor metalloproteinase-1, 2, 3), PAI-1 (plasminogen activator inhibitor 1)
Cytokines	IL-10, IL-12, IL-18
Trace element	Zn (zinc)
Miscellaneous molecule	Prolactin and its 16-kD terminal fragment

- Cancer stem cells (CSCs), like normal cells, are unable to grow without vascular supply to bring oxygen and nutrients, and remove waste metabolic products.
- Tumor angiogenesis occurs through proliferation of circulating endothelial progenitor cells (EPCs) and differentiation of vascular endothelial cells.
  - The acquisition of new vasculature permits much degree of CSC proliferation and development of malignant growth. Hence, malignant tumors must induce angiogenesis for their progression.
  - Malignant tumor needs to trigger the formation of new vasculature by releasing proangiogenic growth factors (i.e. VEGF, FGS, TNF-α, TGF-β, and angiopoietin). It has been established that malignant tumors go through an '**angiogenic switch**' that allows them to grow from microscopic to macroscopic malignant tumor growth.
- Angiogenesis occurs through one or more of the following mechanisms: sprouting angiogenesis from mature quiescent endothelial cells (ECs), intussusceptive angiogenesis (mid-vessel lateral budding, and remodeling), vasculogenesis ('*de novo*' neovascularization from bone marrow derived endothelial progenitor cells), vascular mimicry induced by VEGF-VEGFR signaling pathway promoting epithelial–mesenchymal transition (EMT) mimicry by upregulating the expression of EMT-related genes. VEGF inhibitors are therapeutic targets of this signaling pathway.
  - **Proliferation of vascular endothelial cells:** Binding of VEGF to VEGFR can interact with Grab/Src/Gab1/Shb/PKC-γ, which activate RAS/RAF/MEK/ERK (MAPK) and phosphoinositide 3-kinase (PI3K)/AKT/mTOR signaling pathways and promote the proliferation of vascular endothelial cells and formation of a capillary sprout from a pre-existing mature blood vessel.
  - **Migration, invasion and survival of vascular endothelial cells:** VEGFR can interact with three RAS-related GTP-binding proteins (GTPases) such as Rho/Rac/cdc42, that regulate the assembly and disassembly of the actin cytoskeleton in response to extracellular signals. VEGFR interacts with Rho/Rac/cdc42 that activates phosphoinositide 3-kinase (PI3K)/AKT/mTOR signaling pathway, that promotes vascular endothelial cell migration, invasion and survival leading to vascular tube formation.
  - **Maturation of the newly formed vessel:** Maturation of the newly formed blood vessel requires remodeling of the vascular network into large and small blood vessels, along with the recruitment of supporting pericytes and smooth muscle cells. Angiopoietin 1 binds to Tie receptors on vascular endothelial cell and results in endothelial stabilization, mesenchymal cell activation and pericyte activation. Under physiologic state, newly formed blood vessels are stabilized by pericytes.
  - **Increased vascular permeability:** VEGFR can enhance vascular permeability by activating NFAT/β-catenin/VE-cadherin, eNOS and PLC-γ signaling pathway.
  - **Vascular mimicry:** VEGFR can promote epithelial–mesenchymal transition (EMT)-induced vascular mimicry by upregulating the expression of EMT-related genes.

Angiogenesis during Tissue Healing

During tissue healing, vascular endothelial growth factor (VEGF) is produced by monocytes/macrophages, fibroblasts, mast cells and keratinocytes, that plays a role in wound healing. During acute phase of tissue healing, VEGF increases blood vessel permeability and expression of cell adhesion molecules, which assist in the recruitment of inflammatory cells. VEGF levels can influence the rate of wound closure/reepithelialization, inflammation, angiogenesis, granulation tissue formation, and scar tissue deposition.

Tumor Angiogenesis

Tumor angiogenesis is defined as the growth of newly formed blood vessels which develop due to stimulation of vascular endothelial cells within existing vascular networks near the malignant tumor, providing a supportive microenvironment rich with oxygen and nutrients to sustain optimum tumor growth. Angiogenesis plays a key role in tumor growth, invasion and metastasis.

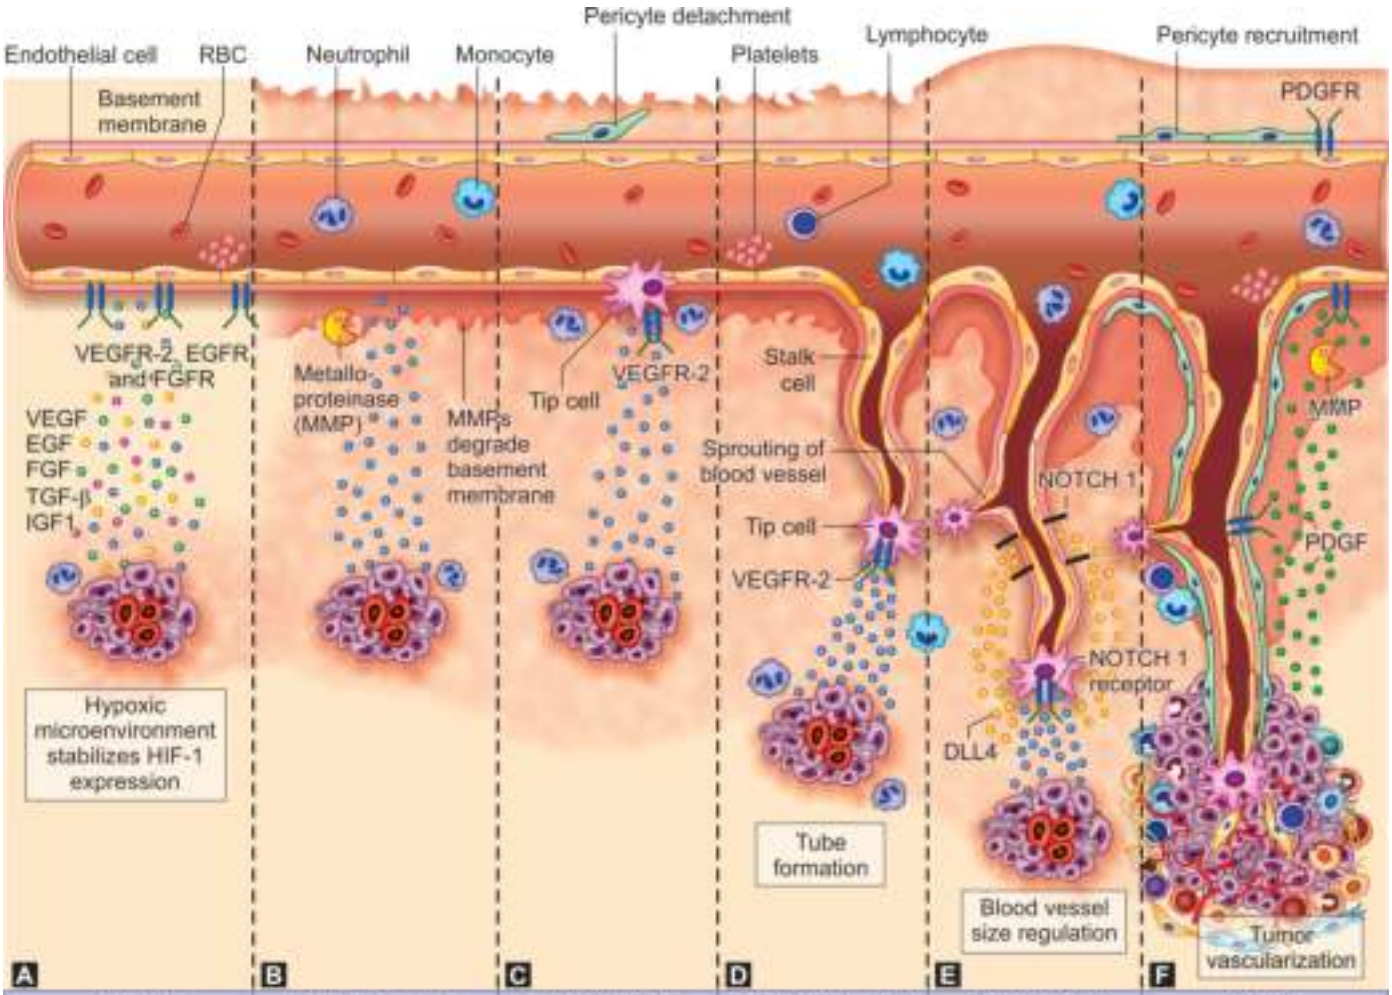
- Tumor angiogenesis plays a critical role in the growth of solid cancer beyond 1–2 mm in size microscopic cancer to attain macroscopic malignant tumor, as it requires adequate supply of oxygen and nutrients to survive, proliferate and invade in surrounding tissues. Cancer stem cells need to reside in close proximity to blood vessels to access the blood circulatory system essential for metastasis to distant organs(s).
- Tumor angiogenesis occurs through several distinct biological processes in anatomic location and within tumor microenvironment orchesterized by a range of secreted angiogenic factors and their binding to their cognate membrane-bound receptors (e.g. receptor tyrosine kinase) and transduce their signal downstream inside endothelial cells.
  - Common growth factor signaling pathways involved angiogenesis in human cancers include vascular endothelial growth factor (VEGF), platelet-

derived growth factor (PDGF), fibroblast growth factor (FGF), epidermal growth factor (EGF), hepatocyte growth factor (HGF) via binding to receptor tyrosine kinases (RTKs), and transforming growth factor-β (TGF-β) via binding to serine/threonine kinase receptors. TGF-β can act as stimulator and inhibitor in wound healing and carcinogenesis.
  - Signal transduction involves the communication process where signals from outside the cells are transferred to the nucleus inside the cell.
  - The existing quiescent vasculature sprouts to form new blood vessels as a result of vascular endothelial cell proliferation, migration, survival and stabilization by pericytes, that help to sustain expanding tumor growth exponentially.
- Vascular endothelial growth factor (VEGF) is the potent promoter of angiogenesis, which involves binding to membrane receptor tyrosine kinase, 'switches on' signaling pathways, stimulates the growth, survival and profanation of vascular endothelial cells and promotes malignant tumor growth, invasion and metastasis.
  - Tumor vasculature formed under the influence of VEGF is structurally and functionally abnormal, irregularly shaped, tortuous, having dead ends and not organized into venules, arterioles and capillaries, leaky and hemorrhagic due to poor stabilization by loose and incomplete pericytes around vascular endothelial cells, which result in high interstitial pressure, suboptimal blood flow and further VEGF production.
  - The central role of VEGF in the production of tumor vasculature makes it a rational target for anticancer therapy.
- Sequence of events in tumor angiogenesis is discussed as under:
  - **Hypoxic microenvironment:** Hypoxia induces HIF-1 expression and consequent release of proangiogenic factors (e.g. VEGF, EGF, FGF, TNF-α, TGF-β, IGF1), which bind to their cognate receptors on vascular endothelial cells. Vascular endothelial growth factor (VEGF) is the most important proangiogenic factor and synthesized by CSCs, and macrophages. VEGFA binds to and activates both cognate VEGFR-1 and VEGFR-2 receptor leading to mobilization and recruitment of endothelial progenitor cells (EPCs) from bone marrow, vascular endothelial cell activation, proliferation, migration, sprouting, increased vascular permeability, upregulation of anti-apoptotic genes in vascular endothelial cells, and vascular mimicry by upregulating the expression of epithelial–mesenchymal transition (EMT)-related genes. Mechanism and its regulation of tumor angiogenesis are shown in Fig. 6.79A. Vascular endothelial growth factor (VEGF) signaling pathways in the induction of angiogenesis are shown in Fig. 6.79B.
  - **Proteolytic degradation of basement membrane by matrix metalloproteinases (MMPs):** Hypoxic microenvironment also upregulates MMPs expression, leading to degradation of basement membrane and detachment of pericytes of vascular endothelium.
  - **Tip cell migration along angiogenic gradient:** Tip cells are specialized endothelial cells, which migrate along angiogenic factor gradient.
  - **Vascular endothelial cell differentiation to stalk cell and tube formation:** VEGF binds to VEGFR-1 receptor and mediates vascular endothelial cell proliferation leading to highly proliferative stalk cells, tube formation, the main body of the newly formed blood vessel.
  - **Regulation of blood vessel lumen size:** VEGF stimulates synthesis of DLL4, which binds to NOTCH-1 receptors resulting in downregulation of VEGFR and suppression of vascular endothelial cell proliferation.
  - **Vascular and stabilization:** Angiopoietins (Ang1 and Ang4) promote vascular endothelial cell migration, proliferation, sprouting and survival. Angiopoietin 1 binds to Tie2 receptors on vascular endothelial cells, recruits pericytes around vascular endothelial tubes. PDGF-β induces attachment of incomplete and loose pericytes, vascular endothelial cell proliferation and VEGF sensitivity. Maturation and stabilization with remodeling of blood vessels occur under the influence of angiopoietin 2 and local growth factors. Enhanced blood supply stimulates further malignant tumor growth.

Microvasculature in Healthy Tissue and Malignant Tumor

Tumor angiogenesis occurs as a result of an intricate balance between proangiogenic and anti-angiogenic factors. Morphologic and functional characteristics of microvasculature differ in healthy tissue, and tumor stroma.

- **Microvasculature in healthy tissue:** Microvasculature in healthy tissue displays an organized and hierarchical branching pattern of arteries, veins and capillaries, which are supported by basement membrane and complete and firm pericyte coverage and they are tightly connected by stable cell–cell junctions.



A Hypoxic microenvironment	B MMPs degrade basement membrane	C Tip endothelial cell migration	D Tube formation in angiogenesis	E Regulation of blood vessel size	F Tumor vascularization
• Hypoxia → ↑HIF-1 → synthesis of angiogenic factors (e.g. VEGF, EGF, FGF, TNF-α, TGF-β, IGF1) • Angiogenic factors bind to their receptors on endothelial cells	• Hypoxia → ↑HIF → MMPs • MMPs degrade basement membrane • Detachment of pericytes from basement membrane	• Tip cells are specialized endothelial cells • Tip cells migrate along angiogenic factor gradient	• Endothelial cells are differentiated into highly proliferative stalk cells • Stalk cells form the main body of the new blood vessel	• VEGF → ↑DLL4 • DLL4 binds to NOTCH 1 receptors → downregulation of VEGFR → suppression of proliferation of endothelial cells	• PDGF → ↑pericyte recruitment and attachment to endothelium • Reduction in endothelial cell • Reduction in VEGF sensitivity • Tumor angiogenesis → tumor growth

Fig. 6.79A: Mechanism and its regulation of tumor angiogenesis. Tumor angiogenesis is multistep process involving extensive interplay between cells, soluble factors, and extracellular matrix components.

- **Microvasculature in malignant tumor stroma:** Microvasculature in tumor stroma has dead ends and not organized into venules, arterioles and capillaries. Microvasculature in malignant tumor stroma displays vascular endothelial cell sprouting, small diameter of lumen, disruption of endothelial cell junctions, incomplete and loose pericytes coverage, irregular and chaotic branching, tortuous with blunt ends, leaky and heterogenous microvascular density resulting in increased tissue hypoxia and intravasation of cancer stem cells.
  - Moreover, microvasculature in stroma of malignant tumor exhibits abnormal vascular endothelial cell basement membrane, loose association of endothelial cells and variable thickness of endothelial cells. Leaky newly formed blood vessels cause hemorrhage, that results in high interstitial pressure leading to suboptimal blood flow and further VEGF production.

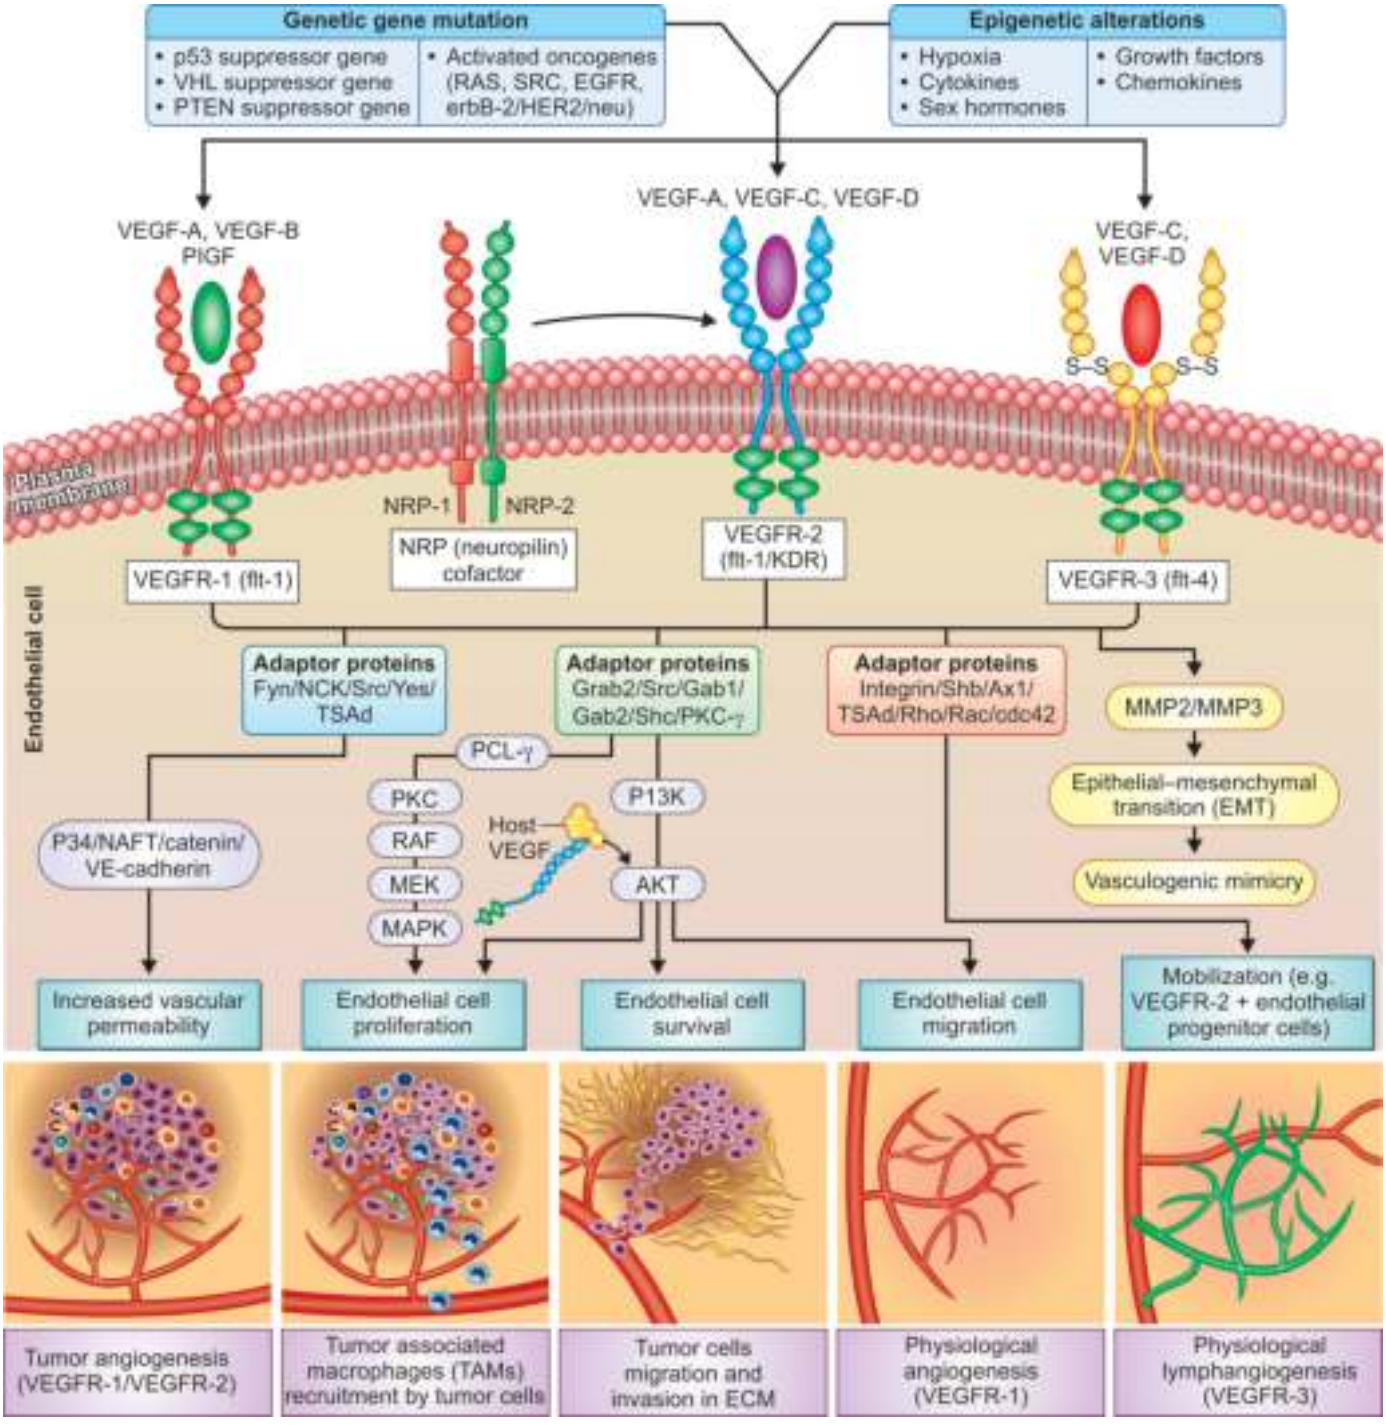


Fig. 6.79B: Vascular endothelial growth factor (VEGF) signaling pathways in the induction of angiogenesis. The vascular endothelial growth factor (VEGF) and its receptor (VEGFR) have been shown to play major roles not only in pathological angiogenesis but also most pathological angiogenesis in cancer. The VEGF-VEGFR system is an important target for anti-angiogenic therapy in cancer.

- Growth of the vascular network in malignant tumor is important for metastasis, as CSCs require a sufficient supply of nutrients and oxygen, and removal of waste metabolic products, which is achieved by angiogenesis and lymphangiogenesis, respectively. Morphologic and functional characteristics of microvasculature differ in healthy tissue and tumor stroma are given in Table 6.55.

Angiogenesis in Cancer Susceptibility Syndromes

Proangiogenic factors are also produced in human cancer susceptibility syndromes. Fumarate hydratase (FH) and von Hippel-Lindau (vHL) tumor suppressor

Table 6.55 Morphologic and functional characteristics of microvasculature in healthy tissue and tumor stroma

Characteristics	Vasculature in Normal Tissue	Vasculature in Tumor Stroma
Vascular endothelium	Continuous vascular endothelium	Discontinuous vascular endothelium
Basement membrane	Intact basement membrane	Discontinuous basement membrane
Pericyte coverage	Complete and compact	Incomplete and loose
Nerve supply	Innervation present	Innervation absent
Branching of microvasculature	Proper arborization and quasifractal branching	Abnormal and chaotic branching
Lumen diameter	Gradual changes in lumen diameter	Paradoxical changes in lumen diameter
Shunts or corkscrew structures	Absent	Present
Blunt ends and tortuosities	Absent	Present
Architecture	Organ specific architecture	Heterogenous vascular density ('hot spots')

proteins are mutated in familial cancer syndromes. Mutations in tumor suppressors such as FH and vHL cause upregulation of proangiogenic factors that induce tumor angiogenesis. Effects on the vasculature are not limited to the primary tumor microenvironment, but altered vascular function is also present in distant organs in persons with cancer.

Role of Hypoxia-inducible Factor (HIF) in Angiogenesis

Activation of signaling pathways of phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR and RAF/MEK/ERK/mitogen-activated protein kinase (MAPK) signaling pathways via receptor tyrosine kinases (RTKs), nonreceptor tyrosine kinases or G protein-coupled receptors regulate synthesis of hypoxia-inducible factor-1α (HIF1A) protein.

- **Normoxic state:** In normoxic state, HIF1A gene is constitutively transcribed to HIF1A messenger RNA, which is then translated to HIF1A protein. Degradation of HIF1A protein is regulated by O_2-dependent prolyl hydroxylation by prolyl hydroxylases (PHDs) enzymes, which targets the protein for ubiquitylation by E3 ubiquitin-protein ligases. The E3 ubiquitin-protein ligases contain the von Hippel-Lindau (vHL) tumor suppressor protein, which binds specifically to hydroxylated HIF1A. Ubiquitylated HIF1A is rapidly degraded by the proteasome.
- **Chronic hypoxic state:** During chronic hypoxic state, HIF1A no longer binds to vHL protein and accumulates, enabling HIF1A protein to move into the nucleus leading to formation of active HIF transcription complex.
  - **HIF1B expression:** HIF1B is also known as ARNT (acryl hydrocarbon receptor nuclear translocator), which is involved in expression of genes involved in metabolism such as c-Jun proto-oncogene, CREEB-cAMP responsive element binding protein 1, EP300-E1A binding protein. HIF1B activates the transcription of many genes that encodes proteins involved in angiogenesis, glucose metabolism, CSC proliferation, survival, invasion and metastasis to distant organs.
  - **HIF1A expression:** HIF1A is overexpressed in human cancers as a result of intratumoral hypoxia as well as genetic alterations, i.e. gain-of-function mutations in oncogenes (ERBB2), and loss-of-function mutations in tumor suppressor genes (i.e. vHL, PTEN). HIF1A overexpression is associated with treatment failure and mortality. Role of hypoxia-inducible factor (HIF) in angiogenesis under normoxic state and chronic hypoxic state is shown in Fig. 6.80.

Pathology Pearls: Chronic Hypoxic State and Tumor Invasion and Metastasis

- Chronic hypoxic state resulting from poor vasculature in malignant tumor stroma leads to subsequent recruitment of macrophages and neutrophils and increased vascular permeability by secretion of additional proangiogenic factors.
- Sustained hypoxia stimulates CSCs invasiveness by induction of epithelial–mesenchymal transition (EMT) and contributes to impaired therapy response.
- Tumor cell-derived cytokines and proangiogenic factors are carried throughout the body in plasma or cargo in platelets or microvesicles and can contribute to formation of premetastatic or antimetastatic niches in organs that exert sites for metastasis. Recruitment of leukocytes to the metastatic sites mediate metastatic colonization.

ACTIVATING TISSUE INVASION AND METASTASIS

A key feature that distinguishes malignant neoplastic cells, i.e. CSCs from all other cells is the capability of CSCs to disseminate throughout the body by two related mechanisms: invasion and metastasis. Hanahan

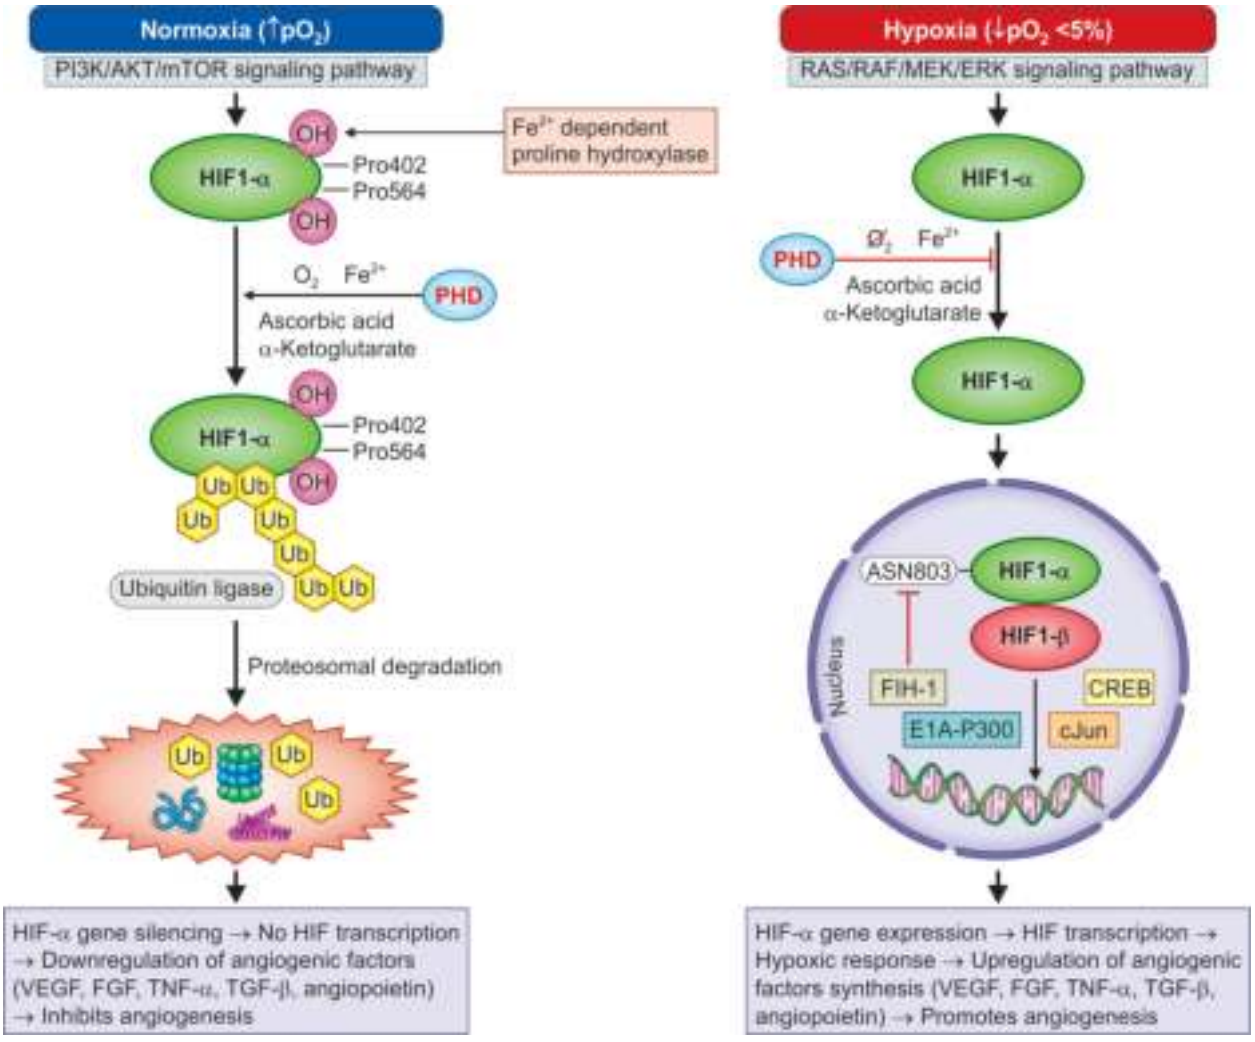

Fig. 6.80: Role of hypoxia-inducible factor (HIF) in angiogenesis under normoxic state and chronic hypoxic state. In normoxic state, HIF1A gene is constitutively transcribed to HIF1A messenger RNA, which is then translated to HIF1A protein, which HIF1A protein is rapidly hydroxylated by the prolyl hydroxylases (PHD) enzymes, which enables binding von Hippel-Lindau tumor suppressor protein (pvHL) and the ubiquitin ligase, leading to proteasomal degradation. During chronic hypoxic state, HIF1A no longer binds to pvHL and accumulates, enabling HIF1A to move into the nucleus and form the active HIF transcription complex (HIF1B also known as ARNT-aryl hydrocarbon receptor nuclear receptor, c-Jun proto-oncogene, CREB-cAMP response element binding protein 1, EP300 gene—E1A binding protein p300) and subsequent transcription.

and Weinberg recognized invasion and metastasis as hallmarks of cancer in solid malignant tumors. CSCs proliferate locally, accumulate genetic alterations, and synthesis of growth factors, chemokines and proangiogenic factors leading to development of primary malignant epithelial tumor.

- Local invasion is the direct extension and penetration of CSCs into the neighboring tissues. The proliferation of transformed CSCs and the progressive increase in malignant epithelial tumor size eventually leads to breach in the barriers (basement membrane), and invades in adjacent tissue by allowing modifications in CSC interactions with their surrounding environment through E-cadherin, integrins, and other cell adhesion molecules, synthesis of MMP, and downregulation of tissue inhibitors of metalloproteinases (TIMPs).
- Then CSCs intravasate lymphatic channel and/or blood vessel, travel the bloodstream as single cell/cluster in the form of tumor emboli, extravasate and colonize as single/multiple metastases at a secondary site in various distant organs (e.g. lungs, bones, liver, and brain).
- Local invasion is the first stage in the process that leads to the development of metastases in secondary organs/tissues. The ability of CSCs to migrate from a primary site of disease is attributed to the mutation of genes that regulate synthesis of proteins and normally tether to their surrounding tissues.

- Metastasis refers to the ability of CSCs to penetrate into lymphatic and blood vessels, circulate through these lymphovascular systems and invade normal tissues elsewhere in the body. This process proceeds in an orderly and predictable manner and termed 'metastatic cascade' that consists of multiple steps (i.e. local invasion, intravasation, and extravasation).
- Tumor microenvironment regulates tumor growth, recurrence and metastasis. Different populations of cells of innate immune system are involved in different stages of the metastatic cascade both locally and in distant organs/tissues, which regulate the survival and unrestricted proliferation of CSCs and assisting in the establishment of a permissive tissue environment enabling tumor invasion and metastasis.
- Some CSCs undergo dormancy and metabolic changes as an adaptation mechanism to new stressful tumor microenvironment in distant organs. Tumor microenvironment regulates tumor growth, recurrence and metastasis.
- Notably, both epithelial–mesenchymal transition (EMT) and mesenchymal–epithelial transition (MET) are required for the process of metastasis, while EMT mobilizes CSCs in the primary malignant epithelial tumor. MET terminates the migration process and thereby resulting in the colonizing of cancer stem cells (CSCs) in distant organs as single/multiple metastases.
- Biomolecules involved in activation of invasion and metastasis are given in Table 6.56. Schematic representation of the malignant epithelial tumor invasion and metastasis is shown in Fig. 6.81.

Primary Malignant Epithelial Tumor and Local Invasion

Normal cells are transformed into CSCs, which have same genetic abnormalities in key genes coding for aberrant proteins (e.g. growth factors, growth factor receptors, signal transduction proteins, transcription factor and DNA repair system).

- Carcinoma arising from epithelial tissue usually undergoes through several stages of development: atypical hyperplasia, carcinoma *in situ*, and then invasive carcinoma, which might further metastasize to distant organs.
- As the malignant epithelial tumor develops, it undergoes further somatic gene mutations resulting in additional oncogene activation and/or inactivation/biallelic loss of tumor suppressor gene. Malignant epithelial tumor has clones with different genetic make-up. Some subclones possess ability to metastasize to distant organs, while other

Table 6.56 Biomolecules involved in activation of invasion and metastasis

Key Biomolecule of Components	Functions
Extracellular matrix (ECM) component	
Hyaluronan	▪ Hyaluronan is a glycosaminoglycan found in the extracellular matrix (ECM) ▪ Hyaluronan is dramatically upregulated in most human malignancies
Versican	Versican in ECM is either expressed by CSCs or stromal cells, which activates EGFR signaling leading to carcinogenesis progression, invasion and metastasis
Collagen IV	Collagen IV is essential for tumor angiogenesis by modulating cell growth and proliferation
Adhesion molecules	
Carcinoembryonic antigen related cell adhesion molecule 1 (CEACAM1)	▪ L-Form CEACAM1 has tumor suppressor function and found in the early carcinogenic process ▪ CEACAM1 is downregulated in several human malignancies
DCC deleted in colorectal cancer	▪ Netrin-1 transmembrane receptor DCC or colorectal suppressor is a protein encoded by the DCC gene, which is involved in development of nervous system. ▪ Mutations in DCC gene are linked to colorectal carcinoma, esophageal carcinoma and neuroblastoma
E-cadherin	▪ E-cadherin is transmembrane protein that mediates cell-cell adhesion ▪ E-cadherin loss has been observed in subsets of Merkel cell carcinoma, anaplastic carcinoma, lobular carcinoma of breast, small cell neuroendocrine tumors and urothelial carcinoma
Secreted factors	
Tenacin C	▪ Tenacin C interacts with extracellular matrix (ECM) proteoglycans ▪ Tenacin C interferes with tumor suppressor activity of fibronectin
Fibrinogen	Fibrin deposits occur in the stroma of many human malignancies and affect progression of CSCs
Periostin	Periostin is secreted adhesion-related protein expressed and periodontal ligaments and plays a role in oncogenesis

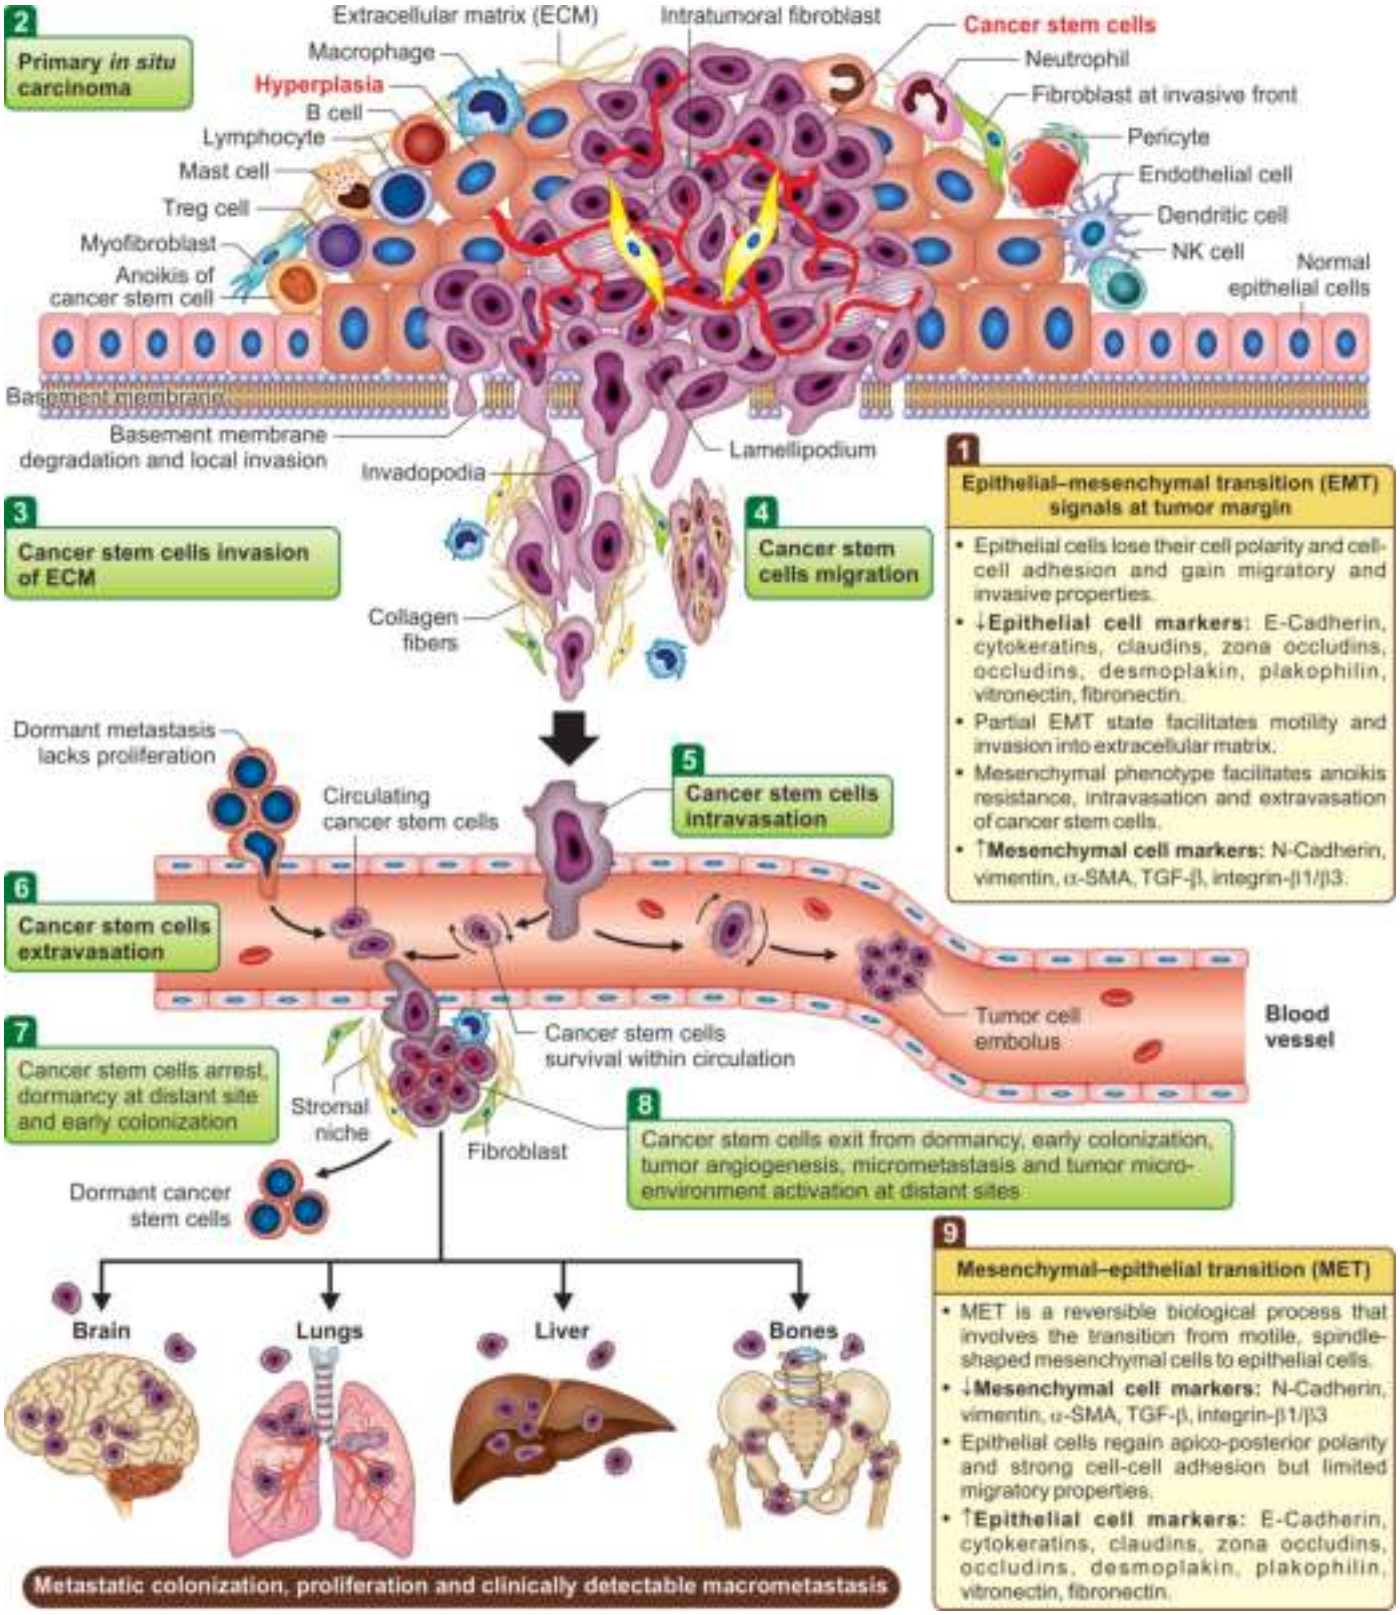

Fig. 6.81: Schematic representation of the malignant epithelial tumor invasion and metastasis. The initial transformation of normal epithelial cells to cancer stem cells results in carcinoma *in situ*. With reduced adhesiveness and enhanced migratory behavior, carcinoma *in situ* progresses to an invasive carcinoma. After enzymatic degradation of the basement membrane by secreted matrix metalloproteinases (MMPs), CSCs invade the surrounding extracellular matrix, migrate and intravasate into lymphatics and blood vessels. Circulating survived CSCs arrest in the capillaries of distant tissues/organs. There, CSCs remain in dormant state without reproliferating for considerable time. Alternatively, CSCs exist blood circulation (extravasate) proliferate and produce secondary tumors after CSC proliferation, tumor angiogenesis in tumor microenvironment and settle in distant organ(s).

subclones undergo rapid proliferation forming poorly-differentiated malignant tumor. The goal of the chemotherapy is to destroy CSCs in the malignant epithelial tumor. Cancer stem cells may develop resistance to chemotherapy. Only resistant cancer stem cells survive after chemotherapy. Cancer stem cells in recurrent malignant tumor remain resistant to chemotherapy.

Tumor Angiogenesis

Tumor angiogenesis is the process of developing new blood vessels from pre-existing blood vessels that has a key role in tumor growth, invasiveness and metastasis. Malignant epithelial tumor needs to trigger the formation of new vasculature by releasing proangiogenic growth signals. It has been established that malignant epithelial tumor undergoes through an 'angiogenic switch' that allows them to grow from microscopic to macroscopic malignant tumor growth. VEGF inhibitors are therapeutic targets of this signaling pathway.

Epithelial–Mesenchymal Transition

Epithelial–mesenchymal transition (EMT) involves the disruption of cell-to-cell adhesion (downregulation of E-cadherin), apical-basal cell polarity, remodeling of the cytoskeleton, and changes in cell-to-extracellular matrix adhesion associated with mesenchymal phenotype, enhanced motility, and invasive properties of CSCs in primary malignant epithelial tumor.

- Epithelial–mesenchymal transition is regulated by transcription factors (i.e. SNAIL, ZEB, TWIST), cell signaling, and epigenetic modification. EMT plays critical roles in metastatic cascade process.
- Notably, both EMT and MET are required for CSC metastasis, while EMT mobilizes CSCs in the primary malignant epithelial tumor. MET terminates the migration of CSCs and thereby resulting in the colonizing of CSCs in distant organs.

Expansile Tumor Growth, Detachment of Cancer Stem Cells from Primary Malignant Epithelial Tumor and their Migration

As the malignant epithelial tumor grows, it exerts mechanical pressure on the surrounding cells and tissues, which eventually undergo cell death due to blockage of blood supply to malignant tumor. Loss of mechanical resistance opens the way for the CSCs to spread along the lines of least resistance and occupy the space once filled with dead cells. CSCs detach from primary malignant epithelial tumor (carcinoma), become motile, undergo a change in their shape to acquire a polarized mesenchymal phenotype, similar to locomoting leukocytes, migrate and invade basement membrane, and then surrounding healthy stromal extracellular matrix.

Tumor Development and Acquisition of Invasive Potential through Basement Membrane

Tumor development and acquisition of invasive potential is regulated by metastatic signature genes (e.g. Ezrin, SNAIL and TWIST genes including microRNA-10b) and metastatic tumor suppressor genes (e.g. NM23, KAI-1, KiSS and NM23).

- Cancer stem cells possess receptors for laminin, a complex glycoprotein in the basement membrane. The receptors for laminin permit the CSCs to attach to the basement membrane forming a bridge-like connection.
- Cancer stem cells expand and breach barriers, i.e. basement membrane, extracellular matrix (ECM) and penetrate into nearby surrounding tissue. Cancer stem cells and stromal cells of tumor microenvironment synthesize matrix metalloproteinases (MMPs), which play important role in degradation of basement membrane and ECM.
- Extracellular matrix has many components that regulate cell migration, growth and differentiation, which include: (a) fibers (i.e. collagen, elastin, laminin, and fibronectin), (b) proteoglycans (syndecan-1 and aggrecan), (c) glycoproteins (tenacin, vitronectin and entactin), and (d) polysaccharides (hyaluronic acid).
- Extracellular matrix is a macromolecule network, composed of collagen (most abundant and can be degraded by MMPs). Triple-helical protein is highly resistant to degradation by MMPs, that gives a structural and biochemical support. Matrix-metalloproteinas (MMPs) are strictly regulated by endogenous tissue inhibitor metalloproteinases (TIMPs).

Anoikis of Cancer Stem Cells

Detachment of CSCs from ECM can also induce a form of apoptotic cell death called '**anoikis**', which acts to control the growth and attachment of the detached CSCs to a different ECM. Resistance to anoikis is an attribute of cancer stem cells with metastatic potential. Anoikis can engage both extrinsic and intrinsic pathways of apoptosis.

Increased Motility of Cancer Stem Cells

Cancer stem cells secrete chemokines that stimulate development of finger-like projections (**invadopodia**) on CSCs involved in their motility to overcome the dense scaffold of local environment. Polarity of cancer stem cells has a leading front and rear region, which depends on a distinct actin cytoskeleton and generation

of various cell junctions. **Lamellipodia** are flat, sheet-like membrane protrusions formed at the leading edge of migrating CSCs.

Matrix metalloproteinases (MMPs) Proteolytic Enzymes Synthesis

Cancer stem cells and stromal cells of tumor microenvironment produce powerful proteolytic MMPs enzymes such as collagenases and proteases, which degrade basement membrane and surrounding tissue and promote CSCs to invade lymphatic channel or blood vessel. In addition, there is downregulation of tissue inhibitor of metalloproteinases (TIMPs).

Intravasation, Transport and Arrest of CSCs

Cancer stem cells exit primary malignant epithelial tumor site through degradation of basement membrane, interstitial tissue, and extracellular matrix (ECM) by matrix metalloproteinases (MMPs) synthesized by CSCs and stromal cells, invade lymphovascular system, enter circulation, and travel as platelet-tumor emboli (single/clusters) thereby becoming circulating cancer stem cells and potential metastatic seeds.

- Only a small number of CSCs survives in the circulation due to evasion from immune system. Circulating CSCs may interact with cavity mesothelial cells and metastasize by transcoelomic route to distant organ(s). In the lymph nodes, communications between the lymphatic channels and venous tributaries allow malignant neoplastic cells, i.e. CSCs access to the systemic circulation.
- Circulating cancer stem cells are involved a cascade of events consisting of CSCs arrest on the vascular endothelium resulting in the formation of dynamic contacts that give rise to significant cytoskeletal alterations, transendothelial migration and subsequent invasion of surrounding ECM degradation by MMPs (proteolytic enzymes).

Extravasation of Cancer Stem Cells

Only a small number of CSCs survives in the circulation and then extravasate through basement membrane and surrounding tissues and remain dormant while retaining a stem-like tumor initiating capacity.

- Invadopodia are required for CSC extravasation and thus remain a therapeutic target for metastasis. CSCs extend invadopodia through the vascular endothelium into extravascular stroma prior to their extravasation at endothelial junctions and distant metastasis and reveals an opportunity for therapeutic intervention in this clinically important process.
- After extravasation, surviving CSCs are disseminated, they must reactivate their epithelial properties by means of the process of EMT, known as the mesenchymal–epithelial transition (MET). MET is a reversible process of EMT, that involves the transition from mobile multipolar or spindle-shaped mesenchymal cells to planar arrays of polarized epithelial cells with cell-to-cell junctions, apical-basal polarity and expression of epithelial markers. The seeding of migrating CSCs may occur quickly with subsequent formation of metastasis in distant tissue/organ sites and therapy resistance.

Pre-metastatic Niche for Distant Metastasis

After extravasation, CSCs undergo adaptation to local tumor microenvironment (TME), successful colonization finally establishment of clinically detectable metastatic disease. Metastasis is modulated by tumor microenvironment and immunity. Genes play pivotal role in both metastatic dormancy and reactivation of CSCs.

Colonization of CSCs in Distant Organ(s) at Secondary Site

Cancer stem cells invade and adapt to tissue microenvironment in distant organs (e.g. liver, lungs, brain, adrenal glands, and bone marrow), and build secondary tumors (micrometastasis or macrometastasis) and tumor angiogenesis or remain in dormant metastasis.

Tumor Dormancy and Reactivation at Secondary Sites

Extravasated CSCs may remain dormant over a period with subsequent reactivation involving intracellular signaling, extracellular signaling, and induction signals originating from bone marrow niche.

- Tumor dormancy can be induced through several mechanisms, such as genetic and/or epigenetic changes in the malignant tumor, tumor hypoxia, angiogenic switch, evasion of immune destruction and inflammatory switch. Extravasated CSCs interact and adapt with tissue microenvironment and induce neoangiogenesis in order to ensure sufficient vascularization of malignant tumor.
- Alteration in the tumor microenvironment can facilitate tumor growth, recurrence and metastasis, and thereby permit the CSCs to exit from dormancy through interaction with vascular endothelial cells, cancer-associated fibroblasts (CAFs), tumor-associated immune cells, inflammatory cells and the extracellular matrix (ECM).
- In the novel stromal environment, CSCs form micrometastasis with the ability to generate macrometastasis, fully malignant secondary tumors elsewhere in distant organs such as the lungs, bones, liver, brain and other tissues.

Pathology Pearls: Activating Invasion and Metastasis: Sequence of Molecular Events

Carcinoma Development and Acquisition of Invasive Potential

- Proto-oncogene mutations (oncogenes)
- Tumor suppressor gene mutations
- Epithelial mesenchymal transition—epithelial cells acquire mesenchymal traits (i.e. loss of adherent cell–cell junctions, change in cellular morphology, expression of matrix metalloproteinases (MMPs), increased motility)
  - EMT signals at primary malignant epithelial tumor margin.
  - Partial EMT state facilitates CSCs motility and invasion into tumor stroma
  - Mesenchymal phenotype CSCs facilitate intravsation and anoikis resistance during dissemination

Expansion of Tumor Growth and Invasion of Basement Membrane into Surrounding Tissue

- Enhanced activity of matrix metalloproteinases (MMPs)
- Decreased tissue inhibitor of metalloproteinase (TIMPs)
- Enhanced mesenchymal CSCs motility, interaction with surrounding tissue ECM stromal cells
- Decreased integrity strength of cell–cell contacts (E-cadherin)

Tumor Angiogenesis, Intravasation and Transport of Mesenchymal Phenotype CSCs around the Body

- Enhanced activity of matrix metalloproteinases (MMPs)
- Decreased tissue inhibitor metalloproteinases (TIMPs)
- Mesenchymal phenotype CSCs migration/interaction through ECM, interaction with vascular endothelial cells and pass-through basement membrane, invasion into the blood vessel, interaction with platelets, lymphocytes and other blood components, and survival in circulation/evade immune destruction.
- Mesenchymal phenotype CSCs interaction with cavity mesothelial cells during transcoelomic metastasis.

CSCs Arrest and Extravasation at Secondary Site

- Mesenchymal phenotype CSCs arrest interacts with vascular endothelium via with integrin and laminin cell adhesion receptors leading to extravasation, survival and invasion into distant tissues/organs.
- Mesenchymal phenotype CSCs interaction occurs with cavity mesothelial cells during transcoelomic metastasis.

Metastasis into Secondary Site and Formation of Micrometastasis and Macrometastasis

- Metastasis of mesenchymal phenotype CSCs depend on blood supply, organ tropism/adhesion and functional loss of E-cadherin.

  Mesenchymal phenotype CSCs extravasation, migration and invasion into secondary tissues, and their survival, interaction and adaptation to tissue microenvironment, MET in secondary site, colonization, CSCs proliferation and formation of micrometastasis and colonization of CSCs forming macrometastasis, establishment of new vasculature in tumor (tumor angiogenesis).
- Secondary tumor can remain in dormancy and reactivated state.

REPROGRAMMING ENERGY METABOLISM (WARBURG EFFECT)

Cellular growth and proliferation depend upon the acquisition and synthesis of specific metabolic products, which fuel the bioenergy, biosynthesis, and redox potential required for duplication of cellular biomass. Normal cells use oxygen to process glucose and produce energy. Metabolism in CSCs is different from normal cells. Cancer stem cells consume >20 times as much glucose compared to normal cells, but produce lactic acid instead of breaking it down completely into carbon dioxide (CO_2).

- Cancer stem cells can switch to aerobic glycolysis even in the presence of oxygen for generation of adenosine triphosphate (ATP) and called 'Warburg effect'. Though aerobic glycolysis is less efficient but faster, that produces several intermediate metabolic products used by CSCs as building blocks, i.e. macromolecules such as proteins and lipids to support unrestricted cell proliferation. Other CSCs use lactate as their main energy source. Aerobic glycolysis inhibitors are therapeutic targets of this signaling pathway.
- Biochemist Otto Warburg observed in 1920 that when CSCs were provided with glucose, that generated large amount of lactate regardless of whether oxygen (O_2) was provided or not. This metabolic difference is referred as the 'Warburg effect' or aerobic glycolysis, where pyruvate is diverted from the Krebs cycle to produce lactate under aerobic conditions that allow more oxygen is delivered to tissues. Comparison of cellular glucose metabolism in normal and CSCs are shown in Fig. 6.82.

Energy Bioenergetics in Normal Cells

Glycolysis is a universal pathway for catabolism of glucose in normal cells via **Embden-Meyerhof pathway** that provides energy and intermediates required for other metabolic pathways.

- Normal cells take up glucose via glucose transporters (GLUTs) and utilize aerobic respiration. Glucose is metabolized to glucose-6-phosphate to produce pyruvate if O_2 supply is limited. Pyruvate in turn is converted to lactate by lactic dehydrogenase A enzyme.

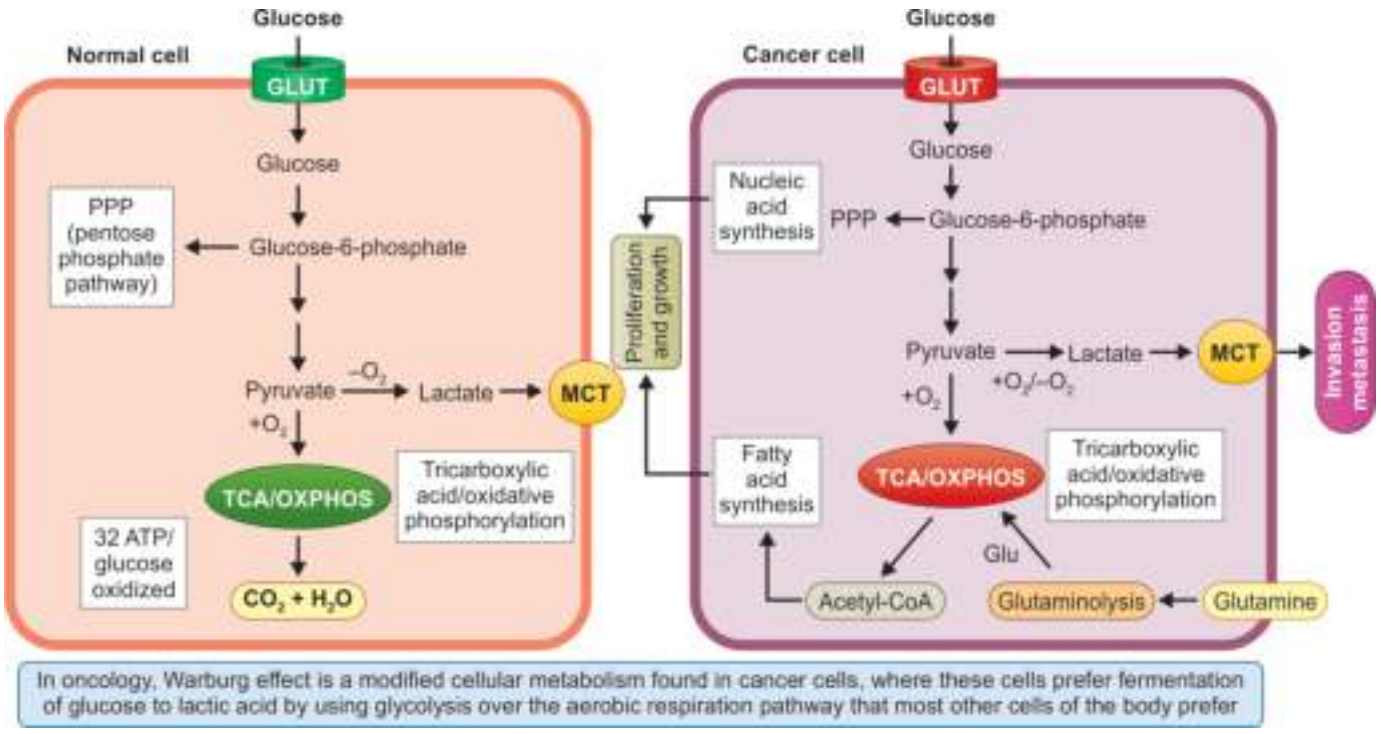

Fig. 6.82: Comparison of cellular glucose metabolism in normal and CSCs. Normal cells do not metabolize glucose to lactate when oxygen is available. When oxygen is absent, normal cells resort to anerobic glycolysis to convert glucose to lactic acid. On contrary, CSCs metabolize glucose to lactate even in the presence of oxygen and fully functioning mitochondria. This process is known as 'Warburg effect'—hallmark of cancer, which prefers fermentation of glucose to lactic acid by using glycolysis over the aerobic pathway that most normal cells of the body prefer.

- Lactate is exported from the normal cell by monocarboxylate transporter protein. Glucose is metabolized to pyruvate, which is completely oxidized to carbon dioxide (CO_2) and abundant ATPs for cellular energy through Krebs cycle, i.e. tricarboxylic acid cycle (TCA cycle) and oxidative phosphorylation process in the mitochondria.
- If O_2 is limited, pyruvate is metabolized to lactate. Altogether, mitochondria can generate as much as 36 ATP molecules per glucose molecule during aerobic glycolysis in normal cells, and 2 ATP per glucose molecule during anaerobic glycolysis. Key markers in reprogramming of energy metabolism (Warburg effect) in cancers are given in Table 6.57.

Altered Bioenergetics ('Warburg Effect') in Cancer Stem Cells

Cancer stem cells (CSCs) in malignant tumor require high levels of energy and nutrients with the ability to survive in hypoxic tumor environment,which is not completely vascularized. To meet energy and nutrients needs, RAS/RAF/MEK/ERK (MAPK) and phosphatidylinositide 3-kinases (PI3K)/AKT/mTOR signaling pathways are altered in human cancers contributing to the Warburg effect in cancer stem cells. Altered signaling pathways and their contribution to the 'Warburg effect' in CSCs are shown in Fig. 6.83.

Table 6.57 Key markers in reprogramming of energy metabolism (Warburg effect) in cancers

Hypoxia State Markers
▪ Hypoxia-inducible factor (HIF1A, HIF2B, HIF1B) is heterodimeric DNA binding transcription factor that regulates a broad range of cellular systems to hypoxia ▪ CAIX is a mediator of hypoxia-induced stress response in a CSC ▪ AP-1/c-Jun transcription factor plays an important role in tumor development and progression ▪ GLUT1 levels can be elevated in hypoxia state. GLUT1 analysis is done to assess the degree of hypoxia
Glycolysis Markers
▪ TOMM20 and GADH are essential for glutamine metabolism. Concentrations of TOMM20 and GADH are increased in various human malignancies ▪ V-ATPase expression is increased in CSCs ▪ AP-1/c-Jun transcription factor plays an important role in tumor development and progression ▪ GLUT1 levels can be elevated in hypoxia, and its analysis can be used to indicate the degree of hypoxia
Mitochondrial Metabolism Markers
▪ COX IV is a marker for assessment of inner membrane of mitochondria ▪ VDAC1/Porin is a marker for assessment of outer membrane of mitochondria ▪ ATPase-β subunit has a crucial role in the structural and functional maturation of Na^+/K^+ ATPase

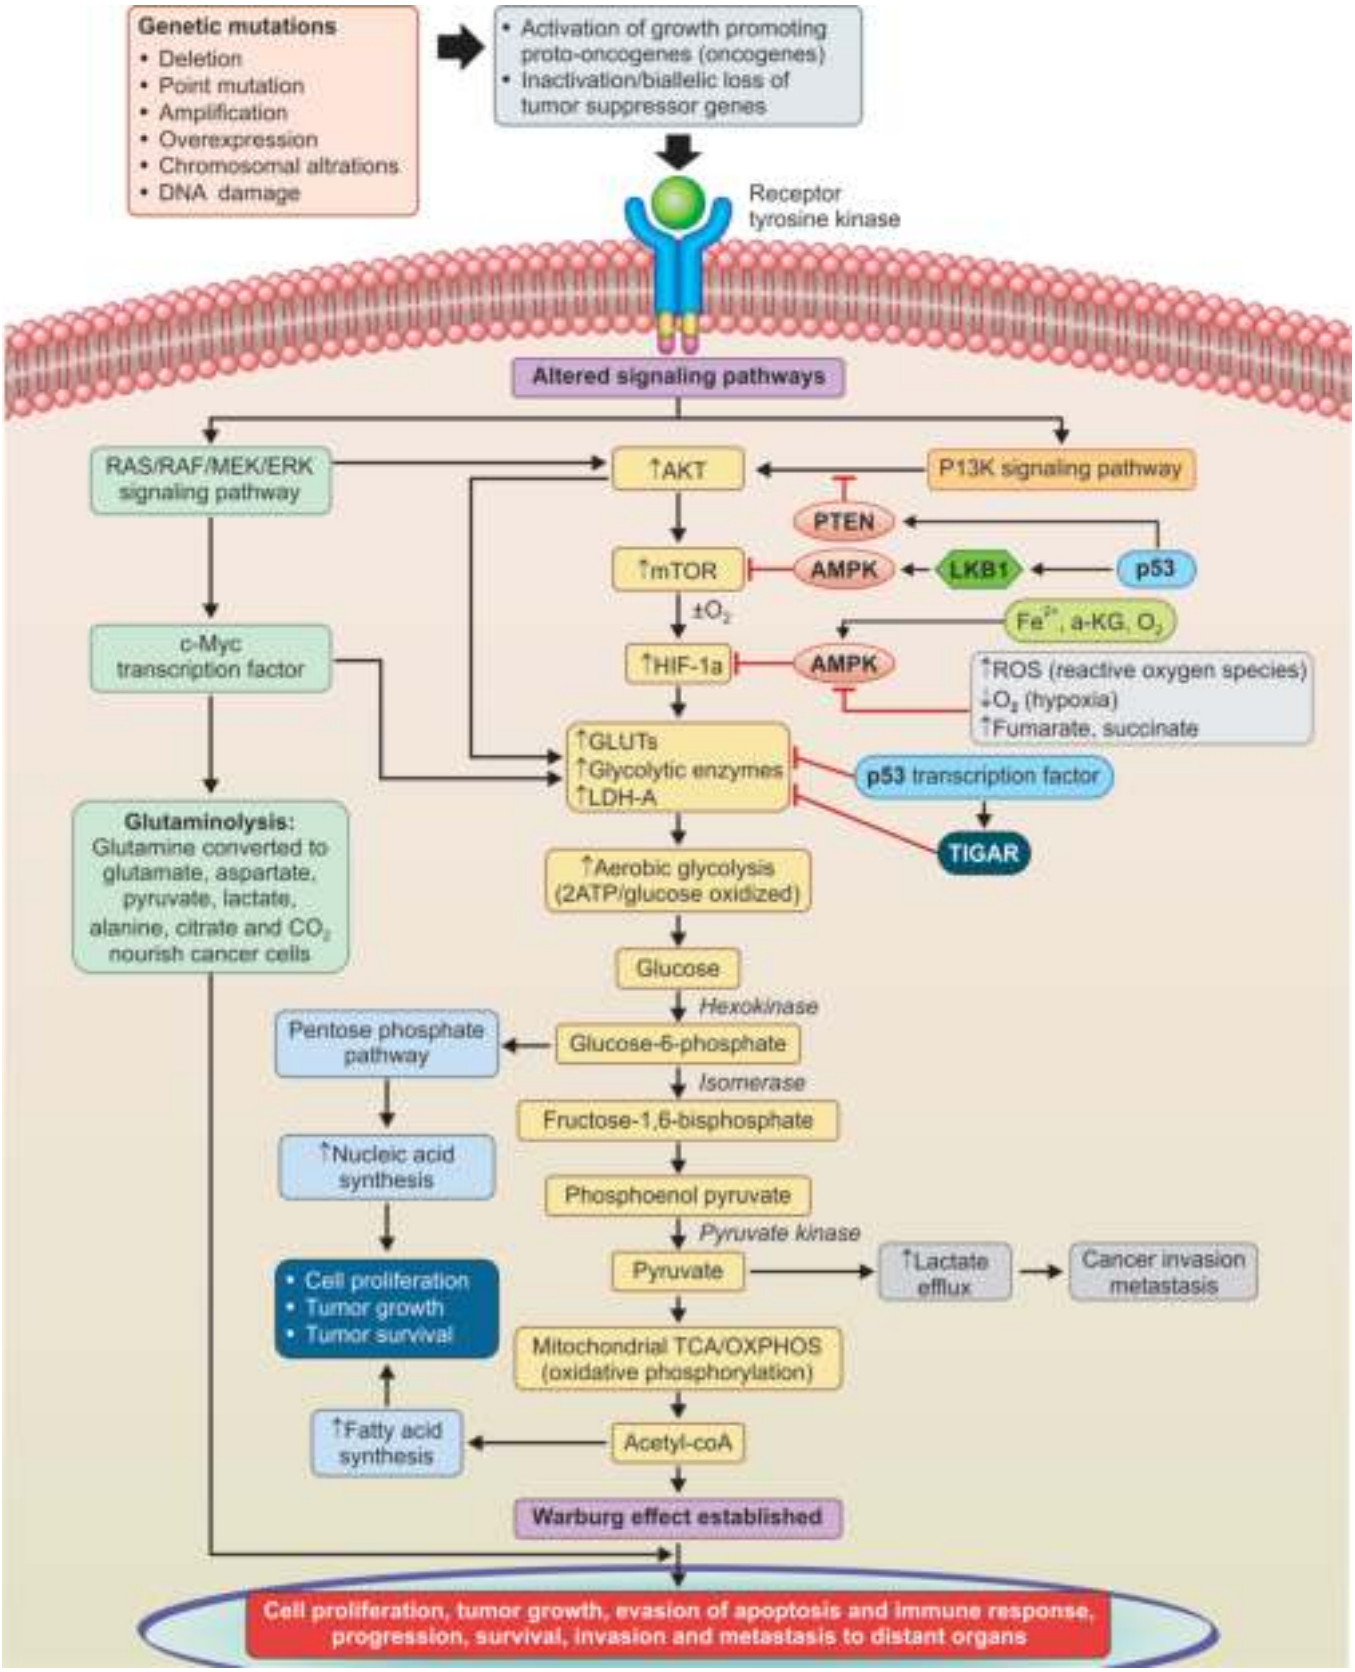

Fig. 6.83: Altered signaling pathways and their contribution to Warburg effect in CSCs. In human cancers, the rate of glucose uptake dramatically increases and lactate is produced even in the presence of oxygen and fully functional mitochondria. This process is known as Warburg effect.

- Phosphatidylinositide 3-kinase (PI3K)/AKT/mTOR signaling pathway increases synthesis of lipids as well activity of cell membrane transporters so that increased amino acids are available to support the proteosynthetic needs of CSCs. Transcription factors such as hypoxia-inducible factor-1α (HIF1A) and c-Myc play a pivotal role in glucose metabolism in CSCs via increased GLUT1 and GLUT3 glucose transporters.
- CSCs rely primarily on aerobic glycolysis 'Warburg effect' even in the presence of oxygen required for glucose metabolism to generate abundant lactate and less ATPs (i.e. 2 ATP per CSC) in mitochondria than aerobic respiration, instead of catabolism of glucose to CO_2, H_2O and ATP.
- Lactate produced from aerobic glycolysis causes acidification of tumor microenvironment (**TME**), favoring the development of a more aggressive, invasive and metastatic phenotype. Lactate can also serve as a nutrient for other cells in the malignant tumor.
- CSCs also increase glutamine metabolism to produce glutamate during glutaminolysis serves as the major substrate to refuel the tricarboxylic acid (TCA)/Krebs cycle. Citrate derived acetyl-CoA is used for lipid production. The increased synthesis of nucleic acids (DNA and RNA) and lipids promote unrestricted proliferation of CSC, and survival.

EVASION OF IMMUNE DESTRUCTION

The immune system (innate/non-specific and adaptive/specific) performs several functions such as defense against exogenous microbes or endogenous altered virally infected transformed cells, homeostasis, destruction of virally transformed cells and surveillance.

- Cytokines are naturally occurring proteins produced by the cells of immune system (macrophages and lymphocytes) that coordinate and initiate effector defense functions. Cytokines include interleukins, interferons, colony-stimulating factor and tumor necrosis factor-α, which mediate and regulate immune defense functions by acting as messengers between various cells of immune system.
- Hanahan and Weinberg discussed evidence supporting the key role played by immune system as a barrier to CSCs. Cells and tissues are under constant surveillance by immune system, that detects and tries to kill CSCs of malignant tumors.
- CD4+ helper T cells assist B cells, that recognize the processed CSC antigen and progress to become plasma cells. T cell and B cell interaction requires the major histocompatibility class II (MHC-II) molecules for presenting a processed CSC antigen, plus two additional recognition connections via CD40, specifically recognizing the MHC class II complex and the CD40 binding to CD40 ligand.
- CD8+ cytotoxic T cells must recognize the processed CSC antigen presented only by major histocompatibility class I (MHC-I). CD8+ cytotoxic T cell activation is enhanced by CD4+ helper T cell binding to processed CSC antigen. Each T cell receptor (TCR) must bind with the processed CSCs antigen presented by appropriate major histocompatibility molecules. CD4+ helper T cell and CD8+ cytotoxic T cell bind to the respective major histocompatibility molecules, i.e. MHC-II and MHC-I respectively.
- CD8+ cytotoxic T cells can only be activated by binding to dendritic cells. Once CD8+ cytotoxic T cells activated, they leave the lymph node and then are attracted by cytokines and chemokines released by the innate immune cells at the malignant tumor site. During transit time, CD8+ cytotoxic T cells synthesize specific proteins such as perforin, granzyme B and Fas ligand. Perforin causes fenestrations within the CSC membrane, allowing entry of granzyme and Fas ligand. Granzyme and Fas ligand induce apoptosis via two different mechanisms leading to CSC death.
- CSCs develop different strategies by acquisition of new gene mutations to escape immune surveillance leading to development of malignant tumor growth.

Pathology Pearls: Cancer Stem Cells Evasion of Immune Destruction

Modulation of Antigens on CSCs

- ↓Tumor immunogenicity
- ↑Maintenance of cancer stem cell clones
- ↓Immunogenic antigens

Antigen Presentation in Lymph Node

- Inhibition of dendritic cells maturation and antigen presentation
- ↑IL-10, MCSF, VEGF, prostaglandins, TGF-β, IDO
- ↑CD4+ T regulatory cells, myeloid-derived suppressor cells (MDSCs)
- ↓IL-12, IFN-γ

Priming and Activation in Lymph Nodes

- Suppression of T cell activation
  - ↑Calcium/NFAT signal
  - ↓B7.1/B7.2:CD28, 4-1BBL:4-1BB, OX40L:OX40
  - ↓CD70:CD27, GITRL:GITR

Trafficking of T Cells to Cancer

- Inhibition of T cell migration and infiltration
- ↑Cleaved CXCR3 ligands, FasL
- ↑VEGF, PGE_2, CXCL12, ECM
- ↓CXCl9, CXCl10, CXCL11

Immune Cell Cycle Regulation
▪ Normal immune cell cycle disruption ▪ Cancer stem cells evade immune destruction
Regulation of CSC by T Cell
▪ Inhibition of CSC recognition by immune cells ▪ ↑Maintenance of CSC clones without antigens, immune response of natural killer cells ▪ ↓MHC-1 (remove, reduce, transform) peptide—MHC components, NKG20 ligands ▪ ↓Antigens, proteosome components, TAP/TAP2, MHC-1 and β-microglobulin
Cancer Stem Cells Killing

Immune System Dysfunction and Cancer Stem Cells Survival

When the immune system loses its function of surveillance, cancer stem cells have ability to form a malignant tumor. CSCs evade immune destruction can be explained by the following proposed potential mechanisms such as CSC antigen recognition, immune system dysfunction, and T cell exhaustion.

- In addition, CSCs evade immune destruction by accumulating specific metabolites and signaling factors within tumor microenvironment (TME) or limiting nutrients available to immune cells.
- Interaction of signaling costimulatory molecules, i.e. CD155 on CSCs and CD226 on effector T cells causes reinforcing the immune response.
- Following the discovery of B7.1 (CD80) on antigen-presenting cells (APCs), several other costimulatory molecules stimulate T cell activation resulting in improving anti-tumor immunity. CSCs evade immune destruction can be explained by the following proposed potential mechanisms.

Decrease in Tumor Immunogenicity

During carcinogenesis, immunosurveillance removes cancer stem cell clones that express strong immunogenic neoantigens. At this point, cancer stem cells (CSCs) evade immune destruction due to modulation of antigens on CSCs by various mechanisms: (a) elimination of immunogenic antigens, (b) entry of neoantigens on CSC, (c) neoantigens on CSCs masked by increased glycocalyx. Modulation of antigen and poor immunogenicity limit the ability of immune system to recognize

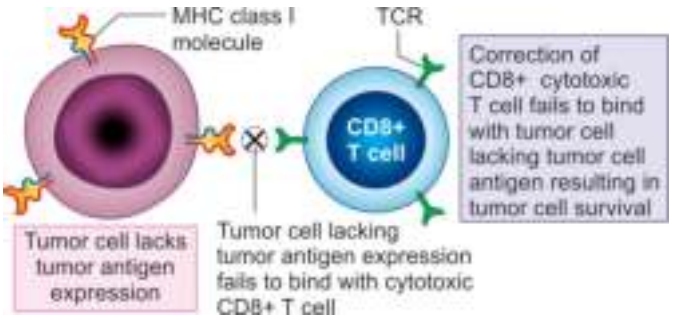

Fig. 6.84: Evasion of immune destruction of cancer stem cells due to modulation of tumor antigens and lack of recognition by CD8+ cytotoxic T cells. Many tumors may be weakly antigenic or lacking antigen. Tumor antigens are masked as a result of increased synthesis of glycocalyx on stem cells. Tumor antigen modulation limits the ability of the immune system to recognize the tumor cells and may avoid immunologic destruction by T cells.

cancer stem cells as non-self during dormancy state. Evasion of immune destruction of cancer stem cells due to modulation of tumor antigens and lack of recognition by CD8+ cytotoxic T cells is shown in Fig. 6.84. Immunogenicity of malignant tumor is shown in Fig. 6.85.

Inhibition of Dendritic Cell Maturation

Cancer stem cells do not give off inflammatory warning signals, hence evade immune destruction. In tumor-promoting inflammation, damaged-associated molecular patterns (DAMPs) are endogenous danger molecules that are released from damaged or dying normal cells into tumor microenvironment and activate dendritic cell (DC) maturation of innate immune system by interacting with pattern recognition receptors (PRRs).

- Cancer stem cell-derived factors such as IL-10, macrophage colony stimulating factor (M-CSF), vascular endothelial growth factor (VEGF), prostaglandins, TGF-β, and indoleamine 2,3-dioxygenease (IDO) inhibit maturation and function of DC.
- In addition, immunosuppressive cells in tumor microenvironment (TME) such as CD4+ regulatory T cells, and myeloid-derived suppressor cells (MDSCs) express inhibitory factors, that suppress dendritic cell maturation, reducing the expression of major histocompatibility complex molecules and co-stimulatory factors in dendritic cells, leading to reduced production of inflammatory cytokines, such as IL-12, and IFN-γ, which inhibit proliferation of T cells.

Suppression of T Cell Activity

Both antigen recognition and co-stimulatory signals are required for T cell activation. Co-stimulatory interactions between dendritic cells and CD4+ helper/

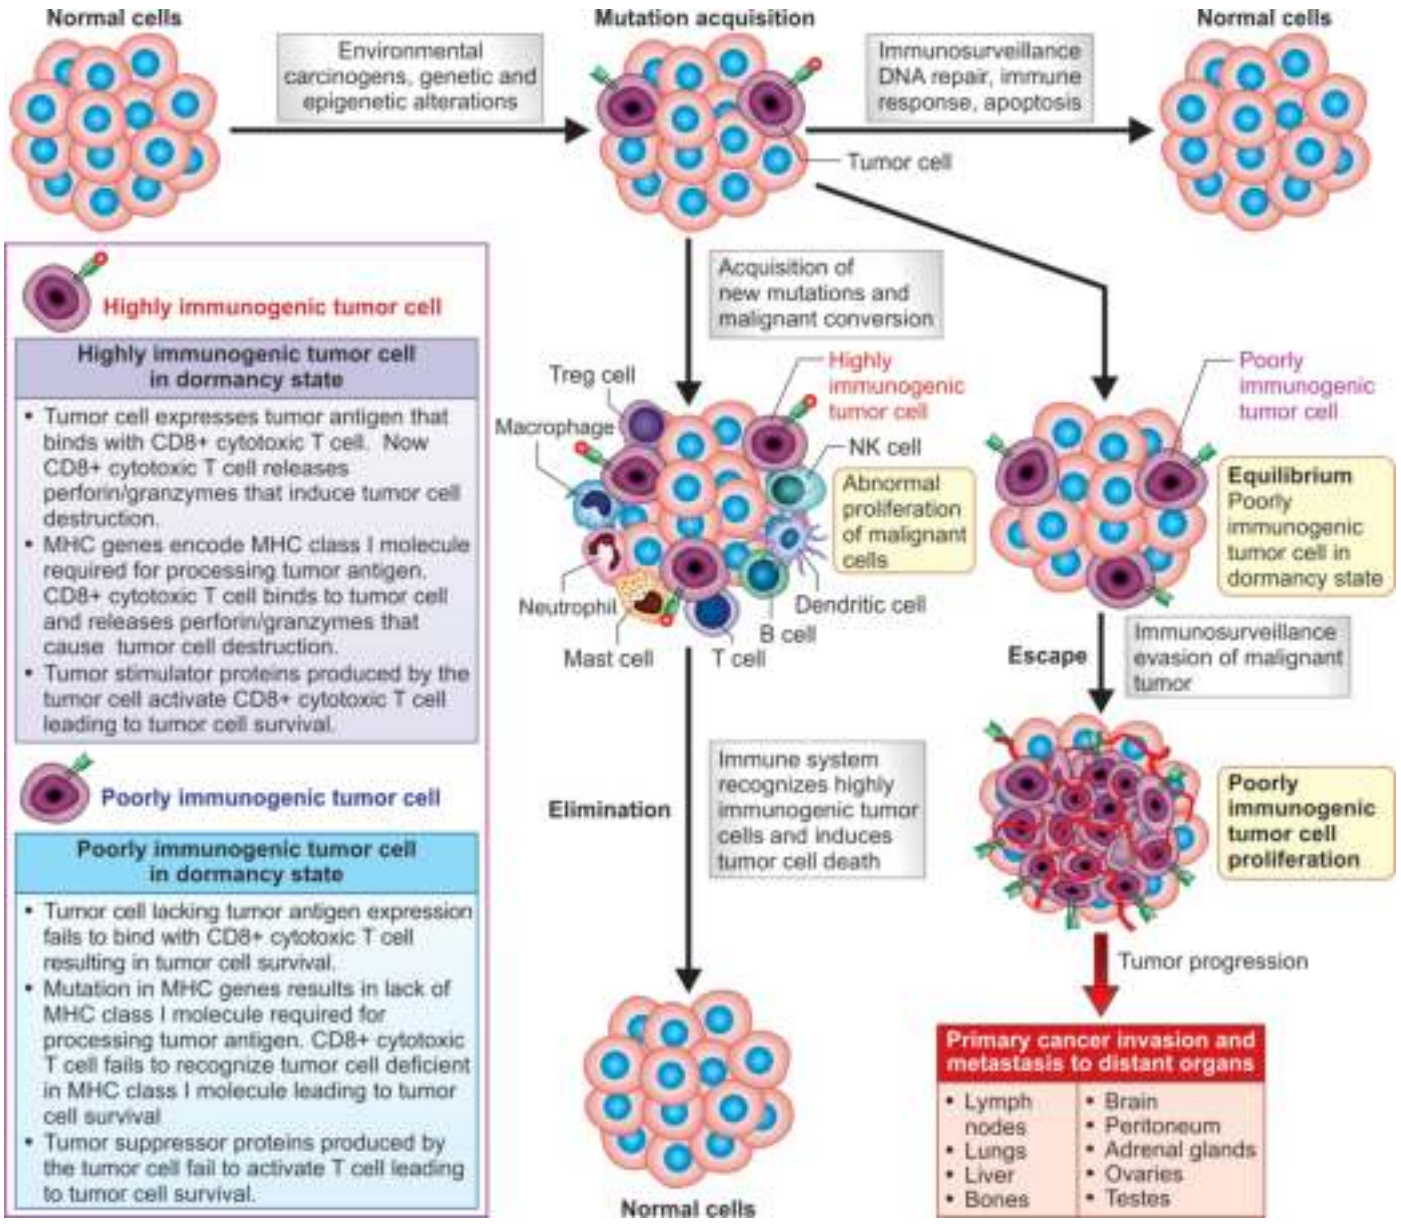

Fig. 6.85: Immunogenicity of malignant tumor. Tumor dormancy is an arrest in tumor growth, which may occur during the formation of primary tumor or after dissemination to distant organs. Primary tumor dormancy and metastatic dormancy appear to be distinct processes. Immunogenic tumors with sufficient antigens and priming elicit good CD8+ cytotoxic T cell responses, while poorly immunogenic tumors fail to generate CD8+ cytotoxic T cell responses.

CD8+ cytotoxic T cells include B7.1 or B7.2:CD28, 4-1BBL:4-1BB, OX40L:OX40, CD70:CD27, GITRL: GITR. These co-stimulatory interactions play key roles in cell proliferation, differentiation, survival, cytotoxic function, memory, and cytokine synthesis of T cells.

- Cancer stem cells inhibit priming and activation of T cells in lymph nodes by reducing the expression of co-stimulatory factors and major histocompatibility complex (MHC), thus limiting the co-stimulation required for T cells.
- When the T cell receptor (TCR) is activated without co-stimulation, excessive activity of calcium/nuclear factor of activated T cell (NFAT) signals induce the expression of negative modulating factors and T cells become unresponsive (T cell anergy).

Inhibition of T Cell Migration and Infiltration into Malignant Tumor

Malignant tumors exploit a number of mechanisms to limit T cell homing and infiltration. T cell trafficking across vascular endothelial barriers into the tissues

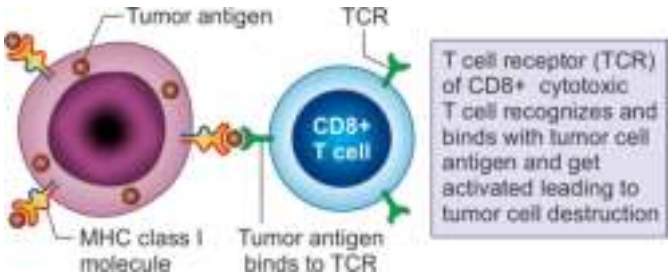

Fig. 6.86: Role of CD8+ cytotoxic T cells in anti-tumor immune response. CD8+ cytotoxic T cells recognize tumor antigen presented by antigenic presenting cell leading to destruction of cancer stem cells.

is highly regulated. In nonlymphoid tissues, resting vascular endothelial cell lining capillaries and venules are normally refractory to leukocyte entry.

- Transmigration of T cells and monocytes occurs in the tumor microenvironment (TME). Presence of CD8+ cytotoxic T cells within tumor microenvironment is a positive prognostic factor for patients towards better clinical outcomes. Role of CD8+ cytotoxic T cells in anti-tumor immune response is shown in Fig. 6.86.
- Conversely, impaired anti-tumoral immune response is a hallmark of growing malignant tumors. The concept of T cell-driven immunosurveillance against malignant tumor has led to the development of immunotherapies. Malignant tumors enriched in T cells especially CD8+ cytoxic T cells are more susceptible to be controlled by programmed cell death 1 (PD-1) blockade.
- CD4+ regulatory T cells (**Tregs**) are key immunosuppressive cells that promote malignant tumor growth by hindering the effector immune response.
  - CD4+ regulatory T cells (Tregs) utilize multiple suppressive mechanisms to inhibit proinflammatory responses within the TME by inhibition of effector function and immune cell migration, secretion of inhibitory cytokines and metabolic disruption.
  - In addition to immunosuppressive function, Tregs also serve as key interactors in the peritumoral stroma, vasculature and lymphatics to limit anti-tumor immune response.
  - CD4+ regulatory T cells promote a physical and biological barrier resulting in exclusion of immune and non-immune cells outside and within TME by various mechanisms. Within TME, CD4+ regulatory T cells (Tregs) utilize inhibitory receptors (PD1, TIM3, TIGIT and LAG3), inhibitory cytokines (IL-10, IL-35 and TGF-β), dendritic cell modulation (via CTLA-4 and LAG-3) and metabolic disruption (via CD39/CD73) to suppress the anti-tumoral T cell immune response.
  - CD4+ regulatory T cells (Tregs) derived TGF-β induce cancer-associated fibroblasts (CAFs) increase extracellular matrix (ECM) production and deposition within the peri-tumoral stroma to inhibit trafficking of effector T cells.
  - CD4+ regulatory T cells (Tregs) inhibit entry of effector T cells through preventing proper cytokine signals that promote vascular endothelial venule formation as well as production of cytokines such as IL-10 and vascular endothelial growth factor (VEGF) by CSCs to promote dysregulated angiogenesis. VEGF also reduces the expression of cell adhesion molecules on vascular endothelial cells and inhibits migration of T cells outside and within microenvironment (TME).
  - CD4+ regulatory T cells (Tregs) can modulate dendritic cell maturation in lymphoid organs and induce apoptosis of CD8+ cytotoxic T cells to prevent proper effector T cell activation.

Inhibition of Recognition of CSCs by Immune Cells

Normally, co-stimulatory signaling major histocompatibility complex class I (MHC-I) molecules play key role in CSC antigen presentation to immune cells. MHC class I molecule downregulation/allelic loss allows CSC antigen to go unrecognized by antigen-presenting cells (APCs), that facilitates CSCs to escape from CD8+ cytotoxic T cell-mediated immunosurveillance. Evasion of immune destruction of CSCs due to mutations in MHC genes normally needed for antigen processing is shown in Fig. 6.87.

- Approximately, 40–90% of human cancers express downregulation/allelic loss of major histocompatibility complex class I molecules. Downregulation/loss of MHC class I antigen expression is frequently

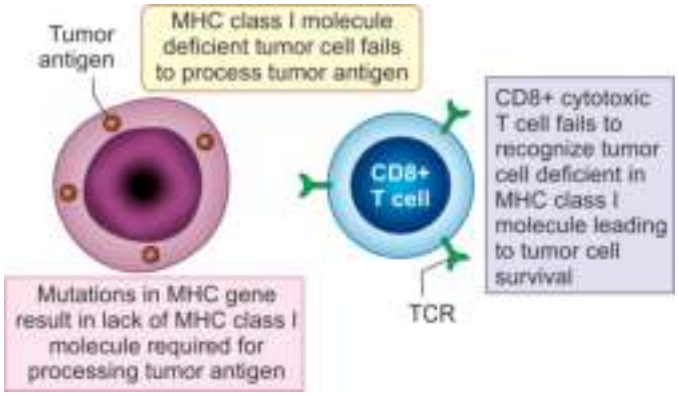

Fig. 6.87: Evasion of immune destruction of CSCs due to mutations in MHC gene normally needed for antigen processing. Silencing, downregulation, or loss of HLA alleles inhibits peptide antigen presentation and facilitates CSCs to escape from immunosurveillance.

associated with invasive and metastatic tumor phenotype. Altered MHC class I involves complete loss of expression, haplotype, and loss/downregulation of locus, alleles, and combinations.

Synthesis of Immunosuppressive Molecules by CSCs

Cancer stem cells synthesize excess immunosuppressive molecules, that inhibit the body's immune response resulting from failure of priming and activation of antigen-presenting cells (APCs), and recognition of antigen by T cells via the T cell receptor (TCR) in the lymph node, which normally attack CSCs.

Downregulation of Antiapoptotic Proteins

Downregulation of antiapoptotic proteins (BCL-2, c-FLIP, IAPs) and poor stimulation of CD8+ cytotoxic T cells limit the ability of immune system to recognize and destroy CSCs.

Aberrant Signaling Pathways

Aberrant signaling pathways, i.e. phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR, RAF/MEK/ERK mitogen-activated protein kinase (MAPK), JAK/STAT, Wnt/β-catenin, Hedgehog and NF-κB signaling pathways limit destruction of CSCs by immune system.

Synthesis of Factors by CSCs and Creation of Physical Barrier to the Immune Cells in Tumor Microenvironment

Synthesis of factors by CSCs leads to creation of physical barrier to the immune cells in tumor microenvironment (e.g. macrophages, CD4+ helper T cells, CD8+ cytotoxic T cells, B cells and natural killer cells), hence limit destruction of CSCs by immune system.

Synthesis of Co-suppressor Molecules by CSCs

Cancer stem cells synthesize co-suppressor molecules, which include: checkpoint programmed cell death ligands 1 and 2 (PD-L1, PD-L2), transforming growth factor-β (TGF-β), CD155, HVEM, MHC class II, galectin-3, lymphocyte blastogenesis inhibitory factor (LBIF), p15E, and suppressive E-receptor (SER). Co-suppressor molecules (e.g. PD-1, TIGIT, BTLA, TIM-3, LAG-3) are expressed on T cells. RAS/RAF/MEK/ERK (MAPK), phosphatidylinositide 3-kinase (PI3K)/AKT/mTOR, JAK/STAT, Wnt/β-catenin, Hedgehog and NF-κB signaling pathways promote the expression of PD-1/PD-L1 axis. Moreover, increasing understanding of co-inhibitory receptors has highlighted key additional signaling pathways that can dominantly inhibit anti-tumor T cell function.

- **Programmed cell death protein 1 (PD-1):** Programmed cell death protein 1 (PD-1) expressed on CSCs plays key role in suppression of immune response and promoting self-tolerance through modulating the activity of T cells, activating apoptosis of antigen-specific T cells, and inhibiting apoptosis of CD4+ regulatory T cells.
- **Programmed cell death ligand 1:** Programmed cell death ligand 1 (PD-L1), a transmembrane protein, is considered to be co-suppressor molecule of the immune response. PD-L1 can combine with PD-1 to reduce proliferation of PD-1 positive T cells, inhibit their cytokine secretion and induce apoptosis.
  - Programmed cell death protein 1 (PD-1) also plays an important role in various human malignancies where it attenuates the immune response to CSCs. Based on these perspectives, PD-1/PD-L1 axis is responsible for CSCs immune escape and makes a huge effect on cancer therapy.
  - On the other hand, binding of B7 on CSC to CD8+ cytotoxic T lymphocyte antigen-4 (CTLA-4) inhibits T cell activation, that prevents destruction of CSC. Blocking CTLA-4 or B7 allows T cell to kill CSCs. Some checkpoint inhibitors are used to treat human cancers.
  - Improving positive costimulation, and interfering with negative regulation, continues to represent an attractive immunotherapeutic approach for the treatment of human cancers. Immune checkpoint targets such as PD1/PD-L1, TIM3, and LAG3 are all critical checkpoint molecules that have revolutionized caner immunotherapy.
  - Cancer stem cells evading immune destruction due to synthesis of immunosuppressive proteins (TGF-β) are shown in Fig. 6.88. PD-1/PD-L1 axis in CSCs and immune checkpoint inhibitors used in cancer treatment are shown in Fig. 6.89.

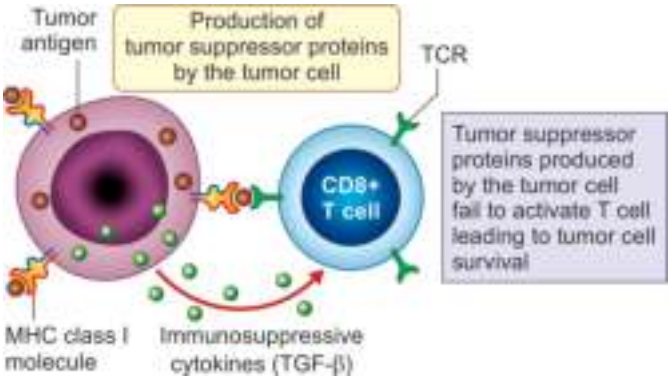

Fig. 6.88: Cancer stem cells evading immune destruction due to synthesis of immunosuppressive proteins (TGF-β). Some well-characterized immunosuppressive molecules synthesized by CSCs include transforming growth factor-β (TGF-β), checkpoint programmed cell death protein 1 (PD-1)/programmed cell death ligands 1 and 2 (PD-L1, PD-L2), galectin-3, lymphocyte blastogenesis inhibitory factor (LBIF), p15E and suppressive E-receptor (SER). Checkpoint programmed cell death protein 1 (PD-1)/programmed cell death ligands 1 and 2 (PD-L1, PD-L2) are negative immunoregulatory molecules that promote immune evasion of CSCs.

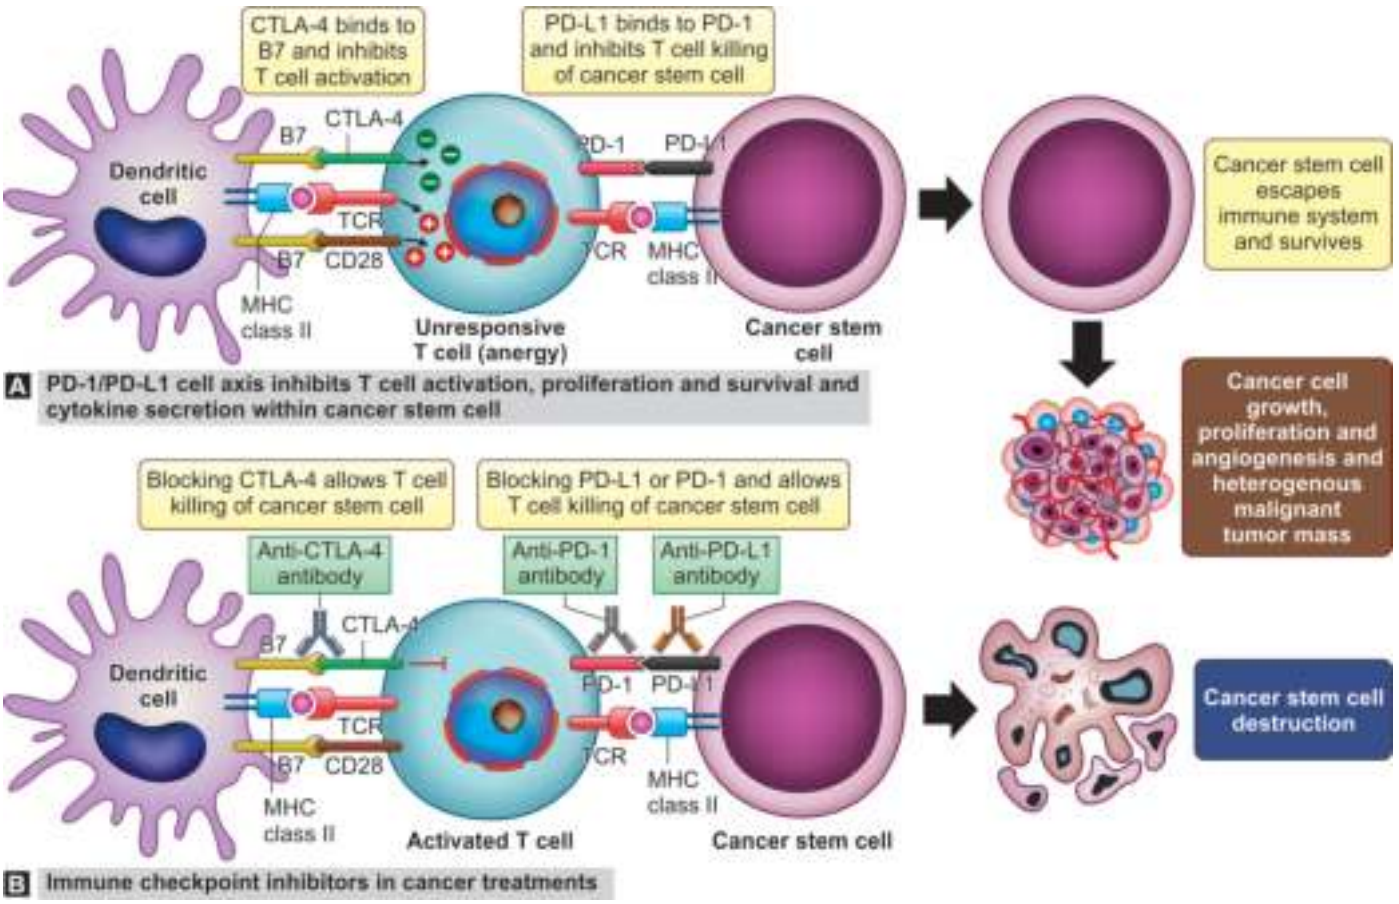

Fig. 6.89: PD-1/PD-L1 axis in CSCs and immune checkpoint inhibitors used in cancer treatment. Antigen-presenting cells (APCs) such as dendritic cells (DCs), regulate antigen-specific T cell responses to CSCs. Checkpoint proteins are found on CSCs (PD-L1 and B7) and on T cell (PD1 and CTLA-4). PD-1 (programmed cell death protein 1)/PD-L1 (programmed cell death ligand 1) cell axis inhibits T cell activation, proliferation and survival and cytokine secretion within CSCs, which lead to escape of CSCs destruction and survive. Blocking PD-L1 or PD-1 allows T cell to kill CSCs. On the other hand, binding of B7 on cancer stem cell with CTLA-4 (cytotoxic T lymphocyte antigen 4) on T cell inhibits T cell activation, that prevents destruction of cancer stem cell. Blocking CTLA-4 on T cell or B7 on cancer stem cell allows T cell to kill CSC. Some checkpoint inhibitors are used to treat cancers.

Pathology Pearls: Cancer Stem Cells Destruction by Immune System

- Tumor antigens are presented and processed by major histocompatibility complex (MHC) class II molecule on antigen-presenting cells (APCs) in the lymph node, that leads to priming and activation of APCs.
- Recognition of tumor antigens on the MHC class I molecule by T cell receptor (TCR) especially CD8+ cytotoxic T cells leads to priming and activation of CD8+ cytotoxic T cells in the lymph node.
- Trafficking of activated CD8+ cytotoxic T lymphocytes (CTLs) occurs around cancer stem cells (CSCs) in tumor microenvironment (TME).
- Activated CD8+ cytotoxic T cells infiltration occurs into TME.
- Recognition of tumor antigens on the MHC class I molecules by CD8+ cytotoxic T cells within tumor microenvironment and leads to destruction of CSCs.
- CD8+ cytotoxic T cells directly destroy CSCs.

GENOMIC INSTABILITY (MUTATED PHENOTYPE)

Normal eukaryotic cells have 23 pairs of chromosomes per cell, stored in the nucleus. The maintenance of genomic stability is essential for cellular genomic integrity to prevent errors from DNA replication, endogenous genotoxic stress, i.e. reactive oxygen species (ROS), reactive nitrogen intermediates (RNI) derived from cellular metabolism, and exogenous genotoxic carcinogenic insults such as ultraviolet light, ionizing radiation and chemical agents. Genomic stability and instability mechanisms are shown in Fig. 6.90. Genomic instability due to defective DNA repair machinery is given in Table 6.58.

- **Genomic stability:** Genomic stability (integrity) is closely monitored by several surveillance mechanisms: DNA repair machinery and mitotic checkpoints and telomere maintenance during cell division. The response to DNA damage can result in two major physiologic consequences during cell

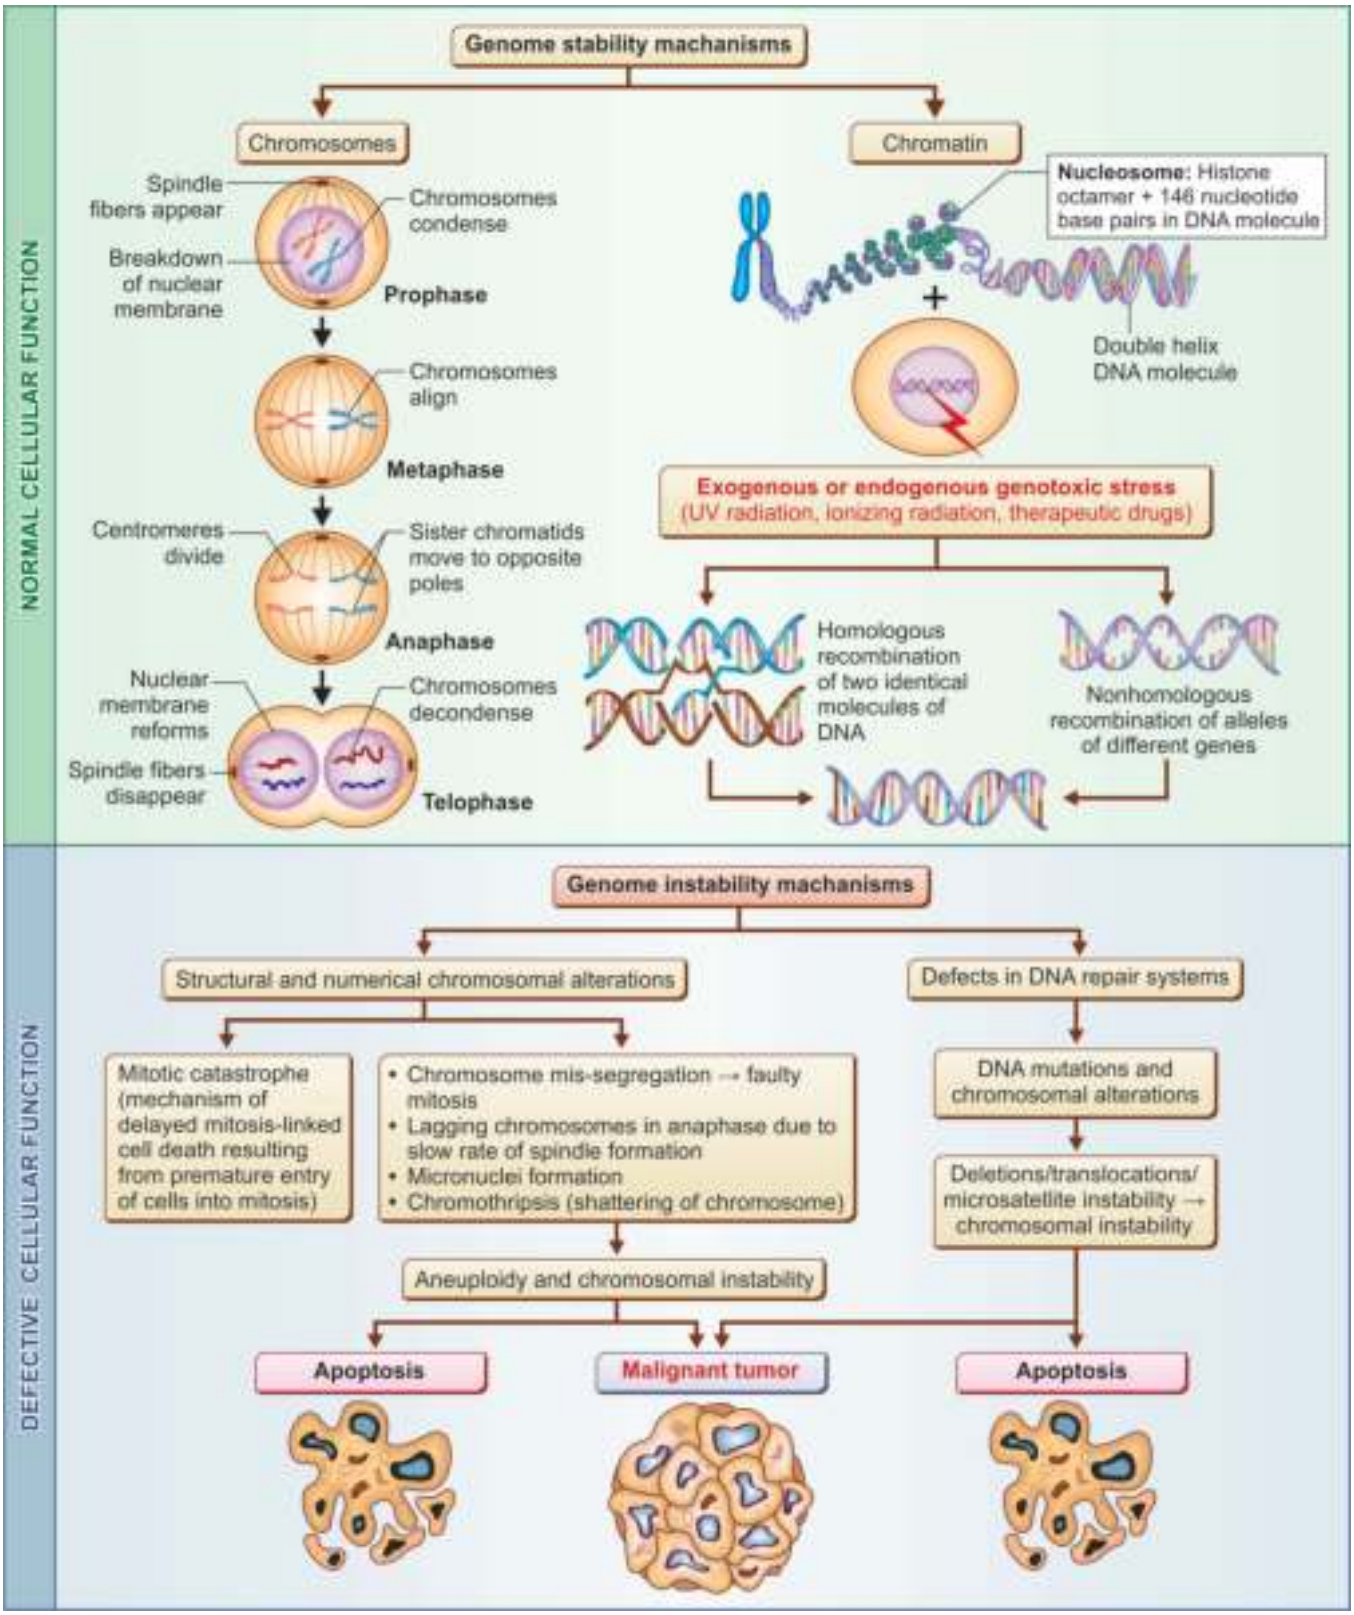

Fig. 6.90: Genomic stability and instability mechanisms. Genomic stability is critical for cell survival and cell growth. Genomic chromosomal rearrangements and defective repair systems result in gene mutations that underlie many human diseases, ongoing genomic instability likely contributes to the development of many cancers.

Table 6.58 Genomic instability due to defective DNA repair machinery

Key Molecule	Function
Nucleotide excision repair of DNA	
ERCC-XPF (endonuclease)	DNA damage repair (DNA interstrand crosslinks and double-strand break repair)
XPA (zinc finger protein)	DNA damage repair
TFIID complex (transcription factor IID)	TFIID complex binds to the TATA box in the core promoter of the gene
Nucleotides base excision repair of DNA	
APEX1/APEX2 (endonuclease)	DNA repair
PNKP (polynucleotide kinase 3-phosphatase), DNA processing enzyme	Catalyzes 5'-kinase and 3'-phosphatases activity
FEN1 (flap endonuclease 1)	Removes 5' overhanging flaps in DNA repair
Double-strand break (DSB) repair of DNA	
Gamma H2AX (component of histone octamer in the nucleosome)	Gamma H2AX is phosphorylated in DNA damage
XRCC4 (XRCC4 + DNA ligase IV + DNA dependent protein kinase)	DNA double-strand break (DSB) repair
BRCA1 gene	DNA repair and cell cycle regulation
53bp1 (53bp1 + damaged chromatin)	DNA repair
KAP1 gene product	DNA repair
Mismatch nucleotide base repair of DNA	
MSH1 and MSH2 gene products	DNA mismatch nucleotide base repair
MSH2 and MSH3 gene products	DNA repair by insertion/deletion loop repair
PMS2	DNA mismatch nucleotide base repair
KAP1 gene product	Key regulator of normal development and differentiation

division: (a) cell can undergo cell cycle arrest to repair damaged DNA, and (b) if damaged DNA is not repaired, the cell undergoes apoptosis.

- **Genomic instability:** Genomic instability is a characteristic of most human cancers. DNA damage in a normal cell results in cell cycle arrest followed by either DNA repair and restoration of normal functions, or apoptosis of cell unable to repair DNA damage. Interference in DNA repair may occur either due to loss of recognition and repair of damaged DNA cell or abnormal gatekeeping of cell cycle. Genomic instability and mutation act as enabling molecular hallmark of cancer. Poly (ADP-ribose) polymerase (PARP) inhibitors are used in clinical practice.
  - Genomic instability occurs due to high frequency of genomic alterations such as nucleic acid sequences, DNA strand breaks, crosslinks, mismatches, microsatellite instability, chromosome rearrangements or aneuploidy, or telomere stability and/or DNA damage response during cell division.
  - Genomic instability occurs in 90% of human cancers (e.g. breast carcinoma, prostatic carcinoma, small cell lung carcinoma, neuroblastoma, leukemia). Changes in genome may arise through direct DNA genetic mutations or through epigenetic modifications that can change protein expression levels and adversely affect genomic stability (integrity). Cancer stem cells generally have several chromosomal abnormalities.
  - Based on the level of disruption, genomic instability is of two types: (a) nucleotide instability occurs due to nucleotide substitution, deletion or insertion (e.g. xeroderma pigmentosum, MYH associated polyposis), and (b) microsatellite instability occurs due to defect in mismatch repair (e.g. Lynch syndrome).
  - Chromosomal instability is most prominent form of genomic instability. About 90% of human cancers exhibit chromosomal aneuploidy, gene amplification, deletions, translocations and inversion in the settings of breast carcinoma, prostatic carcinoma, non-small cell lung carcinoma and chronic myelogenous leukemia (CML). Karyotyping is performed to asses genomic instability.
  - Defects in the caretaker genes result in DNA damage, and inactivation of DNA repair machinery. Inability to inactivate genome mutagenic molecules results in DNA damage and genomic instability.

Comparative genomic hybridization (CGH) is a molecular genetic analysis technique to compare patient DNA to reference DNA to check the gains and losses of gene copies in the patients' cell genome by using fluorescent dye.

Tumor Suppressor Genes: Genome Stability Enablers

Tumor suppressor genes regulate different critical cell processes, i.e. apoptosis, cell division, cell differentiation, signal transduction, cell adhesion, maintenance of genomic integrity and DNA (deoxyribonucleic acid) damage repair.

- Tumor suppressor genes can be divided into two major categories: (a) caretaker genes [e.g. BRCA1, BRCA2, DNA mismatch repair genes (MLH1, MSH2, MSH3, MSH6, PMS1, PMS2), Fanconi anemia DNA repair genes, DNA nucleotide excision repair genes, and (b) gatekeeper genes (e.g. TP53, RB1, APC, BRCA, APC/β-catenin).
- Caretaker genes regulate the maintenance of the genome stability, while gatekeeper genes inhibit cell growth or induce apoptosis. Inactivation of caretaker and gatekeeper tumor suppressor genes contributes to development of malignant tumor and its progression.

Adenomatous Polyposis Coli Tumor Suppressor Gene

Adenomatous polyposis coli (APC) tumor suppressor gatekeeper gene mapped on chromosome 5q22.2 codes for APC protein product involved in regulation of Wnt/β-catenin signaling pathway.

- Adenomatous polyposis coli gene mutation is linked to familial tumors (FAP—familial adenomatous polyposis) and sporadic tumors (gastric carcinoma, thyroid carcinoma and melanoma).
- Classic FAP is diagnosed when a person develops >100 adenomatous polyps in colon. An adenomatous polyp is an area where normal cells that line the inside of colon form a mass on the inside of the intestinal tract. Surgical excision of adenomatous polyps in the colon is the standard treatment to reduce the risk of development of colon carcinoma.

Retinoblastoma Tumor Suppressor Gene

Retinoblastoma (RB) tumor suppressor gene mapped on chromosome 13p14 encodes RB protein (pRB) product, which acts as master brake on cell cycle and inhibits G1/S transition during cell cycle. RB protein (pRB) inhibits transcription factor. RB gene germline mutation is linked to hereditary tumors (retinoblastoma, osteosarcoma), and acquired (somatic) gene mutation linked sporadic tumors (retinoblastoma, osteosarcoma, breast carcinoma, colon carcinoma, prostatic carcinoma, urinary bladder carcinoma and lung carcinoma).

CDKN2A Tumor Suppressor Gene

CDKN2A tumor suppressor gene mapped on chromosome 9p21 codes for CDK inhibitor proteins such as $p16^{INK4a}$ and $p14^{ARF}$ indirectly activates TP53 tumor suppressor gene. Germline mutation in CDKN2A gene is linked to familial melanoma (40%) and acquired (somatic) mutation linked sporadic human cancers (e.g. breast carcinoma, pancreatic carcinoma, esophageal carcinoma).

TP53 Tumor Suppressor Gene

TP53 tumor suppressor gene mapped on chromosome 17p13.1 encodes p53 protein, which is important genome stability enabler (known as guardian of genome). TP53 gene mutation promotes carcinogenesis, invasion and metastasis.

- TP53 gene product (p53) sensors DNA damage by two protein kinases such as ATM and ATR (ataxia-telangiectasia RAD-3 related), which halts cell cycle in G1/S transition for DNA repair by inhibiting MDM2 transcription factor, until the damaged DNA gets repaired. The p53 protein activates proapoptotic BAX gene resulting in apoptosis. The p53 protein also interacts with at least 17 cellular and viral proteins. It must be noted that MDM2 transcription factor degrades p53 protein.
- TP53 gene product (p53 protein) is inactivated by viral oncoproteins like E6 protein of HPV. More than 50% of human cancers show mutations in TP53 gene. Germline mutation in TP53 gene is linked to familial Li-Fraumeni syndrome characterized by breast carcinoma (100%), adrenal cortex cancer, sarcoma, leukemia, brain tumors, and many acquired (somatic) mutation linked sporadic tumors.

BRCA1 and BRCA2 Genes

BRCA1 (17p21) and BRCA2 (13q12-13) tumor suppressor genes code for BRCA1 and BRCA2 proteins respectively, which move to the site of DNA damage and bind RAD51 molecule that mediates repair of double-stranded breaks in DNA.

- BRCA1 protein also activates TP53 gene product (p53 protein) involved in activating apoptosis in response to irreparable DNA damage. The essential roles of BRCA1 and BRCA2 gene products in DNA repair help in understanding their functions as molecular caretakers in our genome surveillance system. Both BRCA1 and BRCA2 are high-penetrance caretaker tumor suppressor genes responsible for breast carcinoma and ovarian carcinoma.
- Mutations in either of BRCA1 or BRCA2 genes result in failure to produce DNA repair complexes.

Therefore, DNA damaged cells become hypersensitive to ionizing radiation, radiomimetic chemical carcinogens and mechanical stress on chromosomes, that cause DNA damage. Thus, BRCA1 and BRCA2 proteins are crucial for the activation of cell cycle checkpoints.

- BRCA1 gene mutation is responsible for germline mutation related familial breast carcinomas (52%), and acquired (somatic) mutation related breast carcinomas (1–2%). On the other hand, BRCA2 gene germline mutation is responsible for familial breast carcinomas (32%), and acquired (somatic) mutation related breast carcinomas (≤2%).
- BRCA1 gene germline mutation is linked to familial tumors (breast carcinoma, ovarian carcinoma, prostatic carcinoma, pancreatic carcinoma and fallopian tube carcinoma), and acquired (somatic) mutation linked sporadic breast carcinomas (breast medullary carcinoma and rarely breast metaplastic carcinoma).

Poly (ADP-ribose) Polymerase 1 (PARP1) Gene

Poly (ADP-ribose) polymerase 1 (PARP1) gene encodes PARP 1 enzyme, that regulates several proteins involved in DNA repair, and maintenance of genome integrity by modulating chromatin structure. Inhibitors of PARP1 enzyme comprise a new type of anticancer chemotherapeutic drug that selectively destroy CSCs by targeting homologous recombination in DNA repair defects.

Mismatch DNA Repair Genes

Mismatch repair genes such as MLH1 gene (3p21), MSH2 gene (2p15), MSH3 gene (5q11.12), MSH6 gene (2p16), PMS1 gene (2p32) and PMS2 gene (7p22) belong to tumor suppressor caretaker genes. Their gene products ensure the integrity of the cellular genome by replication and mismatch DNA repairs. These are also known as mutator genes, which increase the rate of mutation of one or more other genes.

- Mutation of DNA mismatch repair genes are unable to correct errors in nucleotide pairing resulting in accumulation of numerous mismatched errors in DNA replication. DNA blood tests are now available for evaluation of all these genes.
- DNA repair gene mutations are linked to familial tumors (hereditary nonpolyposis colorectal cancer—HNPCC inherited syndrome), known as Lynch syndrome, characterized by increased risk for endometrial carcinoma, ovarian carcinoma, right colon carcinoma, and sporadic tumors (colorectal carcinoma, endometrial carcinoma, Muir-Torre syndrome, hepatobiliary carcinoma, genitourinary carcinoma, glioblastoma multiforme). Extensive history of screening of early development of these cancers is required in the management of these patients with hereditary nonpolyposis colorectal cancer (HNPCC).

Pathology Pearls: Hereditary Nonpolyposis Colon Cancer: Lynch Syndrome

- Hereditary nonpolyposis colon cancer (HNPCC) also called Lynch syndrome occurs due to inactivation of DNA mismatch repair genes principally MLH1 gene (3p21), MSH2 gene (2p15), MSH3 gene (5q11.12), MSH6 gene (2p16), PMS1 gene (2p32) and PMS2 gene (7p22). These mutator genes (MLH1, MSH2, MSH3, MSH6, PMS2) are unable to correct errors in nucleotide base pairing in DNA.
- In patients with HNPCC, there is increased risk for human cancers in decreased frequency (e.g. endometrial carcinoma, ovarian carcinoma and right colon carcinoma, urothelial carcinoma, gastric carcinoma and brain tumors). Right colon carcinoma is often preceded by serrated adenomas, rather than tubular adenomas seen in the traditional APC tumor pathway.
- Microsatellite instability is observed in 90% of the tumors that develop in HNPCC patients. A variant that involves a propensity for sebaceous tumors of the skin is known as Muir-Torre syndrome.

DNA Damage by Endogenous and Exogenous Genotoxic Agents

Prolonged exposure to endogenous and exogenous genotoxic agents can cause DNA damage including nucleotide base modifications, DNA strand breaks, crosslinks and mismatches.

- Spontaneous DNA damage occurs when DNA nucleotide base pairs react with environmental mutagenic agents, which hydrolyze a nucleotide base pair causing it to pair with an incorrect nucleotide base pair by two mechanisms: (a) deamination of adenine, cytosine and guanine, and (b) depurination (loss of purine bases) resulting from cleavage of the bond between the purine bases and deoxyribose, leaving an apurinic (AP) site in DNA. DNA replication errors are minimized by proofreading. Sometimes mismatched nucleotide base pairs escape proofreading. Chemical agents modify nucleotide base pairs and interfere with DNA replication.
  - Nitrosamines, which are found in products such as pickled foods and beer can cause alkylation of DNA nucleotide bases (addition of alkyl group such as methyl or ethyl at O6 position of guanine results in the formation of O6-methylguanine).
  - Ultraviolet (UV) rays can cause production of oxygen-derived free radicals, which fuse adjacent pyrimidines creating pyrimidine dimers that prevent DNA replication.
  - Oxidizing agents and ionizing radiation create oxygen-derived free radicals in the cells that oxidize

nucleotide base pairs, especially guanine (G). Ionizing radiation and certain chemotherapeutic agents such as bleomycin, can block DNA replication by creating double-stand breaks (DSBs) in DNA. These agents can also cause breaks in single-strand DNA, though this form of damage is most often easier for the cells to overcome.
  - Base analogs and intercalating agents can cause abnormal insertions and deletions in the DNA sequence.
- Many carcinogens (e.g. benzo-(a)pyrene) react with DNA nucleotide bases, resulting in the addition of large bulky chemical groups to the DNA molecule.
- DNA repair comes from the double helix structure of DNA, that carries two separate copies of all the genetic information in each of its two strands. When one strand of DNA is damaged, another strand is used as a template to restore the DNA nucleotide base pairs sequence to the damaged strand. When both strands of the double helix DNA molecule are broken, however, leaving no template strand for repairs, the cells may use one of two distinct alternative mechanisms to address repairs. Enzymes involved in DNA nucleotide excision repair are given in Table 6.59. Defective DNA repair syndromes are given in Table 6.60.

TUMOR-PROMOTING INFLAMMATION

Chronic inflammation can contribute to multiple hallmarks of cancer capabilities by supplying bioactive molecules for initiation, promotion, transformation of normal cell to CSC, and favorable tumor microenvironment, which include: (a) growth factors that induce proliferative signaling in CSCs, (b) survival factors that limit CSCs apoptosis, (c) synthesis of proangiogenic factors that induce tumor angiogenesis, and (d) extracellular matrix (ECM) modification that facilitate angiogenesis, invasion, metastasis, and chemoresistance, through gene mutations, genomic instability, and epigenetic modifications.

- Chronic inflammatory cells infiltrate within and around most developing solid malignant tumors and secrete diverse factors that facilitate invasion and metastasis.
- Chronic inflammation linked to carcinogenesis, progression and metastasis is shown in Fig. 6.91. Chronic inflammation linked to carcinogenesis, invasion, metastasis and chemoresistance is given in Table 6.61. Dysregulation of signaling pathways and tumor-associated macrophages in chronic inflammation linked to carcinogenesis is given in Table 6.62.
- Cancer stem cells, surrounding stromal cells and inflammatory cells in malignant tumor, engage in well-orchesterized reciprocal interactions to form an inflammatory tumor microenvironment (TME). Cells within the tumor microenvironment are highly plastic, continuously changing their phenotypic and functional characteristics. Tumor-promoting inflammation closely resembles inflammatory

Table 6.59 Enzymes involved in DNA nucleotide–excision repair

Human DNA Repair Protein	Yeast Functional Homolog of Human DNA Repair Protein	Function
XPA	RAD14 (zinc metalloproteinase)	Recognition of DNA damage by ultraviolet light
XPB	RAD25	ATP-dependent helicase
XPC	RAD4	DNA binding
XPD	RAD3	Helicase
XPF	RAD1	5'-Endonuclease
XPG	RAD2	3'-Endonuclease
ERCC1 (DNA repair excision protein)	RAD10	Dimer with XPF

XP: Xeroderma pigmentosum

Table 6.60 Defective DNA repair syndromes

Syndrome	Inheritance Pattern	Gene Mutation	Associated Neoplasm(s)
Xeroderma pigmentosum	Autosomal recessive	One of several nucleotides' excision repairs	Skin cancer
Ataxia-telangiectasia	Autosomal recessive	ATM (ataxia-telangiectasia)	Lymphoid malignancies
Hereditary nonpolyposis colon cancer (HNPCC)	Autosomal dominant	MSH2, MLH1, MSH6	Colon adenocarcinoma

Ataxia-telangiectasia due to ATM gene mutation is also associated with cerebellar ataxia.

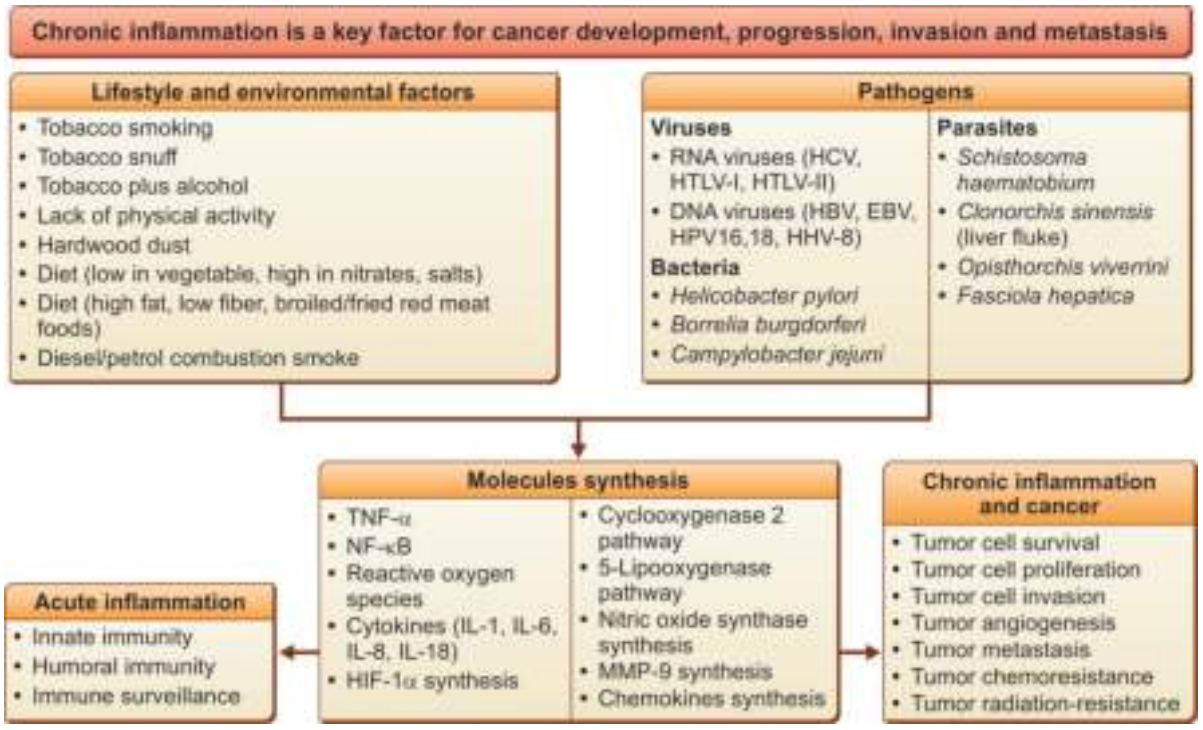

Fig. 6.91: Chronic inflammation linked to carcinogenesis, progression and metastasis. Chronic inflammation induces gene mutation and creates an environment that is conductive to transformation of normal cell to CSC, malignant tumor growth, invasion and metastasis.

Table 6.61 Chronic inflammation linked to carcinogenesis, invasion, metastasis and chemoresistance

Gene mutations
Genomic instability
Immunosuppression
Tumor promotion, tumor cell growth and survival
Tumor angiogenesis

Tumor re-emergence
Tumor chemoresistance

response observed during innate/adaptive immunity, and maintenance of tissue hemostasis.

- Additionally, tumor-promoting inflammation occurs because CSCs cause necrosis of normal cells which release cell contents into tumor microenvironment, triggering the release of proinflammatory chemical mediators, notably reactive oxygen species (ROS), that are actively mutagenic for nearby stem cells, accelerating their genetic evolution toward states of heightened malignancy.
- Several types of inflammation can promote tumor development and progression. Persistent *Helicobacter*

Table 6.62 Dysregulation of signaling pathways and tumor-associated macrophages in chronic inflammation linked to carcinogenesis

Key Marker	Function
Signaling pathways	
NF-κB signaling pathway	▪ NF-κB is a transcription factor that plays an important role in the regulation of cytokines ▪ Dysregulation of NF-κB is linked to inflammatory autoimmune diseases and human malignancies
IKK-β signaling pathway	IKK-β is a part of the IKK complex which is a negative regulator of nuclear factor kappa-B (NF-κB) transcription factor
Tumor-associated macrophages (TAMs)	
CD68 marker	CD68 is a key marker to recognize both M1 and M2 macrophages in tumor microenvironment
CD163 marker	CD163 is a scavenger receptor upregulated in macrophages in an anti-inflammatory environment
iNOS marker	iNOS is one of the major markers of M1 tumor-associated macrophages (TAMs)

pylori infection is linked to gastric carcinoma and MALT (mucosa-associated lymphoid tissue) lymphoma. Infection with hepatitis B virus (HBV) and hepatitis C virus (HCV) increase the risk for hepatocellular carcinoma (HCC). Infection with *Schistosoma haematobium* is linked to urinary bladder carcinoma. Bacteroides species infection is linked to colon carcinoma. Selective anti-inflammatory drugs are used in clinical practice.

PHENOTYPIC PLASTICITY AND DISRUPTED DIFFERENTIATION

Terminal differentiation in normal cells is associated with a permanent cell proliferation arrest. Stem cell phenotype plasticity is the ability of adult tissue-specific stem cells to switch to new identities, i.e. different phenotypes (traits), that are not associated with their cell of origin, and depending on environment that is more inclined to proliferate.

- Cancer stem cells evade differentiation and unlock what is known as **phenotype plasticity**, which continue to grow and change their identity into different phenotypes depending on environment that is more inclined to 'proliferate'.
- Hanahan observed that phenotype plasticity is not a novel invention of CSCs, but rather a 'malignant twist' of normal cells.
- Main strategies for targeting therapy include: inhibiting EMT, selectively killing mesenchymal phenotype and reverting the cells.

Phenotypic Plasticity in Normal Cells

During the process of organogenesis, cells undergo terminal differentiation, and are organized into tissues/organs and assume homeostatic functions.

- During terminal differentiation, most cells exit cell cycle and enter into a permanent G0 phase of cell cycle. Hence, cell cycle arrest prevents cell proliferation upon terminal differentiation.
- Cell cycle arrest is usually initiated through the repression of cell cycle gene expression by forming a transcriptional repressor complex, called DREAM complex (RB/E2F/MuvB).
- The cells change their phenotypic characteristics as they migrate to the surface and undergo terminal differentiation. For examples, keratinocytes migrate to the surface of epidermis and become keratinized and ultimately die.

Phenotypic Plasticity in Cancer Stem Cells

In contrast, epithelial cell-derived CSCs evade terminal differentiation and unlock what is called '**phenotypic plasticity**', and continue to proliferate and survive in the face of environmental change.

- Phenotype plasticity represents the most relevant molecular 'hallmark of cancer' that alters morphologic and functional features of epithelial-derived CSCs.
- The unlocking of terminal differentiation can be done in different ways: (a) de-differentiation from mature states to progenitor states, (b) block of differentiation (terminal or maturation arrest), and (c) transdifferentiation into different lineages.

De-differentiation of Cells Linked to Colon Carcinoma

De-differentiation is a cellular process by which cells grow in reverse, from a partially or terminally-differentiated mature cell stage to less-differentiated progenitor cell-like stage within their own lineage. Colon carcinogenesis exemplifies disrupted cellular differentiation. The transition of an intestinal epithelial cell into fully transformed metastatic intestinal cancer follows a series of activating (Wnt/β-catenin signaling pathway in APC), and inactivating mutations in numerous oncogenes and tumor suppressor genes, respectively. Initially, expansion and transformation of the stem cell compartment leads to the development of adenomatous polyps in colon. Acquiring additional mutations in K-RAS oncogene and TP53 tumor suppressor gene, patient develops colon carcinoma.

Block of Differentiation (Terminal Maturation Arrest) of Cancer Stem Cells in Acute Leukemias and Melanoma

Block of differentiation (terminal differentiation block, or maturation arrest) occurs in acute promyelocytic leukemia (APL) and acute myelogenous leukemia (AML-M1), in which leukemia cells proliferate and/or prevents the terminal differentiation into granulocytes and apoptosis seen in normal myeloid-derived white blood cells. Melanoma is other example of blocked differentiation (terminal maturation arrest).

- **Block of differentiation in acute promyelocytic leukemia:** Acute promyelocytic leukemia (APL) has been documented to result from chromosomal translocation that fuses with PML locus on gene encoding the retinoic acid receptor (RAR). Myeloid progenitor cells bearing such chromosomal translocations are unable to continue their usual terminal differentiation into granulocytes, resulting in cells trapped in a proliferative promyelocytic progenitor stage.
- **Block of differentiation in acute myelogenous leukemia:** Another example of block of differentiation (terminal maturation arrest) is acute myelogenous leukemia (AML-M1) carrying chromosomal

translocation t(8;21), which produces AML1-ETO fusion protein in its own can transform myeloid progenitors, at least in part by blocking their differentiation.

- **Block of differentiation in melanoma:** Another example of block of differentiation (maturation arrest) is melanoma, that involves a developmental transcription factor SOX10, which is normally downregulated during melanocyte differentiation. Gain- and loss-of-function BRAF-induced melanoma maintains aberrantly expression of SOX10, that blocks differentiation of neural progenitor cells into melanocytes.

Transdifferentiation of Cancer Stem Cells in Adenocarcinomas of Esophagus and Pancreas

Transdifferentiation is defined as the conversion of one type stem cell switches to different cell lineage. The concept of transdifferentiation has been recognized in the form of tissue metaplasia, wherein cells of a particular differentiated phenotype markedly change their morphology to become clearly recognizable as elements of another tissue.

- Transdifferentiation of stratified to columnar epithelium inducing Barrett's esophagus → esophageal adenocarcinoma: One example of transdifferentiation is Barrett's esophagus, where chronic inflammation of the stratified squamous epithelium of the distal esophagus induces transdifferentiation into a simple columnar epithelium that is characteristic of the intestine, thereby facilitating the subsequent development of esophageal adenocarcinoma, and not squamous cell carcinoma.
- Acinar-to-ductal cell transdifferentiation → pancreatic ductal adenocarcinoma: one example of transdifferentiation is pancreatic ductal adenocarcinoma, in which acinar-to-ductal cell transdifferentiation that encompasses cellular reprogramming and phenotypic switch-over making in a cardinal event during carcinogenesis and development of highly aggressive malignant tumor associated with extremely poor prognosis.
  - The CSCs of pancreatic ductal adenocarcinoma have acquired a mesenchymal phenotype during the process of epithelial–mesenchymal transition (EMT). Epithelial–mesenchymal transition is driven by master transcription factors, i.e. SNAIL1 and SNAIL2/SLUG, encoded by the SNAI1 and SNAI2 genes, respectively resulting in reduced membrane expression of the epithelial marker E-cadherin and upregulation of mesenchymal markers such as vimentin.
  - In many epithelial tissues, the EMT programme is associated with generation of CSCs, which in pancreatic ductal adenocarcinoma promote growth metastatic spread, chemoresistance and tumor relapse after chemotherapy.

NON-MUTATIONAL EPIGENETIC REPROGRAMMING IN CANCER STEM CELLS

In the eukaryotic nucleus, deoxyribonucleic acid (DNA) is a double helical structure composed of nucleotide base pairs, i.e. adenine (A) and thymine (T) pair, cytosine (C) and guanine (G) pair. Two strands of DNA run in opposite directions to each other and are thus antiparallel. Two helices are joined together by hydrogen bonds. DNA also bears a sugar-phosphate backbone.

- Deoxyribonucleic acid (**DNA**) is organized into chromatin structure with the nucleosome as the basic unit, in which histone octamer is surrounded by the nucleotide base pairs of DNA. The histone octamer consists of two elements of the histone octamer proteins (H3, H4, H2A and H2B). The packaging of DNA into chromatin structure presents a potential barrier to factors that require DNA as their template.
- Human genome contains about 3.2 billion DNA nucleotide base pairs. Within the genome, there are about 20,000–25,000 protein encoding genes comprising only 1.5% of the genome. DNA performs several functions: chromosome duplication in DNA replication using telomerase enzyme before cell division, transcription, and translation to make proteins.
- Genetic and epigenetic modifications are interrelated that contribute to altered gene expression in human cancers. The link between genetics and epigenetics in cancer is further demonstrated by existence of aberrant metabolism, and biochemical pathways involving aberrant gene function and altered patterns of gene expression.
- Epigenetic modifications are heritable changes in gene expression (i.e. 'turning on' or 'turning off') without alterations in DNA sequences in different organs, through DNA methylation, histone octamer modifications and microRNAs, but they can change how body reads the DNA sequence. Epigenetic modifications may be caused by environmental agents (chemical agents, tobacco smoke and infection with specific microbes), cytotoxic/pharmaceutical drugs, dietary factors, obesity, physical activity, alcohol consumption, psychological stress and advancing age.
  - External and internal signaling pathways may induce epigenetic modifications and altered gene expression, that provide a permissive

microenvironment for transformation of normal cell to CSC involving different driver and passenger gene regulatory pathways. In cancer research, epigenetics is vital in early-stage cancer diagnosis and novel therapeutic design.

DNA Methylation

DNA methylation is a widespread epigenetic modification of DNA during DNA replication, and considered as a stable gene silencing mechanism. DNA methylation is a heritable epigenetic mechanism of DNA, that occurs by the addition of a methyl (CH3) group to the C-5 position of the cytosine at CpG dinucleotide islands present in the promoter regions in the DNA sequence by DNA methyltransferases encoded by family of DNMTs genes (i.e., DNMT3A, DNMT3B and DNMT1), thereby often modifying the function of genes during embryogenesis and postnatal life.

- Human genome DNA constitutes 70–75% of methylated DNA. Global changes in DNA methylation occur in both normal cells and CSCs. DNA methylation is important for establishing and maintaining cell identity and genomic stability.
- Carcinogenesis is accompanied by a global loss in DNA methylation, which facilitates the transformation of normal cell to CSC resulting from activation of previously silent proto-oncogenes (i.e. DLX1, POU3F3) after hypermethylation, and silencing tumor suppressor genes (e.g. TP53, BRCA1, p16), after methylation of gene in the promoter region.
- Global (genome-wide) hypomethylation may also cause genomic instability through interference with protective function of telomeres and centromeres, and activation of growth promoting genes (proto-oncogenes), thereby 'turning on' mitotic signals. DNA hypomethylation can also result in loss of imprinting.
- DNA methylation inhibitors and histone acetylase inhibitors have been under clinical trials with the focus on DNA methylation and histone octamer modifications in the epigenetics field in cancer patients.

CpG Dinucleotide Islands Hypermethylation

In normal cells, CpG dinucleotide islands are present in the promoter regions in the DNA sequence, which comprise cytosine followed by guanine (i.e. phosphate-linked cytosine-guanine pairs) from 5′ to 3′ direction. CpG dinucleotide islands are usually unmethylated/hypomethylated to maintain euchromatin structure and activate gene expression, thus allowing post-translational activation. Hypermethylation of CpG dinucleotide islands linked to human malignancies is given in Table 6.63.

- Hypermethylated CpG dinucleotide islands down-regulate DNA repair genes, induce epithelial–mesenchymal transition (EMT), unrestricted CSC proliferation, development of malignant tumor growth, invasion, and metastasis.
- Hypermethylation of CpG dinucleotide islands in promoter region of the mismatch repair gene MLH1 has been observed in 13% of sporadic cases of human colorectal cancers, that show microsatellite instability.
- Hypermethylation of CpG dinucleotide islands in promoter region of the mismatch repair genes (i.e. hMLH1 and hMSH2) are linked to hereditary nonpolyposis (HNPCC), also called Lynch syndrome.

Table 6.63 Hypermethylation of CpG dinucleotide islands linked to human malignancies

Methyl-CpG Binding Proteins	Human Malignancies
MeCP2	Breast, colorectal region, gastric region, and prostate
MBD1	Pancreas and prostate
MBD2	Breast, colon, pancreas, and lung
MBD4	Breast, colon, prostate, lung, and chronic myelogenous leukemia (CML)
ZBTB33 (KAISO)	Breast, colon, cervix, ovary
ZBTB38	Urinary bladder
UHR1	Esophagus, gastric region, colon, pancreas, liver, hepatic ducts, thyroid, skin (squamous cell carcinoma, melanoma), kidney, and retinoblastoma
UHR2	Colon, liver and hepatic ducts

Dysregulated methyl-CpG binding proteins promote epithelial–mesenchymal transition (EMT), cell proliferation, invasion, and metastasis.

DNA Methyltransferases (DNMTs) Gene Mutations induce DNA Hypermethylation

Aberrant expression of DNMT1, DNMT3A and DNMT3B genes induce DNA hypermethylation, oncogenic activation, genomic instability, transformation of normal cell to CSCs and development of various human malignancies of colon, breast, ovary, and cervix.

- **Mutation in DNMT1 gene-linked cancers:** Mutation in DNMT1 gene is linked to solid malignant tumors of thyroid, breast, gastric region, colorectal region, pancreas, liver, cervix, prostate, and ovary associated with lymph node metastasis and poor prognosis in these patients. Overexpression of DNMT1 protein in gastric carcinoma is significantly related to decreased E-cadherin expression, which indicates that an increase in DNMT1 expression will enhance the migration ability of the CSCs.

- **Mutation in DNMT3A gene-linked cancers:** DNMT3A mutation is linked to lung carcinoma, melanoma, vulva, squamous cell carcinoma and acute myelogenous leukemia (AML) associated with poor prognosis. DNMT3A can act both as an oncogene and as a tumor suppressor gene in malignant tumor.
- **Mutation in DNMT3B gene-linked cancers:** DNMT3B *de novo* methyltransferase is related to abnormal methylation of tumor suppressor genes. DNMT3B overexpression is linked to breast carcinoma, hepatocellular carcinoma, colon carcinoma, urinary bladder carcinoma and ovarian carcinoma.

Histone Octamer Protein Modifications

DNA exists in the condensed chromatin form to fit into the nucleus. Histones are chromosomal proteins wrapped by DNA that form a nucleosome ('beads on string'), the fundamental unit of chromatin. A tight packaging of histone octamer proteins prevents the access of gene expression-regulating proteins to DNA, thus inhibiting gene expression. A loose packing of histone octamer proteins enhances the access of gene expression-regulating proteins to DNA thus turning on gene expression.

- Histone octamer proteins modification refers to addition or removal of chemical groups from histone to regulate the tight or loose packaging and spacing of nucleosomes. Histone octamer consists of two copies each of four histone proteins; H2A, H2B, H3 and H4. Each one of these proteins has a globular C-terminal tail extension, and tails are the targets of nucleosome modification.
- Linker H1 histone octamer protein binds to the 'linker DNA' (about 20–80 nucleotides in length) region between nucleosomes, helping in stabilization of the zigzagged 30 nm chromatin fibers into high-order chromatin structure.
- Histone octamer remodeling and modification regulate the DNA replication and transcription. During DNA replication, polymerase only accesses the DNA, which is not bound by histones.
- Phosphate group give histone octamer a negative charge. Lysine and arginine give histone octamer a positive charge. Global levels of lysine methylations are quite different between cell types and corelated in various human malignancies.
  - H3K4me1 is an epigenetic modification of the DNA packaging histone octamer protein H3, which indicates mono-methylation at the 4th lysine residue of the histone H3 protein and associated with gene enhancers.
  - H3K4me2 is an epigenetic modification of the DNA packaging histone octamer protein that di-methylation at the 4th lysine residue of the histone octamer protein H3 and associated with accessible chromatin structure and gene activation.
  - H3K4me3 is an epigenetic modification of the DNA packaging histone octamer protein, that indicates tri-methylation at the 4th lysine residue of the histone octamer protein H3 around transcription start sites and associated with gene activation and active transcription.
  - Dysregulated H3K4me1, H3K4me2, and H3K4me3 histone octamer proteins are linked to many human cancers.
- In addition, lysine methyltransferases and demethylases are deregulated on various cancers. These molecular alterations lead to permanent changes in the patterns of gene expression that regulate the malignant phenotype such as unrestricted cellular growth, and invasiveness. Histone demethylases are enzymes that remove the methyl marks on lysine in nucleosome's histone octamer tails. These alterations in methylation mark regulate gene expression during transformation of normal cell to CSC and development of malignant tumor.
- Global histone lysine methylation patterns in human cancers are given in Table 6.64. Histone lysine methyltransferases linked to human cancers are given in Table 6.65. Global histone lysine demethylases linked to human cancers are given in Table 6.66.

Table 6.64 Global histone lysine methylation patterns in human cancers

Histone Octamer Modification	Histone Octamer Modifications and Expression Compared to Normal Tissues	Associated Human Cancers
H3K4me1 (mono-methylation at the 4th lysine residue of H3) protein	▪ Downregulation ▪ Upregulation upon progression	Prostatic carcinoma and urinary bladder carcinoma
H3K4me2 (di-methylation at the 4th lysine residue of H3) protein	▪ Downregulation ▪ Upregulation upon progression	▪ Small cell lung carcinoma, renal cell carcinoma, hepatocellular carcinoma, pancreatic carcinoma and breast carcinoma ▪ Prostatic carcinoma
H3K4me3 (tri-methylating at the 4th lysine residue of H3) protein	▪ Downregulation ▪ Upregulation	▪ Urinary bladder carcinoma ▪ Prostatic carcinoma and renal cell carcinoma

Table 6.65 Histone lysine methyltransferases linked to human cancers

Writer	Alterations in Human Cancers	Associated Human Cancers
MLL1 (new name: KMT2A) gene	Translocation, amplification, tandem duplication	Hematolymphoid neoplasms and myelodysplastic syndrome
Menin gene	▪ Gene mutation ▪ Reduced expression ▪ Increased expression	▪ Multiple endocrine neoplasia type 1 (MEN1) ▪ Lung adenocarcinoma ▪ Prostatic carcinoma
Ash2L gene	Increased expression	Squamous cell carcinomas of cervix and larynx, melanoma, rhabdomyosarcoma, carcinomas of breast and colon, pancreatic carcinoma and neuroendocrine carcinomas

Table 6.66 Global histone lysine demethylases linked to human cancers

Gene Name	Alterations in Cancer	Associated Human Cancers
KDM1	▪ Overexpression ▪ Downregulation	▪ Prostatic carcinoma, breast carcinoma, neuroblastoma ▪ Hepatocellular carcinoma
KDM2B	▪ Gene mutation ▪ Downregulation	▪ Lymphoma ▪ Glioblastoma multiforme
KDM4C	Overexpression	Prostatic carcinoma, esophageal squamous cell carcinoma, desmoplastic medulloblastoma, MALT lymphoma
KDM5A	Overexpression	Gastric carcinoma
KDM5B	Overexpression	Breast carcinoma, testicular and ovarian cancers, lung carcinoma, urinary bladder carcinoma
KDM6A	Gene mutation	Multiple myeloma, renal cell carcinoma and several malignancies
KDM6B	Overexpression	Prostatic carcinoma, pancreatic carcinoma, lymphoma

Pathology Pearls: Histone Octamer Protein Modifications—Mechanisms

Histone octamer protein modifications can occur by various mechanisms: methylation, acetylation/deacetylation, phosphorylation, ubiquitination, and sumoylation.

- **Histone octamer proteins methylation:** Histone octamer proteins methylation can activate oncogene (‘**turning on**’) or repress (‘**turning off**’) tumor suppressor gene expression, and favor the acquisition of molecular hallmark of cancer capabilities such as cell cycle dysregulation, evasion of apoptosis, invasion, and metastasis. Dysregulation of histone octamer proteins methylation can lead to inappropriate turning off (silencing) of tumor suppressor genes or ‘turning on’ (activation) of oncogenes, thus contributing to the development of cancers (gliomas, sarcomas, and phenotypic mixed lineage leukemia).
- **Histone octamer proteins acetylation/deacetylation:** Histone octamer proteins acetylation/deacetylation affects nucleosome spacing and gene expression.
  - Histone octamer proteins acetylation results in loose packaging and spacing of nucleosomes, hence transcription factors can bind the DNA and recruit acetylating enzymes resulting in ‘turning on’ gene expression, which is essential for cell cycle progression and differentiation. Histone octamer proteins acetylation with enhanced activity of HDACs can lead to development of malignant phenotype.
  - On the contrary, histone octamer proteins deacetylation results in compact packaging and spacing of nucleosomes, hence transcription factors cannot bind the DNA and recruit deacetylating enzymes resulting in ‘turning off’ tumor suppressor gene expression (repression/silencing), and transcription repression of various genes.
- **Histone octamer proteins phosphorylation:** Histone octamer proteins phosphorylation occurs during cellular response to DNA damage. Phosphorylation of serine and threonine residues facilitates chromatin condensation during mitosis and transcriptional activation and expression of immediate-early targeted genes.
- **Histone octamer proteins ubiquitination:** Histone octamer proteins ubiquitination plays key roles in DNA transcription, maintenance of chromatin structure and DNA repair.
- **Histone octamer proteins sumoylation:** Histone octamer proteins sumoylation regulates the functional properties of many proteins and thereby plays key role in the normal functions of cells.

MicroRNAs

MicroRNAs are regulators of chromatin modifying machinery, and gene expression, which play pivotal roles in numerous biological processes to maintain cell growth, and differentiation. DNA sequences are transcribed to coding (generating proteins), and

noncoding RNAs (lacking building blocks of proteins). Noncoding RNAs are comprised of transfer RNAs, ribosomal RNAs, small RNAs (<200 nucleotides) and long RNAs (>200 nucleotides) based on their length. Both small and long noncoding RNAs are transcribed by RNA polymerase II or polymerase III and endogenously processed by endonuclease. Schematic representation of epigenetic related small and long non-coding RNAs is shown in Fig. 6.92.

- **Biogenesis of MicroRNAs and regulation of gene expression:** Human genome contains about 1000 noncoding microRNAs constituting 5% of total genome. MicroRNAs regulate the expression of multiple proteins in the post-translation process. MicroRNAs are transcribed from DNA sequences by RNA polymerases II and III, generating primary microRNAs and processed into precursor miRNAs, and finally mature miRNAs. Biogenesis and function of noncoding microRNA are shown in Fig. 6.93.
  - **Ribonuclease DROSHA** enzyme processes the primary miRNA to generate double-stranded premiRNA in the nucleus, which is then exported to cytoplasm via **Exportin-5 (EXPO5)**. Once the premiRNA is in cytoplasm, an enzyme called '**DICER**' trims the pre-miRNA by removal of its hairpin loop and cleaves the molecule into two strands, i.e. functional leading strand and passenger strand undergoing degradation.
  - The aspartylglucosaminidase (AGA) proteins bind to the leading strand of miRNA to form the RNA-induced silencing complex 'RISC' functional unit, which facilitates the binding of miRNA into the targeted messenger RNA (mRNA) resulting in either translation repression or target degradation of the Poly-A tail via deadenylation process. In most cases, miRNAs interact with the 3′ untranslated regions (3′ UTRs) of target mRNAs to induce mRNA degradation and translation repression. Noncoding miRNAs participate in silencing posttranscriptional genes by inhibiting messenger RNA (mRNA) translation.
  - Dysregulation of microRNA biogenesis can occur because of aberrant expression of DROSHA, DICER, DGCR8, EXPO-5, AGO1/AGO2 and TRBP, which lead to carcinogenesis, invasion and metastasis.
- **Functions of microRNAs:** MicroRNAs regulate gene expression through various mechanisms at the post-transcriptional level mainly by binding with messenger RNA (mRNA) in the cell cytoplasm and play key roles in cell differentiation, cell cycle regulation, growth, proliferation, differentiation, migration, metabolism, and apoptosis. MicroRNAs

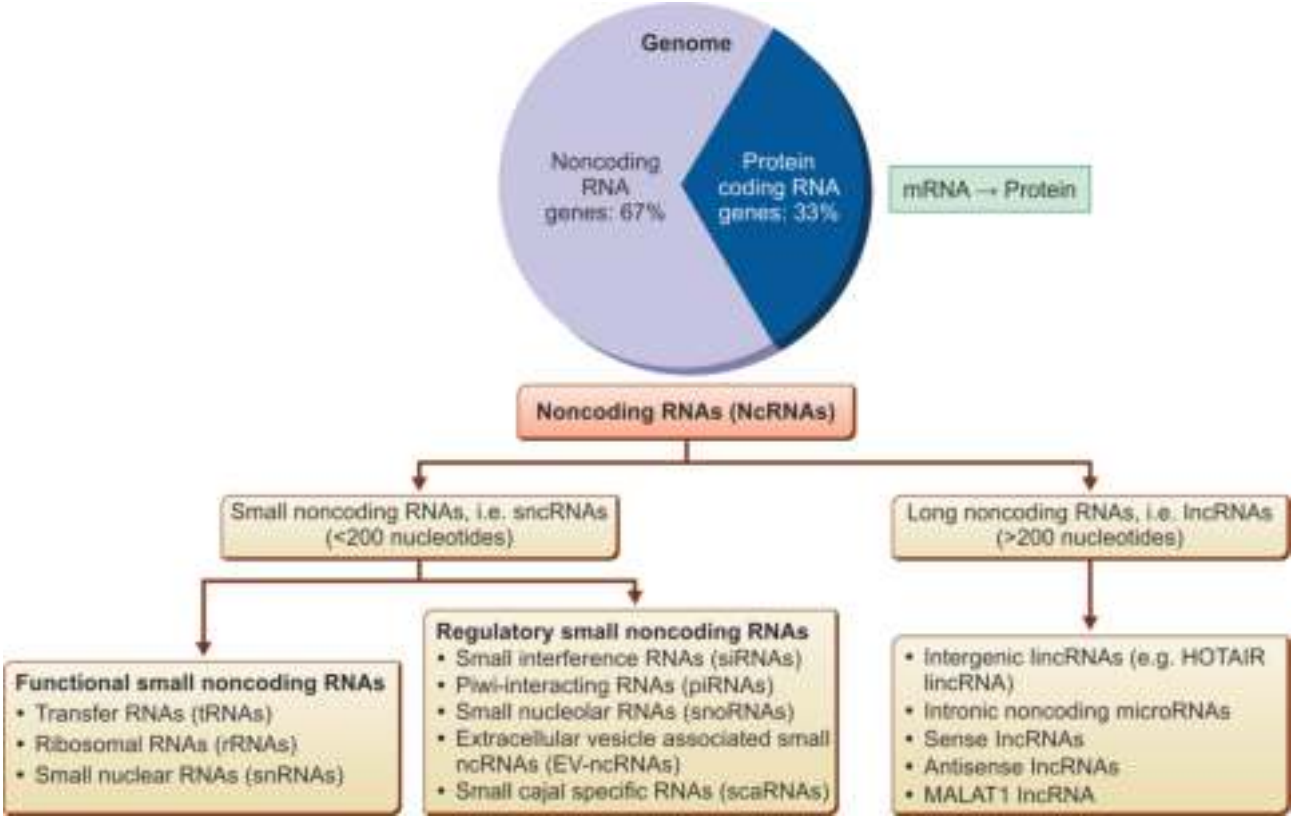

Fig. 6.92: Schematic representation of epigenetic-related small and long noncoding RNAs.

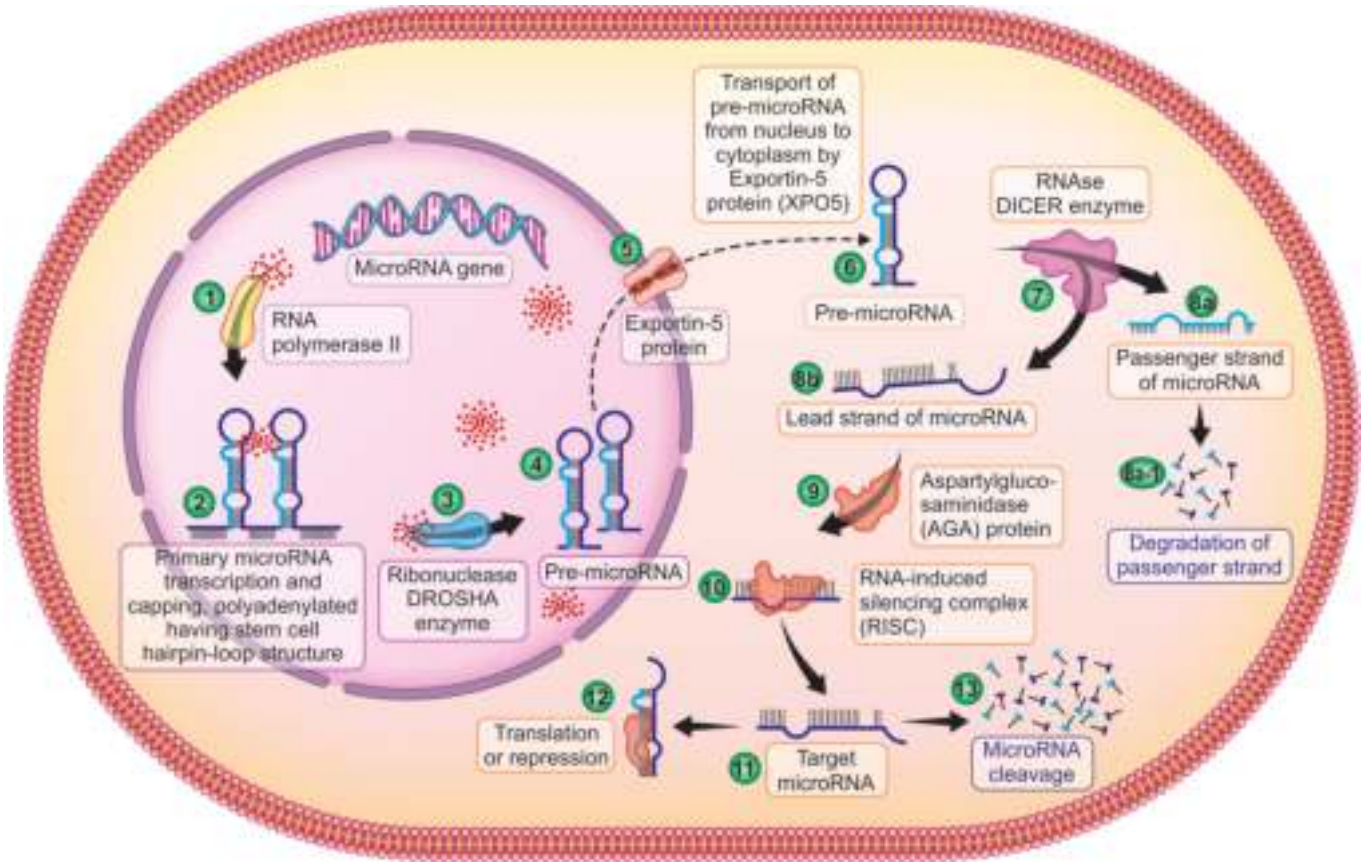

Fig. 6.93: Biogenesis of microRNA. MicroRNA is transcribed as longer precursors by RNA polymerase I and II, that undergoes series of cleavage events to form mature microRNA. MicroRNAs are transcribed as longer precursors by RNA polymerase II and III, that undergo series of cleavage events to form mature microRNA. The conventional biogenesis pathway consists of two cleavage events, one nuclear and one cytoplasmic. The pre-miRNA is exported from the nucleus by Exportin-5-Ran-GTP. In the cytoplasm, RNase DICER in complex with the double-stranded RNA-binding protein (DRBP) cleaves the pre-miRNA hairpin to its mature length. The functional strand of the mature miRNA is loaded together with Argonaute (Agp2) proteins into the RNA-induced silencing complex (RISC), where its guides the RISC to target mRNA through mRNA cleavage, translational repression or deadenylation, whereas the passenger strand undergoes degradation. Noncoding RNAs can be secreted into the extracellular space, stabilized in vesicles or protein-binding partners.

are involved in epigenetic processes such as heterochromatin formation.

- **Dysregulation of microRNAs:** Majority of microRNA genes are present in cancer-associated regions in genome. Recent studies revealed that different microRNAs regulate the interaction between CSCs and their surrounding cells within tumor microenvironment, and can function as oncogenic microRNAs or tumor suppressor microRNAs based on their modulating effect on the expression of their target post-translational gene silencing.
  - Oncogenic RNAs play a pivotal role in initiating carcinogenesis and development of malignant tumor by inhibiting tumor suppressor microRNAs and apoptosis.
  - Tumor suppressor microRNAs regulate the expression of their target genes post-transcriptionally by degrading messenger RNA (mRNA) transcripts or by inhibiting mRNA translation.
  - MetastamicroRNAs play crucial role in the metastatic process. MicroRNAs that act as oncogenes and tumor suppressors linked to human cancers are given in Table 6.67. Dysregulation of microRNAs casually related to epigenetic alterations linked to human cancers is given in Table 6.68.
- **Mechanisms of dysregulation of microRNAs:** MicroRNAs have been implicated in the regulation of virtually all signaling circuits within cell, and their dysregulation has been shown to play an essential role in the development and progression of cancer. Dysregulation of microRNAs expression in human cancers occurs through various mechanisms: (a) amplification of oncogenic microRNAs, (b) deletion of chromosomes harboring microRNAs, (c) abnormal transcriptional regulation, (d) defects in the biogenesis machinery, and (e) epigenetic alteration and gene silencing.

Table 6.67 MicroRNAs that act as oncogenes and tumor suppressors linked to human cancers

MicroRNAs	Human Malignancies
Oncogenic microRNAs	
MiR-9	Neuroblastoma
MiR-10b	Breast
MiRs-15a, 15b, 16, 16-1	Leukemia, pituitary adenoma
MiRs-17-5p, 17-92, 20a	Lung, lymphoma
MiR-21	Breast, esophagus, colorectal region, hepatic ducts, lung, pancreas, cervix, prostate and CLL
MiR-23	Breast, urinary bladder, and CLL
MiR-29, 29a	Hepatic ducts, leukemia
MiRs-31, 133b, 135, 183	Colorectal region
MiR-143	Colorectal region, cervix
MiR-146	Thyroid
MiR-155	Breast, pancreas, leukemia
MiR-221	Thyroid, liver, pancreas, prostate, glioblastoma multiforme, AML, and CLL
MiRs-17-92 cluster includes structurally homologous mircoRNAs 17-30, 17-5p,18a,19a,19b, 20a and 93a-1	Colorectal region, lung, ovary, AML, and CLL
MiR-155	Hodgkin's disease, diffuse large B cell lymphoma, Burkitt lymphoma, and CLL
MiRs-181, 181a, 181b, 181c	Glioblastoma multiforme, breast, thyroid, and CLL
Tumor suppressor microRNAs	
MiR-143	Breast, colorectal region, lung, prostate, and CLL
MicroRNA-let group (let7-1-a1 through-a3-b through-g,-1 and microRNA-98)	Breast, colorectal region, lung, prostate, AML, and CLL
MiR-145	Urinary bladder, breast, colorectal region, lung, ovary, and prostate
Multifunctional role of microRNAs that act as both oncogenic and tumor suppressors	
MiR-23 group	▪ Oncogenic MiR: breast, urinary bladder, and CLL ▪ Tumor suppressor MiR: prostate
MiR-34s	▪ Oncogenic MiR: kidney, liver and colon ▪ Tumor suppressor MiR: lung, pancreas, and neuroblastoma
MiR-181 group	▪ Oncogenic MiR: breast, urinary bladder, and CLL ▪ Tumor suppressor MiR: prostate
MiR-125 group	▪ Oncogenic MiR: pancreas, prostate, and ALL ▪ Tumor suppressor MiR: breast, thyroid, liver, ovary, prostate, glioblastoma, AML, and CLL
Let-7	▪ Oncogenic MiR: breast, colorectal region, lung, prostate, AML, and CLL ▪ Tumor suppressor MiR: breast, lung, prostate

AML (acute myelogenous leukemia), ALL (acute lymphoblastic leukemia), CLL (chronic lymphocytic leukemia)

Table 6.68 Dysregulation of microRNAs casually related to epigenetic alterations linked to human cancers

MicroRNAs	Negative Regulation of Target Gene	Effect in Cancer
MicroRNA-29 family (29a, 29b, 29c)	▪ DNMT3A ▪ DNMT3B	Aberrant DNA methylation due to DNMT3A in acute myelogenous leukemia
MicroRNAs (152, 148a, 185, 342)	DNMT1	Aberrant DNA methylation in colorectal carcinoma
MicroRNAs (101, 26A, 98, 124, 214, let-7)	EZH2	Silencing of target genes

DNMT3A, DNMT3B and DNMT1 genes encode DNA methyltransferase involved in DNA methylation. EZH2 encodes histone methyltransferase enzyme involved in histone methylation

- **Amplification of oncogenic microRNAs:** Amplification of oncogenic microRNAs can downregulate tumor suppressor genes and lead to uncontrolled cell growth, cell proliferation, epithelial–mesenchymal transition (EMT), invasion and metastasis to distant organs. Amplification of microRNA-200 is linked to ovarian carcinogenesis, EMT, invasion and metastasis. Amplification of microRNA-17/92 cluster gene results in B cell lymphoma and lung carcinoma. Amplification of microRNA-221 is linked to triple negative primary breast carcinoma.
- **Deletion of chromosomes harboring microRNAs:** Deletion of chromosome 13q14 region harboring microRNAs 15-α/16-1 cluster gene upregulates antiapoptotic BCL-2 protein resulting in chronic lymphocytic leukemia (CLL). Deletion of chromosome 5q33 region harboring microRNAs-143/145 is linked to lung carcinoma. Germline defects in DICER enzyme are linked to tumors of testes and ovaries. DICER is a microRNA processing factor, that codes for endonuclease required for synthesis of functional microRNAs.
- **Aberrant expression of transcription factors:** Normally, Myc proto-oncogene and TP53 tumor suppressor gene code for transcription factors, which tightly regulate microRNAs. Aberrant expression of transcription factors is linked to many human malignancies. The c-Myc oncogene encodes transcription factor that induces carcinogenesis, unrestricted CSCs proliferation, angiogenesis, epithelial–mesenchymal transition (EMT), invasion and metastasis. The c-Myc oncogene encoding transcription factor can enhance or repress transcription activity of microRNAs. TP53 tumor suppressor gene encodes p53 protein, that plays a central role in tumor suppression through transcriptional regulation of many target genes. TP53 gene mutation is linked to many human cancers. Recent studies have demonstrated that some microRNAs regulate the activity of TP53 gene through directly targeting p53 protein, and indirectly targeting through MDM2/MDM4 proteins. These findings have demonstrated that microRNAs are key regulators and mediators of TP53 gene signaling pathway, which highlights a pivotal role of miRNAs in the TP53 network and development of human cancers.
- **Defects in biogenesis process of mircoRNAs:** Dysregulation of microRNA biogenesis can occur because of aberrant expression of DROSHA, DICER, DGCR8, EXPO-5, AGO1/AGO2 and TRBP has been linked to carcinogenesis, malignant tumor development, invasion, and metastasis.
- **Epigenetic alterations and gene silencing:** Epigenetic alterations can affect gene expression by '**turning on**' or '**turning off**' without changes in DNA sequence through various mechanisms, which include DNA methylation, histone covalent modification and mircoRNAs. Thus, microRNAs are modulators of chromatin machinery, gene expression and play pivotal roles in numerous biological processes. Recent studies have revealed that DNA methylation and histone modifications are the major causes of microRNAs dysregulation resulting in human cancers.

Oncogenic MircoRNAs and Cancer: Promoting Mechanisms

Oncogenic microRNAs play a pivotal role in initiation and progression of human cancers by inhibiting the expression of tumor suppressor genes involved in different biological processes. Deregulation of oncogenic microRNAs is associated with genetic and/or epigenetic alterations, including deletion, amplification, point mutation and aberrant DNA methylation. Their expression profiling of human malignancies has identified signatures involving in initiation, progression, diagnosis and prognosis.

- **Oncogenic microRNAs and cell cycle progression:** Cell cycle is a series of events that takes place in a cell as it grows and divides into two identical daughter cells.
  - Oncogenic microRNAs contribute to cell cycle progression by targeting CDK inhibitors and tumor suppressor proteins such as p53, RB1, INK family of proteins (p15, p16, p18, p19), CIP family of proteins (p21, p27, p29), BRCA1, BRCA2, DNA repair proteins, ATM protein involved in cell cycle progression and unrestricted CSCs proliferation leading to human cancers. TP53 is a master regulator of human genome.
  - Oncogenic microRNA 504 acts as negative regulator of p53 protein by binding to promoter region of TP53 gene resulting in reduction in p53 protein-mediated apoptosis as well as cell cycle arrest in human cancers. Depletion of oncogenic microRNAs increases the expression of p53 protein.
  - Oncogenic mircoRNA-21 targets numerous tumor suppression genes associated with invasion and metastasis of breast carcinoma, colorectal carcinoma, ovarian carcinoma, and lung carcinoma. Oncogenic microRNAs involved in cell cycle progression and associated human malignancies are given in Table 6.69.
- **Oncogenic microRNAs as regulators and mediators of Myc proto-oncogene:** Regulation of Myc proto-oncogenes (c-Myc, N-Myc and L-Myc) is connected to microRNAs.

Table 6.69 Oncogenic microRNAs involved in cell cycle progression and associated human malignancies

Oncogenic MicroRNAs	Target Cell Cycle Negative Regulators	Human Malignancies
MiR-132,-212	↓RB1	Pancreatic carcinoma
MiRs-17–92	↓RB2	Lung carcinoma
MiRs-195,-128a, -155,-516a-3p,-372	↓Wee1*	Skin (melanoma), pituitary adenomas
MiRs-504, 25, 30d, 125b,-214,-1285	↓p53	Breast carcinoma, lung carcinoma, colorectal carcinoma, ovarian carcinoma, hepatoblastoma, osteosarcoma, neuroblastoma
MiRs-24,-31	↓$p16^{INK4A}$	Cervical carcinoma, human diploid fibroblasts

MiRs-520 g,-106b family,-128-2	↓p21	Breast carcinoma, gastric carcinoma, colorectal carcinoma, Barrett's esophagus, non-small cell lung carcinoma, renal cell carcinoma, prostatic carcinoma
MiRs-18a,-181a/-181b,-421	↓ATM	Breast carcinoma, colorectal carcinoma, neuroblastoma

**Wee1 is nuclear serine/threonine kinase protein, a negative regulator of G2/M checkpoint acting by phosphorylating cyclin B/CDK1 at position tyrosine 15, determining protein complex inactivation*

- Myc proto-oncogenes code for oncogenic transcription factor, that regulates transcription activity of microRNA-17-92 cluster, MiR-9, MiR15a/16-1 and MiR-34a involved in numerous cellular processes, i.e. cell cycle progression, metabolism, angiogenesis, development of malignant tumor growth, epithelial–mesenchymal transition (EMT), invasion and metastasis.
- Moreover, microRNAs regulate the expression and activity of c-Myc. N-Myc amplification induces expression of numerous microRNAs, e.g. 92, 106a, let-7b, 17-5p, 93, 99 and 221 in **neuroblastoma**. Both c-Myc and N-Myc can directly bind to the promoter of microRNA-17/92 cluster and initiates transcription. N-Myc upregulates microRNA-17/92 in neuroblastoma.

- **Oncogenic microRNAs as regulators and mediators of RAS proteins:** MicroRNAs regulate gene expression by modulating the translation of protein-coding RNAs. Their aberrant expression is linked to many human cancers.
  - Dysregulated microRNA expression can lead to RAS (H-RAS, K-RAS or N-RAS) activation irrespective of their oncogenic mutations at codons 12, 13 and 61.
  - Activation of RAS proteins is linked to many human cancers. RAS belongs to a family of membrane associated GTPases that function as intracellular switches to regulate cell growth, proliferation, survival and motility to extracellular signals by initiating multiple mitogenic signal transduction pathways and its co-expression with Myc family proteins is responsible for cell proliferation.
- **DNA damage response machinery and oncogenic microRNAs:** DNA damage response (DDR) is a network of cellular pathways that contain three major components (some with overlapping functions): sensors, signal transducers and effectors.
  - Alterations in the components of the DNA repair response machinery is associated with tumorigenesis and chemoresistance.
  - DDR requires core sensors such as ATM (ataxia-telangiectasia mutated) or ATR (ATM-RAD3-related) proteins that have ability to bind to damaged DNA and to activate TP53 tumor suppressor gene product (p53) that in turn leads to DNA repair, cell cycle arrest or apoptosis, depending on the entity of the damage.
  - Surveillance ATR and ATM proteins that monitor DNA integrity can activate cell cycle checkpoints and DNA repair response machinery in response to DNA damage to prevent the generation of potentially deleterious gene mutations.
  - ATM or ATR proteins also trigger a phosphorylation cascade that activates two kinases CHK1 and CHK2. These two kinases (CHK1 and CHK2) stimulate the expression of DNA repair enzymes known as cyclin-dependent kinase inhibitors (CDKIs). Oncogenic microRNAs downregulate the expression of ATM protein resulting in tumorigenesis and progression.
- **Apoptotic pathway and oncogenic microRNAs:** In eukaryotes, numerous microRNAs perform

basic cellular functions such as cell proliferation, differentiation and apoptosis.

- Abnormal expression of microRNAs modifies/weakens various apoptotic pathways leading to development of human cancers.
- Apoptosis is mediated by three apoptosis pathways: (a) extrinsic (death receptors anchored at the cell membrane through binding of FasL TNF and TRAIL ligands), (b) intrinsic (mitochondrial), and (c) perforin/granzyme pathways.
- Several studies revealed that some oncogenic noncoding microRNAs alter apoptotic response by downregulating proapoptotic proteins (i.e. TRAIL, BAX, BAK, PUMA, BIM, caspase-3,-7,-9), and alter their functions at different levels in both extrinsic and intrinsic pathways leading to carcinogenesis, invasion, metastasis and chemotherapy resistance.
- Caspase-3,-7,-9 are downregulated by mir-106b, MiR-363, MiR-582-5p and let-7.
- Tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) involved in extrinsic pathway is downregulated by MiR-22 and MiR-222. Oncogenic microRNAs involved in apoptotic pathway and associated human malignancies are given in Table 6.70.

- **Modulation of p53 protein by oncogenic microRNAs:** TP53 tumor suppressor gene product (p53) plays a crucial role in maintaining genomic stability and tumor suppression.
  - Mutant TP53 gene gain-of-function induces epithelial–mesenchymal transition (EMT) and tumor metastasis through modulation of the microRNA's expression. Thus, microRNAs could be considered attractive targets for new chemotherapeutic agent therapies.
  - Oncogenic MiR-504 acts as a negative regulator of TP53 gene product (p53) through its binding to two sites in promoter region. Oncogenic MiR-504 reduces TP53 gene product (p53) mediated apoptosis leading to osteosarcoma and lung carcinoma. Oncogenic MiR-504 reduces p53-mediated cell cycle arrest resulting in **colon carcinoma**.
- **Oncogenic microRNAs as metastamiR:** Metastasis is a major obstacle to the efficient and successful treatment of cancer. MetastamiRs are specific family of microRNAs, that can promote or inhibit metastasis. Metastasis involves multiple steps including local invasion, intravasation in lymphatic and blood vessels, circulation, extravasation, and colonization in distant organs. Oncogenic microRNAs as pro-metastamiR in human malignancies are given in Table 6.71.
  - **MiRs-126,-141,-21:** MiRs-126,-141,-21 overexpression leads to early-stage **colorectal carcinoma** metastasis to liver.
  - **MiR-9:** MiR-9 downregulates metastasis suppressor E-cadherin that leads to enhanced metastasis of breast carcinoma.
  - **MiR-373,-520c:** Prometastatic MiR-373,-520c promote migration of nonmetastatic MCF-7 breast cancer stem cells potentially through suppression of adhesion molecule CD44. MiR-373 drives the epithelial-to-mesenchymal transition (EMT) and metastasis via the MiR-TXNIP—HIF1A TWIST signaling axis in breast carcinoma.
  - **MiR-21:** MiR-21 promotes growth, invasion and metastasis by targeting multiple tumor/metastasis suppressor genes such as TPM1, PDCD4 and maspin in metastatic breast carcinoma.

Table 6.70 Oncogenic microRNAs involved in apoptotic pathway and associated human malignancies

Oncogenic MicroRNAs	Target Pro-apoptotic Proteins	Human Malignancies
MiRs-221,-222	↓TRAIL ↓BMF ↓PUMA	Non-small cell lung carcinoma, hepatocellular carcinoma Hepatocellular carcinoma Epithelial malignant tumors
MiR-221,-222,-21,-18a,-144,-32,-216a,-217	↓PTEN	Non-small cell lung carcinoma, hepatocellular carcinoma, gastric carcinoma, colorectal carcinoma, nasopharyngeal carcinoma

MiRs-582-5p, 363	↓Caspase 9	Glioblastoma multiforme

Table 6.71 Oncogenic microRNAs as pro-metastamiR in human malignancies

Oncogenic MicroRNAs (Pro-metastamiR)	Mechanism	Human Malignancies
MiR-126,-141,-21	Upregulation of oncogenic MiRs	Colorectal carcinoma metastasizing to liver
MiR-9	Downregulation of metastasis suppressor E-cadherin	Breast carcinoma
MiR-373,-520c	Upregulation of MCF-7 commonly used as breast cancer cell line are CD44 cell adhesion molecule	Breast carcinoma
MiR-21	Targeting metastasis suppressor proteins (e.g. TPM1, PDCD4 and maspin)	Breast carcinoma
MiR-10b	▪ MiR-10b induced by TWIST transcription factor ▪ MiR-10b upregulation RhoC and AKT phosphorylation through targeting HOXD10 ▪ MiR-10b modulates expression of invasive factors MMP14 and uPAR via target HOXD gene	▪ Breast carcinoma ▪ Gastric carcinoma ▪ Glioblastoma multiforme
MiR-885-5p	Downregulation of SMAD4	Colorectal carcinoma metastasizing to liver

All these microRNAs metastatic biomarkers need further exploration

- **MiR-10b:** Tumor invasion and metastasis is initiated by overexpressed MiR-10b in breast carcinoma. Expression of MiR-10b is induced by the transcription factor TWIST, which binds directly to the putative promoter of MiR-10b. High level of MiR-10b expression is linked to early progression of breast carcinoma. High MiR-10b modulates invasive factors MMP14 and uPAR expression via target HOXD gene that is associated with poor prognosis in glioblastoma multiforme patients. The aberrant expression of MiR-10-mediated downregulation of HOXD10 leads to increased RhoC expression and AKT phosphorylation resulting in rapid progression of gastric carcinoma.
- **MiR-885-5p:** Recent studies revealed that MiR-885-5p is upregulated in colorectal carcinoma that leads to early metastasis to liver.

▪ **Oncogenic microRNAs and chemoresistance:** Recent studies revealed that oncogenic microRNAs are responsible for chemoresistance by interfering with apoptotic pathway or DNA-repair pathway. All these lines of evidence have highlighted a pivotal role of oncogenic microRNAs in cancer cell treatment response. Oncogenic microRNAs and chemoresistance by interfering with apoptotic pathway or DNA repair pathway are given in Table 6.72. Oncogenic microRNAs and chemoresistance by interfering with apoptotic pathway or DNA repair pathway are given in Table 6.73.

Table 6.72 Oncogenic microRNAs and chemoresistance by interfering with apoptotic pathway or DNA-repair pathway

Oncogenic MicroRNAs	Mechanism	Human Cancer	Human Cancer Chemoresistance
MiR-125b	▪ ↓Apoptotic p53 and BAK proteins ▪ ↓Apoptotic BAK protein	▪ Ewing sarcoma/primitive neuroectodermal tumor ▪ Prostatic carcinoma ▪ Breast carcinoma	▪ Vincristine, doxorubicin, etoposide ▪ Paclitaxel
MiR-21	▪ ↓hMSH2 and hMSH6, the core mismatch repair (MMR) recognition protein complex ▪ ↓MicroRNA-21 binds to PTEN 3' UTR, determining PTEN depletion	▪ Colorectal carcinoma ▪ Non-small cell lung carcinoma ▪ Cholangiocarcinoma ▪ Gastric carcinoma	▪ 5-Fluorouracil ▪ Cisplatin, doxorubicin, 5-Fluorouracil ▪ Gemcitabine ▪ Cisplatin
MiR-128-2	↓Apoptotic PTEN protein	Lung carcinoma	Cisplatin, doxorubicin, 5-fluorouracil
MiR-17-5p	↓Modulation of apoptotic PTEN signaling pathway	Ovarian carcinoma	Cisplatin
MiR-217	↓Caspases 3 and 7 activities	Breast carcinoma	Cyclophosphamide
MiR-let-7a	↓Caspases 3 activity	▪ Hepatocellular carcinoma ▪ Oral squamous cell carcinoma	Interferon-gamma (INF-γ), doxorubicin

Table 6.73 Oncogenic microRNAs and chemoresistance by interfering with apoptotic pathway or DNA-repair pathway

Oncogenic MicroRNAs	Mechanism	Human Cancer	Human Cancer Chemoresistance
↑Oncogenic microRNA-125b	▪ ↓Apoptotic p53 and BAK proteins ▪ ↓Apoptotic BAK protein	▪ Ewing sarcoma/primitive neuroectodermal tumor ▪ Prostatic carcinoma and breast carcinoma	▪ Vincristine ▪ Doxorubicin ▪ Etoposide ▪ Paclitaxel
↑Oncogenic microRNA-21	↓ hMSH2 and hMSH6, the core mismatch repair (MMR) recognition protein complex	Colorectal carcinoma	5-Fluorouracil
↑Oncogenic microRNA-128-2	↓Apoptotic PTEN protein	Lung carcinoma	▪ Cisplatin ▪ Doxorubicin ▪ 5-fluorouracil
↑Oncogenic microRNA-21	↓MicroRNA-21 binds to PTEN 3' UTR, determining PTEN depletion	▪ Non-small cell lung carcinoma ▪ Cholangiocarcinoma ▪ Gastric carcinoma	▪ Cisplatin ▪ Doxorubicin ▪ 5-Fluorouracil ▪ Gemcitabine ▪ Cisplatin
↑Oncogenic microRNA-17-5p	↓Modulation of apoptotic PTEN signaling pathway	Ovarian carcinoma	Cisplatin
↑Oncogenic microRNA-217	↓Caspases 3 and 7 activities	Breast carcinoma	Cyclophosphamide
↑Oncogenic microRNA-let-7a	↓Caspase 3 activity	Hepatocellular carcinoma and squamous cell carcinoma	▪ Interferon-gamma (INF-γ) ▪ Doxorubicin

- **MiR-125b:** MiR-125b downregulates apoptotic pathway mediators (i.e. p53 and BAK protein) that leads to chemoresistance to vincristine, doxorubicin and etoposide in Ewing sarcoma/primitive neuroectodermal tumor. MiR-125b also downregulates apoptotic mediator (i.e. BAK protein) that leads to chemoresistance to paclitaxel in prostatic carcinoma and breast carcinoma.
- **MiR-21:** MiR-21 increases chemoresistance to 5-fluorouracil in colorectal carcinoma by downregulation of hMSH2 and hMSH6, the core mismatch repair (MMR) recognition protein complex.
- **MiR-128-2:** MiR-128-2 increases chemoresistance to cisplatin, doxorubicin and 5-fluorouracil in **lung carcinoma** by downregulation of PTEN. PTEN plays a pivotal role in the apoptotic pathway and its inactivation often determines chemoresistance.
- **MiR-21:** Recent study revealed that MiR-21 binds to PTEN 3' UTR, determining PTEN depletion and inducing chemoresistance in non-small cell lung carcinoma. MiR-21 also increases chemoresistance to gemcitabine in cholangiocarcinoma and to cisplatin in gastric carcinoma, through modulation of PTEN and AKT proteins.
- **MiR-17-5p:** MiR-17-5p induces chemoresistance in **ovarian carcinoma** by modulation of PTEN signaling.
- **MiR-217:** MiR-217 increases chemoresistance in **breast carcinoma** by inhibiting the activities of caspases 3 and 7.
- **MiR-let-7a:** MiR-let-7a induces chemoresistance to IFN-γ and doxorubicin in **hepatocellular carcinoma** and squamous cell carcinoma by downregulating caspase-3 activity.

Tumor Suppressor MircoRNAs and Cancer-inhibiting Mechanisms

MicroRNAs regulate the expression of their target genes post-transcriptionally by degrading mRNA transcripts or by inhibiting mRNA translation. Normally, microRNAs regulate of cell cycle, cell proliferation, apoptosis, energy metabolism and immune response. MicroRNAs have been identified to act as tumor suppressors or oncogenes based on their modulating effect on the expression of their target genes. Upregulation of oncogenic microRNAs blocks tumor suppressor genes resulting in development of malignant tumors. In contrast, downregulation of tumor suppressor function increases translation of oncogenes. Recent studies revealed that several microRNAs exhibiting tumor suppressor properties regulate the interaction between CSCs and their surrounding cells within tumor microenvironment by targeting genes either by oncogenes or tumor suppressor genes under certain circumstances. Carcinogenesis is a stepwise accumulation of genetic alterations (e.g. gene

amplification, aberrant oncoproteins as well as biallelic loss or inactivation of tumor suppressor genes) leading to unrestricted proliferation of CSCs, angiogenesis, invasion, epithelial-to-mesenchymal transition (EMT) and metastasis to distant organ(s).

- **Tumor suppressor microRNAs downregulation in CSCs and targets:** Tumor suppressor microRNAs (e.g. let-7, -15/16, MiR-34 cluster and MiR-200) prevent initiation of carcinogenesis through downregulation of target gene expression encoding oncoproteins. Tumor suppressor microRNAs promote apoptosis and inhibit cell proliferation, epithelial–mesenchymal transition (EMT), and oncogene expression.
- **Tumor suppressor microRNAs promote apoptosis of CSCs:** MiRs-15/16 cluster function as tumor suppressor microRNAs inhibits cell proliferation, promotes apoptosis of CSCs and suppresses tumorigenesis. MiRs-15/16 cluster is most often deleted or downregulated in various malignant tumors such as chronic, lymphocytic leukemia (CLL), prostatic carcinoma, colorectal carcinoma, melanoma, malignant pleural mesothelioma and pituitary adenomas.
  - The main target of MiRs-15/16 cluster is BCL-2 that triggers apoptosis by suppressing the expression of BCL-2 and also targets CCND1, MCL1, WNT3A, CDC2, ETS and Jun involved in genomic instability, unrestricted CSC proliferation, tumor angiogenesis, apoptosis resistance, immunologic escape, invasion and metastasis.
  - Recent gene profiling studies of patients with chronic lymphocytic leukemia [B cell with different immunoglobulin heavy chain variable (IgVH)] has revealed increased expression of ROR1, an oncoembryonic surface receptor tyrosine kinase protein for WNT5a on leukemic cells, that promote leukemic cell proliferation and survival. ROR1 serves as a putative target for therapy.
- **Tumor suppressor microRNAs inhibit epithelial–mesenchymal transition (EMT):** Epithelial–mesenchymal transition (EMT) is associated with reduction in the epithelial-like features of CSCs and acquisition of mesenchymal-like features that are essential to mediate effective invasion and migration.
  - EMT mechanism is regulated by transcription factors (i.e. SNAIL, ZEB, TWIST), which are repressed by some tumor suppressor MiRs (i.e. MiR-29b, MiR-30a, MiR-200 family members, MiR-205) leading to reversal of EMT and CSCs invasion. MiR-29b and MiR-30a repress translation of SNAIL-1 transcription factor.
  - Members of the MiR-200 family and MiR-205 repress translation of ZEB1 and ZEB2 transcription factors. These tumor suppressor MiRs are downregulated in various cancers, which increase the translation of transcription factors and play a crucial role in the regulation of EMT mechanism.
- **Tumor suppressor microRNAs inhibit CSC proliferation:** Tumor suppressor MiRs inhibit CSC proliferation and carcinogenesis. It is well known that Wnt/β-catenin signaling pathway drives carcinogenesis and progression of malignant tumor growth.
  - Wnt/β-catenin signaling pathway gives rise to epithelial–mesenchymal transition, which characterized by nuclear translocation of β-catenin and E-cadherin suppression.
  - MiR-340 and MiR-200 suppress Wnt/β-catenin signaling pathway by targeting transcription factor and binding to β-catenin mRNA and thus inhibits CSC proliferation. Downregulation of these MiRs is linked to human cancers.
- **Tumor suppressor microRNAs inhibit oncogene expression:** MiR-34 family (MiRs-34a,-34b,-34c) is a master regulator of tumor suppressor. Downregulation of MiR-34 family has been observed in breast carcinoma, colorectal carcinoma, lung carcinoma and prostatic carcinoma. MiR-34 inhibits numerous CSC types and suggests that it function at the core of carcinogenesis processes shared among CSCs (i.e. cell cycle, cell proliferation, antiapoptosis, cancer stemness, metastasis, oncogenic transcription and chemoresistance). Aberrant expression of MiR-34 is linked to many cancers.

MicroRNAs and Epigenetics in Cancer Diagnosis

Early cancer detection is the major step towards successful cancer treatment. Targeted sequencing is promising approach that works by detecting abnormal methylation patterns associated with cancer development. The detection of promoter hypermethylation has gained considerable attention in cancer diagnosis.

- Histone octamer modification is another potential epigenetic biomarker used in cancer diagnosis. Detection of abnormal post-translational modifications is an emerging approach for cancer diagnosis and outcome predictions. In lung carcinoma, specific histone octamer modifications, such as lower H3 and H3 methylation levels, have been found to associated with poor prognosis and mortality.
- Aberration expression of microRNAs are linked to many human cancers and therefore can be excellent diagnostic/prognostic markers in cancers. They may be targeted by therapeutic agents. MicroRNA methylation is novel epigenetic biomarker in different cancers such as lung carcinoma. Hypermethylation of microRNA-124 and microRNA-219 has been found to be associated with poor prognosis in lung carcinoma.

Table 6.74 MicroRNAs targeting the hallmarks of cancer

Noncoding MicroRNAs Therapeutics	Targets Hallmark of Cancer
↑MiR-21, ↑MiR-17-92, ↓MiR-34	Reduction of unlimited stem cell proliferation
↑MiR-9, ↑MiR-10b, ↑MiR-21, ↑MiR-103/107, ↓MiR-200	Limit tissue invasion and metastasis
↑MiR-17-92, ↑MiR-210	Limit sustained angiogenesis
↑MiR-21, ↓MiR-15-16, ↓MiR-34	Antagonize evasion of apoptosis

MicroRNAs and Epigenetic Therapy in Cancer Treatment and Future Challenge

Combined epigenetic therapies have shown promising outcomes in treating cancer patients, as tumorigenesis is associated with many epigenetic changes. Specific genetic and epigenetic changes associated with tumorigenesis should be assessed in each patient to get the highest benefits from epigenetic therapy.

- In urinary bladder carcinoma, the expression of tumor suppressor genes is inhibited by the polycomb repressive complex or *de novo* DNA methylation, which can be treated with inhibitors of histone methyltransferase enzyme. Similarly, *de novo* methylation can be blocked by inhibitors of DNA methylation.
- MicroRNAs may function as either oncogenes or tumor suppressors.
  - Oncogenic ncRNA-155 and tumor suppressor ncRNA-let may be therapeutic targets in cancer. Thus, ncRNAs could augment current cancer therapies.
  - RNA sequencing is an approach to transcriptome profiling that uses deep-sequencing molecular diagnostics to detect accurately quantity RNA molecules originating from genome by quantitative real-time polymerase chain reaction (RT-PCR) at a given moment in time. MicroRNAs targeting the hallmarks of cancer are given in Table 6.74.

POLYMORPHIC MICROBIOMES AND CANCER

Human body is colonized by a vast array of micro-organisms—microbiota that reside on and inside body surface epithelial barriers (skin, gastrointestinal tract, respiratory tract, genitourinary tract), that influence cancer susceptibility, in part, via their tremendous metabolic capacity, and their profound influence on immune cell function. Their profound influence to health and disease is now appreciated. Some of polymorphic microbiomes can exert deleterious effects on cancer development, progression, and favor the acquisition of hallmark capabilities. Non-antibiotics gut microbiome targeted therapeutic drugs, i.e. THIP hydrochloride, methenamine and mesna are used in clinical oncology.

- The microbiota most often exhibits commensalism with the host; however, when intestinal ecology undergoes disruption (dysbiosis), certain commensal bacteria (i.e. *Clostridium difficile* or vancomycin resistant enterococci) may expand and induce carcinogenesis. Metagenomic sequencing analysis revealed that large number of human malignancies have altered composition of commensal microbiota (**dysbiosis**).
- Microbiota are abundant in the lower intestinal tract. The abundant microbiota present on the gastrointestinal mucosa, translocates bacterial products and metabolites, that adversely affect local mucosal homeostasis functions and immunity, and systemic physiologic hemostasis functions.
- Altered composition of gut commensal microbiota (dysbiosis) induce pathologic local effects (i.e. inflammatory bowel disease, *Helicobacter pylori*-related chronic atrophic gastritis and gastric adenocarcinoma, *Fusobacterium* species-related colorectal carcinoma, *Salmonella enterica* or *Salmonella typhi*-related gallbladder carcinoma in 15–20% of cancer cases) and systemic effects (MALT lymphoma).
- Microbiota can alter cancer susceptibility and progression by different mechanisms, i.e. modulating inflammation, inducing DNA damage, and producing metabolites involved in the oncogenesis or tumor suppression. In addition to its association with carcinogenesis, metabolic active tumor microbiota can alter chemical structure of some chemotherapeutic agents, and modulate the efficacy and toxicity of cancer chemotherapy.
- Microbiomes selectively target malignant tumors that have rich vascular networks and chemotactic magnetism, which enhance cancer progression and chemoresistance. Anaerobic and/or facultative bacteria can survive in hypoxic tumor environments. Intratumoral gammaproteobacteria in pancreatic carcinoma express the enzyme cytidine deaminase (**CDD**), whose long form (CDDL) has been shown to metabolize gemcitabine into its inactive CDDL resulting in chemoresistance used in treating gastrointestinal malignancies.
- Non-antibiotic drugs such as THIP hydrochloride, methenamine and mesna are administered to modulate gut microbiome. Drug–microbiome interaction

has laid the foundation for a new era of more precise gut microbiome through drug repurposing, aimed at targeting specific dysbiotic events.

Helicobacter pylori-induced GIT Cancers

Helicobacter pylori is a gram-negative microaerophilic bacterium and the most crucial etiologic agent for gastric adenocarcinoma that is involved in 90% of all gastric malignancies.

- *Helicobacter pylori* contains virulence factors such as cagA (cytotoxin-associated gene A), island (cag PAI), and vacA (vacuolated cytotoxin A), which efficiently trigger atrophic gastritis (associated with hypochlorhydria/achlorhydria), which progresses to intestinal metaplasia, dysplasia, early gastric carcinoma, and advanced intestinal-type gastric adenocarcinoma.
- Environmental factors such as high-salt and tobacco smoking may also play a role in gastric carcinogenesis.

Pathophysiology of Helicobacter pylori-induced Gastrointestinal Disorders

The cag PAI encodes a type IV secretion system (T4SS) that injects at least 18 proteins including cagA pore-forming protein into host cells. CagA binds to epithelium via interaction with protein-tyrosine phosphatases induces morphologic changes of the cell, and influences various intracellular signal transduction pathways such as the RAS/mitogen-activated protein kinase/extracellular signal-regulated tyrosine kinase pathway, nuclear factor κB (NK-κB) pathway and β-catenin pathway resulting in malignant phenotype.

- The nature of the inflammatory response to *Helicobacter pylori* is also determined by proinflammatory IL-1 gene cluster polymorphisms in several host genes encoding cytokines and cytokine receptors, which induce intense inflammatory response leading to hypochlorhydria/achlorhydria and high risk for gastric carcinoma.
- The clinical manifestations of *Helicobacter pylori* include gastric chronic gastritis, duodenal ulcer (10–15%), gastric ulcer (1–3%), gastric adenocarcinoma and gastric mucosa-associated lymphoid tissue lymphoma (MALToma, 01%).

Prevention of Gastrointestinal Disorders via Helicobacter pylori Eradication

Peptic ulcer disease, MALToma and endoscopic treatment of early gastric carcinoma are well-known indications of *Helicobacter pylori* eradication. Prevention via *Helicobacter pylori* eradication and controlling environment factors such as diet and tobacco smoking is an important strategy to inhibit *Helicobacter pylori*-induced gastric carcinogenesis.

Gut Microbiome-induced Colorectal Carcinoma

The gut microbiota is critical in maintenance of host homeostasis that provides essential health benefits to its host by converting carbohydrates into short-chain fatty acids, which are an energy source.

- Goblet cells secrete mucus that serves as a physical barrier keeping gut bacteria separated from epithelial cells.
- Paneth cells eliminate opportunistic pathogens by the synthesizing antimicrobial peptides (AMPs).
- Microfold cells are present in the gut-associated lymphoid tissue of the Peyer's patches and can translocate B cells and T cells to the gut lumen in order to eliminate bacteria. Microfold cells can also present bacterial antigens to dendritic cells and elicit an IgA-specific immune response.

Dysbiosis of Gut Microbiota: Mechanism

Alteration in the gut microbiota can result from exposure to various environmental factors, including diet, toxins, antibiotics and pathogens. When the gut microbiota hemostasis is disrupted, dysbiosis occurs. Three types of dysbiosis include: (a) loss of beneficial bacteria, (b) overgrowth of potentially pathogenic bacteria and (c) loss of local microbiota bactericidal diversity. The environmental factors reduce oxygen consumption in the colonic epithelium, which drives dysbiosis by increasing the diffusion of oxygen into the intestinal lumen. Dysbiosis of the gut microbiota has been linked to inflammatory bowel disease (IBH), irritable bowel syndrome, celiac disease and colorectal cancer (CRC).

Dysbiosis of Gut Microbiota and Colorectal Carcinogenesis

Recently several studies revealed that gut microbiota can alter colorectal carcinoma susceptibility and progression by modulating mechanisms, i.e. inflammation and DNA damage. CRC is caused by combination of environmental, genetic and epigenetic factors. Several mechanisms have been identified how bacteria induce cellular transformation and promote tumor progression.

- Unlike viruses, which express consequently active viral mimics of cellular proto-oncogenes, tumor initiation and progression associated with dysbiosis of gut microbiota is a multifactorial event arises following '**multiple hits**' involving genes. Genetic heterogenicity in the gut microbiota as well as the host, in addition to environmental factors, determines colorectal carcinoma prevalence and severity.
- Dysbiosis of gut microbiota (PAMPs—pathogen-associated molecular patterns) activates the innate

immune system through pattern recognition receptors (PPRs) resulting in an inflammatory response in intestinal epithelial cells. Toxic metabolites or genotoxins (Colibactin, cytolethal distending toxin, hydroxyl radicals) produced by altered gut microbiota, damage DNA in intestinal epithelial cells resulting in initiation and progression of malignant tumor.

- *Fusobacterium nucleatum* plays important role in colorectal carcinogenesis through toll-like receptor 2 (TLR2)/toll-like receptor 4 (TLR4) signaling and microRNA-21 expression on cancer stem cells. In addition, *Fusobacterium nucleatum* increases colorectal carcinoma recurrence along with chemoresistance by mediating a molecular network of microRNA-18a and autophagy. Intratumoral bacteria further modulate the immune system.
- Dysregulated microbiota can interact directly with intestinal epithelial cells and immune cells, and can activate colorectal carcinoma-related signaling pathways such as phosphatidylinositide 3-kinase (PI3K)/AKT/mTOR signaling pathway and Wnt/β-catenin signaling pathway involved in unrestricted CSC proliferation and survival.
- Additionally, some genotoxins can also enhance signal transduction and activation of transcription 3 (STAT3) signaling pathway, which leads to cell proliferation, and T cell activation and can thereby elicit a Th17 cell mediated immune response. Th17 cells are proinflammatory CD4+ helper cells that secrete IL-17A, IL-17F, IL-21, IL-22 and provide immunity to several extracellular pathogens but have been described as uniquely pathogenic in multiple inflammatory diseases.

Dysbiosis of Host Gut Microbiota and Therapeutic Modalities of Colorectal Carcinoma

The gut microbiota has also been implicated in the metabolism of conventional chemotherapeutic agents as well as in the modulation of therapy responses and targeted immunotherapy. These findings suggest that the efficacy of a given anti-cancer therapy depends on the composition of the host' gut microbiota and may therefore vary from patient to patient.

- *Fusobacterium nucleatum* outer membrane FAP2 protein prevents the activation of natural killer (NK) cells protecting colorectal adenocarcinoma cell lines from NK cell antitumor immunity.
- Cancer treatment can be improved by manipulating microbiota by incorporating probiotics as adjuvants for checkpoint immunotherapy or designing small molecules that target microbial enzymes.

CARCINOGENIC AGENTS: CELLULAR INTERACTION AND CARCINOGENESIS

Cellular proliferation is tightly regulated by two sets of opposite functioning genes, i.e. proto-oncogenes (growth-promoting genes that stimulate cell division) and tumor suppressor genes (growth suppressor genes that halt cell division), which participate in cell growth and cell proliferation during G1, S, G2, M and G0 phases of cell cycle.

- **Carcinogenesis:** Carcinogenesis is a multistep molecular process driven by genetic and epigenetic alterations of multiple genes in the target cells involving activation of proto-oncogene (oncogene tumor promoting) and inactivation/biallelic loss of tumor suppressor (growth-inhibiting) genes, apoptosis regulatory genes, and DNA repair genes by which normal cell is transformed to CSC either spontaneously or induced by environmental mutagenic agents leading to unrestricted rapid proliferation of clonal somatic CSCs, which are genetically different from each other but part of the same malignant tumor that is known as the genetic heterogenicity. The clonal CSCs become resistant to chemotherapy, and will survive and persist. Multistep molecular carcinogenesis is shown in Fig. 6.94.
- **Carcinogen-linked malignancies:** Carcinogens are capable of causing human cancers, which may occur spontaneously or induced by environmental mutagenic agents, which include: (a) chemical carcinogens—asbestos, components of tobacco smoke, alcohol consumption, aflatoxin B1 synthesized by *Aspergillus flavus* (food contaminant in stored grains) and arsenic in drinking water contaminant, (b) physical carcinogens—ultraviolet rays and ionizing radiation, and (c) biological carcinogens—viruses, i.e. HPV, Epstein-Barr virus, HBV, HTLV-1, bacteria—*Helicobacter pylori, Borrelia burgdorferi, Campylobacter jejuni* and *Chlamydia psitacci,* parasites—*Schistosoma haematobium, Clonorchis sinensis* and *Opisthorchis viverrini*. Latent period is the time period between the exposure of the cell to the initiator carcinogenic agent till the malignant tumor becomes clinically detectable. However, some of these etiological factors can act both initiator and promoter in the process of carcinogenesis. There is

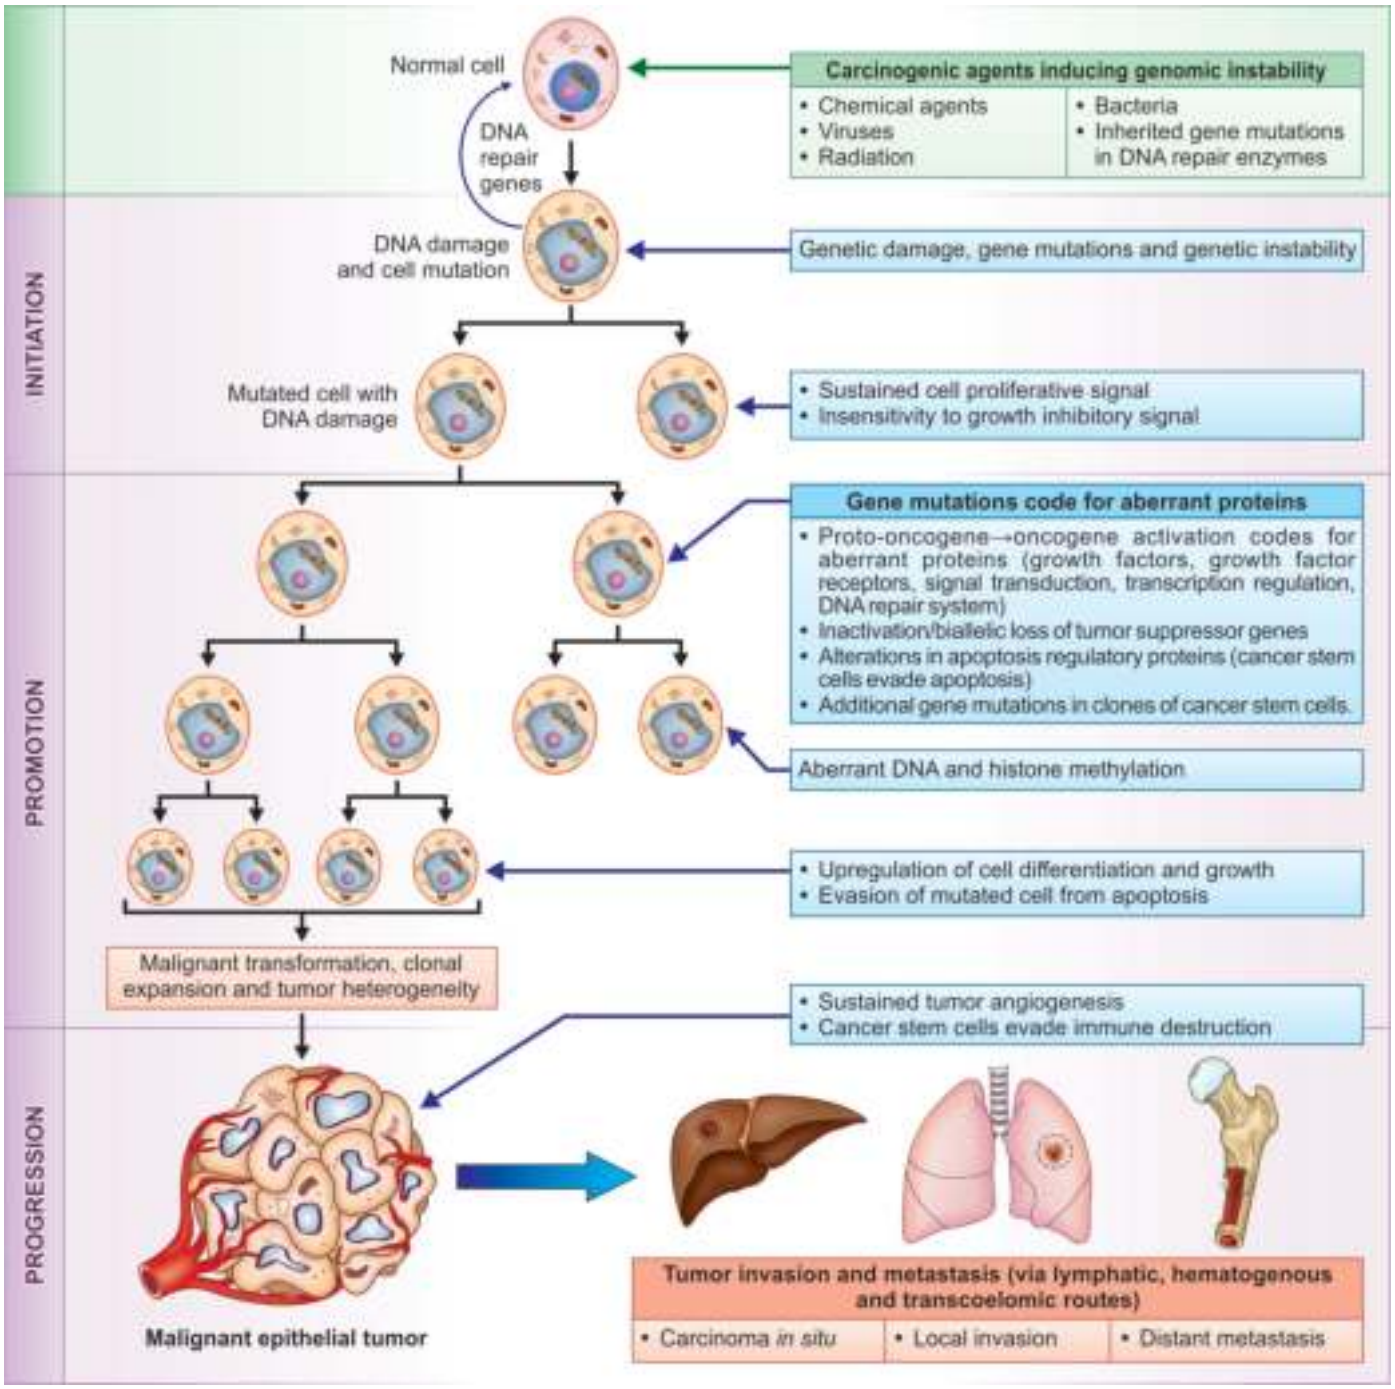

Fig. 6.94: Multistep molecular carcinogenesis. Schematic representation shows inherited/acquired gene mutations transforming normal cell to cancer cell by uncontrolled monoclonal proliferation and decreased apoptosis. Tumor progression occurs by additional gene mutations, angiogenesis, escape from host immune response. Cancer cells invade and metastasize to distant organs.

a normal history from metaplasia to dysplasia to invasive malignant neoplasm. This is best evidence in development of malignant neoplasms in uterine cervix and respiratory tract.

- **Occupational and air pollutants:** Environmental air pollutants such as arsenic, asbestos, polyvinyl chloride, other industrial emissions as well as vehicle exhaust have carcinogenic properties. In certain occupations, workers exposed to asbestos are at high-risk for lung carcinoma and mesothelioma. Workers involved in the production of aniline dyes, rubber, paint and β-naphthylamine are at high-risk for urinary bladder carcinoma.
- **Cigarette smoking:** Cigarette smoke contains carcinogens, which cause gene mutations. Risk of development of lung carcinoma correlates with

the duration of cigarette smoking and number of cigarettes smoked per day. Researches also showed that a person who stops cigarette smoking has lower risk for development of lung carcinoma. Inhalation of 'second hand cigarette smoke' (passive tobacco smoking in nonsmokers) also increases risk for lung carcinoma and oral squamous cell carcinoma.

- **Alcohol consumption:** Excessive alcohol consumption is linked to cirrhosis, a precursor of hepatocellular carcinoma, breast carcinoma and colorectal carcinoma. Excessive alcohol consumption and cigarette smoking synergistically increase the incidence of cancers of the mouth, esophagus and larynx. It is likely that alcohol acts as a solvent for the carcinogenic substances in cigarette smoke, thus enhancing its absorption.
- **Sexual factors:** The early age of first intercourse and women with multiple sexual partners is positively correlated with risk of cervical carcinoma. The suspected mechanism of developing cervical carcinoma involves transmission of human papillomavirus (HPV 16, 18). Steroid hormones, i.e. estrogen, progesterone and testosterone have been implicated as promoters of breast carcinoma, endometrial carcinoma and prostatic carcinoma.
- **Ultraviolet and ionizing radiation:** Exposure to solar ultraviolet radiation induces TP53 tumor suppressor gene mutation, that induces pyrimidine dimers in DNA formation and promotes development of skin cancers (e.g. squamous cell carcinoma, basal cell carcinoma and melanoma). Sunlight also releases tumor necrosis factor-α (TNF-α) in exposed skin, possibly diminishing immune response. Ionizing radiation such as X-rays is linked to developing acute leukemia, multiple myeloma and cancers of thyroid, gastric region, colon, lung, urinary tract. **Ionizing radiation** causes DNA damage via two mechanisms: (a) direct mechanism—direct toxicity and DNA breakage and subsequent cellular death, and (b) indirect mechanism—based on the ionizing radiation-induced free radicals with further fragmentation of the DNA or ionization of water or other molecules within the cells. The damaged tissue and blood vessels are replaced by fibroblasts that are unable to synthesize collagen fibers. Low doses of radiation can cause DNA mutations and chromosomal abnormalities.
- **Dietary factors:** Numerous aspects of diet are linked to various human cancers resulting from obesity, high consumption of smoked foods and salted fish or meat containing traces of polycyclic aromatic hydrocarbons and foods containing nitrates and nitrites, diet low in fibers, and naturally occurring carcinogen such as aflatoxin B1 produced by *Aspergillus flavus* in stored food crops. Aflatoxin B1 produced by *Aspergillus flavus* is linked to hepatocellular carcinoma. High-fat diet-related obesity is linked to cancers of colon, breast, kidney, esophagus, endometrium and gallbladder. Adequate consumption of fruits and vegetables probably lower the risk of developing gastrointestinal tract carcinomas.
- **Infectious agents:** About 20% of human cancers are attributable to biological pathogens (e.g. viruses, bacteria and fungi). Pathogenetic infections result in deregulation of gene expression both by genetic and epigenetic mechanisms and eventually result in transformation of normal cell to CSC and malignant phenotype. Another characteristic of pathogen-induced human cancers is the occurrence of chronic inflammation as a result of activation of innate and adaptive immune system. Human papillomavirus (HPV 16, 18) is implicated in cervical carcinoma. Epstein-Barr virus (EBV) is linked in African Burkitt's lymphoma, nasopharyngeal carcinoma and Hodgkin's disease. Hepatitis B virus (HBV) and hepatitis C virus (HCV) are implicated in development of hepatocellular carcinoma. Human T cell leukemia virus type 1 (HTLV-1) is linked to T cell leukemia/lymphoma. Infection with human immunodeficiency virus (HIV) increases risk of developing Kaposi sarcoma. Microbial carcinogenic agents associated human cancers are given in Table 6.75.

- **Genetic and epigenetic alterations and cancers:** Multiple genetic alterations are required before transformation of a normal cell to CSC. In the early studies on carcinogenesis, it has been observed that a long latent period could elapse from exposure to carcinogen to the development of malignant phenotype.
  - Any change in the DNA sequence can alter the genetic code and therefore may alter synthesis of the protein that it encodes. DNA sequence of a CSC genome generally acquires molecular alterations such as multiple cancer driving mutations (oncogenes and inactivation/biallelic loss of tumor suppressor genes), substitutions, insertions, deletions of small or large fragments of DNA, gene amplification, gene rearrangements and post-translational modifications. These genetic alterations modulate gene expression during cancer progression. DNA methylation and demethylation are also common occurrence in cancer and leads to altered gene expression. Whole genomic sequencing analysis reveals recurrent somatic mutations in various epigenic regulators.

Table 6.75 Microbial carcinogenic agents associated human cancers

Cancer	Associated Pathogens
Burkitt's lymphoma	Epstein-Barr virus
Cervical carcinoma	Human papillomavirus (16, 18)
Cholangiocarcinoma	*Clonorchis sinensis* (liver fluke), *Opisthorchis viverrini, Fasciola hepatica, Salmonella typhi*
Colorectal carcinoma	*Streptococcus bovis*, John Cunningham virus
Cutaneous MALT lymphoma	*Borrelia burgdorferi*
GIT non-Hodgkin's lymphoma	*Borrelia burgdorferi*
Gastric carcinoma (distal half of stomach), gastric MALT lymphoma	*Helicobacter pylori*
Gliomas (astrocytomas)	John Cunningham virus
Hepatocellular carcinoma	HBV, HCV, *Clonorchis sinensis* (liver fluke), *Schistosoma japonicum*, aflatoxin B1 (*Aspergillus flavus*)
Hodgkin's disease	Epstein-Barr virus (EBV)
Kaposi sarcoma	Human herpesvirus 8 (HHV8)
Merkel cell carcinoma	Merkel cell polyomavirus
Malignant mesothelioma	Simian virus 40 (SV40), oncogenic DNA virus
Non-Hodgkin's lymphoma	Simian virus 40 (SV40), oncogenic DNA virus
Orbital adnexal lymphoma	Orbital adnexal lymphoma
Primary brain tumors	Simian virus 40 (SV40), oncogenic DNA virus
Prostatic carcinoma	Xenotropic murine leukemia virus
T cell acute lymphoblastic leukemia	Human T-lymphotropic virus 1
Urinary bladder carcinoma	*Schistosoma haematobium*

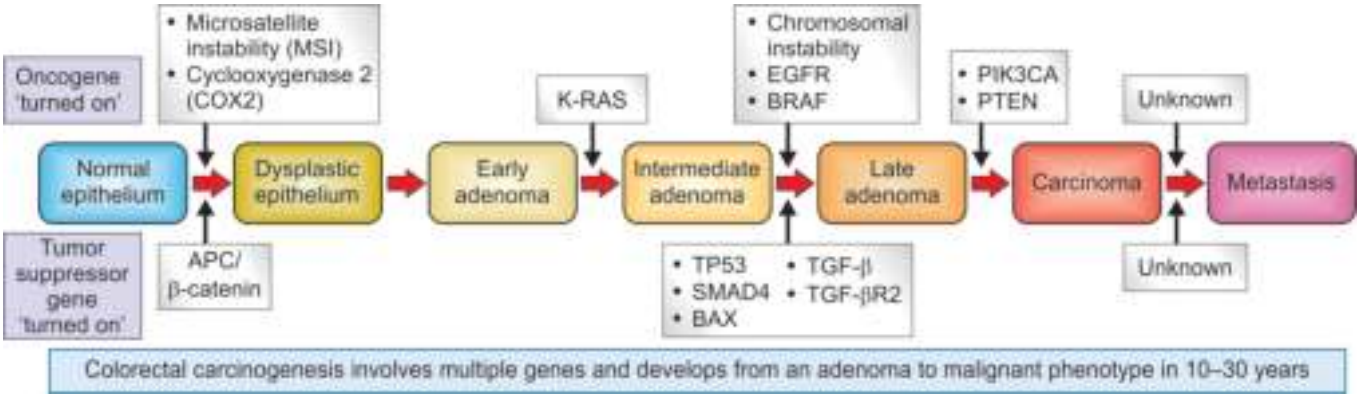

Fig. 6.95: Molecular carcinogenesis revealing adenoma–colorectal carcinoma sequence. It is postulated by Knudson's hypothesis that losses of normal copy of tumor suppressor APC gene occurs early in life. This is the first hit. Loss of intact copy of APC gene follows (second hit). Other gene mutations include K-RAS, losses at 18q21 involving SMAD2 and SMAD4 and inactivation/biallelic loss of tumor suppressor TP53 gene. It leads to the emergence of colorectal carcinoma and metastases, in which additional gene mutations occur.

Multistep carcinogenesis showing morphologic and molecular changes in the adenoma–colorectal carcinoma sequence is shown in Fig. 6.95. Molecular carcinogenesis revealing development of pancreatic carcinoma is shown in Fig. 6.96.

- Epigenetics can be defined as heritable changes in gene expression that are not accompanied by changes in DNA sequence. Epigenetic regulation of gene expression is mediated by three main mechanisms: (a) DNA methylation, (b) histone

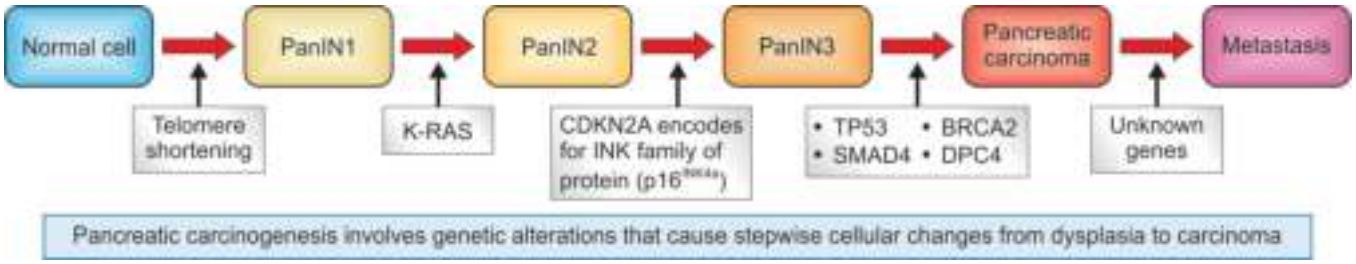

Fig. 6.96: Molecular carcinogenesis revealing development of pancreatic carcinoma. It demonstrates genomic and histopathologic steps from the initiating gene mutation in the founder cell to metastasis formation. It has been convincingly shown that the genomic landscape of solid tumors such as pancreatic carcinoma requires the accumulation of many genetic events, a process that requires decades to complete.

octamer modifications, and (c) microRNAs. Epigenetic alterations result in remodeling of DNA repair genes, which cause DNA repair system failure. Epigenetic alterations lead to increase in permanent DNA damage and a considerable increase in somatic mutations and stable phenotype malignant phenotype.

- Conventional histology is unable to detect genomic changes, and biochemical alterations associated with tumor promotion and progression. Ancillary technologies such as immunohistochemistry and molecular genetics are employed to identify products of activated proto-oncogenes (oncogenes), which offer promise in distinguishing the various stages of progression in the evolution from benign to malignant tumors.

CHEMICAL CARCINOGENESIS

Chemical carcinogenic agents are considered to be the key etiological factor of human malignancies by inducing cellular genetic damage causing DNA abnormalities in somatic cells that alter cell growth, unrestricted proliferation of clonal CSCs and survival. Application of an initiator or a promoter chemical carcinogenic agent alone is not sufficient to induce carcinogenesis. Both initiator and promoter must act sequentially to induce carcinogenesis. The interval between tumor initiation and promotion can be long or short. Tumor initiation occurs due to permanent gene mutations in the target cell. Multiple genetic alterations are required before transformation of a normal cell to CSC. In the early studies on carcinogenesis, it has been observed that a long latent period could elapse from exposure to carcinogen to the development of malignant tumor growth.

- **Chemical carcinogenic agents—classification:** Chemical carcinogenic agents can be classified into several groups—direct and indirect, which include: (a) genotoxic chemical carcinogenic agents cause direct damage to DNA by forming chemical DNA adducts that are prone to damage in DNA replication or resistant to DNA repair mechanisms, (b) mitogenic chemical carcinogenic agents act as mitogen factor that binds to receptors or in cells and stimulate mitosis by activation of receptor tyrosine kinase activity without causing direct DNA damage, and (c) cytotoxic chemical carcinogenic agents cause tissue damage leading to hyperplasia and tissue regeneration. Complete (direct acting) carcinogenic agents can carry out both tumor initiation and promotion functions (e.g. ultraviolet rays, ionizing radiation, tobacco smoke).
  - **Exposure to complete chemical carcinogenic agents:** Exposure to a complete chemical carcinogen alone is sufficient to induce carcinogenesis. Procarcinogens are metabolized to ultimate carcinogen to cause cancer. Hormones can only promote but unable to initiate carcinogenesis. Cocarcinogens cause cancer by acting with another chemical carcinogenic agents. Germline mutation in proto-oncogene (oncogene) or tumor suppressor gene is linked to numerous human cancers.
  - **DNA-adduct formation:** The principal reactive products of the nitrosamines and similar alkylating agents with DNA are N^7 and O^6 guanine derivatives, which bind and react with DNA nucleotide base pairs, RNA and proteins resulting in the formation of DNA adducts with these cellular components. If DNA adducts escape DNA repair mechanisms and persist, they may lead to miscoding, resulting in permanent mutations.
  - **Consequences of DNA-adduct formation:** Polycyclic aromatic hydrocarbon double-helical DNA-adduct formation occurs by frameshift mutation during DNA replication. Alkylated nucleotide base pairs in DNA can mispair with the wrong nucleotide base pairs during DNA replication. There are loss of nucleotide bases due to induction of instability in the glycosidic bond between the purine base and deoxyribose. Some chemical carcinogenic agents cause

conformational transition of DNA from its usual double-helical B form to a Z-DNA form.

- **Chemical carcinogenic agents—metabolism:** Carcinogenic agents may be absorbed via oral, inhalation, cutaneous and injection routes and dispersed among human tissues. The absorption lies on the physiochemical properties of chemical carcinogens through active or passive transport mechanisms, which undergo metabolic conversion through various enzymatic pathways, with differences in saturation levels. Metabolic bioactivation, detoxification and genotoxic property of chemical carcinogens play an important role in carcinogenesis.
  - Metabolic bioactivation of chemical carcinogenic agents and production of reactive electrophilic intermediates leads to the covalent binding to cellular macromolecules such as DNA, RNA and proteins. DNA adducts can be generated from products of lipid peroxidation.
  - Such metabolic conversion by enzymatic pathways may detoxify noxious chemical carcinogenic agents by phase I and phase II enzymes: (a) oxidation, reduction and hydrolytic reactions involve phase I enzymes such as cytochrome P450 dependent monooxygenases and epoxide hydrolases, which enhance the aqueous solubility and causing increased excretion, and (b) conjugation reactions involve phase II enzymes such as glutathione (GSH) transferases, UDP-glucuronosyltransferases and sulfotransferases, which are not only protective but also activate chemical carcinogenic agents.
- **Chemical carcinogenesis:** Chemical carcinogenesis occurs due to biotransformation failure, initiation (covalent binding to DNA), gene mutation, transformation of normal cell to CSC, unrestricted CSC proliferation, tumorigenesis, epithelial–mesenchymal transition (EMT), invasion and metastasis.
  - Numerous cellular and molecular events cause transformation of normal cell to malignant neoplastic cells, i.e. cancer stem cells in the process of carcinogenesis. It has been observed that endogenous molecular signaling pathways could instigate gene mutations in target genes with the support of reactive oxygen species (ROS), which induce to DNA damage.
  - On exposure to a chemical carcinogenic agent, body makes an attempt to eliminate it through a process called biotransformation by making it more water-soluble. When biotransformation fails, most chemical carcinogens require metabolic conversion to become ultimate potent carcinogens.
  - Potent (complete) chemical carcinogenic agents possess the capability of both initiation and promotion of carcinogenesis, which possess electron deficient (electrophilic) molecules, that interact and form covalent or noncovalent bonds with cellular electron-rich DNA, RNA and proteins of human tissues, resulting in alterations in the nucleotide base pairs in DNA and thus impairing DNA replication and transcription.
  - Partial (incomplete) chemical carcinogenic agents can only carry out either tumor initiation or promotion in the process of carcinogenesis. Hormones can only promote but unable to initiate carcinogenesis. Indirect-acting chemical carcinogenic agents do not possess carcinogenic properties in their original state, which require metabolic conversion to become ultimate potent carcinogens by cytochrome P450 dependent monooxygenases.
  - Such cell with DNA damage undergoes apoptosis. Failure of apoptosis, certain genes especially RAS gene and TP53 gene transform normal cell to CSC with DNA damage to malignant phenotype. It is thought that altered cells are primed but require a second change to bring about molecular genetic changes to induce carcinogenesis. Mechanism of chemical carcinogen-induced carcinogenesis is shown in Fig. 6.97.

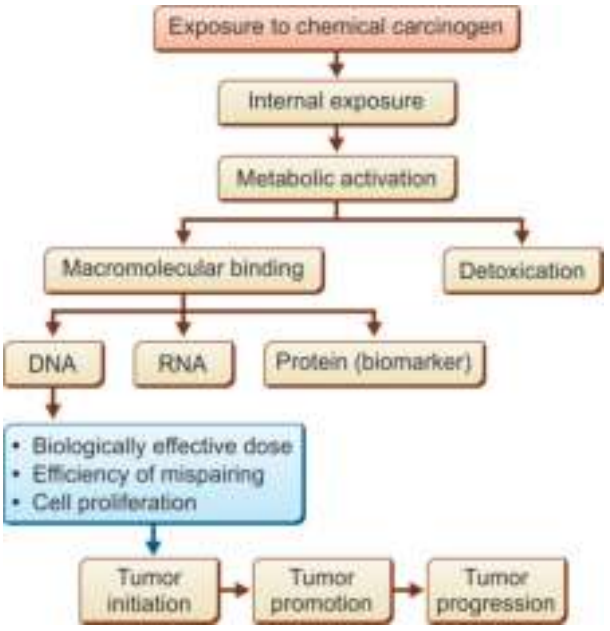

Fig. 6.97: Mechanism of chemical carcinogen-induced carcinogenesis.

MULTISTEP CARCINOGENESIS: MECHANISMS

The multistep carcinogenesis consists of several cellular and molecular events and includes multiple steps—tumor initiation, promotion and progression to bring about transformation of normal cell to CSC, which clearly involve both genetic and epigenetic events.

- Tumor initiation occurs due to exposure of normal cells to an adequate quantity of chemical carcinogenic agent and cause permanent DNA damage. Promoters induce tumorigenesis in an initiated (mutated) cell, but are non-tumorigenic themselves through progression of cell cycle, and propagation of gene mutations.
- Neither an initiator nor a promoter chemical carcinogenic agent acting on its own to cause neoplasia; therefore, both initiator and promoter must act on the cells to induce tumorigenesis.
- Initiation–promotion model of carcinogenesis is shown in Fig. 6.98. Simplified scheme of carcinogenesis is shown in Fig. 6.99. Multistep process of chemical carcinogenesis is given in Table 6.76. Basic classes of chemical carcinogenic agents acting as initiators and promoters are given in Table 6.77.

Tumor Initiation

During initiation, chemical carcinogenic agent can induce rapid non-lethal stable gene mutations in the genome of daughter cell leading to transformation of normal cell to CSC leading to tumorigenesis. Development of malignant tumor depends on the quantity of chemical carcinogenic agent. Increased quantity of carcinogenic agent induces carcinogenesis, whereas decreased quantity inhibits neoplastic process.

- Direct-acting chemical carcinogenic agents do not require metabolic conversion activation or molecular modification in order to induce DNA damage and examples include nitrosamines, ultraviolet rays, alkylating and acylating agents.
- Indirect-acting chemical carcinogenic agents do not possess carcinogenic properties in their original state and require metabolic conversion to become ultimate potent chemical carcinogens by cytochrome P450 oxidases within the body before they are able to bind and induce DNA damage. Examples of carcinogenic agents include polycyclic aromatic amines, nitrosamines, organohalogen compounds, and aflatoxin B1 (synthesized by fungus *Aspergillus flavus* in growing stored grains, nuts and peanut).
- The damaged DNA does not get repaired as the proliferating cells get less time and consequently, the bonds that chemical agents establish with the **DNA (adducts)** are not removed. Thus, this process verifies that cell division stays symmetrical leading to transformation of normal cell to CSC. The process of initiation encompasses a non-lethal gene mutation.
- Genetic alterations can result in aberrant biochemical signaling pathways associated with CSCs proliferation, survival and differentiation, which can be influenced by a number of factors, which include rate and type of metabolism of carcinogenic agents and DNA repair system response. DNA methylation in the genes can transcriptionally kill tumor suppressor genes leading to unrestricted CSC proliferation and survival in individual's life.
- Mitogenic stimulation results in unrestricted CSC proliferation and disruption in apoptosis through extrinsic (death receptor) and/or intrinsic (mitochondrial) pathways, thus leading to clonal expansion of initiated (mutated) cells that survives later. Reactive oxygen species (ROS) are considered to assist in the activation of chemical carcinogenic agents through hydroperoxide-dependent oxidation, which is mediated by peroxyl radicals.

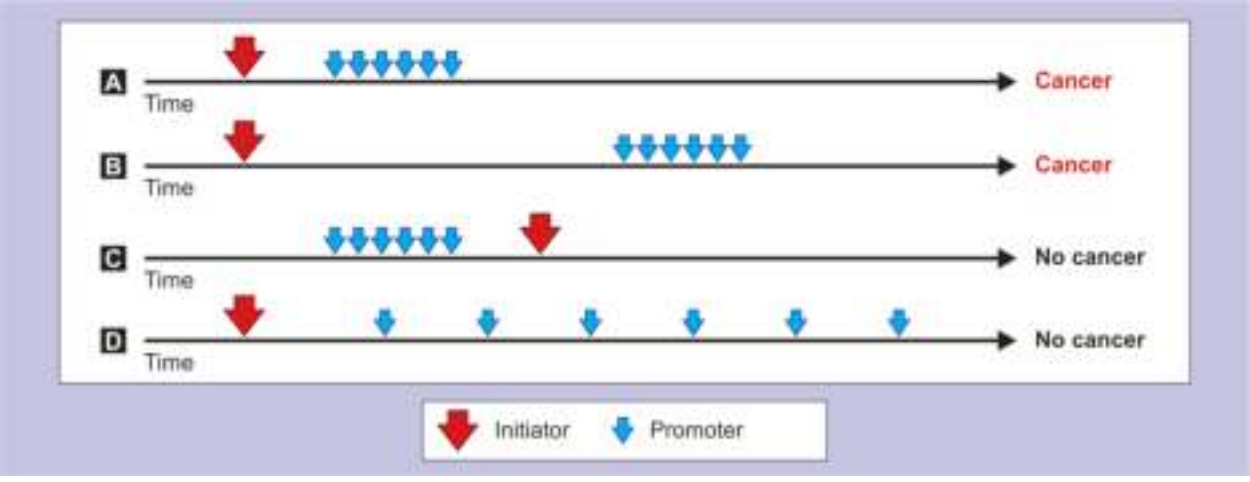

Fig. 6.98: Initiation–promotion model of carcinogenesis developed by Berenblum and P. Shubik by painting polycyclic aromatic hydrocarbons and croton oil on mouse skin. (A) Simultaneously exposure to initiator and then promoter leads to cancer, (B) exposure to initiator and then promoter after long time also causes cancer, (C) exposure first to promoter and then initiator does not cause cancer, (D) exposure to initiator then promoter at wide intervals does not cause cancer.

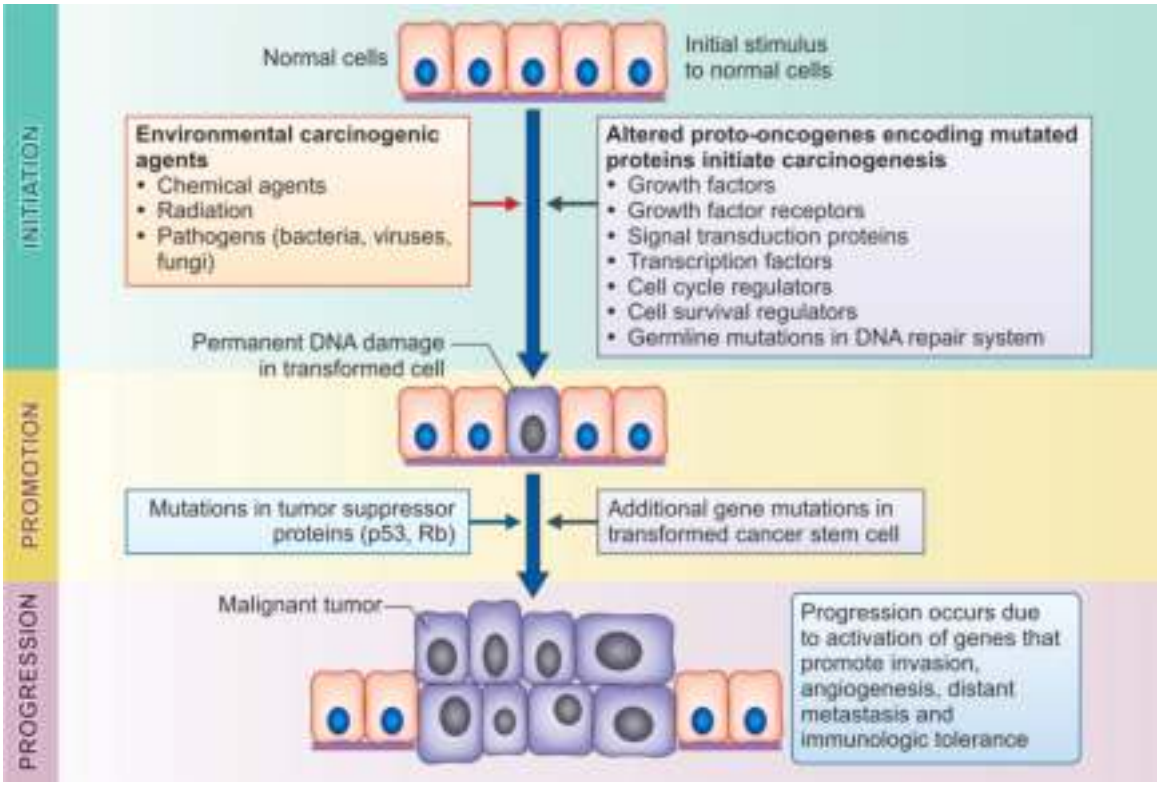

Fig. 6.99. Simplified scheme of carcinogenesis. Exposure to chemical carcinogenic agents, radiation and biological agents and altered genes cause DNA damage. DNA of normal cell resulting in transformed CSCs. Additional mutations and inactivation/biallelic loss of tumor suppressor genes participate in promotion process by proliferation of clonal of cells.

Table 6.76 Multistep process of chemical carcinogenesis

Multistep Process of Carcinogenesis	Normal Cell	Initiation Process	Promotion Process	Progression Process
Chemical carcinogen	Chemical carcinogen binds but does not induce genetic mutations	Chemical carcinogen binds to DNA, forms DNA adducts and induces genetic mutations	Chemical carcinogen induces selective clonal growth of initiated (mutated) cells	Chemical carcinogen induces final conversion of clonally expanded cells into malignant tumor growth
Chemical carcinogen effect	DNA damage undergoes repair	Altered cell (initiated/mutated cell)	Initiated (mutated) cell leads to unrestricted proliferation and formation of focal malignant tumor mass	Growth advantage and genetic instability lead to development of malignant tumor
Apoptosis	Intact	Impaired	Impaired	Impaired

- Reactive oxygen species (ROS) are group of short-lived, highly reactive, oxygen-derived molecules such as superoxide anion, hydrogen peroxide and hydroxyl radical that can induce DNA damage and affect the DNA damage repair response (DDR).
  - Cellular membranes or organelle membrane, due to their high polyunsaturated fatty acids are especially susceptible to ROS damage, which is called 'lipid peroxidation'. ROS activate chemical carcinogens through hydroxyperoxide-dependent oxidation which is mediated by peroxyl radicals. ROS-induced lipid peroxidation directly reacts with DNA to produce DNA adducts.
  - DNA adducts lead to alterations in DNA structure such as DNA nucleotide base pair modifications and frameshifts. Reactive oxygen species (ROS)-induced lipid peroxidation has been implicated in carcinogenesis.

Tumor Promotion

Tumor promotion is defined by propagation of gene mutations by non-mutagenic co-carcinogens (e.g. croton

Table 6.77 Basic classes of chemical carcinogenic agents acting as initiators and promoters

Characteristics	Initiators of Cancer	Promoters of Cancer
Nature of agent	Electrophilic (electron deficient) carcinogenic agents	Non-electrophilic (electron-rich and noncarcinogenic agents
Action	Induces non-lethal mutation(s) in a cell	Induces cell proliferation (clonal expansion)
Reversibility	Irreversible changes in DNA after cell proliferation after one cell cycle	Reversible influence on cell growth without change in DNA
Order	Exposure of the cell to initiator before promoter for carcinogenesis	Exposure of the cell to promoter after the initiator for carcinogenesis
Examples (carcinogen acting as both initiator and promoter)	▪ Polycyclic aromatic amines ▪ Ultraviolet rays/ionizing radiation ▪ Epstein-Barr virus ▪ Hepatitis B and C virus ▪ Pesticides (some)	▪ Polycyclic aromatic amines ▪ Ultraviolet/ionizing radiation ▪ Epstein-Barr virus ▪ Hepatitis B and C virus ▪ Pesticides
Examples (carcinogen acting as initiator only)	▪ Asbestos ▪ Azo dyes ▪ Benzene ▪ Metals (nickel, chromium) ▪ Nitrates/nitrites (N-nitroso compounds)	Not applicable
Examples (carcinogen acting as promoter only)	Not applicable	▪ Alcohol ▪ *Helicobacter pylori* ▪ Hormones ▪ Alcohol ▪ Chronic irritation or wound ▪ Pesticides (some act as initiators) ▪ Polychlorinated biphenols (PCBs)

(a) Initiators induce genomic instability and initiate cancers. Promoters promote cell proliferation and survival.
(b) Carcinogens acting as both initiators and promoters of cancer include ionizing radiation, polycyclic aromatic hydrocarbons and oncogenic viruses (Epstein-Barr virus, hepatitis B virus, hepatitis C virus, and human papillomavirus (HPV).

oil and turpentine oil) induced by initiators leading to unrestricted CSC proliferation (clonal expansion) and accumulation of additional multiple gene mutations. The rate accumulation gene mutation is directly proportional to the rate of cell division.

- Clonal expansion of the initiated (mutated) cells occurs due to promotional non-mutagenic co-carcinogens leading to development of malignant phenotype and CSCs survival. Reversibility is considered to be one of the essential features of the promotion response. This implies that the removal of the promoting agent causes no further proliferation of the initiated (mutated) cell population.
- The promoters such as phorbol esters, phenols, hormones and drugs are themselves non-tumorigenesis, but intensify the carcinogenicity of chemical carcinogenic agents, which induce unrestricted CSC proliferation in vulnerable tissues, fixation of gene mutations, augmentation of genetic changes leading to clonal expansion of initiated (mutated) cells. These promoters could indirectly induce DNA damage by production of reactive oxygen species (ROS), that is directly associated to P450 monooxygenases activity wherein oxidative stress could aid in the clonal expansion of the initiated (mutated) cells.

Tumor Progression

Genetic heterogenicity in the promoted cell population takes place when the initiated (mutated) cell population is extended during promotion and attains further genetic damage, continuous accumulation of new different gene mutations with high-proliferative potential and different behaviors, invasive phenotype with development of new sub-clones of CSCs, angiogenesis and distant metastasis. Metastasis involves the spread of CSCs from the primary tumor site to other parts of the body through lymphovascular and transcoelomic routes. Some of the nonviable cells undergo apoptosis.

- As the heterogenous malignant tumor grows, it becomes complex due to clonal expansion of CSCs, and each clone with different behaviors. CSCs possess several unique capabilities such as self-renewal of cells and metastasis. With time, it becomes increasingly difficult to eliminate all CSCs with chemotherapeutic agents (e.g. tamoxifen for

breast carcinoma) because each group can respond differently to the treatment.

- Malignant tumor heterogenicity is an important characteristic of tumor progression, which allows for antigenic and protein products ability to produce proangiogenic factors, emergence of chromosomal alterations, development of metastatic capability, altered cellular metabolism and decreased sensitivity to chemotherapeutic agents and radiation therapy. Alternatively, genetic heterogenicity observed in malignant tumor progression may be generated by epigenetic regulatory mechanisms operative as a continuation of the process of promotion.
- Associated with progression, there is development of genomic instability and aneuploidy in malignant tumors. Finally, chromosomal rearrangement is associated with malignant tumors, especially chronic myelogenous leukemia (CML) and acute lymphoblastic leukemia (ALL).
- Chemopreventive agents are known to inhibit tumor angiogenesis and invasion of primary malignant tumors and thus could be utilized to inhibit the metastasis of cancer. Debulking of malignant tumor done by surgery or radiation is one the strategies in the management of malignant tumors.

CHEMICAL CARCINOGENIC AGENTS: CLASSIFICATION

Chemical carcinogenic agents bring about the process of carcinogenesis by covalently or non-covalently binding to DNA, RNA and proteins of human tissues leading to genetic alterations. Process of carcinogenesis consists of several molecular and cellular events and includes the three major steps—initiation, promotion and progression to bring about transformation of normal cell to CSC.

- Chemical carcinogenic agents that assist to initiate carcinogenesis are classified into two categories: (a) direct-acting chemical carcinogens initiate carcinogenesis without undergoing metabolic conversion, and (b) indirect-acting chemical carcinogens (procarcinogens) promote carcinogenesis involving metabolic conversion.
- Direct-acting chemical carcinogenic agents associated human cancers are given in Table 6.78. Indirect-acting chemical carcinogenic agents associated human cancers are given in Table 6.79.

Direct-acting Genotoxic Chemical Carcinogenic Agents

Direct-acting genotoxic chemical carcinogens do not require metabolic conversion or any molecular modification in order to induce DNA damage. Examples of direct-acting genotoxic chemical carcinogens are alkylating and acylating agents, which have highly reactive electrophilic groups that directly cause DNA damage leading to gene mutations and eventually development of malignant tumor.

Alkylating Agents

Primary mechanism of action for most alkylating drugs after undergoing metabolic activation by cytochrome P450 dependent monooxygenases is via cross-linking and/or transfer of alkyl group to form monoadducts in DNA strands, which results in the misreading of the DNA code and inhibition of DNA replication,

Table 6.78 Direct-acting chemical carcinogenic agents associated human cancers

Direct-acting Chemical Carcinogens	Direct-acting Chemical Carcinogenic Agents: Examples	Associated Cancers
Alkylating agents	Nitrogen mustard (busulfan, chlorambucil, melphalan)	▪ Hodgkin's disease ▪ Non-Hodgkin's lymphoma ▪ Leukemias ▪ Ovarian carcinoma
	Cyclophosphamide	▪ Leukemias ▪ Multiple myeloma
	Hydralazine (temozolomide)	Glioblastoma multiforme
	Platinum-based agents (cisplatin, carboplatin, oxaliplatin cause cross-links between DNA strands → impaired DNA replication and degradation)	▪ Urinary bladder carcinoma ▪ Lung carcinoma ▪ Testicular cancer ▪ Ovarian carcinoma
	Chlorambucil chemotherapeutic agent in treatment of chronic lymphocytic leukemia (CLL)	Secondary malignancy
	Nitrosoureas chemotherapeutic agent in treatment of primary intracerebral tumor and multiple myeloma	Secondary malignancy
	β-Propiolactone, dimethyl sulphate and diepoxibutane	Cancers in experimental animals
Acylating agents	Dimethylcarbamyl chloride, dichloroacetyl chloride (DCAC) and ethyl chloroformate (ECF)	▪ Squamous cell papilloma of skin ▪ Squamous cell carcinoma of skin

Table 6.79 Indirect-acting chemical carcinogenic agents associated human cancers

Indirect-acting Chemical Carcinogens	Indirect-acting Chemical Carcinogenic Agents: Examples	Associated Cancers
Polycyclic aromatic hydrocarbons	Benz(a)anthracene, dibenz(a, h)anthracene, 7-12-dimethylbenz(a) anthracene, benz(a) pyrene and 3-methylcholanthine) in smoked meat and fish consumption and cigarette smoke	▪ Head and neck cancers (oral cavity squamous cell carcinoma and esophageal carcinoma of middle and lower region) ▪ Pancreatic carcinoma ▪ Lung carcinoma ▪ Urothelial carcinoma (renal pelvis/urinary bladder)
Aromatic amines	β-Naphthylamine, benzidine-O, anisidine-O, toluidine used in production of rubber and aniline dyes used to dye fabrics and produce cancer at distant site	Urinary bladder carcinoma (mucosal glucuronidase in the urinary bladder converts β-naphthylamine glucuronide (aromatic amine) to the carcinogenic molecule β-naphthylamine results in urinary bladder cancer)
Azo dyes (derivatives of aromatic amines)	Acid orange 5/7/19, acid red 13/88, alcian yellow R, alizarine yellow R, Allura red AC (used in textile, printing and paper manufacturing, and dimethylaminoazobenzene is used to impart yellow color to butter called 'yellow butter')	Hepatocellular carcinoma
Nitrosamines	Nitrates and nitrites are widely used as fertilizers and as food additives, which get converted to nitrosamines by gut bacteria in hypochlorhydria	Gastric carcinoma
Organohalogen compounds	Polyvinyl chloride, carbon tetrachloride, chloroform, hexachlorobenzene, trichloroethylene	Liver angiosarcoma
Natural occurring carcinogenic products in plants	Aflatoxin B1 synthesized by fungus *Aspergillus flavus* in growing stored grains, betel nuts and peanut, safrole, actinomycin D and mitocin C	Hepatocellular carcinoma
Industrial carcinogens in occupational workers	Nickel (used in nickel plating ceramics, ferrous alloys, batteries and stainless-steel welding)	▪ Nasal cavity squamous cell carcinoma ▪ Lung carcinoma
	Arsenic (used in alloys, medication, preparation of fungicides and herbicides)	▪ Squamous cell carcinoma of skin ▪ Basal cell carcinoma of skin ▪ Squamous cell lung carcinoma ▪ Liver angiosarcoma
	Asbestos (used in building material)	▪ Mesothelioma ▪ Bronchogenic carcinoma ▪ Esophageal carcinoma ▪ Gastric carcinoma
	Beryllium (used in missile fuel, nuclear reactors, aerospace application and light weight alloys)	Lung carcinoma
	Chromium (used in paints, pigments and preservatives)	Lung carcinoma
	Uranium exposure in mine workers	Lung carcinoma
	Cadmium (used in batteries and metal paintings)	Prostatic carcinoma
	Vinyl chloride	Hepatic angiosarcoma
	Benzene in crude oil	Leukemia
	Benzanthracene	Skin cancer
Drugs	Thorotrast (radiocontrast media)	Hepatic angiosarcoma
	Diethylstilbestrol (DES)	Clear-cell adenocarcinoma of vagina (occurs in daughters of patients who received diethylstilbestrol during pregnancy)

Contd...

Table 6.79 Indirect-acting chemical carcinogenic agents associated human cancers (*Contd...*)

Indirect-acting Chemical Carcinogens	Indirect-acting Chemical Carcinogenic Agents: Examples	Associated Cancers
Lifestyle associated cancers	Tobacco smoking	▪ Urinary bladder carcinoma ▪ Renal cell carcinoma
	Betel nuts	Oral cancer
	Diet (low in vegetable, high in nitrates, salts)	▪ Gastric carcinoma ▪ Esophageal carcinoma
	Diet (high fat, low-fiber, broiled/fried foods)	▪ Colon carcinoma ▪ Pancreatic carcinoma ▪ Prostatic carcinoma ▪ Breast carcinoma
	Alcohol plus tobacco smoking	▪ Oral squamous cell carcinoma ▪ Esophageal squamous cell carcinoma
	Alcohol	Cirrhosis-linked hepatocellular carcinoma
	Snuff	Oral squamous cell carcinoma
	Hardwood dust	Nasal adenocarcinoma

transcription of RNA, and protein synthesis, and triggering apoptosis in unrestricted rapidly proliferating CSCs.

- Alkylating agents are used to treat leukemia, Hodgkin's disease, non-Hodgkin's lymphoma, multiple myeloma, breast cancer and sarcoma including cancers of ovary, and lung. Alkylating agents can cause bone marrow depression (i.e. anemia, leukopenia and thrombocytopenia), nausea and vomiting.
- Therapeutic administration of alkylating agents in cancer patients can cause another cancer, i.e. leukemia. Alkylating agents exert their lethal effects on cells throughout the cell cycle, but tend to be more effective against rapidly dividing cells, which do not have time for DNA repair.

Pathology Pearls: Six Classes of Alkylating Agents

- Nitrogen mustards cyclophosphamide, mechlorethamine, melphalan, chlorambucil, ifosfamide
- Ethylenimine and methylenamine derivatives (altretamine, thiotepa)
- Alkyl sulfonates (busulfan)
- Nitrosoureas (carmustine, lomustine)
- Triazenes (dacarbazine, procarbazine, temozolamide)
- Platinum-containing chemotherapeutic agents (cisplatin, carboplatin, oxaliplatin).

Acylating Agents

In chemistry, acylation is a chemical process in which an acyl group (R-C=O) is added to a chemical molecule or compound. Acylating agents and their derivatives are important class of highly reactive electrophilic agents with mutagenic and/or carcinogenic properties, which can interfere with normal biological processes. Dimethylcarbamyl chloride (DMCC), which is being used in the preparation of pharmaceutical agents, which possesses direct-acting chemical carcinogenic potential linked to squamous cell papilloma of skin, squamous cell carcinoma of skin and sarcomas.

Indirect-acting Chemical Carcinogenic Agents

Most chemical carcinogenic agents require metabolic conversion from procarcinogen to active ultimate carcinogen. The metabolic conversion process occurs by hydroxylation by aryl carbohydrate hydroxylase in microsomal fraction of endoplasmic reticulum with cytochrome P450 dependent monooxygenase. Hydroxylating enzyme (e.g. aryl carbohydrate hydroxylase) is ubiquitous in human tissues and readily induces malignant tumors in susceptible individuals.

Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons (PAHs) are among the most extensively studied carcinogens, which include benzene, naphthalene, phenanthrene, anthracene and benz(a) pyrene. PAHs are organic compounds containing carbon and hydrogen and composed of multiple aromatic rings.

- PAHs occur naturally in coal, crude oil and gasoline, which are also derived from incomplete combustion of organic matter such as coal, wood and garbage, and animal fat by process of broiling of meats (e.g. smoked meat and fish), and tobacco smoking.
- PAHs induce DNA damage by frameshift mutations, mispairing with wrong nucleotide base pairs during

DNA replication, loss of nucleotide base pairs, breakage of glycosidic bonds between purine bases and deoxyribose sugar.

- Some polycyclic aromatic hydrocarbons (PAHs) cause conformational transition of DNA from its usual double-helical B form to a Z-DNA form. PAHs are linked to human cancers such as squamous cell carcinoma (oral cavity, mid and lower esophagus), lung carcinoma, pancreatic carcinoma, and transitional cell carcinoma of renal pelvis and urinary bladder.
- Polycyclic aromatic hydrocarbons (PAHs) in smoked fish and/or meat undergoes hydroxylation in liver and metabolized by cytochrome P450 dependent monooxygenases to form benzopyrene epoxide, which irreversibly bind to cellular DNA, RNA and proteins and alter the genome. PAHs are linked to development of oral squamous cell carcinoma, esophageal squamous cell carcinoma and pancreatic carcinoma.
- Benz(a)pyrene is well studied prototype of (PAHs due to its mutagenic and carcinogenic activity.
  - Benz(a) pyrene is **highly reactive chemical carcinogenic component** in tobacco smoke that reaches liver via circulation and is metabolized in the liver by cytochrome P450 dependent monooxygenases.
  - Benz(a) pyrene gets converted to benz(a) pyrene-epoxide resulting in formation of vicinal-diol-epoxide (unstable compound) and then highly reactive benz(a) pyrene-diol-epoxide (**BPDE**) compound, that can irreversibly bind to DNA at N2 position of guanine to form benz(a) pyrene-diol-epoxide adducts and produce N2 guanine mutagenic lesions resulting in lung carcinoma (local site) and renal cell carcinoma and urinary bladder carcinoma (distant sites).
  - In addition to benz(a) pyrene, other components present in tobacco smoke produce oxidative free radicals, that cause DNA fragmentation. If DNA damage left unrepaired, BPDE-DNA adducts may lead to permanent gene mutations resulting in transformation of normal to malignant cells, i.e. CSCs, tumorigenesis, angiogenesis, invasion and metastasis.

Aromatic Amines

Aromatic amines are derivative of aromatic hydrocarbons in which a hydrogen of benzene ring has been replaced by amino group. All such compounds in which an amino or substituted amino group is bonded directly to an aromatic ring are termed aromatic amines. Examples of aromatic amines include aniline, 4-methylaniline, 4-chloroaniline and 4-nitroaniline. Aromatic amines are used as intermediates as antioxidants, in the manufacture of drugs, pesticides, rubber (tyres and cables), as cutting agents in plastics preparation. In addition, these are widely used as intermediates in the preparation of dyes and pigments extensively employed to color textiles, leathers, rubber, printing inks, paints, lacquers, metal finishing, plastic and paper products.

- **β-Naphthylamine:** β-naphthylamine is used in the manufacture of synthetic aniline dyes. Incidence of transitional cell carcinoma of urinary bladder is increased in aniline dye workers heavily exposed to β-naphthylamine (aromatic amines).
  - The β-naphthylamine undergoes hydroxylation in the liver and converted to 1-hydroxy-2-naphthylamine (water-soluble active carcinogenic metabolite) by cytochrome P450 dependent monooxygenases.
  - The active carcinogenic metabolite 1-hydroxy-2-naphthylamine combines with glucuronic acid in liver, and excreted and deconjugated in urinary bladder by mucosal enzyme glucuronidase, thus exposing the urothelium to the active chemical carcinogenic metabolite results in development of urinary bladder carcinoma. Role of β-naphthylamine (aromatic amines) in the pathogenesis of urinary bladder carcinoma is shown in Fig. 6.100.
- **Benzene:** Benzene is a colorless or light-yellow liquid chemical carcinogenic agent at room temperature. It is used primarily as a solvent in the chemical and petrochemical industries to synthesize numerous chemical agents.
  - Benzene is produced by both natural and man-made processes.
  - Benzene is derived from crude oil, gas emissions from volcanoes and forest fires, glues, adhesives, cleaning products, paint strippers, gasoline fumes, motor vehicle exhaust and industrial emissions.
  - Occupational workers in benzene chemical agent used in petrochemical industries are at risk of development of leukemia and Hodgkin's disease.
- **Dimethylaminoazobenzene:** Dimethylaminoazobenzene is a yellow crystalline solid compound. It was used as an azo-dye for coloring wax products, polishes, and soap and butter. It is reasonably anticipated to be a human chemical carcinogenic agent. Azo dyes have been used to color the butter and linked to hepatocellular carcinoma.

Nitrosamines

Nitrosamines are produced by chemical reactions of nitrates, nitrites and other proteins. Nitrosamines are present in tobacco smoke, drinking water contaminated by fertilizers, many dietary foods such as fruits, vegetables, fish, processed meat, beer and fried foods. In the same time, nitrates and nitrites are often used as

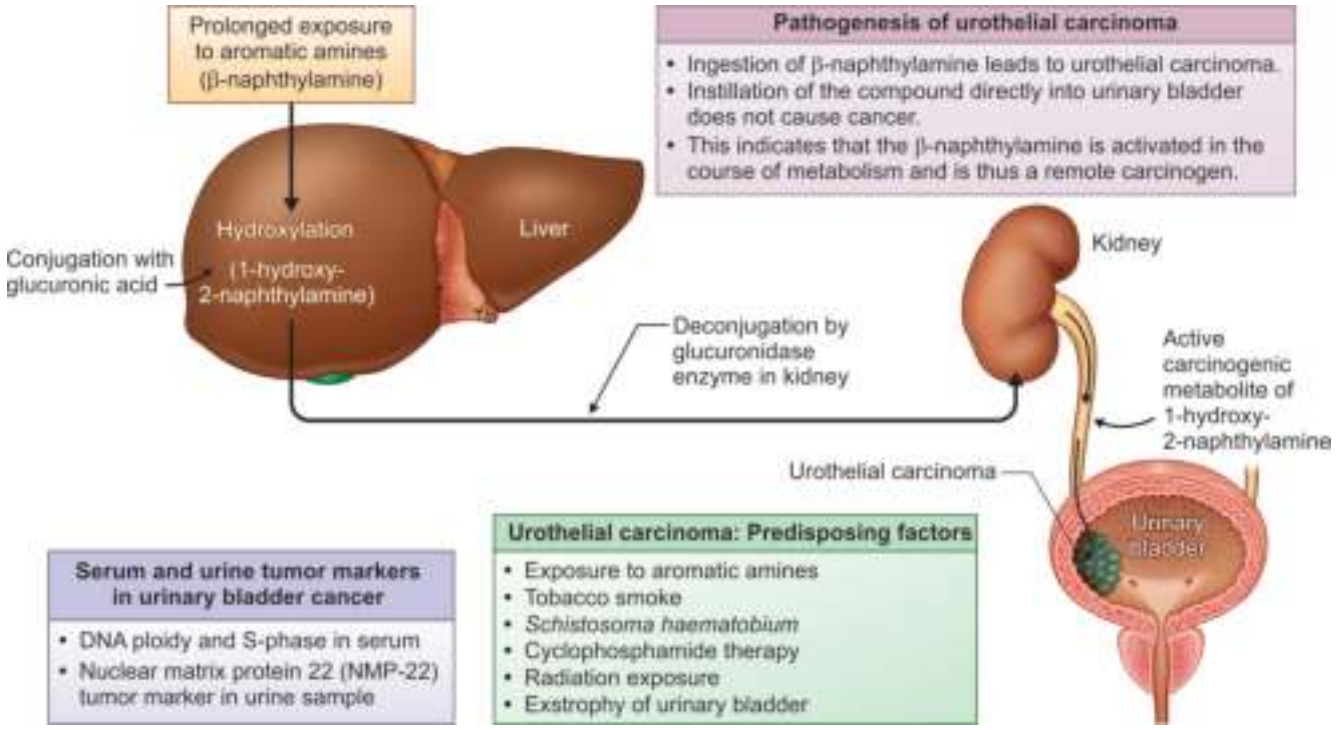

Fig. 6.100: Role of β-naphthylamine (aromatic amines) in the pathogenesis of urinary bladder carcinoma. β-Naphthylamine is metabolized in the course of metabolism in the body to become carcinogen involved in urothelial carcinoma.

food additives in the processed meats to retard microbial spoilage and preserve meat products.

- Dietary foods contain nitrates and nitrites. During gastric hypochlorhydria, overgrowth of commensal bacteria in stomach converts dietary nitrates and nitrites into nitrosamines (potent carcinogen) resulting in development of gastric carcinoma. A high consumption of processed meat products rich in nitrosamines is linked to gastric carcinoma.
- Our diet contains nitrosamine in the form of N-nitrosodimethylamine (NDMA), which is a potent chemical carcinogen, capable of carcinogenesis and development of malignant tumors in stomach, liver and lung.

Organohalogen Compounds

Organohalogen compounds contain at least one halogen, i.e. fluorine (F), chlorine (Cl), bromine (B) or iodine (I) bonded with carbon, which are subdivided into acyl, vinyl, aryl and acyl halides.

- Organohalogen compounds include polyvinyl chloride, carbon tetrachloride (CCL_4), chloroform, vinylidene chloride, hexachlorobenzene and trichloroethylene.
- Polyvinyl chloride (PVC) is used in a variety of applications in the building and construction, electronics, healthcare and automobiles sectors to manufacture products ranging from pipes and dashboards, blood bags and tubing, wire and cable insulation, windshield system components, raincoats, toys and food packaging.
- Persistent exposure to organohalogen compounds chemical carcinogenic agents (i.e. carbon tetrachloride, chloroform, vinyl chloride, hexachlorobenzene and trichloroethylene) is linked to hepatic angiosarcoma.
  - Carbon tetrachloride is used to make refrigerants and propellants for aerosol cans, as a solvent for fats, oils, lacquers, varnishes, rubber waxes and resins as a grain fumigant and a dry-cleaning agent.
  - Chloroform is used as a solvent for floor polishes. Lacquers, resins, adhesives, alkaloids, oils, fats and rubber.
  - Vinylidene chloride is used to manufacture certain plastics such as flexible films like food wrap and in packaging materials and coating steel pipes.
  - Hexachlorobenzene has been used as a pesticide to protect the seeds of onions, sorghum, wheat and other grains against fungus; and to make fireworks. Synthetic rubber and ammunition.
  - Trichloroethylene is used as a solvent in paints, adhesives and cleaners, as a reactant to produce pesticide intermediates and pharmaceutical drugs.

Aflatoxin B1: Natural Carcinogenic Agent

In human beings, *Aspergillus flavus* is predominantly an opportunistic pathogen in immunocompromised patients. Aflatoxin B1 is potent natural carcinogen

synthesized by *Aspergillus flavus* grown on crops stored in hot humid conditions (e.g. peanuts, maize, oil-seeds, cotton-seeds, dried fruits and grains).

- *Aspergillus flavus* synthesizes toxic metabolites (aflatoxin B1, aflatrem, aflavinin, aspergillic acid, neoaspergillic acid, kajoic acid, paspalinine and β-nitropropionic acid).
- After consumption of contaminated crops, aflatoxin B1 reaches the liver and activates cytochrome P450 dependent monooxygenases resulting in formation of aflatoxin-2,3-epoxide, a chemical carcinogenic compound that binds to guanine of DNA and induces specific point mutations in the **TP53 gene** resulting in development of hepatocellular carcinoma in Asian and African population.

Occupational Workers Exposed to Chemical Carcinogenic Agents

Occupational workers are exposed to numerous hazardous chemical carcinogenic agents, which include aniline, chromates, arsenic, nickel, beryllium compounds, dusts (asbestos, and crystalline form of silica), coal tar pitch volatiles, coke oven emissions, diesel exhaust, and tobacco products and certain industrial processes (e.g. nickel, arsenic, beryllium, aluminum, cadmium, chromium, asbestos, underground mining of uranium, iron and steel founding).

- Prolonged exposure to chemical carcinogenic agents has been linked to lung carcinoma, mesothelioma, urinary bladder carcinoma, prostatic carcinoma, sinonasal carcinoma and nasopharyngeal carcinoma, esophageal carcinoma, gastric carcinoma, liver angiosarcoma, and squamous cell carcinoma and basal cell carcinoma of skin. Prolonged exposure to asbestos increases the risk for development of mesothelioma, bronchogenic carcinoma, esophageal carcinoma and gastric carcinoma.
- Exposure to nickel compounds are linked to sinonasal and nasopharyngeal carcinoma. Arsenic compounds are linked to skin cancers (e.g. squamous cell carcinoma, basal cell carcinoma), squamous cell lung carcinoma and liver angiosarcoma.
- Exposure to beryllium, chromium and uranium compounds are linked to lung carcinoma. Persistent exposure to cadmium can cause prostatic carcinoma. Exposure to vinyl chloride is linked to liver angiosarcoma.

Thorotrast Radiocontrast Medium used in Imaging Techniques

Thorotrast radiocontrast medium is drug used to improve the visibility of internal organs and structures in X-ray based imaging technique. Thorotrast is a suspension containing particles of the radioactive compound thorium dioxide, which was used as radiocontrast medium in medical radiography linked to development of hepatic angiosarcoma.

Lifestyle-related Exposure to Chemical Carcinogenic Agents

Lifestyle-related exposure to chemical carcinogenic agents include tobacco smoke, dietary factors (low in vegetable, high in nitrates, salts, high fat, low fiber, broiled/fried foods, saccharin and sodium cyclamates).

- **Tobacco smoking:** Tobacco smoking is linked to carcinomas of lung, kidney, urinary bladder, oral cavity, pharynx, larynx, esophagus, colon, rectum, stomach and liver. Tobacco smoking is also linked to acute myelogenous leukemia (AML).
- **Dietary factors:** Diet low in vegetable, and rich in nitrates may cause gastric carcinoma and esophageal carcinoma. High fat, low fiber, broiled/fried dietary foods increase risk for development of carcinomas such as colon, pancreas, prostate and breast. Tobacco smoke, alcohol and snuff are linked to oral squamous cell carcinoma.
- **Hardwood dust:** Hardwood dust may cause sinonasal adenocarcinoma. Chronic alcoholics may develop oropharyngeal carcinoma, esophageal carcinoma, hepatocellular carcinoma, breast carcinoma and colorectal carcinoma.
- **Alcohol:** Alcohol acts as indirect-acting carcinogen. Normally, alcohol is metabolized to acetaldehyde and then converted to acetate by aldehyde dehydrogenase enzyme.
  - Chronic consumption of alcohol reduces the function of aldehyde dehydrogenase enzyme leading to accumulation of acetaldehyde, that acts as a complete carcinogen responsible for DNA adducts formation, cellular damage and unrestricted CSC proliferation and malignant tumor growth.
  - Alcohol abuse also causes oxidative stress of CYP2E1, allowing reactive oxygen species (ROS) to react with DNA, and then DNA damage. Further, chronic alcoholics develop multiple vitamin (B_{12}, B_6 and A) deficiencies, that may contribute to development of cancer.

RADIATION-INDUCED CARCINOGENESIS

Radiation-induced carcinogenesis is a biological phenomenon, whereby damage to normal cells results in malignant phenotype. Ionizing radiation has enough energy to break chemical bonds and cause DNA damage resulting in the development of human cancers. Some of the elementary forms of radiation are protons, neutrons, X-rays, and γ-rays. X-rays originate outside of the nucleus of an atom while γ-rays originate within

Table 6.80 Radiosensitivity of specialized cells

Degree of Sensitivity	Characteristics
Most radiosensitive cells	Lymphoid cells, hematopoietic cells, germ cells, gastrointestinal mucosal cells, and rapidly dividing cancer stem cells
Intermediate radiosensitive cells	Fibroblasts; cells of endothelium, elastic tissue, salivary glands, and eye
Radioresistant cells	Cells of bone, cartilage, muscle, central nervous system, kidney, liver, and most endocrine glands. These cells cease division shortly after complete fetal development

genomic nucleus, which have variable energies. Radiosensitivity of specialized cells vary in various tissues (Table 6.80).

- Exposure to non-ionizing radiation is usually non-carcinogenic and described as series of low energy waves on the electromagnetic spectrum travelling at the speed of light, covering two main regions: optical radiation (ultraviolet rays, visible rays and infrared rays), and electromagnetic fields (e.g. radiowaves, microwaves, infrared waves).
- Exposure to ionizing radiation (electromagnetic X-rays, γ-rays, and particulate radiation) poses a potential world-wide threat in this nuclear age. Exposure to ionizing radiation increases risk of human cancers (Table 6.81).
  - Ionizing radiation is strong enough to induce ionization of atoms and cause damage to cellular DNA, RNA and proteins, which depends on the magnitude of exposure, penetration and capacity to cause ionization in the tissues.
  - Survivors of atomic bombs dropped in World War II develop AML, CML, but not lymphoid leukemias and other cancers.
  - Radium watch-dial workers have higher risk to develop osteosarcoma. Radiologists may develop AML and CML and other cancers.

ULTRAVIOLET RADIATION-INDUCED CARCINOGENESIS

The sun is the dominant source for visible light waves our eyes can detect wavelengths from 380–780 nm. The ultraviolet (UV) region covers the wavelength range 100–400 nm and is divided into three bands: UV A (90–95%), UV B (5–10%) and UV C. Both UV A (320–400 nm) and UV B (280–320 nm) radiations are able to penetrate to different depths of skin, and hence affect cells in the epidermis and dermis.

- The skin is organized into two regions—the superficial epidermis composed of epithelium and an underlying

Table 6.81 Radiation-induced human cancers

Radiation Source	Radiation Types	Radiation-induced Malignant Tumors
Sunlight radiation	Ultraviolet B (UV B) rays: 290–320 nm	▪ Melanoma of skin ▪ Squamous cell carcinoma of skin ▪ Basal cell carcinoma of skin
Nuclear explosions (e.g. atom bombs)	Ionizing radiation	▪ Acute myelogenous leukemia (AML) ▪ Chronic myelogenous leukemia (CML) ▪ Lung carcinoma ▪ Breast carcinoma ▪ Thyroid carcinoma
Therapeutic radiation	Ionizing radiation	▪ Carcinomas (various sites) ▪ Thyroid carcinoma ▪ Sarcomas ▪ Leukemia
Mining radioactive substances, i.e. uranium induces DNA mutations and chromosomal abnormalities	Ionizing radiation	Lung carcinoma
X-ray workers	Ionizing radiation	▪ Skin carcinoma ▪ Leukemia
Thorium dioxide byproduct of uranium	Ionizing radiation	Liver angiosarcoma

**Ultraviolet radiation causes TP53 gene mutation, tumor necrosis factor-α (TNF-α) released by exposed skin diminishes immune response. It induces dimer formation between neighboring thymine pairs in DNA.*

connective tissue dermis, which are firmly attached to each other. UVA radiation penetrates deeply into dermis reaching well into the dermis and dermal fibroblasts. In contrast, UVB radiation has shorter wavelengths, and is almost completely absorbed by the skin epidermis causing DNA and cellular damage, with comparatively little reaching the dermis.

- Ultraviolet radiation is classified as a 'complete carcinogen' because it acts as a mutagenic agent that causes DNA damage and has properties of both a tumor initiator and a tumor promoter.
- Ultraviolet radiation (UVA and UVB)-induced skin cancers include squamous cell carcinoma, basal cell carcinoma and melanoma. Unprotected exposure to UVA and UVB radiations can also cause ocular damage including cataracts and eyelid cancers.
- Ultraviolet and ionizing radiation associated human cancers are given in Table 6.82.

Ultraviolet A (UVA) Radiation

Ultraviolet A (UVA) radiation has longer wavelength (320–400 nm), that penetrates deeply into the skin dermis, and causes damage to DNA, RNA and proteins via indirect photosensitizing reactions. It also induces photo-aging (e.g. wrinkling) and immune system suppression.

Ultraviolet B (UVB) Radiation

Ultraviolet B (UVB) radiation has shorter wavelengths (280–320 nm), that is mainly absorbed by skin epidermis and causing damage to DNA, RNA and proteins. UVB radiation has been described as the most carcinogenic agent among all types of solar radiation. UVB radiation is linked to development of cutaneous squamous cell carcinoma, basal cell carcinoma and melanoma. Early detection of skin cancers helps in the management of these patients.

- **Squamous cell carcinoma of skin** is a malignancy of epidermal keratinocytes, that displays variable degrees of differentiation, and cytologic features that most often affects sun-exposed regions such as face, ears, lips, nose, eyelids chest, upper back, arms, hands and legs.
  - Exposure to ultraviolet B radiation, patients with Bowen disease, xeroderma pigmentosum, AIDS and immunocompromised persons increase risk for squamous cell carcinoma of skin.
  - Tumor may grow beyond epidermis and appear as flat reddish or brown patches in the skin, often with a rough, scaly, or crushed surface. It may sometimes invade surrounding tissues and metastasize to lymph nodes and bones.
  - Ultraviolet B (UVB) radiation-induced mutations involving genes (e.g. TP53, CDKN2A, NOTCH1, NOTCH2, EGFR and TERT) and RAS/RAF/MEK/ERK (MAPK) and PI3K/AKT/mTOR signaling pathways play key role in the pathogenesis of squamous cell carcinoma of skin.
  - Most patients have a favorable outcome after surgical resection. Only a subset of patients may

Table 6.82 Ultraviolet and ionizing radiation associated human cancers

Types of Radiation	Mechanism	Associated Cancers
Ultraviolet radiation (excessive exposure to sunlight)	▪ UV radiation causes genetic mutation in TP53 tumor suppressor gene ▪ UV radiation releases tumor necrosis factor-α (TNF-α) in exposed skin, possibly diminishing immune response ▪ UV radiation induces dimer formation and causes damage to DNA, RNA and proteins ▪ Xeroderma pigmentosum is an autosomal recessive disorder due to failure of DNA excision repair mechanisms	▪ Squamous cell carcinoma of skin ▪ Basal cell carcinoma of skin ▪ Melanoma of skin
Ionizing radiation	▪ Low doses of ionizing radiation can cause DNA mutations and chromosomal abnormalities, and large doses can inhibit cell division ▪ Ionizing radiation also can enhance the effects of genetic abnormalities	▪ Lung cancer in uranium workers ▪ Osteosarcoma in radium watch-dial workers ▪ Acute myelogenous leukemia (AML) and chronic myelogenous leukemia (CML) (but not lymphoid) in survivors of atomic blasts ▪ Thyroid cancer in patients, who have received head and neck radiation therapy ▪ Skin cancer and acute myelogenous leukemia (AML) and chronic myelogenous leukemia (CML) may occur in radiologists

develop local recurrence and distant metastasis associated with fatal outcome.

- **Basal cell carcinoma of skin:** Basal cell carcinoma of skin is most common malignant tumor on ultraviolet-exposed skin in the head and neck region. Multiple basal cell carcinomas develop early in life with basal cell nevus syndrome (Gorlin syndrome), or Bazex syndrome or xeroderma pigmentosum.
  - Mutation of PTCH gene located on chromosome 9q22.3 is detected in most syndromic and sporadic basal cell carcinoma. Multiple basal cell carcinomas develop early in life with basal cell nevus syndrome (Gorlin syndrome), or Bazex syndrome or xeroderma pigmentosum.
  - Mutated PTCH gene mapped on chromosome 9q22.3 in the mitogenic Sonic Hedgehog signaling pathway, and inactivated/biallelic loss of TP53 tumor suppressor gene plays key role in development of syndromic and sporadic basal cell carcinoma.
- **Melanoma of skin:** Melanoma is an aggressive skin cancer, that arises from melanin producing melanocytes, that most often disseminates to distant organs. Classic features of melanoma include junctional activity with obscured dermoepidermal junction and pagetoid spread individually and in clusters throughout epidermis.
  - Risk factors for melanoma include prolonged exposure to ultraviolet radiation, fair-skin persons, and a family history of melanoma. In most cases, melanomas have an irregular shape and are more than one color.
  - Melanoma can be superficial spreading melanoma (fair colored persons), nodular melanoma (head and neck, chest and back regions), lentigo maligna melanoma, acral lentiginous melanoma (face region) and amelanotic melanoma (little or no color).
  - An activated mitogenic RAS/RAF/MEK/ERK (MAPK) signaling pathway and inactivated/balladic loss of TP53 and p16 tumor suppressors are linked to melanoma.

Pathology Pearls: Ultraviolet B (UVB) Radiation-induced Carcinogenesis

Ultraviolet B (UVB) radiation has slightly more energy than UVA radiation. During cutaneous carcinogenesis, variable alterations in the oncogenes, tumor suppressor genes, and cell cycle control signaling pathways occur.

- UVB radiation is directly absorbed by DNA, which causes molecular rearrangements forming **photoproducts** such as **cyclobutane pyrimidine** dimers (CPDs), and **pyrimidine** (6–4) photoproducts (6–4 PPs), which may induce DNA breaks.
- Besides formation of photodimers in the genome, UVB radiation induces gene mutations by generating reactive oxygen species (ROS) such as superoxide anion, hydrogen peroxide, and hydroxyl radical. Nucleotide base pairs in DNA are highly susceptible to oxidative free radical induced injury.
- Oxidation of nucleotide base pairs promotes mispairing outside of normal Watson-Crick parameters causing mutagenesis. These oxidative free radical avidly attack DNA macromolecules such as RNA, proteins and lipids altering their structure and interfering with their function. These lesions are associated with DNA replication/transcription blockage, that may result in production of DNA double-strand breaks (DSB1) at the sites of collapsed DNA replication forks of cyclobutane pyrimidine dimers (CPDs)-containing DNA.
- Most of the DNA damage is temporary. The human body has inbuilt DNA repair systems (e.g. nucleotide excision repair and base excision repair) to recognize, excise and repair by replacing with correct DNA sequence.

Ultraviolet C (UVC) Radiation

Ultraviolet C (UVC) rays (200–280 nm) are highly mutagenic that do not reach the earth's surface and are completely absorbed by the stratospheric ozone layer in our atmosphere.

IONIZING RADIATION-INDUCED CARCINOGENESIS

Ionizing radiation can penetrate the human body and the radiation energy can be absorbed in tissues. This has the potential to induce harmful effects to persons especially at high levels of exposure.

- Ionizing radiation can fall into two categories: Natural and man-made. Natural sources of ionizing radiation include: (a) radiation from space (cosmic and solar radiation), (b) radiation from earth (terrestrial radiation, i.e. radon gas), and (c) radiation from building materials.
  - Ionizing radiation from natural sources is typically at low levels. The usual low dose of ionizing radiation from natural sources is absorbed by our body.
  - Ionizing radiation from man-made sources includes X-rays, computed tomography, positron emission tomography, fluoroscopy and nuclear medicine procedures. The direct and indirect effects of ionizing radiation on DNA are given in Fig. 6.101.
- In natural or man-made ionizing radiation, energy is released by atoms in the form of electromagnetic waves or radioactive particles.
- Ionizing radiation can travel unseen and pass through these materials. Ionizing radiation has more energy

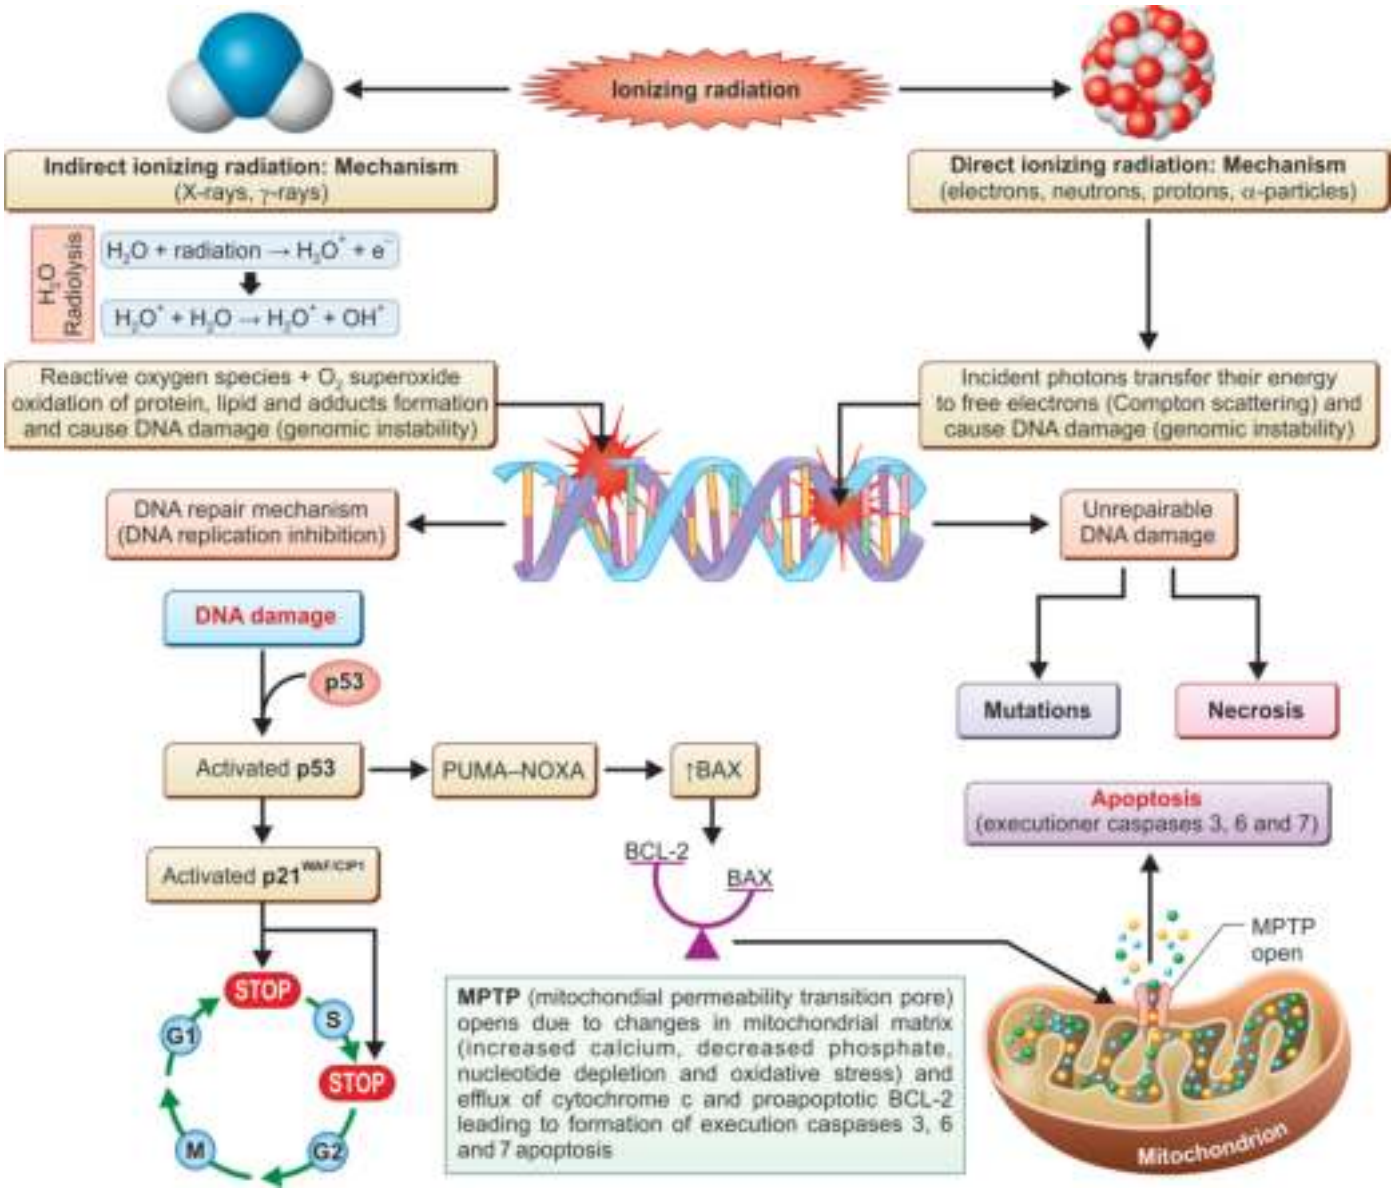

Fig. 6.101: The direct and indirect effects of ionizing radiation on DNA. Incident photons transfer part of their energy to free electrons (Compton scattering). These electrons can directly interact with DNA to induce DNA damage or they can first interact with water to produce hydroxyl radicals that can then induce DNA damage. Indirect ionization occurs when non-charged particles, e.g. interact with cellular water. The energy absorbed by an H_2O molecule results in the formation of ion pairs and reactive oxygen metabolites such as hydroxyl radicals. In turn, these free radicals interact with cellular atoms and molecules damaging cellular proteins and may form additional free radicals. The process is known as indirect effect because of the intermediate step of H_2O-based free radical formation.

than non-ionizing radiation, that is absorbed by material surrounding the ionized atom.

- Ionizing radiation deposits a large amount of energy into a small region. In fact, energy from ionizing radiation is enough to break chemical bonds between the carbon bonds, which can cause damage to the living tissues.
- For clinical oncologists, it is essential to understand the mechanism of ionizing radiation-induced carcinogenesis and development of ionizing metachronous malignancies after radiotherapy for proper patient's follow-up. In medical practice, radiation is used for diagnosis (0.1–10 mSv procedure) and therapeutic purposes (20–60 Gy unit per targeted tissue).

Ionizing Radiation-induced Carcinogenesis—Mechanisms

The mechanisms by which ionizing radiation may induce carcinogenesis by various mechanisms: (a) DNA mutations including alterations in the structure of genes and chromosomes, (b) alterations in gene expression with mutations, and (c) induction of oncogenic viruses. Patient receiving radiotherapy in head and neck may thyroid carcinoma.

Ionizing Radiation-induced Direct DNA Damage

The incident photons of ionizing radiation (>2000 rad) penetrate cell membrane, transfer part of their energy to free electrons (known as Compton scattering) in the cytoplasm, and breaks bonds in DNA and RNA. Ionizing radiation induce breaks in single stand or double-strands and deamination or depurination. In addition, ionizing radiation can degrade the amino acid in the side chains of proteins to cause reduced function, and can cause alterations in the tertiary protein structure. DNA-DNA and DNA-protein cross-links and subsequent cellular necrosis with formation of oxidative free radicals and fragmentation of DNA.

Ionizing Radiation-induced Indirect DNA Damage

Incident photons of ionizing radiation (300–1000 rad) first interact with water to produce reactive oxygen species (ROS) such as hydroxyl (OH^-) radicals, that interact with DNA nucleotide base pairs of proliferating cells and induce DNA damage by breaking of hydrogen bonds in macromolecules and formation of protein and lipid adducts resulting in apoptosis.

Ionizing Radiation-induced Bystander Effects

Besides causing gene mutations and macromolecules destruction, ionizing radiation can also cause alterations in signaling pathways leading to release of cytokines and growth factors. The bystander effects may be responsible for inducing cell proliferation in irradiated cells, allowing promotion to take place. Cells can adapt to prolonged radiation exposure; the cells have been primed by low-dose of radiation. DNA repair and cell cycle regulation pathways are upregulated to prepare for impending ionizing radiation damage. The bystander effect lasts for weeks to months.

Therapeutic Ionizing Radiation in Human Cancers

Therapeutic ionizing radiation used for malignant tumors includes: (a) photon ionizing radiation (X-rays or γ-rays: pure energy photons), and (b) particle ionizing radiation (e.g. electrons, protons, neutrons, carbon ions, α, and β particles). The α, and β particles are not part of electromagnetic spectrum, but are energetic particles as opposed to pure energy photons. Photon ionizing radiation is used to treat deep-seated localized malignancies. Carbon ion radiation is used for radiation-resistant malignant tumors.

Ionizing Radiation using α and β Particles

Ionizing radiation using α and β particles or high-energy photons (γ-rays and X-rays) are contained in radioactive particles, that can be swallowed or inserted into the body.

- Based on the source of radiation, therapeutic radiation is classified into two main groups: (a) **external beam radiotherapy** by placing X-ray tube outside the patient's body, and (b) **brachytherapy** by using an isotope (e.g. cadmium-226, cesium-137, iridium-192, iodine-125) is inserted within the malignant growth or cavity.
- Ionizing radiation using α and β particles scan, travel different distances, and interact with the atoms of absorbing materials in their paths, causing ionization of the atoms. In ionizing radioactive α and β particles, electron beams produced by a linear accelerator are used to treat cutaneous malignancies close to the body surface.
- Proton beam radiation needs highly advanced equipment and hence is not routinely performed in oncology departments.
- Neutron beam radiation is used for head and neck cancers especially inoperable malignancies, but its use adversely affects surrounding normal tissues.

X-Rays and γ-Rays—Ionizing Radiation

X-rays and γ-rays are examples of ionizing radiation at upper end of electromagnetic spectrum. Ionizing radiation in this electromagnetic spectrum has high energy, that can remove electrons from an atom. Very high-energy ionizing radiation removes electrons and breaks up the nucleus of the atom. A familiar example of ionizing radiation is the X-rays frequently used in clinical practice. X-rays have unique capability to remove electrons from atoms and molecules in the matter through which they pass. Ionizing radiation activity can alter the molecules within the cells, that may produce damage to skin and tissue and increased risk for malignant tumors.

Basis of Ionizing Radiation Therapy for Malignancies

Ionizing radiation can be used to treat malignancies. The principle of ionizing radiation therapy is to irradiate the malignant tumor at specific time intervals. Each ionizing radiation exposure induces DNA damage in both CSCs and surrounding normal cells by direct and indirect mechanisms. Following ionizing radiation, normal cells can stop the cell cycle to repair DNA damage, while CSCs continue to undergo unrestricted proliferation despite lethal DNA damage inducing apoptosis causing cell death. The fractional killing term refers to the proportion of CSCs killed by each dose of ionizing radiation.

Pathology Pearls: Effects of Ionizing Radiation Depend on Several Factors

- **Size of irradiation field, dose fractionation and total dose:** Whole body ionizing irradiation of 100–300 rad can induce acute radiation sickness. While higher doses (500 or >1000 rad) over couple of days can cause bone marrow depression and multi-organs failure leading to mortality.

- **Exposure time and time interval between fractions:** Patient develops bone marrow suppression and mucosal gastrointestinal ulcerations. Radiation-induced second malignancy usually occurs years after therapeutic ionizing radiation.
- **Type of technique of irradiation:** Most aggressive forms of ionizing radiation are α-particle radiation followed by β-particle radiation. X-rays possess highly penetrative effect with minimal tissue damage, but can break weak bonds between nucleic acids and induce chromosomal alterations.
- **Radiation sensitivity of tissue:** Bone marrow, ovaries, testes, lymphatic tissue and gastrointestinal mucosa are highly sensitive to ionizing radiation. Connective tissue, blood vessels and urothelium are medium sensitive to radiation. Relatively radiation resistant tissues include skeletal muscle, cardiac muscle, smooth muscle, cartilaginous tissue, ovarian stroma, corpus luteum, liver, kidneys, pancreas and brain.
- **Individual sensitivity:** Consequences of ionizing radiation therapy are more severe in patients, who have previously received radiotherapy and also depend on the patient's gender and genetic factors.

Therapeutic Radiation-induced Second Malignancies

Radiation therapy is one of the modalities of treatment of malignancies in more than 50% of cases. Therapeutic radiation-induced malignancies (RIMs) are late complications of radiotherapy, seen among the survivors of both adult and pediatric cancers in 15–20% of cases. Second malignancy occurs primarily in the region or near the first irradiated site. Many factors contribute to radiation-induced second malignancies such as age of patient at radiation, volume of irradiated region, type of irradiated organ and tissue, radiation technique and personal history and family history of cancer.

- **External beam radiation therapy** is used to treat various human cancers. Brachytherapy is most often used to treat breast cancers of the head and neck, breast, cervix, prostate and eye. Systemic therapeutic radiation is called radioactive iodine (^{131}I) and is most often used to treat thyroid carcinoma. Another type of systemic therapeutic radiation is called targeted radionuclide therapy or molecular therapeutic radiation is used to treat some patients suffer from advanced prostatic carcinoma and gastrointestinal tract carcinoma, and pancreatic neuroendocrine tumors.
- Genetic susceptibility is a well-known fact for development of cancer. Ionizing radiation or chemotherapeutic agents induce clonal unbalanced cytogenetic abnormalities (i.e. chromosome 5 or 7 and TP53 gene mutation), DNA repair genes, and genes regulating hematopoietic microenvironment leading to increased susceptibility to treatment-related leukemia. This supports the thought of genetic susceptibility to therapeutic radiation-related second malignancy.
- Carcinogenic potential of ionizing radiation is well-known effect. Exposure to ionizing radiation induce single strand and double DNA breaks. Double-strand break can result in gene mutation and subsequent transformation of irradiated cell to cancer stem cell (CSC). Alterations in the DNA repair proteins may also lead to increased risk for development of second malignancies. For example, ataxia-telangiectasia mutated (ATM) protein senses the DNA damage and initiates DNA repair. Mutation in ATM gene can lead to increased cancer susceptibility to develop second malignancy. Recent study revealed that patient with tongue carcinoma undergoing radiation therapy developed second malignancies such as osteosarcoma of mandible, and papillary thyroid carcinoma after many years.

Therapeutic Ionizing Radiation-induced Second Malignancies: Examples

Most common second malignancies develop in patients following therapeutic radiation to treat primary cancers such as cutaneous carcinomas, gastrointestinal carcinomas, head and neck malignancies, lymphomas, breast carcinoma, sarcoma and lung carcinoma in decreased frequency. Mutagenesis of normal tissues is the basis for therapeutic radiation-induced malignancies. Therapeutic ionizing radiation-induced second malignancies are given in Table 6.83.

VIRAL CARCINOGENESIS

Carcinogenesis is a multistep process that results in the transformation of normal cell to CSC, which requires a progression of changes at the cellular, genetic and epigenetic levels that ultimately results in cellular changes for unrestricted CSC division, and development of malignant tumor growth. The essential feature of mode of action of **oncogenic DNA viruses** is addition of new viral DNA into the nucleus of host cells resulting in induction of mutant cells. Mode of action differs in oncogenic DNA and RNA viruses.

- Some oncogenic viruses store their genetic information using DNA and others use single-stranded RNA. Oncogenic viruses are classified as either DNA and RNA viruses.
  - DNA viruses contain two complementary and intertwined strands of nucleic acid (double-helix).
  - Oncogenic RNA viruses include hepatitis C virus (HCV) and HTLV-I and HTLV-II.
  - Examples of oncogenic DNA viruses include HPV (16, 18), Epstein-Barr virus (EBV), HBV, and

Table 6.83 Therapeutic ionizing radiation-induced second malignancies

Ionizing Radiation given for Primary Tumors	Post-radiation-induced Second Malignances in the Vicinity of Organs
Head and neck and mediastinal malignancies	Papillary thyroid carcinoma (8–20 years after radiotherapy), laryngeal carcinoma (20–40 years after radiotherapy), lung carcinoma and prostatic carcinoma
Breast carcinoma	Lung carcinoma, esophageal carcinoma, breast angiosarcoma, and contralateral breast carcinoma after many years
Prostatic carcinoma	Urinary bladder carcinoma and rectal carcinoma
Cervical carcinoma	Colorectal carcinoma, carcinoma of anal canal, and malignancies of uterus and other pelvic structures even after long follow-up
Pelvic malignancies	Colorectal rectal carcinoma (50 Gy-median, dose) and carcinosarcoma of uterine body (months to five years)
Non-Hodgkin's lymphoma (NHL)	Solid malignancies and leukemia
Pediatric malignancies	Glioma, meningioma and gastrointestinal malignancies
Chondrosarcoma of bone	Fibrosarcoma, osteosarcoma with chondroid differentiation, and chondrosarcoma of urinary bladder
Basal cell carcinoma of skin	Brain sarcoma
Desmoid tumor	Fibrosarcoma

HHV-8, which integrate their genomes into host cells and enter a period of latency.

- Both oncogenic RNA and DNA viruses play an important role in carcinogenesis by disrupting cellular genes in the host. Oncogenic viruses associated human cancers are given in Table 6.84.

- The mode of virally induced tumors can be divided into acute transforming viruses, and slowly transforming viruses.
  - Acute transforming oncogenic DNA and RNA viruses induce tumorigenesis as they carry an overactive viral-oncogene. The infected cell is transformed to CSCs as soon as v-onc is over-expressed. An example of an acute transforming virus is the Rous sarcoma virus (RSV), that carries the v-src oncogene.
  - Slowly transforming viruses induce slow tumor growth, since they do not carry any viral oncogenes,

Table 6.84 Oncogenic viruses associated human cancers

Virus	Type of Virus	Virus Associated Malignant Tumors
Epstein-Barr virus (EBV)	DNA virus	Burkitt's lymphoma, Hodgkin's disease (mixed cellularity variant), nasopharyngeal carcinoma, extranodal marginal zone B cell/T cell NHL, extranodal NK/T cell lymphoma (nasal type), CNS lymphoma in AIDS, primary CNS diffuse large B cell lymphoma (DLBCL), gastric MALT lymphoma, follicular dendritic cell sarcoma, primary effusion lymphoma, lymphomatoid granulomatosis, post-transplant lymphoproliferative disease and gastric and smooth muscle tumors
Human herpesvirus 8 (HHV-8)	DNA virus	Kaposi sarcoma in AIDS, primary effusion lymphoma, Castle disease
Human papillomavirus (e.g. HPV 16, 18)	DNA virus	Cervical carcinoma (70%), carcinoma of vulva and vagina, anorectal carcinoma, oropharyngeal carcinoma, penile carcinoma, head and neck cancers
Hepatitis B (HBV)	DNA virus	Hepatocellular carcinoma
Merkel cell polyomavirus	DNA virus	Merkel cell carcinoma
Hepatitis C persists in hepatocytes	RNA virus	Hepatocellular carcinoma, lymphoplasmacytic lymphoma
Human T cell lymphotropic virus 1 (HTLV-I retrovirus) persists in T cells and B cells	RNA virus	Adult T cell leukemia/lymphoma, primary effusion lymphoma
Human T cell lymphotropic virus 1 (HTLV-II retrovirus) persists in T cells	RNA virus	Hairy cell leukemia

which induce tumor growth by transcriptionally acting proto-oncogenes particularly the long terminal repeat (LTR) in the proto-oncogenes.

- Oncogenic viruses utilize a variety of carcinogenic mechanisms to transform normal cell to CSC: (a) oncogenic viruses express viral oncogenes, that directly transform an infected normal cell to CSC; and (b) several oncogenic viruses such as human papillomavirus (HPV), Epstein-Barr virus (EB virus), HCV, HTLV-1, KSHV and SV40 encode oncoproteins that employ several mechanisms to inactivate two of the major regulators of genome stability, cell viability and cell cycle; namely the TP53 tumor suppressor gene product (p53 protein) and retinoblastoma (RB) gene product (pRB).

Pathology Pearls: Viral Carcinogenesis

- Virus integrates into the cellular genome and disrupts cellular genes.
- Virus carries mutated cellular proto-oncogene (oncogenes).
- Viral gene products act as transcription factors.
- Viral gene products inactivate cell cycle regulatory proteins (p53, pRB).
- Viral infection results in immunodeficiency state.

ONCOGENIC RNA VIRUSES ASSOCIATED CANCERS

RNA viruses are also known as 'retroviruses' and most common cause of emerging diseases in human beings, attributable to the high mutation rate in RNA viruses compared to DNA viruses. Oncogenic RNA viruses include hepatitis C (HCV), and human T lymphocyte virus type I and II (HTLV-I and HTLV-II). The range of following infection with oncogenic RNA is shown in Fig. 6.102.

- Oncogenic RNA viruses generally undergo replication by binding to a cellular receptor and causing transcription of genomic RNA into proviral DNA and integration of proviral DNA into chromosomal DNA. Latency may be established at this point. Transcription may occur to generate new genomes and messenger RNA. RNA virus is released by budding usually without cytopathology. Carriers of RNA viruses are symptomatic. There is usually a latency period of 20–30 years following primary infection with HTLV-I.
- Francis Peyton Rous in 1910 isolated retrovirus from a chicken tumor later named the Rous sarcoma virus. Non-oncogenic retroviruses possess no oncogenes and hence direct their own life cycle. For example, HIV infects CD4+ helper T cells and destroys them.
  - **Transduction:** Retroviral oncogenes are formed from proto-oncogenes (cellular genes), which cause cancer. The process is called transduction. Genomic DNA sequences in retroviruses are known as viral oncogenes (v-onc), genomic DNA sequences in human beings are known as cellular oncogenes (c-onc).
  - **Genes in RNA viruses:** Most retroviruses contain three types of genes: (a) gag (group antigen) codes for protein core, (b) pol (polymerase) codes for reverse transcriptase enzyme for proviral integration, and (c) env (envelope) codes for envelope glycoproteins.
  - **Entry of retrovirus:** Oncogenic retroviruses (v-onc) enter the host cell by reverse transcriptase and mutate genome. Proviral DNA and host chromosome DNA crossover and are joined by recombination.
  - **Transcription:** Host RNA polymerase transcribes proviral DNA and produces viral mRNAs required for the virus life cycle. Proviral promoters can activate transcription of nearby genes.
  - **Oncogenic RNA viruses induced carcinogenesis:** Oncogenic RNA viruses are also called transducing viruses. Most transducing viral oncogenes are defective and cannot replicate independently. Viral encoded TAX protein induces carcinogenesis by different mechanisms: (a) TAX protein inactivates $p6^{INK4a}$ and enhances cyclin deactivation resulting in increased DNA replication, (b) TAX protein interferes with DNA repair mechanism resulting

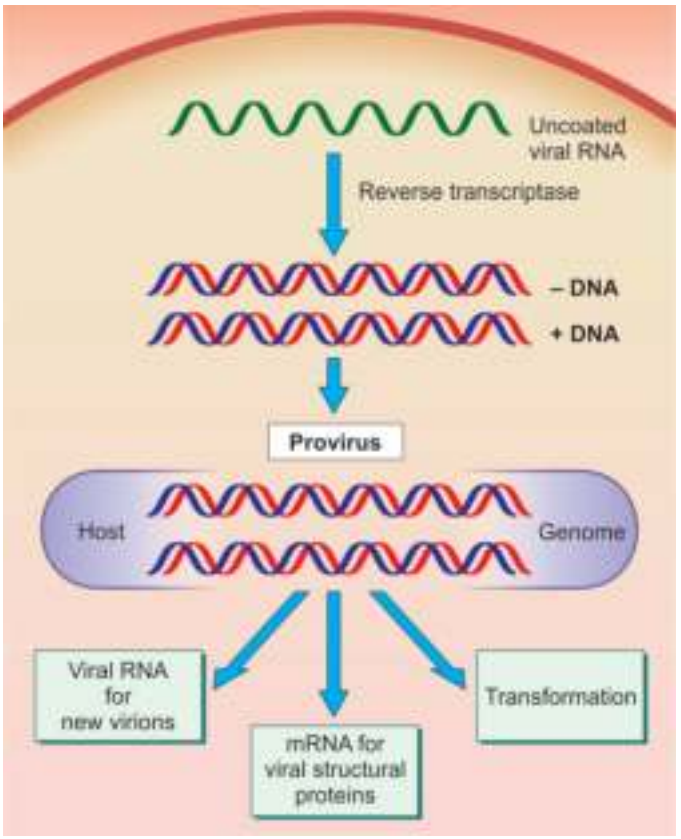

Fig. 6.102: The range of following infection with oncogenic RNA virus.

in genomic instability, and (c) TAX protein also activates NF-κB transcriptional factor to form monoclonal CSCs and malignant phenotype.

Human T Cell Leukemia Virus I and II (HTLV-I and II)

Human T cell leukemia virus I (**HTLV-I**) is linked to development of human **T cell leukemia/lymphoma** endemic in Southern islands of Japan and Caribbean basin, and primary effusion lymphoma. On the contrary, **HTLV-II** is linked to **hairy cell leukemia**. HTLV-I differs from other oncogenic retroviruses, which lacks a viral oncogene, and does not integrate into specific sites of the human genome to disrupt proto-oncogenes.

HTLV-I and II Infection-linked T Cell Leukemia/Lymphoma

Human T cell leukemia virus I (HTLV-I) infects CD4+ helper T cells via sexual intercourse, blood transfusion or breastfeeding. Only 1% of infected persons will develop T cell leukemia/lymphoma and only after a period of 20–30 years.

- During HTLV replication, **TAX gene** encodes TAX protein, which acts through binding host cAMP response protein (CREB) to recruit histone acetyl transferases to the TAX-response element 1 (**TRE1**) to promote transcription of host genes (c-Fos).
- TAX protein alters function of cellular proteins resulting in activation, proliferation and survival of infected CD4+ helper T cells. TAX protein can also inactivate TP53 gene product (p53 protein), which results in DNA repair failure induces cell cycle progression.
- TAX protein also alters the expression of many host cellular proteins associated with cell cycle progression through G1 phase by disabling checkpoints of cell cycle. TAX protein also inhibits apoptosis and stimulates telomerase expression resulting in unrestricted cell proliferation, and development of human T cell leukemia/lymphoma.
- The host cellular alterations confer a fitness advantage for viral replication, which cause chromosomal instability, and accumulation of host genomic mutations.

Clinical Features of T Cell Leukemia/Lymphoma

Patient presents with hypercalcemia, lymphadenopathy, skin lesions caused by infiltration of leukemic cells, spleen and liver involvement and immune suppression.

Hepatitis C Virus (HCV)-induced Cirrhosis and Hepatocellular Carcinoma

Hepatitis C virus (HCV) affects persons across world. It is mainly acquired by blood transfusions, and intravenous drug abuse. It may be transmitted by transplacental infection of the fetus, breastfeeding and co-infection with HBV, but is not efficiently sexually transmitted. In contrast to HBV, HCV cannot integrate into the human genome. Majority of infected patients are unable to clear the HCV infection and develop chronic hepatitis, that induce hepatic lesions frequently associated with steatohepatitis, progressive fibrosis, and cirrhosis over 20–40 years involving a variety of signaling pathways.

- Hepatitis C virus (**HCV**) is major cause of cirrhosis that may progress to hepatocellular carcinoma frequently together with HBV. Hepatocellular carcinoma risk appears to be dependent on viral genotype. HCV genotypes 3, 25, 26 and 27 are more carcinogenic.
- Hepatocarcinogenesis is a multistep process that may last for years, which involves progressive accumulation of different genetic mutations leading to malignant transformation of hepatocytes.
  - HCV core proteins can directly upregulate mitogenic signaling pathways, inhibit apoptosis and induce reactive oxygen species (ROS) production. Reactive oxygen species can cause genomic instability by inducing several gene mutations (e.g. TP53, CTNNB1 and TERT).
  - HCV also triggers persistent chronic inflammation in liver and production of various lymphotoxins (LT-α and LT-β), which are linked to hepatocellular carcinoma.
  - Chronic inflammation in liver exacerbates reactive oxygen species (ROS), which are considered a main source of several genetic mutations. Reactive oxygen species induce TGF-β signaling pathway activates hepatic stellate cells leading to fibrogenesis. TGF-β together with TLR4 plays a pivotal role in epithelial–mesenchymal transition (EMT).
  - HCV dysregulates host lipid metabolism resulting in accumulation of fat in the hepatocytes in many patients. HCV can also induce angiogenic and metastatic signaling pathways.
  - Epigenetic regulatory genes are dysregulated in hepatocellular carcinoma, which can result in permanent modification of gene expression. Recent studies revealed polymorphisms in the DEPDC5 and MICA genes increase the risk for hepatocellular carcinoma.

Clinical Features

Majority of patients infected with HCV remain asymptomatic. Symptomatic patients may experience jaundice, malaise, nausea, dark urine and right upper quadrant pain 2–12 weeks after exposure to HCV. Patients with acute HCV infection have moderate to high serum aminotransferase levels. Chronic HCV infection can progress to cirrhosis and hepatocellular carcinoma.

ONCOGENIC DNA VIRUSES ASSOCIATED CANCERS

DNA virus has a genome-made of deoxyribonucleic acid (DNA), that replicates using DNA-dependent DNA polymerase. DNA viruses can be grouped into two classes: **double-stranded (ds) viruses** (e.g. polyomaviruses, adenoviruses and herpesviruses) and **single-stranded (ss) DNA viruses.**

- Most double-stranded DNA viruses replicate within the host cell nucleus. DNA viruses linked to human cancers include Epstein-Barr virus (EBV), human papillomavirus (HPV 16, 18), hepatitis B virus (HBV) and human herpesvirus 8 (HHV-8).
- DNA viruses integrate viral DNA into host genome resulting in expression of viral mRNA coding for specific proteins in host cells, which target key cellular regulatory proteins (pRB and p53 proteins encoded by RB and TP53 tumor suppressor genes).

Epstein-Barr Virus (EBV)-induced Human Cancers

Epstein-Barr virus (EBV) has been linked to various human cancers. EB virus enters through binding with CD21 and infects B cells, one of the principal infection-fighting white blood cells of the immune system.

- EBV viral genes activate the transcription of latent membrane protein 1 (**LMP-1**), which induces activation of NF-κB and JAK/STAT (Janus/kinase) signaling pathway that promotes B cell survival.
- EB virus does not replicate within B cells; instead, it alters genetic code of B cells and transforms these cells into lymphoblasts, which have an indefinite life span. In other words, EB virus renders lymphoblasts immortal. Epstein-Barr virus-linked human cancers are given in Table 6.85.

Table 6.85 Epstein-Barr virus-linked human cancers

Burkitt's lymphoma
Hodgkin's disease (mixed cellularity variant)
Nasopharyngeal carcinoma
Extranodal marginal zone B cell/T cell non-Hodgkin's lymphoma
Extranodal NK/T cell lymphoma (nasal type)
Central nervous system lymphoma in AIDS
Primary central nervous system diffuse large B cell lymphoma (DLBCL)
Gastric MALT lymphoma
Follicular dendritic cell sarcoma
Primary effusion lymphoma
Lymphomatoid granulomatosis
Post-transplant lymphoproliferative disease
Gastric carcinoma, and smooth muscle tumors

EBV Infection-associated Burkitt's Lymphoma

The hallmark of EBV infection-linked Burkitt's lymphoma is the translocation between the Myc gene and one of the immunoglobulins (Ig) heavy or light chain loci, that results in overexpression of the **Myc gene**, which codes for a transcription factor, that modulates genes related to cell cycle progression, apoptosis, and cellular transformation.

- EBV infection may lead to Myc gene mutation that allows human B cells to proliferate indefinitely.
- Depending on the stage of B cell development, EBV infection can cause different forms of Burkitt's lymphoma: **endemic Burkitt's lymphoma** (4–7 years of age group), **sporadic Burkitt's lymphoma** (worldwide), and immunodeficiency (HIV/AIDS)-associated Burkitt's lymphoma. Molecular genetic alterations t(8;14), t(2;8) and t(8;22) are demonstrated in patients with Burkitt's lymphoma.

EBV Infection-associated Hodgkin's Disease

Hodgkin's disease is a malignant neoplasm of single/multiple lymph nodes. Diagnostic criteria include presence of neoplastic component of Hodgkin's disease and presence of Reed-Sternberg cells constituting 1–10% of cell population in Hodgkin's disease. Up to 40% of Hodgkin's disease cases are associated with the Epstein-Barr virus (EBV) infection.

- EBV-associated Hodgkin's disease is more frequent in cases with mixed cellularity histology affecting children and older adults in developing countries. EB virus may directly trigger tumorigenesis through constitutive expression of **Myc oncogene**.
- Clonal viral genomes can be demonstrated in Reed-Sternberg cells, the tumor component of Hodgkin's disease (mixed cellularity) in 50% of cases. EBV may actually protect the Reed-Sternberg cell from apoptosis, and immune response of natural killer T cells and mutation in the TP53 gene.
- Circulating EBV-DNA may serve as a biomarker to monitor response to therapy, and eventually, EBV will become a target for therapeutic intervention in Hodgkin's disease.

EBV Infection-associated Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma is an Epstein-Barr virus (EBV)-associated malignancy that is common in Thailand, which might be a result of virus latency in nasopharyngeal cells.

- EBV is transmitted from the carrier through the saliva and enters the host via oropharyngeal region where it can infect '**naïve tonsillar B cells**' via interaction of the viral envelope glycoprotein gp350 and CD21 expression on B cells.

- Epstein-Barr virus nuclear antigen 2 (**EBVN2**) transactivates latent membrane protein 1 (**LMP1**) leading to phenotypic changes in B cells. The genetic mutations induced by EBV infection depend on the viral type and strain. Tobacco smoking has been associated with nasopharyngeal carcinoma possibly due to reactivation of latent EBV.

EBV Infection-associated T Cell/NK Cell Lymphoproliferative Diseases

EBV-associated T cell/NK cell lymphoproliferative diseases result from ectopic infection of T cell or natural killer (NK) cells with Epstein-Barr virus.

Human Papillomavirus (HPV)

Human papillomavirus (HPV 16, 18) is linked to cervical carcinoma. HPV is the most common sexually transmitted virus in the world. The HPV genome is divided into three regions: (a) noncoding upstream regulatory region, (b) 'early region', (c) and 'late region'. The early region of HPV is involved in viral replication and oncogenesis. The late region of HPV encodes structural proteins for the viral capsid. Oncogenic risk of anogenital human papillomavirus is given in Table 6.86.

HPV 16 and 18 Infection-associated Cancers

HPV 16 and 18 are high-risk types known to significantly increase the risk for cervical, vaginal and vulvar cancers, as well as penile cancer in men. HPV 16 and 18 can infect only the immature squamous epithelial basal cells at the squamocolumnar junction of cervix resulting in a cytopathic effect, 'koilocytic atypia', consisting of nuclear atypia and a cytoplasmic perinuclear halo. HPV does not infect the mature superficial squamous cells that cover the ectocervix, vagina, and vulva.

HPV 16 and 18 Infection-associated Cervical Carcinoma

HPV integrates its DNA into the host genome and induces disruption of E2 protein resulting in significantly, increased expression of the E6 and E7 oncoproteins encoded by E6 and E7 oncogenes, which interfere with the function of TP53 and RB respectively knocking those proteins out of action, and allowing the cell to grow and divide. These cellular alterations cause deregulated cell cycle by interrupting checkpoint proteins (p53 and pRB), inhibition of apoptosis, increased genomic instability, cell proliferation, immortalization and transformation of infected cells to CSCs. E6 and E7 oncoproteins of HPV-16 and HPV-18 bind to the pRB and p53 proteins very tightly; in contrast, the E6 and E7 proteins of HPV-6 and HPV-11 (low-risk types) bind pRB and p53 proteins with low affinity. Principles of HPV E6/E7 oncogene activity in cervical carcinoma are shown in Fig. 6.103.

- **E6 protein of high-risk HPV:** E6 protein binds to the TP53 gene product (p53 protein known as guardian of the genome) tumor suppressor protein and targets it for ubiquitin-mediated degradation of p53. The E6 protein increases telomerase activity in keratinocytes through increased transcription of the telomerase catalytic subunit gene (**TERT**) resulting in increased receptor tyrosine kinase activity and eventually genomic instability and malignant tumor.
- **E7 protein of high-risk HPV:** E7 protein binds to retinoblastoma protein (pRB) and displaces E2F transcription factor. Now displaced free E2F transcription factor binds to the promoters of genes (like c-Myc) that cause the cell to enter the cell cycle. The E7 oncoprotein increases the activity of cyclin D/CDK4 as a result of inactivation of CDK inhibitors (e.g. p21 and p27) resulting in genome instability, and

Table 6.86 Oncogenic risk of anogenital human papillomavirus

Oncogenic Risk for Cervical Cancer	Human Papillomavirus	Histologic Features
High-risk anogenital human papillomavirus	16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 59, 66, 68	▪ High-grade squamous intraepithelial lesion (HSIL) ▪ Koilocytosis occasional present ▪ Aneuploidy usually ▪ Abnormal mitoses frequent ▪ Undifferentiated cells and abnormal mitoses in upper two-thirds of cervical epithelium
Low-risk anogenital human papillomavirus	6, 11, 42, 43, 44, 53	▪ Low-grade squamous intraepithelial lesion (LSIL) ▪ Koilocytosis frequently present ▪ Diploid or polyploid most often present ▪ Abnormal mitoses absent ▪ Undifferentiated cells, and bipolar mitoses in lower third of cervical epithelium

Medium risk human papillomavirus includes 33, 35, 39, 51, 52, 56, 57, 58, 59, 68

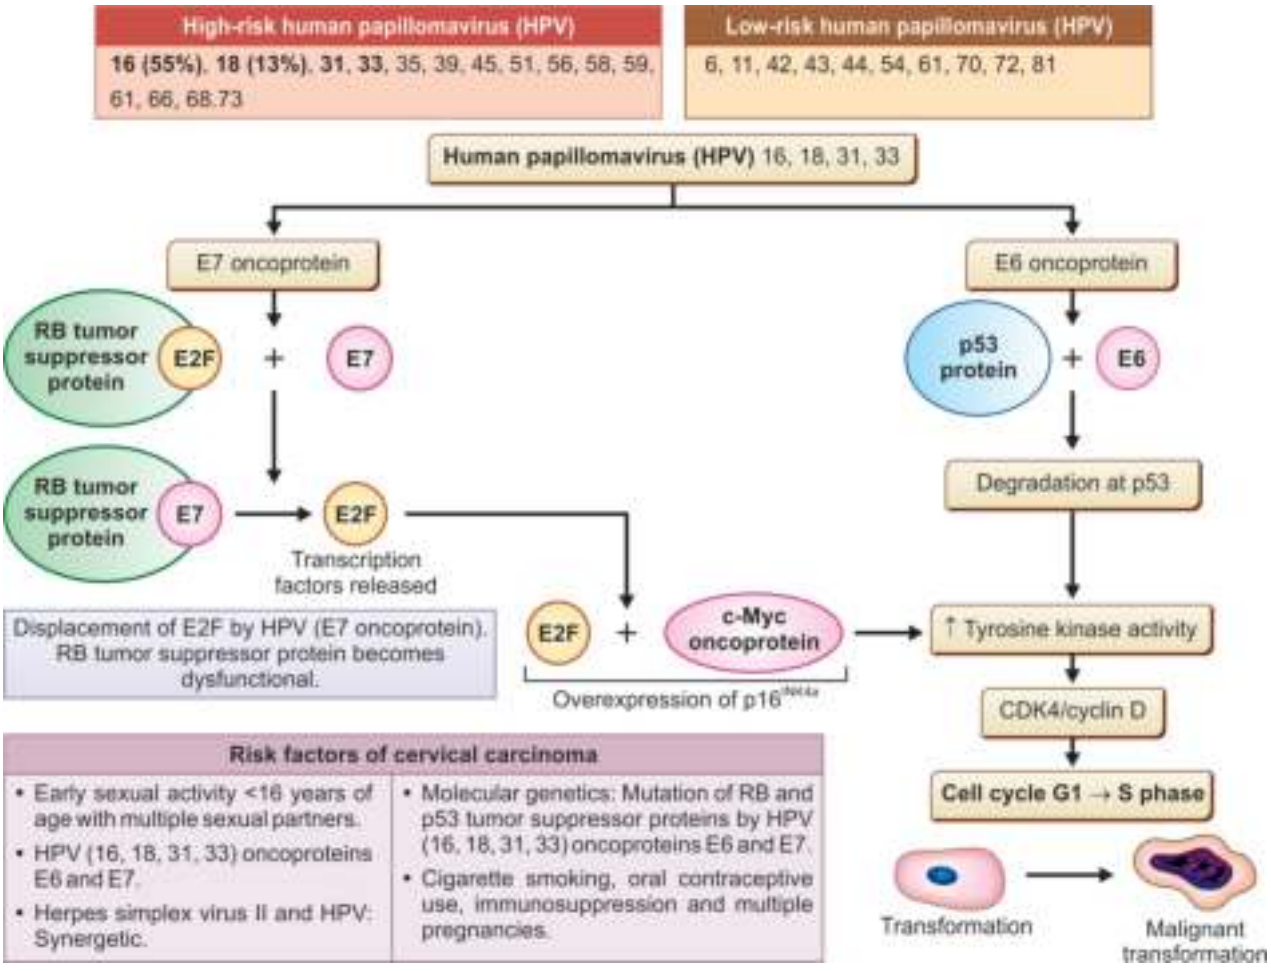

Fig. 6.103: Principles of HPV E6/E7 oncogene activity in cervical carcinoma. E6 protein of HPV binds to the TP53 gene tumor suppressor product (p53 protein known as guardian of the genome) tumor suppressor protein and targets it for ubiquitin-mediated degradation. E7 protein of HPV inhibits retinoblastoma protein (pRB) tumor suppressor.

eventually malignant tumor. The mutagenic potential along with dysregulated cell cycle allows HPV to induce cervical carcinogenesis in host cells.

Cervical Carcinoma Screening, Vaccination and Molecular Techniques

In countries with accessible preventive services, there has been a steep decline in mortality caused by cervical carcinoma due to the development and widespread acceptance of cervical carcinoma screening (Papanicolaou smear).

- Further, the HPV vaccination is now available for women up to 45 years of age, which prevents cervical carcinoma in 70–80% of cases.
- Therapeutic vaccines and gene therapy are primarily directed against E6 and E7 oncoproteins. The link between HPV and cervical carcinoma has led to the development of molecular methods often based on the detection of E6 and E7 oncoproteins, for screening and diagnosis.

Human Herpesvirus 8-induced Kaposi Sarcoma

Kaposi sarcoma is the most common locally aggressive vascular cancer caused by human herpesvirus 8 (HHV-8) in immunocompromised persons with HIV-positive status.

Human Herpesvirus 8 Infection: Pathogenesis

Human herpesvirus 8 infects vascular endothelial cells and modulates signaling pathways, that regulate cell proliferation, gene expression, and metabolism. In HIV/AIDS-related Kaposi sarcoma, most common sites are mucosal surfaces, skin, face, lower extremities, visceral and cutaneous lesions in HIV infected homosexual or bisexual persons.

Clinical Features

Patient presents with cutaneous violaceous patch, plaque, macule or tumor mass usually on lower extremities. Lymphedema is demonstrated in occasional patient. Involvement of viscera and lymph nodes

presents with hemorrhagic mass. In **endemic (African) Kaposi sarcoma**, young male patient presents with bulky lymphadenopathy and soft tissue tumor. Disease has indolent clinical course in adults; and aggressive clinical course in African children with bulky lymphadenopathy.

Hepatitis B Virus-induced Hepatocellular Carcinoma

Hepatitis B virus (HBV) infection is a major risk factor for development of hepatocellular carcinoma (**HCC**), which is endemic in South-East Asia and sub-Saharan Africa and leading cause of cancer deaths. The precise role of hepatitis B virus in causing hepatocellular carcinoma is unknown, but evidence suggests that viral proteins disrupt signal transduction and thereby deregulate cell growth. HBV-related chronic inflammation **cytokines** and reactive oxygen species (**ROS**) play important roles in the hepatocyte cell proliferation and fibrosis leading to development of hepatocellular carcinoma.

- HBV-DNA integrates into the host genome and replicates within endoplasmic reticulum in the hepatocytes and alters expression of cellular genes that are important in cell growth and differentiation. Some of the gene products favor malignant transformation.
- HBV genes have been observed in infected tissues including truncated pre-S2/S, HBV-X gene and a novel spliced transcript of HBV (hepatitis B spliced protein). The proteins expressed from these integrated genes have been shown to induce genomic instability and cell cycle deregulation contributing to hepatic carcinogenesis.
- HBV-X protein binds TP53 gene and interferes with its function. Several cell mediators (e.g. p53, FAS, TNF-α and TGF-β) decrease apoptosis of HBV-infected hepatocytes. **HBsAg** is a popular marker to establish diagnosis of active hepatitis B.

Pathology Pearls: Hepatitis B (HB) and Hepatitis C (HC) Linked to Hepatocellular Carcinoma

Immune-mediated Mechanism

- Immune response
- Chronic hepatocellular damage and regeneration
- Enhanced mutagenesis and cell proliferation
- Development of hepatocellular carcinoma

Molecular Mechanism

- Alteration of DNA repair system
- Alteration of centrosome duplication mechanism
- Viral encoded oncoprotein
- Altered cytokine expression and modulation of microenvironment
- Development of hepatocellular carcinoma

BACTERIAL CARCINOGENESIS

Helicobacter pylori is the first bacterium to be termed a definite cause of human cancers by World Health Organization. Other bacteria such as *Borrelia burgdorferi* and *Campylobacter jejuni* are also linked to human cancers.

HELICOBACTER PYLORI-INDUCED GASTRIC CARCINOGENESIS

World Health Organization has designated *Helicobacter pylori*, a potential human carcinogen, that can induce gastric adenocarcinoma in distal region, and mucosa-associated lymphoid tissue (**MALT**) low-grade B cell NHL by two mechanisms: induction of chronic inflammation and production of reactive oxygen species (ROS), and N-nitroso compounds, that can react with mutated DNA.

- *Helicobacter pylori* induces sequential changes in the stomach, i.e. chronic gastritis, gastric atrophy, intestinal metaplasia, dysplasia, early gastric carcinoma and advanced gastric carcinoma.
- *Helicobacter pylori* itself is not mutagenic but acts solely as promoter by creating an environment where chronic inflammation induces DNA damage, DNA repair failure, DNA methylation and genomic instability, which are emerging hallmarks of cancers.
- *Helicobacter pylori*—Cag PAI gene codes for oncogenic CagA pore-forming cytotoxin that binds to epithelium via interaction with protein–tyrosine phosphatases resulting in morphologic changes of the cell, and influences various intracellular signal transduction pathways such as the RAS/mitogen-activated protein kinase/extracellular signal-regulated tyrosine kinase pathway, nuclear factor kappa B (NF-κB) pathway and β-catenin pathway and proteins that leads to aberrant DNA methylation, decreased expression of DNA repair genes, increased expression of activation-induced cytidine deaminase, and induction of double-strand DNA breaks (DSBs), unrestricted CSC division, epithelial–mesenchymal transition (**EMT**), angiogenesis, invasion and metastasis. Because bacterial infections can be cured by antibiotics, identification of bacterial etiology of human cancers could have important amplifications for cancer prevention.
- The nature of the inflammatory response to *Helicobacter pylori* is also determined by proinflammatory **IL-1** gene cluster polymorphisms in several host genes encoding cytokines, and cytokine receptors, which induce intense inflammatory response leading to

hypochlorhydria/achlorhydria and high-risk for gastric adenocarcinoma.

BORRELIA BURGDORFERI-INDUCED BREAST CARCINOGENESIS

One of the known human pathogens *Borrelia burgdorferi* is the causative agent for Lyme disease and is migrate through mammalian tissue and persists in joints and skin. *Borrelia burgdorferi* has been shown to be present in breast cancer and is associated with poor prognosis. *Borrelia burgdorferi* can invade breast tissue and increase risk for breast carcinoma.

CAMPYLOBACTER JEJUNI-INDUCED COLORECTAL CARCINOGENESIS

All *Campylobacter jejuni* species produce a genotoxin, which induce breaks in DNA double-strands and increase risk of cancer especially in the gastrointestinal tract. *Campylobacter jejuni* promotes colorectal tumorigenesis through the action of cytolethal distending toxin.

PARASITE-INDUCED CARCINOGENESIS

Only three helminths (e.g. *Schistosoma haematobium*, *Opisthorchis viverrini* and *Clonorchis sinensis*) are directly linked to carcinogenesis.

- *Schistosoma haematobium* resides in the venous network around urinary bladder, where it causes foci of squamous metaplasia of urothelium leading to urinary bladder squamous cell carcinoma in Egypt population. Patient initially presents with sudden painless hematuria and in later stage urinary bladder may become irritable, painful urination. Cystoscopy reveals exophytic (cauliflower-like) or ulcerated cancerous lesion.
- *Opisthorchis viverrini*, also known as South-East liver fluke, is a major cause of cholangiosarcoma especially in North-Eastern Thailand. The definitive host (mammals including human beings) becomes infected by ingestion of undercooked fish containing metacercariae. After ingestion, the metacercariae excyst in the duodenum and ascend through the ampulla of Vater into the biliary ducts, which lay eggs after 3–4 weeks. The adult fluke resides in the biliary and pancreatic ducts of the host, where it attaches to the mucosa, and induces cholangiocarcinoma.
- *Clonorchis sinensis* (liver fluke) is transmitted through consumption of raw or undercooked vegetables. It resides in the biliary tree and may result in cholangiocarcinoma in far east population. It also causes hepatocellular carcinoma and pancreatic carcinoma.

HORMONAL CARCINOGENESIS

Hormones are chemical messengers that travel in bloodstream to tissues/organs. Hormones (natural or synthetic) act by binding to receptors on the cell surface and influence biological processes through signaling pathways.

- There are major classes of hormones based on chemical structures, which include: (a) peptide/protein hormones, (b) amino acid or fatty acid-derived hormones and (c) steroid hormones (e.g. estrogen, progesterone and testosterone).
- Excessive hormonal stimulation of cells increases the risk for gene mutations, and subsequent unrestricted cell proliferation of clones of mutated cells.
- Hormones are powerful carcinogens and considered a 'complete carcinogen' because of their ability to both initiate and promote the development of cancers of breast, endometrium, ovary, testis, prostate, thyroid, and bone (osteosarcoma), share a unique mechanism of carcinogenesis.
- Excess of endogenous and exogenous hormones drive unrestricted cell proliferation, and thus the opportunity for the accumulation of random genetic mutations. The emergence of a malignant phenotype depends on a series of somatic gene mutations, that occur during the cell division.
- Endogenous hormones include estrogen, and progesterone and testosterone. Estrogen regulates development of female genital system and secondary sex characters. Progesterone hormone synthesized by corpus luteum in the ovary regulate menstrual cycle and maintenance of early stages of pregnancy.
  - Estrogen hormone is linked to many women cancers (e.g. endometrial carcinoma, breast carcinoma, ovarian carcinoma).
  - Testosterone hormone is mostly synthesized in the testis, and small quantity by adrenal glands. Testosterone regulates changes in boys to go through puberty to become men such as sex drive, spermatogenesis (fertility), bone mass, fat distribution, muscle mass, strength, and erythropoiesis. Testosterone has been implicated in the genesis of prostatic adenocarcinoma.
- Exogenous steroid hormones in the form of oral contraceptives and hormonal replacement therapy (**HRT**) are frequently given to women, that can influence unrestricted cell proliferation, and increase risk of breast carcinoma, ovarian carcinoma, endometrial carcinoma and cervical carcinoma.

ROLE OF HORMONES IN BREAST CARCINOMA

Increased exposure to steroid hormone estrogen to breast tissue in females increases risk for development

of breast carcinoma. The early onset of menstruation, late first pregnancy, obesity, late menopause and the use of oral contraceptives increase risk exposure of breast tissue to estrogen, stimulate unrestricted CSC proliferation, and development of breast carcinoma.

- The primary source of estrogen in postmenopausal women is from the conversion of androstenedione to estrone in the adipose tissue; thus, increased synthesis of estrone in adipose tissue is linked to breast carcinoma.
- Obesity is also associated with decreased serum sex hormone binding globulin (**SHBG**) and increased proportions of free and albumin-bound estrogens.
- Oral contraceptives (birth control pills) are medications that contain synthetic versions of the natural female hormone's estrogen and progesterone, and prevent pregnancy by inhibiting ovulation, and also by preventing spermatozoa to penetrate through cervix. Various studies have provided consistent evidence that increases the risk for breast carcinoma, who use oral contraceptives.
- Combined hormonal replacement therapy (HRT) in postmenopausal women (estrogen plus progestin—synthetic version of the female progesterone hormone) can increase a woman's risk for breast carcinoma.
- Thus, interruption of estrogen hormone induced stimulus is done through anti-hormonal therapy in breast cancer patients. Estrogen receptor-positive breast carcinoma is treated by '**tamoxifen**' to interfere with attachment of steroid hormones to receptors on mammary glands and antagonize the action of estrogen hormone, and thus interrupting unrestricted CSC proliferation. Anti-hormonal therapies have been effective in inhibiting progression of breast cancer disease and thereby increasing the time to recurrence and mortality.
- Polymorphisms in genes such as 17β-hydroxysteroid dehydrogenase 1 (**HSD17B1**), cytochrome P459c17α (**CYP17**), aromatase (**CYP19**) and estrogen receptor (ER)-related to estrogenic action, metabolism and transport can increase risk for breast carcinoma.

HORMONAL REPLACEMENT THERAPY (HRT) IN PREGNANT WOMEN LINKED TO CLEAR CELL CARCINOMA OF VAGINA IN THEIR DAUGHTERS

Diethylstilbestrol (DES) is a form of estrogen that is administered to some pregnant women to prevent miscarriages, premature labor and other pregnancy-related problems. Their daughters have an increased risk for cancers of the vagina and cervix. Patient initially develops **vaginal adenosis** characterized by mucosal columnar epithelium-lined crypts in areas normally lined by stratified squamous epithelium. Vaginal adenosis is thought to be a precursor of clear cell adenocarcinoma of vagina in their daughters.

ROLE OF HORMONES, OBESITY AND LEPTIN IN ENDOMETRIAL CARCINOMA

Endometrial carcinoma is most common malignancy across world. Tumor is usually low-grade associated with good prognosis. Tumor may show microsatellite instability and mutations in PTEN, PIL3CA, K-RAS and CTNNB1. Majority of patients with endometrial carcinoma present with vaginal discharge, and abnormal uterine bleeding in premenopausal or postmenopausal women. A routine Papanicolaou (Pap) smear examination shows endometrial cells in postmenopausal women. Endometrial biopsy is performed to establish diagnosis.

Role of Steroid Hormones in Endometrial Carcinoma

Estrogen and progesterone are steroid hormones that activate receptors in target endometrial tissue to influence endometrial growth. According to the unopposed estrogen hypothesis, increased levels of estrogen and decreased levels of progesterone cooperate to increase the mitotic activity in endometrial cells.

- Sustained endometrial cell proliferation and greater rates of DNA mutation ultimately result in transformation to CSCs. Similarly, women who undergo estrogen replacement without progesterone have an increased risk for endometrial carcinoma.
- Unopposed estrogen partially explains the risk factors for endometrial carcinoma, which include obesity, diabetes mellitus, polycystic ovarian syndrome, nulliparity, and hormonal replacement therapy. In pre-menopausal women, obesity is thought to operate through increased anovulatory menstrual cycles and associated progesterone insufficiency.

Role of Obesity in Endometrial Carcinoma

Obesity has been associated with 2–5-fold increased risk of endometrial carcinoma in post-menopausal women. The mechanism involves conversion of androstenedione to estrone in adipose tissue by the enzyme aromatase present in adipose tissue and fibrovascular stroma.

- Aromatase activity is enhanced by increased adrenal gland synthesis of cortisol, and androgens in obese women.
- Estrone can also be decreased by the enzyme 17β-hydroxysteroid dehydrogenase to form the most potent estrogen and estradiol.

- In obese women, plasma estradiol levels are also elevated due to decrease in sex hormone binding globulin (SHBG) level.

Role of Leptin in Endometrial Carcinoma

Leptin is a protein encoded by the obese gene (Ob) that binds to its receptor (ObR) belonging to cytokine family and induces unrestricted endometrial CSC proliferation by activation of cyclooxygenase-2 through the JAK2/STAT, RAF/MEK/ERK mitogen-activated protein kinase (MAPK) signaling pathway and phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR (mammalian target of rapamycin) signaling pathway.

- Angiogenesis in endometrial carcinoma occurs through activation of vascular endothelial growth factor (VEGF), and VEGF receptor (VEGFR) resulting in increased malignant tumor growth.
- Overexpression of leptin and ObR in endometrial carcinoma is associated with invasion and metastasis. Mechanistically, leptin enhances aromatase expression and increases estradiol synthesis in endometrial CSCs.

ROLE OF HORMONES IN PROSTATIC ADENOCARCINOMA

The causes of prostatic adenocarcinoma are not entirely certain, but it is postulated that steroid androgenic hormones such as testosterone and more potent dihydrotestosterone exert their effects by binding to the androgen receptor (AR) in the cytoplasm of cells causing oncogenic genetic alterations that play a major role in its development. Polymorphisms in genes such as androgen receptor (AR), steroid 5β-reductase type II (SRD5A2), P459c17α (CYP17), and 3β-hydroxysteroid dehydrogenase (HSD3B2)-related to action, metabolism and transport can increase risk for prostatic adenocarcinoma.

ROLE OF ONCOGENES AND TUMOR SUPPRESSOR GENES IN CARCINOGENESIS

Tissue homeostasis depends on the regulated cell division and apoptosis (programmed cell death) of each of its constituents except stem cells. A malignant tumor arises as a result of unrestricted cancer stem cell (CSC) proliferation and failure of apoptosis. DNA stability genes monitor and maintain genomic integrity, and their loss of function results in accumulation of gene mutations. Cellular proto-oncogenes are normal growth-promoting genes which stimulate cell division. Tumor suppressor genes encode proteins that prevent development of malignant tumor by reliably controlling cell division in check, promoting apoptosis and suppressing metastasis. Alterations in proto-oncogenes and tumor suppressor genes induce malignant tumors. Gain-of-function mutations that convert proto-oncogene to oncogene act dominantly; that is, mutation in only one of the two alleles is sufficient to induce malignant tumor. On contrary, recessive loss-of-function mutations in tumor suppressor genes possess oncogenic potential. Role of proto-oncogenes in normal cell growth and differentiation is shown in Fig. 6.104. Tumor suppressor gene proteins and normal cell growth regulatory pathway is shown in Fig. 6.105.

- **Cellular proto-oncogenes normal gene products:** Cellular proto-oncogenes encode normal gene proteins involved in cell proliferation. Binding of growth factor to cell surface receptor sends a signal transduction through the cytoplasm to the nucleus,

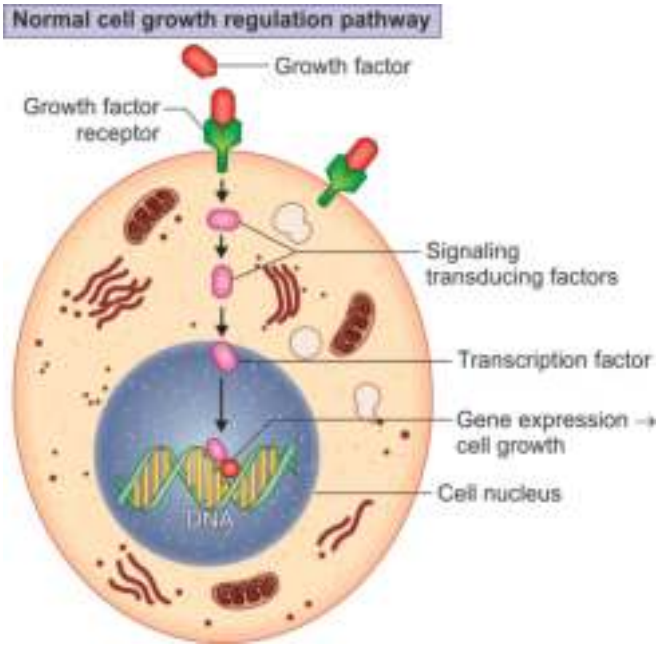

Fig. 6.104: Role of proto-oncogenes in normal cell growth and differentiation. Proto-oncogenes are normal cellular genes that encode intracellular regulatory proteins involved in signal transduction responsible for cell growth and differentiation during embryogenesis and postnatal life. **Oncogenes** are mutated forms of normal proto-oncogenes generally involved in promoting unrestricted cell proliferation. Oncogenes result in dominant gene function. Perturbations in the regulatory pathways lead to alterations of cell proliferation, growth and differentiation leading to development of cancer.

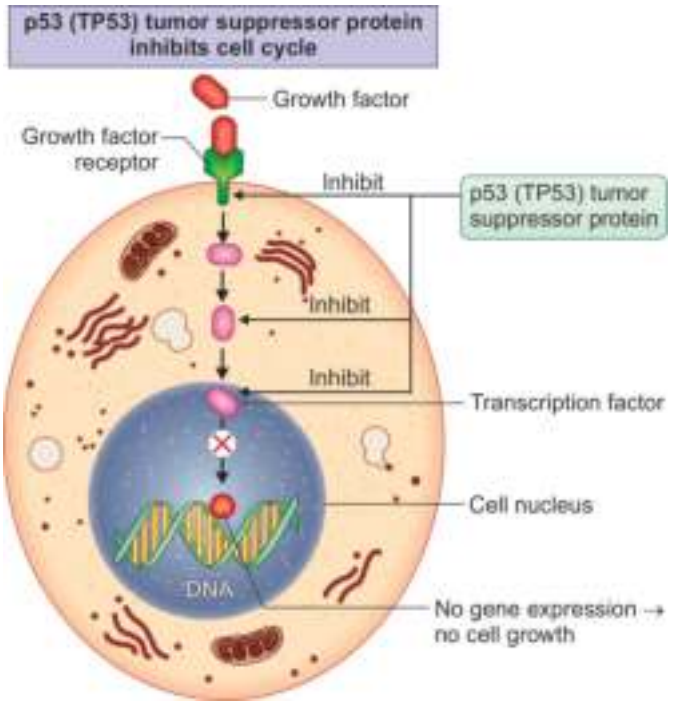

Fig. 6.105: Tumor suppressor gene proteins and normal cell growth regulatory pathway. Tumor suppressor gene encode proteins, which regulate orderly cell growth and cell differentiation, and play a critical role of the normal processes of the cell cycle by sensing the surrounding environment, transmitting signals to the nucleus and directly affecting transcription, translation, survival, or cell division. Inactivation/biallelic loss of tumor suppressor gene is linked to development of malignant tumor. Mutations in tumor suppressor gene result in recessive loss of function.

that activates nuclear regulating proteins, i.e. transcription factors, which promotes cell growth and cell division. When normal cellular proto-oncogenes are permanently altered to become oncogenes, which induce unrestricted CSC proliferation.

- **Cellular proto-oncogenes/oncogenes classification according to function of gene products:** Proto-oncogenes can be classified according to the function of their gene products, which include: (a) growth factors, (b) cell surface growth factor receptors, (c) signal transducing proteins (GTP-binding proteins, and nonreceptor protein kinase), (d) transcription factors (i.e. nuclear regulatory proteins), (e) chromatin modeler proteins, (f) cell cycle regulatory proteins, (g) apoptosis regulatory proteins, and (h) DNA repair proteins.
- **Cellular proto-oncogenes conversion into oncogenes—mechanisms:** Conversion of a proto-oncogene into an oncogene generally involves a gain-of-function mutation. Oncogenes (mutated proto-oncogenes) produce oncoproteins that induce malignant tumor. At least three mechanisms can produce oncogenes from the corresponding proto-oncogenes, i.e. point mutation (deletion/insertion), gene amplification (localized reduplication), and chromosomal rearrangements. Oncogene formed by point mutation encodes an oncoprotein that differs slightly from the normal protein encoded by corresponding proto-oncogene. In contrast, gene amplification and chromosomal rearrangement mechanisms generate oncogenes whose gene products are identical with the normal proteins. **Gain-of-function mutations** that convert proto-oncogene into oncogenes act dominantly; that is, mutation in only one of the gene alleles is sufficient to induce malignant tumor. Activated oncogenes can produce either excess normal protein or functionally abnormal protein. Excess production of nonfunctional protein can occur by two mechanisms: gene amplification (e.g. Myc gene linked to neuroblastoma) and increased mRNA transcription (Burkitt's lymphoma).
  - **Point mutation:** Point mutation (deletion or insertion) in the promoter region of proto-oncogene increases transcription, and production of hyperactive functionally gene product that induces unrestricted CSC proliferation. Point mutation in RAS proto-oncogene in certain codons that renders it constitutively active, and is linked to lung carcinoma, colon carcinoma and pancreatic carcinoma.
  - **Gene amplification:** Gene amplification is frequent genetic abnormality in human CSCs and consists of multiple extra (additional) copies of a proto-oncogene in subchromosomal region of DNA. Sometimes, proto-oncogenes only need to be overexpressed (not mutated) to cause solid malignant tumors associated gene amplification of ribosomal genes, and histone octamer genes can be found clustered in tandem arrays in the genome. HER2/neu gene amplification results in the production of excess HER2 protein on the surface of CSCs in breast carcinoma. Amplification of N-Myc oncogene occurs in subset of **neuroblastomas**. Gene amplification is most often observed in the family members of Myc (transcription factor), RAS (signal transduction protein), FGF (fibroblast growth factor), EGFR (epidermal growth factor receptor), and cell cycle regulatory genes (CCND1, CCNE, MDM2, SDK4). Gene amplification can be detected by several methods: (a) conventional cytogenetics, (b) Southern blotting, (c) polymerase chain reaction (PCR) is a technique, (d) fluorescence *in situ* hybridization (FISH), (e) comparative genomic hybridization (CGH); and (f) microarray technology.

- **Chromosomal translocation:** A chromosomal translocation is defined as genome abnormality in which a chromosome breaks and either the whole or a portion of it reattaches to a different chromosome. Depending on the location of breaks, chromosomal translocation events that relocate a proto-oncogene to a new chromosomal site, that leads to higher expression. Chromosomal translocation that leads to a fusion between a proto-oncogene and second proto-oncogene, which produces chimeric fusion protein with oncogenic activity. Genetic mutation that can occur due to shattering of chromosome known as '**chromothripsis**'. Chromosomal translocation t(8;14)(q24;q32), involving c-Myc oncogene on chromosome 8 and immunoglobulin heavy (IgH) gene locus on chromosome 14 is characteristic of Burkitt's lymphoma (90%). High levels of c-Myc may boost the global gene expression and influence a wide spectrum of cellular signaling pathways by acting on multiple genes leading to increased mRNA transcription and excess Myc protein. Philadelphia chromosome is demonstrated in chronic myelogenous leukemia (**CML**), in which chromosomal translocation t(9;22) that juxtaposes the BCR gene on chromosome 22 with the c-ABL proto-oncogene on chromosome 9. The BCR-ABL-1 fusion creates a constitutively active nonreceptor tyrosine kinase product that promotes cell proliferation independent of extrinsic regulation.

- **Loss of function mutations in tumor suppressor genes with oncogenic activity:** Tumor suppressor genes encode proteins that can inhibit cell proliferation. Since only copy of a tumor suppressor gene is sufficient to inhibit cell proliferation, both alleles of a tumor suppressor gene must be inactivated or lost in order to induce malignant tumor. Thus, oncogenic loss-of-function mutations in tumor suppressor genes act recessively.
- **Carcinogenesis:** Carcinogenesis is multistep process of transformation of normal cell to CSC, and subsequent development of malignant tumor. The process involves genetic and epigenetic alterations, and accumulation of mutated multiple genes coding for abnormal growth factors, cell surface growth factor receptors, signal transducing proteins (G proteins and nonreceptor kinase protein), transcription factors, chromatin remodeler proteins, cell cycle regulatory proteins, apoptosis regulatory proteins and DNA repair proteins, leading to unrestricted CSC proliferation that prevent normal cellular functions.
  - Conversion of one of the two alleles of proto-oncogene to an oncogene is sufficient for initiation, promotion and progression of malignant tumor. However, it requires inactivation/biallelic loss of tumor suppressor genes to promote malignant tumor.
  - Carcinogenesis by oncogenes and mutated tumor suppressor genes is shown in Figs 6.106 and 6.107. Cell proliferation in normal cell and malignant neoplastic cell is shown in Fig. 6.108.
- **Diagnostic molecular techniques to detect oncogenes:** Diagnostic molecular techniques to detect oncogenes include: (a) microarray analysis compares expression of proteins in CSCs versus normal cells, (b) polymerase chain reaction (PCR) assay detects gene arrangement, (c) RNA interface assay is used to detect gene function such as complete or incomplete knockdown, (d) transfection assay is used to study the gene overexpression by introduction of genes under control of an inducible promoter into the cell culture, (e) laser microdissection technique detects expression of genes by cutting out an area of interest on a slide with a laser in order to use other assay (PCR), and (f) cytogenetics refers to study of chromosome translocations in CSCs and identification of genes involved.

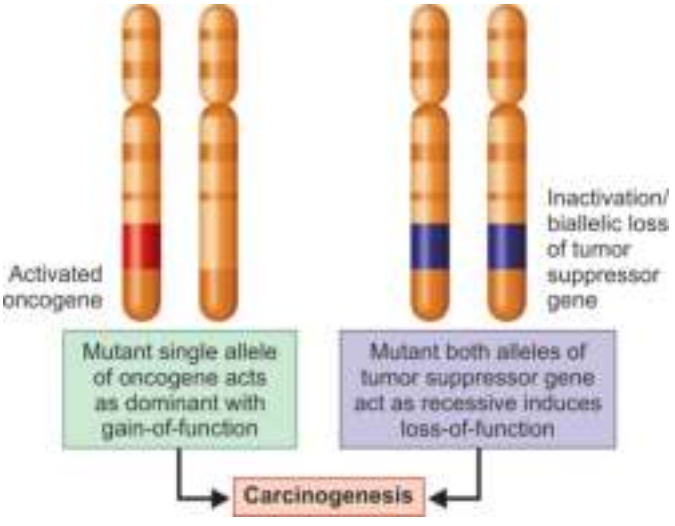

Fig. 6.106: Carcinogenesis by oncogenes and mutated tumor suppressor genes. Proteins produced by proto-oncogenes have normal regulatory functions, whereas proteins produced by oncogenes lack normal regulatory functions. Oncogene (mutated gene) induces aberrant cell division through activation and a gain-of-function; and loss of both copies of tumor suppressor gene (turning off) contribute to oncogenesis. Both types of mutations work together to induce cancer. For example, breast cancer progression involves multiple genetic alterations, which activate dominant-acting oncogenes and disrupt function of specific BRCA1, BRCA2 and p53 tumor suppressors.

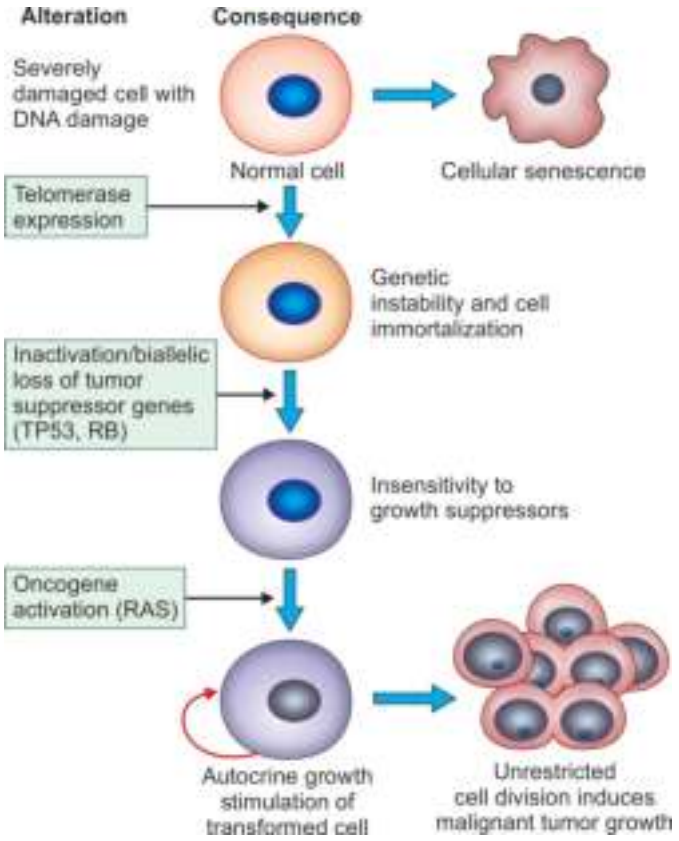

Fig. 6.107: Carcinogenesis by oncogenes and mutated tumor suppressor genes. Proteins produced by proto-oncogenes have normal regulatory functions, whereas proteins produced by oncogenes lack normal regulatory functions. The process by which normal healthy cells transform into malignant neoplastic cells is termed carcinogenesis. Oncogenes are mutated proto-oncogenes, whose alterations cause gain-of-function, while inactivation/biallelic loss of tumor suppressor genes cause loss-of-function that induce transformation of normal cell into malignant neoplastic cell leading to development of malignant tumor.

Pathology Pearls: Oncogenes (Mutated Proto-oncogenes) and Cancer

- Cellular proto-oncogenes encode proteins that promote cell proliferation. When normal cellular proto-oncogenes are permanently altered to become oncogenes, which induce unrestricted cancer stem cell proliferation.
- Gain-of-function (dominant) mutations that convert proto-oncogene to oncogene act dominantly; that is, mutation in only one of the two alleles is sufficient to induce malignant tumor. On contrary, recessive loss-of-function mutations in tumor suppressor genes possess oncogenic potential.
- Activating mutation of one of the alleles of a proto-oncogene to become an oncogene can occur by three mechanisms: point mutation (deletion/insertion), gene amplification (localized reduplication) and chromosomal rearrangements.
- Activated oncogenes can produce either excess of protein or functionally abnormal protein.
- Oncogenes (mutated proto-oncogenes) encode oncoproteins such as growth factors, cell surface growth factor receptors, signal transducing proteins (GTP-binding proteins, and nonreceptor protein kinase), transcription factors (i.e. nuclear regulatory proteins), chromatin modeler proteins, cell cycle regulatory proteins, apoptosis regulatory proteins, and DNA repair proteins.
- RAS oncogene encoding RAS oncoprotein has been isolated from human urinary bladder carcinoma.
- The first recognized oncogene, v-src, was detected in Rouse sarcoma virus—cancer causing virus. Retroviral oncogenes arose by transduction of cellular proto-oncogenes into the viral genome and subsequent mutation.
- Slow-acting retroviruses can induce malignant tumor near a proto-oncogene in such as way that gene transcription is activated continuously and inapparently.

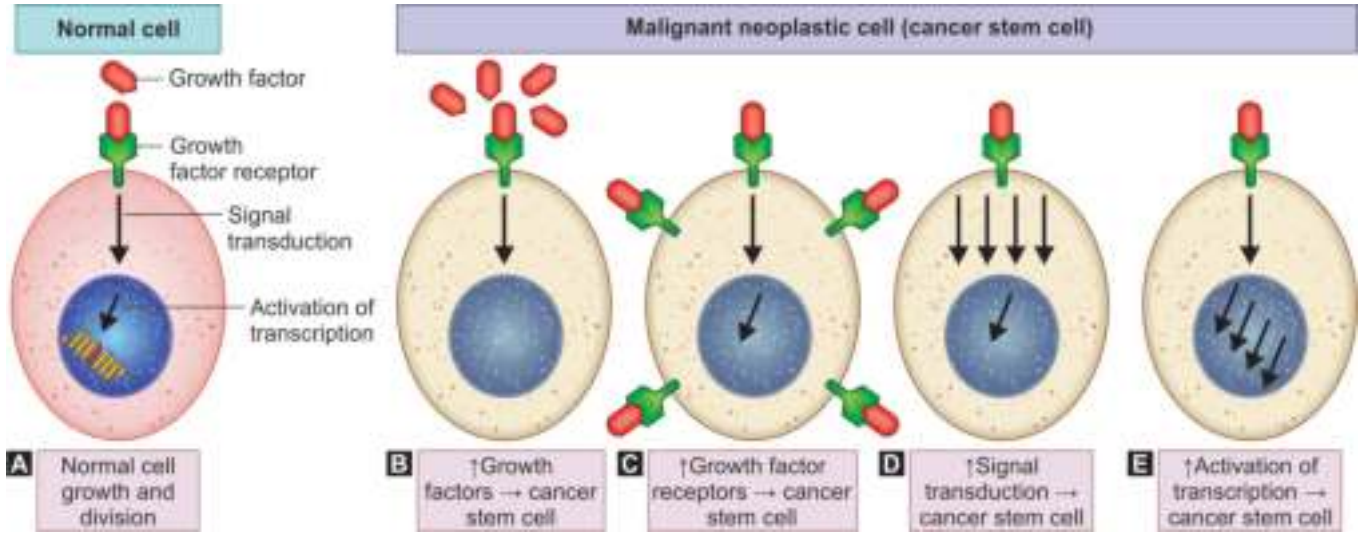

Fig. 6.108: Cell proliferation in normal cell and malignant neoplastic cell: (A) Proliferation of normal cell population result from a sequence of operations involving the binding of growth factors to cell surface growth factor receptors, transcription of the growth promoting signal and activation of DNA transcription. The abnormal degree of proliferation in neoplastic cell populations results from the upregulation of one or more than one of these steps, (B) increased growth factors, (C) increased cell growth factor receptors, (D) increased signal transduction, (E) increased transcription.

Pathology Pearls: Inactivation/Biallelic Loss of Tumor Suppressor Genes and Cancer

- Tumor suppressor gene encodes protein that acts to regulate cell division, keeping it in check. Even one allele of tumor suppressor gene regulates cell division, keeping it in check.
- Tumor suppressor genes encode proteins that prevent malignant tumor by reliably controlling cell division in check, promoting apoptosis and suppressing metastasis.
- Oncogenic loss-of-function (recessive) mutations in tumor suppressor genes act recessively. Inactivation/biallelic loss of tumor suppressor gene induce unrestricted cell division and thus malignant tumor.
- TP53 tumor suppressor gene mutation is associated with 50% of human cancer cases. TP53 tumor suppressor gene induces the transcription of other tumor suppressors, such as **p21** and **p16**, triggers DNA repair and initiates cell apoptosis.
- Germline mutation in **RB** tumor suppressor gene is linked to hereditary retinoblastoma in both eyes as an autosomal dominant trait in children.
- Germline mutation in **BRCA1** tumor suppressor gene is linked to breast carcinoma. Germline mutation in **APC** tumor suppressor gene is implicated in inducing colorectal carcinoma.
- Loss-of-function mutations in tumor suppressor genes have been identified in many human cancers in ovary, breast, lung, colorectal region, head and neck region, pancreas, uterus, and urinary bladder.
- A cell containing one normal and one mutant allele of a tumor suppressor gene is generally phenotyping normal.
- Loss of heterozygosity (**LOH**) of tumor suppressor genes occurs by two mechanisms: mitotic recombination and chromosome mis-segregation.

CELL SIGNALING

The cells of our body are constantly receiving and interpreting signals from our environment. Cell signals are most often chemical molecules found in the extracellular fluid around cells, essential for normal cellular functions, cell division and differentiation. Signaling chemical molecules can trigger cellular responses, including altered cell metabolism, gene expression (transcription) within the nucleus of the cell by endocrine, paracrine and autocrine signaling mechanisms. In 'endocrine signaling', the signaling chemical molecules (hormones) are secreted by endocrine cells and carried through bloodstream to act of target cells at distant body sites. In 'paracrine signaling', the chemical signaling molecule released by one cell acts on neighboring target cells. In 'autocrine signaling', the chemical signaling molecules released from the cell and bind on the same cell membrane to induce cellular response by forming autocrine loop. Cell signaling can be divided into three stages: (a) reception of signaling chemical molecules, (b) signal transduction and (c) specific cellular response.

- **Reception of signaling chemical molecules:** Cell detects a signaling chemical molecule (also known as a ligand) from the outside of the cell, that binds to a receptor protein on the cell surface or inside the cell.
  - **Cell membrane receptors:** Cell membrane receptors function by binding the signal molecule (ligand) and causing the production of second signaling messenger molecule, that induces a cellular response. Cell membrane receptors transmit signal from the extracellular environment to inside the cell by changing shape or by joining another protein once a specific growth factor ligand binds to it. Examples of cell membrane receptors include G protein-coupled receptors and receptor tyrosine kinases (RTKs).
  - **Intracellular receptors:** Intracellular receptors are found inside cells, either in cytoplasm or in the nucleus of the target cell receiving signal. Chemical messengers that are very small or hydrophobic (steroid hormones) can pass through the plasma membrane without assistance and bind theses intracellular receptors. Once bound and activated by signaling chemical molecule, the activated intracellular receptor can initiate a specific cellular response, such as a change in gene expression.
- **Signal transduction:** Signaling chemical molecules bind to cell membrane receptor protein, and initiate the process of multi-step signal transduction pathway, that transmits the signal quickly and amplifies the signal to numerous next signaling molecules at each step. Steps in the signal transduction signaling pathway often involve the addition or removal of phosphate groups which results in the activation of proteins.
  - **Protein kinases:** Enzymes that transfer phosphate groups from ATP to the protein are called protein kinases, which often act on other protein in the signaling pathways, and create phosphorylation cascade, leading to chain reaction.
  - **Protein phosphatases:** Protein phosphatases are important enzymes involved in phosphorylation process, that can rapidly remove phosphate groups from proteins by dephosphorylation process and inactivate protein kinases. Protein phosphatases act as switch, which 'turn off' the transduction pathway. Dephosphorylation process also makes protein kinases available for further use, and enables the cell to respond again, when another signal is received within cell.

- **Secondary messengers:** Other than protein kinases, small non-protein, water-soluble molecules called 'secondary messengers' also transmit signals received by receptors on the cell surface to target molecules in the cytoplasm or the nucleus. The **examples** of second messengers include cyclic AMP (cAMP) and calcium ions.

- **Specific cellular response:** Finally, signaling chemical molecule triggers a specific cellular response through cell membrane receptors such as G protein-coupled receptors, and receptor tyrosine kinases (RTKs). Cell signaling pathway regulates cellular processes, i.e. cell division or apoptosis by 'turning on' or 'turning off' transcription of specific genes. Signaling pathway also regulate the activity of a protein, for example, opening and closing an ion channel in the plasma membrane or promoting a change in cell metabolism such as catalyzing the breakdown of glycogen.

GROWTH FACTORS

Growth factors are relatively small secreted or membrane bound polypeptide ligands, which enable constant communication between nearby and distant cells. Binding of growth factor to cognate specific cell surface receptors, which initiates the intracellular signaling cascade events, that regulate cell cycle, cell proliferation, growth, differentiation, survival, angiogenesis, inflammation, tissue healing and repair. Oncogenes (mutated proto-oncogenes) synthesize aberrant growth factors that enhance unrestricted CSC proliferation, growth, survival, angiogenesis and development of malignant phenotype. Mutated cells with oncogenic activity become self-sufficient to synthesize growth factors to which they respond by creating 'autocrine loop'. The increase in growth factors alone does not lead to cancer but can cause rapid cell growth that increases the chance of gene mutations.

- **Growth factors classification:** Growth factors can be classified according to their roles involved in biological processes, which include: (a) embryogenesis and development, i.e. EGF and IGF, (b) adult labile cells with high turnover rates such as hematopoietic cells and epithelial cells, and (c) wound healing and repair such as PDGF and TNF-α.
- **Growth factors regulate cell cycle:** The transition from G0 to G1 phase of cell cycle is regulated by different growth factors, which include epidermal growth factor (EGF), platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), transforming growth factor-α (TGF-α), transforming growth factor-β (TGF-β), fibroblast growth factor (FGF), placental growth factor (PGF), hepatocyte growth factor (HGF), insulin growth factor (IGF), tumor necrosis factor-α (TNF-α), granulocyte-colony stimulating factor (G-CSF), nerve growth factor (NGF) and keratinocyte-derived growth factor (KGF) also called FGF-7.
- **Growth factor signaling mechanisms:** Growth factors can act as initiators of signaling cascade in cells by paracrine–endocrine, or autocrine interactions.
  - Paracrine signaling allows cells to communicate each other by releasing molecules, that bind and activate surrounding cells such as platelet-derived growth factor (PDGF), that stimulates proliferation of vascular muscle cells. Paracrine communication maximizes cellular response fidelity in wound signaling to activate wound healing process in the surrounding cells.
  - Endocrine signaling uses circulatory system to transport ligands (hormones synthesized by endocrine cells) to communicate with distant target cells far away from the site of synthesis.
  - Autocrine signaling is characterized by the ability of a cell to respond to its own synthesized growth factors to initiate signal transduction.
- **Aberrant growth factors signaling and cancer:** Mutated cells with oncogenic potential become self-sufficient to synthesize the growth factors to which they respond. The increase in growth factors alone does not lead to development of malignant tumor but can cause rapid cell growth, that increases the chance of gene mutations.
  - Mutations in proto-oncogenes (oncogenes) result in the increased production of aberrant growth factors, e.g. EGF, PDGF, VEGF, TNF-α, TGF-α, TGF-β, FGF, PGF, HGF, IGF, G-CSF, NGF and KGF also called FGF-7 that enhance unrestricted CSC proliferation development of malignant tumor.
  - Proto-oncogenes may be altered to become oncogenes by various mechanisms, i.e. gene amplification, point mutation, chromosomal translocation, chromothripsis ('chromosome shattering of large stretches undergoing rearrangements in a single catastrophic event), and viral activation. Oncogenes (mutations in proto-oncogenes) result in the excess production of aberrant growth factor, that enhances unrestricted CSC proliferation and carcinogenesis.
  - Cancer stem cells (CSCs) often acquire the ability to become self-sufficient to synthesize their own growth factors (e.g. PDGF) to which they respond by forming '**autocrine loop**'. Autocrine signaling in CSC is shown in Fig. 6.109.

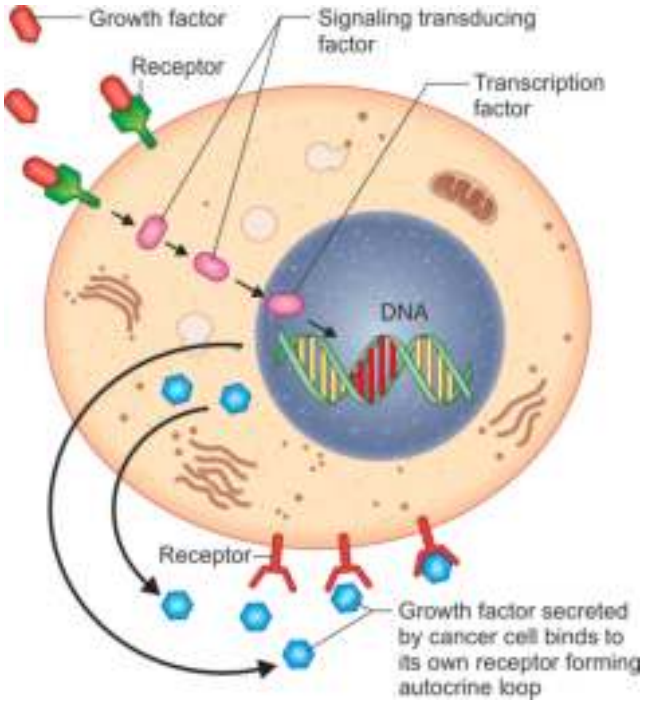

Fig. 6.109: Autocrine signaling in CSC. CSCs become self-sufficient to synthesize excessive aberrant growth factors to which they respond by forming an autocrine loop that enhances unrestricted cell division and induces malignant tumor.

Pathology Pearls: Four Classes of Growth Factors

- Class I growth factors bind to their cognate cell surface receptors.
- Class II growth factors bind to cytoplasmic domain of receptor tyrosine kinase (RTK).
- Class III growth factors consist of a group of intracellular signal transducers (e.g. RAS, SRC).
- Class IV growth factors are nuclear regulatory proteins that bind to DNA segments such as promoters, leading to either initiation of mRNA transcription or suppression of DNA transcription.
  - Fos, Myc, N-Myc and Myb initiate DNA transcription.
  - Tumor suppressors, i.e. TP53 gene (p53 protein) and RB gene (pRB) inhibit cell division.

Epidermal Growth Factor (EGF) Family

Epidermal growth factor (EGF) is synthesized by macrophages and platelets. EGF is also present in saliva, urine, milk and plasma. EGF binds to ErbB family of receptor tyrosine kinases such as ErbB1 (HER1), ErbB2 (HER2), ErbB3 (HER3), and ErbB4 (HER4). The binding between EGFR and ligand triggers series of downstream intracellular signaling.

Physiologic State

Epidermal growth factor (EGF) stimulates proliferation of normal cells (e.g. fibroblasts and epithelial cells), cell growth, differentiation, and granulation tissue formation. EGF plays an essential role in wound healing through stimulation of regeneration of epidermal and dermal cells.

Pathologic State

Aberrant EGF signaling can induce angiogenesis, unrestricted CSC proliferation malignant tumor growth, survival, invasion, metastasis and resistance to chemotherapy. EGFR mutation is implicated in development of lung adenocarcinoma, glioblastoma multiforme, and colon carcinoma.

Platelet-derived Growth Factor Family

Platelet-derived growth factor (PDGF) is a polypeptide synthesized by macrophages, smooth muscle cells, endothelial cells, and keratinocytes, and stored in platelets α-granules and released on platelet activation upon clotting process. PDGF binds to cognate cell receptor tyrosine kinase (i.e. PDGFRA or PDGFRB), and induces angiogenesis in healthy tissue and malignant tumor stroma.

Physiologic State

Platelet-derived growth factor (PDGF) plays a pivotal role in cell proliferation of connective tissue, migration, maturation of blood vessels and recruitment of pericytes by angiopoietins through the four isomers of PDGF (PDGFA, PDGFB, PDGFC, PDGFD). PDGF is a potent attractant for fibroblasts, which swam into wound site in order to reconstruct the tissue by wound contraction in tissue healing and repair within 48 hours. PDGF stimulates the production of matrix metalloproteinases (**MMPs**), and inhibits platelets aggregation and integrin expression.

Pathologic State

Certain PDGF receptor-bearing CSCs produce isoforms, which stimulate cell growth and survival by forming autocrine loop.

- Aberrant PDGF signaling plays a key role in tumorigenesis, unrestricted CSC proliferation, angiogenesis, evasion of apoptosis, migration, invasion, metastasis and chemoresistance in glioblastoma multiforme, breast carcinoma, lung carcinoma, gastric carcinoma, colon carcinoma, prostatic carcinoma, leukemia and other cancers.
- Overexpression of PDGF ligands and their cognate receptors on CSCs of malignant ovarian tumors is associated with ascites and poor prognosis. On contrary, paracrine aberrant signaling has been found in human cancers that originate from epithelial cells, where it may be involved in stromal cell recruitment, metastasis and epithelial–mesenchymal transition (**EMT**). Inhibition of PDGF receptor signaling has

proven useful for treatment of patients with certain rare cancers.

Vascular Endothelial Growth Factor Family

Vascular endothelial growth factor (VEGF) is a potent essential proangiogenic growth factor for vascular endothelial cells involved in angiogenesis during embryogenesis and postnatal life after sustaining an injury and notably in malignant tumors.

- VEGF family comprises VEGF-A, VEGF-B, VEGF-C, VEGF-D, and placental growth factor (PlGF). Some VEGF family members can also bind to NRPs, which function as coreceptors.
- VEGF and PlGF can interact with a combination of many VEGF receptors (VEGFR-1, VEGFR-2, VEGFR-3), which are part of the receptor tyrosine kinase superfamily.
- VEGF-A, VEGF-B, and PlGF ligands bind to VEGFR-1. VEGFR-2 interacts with VEGF-A, VEGF-B, and VEGF-C ligands. VEGFR-3 can bind to VEGF-C and VEGF-D.
- VEGF-VEGFR system is crucial for angiogenesis in healthy tissue and cancer stroma. Angiopoietin I and II stabilize the mature newly formed blood vessels.

Physiologic State

Vascular endothelial growth factor (VEGF) plays key role in angiogenesis in healthy tissue. Angiopoietin I and II stabilize mature newly formed blood vessels. VEGF signaling is induced by the binding of VEGF ligand to its cognate transmembrane receptor tyrosine kinase, which results in the activation of multiple downstream signaling pathways, which include: (a) RAS/RAF/MEK/ERK (MAPK) signaling pathway regulates vascular endothelial cell proliferation, survival, and gene expression, (b) PI3K/AKT/mTOR signaling pathway regulates cell survival, (c) phospholipase-C-γ (PLCγ) signaling pathway regulates vascular permeability, and (d) FAK/paxillin signaling pathway is involved in the rearrangement of cytoskeleton in vascular endothelial cells.

Pathologic State

Angiogenesis is prerequisite for continued growth of malignant tumor beyond 1–2 mm, but also for invasion and metastasis. Tumor angiogenesis supplies nutrients and oxygen to promote malignant tumor growth, invasion and metastasis. VEGF is overexpressed in a variety of solid malignant tumors and certain hematologic malignancies associated with poor prognosis.

- The production of VEGF and other growth factors by the malignant tumor results in the angiogenic **switch** '**turning on**', where new vasculature is formed within and around the malignant tumor, allowing it to grow exponentially.
- Tumor vasculature formed under the influence of VEGF is structurally and functionally abnormal. Newly formed tumor vasculature is irregularly shaped, tortuous, leaky and hemorrhagic having dead ends, and not organized into venules, arterioles and capillaries, which result in high interstitial pressure, suboptimal blood flow, and further VEGF production.

Fibroblast Growth Factors

Fibroblast growth factors (FGFs) are potent regulators of cells proliferation chemotaxis, migration and differentiation of fibroblasts and keratinocytes. FGFs are synthesized by macrophages, T cells, mast cells, endothelial cells, and fibroblasts. FGFs have a high affinity for heparan sulfate proteoglycans, leading to activation of one of four cell surface FGF receptors.

Physiologic State

In human beings, 22 members of the FGFs family have been identified, all of which are structurally related signaling molecules, which include: FGF1 (acidic FGF), FGF2 (basic FGF), and FGF7 (keratinocyte growth factor). FGFs bind to fibroblast growth factor receptor family, that has four members: FGFR1, FGFR2, FGFR3 and FGFR4.

- FGF signaling pathway is mediated by RAS/RAF/MEK/ERK (MAPK) signaling pathway, phosphatidylinositol-4,5-bisphosphate 3-kinase (PI3K)/AKT/mTOR signaling pathway and phospholipase C-γ (PLC-γ), signal transducers and activators of transcription (STAT), which intersects and synergizes with Wnt/β-catenin of signaling pathways.
- FGFs are critically important in normal development of tissue, maintenance, angiogenesis in somatic stem cells, complete regeneration of a tissue, tissue repair, wound contraction, and matrix deposition in response to injury in postnatal life. Recent studies have revealed that FGF can act synergistically with VEGF to amplify angiogenesis.

Pathologic State

Aberrant expression of some FGFs can contribute to carcinogenesis, FGFs exert autocrine and paracrine functions on tumor cells and stromal cells. Aberrant FGFs play key role in unrestricted cell proliferation, migration, angiogenesis, invasion, metastasis, chemoresistance, and recurrence associated with poor survival.

- **FGF1 gene mutation:** FGF1 mutation is linked to urothelial carcinoma, solid malignant tumors, multiple myeloma, anaplastic astrocytoma, anaplastic oligodendroglioma, glioblastoma multiforme, endometrial carcinoma, cholangiocarcinoma, gastric

carcinoma, and squamous cell lung carcinoma. FGF1 also induces resistance to chemotherapy in ovarian granulosa cell tumor through inhibition of p53 transcriptional activities.

- **FGF2 gene mutation:** FGF2 gene mutation and its overexpression is linked to esophageal carcinoma, renal cell carcinoma, non-Hodgkin's lymphoma, chronic lymphocytic leukemia (CLL), hairy cell leukemia (HCL), multiple myeloma (MM), pancreatic carcinoma, hepatocellular carcinoma, small cell lung carcinoma, non-small cell lung carcinoma, breast carcinoma, prostatic carcinoma, colorectal carcinoma, Ewing sarcoma, hepatocellular carcinoma, ovarian carcinoma, urothelial carcinoma, gastric carcinoma and Kaposi sarcoma.
- **FGF3 gene mutation:** FGF3 gene mutations such as amplification, missense mutations, silent mutations and frameshift insertion have been observed in endometrial carcinoma, gastric carcinoma, colon carcinoma, invasive ductal and lobular breast carcinoma, urothelial carcinoma, lung carcinoma and skin melanoma.

Transforming Growth Factor-α

Transforming growth factor-α (TGF-α) is a protein encoded by the TGF-α gene synthesized by macrophages, T cells, vascular endothelial cells, platelets and keratinocytes. Binding of TGF-α to epidermal growth factor receptor (EGFR) activates a signaling pathway involved in regulation of cell proliferation, differentiation, migration and development.

Physiologic State

TGF-α participates in cell proliferation and migration of keratinocytes involved in granulation tissue formation. TGF-α and its cognate EGF receptor are involved in numerous developing adult epithelial and mesenchymal tissues including gastrointestinal mucosa, lung, liver, kidney, mammary gland, dermis, gonads, skeletal muscle, and nerve cells in central peripheral nervous systems.

Pathologic State

Aberrant TGF-α autocrine and paracrine signaling has been implicated in many human cancers including primary breast carcinoma (50–70%), colorectal carcinoma, hepatocellular carcinoma, urothelial carcinoma, neuroblastoma, astrocytoma, cervical carcinoma, and vulvar carcinoma.

Transforming Growth Factor-β

Transforming growth factor-β (TGF-β) is a multifunctional cytokine belonging to the TGF superfamily, that include TGF-β1, TGF-β2 and TGF-β3. TGF-β is synthesized by all white blood cell lineages, vascular endothelial cells, smooth muscle cells, fibroblasts and keratinocytes. TGF-β inhibits synthesis of matrix metalloproteinases (MMPs) and keratinocytes. TGF-β regulates integrin expression and other cytokines.

Physiologic State

Transforming growth factor-β (TGF-β) cytokine plays critical roles in embryonic stem cell self-renewal and differentiation, homeostasis of differentiated cells, suppression of immune system, and inhibition of cell cycle progression.

Pathologic State

Transforming growth factor-β (TGF-β) cytokine plays dichotomous role in tumor progression. In normal and premalignant cells, TGF-β promotes cell-cycle arrest and apoptosis via induction of tumor suppressors (CDK inhibitors $p15^{INK4B}$ and $p21^{CIP1}$), and c-Myc suppression.

- In the late-stage, upregulation of TGF-β activates downstream oncogenes resulting in tumor initiation and promotion, epithelial–mesenchymal transition (EMT), unrestricted proliferation of CSCs, metastasis and chemoresistance.
- Due to its potent tumor suppressor effects in early stage, TGF-β signaling is lost in human cancers, which is a hallmark of cancer. Mutations or deletions of genes encoding components of the signaling pathway frequently occur in a variety of human cancers of colon, gastric region and pancreas. Taking TGF-β/SMAD4 as an example, its mutations or deletions are demonstrated in 50% of pancreatic cancer patients.

Insulin-like Growth Factor Family

The insulin-like growth factors (IGFs) are proteins with high sequence, similarity to insulin. IGF family has two members: IGF1 and IGF2. IGF1 gene encodes growth hormone. IGF2 gene provides instructions for making a protein called IGF2.

Physiologic State

Binding of IGF1 or IGF2 proteins with specific cell surface receptors activate various intracellular signaling pathways, and regulate cellular functions such as skeletal muscle growth and differentiation.

- IGF1 plays an essential role in brain growth and development, and tissue repair in response damaged to central and peripheral nervous systems during postnatal life.
- IGF2 regulates cell growth, cell proliferation in various tissues, apoptosis, and embryonic development. IGF2 gene is highly active during fetal development, but it is much less active after birth. IGF2 induces expression of the cyclin-dependent kinase inhibitor p21 to promote cell cycle exist.

Pathologic State

Aberrant insulin-like growth factor 1 (IGF-1) promotes development of malignant tumor growth by stimulating unrestricted CSC proliferation, angiogenesis and inhibition of apoptosis. Aberrant insulin-like growth factor 1 (IGF-1) signaling pathway is linked to breast carcinoma, colorectal carcinoma, and prostatic carcinoma. Therapy is aimed to block IGF-IR signaling, that inhibits downstream signaling pathways in these cancers.

Hepatocyte Growth Factor

Hepatocyte growth factor (HGF)/scatter factor (SF) is synthesized by mesenchymal stem cells (e.g. fibroblasts, vascular endothelial cells, and hepatocyte mesenchymal cells).

Physiologic State

HGF/SF plays key roles in regulation of cell growth, motility, morphogenesis of epithelial cells, and hematopoietic stem cells through its receptor c-Met. On binding of HGF to its cognate cell surface receptor c-Met activates signaling pathways resulting in angiogenesis, development of organs, and other morphogenesisprocesses.

Pathologic State

Increased baseline activity of HGF oncogene product and its receptor Met activation triggers RAS/RAF/MEK/ERK (MAPK) signaling pathway, PI3K/AKT/mTOR signaling pathway, and JAK/STAT signaling pathway, which promote angiogenesis, epithelial–mesenchymal transition (EMT), inhibition of E-cadherin expression, cell scattering, unrestricted CSC proliferation, cell survival, evasion of apoptosis, invasion and metastasis of various human cancers (e.g. colon carcinoma, hepatocellular carcinoma, and thyroid carcinoma).

Neurotrophic Factor Family

Neurotrophic factor family members include nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4/-5 (NT-4/-5). These are small, basic secretory proteins that allow the survival of specific neuronal populations during embryo development and postnatal life.

Physiologic State

Binding of neutrophins to their cognate Trk (tropomyosin-receptor kinase) tyrosine kinase receptors (TRKA, TRKB, TRKC), activate RAS/RAF/MEK/ERK mitogen-activated protein kinases (MAPKs) signaling pathway, phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR signaling pathway, and phospholipase C-γ (PLC-γ) signaling pathway, which are involved in cell survival, proliferation, differentiation, and apoptosis.

Pathologic State

Overexpression or mutation of Trk and receptor tyrosine kinases (RTKs) has been demonstrated in CNS tumors (neuroblastoma and medulloblastoma), thyroid carcinoma, breast carcinoma, lung carcinoma and prostatic carcinoma. Recent studies revealed that neurotrophic factors as well as neurotrophin receptors are present within the normal human prostate gland, benign nodular hyperplasia of prostate and prostatic carcinoma.

CELL SURFACE RECEPTORS

Cell surface receptors are membrane-anchored proteins either inside cell or its cell surface, which receive a signal. Majority of cell surface growth factor receptors are transmembrane receptor tyrosine kinases (RTKs). Growth factor binding to transmembrane receptor kinases leads to phosphorylation of tyrosine residues on several intracellular signaling molecules, which transmit signal to inside the cell, and involved in numerous cellular processes such as cell migration, proliferation, differentiation and survival. Oncogenes (mutated proto-oncogenes) result in the increased activation of aberrant transmembrane receptor tyrosine kinases. Oncogenes can induce transmembrane receptor tyrosine kinases to become constitutively active without need for growth factors (e.g. EGFR, PDGFR, VEGFR, TGF-αR, TGF-βR, FGFR, HGFR, IGFR) on the surface of cells to which growth factors bind.

- **Cell surface receptor components:** Each cell surface receptor has three main components: (a) external ligand-binding domain (extracellular domain), (b) hydrophobic membrane spanning region, and (c) intracellular domain inside the cell. The size and extent of each of these domains of cell surface receptors vary widely, depending on the type of receptors such as PDGFR, EGFR (EGFR-A, EGFR-B, EGFR-C, EGFR-D)/ErbB1, HER2/neu/ErbB2, FGFR2/ErbB1, FGFR3, c-Met, VEGFR, IGFR, RET (rearranged during transfection), KIT, Ret, FLT-3, ErbB3 and ErbB4.
- **Three general categories of cell surface growth factor receptors:** Three general categories of cell surface receptors include: G protein-linked receptors (seven-transmembrane receptors), enzyme-linked receptors, and ion channel-linked receptors. Signal transducing cell surface receptors involved in carcinogenesis are given in Table 6.87.
  - **G protein-coupled cell surface receptors:** G protein-coupled linked cell surface receptors (GPCRs), also called seven-transmembrane receptors are present in the cell membrane.

Table 6.87 Signal transducing cell surface receptors involved in carcinogenesis

Cell Receptor Category	Prototypical Ligands
Receptor tyrosine kinases (RTKs)	EGF, IGF-1
G protein-coupled receptor (GPCR)	Prostaglandins, RANTES, SDF1
Serine/threonine kinases	TGF-β
Kinase associated receptors	GH, TCR, IL-2
Nuclear receptors	Androgen, estrogen, other steroid hormones
Extracellular matrix (ECM) receptors	Fibronectin. collagen, laminin

EGF: Epidermal growth factor; IGF-1: Insulin-like growth factor 1, RANTES: Regulated upon activation, normal T cell expressed and secreted, also known as CCL5; SDF1: Stromal cell-derived factor-1, also known as CXCL12; TGF-β: transforming growth factor-β, GH: Growth hormone; TCR: T cell receptor, IL-2; interleukin-2.

G protein-linked cell surface receptors bind to cognate growth factor ligands on cell surface receptors and transmit signals into intracellular G protein (guanine nucleotide-binding protein), molecule including peptide hormones and neuropeptides. G proteins have three subunits: α, β, and γ. When a signaling molecule binds to G protein-linked receptor in the plasma membrane, GDP molecule associated with the α subunit is exchanged for GTP. The β, and γ subunits dissociate from the α subunit, and a cellular response is triggered either by α subunit or the dissociated β pair. Hydrolysis of GTP to GDP terminates the signal. Aberrant expression and activation of G proteins, and G protein-linked receptors are frequently associated with carcinogenesis.

- **Enzyme-linked cell surface receptors:** Enzyme-linked cell surface receptors bind to cognate growth factor with intracellular domains that are associated with an enzyme such as receptor tyrosine kinases (RTKs), receptor serine/threonine kinases, receptor-like tyrosine phosphatases, histidine kinase associated receptors and receptor guanylyl cyclases.
- **Ligand-gated ion channel cell surface receptors:** Ion channel-linked cell surface receptors have an extensive membrane spanning region, which bind a ligand and open a gated channel through the membrane that allow specific ions to inflow into the cell or outflow from the cell. Ion channel-linked receptors are involved in the cellular response to toxins and venoms in various cells such as cardiac, skeletal and smooth muscle contraction, T cell activation and hormone release.

- **Integrin receptors:** Integrins are heterodimeric transmembrane receptors bind to extracellular matrix (ECM) glycoproteins (i.e. laminin, collagen in the basement membrane and fibronectin), and the actin cytoskeleton.
- **Deregulated firing of cell surface receptors:** Normally functioning cell surface receptors displayed on the plasma membrane of a cell emit signals into the cell interior only when the extracellular domain of the cell surface receptor has bound appropriate growth factor ligand.
  - Excessive numbers of normal structured cell surface receptor molecules can also drive ligand-independent signaling into cell interior.
  - In contrast, in many types of human cancers, CSCs acquire the ability to make a ligand for a cell surface receptor that they also display. This creates an auto-stimulatory or autocrine signaling loop.
  - An example of autocrine signaling is seen in these successive sections of an invasive breast carcinoma, in which islands of CSCs are surrounded by non-staining stroma.
  - However, if the extracellular domain of certain cell surface receptors is deleted because of a mutation in gene encoding cell surface receptor or alternate splicing of the receptor pre-mRNA or subtle alterations in protein structure, such as amino acid substitutions, the resulting truncated extracellular domain receptor protein then emits signals into the cell ligand-independent firing without binding its cognate growth factor ligand leading to unrestricted proliferation of cancer stem cells. Mutant growth factors and receptor tyrosine kinases linked to human cancers are given in Table 6.88.
- **Receptor tyrosine kinase (RTK) activation in normal cells:** Receptor tyrosine kinases can be further categorized into RTKs and nonreceptor tyrosine kinases (NRTKs). RTKs are transmembrane cell proteins, that act as signal transducers, which regulate cell proliferation, differentiation, survival apoptosis and metabolism.
  - **Structure of receptor tyrosine kinases:** All the RTKs possess similar structures except platelet-derived growth factor receptor (PDGFR): (a) ecto-domain protrudes into the extracellular space that binds to extracellular ligands (e.g. Sis, Hst), and (b) cytoplasmic domain transmits signals within the cell.
  - **Classification of receptor tyrosine kinases family:** Receptor tyrosine kinases are classified by according to family, which include: EGFR, PDGFR, VEGFR, FGFR, HGFR, NGFR, EPHR, TIE, DDR, RET, ROS, LTK, ROR, MUSK, and LMR.

Table 6.88 Mutant growth factors and receptor tyrosine kinases (RTKs) linked to human cancers

Growth Factor Main Ligand	Growth Factor Receptor	Cells Responding to Growth Factor	Type of Genetic Alteration	Type of Human Cancer
PDGF (A, B, C, D) (platelet-derived growth factor)	PDGFR	Endothelial cells, vascular smooth muscle cells, other mesenchymal cells, glial cells	Translocation	Chronic myelomonocytic leukemia
EGF (epidermal growth factor)	EGFR-A, EGFR-B, EGFR-C, EGFR-D	Epithelial cells, some mesenchymal cells	Overexpression	▪ Non-small cell lung carcinoma ▪ Breast carcinoma ▪ Colorectal carcinoma ▪ Esophageal carcinoma ▪ Head and neck carcinoma ▪ Prostatic carcinoma ▪ Renal cell carcinoma ▪ Urinary bladder carcinoma ▪ Ovarian carcinoma ▪ Glioblastoma multiforme
No ligand	EGFR/ERBB1	Not applicable	Truncation of ectodomain	▪ Lung carcinoma ▪ Glioblastoma multiforme
NRG (neuregulin), EGF	HER2/neu/ErbB2	Neurons	Overexpression	Breast carcinoma (30%)
FGF (fibroblast growth factor)	FGFR2/ErbB1	Mesenchymal cells, neuroectodermal cells	Amino acid substitutions	▪ Breast carcinoma ▪ Gastric carcinoma ▪ Endometrial carcinoma
FGF (fibroblast growth factor)	FGFR3	Endothelial cells, hematopoietic cells	▪ Overexpression ▪ Amino acid substitutions ▪ Translocations	▪ Urinary bladder carcinoma ▪ Cervical carcinoma ▪ Acute myelogenous leukemia (AML) ▪ Multiple myeloma
HGF/SF (hepatocyte growth factor/scatter factor)	c-Met	Epithelial cells	Overexpression	▪ Osteosarcoma ▪ Glioblastoma multiforme ▪ Breast carcinoma ▪ Prostatic carcinoma ▪ Lung carcinoma
VEGF (vascular endothelial growth factor)	VEGFR	Endothelial cells lining capillaries and lymphatic channels	Overexpression	▪ Breast carcinoma ▪ Angiosarcoma
IGF (insulin growth factor)	IGFR	Wide variety of cell types	Overexpression	▪ Breast carcinoma ▪ Prostatic carcinoma ▪ Lung carcinoma ▪ Colorectal carcinoma
GDNF (glial cell line-derived neurotrophic factor)	RET (rearranged during transfection)	Neuroectodermal cells	Overexpression	▪ Breast carcinoma ▪ Multiple endocrine neoplasia 2 (MEN-2)
SCF (stem cell factor)	KIT	Hematopoietic cells, mesenchymal cells	Amino acid substitutions	Gastrointestinal stromal tumors

Contd...

Table 6.88 Mutant growth factors and receptor tyrosine kinases (RTKs) linked to human cancers (*Contd...*)

Growth Factor Main Ligand	Growth Factor Receptor	Cells Responding to Growth Factor	Type of Genetic Alteration	Type of Human Cancer
GFL	Ret	Thyroid follicular cells	Fusion with other proteins	▪ Papillary thyroid carcinoma ▪ Multiple endocrine neoplasia 2A and 2B
FL (FLT-3)	FLT-3	Myeloid precursors	Tandem duplication	Acute myelogenous leukemia (AML)
Various ligands	ErbB3, ErbB4	Oral epithelial cells	Overexpression	Oral squamous cell carcinoma

Once converted from proto-oncogenes, oncogenes function by synthesizing mutant forms of cellular proteins such as growth factors, cell surface growth factor receptors, signal transducing proteins, nuclear regulatory proteins (transcription factors), chromatin remodeler proteins, cell cycle regulatory proteins, apoptosis regulatory proteins and DNA repair proteins resulting in carcinogenesis.

- **Activation of receptor tyrosine kinases:** RTK activation occurs through the binding of a ligand to the cell surface receptor, which then induces cell surface receptor dimerization. Once ligand-induced dimerization occurs, it activates the intracellular receptor tyrosine kinase domain through the transmembrane domain. RTK activation occurs when this *cis*-autoinhibition is released after ligand binding and dimerization.

- **Receptor tyrosine kinase (RTK) activation in cancer stem cells:** Oncogenes may activate or increase expression of cellular receptors to which growth factors bind. Mutant cellular receptors deliver continuous mitogenic signals to the cell, even in the absence of growth factor in the environment allowing cell surface receptor to signal downstream unrestricted CSC proliferation. For example, an oncogene can code for an incomplete EGF receptor that no longer requires ligand binding for activation.
  - **Mechanisms of receptor tyrosine kinase activation:** Increased receptor tyrosine kinase (RTK) activity occurs by several mechanisms: overexpression, gain-of-function mutations, autocrine activation and chromosomal translocation/chimeric fusion protein. RTK activation can be influenced by tyrosine kinase domain duplications, microRNAs, alterations in tumor microenvironment, and negative RTK signaling regulators and deregulation of RTK. Genetic alterations of RTKs deliver continuous mitogenic signals to the cell, even in the absence of growth factor in the extracellular environment leading to unrestricted CSC proliferation and initiation of carcinogenesis. For example, an oncogene can code for an incomplete EGF receptor that no longer requires ligand binding for activation.
  - **Tyrosine kinase inhibitors in clinical oncology:** Tyrosine kinase inhibitors (TKIs) influence RTK activation and their downstream signaling pathways resulting in increased apoptosis, decreased CSC proliferation and migration in malignancies.

Epidermal Growth Factor Receptor (EGFR) Family Members: Receptor Tyrosine Kinase

Epidermal growth factor receptor (EGFR) family has four members, which include ErbB1, ErbB2 (HER2/neu), ErbB3 and ErbB4. Mutations in epidermal growth factor receptor (EGFR) family are implicated in development of many human cancers.

Physiologic State

Epidermal growth factor receptor (EGFR) binds at least seven different ligands, which include: EGF, TNF-α, heparin-binding EGF-like growth factor (HBEGF), β-cellulin (BTC), amphiregulin (AREG), epiregulin (EREG) and epigen (EPGN). Binding of EGFR to cognate EGF ligand activate multiple signaling pathways, i.e. RAS/RAF/MEK/ERK (MAPK/ERK) signaling pathway, phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR signaling pathway, and JAK/STAT signaling pathway resulting in cell migration, proliferation and survival respectively.

Pathologic State

Epidermal growth factor receptor (EGFR) family members are activated in many high-grade human cancers. Point mutation, amplification and overexpression of EGFR family members (ErbB1, ErbB2 [HER2/neu], ErbB3, and ErbB4) are linked to high-grade human cancers.

- **Point mutation in EGFR gene:** Point mutation in EGFR gene results in constitutive activation of epidermal growth factor receptor tyrosine kinase leading to unrestricted CSC proliferation.
- **Amplification in EGFR gene:** Amplification of EGFR family members such as ErbB1, ErbB2 (HER2/neu) and ErbB3 genes has been implicated in many human cancers. EGFR gene amplification causes sustained activation of EGFR receptor tyrosine kinase activity that stimulates unrestricted CSC proliferation, angiogenesis, cell survival, cell migration and metastasis.

Table 6.89 Gene amplifications in ErbB family of cell surface receptors associated with human cancers

Gene Amplification	Human Cancers
ErbB1 gene	Lung adenocarcinoma
ErbB2 gene (HER2/neu)	Breast carcinoma, ovarian carcinoma, adenocarcinoma lung cancers (adenocarcinoma, squamous cell carcinoma) and salivary gland cancers
ErbB3 gene	Breast carcinoma. prostatic carcinoma and urinary bladder carcinoma

- **ErbB1 gene amplification** is implicated in development of lung adenocarcinoma, breast carcinoma, prostatic carcinoma and urinary bladder carcinoma.
- **ErbB2 gene (HER2/neu) gene amplification** is linked to breast carcinoma, ovarian carcinoma, lung adenocarcinoma, squamous cell lung carcinoma and salivary gland cancers.
- Gene amplifications in ErbB family of cell surface receptors associated with human cancers are given in Table 6.89.

- **Overexpression of EGFR gene:** Overexpression of EGFR gene in human cancers is indicative of high-grade malignant tumor, invasion of lymph nodes with high rate of recurrence and fatal outcome. EGFR family member ErbB proteins can be demonstrated by immunohistochemistry technique by application of monoclonal antibody on the cell membrane, or using fluorescent *in situ* hybridization (FISH) technique.

Targeted Therapy

Monoclonal antibodies and tyrosine kinase inhibitors (TKIs) are currently used to target EGFR mutations in human cancers. Monoclonal antibodies (e.g. cetuximab and panitumumab) bind to extracellular domain of EGFR to prevent ligands from activating the EGFR. TKIs bind to the cytosolic domain of EGFR, and prevents activation process. Anti-EGFR antibodies are targeted to the external ligand binding domains while the small inhibitors or TKIs target its cytoplasmic receptor tyrosine kinase domains. Genetic mutations in K-RAS, BRAF, and ALK translocation predict poor response to EGFR therapy.

Vascular Endothelial Growth Factor Receptor

Vascular endothelial growth factor receptor is receptor tyrosine kinase (RTK) expressed on the plasma membrane of endothelial cells. There are three types of vascular endothelial growth factor receptors (VEGFRs), namely VEGFR1, VEGFR2, VEGFR3, whereas there are five structurally related VEGF ligands including VEGF-A, VEGF-B, VEGF-C, VEGF-D, and placental growth factor. There are also co-receptors involved in ligand binding called neuropilins (NRPs).

Physiologic State

Normally, VEGF binding to cognate VEGFR and transmit signals via intracellular signaling pathways, i.e. RAS/RAF/MEK/ERK (MAPK) pathway, PI3K/AKT/mTOR pathway and phospholipase C-γ (PLC-γ) pathway to other signal transduction effectors via autophosphorylation of specific residues in its structure leading to induction of angiogenesis and lymphangiogenesis during embryonic development and adult life.

Pathologic State

Binding of VEGF ligand to mutated VEGFR activates angiogenic switch signal, which remains constantly 'turning on' without 'urning off' leading to formation of structurally and functionally new blood vessels in and around malignant tumor growth, before a malignant tumor can grow beyond 1–2 mm. The newly formed blood vessels are irregularly shaped, tortuous, leaky, hemorrhagic, having dead ends, and not organized into venules, arterioles and capillaries. Tumor angiogenesis plays a key role in malignant tumor growth, invasion and metastasis.

- Amplification of vascular endothelial growth factor receptor (VEGFR) gene is linked to breast carcinoma, lung carcinoma, urothelial carcinoma, colorectal carcinoma, ovarian carcinoma, gastric carcinoma, pancreatic carcinoma, glioblastoma multiforme, renal cell carcinoma and multiple myeloma.

Targeted Therapy

Targeted therapy works in two different ways to inhibit VEGFR: (a) therapeutic agent prevents a VEGF ligand from binding to VEGFR outside the cell, or (b) therapeutic agent prevents signal from VEGFR from reaching other intracellular proteins inside the cell, that inhibit growth of malignant tumor.

Fibroblast Growth Factor Receptor

Fibroblast growth factor receptor (FGFR) family consists of four members (FGFR1, FGFR2, FGFR3, and FGFR4) encoded by different genes. FGFRs are receptor tyrosine kinases (RTKs). All of them have two different isomers produced by alternative splicing except FGFR4.

Physiologic State

Fibroblast growth factor receptors (FGFRs) are receptor tyrosine kinases expressed on the cell membrane. FGFR binds to FGF ligand and activates downstream signaling pathways, which play essential role in cellular processes such as cell growth, proliferation, differentiation, angiogenesis, and wound healing during embryonic development and adult life.

Pathologic State

In malignant tumors containing genetically altered FGFRs, the most frequent genetic alteration in FGFR1 (most common), FGFR2, FGFR3 and FGFR4 (least common) can be observed in decreased frequency. Genetic alterations in FGFRs occur due to gene amplification, point mutation and formation of oncogenic gene fusions.

- **FGFR gene amplification:** The most common genetic alteration is the amplification of FGFR genes.
  - FGFR1 gene amplification is linked to lung carcinoma and breast carcinoma.
  - FGFR2 gene amplification is linked to gastric carcinoma.
- **FGFR gene point mutation:** Point mutations in FGFRs are found in breast carcinoma, colon carcinoma, lung carcinoma, head and neck squamous cell carcinoma, and glioblastoma multiforme.
- **Oncogenic FGFRs-TCCC3 gene fusions:** FGFR2 and FGFR3 are commonly involved in the formation of oncogenic fusion gene. FGFR3-TACC3 oncogenic fusion gene has been observed in lung carcinoma, cervical carcinoma, urinary bladder carcinoma, nasopharyngeal carcinoma, and glioblastoma multiforme.

Targeted Therapy

FGFRs have been considered as promising drug targets for therapy of various human cancers. Multiple small molecule inhibitors targeting FGFRs family of receptor tyrosine kinases have been developed. Pan-FGFR inhibitor erdafitinib has been recently approved for the treatment of metastatic or unresectable urothelial carcinoma.

Platelet-derived Growth Factor Receptor Family

Platelet-derived growth factor receptor (PDGFR) is cell surface receptor tyrosine kinase (RTK). PDGFR has four members, which include: PDGFRA, PDGFRB, PDGFRC, and PDGFRD. Mutations in PDGFR family are linked to human cancers.

Physiologic State

Platelet-derived growth factor receptor (PDGFR) is essential for regulation of embryonic development, cell proliferation, migration, and angiogenesis.

Pathologic State

Mutation in PDGFR is linked to cancer progression by stimulating proliferation of CSCs, angiogenesis, epithelial–mesenchymal transition (EMT), evasion of apoptosis, migration, invasion, metastasis, and chemoresistance of certain human cancers.

- **Mutations in PDGFR genes:** Mutations in PDGFR receptor genes have been found in certain human cancers. Increased PDGF signaling has a key role in cancer progression, unrestricted CSC proliferation of angiogenesis, evasion of apoptosis, migration, invasion, metastasis and chemoresistance.
- **Autocrine PDGFR signaling:** Autocrine PDGFR signaling has been implicated in the development of glioblastoma multiforme and leukemia.
- **Paracrine PDGFR signaling:** In contrast, paracrine signaling due to overexpression of PDGFR has been observed in human cancers that originate from epithelial cells (e.g. breast carcinoma, lung carcinoma, gastric carcinoma, colon carcinoma, prostatic carcinoma and other cancers), where it may be involved in epithelial–mesenchymal transition (EMT), invasion and metastasis.

Insulin-like Growth Factor-1 Receptor

Insulin-like growth factor-1 receptor (IGF1R) is transmembrane receptor tyrosine kinase (RTK), that binds insulin-like growth factor-1 (IGF1) with high affinity and IGF2 with a lower affinity. IGF1R plays a key role in cellular transformation events. Cleavage of the precursor generates α and β subunits of IGF1R.

Physiologic State

Insulin-like growth factor-1 (IGF1) binding to receptor tyrosine kinase results in its activation and autophosphorylation as well as phosphorylation of multiple substrates, that function as adaptor proteins, including insulin receptor substrates (IRS1/IRS2), SHC1 transforming protein (apoptosis protein) and 14-3-3-signaling proteins such as kinases, phosphatases and transmembrane receptors.

- Phosphorylation of IRS1/IRS2 proteins activate RAS/RAF/MEK/ERK (MAPK/ERK) signaling pathway, and phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR signaling pathway.
- Activated RAS/RAF/MEK/ERK (MAPK) pathway regulates cell proliferation, and phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR signaling pathway stimulates protein synthesis, and inhibits apoptosis.

Pathologic State

Insulin-like growth factor-1 receptor (IGF1R) is overexpressed in most human cancers, where it inhibits apoptosis of CSCs, and thus enhances their survival. Mutations in IGF1R (i.e. missense mutations, nonsense mutations, silent mutations, frameshift deletions) are linked to development of colon carcinoma, gastric carcinoma, breast ductal carcinoma, lung adenocarcinoma, and cutaneous melanoma. IGF1R is a membrane

protein that binds SHC/ERa. Overexpression of SHC proteins is associated with malignant tumor development, invasion and metastasis.

Hepatocyte Growth Factor Receptor

The hepatocyte growth factor receptor (HGFR), also known as MET or c-Met is a receptor tyrosine kinase (RTK) encoded by MET gene, which binds to its ligand hepatocyte growth factor/scatter factor (HGF/SF) and its splicing isoform (NK1, NK2) involved in cell proliferation, migration and morphogenesis.

Physiologic State

Normally, HGF-induced Met receptor tyrosine kinase is tightly regulated by paracrine ligand delivery, ligand activation on the target cell surface, and the ligand activated Met receptor tyrosine kinase internalization and degradation.

- Hepatocyte growth factor and its HGF receptor tyrosine kinase (RTK) encoded by c-Met proto-oncogene are essential for embryonic development, organogenesis, and wound healing. The ligand/receptor system regulates essential cellular processes such as cell proliferation and motility, morphogenesis and differentiation.
- Hepatocyte growth factor (HGF) messenger RNA is expressed primarily is mesenchymal cells, but not in epithelial cells, while its receptor (HGFR) is predominantly expressed in epithelial cells. This pattern of HGH and HGFR gene expression in combination with the unique biological effects of HGF on its target cells has suggested that HGF mediates crosslink between the epithelial and stromal components of a given tissue/organ.

Pathologic State

Hepatocyte growth factor (HGF)-induced Met receptor tyrosine kinase signaling contributes to oncogenesis and tumor progression in many human cancers and promotes tumor angiogenesis, invasion and metastasis. Expression of HGF and HGFR genes is orchesterized in stromal and epithelial respectively by extracellular signals derived from steroid hormones and cytokines such as IL-1, IL-6 and TNF-α.

- Overexpression of HGF and HGFR genes is linked to development of breast carcinoma, non-small cell lung carcinoma and associated with lymph node invasion mediated by **rho overexpression**, ovarian carcinoma, gastric carcinoma, colon carcinoma, lung carcinoma, skin carcinoma and hereditary or sporadic papillary renal cell carcinoma.
- Met exon mutations predominantly occur in elderly patients with lung adenocarcinoma.
  - Patients with advanced-stage non-small cell lung carcinoma have c-Met mutations, and also concurrent Met gene amplification and gene fusions at exon 15 such as HLA-DRB1-Met, KIF5B-Met, METUBE2H and MET-ATXNL7L1.
  - Overexpression of c-Met is correlated to distant metastasis, large tumor size and high histologic grade in breast carcinoma.
- Autocrine activation of HGF/c-Met signaling has been observed in colorectal carcinoma and acute myelogenous leukemia (AML) involving β-catenin and co-activation of FGFR1, and also development of chemoresistance against multikinase inhibitors in hepatocellular carcinoma.

RET (Rearranged during Transfection) Receptor Tyrosine Kinase

RET (rearranged during transfection) proto-oncogene located on chromosome 10q11.2 encodes a RET receptor tyrosine kinase involved in glial cell-derived neurotrophic factor (GDNF) of extracellular signaling molecules. RET protein dimerization results in autophosphorylation of several intracellular transduction proteins tyrosine kinase.

Physiologic State

RET receptor tyrosine kinases are present on normal cells. Upon binding of GDFN family ligand to RET receptor tyrosine kinase activates RAS/RAF/MEK/ERK (MAPK) signaling pathway, phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR signaling pathway induce cell proliferation, differentiation, neuronal navigation and cell migration.

Pathologic State

Point mutation in RET receptor tyrosine kinase is linked to development of human cancers such as familial or sporadic medullary thyroid carcinoma, and papillary thyroid carcinoma; and multiple endocrine neoplasia 2A, 2B (MEN-2A, MEN-2B).

Targeted Therapy

Targeted cancer therapies block RET receptor tyrosine kinase by two mechanisms: (a) outside the cell, chemotherapeutic agent can prevent a ligand from binding RET receptor, and (b) inside the cell, chemotherapeutic agent can prevent the signal from RET receptor from reaching other proteins, which promote cell growth and progression of malignant tumor.

c-KIT (CD117) Proto-oncogene Encodes Receptor Tyrosine Kinase

c-KIT (CD117) proto-oncogene mapped on chromosome 4q12 encodes a transmembrane protein with

intrinsic tyrosine kinase activity, which functions as the receptor for stem cell factor (SCF). It is expressed on mast cells, hematopoietic progenitor cells (myeloid, lymphoid, erythroid, and megakaryocytic progenitor cells), gastrointestinal pacemaker cells, melanocytes and germ cells. SCF assists in the recovery of cardiac function following myocardial infarction by increasing the number of cardiomyocytes and vascular channel.

Physiologic State

c-KIT (CD117) through interactions with its ligand stem cell factor (SCF) induces receptor tyrosine kinase (RTK) dimerization, activation of receptor tyrosine kinase activity and initiation of several signal transduction pathways that regulate cell proliferation, differentiation, mobilization of hematopoietic stem cells and progenitor cells (myeloid, lymphoid, erythroid and megakaryocytic cells).

Pathologic State

c-KIT (CD117), a receptor tyrosine kinase is involved in intracellular signaling. Overactivation of receptor tyrosine kinase c-KIT (CD117) induces alterations in the signaling pathways leading to unrestricted CSC proliferation, differentiation, migration and survival. Gain-of-function or point mutations in c-KIT (CD117) receptor tyrosine kinase have been linked to several human cancers such as gastrointestinal stromal tumors (GISTs), seminoma and acute myelogenous leukemia (AML).

Targeted Therapy

Targeting receptor tyrosine kinase c-KIT mutations in solid tumors are scientific rationale and novel therapeutic options.

Anaplastic Lymphoma Kinase (ALK) Proto-oncogene Encodes ALK Receptor Tyrosine Kinase

Anaplastic lymphoma kinase (ALK) proto-oncogene encodes ALK receptor tyrosine kinase (RTK), that binds to growth factors such as pleiotrophin (PTN) and midkine (MK); and transmits signals from the cell surface to within the cell through a process called transduction. ALK protein dimerization results in autophosphorylation of several intracellular ALK receptor tyrosine kinase.

Physiologic State

Anaplastic lymphoma kinase (ALK) receptor tyrosine kinase plays a pivotal role in cellular communication, normal development and function of the nervous system.

Pathologic State

Translocation/amplification of ALK (anaplastic lymphoma kinase) receptor tyrosine kinase is demonstrated in neuroblastoma.

- Point mutation of ALK receptor tyrosine kinase is demonstrated in lung adenocarcinoma.
- Constitutive activation of receptor tyrosine kinases (RTKs) via chromosomal translocation or somatic mutations can lead to aberrant stimulation of signaling pathways resulting in development of malignant tumor, invasion and metastasis.
- Hybrid NPM-ALK gene formed due to chromosome t(2;5) is linked to development of anaplastic large cell lymphoma.

ROS1 Proto-oncogene Encodes Receptor Tyrosine Kinase

ROS1 is a proto-oncogene located on chromosome 6q22.1 that encodes a type 1 integral membrane protein with receptor tyrosine kinase (RTK) activity.

Physiologic State

ROS1 is a member of the insulin receptor tyrosine kinase family related to ALK, that activates downstream signaling pathways involved in cell growth, proliferation and differentiation. ROS1 has been described as an 'orphan' RTK and has no known ligand.

Pathologic State

Mutation in ROS1 proto-oncogene encoding aberrant receptor tyrosine kinase is linked to development of non-small cell lung carcinoma (NSCLC), glioblastoma multiforme, renal oncocytoma, gastric carcinoma, colorectal carcinoma, cholangiocarcinoma and chronic myelomonocytic leukemia. Novel hybrid genes (CD74-ROS1, SLC32A-ROS1 and FIG-ROS1) have been demonstrated in non-small cell lung carcinoma. ROS1-GOPC/FIG1 novel fusion gene product has been detected in hepatic angiosarcoma.

Targeted Therapy

ROS1 proto-oncogene inhibition may be an effective treatment strategy for the subsets of patients with non-small cell lung carcinoma (NSCLC) which express CD74-ROS1, SLC32A-ROS1 and FIG-ROS1 novel fusion genes.

FMS-like Receptor Tyrosine Kinase 3

FMS-like tyrosine kinase 3 (FLT3) is a receptor tyrosine kinase that is expressed almost exclusively in the hematopoietic progenitor cells (CD34+/c-KIT+).

Physiologic State

Binding of receptor FMS-like tyrosine kinase 3 (FLT3) to its ligand protein induces dimerization, and activation of receptor tyrosine kinase activity through RAS/RAF/MEK/ERK (MAPK) signaling pathway and phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR signaling pathway resulting in proliferation of hematopoietic progenitor cells.

Pathologic State

Mutations in FMS-like tyrosine kinase 3 (FLT3) gene lead to constitutive ligand independent autophosphorylation of the FMS-like receptor tyrosine kinase resulting in development of malignant tumor through signaling pathways involved in unrestricted CSC proliferation, differentiation and survival. Point mutations in codon 835 or deletions of codon 836 in FMS-like tyrosine kinase 3 (FLT3) gene are demonstrated in acute myelogenous leukemia (AML) in 25–30% of patients.

Targeted Therapy

Multiple small molecule inhibitors are under development to target aberrant FLT3 activity that confers a poor prognosis in AML patients.

AKT1 Proto-oncogene Encodes Putative Receptor Serine/Threonine Protein Kinase

AKT1 proto-oncogene mapped on chromosome 14q32–33 encodes putative AKT1 serine/threonine protein kinase found in variety of cells. AKT1 serine/threonine kinase plays a key role in many signaling pathways involved in cell growth, proliferation, differentiation, survival, glycogen metabolism, and apoptosis.

Physiologic State

ATK1 serine/threonine protein kinase via PI3K/AKT/mTOR signaling pathway appears to be essential for the normal development of nervous system, cell-to-cell communication among neurons, neuronal survival, and formation of memories.

Pathologic State

AKT1 gene mutation has oncogenic potential to transform normal cells into CSCs. Amplification of AKT1 gene encoding aberrant serine/threonine kinase is linked to lung adenocarcinoma, gastric carcinoma, colon carcinoma, endometrioid carcinoma, and breast invasive ductal carcinoma.

AKT2 Proto-oncogene Encodes Putative Receptor-like Serine/Threonine Protein Kinase

AKT2 proto-oncogene mapped on chromosome 19q13.2 encodes a putative receptor-like serine/threonine protein kinase, which is capable of phosphorylating several intracellular proteins, that is an effector molecule in the signaling pathway linked to insulin's metabolic effects.

Physiologic State

AKT2 serine/threonine protein kinase plays important role in cell metabolism, proliferation, survival, growth and angiogenesis.

Pathologic State

Amplification of AKT2 serine/threonine kinase is implicated in development of ovarian carcinoma, pancreatic carcinoma, breast carcinoma, and prostatic carcinoma.

BTAK Proto-oncogene Encodes Putative Receptor-like Serine/Threonine Protein Kinase

BTAK proto-oncogene mapped on chromosome 20q13 encodes a putative receptor-like serine/threonine protein kinase involved in cellular transformation activity. Amplification of BTAK gene is linked in development of breast carcinoma, ovarian carcinoma and gastric carcinoma.

RAF1 Proto-oncogene Encodes Putative Receptor-like Serine/Threonine Protein Kinase

RAF1 proto-oncogene is a cellular homolog of viral RAF gene (v-RAF) located on chromosome 3p25.2 encodes a putative receptor-like serine/threonine kinase.

Physiologic State

Putative receptor-like serine/threonine kinase acts as a regulatory link between the membrane-associated RAS GTPase, and RAS/RAF/MEK/ERK/MAPK signaling pathway leading to sequential phosphorylation of the dual-specific protein kinases MEK1 and MEK2, which in turn phosphorylate to activate serine/threonine specific protein kinases, ERK1 and ERK2. This regulatory link functions as a switch determining cell fate decisions including cell growth, proliferation and differentiation, survival, apoptosis and angiogenesis in wound healing.

Pathologic State

Point mutations in RAF1 gene are involved in the development of lung carcinoma, colorectal carcinoma and ovarian carcinoma.

Phosphatidylinositol 3-Kinase Catalytic Subunit Alpha Proto-oncogene Encodes p110α Subunit with Kinase Domain

Phosphatidylinositol 3-kinase catalytic subunit alpha (PIK3CA) proto-oncogene located on chromosome 3q26.3 encodes p110α protein, which is a major catalytic subunit of an enzyme phosphatidylinositol 3-kinase

(PIK3). Somatic mutations in the PIK3CA gene are linked to lung carcinoma, squamous cell carcinoma of skin, breast carcinoma and ovarian carcinoma.

GTP-BINDING PROTEINS (G PROTEINS)

G protein-coupled receptors (GPCRs) are cell surface receptors associated with GTP-binding proteins (also called G proteins).

- Guanosine triphosphate (GTP) binding proteins transmit signals outside the cell and induce changes within the cell.
- RAS family genes encoding proteins are small guanosine triphosphatases (GTPases), which exist in equilibrium between guanosine diphosphate (GDP) and guanosine triphosphate (GTP) bound forms.
- GTP-binding proteins act as molecular switches and induce conformational changes in molecular regions when RAS transitions from inactive GDP-bound state (turning off) to active GTP-bound state '**turning on**'. Nonreceptor protein kinases transmit the signal from the cell surface receptor to the nucleus.
- Proteins can be activated or inactivated by altering protein activity is the addition of phosphate group to one or more sites on the protein, a process is called **phosphorylation**.

Physiologic State

RAS family of genes (i.e. K-RAS, N-RAS and H-RAS) encode GTP-binding proteins, that act as molecular switches which can '**turn on**' when RAS protein is bound to GTP (guanosine triphosphate) to form complex in the active state of signal transduction, and '**turn off**' when bound to GDP (guanosine diphosphate) form complex in inactive state of signal transduction-bound conformation of RAS protein shows high affinity interactions with effector proteins that propagate downstream signaling from the receptor to the nucleus via nonreceptor protein kinases, and regulate cell growth, proliferation, differentiation, and apoptosis.

Pathologic State

The oncogenic mutation in RAS gene encodes aberrant RAS protein that loses its GTPase activity, so remains activated, resulting in continual promotion of transcription thus leading to development of malignant tumors in 30% cases.

- K-RAS is linked to non-small cell lung carcinoma, colorectal carcinoma and pancreatic carcinoma.
- N-RAS is linked to colorectal carcinoma and melanoma.
- H-RAS is linked to breast carcinoma. RAS gene mutations also make cells resistant to chemotherapy.

SIGNAL TRANSDUCTION PROTEINS

Signal transduction defines the series of molecular events, that occur to convert an external stimulus into cellular response by involving phosphorylation of target molecules by enzymes with protein kinase activity. A signal transduction pathway is initiated, when a ligand binds to its cellular receptor resulting in a conformational change. The ability of cells to sense external signals and respond to external signal is essential for tissue development and repair, immunity and homeostasis during embryogenesis and postnatal life.

- **Signal transduction pathways:** The most important signaling pathways have been shown to be implicated in human cancers include: (a) RAS/RAF/MEK/ERK (MAPK/ERK) signaling pathway, (b) phosphatidylinositol 3-kinase (P13K)/AKT/mTOR signaling pathway, (c) JAK/STAT signaling pathway, (d) Hedgehog signaling pathway, (e) NOTCH signaling pathway, (f) Wnt/β-catenin signaling pathway, (g) NF-κB signaling pathway, (h) receptor tyrosine kinases (RTKs) signaling pathway and (i) integrin pathway.
  - Out of these signaling pathways, the most common JAK/STAT and NF-κB signaling pathways have been shown to be disrupted and implicated in human cancers.
  - Cell signaling pathways are shown in Fig. 6.110. Cell signaling paradigms in cell division are shown in Fig. 6.111.
- **Signal transduction pathway and crosstalk mechanisms:** Signaling crosstalk can occur via different mechanisms: (a) the molecule in one signaling transduction pathway can affect the rate of activation of signaling molecules, (b) two signaling pathways can compete for common component, and (c) growth factor receptors can have altered ability to recognize ligands.
- **Mutations in signal transduction molecules and cancers:** Components of signaling molecules can be mutated or overexpressed leading to development of malignant tumor. Some oncogenes encode aberrant signal-transduction proteins involved in transmitting signals from the growth factor receptor tyrosine kinase (RTK) of the cell to the nucleus.
  - If cell surface receptors (e.g. HER2/neu) are overexpressed, signaling can happen in the absence of ligand (receptor function crosstalk). Non-receptor protein kinases are also included in the signaling cascade that transmit the signal from the cell receptor to the nucleus.
  - Individual signaling pathways could have opposite effects on transcription factor activation (gene expression crosstalk). Ligand availability can be

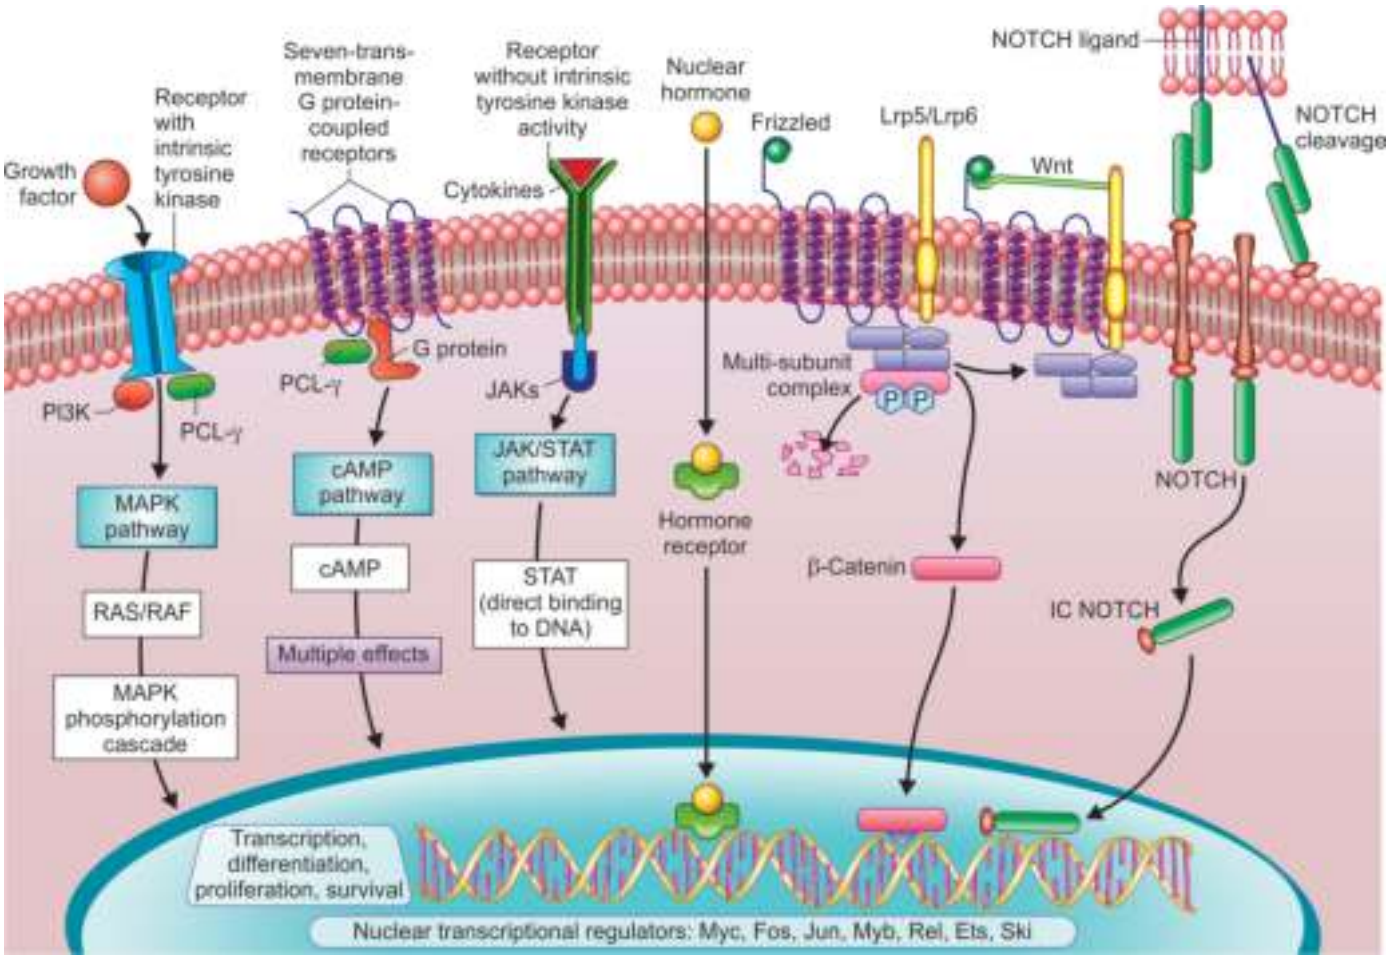

Fig. 6.110: Cell signaling pathways: Cell signaling pathways are the key biological mechanisms that transduce extracellular signals to affect transcription-mediated gene regulation within cells. Cell signaling pathways regulate cell proliferation and survival and are therefore important for maintaining homeostasis and development, which include: phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR, RAS/RAF/MEK/ERK (MAPK/ERK), JAK/STAT, Wnt/β-catenin, NOTCH, Hedgehog, NF-κB, TGF-β and ABL nonreceptor pathways.

altered due to different mechanisms, but often occurs in response to gene expression changes (intracellular crosstalk).

- Selected cellular oncogenes (mutated proto-oncogene) associated with many human cancers include HER2/neu (also called ErbB2), RAS, Myc, SRC, hTERT, and BCL-2.
- BCR-ABL1 oncogene (Philadelphia chromosome) caused by translocation of segments of chromosome 9 and chromosome 22. When the protein synthesized by BCR-ABL1 oncogene, a receptor tyrosine kinase (RTK), is continually synthesized that results in continuous transmission of signal responsible for cell growth and cell division of leukemia cells in chronic myelogenous leukemia (**CML**), and acute lymphoblastic leukemia (**ALL**). Status of signaling pathways with oncogenic potential linked human cancers are given in Table 6.90.
- **Analysis of signal transduction pathways and targeted therapy:** It is essential to analyze key signaling pathway including their communication with other signaling pathway (crosstalk) involved in development of malignant tumor, progression, and targeted therapy.

RAS/RAF/MEK/ERK (MAPK/ERK) Signaling Pathway

RAS/RAF/MEK/ERK (MAPK—mitogen-activated protein kinase) signaling cascade is essential for cell-to-cell and intracellular communication, which regulates cell adhesion, proliferation, differentiation, migration and survival.

Physiologic State

RAS/RAF/MEK/ERK (MAPK/ERK) signaling pathway plays an integral part in transducing signals from growth factors and cytokines through receptor tyrosine kinase (RTK).

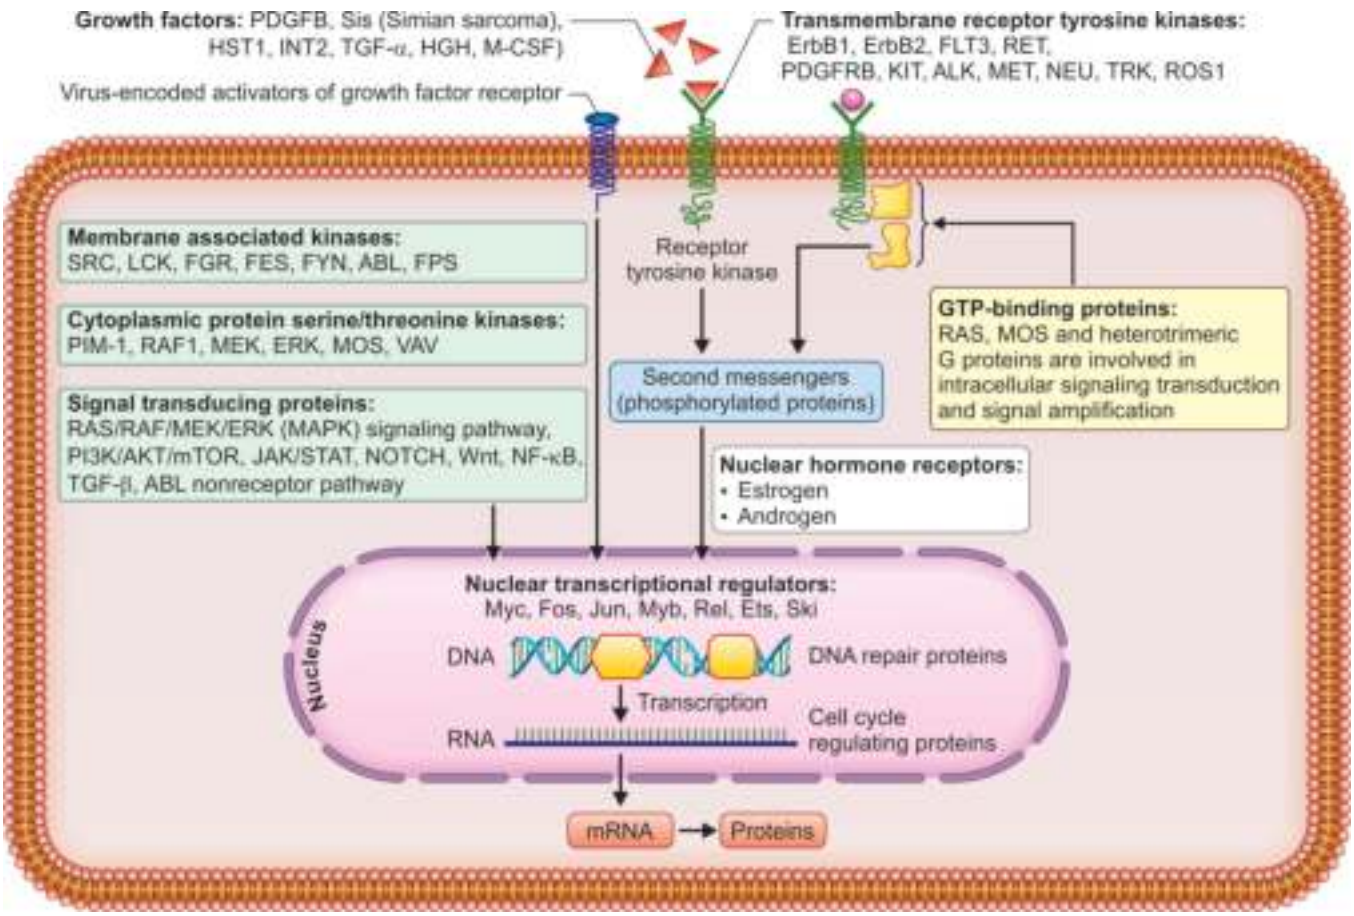

Fig. 6.111: Cell signaling paradigms in cell division. Extracellular ligands (e.g. Sis, HST) bind to cell membrane receptors (EGFR, ErbB2, KIT). One of several signaling pathways is then activated. The receptor may be a G protein-coupled receptor (e.g. RAS, MOS, heterotrimeric G proteins), which stimulates guanine nucleotide-related signaling, or the ligand may traverse the cell membrane to activate receptors within the cytosol, without a cell membrane intermediate. Cellular intermediates of many cells are activated. The end result for all signaling pathways is activation of transcription, particularly of proteins that help take the cell through the cell cycle.

Table 6.90 Status of signaling pathways with oncogenic potential linked human cancers

Signaling Pathways	Target Gene Expression	Human Cancers
RAS/RAF/MEK/ERK (MAPK/ERK) signaling pathway with oncogenic potential	↑K-RAS (point mutation) GTPase	▪ Colon carcinoma ▪ Lung carcinoma ▪ Pancreatic carcinoma
	↑H-RAS (point mutation) GTPase	▪ Renal cell carcinoma ▪ Urinary bladder carcinoma
	↑N-RAS (point mutation) GTPase	▪ Melanomas ▪ Hematologic malignancies
	↑GNAO (point mutation)	Uveal melanoma
	↑GNAS (point mutation)	▪ Pituitary adenoma ▪ Other endocrine tumors
	↑B-RAF (point mutation/translocation)	▪ Hairy cell leukemia (100%) ▪ Melanoma (60%) ▪ Colon carcinoma ▪ Dendritic cell tumor ▪ Benign nevi

Contd...

Table 6.90 Status of signaling pathways with oncogenic potential linked human cancers (*Contd...*)

Signaling Pathways	Target Gene Expression	Human Cancers
PI3K/AKT/mTOR signaling pathway with oncogenic potential	↑AKT	▪ Breast carcinoma ▪ Ovarian carcinoma ▪ Thyroid carcinoma
	↓PTEN	▪ Glioblastoma multiforme ▪ Melanoma ▪ Lung carcinoma
JAK/STAT signaling pathway with oncogenic potential	↑STAT	▪ Lung carcinoma ▪ Head and neck cancers ▪ ALL
NOTCH signaling pathway with oncogenic potential	↑NOTCH (point mutation/translocation/gene rearrangement)	▪ T-ALL ▪ Lymphomas ▪ Breast carcinoma
Wnt/β-catenin signaling pathway with oncogenic potential	↑β-Catenin	▪ Small intestine adenocarcinoma ▪ Gastric polyps
	↓APC	▪ Colon carcinoma ▪ Gastric adenomas
NF-κB signaling pathway with oncogenic potential	↑Rel	▪ Hodgkin's disease ▪ NK/T cell lymphoma
TGF-β signaling pathway with oncogenic potential	↓SMAD	Pancreatic carcinoma
	↑BMP2	Lung carcinoma
Non-receptor tyrosine kinase signaling pathway with oncogenic potential	↑ABL-BCR	CML

ALL: Acute lymphoblastic leukemia; T-ALL: T cell acute lymphoblastic leukemia; CML: Chronic myelogenous leukemia.

- Central to this signaling cascade is RAS, a small membrane-bound GTPase switch protein that shuttles between two conformational states: active GTP bound and inactive GDP-bound. It is activated by guanine exchange factor usually found in the cytoplasm of the cell.
- Activated GTP bound RAS activates the serine/threonine RAF kinase, the latter proceeds to phosphorylate and activate MEK. Then MEK phosphorylates and activates ERK-1 and ERK-2 (MAPKs). ERK-1 and ERK-2 can phosphorylate kinases in the cytoplasm that regulate translation of transcription factors and translocation into the nucleus leading to cell proliferation.

Pathologic State

Some components of RAS/RAF/MEK/ERK (MAPK/ERK) signaling cascade (e.g. RAS, BRAF) are mutated or aberrantly expressed leading to unrestricted CSC proliferation, development of malignant tumor and chemoresistance.

- Mutations can also occur at genes encoding upstream receptors (e.g. EGFR and FLT-3) and chimeric chromosomal translocations (e.g. BCR-ABL1), which transmit their signals through these signaling cascades.
- Hyperactivation of RAS/RAF/MEK/ERK (MAPK) signaling is associated with acute myelogenous leukemia (AML) in >50%, acute lymphoblastic leukemia (ALL), breast carcinoma, colon carcinoma, pancreatic carcinoma, melanoma and prostatic carcinoma associated with poor prognosis.
- Consequently, RAS/RAF/MEK/ERK (MAPK/ERK) signaling pathway is a formidable target for therapeutic intervention, which has received tremendous attention.

JAK (Janus Kinase)/STAT Signaling Pathway

JAK/STAT signaling pathway in response to growth factors (e.g. EGF, PDGF), and cytokines (e.g. IL-6) plays key role in mediating cell proliferation, differentiation, migration, and survival, angiogenesis stem cell maintenance, apoptosis, hematopoiesis, immune system, and embryological processes (mammary gland development). There are four members of the JAK family and seven members of STATs.

Physiologic State

The binding of extracellular ligand results in activation of JAK/STAT signaling pathway via changes to the transmembrane receptor tyrosine kinase family

that permits the intracellular JAKs associated proteins with them to phosphorylate one other. Transphosphorylated JAKs can phosphorylate downstream substrates, such as receptors, and STATs. Activated STATs enter the nucleus and bind target genes, thus regulate their transcription.

Pathologic State

Aberrant JAK/STAT signaling pathway is implicated in development of malignant epithelial tumors in various organs (breast, stomach, liver and pancreas).

- Aberrant cytokine production, mutations of receptor tyrosine kinases (RTKs), and rearrangements and mutations in both JAK (JAK1, JAK2 and JAK3) and STAT proteins lead to development of malignant tumors.
- Gain-of-function of JAK1 and JAK3 is linked to leukemia and lymphoma. STAT3 is constitutively activated in over 50% of human cancers such as lung carcinoma, breast carcinoma, head and neck carcinomas, and hematologic malignancies.

NF-κB Signaling Pathway

Nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) transcription factor family consists of five distinct proteins as follows: RelA, RelB, Relc, p100 and p50.

Physiologic State

Rel gene encodes NF-kB transcription factor that regulates transcription of DNA and cytokines production, i.e. IL-1 and TNF-α involved in cell proliferation, oxidative stress response, innate immune response, inflammation and apoptosis.

- In response to injurious stimuli, NF-κB transcription factor undergoes phosphorylation on serine 32 and 36 by IκB kinase (IKK).
- Phosphorylated NF-κB is ubiquitinated by the E3 ubiquitin ligase complex and targeted for degradation by 26S proteasome. The released NF-κB dimers can then translocate into the nucleus and activate transcription of target genes.

Pathologic State

Mutations of NF-κB signaling pathway have been linked to human cancers. Amplification of Rel gene encoding mutated NF-κB transcription factor is linked to Hodgkin's disease, B cell non-Hodgkin's lymphoma and natural killer/T cell non-Hodgkin's lymphoma. Immunohistochemical analysis of B cell-derived lymphoma samples with Rel amplifications have established nuclear Rel expression in several cases.

Phosphatidylinositol 3-Kinase (PI3K)/AKT/mTOR Signaling Pathway

Phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR signaling pathway is a major prosurvival intracellular network, that regulates protein synthesis, growth, proliferation, migration, survival, metabolism, angiogenesis and cell cycle progression.

Physiologic State

Phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR signaling pathway is activated by receptor tyrosine kinases, integrins, B cell and T cell receptors, G protein-coupled receptors and other stimuli, that induce production of phosphatidylinositol-3,4,5-triphosphates (PIP3) by phosphoinositol 3-kinase (PI3K).

Pathologic State

Aberrant activation of PI3K/AKT/mTOR signaling pathway has a significant role in carcinogenesis, unrestricted CSC proliferation, angiogenesis, epithelial–mesenchymal transition (EMT), and chemoresistance in various organs such as breast, endometrium, colon, lung and head and neck regions.

- **Genetic alterations in the PI3K gene:** The p100-α (100α) subunit encoded by PI3K gene is the most prevalent altered catalytic subunit of PI3K isoform in human cancers. Binding of transmembrane receptor tyrosine kinases, i.e. ErbB2, EGFR, Met, Ret and VEGFR to PI3K signaling pathway activates RAS proteins. After RAS proteins being activated, PI3K-100α transforms its lipid substrate phosphatidylinositol-4,5-bisphosphate (PIP2) to phosphatidylinositol-3,4,5-trisphosphate (PIP3), which active AKT/mTOR signaling pathway.
- **Genetic alterations in the mTOR gene:** The mTOR protein encoded by mTOR gene belongs to a serine/threonine kinase that regulates cellular responses to stressors such as DNA damage and nutrient deprivation. The mTOR activation mutations increase threonin kinase activity of mTOR leads to overactivated downstream signaling overactivity and unrestricted cell proliferation resulting in development of malignant tumors of endometrium, esophagus, stomach, colon, kidney, urinary bladder, and skin melanoma.

NOTCH Signaling Pathway

NOTCH signaling pathway consists of membrane tethered proteins, that upon binding to cognate NOTCH ligand in transmembrane region undergoes proteolytic cleavage, and releases transcription factor that shuttles to the nucleus.

Physiologic State

NOTCH signaling pathway plays an important role in cell proliferation, differentiation, and apoptosis including earliest stages of T cell development.

Pathologic State

Mutation is the NOTCH signaling pathway has been detected in human T cell acute lymphoblastic leukemia (T-ALL). Recurrent chromosomal translocation t(7;9)(q34;q34.3) involving human NOTCH 1 gene has been found in a small subset of T cell acute lymphoblastic leukemia (**T-ALL**).

- Aberrant notch signaling possibly increases cell proliferation through activation of c-Myc transcription factor, whose deregulated expression has been linked in the development of T cell acute lymphoblastic leukemia, non-Hodgkin's lymphomas, breast carcinoma, melanoma, medulloblastoma and ovarian carcinoma.
- In the case of human breast carcinoma, amplification of NOTCH receptors and the presence of cognate Jagged 1 ligands, correlate with a more aggressive malignant phenotype.

Wnt/β-Catenin Signaling Pathway

Wnt/β-catenin signaling pathway consists of >30 extracellular Wnt-ligands, which interact with receptors of the '**Frizzled family**', and induces accumulation of β-catenin in the cytoplasm and its eventual translocation into the nucleus, where it interacts with DNA-binding proteins such as TCF/LEF (T cell factor/lymphocyte enhancer binding factor). TCF/LEF DNA binding proteins act as transcriptional activators, which induces cell proliferation via activation of c-Myc, and cyclin D genes.

Physiologic State

The β-catenin is a core component of the cadherin protein complex, whose stabilization is essential for the activation of Wnt/β-catenin signaling pathway involved in cell growth, polarity, migration, and differentiation; neural patterning, and organogenesis during embryonic development. Wnt/β-catenin signaling pathway is essential for intestinal homeostasis.

Pathologic State

Mutation-induced activation of Wnt/β-catenin signaling pathway either activates adenomatous polyposis coli (APC) tumor suppressor gene and stabilizes β-catenin by rendering it unfit for phosphorylation/degradation, through mutations of residues located in its exon 3.

- The aberrant Wnt/β-catenin signaling pathways causes mutation of adenomatous polyposis coli (APC) tumor suppressor gene, and facilitates CSC renewal, unrestricted CSC proliferation and differentiation, thus exerting crucial roles in development of colorectal carcinoma, and chemoresistance.
- In more than 50% of cancers of breast, colorectal region, stomach, liver, endometrium and ovary including skin melanoma, β-catenin accumulates within the nucleus or cytoplasm.

SMAD/Transforming Growth Factor-β Signaling Pathway

The SMAD-dependent transforming growth factor-β (TGF-β) signaling pathway plays important role in embryogenesis and tissue hemostasis. TGF-β superfamily includes a diverse range of structurally and functionally related proteins, such as bone morphogenetic proteins (BMPs), activins, inhibins, growth differentiation factors (GDFs), and glial-derived neurotrophic factors (GDNFs). These proteins transmit signal by stimulating formation of specific heteromeric complexes of type 1 and type 2 serine/threonine kinase receptors.

Physiologic State

SMADs are intracellular regulatory proteins that can be categorized based on their functions: (a) **receptor-regulated SMADs** (R-SMAD, e.g. SMAD1, SMAD2, SMAD3, SMAD5, and SMAD8), (b) **common-mediator SMADs** (CO-SMADs, e.g. SMAD4), (c) **inhibitory SMADs** (I-SMADs, e.g. SMAD6 and SMAD7).

- Receptor-regulated SMADs (R-SMADs) bind to membrane-bound serine/threonine receptors, and are activated by their kinase activity. Co-factor SMADs bind to the activated R-SMADs to form a complex that translocates into the nucleus, where they function to regulate gene expression, i.e. transcriptional activation and repression. In addition, nuclear accumulation of active nuclear SMAD complexes is maintained in strict accordance with the degree of receptor activation at any time of signaling. SMAD phosphorylation by active receptors, and constitutive SMAD dephosphorylation by nuclear phosphates, are coupled through nucleocytoplasmic shuttling of SMADs.
- Inhibitory SMADs counteract the effects of R-SMADs, thus exerting an inhibitory effect on TGF-β superfamily signaling by various mechanisms. The SMAD2, SMAD3, and SMAD4 stable complexes activate transcription of cell cycle suppressors ($p15^{INK4b}$, $p21^{CIP1/WAF1}$ and $p27^{KIP1}$) and repressors transcription of the proliferation activator c-Myc.

Pathologic State

SMAD/transforming growth factor-β (SMAD/TGF-β) signaling pathway has dichotomous roles. It has been observed that TGF-β acts as a tumor suppressor, and apoptosis in the early stage of the disease, and as a tumor promoter in its late stages.

- **In the initial stage**, SMAD/TGF-β signaling pathway inhibits the proliferation of normal cells and promotes apoptosis of premalignant cells by increasing expression of cyclin-dependent kinase inhibitors (CDKIs) such as $p15^{INK4b}$, $p21^{CIP1/WAF1}$ and $p27^{KIP1}$.
- **In the late-stage**, mutations in constituent proteins of the SMAD/TGF-β signaling pathway impair the antiproliferative and proapoptotic activities of TGF-β, and activates downstream oncogenes leading to unrestricted CSC proliferation, cell growth, epithelial–mesenchymal transition (EMT), metastasis and chemoresistance. Mutations in TGF-β receptors, and SMADs are linked to colorectal carcinoma and pancreatic carcinoma.

Hedgehog Signaling Pathway

Hedgehog (Hh) signaling pathway plays an essential role in cell differentiation of embryonic cells during embryogenesis and tissue homeostasis. Aberrant Sonic Hedgehog (**Shh**) signaling pathway plays key role in evolution of chemoresistance and radioresistance of several human cancers.

Physiologic State

Hedgehog (Hh) signaling pathway is composed of three specific proteins: Hh signal peptide (i.e. Shh, Dhh, Ihh), transmembrane receptors (patched—PTCH, smoothened—Smo), and downstream transcription factor (Gli).

- Hedgehog (Hh) signaling pathway is initiated at the plasma membrane, where Hh signal peptide interacts with its 12 transmembrane protein receptors (patched—PTCH, smoothened—Smo). PTCH normally inhibits another transmembrane protein is called 'smoothened' (Smo), which itself prevents specific genes from transcribed RNA.
- When Hh signal peptide ligand binds to PTCH protein, it activates the Smo protein. The Smo protein interacts with other molecules through the cell's cytoplasm and into the nucleus. Smo transmembrane protein regulates gene transcription through the downstream transcription factor Gli.

Pathologic State

Hedgehog (Hh) signaling pathway is disrupted in diverse types of human cancers such as basal cell carcinoma, small cell lung carcinoma, pancreatic carcinoma, prostatic carcinoma, medulloblastoma and gastrointestinal malignancies.

Integrin Signaling Pathway

Integrin belongs to the family of cell adhesion molecules. Integrins are heterodimeric receptor proteins used by cells to bind to extracellular matrix (ECM), and actin cytoskeleton.

Physiologic State

An integrin molecule is composed of two noncovalently associated glycoprotein subunits α and β, which binds to induce intracellular signals leading to cellular responses such as cell-to-cell interaction (adhesion), cell growth, proliferation, migration and apoptosis.

Pathologic State

In human cancers, aberrant expression with normal functioning, rather than dominant genetic variations of genes encoding integrins has been observed. The aberrant expression is mediated through integrin signaling pathway, that leads to unrestricted CSC proliferation, migration, angiogenesis, evasion of apoptosis, interactions between CSCs and extracellular matrix, extracellular matrix remodeling, invasion and metastasis. Interaction between extracellular matrix glycoproteins and CSC integrins is given in Table 6.91.

Targeted Therapy

A number of molecules targeting integrins have been developed for treatment of many human cancers such as prostatic carcinoma and melanoma.

Receptor Tyrosine Kinase (RTK) Signaling through RAS Proteins

RAS, a small GTP-binding protein, is essential component of signal transduction pathway used by growth factors binding to receptor tyrosine kinases (RTKs), which initiates cell proliferation, growth, modulation of metabolism and differentiation.

Physiologic State

GTP-binding proteins are small GTPases, which act as '**molecular switches**' in signaling pathways to regulate functions of other proteins.

- GTPase liberates free inorganic phosphates (P). Cell activation with growth factors such as epidermal growth factor (EGF) induces RAS to move from an

Table 6.91 Interaction between extracellular matrix glycoproteins and cancer stem cell integrins

Binding Integrin Molecules on Tumor Cell	Extracellular Matrix Glycoproteins
VLA-2 (α_2, β_1)	Collagen and laminin
VLA-4 (α_4, β_1)	Fibronectin variant
VLA-5 (α_5, β_1)	Fibronectin
VLA-6 (α_6, β_1)	Laminin
α_6, β_4	Laminin
αv, β_3	Vitronectin

VLA: Very late activation antigen

inactive GTP bound (**switch turning off**) to an active GTP bound state (**switch turning on**).
- After binding of EGF ligand to cognate EGF receptor tyrosine kinase (RTK) leads to receptor autophosphorylation residues, which induce multiple signaling cascades.
- Activation of RAS/RAF/MEK/ERK (MAPK) signaling pathway plays essential role in cell proliferation, survival and differentiation.

Pathologic State

RAS/RAF/MEK/ERK (MAPK/ERK) signaling pathway transmits extracellular signals to specific intracellular targets.
- Aberrant activation of RAS/RAF/MEK/ERK/MAPK signaling pathway is linked to transformation of normal cell to CSCs and development of malignant tumor.
- About 30% of malignant tumors harbor RAS mutations, while 8% of malignant tumors are driven by RAF mutations.

TRANSCRIPTION FACTORS

In molecular biology, nuclear regulatory proteins are sequence-specific DNA binding '**transcription factors**' excluding RNA polymerase, synthesized in the cytoplasm, and have to be transported into the nucleus of the target cells. Transcription factors bind nearby specific DNA sequence and help specific target genes to 'turn on' (gene activation) or 'turn off' (gene silencing). Hence, transcription factors can either act as activators (enhancers) or repressors (silencers), that boost a gene's transcription. Hence, transcription factors regulate the rate of transcription of genetic information from DNA to messenger RNA.

Pathology Pearls: Transcription Factor—Terminology

- **Human gene:** Human gene contains 5'→3' untranslated, promoter, enhancer and silencer regions.
- **Gene expression:** Gene expression is the process by which information from a gene is used in the synthesis of a unique set of functional proteins and RNA molecules in each cell type of our body.
- **Promoter sequences:** Promoter sequences are regions on DNA, where transcription of a gene is initiated with the help of enzyme RNA polymerase by interacting with different transcription factors.
- **TATA box:** A TATA box is a conserved DNA sequence that indicates, where a genetic sequence can be read and decoded. TBP gene encodes the TATA box binding protein.
- **DNA bending:** DNA bending is essential in transcription regulation, which brings distal promoter and enhancer regions into its close proximity.
- **Transcription:** Transcription is the process, in which DNA sequence is transcribed into RNA molecule essential for protein synthesis with the help of enzyme RNA polymerase.
- **Transcription factor:** Gene expression requires transcription factor (sequence-specific DNA binding factor), that binds to DNA and regulates gene expression by promoting or suppressing transcription.
- **Transcription regulation:** Transcription regulation is defined as rate of gene transcription by helping or hindering RNA polymerase binding to the DNA. Increase in the rate of transcription is called upregulation, activation or promotion. Decrease in the rate of gene transcription is known as downregulation, repression or suppression.
- **Coactivator:** Coactivator is small protein molecule, that works with transcription factors to increase the rate of gene transcription.
- **Corepressor:** Corepressor is a small protein molecule, that works with transcription factors to decrease the rate of gene transcription.
- **Response elements:** Response elements are short sequences of DNA within a gene promoter or enhancer region, that are able to bind specific transcription factors and regulate gene transcription.

Transcription Factors: Domains and Motifs

Transcription factors consist of two types of structural components: (a) **domain**—an independent tertiary structural unit of a protein assumed to fold independently of the rest of the protein possessing autonomous function (e.g. leucine zipper motif, helix-loop-helix), and (b) **motif**—a short conserved region formed by the spatial arrangement of amino acids in a protein sequence (e.g. helix-turn-helix motif, zinc finger motif, homeodomain motif).
- **DNA binding domain:** DNA binding domain is usually a basic α-helix, which recognizes a specific sequence (response element), mainly located in the major grove of DNA.
- **Transactivation domain:** Transactivation domain interacts with RNA polymerase II transcription initiation complex, and activates transcription, or repress transcription in some cases.
- **Dimerization domain:** Many of the transcription factors bind to DNA as homodimer/heterodimer domains.
- **Ligand binding site:** When an effector binds to ligand binding site, it produces a 3D conformational change, thus activating or inactivating the transcription factors.

Transcription Factors: Functions

Transcription factors (TFs) are regulatory proteins possessing domains mainly located in the major groove of DNA, which bind to specific upstream 5'→3' regulatory DNA, sequences, i.e. promoter or enhancer

regions of specific target genes without breaking the hydrogen bonds. Target genes, which include Fos-related genes (Fos-B, Fra-1, Fra-2), egr-1, egr-2, Nur77, Srf-1), JunB gene, EGR-1 gene, Nur77 gene, Srf-1 gene and Myc (c-Myc, L-Myc, N-Myc).

- Transcription factors also possess a domain that interacts with RNA polymerase II or other transcription factors and consequently regulates transcription of DNA into RNA. Their function is to recruit or inhibit the binding of RNA polymerase to the promoter region of DNA. Other nuclear regulatory proteins can work with transcription factors to either promote or inhibit the transcriptional activity of a target gene being expressed.
- Hence, transcription factors regulate the rate of transcription of genetic information from DNA to messenger RNA (mRNA) to synthesize unique set of functional proteins, thus acting as 'nuclear messengers' by involving multiple intracellular signal transduction pathways stimulated by cell surface receptors.
- Other proteins (e.g. coactivators, corepressors, chromatin modelers, histone acetyltransferases, histone deacetylases, kinases and methylases) are also essential in regulation of gene expression, but lack DNA binding domains, and therefore are not transcription factors.
- Transcription factors can act as either activators (enhancers) or repressors, that can **turn on/turn off** genes and their transcription respectively.
  - Binding of enhancer (activator) transcription factors causes the DNA to bend, bringing them near a gene promoter, even though they may be thousands of nucleotide base pair away.
  - Other transcription factors join the enhancer (activator) transcription factors, forming a protein complex, which bind to the gene promoter. This protein complex makes it easier for RNA polymerase to attach to the promoter and start transcription of gene.
- An insulator can stop the enhancer (activator) transcription factors from binding to the gene promoter region of zinc finger protein is called CTCF transcription factor repressor (named from the sequence CCCTC, which occurs in all insulators) binds to it.
- DNA methylation, a process of adding a methyl group to nucleotide base pairs done by a DNA methyl transferase enzymes is a epigenetic alteration, which '**turns off**' tumor suppressor gene leading to development of cancers. Modulation of transcription process is shown in Fig. 6.112.

Transcription Factors with Altered Activity Mechanisms

Transcription factor activity is altered by two mechanisms: (a) **direct mechanism** through chromosome translocation, gene amplification, gene overexpression, point mutation, and (b) **indirect mechanism** through noncoding DNA mutations that affect binding of transcription factor. Altered activity of transcription factors is linked to many human cancers, which include: c-Myc (Burkitt's lymphoma), L-Myc (small cell lung carcinoma), N-Myc (neuroblastoma), JunB (breast carcinoma, prostatic carcinoma), Fos-B (promotion of CSC-like properties), serum response factor 1 (SRF-1: **hepatocellular carcinoma**), and NUR-77 (**melanoma**).

CHROMATIN REMODELER PROTEINS

In eukaryotes, DNA is tightly wrapped into a complex called 'chromatin' consisting of DNA, RNA and protein. DNA carries the cell's genetic instructions. The histone octamer proteins in the chromatin help to organize DNA into 'bead-like' structures are called '**nucleosomes**' by using energy of ATP by providing a base on which the DNA is wrapped around in compact form that fits in the nucleus.

- Rearrangement of chromatin from a condensed state to a transcriptionally accessible state, allows transcription factors or other DNA binding proteins to access DNA and regulate gene expression.
- Chromatin is essential for all DNA-dependent biological processes (i.e. DNA replication, transcription, DNA repair, genetic recombination and cell division).
- Mutated chromatin remodular proteins have now been detected in most human cancers, which are regarded a novel therapeutic target.

Chromatin: Major Proteins and their Functions

The major proteins in the chromatin are histone octamer proteins, that help to organize DNA into 'bead-like' structures are called 'nucleosomes' by providing a base on which the DNA is wrapped around in compact form that fits in the nucleus.

- A nucleosome consists of 146 nucleotide base pairs of the DNA that is wrapped around a set of 8 histones called histone octomer proteins. Histones H2A, H2B, H3 and H4 are known as histone octamer core proteins, and they come together to form one nucleosome. The nucleosome is formed by two H2A-H2B dimers and an H3-H4 tetramer.
- Extensive studies revealed that chromatin plays a critical role in regulation of transcription. There are two key players in regulation of chromatin dynamics: (a) chromatin remodelers that alter DNA–histone interactions by energy harnessed through ATP hydrolysis, and (b) nucleosome-modifying enzymes

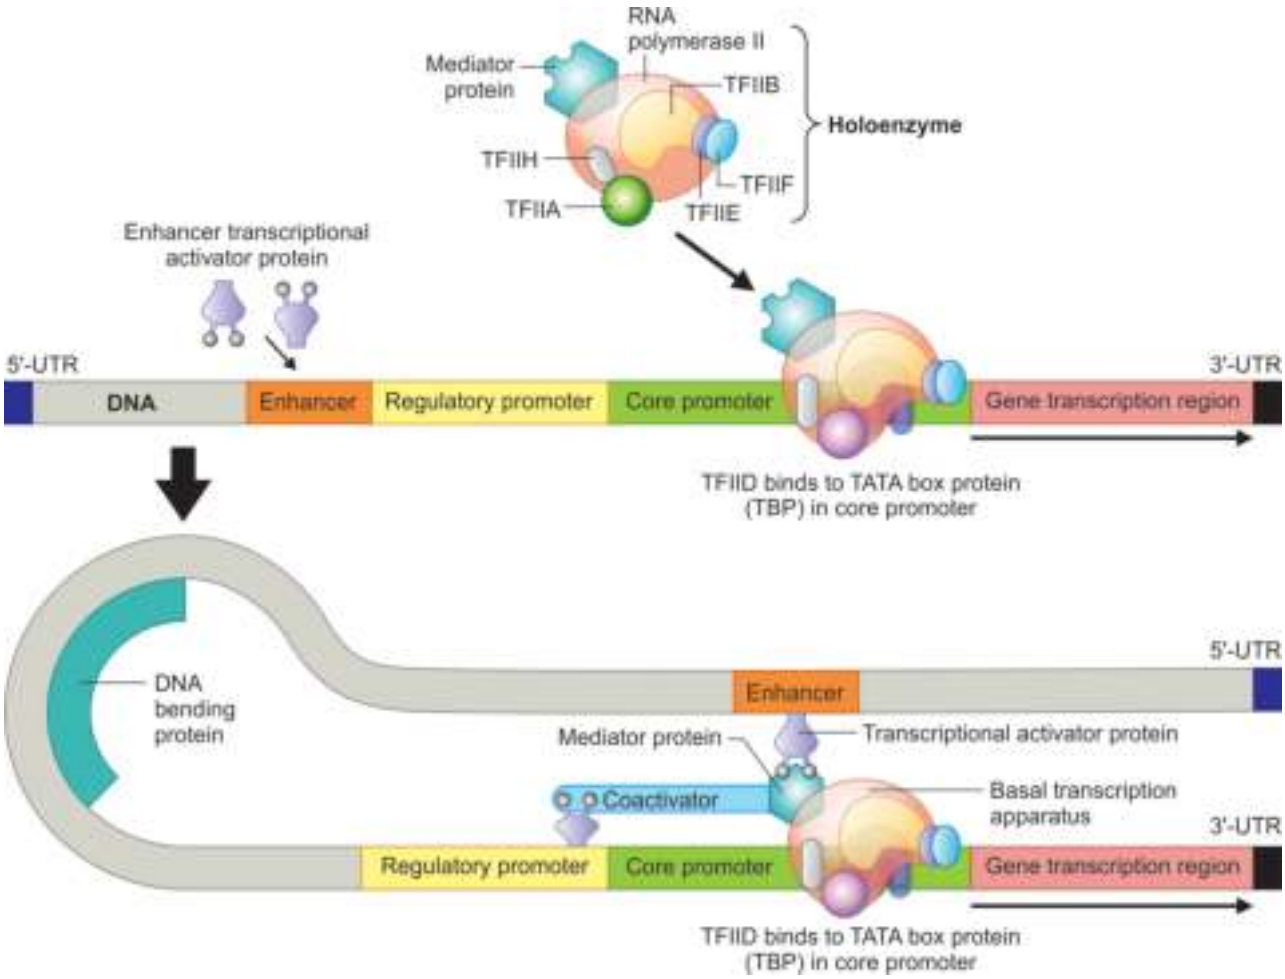

Fig. 6.112: Modulation of transcription process. Transcription is the process in which DNA sequence is transcribed into RNA molecule essential for protein synthesis with the help of enzyme RNA polymerase positioned on DNA with the help of TATA binding proteins. TATA binding proteins bind the TATA box, a DNA sequence that compromises part of the promoter. DNA can loop around itself to cause interaction between an activator protein and other proteins that mediates the activity of RNA polymerase.

(histone acetylases or deacetylases) that modulate DNA and histone residues by specifically adding or removing covalent modifications.

- Specific DNA-binding transcription factors recruit histone acetylases and histone deacetylases to promote activation or repression of transcription respectively. These findings strongly support that transcription is regulated by histone acetylation and deacetylation. ATP-dependent chromosome-remodeling activity enhances the histone deacetylase activity. Therefore, these two mechanisms are involved in regulation of transcription. Both DNA methylation and histone modification are involved in establishing patterns of gene repression during embryonic development.
- DNA methylation should not be confused with histone methylation. DNA methylation leads to stable long-term repression due to conversion of cytosine nucleotide base pairs of DNA to 5-methyl-cytosine, whereas histone octamer methylation causes local formation of heterochromatin, which is a reversible event. DNA methylation and histone octamer modification pathways are dependent on one another, and this crosslink is mediated by biological interactions between DNA methyltransferases and SET domain histone methyltransferases.
- Relationship between DNA methylation and histone octamer modification is involved in normal development as well as somatic cell reprogramming and malignant tumor.

Gene Mutations Encoding Chromatin Structure Linked to Human Cancers

Genes encoding proteins regulate chromatin structure. DNA and histone octamer harbor recurrent mutations (e.g. point mutations, amplification, deletion, fusion) in most human cancers. These gene mutations lead to modifications in chromatin and DNA, and an altered epigenetic state that contribute to tumorigenesis.

- Deregulation of chromatin remodelers transform normal cell to CSC. Mutated chromatin remodular proteins have now been detected in most human cancers, which are regarded a novel therapeutic target.
- ALL1 gene (also called MLL) encodes chromatin remodular protein under physiologic state. ALL1 gene mutation encodes abnormal chromatin remodular protein, which is linked to acute lymphoblastic leukemia (ALL).
- In addition, recurrent gain-of-function point mutations in histone variants HIST1 H3A (H3.1) and H3F3A (H3.3) result in critical epigenetic alterations leading to tumorigenesis in pediatric glioblastoma multiforme, chondroblastoma, and undifferentiated sarcoma.
- Genetic alterations in components of ATP-dependent chromatin remodeling complexes are quite common in human cancers.

Pathology Pearls: Gene Expression—Mechanisms

Nucleosome is fundamental subunit of chromatin composed of 146 nucleotide base pairs around histone octamer. Nucleosome can slide over along DNA. Chemical modifications to DNA and histone octamer affect nucleosome spacing.

- Gene silencing and repression of transcription methylation of DNA and histone octamer tail causes nucleosomes to pack tightly together due to condensation of heterochromatin, which inhibits binding of transcription factors to DNA sequence; hence DNA becomes inaccessible to transcription factors resulting in gene silencing (turning off) and transcription repression.
- On the contrary, acetylation of DNA and histone octamer results in loose packing of nucleosomes due to relaxation of euchromatin, which enhances binding of transcription factors to DNA sequence, hence DNA becomes accessible to transcription factors leading to gene activation (turning on), induction of transcription and production of protein.

CELL CYCLE REGULATORY PROTEINS

Cell cycle regulatory proteins are products of proto-oncogenes commonly represented by cyclins, cyclin-dependent kinases (CDKs) and CDK inhibitors and some of their substrates interacting partners and upstream regulators, that can affect the cell cycle in several different ways.

- Cell cycle is the ordered sequence of events that occur in a somatic cell in preparation for cell division into two identical daughter cells.
- Cell cycle has interphase (G1, S and G2 phases), followed by the mitotic phase (mitosis and cytokinesis), and G0 phase.
- For the cell to move past each of the cell cycle checkpoints, all positive regulatory molecules must be '**turned on**' and all negative regulatory molecules must be '**turned off**'.

Cell Cycle Regulation under Physiologic State

Cell cycle is regulated by positive and negative regulatory proteins. Disruption of normal regulation of the cell cycle can lead to unrestrained CSC proliferation and accumulation of genetic errors resulting in development of malignant tumor.

Positive Regulation of Cell Cycle

Positive cell cycle regulatory proteins include cyclins and cyclin-dependent kinases (CDKs) responsible for the progression of the cell cycle through various checkpoints (i.e. one near the end of G1, a second at the G2/M transition, and the third at metaphase). Other positive cell regulatory proteins are maturation/mitosis promoting factor, anaphase-promoting complex, E2F/DP1 complex, MDM2 protein, and Myc protein.

- Cyclins regulate the cell cycle only when cyclins are tightly bound to CDKs to form cyclin/CDKs complex, that causes the cell to enter S phase by phosphorylation of RB protein. The integrity of the DNA and proper chromosome duplication are assessed at the G1 checkpoint. Attachment of each kinetophore to a specific chromatin fiber is assessed at the M checkpoint.
- Positive cell cycle regulatory proteins allow the cell cycle to progress to the next phase. The concentrations of cyclin proteins fluctuate throughout the cell cycle in a predictive pattern. There is direct correlation between accumulation of cyclin, and three major cell cycle checkpoints.
- Increase in the concentration of cyclin proteins is triggered by both external and internal signals. After cell progresses to the next phase of the cell cycle, there is sharp decline of cyclin levels following each cell cycle checkpoint as a result of degradation by cytoplasmic enzymes.

Negative Regulation of Cell Cycle

Negative cell cycle regulatory proteins include pRB, p53 protein, INK family of proteins (p27, p21 and p57) and CIP/KIP family of proteins (p16, p15, p18 and 19) involved in monitoring the DNA damage and restriction of cell cycle progression from G1/S phase until damage is repaired. If DNA of cell is not repaired, cell undergoes apoptosis. Defect in G1/S checkpoint is linked to tumor cancers.

- TP53 tumor suppressor gene encodes p53 encodes, that arrest the cell cycle in G1 phase by inhibiting CDK4. The p53 also prevents pRB phosphorylation that may provide time for repair of DNA in the cell.

- Two most important tumor suppressor genes (e.g. RB and TP53) encode proteins that inhibit G1/S progression. RB protein halts the cell cycle in the G1 phase. RB binds to E2F transcription factor, which cannot bind the DNA, and transcription is inhibited. Cell growth triggers the phosphorylation of RB protein. Phosphorylated of pRB releases E2F, which binds to DNA, and '**turns on**' gene expression, thus advancing the cell cycle.

Cell Cycle Dysregulation and Cancer

Cell cycle dysregulation is a hallmark of cancer. The proteins involved in cell division events no longer appropriately drive cell cycle progression from one phase to the next.

- The ability of normal cells to undergo cell cycle halt after damage to DNA is crucial for the maintenance of genomic integrity. The biochemical pathways that halt the cell cycle progression in response to cellular stressors are called cell cycle checkpoints.
- There are three major checkpoints in the cell cycle; one near the end of G1/S transition, second at G2/M transition, and the third at metaphase. The integrity of the DNA is assessed at the G1 checkpoint. Proper chromosome duplication is assessed at the G2 checkpoint. Attachment of each kinetophore to a specific chromatin fiber is assessed at the M checkpoint.
- Defective checkpoint function resulting in genetic modifications lead to tumorigenesis. The regulation of cell cycle checkpoint signaling also has clinical implications, because the abrogation of checkpoint function can alter sensitivity of CSCs to chemotherapeutic agents.
- Dysregulation of cyclin D1 gene expression contributes to the loss of normal cell cycle control during tumorigenesis. Amplification of cyclin D1 is linked to breast carcinoma, esophageal squamous cell carcinoma and multiple myeloma. Amplification of cyclin E is implicated in gastric carcinoma.
- The family of cyclin-dependent kinases (CDKs) has critical role in cell cycle regulation and controlling transcriptional elongation.
- Dysregulated CDKs have been linked to tumorigenesis, invasion and metastasis.
  - Amplification of CDK4 gene (12q13) is linked to glioblastoma multiforme, melanoma and sarcoma.
  - Amplification of CDK6 gene (19q21–22) is implicated in breast carcinoma, colon carcinoma, glioblastoma multiforme and esophageal adenocarcinoma.

APOPTOSIS REGULATORY PROTEINS

Proto-oncogenes may also synthesize gene protein products that regulate apoptosis process. Caspases, a family of cysteine proteases, are the '**central regulators of apoptosis**'.

- Apoptosis is a programmed cell death, and characterized by nuclear condensation, cell shrinkage, cell membrane blebbing, intact, and preserved cytoplasmic organelles, swelling of the endoplasmic reticulum, chromatin condensation (pyknosis), and chromosomal DNA fragmentation (karyorrhexis), DNA laddering, and the eventual formation, and phagocytosis of apoptotic bodies by macrophages and surrounding tissue cells within an hour, rendering their appearance very transient. Phagocytic cell synthesizes cytokines (TGF-β, IL-10), which inhibit inflammation in apoptosis.
- Apoptotic signals contribute to safeguarding the genomic integrity, while defective apoptosis can cause genetic alterations, that deregulate cell proliferation, interfere with differentiation, promote angiogenesis, evasion of apoptosis, escape immune destruction by CD8+ cytotoxic T cells and natural killer cells, invasion, metastasis and resistance to chemotherapy and/or radiotherapy.

Regulation of Apoptotic Signaling in Normal Cells

Apoptosis is programmed cell death regulated by pro-apoptotic protein (BAX, BAK, DIVA, BCL-Xs, BIK, BIM, BID, BAD, EGL) and anti-apoptotic protein (BCL-2, BCL-XL, MCL-1, CED-9, A1 summate) molecules, and mediated by intrinsic (mitochondrial) pathway and extrinsic (death receptor pathway), that maintains cell hemostasis.

- Caspases, a family of cysteine proteases, are the central regulators of apoptosis, which cleave cellular components (i.e. structural proteins in the cytoskeleton and nuclear DNA).
- Both extrinsic and intrinsic pathways initiated by initiator caspases (2, 8, 9, 10, 11, 12), which can flow independently until the last step of DNA degradation by executioner caspases 3, 6 and 7.
- The perforin/granzyme apoptosis pathway activates executioner caspase 3.

Aberrant Apoptotic Signaling Associated Cancers

Aberrant apoptotic signaling results in cancers, which occurs by several mechanisms: (a) upregulation of anti-apoptotic proteins (e.g. BCL-2 protein present in integral outer mitochondrial membrane encoded by BCL-2 proto-oncogene), (b) downregulation of pro-apoptotic proteins (e.g. BAX), (c) TP53 tumor suppressor gene inactivation/biallelic loss, (d) loss of apoptotic peptidase activating factor 1 (APAF1), and (e) inactivation of death-induced signaling complex FADD.

- BCL-2 is human proto-oncogene located on chromosome 18, that encodes BCL-2 anti-apoptotic protein in the integral outer mitochondrial membrane, that works to prevent apoptosis by intrinsic apoptotic pathway. Aberrant anti-apoptotic BCL-2 (B cell lymphoma 2) protein signaling induces genetic alterations leading to transformation of normal cell to unrestricted CSC proliferation, evasion of apoptosis, angiogenesis, escape immune destruction by CD8+ cytotoxic T cells and natural killer cells, invasion, metastasis, chemoresistance, and resistance to radiotherapy in certain human cancers.
- B cell lymphomas with concurrent IgH-BCL-2 and Myc rearrangements are aggressive neoplasms, which exhibit chromosomal translocations t(8;14)(q24;q32) involving IgH gene resulting in juxtaposition and overexpression of BCL-2 anti-apoptotic protein. This chromosomal translocation is a hallmark of B cell lymphoma and is also found in 20–30% of *de novo* diffuse large B cell lymphoma (DLBCL), chromosomal translocations involving Myc at 8q24 and immunoglobulin partners, including IgH and kappa (κ) and lambda (λ) chains are characteristic of Burkitt's lymphoma.
- BCL-2 inhibitors are being developed to down-regulate BCL-2. BCL-2 consists of four conserved domains (BH4, BH3, BH1 and BH2), which differentiate it from other BCL-2 family of members (e.g. BIM, BID, PUMA, NOVA, BAD, HRK, BMF and BIK). Among these homologies, motifs, BH3, BH1 and BH2 are the most common targeted therapy in clinical oncology.

DNA REPAIR PROTEINS MAINTAINING GENOME INTEGRITY

DNA repair mechanisms maintain the integrity of genome, and thus prevent carcinogenesis. DNA glycosylases remove the damaged nucleotide base pairs by cutting them out of the DNA strand through cleavage of the covalent bonds between the nucleotide base pairs and the sugar phosphate backbone. The resulting gap is then filled by a specialized repair polymerase enzyme and sealed by ligase.

- XPA is DNA repair protein that recognizes damaged DNA and forms complexes with other proteins such as XPB and XPD, which are involved in DNA repair process. XPB and XPD proteins act as helicases that unwind the damaged DNA.
- Most DNA damage gets repaired by DNA repair proteins. But if the DNA damage persists, cell has less ability to repair itself and hence, errors will build up in other genes overtime and allow development of malignant tumor.

PROTO-ONCOGENES, ONCOGENES AND VIRAL ONCOGENES

Our cells contain many important normal proto-oncogenes that regulate cell growth and division. The mutated forms of proto-oncogenes are called **oncogenes**. When the viral oncogene infects host cell, the reverse transcriptase enzyme generates cDNA, which is then integrated into the genome. Currently, there are seven recognized human oncogenic viruses, which include Epstein-Barr virus (EBV), human papillomavirus (HPV), hepatitis B and C viruses (HBV and HBC), human T cell lymphotrophic virus 1 (HTLV-1), human herpesvirus 8 (HHV-8) and Merkel cell polyomavirus.

- **Proto-oncogenes:** Proto-oncogenes are normal cellular genes, which perform different functions in the cells.
  - Each proto-oncogene codes for growth factor, cell surface receptor and specific intracellular regulatory proteins responsible for providing positive signals, that lead to cell growth, cell division, apoptosis and maintenance of normal cell.
  - Proto-oncogenes can be classified into various groups based on the functional and biochemical properties of protein products, which include: (a) growth factors, (b) cell surface receptors, (c) members of signal transduction pathways such as guanosine triphosphate (GTP)-binding proteins and nonreceptor protein kinases, (d) nuclear regulatory proteins, i.e. transcription factors, (e) cell cycle regulatory proteins, (f) apoptosis regulatory proteins, and (g) DNA repair proteins. Cellular compartments in which proto-oncogene or oncogene products reside involved in cell division are shown in Fig. 6.113.
  - Examples of proto-oncogene encoding growth factors include EGF, PDGF, VEGF, TGF-α, TGF-β, FGF, HGF, IGF, G-CSF, GM-CSF, KGF, NGF, BMP, erythropoietin and thrombopoietin, which bind to their cognate cell surface receptors, which span the plasma membrane and bridge communication between the extracellular environment and inside of the cell.
  - In general, extracellular growth factors bind cell surface receptors, which activate intracellular downstream signal transducers, which initiate DNA transcription of target genes. Many proto-oncogenes play an important role in growth of fetus during embryogenesis.
  - Proto-oncogenes are '**turned off**' once the developmental cellular processes are completed. Examples

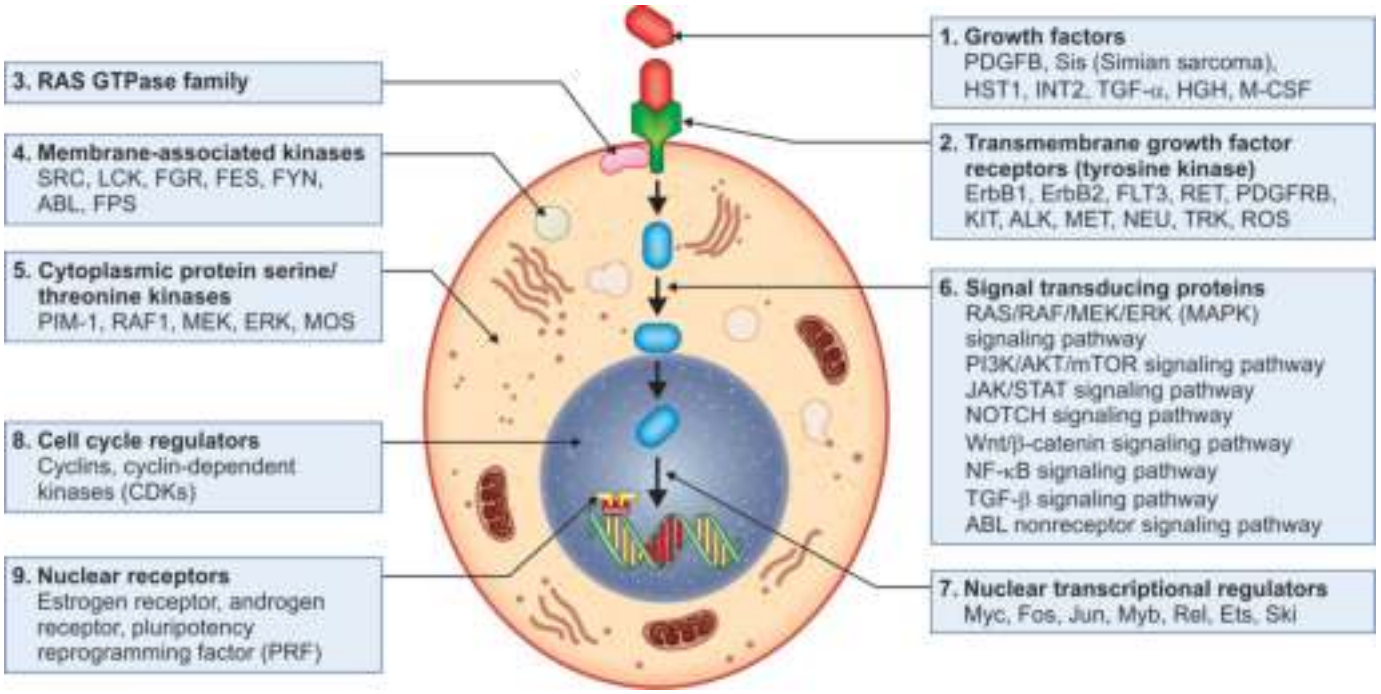

Fig. 6.113: Cellular compartments in which proto-oncogene or oncogene products reside involved in cell division: (1) growth factors, (2) membrane receptor tyrosine kinase, (3) RAS GTPase family, (4) membrane-associated kinases, (5) cytoplasmic protein serine/threonine, (6) cell signaling pathways, (7) nuclear transcriptional regulators, (8) cell cycle regulators and (9) nuclear receptors. Categories of signaling receptors including receptors that utilize a receptor tyrosine kinase (RTK), a nonreceptor tyrosine kinase, a nuclear receptor that binds its cognate ligand.

of proto-oncogenes to convert into oncogenes include HER2/neu (also called ErbB2), RAS, Myc, SRC, hTERT, BCL-2 and EGFR.

- **Oncogenes:** Mutated forms of proto-oncogenes, which occur by various genetic mechanisms: insertional mutagenesis, point mutation, amplification, and chromosomal rearrangements. Oncoproteins are the products of oncogenes leading to transcription, and translation to RNA and abnormal protein.
  - Mutations altering the structure or expression of proteins (e.g. growth factors, cell surface receptors, signal transducing proteins, transcription factors, DNA repair proteins, chromatin remodelers, cell cycle proteins and apoptosis regulators), generally give rise to dominantly active oncogenes resulting in carcinogenesis.
  - HER2 oncogene can result in increased expression of HER2/neu protein on cell surface of CSCs of breast carcinoma. EGFR overexpression is observed in non-small cell lung carcinoma. Oncogenes, mode of activation and associated malignant tumors are given in Table 6.92.

Table 6.92 Oncogenes, mode of activation and associated tumors

Oncogene Category	Proto-oncogene	Mode of Activation	Associated Malignancies
Growth factors			
PDGFB chain	PDGFB (Sis—Simian sarcoma)	Overexpression	▪ Astrocytoma ▪ Osteosarcoma
Fibroblast growth factors (FGFs)	▪ HST1 ▪ FGF3	▪ Overexpression ▪ Amplification	▪ Osteosarcoma ▪ Osteosarcoma ▪ Gastric carcinoma ▪ Urinary bladder carcinoma ▪ Breast carcinoma ▪ Melanoma
TGF-α	TGFA	Overexpression	Astrocytoma

Contd...

Table 6.92 Oncogenes, mode of activation and associated tumors (*Contd...*)

Oncogene Category	Proto-oncogene	Mode of Activation	Associated Malignancies
HGF (hepatocyte growth factor)	HGF	Overexpression	▪ Hepatocellular carcinoma ▪ Thyroid carcinoma
Growth factor receptors			
EGF-receptor family	▪ ErbB1 (EGFR), ErbB2 (avian erythroblastosis) ▪ ErbB2 (HER2/neu)	▪ Amplification ▪ Amplification	▪ Lung adenocarcinoma ▪ Breast carcinoma (marker of aggressiveness)
FMS-like tyrosine 3 kinase	FLT3	Point mutation	Leukemia
Receptors for neurotrophic factors	RET	Point mutation	Multiple endocrine neoplasia: MEN-2A. MEN-2B familial thyroid medullary carcinoma
PDGF receptor	PDGFRB	Overexpression or translocation	▪ Gliomas ▪ Leukemias
Receptor for KIT ligand	KIT	Point mutation	▪ Gastrointestinal stromal tumors (GISTs) ▪ Seminomas ▪ Leukemias
ALK receptor	ALK	▪ Point mutation ▪ Translocation/ amplification ▪ NPM/ALK fusion gene encodes hybrid NPM-ALK protein	▪ Lung adenocarcinoma ▪ Neuroblastoma ▪ Diffuse large B cell lymphoma (DLBCL)
Signal-transducing proteins			
GTP-binding proteins (G proteins)	▪ K-RAS ▪ H-RAS ▪ N-RAS ▪ GNAP ▪ GNAS	▪ Point mutation ▪ Point mutation ▪ Point mutation ▪ Point mutation ▪ Point mutation	▪ Colon carcinoma ▪ Lung carcinoma ▪ Pancreatic carcinoma ▪ Urinary bladder carcinoma ▪ Renal cell carcinoma ▪ Melanomas ▪ Hematologic malignancies ▪ Uveal melanoma ▪ Pituitary adenoma ▪ Other endocrinal tumors
Non-receptor tyrosine kinase	ABL (Abelson mouse leukemia)	▪ Chromosomal translocation (9;22) ▪ Point mutation	▪ CML ▪ ALL
RAS signal transduction	BRAF	▪ Point mutation ▪ Translocation	▪ Melanoma ▪ Leukemia ▪ Colon carcinoma
NOTCH signal transduction	NOTCH1	▪ Point mutation ▪ Translocation	▪ Breast carcinoma ▪ Leukemia/lymphomas
JAK/STAT signal transduction	JAK2	Translocation	▪ ALL ▪ Myeloproliferative disorders

Contd...

Table 6.92 Oncogenes, mode of activation and associated tumors (*Contd...*)

Oncogene Category	Proto-oncogene	Mode of Activation	Associated Malignancies
Transcription factors (nuclear regulatory proteins)			
Myc (myelocytomatosis) transcriptional factor	▪ c-Myc	▪ Translocation (8;14) involving IgH	▪ Burkitt's lymphoma
	▪ N-Myc	▪ Amplification	▪ Neuroblastoma
	▪ L-Myc	▪ Amplification	▪ Small cell lung carcinoma
Cyclins and cyclin-dependent kinases (cell cycle regulators)			
Cyclins	CCND1 (cyclin D1)	▪ Translocation t(11;14) involving IgH	▪ Mantle cell lymphomas
		▪ Amplification	▪ Multiple myeloma ▪ Breast carcinoma ▪ Esophageal carcinoma
Cyclin-dependent kinase	CDK4	Amplification or point mutation	▪ Glioblastoma multiforme ▪ Melanoma ▪ Sarcoma

ALL: Acute lymphoblastic leukemia; CML: Chronic myelogenous leukemia

- **Viral oncogenes:** Viral oncogenes play important role in carcinogenesis, when viral oncogene infects human cell, and the reverse transcriptase enzyme generates cDNA, which is then integrated into the human genome.
  - Viral oncogenesis can be defined as the feature of oncogenic viruses that induces benign and malignant proliferation of infected cells.
  - Oncogenic viruses code different oncoproteins, which can override growth suppressor signals, interfere with cellular receptor-mediated signal transduction pathways, and target cellular genes to immortalize and/or transform virus infected cell to CSC leading to unrestricted cell proliferation and development of malignant tumor growth.

PROTO-ONCOGENES FUNCTION DURING PHYSIOLOGIC AND PATHOLOGIC STATE

Proto-oncogene plays a role in regulating normal cells division. An oncogene is a mutated proto-oncogene that has potential to induce cancer. Proto-oncogene can become activated by several genetic mechanisms inclucing transduction, insertional mutagenesis, amplification, point mutations, and chromosomal translocations. Proto-oncogenes function during physiologic and pathologic state are being discussed here.

HER2/neu (ERBB2) Proto-oncogene

HER2/neu (also called ERBB2) proto-oncogene encodes the transmembrane receptor tyrosine kinase (RTK) called human epidermal growth factor receptor 2 (EGFR-2) on breast tissue cells, which are involved in cell growth, DNA repair and cell division.

Physiologic State

HER2/neu encodes transmembrane growth factor receptors, which include epidermal growth factor receptor 2 (EGFR-2), HER2/neu, HER3 and HER4. HER2/neu consists of an extracellular domain, which interacts with other EGFR family members, and an intracellular tyrosine kinase domain. HER2/neu forms heterodimers with other EGFR family members, induced by binding of EGF to EGFR. Hence, HER2/neu serves as a coreceptor of EGFR.

Pathologic State

There are two copies of HER2/neu gene in the normal breasts. HER2/neu gene amplification, i.e. extra copies (i.e. >2 copies) results in development of breast carcinoma in 30% of women as a result of unrestricted CSC division than normal cell division in normal breasts.

- HER2/neu amplification can alter the response to chemotherapeutic agents, and associated with aggressive clinical course of breast cancer patients.
- HER2/neu positive breast carcinoma cases are treated by humanized 'Trastuzumab' (**Herceptin**) monoclonal antibody, that binds to the HER2/neu protein, and block its activity, preventing excessive cell proliferation of breast carcinoma.

RAS Proto-oncogene Family

RAS proto-oncogene family includes K-RAS, H-RAS, and N-RAS. RAS gene encodes a 21-kDa guanosine

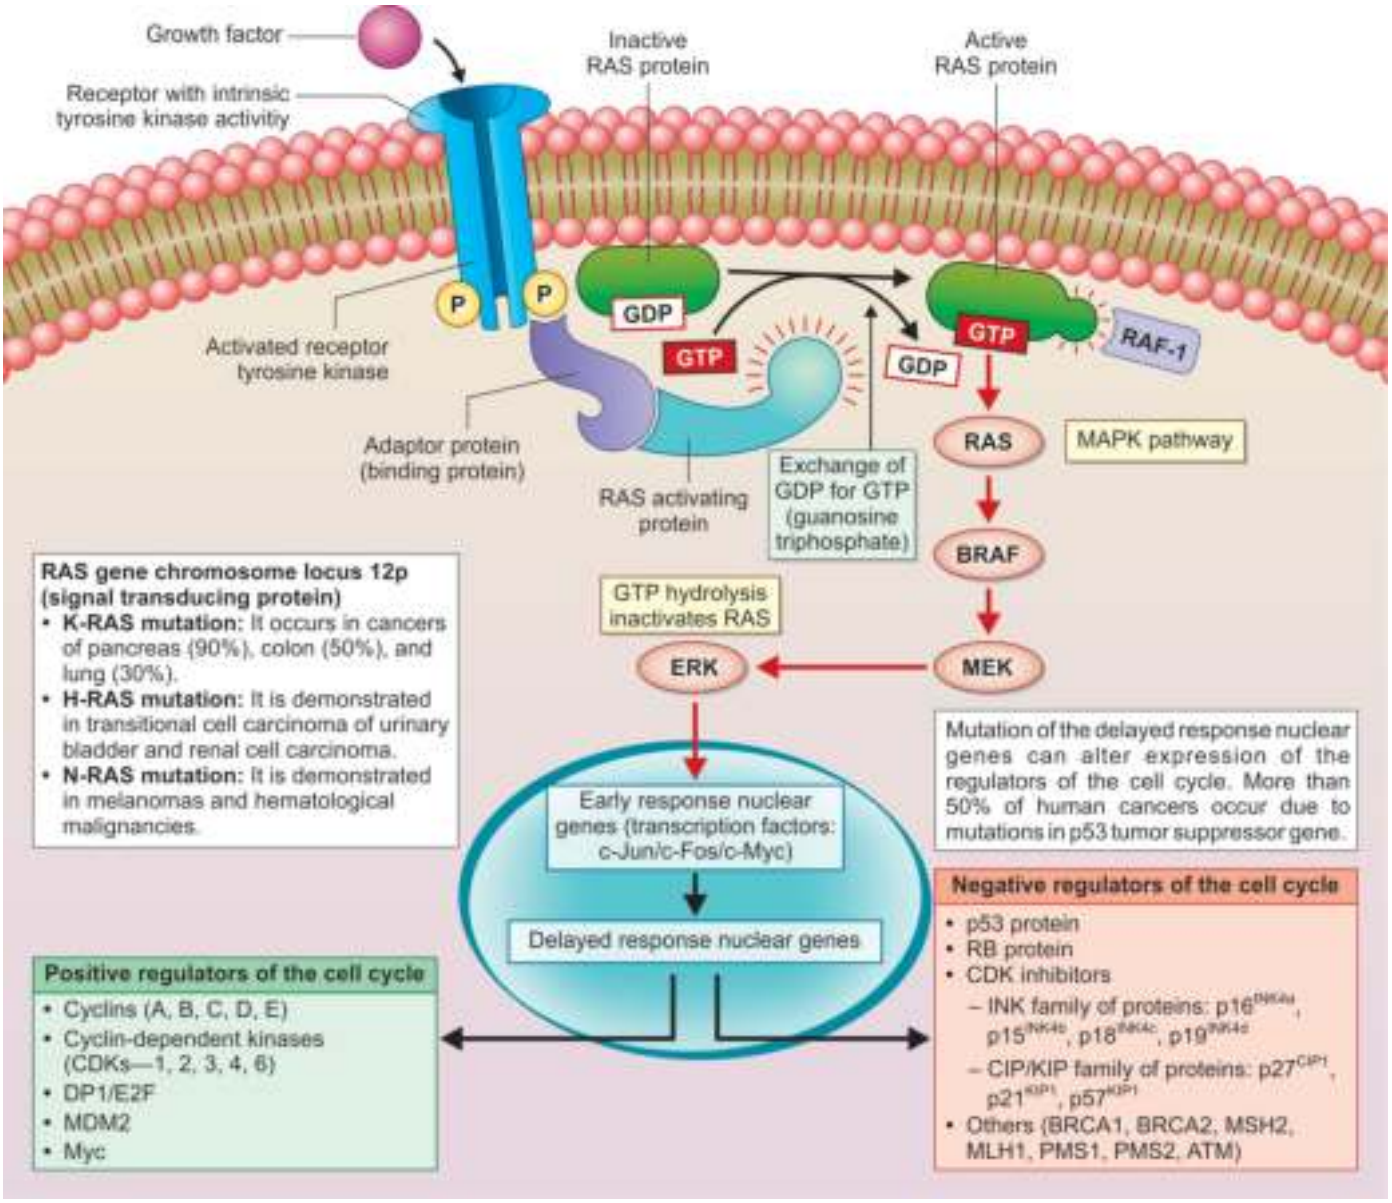

Fig. 6.114: RAS signaling pathway. RAS family proteins (K-RAS, H-RAS, and N-RAS) belong to superfamily of small GTP-binding and hydrolyzing proteins (GTPases), which regulate intracellular signal transduction networks such as mitogen-activated protein kinases (MAPK: RAS → BRAF → MEK → ERK) and phosphoinositol 3-kinase (PI3K) pathways, and induce cell growth, cell differentiation, migration and cell survival. In a normal cell, binding of a ligand to the tyrosine kinase receptor (RTK) stimulates autophosphorylation of specific tyrosine on the tyrosine kinase receptors, inactive (GDP-bound) RAS is activated to a GTP-bound state through GTPase activity of RAS that keeps RAS-mediated signaling in check. Mutations in RAS family of genes are linked to cancers.

triphosphate (GTP)-binding protein that plays key role in many cellular processes including actin cytoskeletal integrity, cell proliferation, differentiation, migration, cell adhesion, and apoptosis. RAS signaling pathway is shown in Fig. 6.114.

Physiologic State

RAS protein is the one of the on/off switches in a series of steps. GTP-binding protein binds to its cognate receptor [EGFR receptor tyrosine kinase (RTK) activates RAS/RAF/MEK/ERK/MAPK signaling pathway and phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR signaling pathway.

- GTP-binding protein activity is regulated by growth factors (e.g. EGF), that control its ability to bind and hydrolyze guanosine triphosphate (GTP) to guanosine diphosphate (GDP).
- Cell activated by growth factors induces RAS from an active GTP-bound state to inactive GDP-bound state. To turn the 'switch on' of the signaling pathway, RAS protein must bind to guanosine triphosphate (GTP) in the cells. To turn 'switch off' the signaling pathway,

RAS gene product must break up (hydrolyze) the GTP molecule to GDP. GTP proteins belong to the larger group of enzymes called GTPase.

Pathologic State

RAS gene mutation encodes RAS oncoprotein that causes an uncontrolled growth-promoting signal. RAS gene amplification is implicated in many human cancers. Point mutations of RAS gene at codons 12, 13, 59 and 61 are linked to carcinogenesis, and hence are targets for novel approaches for cancer treatment.

- K-RAS mutation is demonstrated in pancreatic carcinoma (90%), lung carcinoma, colon carcinoma (50%), and thyroid carcinoma (50%). Identification of RAS gene mutations in the DNA of pancreatic carcinoma shed into the feces may enable clinicians to differentiate between chronic pancreatitis and pancreatic carcinoma.
- H-RAS mutation is found in renal cell carcinoma and urinary bladder carcinoma. Mutations in N-RAS and BRAF (MAPK signaling pathway) are demonstrated in melanoma. All the cancer therapies are targeted toward anti-RAS modalities.

Myc Proto-oncogene

Myc is a family proto-oncogene (c-Myc, L-Myc and N-Myc genes) encodes transcription factors, which binds and regulates the transcription of specific targeted genes regulating biological processes such as cell proliferation, cell growth, stem cell self-renewal, survival, metabolism, protein synthesis, cell differentiation and apoptosis.

Physiologic State

Myc proto-oncogene plays important roles in stem cells including pluripotent stem cells. In neural stem cells, N-Myc promotes a rapidly proliferative stem cell and precusor-like state in the developing brain while inhibiting differentiation.

Pathologic State

Myc gene mutation induces tumorigenesis by evading multiple tumor suppressor checkpoint mechanisms. Myc gene amplification is linked to human cancers (e.g. Burkitt's lymphoma, diffuse large B cell lymphoma (DLBCL), acute lymphoblastic leukemia (ALL), breast carcinoma, lung carcinoma, colon carcinoma, and other carcinomas).

- Chromosomal translocation t(8;14) (q24;q32) involves the c-Myc gene (8q24), and the immunoglobulin heavy chain (IgH) locus (14q32) results in fusion of BCL-2 gene located near to IgH locus (14q32) leading to overexpression of BCL-2 anti-apoptotic protein. These findings are characteristic of B cell malignancies such as Burkitt's lymphoma (90%), diffuse large B cell lymphoma (2–5%), and acute lymphoblastic leukemia (ALL).
- Long distance polymerase chain reaction (LD-PCR) assays can detect oncogene/Ig gene rearrangement and fusion genes. L-Myc gene amplification is demonstrated in small cell lung carcinoma. N-Myc gene amplification is characteristic of neuroblastoma.

SRC Family of Nonreceptor Tyrosine Kinase Proto-oncogene

SRC proto-oncogene is a nonreceptor tyrosine kinase distributed in different locations within the cell such as plasma membrane, perinuclear membrane and endosomal membrane that plays key roles in cell signaling. SRC proto-oncogene can also be present in the cytoplasm, and between cells at adherens junctions, where it performs different functions.

Physiologic State

SRC proto-oncogene nonreceptor tyrosine kinase coordinates embryonic development, cell adhesion, cell growth, cell migration and cell differentiation.

- SRC proto-oncogene encodes SRC protein, that transfers phosphate groups to the target molecules. Addition/removal of phosphate groups acts like switch, which can turn on/turn off switch and alter several target biomolecules resulting in the transmission of signals to the nucleus, that help in regulation of cells.
- SRC protein present on plasma membrane, which can transduce signals from immune cell receptors, integrin receptors, G protein-coupled receptors and cytokine receptors to intracellular signaling pathways that transmit signals to the nucleus, cytoskeleton and other cellular components; and regulate gene transcription, immune response, cell adhesion, cell cycle progression, migration, and apoptosis.
- SRC proto-oncogene located within the nucleus, regulates cell cycle progression, and cell division by its interaction with other cellular proteins. For example, SRC can interact with Sam68, and regulate gene expression.
- SRC proto-oncogene regulates the respiratory enzyme '**cytochrome c**' oxidase (Cox) in bone osteoclasts, where SRC-induced phosphorylation of Cox is required for maintaining high levels of ATP to meet high energy requirements of cells.

Pathologic State

SRC proto-oncogene belongs to SRC family of kinases, which is similar to v-SRC gene of Rous sarcoma virus. SRC oncogene (mutated SRC proto-oncogene gene) has been suggested to play a key role in tumorigenesis,

where it may facilitate malignant tumor progression through angiogenesis, invasion and metastasis to distant organs.

- Overexpression of c-SRC gene leads to the constitutive activation of STAT3, increased DNA binding of STAT3 at DNA consensus elements, and the cell cycle, thus resulting in unrestricted CSC proliferation.
- SRC proto-oncogene nonreceptor tyrosine kinase protein activity is increased in colon carcinoma, breast carcinoma pancreatic carcinoma and brain tumors. SRC is a promising target for cancer therapy.

Telomerase Reverse Transcriptase Proto-oncogene

Telomerase reverse transcriptase (TERT), also known as human telomerase reverse transcriptase (hTERT), is a proto-oncogene located on short arm of chromosome 5 in the region of 5p15.33, that codes for the catalytic subunit of telomerase enzyme. TERT promoter mutations are demonstrated in 80–90% of human cancers, and can be used as biomarker in diagnosis and outcome prediction.

Physiologic State

Telomerase is ribonucleoprotein enzyme; whose mechanism is to add nucleotide base pairs to telomeres, which maintain chromosomal ends. In normal cells, telomerase enzyme activity is only present during fetal development. In adults, normal somatic cells lack telomerase activity.

Pathologic State

Evasion of replicative senescence and CSC proliferation without restriction, sometimes designated as immortalization, is one of the hallmarks of cancer that may be attained through reactivation of telomerase in somatic cells in adults.

- Telomerase enzyme is abnormally active in most CSCs, which undergo cell growth and unrestricted CSC proliferation. TERT gene mutation can occur by various mechanisms: mutation within promoter region, gene amplification, and rearrangements in 4% of human cancers.
- TERT gene mutations within promoter region enhance TERT transcription activity in urothelial carcinoma (68%), central nervous system tumors (28%), thyroid cancers—follicular thyroid carcinoma, papillary thyroid carcinoma and differentiated/anaplastic thyroid carcinoma (15%), prostatic carcinoma, endometrial carcinoma, rhabdomyosarcoma (2%), neuroblastoma, lung carcinoma, colorectal carcinoma, ovarian carcinoma, breast carcinoma, adrenocortical carcinoma, and acute myelogenous leukemia (AML).
- Rearrangements in the TERT gene within promoter region have been implicated in neuroblastomas. Mutations in TERT gene have been demonstrated in familial idiopathic pulmonary fibrosis, and dyskeratosis congenita, e.g. aplastic anemia or malignancies.

BCL-2 Proto-oncogene

BCL-2 (B cell lymphoma 2) proto-oncogene located on chromosome 18 encodes an integral outer mitochondrial membrane protein (called BCL-2), that works to prevent apoptosis via intrinsic apoptotic (mitochondrial) pathway.

Physiologic State

BCL-2 proto-oncogene prevents BAX/BAK oligomerization, which would otherwise lead to the release of several apoptogenic molecules from the mitochondrion. BCL-2 binds to and inactivates BAX and other pro-apoptotic proteins, thereby inhibiting apoptosis.

Pathologic State

BCL-2 gene overexpression can contribute to metastasis in certain **human hematolymphoid malignancies**. For examples, follicular lymphoma, Burkitt's lymphoma, diffuse large B cell lymphoma, chromosomal translocation t(8;14) (q24;q32) involves the c-Myc gene (8q24) and the immunoglobulin heavy chain (IgH) locus (14q32) results in fusion of BCL-2 gene located near to IgH locus (14q32) resulting in overexpression of BCL-2 anti-apoptotic protein and thus evasion of apoptosis of malignant cancer stem cell (CSC). BCL-2 inhibitors are being developed to downregulate BCL-2.

- BCL-2 consists of four conserved domains (BH1, BH2, BH3 and BH4), which belongs to BCL-2 family members (e.g. BIM, BID, PUMA, NOVA, BAD, HRK, BMF and BIK).
- Among these homologies, motifs, BH3, BH1 and BH2 are the most commonly targeted therapy for cancers in clinical oncology.

Epidermal Growth Factor Receptor Proto-oncogene

Epidermal growth factor receptor (EGFR) is a transmembrane protein encoded by EGFR gene, which spans the cell membrane so that one end of the spanning protein remains inside the cell's cytosol, and the other end of the protein projects outer surface of the cell. EGFR is a member of the ErbB family of receptors, a subfamily of four closely related receptor tyrosine kinase (RTK): EGFR (ErbB-1), HER2/neu (ErbB-2), HER3 (ErbB-3) and HER4 (ErbB-4).

Physiologic State

Epidermal growth factor receptor (EGFR) binds at least seven different ligands: epidermal growth factor (EGF), transforming growth factor-α (TGF-α), heparin

binding EGF-like growth factor (HBEGF), β-cellulin (BTC), amphiregulin (AREG), epiregulin (EREG) and epigen (EPGN).

- Binding of EGF to EGFR induces two EGFR proteins to stick to each other. The joined EGFR proteins are called a dimer, that activates cell surface receptor leading to a process of autophosphorylation of two copies of the EGFR protein. EGFR activation increases the activity of multiple signaling pathways.
- In particular RAS/RAF/MEK/ERK/MAPK signaling pathway, PI3K/AKT/mTOR signaling pathway and JAK/STAT signaling pathway downstream signals into nucleus (e.g. SP1, Myc, Jun, Fos, Elk, ERG1, STAT), and ultimately evokes a variety of biological responses such as cell proliferation, differentiation, migration, adhesion and apoptosis.

Pathologic State

Epidermal growth factor receptor (EGFR) gene is mutated or upregulated in many human cancers (e.g. breast carcinoma, lung carcinoma, and head and neck squamous cell carcinoma). Upregulation of EGFR leads to angiogenesis, invasion, unrestricted CSC proliferation survival and metastasis.

- Monoclonal antibodies and tyrosine kinase inhibitors (TKIs) are currently used to target EGFR mutations in human cancers.
- Monoclonal antibodies (e.g. cetuximab and panitumumab) bind to extracellular domain of EGFR to prevent ligands from activating the EGFR. TKIs bind to the cytosolic domain of EGFR and prevents activation process.

CCND1 Proto-oncogene Encodes Cyclin D Protein

CCND1 proto-oncogene located on chromosome 11q13.3 encodes cyclin D1 protein that regulates cell proliferation, metabolism, growth and differentiation.

- During G1 phase of cell cycle, cyclin D1 is synthesized rapidly, that accumulates in the nucleus, and undergoes degradation as the cell enters the S phase of cell cycle.
- Cyclin D1 is a regulatory subunit of cyclin-dependent kinases CDK4 and CDK6. The protein dimerizes with CDK4/CDK6 to regulate the G1/S phase transition, and entry into the S phase.

Physiologic State

Recent studies revealed that cyclin D1 can also regulate cell cycle via CDK-independent pathway. Cyclin D1 regulates the activity of transcription factors, coactivators and corepressors that govern histone octamer acetylation and chromatin remodeling proteins. Mitogens via RAS-mediated signaling pathways and hormones induce cyclin D1 synthesis, inhibit its proteolysis, and export from the nucleus during the G1 phase of cell cycle. Degradation of cyclin D1 occurs via ubiquitin-mediated proteolysis pathway at the end of S phase of cell cycle.

Pathologic State

Genomic rearrangement or gene amplification of CCND1 proto-oncogene codes for excess of aberrant cyclin D1 leading to unrestricted CSC proliferation, cell growth, angiogenesis via VEGF production, evasion of apoptosis, invasion and metastasis and chemoresistance in many cancers.

- Cyclin D1 overexpression is linked to development of non-small cell lung carcinoma (30–45%), head and neck squamous cell carcinoma (30–50%), pancreatic carcinoma (25%), urothelial carcinoma (15%), breast carcinoma (13%), and parathyroid adenomas. Cyclin D1 overexpression is strongly correlated with ER+ breast carcinoma and chemoresistance.
- Mantle cell lymphoma (MCL) is a hematologic neoplasm characterized by the presence of chromosomal translocation t(11;14) (q13;q32), which extraposes CCND1 gene (also called BCL-1, PRAD-1) at 11q13 with an enhancer of the immunoglobulin heavy chain (IgH) at 14.32q. The resultant aberrant cyclin D1 expression plays a key role in the pathogenesis of mantle cell lymphoma. Chromosomal translocation of cyclin D1 gene locus is also demonstrated in 15–20% of multiple myeloma patients.

TUMOR SUPPRESSOR GENES

Tumor suppressor genes encode proteins that normally function to inhibit cell proliferation and tumorigenesis by regulation of cell cycle, differentiation, signal transduction, cell adhesion, maintenance of genomic integrity, DNA (deoxyribonucleic acid) damage repair, and inducing apoptosis. Loss-of-function mutations in tumor suppressor genes possess oncogenic potential. Since, one copy of a tumor suppressor gene is sufficient to regulate cell proliferation, both alleles of a tumor suppressor gene must be lost or inactivated in order to induce malignant tumor. Thus, oncogenic loss-of-function mutations in tumor suppressor genes act recessively. Deletions or point mutations in tumor suppressor genes prevent production of any protein or enhance production of a nonfunctional protein. Oncogenes resulting from activation of proto-oncogene (i.e. turning on) and inactivation/biallelic loss of tumor suppressor genes (i.e. turning off) may result in unrestricted CSC proliferation, and development of malignant tumors. Tumor suppressor gene in physiologic state and pathologic state is shown in Fig. 6.115.

- Five broad classes of tumor suppressor proteins are generally recognized as being encoded by tumor suppressor genes: (a) intracellular proteins such as

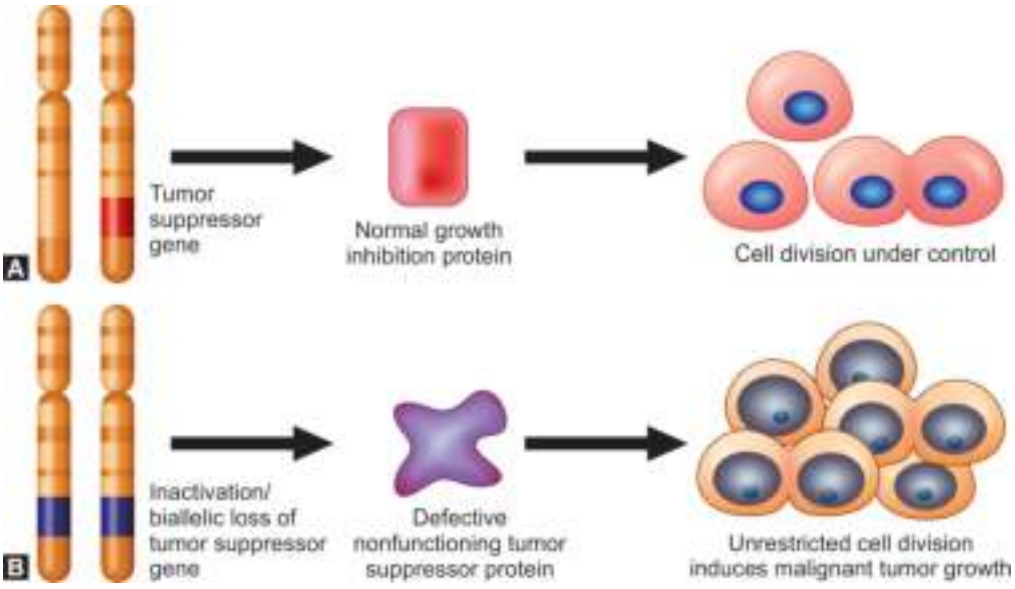

Fig. 6.115: Tumor suppressor gene in physiologic state and pathologic state. (A) Normally, tumor suppressor gene regulates cell division under control, (B) inactivation/biallelic loss of tumor suppressor gene causes unrestricted cell division and induces malignant tumor.

p16 cyclin-dependent kinase inhibitor, that regulate or inhibit progression through a specific stage of the cell cycle, (b) receptors for hormones that function to inhibit cell proliferation, (c) cell cycle checkpoint regulatory proteins, that arrest cell cycle, if DNA gets damaged or abnormalities in chromosomes, (d) proteins that promote programmed cell death (apoptosis), and (e) enzymes that participate in DNA repair. Inherited germline mutations in tumor suppressor genes are responsible for familial cancer syndromes running in families. However, somatic mutations in tumor suppressor genes are most common and acquired, and not inherited. Tumor suppressor genes can be divided into two major categories, known as gatekeepers and caretakers. Inactivation of gatekeeper and caretaker genes contribute to development of malignant tumor, invasion and metastasis.

- **Tumor suppressor gatekeeper genes** encode proteins, that regulate cell proliferation. They act as guards that inhibit cells from passing through cell cycle checkpoints by countering the progression of cellular growth and encouraging apoptosis. Examples of tumor suppressor gatekeeper genes include **TP53, APC,** and **RB1**.
- **Tumor suppressor caretaker genes** encode proteins, that regulate the maintenance of the genetic information integrity in each cell. Examples of tumor suppressor caretaker genes include **DNA repair genes** (e.g. BRCA1, BRCA2), **mismatch repair genes** (e.g. MLH1, MSH2, MSH6, PMS2), CDKN2A and XP. Functional categories of mutations in tumor suppressor genes and associated cancers are given in Table 6.93.

- Tumor suppressor gene has two alleles. If only one allele for the tumor suppressor gene is mutated, but

Table 6.93 Functional categories of mutations in tumor suppressor genes and associated cancers

Gene and Locus	Protein	Function	Germline/Somatic Mutations and Familial/Sporadic Tumors
Tumor suppressor genes function to inhibit Wnt/β-catenin mitogenic signaling activator pathway			
APC gene (5p22.2)	APC protein	APC inhibits Wnt/β-catenin signaling activator pathway, thus prevents nuclear transcription, and also degrades β-catenin	▪ Familial tumors—familial adenomatous polyposis coli and colon carcinoma ▪ Sporadic tumors—colon carcinoma, gastric carcinoma, pancreatic carcinoma, thyroid carcinoma and melanoma
NF1 gene (13p11)	Neurofibromin protein 1	NF1 inhibits RAF/MEK/ERK/MAPK signaling activator pathway	▪ Familial tumors—neurofibromatosis type 1 and malignant peripheral nerve tumors ▪ Sporadic tumors—juvenile chronic myelogenous leukemia, neuroblastoma and schwannoma

Contd...

Table 6.93 Functional categories of mutations in tumor suppressor genes and associated cancers (*Contd...*)

Gene and Locus	Protein	Function	Germline/Somatic Mutations and Familial/Sporadic Tumors
NF2 gene (22q)	Merlin protein	NF2 stabilization of cytoskeleton membrane linkage	▪ Familial tumors—neurofibromatosis type 2 (acoustic schwannoma and meningioma) ▪ Sporadic tumors—schwannoma and meningioma
PTCH-1 gene (9q22.3)	Patched protein	Patched protein inhibits Hedgehog signaling pathway	▪ Familial tumors—Gorlin's syndrome (basal cell carcinoma, medulloblastoma, other benign tumors) ▪ Sporadic tumors—basal cell carcinoma and medulloblastoma
SMAD2 gene (18q21) and SMAD4 gene (18q22)	SMAD2/SMAD4 protein	Both SMA2/SMAD4 inhibit TGF-β signaling activator pathway, repress CDK4 and Myc and induce expression of CDK inhibitor	▪ Familial tumors—juvenile polyposis ▪ Sporadic tumors—colon carcinoma and pancreatic carcinoma
PTEN gene (10q23.3)	Phosphatase and tensin homologue	PTEN protein inhibits AKT/PKB signaling pathway	▪ Familial tumors—Cowden syndrome (cancers of breast, endometrium and thyroid gland) ▪ Sporadic tumors—lymphoid neoplasms, glioblastoma multiforme, endometrial carcinoma, prostatic carcinoma, breast carcinoma and lung carcinoma
Tumor suppressor genes function to inhibit cell cycle progression			
CDKN2A gene (9p2)	▪ $P16^{INK4a}$ protein ▪ $P14^{ARF}$ protein	$P16^{INK4a}$ protein inhibits CDK. $P14^{ARF}$ protein indirectly activates p53 tumor suppressor gene	▪ Familial tumors—familial melanoma ▪ Sporadic tumors—breast carcinoma, pancreatic carcinoma, urothelial carcinoma, lung carcinoma, head and neck squamous cell carcinoma and esophageal carcinoma
RB gene (13p14.2)	RB protein	RB gene codes for pRB protein, master brake on cell cycle, and inhibits G1 to S transition during cell cycle, and also inhibits nuclear transcription factor	▪ Familial tumors—retinoblastoma and osteosarcoma ▪ Sporadic tumors—retinoblastoma, osteosarcoma, breast carcinoma, colon carcinoma, prostatic carcinoma, urinary bladder carcinoma and lung carcinoma
Tumor suppressor genes function to inhibit angiogenesis			
von Hippel-Lindau (vHL) gene (3p25)	von Hippel-Lindau (vHL) protein	vHL inhibits hypoxia-inducible factor 1α (HIF1α) and regulates nuclear transcription	▪ Familial tumors—von Hippel-Lindau syndrome (cerebellar hemangioblastoma, retinal angiomas, bilateral renal cell carcinoma and pheochromocytoma) ▪ Sporadic tumors—renal cell carcinoma
SDH (SDHA, SDHB, SDHC, SDHD) genes (11q23)	Succinate dehydrogenase subunits of B and D	These gene proteins participate in TCA cycle and oxidative phosphorylation	▪ Familial tumors—paraganglioma and pheochromocytoma ▪ Sporadic tumor—paraganglioma
STK11 gene (19q13.3)	Liver kinase B1 (LKB1) or STK11 protein	Gene protein activates AMPK family of kinases and suppresses cell growth when cell nutrients and energy levels are low	▪ Familial tumors—Peutz-Jeghers syndrome (cancers of GIT, pancreas, cervix, ovary, and breast) ▪ Sporadic tumors—non-small cell lung carcinoma, cervical carcinoma, colorectal carcinoma, pancreatic carcinoma and melanoma
CDH1 gene (16q22.1)	E-cadherin	Gene protein participates in cell adhesion. It inhibits cell motility	▪ Familial tumors—gastric carcinoma ▪ Sporadic tumors—gastric carcinoma and breast lobular carcinoma

Contd...

Table 6.93 Functional categories of mutations in tumor suppressor genes and associated cancers (*Contd...*)

Gene and Locus	Protein	Function	Germline/Somatic Mutations and Familial/Sporadic Tumors
Tumor suppressor gene function as genomic stability enabler (most important)			
TP53 gene (17p13.1)	p53 protein	p53 inhibits cell cycle G1 to S phase, repairs DNA and induces cell apoptosis by activating BAX gene	▪ Familial tumors—Li-Fraumeni syndrome (breast carcinoma, adrenocortical carcinoma, osteosarcoma, rhabdomyosarcoma, leukemia, brain tumors) ▪ Sporadic tumors—many human cancers (>50% of human cancers)
Tumor suppressor genes function to repair damaged DNA			
BRCA1 caretaker gene (17q21)	BRCA1 protein	BRCA1 binds RAD51 molecule that mediates repair of double-stranded breaks in DNA	▪ Familial tumors—ovarian carcinoma, breast carcinoma, prostatic carcinoma and fallopian tubal carcinoma ▪ Sporadic tumors—breast medullary carcinoma and metaplastic carcinoma
BRCA2 gene (13q12)	BRCA2 protein	BRCA2 binds RAD51 molecule that mediates repair of double-stranded breaks in DNA	▪ Familial tumors—breast carcinoma, ovarian carcinoma, gastric carcinoma, fallopian tubal carcinoma ▪ Sporadic tumor—Fanconi anemia
MLH1 gene (3p21), MSH2 gene (2p15), MSH3 gene (5q11.12), MSH6 gene (2p16), PMS1 gene (2p32), PMS2 gene (7p22)	MLH1, MSH2, MSH3, MSH6, PMS1, PMS2 proteins	DNA nucleotide excision repair pathway, mutation is associated with accumulation of numerous mismatched errors in DNA replication	▪ Familial tumors—hereditary non-polyposis colorectal cancer—HNPCC (Lynch syndrome) increased risk of development of carcinoma of endometrium (first most common cancer), ovary and right colon carcinoma ▪ Sporadic tumors—colorectal carcinoma, endometrial carcinoma, Muir-Torre syndrome, hepatobiliary carcinoma, genitourinary carcinoma and glioblastoma multiforme
Tumor suppressor genes functions by various mechanisms			
WT1 (11p13.)	WT1 gene protein	Transcription factor	▪ Familial tumors—Wilm's tumor ▪ Sporadic tumors—Wilm's tumor and certain leukemias
MEN1 (11q13)	Menin protein	Transcription factor	▪ Familial tumors—multiple neoplasia syndrome 1 (MEN1) ▪ Sporadic tumors—parathyroid adenoma, pancreatic islet cell tumor, and pituitary tumor
DPC4 (18q21.1)	DPC4 protein	DPC4 encodes relay molecule in cell division inhibitory pathway	▪ Familial tumors—rarely occur ▪ Sporadic tumors—pancreatic carcinoma (most common), breast carcinoma and ovarian carcinoma
ATM (l11p22)	ATM protein	Receptor tyrosine kinase (RTK)	▪ Familial tumors—ataxia-telangiectasia, breast carcinoma, gastric carcinoma and leukemia/lymphoma ▪ Sporadic tumors—unknown
p16 (9p21)	p16 protein	p16 inhibits nuclear cyclin-dependent kinase activity	▪ Familial tumors—familial melanoma ▪ Sporadic tumors—mesothelioma, pancreatic carcinoma, melanoma and astrocytoma

Contd...

Table 6.93 Functional categories of mutations in tumor suppressor genes and associated cancers (*Contd...*)

Gene and Locus	Protein	Function	Germline/Somatic Mutations and Familial/Sporadic Tumors
TGF-β (19q)	TGF-β protein	TGF-β inhibits G1 to S phase	▪ Familial tumors—not occur ▪ Sporadic tumors—pancreatic carcinoma and colorectal carcinoma
CHEK2 (22q12)	CHEK2 protein	CHEK2 induces cell cycle arrest, repairs damaged DNA; and activates BRCA1 and p53 tumor suppressor genes by phosphorylation	▪ Familial tumors—breast carcinoma (5%) ▪ Sporadic tumors—post-radiation induced breast carcinoma, prostatic carcinoma, thyroid carcinoma and renal cell carcinoma

1. Tumor suppressor gatekeeper genes inhibit the cell with damaged DNA proliferation and also promote apoptosis of damaged cells. Tumor suppressor gatekeeper genes include TP53, RB and APC.
2. Tumor suppressor caretaker genes maintain the integrity of the genome by repairing DNA damage.
3. Tumor suppressor caretaker genes include BRCA1, BRCA2, MLH1, MSH2, MSH6, PMS2, FAMC, and Xp.

the other allele can still produce enough of normal protein to retain the appropriate function. This means that mutations in tumor suppressor gene tend to be recessive, and thus both alleles must be mutated in order to allow abnormal cell growth to proceed to induce malignant tumor, invasion and metastasis. On the contrary, mutant oncogene alleles are typically dominant.

- Loss of heterozygosity (LOH) of tumor suppressor genes occurs by mitotic recombination, or chromosome misaggregation in the genomic DNA regions during mitosis process. LOH is defined as the loss of one parent's contribution to the somatic cell. LOH is a common form of allelic imbalance by which heterozygous somatic cells become homozygous somatic cells, because one of the two alleles gets lost.
- Hypermethylation of gene refers to epigenetic alterations due to increase in DNA methylation by addition of cytosine and adenosine residues in the promoter region of gene(s), which can silence gene expression or loss of gene function associated with transcriptional loss in the absence of structural alterations. Aberrant DNA methylation is a common phenomenon in carcinogenesis, and the DNA methylation profiles are altered in various human cancers.

TUMOR SUPPRESSOR GATEKEEPER GENES

Tumor suppressor gatekeeper genes encode proteins, that inhibit cell cycle progression on detection of DNA damage, and also induce apoptosis. When both copies of a tumor suppressor gene are inactivated/lost in a cell, the inhibitory gene product can no longer be produced, and the cells have less control of their growth leading to the unrestricted CSC proliferation, and development of malignant tumor. Examples of tumor suppressor gatekeeper genes are TP53, APC, and RB1.

TP53 Tumor Suppressor Gatekeeper Gene

TP53 tumor suppressor gatekeeper gene is located on chromosome 17p13.1, that encodes a tumor suppressor p53 protein, which acts as a transcription factor and 'guardian of the genome'.

Physiologic State

The p53 protein is activated as a result of DNA damage. The p53 protein activates p21, which in turn inhibits the cyclin/CDKs complexes required for cell cycle progression past G1 phase. Cell cycle arrest allows time for DNA repair to occur. If DNA damage is beyond repair, p53 protein can induce apoptosis via activating proapoptotic BAX gene in the mutated cell, an important function, that is crucial for preventing carcinogenesis. TP53 gene guardian of human genome is shown in Fig. 6.116.

Pathologic State

Somatic mutations in the TP53 tumor suppressor genes are one of the most frequent alterations in human cancers of ovaries, esophagus, colorectal region, head and neck, larynx, lung, cervix, skin (melanoma) and leukemia in >50% of cases.

- Germline heterogenous mutations are the underlying cause of **Li-Fraumeni syndrome**, which predisposes to a wide spectrum of early-onset cancers of breast and adrenal cortex, sarcoma, leukemia, brain tumors. TP53 tumor suppressor gene mutations are also potential prognostic and predictive markers, as well as targets for pharmacological intervention.
- TP53 tumor suppressor gene has two alleles (i.e. wild and mutant types). TP53 gene mutant allele inhibits TP53 wild type allele in CSCs.

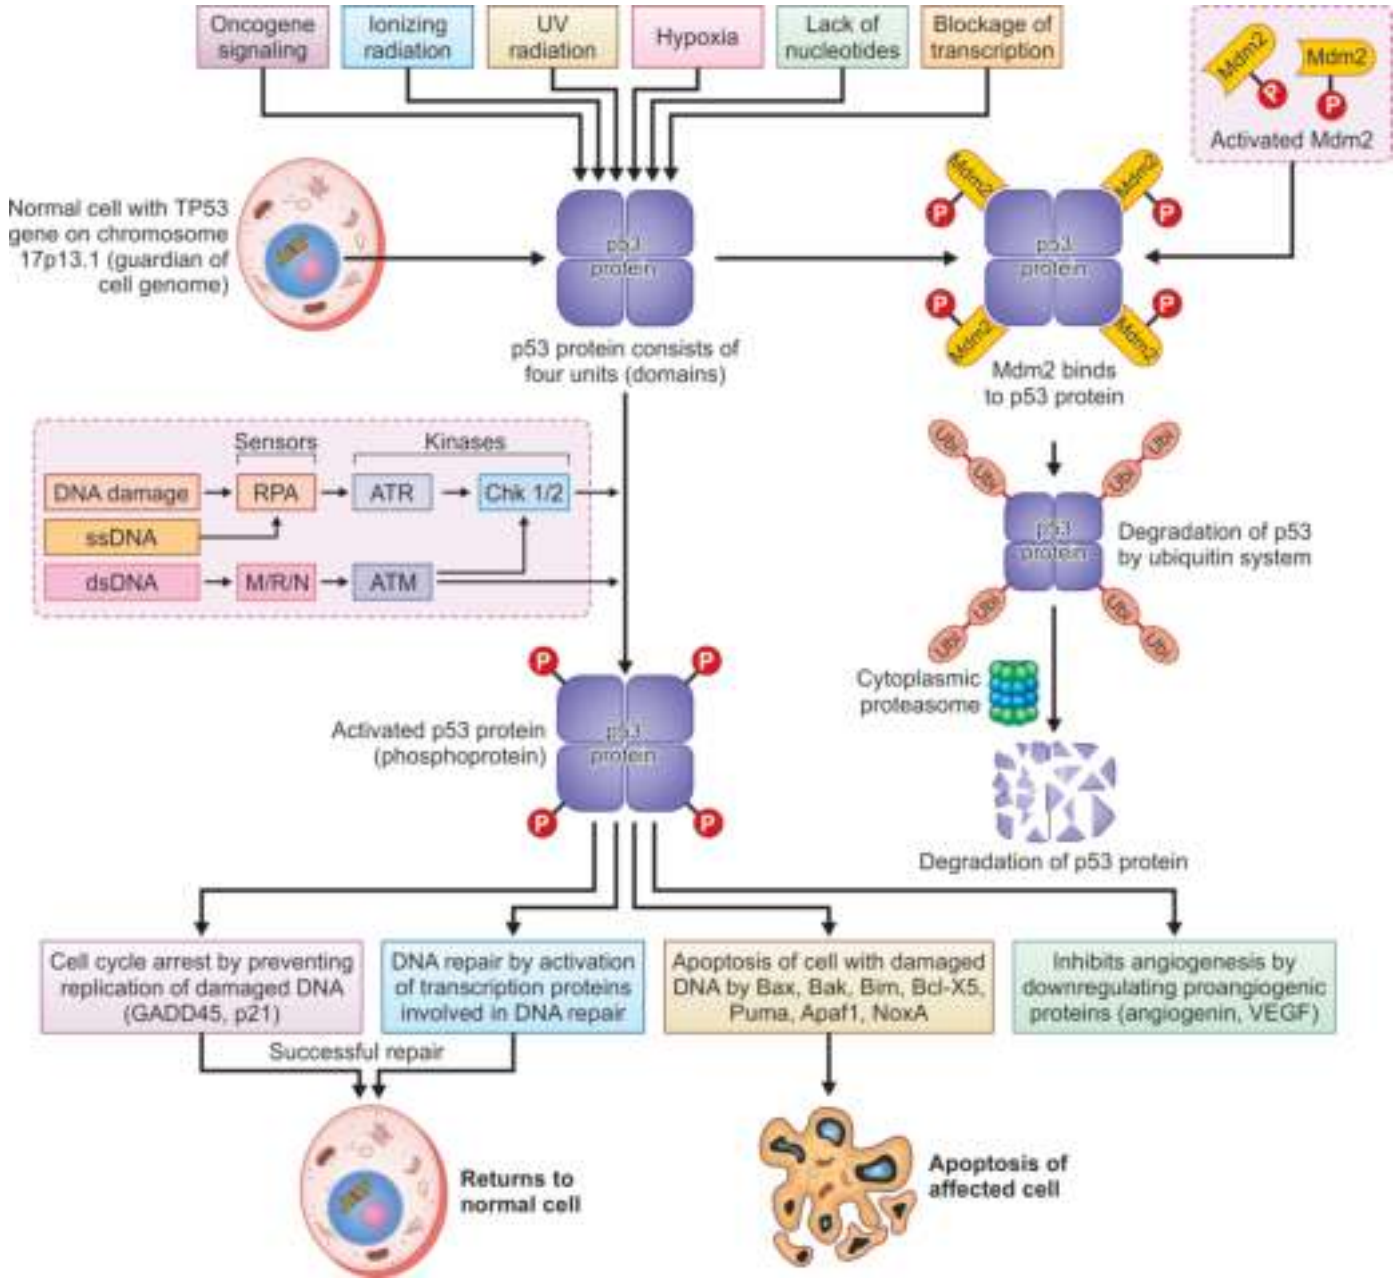

Fig. 6.116: TP53 gene guardian of human genome. TP53 tumor suppressor gene product p53 protein maintains integrity of the human genome. Inactivation/biallelic loss of TP53 tumor suppressor gene causes cell cycle arrest in G1 phase due to upregulation of cyclin-dependent kinase inhibitor CDKN1A and GADD45 genes until either the DNA mutation is repaired in mild damage or undergoing apoptosis in severe damage. If p53 is defective, carcinogen-induced damaged cell proceeds to S phase. Such mutations are propagated to daughter cells, possibly leading to malignant tumor formation.

- Wild-type of TP53 allele occurs in individuals with normal phenotype possessed by majority of the natural population and its p53 protein binds DNA in a sequence-specific manner to mediate its function.
- Mutant type of TP53 allele product p53 is unable to bind wild-type of p53 protein on DNA sequence and may exert 'gain-of-function' activities, that favor development of malignant tumor, invasion and metastasis. TP53 tumor suppressor gene mutation linked to carcinogenesis is shown in Fig. 6.117.

Retinoblastoma 1 Tumor Suppressor Gatekeeper Gene

Retinoblastoma 1 (RB1) is a gatekeeper tumor suppressor gene mapped on chromosome 13q14.2, that encodes a tumor suppressor pRB protein (pRB, i.e. master brake on cell cycle).

- RB protein (pRB) inhibits G1/S phase by inhibiting nuclear transcription factor. Mutation of RB gene (deletion and nonsense) induces loss of regulation of cell cycle activation through sequestration of transcription factors. Dephosphorylated RB gene inhibits cell cycle.

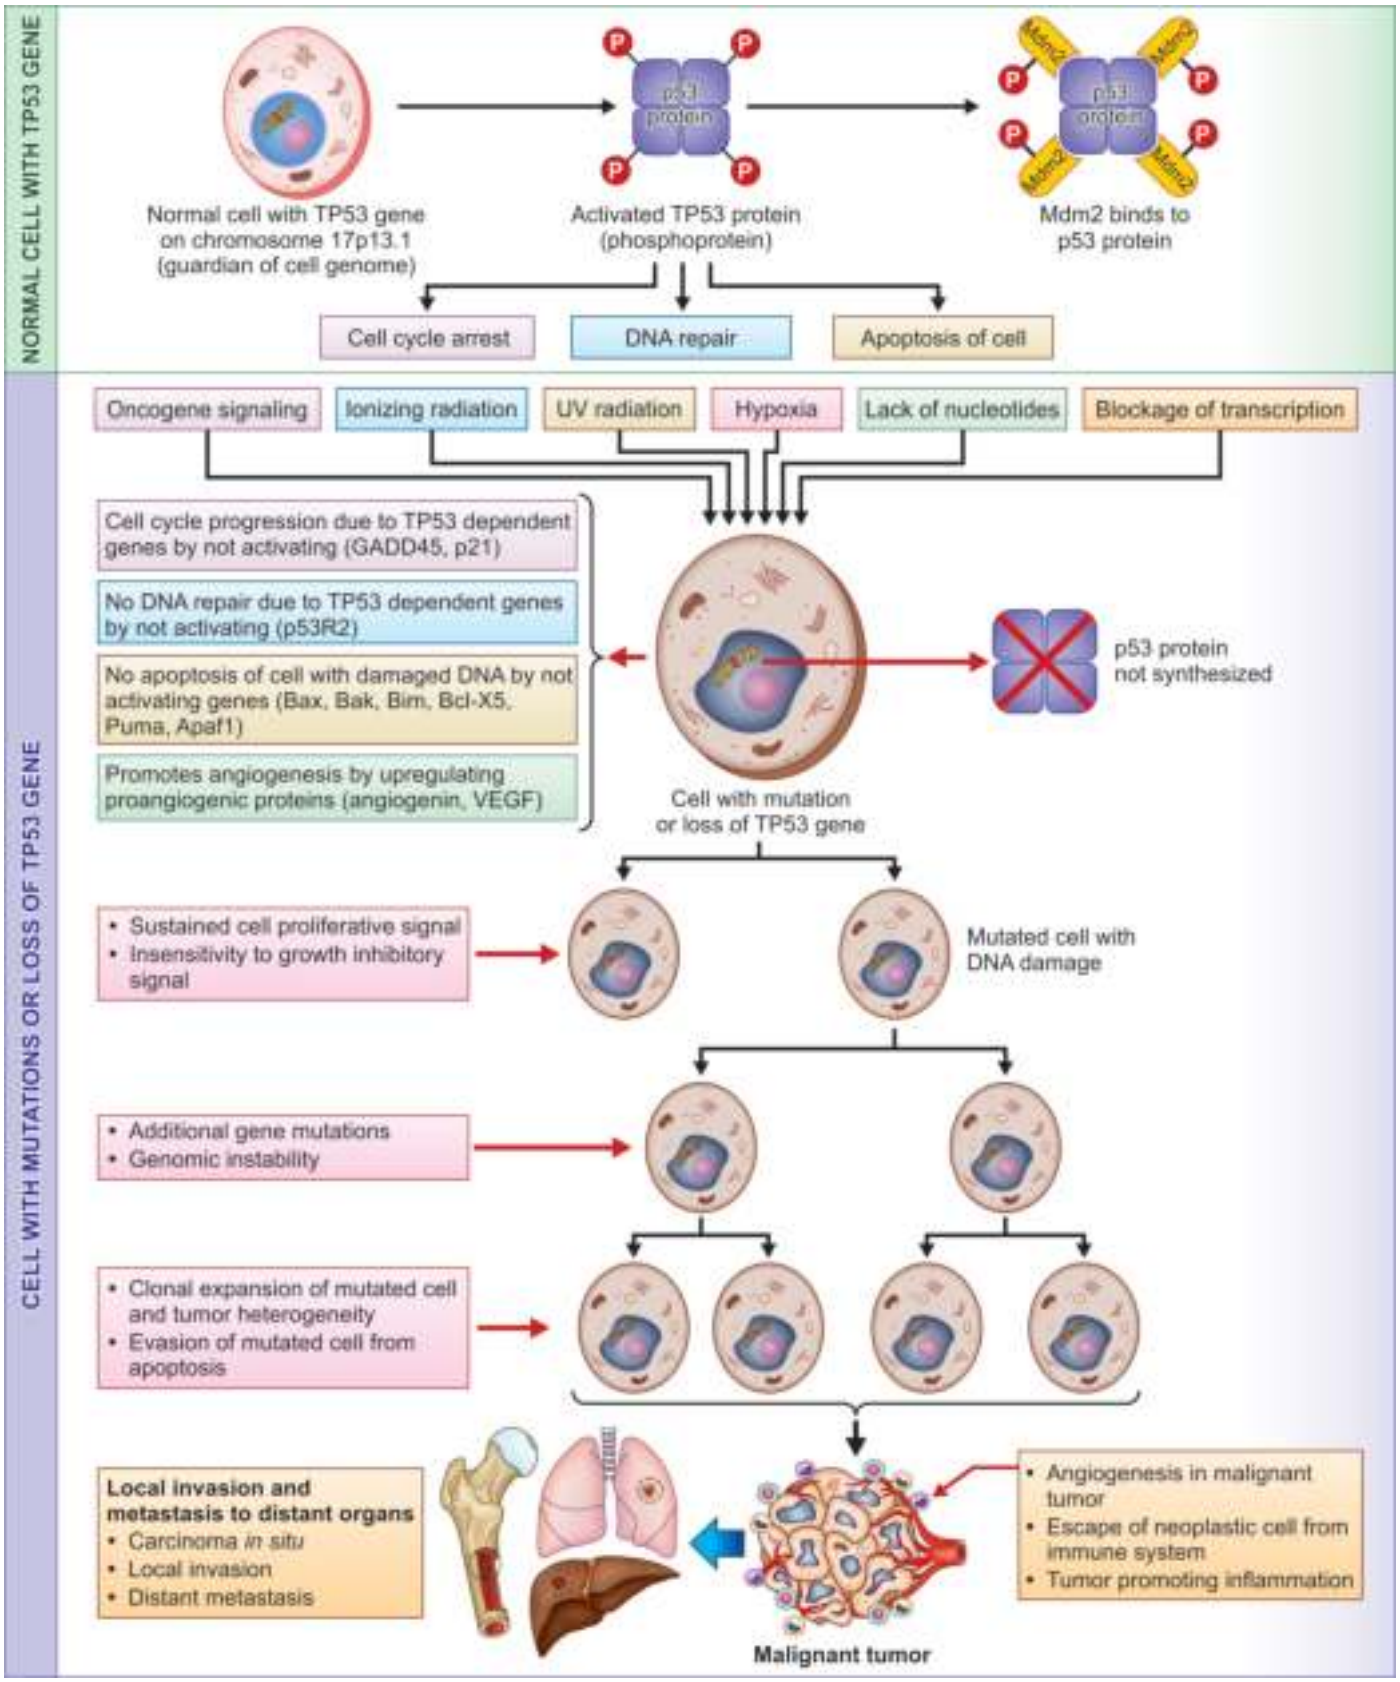

Fig. 6.117: TP53 tumor suppressor gene mutation linked to carcinogenesis. Mutations in TP53 tumor suppressor gene change single amino acid in p53, which impair p53 protein's function. Without normal functioning of p53 protein, DNA damage can accumulate mutations in the cells, which may continue to divide in unrestricted manner and induce malignant tumor.

Table 6.94 pRB tumor suppressor phosphorylation and dephosphorylation in cell cycle

Characteristics	pRB Phosphorylation	pRB Dephosphorylation
Definition	pRB phosphorylation is the addition of a phosphate group to a molecule by protein kinase	pRB dephosphorylation is the removal of a phosphate group to a molecule by phosphatase
Phosphate group	Addition of phosphate group to a molecule	Removal of phosphate group from a molecule
Enzyme involved	Protein kinase	Phosphatase
Consequence	Phosphorylation induces conformational change and provides platform for phosphate-binding proteins	Dephosphorylation induces changes in protein, i.e. stability, activity, interaction and subcellular localization

- When RB gene is phosphorylated, cell division takes place. pRB tumor suppressor phosphorylation and dephosphorylation in cell cycle are given in Table 6.94.

Physiologic State

Retinoblastoma 1 (RB1) tumor suppressor gatekeeper gene provides instructions for making a protein called pRB, that acts as a tumor suppressor, and regulates cell growth by keeping cells from dividing, in an unrestricted manner.

Pathologic State

RB tumor suppressor gatekeeper gene mutations have been demonstrated in familial cancers (retinoblastoma, osteosarcoma) in 40% of cases, and sporadic cancers (retinoblastoma, osteosarcoma, breast carcinoma, prostatic carcinoma, urinary bladder carcinoma, glioblastoma and small cell lung carcinoma) in 60% of cases. Healthy persons have two alleles of the RB gene.

- **Familial retinoblastoma** develops in genetically predisposed in 40% of persons, who have only one active allele of the RB gene. The second allele of RB gene has either lost due to deletion of a portion of the long arm of chromosome 13 or inactivated by a mutation.
- **Sporadic retinoblastoma** occurs only if both alleles of RB gene are lost or inactivated in 60% of persons.

Adenomatous Polyposis Coli Tumor Suppressor Gatekeeper Gene

Adenomatous polyposis coli (APC) is a tumor suppressor gatekeeper gene located on chromosome 5p22.2, that encodes a tumor suppressor APC protein. The APC gene alterations play an important role in the development of malignant tumors in multistep process of carcinogenesis.

Physiologic State

Adenomatous polyposis coli (APC) tumor suppressor gene encodes APC protein that suppresses canonical Wnt/β-catenin signaling, thus prevents accumulation of β-catenin. The β-catenin helps control the expression of particular genes, and promotes the cell growth, cell proliferation and differentiation.

Pathologic State

Adenomatous polyposis coli (APC) tumor suppressor gene mutation is implicated in heritable (e.g. familial adenomatous polyposis (FAP) and colon carcinoma) and nonheritable tumors (e.g. colon carcinoma, gastric carcinoma, pancreatic carcinoma, thyroid carcinoma and melanoma). FAP is autosomal dominant syndrome characterized by germline mutations in APC gene resulting in intestinal adenomatous polyposis and a very high incidence of colorectal adenocarcinoma.

- **Current familial adenomatous polyposis diagnostic criteria:** Current familial adenomatous polyposis (FAP) diagnostic criteria of any one of the mentioned: germline mutation in APC gene or 100–1000 colorectal adenomatous polyps (classic definition) first appear at 10–20 years of age, or colorectal adenomas identical to tubular adenomas under the 30 years of age in patient with a family history of FAP, or intra-abdominal desmoid fibromatosis, osteoma of mandible, or multiple epidermoid cysts in patient with a family history of FAP.
- **Gardner syndrome:** Gardner syndrome is characterized by familial adenomatous polyposis, osteomas especially in mandible, mesenteric and rarely abdominal desmoid fibromatosis, and cutaneous epidermoid cysts.
- **Turcot syndrome:** Turcot syndrome is associated with hereditary colorectal carcinoma. Turcot syndrome includes two distinct syndromes: familial adenomatous polyposis with medulloblastoma or hereditary nonpolyposis colon carcinoma (HNPCC) with glioblastoma multiforme. Some cases of Turcot syndrome can develop hepatoblastoma (≤2%) and rarely pancreatic, biliary and endocrine neoplasms.

TUMOR SUPPRESSOR CARETAKER GENES

Tumor suppressor caretaker genes repair damaged DNA during cell cycle arrest, and maintain genomic stability. Tumor suppressor caretaker genes include DNA repair genes (e.g. BRCA1, BRCA2), mismatch DNA repair genes (e.g. MLH1, MSH2, MSH3, MSH6, PMS1, PMS2), CDKN2A and XP.

BRCA1 and BRCA2 Tumor Suppressor Caretaker Genes

BRCA1 and BRCA2 tumor suppressor caretaker genes encode proteins involved in DNA repair by resolution of DNA crosslinks.

Physiologic State

BRCA1 and BRCA2 tumor suppressor caretaker genes encoding proteins are unrelated, both are normally expressed in the cells and breast and ovarian tissues, where they function to repair damaged DNA, or destroy cells by apoptosis mechanism if DNA cannot be repaired.

Pathologic State

Loss of BRCA1 tumor suppressor caretaker genes result in DNA strands breaks and aneuploidy after cell division. High-penetrance BRCA1 and BRCA2 tumor suppressor caretaker genes are responsible for **hereditary breast carcinoma** and **ovarian carcinoma**.

Mismatch Repair System Tumor Suppressor Caretaker Genes

Mismatch repair (MMR) system genes, i.e. MLH1 gene (3p21), MSH2 gene (2p15), MSH3 gene (5q11.12), MSH6 gene (2p16), PMS1 gene (2p32) and PMS2 gene (7p22) belong to tumor suppressor caretaker genes. Their gene products ensure the genome integrity by proofreading and fixing mismatched nucleotide base pairs during DNA replication.

Physiologic State

The principal function of DNA mismatch repair (MMR) system is to correct DNA polymerase misincorporation errors (i.e. nucleotide base-base mismatches and insertion/deletion mispairs) that arising during DNA replication and recombination leading to maintenance of genomic stability.

Pathologic State

Mutations in one or more mismatch DNA repair system genes induce genomic instability regions of repeating nucleotides called '**microsatellite regions**'.

- While microsatellite instability does not directly affect carcinogenesis, rather it indicates pathogenicity of tumorigenesis likely reflective of underlying defect in DNA repair system.
- Mutations in one or more mismatch repair (MMR) system genes are linked to **hereditary nonpolyposis colon carcinoma (HNPCC)** also known as **Lynch syndrome**. Colorectal carcinoma with high microsatellite instability confers very poor prognosis.

Cyclin-dependent Kinase Inhibitor 2A (CDKN2A) Tumor Suppressor Caretaker Gene

Cyclin-dependent kinase inhibitor 2A (CDKN2A) is a tumor suppressor caretaker gene located on chromosome 9p21.3, that encodes several proteins including well studied $p16^{INK4A}$ and $p14^{ARK}$ proteins. Both proteins inhibit cell growth and cell division in older cells (senescence).

Physiologic State

CDKN2A tumor suppressor caretaker gene provides instructions for making several proteins such as $p16^{INK4A}$ and $p14^{ARK}$ proteins, which function to induce cell cycle arrest in G1 and G2 phases. The $p16^{INK4A}$ inhibits cyclin-dependent kinases (e.g. CDK4 and CDK6) and restricts cell cycle progression. The $p14^{ARF}$ protein protects p53 tumor suppressor protein from being degradation, thus indirectly activates p53 protein.

Pathologic State

Germline mutation in cell cycle-associated CDKN2A tumor suppressor caretaker gene is linked to familial melanoma and pancreatic carcinoma. Somatic mutations in the cell cycle-associated CDKN2A tumor suppressor caretaker gene are found in 25% of head and neck cancers and also in colorectal cancer by promoting invasion and metastasis by inducing epithelial–mesenchymal transition (EMT).

Xeroderma Pigmentosum Tumor Suppressor Caretaker Genes

Xeroderma pigmentosum (XP) gene provides instructions for making a protein that is involved in repairing of damaged DNA. Ultraviolet B (UVB) solar rays, toxic chemical radiation, and unstable oxygen derived free radical molecules can also cause DNA damage.

Physiologic State

Eight of the XP genes make up the nucleotide excision repair pathway (NER) that detects and repairs ultraviolet induced DNA damage. The ninth XP gene acts to bypass unrepaired DNA damage.

Pathologic State

The ultraviolet B (UVB) component of the solar spectrum induces DNA damage, in the absence of error-free DNA repair, may give rise to mutations in caretaker and gatekeeper genes. DNA repair genes are best candidates for caretaker genes as exemplified by autosomal recessive XP-linked to skin carcinogenesis.

TUMOR SUPPRESSOR GENES FUNCTION AS INHIBITORS OF Wnt/β-CATENIN MITOGENIC SIGNALING ACTIVATOR PATHWAY

Gene products of various tumor suppressor genes such as APC, NF1, NF2, PTCH, SMAD2, SMAD4 and PTEN function to inhibit Wnt/β-catenin mitogenic signaling pathway, and thus inhibits transcription of DNA sequence into an RNA molecule with the help of enzyme RNA polymerase.

Adenomatous Polyposis Coli Tumor Suppressor Gene

Adenomatous polyposis coli (APC) tumor suppressor gene is located on chromosome 5q22.2, that encodes a protein. Germline APC gene mutation is associated with familial adenomatous polyposis progressing to colon carcinoma. Somatic APC gene mutation is linked to colon carcinoma, gastric carcinoma, pancreatic carcinoma, thyroid carcinoma, and melanoma.

Physiologic State

Adenomatous polyposis coli (APC) gene product plays a critical role in several cellular processes such as cell adhesion, cell migration, organization of the actin and microtubule networks, spindle formation, and chromosome segregation. APC gene product suppresses canonical Wnt/β-catenin signaling pathway.

Pathologic State

Due to APC gene mutation, aberrant activation of canonical Wnt/β-catenin signaling pathway gives rise to accumulation of β-catenin in the nucleus, and promotes transcription of targeted oncogenes such as c-Myc and cyclin D1. As a result, it contributes to carcinogenesis, and progression of several human epithelial and lymphoid cancers.

- **Germline mutation in APC tumor suppressor gene** is associated with familial malignant tumors (e.g. familial adenomatous polyposis progressing to colon carcinoma). **Turcot syndrome** related to familial adenomatous polyposis associated with medulloblastoma in Ashkenazi Eastern and Central European Jewish heritage.
- **Somatic mutation in APC tumor suppressor gene** is linked to sporadic malignant tumors (e.g. colon carcinoma, gastric carcinoma, pancreatic carcinoma, thyroid carcinoma and melanoma).
- Summary of adenomatous polyposis syndrome, genetics, inheritance and clinical manifestations is given in Table 6.95.

Neurofibromatosis Type 1 Tumor Suppressor Gene

Neurofibromatosis type 1 (NF1) tumor suppressor gene is located on chromosome 17p11, that encodes neurofibromin protein. **Neurofibromin** produced by oligodendrocytes and Schwann cells plays key role in the formation of protective myelin sheaths around nerves.

Table 6.95 Summary of adenomatous polyposis syndrome, genetics, inheritance and clinical manifestations

Adenomatous Polyposis Syndrome	Genetics	Clinical Manifestations
Autosomal dominant inheritance		
Classic familial adenomatous polyposis (FAP)	Germline adenomatous polyposis coli (APC) gene mutations	▪ Adenomatous polyposis in colon (100–1000 polyps), gastric region, duodenum and periampullary region ▪ Colorectal carcinoma ▪ Garner's syndrome (desmoid tumor fibromas, lipomas, sebaceous cyst, epidermoid cyst) ▪ Turcot's syndrome (multiple adenomatous polyps and medullo-blastoma) ▪ Congenital hypertrophy of the retinal pigmented epithelium (CHRPE)
Attenuated familial adenomatous polyposis (AFAP)	Germline adenomatous polyposis coli (APC) gene mutations	▪ Multiple adenomatous polyps (<100) in colon, upper gastrointestinal tract (fundus, duodenum) ▪ Colorectal carcinoma (70% risk) ▪ Hepatoblastoma ▪ Gastric carcinoma ▪ Breast carcinoma

Contd...

Table 6.95 Summary of adenomatous polyposis syndrome, genetics, inheritance and clinical manifestations (*Contd...*)

Adenomatous Polyposis Syndrome	Genetics	Clinical Manifestations
Polymerase proofreading-associated polyposis (PRAP)	Germline POLE or POLD1 gene mutations	▪ Colonic (Number of polyps unknown) ▪ Colorectal carcinoma ▪ Ovarian carcinoma ▪ Endometrial carcinoma ▪ Pancreatic carcinoma ▪ Brain malignancies
Autosomal recessive inheritance		
MUTYH-associated polyposis (MAP)	Biallelic MUTYH gene mutations	▪ Multiple adenomatous polyps (<100) ▪ Colorectal carcinoma ▪ Duodenal carcinoma ▪ Ovarian carcinoma ▪ Urinary bladder carcinoma ▪ Skin malignancies
NTHL1 associated polyposis (NAP)	Germline homozygous or compound heterozygous NTHL1 gene mutations	▪ Colonic (Number of polyps unknown) ▪ Colorectal carcinoma ▪ Endometrial carcinoma ▪ Duodenal carcinoma ▪ Breast carcinoma ▪ Pancreatic carcinoma

Physiologic State

Neurofibromin encoded by NF1 tumor suppressor gene acts as a tumor suppressor protein by '**turning off**' another p21-RAS protein, that inhibits a stimulatory GTPase (RAS) protein of cell growth, and division via RAS/RAF/MEK/ERK (MAPK) signaling pathway.

Pathologic State

NF1 tumor suppressor gene mutation is linked to development of neurofibromatosis type 1, juvenile myelomonocytic leukemia, myelodysplastic syndrome (MDS) and acute myelogenous leukemia (AML). Patient with neurofibromatosis type 1 (NF1) presents with two or more neurofibromas or one plexiform neurofibroma, 6 café-au-lait macules >5 mm (pubertal) or >15 mm (post-pubertal), ocular iris hamartomas, sphenoid bone dysplasia and first degree relative with neurofibromatosis type 1.

Neurofibromatosis Type 2 Tumor Suppressor Gene

Neurofibromatosis type 2 (NF2) tumor suppressor gene is located on chromosome 22q.12.2 encodes merlin protein, also known as schwannomin, that stabilizes cytoskeleton membrane linkage. Merlin protein is produced by Schwann cells, that wrap round and insulate nerves.

Physiologic State

Merlin encoded by NF2 tumor suppressor gene plays key role in regulation of signaling pathways, which is important for controlling cell shape, cell growth and cell adhesion. Merlin protein functions as a tumor suppressor, that restricts cell growth and cell division.

Pathologic State

Neurofibromatosis type 2 (NF2) tumor suppressor gene mutation (deletion or nonsense) is associated NF2, schwannomatosis and tumors.

- Neurofibromatosis type 2 occurs due to germline mutations present in all the cells of the body. These patients can also develop meningiomas and ependymomas.
  - Diagnostic criteria of neurofibromatosis type 2 include bilateral vestibular schwannomas or family history of NF2 in first degree relative and unilateral vestibular schwannoma in below 30 years of age and any two of the lesions, i.e. meningioma, schwannoma, glioma, posterior subcapsular lenticular opacities/juvenile cortical cataract.
  - The majority of patients present with hearing loss which is usually unilateral at onset and may be accompanied by tinnitis.
- Somatic mutation in the NF2 gene is implicated in schwannomatosis characterized by the development of multiple schwannomas involving nerves through the body, and additional isolated nervous system benign and malignant tumors including meningiomas, ependymomas and schwannomas, inactivation or loss of NF2 gene is associated with mesothelioma arising from pleural cavity and abdominal cavity.

PTCH 1 Tumor Suppressor Gene

PTCH 1 is a tumor suppressor gene located on chromosome 9q22.32, that encodes patched 1 protein, which functions as a receptor protein, that possesses specific sites to which ligand fits like keys into locks.

Physiologic State

A patched 1 protein encoded by PTCH 1 gene acts as a ligand for patched 1 receptor, which triggers Sonic Hedgehog signaling pathway essential for cell growth, cell differentiation and determining the shape of cells of different body parts during embryonic development. When Sonic Hedgehog signaling is absent, patched 1 protein inhibits cell growth and division.

Pathologic State

Mutations in PTCH 1 gene are implicated in development of Gorlin syndrome, nonsyndromic holoprosencephaly (failure of embryonic forebrain), 9q22.32 microdeletion, coloboma, cancers and other disorders.

- Gorlin syndrome (also known as nevoid basal cell carcinoma syndrome) increases the risk for development of various benign and malignant tumors, microcephaly, skeletal abnormalities and small pits in the skin of palms and soles.
- The chromosomal 9q22.32 microdeletions are characterized by delayed development, intellectual disability, overgrowth of the body due to loss of additional genes in the deleted region of chromosome 9.
- Somatic mutations in PTCH 1 gene are implicated in development of coloboma involving retina, basal cell carcinoma, medulloblastoma, breast carcinoma, colon carcinoma and keratocystic odontogenic tumor.

SMADs for Tumor Suppressor Gene

SMAD4 is a tumor suppressor gene located on chromosome 18q21.2, that encodes a DNA binding protein, which transmits chemical signal from the cell surface to the nucleus. SMAD4 mediates the downstream effect of TGF-β signaling pathway resulting in cell cycle arrest, apoptosis, and inhibition of epithelial–mesenchymal transition (EMT).

Physiologic State

Transforming growth factor-β (TGF-β) binds to transmembrane serine/threonine kinase receptors (TGFR1 and TGFR2) and initiates TGF-β/SMAD4 signaling pathway, which phosphorylates SMAD2/SMAD3. The phosphorylated SMAD2/SMAD3 form a heterodimeric complex with SMAD4 and undergo nuclear accumulation, and then bind to SMAD binding element directly, and regulate transcription of target genes with the help of transcriptional factors. These target genes are involved in cell growth arrest and apoptosis.

Pathologic State

Mutation in SMAD tumor suppressor gene is implicated in hereditary hemorrhagic telangiectasia characterized by arteriovenous malformations, and risk for development of intestinal polyps and malignant transformation, juvenile polyposis syndrome, Myhre syndrome, pancreatic adenocarcinoma, breast carcinoma, prostatic carcinoma, squamous cell carcinoma of head and neck, non-small cell lung carcinoma, and cholangiocarcinoma.

PTEN (Phosphatase and Tensin Homolog) Tumor Suppressor Gene

PTEN (phosphatase and tensin homolog) is a tumor suppressor gene located on chromosome 10q23, that encodes lipid phosphatase, that serves to antagonize cell proliferation and survival generated by the phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR signaling pathway.

Physiologic State

Normally, phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR signaling pathway plays an important role in regulation of signal transduction, that plays an important role in cell cycle regulation and apoptosis in response to extracellular signals.

- Normal binding of growth factor to its cell surface receptor leads to phosphorylation of phosphatidylinositol-3,4,5-triphosphate (PIP3). The level of PIP3 is regulated by PTEN dephosphorylation.
- PTEN is a multifunctional protein, that maintains the stability of the genome and chromosomes by regulating proper spindle formation, and accurate chromosome segregation to prevent gross genomic instability via regulation of mitotic arrest deficient 2 (MAD2). PTEN gene expression knockdown induces G2/S checkpoint cell cycle arrest, and abnormal chromosome segregation.

Pathologic State

Frequent inactivation of PTEN tumor suppressor gene has been implicated in development of PTEN hamartoma tumor syndromes, glioblastoma multiforme, endometrial carcinoma, prostatic carcinoma, lung carcinoma, breast carcinoma and lymphomas. Polymerase chain reaction and next generation sequencing have been used to detect PTEN gene mutations.

TUMOR SUPPRESSOR GENES FUNCTION TO INHIBIT CELL CYCLE PROGRESSION

Gene products of CDKN2A and RB tumor suppressor genes inhibit progression of cell cycle. Tumor suppressor gene products restrict cell cycle progression. Their control over cell division is lost due to genetic alterations resulting in their inactivation.

- CDKN2A tumor suppressor gene encodes $p16^{INK4A}$ and $p14^{ARK}$ proteins, which inhibit cell growth and cell division in older cells (senescence). The $p16^{INK4A}$ inhibits CDK4 and CDK6 and restricts cell cycle. The $p14^{ARK}$ inhibits degradation of p53 protein, thus indirectly activates p53 protein.
- Tumor suppressor protein p53 regulates progression of cell cycle through the G1/S checkpoint. In particular, p53 is activated in response to DNA damage and serves to restrict cell cycle progression in G1/S checkpoint and hence allow time for DNA repair. The RB gene product is a tumor suppressor, which plays a pivotal role in the negative control of cell cycle and prevents tumorigenesis. The RB protein is responsible for G1 checkpoint, blockage of S phase entry and cell growth.

CDKN2A Tumor Suppressor Gene

Cyclin-dependent kinase inhibitor 2A (CDKN2A) is a tumor suppressor gene located on chromosome 9p21.3, that encodes several proteins including well studied $p16^{INK4A}$ and $p14^{ARK}$ proteins. Both proteins inhibit cell growth and cell division in older cells (senescence).

Physiologic State

The $p16^{INK4A}$ encoded by CDKN2A tumor suppressor gene inhibits cyclin-dependent kinases (e.g. CDK4 and CDK6) and restricts cell cycle progression. CDK4 and CDK6 normally stimulate cell division through the cell cycle progression.

- The $p14^{ARF}$ protein encoded by CDKN2A tumor suppressor gene protects a different tumor suppressor protein is called p53 protein from its degradation, thus indirectly activates p53 protein. The p53 protein regulates cell division, senescence and apoptosis. By protecting p53 protein, $p14^{ARF}$ also inhibits tumorigenesis. Both $p14^{ARF}$ and p53 proteins are produced in the cells, that are unable to undergo cell division.
- In human papillomavirus (HPV) infection, HPV produces oncoproteins E6 and E7. E6 oncoprotein induces the degradation of the tumor suppressor p53 protein. E7 oncoprotein inactivates RB protein (pRB) and thus resulting in cytoplasmic overexpression of $p16^{INK4A}$. The $p16^{INK4A}$ interaction with other proteins Y2 chain of laminin, β-catenin or vascular endothelial growth factor (VEGF) is thought to be related to new functions of $p16^{INK4A}$ by inhibition of angiogenesis and CSC invasion.

Pathologic State

CDKN2A tumor suppressor gene mutation is associated with familial (germline gene mutation associated melanoma), and sporadic tumors (e.g. somatic mutation associated breast carcinoma, pancreatic carcinoma, urothelial carcinoma, lung carcinoma, esophageal carcinoma, and head and neck squamous cell carcinoma). Promoter hypermethylation of CDKN2A gene turns off the partial or complete production of $p16^{INK4A}$ and $p14^{ARF}$. Without one of these tumor suppressor proteins, resulting in unrestricted CSC proliferation, development of malignant tumor, invasion and metastasis.

RB1 Tumor Suppressor Gene

Retinoblastoma 1 (RB1) is a tumor suppressor caretaker gene mapped on chromosome 13q14.2. Normal people have two alleles of the RB gene, also known as governor of cell cycle encodes RB protein, which acts as master brake on cell cycle.

- Retinoblastoma is the most common primary intraocular malignant tumor caused by inactivation/biallelic loss of tumor suppressor. Genetic testing can determine whether a child has heritable or nonheritable form of retinoblastoma.
- Knudson two-hit hypothesis explains that most tumor suppressor genes require inactivation/biallelic loss, either through mutations or epigenetic silencing to cause a phenotypic change and development of malignant tumor.
  - If a person is born with mutation in one allele of RB tumor suppressor gene, that person already has 'first hit' (germline inherited mutation in one allele), somatic mutation 'second hit' involving remaining functional allele of RB tumor suppressor gene, essential for development of retinoblastoma.
  - The acquisition of the 'second hit' is called loss of heterozygosity (**LOH**). If retinoblastoma is left untreated, tumor can eventually metastasize to distant organs.

Physiologic State

RB protein encoded by RB tumor suppressor gene plays a pivotal role in the negative control of cell cycle and tumor progression. Dephosphorylated RB protein inhibits cell division, whereas phosphorylated RB protein promotes cell division. RB protein represses gene transcription required for transition from G1/S phase of cell cycle, and DNA replication. Additionally,

RB protein interacts with other proteins to influence cell survival, apoptosis and cell differentiation.

Pathologic State

RB1 tumor suppressor caretaker gene germline mutation is implicated in heritable tumors (e.g. retinoblastoma and osteosarcoma) and nonheritable tumors (e.g. retinoblastoma, osteosarcoma, breast carcinoma, colon carcinoma, prostate carcinoma, urothelial carcinoma and lung carcinoma).

- Heritable retinoblastoma develops due to a RB1 germline mutation and subsequent somatic inactivation of the other allele of RB gene. This form of retinoblastoma may be multifocal and/or bilateral or unilateral. Mean age of diagnosis is within first year of life.
- Nonheritable retinoblastoma develops in children with no family history, and accounts for 60% of all cases. Tumor is unilateral with onset after the first year of life in majority of cases. Both alleles of RB gene must mutate to produce the disease. Adult relatives of patients with retinoblastoma may show retinal scars, which are indicative of benign nonprogressive tumors.
- Diagnostic testing to diagnose retinoblastoma includes fundus examination, fundus photography, ultrasonography, MRI scan and genetic testing. Histologic examination of enucleated tumor reveals features of retinoblastoma.
- Significant advancements have been made in retinoblastoma treatment, which include systemic venous or intra-arterial or local intravitreal administration of chemotherapy, laser treatment and enucleation.

TUMOR SUPPRESSOR GENES FUNCTION TO INHIBIT TUMOR ANGIOGENESIS

Angiogenesis is a biological process in which novel capillary blood vessels grow from pre-existing vasculature providing tissues with oxygen and nutrients.

- In normal conditions, angiogenesis only occurs during embryonic development, female reproductive cycle and wound healing.
- Vasculogenesis is the embryonic establishment of the blood supply from mesodermal precursors (i.e. angioblasts and hemangioblasts).
- However, aberrant angiogenesis is an essential step in the growth of malignant tumors. Numerous investigators have established the association between tumor angiogenesis and tumor metastasis.
- Numerous gene products of vHL, SDHB, SDHD and STK11 tumor suppressor genes inhibit tumor angiogenesis.

vHL (von Hippel-Lindau) Tumor Suppressor Gene

The vHL (von Hippel-Lindau) tumor suppressor gene is located on chromosome 3p25.3, that encodes vHL protein involved in regulation of other genes, cell division, and synthesis of extracellular matrix. vHL protein is found in both nuclear and cytoplasmic compartments. Trafficking between these compartments is essential for vHL protein function.

Physiologic State

The vHL protein functions as a subunit of a multiprotein ubiquitin ligase, that inhibit expression of hypoxia-inducible genes controlled by hypoxia inducible factors (HIFs).

- The vHL ubiquitin ligase prevents inappropriate expression of these hypoxia-inducible genes, when cells are grown in abundant supply of oxygen by targeting **HIFs** for rapid ubiquitylation and degradation by the proteosome, when they are no longer needed. Protein degradation is a normal process that removes damaged or unnecessary proteins and helps in the maintenance of normal cellular functions.
- Hypoxia-inducible factor 2α (HIF-2α) is a multiprotein complex called HIF, which plays a pivotal role in the body's ability to adapt to change in oxygen levels. HIF controls several genes involved in cell division, angiogenesis (VEGF synthesis), and erythropoiesis. HIF functions when oxygen levels are lower than normal in the body. However, when adequate oxygen is available, VCL-CUL2 multiprotein complex keeps HIF from building up in approximately in the cells.

Pathologic State

Mutation in vHL tumor suppressor gene encoding defective vHL protein can give rise to heritable von Hippel-Lindau syndrome, familial erythropoiesis, nonsyndromic paraganglioma of nervous system, pheochromocytoma and hemangioblastoma. Somatic nonheritable vHL mutation is implicated in development of clear cell variant of renal cell carcinoma.

- The vHL gene mutation encodes abnormally short vHL protein as a result of change in single amino acids in the vHL protein is found in nonsyndromic paraganglioma and pheochromocytoma. These changes disrupt the function of the protein.
- HIF-2α protein is not broken down and instead accumulates in the cells. Excess of HIF-2α stimulates cell division, and triggers angiogenesis, which can lead to the development of paraganglioma or pheochromocytoma.

SDH Tumor Suppressor Genes

SDH tumor suppressor genes (SDHA, SDHB, SDHC and SDHD) encode the four subunits of succinate dehydrogenase (SDH; mitochondrial complex II), mitochondrial enzyme involved in two essential energy producing metabolic processes: oxidative phosphorylation of the cell, the Krebs cycle (also called TCA—tricarboxylic acid), and the electron transport system.

Physiologic State

SDH tumor suppressor gene encodes succinate dehydrogenase that inhibit genetic and epigenetic alterations and thus prevent carcinogenesis.

Pathologic State

Germline mutations in any of the SDH tumor suppressor genes or assembly factor (SDHAF2) cause heritable paraganglioma/pheochromocytoma syndrome through an unknown mechanism. Tumorigenesis generally follows the Knudson 'two-hit' hypothesis. The first copy of the gene is mutated in all cells, however the second copy functions normally. Mutation in SDH tumor suppressor gene encodes defective succinate dehydrogenases, that can result in genetic and epigenetic changes like hypermethylation, which can lead to succinate-mediated inhibition of α-ketoglutarate-dependent dioxygenases. So, hypoxic conditions can generate subsequent transformation of normal cell to cancer stem cell (CSC).

STK11 Tumor Suppressor Gene

STK11 is a tumor suppressor gene, also called liver kinase B1 (LKB1), located on chromosome 19p13.3. STK11 gene, that encodes an enzyme serine-threonine kinase 11, involved in activation of RAS/RAF/MEK/ERK/MAPK signaling pathway.

Physiologic State

STK11 tumor suppressor gene product plays a pivotal role in correct orientation of cells within the tissues (polarization), determination of amount of energy used by the cells, apoptosis, and suppression of cell growth, when nutrients and energy levels are low.

Pathologic State

Germline mutation of STK11 tumor suppressor gene is linked to **Peutz-Jeghers syndrome**. Patient with Peutz-Jeghers syndrome have a high risk for developing carcinomas at different locations (e.g. stomach, colorectal region, pancreas, lung, cervix, ovary and breast) during their lifetime. Somatic mutation of STK11 gene is demonstrated in non-small cell lung carcinoma, cervical carcinoma, colorectal carcinoma, pancreatic carcinoma, skin melanoma and testicular tumor.

TUMOR SUPPRESSOR GENES: GENOMIC STABILITY ENABLER (MOST IMPORTANT)

Genomic stability is a feature of every organism to preserve and faithfully transmit the error-free genetic material (DNA or RNA) from generation to next generation or from one somatic cell to another. Individual survival depends on genomic stability.

- DNA polymerase and DNA ligase are essential for DNA replication. In addition to maintain the integrity of DNA sequences by DNA repair, an accurate duplication of DNA is a prerequisite for cell division.
- In contrast, genomic instability refers to high frequency of mutations within genome of a cellular lineage caused by external and internal factors. Fortunately, cells have evolved several response systems to tackle DNA damage by accurate DNA repair in order to maintain their genomic integrity. Genomic instability is a defined hallmark of cancer. Example of DNA stabilizer enabler is TP53 tumor suppressor gene.

TP53 Tumor Suppressor Gene

TP53 tumor suppressor gene located on chromosome 17p13.1 encodes p53 protein, that binds directly to DNA and control cell division under check.

Physiologic State

The p53 protein encoded by TP53 tumor suppressor gene is activated as a result of DNA damage caused by toxic chemical agents, ionizing radiation or ultraviolet rays. The p53 protein plays a pivotal role in determining whether damaged has been repaired or not. Failure to repair DNA damage, cell undergoes apoptosis. If the damaged DNA undergoes repair, the p53 protein activates p21, which in turn inhibits the cyclin/CDKs complexes required for cell cycle progression past G1 phase. Cell cycle arrest allows time for DNA repair to occur.

- If DNA damage is beyond repair, p53 protein can induce apoptosis in the mutated cell, an important function, that is crucial for preventing development of malignant tumor growth. Because p53 is essential for regulating DNA repair and cell division, it has been called 'guardian of genome'.
- Without p53 protein, the cell cycle progresses despite DNA damage. The cell eventually accumulates enough mutations through the activation of oncogenes or inactivation/biallelic loss of tumor suppressor genes to transformation of normal cell to CSC to invasion and metastasis. The lack of apoptosis allows multiple cycles of DNA damage and cell proliferation to occur.

Pathologic State

Germline or somatic mutations of TP53 tumor suppressor gene are linked to many human cancers.

- **Germline TP53 tumor suppressor gene mutation and associated cancers:** Germline TP53 tumor suppressor gene mutation is implicated in many human cancers in Li-Fraumeni syndrome (e.g. breast carcinoma, osteosarcoma, rhabdomyosarcoma, brain tumors, leukemias and adrenocortical carcinoma). Li-Fraumeni syndrome is diagnosed based on clinical criteria and/or genetic testing for the mutation in the TP53 gene.
- **Somatic TP53 tumor suppressor gene mutation and associated cancers:** Somatic mutation in TP53 tumor suppressor gene is implicated in breast carcinoma, urothelial carcinoma (50%), cholangiocarcinoma, head and neck squamous cell carcinoma, small cell lung carcinoma, non-small cell lung carcinoma, melanoma, ovarian carcinoma, Wilm's tumor, osteosarcoma, rhabdomyosarcoma, and adrenocortical carcinoma. Most of the mutations involved in these cancers occur due to change single amino acid in TP53 tumor suppressor gene.

TUMOR SUPPRESSOR GENES FUNCTION DNA REPAIR SYSTEM

DNA damage is defined as any modification of DNA in the chemical structure of DNA (i.e. DNA strands and nucleotide base pairs), that changes its coding properties such as DNA replication and transcription.

- DNA damage can be caused by chemical agents, oxidizing agents, ultraviolet (UV) rays, ionizing radiation and chemotherapeutic agents leading to DNA breaks in single/double-strands and missing of nucleotide base pairs from the backbone of DNA.
- DNA replication errors and DNA damage are actually happening in the cells of our bodies all the time. Many DNA replications are minimized or corrected by proofreading. Sometimes mismatched nucleotide base pairs escape proofreading.
- DNA repair systems are essential for the maintenance of genome integrity. Human DNA repair genes function in a diverse set of pathways that involve the recognition and excision of DNA lesions, tolerance to DNA damage, and protection from errors of incorporation made during DNA replication or DNA repair. Additional genes indirectly affect DNA repair by regulating the cell cycle to provide an opportunity for DNA repair or to direct the cell to undergo apoptosis.
- Major DNA repair pathways are direct reversal by cellular enzymes, base excision repair (BER), nucleotide excision repair (NER), mismatch repair (MMR), double-stranded break repair (e.g. non-homologous end joining and homologous recombination).
  - DNA repair comes from the double helix structure of DNA, that carries two separate copies of all the genetic information in each of its two strands. When single strand of DNA is damaged, another DNA strand is used as a template to restore the DNA nucleotide base pair sequence to the damaged strand. **PARP-1** encodes a protein, that assists with the repair of single-stranded breaks in the DNA. When both strands of the double helix DNA molecule are broken, however, leaving no template strand for repair, the cells may use one of two distinct alternative mechanisms to address repair.
  - Double-stranded breaks are dangerous because large segments of chromosomes along with their numerous genes may be lost, if DNA break is not repaired. Two pathways are involved in the repair of double-stranded DNA breaks: non-homologous end joining (NHEJ), and homologous recombination (HR) pathways. In NHEJ, chromosome is 'glued back' together, usually a small mutation at the break site. In homologous recombination, the broken chromosome pairs up with its homologue, and the damaged region is replaced via recombination, using sequences copied from the homologue. Homologous recombination is 'cleaner' than NHEJ and it does not usually cause mutations.

Tumor Suppressor Genes Function Mismatch DNA Repair

MLH1 gene (3p21), MSH2 gene (2p15), MSH3 gene (5q11.12), MSH6 gene (2p16), PMS1 gene (2p32) and PMS2 gene (7p22) belong to tumor suppressor caretaker genes. Their gene products ensure the genome integrity by proofreading and fixing mismatched nucleotides during DNA replication.

Physiologic State

A mismatch nucleotide base pair is detected in newly synthesized DNA. The new DNA strand is cut and the mismatch nucleotide base pair and its neighbors are removed. The missing patch of nucleotide base pair is replaced with correct nucleotide base pair by DNA polymerase. DNA ligase seals the gap in the DNA backbone.

Pathologic State

Mutations in one or more mismatch DNA repair genes cause instability regions of repeating nucleotides called 'microsatellite regions'.

- Mutations in one or more mismatch repair genes are linked to hereditary nonpolyposis colon carcinoma (**HNPCC**) also known as **Lynch syndrome**, characterized by increased risk of development

of carcinoma of endometrium, ovary and right colon carcinoma) and sporadic tumors (e.g. colorectal carcinoma, endometrial carcinoma, Muir-Torre syndrome, hepatobiliary carcinoma, genitourinary carcinoma, glioblastoma multiforme).
- Hereditary nenpolyposis colorectal carcinoma with high microsatellite instability confers very poor prognosis. Extensive history of screening of early development of these cancers is required in the management of these patients.

Tumor Suppressor Genes Function Double-stranded Breaks Repair

BRCA1 (17q21), BRCA2 (13q12), ATM (11q22.3), TP53 (17p1.2), and CHEK2 (22q12.1) belong to tumor suppressor genes. Their gene products mediate repair in double-strand breaks caused by ionizing radiation, radiomimetic chemical agents and mechanical stress on chromosomes.

BRCA1 and BRCA2 Tumor Suppressor Genes

BRCA1 and BRCA2 are tumor suppressor genes that encode proteins involved in the repair of DNA double-stranded breaks through homologous recombination repair system pathways. Thus, their gene products are crucial for the activation of cell cycle checkpoints. Both BRCA1 and BRCA2 are high-penetrance caretaker tumor suppressor genes responsible for **breast carcinoma** and **ovarian carcinoma**.

TP53 Tumor Suppressor Gene

TP53 is a tumor suppressor gene located on chromosome 17p13.1, that encodes p53 protein, that maintains genome integrity hence known as 'guardian of genome'.
- **Physiologic state:** TP53 gene products sensors DNA damage and halts cell cycle in G1/S checkpoint for DNA repair by inhibiting nuclear transcription factor, until the DNA is repaired or force the cell to undergo apoptosis via activation of proapoptotic BAX gene.
  - Mutation in TP53 gene is detected in human neoplasia, however its absence does not rule of malignancy.
  - Germline heterogenous mutation in TP53 gene is demonstrated in Li-Fraumeni syndrome (cancers of breast and adrenal cortex, sarcoma, leukemia, brain tumors) and many sporadic tumors.
- **Pathologic state:** TP53 gene mutation promotes carcinogenesis, invasion and metastasis. The p53 immunomarker differentiates malignant tumors, which are most often p53 positive (carcinoma *in situ* and invasive carcinoma) from p53 negative conditions (reactive and metaplastic conditions). The p53 immunomarker can distinguish serous endometrial carcinoma, which is p53 positive from p53 negative endometrioid carcinoma. The p53 immunomarker may be useful as serum tumor marker.

Checkpoint Kinase 2 Tumor Suppressor Gene

Checkpoint kinase 2 (CHEK2) is a tumor suppressor gene located on chromosome 22p12.1, that encodes checkpoint kinase 2 protein that plays key role in activation of DNA repair, cell cycle arrest in G1 phase, and apoptosis in response to the presence of DNA double-stranded breaks.
- **Physiologic state:** CHEK2 tumor suppressor gene encodes checkpoint kinase 2 protein phosphorylates CDC25A, CDC25B and CDC25C, that induces cell cycle arrest in G1 phase, and apoptosis by DNA double-stranded damage. CHEK2 protein also phosphorylates NEK6, which is involved in cell cycle arrest in G2/M phase. CHEK2 protein promotes DNA repair via phosphorylation of BRCA1 and BRCA2 proteins and regulates apoptosis through phosphorylation of TP53 (p53), MDM2 and PML.
- **Pathologic state:** Mutations in CHEK2 gene have been implicated in familial breast carcinoma, sporadic breast carcinoma, ovarian carcinoma, prostatic carcinoma, thyroid carcinoma, and renal cell carcinoma following radiation therapy.

Tumor Suppressor Genes Function Nucleotide Excision Repair

XPA gene (9p22.33), XPB (ERCC3) gene (2q21), XPC gene (3p25.1), XPD gene (19q13.32), XPE gene (11p11.2), XPF gene (16p13.12), XPG gene (2q13.3) and XPV gene (6p21.1) belong to tumor suppressor genes, that encode XP proteins involved in nucleotide excision repair.

Physiologic State

XPA to XPG genes make up the nucleotide excision repair (NER) pathway that detects bulky DNA adducts induced by ultraviolet (UV) radiation and repairs. DNA damage lesion is removed, and replaced by DNA synthesized using the undamaged DNA strand as template by DNA polymerase. XPV gene acts to bypass unrepaired damage.

Pathologic State

Xeroderma pigmentosum is an autosomal recessive disorder caused by alterations in nine different XP genes. XPA and XPC gene mutations are relatively common, XPE gene mutation is rare in XPG. XPG gene mutation results in severe disorder. XPF gene mutation results in mild disorder.
- Xeroderma pigmentosum is characterized by an excessive sensitivity to ultraviolet rays from sunlight affecting exposed parts of body (face, lips and upper limbs).

- There is increased risk for development of skin cancers (e.g. squamous cell carcinoma, basal cell carcinoma and melanoma) in the affected persons.

Tumor Suppressor Genes Function DNA Replication Fork Repair

DNA replication is the process by which DNA makes a copy of itself during cell division. During DNA replication, double helix structure of the DNA is unzipped by **helicase enzyme**, which breaks the hydrogen bonds holding the complementary bases of DNA together (adenine with thymine, cytosine with guanine).

- The separation of the two strands of DNA creates a 'Y' shape called a DNA replication fork. One of the DNA strands is oriented in the 3′ to 5′ direction (towards the replication fork) called 'leading strand'. Other DNA strand is oriented in the 5′ and 3′ direction (away from the replication fork), called 'lagging strand'. As a result of their different orientations, the two strands (i.e. leading and lagging strands) are replicated differently.
- Primase enzyme synthesizes a short piece of RNA called primer, that binds to the end of the leading strand. The primer acts as the starting point for DNA synthesis.
- DNA polymerase binds to leading strand and then walks along it, adding new complementary nucleotide bases (adenine, cytosine, guanine and thymine) to the strand of DNA in 5′ to 3′ direction. This sort of DNA replication is known continuous.
- Chunks of DNA, called '**Okazaki fragments**', are then added to the lagging strand in 5′ to 3′ direction. Once all the nucleotide base pairs are matched (A with T, C with G), exonuclease enzyme strips away the primer(s). These gaps created by stripping away of primer(s) are then filled by more complementary nucleotides.
- Proofreading of new strand ensures no mistake in the new DNA sequence. Finally, DNA ligase enzyme seals up the sequence of DNA into two continuous double-strands. The result of DNA replication is two DNA molecules consisting of one new and one old chain of nucleotide base pairs. That is the reason that DNA is described as semi-conservative, half of the chain is part of this original DNA molecule and half is a brand new. Following DNA replication, the new DNA automatically winds up into double helix.

Werner Syndrome Tumor Suppressor Gene

Werner syndrome (WRN) tumor suppressor gene located on chromosome 8p, that encodes WRN protein involved in replication fork progression, facilitation of repair of stalled forks and DNA double-strand breaks associated with replication fork. WRN protein also blocks nuclease-mediated excessive processing of replication fork.

- Mutation in WRN gene results in an autosomal recessive disorder is called Werner syndrome characterized by premature development of aging features and higher risk for cancer of mesenchymal origin.
- Patient with Werner syndrome shows great predisposition to arteriosclerosis, cataracts, osteoporosis and type 2 diabetes mellitus. Myocardial infarction and development of malignant tumors are most common causes of mortality among patients with Werner syndrome.

RECQL4 Tumor Suppressor Gene

RECQL4 is a tumor suppressor gene located on chromosome 8q24.3, that encodes protein family called RECQ (RECQL4) helicase, which binds to DNA temporarily and unwind the two spiral double helix strands of the DNA molecule, which are essential for the initiation of DNA replication in preparing for cell division, sister chromatids separation, double-strand break (DSB) repair, base excision repair (BER), and telomere replication leading to maintenance of genomic stability. RECQ (RECQL4) helicase protein remains active many cells during embryogenesis and postnatal life. RECQL4 gene mutation is linked to Baller Gerold syndrome, PAPADILNO syndrome and Rothmund-Thompson syndrome. Overall, the prevalence of cancer among RECQL4 heterozygous family members is 2.5%.

TERT Tumor Suppressor Gene

Telomerase reverse transcriptase (TERT) is a tumor suppressor gene located on chromosome 5p15.33, that encodes telomerase enzyme, which maintains structure of chromosomes called telomeres. Telomeres are composed of repeated segments of DNA (tandem repeats of ATTAGGG) found at the ends of the chromosomes.

Physiologic State

Telomeres protect structure of chromosomes from DNA repair pathways initiated by a DNA damage response. In most cells, telomeres become progressively shorten, as the cell divides a certain number of cell divisions, then telomeres become so short, that these trigger the cell to stop dividing and undergoing apoptosis.

- Telomerase enzyme counteracts the shorting of telomeres by adding small repeated segments of DNA to the ends of chromosomes each time the cell divides. In most type of cells, telomerase activity is either undetectable or active at low levels.

- However, telomerase activity is high in lungs, gastrointestinal tract and bone marrow during embryonic development. Telomerase enzyme allows these cells to divide many times without undergoing apoptosis.

Pathologic State

Telomerase enzyme is abnormally active in most CSCs, which grow and proliferate in uncontrolled manner.

- TERT gene can be upregulated by gene amplification, rearrangements and mutations within promoter region in 4% of human cancers.
- TERT promoter mutations are demonstrated in 80–90% of human malignant tumors and can be used as biomarker in diagnosis and outcome prediction.
- TERT promoter mutations cause upregulation of TERT transcription/activity in urothelial carcinoma (68%), central nervous system tumors (28%) and thyroid follicular, papillary and differentiated/anaplastic carcinomas (15%), prostatic carcinoma, endometrial carcinoma, rhabdomyosarcoma (2%), neuroblastoma, lung carcinoma, colorectal carcinoma, ovarian carcinoma, breast carcinoma, adrenocortical carcinoma and acute myelogenous leukemia (AML).
- Rearrangements of TERT promoter have been implicated in neuroblastomas.
- Mutations in TERT gene have been demonstrated in familial idiopathic pulmonary fibrosis and dyskeratosis congenita (e.g. aplastic anemia or cancer).

Fanconi Anemia (FA) DNA Repair Tumor Suppressor Genes

The maintenance of genomic stability is crucial for species survival, and its failure is closely associated with carcinogenesis.

- Fanconi anemia DNA repair pathway, involving 22 identified Fanconi anemia DNA repair genes, plays a central role in repairing DNA inter-strand cross-links (ICLs).
- Recent studies reveal that the Fanconi anemia DNA repair pathway functions in a critical tumor suppressor network to preserve genomic integrity by stabilizing replication forks, migrating replicating stress and regulating cytokinesis.

Physiologic State

The canonical function of the Fanconi anemia (FA) proteins is to collaborate with several other DNA repair proteins to eliminate chromosome-breaking (clastogenic) effects of DNA inter-strand crosslinks.

Pathologic State

Germline mutations in Fanconi anemia DNA repair tumor suppressor genes are linked to Fanconi anemia, inability to repair DNA inter-strand crosslinks and cancer predisposition (e.g. acute myelogenous leukemia, liver tumors, and squamous cell carcinoma of oropharyngeal and anogenital regions). Fanconi anemia significantly increases cancer susceptibility sporadically especially breast carcinoma in the general population.

TUMOR SUPPRESSOR GENES FUNCTION BY VARIOUS MECHANISMS

Numerous tumor suppressor genes function by different mechanisms to inhibit tumorigenesis, which include WT1, MEN1, DPC4 (MADH4/SMAD4), ATM, p16, TGF-β, and CHEK2 genes.

WT1 Tumor Suppressor Gene

WT1 tumor suppressor gene is located on chromosome 11p13, that encodes WT1 protein that is essential for the development of kidneys and gonads (ovaries in females and testes in males) during intrauterine life. WT1 protein activity is limited to glomerulus after birth. WT1 protein plays a key role in cell growth, differentiation and apoptosis.

Physiologic State

WT1 protein encoded by WT1 tumor suppressor gene binds to specific regions of DNA via zinc finger proteins to the promoter regions of >20 putative downstream target genes, and regulates their activity either by repression or activation of the target genes.

Pathologic State

WT1 gene mutation is associated with Wilm's tumor (heritable/nonheritable), Denys-Drash syndrome, WAGR syndrome, Frasier syndrome, congenital nephrotic syndrome, cytogenetically normal acute myelogenous leukemia (AML), aggressive desmoplastic round cell tumors, and prostatic carcinoma. WT1 gene mutations, including deletions, truncations, translocations have been observed in approximately 20% of Wilm's tumors.

- WAGR syndrome is diagnosed on the basis of clinical manifestations (e.g. Wilm's tumor, aniridia, genitourinary abnormalities and intellectual disability) and genetic testing (karyotyping 11p13 deletion). A more specific genetic testing is done by fluorescent *in situ* hybridization (FISH) to detect deletion of specific genes on chromosome number 11.
- Development of Wilm's tumor is unusual in Frasier syndrome. However, gonadoblastoma is more common in Frasier syndrome than in Denys-Drash syndrome.

MEN1 Tumor Suppressor Gene

The MEN1 gene located on chromosome 11p13.1 encodes a tumor suppressor protein called menin present in the nucleus of numerous cells.

Physiologic State

Menin protein encoded by MEN1 gene binds to specific sequences of DNA and control expression of targeted genes. Some of these play a pivotal role in DNA repair, cell growth, cell division and apoptosis.

Pathologic State

Mutation in MEN1 tumor suppressor gene is associated with familial isolated hyperparathyroidism, multiple endocrine neoplasia (tumors of pituitary, parathyroid and pancreas), primary macronodular adrenal hyperplasia and other tumors (e.g. parathyroid adenoma, nonfunctioning neuroendocrine tumor of pancreas, gastrinoma, insulinoma, bronchial carcinoids). Somatic mutation in MEN1 gene is associated with tumors of pituitary, parathyroid and pancreas.

- MEN1 is an autosomal dominant tumor predisposition syndrome characterized by pituitary, parathyroid and pancreatic tumors. MEN1 shows germline heterozygous mutations in one allele of MEN1 gene. Tumor development occurs upon loss of remaining normal copy of the MEN1 gene in MEN1-targeted tissues.
- MEN1 syndrome is diagnosed on the basis of clinical manifestations, family history, physical examination, hormonal analysis, imaging to look for endocrine system tumors.

DPC4 (MADH4/SMAD4) Tumor Suppressor Gene

DPC4 (MADH4/SMAD4) tumor suppressor gene located on chromosome 18q21.1 encodes DPC4 protein.

Physiologic State

DPC4 protein encoded by DPC4 (MADH4/SMAD4) tumor suppressor gene mediates the downstream effect of the TGF-β-stimulated gene transcription through sequence-specific binding to DNA and inhibit cell growth and apoptosis.

Pathologic State

Somatic mutation in DPC4 (MADH4/SMAD4) tumor suppressor gene is specific for pancreatic adenocarcinoma (55%), colorectal carcinoma (20%), breast carcinoma, and ovarian carcinoma. Loss of nuclear immunostaining is considered an abnormal positive result with adjacent pancreatic stroma retaining expression.

ATM Tumor Suppressor Gene

ATM gene is located on chromosome 11p22, that encodes ATM kinase protein, which is recruited and activated by DNA double-strand breaks.

Physiologic State

ATM protein encoded by ATM tumor suppressor gene plays an essential role in the maintenance of **genomic stability** by phosphorylation of downstream targets for activation of the DNA damage-induced cell cycle checkpoints resulting in cell cycle arrest, repair of DNA damage or apoptosis of mutated cell.

Pathologic State

Mutations in both copies of ATM gene result in ataxia-telangiectasia, an autosomal recessive disorder. Depending on the extent of the ATM mutation, the resultant ATM protein expression can result in pleiotropic clinical phenotypes including neurodegeneration, hematologic malignancies (e.g. **leukemia, lymphoma**), immunodeficiency and hypersensitivity to ionizing radiation.

Transforming Growth Factor-β Tumor Suppressor Gene

Transforming growth factor-β (TGF-β) ligands (TGF–β1, TGF-β2 and TGF-β3) transmit through the type 1 and type 2 (TGFR-β1 and TGFR-β2 respectively). Canonical signaling proceeds with phosphorylation of SMAD2 and SMAD3, which then bind with SMAD4 to enter the nucleus to modulate transcription in cooperation with other transcription factors, coactivators and corepressors. In addition, TGF-β ligands bind to its cognate receptors leading to activation of many noncanonical signaling pathways.

- TGF-β can function as tumor suppressor or tumor promoter. Recent studies show that receptors and proteins involved in TGF-β signaling may act as tumor suppressors. Loss of response to TGF-β may be an important step in the tumorigenesis and progression of cancer.
- TGF-β suppresses tumor progression through inhibition of cell cycle (G1/S transition) progression, inducing apoptosis, and suppression of expression of growth factors, cytokines and chemokines.

Physiologic State

One of the significant effects of TGF-β is to inhibit tumor immunosurveillance in the host by directly suppressing the transcription of genes encoding multiple key proteins of the CD8+ cytotoxic T cells, such as perforin and granzymes, and cytotoxins that act through the granule exocytosis pathway.

Pathologic State

TGF-β mediates inflammatory reaction via chemokines and their receptors in the tumor microenvironment. The inflammatory cells provide proangiogenic factors, growth factors, proteases and cell adhesion molecules, that facilitate cancer stem cell proliferation, angiogenesis, epithelial–mesenchymal transition (EMT), invasion and metastasis.

- Alterations in TGF-β signaling have significant effects on tumorigenesis and progression. The mechanisms determining when and how TGF-β switches form a tumor suppressor to a tumor promoter are great challenge in understanding dual role of TGF-β.
- TGF-β is most often produced in large quantity in many human cancers due to its oncogenic activity. Somatic mutation in TGF-β is linked to **pancreatic carcinoma** and **colorectal carcinoma**.

Pathology Pearls: Regulation of TGF-β/SMAD4 Pathway

RAS/RAF/MEK/ERK/MAPK, phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR and Wnt/β-catenin signaling pathways regulate TGF-β/SMAD4 pathway.

- **RAS/RAF/MEK/ERK/MAPK signaling pathway:** RAS/RAF/MEK/ERK/MAPK signaling pathway regulates the TGF-β/SMAD4 pathway by three mechanisms: (a) prevention of phosphorylated SMAD2/SMAD3 translocation into the nucleus, (b) mediating SMAD4 degradation, and (c) promoting activator protein 1 (AP-1) complex formation at the TGF-β1 promoter, thus boost the TGF-β1 transcription and secretion.
  - Binding of substrate of c-Jun N-terminal kinases (JNKs) to the transcriptional corepressor TG-interacting factor (TGIF) inhibits SMAD2-dependent transcription.
  - The p38 can phosphorylate SMAD binding partners, such as activating transcription factor 2 (ATF-2) in the nucleus and therefore enhances TGF-β/SMAD4 induced genes transcription.
- **Phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR signaling pathway:** Phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR signaling pathway suppresses the TGF-βR1 mediated SMAD3 phosphorylation through its downstream mTOR molecule. AKT can directly phosphorylate FOXO and keep in the cytoplasm to prevent its binding to the promoter of p27 and p21, thus blocks the TGF-β1/SMAD-mediated cytostatic signals.
- **Wnt/β-catenin signaling pathway:** Wnt ligand can bind to Frizzled family receptor and initiates Wnt/β-catenin signaling pathway and pass the signal to protein inside nucleus and subsequently to the β-catenin destruction complex consisting of AXIN, APC, GSK3b and CKIa, that causes SMAD7 ubiquitination and degradation. In turn, SMAD7 can disassemble the β-catenin destruction complex by binding AXIN and hence stabilize β-catenin and promotes its translocation in the nucleus.

CHEK2 (Checkpoint Kinase 2) Tumor Suppressor Gene

CHEK2 is a tumor suppressor gene located on chromosome 22p12.1, that encodes CHEK2 protein, CHEK2 protein, which plays key role in activation of DNA repair, cell cycle arrest in G1 phase, and apoptosis in response to the presence of DNA double-stranded breaks.

Physiologic State

CHEK2 protein encoded by CHEK2 tumor suppressor gene phosphorylates numerous effectors (CDC25A, CDC25B and CDC25C) preferentially at the consensus sequence, and inhibit their activities resulting in cell cycle arrest in G1 phase.

- Inhibition of CDC25 phosphatase activity results in increased inhibitory phosphorylation of cyclin/CDK complexes, and inhibits cell cycle progression.
- CHEK2 protein may also phosphorylate NEK6, which is involved in cell cycle arrest in G2/M phase.
- CHEK2 protein interacts with phosphorylates BRCA1 and BRCA2 to restore cell survival after DNA damage, and also protein regulates DNA repair through activation of transcription factor FOXM1, and apoptosis through phosphorylation of p53/TP53, MDM2 and PML. Phosphorylation of MDM2 protein may also reduce degradation of p53.

Pathologic State

Mutation in CHEK2 tumor suppressor gene is implicated in **familial breast carcinoma**, and sporadic tumors such as breast carcinoma, ovarian carcinoma, prostatic carcinoma, thyroid carcinoma, and renal cell carcinoma following radiation therapy.

The $p16^{INK4A}$ Tumor Suppressor Gene

The $p16^{INK4A}$ is the principal members of the INK4 family of cyclin-dependent kinase inhibitor (CDKI). It is encoded by the CDK2NA gene located on chromosome 9p21.3 within the INK4A/ARF locus, which encodes for two different proteins with different promoter activities: $p16^{INK4A}$ and $p14^{ARK}$.

Physiologic State

Both $p16^{INK4A}$ and $p14^{ARK}$ proteins inhibit cyclin-dependent kinases (e.g. CDK4 and CDK6) and restrict cell cycle progression, and are involved in the retinoblastoma (RB) and p53 signaling pathways respectively. The $p16^{INK4A}$ protein inactivates CDKs, that phosphorylate RB, therefore, $p16^{INK4A}$ protein induces cell cycle arrest.

- In human papillomavirus (HPV) infection, the HPV oncoprotein E6 and E7. E6 oncoprotein induces the degradation of the tumor suppressor p53 protein. E7 oncoprotein inactivates RB protein (pRB) and thus resulting in cytoplasmic overexpression of $p16^{INK4A}$.

- The $p16^{INK4A}$ interaction with other proteins Y2 chain of laminin, β-catenin or vascular endothelial growth factor (VEGF) is thought to be related to new functions of $p16^{INK4A}$ such as inhibition of angiogenesis as well as cell division.

Pathologic State

Genetic alterations of the $p16^{INK4A}$ locus may impair both ($p14^{ARK}$ $p16^{INK4A}$)/RB pathways, and provide a selective advantage in carcinogenesis, angiogenesis, invasion and metastasis. Germline mutation in $p16^{INK4A}$ locus is linked to familial melanoma. Somatic mutation in $p16^{INK4A}$ locus is associated with melanoma, mesothelioma, pancreatic carcinoma and astrocytoma.

EPIGENETICS IN CANCER

Epigenetics literally means 'above' or 'on top' of genetics. Epigenetic alterations induce genetic modifications that impact gene expression ('turning on'/'turning off') without changing the nucleotide base sequences of DNA building blocks.

- Epigenetic changes may be caused by environmental chemical agents, cytotoxic drugs/pharmaceutical drugs, dietary factors and advancing age, that alter the physical structure of DNA. Aberrant gene function and altered patterns of gene expression are key features of cancer. Epigenetic machinery governing epigenetic processes is shown in Fig. 6.118.
- Nucleosomes are structural units of the chromosome consisting of DNA wrapped around histone octamer proteins, and play important roles in compaction and regulation of the chromatin structure. When nucleosomes are spaced closely together, transcription factors cannot bind and gene expression is 'turned off'. When the nucleosomes are spaced far apart, the DNA is exposed. Transcription factors can bind to exposed DNA and induce gene expression 'turned on'. Histone octamer proteins also play an important role in the maintenance of gene expression.
- Epigenetic regulation of gene expression is mediated by three main mechanisms: (a) histone octamer modifications, (b) DNA methylation (additional of methyl group to DNA by DNA methyltransferases), and (c) small noncoding RNA (e.g. microRNAs).
  - Histone octamer proteins can be modified by the addition or removal of chemical methyl groups or acetyl groups, which determine how tightly DNA is wrapped around histone octamer proteins and affect whether a gene can be 'turned on'/'turned

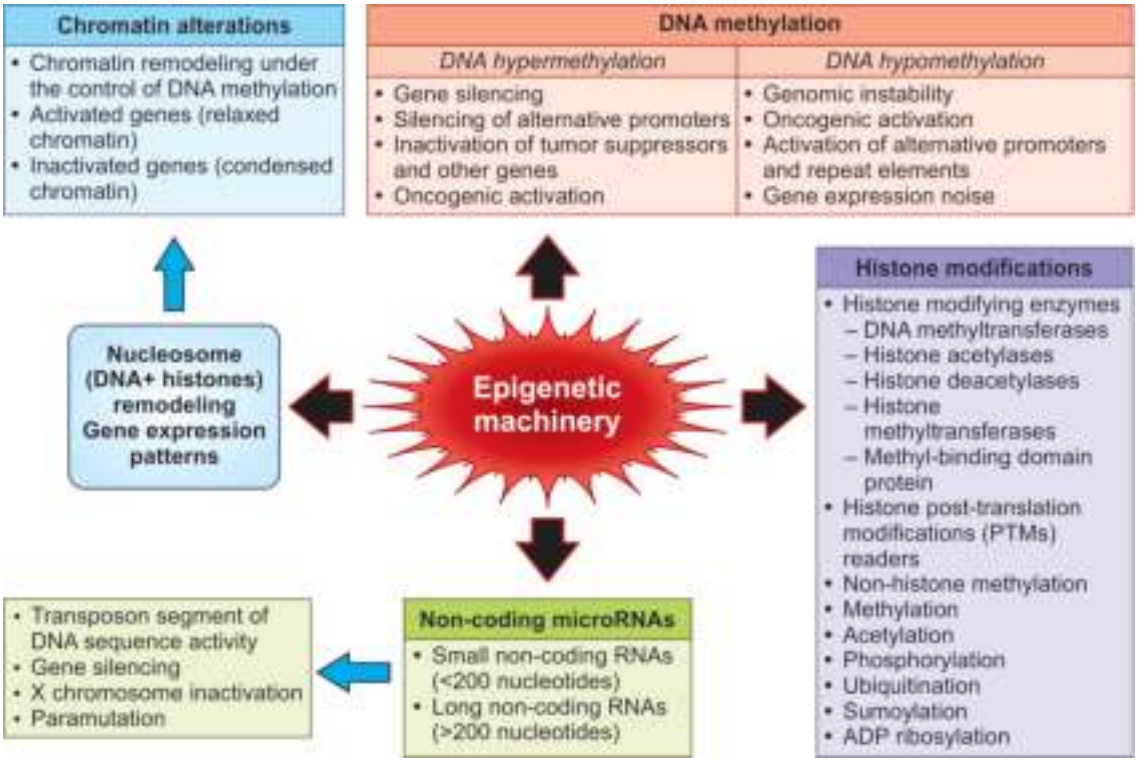

Fig. 6.118: Epigenetic machinery governing epigenetic processes. Three main protein groups control major epigenetic mechanisms targeting DNA, histones, and nucleosome positioning. Genome-wide epigenetic marks introduced by these targeting proteins regulate various biological processes, including gene expression, DNA-protein interactions, chromosomal stability, DNA repair, DNA replication, chromosome structure and recombination events.

off'. An active gene is less bound by histone octamer proteins, whereas inactive gene is highly bound by histone octamer proteins.
  - Transcription-related modifications in histone octamer proteins can occur by methylation (lysine and arginine residues), acetylation (lysine residue), phosphorylation (serine, tyrosine, and threonine residues), ubiquitination (lysine residue) and sumoylation (lysine residue).
  - Proper coordination of temporal activation and silencing of gene expression is the key to the orchestration of normal physiological processes.
  - Deregulation of gene expression results in disruption of normal cellular processes, which in turn, paves the way to the development of cancers.
  - Epigenetic changes can collaborate with genetic changes to cause the evolution of human cancers.
- Recent studies revealed that genome in CSCs in malignant tumor is characterized by global (genome-wide) hypomethylation and site-specific promoter hypermethylation. Many of the epigenetic changes probably contribute in the initiation of malignant tumor growth.
  - Global (genome-wide) hypomethylation increases genomic instability due to chromosomal rearrangements and activates growth-promoting genes (proto-oncogenes), thereby 'turning on' mitotic signals. DNA hypomethylation can also result in loss of imprinting (**LOI**).
  - Methylation-mediated silencing of tumor suppressor genes provides one of the two hits advocated in Knudson's two-hit hypothesis.
  - Silencing of gene expression in carcinogenesis also involves global (genome-wide) loss of transcription-activating histone modifications such as acetylation and activating methylation. Histone tail acetylation enhances transcriptional activity of the gene promoter region.
  - On the contrary, histone octamer methylation can activate either transcription (e.g. H4 lysine 20 methylation) or represses transcription (e.g. histone H3 lysine 9 and lysine 27 methylation). Loss of histone acetylation is carried out by histone deacetylase (HDAC), which is often upregulated in various human cancers.
- The third component of epigenetic regulation is the deregulation of microRNAs demonstrated in many human cancers. Normally, microRNAs are involved in transcriptional regulation, cell proliferation and apoptosis. MicroRNAs regulate interaction of CSCs in tumor microenvironment.
  - In the tumor microenvironment, microRNAs regulate the interaction between CSCs and their tumor microenvironment by targeting several genes involved in this interaction.
  - Several tumor suppressor microRNAs are deregulated in the tumor microenvironment through various mechanisms: (a) amplification, (b) deletion, (c) abnormal transcriptional regulation, (d) epigenetic alteration and gene silencing, and (e) defects in the biogenesis machinery. Amplification of oncogenic microRNAs can downregulate tumor suppressor genes. Onco-RNAs are linked to CSCs growth, proliferation, EMT, invasion, and metastasis to distant organs.
  - Downregulation of tumor suppressor miR-29 and miR-148 in cancer-associated fibroblasts (CAFs) target several genes such as ANGPTL4, PDF, LOX, MMPs and VEGF-A for miR-29 and DNMT1 for miR-148, which stimulate CSCs invasion and metastasis.
  - Hypoxia in the tumor microenvironment has a tumor promoting role by altering the expression of tumor suppressor microRNAs, such as miR-200, miR-34, miR-34, miR-29 and miR-15/16. Inhibition of tumor suppressor miR-200 can significantly increase the expression of ETS-1, resulting in the induction of angiogenesis.
  - Hypoxia-inducible factor 1 (HIF1) gene plays a crucial role in the tumor microenvironment and has been associated with the downregulation of microRNAs. Cancer-associated fibroblasts (CAFs) play an important role in unrestricted proliferation of CSCs during carcinogenesis and metastatic process.
  - Tumor suppressor miR-200 plays role in transformation of normal fibroblasts (NFs) to cancer-associated fibroblasts (CAFs). Tumor suppressor miR-320 targets ETS2, a cancer-specific transcription factor, resulting in increased oncogenic secretome synthesis, and this oncogenic secretome transforms normal fibroblasts (NFs) to cancer-associated fibroblasts (CAFs) in the tumor microenvironment.

TUMOR INVASION AND METASTASIS: MOLECULAR MECHANISMS

Tumor invasion and metastasis are 'hallmarks of cancer' specified by Hanahan and Weinberg. The initial transformation of normal epithelial cell to CSC results in carcinoma *in situ*. With reduced adhesiveness and enhanced migratory behavior, CSCs progress to

invasive stage. After degradation of basement membrane, CSCs invade the surrounding stroma, migrate and intravasate into lymph and blood circulation, surviving CSCs arrest in capillaries, and colonize in the distant organs. CSCs may remain in dormant state without reproliferating for considerable time. **Tumor dormancy** can be induced in malignant epithelial tumor through genetic and epigenetic changes, hypoxia, angiogenic switch, immune evasion, and inflammatory switchover. A change in the tumor microenvironment can facilitate tumor progression/recurrence and thereby permit the tumor to exit from dormancy through interaction with vascular endothelial cells, cancer-associated fibroblasts (CAFs), tumor-associated immune/inflammatory cells, and extracellular matrix (ECM). Subsequent reactivation of metastatic dormancy results in micrometastasis, and then macrometastasis in the distant tissues/organs. In the lymph nodes, communications between the lymphatic channels and venous tributaries allow CSCs access to the systemic circulation. Alternately, CSCs may extravasate the lymph, and blood circulation and lead to formation of secondary tumors resulting in unrestricted CSCs proliferation, angiogenesis and tissue microenvironment activation.

- **Tumor angiogenesis:** Angiogenesis plays a key role in increasing malignant tumor growth, invasion, and metastasis. Vascular endothelial growth factor (VEGF) is the most potent stimulator of endothelial cells within existing vascular networks and near the malignant epithelial tumor.
  - Tumor angiogenesis facilitates dissemination of CSCs from primary malignant epithelial tumor to distant tissues/organs via lymphatic and hematogenous routes.
  - Vascular endothelium of newly malformed blood vessels limits immune CD8+ cytotoxic T cells access to the tumor microenvironment, and expresses FasL, that induces apoptosis of effector CD8+ cytotoxic T cells. FasL on vascular endothelium also poses as a physical barrier, that prevents their extravasation into the tumor microenvironment.
  - Poor perfusion and density-packed glycolytic CSCs create a pocket of diminished oxygen levels, acidic pH, poor nutrition loads, anti-inflammatory signaling factors (e.g. cytokines, chemokines), and accumulated metabolic by-products such as lactate.
- **Tumor invasion in local neighboring tissue:** Tumor invasion is the mechanism by which CSCs in primary malignant epithelial tumor site directly extend and penetrate neighboring tissue.
  - Proliferation of transformed CSCs increases malignant epithelial tumor size eventually leads to breach in the barriers between tissues resulting in CSCs extension into surrounding tissue.
  - Local tissue invasion is also the first stage of dissemination, that leads to the development of secondary tumor in distant tissues/organs.
- **Tumor metastasis:** Metastasis is the multistep process by which CSCs detach from original primary malignant epithelial tumor, invades interstitial tissue and extracellular matrix (ECM), intravasate lymphatic and blood vessels, circulate in the bloodstream as single or clusters, survive, extravasate, establishment of the micrometastasis, and eventually colonize as single or multiple metastases and remain in metastatic dormancy and their subsequent reactivation in the distant tissues/organs.
  - Subsequent reactivation of dormant metastasis through interaction with cancer-associated fibroblasts (CAFs), immune cells, vascular endothelial cells, inflammatory cells, and the ECM involving intracellular signaling, extracellular signaling and induction of signals originating from the bone marrow niche.
  - Metastasis is most often associated with several clinical, pathologic, and anatomic characteristics—tumor size, regional lymph nodes involvement, metastasis in distant organs and resistance to therapy.
  - **Integrins' role in cancer progression:** Integrins are the key cellular adhesion receptors, that are involved in nearly every step of cancer progression from primary malignant epithelial tumor to secondary tumor in distant tissues/organs. Altered integrin expression is demonstrated in human cancers, where integrins support oncogenic growth factor receptor, invasion, and metastasis. Furthermore, integrins regulate the colonization process in the distant tissues/organs by easing anchorage independent survival of CSCs.
- **Metastatic cascade—critical steps:** Critical steps to tumor metastasis include alterations in tumor microenvironment and ECM in the formation of pre-metastatic and metastatic niche. Primary malignant epithelial tumor induces premetastatic niche (PMN) in sequence-wise mechanisms.
  - **Step 1:** At primary malignant epithelial tumor site, synthesis of some molecules (VEGF, TGF-β, MMP2, MMPs, CXCR4, SDF-1) induce inflammation and hypoxia responses, which assist proliferation of primary malignant epithelial tumor and unregulation of molecules, e.g. TNF-α, TGF-β, VEGF-1, and G-CSF.

- **Step 2:** TNF-α, TGF-β, VEGF-1, and G-CSF molecules are transported from primary site to secondary site through hematogenous route.
- **Step 3:** TNF-α. TGF-β, VEGF-1, and G-CSF molecules induce pre-metastatic niche (PMN). These molecules function in similar way at primary and secondary sites. The change of PMN build a unique environment which favor metastatic CSCs colonization in distant tissues/organs.

Pathology Pearls: Liquid Biopsy Significance in Metastatic Cascade

- Liquid biopsy has diagnostic, prognostic, and predictive significance in cancer patients. Liquid biopsy is based on the analysis of cellular or molecular biomarkers such as circulating tumor cells (CTCs), free nucleic acids (DNA or RNA), and exosomes in a biological fluid, usually blood. During metastatic cascade different liquid biopsy analytes are involved. Advantages of liquid biopsy is to monitor tumor progression.
- Liquid biopsy has broad potential applications for cancer diagnosis, study of tumor heterogeneity, clonal evolution, and detection of minimal residual disease.
- During cancer progression, liquid biopsy might help the clinical oncologist to stratify patients for treatment and personalization, monitor the treatment response and the development of resistance to chemotherapy and radiation therapy.
- Liquid biopsy analyte involved during metastatic cascade is given in Table 6.96.

- **Chromosomal instability:** Chromosomal instability initially triggers tissue invasion and metastasis that results from unexpected errors in segregation of chromosomes during mitosis leading to structural and numerical chromosomal abnormalities. The chromosomes are susceptible to damage by ionizing radiation and drugs.
  - Chromosomal instability is associated with poor prognosis as a result of invasion, metastasis, and therapeutic resistance. Chromosomal instability differs from microsatellite instability.
  - Microsatellite instability is defined as increased predisposition to mutation that results from impaired DNA mismatch repair.
  - Microsatellite instability (**MSI**) represents phenotypic evidence that mismatch repair is not functioning normally. Each microsatellite consists of a short motif (1–6 nucleotide base pairs) repeated in tandem to form an array over 6,00,00 unique satellites exist in human genome.
- **Epithelial–mesenchymal transition:** Epithelial–mesenchymal transition (EMT) involves the disruption of cell-cell adhesion and cellular polarity, remodeling of the cytoskeleton and changes in cell-matrix adhesion. It is associated with enhancement in migratory and invasive properties.
  - Epithelial cells are characterized by intact cell-cell interactions through cell adhesion molecules such as E-cadherin and cytokeratin within tight junctions, adherens junctions, desmosomes, and gap junctions.
  - Desmosomes are adhering junctions between the membranes of adjacent cells.
  - Hemidesmosomes are present between epithelial cells and their underlying basement membrane. Desmosomes are composed of desmoplakin and other proteins, which form an electron dense structure immediately beneath the plasma membrane.
  - Cadherins are calcium-dependent adherens proteins associated with desmosomes and penetrate the cell membrane to interact with cognate proteins on adjacent cells. Cadherins function to hold the cells in contact with one another across desmosomes.

Table 6.96 Liquid biopsy analyte involved during metastatic cascade

Metastasis Steps	Liquid Biopsy Analyte Involved
Cancer stem cell proliferation in primary malignant tumor	ctDNA, EVs
Angiogenesis in primary malignant tumor	ctDNA, EVs
Local tissue invasion and detachment and intravasation of CSCs	ctDNA, EVs
Embolization and survival of CSCs	ctDNA, TEPs
Cancer stem cells arrest and extravasation at target organs	ctDNA, EVs
Micrometastasis	ctDNA, EV
Macrometastasis	ctDNA

CtDNA: Circulating DNA; EVs: EV-associated metabolite biomarkers (proteins, DNA and RNA), TEPs are used to diagnose glioblastoma multiforme.

EPITHELIAL–MESENCHYMAL TRANSITION IN DEVELOPMENT OF MALIGNANT TUMOR AND ITS CLINICAL SIGNIFICANCE

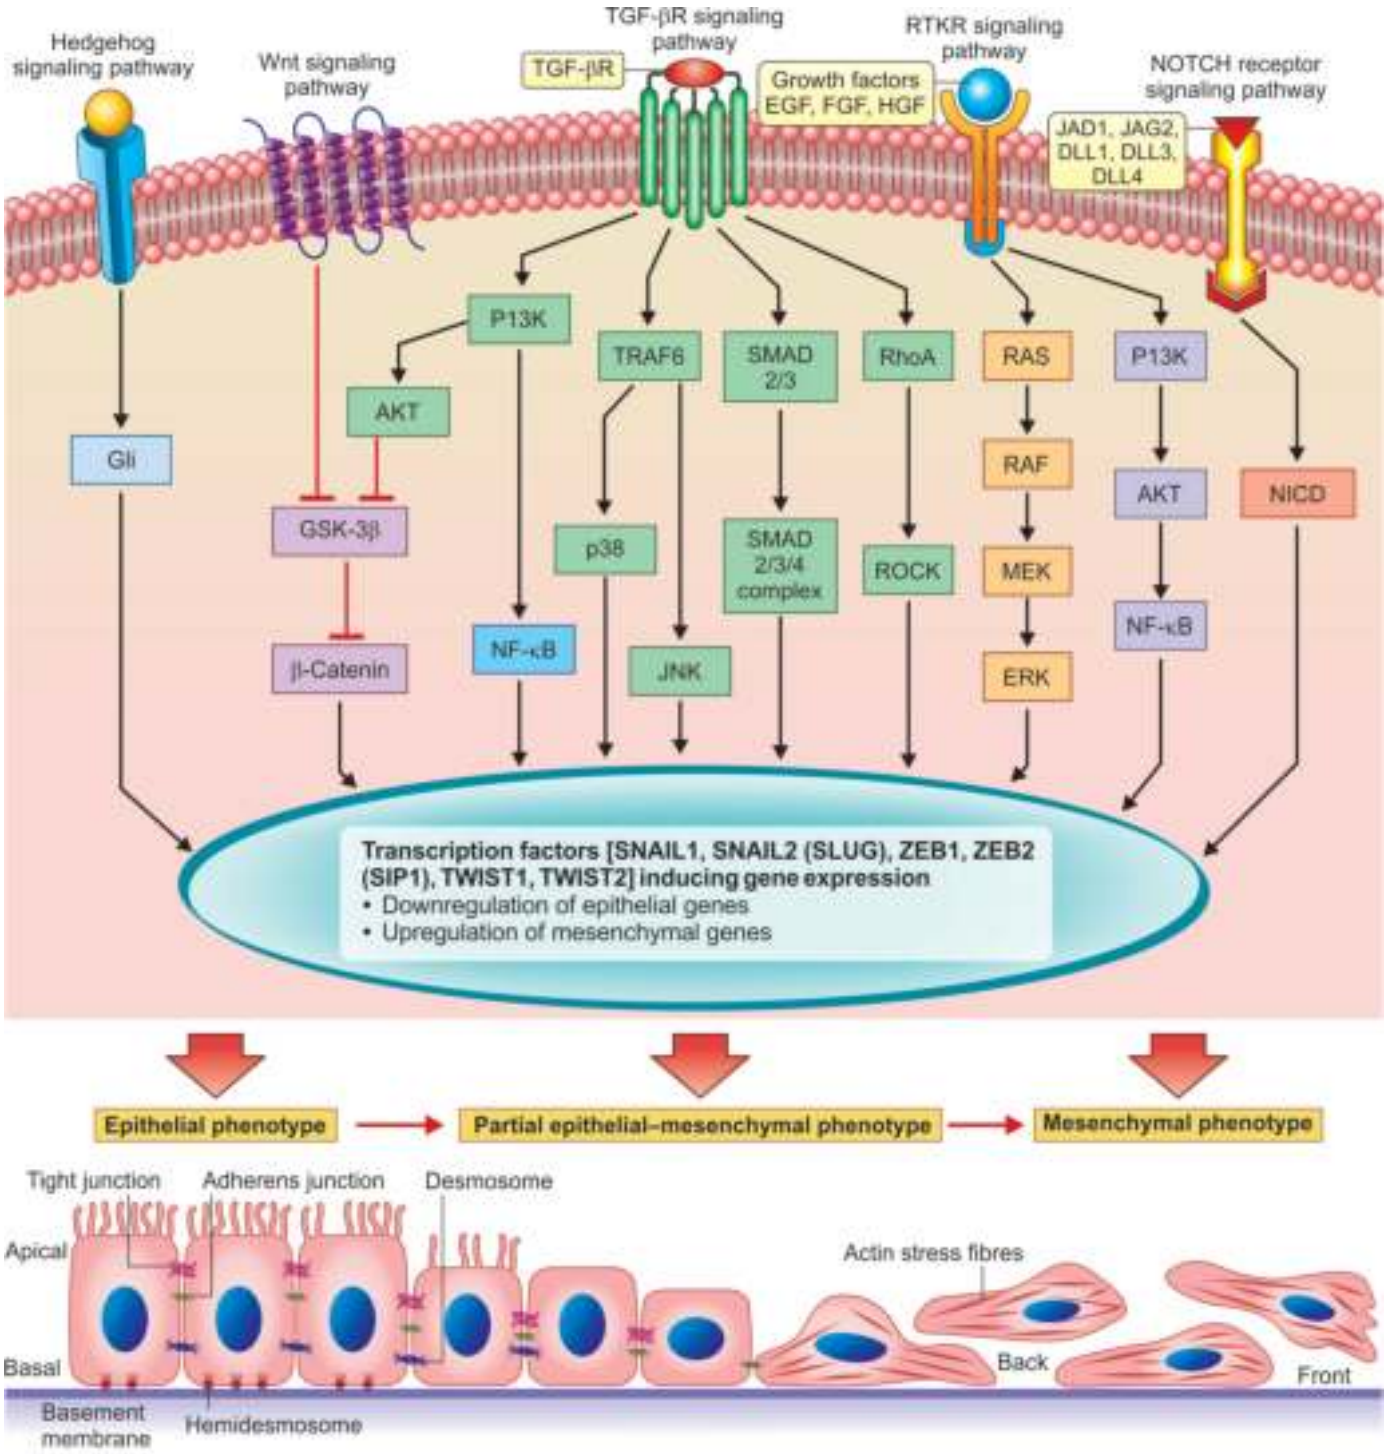
Epithelial–mesenchymal transition (EMT) is biologic process by which epithelial cells lose their cell polarity and cell–cell adhesion and gradually acquire migratory and invasive properties to become mesenchymal stem cells.

- Type I EMT is associated with embryogenesis involved in implantation of embryo, placenta formation and organogenesis. Type II EMT is involved in inflammation, wound healing, and tissue remodeling. Type III EMT plays a critical role in carcinogenesis, invasion, metastasis, recurrence and chemoresistance.
- Cancer stem cells (CSCs) undergoing EMT can acquire invasive properties and enter the surrounding stroma resulting in the creature of favorable microenvironment for invasion and metastasis. EMT signals occur at primary malignant epithelial tumor. Partial EMT state facilitates motility and invasion into basement membrane and extracellular matrix (**ECM**). Mesenchymal phenotype facilitates intravasation and anoikis resistance during lymphatic and blood vessel dissemination and extravasation of CSCs.
- After extravasation, migrating CSCs survive and remain in dormancy in solitary or micrometastasis at distant sites, which later exit from dormancy and undergo mesenchymal–epithelial transition (**MET**), colonization, CSC proliferation, and formation of macrometastasis. Recent studies revealed that CSCs and microRNAs could be involved in EMT process.
- Development of metastasis in distant tissues/organs is the final stage of solid malignant tumor progression and is responsible for cancer-related deaths. The metastasis process consists of multiple steps.
  - First, CSCs escape from the primary malignant tumor site. Then, CSCs invade basement membrane and extracellular matrix (ECM), migrate and invade lymphatic or blood vessels and circulate. Most circulating CSCs undergo apoptosis due to anoikis conditions. If CSCs survive in bloodstream, they may reach more suitable distant sites by attaching to endothelial cells and extravasating from the circulation into the surrounding tissues.
  - Finally, distal colonization requires CSCs to invade and grow in the new microenvironment. The biology of EMT has been clarified in malignant tumor samples through use of EMT-associated markers such as mesenchymal-specific markers (i.e. vimentin and fibronectin), epithelial-specific markers (i.e. E-cadherin and cytokeratin), and transcription factors (i.e. SNAIL and SLUG).

Involvement of Epithelial–Mesenchymal Transition in Cancer Progression

Epithelial–mesenchymal transition is a highly dynamic process by which epithelial CSCs can convert into mesenchymal phenotype, which is involved malignant tumor progression with metastatic expansion and generation of cancer cells with stem cell properties with resistance to cancer treatment.

- Epithelial–mesenchymal transition induces disintegration of cell-to-cell junctions and cell-to-ECM junctions with loss of apical–basal polarization, cytoskeletal modifications (i.e. actin rich membrane projections—invadopodia, lamellipodia, and filopodia; actin stress fiber formation), downregulation of E-cadherin, cytokeratins, claudins and upregulation of mesenchymal markers (i.e. fibroblast-like shape, acquisition of front–rear polarization, N-cadherin, vimentin, fibronectin), multipotency (stem cell traits), motility, invasiveness, anoikis resistance, chemoresistance and radiation resistance, recurrence, immune suppression, metabolic reprogramming, modulation of expression/secretion of invasion-mediated proteolytic enzymes such as matrix metalloproteinases (MMPs).
- Epithelial–mesenchymal transition (EMT) allows CSCs to acquire mobility, invade the surrounding tissue, intravasate into the vasculature, and then extravasate at distant sites, and establish in the tissue stroma, a process that is influenced by cellular plasticity, that requires the ability of CSCs with mesenchymal properties to revert to an epithelial state through mesenchymal–epithelial transition (**MET**). Proliferation of the established CSCs results in clinically relevant macrometastases in distant tissues/organs.
- Signaling pathways in EMT and MET in malignant epithelial tumor progression are given in Fig. 6.119. Signaling pathways in induction of EMT are given in Table 6.97. EMT and MET malignant epithelial tumor progression given in Fig. 6.120. Cellular changes associated with EMT and MET in malignant epithelial tumor progression are given in Table 6.98. EMT-associated biomarkers in clinical tissue samples to predict prognosis of cancer patients are given in Table 6.99.



Epithelial–mesenchymal transition (EMT) transcription factors

- **Epithelial phenotype (downregulation of epithelial markers):** ↓E-cadherin, ↓cytokeratins, ↓claudins, ↓zona occludin 1 (ZO-1), ↓desmoplakin, ↓plakophilin, ↓vitronectin, ↓fibronectin
- **Mesenchymal phenotype (upregulation of mesenchymal markers):** ↑N-cadherin, ↑vimentin, ↑α-SMA, ↑integrins, ↑β1/β3 integrins, ↑MMPs, AKT/GSK3β pathway, ↑neuropilin 2, ↑ETS-1/NF-κB pathway, ↑β-catenin, ↑TGF-β, ↑FGFR2 IIIb/IIIc, ↑rho-kinase, ↑DDR2, ↑ILK, ↑FOXC2

Fig. 6.119: Signaling pathways in epithelial–mesenchymal transition (EMT) and mesenchymal–epithelial transition (MET) in malignant epithelial tumor progression. EMT is essential mechanism in embryonic development and tissue repair. EMT also contributes to the progression of cancer. MET is often implicated in colonization of carcinoma—the last step in the metastatic cascade.

Table 6.97 Signaling pathways in induction of epithelial–mesenchymal transition

Receptor	Ligand	Signaling Molecules	Intermediate Signaling End Point	Effect
TGF-β receptor	TGF-β	▪ SMAD family of signaling pathway ▪ Rho signaling pathway	ZEB	Migration of cancer stem cells
Receptor tyrosine kinase	FGF, HGF, EGF, IGF	▪ Src signaling pathway RAS/RAF/MEK/ERK/MAPK signaling pathway ▪ PI13K/AKT/mTOR signaling pathway	SNAIL2	▪ Cytoskeleton activation ▪ Migration of cancer stem cells ▪ Focal adhesion rearrangement
Integrins	Collagen Fibronectin	▪ FAK signaling pathway ▪ Paxillin signaling pathway ▪ Rac signaling pathway	SNAIL2	Migration of cancer stem cells
Frizzled	Wnt	▪ APC signaling pathway ▪ Axin signaling pathway ▪ GSK3β ▪ β-Catenin	SNAIL2	▪ E-cadherin downregulation ▪ Reduced cell adhesion

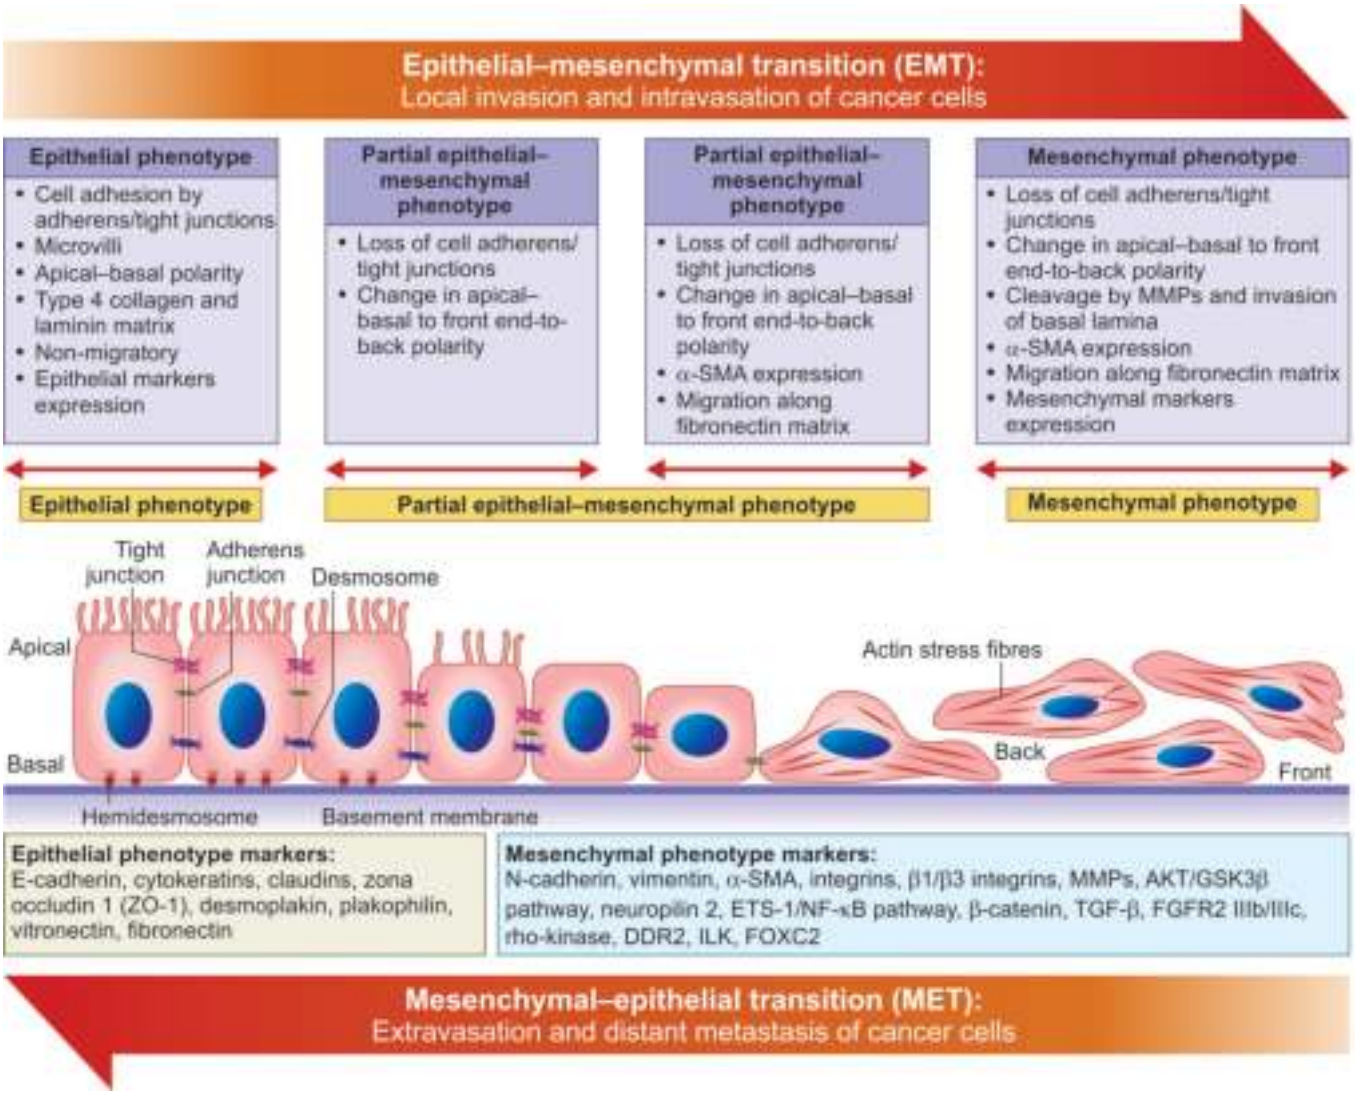


Fig. 6.120: Epithelial–mesenchymal transition (EMT) and mesenchymal–epithelial transition (MET) in malignant epithelial tumor progression. During initial steps of metastatic cascade, epithelial cancer cells undergo an EMT. MET is the reverse process of EMT, and it has been shown to occur in normal development induced pluripotent stem cell reprogramming, cancer metastasis and wound healing.

Table 6.98 Cellular changes associated with epithelial–mesenchymal transition (EMT) and mesenchymal–epithelial transition in malignant epithelial tumor progression

Downregulation/Loss of Epithelial Cell Phenotype during EMT
Downregulation/loss of E-cadherin (epithelial adherens junction protein)
Noninvasive properties of cancer stem cell
Apical–basal cell polarity
Cytokeratin (intermediate filament) expression
Epithelial gene expression programme
Downregulation/loss of occludin (integral membrane protein), claudin and TJPZO1 (tight-junction protein zona occludin 1)
Acquisition of Mesenchymal Cell Phenotype: Stem Cell-like during EMT
Downregulation/loss of E-cadherin (epithelial adherens junction protein) results in loss of cell-cell interaction and repression of polarity complex proteins
Fibroblast-like shape of CSC
Front-to-back cell polarity
Cytoskeletal changes and motility ▪ Reorganization of actin cytoskeleton to enable cell elongation and directional motility ▪ Formation of actin rich membrane projections: invadopodia—proteolytic, lamellipodia—sheet-like and filopodia—spike-like ▪ Actin stress fiber formation results in increased cell contraction ▪ Actin dynamics are regulated by RHO GTPases: RHO A: actin stress fibers formation, and RAC1 and CDC42—lamellipodia and filopodia ▪ Cytoskeleton changes induce cell shape changes and front–rear polarity essential for migration
Invasiveness and migratory properties (self-renewal, invasion, metastasis, anoikis resistance, evasion of the immune system, resistance to chemotherapy and radiation)
Mesenchymal gene expression programme
N-cadherin (mesenchymal adherens junction protein) expression
Vimentin (intermediate filament) expression
Fibronectin secretion
Protease secretion (MMP2, MMP3, MMP9)
PDGF receptor expression
$\alpha 6\beta 4$ Integrin expression

Transcription factors involved in induction of EMT include SNAIL-1/SNAIL-2, TWIST1, TWIST2, ZEB1, ZEB2, and SMAD2/SMAD3.

Table 6.99 Epithelial–mesenchymal transition (EMT)-associated biomarkers in clinical tissue samples to predict prognosis of cancer patients

EMT-associated Gene	Characteristics	Human Cancers
Downregulation/loss of epithelial biomarkers		
E-cadherin (epithelial cadherin)	Cell-to-cell adhesion glycoprotein	▪ Breast carcinoma ▪ Gastric carcinoma ▪ Colorectal carcinoma
Claudin-1	Cell-to-cell tight junctions restrict lateral diffusion of lipids and membrane proteins	▪ Lung carcinoma ▪ Renal cell carcinoma ▪ Ovarian carcinoma ▪ Colorectal carcinoma ▪ Esophageal carcinoma
Occludins	Cell-to-cell tight junctions	Metastatic breast carcinoma
Desmoplakin	Component of desmosomes present in cytoplasm	Breast carcinoma
ZO-1	Peripheral phosphoprotein	Breast carcinoma

Contd...

Table 6.99 Epithelial–mesenchymal transition (EMT)-associated biomarkers in clinical tissue samples to predict prognosis of cancer patients (*Contd...*)

EMT-associated Gene	Characteristics	Human Cancers
Syndecan-1	Transmembrane proteoglycans	Metastatic breast carcinoma
Nidogen-1 (NID1)	Nidogen-1 (NID1) binds to laminin, collagen IV, fibrinogen, fibronectin; and induces EMT, invasion, metastasis and chemoresistance	Ovarian carcinoma
Upregulation/activators/acquisition of mesenchymal biomarkers		
Vimentin	Intermediate filament represents a class of cytoskeletal elements	▪ Breast carcinoma ▪ Gastric carcinoma ▪ Lung carcinoma
N-cadherin (neutral cadherin)	Cell-to-cell adhesion glycoprotein	▪ Esophageal carcinoma ▪ Lung carcinoma ▪ Urothelial carcinoma
OB-cadherin (osteoblast cadherin)	Calcium-dependent cell adhesion molecule	Prostatic carcinoma
Fibronectin	High molecular weight extracellular matrix glycoprotein	▪ Urinary bladder carcinoma ▪ Colorectal carcinoma ▪ Ovarian carcinoma ▪ Metastatic breast carcinoma
Vimentin	Intermediate filament	Metastatic breast carcinoma
Vitronectin	Glycoprotein	Metastatic ovarian carcinoma
Syndecan-1	Transmembrane heparan sulphate proteoglycans	▪ Metastatic triple negative breast carcinoma ▪ Metastatic endometrial carcinoma
$\beta1\beta3$ Integrin	Cell adhesion molecule	▪ Breast carcinoma ▪ Prostatic carcinoma ▪ Pancreatic carcinoma
$\alpha2\beta2$ Integrin	Cell adhesion molecule	Breast carcinoma
Neuropilin-2	Transmembrane non-receptor tyrosine kinase glycoprotein	▪ Breast carcinoma ▪ Prostatic carcinoma
Transcription factors		
SNAIL-1	CH2H2 type zinc finger transcription factor	▪ Breast carcinoma ▪ Ovarian carcinoma ▪ Skin cancer ▪ Hepatocellular carcinoma ▪ Head and neck cancer
SNAIL-2	CH2H2 type zinc finger transcription factor	▪ Breast carcinoma ▪ Melanoma
SLUG	Zinc finger transcription factor	▪ Lung carcinoma ▪ Colorectal carcinoma ▪ Esophageal carcinoma
TWIST-1	Basic helix-loop-helix (bHLH) transcription factor	▪ Cervical carcinoma ▪ Ovarian carcinoma ▪ Breast carcinoma ▪ High-grade melanoma ▪ Neuroblastoma
TWIST-2	Basic helix-loop-helix (bHLH) transcription factor	Metastatic breast carcinoma

Contd...

Table 6.99 Epithelial–mesenchymal transition (EMT)-associated biomarkers in clinical tissue samples to predict prognosis of cancer patients (*Contd…*)

EMT-associated Gene	Characteristics	Human Cancers
ZEB1 (δ-EF1)	Basic helix-loop-helix (bHLH) transcription factor	▪ Pancreatic carcinoma ▪ Lung carcinoma ▪ Hepatocellular carcinoma ▪ Colon carcinoma ▪ Breast carcinoma
ZEB2 (SIP-1)	Basic helix-loop-helix transcription factor	▪ Ovarian carcinoma ▪ Breast carcinoma ▪ Hepatocellular carcinoma
E12/E-47 (associated with E-cadherin promoter)	Basic helix-loop-helix (bHLH) functions as a subunit of heterodimeric	Gastric carcinoma
ETS (electron transport system)	Helix-turn-helix DNA binding transcription factor	Prostatic carcinoma
LEF1 (lymphoid enhancer binding factor 1)	Transcription factor	▪ Lung adenocarcinoma ▪ Colon carcinoma ▪ Endometrial carcinoma ▪ Prostatic carcinoma ▪ Leukemia
Homeobox protein goosecoid (GSC)	Paired homeodomain	▪ Ovarian carcinoma ▪ Lung carcinoma ▪ Breast carcinoma
FSP1 (fibroblast specific protein 1)	Ferroptosis suppressor protein	Non-small cell lung carcinoma

Pathology Pearls: Epithelial–Mesenchymal Transition and Mesenchymal–Epithelial Transition in Malignant Epithelial Tumor Progression

- Carcinoma arises from epithelial tissues and begins when genetic mutations transform a normal cell into CSC.
  - Loss of E-cadherin, the principal adhesion molecule of epithelial cells is important in the development of carcinoma.
  - Genetic mutations and tumor microenvironment initiate the cancer metastasis via epithelial–mesenchymal (EMT) process.
  - EMT might not be essential for metastasis of lung and pancreatic cancers.
- Epithelial–mesenchymal transition (EMT) and mesenchymal–epithelial transition (MET) are involved in invasion and metastasis of malignant tumor to distant tissue/organ sites.
- Cancer stem cells (CSCs) undergoing EMT detach from primary malignant epithelial tumor, penetrate through the fragmented basement membrane, and degrade extracellular matrix (ECM) and then subsequently intravasate into the blood vessels and lymphatic channels and circulate in the bloodstream as the form of single and clusters.
- Only a small number of CSCs survive and extravasate through basement membrane and surrounding tissues. After CSCs are disseminated, they must reactivate their epithelial properties by means of the reversion of the process of EMT, known as MET. One of the keys to the process of MET is the re-expression of E-cadherin, which enables CSCs to interact the tissue of the recently colonized tissues/organs.
- However, extravasated CSCs may remain dormant over a long period before they activate MET process and proliferate to form micrometastasis and then subsequent formation of macrometastases in distant tissues/organs and become therapy resistance.
- Extravasated CSCs synthesize chemokines and other proteins, which attract immune cells and stimulate angiogenesis, thus promoting the development of highly vascularized and inflammatory niche.
- Cancer-associated fibroblasts (CAFs) drive direct CSCs migration through fibronectin alignment. In addition, hypoxia, metabolic suppressors, and extracellular matrix (ECM) stiffens trigger the EMT programme in CSCs.
- Transcriptional repress epithelial genes and activate mesenchymal genes. Epigenetic and post-transcriptional modulators also play important role in regulation of EMT process.

Molecular Mechanisms of Epithelial–Mesenchymal Transition (EMT) in Cancer Progression

Multiple complexes signaling systems are required for the induction of EMT because epithelial CSCs undergoing EMT must undergo both morphologic and functional changes. Recent studies of the crosstalk among the intracellular signal networks (i.e. receptor tyrosine kinases, Wnt/β-catenin, NOTCH, Hedgehog signaling pathway, and bone morphogenic proteins) and molecules such as E-cadherin inducer of EMT,

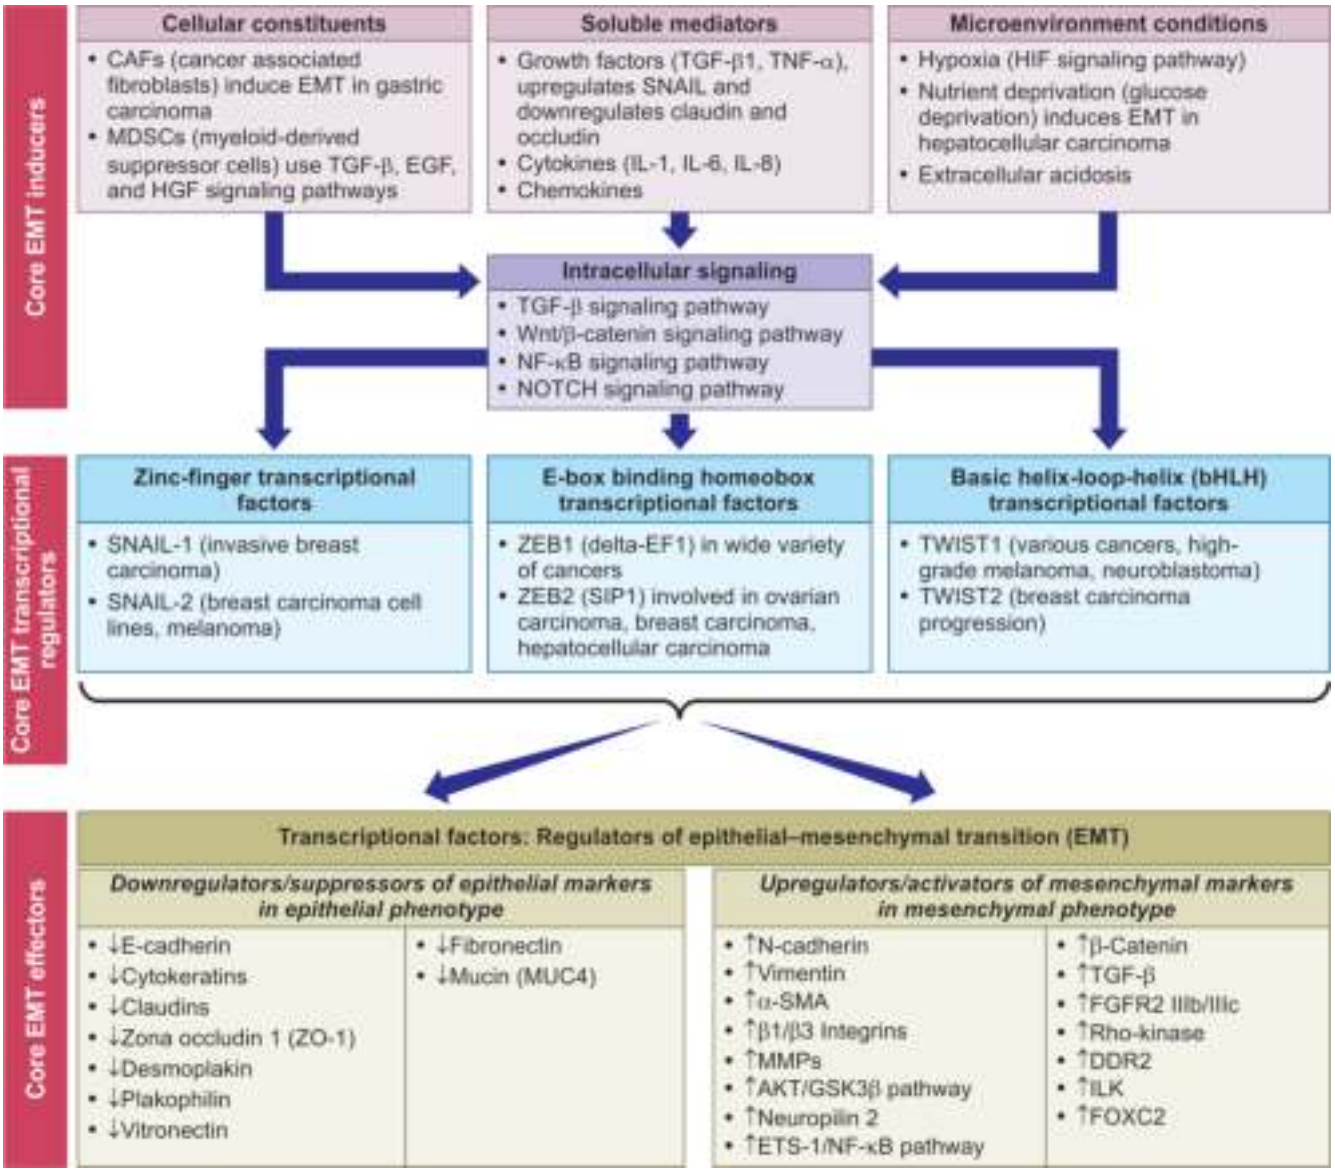

Fig. 6.121: Regulators and biomarkers of EMT in cancer. During the process of EMT, cells undergo changes and molecular alterations representing mesenchymal differentiation. This leads to cancer cells losing epithelial markers and gaining mesenchymal markers. Regulators and biomarkers of EMT include core inducers, transcriptional regulators, and effectors.

transforming growth factor-β (TGF-β) signaling pathway and microRNAs could help to understand the mechanism of regulating EMT. Regulators and biomarkers of EMT in cancer are shown in Fig. 6.121.

E-Cadherin Transmembrane Glycoprotein-associated EMT

The CDH1 tumor suppressor gene provides instructions for making a protein called E-cadherin (i.e. epithelial cadherin) that maintains epithelial tissue structure and its integrity.

- E-cadherin is calcium-dependent transmembrane adherens glycoprotein associated with desmosomes and penetrate the cell membrane, which facilitates normal cell-cell adhesion of most epithelial cells and desmosomes and maintains tissue homeostasis.
- Altered E-cadherin expression occurs due to somatic nonsense or frameshift mutations, hypermethylation of histones or transcriptional repression (SNAIL, SLUG, TWIST), and phosphorylation and degradation.
- Methylation of the E-cadherin promoter region plays a vital role in tumorigenesis (i.e. gastric carcinoma and breast lobular carcinoma), angiogenesis, EMT, invasion, and metastasis in distant tissues/organs. Besides genetic and epigenetic regulation, E-cadherin is regulated by various signaling networks and transcription factors.
- Tumor suppressor gene E-cadherin and its role in normal and cancer stem cells are shown in Fig. 6.122.

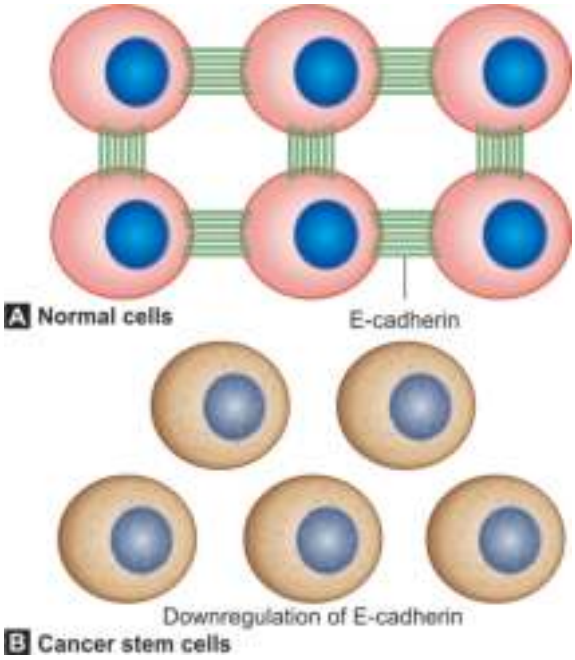

Fig. 6.122: Tumor suppressor gene E-cadherin and its role in normal and cancer stem cells. E-cadherin is a transmembrane glycoprotein, which mediates calcium-dependent cell-cell adhesion, regulates cell growth and differentiation, and maintains tissue homeostasis. Altered E-cadherin expression plays a vital role in tumorigenesis, angiogenesis, EMT invasion, and metastasis.

Transforming Growth Factor-β Signaling-associated Epithelial–Mesenchymal Transition

Transforming growth factor-β (TGF-β) produced by cancer associated fibroblasts (CAFs), and hypoxia-inducible factor in the tumor microenvironment activate EMT in epithelial CSCs, which maintain mesenchymal phenotype through both paracrine and autocrine signaling.

- Canonical TGF-β signaling proceeds with phosphorylation of SMAD2 and SMAD3, which then bind with SMAD4 to enter the nucleus to modulate transcription in cooperation with other transcription factors, coactivators, and corepressors. In addition, TGF-β ligands bind to its cognate receptors leading to activation of many noncanonical signaling pathways.
- TGF-β cytokine plays dichotomous role, i.e. tumor suppressor in normal cells or premalignant cells in initial stage, or tumor promoter in the late-stage by induction of EMT through multiple signaling pathways, including phosphorylation of SMAD2 and SMAD3, invasion, tumor angiogenesis, protection against apoptosis, immune suppression, and metastasis.
- Mutations in TGF-β and SMAD4 are linked to pancreatic carcinoma and colorectal carcinoma. TGF-β activates other EMT-related Wnt/β-catenin, NOTCH, and integrin signal pathways, also trigger EMT programmes.

Transcription Factors Repress E-Cadherin-associated Epithelial–Mesenchymal Transition

Epithelial–mesenchymal transition (EMT) is driven by master transcription factors such as E-box zinc finger proteins (ZEB1, ZEB2), basic helix-loop-helix (bHLH) proteins (TWIST1/TWIST2) and the SNAIL family of zinc finger proteins (SNAIL1, SNAIL2/SLUG), SMADs (SMAD2, SMAD3), SLUG, NF-κB, Gli, E47 via connected TGF-β, Wnt/β-catenin, PI3K (phosphatidylinositol 3-kinase)/AKT/mTOR signaling pathways, that results in the repression of E-cadherin, acquisition of mesenchymal phenotypic traits and activation of extracellular matrix (ECM) degradative enzymes. SNAIL1 and ZEB2 transcription factors would initiate downregulation of E-cadherin. SNAIL2/SLUG and ZEB1 transcription factors would maintain repression of E-cadherin. In the induction of EMT, the activated **SMADs** mediate regulation of transcription through three families of transcription factors leading to repression of epithelial marker gene expression and activation of mesenchymal gene expression.

- **SNAIL family of zinc finger transcription factor:** SNAIL transcription factor blocks the cell cycle and confers resistance to apoptosis. SNAIL causes metabolic reprogramming, confers CSCs with stem cell-like traits resistant to immunosuppression, induces EMT, promotes invasion metastasis, and recurrence.
  - SNAIL-1 overexpression is linked to progression of breast carcinoma, cervical carcinoma, and ovarian carcinoma.
  - SNAIL-2 overexpression is linked to progression of breast carcinoma, and ovarian carcinoma.
- **E-box zinc finger binding transcription factor:** ZEB1 transcription factor represses E-cadherin promoter and induces EMT process by recruiting SMARCA4/BRG1. ZEB2 is involved in chemical signaling pathways that regulate early growth and development of colon carcinoma, breast carcinoma and ovarian carcinoma.
- **Basic helix-loop-helix (bHLH) transcription factor:** TWIST1 transcription factor exerts its multiple biological effects (e.g. angiogenesis, chemoresistance, metastasis, senescence, and stemness) via various downstream signaling pathways, acting as a transcription factor regulating the expression of an array of target genes such as PDGFRA, YB1, MDR1, AKT2, N-cadherin, E-cadherin, ARF, P53 and CD24 in the nucleus or modulating the function of effectors (e.g. Jagged-1, VEGF, mTOR, BCL-2, p53, and Bmi-1) at the protein level in the cytoplasm. Overexpression of TWIST1 induces EMT, a key process in metastasis of breast carcinoma and gastric carcinoma.

- **SLUG, FOXC1/FOXC2, NF-κB and E12/E47 transcription factors:** SLUG transcription factor downregulates E-cadherin during EMT process. FOXC1 partially promotes tumor metastasis by EMT process to support microvascular invasion, thereby increasing angiogenesis. FOXC2 overexpression is linked to breast carcinoma. E12/E-47 basic helix-loop-helix transcription factor represses E-cadherin and induces EMT leading to development of gastric carcinoma.

Regulation of Epithelial–Mesenchymal Transition by Small Non-coding MicroRNAs

Small noncoding microRNAs regulate target gene expression at the post-translation level involved in a wide array of biological processes including carcinogenesis with metastatic potential.

- MicroRNAs are most often dysregulated in human cancers. MicroRNA-10b is overexpressed by EMT transcription factor by TWIST in metastatic breast carcinoma.
- MicroRNA-200 family (miR-200a, miR-200b, miR-200c, miR-141, miR-29) and miR-205 play key roles in regulating of EMT and targeting E-cadherin repressors ZEB1 and ZEB2. MicroRNA-200 family can induce EMT process.

Tumor Microenvironment and Epithelial–Mesenchymal Transition

Tumor microenvironment (TME) is composed of extracellular matrix (ECM), cancer-associated fibroblasts (CAFs), myofibroblasts, immune cells, and soluble factors required for invasion and metastasis. Interaction among CSCs in the tumor microenvironment can induce EMT by autocrine and/or paracrine synthesis of cytokines, growth factors, and ECM proteins.

Cancer Drug Resistance induced by Epithelial–Mesenchymal Transition

Epithelial–mesenchymal transition (EMT) plays a role in development of CSCs properties of invasiveness, metastasis, recurrence and chemoresistance. Cancer drug resistance is still a major persistent challenge for cancer patient management in clinical oncology.

- Cancer stem cells undergoing EMT have invasive and migratory capabilities, and develop resistance to anti-cancer agents. Lung CSCs undergoing EMT express vimentin and/or fibronectin become insensitive to EGFR inhibitors.
- There are several mechanisms of cancer drug resistance induced by EMT, i.e. inactivation of the anti-cancer drug, multidrug resistance, changes in drug targets, alteration in drug metabolism, epigenetic alterations, cell death inhibition (apoptosis evasion), gene amplification, and enhance DNA repair system cause resistance to chemotherapy. Hence, it is important to overcome therapy resistance by using new targeted-therapy strategies.
- The novel cancer treatments by analyzing molecular targets of oncogenes, tumor suppressor genes and RNA interference (RNAi) are expanded, which include: inhibition of receptor tyrosine kinase involved in unrestricted CSC proliferation, enhancement of immune system response in cancer, promotion of drug delivery to CSCs, alteration of drug metabolism and reduction of side effects of anticancer drugs.

Clinical Significance of Epithelial–Mesenchymal Transition

Most EMT-associated markers have been identified in histologic specimens. Clinical significance of the EMT process has been implicated in carcinogenesis, invasion, metastasis, recurrence and chemoresistance.

TUMOR MICROENVIRONMENT

Tumor microenvironment (TME) consists of CSCs, nonmalignant stromal cells such as cancer-associated fibroblasts (CAFs), tumor-associated adipocytes, vascular endothelial cell and extracellular matrix (ECM), activating immune cells such as CD8+ cytotoxic T cells, natural killer cells (NK cells) and dendritic cells (DCs) and immunosuppressive immune cells such as CD4+ regulatory T cells (Tregs), myeloid-derived suppressor cells (MDSCs), tumor associated neutrophils (TANs) and tumor-associated macrophages (TAM-1, TAM-2), signaling molecules and ECM. Malignant epithelial tumor and the surrounding microenvironment are closely related and interact constantly.

- CSCs recruit immune cells and stromal cells from neighboring tissue. CSCs interact with surrounding stromal cells via production of soluble and other mediators, through lymphatic and blood vessels to influence the tumor growth and progression.
  - Stromal cells in the tumor microenvironment play critical roles in all stages of carcinogenesis by stimulating and facilitating uncontrolled cancer cell proliferation.
  - Important inflammatory mechanisms that are corrupted by the malignant epithelial tumor include NF-κB transcription factor, immune checkpoints signaling, and inflammasome signaling.
- Fibroblasts are recruited by CSCs and activated in the local microenvironment via TGF-β, VEGF, PDGF, FGF, EGF, HGF and other signaling molecules.

- Cancer-associated fibroblasts (CAFs) synthesize TGF-β, which provide a positive feedback mechanism encouraging fibroblast activation, as well as guiding the tumor microenvironment (TME).
- CAFs also synthesize paracrine signaling molecules including IL-1, IL-8, NF-κB, IFN-γ, CTGF, CCL5, HGH and PGE_2, as well as extracellular matrix (ECM) molecules such as collagen fibers, MMPs, tenascin C, and periostin.
- Growth factors and cytokines secretion in tissue microenvironment are given in Fig. 6.123.

▪ Immune cells of myeloid and lymphoid lineage such as neutrophils, lymphocytes, macrophages, and natural killer cells respond to the malignant tumor. Both CSCs, via VEGF synthesis and CAFs, are involved in stimulating tumor angiogenesis. Newly formed blood vessels are leaky and dysfunctional, which can limit immune cells to access to the tumor. CAFs regulate the immune response in tumor microenvironment.

▪ Cancer stem cells, under the influence of CAFs signaling, can undergo EMT with downregulation of E-cadherin expression and upregulation of β-catenin and TWIST, and escape through basement membrane, extracellular matrix (ECM), and access to vasculature for dissemination to distant tissues/organs. CSCs can also metastasize to lymph nodes via lymphatic route.

▪ Immunosuppressive tumor microenvironment occurs through several mechanisms: (a) immune

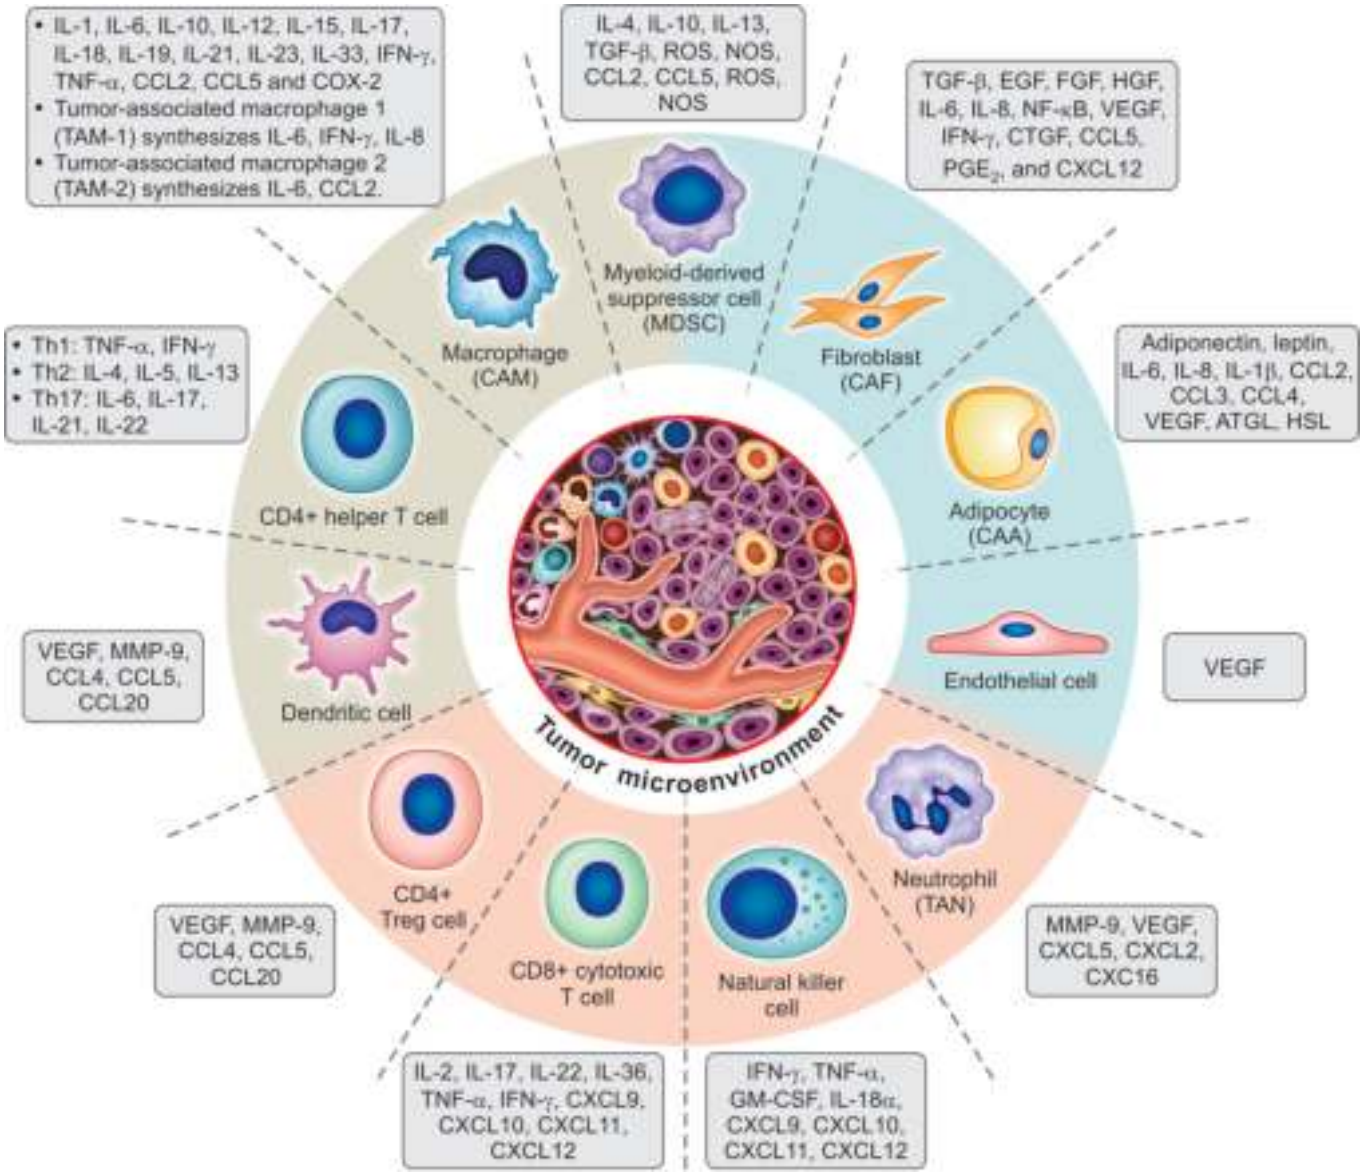

Fig. 6.123: Growth factors and cytokines secretion in tumor microenvironment. The tumor microenvironment is composed of CSCs and surrounding cells, which secrete growth factors and cytokines involved in tumor growth and survival.

checkpoint (PD-1/PD-L1, CTLA-4/B7 and LAG-3, TIM-3), (b) immunosuppressive cells (M2-polarised TAM, CD4+ regulatory T cells and MDSCs), and (c) immunosuppressive tumor microenvironment due to dense extracellular matrix (ECM).

- Molecules expression in tumor microenvironment are given in Table 6.100. Activating immune cells and immunosuppressive cells in tumor microenvironment are given in Table 6.101. Key chemokines involved in recruitment of activating immune cells and immunosuppressive cells into solid malignant epithelial tumors are given in Table 6.102.

Pathology Pearls: Immune Checkpoint Molecules in Cancers

- Immune checkpoint molecules are inhibitory regulators of the immune system, that are crucial in maintaining self-tolerance, preventing autoimmunity, and regulating the duration and extent of immune responses in order to minimize collateral tissue damage.
- Immune checkpoint molecules are expressed on cancer stem cells (CSCs), which play important roles in the maintenance of self-renewal, angiogenesis, EMT, metastasis, chemoresistance, and altered energy metabolism. Immune checkpoint mechanisms are often activated to suppress nascent immune system in cancers.
- Four stimulatory checkpoint molecules belong to tumor necrosis factor receptor superfamily, which include CD27, CD40, OX40, GITR and CD137.
- In addition, two stimulatory immune checkpoint molecules belong to B7-CD28 superfamily, which include CD28 and 40-inducible co-stimulator (ICOS).
- Programmed cell death protein 1 (**PD-1**) receptor and its programmed cell death ligand 1 (**PD-L1**) are checkpoint proteins found on the surface of T cells.

Recruitment of Activating Immune Cells in Tumor Microenvironment

Tumor microenvironment (TME) contains various immune cells: CD8+ cytotoxic T cells, natural killer cells (NK cells), dendritic cells (DCs), B cells, cancer-associated macrophages (CAMs), tumor-associated neutrophils (TANs) and delta-gamma T cells (δ-γ T cells). It is worth mentioning that tumor associated neutrophils and delta-gamma T cells (δ-γ T cells) can have both pro-tumor and anti-tumor activity.

- Activating immune cells secrete cytokines in the tumor microenvironment. Delta-gamma T cells recognize CSCs and release perforin and granzyme leading to CSC destruction.
- Signaling molecules within tumor microenvironment (TME) operate to hijack immune cells to evade CSCs destruction leading to promote CSCs survival.

Table 6.100 Molecules expression in tumor microenvironment

Upregulation of Molecules in Tumor Microenvironment
↑↑**Adenosine**
↑↑**VEGF** (angiogenesis, CSCs proliferation and stromal invasion)
↑↑**TGF-β** (angiogenesis, chemoresistance, EMT, CSCs proliferation)
↑↑**IL-4**
↑EGF (CSCs proliferation and stromal invasion, EMT)
↑FGF (angiogenesis, CSCs proliferation, EMT, chemoresistance)
↑HGF (angiogenesis, CSCs proliferation and stromal invasion, chemoresistance)
↑Hypoxia/acidosis
↑Lactate
↑IL-10
↑IL-1β
↑CXCL10
↑Integrins
Downregulation of Molecules in Tumor Microenvironment
↓IFN-γ
↓TNF-α
↓IL-12
↓Glucose
↓Amino acids
↓Oxygen

- Immunosuppressive molecules within tumor microenvironment and metabolic competition for nutrients have been shown to induce the exhaustion and inactivation of CD8+ cytotoxic T cell infiltrates, thereby limiting the durability of immune checkpoint inhibition leading to survival of CSCs.

T Cells in Tumor Microenvironment

Immune T cells are abundant in most human cancers, which constitute ≤10% of cells of tumor microenvironment within and surrounding the malignant tumor. Phenotypes of pro-tumor or anti-tumor T cells can vary with malignant tumor type and stage. CD8+ cytotoxic T cells, CD4+ helper T cells (Th1) and γ-δ T cells are usually associated with a good prognosis. FOXP3+ T cells, CD4+ helper T cells (Th2 and Th17 cells) are usually associated with poor prognosis.

B Cells in Tumor Microenvironment

Immune B cells are sometimes found at the invasive margin of some solid malignant tumors, but more often in secondary and tertiary structures adjacent to the tumor microenvironment. B cell infiltration in some solid malignant tumors is associated with good prognosis.

Table 6.101 Activating immune cells and immunosuppressive cells in tumor microenvironment

Immune Cells	Upregulation of Molecules
Activating immune cells	
CD4+ helper T cells	▪ Th1 (TNF-α, IFN-γ) ▪ Th2 (IL-4, IL-5, IL-13) ▪ Th17 (IL-6, IL-17, IL-21, IL-22)
CD8+ cytotoxic T cells	IL-2, IL-17, IL-22, IL-36, TNF-α, IFN-γ, CXCL9, CXCL10, CXCL11, CXCL12
Natural killer cells (NK cells)	IFN-γ, TNF-α, GM-CSF, IL-18α, CXCL9, CXCL10, CXCL11, CXCL12
Dendritic cells (DCs)	VEGF, MMP-9, CCL4, CCL5, CCL20
Immunosuppressive immune cells	
CD4+ regulatory T cells (Treg cells)	TGF-β, IL-10, IL-35, IL-37, CCL17, CCL22
Myeloid-derived suppressor cells (MDSCs)	IL-4, IL-10, IL-13, TGF-β, ROS, NOS, CCL2, CCL5
Tumor-associated neutrophils (TANs)	MMP-9, VEGF, CXCL5, CXCL2, CXC16
Tumor-associated macrophages (TAM-1, TAM-2)	▪ IL-1β, IL-6, IL-10, IL-12, IL-15, IL-17, IL-18, IL-19, IL-21, IL-23, IL-33, IFN-γ, TNF-α, CCL2, CCL5 and COX2 ▪ Tumor-associated macrophage 1 (TAM-1) synthesizes IL-6, IFN-γ, IL-8 ▪ Tumor-associated macrophage 2 (TAM-2) synthesizes IL-6, CCL2
Other components in tumor microenvironment	
Cancer-associated fibroblasts (CAFs)	TGF-β, EGF, FGF, HGF, IL-6, IL-8, NF-κB, VEGF, IFN-γ, CTGF, CCL5, and PGE_2, and CXCL12
Tumor-associated adipocytes	Adiponectin, leptin, IL-6, IL-8, IL-1β, CCL2, CCL3, CCL4, VEGF, ATGL, HSL (lipolysis and decreased adipose tissue mass)
Extracellular matrix (ECM)	Matrix metalloproteinases (MMPs)
Vascular endothelial cell	Vascular endothelial growth factor (VEGF)

Immunosurveillance evasion, tumor growth, angiogenesis, invasion, and metastasis.

Table 6.102 Key chemokines involved in recruitment of activating immune cells and immunosuppressive cells into solid malignant epithelial tumors

Cells	Cell Surface Receptors	Chemokines Secretion
Activating immune cells		
CD8+ cytotoxic T cell	CCR3	CXCL12
	CCR4	CXCL9, CXCL10, CXCL11
Natural killer cell (NK cell)	CCR3	CXCL12
	CCR4	CXCL9, CXCL10, CXCL11
Dendritic cell (DCs)	CCR5	CCL4, CCL5, CCL20
	CCR6	CCL20
Immunosuppressive cells		
CD4+ regulatory T cells (Tregs)	CCR4	CCL17, CCL22
Myeloid-derived suppressor cells (MDSCs)	CCR2	CCL2
	CCR5	CCL5
Cancer-associated macrophages (CAMs)	CCR2	CCL2
	CCR5	CCL5
Tumor-associated neutrophils (TANs)	CCR1	CXCL2, CXCL5, CXCL6
	CCR2	CXCL2, CXCL5, CXCL6

Natural Killer Cells in Tumor Microenvironment

Natural killer cells (NK cells) are innate cytotoxic, large granular lymphocytes found outside region of malignant tumor. Unlike lymphocytes, natural killer cells lack antigen-specific receptors. Presence of natural killer cells in tumor microenvironment is associated with good prognosis in some human cancers.

Dendritic Cells in Tumor Microenvironment

Dendritic cells (DCs) are professional antigen-presenting cells (APCs), uniquely able to induce naïve T cells activation, and effector differentiation. Dendritic cells are involved in linking of innate and adaptive immune systems leading to induction of protective immune responses. Dendritic cells stimulate immune response against tumor-associated antigens in the tumor microenvironment.

Recruitment of Immunosuppressive Cells in Tumor Microenvironment

Tumor microenvironment contains many immunosuppressive cells such as cancer-associated fibroblasts (CAFs), myeloid-derived suppressor cells (MDSCs), tumor-associated neutrophils (TANs: N1 and N2), which evade CSCs destruction by immune system.

- Signaling within the tumor microenvironment (TME) operates to hijack immune cells to promote CSCs survival. Immune cells within the TME secrete various cytokines, that allow growth and metastasis, rather than recognizing and destroying the cancer stem cells (CSCs).
- Important inflammatory mechanisms, that are corrupted by the tumor microenvironment include: NF-κB transcription factor, immune checkpoints signaling, and inflammasome signaling. The inflammasome promotes the cleavage of capase 1 and subsequent cleavage of proinflammatory cytokines IL-1β and IL-18.

Myeloid-derived Suppressor Cells (MDSCs) in Tumor Microenvironment

Myeloid-derived suppressor cells (MDSCs) are heterogenous population of immature myeloid progenitor cells, which fail to differentiate into granulocytes, macrophages, and dendritic cells.

- Immunosuppression is the main functional feature of MDSCs, which inhibit T cell activity in the tumor microenvironment (TME) and promote tumoral immune escape. In the context of malignant epithelial tumors, MDSCs are abnormally produced and recruited to assist in the establishment of an immunosuppressive TME that facilitates CSCs escape. Additionally, MDSCs contribute to non-immunologic aspects of tumor biology, including angiogenesis, invasion, metastasis, and chemoresistance.
- MDSCs are capable to deplete amino acids required for T cell activation and proliferation. A high level of arginase 1 (**ARG1**) expression by MDSCs depletes L-arginine leading to downregulation of the CD3 ζ-chain of the TCR complex, and proliferative arrest of T cells.
- MDSCs synthesize excess IL-10 and TGF-β, which stimulate CD4+ regulatory T cells (Treg) cells. Presence of CD4+ regulatory T cells (Treg cells) in tumor microenvironment (TME) suppresses the immune system by inhibiting functions of CD8+ cytotoxic T cell, and natural killer cells (NK cells), thus paving the way for oncogenesis. MDSCs inhibit CD8+ cytotoxic T cells, and polarize tumor associated macrophages (TAMs) to be a tumor promoting phenotype.

Tumor-associated Neutrophils in Tumor Microenvironment

Neutrophils originating from bone marrow are recruited in the tumor microenvironment by cytokines and chemokines. Tumor associated neutrophils (TANs) are categorized into N1-TANs (anti-tumor activity) and N2-TANs (immunosuppression and tumor progression).

- In cancer patients, either a high number of TANs and neutrophil-to-lymphocyte ratio (NLR) are associated with poor prognosis. TANs count and NLR can be regarded as biomarkers.
  - TANs are exposed to hypoxia as well as stroma cell signals, which can trigger the formation of neutrophil extracellular traps (NETs).
  - NET-associated proteases alter the extracellular matrix (ECM) and NET-derived HMGB1 molecules activate CSCs to jointly promote angiogenesis, unrestricted cancer stem cell proliferation, migration, invasion, and metastasis to distant tissues/organs.
- Owing to the pivotal role of TANs in stimulating angiogenesis, and tumor progression; therapeutic strategies to target TANs have been proposed: (a) targeting the CXCL8/CXCR-1/CXCR-2 axis, which block TANs, and (b) targeting substances synthesized by polymorphonuclear cells, which promote tumor growth. Clinical trials are restrained due to risk of induction of immunosuppression. Ongoing clinical trials aimed to inhibit neutrophil recruitment into the tumor microenvironment are also accurately debated.

Tumor-associated Macrophages in Tumor Microenvironment

Tumor-associated macrophages (TAMs—M1 and M2) are derived from bone marrow stromal cells, that promote tumor development, angiogenesis via vascular endothelial growth factor (VEGF), fibrous stroma deposition, invasion, and metastasis to distant organ(s). TAMs synthesize TGF-β that negatively regulates effector T cells function, and induces CD4+ regulatory T (Treg) cells differentiation, and maintenance.

Defective Terminally-differentiated Myeloid Dendritic Cells in Tumor Microenvironment

Terminally-differentiated myeloid dendritic cells might be defective in the tumor microenvironment, which cannot adequately stimulate an immune response to tumor-associated antigens.

Recruitment of Nonmalignant Stromal Cells in Tumor Microenvironment

Cancer stem cells recruit nonmalignant stromal cells from neighboring tissue in tumor microenvironment. Stromal cells and CSCs are in dynamic relationship promoting the malignant tumor progression. As CSCs enter different locations, they encounter distinct stromal microenvironments in the primary tumor site, locally invasive tumor phenotype, and disseminated tumor phenotype in distant tissues/organs.

- Tumor microenvironment contains another stromal cell component, which is composed of cancer-associated fibroblasts (CAFs), cancer-associated adipocytes (CAAs), and cancer-associated angiogenic vascular and lymphatic endothelial cells. There is downregulation of perivascular stromal cells (i.e. pericytes).
- Tumor microenvironment orchestrates angiogenesis, unrestricted cell cancer stem proliferation, clonal expansion, invasion, and metastasis through the secretion of growth factors, and cytokines, resistance to radiation and chemotherapy and recurrence.

Cancer-associated Fibroblasts in Tumor Microenvironment

Cancer-associated fibroblasts (CAFs) are found in many human cancers especially at the margins. CAFs are recruited by CSCs within tumor microenvironment.

- CAFs secrete tumor-promoting growth factors (TGF-β, PDGF, HGF EGF, FGF, HGF, VEGF), chemokines (CCL5, CXCL12), cytokines (IL-6, IL-8), extracellular-matrix (ECM) components and ECM remodeling enzymes.
- CAFs regulate immune response in the tumor microenvironment. Cancer stem cells via vascular endothelial growth factor (VEGF), and CAFs are involved in stimulating angiogenesis within tumor microenvironment.
- CAFs can also have important immunosuppressive activity by secreting 'fibroblast activating protein-α' (**FAP-α**) protein that restricts T cells to the stroma and prevents them from accumulating in the vicinity of CSCs by two mechanisms: (a) production of dense extracellular matrix (ECM) traps T cells in the stroma access to CSCs, and (b) cancer-associated fibroblasts secrete C-X-C motif chemokine 12 (CXCL12), that alters the behavior of cancer cells and helps in progression of tumor.
- CAFs have been demonstrated to enhance malignant tumor phenotype, notably unrestricted CSC proliferation, epithelial mesenchymal transition (EMT), angiogenesis, invasion, and metastasis to distant tissues/organs.

Cancer-associated Adipocytes in Tumor Microenvironment

In some malignant tumors, adipocytes derived from mesenchymal stem cells from bone marrow play pivotal role in recruitment of CSCs through the secretion of adipokines. They also promote malignant epithelial tumor cell growth by providing fatty acids as fuel for CSCs.

Cancer-associated Vascular Endothelial Cells in Tumor Microenvironment

Proangiogenic factors produced by CSCs, myeloid cells or cancer-associated fibroblasts in the tumor microenvironment stimulate sprouting of tumor associated vascular endothelial cells. The new vessels have chaotic branching and uneven vessel lumina. Newly formed blood vessels are also leaky, raising interstitial pressure and uneven blood flow, oxygenation, nutrients, and chemotherapeutic agent delivery in tumor microenvironment.

Cancer-associated Lymphatic Endothelial Cells

Cancer stem cells (CSCs) can invade existing lymphatics or stimulate lymphatic vessel sprouting with the production of factors such as VEGFC or VEGFD. Lymphatic vessels are important in dissemination of CSCs, but might also promote malignant epithelial tumor development by mechanomodulation of the tumor microenvironment, and altering the host immune response to the tumor.

Cancer-associated Perivascular Stromal Cells

Perivascular stromal cells and pericytes provide structural support to blood vessels. Tumor microenvironment demonstrates low pericyte coverage of blood vessels, which correlate with poor prognosis, and increased metastasis.

Extracellular Matrix in Tumor Microenvironment

Extracellular matrix (ECM) provides critical signals to preserve tissue architecture, polarity, and homeostasis, and regulates cell growth and apoptosis.

- The normal tissue ECM comprises a network of biochemically distinct components, including water, minerals glycoproteins, proteoglycans, polysaccharides, and fibrous proteins, such as collagen, elastin and laminin secreted by the resident cells.
- ECM is the major component of the tumor microenvironment, which interacts with the CSCs, immune cells, stromal cells, and cells of myeloid and lymphoid lineage cells. During malignant epithelial tumor progression, alterations in CSCs and ECM interactions drive angiogenesis invasion, metastasis, and treatment resistance.

Versican in Extracellular Matrix

Versican is an extracellular matrix (ECM) proteoglycan present in most tissues. Versican encoded by VCAN gene interacts with cells by binding to non-integrin receptors and other ECM components to influence the ability of CSCs to proliferate, migrate, adhere, and assemble. Versican present in ECM activates EGFR signaling, which leads to CSCs invasion and metastasis.

Chondroitin Sulfate Proteoglycan 4 in Extracellular Matrix

Chondroitin sulfate proteoglycan 4 (CSPG4) present in ECM stabilizes the interactions between cells in the ECM. CSPG4 interacts with the integrin-αβ upon collagen type VI binding to activate phosphatidylinositol 3-kinase (PI3K)/AKT/mTOR signaling pathway in sarcoma cells. CSPG4 also forms complexes with MMP2 and MMP3 on the surface of melanoma cells to facilitate MMP2 activation, and eventual degradation of the ECM.

Lumican in Extracellular Matrix

Lumican present in ECM organizes fibril organization and growth. Lumican plays key role in corneal transparency, epithelial cell migration and tissue repair. Lumican plays a major role in proliferation, migration, and invasion of breast CSCs. Lumican also modifies cellular junction and promotes mesenchymal–epithelial transition (MET) through direct interactions with other ECM molecules or by the modification of membrane receptors and MMP14.

Glypicans in Extracellular Matrix

Glypicans are proteoglycans that play major role in the developmental morphogenesis. Depending on the context, glypicans may have stimulatory or inhibitory activity on Wnt-β, Hedgehog and FGF signalizing pathways.

- Decreased glypican 3 expression is linked to CSCs invasion and metastasis. Complete loss of glypican 3 is associated with overall poor prognosis. However, elevated expression of glypican 3 is linked to reduced CSC differentiation, and lymph node metastasis in lung carcinoma.
- Glypican 5 overexpression promotes tumor invasion and metastasis in salivary adenoid cystic carcinoma and in rhabdomyosarcoma.

Hyaluronic Acid in Extracellular Matrix

Hyaluronic acid is a glycosaminoglycan present in moist skin, connective tissue, and eyes. Hyaluronic acid retains water in the tissues. It is a principal constituent of the tumor microenvironment stroma and CSC surfaces. Metastatic cancers express increased levels of hyaluronic acid, its receptor, and its synthase in the tumor microenvironment, especially in cancers of breast, prostate, ovarian and oral cancers.

- Hyaluronic acid plays major role in EMT driven by the expression of zinc finger E-box-binding homeobox 1 (ZEB1), and its interaction with CD44, which in turn activates hyaluronic acid synthase 2 (HAS2) expression. HAS2 expression regulates TGF-β induced EMT through the expression of fibronectin, SNAIL1 and ZEB1.
- Hyaluronic acid synthase 2 (HAS2) is essential for interaction between CSCs and tumor-associated macrophages (TAMs). This interaction results in enhanced synthesis of PDGF-BB by tumor-associated macrophages (TAMs), which activates stromal cells and rejuvenates CSCs. Inhibiting HAS2 activity via 4-methylumbelliferone limits hyaluronic acid synthesis and prevents tumor metastasis. The striking effect of hyaluronic acid on tumor progression is highly linked with its low-molecular weight, and interactions with other proteins in the ECM.
- Low-molecular weight of hyaluronic acid has well-established tumorigenic properties. In breast carcinoma, decreased hyaluronic acid synthesis significantly inhibits CSCs migration and invasion.
- Moreover, excess hyaluronic acid in the tumor microenvironment facilitates lymphatic metastasis via disruption of intercellular adhesion among lymphatic endothelial cells.
- In addition, excess hyaluronic acid in the interstitial fluid of colorectal carcinoma patients is associated with lymphatic vessel invasion by CSCs and the development of lymph node metastasis. Although, extracellular matrix (ECM) is a complex and dynamic system, that is composed of a wide spectrum of cells and matrikines that participate in invasion and metastasis.

METASTASIS MULTI-STEP PROCESS

Cancer metastasis is the major cause of cancer-related morbidity and mortality. Metastasis is multi-step process in which CSCs from primary malignant epithelial tumor invade basement membrane, and surrounding tissue, intravasate into lymphatics and blood vessels, transport, survive in the circulation, and arrest on vascular endothelium, extravasate, arrest in the capillaries and colonize and subsequent undergo proliferation, angiogenesis, micrometastasis and macrometastasis in favorable secondary sites/organs. Sequence of events of metastatic cascade is given in Table 6.103. (Kindly refer to tumor invasion and metastasis are shown in Figs 6.53 and 6.81 in this chapter).

Malignant Epithelial Tumor Development at Primary Site

Normal cells are transformed to CSCs, which have same genetic abnormalities in key genes coding for aberrant proteins (e.g. growth factors, growth factor receptors, signal transduction proteins, transcription factor and DNA repair system).

- Carcinoma arising from epithelial tissue usually goes through several stages of development: atypical hyperplasia, carcinoma *in situ*, and then invasive carcinoma, which might further metastasize via lymphatic and hematogenous routes to distant tissues/organs.
- Malignant epithelial tumor results from alterations in the expression of multiple somatic oncogene activation and/or inactivation/biallelic loss of tumor suppressor gene involved in cell adhesion, cell survival through growth factors, proangiogenic factors (angiogenesis), and microRNAs.
- Tumor angiogenesis is the process of developing new dysfunctional and leaky blood vessels from pre-existing blood vessels that has a key role in increase malignant epithelial tumor growth, invasiveness, and metastasis.
- Epithelial–mesenchymal transition (EMT) involves the disruption of cell-to-cell adhesion (down-regulation of E-cadherin), apical–basal cell polarity, remodeling of the cytoskeleton and changes in cell-to-extracellular matrix adhesion associated with mesenchymal phenotype, enhanced motility, and invasive properties of CSCs in primary malignant epithelial tumor.
  - Notably, both epithelial–mesenchymal transition (EMT) and mesenchymal–epithelial transition (MET) are required for the process of invasion and metastasis.

Table 6.103 Sequence of events of metastatic cascade

▪ Primary epithelial malignant tumor (carcinoma development and acquisition of invasive potential) • ↑Tumor metastatic signature genes (e.g. EZRIN, SNAIL and TWIST genes) • ↓Metastatic suppressor genes (e.g. NM23, KAI-1, KiSS and NM23) • MicroRNA-10b dysregulation
▪ Expansive malignant epithelial tumor growth, angiogenesis, erosion of tissue boundaries (basement membrane and ECM) and invasion in surrounding tissue • Downregulation of E-cadherin • Loss of cell-cell interaction • Anchorage-independent autonomous cell growth • Protection against apoptosis • Dynamic actin rearrangement • Epithelial–mesenchymal transition (EMT)—loss of apicobasal polarity, stem cell properties, therapeutic resistance • Basement membrane disruption • ECM degradation (MMPs activity, TIMPs loss and integrin downregulation), and migration • Detachment and CSCs (ECM) and access of CSCs to microvasculature
▪ Intravasation of CSCs (MMPs activity), transport through circulation, interaction with platelets, immune cells, and other cells, avoid immune destruction (downregulation/loss of MHC class I antigen, and shedding of ICAM-1 blocks T cell receptor), arrest on endothelium in microvasculature of various organs
▪ Extravasation of CSCs (regulated by MMPs, integrin and laminin receptor), invasion into tissue microenvironment and metastatic dormancy
▪ After extravasation of CSCs, mesenchymal–epithelial transition (MET) is the reverse process of EMT and involved in colonization of CSCs in distant organs
▪ Colonization of CSCs in favorable secondary organs, interaction, and adaptation to tissue microenvironment
▪ Formation of micrometastasis, angiogenesis and macrometastasis in favorable secondary organs

- While EMT mobilizes CSCs in the primary malignant epithelial tumor. MET terminates the migration process and thereby resulting in the distal colonizing of CSCs.

- Cancer stem cells (CSCs) must acquire certain characteristics for cell migration to occur, such as polarity and dissociation from their point of origin. There can be individual or collective CSC invasion.
- Malignant epithelial tumor has clones with different genetic make-up. Some subclones possess ability to metastasize, while other subclones undergo unrestricted proliferation forming poorly-differentiated malignant epithelial tumor.
- The goal of the chemotherapy is to destroy CSCs in the malignant epithelial tumor. CSCs may develop resistance to chemotherapy. Only resistant CSCs survive after chemotherapy. CSCs in recurrent malignant tumor remain resistant to chemotherapy.

Priming of Premetastatic Niche

Primary malignant epithelial tumor primes the tumor microenvironment, termed the premetastatic niche (PMN) before the initiation of metastasis. Development of PMN is a multistep process involving secretory products and membrane bound extracellular vesicles (exosomes), that induce vascular leakage, extracellular matrix (ECM) remodeling and immunosuppression.

- Moreover, exosomes synthesize EMT inducers that stimulate EMT progression in host epithelial cells, providing them the ability to invade and metastasize to distant organs. Exosome-altered ECM along with chemokines, and growth factors results in the formation of a new host microenvironment for CSCs, immune cells and other stromal constituents that is referred to as the priming PMN, where metastatic cancer stem cells may arrest, extravasate and ultimately colonize in secondary organs.
- Microbiomes selectively targets tumors that have rich vascular networks and chemotactic magnetism, which can cause immunosuppression, cancer progression and resistance to treatment.
- In addition to the PMN, exosomes enhance CSCs metastasis to specific target organs, a process known as 'metastatic organotropism'. This metastatic prejudice towards specific organs occurs due to exosomal proteomic avidity for specific CSCs. For example, bone malignant tumor demonstrates different exosomal integrin patterns. Exosomal integrins are linked to metastasis, i.e. α6-β4, α-β1 (lung metastasis) and avβ5 integrin (liver metastasis).
- Possible synapses in CSCs and neural-related factors, such as neurotrophic factors, neuropilins, axonal guidance molecules, neurotransmitters and their receptors make, it possible to establish direct connections between the nervous system, and primary malignant epithelial tumor. Perineural invasion offers another pathway for CSCs dissemination and colonization in distant organs.

Expansile Primary Malignant Epithelial Tumor Growth, Detachment and Migration of Cancer Stem Cells

As the malignant epithelial tumor grows, it exerts mechanical pressure on the surrounding cells and tissues, which eventually undergo cell death due to blockage of blood supply to tumor.

- Loss of mechanical resistance opens the way for the CSCs to spread along the lines of least resistance and occupy the space once filled with dead cells.
- CSCs detach from primary malignant epithelial tumor (carcinoma) due to loss of diverse epithelial proteins such as E-cadherin and α- and β-catenin, claudin, occludin, cytokeratins; diminished number of cell junctions; and other alterations in surface membrane structures and gain of mesenchymal proteins such as vimentin, fibronectin, matrix metalloproteinases, actin and integrins, become motile, undergo a shape change to acquire a polarized phenotype, migrate, and invade through degradation of basement membrane, interstitial tissue, and then extracellular matrix (ECM) by matrix metalloproteinases (MMPs) synthesized by CSCs and stromal cells.

Acquisition of Invasive Potential of Detached Cancer Stem Cells Through Basement Membrane and Extracellular Matrix

Expansile malignant tumor growth and acquisition of invasive potential of CSCs is regulated by metastatic signature genes (e.g. EZRIN, SNAIL and TWIST genes including microRNA-10b) and metastatic tumor suppressor genes (e.g. NM23, KAI-1, KiSS and NM23).

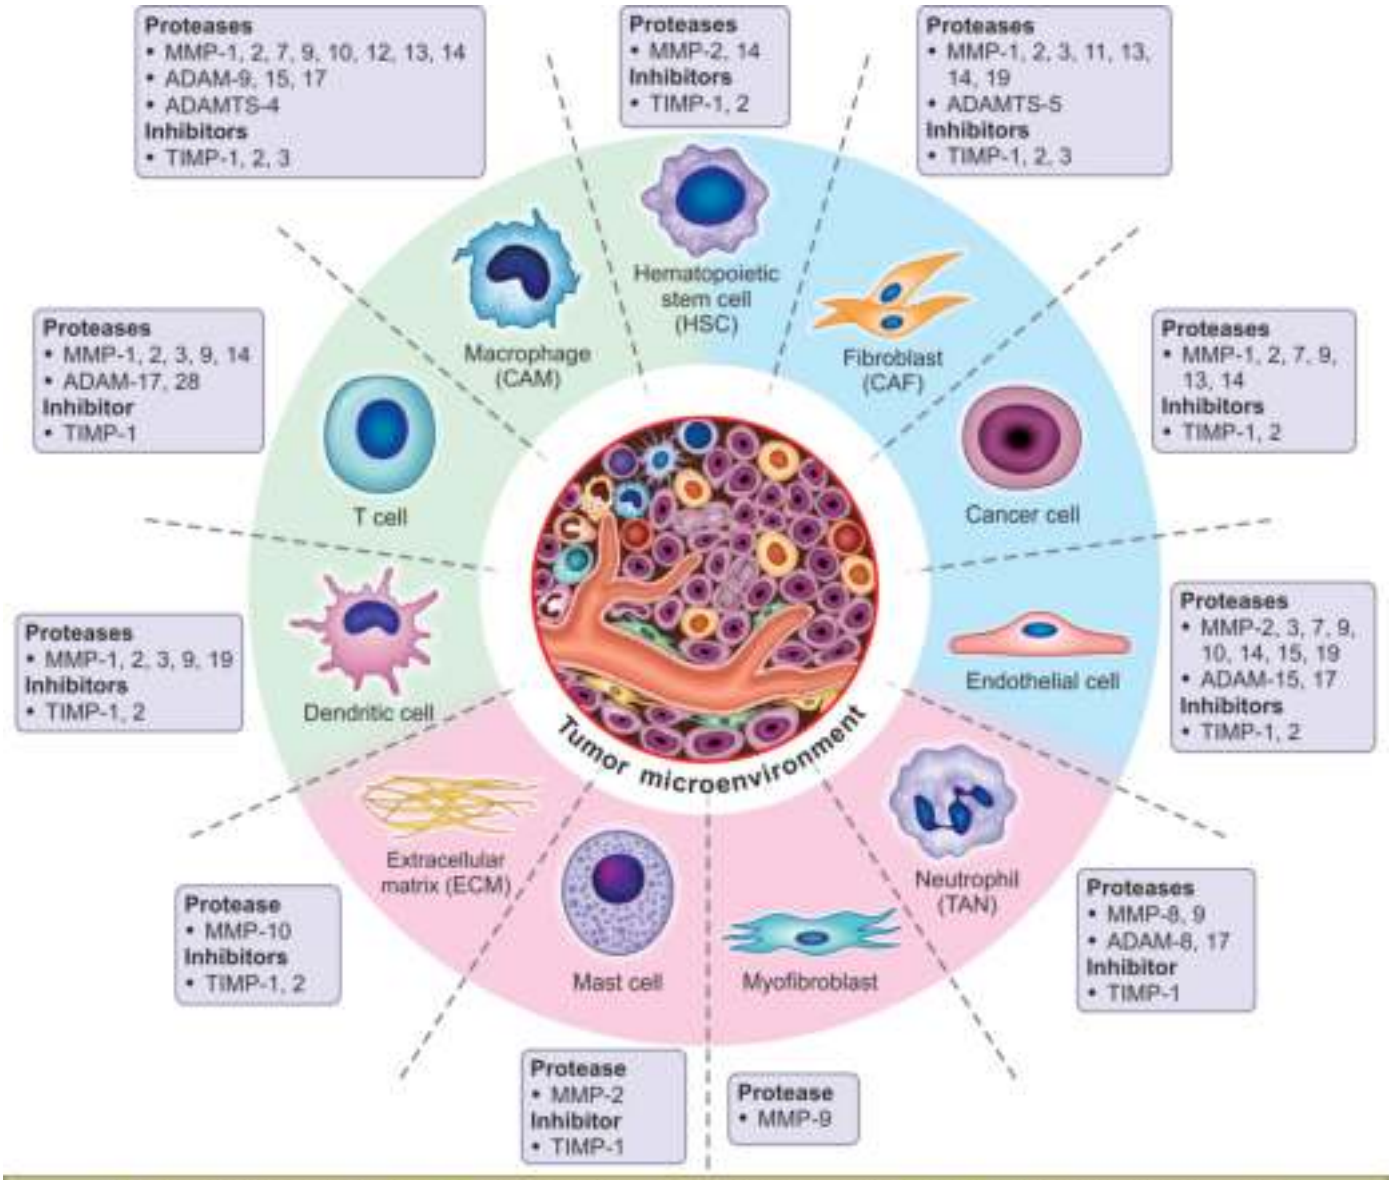
- CSCs possess receptors for laminin, a complex glycoprotein in the basement membrane. Laminin binding to receptors on CSCs permit the CSCs to attach to the basement membrane forming a bridge-like connection.
- Extracellular matrix (ECM) degradation is essential for migration of CSCs detached from primary malignant epithelial tumors. ECM degradation is carried by families of proteases: matrix metalloproteinases (MMP-2 and MMP-9), cathepsin-D and urokinase plasminogen activator. MMP-9 plays most important function in metastatic cascade. MMP-9 induces angiogenesis through VEGF. MMP-9 also acts as gelatinase, that helps in degradation of collagen type IV of epithelial and vascular basement membrane.

- Invading CSCs and surrounding stromal cells in tumor microenvironment synthesize powerful proteolytic matrix metalloproteinases (MMPs) enzymes (e.g. **collagenases** and **proteases**), urokinase-type plasminogen activator (u-PA), elastase, cathepsins. These molecules cause breakdown of collagenous and noncollagenous components of extracellular matrix (ECM). Matrix metalloproteinases (type IV collagenases) cleave (dissolve) basement membrane collagen type IV fibers.
- Plasminogen activator activates elastase and cathepsins, which cleave noncollagenous matrix of basement membrane matrix. Plasminogen activator converts serum plasminogen to plasmin, a serine protease, that degrades laminin. Plasminogen activator also stimulates CSCs to synthesize collagenases in abundance (autocrine action).
- The principal biologic function of MMPs is to degrade ECM proteins and glycoproteins, membrane receptors, growth factors and cytokines. MMPs are strictly regulated by endogenous tissue inhibitor matrix metalloproteinases (TIMPs).
- Localization and interactions between matrix metalloproteinases (MMPs) and tissue inhibitor matrix metalloproteinases (TIMPs) in the tumor microenvironment are shown in Fig. 6.124. Family of matrix metalloproteinases (MMPs) is given in Table 6.104.
- Following extracellular matrix (ECM) breakdown, CSCs become motile and migrate along blood vessels and undergo proliferation to form progeny cells. CSCs are ready to invade lymphatics or vascular channels (capillaries and venules).
- ECM is a macromolecules network, composed of many components: (a) fibers (i.e. collagen, elastin, laminin, and fibronectin), (b) proteoglycans (syndecan 1 and aggrecan), (c) glycoproteins (tenascin, vitronectin and entactin), and (d) polysaccharides (hyaluronic acid), that regulates cell migration, cell growth and differentiation. ECM provides structural and biochemical support. Chondroitin sulphate proteoglycan 4 (CSPG4) present in ECM plays an integral role in stabilizing the interactions between cells in the ECM.
- One important step in tumor invasion is the disassembly of the ECM and its constituents through MMPs.
  - Disassembly of ECM plays a major role in unrestricted CSC proliferation, survival, and angiogenesis, in addition to invasion.
  - **Versican** present in interstitial ECM promotes CSC growth and invasion.
  - **Lumican** in ECM attenuates the CSC proliferation, migration, and invasion of CSCs of breast carcinoma.
  - Glypican 3 in ECM exhibits a tumor suppressor phenotype.
  - Downregulation/loss of **glypican 3** is associated with poor prognosis in cancer patients. **Serglycin** is an intracellular proteoglycan expressed in hematopoietic cells.
  - Serglycin induces EMT, CSCs growth, invasion, metastasis and chemoresistance.
- Autophagy is a highly regulated process through which cells recycle their own constituents by delivering them into lysosomes. In cancer, autophagy has paradoxical roles, acting both as tumor suppressor in early stage and as tumor promoter in more advanced stage (CSC motility, viability, and invasion). Autophagy may exert different functions in response to cancer therapy, causing malignant tumors resistance or increasing sensitivity to chemotherapeutic drugs and radiation.

Resistance to Anoikis of Cancer Stem Cells (CSCs)

Anoikis (Greek word: homelessness) is the name given to induction of apoptosis (programmed cell death) in anchorage-dependent epithelial cells, upon disruption in cell-cell attachment or cell–extracellular matrix (ECM) attachment, due to disruption of integrin ligation. Anoikis is important for maintaining tissue homeostasis.

- Anoikis inhibits detached CSCs from dissemination and colonization in distant tissues/organ(s). Anoikis can engage both extrinsic as well as the intrinsic pathway of apoptosis.
- Resistance to anoikis is an attribute of CSCs with metastatic potential. Numerous studies have revealed that stimulation of pro-survival signals (PI3K/AKT/mTOR, RAS/RAF/MEK/ERK/MAPK and Rho-GTPase), and suppression of death signals including growth factor proteins, cellular acidosis, oxidative stress in CSCs is involved in 'anoikis' resistance, thus enhancing CSC proliferation, invasiveness, and metastasis. This can be achieved through autocrine signaling of growth factors such as fibroblast growth factor (FGF), hepatocyte growth factor (HGF) and platelet-derived growth factor (PDGF).
  - In addition, overexpression of growth factor receptors such as EGF receptor, TrkB receptor and HGF receptor can suppress anoikis.
  - Similarly, the expression of long noncoding RNA (incRNA) has been linked to anoikis resistance.
- Currently, **anoikis resistance** becomes a hot topic in cancer research. Detailed molecular and functional analyses of 'anoikis' resistant CSCs may provide insight into biology of cancer metastasis and identify novel therapeutic targets for prevention of cancer dissemination to distant organs.



Matrix metalloproteinases (MMPs) and tissue inhibitor metalloproteinases (TIMPs) in tumor microenvironment		
Tissue inhibitor metalloproteinases	*Localization*	*MMPs degradation by TIMPs*
TIMP-1	Soluble and cell surface	• MMP-1, MMP-2, MMP-3, MMP-7, MMP-8, MMP-9 • ADAM-10
TIMP-2	Soluble and cell surface	• MMP-2, MMP-9, MMP-14, MT1-MMP • ADAM-12
TIMP-3	Extracellular matrix and cell surface	• MMP-2, MMP-9 • ADAM-17, ADAM-10 • ADAMPTS4
TIMP-4	Soluble and cell surface	• MMP-1, MMP-2, MMP-26 • MT1-MMP • ADAM-28

- Metalloproteinases (MMPs) are zinc-dependent proteolytic enzymes that degrade both extracellular matrix (ECM) and non-matrix proteins. MMPs play key roles in morphogenesis, wound healing, tissue repair and remodeling in response to injury and progression of cancer.
- Tissue inhibitors of metalloproteinases (TIMPs) play key role in the homeostasis of extracellular matrix (ECM) by regulating the activity of metalloproteinases (MMPs). TIMPs are well-known for their ability to inhibit metalloproteinase activity thereby inhibiting tumor growth and metastasis.

Fig. 6.124: Localization and interactions between matrix metalloproteinases (MMPs) and tissue inhibitor metalloproteinases (TIMPs) in the tumor microenvironment. MMPs degrade both extracellular matrix (ECM) and non-matrix proteins and play key role in malignant tumor invasion and metastasis. TIMPs inhibit MMPs activity thereby inhibiting tumor growth and metastasis.

Table 6.104 Family of matrix metalloproteinases (MMPs)

MMP	Name of MMP	Substrate Cleaved (Degraded) by MMP	
Collagenases family			
MMP1	Collagenase 1	▪ Collagen fiber types I, II, III, VII and X	▪ HIV Tat protein
MMP8	Collagenase 2	Collagen fiber types I, II, III	
MMP13	Collagenase 3	▪ Collagen fiber types I, II, III, IV, XIV, X	▪ Soluble type II
Stromelysins family			
MMP3	Stromelysin 1	▪ Fibronectin ▪ Laminin ▪ Gelatin types I, II, III, IV	▪ Aggrecan ▪ Collagen types III, IV, X and IX ▪ Activates procollagenase
MMP10	Stromelysin 2	▪ Fibronectin	▪ Gelatin types I, II, III, IV and V
MMP11	Stromelysin type 3	▪ Weakly structures of extracellular matrix	▪ α_1-Proteinase inhibitor
MMP21	Stromelysin type 3	▪ α_1-Anti-trypsin inhibitor	▪ Specific functions in embryogenesis
MMP28	Stromelysin type 3	▪ Casein	▪ Structural proteins of extracellular matrix
MMP19	Stromelysin type 3	▪ Broad range of substrates close to MMP11 and MMP7	
Gelatinases family			
MMP2	Gelatinase A	▪ Gelatin type I ▪ Collagen fiber types IV, V, VII and X	▪ Collagen-like sequence
MMP9	Gelatinase B	▪ Gelatin types I and V ▪ Collagen fiber types IV and V	▪ Fibronectin
Other metalloproteinases (MMPs) family			
MMP12	Not specified	▪ Soluble and insoluble elastin	▪ β-Chain of insulin
MMP20	Not specified	▪ Amelogenin ▪ Aggrecan	▪ Cartilage oligomeric matrix protein (COMP)
MMP27	Not specified	▪ Fibronectin ▪ Laminin	▪ Gelatins ▪ Collagen fibers
Matrilysins family			
MMP 7	Matrilysin 1	▪ Casein ▪ Gelatin types I, III, IV and V ▪ Fibronectin	▪ Activates procollagenase ▪ Specific sequence of β-chain of insulin
MMP 26	Matrilysin 2	▪ Collagen type IV ▪ Fibronectin ▪ Fibrinogen ▪ β-Casein	▪ Gelatin type I ▪ α_1-Proteinase inhibitor ▪ Activates progelatinase B
MT-MMP GPI family			
MMP17	MT4-MMP	▪ Fibrinogen and fibrin ▪ Collagen type I ▪ Gelatin type I ▪ Fibronectin	▪ Laminin ▪ Tenascin ▪ Cartilage oligomeric matrix protein (COMP) ▪ α_2-Microglobulin
MMP25	MT6-MMP	▪ Vimentin	▪ α_1-Proteinase inhibitor
MT-MMP transmembrane type I family			
MMP14	MT1-MMP	▪ Aggrecan ▪ Collage fibers	▪ Activates MMP2 and MMP13
MMP15	MT2-MMP	▪ Broad range of substrates	

Contd...

Table 6.104 Family of matrix metalloproteinases (MMPs) (*Contd...*)

MMP	Name of MMP	Substrate Cleaved (Degraded) by MMP	
MMP16	MT3-MMP	▪ Collagen type 3 ▪ Fibronectin	▪ Activates MMP2
MMP24	MT4-MMP	▪ N-cadherin (CDH2) ▪ Fibronectin partially	▪ Activates MMP2
MT-MMP transmembrane type II family			
MMP23A and MMP23B	Not specified	Regulates the surface expression of some potassium channels	

- Therefore, it is essential to understand molecular and cellular mechanisms underlying anoikis and 'anoikis resistance' in relation to intrinsic and extrinsic death signaling, EMT, growth factors, energy metabolism, acidic environment, reactive oxygen species, oxidative stress, microRNA modulation, membrane microdomains, and lipid domains of plasma membrane.

Cancer Stem Cells Motility

Cancer stem cells (CSCs) secrete chemokines, that stimulate development of finger-like projections (invadopodia) on CSCs involved in motility of CSCs to overcome the dense scaffold of local tissue environment by degradation of extracellular matrix (ECM).

- **Invadopodia:** Invadopodia are actin rich membrane protrusion that facilitates CSCs dissemination on proteolytic activity and clearing paths for migration through physical barriers, such as basement membrane, ECM and endothelial cells.
  - Actin regulatory proteins such as N-WASP, cortactin, and ARP2/ARP3 assist in invadopodia formation. TKS5 regulatory protein plays a key role in invadopodia and maturation of invadopodia because of the delivery of proteins, such as integrins and MT1-MMP.
  - Polarity of CSCs has a leading front and rear regions, which depends on a distinct actin cytoskeleton and generation of various cell junctions.
- **Lamellipodia:** Lamellipodia are flat, sheet-like membrane protrusions formed at the leading edge of migrating CSCs. Lamellipodia contain dendritic arrays of filaments and molecular machinery, that regulates polymerization/depolymerization and organization of actin filaments.

Intravasation, Transport in Circulation and Arrest of Cancer Stem Cells on Vascular Endothelium

Vascular endothelium poses a barrier to CSC intravasation. CSC invasion and transendothelial transmigration is the first step of metastasis to distant tissues/organs.

- Intravasation is the key step in cancer metastasis during which the CSCs invade wall of lymphatic vessel or blood vessel and the lumen of vasculature, thereby becoming circulating CSCs and becoming potential metastatic seeds in distant organs after extravasation to the host tissue environment.
- Intravasation of CSCs depends on the malignant epithelial tumor type, mitosis, tumor microenvironment, microvessel density (MVD) and diameter of vasculature. TGF-β signaling can enhance intravasation of CSCs in part through induction of EMT. In addition to TGF-β signaling, numerous studies demonstrated that activation of EGF receptor family members stimulate intravasation, with downstream signaling through PI3K/AKT/mTOR, N-WASP, RhoA and WASP pathways to induce invadopodia.
- With respect to proteases, there is strong evidence for contributions by urokinase-type plasminogen activator (u-PA)/urokinase-type plasminogen activator receptor (u-PAR), while the roles of matrix metalloproteinases (MMPs) in intravasation may be more tumor specific. Other cells such as macrophages, fibroblasts, neutrophils, and platelets can also play a role in enhancing intravasation of CSCs.
- Furthermore, the architectural constraints of tissue impose some mechanical pressures on invading CSCs during intravasation. Nuclear squeezing of the invading CSC causes genomic rearrangement, which increases the metastatic potential.
- Integrins are the key cell adhesion molecules involved in nearly every step of malignant epithelial tumor progression from primary tumor development to metastasis to distant tissues/organs. Altered integrin expression is most often detected in human cancers.
- A clear understanding of intravasation may provide opportunities for developing new prognostic markers as well as therapeutic options for preventing the spread of malignant tumors.

Cancer Stem Cells Survival in Circulation

The circulatory journey is harsh for most circulating CSCs. Interactions between circulating CSCs and

the microenvironmental components of circulation determine survival, and the ability of circulating CSCs to eventually extravasate in distant tissues/organs via lymphatic and hematogenous routes.

- Majority of circulating stem cells circulate as single cells, whereas others circulate in clusters by forming platelet tumor emboli. However, circulating CSCs in clusters are more likely to form metastases. In addition to intravasating CSCs, clusters contain stromal cells, and immune cells from the original tumor microenvironment that may contribute to the heterogeneity of the cluster of CSCs and enhance their survival in circulation due to evasion of destruction by immune system.
- Neutrophils participate in cluster formation of CSCs and suppress leukocyte activation, which enhance the chances of CSCs survival. Neutrophil clustering with circulating CSCs increases the metastatic potential of CSCs.
- Moreover, circulating CSCs also interact with tumor educated platelets (**TEPs**) result in formation of coating shield of platelets around CSCs that prevent detection of circulating tumor cells by immune cells. Platelets coating cancer stem cells (CSCs) provide protection against physical stresses of circulation.
- Small number of platelets coated CSCs are apparently able to establish metastatic disease. The survival and growth of metastatic CSCs is not a random process but depends upon the selection of CSCs possessing specific properties needed for metastatic growth. Circulating CSCs either arrest, and grow in capillaries or extravasate by transendothelial migration, and colonize premetastatic niche (PMN).

Cancer Stem Cells Margination and Adhesion on the Microvascular Endothelium in Circulation

Margination and adhesion of CSCs on the microvascular endothelium are two critical and closely related steps in tumor metastasis, and generally the former margination step is most often regarded as a prerequisite for the later adhesion step, which may determine the destination of CSCs after extravasation.

- CSCs are more frequently found to adhere at the microvascular bifurcations, and there is a positive correlation between the CSCs adhesion and the microvasculature wall-directed hemodynamic force of the red blood cells (RBCs).
- The larger the wall-directed hemodynamic force is, the closer the CSCs are marginated towards the microvasculature wall, and higher the probability of their adhesion on vascular endothelium. A relatively low or high hematocrit and increasing the shear rate of blood flow can assist to prevent the adhesion of CSCs.
- CSCs may be more likely to extravasate at the microvascular bifurcations, if the shear rate blood flow is slow, and the hematocrit value remains moderate due to high wall directed hemodynamic force from the surrounding red blood cells. These observations suggest the CSCs may be prone to adhere to vascular endothelium at the microvascular bifurcations with low shear rate and moderate hematocrit.
- Hemodynamic forces, cytoskeletal alterations and remolding of microvascular endothelium play important role in the CSCs arrest, adhesion, transendothelial migration, subsequent invasion of surrounding tissue, extracellular matrix (**ECM**) degradation by matrix metalloproteinases (MMPs), and extravasation of CSCs into tissues.

Extravasation of Cancer Stem Cells

Extravasation is a multistep process during which circulating CSCs pass through the blood vessel wall into the tissue.

- Only a small number of CSCs survive in the circulation and extravasate into the tissues, and remain in dormant state, while retaining a stem-like tumor initiating potential.
- Invadopodia are actin rich membrane protrusion that facilitates CSCs dissemination on proteolytic activity (local synthesis of MMPs) and clearing paths for migration of CSCs, local invasion, intravasation and extracellular events through physical barriers, such as basement membrane, extracellular matrix (ECM) and vascular endothelial cells. Invadopodia of CSCs have become therapeutic target for metastasis.

Integrins Role in Extravasation of Cancer Stem Cells

Circulating CSCs express numerous integrins mediating their adhesion via CD44 adhesion molecules on the microvascular endothelial surface, which may either induce retraction of vascular endothelial cells or degradation of vascular basement membrane by matrix metalloproteinases (MMPs) and thereby promoting extravasation, subsequent metastasis in distant organs.

- Secondly, transendothelial migration of CSCs follows subsequent invasion into the vascular basement membrane extracellular matrix (ECM), that requires genetic and molecular mediation to be able to transmigrate and colonize in the new stressful tissue environment.
- In other organs, CSCs extravasation face tight barriers and basement membranes, that require genetic and molecular mediation to be able to migrate. Recent studies revealed that CSCs induce programmed cell death (apoptosis) of vascular endothelial cells, driving metastatic CSCs to extravasate.

Chemokines Role in Extravasation of Cancer Stem Cells

Transendothelial migration of circulating CSCs is dependent on a spectrum of chemokines and complement system components.

- Granulocyte/macrophage colony-stimulating factors (GM/CSFs) and cytokine (IL-5) aid in metastasis of breast carcinoma.
- Circulating CSCs enhance the production of cytokines (IL-6, IL-8), that stimulate biochemical pathways and CSCs migration.
- Dysregulation of interleukin-1β (IL-1β) has been implicated in tumor progression, invasion, and metastasis by inducing the expression of proangiogenic genes and growth factors. In addition, loss of TP53 in CSCs induces the synthesis of Wnt ligands, that stimulate the production of IL-1β, thus driving neutrophilic inflammation.

Cancer Stem Cells Revert to Mesenchymal–Epithelial Transition

After extravasation, CSCs revert to mesenchymal–epithelial transition that involves the transition from mobile, multipolar, or spindle-shaped mesenchymal cells to planar arrays of polarized epithelial cells with cell-to-cell junctions, apical–basal polarity, and epithelial markers. Epithelial–mesenchymal transition (EMT) and its reversal to mesenchymal–epithelial transition (MET) play important roles in metastatic dissemination of CSCs of malignant epithelial tumor subsequent metastasis to distant tissues/organs and therapy resistance.

Cancer Stem Cells Colonization in Secondary Organs at Distant Sites

After extravasation, CSCs undergo adaptation to local tumor microenvironment (TME), successful colonization, and finally establishment of clinically detectable metastatic disease.

- Secondary tumor is defined as metastasis from the primary malignant epithelial tumor at original site. Metastasis suppressors halt metastatic CSCs proliferation at the secondary site without changing the characteristics of primary malignant epithelial tumor. They work through oncogenic signaling pathways to suppress invasion and eventual colonization in tissues/organs.
- Metastasis is a multistep process during which CSCs from primary malignant epithelial tumor disseminate via lymphatic route to lymph nodes and via hematogenous route to lungs, liver, bone marrow, brain, and skin, that represents the main cause of morbidity and mortality. Metastasis is modulated by tumor microenvironment and immunity. Genes play pivotal role in both metastatic dormancy and reactivation of CSCs.

Cancer Stem Cells Evasion of Immune Destruction

Factors which influence the establishment of tumor metastases include: genetic instability of CSCs; enzymatic degradation of basement membrane and extracellular matrix (ECM); ability to withstand rheologic trauma; size of the CSC cluster; interaction with CD8+ cytotoxic T cells, natural killer cells (NK cells), and macrophages; entrapment by fibrin or platelets; and surface glycoproteins. These factors favor the ability of variant CSCs to reach and colonize specific organs.

Cancer Stem Cells Evasion of Immune Surveillance

Cancer stem cells (CSCs) can be recognized by immune system. MHC class I molecules on antigen-presenting cell process and present CSCs to CD8+ cytotoxic T cells leading to CSCs destruction. There is increased risk for cancers in immunocompromised persons. CSCs escape from immune destruction in immunocompetent patients by the following mechanisms: (a) selective outgrowth of antigen negative variant of CSCs, (b) loss of MHC-I molecules, immunosuppression due to synthesis of TGF-β, PD1 ligands and galectins by CSCs, (c) antigen on cancer stem cells masked by enhanced synthesis of glycocalyx on CSCs, and apoptosis of CD8+ cytotoxic T cells.

Metastatic Dormancy of CSCs in Secondary Organs at Distant Sites

After extravasation, CSCs may remain in dormant state over a long period, before they activate the mesenchymal–epithelial transition (**MET**) process and proliferate to form macrometastasis in secondary tissues/organs. Following extravasation, metastatic CSCs cease dividing but survive in a quiescent state of cell cycle in G0–G1 for long-time. Quiescent CSCs possess angiogenic dormancy and immune-mediated dormancy in which the malignant tumor mass is preserved by immune cell cytotoxicity.

- Metastatic dormancy occurs due to the delayed acclimatization of disseminated CSCs to their secondary niches. When the microenvironmental conditions are favorable, these CSCs reinitiate proliferation and colonize sometimes years after treatment of the primary malignant epithelial tumor.
- Metastatic tumor dormancy can be induced in malignant epithelial tumors through several environmental and signaling transcriptional mechanisms involving intracellular signaling, extracellular

signaling and induction signals originating from the bone marrow niche: (a) interaction with vascular endothelial cells, cancer-associated fibroblasts (CAFs), cancer-associated immune cells and the extracellular matrix (ECM), (b) genetic alterations in the tumor microenvironment and induction of EMT, (c) epigenetic alterations in the malignant epithelial tumor, (d) malignant tumor hypoxia, (e) angiogenic switch turning off, (f) immune evasion, and (g) inflammatory switchover.

- Metastatic dormancy occurs due to suppression of RAS-MEK-ERK/MAPK and PI13K/AKT signaling cascades and activation of tumor suppressors. Restricted angiogenesis and/or an active immune cell in microenvironment inhibit expansion of CSC clusters into micrometastasis.
- TGF-β induces chondrocyte 2 (DEC2), which inhibits cyclin-dependent kinase 4 (CDK4), and activates p27 resulting in entry of cell to state of quiescence. Blocking tumor angiogenesis through thrombospondin or inhibiting chaperones such as heat shock protein 27 shifts metastatic CSC clusters into dormant state.
- Immune cells such as CD8+ cytotoxic T cells, natural killer cells (NK cells), and cancer-associated macrophages (CAMs) inhibit CSCs proliferation and clear metastatic CSCs through cytolysis. Metastatic dormant CSCs express weak antigens to escape the immune destruction, which could be the reason behind relapse following immunotherapy.

Metastatic Dormancy and Reactivation of CSCs in Secondary Organs at Distant Sites

Extravasated CSCs may remain in dormant state over a long period with subsequent reactivation to mesenchymal–epithelial transition (**MET**) involving intracellular signaling, extracellular signaling, and induction signals originating from bone marrow niche leading to form macrometastasis.

- Tumor dormancy can be induced through several mechanisms, such as genetic and/or epigenetic changes in the malignant epithelial tumor, tumor hypoxia, angiogenic switch, immune evasion, and inflammatory switch.
- Extravasated CSCs interact and adapt with tissue microenvironment and induce neoangiogenesis in order to ensure sufficient vascularization of malignant epithelial tumor.
- Alteration in the tumor microenvironment can facilitate malignant epithelial tumor growth, recurrence, and metastasis, and thereby permit the CSCs to exit from dormancy through interaction with vascular endothelial cells, cancer-associated fibroblasts (CAFs), tumor-associated immune cells, inflammatory cells and the extracellular matrix (ECM).
- In the novel stromal environment, CSCs form micrometastasis with the ability to generate macrometastasis elsewhere in distant organs such as the lungs, bones, liver, brain, and other tissues.

Metastatic Colonization of CSCs in Secondary Organs at Distant Sites

Metastasis is the main cause of mortality in cancer patients. After extravasation of CSCs leading to dissemination in distant tissues/organs (e.g. liver, lungs, brain, adrenal glands, and bone marrow) is termed 'metastatic colonization'. Cancer stem cells either build a secondary tumor (micrometastasis or macrometastasis) or remain in dormant state.

- The extrinsic traits of CSCs, tumor-secreted factors (e.g. exosomes, cytokines, chemokines) and bone marrow-derived cells signal play a pivotal role in forming the premetastatic niche (**PMN**) promoting cancer metastasis.
- Tumor-derived exosomes play important role in educating bone marrow progenitor cells to become metastatic. In patients with pancreatic carcinoma, exosomes also play important role in the initiation of **PMN** in the liver. Recent study revealed that the local microenvironment and cancer cell–host cell interactions of some organs is favorable for colonization of CSCs.
- Disseminated CSCs can create an adequate stromal microenvironment to allow metastasis in the preparation of an adequate **PMN**.
- Primary malignant epithelial tumor synthesizes proangiogenic VEGFA factor to mobilize progenitor hematopoietic stem cells from bone marrow toward the bloodstream and from there to the site of metastasis. In addition, primary malignant epithelial tumor secretes matrix metalloproteinases, fibronectin and growth factors into bloodstream and later accumulate in the target organ to **PMN**.
- Chemokines synthesized by cells attract CSCs and macrophages toward the premetastatic niche to colonize in target organs. Receptor of chemokine CXCR4 plays an important role in the extravasation of breast cancer stem cells toward their target organs.
- The anatomy of some organs provides a barrier to metastasis in lungs and brain. The vascular endothelium of capillaries surrounded by a basal membrane act as barrier to metastasis in lungs. Capillaries in the blood–brain barrier having tight junctions and astrocyte foot processes act as barrier to metastasis in brain. Presence of fenestrated capillaries

in the liver and bone makes these organs susceptible to metastasis.

- Metastasis in the mechanism by which CSCs break from primary malignant epithelial tumor and disseminate to distant organs.
  - Breast carcinoma, prostatic carcinoma and melanoma disseminate to distant organs years before detection of primary tumor.
  - Pancreatic carcinoma and lung carcinoma rapidly acquire the capacity to infiltrate and colonize without requiring a process of quiescence to generate a macrometastasis.
- Establishing a vascular network is crucial for proper metastatic colonization. Vascular mimicry supports malignant tumor perfusion, enhances intravasation and promotes breast carcinoma metastasis through serpin peptidase inhibitor, clade E member 2 (SERPINE2) and secondary leukocyte peptidase inhibitor (SLPI), which drive distant metastasis to lung and brain by enabling breast CSCs to form vascular channels.
- Breast carcinoma can colonize brain by utilizing neuronal signaling pathways for growth and adaptation. The proximity of the breast carcinoma CSCs to neuronal synapses allows CSCs to hijack N-methyl-D-aspartate receptor signaling to promote brain metastasis. Protocadherin 7 is a protein that promotes the assembly of cancer stem cell-astrocyte gap junctions composed of connexin protein. Metastatic breast cancer cells use these astrocyte gap junctions.
- Clinical observations suggest that most primary malignant epithelial tumors metastasize to specific organs, a process known as '**organotropism**'.
  - Breast carcinoma most frequently metastasize to the bone, often after long latency.
  - Bone metastatic breast disease becomes resistant to therapy. Calcium influx has been detected as a mechanism between the osteogenic niche and CSCs, which promotes the progression of bone metastatic breast disease.
  - Patients with postpartum breast carcinoma develop liver metastasis associated with poor prognosis.
- Metastatic organotropism in females and males is shown in Fig. 6.125.

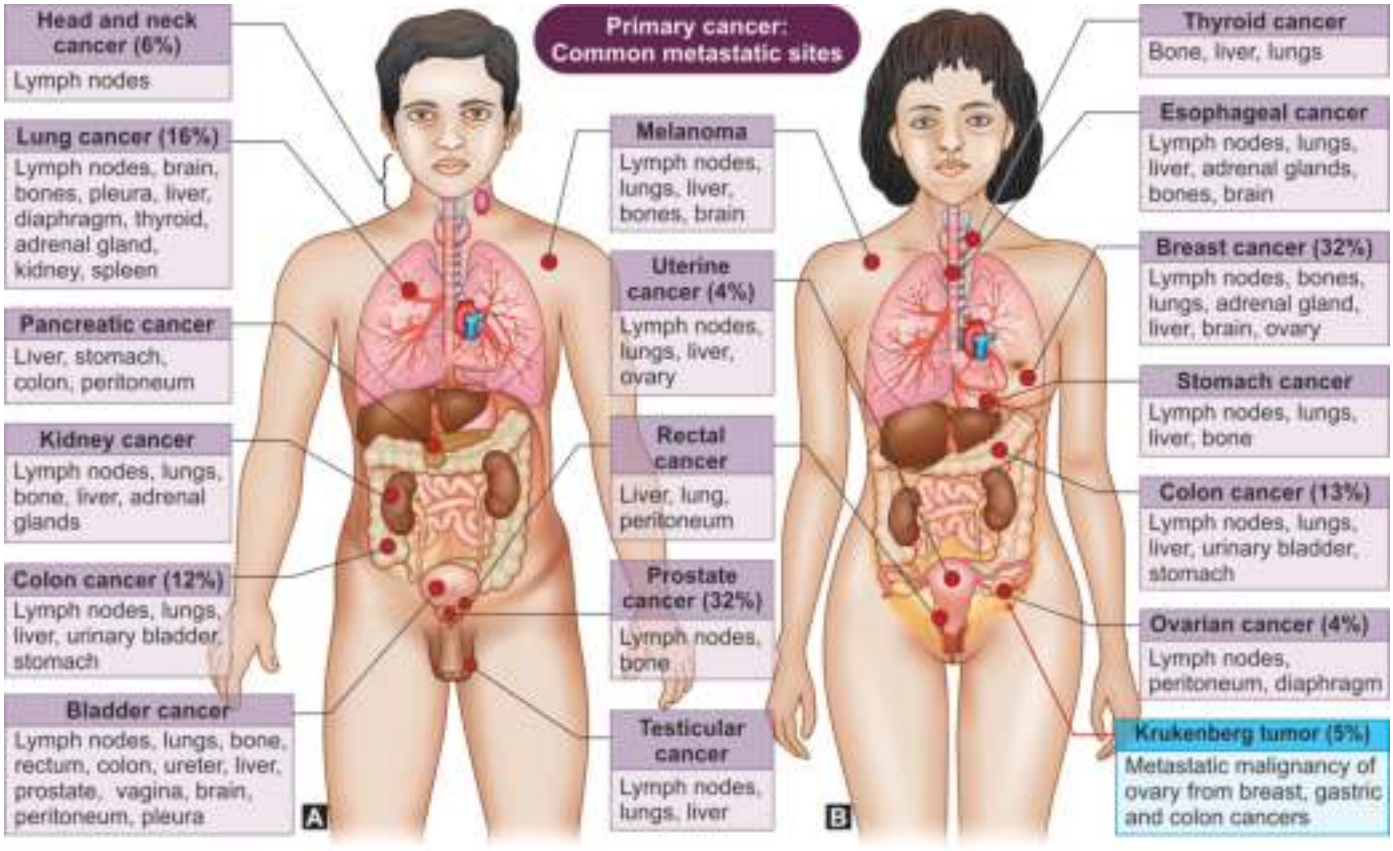


Fig. 6.125: Metastatic organotropism in females and males. Most cancers metastasize to specific target organs, a process known as 'metastatic organotropism.

CLINICAL ONCOLOGY

Cancer develops due to mutations in several key genes, e.g. proto-oncogenes, tumor suppressor genes, apoptosis regulatory genes, and DNA repair genes, that control cell growth, proliferation, and survival.

- **Oncology:** Oncology is a branch of medicine that deals with the prevention, diagnosis, and treatment of cancer. Field of oncology has major areas based on treatments: clinical oncology, medical oncology, radiation oncology, and surgical oncology.
  - **Clinical oncology:** Clinical oncology relates to treatment of diagnosed cancer patients by radiotherapy, chemotherapy, hormonal therapy, biological therapy, and targeted therapy without surgical intervention.
  - **Medical oncology:** Medical oncology focuses on the diagnosis, treatment, and prevention of cancer. Medical oncologist is the main health provider for cancer patients, and also provides supportive care and may coordinate treatment given by other specialists.
  - **Radiation oncology:** Radiation oncology is a type of medicine that uses high-energy radiation to destroy the DNA of CSCs and prevent them from growing and dividing. Radiation oncologist treats cancer using radiation therapy, which is the use of high-energy X-rays or other α and β particles to destroy CSCs.
  - **Surgical oncology:** Surgical oncology is a branch of surgery applied to oncology, that focuses on the surgical management of tumors, especially malignant tumors. Surgical oncologist treats cancer using surgical removal of tumors nearby tissue during operation. Surgical oncologist can also take biopsy to diagnose cancer.
- **Clinical history:** Clinical history of cancer patient is the most important diagnostic tool. Some cancers may be diagnosed by thorough clinical history, and physical examination, even before the person develops signs and symptoms and the suspected body system involved. Other persons may display '**cancer warning signs**': change in bowel or urinary bladder habits, non-healing sore, lump, indigestion/dysphagia, obvious change in a wart/mole, and cough or hoarseness.
  - Common symptoms that point towards cancer include fatigue, weight loss, unexplained anemia, and fever of unknown origin from *Escherichia coli* or *Pseudomonas aeruginosa* infections. Cancers of colon, stomach and kidney over mucosal surface can lead to ulceration, bleeding, and superadded infections.
  - Clinical manifestations of cancer patients are directly attributed to the local effects of the primary malignant tumor or metastases in majority of cases. In 5–10% of cases, systemic effects of cancer on the host independent of direct invasion and metastases occur due to paraneoplastic syndromes mediated by a variety of mechanisms: either 'ectopic' or 'inappropriate' hormone secretion or the production of chemical mediators such as cytokines, interleukins, and growth factors. Immune system effects mediated by antibodies or T cells that cross-react with normal host tissue are particularly observed with neurologic syndromes.
- **Tumor effects on the host:** The effects of tumors on the host depend on the location of tumor. The localized tumor mass may compress neighboring vital structures causing loss of function. Benign endocrine tumors may produce excess hormones. Non-metastatic systemic effects of cancer on the host include cachexia, hormone- and autoantibodies-related paraneoplastic syndromes.
- **Diagnostic modalities:** Cancer is diagnosed by various diagnostic tools such as fine needle spiration cytology, surgical biopsy of the tumor and examining it under light microscope including immunohistochemistry.
  - Other diagnostic tools include endoscopy for gastrointestinal tract, cystoscopy for urinary tract, bronchoscopy for respiratory tract; imaging studies like ultrasonography, X-rays, CT scanning, MRI scanning, scintigraphy, single photon emission computed tomography, positron emission tomography and nuclear medicine.
  - Common diagnostic tests include blood tests for biological or tumor markers. Increased level of tumor markers in blood may be indicative of the cancer.
- **Treatment:** The treatment modalities for cancers include surgery, chemotherapy, and radiation therapy. Cancer therapy varies by the patient's tumor type, and location.
  - **Targeted drug therapy:** Targeted drug therapy uses medicines that targets specific genes and proteins that help CSCs to grow, spread, and survive longer. Two main groups of targeted drug therapy include monoclonal antibodies and small molecule inhibitors. They have side-effects different from chemotherapy.
  - **Bone marrow transplant:** Bone marrow transplant is also called **hemopoietic stem cell transplant**. Bone marrow transplants may use stem cells from

own body (autologous transplant) or from a donor (allogenic transplant). Bone marrow transplant can benefit cancer patients (leukemias, multiple myeloma, and lymphoid neoplasms) and other patients with aplastic anemia, bone marrow failure syndromes, hemoglobinopathies and amyloidosis.

- **Clinical trials:** Clinical trials are studies to discover new methods of treating cancers. Each type of clinical trial is designed to answer different research questions and will help researchers learn things that can help patients in the future.

LOCAL EFFECTS OF TUMORS ON THE HOST

The effects of tumors on the host depend on the location of tumor. The localized tumor mass may compress neighboring vital structures causing loss of function. Benign endocrine tumors may produce excess hormones.

- Pituitary adenoma can compress optic nerve, and cause bilateral temporal hemianopia, and produce excess hormones, e.g. growth hormone causing acromegaly.
- Malignant tumors can impinge on airways, brainstem, nerves, blood vessels, and hollow viscus and cavity.
- Cancers of colon, ovary and urinary bladder may rupture. Colon carcinoma can narrow a hollow viscus, e.g. causing intestinal obstruction, ulceration and bleeding leading to intestinal obstruction, and anemia.
- Pancreatic carcinoma may obstruct common bile duct resulting in obstructive jaundice. A space-occupying tumor can block a cardiac valve orifice. Direct spread of lung carcinoma may compress neighboring viscera, blood vessels and nerves.
- Metastasis to bone causes bone pain and pathologic fracture. Metastasis to the brain causes epilepsy, cerebral stroke and raised intracranial pressure.
- Malignant tumors and their products produce systemic effects such as cachexia, and paraneoplastic syndrome. Initially, cancer patients are asymptomatic, but become symptomatic in advanced disease. Local effects of cancer on the host are shown in Fig. 6.126.
  - **Central nervous system manifestation:** About 2 cm tumor in the brainstem may kill a patient. Central nervous system tumors can compress surrounding normal structures and impair their functions. Intracranial tumors cause compression on brain parenchyma due to inelasticity of the skull vault, that produce headache, nausea, vomiting, confusion, seizure, and localized neurological signs. Invasion of nerve can result in neurologic deficits and pain.

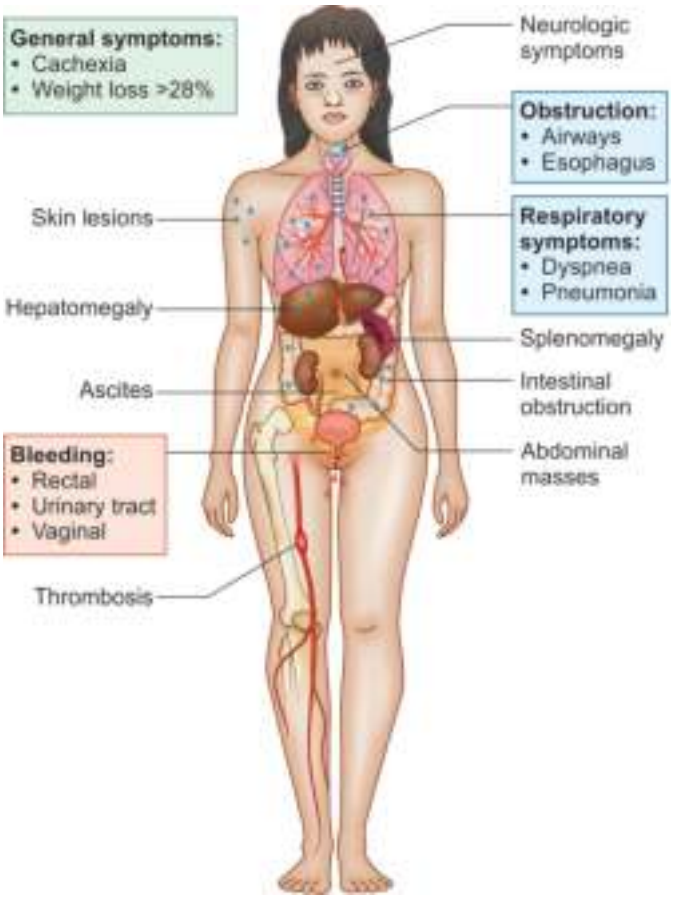

Fig. 6.126: Local effects of cancer on the host. Primary and metastatic tumors can produce same consequences. Malignant tumor can affect normal bodily functions by compressing, invading, and destroying normal tissues.

- **Respiratory system manifestations:** Lung carcinoma can obstruct airways cause pneumonia or bronchiectasis and breathlessness. As the disease progresses, patient develops weight loss, fever, and tiredness. Lung carcinoma metastasizing to lymph nodes and distant organs can develop additional symptoms.
- **Gastrointestinal tract manifestations:** Symptoms and signs of advanced gastric carcinoma include fatigue, weight loss, anemia, black tar stools, severe nausea, and vomiting, some frank blood in stool sometimes. Advanced intestinal and gynecological cancers can cause partial complete bowel obstruction at multiple levels. Peritoneal carcinomatosis has been demonstrated in majority of cases. Patients with malignant tumor developing bowel obstruction present with continuous colic pain, nausea, vomiting, limitation in inferior vena cava venous return, water and electrolytes imbalance, deterioration in general and hemodynamic status, diaphragmatic elevation and ventilatory restriction.

- **Vascular manifestations:** Tumor mass can impinge upon blood vessels leading to ischemia and infarction of tissue/organ. Tumor invasion in blood vessel can lead to hemorrhage within pleural or peritoneal cavity.
- **Trousseau sign:** Trousseau sign is migratory venous thrombosis most often associated with pancreatic adenocarcinoma and bronchogenic carcinoma.
- **Hematologic manifestations:** Space-occupying lesion in the bone marrow causes pancytopenia. Patient develops microcytic hypochromic anemia due to blood loss in colorectal cancer. Macrocytic anemia occurs due to folate deficiency from rapid malignant tumor growth; and bone marrow metastases. Leukopenia and thrombocytopenia occur due to tumor metastasis within bone marrow, chemotherapy, and radiation therapy.
- **Skeletal manifestations:** Bone destruction can lead to pathologic bone fracture in the settings of metastatic bone disease, and multiple myeloma.

NON-METASTATIC SYSTEMIC EFFECTS OF CANCER ON THE HOST

Five non-metastatic systemic cellular and tissue level hallmarks of cancer include: global inflammation, immune system inhibition, metabolic changes-associated cachexia, the propensity to thrombosis and neuroendocrine changes. Other clinical manifestations of cancer are mediated by various mechanisms, other than invasion and metastasis. Systemic effects of cancer on the host include cachexia, hormone- and autoantibodies-related paraneoplastic syndromes.

- **Cancer cachexia:** Cancer cachexia is a wasting disorder that causes extreme loss of adipose tissue and skeletal muscle, anorexia associated with cancer. It occurs either low-caloric intake or altered normal metabolism and switching of CSCs to ineffective aerobic glycolysis. Cancer cachexia is caused by cytokines produced by the malignant tumor and host response to the malignant tumor.
- **Hormone-related paraneoplastic syndromes in cancers:** In minority of patients, CSCs can synthesize hormone-like proteins or substances and produce remote effects, that are not attributable to malignant tumor invasion or to metastasis, and are collectively called paraneoplastic syndromes. Such effects are rarely lethal, but in some cancer patients side effects dominate the clinical course.
  - **Parathormone (PTH)**-related peptide produced by squamous cell lung carcinoma, breast carcinoma and renal cell carcinoma results in osteolysis of bone and thus hypercalcemia.
  - **Adrenocorticotropic hormone (ACTH)**-like protein is produced by small cell lung carcinoma and pancreatic carcinoma results in Cushing syndrome-like manifestations. Small cell lung carcinoma and cerebral tumors are associated with syndrome of inappropriate antidiuretic hormone (SAIDH) leading to retention of water in the body.
  - **Erythropoietin** produced by renal cell carcinoma, cerebellar hemangioblastoma and hepatocellular carcinoma results in polycythemia.
- **Autoantibodies-related paraneoplastic syndromes in cancers:** Autoantibodies-related paraneoplastic syndromes are related to involvement of nerves and skeletal muscles. Lambert-Eaton syndrome is a myasthenia gravis-like syndrome produced by small cell lung carcinoma, in which IgG autoantibodies are formed against presynaptic calcium channels at the neuromuscular junction leading to weakness of pelvic girdles, proximal limbs and trunk due to non-release of acetylcholine. IgG autoantibodies produced by small cell lung carcinoma can cause peripheral neuropathy and cerebellar degeneration.

CANCER-ASSOCIATED CACHEXIA

Cancer-associated cachexia is a syndrome characterized by marked body weight loss (>20%) due to ubiquitin proteasome pathways with specific irreversible loss of skeletal muscle and adipose tissue, weakness, anorexia, anemia, recurrent infections, increased cellular metabolism, high-energy expenditure, and decreased secretion of anabolic hormones in patients with cancers of esophagus, pancreas, gastric region, colorectal region, and lung.

- **Molecular pathogenesis:** Cancer-associated cachexia process involves numerous chemical mediators, e.g. tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), interleukin-6 (IL-6), interferon-γ (IFN-γ) and C-reactive protein (CRP) derived from the CSCs and inflammatory and immune cells such as macrophages within tumor microenvironment, that promote cellular catabolism of skeletal muscles and adipose tissue. In addition, metabolic, endocrine, and central nervous system perturbations combine with these chemical mediators to induce catabolic changes in skeletal muscle and adipose tissue. At the tissue level, mechanisms of cancer-associated cachexia include activation of inflammation, proteolysis, and lipolysis. Nutritional status of patient is compromised by direct response to malignancy-induced alterations in the cellular metabolism. Cytokine milieu and effects in cancer-associated cachexia are given in Table 6.105. Cancer-associated cachexia is shown in Fig. 6.127.

Table 6.105 Cytokine milieu and effects in cancer-associated cachexia

Cytokine	Cytokine Milieu and Effects
Tumor necrosis factor-α (TNF-α)	Lipolysis, skeletal muscle degradation, increased glucose turnover
Interferon-γ (IFN-γ)	Potentiates lipolysis, decreased protein synthesis
Interleukin-1 (IL-1)	Induction of anorexia, early satiety, peripheral proteolysis, potential release of IL-6
Interleukin-6 (IL-6)	Severe skeletal muscle wasting
Proteolysis	Skeletal muscle degradation
Lipid-mobilizing factor	Lipolysis

- **Tumor necrosis factor-α (TNF-α):** TNF-α increases glucogenesis, proteolysis, and lipolysis. It also decreases synthesis of glycogen, proteins, and lipids. TNF-α activates IL-1 production, that stimulates the expression of uncoupling proteins (e.g. UCP2 and UCP3) in cachectic skeletal muscles.
- **Interferon-γ (IFN-γ):** IFN-γ potentiates lipolysis, and decreased protein synthesis.
- **Interleukin-1 and 6 (IL-1 and 6):** IL-1 induces anorexia, early satiety, peripheral proteolysis, potential release of IL-6. **IL-1** induces anorexia in cancer cachectic patients by increasing plasma concentration of tryptophan, which in turn enhancing serotonin production and causing early satiety and suppressing hunger. Excess plasma tryptophan concentration resulting in increased serotonin production from the hypothalamus has been linked to anorexia. **IL-6** is an important mediator in the defense through its regulation of immune system. IL-6 may play a pivotal role in the development of cachexia.
- **Signal transducers and activation of transcription 3 (STAT3):** STAT3 is a member of STAT family of proteins. STAT3 plays an important role in cytokine-induced pathways, that regulate the embryonic development, cell proliferation, differentiation, and homeostasis of many tissues. STAT3 activation is a common feature of skeletal

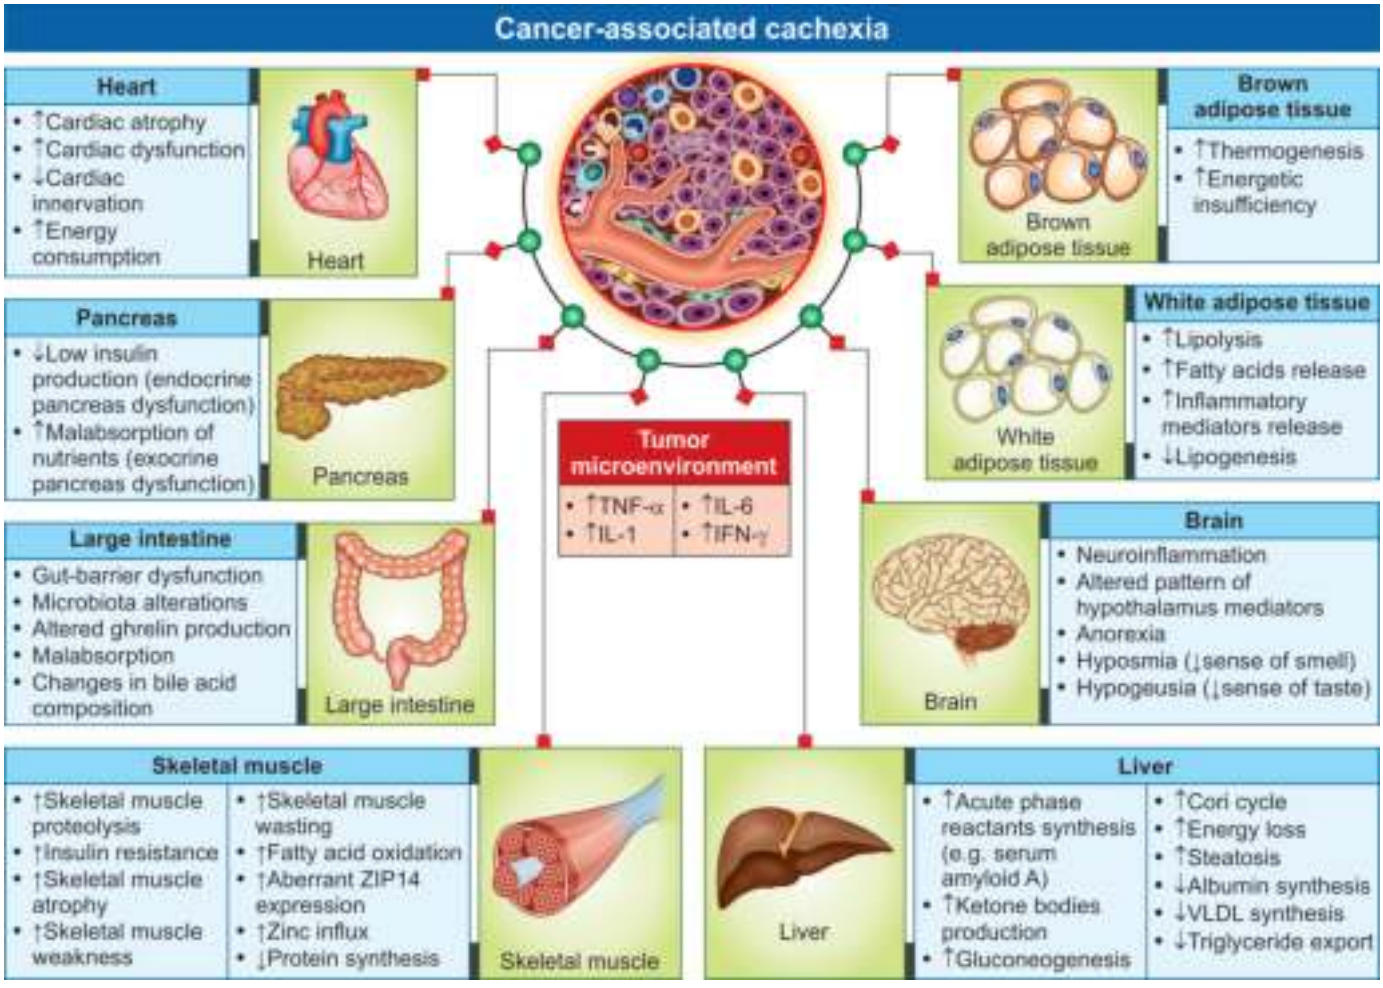

Fig. 6.127: Cancer-associated cachexia. It is host-phagocytic syndrome characterized by a continuous decline in skeletal muscle mass, with or without fat loss, which leads to progressive functional impairment, weakens the effects of chemotherapy, and increases mortality in patients with cancer.

muscle wasting. STAT3 is activated in skeletal muscle wasting by IL-6 in various malignant tumors, and sterile sepsis.

- **Management:** Patients experience impaired quality of life, reduced physical, emotional, and social well-being, and increased use of healthcare resources. The best management strategy of cancer-associated cachexia is to treat the cancer disease as this would completely reverse the cachexia syndrome.

Skeletal Muscle Wasting in Cancer-associated Cachexia

The maintenance of skeletal muscle mass is governed by dynamic processes that regulate protein synthesis and proteolysis. In cancer-associated cachexia, there is a chronic skeletal muscle protein degradation. Changes in the skeletal muscle protein as well as cell organelles, and cytoplasm affect the size of skeletal muscle fibers.

- Mechanical overload, anabolic hormone, insulin, insulin-like growth factor 1 (IGF-1) testosterone and β_2-adrenergic agonists stimulate protein synthesis in skeletal muscle leading to increase in size of skeletal muscle fiber. Binding of insulin and insulin-like growth factor 1 (IGF-1) to the receptors of skeletal muscle fiber activates the phosphatidylinositol 3-kinase (P13K)/AKT/mTOR-mediated signaling propagation system and promotes protein synthesis in skeletal muscle and inhibits its proteolysis.
- **Ubiquitin proteosome pathway (UPP)** is highly-selective proteolytic system, that plays crucial role in protein quality control, cell proliferation, embryonic development, signal transduction, transcriptional regulation, receptor downregulation, and synaptic plasticity. In fact, marked uncontrolled upregulation of UPP pathway underlies the pathogenesis of skeletal muscle wasting in many myopathies and cancer cachexia. These proteolytic systems are activated by various stimuli such as oxidative stress, inflammatory cytokines, growth factors (myostatin/activin A) and glucocorticoids.
- **Myostatin and activin A growth factors** play a central role in the striated muscle growth and skeletal muscle loss in various diseases. Uncontrolled activation of myostatin and activin A cause skeletal muscle wasting in cancer patients. An increase in the extracellular proteases and reactive oxygen species (ROS), severe decrease in pH and follistatin glycoprotein activate myostatin and activin A growth factors.
  - In skeletal muscle fibers, binding of myostatin and actin A to their receptors activate downstream processes, that inhibit IGF-1 P14K/AKT hypertrophy signaling pathway through phosphorylation of AKT resulting in the translocation of SMAD2/SMAD3, and FOXO1 transcription factors into the nucleus and the upregulation of proteolytic genes, and thus inhibits myoblast growth and myogenic differentiation through the suppression of PAX3/PAX7 and myoD.
  - The cycle of events initiates skeletal muscle wasting by upregulating transcription of **atrogin 1**, **MURF1** and **E2 ligases**, which always remain active in the ubiquitin proteasome pathway.
- Recent studies have revealed several emerging mechanisms that may contribute to skeletal muscle wasting including malnutrition, excess cytokines that downregulate genes involved in protein synthesis and upregulation of the ubiquitin proteasome pathway (UPP).

Weight Loss in Cancer-associated Cachexia

Weight loss in cancer-associated cachexia and starvation occurs due to loss of adipose tissue and skeletal muscle mass. In starvation, ketone bodies are produced from the lipid metabolism in the liver, and fat replaces glucose as an energy source and prevents loss of skeletal muscle mass. Depending on the malignant tumor type, weight loss occurs in 30–80% of cancer patients.

- Patients with gastric carcinoma and pancreatic carcinoma have the highest frequency of weight loss. Weight loss frequency is much less in the patients with breast carcinoma, acute myeloid leukemia, non-Hodgkin's lymphoma and sarcoma. Head and neck cancers can cause dysphagia and weight loss.
- Weight loss is an important prognostic factor in cancer; higher the extent of weight loss, the shorter the survival span. Patients with cancer cachexia have fatal outcome, when there is 25–30% of total body weight loss. Proteolysis-inducing factors have been detected, which cause skeletal muscle wasting. Increased energy expenditure is also considered as a factor that contribute to the wasting process.

Increased Resting Energy Expenditure in Cancer-associated Cachexia

Energy expenditure is a metabolic calculator determined by three factors: basal metabolic rate, diet-induced thermogenesis, and physical activity. The best predictor for 24-hour energy expenditure refers to resting energy calculated by indirect calorimetry. Resting energy expenditure (REE) in cancer patients varies with the type of malignant disease.

- **Resting energy expenditure (REE)** is high in lung carcinoma and pancreatic carcinoma. However, REE is not increased in patients with gastric carcinoma and colorectal carcinoma. Reasons for REE alterations depend on acute phase response protein and thermogenesis.

- Acute phase response alterations occur in the liver, where there is a shift from production of albumin to acute phase proteins like C-reactive protein (CRP), fibrinogen, serum amyloid associated (AA) proteins, α_2-macroglobulin and α_1-antitrypsin. There is an increase in the level of C-reactive protein in cachexia patients with head and neck squamous cell carcinoma. Acute phase response induces the rate of loss of body mass. Increased REE occurs due to enhanced thermogenesis in brown adipose tissue (BAT) and skeletal muscle.
- White adipose tissue acts as a fat store, whereas function of brown adipose tissue is thermogenesis related proportional to the oxidative phosphorylation in the mitochondria essential for cellular respiration, and presence of uncoupling proteins in the mitochondria.

- **Uncoupling proteins (UCPs)** mediate protein leakage across the inner mitochondrial membrane decreasing the level in the coupling of cellular respiration to ADP phosphorylation.
  - UCP1 is detected in brown tissue. UCP3 is present in brown tissue and skeletal muscle.
  - Increased levels of UCP3 mRNA in cancer are responsible for increased energy expenditure and tissue catabolism.
  - The increase in UCPs is also associated an increase in circulatory fatty acids. It appears that some cytokines and tumor lipid mobilizing factors (LMFs) can increase the levels of UCP in both brown adipose tissue and skeletal muscle.

Anorexia in Cancer-associated Cachexia

Anorexia is an important cause of weight loss in cancer-associated cachexia. The cancer is associated with activation of proinflammatory cytokines and neuroendocrine responses. These pro-inflammatory cytokines result in reduced food intake and metabolic change. Adrenergic activation and malignant tumor-related lipolytic factors lead to enhanced lipolysis.

- The effects of hypogonadism, insulin resistance, adrenergic activation, and systemic inflammation coupled with semistarvation lead to skeletal muscle atrophy. Protein synthesis in liver and its export is stimulated as part of the acute phase response. In addition, futile substrate of Cori cycle contributes to hypermetabolism. Recent studies also suggest that inflammation plays a role in the increased lipolysis in adipose tissue, and proteolysis in skeletal muscle.
- Primary cause of anorexia is due to increase in proinflammatory cytokines and lactate. Cytokines and lactate modulate the central nervous system neurotransmitter cascades. Numerous causes of anorexia in cancer cachexia can be categorized as being due to central or peripheral mechanisms.
  - Central causes of anorexia in cancer cachexia can be due to alterations in neurotransmitters (e.g. serotonin and corticotropin-releasing factor) leading to depression. Infusion of interferon in cancer patients increases kyreunine/keurinic acid.
  - Peripheral causes of anorexia in cancer cachexia occur in various settings: (a) malignant tumors directly impinging on gastrointestinal tract function, (b) malignant tumors producing substances (e.g. lactate, tryptophan, or parathormone-related peptide) that alter food intake, (c) malignant tumors causing alterations in nutrients such as zinc, or (d) malignant tumor inducing inflammation and cytokine synthesis. Chemotherapy can alter taste perception (dysgeusia) and cause nausea, vomiting, abdominal cramps, bleeding, and paralytic ileus.

PARANEOPLASTIC SYNDROMES

Paraneoplastic syndromes are defined as signs and symptoms, that present distant from the site of malignancy. It is important to recognize paraneoplastic syndromes for several reasons: (a) signs and symptoms of the paraneoplastic syndromes may be the clinical symptoms of a primary malignant tumor, (b) paraneoplastic syndromes may be mistaken for advanced metastatic disease, that need appropriate therapy, and (c) paraneoplastic syndromes can be disabling and treated to relieve palliative effects.

- Recent medical advances have improved the understanding of clinical manifestations, diagnosis, and treatment of paraneoplastic syndromes, which arise from malignant tumor secretion of hormones, peptides or cytokines or immune cross-reactivity between malignant tumor and normal tissues. Paraneoplastic syndrome in small cell lung carcinoma develops due to excessive production of ectopic hormones such as ACTH and ADH.
- Paraneoplastic syndromes may adversely affect diverse organ systems (e.g. brain and skeletal muscle), most notably the endocrine, neurologic, dermatologic, hematologic, and rheumatologic systems associated with the presence of malignancies without direct association with primary malignant tumor invasion and metastasis.
- Paraneoplastic syndromes can occur in the patients with breast carcinoma, gastric carcinoma, small cell lung carcinoma, ovarian carcinoma, pancreatic carcinoma, renal cell carcinoma and hematologic malignancies (i.e. leukemias/lymphomas).

- Symptoms of paraneoplastic syndromes vary depending on the organ systems affected. In >50% of cases, the signs and symptoms appear before an individual is diagnosed with a malignant tumor.
- In addition, patients present with fever, loss of anorexia and weight and night sweats.
- Cancer-associated paraneoplastic syndromes are given in Table 6.106.

Table 6.106 Cancer-associated paraneoplastic syndromes

Syndrome	Underlying Cancers	Mechanism by Synthesis of Molecules
Endocrinopathies manifestations		
ACTH-Cushing's syndrome	▪ Small cell lung carcinoma ▪ Pancreatic carcinoma ▪ Neural tumors	Production of ACTH or ACTH-like hormone
Hypercalcemia	▪ Squamous cell lung carcinoma ▪ Breast carcinoma ▪ Renal cell carcinoma ▪ Ovarian carcinoma ▪ Head and neck cancer ▪ Adult T cell leukemia/lymphoma	Production and release of polypeptide factor with close relationship to parathormone (PTH)
Hypocalcemia	Medullary thyroid carcinoma	Production of calcitonin
Syndrome of inappropriate antidiuretic hormone (SIADH) resulting in hyponatremia	▪ Small cell lung carcinoma ▪ Prostatic carcinoma ▪ Thymoma ▪ Gastric carcinoma ▪ Colon carcinoma ▪ Hodgkin's disease ▪ Non-Hodgkin's lymphoma ▪ Intracranial neoplasms	Production of ADH
Polycythemia	▪ Renal cell carcinoma ▪ Hepatocellular carcinoma ▪ Cerebellar hemangioma	Production of erythropoietin
Hypoglycemia	▪ Fibrosarcoma ▪ Ovarian carcinoma ▪ Medullary thyroid carcinoma ▪ Other mesenchymal sarcomas	Production of insulin-like hormone
Hypocalcemia	▪ Fibrosarcoma ▪ Ovarian carcinoma ▪ Medullary thyroid carcinoma	Production of calcitonin
Bone changes		
Hypertrophic osteoarthropathy and clubbing of fingers	▪ Bronchogenic carcinoma ▪ Thymoma	Bone changes due to periosteal reaction of distal phalanx, often associated with clubbing of nails
Antibody-mediated disorders		
Lambert-Eaton syndrome (myasthenia gravis-like weakness)	▪ Small cell lung carcinoma ▪ Thymoma	Immunologic-mediated disorder due to autoantibodies formed against presynaptic voltage-gated channels in the neuromuscular junction
Peripheral neuropathy	Small cell lung carcinoma	Immunologic-mediated disorder due to IgG autoantibodies against anterior and lateral horn cells of nervous system

Contd...

Table 6.106 Cancer-associated paraneoplastic syndromes (*Contd...*)

Syndrome	Underlying Cancers	Mechanism by Synthesis of Molecules
Stiff-Person syndrome (brain and spinal cord involvement)	▪ Breast carcinoma ▪ Small cell lung carcinoma	Immunologic-mediated disorder due to anti-amphiphysin and anti-GAD antibodies formed
Opsoclonus-myoclonus-ataxia syndrome (uncontrolled eye movements)	▪ Neuroblastoma ▪ Small cell lung carcinoma	Immunologic-mediated disorder due to anti-Ri and anti-Hu antibodies
Cerebellar degeneration	Small cell lung carcinoma	Immunologic-mediated disorder due to IgG autoantibodies against cerebellum resulting in ataxia, vertigo, and dysarthria
Dermatologic manifestations		
Seborrheic keratosis	Gastric carcinoma	Sudden appearance of numerous pigmented seborrheic keratosis (Leser-Trélat sign)
Dermatomyositis	▪ Bronchogenic carcinoma ▪ Breast carcinoma	Immunologic-mediated disorder
Acanthosis nigricans maligna (black verrucoid-appearing lesions)	▪ Lung carcinoma ▪ Gastric carcinoma ▪ Endometrial carcinoma	Acanthosis nigricans occurs by immunologic mechanism due to synthesis of epidermal growth by these cancers
Carcinoid syndrome	▪ Gastric carcinoma ▪ Pancreatic carcinoma ▪ Bronchial adenoma	Production of serotonin
Hematologic and vascular manifestations		
Disseminated intravascular coagulation	▪ Acute promyelocytic leukemia ▪ Prostatic carcinoma	Production of procoagulant factors, which activate coagulation cascade
Trousseau syndrome (superficial migratory thrombophlebitis results in venous thrombosis)	▪ Bronchogenic carcinoma ▪ Pancreatic carcinoma ▪ Solid metastatic tumors	Production of tumor products like mucins that activate clotting
Nonbacterial thrombotic endocarditis	Advanced malignancies	Hypercoagulable state
Renal manifestations		
Nephrotic syndrome	▪ Renal cell carcinoma ▪ Lung carcinoma ▪ Colon carcinoma ▪ Lymphomas	Tumor-derived antigen combined with antibody to form immune complexes deposited in glomeruli leading to glomerular injury
Male breast manifestation		
Gynecomastia	Choriocarcinoma of testis	β-hCG

- In some instances, the timely diagnosis of paraneoplastic syndromes may lead to detection of an otherwise clinically occult malignant tumors at an early and highly treatable stage in 20% of middle-aged persons.
- Treatments include addressing the underlying malignancy, immunosuppression for endocrine, neurologic, dermatologic, hematologic, and rheumatologic systems involved in paraneoplastic syndromes, and correction of electrolyte, and hormonal derangements for endocrinal paraneoplastic syndromes.

Endocrinal Manifestations of Paraneoplastic Syndrome

Endocrinal manifestations of paraneoplastic syndrome are caused by ectopic production of hormones or chemically unrelated substances inducing effects like those of a given hormone.

- The most common endocrinal manifestations include hypercalcemia, syndrome of inappropriate antidiuretic hormone secretion, Cushing's syndrome, and polycythemia. These endocrinal manifestations may be the presenting feature of underlying malignancy.

- Rarely endocrinal manifestations of paraneoplastic syndromes result from ectopic production of less frequently observed bioactive proteins such as growth hormone, human chorionic gonadotropin, insulin-like growth factors, renin and intestinal peptides.

Hypercalcemia

Malignancy-associated hypercalcemia occurs in about ≤10% of all patients with advanced cancer and generally associated with poor prognosis. Biochemical alterations include hypercalcemia (serum calcium >14 mg%), increased excretion of calcium and hydroxyproline containing peptide in the urine indicative of bone matrix destruction.

- Patient with cancer-related hypercalcemia presents with thirst, nocturia, and polyuria due to impaired renal concentrating ability, lethargy, hypotonia, muscular weakness, myoclonus, anorexia, vomiting, abdominal cramps, constipation, psychosis, and coma.
- The pathophysiology of hypercalcemia of malignancy is mainly through four principal mechanisms: (a) excessive secretion of parathyroid-related protein (PTHrP) by CSCs—known as humoral hypercalcemia of malignancy accounts for 80% of cases with squamous cell carcinomas, (b) binding of PTHrP receptor in bone and kidneys regulates bone resorption and renal handling of calcium and phosphate, (c) another 20% of cancer cases arise from osteolytic activity at the sites of skeletal metastases in the settings of breast carcinoma, squamous cell lung carcinoma, head and neck cancers, urinary bladder carcinoma, ovarian carcinoma and non-Hodgkin's lymphoma, and (d) rarely, hypercalcemia may result from secretion of 1,25-dihydroxyvitamin D (calcitriol) in the setting of certain lymphomas or other malignant tumors, which secreting ectopic PTH.

Cushing Syndrome

Cushing syndrome is caused by production of ACTH-like substances by small cell lung carcinoma, bronchial carcinoids, islets cell tumor of pancreas, and thyroid medullary carcinoma. Production of ACTH-like substance causes bilateral adrenal gland hyperplasia,that leads to high plasma concentration of cortisol.

- Biochemical abnormalities produced by continuous exposure to high plasma levels of ACTH-like substance and cortisol are manifested by potassium depletion leading to skeletal muscle weakness and wasting, polyuria and carbohydrate intolerance, sodium retention resulting in edema and hypertension.
- Patient presents with exaggerated facial roundness, weight gain around midsection and upper back, thinning of arms and legs, easy bruising and stretch marks. Pigmentation is a feature in some patients due to secretion of melanocyte-stimulating hormone as well as corticotropin.
- Confirmation of cancer-related Cushing syndrome is obtained by high concentration of 11-hydroxy-corticosteroids and the loss of suppression by exogenous glucocorticoids such as dexamethasone.
- Antihypertensive agents and diuretics, with careful monitoring of serum potassium, may also be used to control symptoms. Mifepristone, which binds competitively to the glucocorticoid receptor, has recently been shown to improve clinical and biochemical parameters of Cushing's syndrome.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

Syndrome of inappropriate antidiuretic hormone (SIADH) secretion results in hyponatremia (decreased serum sodium) in the settings of small cell lung carcinoma (most common), prostatic carcinoma, thymoma, gastric carcinoma, colon carcinoma, Hodgkin's disease, and non-Hodgkin's lymphoma.

- Continued secretion of antidiuretic hormone (ADH) inappropriate to the body needs leads to overhydration in both the intracellular and extracellular compartments. The resulting cerebral edema leads to drowsiness, mental confusion, irritability, disorientation and ultimately to convulsions and coma. The clue to the diagnosis of SIADH is the presence of dilutional hyponatremia rather than depletion hyponatremia type.
- All other plasma constituents will be diluted by the increased plasma content of water (e.g. low blood urea, packed cell volume). Plasma osmolality, which depends on the plasma content of sodium and potassium will also be low.

Spontaneous Hypoglycemia

Spontaneous hypoglycemia occurs due to ectopic secretion of insulin-like hormone in the settings of hepatocellular carcinoma, mesothelioma and leiomyosarcoma that leads to hypoglycemia (blood glucose as low as 20 mg/dl). Non-islet cell tumor hypoglycemia due to increased synthesis of insulin-like hormone, inhibition of insulinase, and impairment of hepatic glucose-6-phosphatase activity are responsible for glucose hunger. Patient presents with sweating, flushing, hunger pain, tachycardia, and drowsiness terminating in convulsions and coma.

Hyperthyroidism

Choriocarcinoma and hydatidiform mole synthesize thyroid stimulating hormone-like substance that

leads to hyperthyroidism. Both serum protein-bound iodine level, and radioactive iodine uptake by thyroid gland are raised. Iodine uptake by thyroid gland is not suppressed by the administration of tri-iodothyronine or thyroxine. Patient presents with tachycardia, increased appetite, heat-tolerance, polydipsia, and muscle weakness.

Hypocalcemia

Fibrosarcoma, ovarian carcinoma and medullary thyroid carcinoma synthesize calcitonin-like protein, that causes hypocalcemia.

Precocious Puberty

Precocious puberty occurs due to increased concentrations of human chorionic gonadotropin in patients with testicular germ cell and Leydig cell tumors. Patient presents with spurt in both weight and height, deepening of voice, virilism, enlargement of penis, and testes and growth of pubic hair. Plasma testosterone and urinary excretion of 17-keto(oxo)steroids are elevated but not suppressed by the administration of exogenous glucocorticoids.

Gynecomastia in Men

Gynecomastia is found in association with tumor producing a luteinizing hormone, which stimulates production of estrogens. Testicular choriocarcinoma secretes β-hCG, that can cause gynecomastia. Males develop gynecomastia in the settings of testicular choriocarcinoma, breast carcinoma, lung carcinoma, choriocarcinoma, metastatic hepatocellular carcinoma, estrogen therapy in prostatic carcinoma, and malignancies treated by cytostatic chemotherapeutic agents.

Gastrin Producing Tumors

Zollinger-Ellison syndrome (**ZES**) is caused by secretion of gastrin by duodenal or pancreatic functional neuroendocrine tumors (e.g. gastrinomas).

- Zollinger-Ellison syndrome is characterized by severe peptic ulcer disease, gastroesophageal reflux disease (GERD, and chronic diarrhea caused by gastrinomas that results in excessive production of hydrochloric acid in the stomach.
- Zollinger-Ellison syndrome also occurs in association with multiple endocrine neoplasia 1 (MEN1). If Zollinger-Ellison syndrome is suspicious, screening for MEN1 needs to investigated by analyzing serum calcium, parathormone level, prolactin, and pancreatic polypeptide.
- Imaging studies are recommended to localize gastrinoma or to evaluate any metastases.

Polycythemia (Erythrocytosis)

Renal cell carcinoma, hepatocellular carcinoma, cerebellar hemangioma, and uterine leiomyoma synthesize excessive **ectopic erythropoietin (EPO)** that interacts with receptor-bearing cells in the bone marrow leading to erythroid hyperplasia, increased red blood cell production, hemoglobin concentration, and packed cell volume. Resection of the tumor reverse the hematological abnormality.

Neurologic Manifestations of Paraneoplastic Syndromes

Paraneoplastic syndromes result from immune cross-reactivity between cancer stem cells (CSCs) and components of the nervous system. In response to developing malignant tumor, patient produces cancer-directed antibodies known as onconeural autoantibodies.

- Because of antigenic similarity, these onconeural autoantibodies and associated onconeural antigen-specific T cells attack components of the nervous system. Immunosuppressive therapy is administered in paraneoplastic neurologic syndromes.
- Depending on the affected nervous system compartment, patient presents with cognitive and personality changes, ataxia, cranial nerve deficits, weakness, or numbness.
- Paraneoplastic neurologic syndromes can affect neuromuscular junction (e.g. Lambert-Eaton myasthenia syndrome), central nervous system (e.g. limbic encephalitis and cerebellar degeneration) or the peripheral nervous system (e.g. autonomic neuropathy and subacute sensory neuropathy).
- Paraneoplastic neurologic syndromes are diagnosed by imaging, serologies, electroencephalography, nerve conduction studies, electromyography, and cerebrospinal fluid analysis for signs of inflammation.
- Onconeural antibodies are classified according to three main categories: (a) cancer-associated onconeural antibodies include anti-amphiphysin, anti-Hu, anti-Yo anti-Ma2, anti-Ri and anti-recoverin, (b) partially characterized onconeural antibodies include ANNA-3, anti-mGluR1, anti-Tr, anti-Zic4, PCA-2, and (c) onconeural antibodies occurring in both cancer and non-cancer-associated syndromes include anti-acetylcholine receptor (AchR), anti-nicotinic AchR, anti-VGCC and anti-VGKC.

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome (LEMS) is characterized by myasthenia gravis like skeletal muscle weakness as a result of autoantibodies formed against presynaptic voltage-gated channels in the neuromuscular junction in the settings of small cell lung carcinoma and thymoma.

- Clinical manifestations of Lambert-Eaton myasthenic syndrome (LEMS) are like myasthenia gravis, which include insidious and progressive skeletal muscle weakness, difficulty in walking, fatigue, tingling sensation in the hands or feet, eyelid dropping, dry mouth, difficulty in speaking and swallowing, urinary bladder and bowel changes and erectile dysfunction.
- The target of the attack of autoantibodies is different in myasthenia gravis as the acetylcholine receptor on the nerve is affected, whereas in LEMS, target of the attack of autoantibodies is the voltage-gated calcium channel on the nerve.

Peripheral Neuropathy

Peripheral neuropathy occurs due to IgG autoantibodies against anterior and lateral horn cells of nervous system in patients with small cell lung carcinoma. Symptoms of peripheral neuropathy depend on the type(s) and location(s) of the damaged nerves. The most common peripheral neuropathy symptoms include numbness, tingling sensations and shooting pain or burning in fingers or toes.

Stiff-Person Syndrome

Stiff-Person syndrome (SPS) is a neurological disorder, that occurs due to formation of anti-amphiphysin and anti-GAD antibodies in patients with breast carcinoma and small cell lung carcinoma.

- Patient presents with progressive muscle stiffness (rigidity) and repeated episodes of painful muscle spasms in the trunk and limbs, severely impaired disability, and heightened sensitivity to stimuli such as noise, touch and emotional distress.
- Stiff-Person syndrome is treated by γ-aminobutyric acid and immunotherapy.

Opsoclonus-Myoclonus-Ataxia Syndrome

Opsoclonus-myoclonus-ataxia (OMA) syndrome is an immune-mediated disorder of the nervous system, that occurs due to formation of anti-Ri and anti-Hu antibodies in patients suffering from neuroblastoma and small cell lung carcinoma. Patient presents with rapid involuntary conjugate fast eye movements, twitching of a skeletal muscle or group of skeletal muscles, cerebellar ataxia, aphasia, mutism, abnormal behavior, sleep dysregulation and difficulty in talking.

Cerebellar Degeneration

Cerebellar degeneration is a rare acquired neurological disorder characterized by ataxia, vertigo, and dysarthria. It occurs due to formation of **IgG autoantibodies** against cerebellum in patient suffering from small cell lung carcinoma.

Dermatologic and Rheumatologic Manifestations of Internal Malignancies

Dermatologic and rheumatologic manifestations of internal malignancies include a wide variety of non-malignant skin disorders in association with malignancy.

- Dermatologic manifestations strongly associated with internal malignancies include acanthosis nigricans maligna, triple palms, Basex's acrokeratosis paraneoplastica, erythema gyratum repens, necrolytic migratory erythema, paraneoplastic pemphigus, florid cutaneous papillomatosis (Leser-Trélat sign), paraneoplastic dermatomyositis, hypertrophic osteoarthropathy, necrolytic migratory erythema, erythema gyratum repens, acquired hypertrichosis lanuginosa and paraneoplastic pemphigus.
- When paraneoplastic dermatoses develop before an internal malignancy is diagnosed, recognition of these cutaneous disorders can aid in the diagnosis of the internal malignancy.

Carcinoid Syndrome: Cyanotic Episodic Flushes over Face and Chest

Carcinoid syndrome is associated with malignant argentaffin tumors of the midgut (i.e. small intestine, cecum and appendix constitute 80% of cases) metastasizing to liver.

- Carcinoid syndrome is associated with argentaffin tumors of bronchus, larynx, pancreas, gallbladder, and ovary. Bronchial carcinoid tumor secretes histamine and 5-hydroxytryptophan in systemic circulation, which lacks decarboxylase to convert the latter into 5-hydroxytryptamine (serotonin).
- Patient presents with watery diarrhea, abdominal cramps, bronchospasm and cyanotic episodic flushes over face and chest, with right-sided valvular stenosis of the heart caused by the secretion of histamine, 5-hydroxytryptophan, and 5-hydroxytryptamine (serotonin) into the portal circulation, and 5-hydroxyindoleacetic acid (**5-HIAA**) found in the urine.

Acanthosis Nigricans Maligna

Acanthosis nigricans maligna differs from a typical acanthosis nigricans, which is characterized by sudden development of extensive and severe skin lesions over mucosa, palms and soles. Papillomatous thickenings around the lips and eyes may be the presenting feature.

- The vast majority of acanthosis nigricans maligna are secondary to **gastric adenocarcinoma**. But, acanthosis nigricans maligna can also be found in cancers of colon, lung, uterus, ovaries, and urinary tract.
- Patient with gastric adenocarcinoma synthesizes epidermal growth factor (EGF) results in hyperkeratosis, and pigmentation of the axilla, neck, intertriginous areas, flexures, and anogenital region

known as acanthosis nigricans. Approximately 50% patients with gastric carcinoma develop acanthosis nigricans maligna.

Tripe Palms: Unusual Cutaneous Paraneoplastic Syndrome

Tripe palms are cutaneous manifestation of paraneoplastic syndrome in internal malignancy and characterized by a curious thickening of the palms with an accentuation of the normal dermatographia ridges and sulci.

- Patient presents with yellowish, velvety, diffuse palmar hyperkeratosis with accentuated dermatoglyphic patterns leading to rough appearance in the settings of gastric carcinoma and lung carcinoma in 50% of cases.
- Less commonly associated malignancies include cancers of head and neck, breast, and genitourinary tract.

Basex's Acrokeratosis Paraneoplastica

Basex's acrokeratosis paraneoplastica is associated with squamous cell carcinoma of the oral cavity, pharynx, larynx, and esophagus. Clinical features are similar to psoriasis. Patient initially develops poorly defined psoriasiform plaques involving ears (helices), nose, fingers and toes including nail changes. Later, larger cutaneous palmoplantar keratoderma with central clearing appears on cheeks followed by involvement of the legs, knees, thighs, and arms.

Erythema Gyratum Repens

Erythema gyratum repens develops in internal malignancy in 80% of cases and lung carcinoma in 20% of cases. Patient presents with widespread serpiginous, polycyclic, and pruriginous erythema, which is fast growing desquamative lesion around the edges.

Necrolytic Migratory Erythema

Necrolytic migratory erythema is associated with slow-growing malignant tumor **glucagonoma** derived from α cells of pancreas. Patient presents with unusual dermatosis, recent onset of diabetes mellitus and weight loss. Although cutaneous manifestations may precede the diagnosis of glucagonoma by several years. Cutaneous lesions develop within 10 days, which begin with erythematous patch that blisters centrally, erodes, and then crusts over and heals by hyperpigmentation.

Paraneoplastic Pemphigus

Paraneoplastic pemphigus is associated with B cell lymphoproliferative disorders, thymoma, and various sarcomas and carcinomas. Patient presents with painful blisters and denuded areas of the mouth, lips, esophagus, and skin.

Florid Cutaneous Papillomatosis

Florid cutaneous papillomatosis is associated with gastric carcinoma. Patient presents with rapid onset of numerous warty papules on the trunk and the extremities that are clinically indistinguishable from viral warts. A skin biopsy is required to establish diagnosis.

Leser-Trélat Sign

Leser-Trélat sign is characterized by the sudden eruptions and rapid increase in size, and number of seborrheic keratoses in the settings of malignancies of gastrointestinal tract, lung, kidney, liver, or pancreas.

Paraneoplastic Dermatomyositis

Paraneoplastic dermatomyositis occurs before the onset of proximal skeletal muscle weakness in 10–25% cases of malignancies of breast, ovary, lung, and prostate.

- Patient presents with purplish skin rashes on upper eyelids, erythematous rash on the face, neck, chest and shoulders, and scaly eruption over the phalangeal joints.
- Diagnosis of dermatomyositis is suggested by an elevated level of **creatine phosphokinase**, electromyography, and muscle biopsy. Histologic examination of muscle biopsy shows mixed B cell and T cell perivascular inflammatory infiltrate and perifascicular muscle fiber atrophy.
- Patients with dermatomyositis must be screened for malignancies by imaging modalities of the chest, abdomen, and pelvis.
- Dermatomyositis is treated by administration of glucocorticoids and immunotherapy.

Hypertrophic Osteoarthropathy

Hypertrophic osteoarthropathy is characterized by periostitis ad subperiosteal new bone formation along the shaft of long bones and distal phalanges (digital clubbing), joint swelling and pain in 10% cases of bronchogenic carcinoma.

- Vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF) and prostaglandin E_2 are possible contributors to hypertrophic osteoarthropathy.
- Bone scan demonstrates symmetric and concentrated tracer uptake along these bones.
- The symptoms of hypertrophic osteoarthropathy resolve with successful cancer therapy. Other treatment options include nonsteroidal anti-inflammatory drugs (NSAIDs), bisphosphonates, opioid analgesics, and localized palliative radiation.

Vascular Manifestations

Vascular manifestations of paraneoplastic syndromes occur in patients with adenocarcinomas and metastatic disease without male or female predominance.

Leukocytoclastic Vasculitis

Leukocytoclastic vasculitis of paraneoplastic syndrome occurs most commonly in patients with hematologic malignancies, lung carcinoma, gastrointestinal tract carcinoma, and urinary tract carcinoma.

- Patient presents with palpable purpura over the lower extremities accompanied by pain, burning and pruritus. Constitutional symptoms such as fever and malaise are also common.
- Paraneoplastic leukocytoclastic vasculitis is attributed to circulating tumor-associated antigens, which leads to antigen–antibody complex deposits in small blood vessels, complement fixation resulting in vasculitis.
- Treatment of the malignancy leads to resolution of inflammation of small blood vessels.
- In addition, other treatment options include colchicine and corticosteroids for mild to moderate disease. Methotrexate, azathioprine or IVIg may be considered for resistant disease.

Thrombotic Microangiopathy

Thrombotic microangiopathy of paraneoplastic syndrome has been associated with mucin-secreting gastric adenocarcinoma, mucin-secreting colon adenocarcinoma, lung carcinoma, breast carcinoma, hepatocellular carcinoma, pancreatic carcinoma, cholangiocarcinoma, prostatic carcinoma, renal cell carcinoma, ovarian carcinoma, and hematologic malignancies (Hodgkin's disease, non-Hodgkin's disease, acute lymphoblastic leukemia, multiple myeloma).

- Thrombotic microangiopathy is characterized by microvascular thrombosis, thrombocytopenia, and ischemic end-organ damage. Hemolytic uremic syndrome and thrombotic thrombocytopenic purpura are the two subtypes of thrombotic microangiopathy.
- Activation of coagulation system cascade and the ensuring procoagulant state in cancer occurs due to release of procoagulant factor from CSCs, defective anticoagulant and fibrinolytic mechanisms, and damaged vascular endothelium.
- Solid malignant tumor may express different procoagulant molecules including tissue factor, which complexes with factor VIIa to activate factor IX and factor X. Cancer procoagulant activates factor X. Mucin secreting adenocarcinoma can induce the formation of platelet microthrombi.
- Endothelial damage can increase the risk of thrombosis by increasing von Willebrand factor, dysfunctional vascular endothelium, impaired coagulation system, and defective fibrinolysis.

Trousseau's Syndrome (Migratory Thrombophlebitis)

Trousseau's syndrome is defined as a migratory thrombophlebitis of paraneoplastic syndrome (venous thromboembolism accompanied by inflammation) in the context of malignancy. **Pancreatic adenocarcinoma** synthesizes thromboplastin-like substance that results in migratory thrombophlebitis.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation of paraneoplastic syndrome is an occasional complication of solid malignant tumors.

- Disseminated intravascular coagulation is characterized by the systemic activation of coagulation and results in the formation of thrombin throughout the microvasculature leading to consumptive coagulopathy. Widespread fibrin deposition within microvasculature leads to organ ischemia, and thrombotic microangiopathy.
- Disseminated intravascular coagulation is triggered by release of thromboplastic substances into the circulation in the settings of acute promyelocytic leukemia, mucin secreting gastrointestinal carcinoma, and prostatic carcinoma.
- Disseminated intravascular coagulation (DIC) has two consequences, i.e. (a) widespread fibrin deposition within microvasculature leads to organ ischemia and thrombotic microangiopathy, and (b) consumptive coagulopathy, and release of plasminogen activators.
- Acute DIC results in bleeding tendencies, whereas chronic DIC presents with thrombotic phenomena.
  - Patient presents with cyanosis, cerebral stroke, convulsions, acute renal failure, breathlessness, shock and coma.
  - Laboratory findings in DIC include thrombocytopenia and increased values of activated partial thromboplastin time (APTT), prothrombin time (PT) and D-dimers.
  - DIC is medical emergency that requires immediate administration of anticoagulants (e.g. heparin) and fresh frozen plasma (FFP).

Nonbacterial Thrombotic Endocarditis of Paraneoplastic Syndrome

Nonbacterial thrombotic endocarditis of paraneoplastic syndrome is characterized by the presence of sterile cardiac vegetations in aortic or mitral valves associated with systemic arterial thromboembolism. Nonbacterial thrombotic endocarditis is a common complication of lung adenocarcinoma, mucus secreting gastric

carcinoma, colorectal carcinoma, pancreatic carcinoma, breast carcinoma, cervical carcinoma, multiple myeloma, leukemias and non-Hodgkin's lymphoma.

Hematologic Manifestations

Hematologic manifestations of paraneoplastic syndrome are rarely symptomatic, which are usually detected after diagnosis of metastatic disease, which may improve with successful treatment of the underlying malignancy.

Secondary Eosinophilia

Secondary eosinophilia in hematology is a manifestation of paraneoplastic syndrome occurs as a result of production of eosinophil growth factors such as GM-CSF, IL-2, IL-3, and IL-5 in the settings of leukemias, non-Hodgkin's lymphoma, lung carcinoma and gynecologic malignancies.

- In contrast, primary eosinophilia is a separate hematologic clonal neoplastic disorder associated with gene rearrangements involving FIP1L1, PDGFRA, PDGFRB and FGFR1.
- Paraneoplastic eosinophilia is typically asymptomatic; however, some patients can develop dyspnea and wheezing, which may respond to corticosteroid therapy.

Agranulocytosis

Agranulocytosis is a hematologic manifestation of paraneoplastic syndrome occurs in about 15% of patients with solid malignant tumors of lung, breast, gastrointestinal tract, brain, and kidney including gynecologic cancers.

- White blood cell count ranges from 12 to 30×10^9/L, but in some patients exceed 5×10^9/L. Some solid malignant tumors have been shown to produce colony-stimulating activity.
- Alternatively, leukocytosis may result from bone marrow involvement by solid malignant tumor. Agranulocytosis manifestation of paraneoplastic syndrome does not require treatment.

Pure Red Cell Aplasia

Pure red cell aplasia (PRCA) with hematologic manifestation of paraneoplastic syndrome is most often associated with **thymoma**. Ineffective eradication of autoreactive T cells by neoplastic thymic tissue results in an autoimmune attack on red blood cell precursors.

- Pure red cell aplasia (PRCA) can also occur in settings of **leukemia** and **lymphoma** due to autoimmune dysfunctional erythropoiesis. It is worth mentioning that PRCA can occur in the settings of myelodysplasia and nonmalignant disorders such as infections with parvovirus B19, HIV, HBV, HCV, and herpesviruses.
- Bone marrow examination demonstrates failure of erythropoiesis but preservation of granulocyte lineage and megakaryocytes.
- Pure red cell aplasia with hematologic manifestation of paraneoplastic syndrome is treated by cancer therapy and immunosuppression. Corticosteroids, azathioprine, antithymocyte globulin, cyclophosphamide, cyclosporine A and monoclonal antibodies (e.g. rituximab and alemtuzumab) are being administered in these patients. Plasma exchange and androgen therapy are also used to treat these cases.

Thrombocytosis

Thrombocytosis occurs in about 35% of cancer patients. Thrombocytosis is defined by platelet count $>400 \times 10^9$/L.

- Thrombocytosis occurs due to malignant tumor production of cytokine IL-6. Serum IL-6 levels are analyzed to distinguish paraneoplastic syndrome-associated thrombocytosis, and reactive thrombocytosis processes from clonal etiologies (e.g. essential thrombocytopenia, polycythemia vera, myelodysplastic syndrome, acute leukemias and chronic leukemias).
- JAK2 V617F gene mutation is present in 50% cases of essential thrombocytopenia but not present in cases of reactive thrombocytosis.
- Thrombocytosis in paraneoplastic syndrome is usually associated with advanced cancer disease.

Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia (AIHA) of paraneoplastic syndrome is associated with malignant solid tumors (e.g. non-Hodgkin's lymphoma).

- Patients with AIHA as paraneoplastic syndrome manifestation are often refractory to corticosteroid therapy. AIHA occurs due to production of autoantibodies against tumor antigens, which cross react with erythrocyte antigen band 3.
- These patients are treated by targeted immunotherapy against autoimmune hemolytic anemia and solid tumors.

Renal Manifestations

Renal manifestations of paraneoplastic syndrome indirectly compromise glomerular and tubular function by electrolyte imbalance, hormone producing tumors or deposition of antigen–antibody complexes in the glomeruli. An early diagnosis and effective treatment

might improve quality of life and alter prognosis of these patients.

- Immune complex-mediated secondary glomerulonephritis has been associated with renal cell carcinoma, lung carcinoma, colon carcinoma, Hodgkin's disease, and non-Hodgkin's lymphoma.
- Tumor-derived antigen combined with antibody to form immune complexes, which are deposited in the glomeruli leading to glomerular injury. Patient presents with features of nephrotic syndrome, which is characterized by massive proteinuria (≥3.5 g/24 hours), hypoproteinemia, hypercholesterolemia, and generalized edema.

HOST DEFENSE AGAINST CANCER

The immune system can recognize and destroy nascent cancer stem cells in a process termed cancer immunosurveillance, which functions as important defense against cancer.

- Potential strength of immune surveillance is based on the knowledge that CSCs express tumor-associated antigens, and tumor-specific antigens (TSAs) of cancer that can be recognized by the immune system as foreign elements.
- Tumor-associated antigens (TAAs) and TSAs of cancer are categorized in four groups: (a) unique antigens specific for an individual malignant tumor, (b) overexpression of peptides or proteins that are found in normal tissues, (c) shared tumor antigens, and (d) viral antigens that may be shared among different cells, but confined to malignancy.
- Natural killer cells and gamma-delta T cells (γδ-T cells) are capable of specifically recognizing and killing CSCs. Cancer patients generate CD4+ helper T cells, CD8+ cytotoxic T cells and B cells specific for these tumor antigens.
- Tumor-specific lymphocytes are found infiltrating malignant tumors and in the peripheral blood of cancer patients. Macrophages are also part of the nonspecific natural immune response to CSCs, which are activated by interferon-gamma (IFN-γ).
- Development of cancer can be explained by the ability of CSCs to evade immune destruction either due to failure of immune system to be adequately generated or by induction of immune tolerance or other inhibitory mechanisms that allows malignant tumor to escape immune detection and destruction.
- In contrast to malignant tumors induced by carcinogens, in which each malignant tumor has unique antigenic specificity regardless of their morphologic appearance of malignant tumors induced by viruses consistently express antigens that cross-react with other malignant tumor induced by the same or similar viruses even though their morphologic appearance may differ.
- The importance of the immune system in preventing cancer is reflected in the increased frequency of malignancies in immunosuppressed and immunodeficient patients. Cancer immune evasion is a major block in designing effective anticancer therapeutic strategies.

CANCER IMMUNOSURVEILLANCE AND IMMUNOEDITING

Carcinogenesis is a multistep process resulting from cross-talk of CSC intrinsic factors and host system effects. During cancer immunosurveillance, immunoediting process consists of three phases: elimination, equilibrium, and escape.

- **Immunoediting elimination phase:** Immunoediting elimination phase corresponds to cancer immunosurveillance in which nascent CSCs are successfully recognized and eliminated by the immune system, thus returning the tissues to their normal state of function.
- **Immunoediting equilibrium phase:** Cancer stem cells (CSCs) that elude the surveillance phase will progress to immunoediting equilibrium phase, where malignant tumor expansion and metastasis are minimal (tumor dormancy), and usually occur without symptoms. In a second scenario, constant interaction of immune system leads to immunoselection of malignant tumor that has been shaped into less-immunogenic state.
- **Immunoediting escape phase:** As immune system may eventually eliminate CSCs during immunoediting equilibrium phase. CSCs are no longer susceptible to immune attack leading to immunoediting escape phase.

Innate Immune System Role in Tumor Immunity

Innate immune system plays an important role in resistance against the development and progression of malignant tumor growth. Macrophages and mast cells activate vascular and fibroblasts, which eliminate cancer cells and initiate local tissue repair.

- Dendritic cells, on the other hand, take up tumor antigens and migrate to lymphoid organs, where dendritic cells process peptides and present to T cells for the induction of specific antibody by B cells and cell-mediated immune responses.
- Natural killer cells also play key role in cellular cross-talk between innate and adaptive immune cells through their ability to interact bidirectionally with dendritic cells.
- Natural killer cells regulate dendritic cells by two mechanisms: (a) elimination of immature dendritic

cells and (b) promotion of maturation and activation of dendritic cells. Induction of efficient adaptive immune response requires direct interactions with tumor-associated antigen-presenting cells (APCs) and a strong proinflammatory milieu.

Adaptive Immune System Role in Tumor Immunity

Tumor-associated antigens (TAAs) consist of short amino acid peptide segments, which are recognized by T cells through T cell receptors (TCRs) in the context of MHC-I molecule on the surface of CSCs and MHC-II molecule on the surface of antigen-presenting cells (APCs). Tumor-associated antigens are processed by exogenous and endogenous pathways.

- MHC (HLA) class I molecule is recognized by CD8+ cytotoxic T cells. MHC (HLA) class II molecules are chiefly found on immunocompetent professional APCs such as macrophages, dendritic cells (DCs), Langerhans cells, B cells, and CD4+ helper T cells.
- Antigen-presenting cells (APCs) present antigen to naïve CD4+ helper T cells, because of their ability to process endocytosed antigens, and partly possessing cell surface proteins, that bind to T cell surfaces. CD4+ helper T cells become activated to synthesize an array of cytokines. Activated CD4+ helper T cells mature and differentiate into CD4+ helper T cell populations (**Th1, Th2, Th17** and **Treg**). Activated CD4+ helper T cells promote cell-mediated immunity and antibody production through B cell interaction.
- Tumor-associated antigens (TAAs) shed from CSCs are endocytosed by resident dendritic cells (DCs) in the tumor microenvironment, and following cognate presentation of MHC-I molecule or MHC-II to CD8+ cytotoxic T cells and CD4+ helper T cells (Th17) activation respectively.
- There is clonal expansion of antitumor CD8+ cytotoxic T lymphocytes (CTLs), that secrete proangiogenic factors (e.g. VEGF) and chemotactic factors for recruitment of dendritic cells (DCs). Activation of Th17 cells synthesize IL-17 that induces CSCs to secrete chemotactic factors (e.g. CXCL9 and CXCL10) leading to the recruitment of additional cytotoxic effector cells (i.e. natural killer cells and CD8+ cytotoxic T cells).

Cross Presentation and Priming of Tumor Antigens

Antigen-presenting cells (APCs) process and present tumor antigens to naïve T cell, and induce antitumor immune responses. T cell activation requires two distinct signals (signal 1 and signal 2).

- **Signal 1** is transmitted by the interaction between T cell receptor (TCR) and antigenic peptide fragments on MHC molecules on APCs.
- **Signal 2** is transmitted by one of co-stimulatory molecules, i.e. binding of CD28 molecule on T cells with B7 family molecules on APCs. CSCs frequently stimulate signal 1 alone and inefficiently signal 2 activate naïve T cells in a process called cross-priming. Accordingly, cancer cells preferentially induce T cell unresponsiveness or immune tolerance.

CD8+ Cytotoxic T Cells and Natural Killer Cells Role in Killing Cancer Stem Cells

Antigen-presenting cells (APCs) process cancer-peptide-loaded MHC-I molecule and present to CD8+ cytotoxic T cells leading to effective CSC killing.

- During transformation of a normal cell to CSC, the CSCs may lose MHC-I molecule on its cell membrane as a part of its evasion strategy to elude its destruction by CD8+ cytotoxic T cells. In the event of loss of MHC-I molecule expression by CSCs, natural killer cells interaction with CSCs can only occur through killer-activating receptor (KAR) ligand, leading to their destruction.
- Natural killer cells can also destroy CSCs by antibody-dependent cytotoxicity (ADCC) mechanism, where the Fab portion of an IgG antibody produced by B cells binds to surface tumor-specific antigen and bridges to the Fc receptor on the natural killer cells.

CD4+ Regulatory T Cells (Treg Cells) Role in Tumor Immunity

CD4+ regulatory T cells (Treg cells) are recruited in the periphery of the tumor microenvironment. Treg cells suppress the immune responses directed against tumor-associated antigens (**TAAs**) by influencing the activity of antigen-presenting cells (APCs) and dendritic cells (DCs), which become dysfunctional by the elaboration of immunoregulatory cytokines IL-10 and TGF-β in the tumor microenvironment.

- T cells are divided into three populations: (a) classic CD4+ CD25+ FOXP3+ regulatory T cells, (b) CD4+ IL-10+ FOXP3– regulatory T cells, and (c) CD4+ TGF-β+ T cells.
- CD4+ regulatory T cell-mediated immune system suppression evades CSCs immune destruction is crucial and it is the main hurdle for the successful tumor immunotherapy. CSCs secrete CCL22 chemokine, that binds to CCL4 chemokine receptor on recruited Treg cells.
- Following cytokines release from CSCs, TAAs are taken up by DCs resulting in activation of effector CD4+ CD25– T cells.
- Cancer stem cells (CSCs) secrete TGF-β that converts CD4+ CD25– T cells into CD4+ CD25+ Treg cells leading to further immunosuppression activity. VEGF secreted by CSCs stimulates angiogenesis.

Antibody-mediated Cancer Stem Cells Destruction

In addition to indirect beneficial role of antibody in the ADDC mechanism of CSCs destruction, and can play a direct role in tumor immunity. Antibody directed to TAAs together with activation of complement system can destroy the CSCs by cytolytic action of the C5b–C9 **MAC** complement cascade. TAA alone or as antigen–antibody complexes can interfere with the CD8+ cytotoxic T cell destruction of CSCs by blocking its activity.

CANCER STEM CELLS EVASION OF IMMUNE RESPONSE

Cancer stem cells (CSCs) escape immune destruction by many potential mechanisms: (a) downregulation of potential target tumor-associated antigens, (b) inhibition of the T cell response, and (c) direct modulation of pro-inflammatory cytokines. These CSC evasion mechanisms may serve as novel targets for cancer therapy.

Role of Immunoregulatory Enzyme Indoleamine 2,3-Dioxygenase

Cancer stem cells (CSCs) escape immune destruction resulting from activation of immunoregulatory enzyme **indoleamine 2,3-dioxygenase (IDO)** produced by macrophages and other immunoregulatory cells. Upregulation of enzyme IDO leads to conversion of tryptophan to kynurenine, which are involved in malignant tumor growth and immunosuppression by blunting T effector cell function as well as recruitment of Treg cells. Enzyme IDO dysregulation induces malignant tumor growth through its ability to inactivate tumor suppressor gene **Bin-1**, as well as by incapacitating effective tumor immunosurveillance mechanisms.

Inflammatory Cytokines Synthesis in Tumor Microenvironment

The inflammatory tumor microenvironment consists of numerous cells, cytokines, enzymes and signaling pathways. Cancer-related inflammation possesses both pro-tumor and anti-tumor features. Activated immune cells induce the production of pro-inflammatory cytokines, which bind to cognate receptors and enzymes, which inhibit malignant tumor growth.

- TNF-α contributes to epithelial–mesenchymal transition (EMT), CSC proliferation and angiogenesis. TGF-β contributes to EMT, evasion of immune destruction of CSCs, and suppresses apoptosis. IL-6 activates STAT proteins, suppression of apoptosis leading to release of reactive oxygen species (ROS) and reactive nitrogen species (RNS).
- Cancer-related inflammation is also involved in initiation, promotion, and progression by various mechanisms.
  - The initiation of carcinogenesis requires a series of genetic mutations and epigenetic modifications, that lead to the activation of tumorigenic pathway as well as loss of tumor suppression.
  - In inflammatory tumor microenvironment, immune cells (i.e. macrophages and neutrophils) synthesize reactive oxygen species (ROS) as well as reactive nitrogen species (RNS), which can cause DNA damage leading to initiation of tumorigenesis process.
- Furthermore, genetic alterations can be induced by cytokines secreted by immune cells in the inflammatory tumor microenvironment. Excess production of TNF-α and other proinflammatory cytokines induce systemic effects of fever, weight loss, malaise, cachexia in cancer patients with extensive disease.

Chronic Inflammation in Tumor Immunity or Progression

Chronic inflammation perturbs innate or adaptive immune responses that initiates tumorigenesis in the settings of ulcerative colitis, rheumatoid arthritis, and pancreatitis. Some infectious pathogens can initiate tumorigenesis.

- *Helicobacter pylori* causes chronic gastritis , metaplasia and dysplasia in infected hosts leading to development of gastric adenocarcinoma and gastric mucosa-associated lymphoid tissue (MALT) lymphoma.
- Hepatitis B virus (HBV) or hepatitis C virus (HCV) are linked to chronic hepatitis, cirrhosis, and hepatocellular carcinoma.
- Human papillomavirus (HPV 16, 18) has been linked to development of cancers of uterine cervix, vulva, vagina, anus, and penis.
- Unresolved inflammation resulting from exposure to carcinogenic agents, ultraviolet rays, cigarette smoking, gastroesophageal reflux disease (GERD), and failure of elimination of injurious agents have been linked to development of cancers.

Myeloid-derived Suppressor Cells

Myeloid-derived suppressor cells (MDSCs) are immature myeloid cells, which have potent mechanism to inhibit T cell and natural killer cell activity to promote malignant tumor growth, development of premetastatic niche, and contribute to resistance to immunotherapy.

- In the bone marrow, hematopoietic stem cells (HSCs) can differentiate into common progenitor cells, and then to immature myeloid cells under the influence of several growth factors (i.e. GM-CSF, M-CSF, SCF, IL-3 and FLT-3). The immature myeloid cells migrate into peripheral tissues, where they can differentiate and participate in either physiologic or pathologic conditions according to the local environment.

- In pathologic conditions there is a partial block in the differentiation of immature myeloid cells, which leads to abnormal expansion of myeloid-derived suppressor cells (MDSCs).
  - MDSCs express STAT-induced immune suppressive factors, such as arginase 1, inducible nitric oxide synthase (iNOS) and reactive oxygen species.
  - MDSCs also induce downregulation in expression of cell surface molecules like MHC-I, and subsequent suppression of antigen-specific T cell activation.

Innate Lymphoid Cells

Innate lymphoid cells (ILCs) lack rearranged antigen-specific receptor (TCR or BCR). In response to tissue damage, ILCs contribute to immunity via the secretion of signaling molecules (cytokines IL-4, IL-5, IL-13, IL-22), and regulation of both innate and adaptive immune responses. ILCs are abundant in tissues of skin, lung, liver, and gastrointestinal tract.

- Innate lymphoid cells (ILCs) are immune cells derived from common lymphoid progenitors (CLPs), which differentiate to produce committed ILC progenitors leading to formation of cytotoxic ILCs (e.g. CD8+ cytotoxic cells, NK cells), and helper T cell-like ILCs (i.e. ILC1, ILC2, ILC3 subsets).
- CD8+ cytotoxic ILCs secrete IFN-γ that kill CSCs and inhibit their proliferation. CD8+ cytotoxic ILCs also stimulate NK cells and upregulate the expression of MHC class I and MHC class II molecules on CSCs, as well as adhesion molecules and transcription factors in T cells that mediate CSCs killing. IFN-γ also induces the expression of CXCL10/IP-10 and MIG, a member of the CXC subfamily of chemokines in endothelial cells, both of which inhibit tumor angiogenesis.

TUMOR MARKERS: DIAGNOSTICS IN CLINICAL PRACTICE

Current clinical practice in oncology has a growing impetus on screening, early diagnosis, proper prognostication, staging, evaluation in postoperative cases, monitoring therapeutic response, surveillance for recurrence, and targets for therapeutic intervention.

- Cancer stem cells (CSCs) produce substances, many of which are proteins, which are helpful in diagnosis and monitoring of treatment. Tumor markers include a variety of substances like cell surface antigens, cytoplasmic proteins, enzymes, isoenzymes, hormones, oncofetal proteins, receptors, oncogenes, and their products. Detection of tumor markers can be done either in tissues or body fluids like pleural fluid, ascitic fluid, serum, urine, and cerebrospinal fluid.

Table 6.107 Characteristics of an ideal tumor marker

Characteristics	Comments
Highly sensitivity tumor marker	Tumor marker is detected in patients with malignant tumor and not detectable in physiologic or benign disease states
Long lead-time over clinical diagnosis	Sufficient time for alteration of natural course of disease
Levels correlate with malignant tumor burden	Prognostic and predictive utility of the tumor marker
Short half-life of tumor marker	Frequent serial monitoring of the tumor marker levels after 5–6 half-lives
Simple and cheap tumor marker test	Applicability as screening test to detect cancer
Easily obtainable specimens for testing	Acceptability of the tumor marker by target population

- An ideal tumor marker has important characteristics: (a) it should be highly-specific to a given malignant tumor, (b) it should provide a lead time over clinical diagnosis, and (c) it should be highly-sensitive to avoid false-positive results. In addition, tumor marker should correlate reliability related to malignant tumor burden, accurately reflecting disease progression and/or regression by doing serial tumor marker analysis. Characteristics of an ideal tumor marker are given in Table 6.107.
- Carcinoembryonic antigen (CEA) represents dedifferentiation process of cancer. HER2/neu and prostate-specific antigen (PSA) reflect increased cellular proliferation. Some tumor markers such as β-hCG and α-fetoproteins are estimated to monitor the response to therapy in germ cell tumors of testes.

MOLECULAR BASIS OF TUMOR MARKERS

Genetic alteration in malignant tumor can be reflected at various levels from viral genome incorporation to genetic defects, which form the molecular basis of tumor markers. Molecular basis of tumor markers is given in Table 6.108.

TUMOR MARKERS: DETECTION METHODS

Detection methods of tumor markers can be classified into six major groups. The most common method in use today is serological enzyme assays. Methods of detection of tumor markers are given in Table 6.109.

- Immunological detection of tumor markers relies on monoclonal antibodies, that specifically bind to epitopes on CSCs and are in turn tagged for

Table 6.108 Molecular basis of tumor markers

Levels of Classification of Tumor Markers	Examples of Tumor Markers
Deoxyribonucleic acid (DNA) level	
Epigenetic alterations	Promoter hypermethylation, e.g. DAP in lung cancers, p15, p16 in hepatocellular carcinoma
Endogenous alterations	Mutations, e.g. NADH dehydrogenase 4
Mitochondrial alterations	ND4 analysis in urine in patients with urinary bladder carcinoma
Gene level	
Oncogene	KAS mutation in pancreatic carcinoma, microsatellite alterations in head and neck cancers
Exogenous viral oncogene	EB virus in nasopharyngeal carcinoma and Burkitt's lymphoma; HPV in cervical carcinoma
Ribonucleic acid (RNA) level	
Cell based endogenous RNA	Tissue-specific markers (PSA mRNA in prostatic carcinoma, cytokeratin 20 mRNA in breast carcinoma)
Cell-free based endogenous RNA	Circulating mRNA, e.g. tyrosinase mRNA in melanoma
Exogenous viral RNA	Viral RNA, e.g. EB virus coded RNA in nasopharyngeal carcinoma
Translational protein level	
Native protein (conventional tumor marker)	Prostate-specific antigen (PSA) in prostatic carcinoma, and CEA in colon carcinoma
Glycan	Aberrant glycosylation in hepatocellular carcinoma

AFP: α-Fetoprotein; CEA: Carcinoembryonic antigen; HPV: Human papillomavirus; mRNA: Messenger RNA; PSA: Prostate-specific antigen.

Table 6.109 Methods of detection of tumor markers

Serology	Assay
Immunological analysis	▪ Immunohistochemistry technique ▪ Radioimmunoassay ▪ Enzyme-linked immunosorbent assay
Flow cytometry	Single or multiple cells suspended in buffered salt-based solution analysis for visible light scatter and fluorescence parameters
Cytogenetic analysis	▪ Fluorescence *in situ* hybridization (FISH) ▪ Spectral karyotyping ▪ Comparative genomic hybridization
Genetic analysis	▪ Sequencing (automated) ▪ Reverse transcription ▪ Gel electrophoresis ▪ DNA microarray analysis
Proteomics	Surface enhanced laser desorption/ionization

identification with dyes in immunohistochemistry (IHC), radioactive tags in radioimmunoassay (RIA) or enzymes in enzyme-linked immunosorbent assay (ELISA). Alternatively, in a suspension, **flow cytometry** can analyze the presence and percentage of antibody tagged CSCs. These diagnostic methods are highly sensitive and can detect quantities in the nanogram to picogram range.

- Of these diagnostic techniques, the most used technique today is immunohistochemistry. Uses of immunohistochemistry technique in clinical oncology include categorization of undifferentiated malignant tumors, leukemia and lymphomas, determination of site of origin of metastatic tumors, and detection of molecules of prognostic or therapeutic significance, e.g. estrogen/progesterone receptors (ER/PR) in breast cancer.

TUMOR MARKERS: CLASSIFICATION AND USES

Tumor markers can be detected in tissues (tissue tumor markers, e.g. in solid malignant tumors, lymph nodes, bone marrow or circulating CSCs in the bloodstream or in the body fluids such as pleural fluid, ascitic fluid, cerebrospinal fluid or serum (serological tumor markers). Monoclonal antibodies are used to detect tumor antigens of specific malignant tumor. These serum tumor markers are most useful for monitoring response to therapy and detecting early relapse.

- Tissue tumor markers are of prime importance to a diagnostic pathologist, while serological markers are more often used by clinical oncologist depending on the clinical scenario ranging from initial clinical presentation, differential diagnosis and recurrence of malignant tumor.
- Laboratory-based tests are potentially useful in screening and early detection, diagnostic confirmation, prognosis, and prediction of therapeutic response or resistance and monitoring therapy in advanced cancer and recurrence. **Ki-67** (proliferative index marker) may help in prognostication and choice of therapy in cancer patients.

- Currently, cancer detection methods are not 100% specific to screen apparently healthy population for occult malignancies using a tumor marker as many tumor markers may be elevated in benign conditions. Some of the most useful tumor markers include: prostate-specific antigen (PSA), prostatic acid phosphatase (PAP), CA 125, carcinoembryonic antigen (CEA), α-fetoprotein (AFP), human chorionic gonadotropin and CA 19-9. CEA and AFP are normally expressed during fetal development, but do not occur normally in the tissues or sera of children and adults.
- Carcinoembryonic antigen (CEA) tumor marker is analyzed in occult blood in early colorectal carcinoma. CEA is increased in malignant epithelial tumors of colon, pancreas, lung, stomach, and breast.
- Expression of AFP by CSCs is considered a manifestation of dedifferentiation. The undifferentiated CSCs tend to resemble their embryonic counterparts. AFP is increased in hepatocellular carcinoma and yolk sac tumor (endodermal sinus tumor) of testis and ovary. AFP is also increased in fetal anencephaly and other neural tube defects.
- CA 125 tumor marker is analyzed to monitor therapy in patients with ovarian surface epithelial carcinoma. Estrogen receptors (ERs) are analyzed to predict response to hormonal therapy (tamoxifen drug). Human epidermal growth factor receptor 2 (HER2) analysis in women with breast carcinoma is likely to respond to trastuzumab (Herceptin).
- Tumor markers in cancers of head and neck, lung, mesenchymal and paraneoplastic syndromes are shown in Fig. 6.128. Tumor markers in cancers of liver, pancreas, colorectal region, gastric region and adrenals are shown in Fig. 6.129. Tumor markers and associated malignancies are given in Table 6.110. Some of the recommended uses of tumor markers in clinical practice are given in Table 6.111. Tumor markers in cancers of breast, kidney, urinary bladder, prostate, testes, ovaries, endometrium, and cervix are shown in Fig. 6.130.

RECOMMENDATIONS FOR ADVISING TUMOR MARKER TESTS

Serum tumor markers are not recommended for screening asymptomatic patients for malignancy, because serum tumor markers lack specificity and sensitivity. Many patients may have an elevated rserum tumor marker level due to benign disease. Many patients with malignancy can have a normal serum tumor marker level.

- Single serum tumor marker test is unreliable by itself. It is worth mentioning in most situations, elevation of serum tumor markers in benign conditions are most often transient, whereas elevations of serum tumor marker with cancer either remain constant or continuously remain elevated.
- Serial serum tumor testing can help in detection of false positivity due to transient elevation. Therefore, treatment of patients cannot be initiated without undisputable documentation of disease on histologic examination.

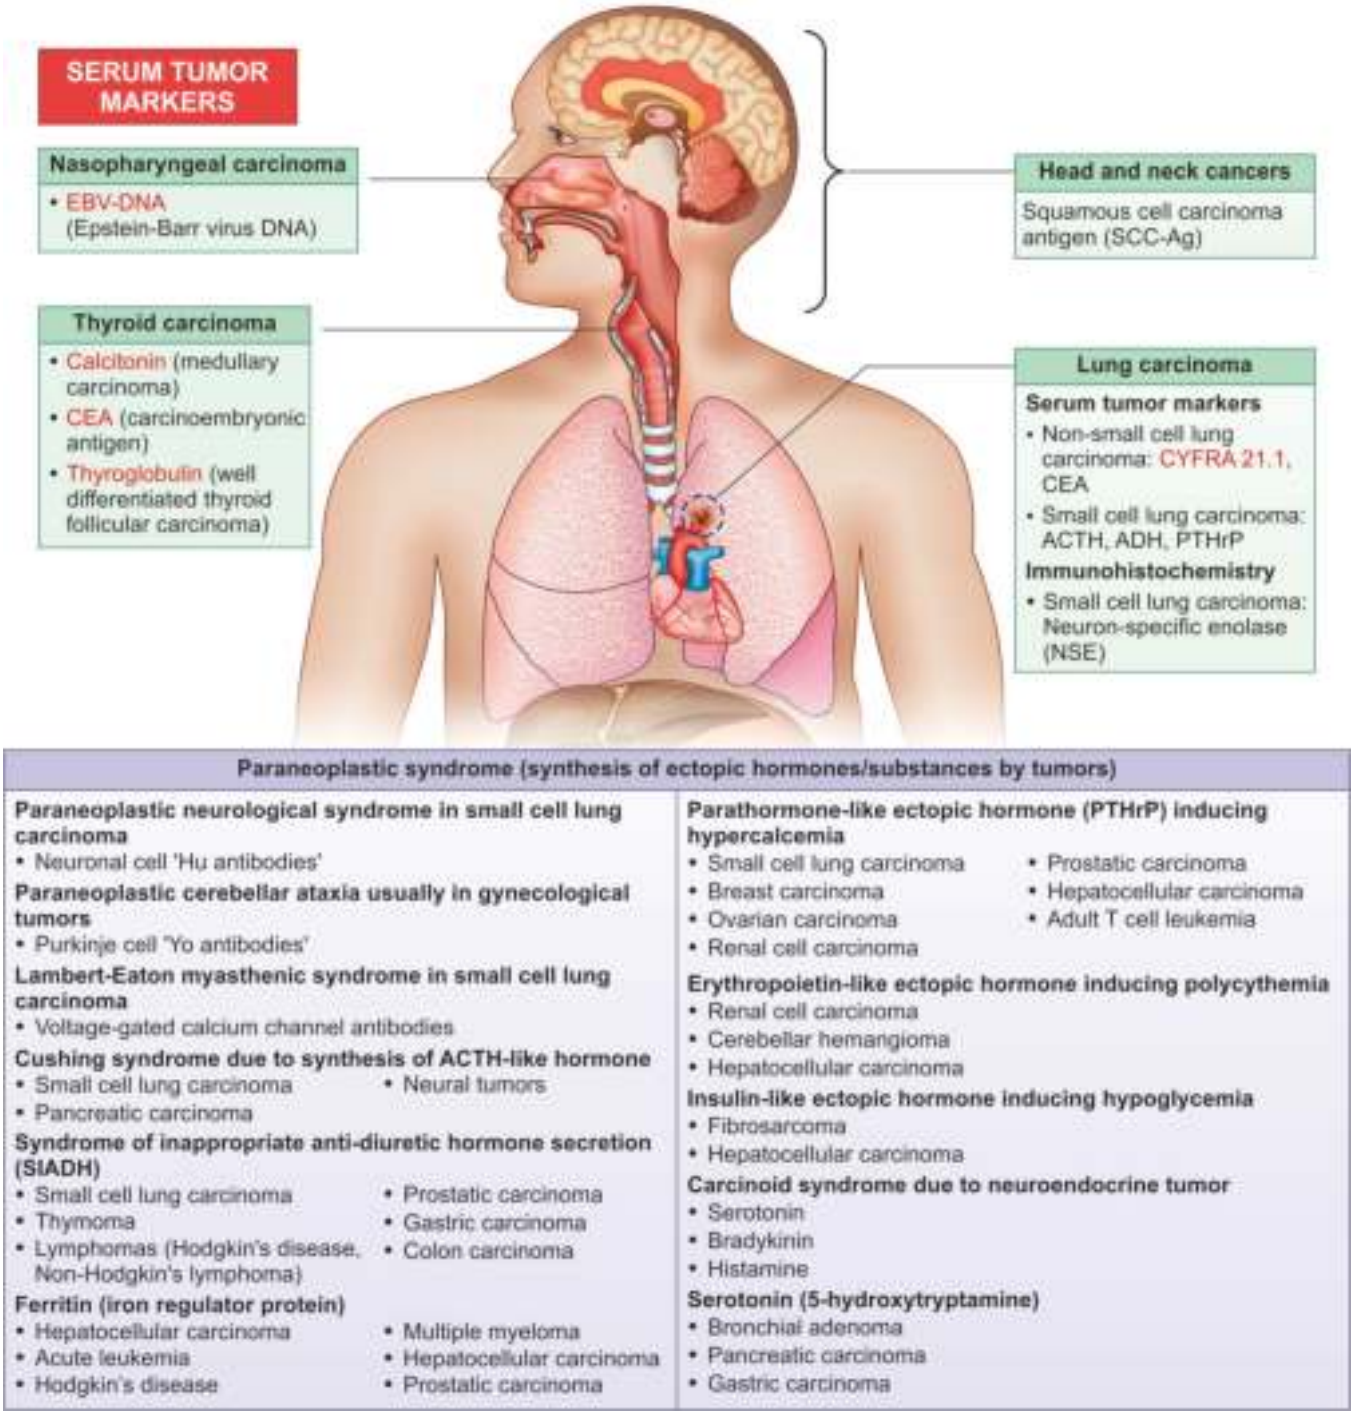
DIAGNOSTIC APPROACH OF CANCER

Cancer diagnostics is concerned with diagnostic approach of cancer taken into consideration of clinical history, physical examination, radiographic evaluation of possible metastatic disease, laboratory blood and urine tests including tumor markers, cytologic examination of cells (e.g. exfoliative cytology, fine needle aspiration cytology, liquid-based cytology), pathologic evaluation of malignant tumors, e.g. gross morphology (tumor characteristics), histologic examination, different immunohistochemical panels to analyze specific histologic dilemma, histochemistry, electron microscopy, and molecular markers for prognosis and predictive value.

CLINICAL HISTORY

The taking of an initial clinical history from the cancer patients, presenting symptoms, lifestyle and his/her family members is challenging as compared with the standard clinical medical history.

- Oncologist should listen to the cancer patient's complaints carefully, and not interrupting and without leading questions.
- Analyzing complaints and collecting anamnesis are the most important factors, and no detail should be overlooked.
- Physical examination of cancer patients should be strictly systemic and based on consistency.
- There are five cancer-specific steps that are essential for completing clinical history and physical examination for a new patient in a cancer care visit: (a) obtaining information according to malignant tumor type, (b) determining cancer diagnostic approach up-to-date, (c) obtaining a relevant cancer-focused clinical history, (d) performing detailed head-to-toe physical examination, and (e) performing appropriate organization of the data to prepare a professional presentation and complete appropriate documentation.



Paraneoplastic syndrome (synthesis of ectopic hormones/substances by tumors)

Paraneoplastic neurological syndrome in small cell lung carcinoma
- Neuronal cell 'Hu antibodies'

Paraneoplastic cerebellar ataxia usually in gynecological tumors
- Purkinje cell 'Yo antibodies'

Lambert-Eaton myasthenic syndrome in small cell lung carcinoma
- Voltage-gated calcium channel antibodies

Cushing syndrome due to synthesis of ACTH-like hormone
- Small cell lung carcinoma
- Neural tumors
- Pancreatic carcinoma

Syndrome of inappropriate anti-diuretic hormone secretion (SIADH)
- Small cell lung carcinoma
- Thymoma
- Lymphomas (Hodgkin's disease, Non-Hodgkin's lymphoma)
- Prostatic carcinoma
- Gastric carcinoma
- Colon carcinoma

Ferritin (iron regulator protein)
- Hepatocellular carcinoma
- Acute leukemia
- Hodgkin's disease
- Multiple myeloma
- Hepatocellular carcinoma
- Prostatic carcinoma

Parathormone-like ectopic hormone (PTHrP) inducing hypercalcemia
- Small cell lung carcinoma
- Breast carcinoma
- Ovarian carcinoma
- Renal cell carcinoma
- Prostatic carcinoma
- Hepatocellular carcinoma
- Adult T cell leukemia

Erythropoietin-like ectopic hormone inducing polycythemia
- Renal cell carcinoma
- Cerebellar hemangioma
- Hepatocellular carcinoma

Insulin-like ectopic hormone inducing hypoglycemia
- Fibrosarcoma
- Hepatocellular carcinoma

Carcinoid syndrome due to neuroendocrine tumor
- Serotonin
- Bradykinin
- Histamine

Serotonin (5-hydroxytryptamine)
- Bronchial adenoma
- Pancreatic carcinoma
- Gastric carcinoma

Fig. 6.128: Tumor markers in cancers of head and neck, lung, mesenchymal and paraneoplastic syndromes.

- Oncologist gathers detailed account of the patient's current symptoms such as change in bowel or urinary bladder habits, non-healing sore, unusual bleeding, or discharge, lump, obvious change in a mole, and persistent cough or hoarseness. General signs and symptoms of advanced and metastatic cancer include: fatigue, unexplained weight loss, and shortness of breath. It should be remembered that pain is not characteristic of early cancer disease. In the presence of malignant tumor related to gynecology, it is essential to clarify the state of menstrual cycle (i.e. time of onset of menstruation, duration, periodicity, and age at which menopause began).
- Examination of cancer patients should be strictly based on consistency, analyzing complaints, and collecting personal history are the most important factors and no detail should be overlooked.

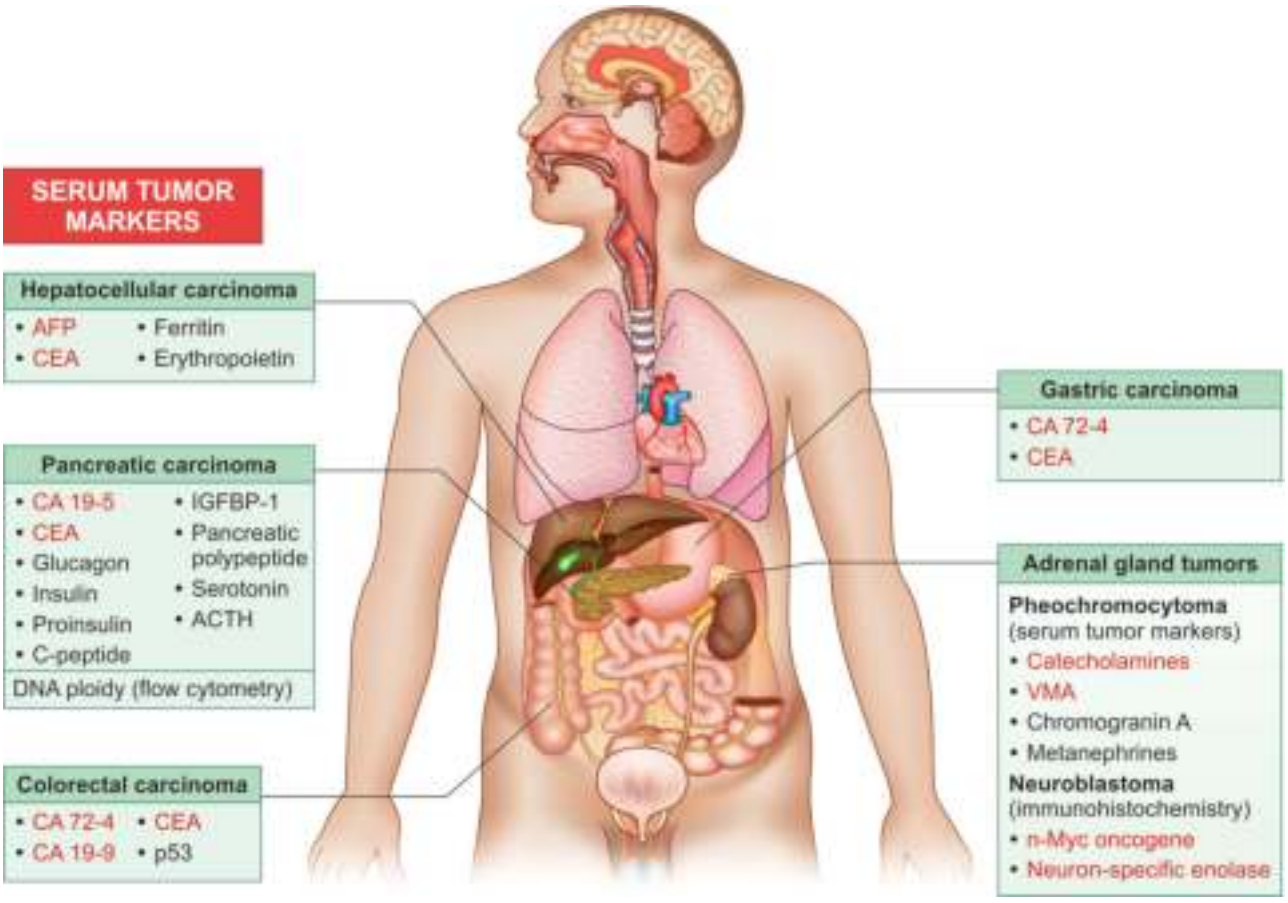


Fig. 6.129: Tumor markers in cancers of liver, pancreas, colorectal region, gastric region and adrenals.

Table 6.110 Tumor markers and associated malignancies

Serum Tumor Markers	Associated Malignancies and Other Disorders
Oncofetal antigens	
α-Fetoprotein (AFP)	▪ Hepatocellular carcinoma (75%) ▪ Yolk sac tumor (endodermal sinus tumor) of testis or ovary ▪ Hepatoblastoma ▪ Benign conditions (pregnancy, hepatitis and cirrhosis, inflammatory bowel disease)
Carcinoembryonic antigen (CEA)	▪ Non-seminomatous germ cell tumors of testes ▪ Colon carcinoma ▪ Gastric carcinoma ▪ Pancreatic carcinoma ▪ Lung carcinoma ▪ Breast carcinoma ▪ Benign conditions (hepatitis, pancreatitis, cigarette smokers, benign nodular hyperplasia of prostate, inflammatory bowel disease and hemolytic anemia)
Hormones	
Human chorionic gonadotropin (hCG) in blood and urine	▪ Choriocarcinoma ▪ Seminoma with syncytiotrophoblastic element ▪ Dysgerminoma with syncytiotrophoblastic element ▪ Benign conditions (pregnancy, tobacco smokers, and marijuana use in patients)
Calcitonin	▪ Medullary thyroid carcinoma ▪ Hepatocellular carcinoma ▪ Renal cell carcinoma
Ectopic adrenocorticotropic hormone (ACTH)	▪ Small cell lung carcinoma ▪ Pancreatic carcinoma ▪ Neural tumors

Contd...

Table 6.110 Tumor markers and associated malignancies (*Contd...*)

Serum Tumor Markers	Associated Malignancies and Other Disorders
Antidiuretic hormone/atrial natriuretic hormone (ADH/ANH)	▪ Small cell lung carcinoma (most common) ▪ Intracranial neoplasms ▪ Thymoma ▪ Prostate carcinoma ▪ Gastric carcinoma ▪ Colon carcinoma ▪ Hodgkin's disease ▪ Non-Hodgkin's lymphoma
Ectopic parathyroid hormone-related protein (PTHrP)	▪ Small cell lung carcinoma ▪ Squamous cell lung carcinoma ▪ Breast carcinoma ▪ Ovarian surface epithelial carcinoma ▪ Renal cell carcinoma ▪ Prostatic carcinoma ▪ Adult T cell lymphoma ▪ Hepatocellular carcinoma ▪ Tumors with neuroendocrine differentiation
Ectopic insulin hormone	▪ Fibrosarcoma ▪ Mesenchymal sarcoma ▪ Hepatocellular carcinoma
Ectopic erythropoietin hormone	▪ Renal cell carcinoma ▪ Cerebellar hemangioma ▪ Hepatocellular carcinoma ▪ Uterine leiomyomas
Serotonin	▪ Bronchial adenoma ▪ Pancreatic carcinoma ▪ Gastric carcinoma
Ferritin	▪ Hepatocellular carcinoma ▪ Acute leukemia ▪ Hodgkin's disease ▪ Multiple myeloma ▪ Malignant lymphoma ▪ Prostatic carcinoma
TSH-like (causing hyperthyroidism)	▪ Hydatidiform mole ▪ Choriocarcinoma ▪ Lung carcinoma (in some cases)
Enzymes	
Prostatic acid phosphatase (PAP)	▪ Prostatic carcinoma ▪ Prostatic acid phosphatase is also increased in prostatitis and benign prostate hyperplasia
Lactate dehydrogenase	▪ Germ cell tumors ▪ Acute leukemias ▪ Malignant lymphoma ▪ Metastatic carcinomas of colon, breast, and lung
5'-Nucelotide phosphodiesterase	▪ Lung carcinoma ▪ Liver metastases
Neuron-specific enolase (NSE)	▪ Small cell lung carcinoma ▪ Neuroblastoma
Terminal deoxynucleotidyl transferase (TdT)	Acute lymphoblastic leukemia
Thymidine kinase	▪ Hodgkin's disease ▪ Certain leukemias ▪ Small cell lung carcinoma
Isoenzymes	
CK-BB (nonspecific marker)	▪ Prostatic adenocarcinoma ▪ Lung adenocarcinoma ▪ Gastric adenocarcinoma
Type 2 macro-CK (oligomeric mitochondrial CK)	▪ Metastatic liver carcinoma ▪ Various malignancies
Type 1 macro-CK (complex between CK-BB and IgG)	Various neoplastic diseases
Mitochondrial CK-IgA complex	Various carcinomas (prognostic role in advanced cancers)
Galactosyltransferase II	▪ Ovarian carcinoma ▪ Hepatocellular carcinoma ▪ Esophageal carcinoma
Placental-type alkaline phosphatase (PLAP), Regan isoenzyme	▪ Germ cell tumors (specific marker) ▪ Advanced colorectal carcinoma (not very specific) ▪ Ovarian carcinoma (not very specific)
Bone alkaline phosphatase (bone ALP)	▪ Osteosarcoma ▪ Bone metastasis
Lactic dehydrogenase 1 (LD1)	Testicular germ cell tumors (i.e. seminomas, yolk sac tumor)
Lactic dehydrogenase 4 and 5 (LD-4 and LD-5) isoenzymes	Most cancers in advanced stage

Contd...

Table 6.110 Tumor markers and associated malignancies (*Contd...*)

Serum Tumor Markers	Associated Malignancies and Other Disorders
Specific proteins	
Immunoglobulin heavy and light chains, Bence-Jones proteins in blood and urine	▪ Multiple myeloma ▪ Other gammopathies
β_2-Microglobulin	Multiple myeloma
Prostate-specific antigen (PSA)	Prostatic carcinoma Prostate-specific antigen is also increased in prostatitis and benign prostate hyperplasia
Thyroglobulin	Follicular thyroid carcinoma (well-differentiated)
Insulin-like growth factor binding protein 2 (IGFBP-2)	Prostatic carcinoma
Human epididymis protein 4 (HE4)	Ovarian carcinoma
Nuclear matrix protein 22 (excreted in urine)	Urothelial carcinoma
Cytokeratin fragment 21-1 (Cyfra 21-1)	Non-small cell lung carcinoma
Synaptophysin (synaptic vesicle membrane protein)	Neuroendocrine tumors (e.g. small cell lung carcinoma)
Chromogranin A	▪ Pheochromocytoma ▪ Neuroblastoma ▪ Small cell lung carcinoma ▪ Carcinoid tumors
Calretinin	Mesothelioma
Mucins and glycoproteins	
CA 125	▪ Ovarian carcinoma ▪ CA 125 level is also increased during menstruation, endometriosis, pelvic inflammatory disease, pregnancy, peritonitis, pancreatitis, and hepatitis
CA 19-9	▪ Pancreatic carcinoma ▪ Gastric carcinoma ▪ Colon carcinoma ▪ Breast carcinoma ▪ CA 19.9 level may also be increased in pancreatitis and ulcerative colitis
CA 72-4	▪ Gastric carcinoma ▪ Colon carcinoma ▪ Pancreas carcinoma ▪ Ovarian carcinoma
CA 15-3	Breast carcinoma
CA 27-29	Breast carcinoma
TAG-72 (new marker)	▪ Gastric carcinoma ▪ Colorectal carcinoma ▪ Lung carcinoma ▪ Pancreatic carcinoma ▪ Ovarian cancers
Viruses	
HPV-DNA	Cervical carcinoma
Epstein-Barr virus (EBV)	▪ Burkitt's lymphoma ▪ Nasopharyngeal carcinoma ▪ Some lymphoproliferative disorders
Metabolic products	
Vanillylmandelic acid (VMA) is a metabolite of catecholamines excreted in urine	Pheochromocytoma
Catecholamines	Pheochromocytoma
5-Hydroxyindoleacetic acid (5-HIAA) is metabolite of 5-hydroxytryptamine in urine	Metastatic carcinoid tumors
Osteoclast activating factor (OAF)	Multiple myeloma

Lipid associated sialic acid in plasma (LASA-P) is expressed in various carcinomas, leukemias/lymphomas, Hodgkin's disease.

Table 6.111 Some of the recommended uses of tumor markers in clinical practice

Malignancy	Tumor Marker(s)	Tumor Marker Detection Method	Tumor Marker Uses
Breast carcinoma			
Breast ductal carcinoma	CA 15-3, CA 27-29	Serology/tissue immunohistochemistry	▪ Monitoring ▪ Recurrence
	ER/PR, HER2/neu, gross cystic disease fluid protein-15 (GCDFP-15), mamma-globin, Ki-67, p53, CK7, GATA3	Tissue immunohistochemistry	▪ Response to therapy ▪ Diagnosis
	DNA ploidy, S phase	Flow cytometry	▪ Diagnosis ▪ Monitoring
	EGFR	Fluorescence *in situ* hybridization (FISH)	▪ Diagnosis ▪ Monitoring
Breast lobular carcinoma	GCDFP-15 (+100%), E-cadherin (–)	Tissue immunohistochemistry	Diagnosis
Breast medullary carcinoma	Triple negative (ER/PR, HER2/neu)	Tissue immunohistochemistry	Diagnosis
Breast metaplastic carcinoma	CK903, p63, CAM 5.2 (most reliable marker), CK7 (most reliable marker)	Tissue immunohistochemistry	Diagnosis
Breast undifferentiated carcinoma	NY-BR1 (highly specific marker)	Tissue immunohistochemistry	Diagnosis
Female genital system			
Ovarian surface epithelial carcinoma	CA 125, CEA, HE4	Serology/tissue immunohistochemistry	▪ Monitoring ▪ Diagnosis ▪ Recurrence
Cervical carcinoma	HPV-DNA, SCC antigen (SCC-Ag), CEA	Serology	▪ Diagnosis ▪ Monitoring
Endometrial carcinoma	Urinary gonadotropin peptide	Urine	▪ Diagnosis ▪ Monitoring
Male genital system cancers			
Choriocarcinoma	β-hCG	Serology/tissue immunohistochemistry	▪ Diagnosis ▪ Prognosis ▪ Monitoring
Germ cell tumors	α-Fetoprotein (AFP), β-hCG	Serology/tissue immunohistochemistry	▪ Diagnosis ▪ Prognosis ▪ Monitoring
	Lactate dehydrogenase (LDH), placental alkaline phosphatase (PLAP) in seminoma	Serology	▪ Prognosis ▪ Monitoring
Prostatic carcinoma	Prostate-specific antigen (PSA), prostatic alkaline phosphatase (PAP), IGFBP2, CEA	Serology/tissue immunohistochemistry	▪ Screening ▪ Monitoring ▪ Diagnosis
Renal cell carcinoma	Erythropoietin, PTHrP, renin, prolactin, neuron-specific enolase (NSE)	Serology	▪ Screening ▪ Monitoring
Urinary bladder carcinoma	Nuclear matrix protein 22	Urine	▪ Diagnosis ▪ Prognosis
	DNA ploidy, S phase	Flow cytometry	▪ Diagnosis ▪ Prognosis
Gastrointestinal tract, pancreas, liver, and adrenal gland cancers			
Gastric carcinoma	CEA, CA 72-4	Serology/tissue immunohistochemistry	▪ Prognosis ▪ Monitoring

Contd...

Table 6.111 Some of the recommended uses of tumor markers in clinical practice (*Contd...*)

Malignancy	Tumor Marker(s)	Tumor Marker Detection Method	Tumor Marker Uses
Colorectal carcinoma	Carcinoembryonic antigen (CEA)	Serology	▪ Prognosis ▪ Monitoring
Pancreatic carcinoma	CA 19-5, CA 50, CEA, glucagon, IFBP-1, pancreatic polypeptide, serotonin, ACTH, γ-glutamyl transpeptidase	Serology	▪ Prognosis ▪ Monitoring
Insulinoma	Insulin, proinsulin, C peptide, IGF-1 binding protein	Serology	▪ Screening ▪ Diagnosis ▪ Prognosis ▪ Monitoring
Hepatocellular carcinoma	α-Fetoproteins, CEA, ferritin, erythropoietin, γ-glutamyl transpeptidase	Serology	▪ Screening ▪ Diagnosis ▪ Prognosis ▪ Monitoring
Carcinoid tumor	Chromogranin A, 5-hydroxyindoleacetic acid (5-HIAA)	Serology/urine	▪ Monitoring ▪ Recurrence
Pheochromocytoma (adrenal medulla)	Metanephrines (catecholamines metabolic products), vanillylmandelic acid (VMA)	Serology/urine	▪ Screening ▪ Diagnosis
Hematolymphoid system cancers			
Leukemia	TdT, ALK, ferritin, LDH, myelin basic protein, adenosine deaminase	Serology	▪ Screening ▪ Monitoring
Lymphomas	β-Microglobulin, TdT, LASA-P, lactic acid dehydrogenase (LDH)	Serology	▪ Diagnosis ▪ Prognosis
Multiple myeloma	Immunoglobulins heavy and light chains, Bence-Jones proteins, β-microglobulin	Serology/urine	▪ Diagnosis ▪ Prognosis
Head and neck cancers			
Nasopharyngeal carcinoma	EBV-DNA (Epstein-Barr virus-DNA)	Serology	▪ Diagnosis ▪ Prognosis
Squamous cell carcinoma of head and neck, cervix, lung	Squamous cell carcinoma-antigen (SCC-Ag)	Serology	▪ Diagnosis ▪ Prognosis
Follicular thyroid carcinoma (well-differentiated)	Thyroglobulin	Serology/tissue immunohistochemistry	▪ Screening ▪ Monitoring
Medullary thyroid carcinoma	Calcitonin, neuron-specific enolase (NSE)	Serology	▪ Screening ▪ Monitoring ▪ Prognosis
Lung cancers			
Small cell lung carcinoma	ACTH, ADH, PTHrP	Serology	▪ Screening ▪ Monitoring
Nonsmall cell lung carcinoma	Cyfra 21-1, CEA	Serology	▪ Screening ▪ Monitoring
Miscellaneous cancers			
Melanoma	Tyrosinase	Serology	Diagnosis
Sarcoma	Cytogenetic alterations	Genetic analysis	Diagnosis

- Once the cancer diagnosis is established, the oncologist can refer to evidence-based National Comprehensive Cancer Network (NCCN) guidelines needed for the complete staging of specific malignant tumor type, size, specific lymph node evaluation and imaging techniques such as ultrasonography, X-rays, CT and MRI performed for possible metastatic disease.
- The National Comprehensive Cancer Network (NCCN) guidelines are recognized standard

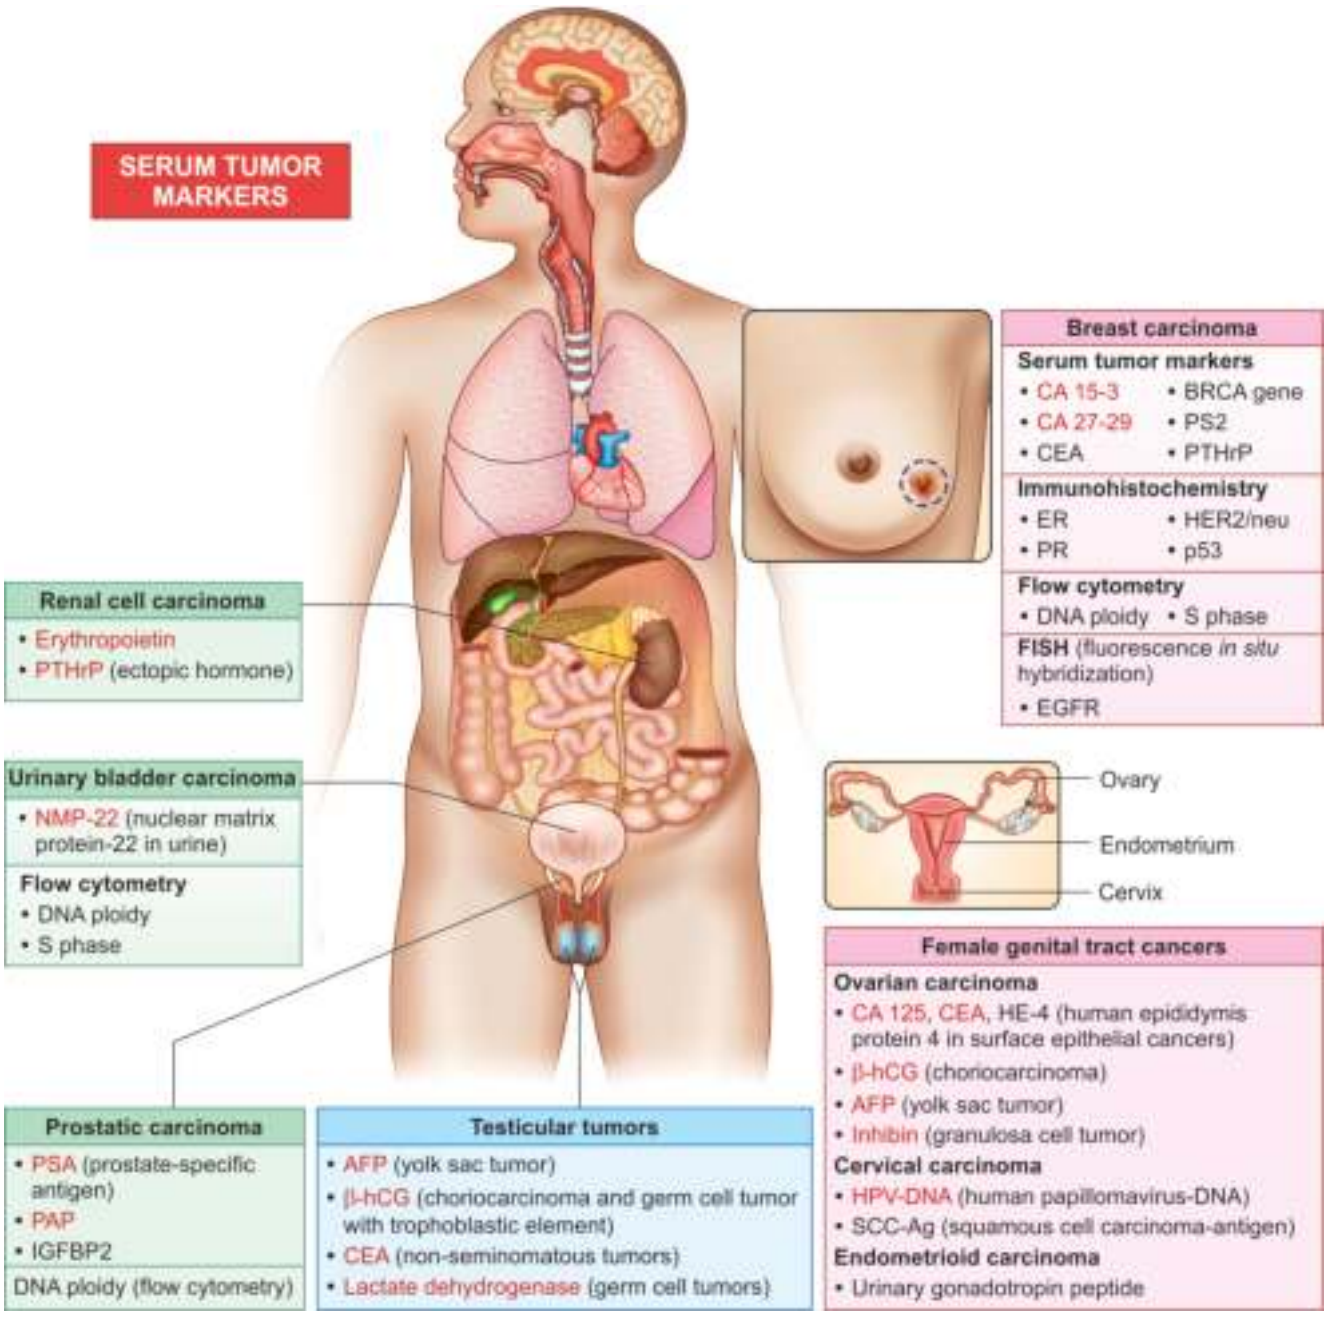

Fig. 6.130: Tumor markers in cancers of breast, kidney, urinary bladder, prostate, testes, ovaries, endometrium, and cervix.

for screening, diagnosis, and treatment of cancer patient.

Clinical Pearls: Some Common Alerts in Oncology History Taking

- Unexplained weight loss
- Persistent pain
- Night sweats
- Dysphagia, change in bowel or urinary bladder habits (blood in the stool, diarrhea, constipation)
- Unresolved cough or hoarseness
- Abnormal lump(s) or mass(es)
- Personal history or family history of cancer
- Abnormal bleeding
- Neurological symptoms
- Suspected paraneoplastic syndromes (endocrine abnormalities)

PAST MEDICAL HISTORY

Taking the patient's past medical history helps in identification of preexisting conditions and highly potential genetic factors that may impact cancer treatment decisions. In the presence of malignant tumors related to gynecology (breast carcinoma, endometrial

carcinoma, cervical carcinoma, ovarian carcinoma), it is essential to clarify the state of menstrual cycle: time of onset of menstruation, duration, periodicity of menstrual cycle and age at which menopause began.

LIFESTYLE, SOCIAL HISTORY AND ENVIRONMENTAL FACTORS

Oncologist should evaluate lifestyle history such as tobacco smoking (duration, number of cigarettes per day), alcohol consumption, dietary habits, and exercise, along with exposure to occupational and environmental carcinogenic agents, which provides insights into potential risk factors. When residing in a territory contaminated with radionucleotides, it is essential to specify the locality, the period of residence, and the time of relocation.

SYSTEMIC EVALUATION OF THE BODY SYSTEMS

Conduction of systemic evaluation of the body systems helps in detection of symptoms related to primary malignant tumor and its treatment. Oncologist should conduct physical examination (palpation, percussion, auscultation), and systemic evaluation of the body systems, and organs including peripheral lymph nodes.

BLOOD TESTS

Blood tests play important role in diagnosing and treating malignant tumors. Renal and liver functions are useful to determine overall health of cancer patients. A complete blood count (CBC) test measures the number of red blood cells, white blood cells and platelets circulating in the bloodstream. CBC test also measures hemoglobin in red blood cells (RBCs) that carries oxygen and hematocrit, the ratio of the red blood cells to plasma. Some cancer treatments may temporarily lower blood counts, oncologists often advise CBC tests throughout treatment to closely monitor a patient's complete blood counts.

URINE ANALYSIS

Urine analysis may be useful in detection of malignant tumors by analyzign various components (e.g. red blood cells, white blood cells, sugars, and proteins) and CSCs, which can detect the presence of certain cancers. Detection of cells in a urinary sediment is called urine cytology. Urine analysis is done to detect malignant epithelial tumors of urinary bladder, prostate, and cervix. Additionally, urinalysis is performed in multiple myeloma and is suspected to look for myeloma protein in the urine. If myeloma protein is detected, additional urine testing is called urine proteins electrophoresis and immunofixation will likely be conducted.

IMAGING TECHNIQUES

Imaging techniques may aid in early detection of malignant tumor in tissue/organ, staging and determination of therapy. Imaging techniques include ultrasonography, X-rays, CT scan, MRI, radioactive isotope imaging, positron emission tomography (PET), and mammography.

Ultrasonography

Ultrasonography uses high-frequency sound waves to detect changes in the density of tissues, thus helps to differentiate cysts from solid malignant tumors.

Conventional Radiography

X-rays use low doses of radiation to identify and evaluate changes in tissue densities such as location of tumor or metastasis.

Computed Tomography

Computed tomography (CT) evaluates successive layers of tissue by using narrow beam X-ray to provide a cross-sectional view of the structure. It also can reveal different characteristics of tissues within a solid organ.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) uses fields and radio-frequencies to demonstrate a cross-sectional view of the body organs and structures.

Radioactive Isotope Scanning

Radioactive isotope scanning involves the use of specialized camera which detects radioactive isotopes that are injected into blood stream or ingested. Radiologist analyzes distribution of radioactive isotopes throughout tissues and organs.

Positron Emission Tomography

Positron emission tomography (PET) scan is an imaging technique, that can help reveal the metabolic function of tissues and organs. The PET scan used a radioisotope drug called a radiotracer to demonstrate both physiologic and pathologic metabolic activity in tissues and organs. The PET imaging can be useful whether a tumor is benign or malignant.

Mammography

Screening mammography is a low-dose X-ray imaging method to examine the breast for early detection of malignant tumor and other diseases such as fibroadenomas or complex cysts. A radiologist examines a mammogram to search for high density regions of unusual configuration that look different from normal tissue. Three recent advances in mammography include digital mammography, computer-aided detection system, and digital breast tomosynthesis.

- **A digital mammography** uses the same X-ray technology as conventional mammograms, but instead of using film, solid-state detectors are used to record X-ray pattern passing through the breast.
- **Computer-aided detection** highlights mammographic images for normal areas of density mass, or calcification that may indicate the presence of breast cancer.
- **Digital breast tomosynthesis**, also called three-dimensional mammography for breast cancer screening in which multiple radiographs of the breast are taken at different angles to generate thin cross-sections.

CYTOLOGIC EXAMINATION

Cytology is mainly used to diagnose or screen for cancer. Diagnosing diseases by looking at single cells/small clusters of cells is called cytology. Methods of obtaining cells for cytologic examination are simple, cost effective and minimally invasive. Cells shed naturally into body fluids, e.g. sputum, urine, cerebrospinal fluid, fluid in pleural and peritoneal cavities.

- The cells to be examined may be taken through various methods: (a) scraping and brushing tissue from the surface of Papanicolaou stained cytologic smears for screening cervix and gastrointestinal tract, (b) exfoliative cytology, i.e. collection of cells shed naturally in body fluids, e.g. sputum, urine, cerebrospinal fluid, fluid in pleural and peritoneal cavities, (c) fine needle aspiration cytology (FNAC) to sample superficial malignant tumors in lymph node, breast, thyroid gland, axillary region, abdomen, and extremities.
- Cytologic smears are prepared and stained by Papanicolaou stain or May-Grünwald-Giemsa (MGG) stain, and examined under light microscopy. Immunohistochemistry is performed on these smears.
- Comparison between air-dried May-Grünwald-Giemsa stained and wet-fixed Papanicolaou stained smears is given in Table 6.112.

Fine Needle Aspiration Cytology

Fine needle aspiration cytology (FNAC) is commonly done using a narrow 22 gauze percutaneous thin hollow needle to collect a sample of solid malignant tumors of breast, thyroid, and pancreas under aseptic conditions and draining lymph nodes for microscopic examination of smears fixed in fixative (95% ethyl alcohol and 2% acetic acid), and stained by May-Grünwald-Giemsa (MGG) stain. In some cases, this technique limits to make a definitive diagnosis. Diagnosing metastatic or recurrent malignancy by FNAC generally has a high specificity and sensitivity, which is ideal for confirming metastasis from a clinically or radiologically suspected primary site. FNAC is used as a diagnostic tool and in the follow-up of certain patients with known lumps.

Scraping and Brushing Tissue Surface of Papanicolaou Stained Cytology Smears

Scraping and brushing tissue surface and examination of Papanicolaou stained cytology smears are prepared from suspected region with endoscope from cervix and gastrointestinal tract. Scrap cytology technique can be useful for rapid intraoperative diagnosis of ovarian mass that acts as an adjunct to frozen section examination, where facility for frozen section is not available. Scrap cytology smears are obtained from tobacco-related oral leukoplakia lesions.

Conventional Exfoliative Cytology

Cancers involving or protruding from the surface of organs continuously shed exfoliative cells into the surrounding space. The exfoliative cells are obtained from cervix (cervical carcinoma), sputum (lung carcinoma), pleural fluid (lung carcinoma), peritoneal fluid (various cancers), cerebrospinal fluid (brain tumors) and urine (transitional cell carcinoma). Cells are obtained during endoscopic procedures. Smears are prepared and stained by Papanicolaou stain and examined under light microscope.

Liquid-based Cytology

Liquid-based cytology (LBC) is two-step procedure that involves the fixation of the fine needle aspiration material in an alcohol-based solution (methanol or ethanol depending on the technique), and automated processing

Table 6.112 Comparison between air-dried May-Grünwald-Giemsa stained and wet-fixed Papanicolaou stained smears

Air-dried May-Grünwald-Giemsa Stained Smears	Wet-fixed Papanicolaou Stained Smears
Good fixation but presence of artefacts	Good fixation
Cell morphology is poorly defined due to heavily stained ground substance	Individual cell morphology is clearly defined
Cytoplasmic details are well demonstrated	Cytoplasmic details are poorly demonstrated
Morphology of nuclear details is variable	Morphology of nuclear details is excellent
Morphology of nucleoli is always not well defined	Morphology of nucleoli is always well defined
Stromal components are well defined	Stromal details are poorly defined

of the material to obtain a thin layer of representative cells with the aim to improve diagnostic accuracy.

- In liquid-based cytology, the brush head of the device is immerged in vial of fixative solution (methanol or ethanol), where it is vigorously rotated several times to ensure release of the sample cells and kept for 30 minutes.
  - The brush head of the device is then removed from the vial. Excess mucus and blood are eliminated by means of washing through succession of centrifugation and resuspension of the sample in mucolytic and hemolytic agents.
  - Subsequently, slides may be stained routinely by Papanicolaou stain or used for molecular diagnostics.
- Two methods are used for cervical smear cytology. The first one is the conventional Papanicolaou (Pap), and the second one is liquid-based cytology, which provides optimal viewing of cellular features attributed to the reduction in the air-dried artifacts obscuring background elements and this reduces the number of unsatisfactory smears.
  - Cervical liquid-based cytology is now widely accepted as superior technique to diagnose cervical carcinoma than conventional technique used in high-risk population.
  - Following pelvic examination and liquid-based cytology from brushings at screening, women with CIN-II or CIN-III then undergo colposcopy and biopsy. Similarly, liquid-based cytology has been applied to thyroid cytopathology.

SURGICAL PATHOLOGY

Surgical pathology is the study of tissues removed in living patients during surgery to diagnose a disease and determine a treatment plan.

- Biopsies can be performed in several different ways. Biopsies should be professionally taken without error and sufficient biopsy from appropriate malignant tumor site for accurate reporting. Some biopsies involve removing a small amount of tissue with a needle, while others involved surgically removing an entire lump or nodule that is suspicious. Biopsies can be safely performed with imaging guidance such as ultrasonography, X-ray, computed tomography (CT), or magnetic resonance imaging (MRI). Breast biopsy is used to determine whether the patient has benign or malignant tumor.
  - **Endoscopic biopsy:** Endoscopy provides a direct view of a body cavity or passage way to detect abnormalities. It is applied to detect lesions in gastrointestinal, respiratory, genital, and urinary tracts. During endoscopy, the medical professionals can excise small tumors, aspirate fluid, or obtain tissue samples for histologic examination. Endoscopic biopsy is performed through fiberoptic endoscope through a natural orifice or a small incision. The clinician can insert the endoscope into gastrointestinal tract (GI endoscopy), urinary bladder (cystoscopy), abdominal cavity (laparoscopy), joint cavity (arthroscopy), mid-portion of the chest (mediastinoscopy), or trachea and bronchial system (laryngoscopy and bronchoscopy).
  - **Tissue biopsy needle:** Needle biopsy is used with a cutting needle to sample suspected lesion in the tissues including those in brain with the guidance of ultrasonography, computed tomography (CT), fluoroscopy, magnetic resonance imaging (MRI). A biopsy needle is generally several inches long, which can capture the tissue specimen. **A core needle biopsy**, also called an automatic spring-loaded, which consists of an inner needle connected through, or shallow receptacle covered by a sheath and attached to a spring-loaded mechanism. Small size biopsy measuring 1–2 mm wide and 2 cm long biopsy can make histopathologic interpretation difficult.
  - **Incisional tissue biopsy:** Scalpel is used to take a biopsy from a lesion. Sample is variable in size depending on nature of lesion. It is applied to surgically accessible lesions only.
  - **Excision tissue biopsy:** Whole abnormal lesion is surgically removed and fixed in 10% buffered neutral formalin to obtain paraffin sections. Sampling of large specimen would include malignant tumor (for histogenetic pattern of differentiation, staging and grading), resection margins, lymph nodes and background tissue. Hematoxylin and eosin-stained sections are studied by light microscopy. Freshly prepared 2% buffered glutaraldehyde is recommended for fixation of tissues for electron microscopy. Prompt refrigeration is required for study of hormone receptors.
- Surgical pathology includes gross examination of processed tissue under a microscope and may be supported by immunohistochemistry and other tests.
- The surgical pathologist's interpretation of a biopsy determines the patient's treatment plan, which provides critical information if the tumor is benign, borderline, or malignant, staging the extent of malignant disease and pinpointing the activity of specific molecular pathways in the malignant tumor.
- Normal cells will appear uniformly organized and have similar sizes, but in the case of malignant tumors, CSCs will be less organized and have different sizes. The surgical pathologist supports the oncologists by determining if the entity of a diseased region has been

removed during surgery and provided information that guides for postoperative treatment. Surgical pathologists diagnose diseases other than cancers.

Pathology Pearls: Frozen Section and Cryostat Techniques

- Frozen section and cryostat techniques are used for rapid diagnosis of malignancy to confirm cytologic diagnosis of malignancy, before proceeding to definite surgery.
- Assessment of excision margins for a wide local excision to ensure complete excision. Assessment of draining lymph nodes is done to identify patients who are lymph node negative and who require only a limited dissection.
- Tissues are quickly frozen, sectioned, mounted on slides, stained, and interpreted within a few minutes, which enable surgeon to take appropriate decisions about the extent of surgery.

Tumor Macroscopic Morphology

Biopsy/surgical specimen of tumor is fixed in **10% buffered neutral formalin** (containing sodium dihydrogen phosphate, disodium hydrogen phosphate, distal water, formalin, and pH 7.2–7.4 and volume of fixative 10–20 times of the specimen) and examined with naked eye, which includes the general color, weight, gross appearance, size, shape, consistency, and cut surface with prominent hemorrhage and necrosis. In mastectomy specimens, lymph nodes should be isolated and processed.

- Histopathology laboratory should be well equipped, which include automatic tissue processor, paraffin wax dispensers, embedded work stations, cryostat, hot plates, oven, weighing machine, knives of different sizes, blade, ruler, board, and staining machines. Grossing room should be well ventilated with an air extractor.
- Tissue processing is the technique by which fixed tissues are made suitable for embedding within supportive paraffin medium and consists of sequential steps: dehydration, clearing, impregnation, and embedding each of as designated duration to ensure completion of the procedure. All hard tissues (bone) should be sent for decalcification.
- Tissue sections obtained are stained by hematoxylin and eosin, mounted, and then microscopically evaluated. Tissue shrinkage is less in microwave-processed tissue as compared to routine manual method and rapid manual routine methods.

Histopathologic Examination

The single most important diagnostic tool is the biopsy for direct histologic study of the tumor tissue. Histopathology is defined as the diagnosis and study of the tissues and/or cells from suspicious lumps under light microscope to diagnose diseases. Histopathologist confirms the diagnosis of cancers and helps clinicians to manage a patient's care. Tissue embedded in paraffin can be sectioned at 4–8 microns in thickness with a microtome having thick metallic knife and stained with hematoxylin and eosin stain and examined under a microscope.

- The concept of quality control in histopathology means standard reagents and equipment, high quality tissue sections, well-stained tissue sections with hematoxylin and eosin, air bubble-free, artifact-free, and well-demonstration of tissue elements and accurate reporting. Primary aim of quality control is to monitor, detect errors, prevent pre-analytic, analytic and post-analytic errors and reliable result/diagnosis.
- First step is to classify the type of malignant tumor based on cellular differentiation and growth patten based on the light microscopic examination of paraffin-embedded tissue by hematoxylin and eosin-stained slides. Microscopic description describes morphology of CSCs, differentiation, invasiveness/noninvasiveness, grade, mitoses, tumor margins, and lymph node status.
- After determining that the lesion is neoplastic in nature, the next step is to analyze whether the malignant tumor is of epithelial origin or mesenchymal origin. The main difference between malignant epithelial tumors and malignant mesenchymal tumors include: (a) tumor cells are oval–round to polygonal in malignant epithelial tumors, but the tumor cells are generally spindle-shaped in malignant mesenchymal tumors, (b) malignant epithelial tumors generally form tumor cell nests, but malignant mesenchymal tumors are arranged in diffuse sheets, without forming tumor cell nests, (c) in malignant epithelial tumors, desmoplastic stroma is well formed between tumor cell nests, but mesenchymal tumors lack desmoplastic stroma, and (d) blood vessels open in the supporting stroma in malignant epithelial tumors, but open directly between CSCs in malignant mesenchymal tumors.
- Next step is to decide, whether the tumor is benign or malignant in nature, based on various characteristics: (a) differentiation, (b) growth rate, (c) growth pattern, and (d) metastasis.
  - A benign tumor is well-differentiated, grows slowly, that shows expansile growth with capsule, and does not metastasize.
  - Malignant tumor is most often poorly differentiated that grows rapidly without a capsule, and frequently metastasizes. In general, malignant tumors show high cellularity, tumor necrosis and nuclear alterations, which include nuclear enlargement with a high nuclear/cytoplasmic ratio, pleomorphism, hyperchromatism, prominent nucleoli and frequent atypical tripolar or quadripolar mitoses.

- For the correct diagnosis of the malignant tumor, immunohistochemistry technique, molecular diagnostic tools such as fluorescence *in situ* hybridization (FISH), and polymerase chain reaction (PCR) technique to map the genetic alterations in tissues or tumors, or possibly electron microscopic evaluation may be required. After establishing diagnosis of malignancy, one should then consider the relevant important prognostic factors (e.g. tumor grade and TNM stage) to be mentioned in the histopathology report.

Grading and Staging Systems

Both grading and staging systems are used to classify malignant tumors for prognostic evaluation and planning of clinical management. Malignant tumor ≥2 cm has inherent ability to metastasize to distant tissues/organs. In general, higher the grade or the stage of malignant tumors, patients have worse prognosis.

- Oncologists use grading and staging systems to describe the characteristics of the malignant tumor to determine prognosis. Staging system is more important than grading of cancers and has great significance to predict prognosis and effective management in clinical practice.
- Some malignant tumors such as melanoma and gastrointestinal carcinomas are staged by how deeply these tumors extend beyond the basement membrane. Invasion of the dermis by melanoma or invasion of gastrointestinal carcinomas through the lamina propria, muscularis mucosa, and serosa represent progressively more extensive invasion and higher risk of metastasis. Grading and staging of breast carcinoma is shown in Fig. 6.131.

Grading System

Grading system is based on histologic cellular and differentiation of malignant tumors (i.e. how much malignant tumor resembles the tissue in which it grows), considers of architectural and nuclear features.

- Well-differentiated (low-grade) carcinoma resembles normal parent tissue. Poorly-differentiated (high-grade) carcinoma does not resemble apparent tissue. Moderately-differentiated carcinoma partially resembles parent tissue.
- Grading is important for determining prognosis. Poorly-differentiated (high-grade) carcinoma is more aggressive than well-differentiated (low-grade) carcinoma.
- Poorly-differentiated is high-grade anaplastic carcinoma that does not resemble parent tissue, which may be difficult to determine without immunohistochemical stains directed against squamous cell-specific proteins.

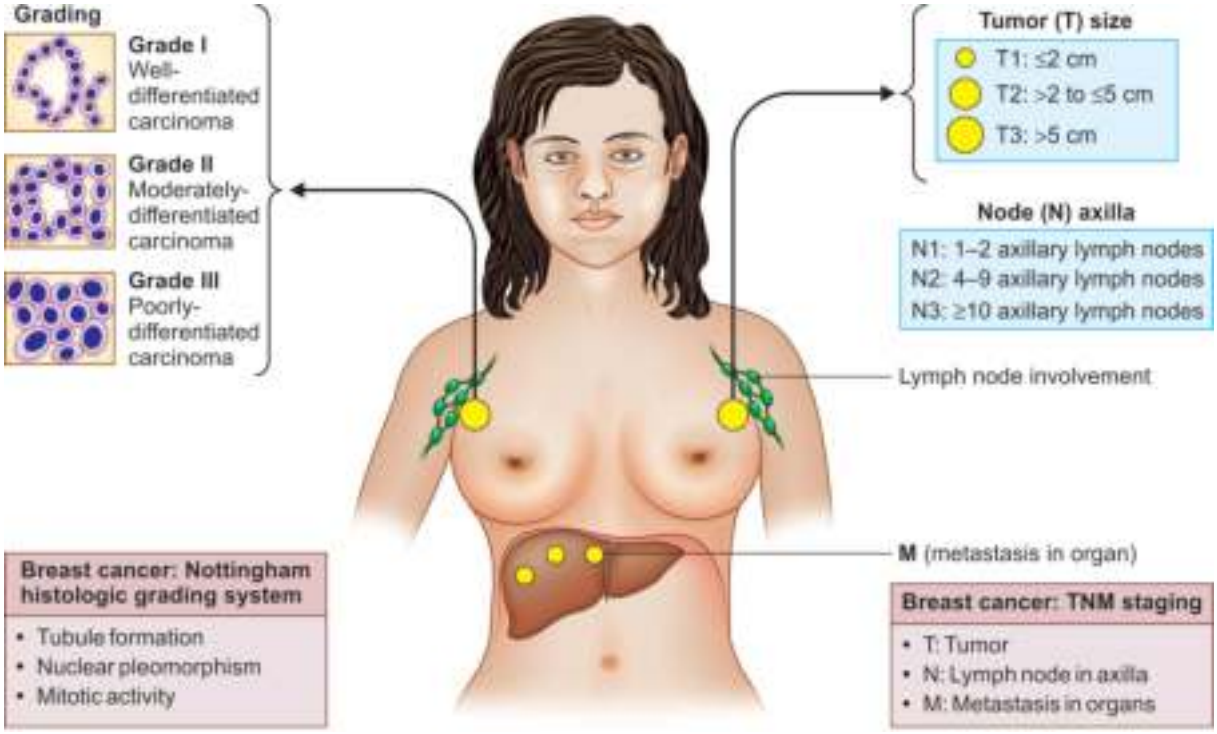

Fig. 6.131: Grading and staging of breast carcinoma. TNM stands for tumor, lymph node metastases and distant metastases [grading classifies tumor according to their light microscopic characteristics. Staging is a clinical exercise that classifies tumors according to their size, invasiveness and spread. Tumors are staged according to the TNM system (T: Tumor size, N: Lymph node involvement, M: Metastases to distant organs). Schemes for TNM classification vary according to tumor type and organ involved].

Staging System

Staging system is based on size of primary malignant tumor, extent of local invasion into surrounding tissue and systemic metastasis to distant organ(s) via lymphatic, hematogenous or transcoelomic routes.

- Staging system generally correlates with prognosis than does histopathologic grading; however, both approaches are useful.
- Staging system is exemplified by TNM system that evaluates the size and/or depth of invasion of tumor into the surrounding tissues, and systemic metastasis.
  - **T**—tumor (size and/or depth of invasion) refers to carcinoma *in situ* (T) followed by T1–T4.
  - **N**—denotes lymph node involvement. N0 denotes absence of lymph node followed by N1–N3 increasing in number of lymph nodes.
  - **M**—denotes systemic metastases (e.g. liver, lung, bone, and brain). M0 refers to absence of metastasis followed by M1 for metastasis.
- Metastasis is single most important prognostic factor. The most employed staging guidelines are those laid out by the American Joint Committee on Cancer (AJCC).

Electron Microscopy

Electron microscopy is a useful diagnostic technique to supplement morphologic, immunohistochemical, cytogenetic, and molecular analysis of tissues, although immunoperoxidase techniques have largely replaced electron microscopy for malignant tumor diagnosis in surgical pathology. Tissue is fixed in 2% glutaraldehyde.

- Electron microscopy plays significant role in the diagnosis of poorly differentiated carcinoma, sarcoma or lymphoma, whose classification is difficult by routine light microscopy.
- Desmosomes and specialized junctional complexes are demonstrated in carcinoma, while absent in sarcoma and lymphoma.
- Carcinoma exhibits short microvilli, blunt with terminal web, while microvilli of lymphoid and mesenchymal tumors do not show a terminal web.
  - Cells of ectodermal origin often have many cilia.
  - Malignant epithelial tumors show presence of bundles of tonofilaments, whereas slender microfilaments are common in malignant mesenchymal tumors.
  - Malignant melanoma shows presence of melanosomes.
  - Small membrane-bound granules with dense core are features of endocrine neoplasms.
- Demonstration of microvillous core rootlets in glandular epithelium of intestines help in diagnosis of metastatic deposits from gastrointestinal carcinoma.

Immunohistochemistry Technique

As the cells differentiate into different tissues like epithelial tissue, mesenchymal tissue and hematolymphoid tissue (T cells and B cells). The cells specialize and express specific proteins (e.g. intermediate filaments), which can be analyzed by purified monoclonal antibodies against tumor antigens aiding identification of the cell of origin of cancer.

- Immunocytochemistry in conjunction with immunofluorescence is a useful diagnostic tool in the identification and classification of tumors arising from T and B cells, and mononuclear phagocytic cell. Immunohistochemistry technique as a diagnostic tool in cancers is given in Table 6.113.
- Immunohistochemical staining may be performed to diagnose, classify, and characterize cellular differentiation of tumors. Cytokeratin immunostaining is helpful to detect metastatic carcinoma to an axillary lymph node, diagnose round cell tumors and metastatic disease in bone marrow and lymph nodes, particularly when small samples of tissues are submitted for diagnosis, because distinct protein expression patterns define different entities.
- Immunohistochemistry technique begins with hybridizing monoclonal antibody solution directed against specific proteins in cell membrane, cytoplasm, and nuclear membrane within the tissue section aiding identification of the cell of origin of a lesion. It is then hybridized with a secondary monoclonal antibody conjugated to a reporter enzyme that precipitates a signal in the cells that are positive for the antigen (using peroxidase-antiperoxidase method).
- **Cytokeratin** is used to differentiate between carcinoma and lymphomas. **Cytokeratin** positivity is seen in carcinoma and mesothelioma. **Desmin** and **myoglobin** are specific for malignant smooth and striated muscle tumors. **Vimentin** is demonstrated in malignant mesenchymal tumors and some carcinomas.
- Immunohistochemical staining may be performed using frozen tissue, formalin-fixed paraffin-embedded tissue sections (routine pathology), or freshly suspended cells (flow cytometry) using either enzyme reporters or fluorescence.
- A growing array of monoclonal antibodies is routinely used. Despite its potential, immunohistochemical staining results must be interpreted with care. The expression pattern of tumor antigens may change as individual CSC dedifferentiate and begin to express an antigen profile unlike original cellular lineage.
- The specificity of a particular immunomarker varies significantly from one malignant tumor type to another.

Table 6.113 Immunohistochemistry technique as a diagnostic tool in cancers

Intermediate Filaments	Tissue Origin of Tumor	Tumors
Cytokeratin	Epithelial tissue	▪ Squamous cell carcinoma of skin ▪ Renal cell carcinoma ▪ Mesothelioma
Vimentin	Mesenchymal tissue	Sarcoma
Desmin	▪ Skeletal muscle ▪ Smooth muscle	▪ Rhabdomyosarcoma ▪ Leiomyoma
Neurofilament	▪ Neurons (brain) ▪ Neural crest derivatives	▪ Brain tumors (e.g. ganglioglioma, gangliocytoma, neurocytoma) ▪ Neuroendocrine tumors (e.g. neuroblastoma, pheochromocytoma, small cell lung carcinoma)
Glial fibrillary acidic protein (GFAP)	Neuroglial cells	▪ Glial tumors of brain ▪ Breast carcinoma
Prostate-specific antigen (PSA)	Prostatic epithelium	Prostatic adenocarcinoma
Estrogen receptor (ER)	Breast epithelium	Breast carcinoma
Thyroglobulin	Thyroid follicular cells	Thyroid carcinoma
Chromogranin	Neuroendocrine cells	Small cell lung carcinoma and carcinoid tumor

Renal cell carcinoma expresses both cytokeratin and vimentin.

- Location of immunoreactivity directed against specific antigens located in cell membrane, cytoplasm, and nuclear membrane of CSCs must be considered.
- For example, monoclonal antibody to thyroid transcription factor 1 (TTF-1) stains the nuclei of small cell lung carcinoma (specific), but it stains the cytoplasm of hepatocellular carcinoma (not specific).
- Immunohistochemistry has been discussed in details in Chapter 14: Cellular–Molecular Diagnostic Techniques in Clinical Practice.

PD-L1 Biomarker Immunohistochemistry Technique

Programmed cell death protein ligand 1 (PD-L1) biomarker immunohistochemistry (IHC) technique is indicated in patients with specific advanced cancers to predict their responses to treatment with PD-L1 inhibitors.

- PD-L1 on CSCs plays a vital role in suppressing immune responses, and promoting self-tolerance through modulating the activity of PD-1 positive CD8+ cytotoxic T cells, activating apoptosis of antigen-specific T cells, and inhibiting apoptosis of CD4+ regulatory T cells.
- PD-L1 is a transmembrane protein on the CSCs that combines with programmed cell death protein 1 (PD-1) positive CD8+ cytotoxic T cells, and inhibits apoptosis of CSCs.
- Monoclonal antibodies that target either PD-1 or PD-L1 can block this binding, and boost the immune response against CSCs. PD-1/PD-L1 axis inhibitors are checkpoint inhibitors as frontline treatment of human cancers.
- PD-1/PD-L1 signaling pathway in cancer is shown in Fig. 6.132.

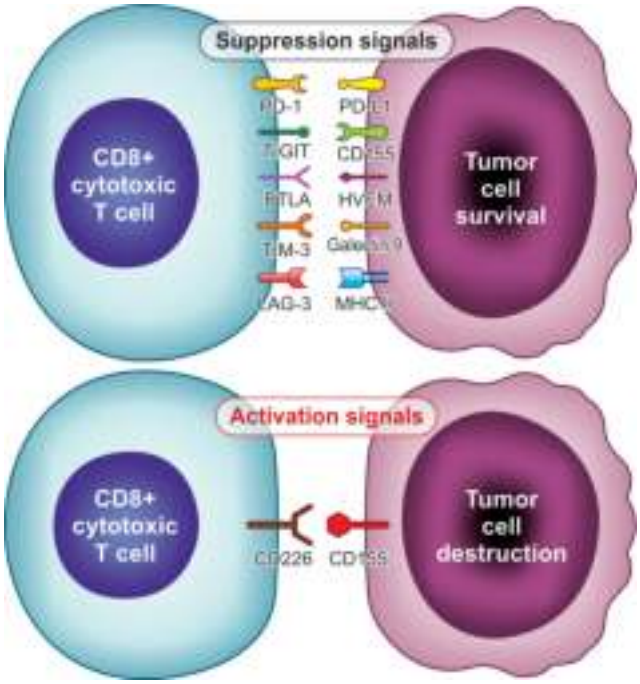

Fig. 6.132: PD-1/PD-L1 signaling pathway in cancer. Interaction between PD-1 and PD-L1 occurs in the tumor microenvironment. PD-1 is expressed on CD8+ cytotoxic T cells and the ligand, PD-L1 is expressed on specific malignant neoplastic cells and antigen-presenting cells. PD-1/PD-L1 axis subsides immune responses and promotes self-tolerance through suppressing the activity of T cells. Blocking the binding of PD-L1 to PD-1 with an immune checkpoint inhibitor (anti-PD-L1 or PD-1) allows the T cells to kill malignant neoplastic cells.

Anaplastic Lymphoma Kinase Mutations Biomarker Immunohistochemistry Technique

Most mutations of the anaplastic lymphoma kinase (ALK) gene are in the form of translocation with another partner NPM gene resulting in formation of NPM-ALK fusion oncogene, which then becomes overexpressed in malignant tumor, and activates many downstream signaling pathways resulting in unrestricted CSCs proliferation and survival. Subsequent ALK-rearrangement has been identified in non-small cell lung carcinoma and diffuse large B cell lymphoma. ALK biomarker of immunohistochemistry technique is used as a predictive biomarker of an underlying ALK translocation to identify patients with specific cancer types who can potentially benefit from ALK inhibitors.

ROS1 Rearrangement Biomarker Immunohistochemistry Technique

Immunohistochemistry technique is a screening diagnostic tool for detection of ROS1 rearrangement in non-small cell lung carcinoma. ROS1 rearrangement occurs in 1–2% of patients in non-small cell lung carcinoma, and it is predictive of treatment response to tyrosine kinase inhibitor. Fluorescence *in situ* hybridization (FISH) is the gold standard method to detect ROS1 rearrangement. ROS1 immunohistochemistry technique has been proposed as a cost-effective screening test for detection of ROS1 rearrangement.

BRAF V600E Mutations Biomarker Immunohistochemistry Technique

BRAF V600 mutations biomarker can be reliably detected by immunohistochemistry technique in primary and metastatic colorectal carcinoma, papillary thyroid carcinoma and melanoma. Molecular analysis for BRAF V600 mutations can be applied to fresh, frozen, or more commonly formalin-fixed paraffin-embedded (FFPE) malignant tumor. Real-time polymerase chain reaction (PCR) is used in detection of BRAF V600 mutations. BRAF V600 is a promising biomarker of prognosis in stage II cancer patients.

TREATMENT MODALITIES FOR TREATING CANCER

Targets for cancer suppression are to reduce CSCs proliferation and promoting apoptosis. Administration of receptor tyrosine kinase inhibits block signal pathways, that induce unrestricted CSC proliferation upregulation of pathways that cause apoptosis. Angiogenesis inhibitors are administered to cut off blood supply of CSCs. The treatment modalities for cancers include surgery, chemotherapy, and radiation therapy.

- Targeted drug therapy uses medicines that targets specific genes and proteins that help CSCs, grow, spread, and survive longer.
  - Two main groups of targeted drug therapy are **monoclonal antibodies** and **small molecule inhibitors**, which have side effects different from chemotherapy.
  - In about 15–20% of breast carcinomas, CSCs make too much of a growth promoter protein known as HER2.
  - The HER2 positive breast carcinomas tend to grow faster and disseminate more aggressively than HER2 negative breast carcinomas.
  - Different types of drugs such as 'Herceptin' have been developed, that target the HER2 protein in breast carcinomas.
- Cancer therapy varies by the patient's tumor type, and location. Site-specific cancer treatments are given in Table 6.114. Therapeutic targeting of the hallmarks of cancer drugs are shown in Fig. 6.133.

SURGICAL TREATMENT

Surgical oncology is the field of cancer care that focuses on surgery to may be used to determine location, remove the malignant tumor, as well as nearby draining lymph nodes and tissues containing CSCs, restore the body's appearance or function (reconstructive surgery) and manage some cancer-related symptoms (palliative surgery). Mastectomy is a surgical procedure to remove one or both breasts and lymph nodes, usually to treat breast cancer. There are different types of mastectomies and the options depend on the histologic type of breast carcinoma: simple total mastectomy, partial mastectomy (skin-sparing mastectomy, nipple-sparing mastectomy), and modified radical mastectomy.

RADIATION THERAPY

Radiation therapy is a cancer treatment that uses high doses of high energy beam radiation to kill CSCs and shrink malignant tumors. Radiation therapy may be of two types: external beam radiation (outside the body), brachytherapy, i.e. internal beam radiation (placed inside the body).

- Radiation therapy may be used in the early stage of cancer (curative radiation therapy). It can be combined with chemotherapy or used before surgery (neoadjuvant radiation therapy).
- Radiation therapy is of three types: (a) proton radiation therapy uses a beam of protons to deliver radiation directly to the malignant tumor, (b) magnetic resonance imaging (**MRI**) linear accelerator is used to track soft tissue-based malignant tumors in real-time during radiation, and

Table 6.114 Site-specific cancer treatments

Treatment Modalities	Method	Aim of Treatment	Site of Cancer
Surgical treatment	Excision of tumor along with lymph nodes	Surgical excision of cancerous growth along with draining lymph nodes is performed	Breast, thyroid gland, lung, colon, ovary, uterus, skin
Radiation therapy	▪ External radiation	▪ Radiation source is outside body	▪ Malignant tumor of brain
	▪ Internal radiation	▪ Radiation source is inside body and radioactive material (capsule, needles, or seeds) is placed inside malignant growth in the organ	▪ Prostatic carcinoma
	▪ Systemic radiation	▪ Radioactive substance (radioactive iodine) is absorbed by thyroid cancers	▪ Thyroid carcinoma
Immunotherapy	▪ Checkpoint inhibitors drugs	▪ Blocking checkpoint proteins from binding with their partner proteins	▪ Melanoma, lung carcinoma
	▪ Adoptive cell therapy (T cell transfer therapy)	▪ T cells are cultured in laboratory	▪ Cervical carcinoma, cholangiocarcinoma
	▪ Cancer vaccines	▪ Boost immune system response	▪ Different types of cancer
	▪ Synthetic monoclonal antibodies	▪ Monoclonal antibodies bind to proteins and transmit signal to immune system that destroy CSCs	▪ Trastuzumab (Herceptin) to treat breast carcinoma ▪ Rituximab to treat chronic lymphocytic leukemia, NHL ▪ Cituximab (Erbitux) to treat bowel cancer and head and neck cancer
	▪ Immune system modulators	▪ Immune system modulators enhance immune system response that kill CSCs	▪ Renal cell carcinoma, leukemia, lymphoma, melanoma, and sarcoma
Hormonal therapy	Hormone therapy in cancer patients	Hormone therapy may slow or inhibit by blocking the body's ability to produce hormones or changing how hormone receptors behave in the body	Breast, prostate, and endometrium
Bone marrow transplantation	Bone marrow transplant	Bone marrow transplant is done by transferring stem cells from one person to another	Leukemia, multiple myeloma, lymphoma

Breast, lung, uterus, cervix, lymphoma (many cancers need combined surgery and radiation therapy).

(c) stereotactic radiation therapy (**SBRT**) has a narrower beam of radiation. Radiation alone is never right for lymphomas.

- Radiation therapy increases the risk for solid malignant epithelial tumors of breast, thyroid, and lung. Radiation therapy also increases the chance of premature coronary artery disease. Risk for acute leukemia, MDS and NHL as a complication of chemotherapy is about 1% per year.

HORMONAL THERAPY

Hormonal therapy is used to treat cancer patients that removes, blocks, or add specific hormones to the body. It is also called hormonal therapy, anti-hormonal therapy, or endocrine therapy. Breast and prostatic carcinomas are commonly treated with hormonal therapy.

- Most cases of breast carcinoma have either estrogen receptors (ERs) or progesterone receptors (PRs) or both, which means these breast carcinoma cases need these hormones to grow and disseminate to distant organs. Tamoxifen, selectively estrogen receptor modulator blocks estrogen in breast carcinoma. Tamoxifen may be recommended after surgery for early ER positive breast carcinoma.
- Aromatase inhibitor works by inactivating aromatase used to make estrogen in the ovaries and other tissues. Aromatase inhibitor is primarily used in premenopausal young women to suppress ovarian function in patients with breast carcinoma before surgery to shrink.
  - Fulvestrant binds to estrogen receptor, completely stopping the hormone from attaching to the receptors.

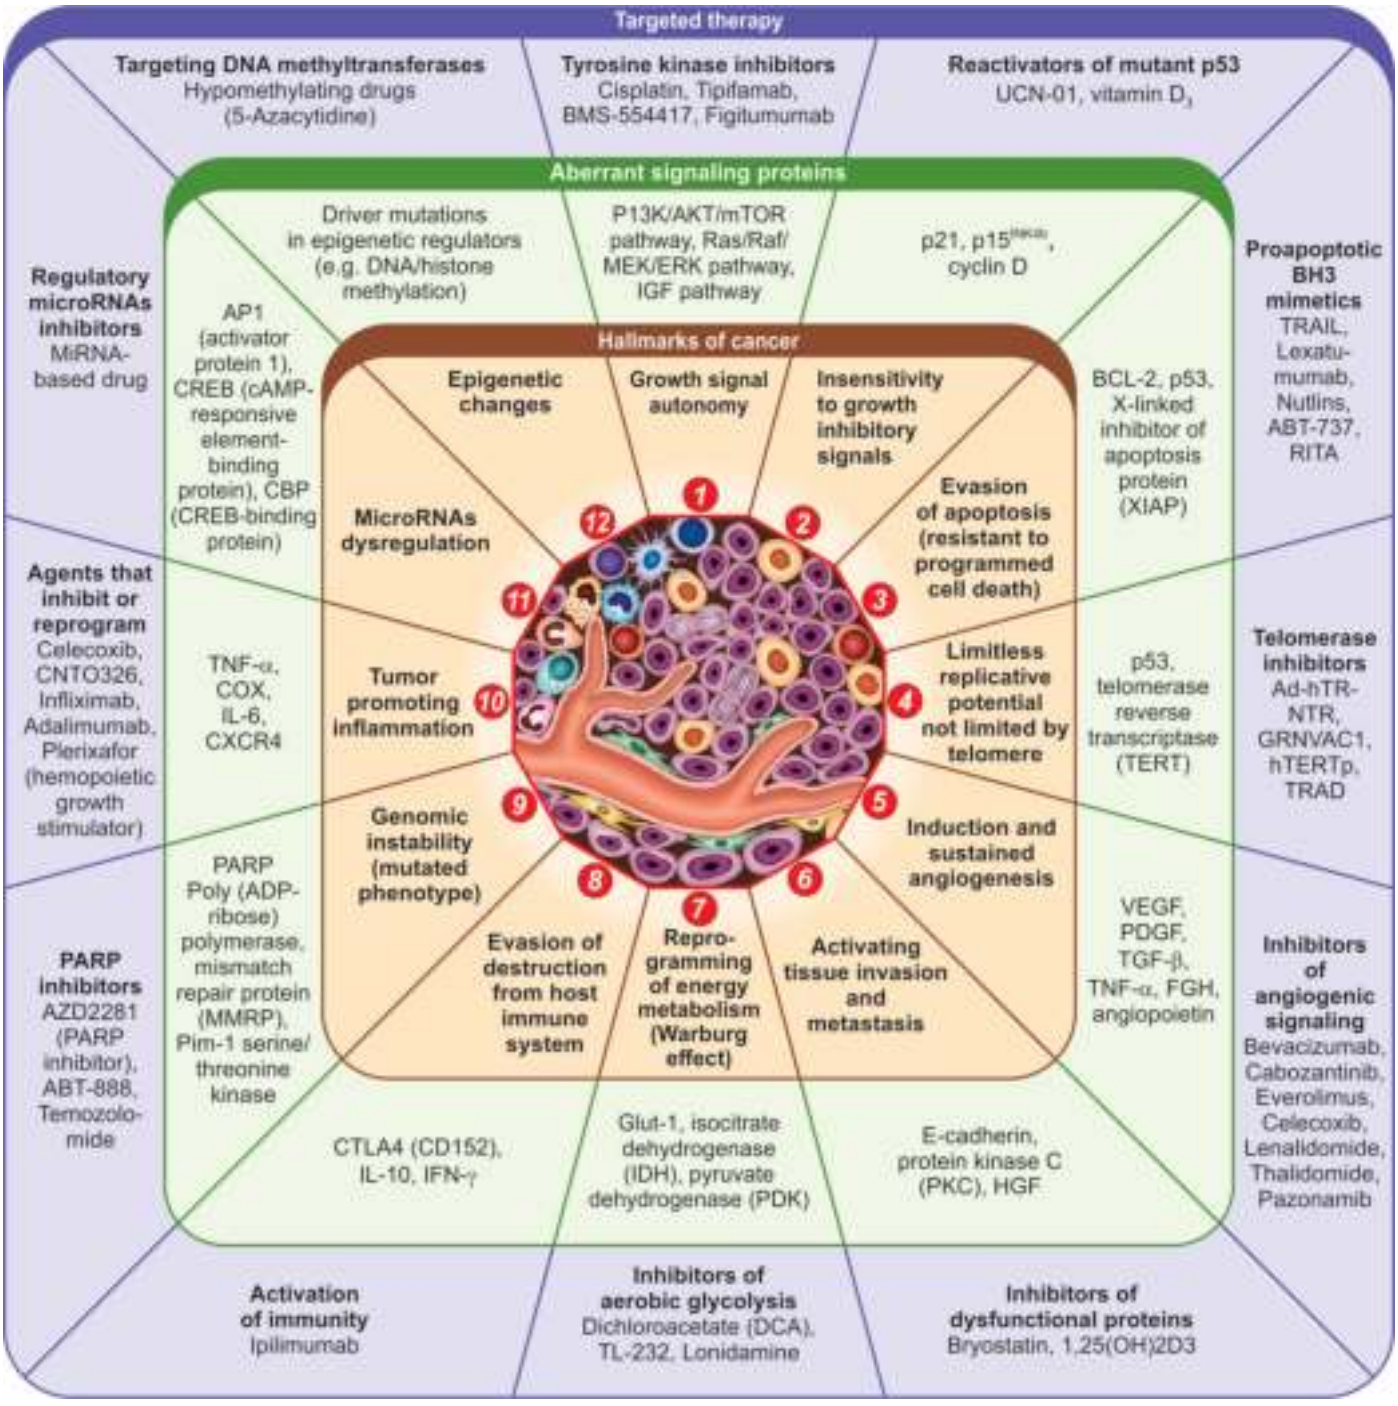

Fig. 6.133: Therapeutic targeting of the hallmarks of cancer drugs that interfere with each of the hallmark capabilities and hallmark-enabling processes have been developed and are in preclinical and/or clinical testing, and in some cases, approved for use in treating certain forms of human cancer. A focus on antagonizing specific hallmark capabilities is likely to yield insights into developing novel, highly effective therapeutic strategies. PARP: Poly (ADP-ribose) polymerase; VEGF: Vascular endothelial growth factor, HGF: Hepatocyte growth factor.

- Fulvestrant is recommended for women who have advanced ER positive breast carcinoma that spreads following treatment with estrogen therapy in ER positive breast carcinoma. Ovarian suppression may involve surgical oophorectomy, drugs, and radiation therapy.
- On the contrary, patient with prostatic carcinoma needs testosterone and other male sex hormones, such as DTH, to grow and metastasize to distant organs. Hormonal therapy may help patient with prostatic carcinoma, so that testosterone and DTH hormones are less available for growing CSCs.

CHEMOTHERAPY

Chemotherapy is an aggressive form of chemical drug therapy meant to destroy rapidly growing and dividing CSCs in the body. Chemotherapeutic agents are classified according to their mechanism of action and include alkylating agents, antimetabolites, topoisomerase inhibitors, antibiotics, mitotic inhibitors, and protein kinase inhibitors.

- Chemotherapeutic agents used in treating cancer patients are given in Table 6.115.
- Chemotherapy is most often administered with surgery, radiation, or hormonal therapy. The use of combination therapy depends on the location, histologic type, and stage of malignant tumors.
- Chemotherapy has been proven to effectively attack CSCs, but it can induce serious side-effects, that can have severe impact on quality of life.
- Chemotherapeutic agents generally affect DNA synthesis, DNA repair, and promote CSCs apoptosis. Cell cycle-specific chemotherapeutic agents prevent DNA synthesis, and act on the synthetic (S) phase of the cell cycle. Cell cycle-independent chemotherapeutic agents act at all phases of cell cycle, and include alkylating agents, which bind to DNA, and anthracyclines, which induce breakage of DNA strand.
- Chemotherapy is associated with wide-range of adverse effects (e.g. nausea, vomiting, immunosuppression, impaired growth, and proliferation of healthy cells and tumor lysis syndrome). Some chemotherapeutic agents increase the risk of development of secondary malignancy. Adverse effects of chemotherapeutic agents are given in Table 6.116.

Table 6.115 Chemotherapeutic agents used in treating cancer patients

Chemotherapeutic Agents Categories	Chemotherapeutic Agents	Mechanism of Action
Microtubule inhibitors	▪ Paclitaxel ▪ Vinblastine ▪ Vincristine ▪ Eribulin	Inhibits cellular mitosis phase
Cell cycle-independent drugs	▪ Platinum agents (e.g. cisplatin) ▪ Alkylating agents (e.g. busulfan, cyclophosphamide, chlorambucil, melphalan, ifosfamide)	Cross-linkage in DNA prevents DNA replication and transcription during G1–G0 phase
Antimetabolites	▪ Methotrexate ▪ Cytosine arabinoside ▪ Azathioprine ▪ Gemcitabine ▪ Fludarabine ▪ Cladribine ▪ 6-Fluorouracil ▪ Hydroxyurea ▪ 6-Mercaptopurine	Block essential enzymes and interfere in the synthesis of DNA and RNA during synthetic (S) phase
Topoisomerase inhibitors	▪ Etoposide ▪ Teniposide ▪ Irrinotecan ▪ Topotecan	Inhibit DNA synthesis and double check repair during G2 phase and S phase
Antibiotics	▪ Bleomycin ▪ Mitomycin ▪ Nitrosoureas	Drug binds to guanosine–cytosine-rich portions of DNA and breaks DNA strand during G2 phase
Receptor tyrosine kinase (RTK) inhibitors	▪ EGFR inhibitors (e.g. gefitinib, erlotinib, cetuximab) ▪ Kit/BCR-ABL inhibitors (e.g. imatinib/dasatinib)	Receptor tyrosine kinase (RTK) inhibitors are potent antineoplastic agents which target protein tyrosine kinases that are altered in CSCs and that account for some of their abnormal growth

Table 6.116 Adverse effects of chemotherapeutic agents

Chemotherapeutic Agent	Toxicity
Doxorubicin (Adriamycin)	Cardiomyopathy analyzed by nuclear ventriculogram for assessing left ventricular ejection fraction. Use the MUGA scan to determine prior to the development of symptoms
Vincristine	Neuropathy
Bleomycin	Pulmonary fibrosis
Cyclophosphamide	Hemorrhagic cystitis
Cisplatin	Nephrotoxicity and ototoxicity

- Oncologist administers some detoxifying agents to avert side-effects of some chemotherapeutic agents in cancer patients such as **leucovorin** administered in the treatment of methotrexate toxicity, and chemotherapy regimens, and mesna injection to lower risk for inflammation, and bleeding of urinary bladder, who receive ifosfamide.

Pathology Pearls: Chemotherapy-induced Secondary Malignancies

- Systemic anticancer treatment with chemotherapy and hormonal therapy are associated with increased risk of screening for secondary malignant neoplasm (**SMN**).
- Prior cytotoxic treatment-related acute myelogenous leukemia (**AML**), and myelodysplastic syndrome (**MDS**) are the most established examples.
- Alkylating agents, topoisomerase II inhibitors and antimetabolites have the highest leukemogenic potential.
- Administration of chemotherapy also increases the risk of development of solid malignancies after 10 years of therapy.
- Exposure to alkylating agents increase the risk of second malignancies such as lung carcinoma, thyroid carcinoma, gastrointestinal carcinoma, urothelial carcinoma, andsarcoma.
- Exposure of urothelium to metabolic product of alkylating agent (e.g. cyclophosphamide) increases the risk of urothelial carcinoma.
- Direct exposure of gastrointestinal epithelium to procarbazine increases the risk of development of treatment-related secondary gastrointestinal tract malignancies.
- Administration of lenalidomide immunomodulator also increases the risk of development of treatment-related AML.

Pathology Pearls: Tumor Lysis Syndrome

- Tumor lysis syndrome is the most common oncologic emergency prevalent in patients undergoing chemotherapy within hour of chemotherapy with characteristic findings of hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia leading to end-organ damage.
  - High uric acid can deposit as crystals in kidneys and impair functioning of kidneys. High phosphatase can also impair functioning of kidneys. High potassium can cause nausea, vomiting, diarrhea, cardiac arrhythmias, and heart attack.
  - Uremia impairs functioning of kidneys and can cause adverse effects on bones, muscles, and blood vessels.
  - Hypocalcemia can cause changes in cardiac rhythm, muscle cramps, contusions, numbness and tingling sensations and potentially cardiac arrest.
- Tumor lysis syndrome is most common in patients diagnosed with **leukemia**, who have a very high white blood cell count. Tumor lysis syndrome also occurs in patients with **diffuse large B cell lymphoma (DLBCL), Burkitt's lymphoma, neuroblastoma** and **hepatoblastoma**.
- Most of symptoms observed in patients with tumor lysis syndrome are related to the release of intracellular chemical substances into the bloodstream that cause impaired functions of target organs (i.e. acute kidney injury, fatal cardiac arrhythmia) and even death.
- ECG is a part of the workup for patients with tumor lysis syndrome to check for findings associated with hyperkalemia and hypocalcemia.
- Blood urea nitrogen (BUN) and creatinine are also elevated in tumor lysis syndrome.

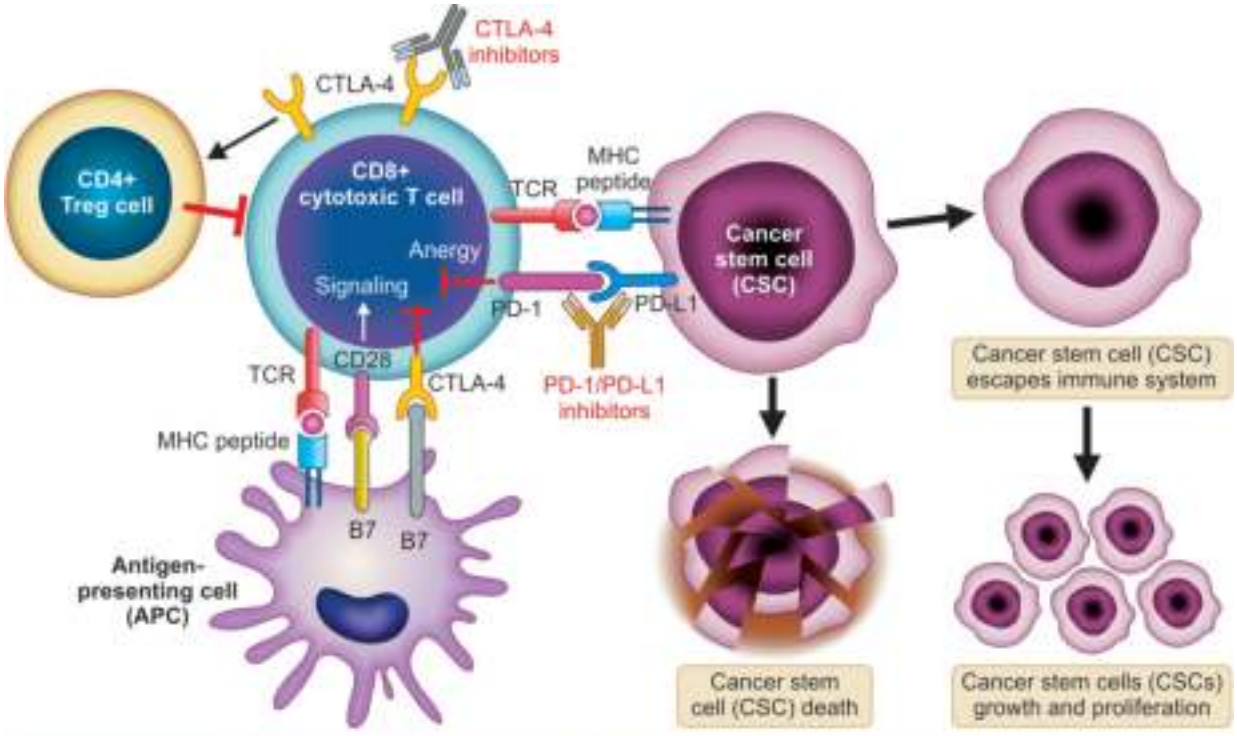
IMMUNOTHERAPY

Immunotherapy is a type of treatment designated to boost immune response, that attacks CSCs by targeting several immune checkpoint pathways. There are five types of immunotherapies: checkpoint inhibitors, adoptive cell therapy (T cell transfer therapy), cancer vaccines, monoclonal antibodies, and immune system modulators. Immunotherapy currently uses antibodies made in the laboratory to boost immunity against malignancies of breast, urinary bladder, cervix, head and neck, liver, kidney, stomach, colorectum and lymph node (Hodgkin's disease). Common side-effects of immune checkpoint inhibitors include skin rashes, diarrhea, and fatigue.

Immune Checkpoints and their Blockade in Cancer Therapy

Normal cells express surface proteins, that bind to immune checkpoint proteins to turn them off, whereby immune system does not attack normal cells. Checkpoint proteins and other proteins regulate flow of signals to T cells telling the cells when to 'turn on' or 'turn off''. T cell 'turning on' kill the CSCs. Immune checkpoint inhibitors in cancer treatment are shown in Fig. 6.134.

- Cancer stem cells (CSCs) can also utilize same protective mechanism by expressing surface proteins that interact with checkpoint proteins on immune cells to overcome the immune surveillance.
- Immunotherapy drugs called immune checkpoint inhibitors work by blocking checkpoint proteins from binding with their partner proteins. These immunotherapy drugs block different checkpoint proteins such as PD-L1 (programmed cell death ligand 1), PD-1 (programmed cell death protein 1), and CTLA-4 (cytotoxic T lymphocyte-associated protein 4). CTLA-4 and PD-1 are found on T cells.
- PD-L1 is present on CSCs. Blocking the binding of PD-L1 to PD-1 with an immune inhibitor (anti-PD-L1) allows the T cells to kill CSCs.
- In clinical oncology, immune checkpoint inhibitors are used to treat cancer patients, which include: monoclonal antibodies blocking CTLA-4 (ipilimumab,



Immunosuppressive mechanisms in the tumor microenvironment (TME)	
Immunosuppressive cells in the tumor microenvironment (TME)	
• CD4+ regulatory T cell (Treg) • Bone marrow-derived suppressor cell (MDSC) • Tumor-associated macrophage (TAM-M2 polarized)	• Tumor-associated neutrophils (TAN) • Extracellular matrix (ECM) restricts activated CD8+ cytotoxic T cells to invasive tumor margin
Immune checkpoints in the tumor microenvironment (TME) and immune checkpoint inhibitors in cancer	
• **PD-1/PD-L1:** Antigen-presenting cells (APCs) patrol the body and pick up cancer stem cells (CSCs) and present to CD8+ cytotoxic T cells in the lymph nodes. CD8+ cytotoxic T cells become activated, undergo proliferation and head out to hunt for CSCs. – PD-1/PD-L1 acts to slow-down CD8+ cytotoxic T cell activity and fails to kill CSCs. – Blocking PD-1 or PD-L1 checkpoints by immune checkpoint inhibitors (monoclonal antibodies) restore CD8+ cytotoxic T cells antitumor activity and relieve immunosuppression leading to destruction of CSCs.	• **CTLA-4/B7:** CTLA-4 acts to slow-down CD8+ cytotoxic T cell activity. Blocking CTLA-4 checkpoints by immune checkpoint inhibitor (monoclonal antibody) allows CD8+ cytotoxic T cell to kill CSCs. • **LAG-3/TIM-3:** LAG-3 checkpoint promotes tumor cell immune escape in the tumor microenvironment. TIM-3 checkpoint plays a role in CD8+ cytotoxic T cell exhaustion, loss of their effector functions, expression of multiple inhibitory receptors and altered transcriptional programme in cancer. Blocking LAG-3/TIM-3 checkpoint inhibitors (monoclonal antibodies) restore CD8+ cytotoxic T cells antitumor activity and relieve immunosuppression leading to destruction of CSCs.

Fig. 6.134: Immune checkpoint inhibitors in cancer treatment. Inability to activate CD8+ cytotoxic T lymphocytes (CTLs) in tumor microenvironment through the suppressive effect or regulatory T cells (Tregs) through immune checkpoints allow CSCs to escape immune attack, survive and grow. B7 ligands expressed on APCs bind to CD28 receptor on CTL leading to T cell amplification and immune response. Alternately, binding of B7 ligands to CTLA-4 expression on T cells suppresses their activity. Cytotoxic T-lymphocyte antigen 4 (CTLA-4) also enhances the activity of Tregs leading to immunosuppressive activity. Programmed cell death 1 (PD-1) is expressed on activated T cells. PD-1 binds to its programmed cell death ligand 1 (PD-L1) leading to the anergy of CTLs further promoting inhibitory signals. Pharmacological inhibition of immune checkpoints with monoclonal antibodies restores CTL antitumor activity and relieves immunosuppression.

tremelimumab), PD-1 inhibitors (nivolumab, pembrolizumab) and PD-L1 inhibitor (atezolizumab).

Cytotoxic Lymphocyte Antigen 4 (CTLA-4) Immune Checkpoint Inhibitor

Cytotoxic lymphocyte antigen 4 (CTLA-4) is a member of immunoglobulin superfamily and expressed on some types of immune cells. CTLA-4 is a regulatory molecule normally acts as type of switch '**turning off**' that suppresses CD8+ cytotoxic T cell effector function following initial activation by costimulatory signals such as TNF-α and interferon-γ (IFN-γ). Fully human monoclonal antibodies such as ipilimumab (Yervoy) and tremelimumab (Imjudo) targeting CTLA-4 have been

shown to increase T cell function, and antitumor responses by elimination of CSCs in patients with advanced metastatic melanoma.

- CD8+ cytotoxic T cells in the tumor microenvironment (TME) are most often supported by CD4+ helper T cells (Th1 cells) that produce IL-2 and IFN-γ. Other CD4+ helper T cells (Th2 cells) support the B cell activity by releasing IL-4, IL-5 and IL-13.
- Moreover, Th17 cells release IL-17A, IL17F, IL-21 and IL-21, which promote malignant tumor growth by fostering an inflammatory tumor environment. Precise understanding of the functions of immune cells and their interaction with other stromal cells as well as CSCs in tumor microenvironment (TME) is essential for the development of a sustainable and effective strategy for cancer immunotherapy.

Programmed Cell Death Protein 1 (PD-1) Immune Checkpoint Inhibitor

Programmed cell death protein 1 (PD-1) is a checkpoint cell surface protein on immune cells (T cells, B cells, macrophages, dendritic cells (DCs), and natural killer cells). PD-1 modulates T cell activity in peripheral tissues via interactions with its soluble ligands PD-L1 and PD-L2.

- PD-1 normally acts as a type of switch (**'turning off'**) that helps keep T cells from attacking other cells in the body. PD-1 does this when it attaches to CSCs. When PD-1 binds to PDL-1, it basically conveys the T cell to leave the other cell alone. Some CSCs have large amount of PD-L1, which helps them hide from an immune attack.
- Monoclonal antibodies that target either PD-1 or PD-L1 can block PD-1/PD-L1 binding and boost the immune system response against CSCs.
- Some anticancer drugs, called immune checkpoint inhibitors, are used to block PD-1 and PD-L1 interaction.
  - Examples of checkpoint inhibitor monoclonal antibodies that target PD-1 include: nivolumab (Opdivo), pembrolizumab (Keytruda) and cemiplimab (Libtayo) administered to treat melanoma, Hodgkin's disease and non-small cell lung carcinoma.
  - Nivolumab is used to treat some patients of renal cell carcinoma and head and neck cancers. Pembrolizumab is used to treat cancers of urinary tract.

Programmed Cell Death Protein–Ligand-1 and 2 (PD-L1 and PD-L2) Immune Checkpoint Inhibitor

Programmed cell death protein–ligand 1 (PD-L1) is a transmembrane protein that plays a major role in suppressing adaptive immune system. PD-L1 drives PD-1-mediated immune inhibition and is consequently expressed on T cells, B cells, macrophages and APCs, heart and lungs parenchymal tissues, and CSCs.

- PD-L1 is also detected in low levels on cardiac endocardium, pancreatic islets and syncytiotrophoblasts in the placenta, highlighting a role of PD-L1 in immunological tolerance.
- Examples of checkpoint inhibitor monoclonal antibodies that target PD-L1 include atezolizumab (Tecentriq), avelumab (Bavencio) and durvalumab (Imfinz). PD-L1 blockade can also be demonstrated efficacy in lung, urinary bladder, and other cancers.
- Programmed cell death protein–ligand 2 (PD-L2) is also an immune checkpoint inhibitor. The engagement of PD-1 by PD-L2 dramatically inhibits TCR-mediated proliferation, and cytokine production by CD4+ helper T cells. Programmed cell death protein–ligand 2 (PD-L2) proteins are being investigated in clinical trials.

LAG-3/TIM-3 Immune Checkpoint Inhibitor

LAG-3 is an immune checkpoint protein expressed on some types of immune cells, that normally suppresses CD8+ cytotoxic T cell effector function.

- On contrary, LAG-3 encourages differentiation of regulatory T cells (Tregs). Relatimab is a monoclonal antibody that attaches to LAG-3 and stops it from working. This can help boost the immune system response against CSCs.
- TIM-3 is an immune checkpoint receptor that suppresses antitumor response by negatively regulating the activity of CD8+ cytotoxic T cell and APCs. Anti-TIM-3 immune checkpoint monoclonal antibody boots immune system response against CSCs.

Pathology Pearls: Immune Checkpoint Inhibitors in Cancer Treatment

- Antigen-presenting cells (APCs) patrol the body and pick up evidence of threat-like CSCs.
- APCs present evidence of CSC to CD8+ cytotoxic T cells in the lymph nodes.
- CD8+ cytotoxic T cells become activated and undergo proliferation and head out to hunt for CSCs. CTLA-4 acts to slow down CD8+ cytotoxic T cell activity. Blocking CTLA-4 by checkpoint inhibitor monoclonal body allows CD8+ cytotoxic T cell killing CSCs.
- CD8+ cytotoxic T cells recognize and kill CSCs. PD-1/PD-L1 acts to slow down CD8+ cytotoxic T cell activity and fails to kill CSC. Blocking PD-1 or PD-L1 by checkpoint inhibitor monoclonal body restores CD8+ cytotoxic T cells anti-tumor activity and relieve immunosuppression leading to destruction of CSCs.

Adoptive T Cell Therapy (T Cell Transfer Therapy)

Adoptive T cell therapy (T cell transfer therapy) with tumor infiltrating lymphocytes or gene modifies T cells expressing novel T cell receptors is a treatment that uses a cancer patient's autologous T cells with anti-tumor activity, expanded *in vitro* in laboratory. The process of growing own T cells in the laboratory can take two to eight weeks. During this time, cancer patients (e.g. acute lymphoblastic leukemia/diffuse large B cell lymphoma, multiple myeloma) are treated with chemotherapy and radiation therapy to get rid of other immune cells. Cultures with high anti-tumor reactivity are expanded to $>10^{10}$ cells and reinfused into the cancer patient (melanoma) following the administration of a conditioning of lymphodepleting interleukin-2 (IL-2).

Cancer Vaccines

Cancer vaccines are used to treat patients with cancers expressing viral antigens called immunotherapy, which work to boost immune response and can destroy CSCs and inhibit metastasis to distant organs. Some cancers are caused by viruses. Cancer vaccines can provide protection against viral infections inducing cancers. Vaccinating children and certain young adults against human papillomavirus (HPV) provide protection against cancers of cervix, anal region, throat, vagina and penis.

Monoclonal Antibody-based Drugs

Monoclonal antibodies are laboratory-produced molecules engineered with plant or bacterial toxin to form immunotoxin complex, that can enhance or modify immune system's attack on the target CSCs only, but sparing normal cells. The monoclonal antibodies kill CSCs, interfere with angiogenesis, and suppress local production of growth factors.

- The monoclonal antibody-based drugs are currently employed in the treatment of breast carcinoma, colorectal carcinoma, and NHL. Selected monoclonal antibody-based drugs used in various cancers are given in Table 6.117.
- Monoclonal antibodies are designed to function in different ways: (a) CSCs coated with monoclonal antibodies are easily detected by immune system and targeted for destruction, (b) monoclonal antibodies can trigger immune system, that destroys membrane of CSCs, (c) monoclonal antibodies block the interaction of CSCs, with proteins, that promote cell growth and unrestricted CSCs proliferation, (d) as blood supply is essential for growth of malignant tumor, hence some monoclonal antibodies block protein–cell interactions, hence inhibit tumor angiogenesis, (e) certain monoclonal antibodies attack and destroy CSCs, (f) certain monoclonal antibodies combined with a small radioactive particle assists in transport of radiation treatment directly to CSCs, and thus minimize the effect of radiation on healthy cells, (g) similarly, monoclonal antibodies combined with chemotherapeutic agents, assist in transport of chemotherapeutic agent directly to CSCs, and thus minimize the effect of radiation on healthy cells, and (h) some drugs combined two monoclonal antibodies, one monoclonal antibody that attaches to CSCs, and

Table 6.117 Selected monoclonal antibody-based drugs used in various cancers

Agent	Target	Process Targeted	Cancer Type
Monoclonal antibody (mAb)			
Bevacizumab (Avastin)	Vascular endothelial growth factor (VEGF)	Angiogenesis	▪ Colorectal carcinoma (metastatic) ▪ Lung carcinoma
Cetuximab	Epidermal growth factor receptor	Growth factor signaling	Colorectal carcinoma
Trastuzumab (Herceptin)	HER2 growth factor receptor	Growth factor signaling	Breast carcinoma
Rituximab	CD20 Receptor	Induction of cell death	Non-Hodgkin's lymphoma (B cell)
Gemtuzumab ozogamicin (Mylotarg)	CD33	Blocks the growth of leukemic cells	Acute myelogenous leukemia
Small molecule inhibitors			
Imatinib	BCL-ABL fusion protein; kit	Growth factor signaling (tyrosine kinase inhibitor)	▪ Chronic myelogenous leukemia ▪ Gastrointestinal stromal tumors
Erlotinib	Epidermal growth factor receptor	Growth factor signaling	Non-small cell lung carcinoma
Bortezomib	Proteosome	Multiple processes affected	Multiple myeloma

Note that these names are coded to end in mAb for short of monoclonal antibody.
Herceptin is the brand name for trastuzumab

other monoclonal antibody, that attaches to immune system cells. This interaction may promote immune system attacks on the CSCs.

Immunomodulators used to Boost Immune System

Immunomodulators are used to boost immune response in cancer patients, which include cytokines (IFN-γ, interleukins), and immunoregulatory drugs (thalidomide, lenalidomide, pomalidomide, imiquimod).

- Cytokines drive communication between cells of immune system and coordinate attacks on specific CSCs and send signals that may help in survival of normal cells.
- Interferon-γ (IFN-γ) activates cellular immunity and stimulates subsequent anti-tumor immune response. Laboratory-prepared IFN-γ affects malignant tumors by virtue of its anti-angiogenic and antiproliferative properties.
- Interleukins bind to high-affinity receptors, and modulate cell growth, differentiation, and activate immune responses during inflammatory. IL-2 increases number of white blood cells especially T cells and B cells in the body.
- Laboratory-made interleukins are used to treat renal cell carcinoma and melanoma. Immunoregulatory drugs, also called biologic response modifiers, are medications, that boost immune system.

Pathology Pearls: Minimal Residual Disease

- Minimal residual disease (MRD) refers to presence of small number of CSCs especially in leukemias/lymphomas that remains occult within the patient after cancer treatment but eventually leads to relapse.
- In patients with acute lymphoblastic leukemia (**ALL**) and acute myelogenous leukemia (**AM**L) monitoring of minimal residual disease (**MRD**) offers a way to precisely assess early treatment.
- Polymerase chain reaction (**PCR**) and next generation sequencing (**NGF**) are performed on bone marrow samples at the time of initial diagnosis to look for genetic mutations in leukemic cells.
- Genetic mutations are reassessed again following treatment to determine minimal residual disease, even if leukemic cells can no longer be observed under the microscope.

PROGNOSIS OF SOLID CANCERS

Several solid malignant tumors can occur in several places such as organs, bones, muscles in adults. Most common solid malignant tumors in children are brain tumor, neuroblastoma, Wilms tumor, retinoblastoma, osteosarcoma, and Ewing sarcoma. Solid malignant tumors are carcinomas and sarcomas and are often treated with surgery. Prognosis of solid malignant tumors varies depends on origin in various organs. Prognosis of solid malignant tumors is given in Table 6.118.

Table 6.118 Prognosis of solid malignant tumors

Prognosis	Solid Malignant Tumors
Good prognosis	▪ Seminoma/dysgerminoma ▪ Basal cell carcinoma
Intermediate prognosis	▪ Breast carcinoma ▪ Colorectal carcinoma ▪ Laryngeal carcinoma ▪ Endometrial carcinoma ▪ Melanoma ▪ Teratoma testes ▪ Osteosarcoma
Poor prognosis	▪ Lung carcinoma ▪ Pancreatic carcinoma ▪ Gastric carcinoma ▪ Esophageal carcinoma ▪ Hepatocellular carcinoma ▪ Malignant mesothelioma

Pathology Pearls: Spontaneous Regression of Malignant Solid Tumors

- Spontaneous regression of pathologically confirmed solid malignant tumors, including those with metastases, is extremely rare but is documented for some malignant tumors of infancy and childhood and of adults.
- Some tumors may regress spontaneously such as renal cell carcinoma, neuroblastoma, retinoblastoma, malignant melanoma, leukemias, lymphomas, choriocarcinoma, hepatocellular carcinoma, cholangiocarcinoma, and osteosarcoma.
- Notably, in this regard is neuroblastoma in infants and childhood, which originates from neuroblasts of the adrenal medulla and usually has a highly aggressive course but, remarkably, in a small proportion of cases regresses by maturation/differentiation to a benign ganglioneuroma or disappears.

PREVENTION MODALITIES OF CANCERS

Cigarette smoking is usually associated with lung carcinoma. In cigarette smokers, there is also increased incidence of cancers of oral cavity and urinary bladder. Alcohol abstinence reduces squamous cell carcinoma of oropharynx and upper/middle esophagus, pancreatic and hepatocellular carcinomas. Increased adipose tissue increases aromatase conversion of androgens to estrogens, which increase risk for endometrial carcinoma and breast carcinoma. Therefore, reduction of body weight decreases risk for endometrial carcinoma and breast carcinoma.

- **Hepatitis B vaccination:** Immunization against HBV decreases the risk for hepatocellular carcinoma due to hepatitis B induced post-necrotic cirrhosis.
- **Screening procedures:** Cervical Papanicolaou smear examination detects cervical dysplasia (preneoplastic lesion), which can be surgically removed.
  - **Colonoscopy** detects numerous polyps that are precancerous.
  - **Mammography** detects non-palpable masses in breasts.
  - **Prostate-specific antigen (PSA)** detects prostatic carcinoma, but lacks specificity as it is increased in benign hyperplasia of prostate.
- **Treatment of conditions that predispose to cancer:** Eradication of *Helicobacter pylori* decreases the risk for developing MALT lymphoma and gastric adenocarcinoma. Treatment of gastroesophageal reflux disease (GERD) decreases the risk for adenocarcinoma arising from Barrett's esophagus.

MOLECULAR DIAGNOSTICS IN ONCOLOGY

Molecular diagnostics in oncology are tests that detect alterations in chromosomes, deoxyribonucleic acid (DNA), ribonucleic acid (RNA), proteins, and metabolites that provide information about screening of high-risk populations, cancer diagnosis, prognosis and severity of disease, therapy selection, molecular stratification of otherwise identical malignant tumors for the purpose of treatment and efficient management, monitoring the clinical course of disease, predicting response to therapy, prevention of cancer, diagnosis of hereditary predisposition to cancer, detection of minimal residual disease (MRD), establishment of baseline values for assessment of future change and clinical research studies. Proteins released by malignant tumors into the serum can be used to screen populations for cancer and to monitor recurrence following treatment.

- Gene consists of three types of nucleotide base pair sequences: (a) coding regions, called exons, which specify a sequence of amino acids, (b) noncoding regions, called introns, which do not specify amino acids, and (c) regulatory sequences, which play a role in determining when and where the protein is produced. Enhancer region of DNA is far away, whereas promoter region near to gene. Transcription factors and mediator proteins complex 'turn on' the gene and help RNA polymerase to the reads the gene.
- Each organ contributes wild-type DNAs to the circulation, while organ metastatic seeds will shed mutant DNA.
- Integrated analysis of DNA, RNA and methylation next generation sequencing will help elucidate all relevant genetic alterations in malignant tumors: gene structural variation, gene copy number variation, gene mutational profile, gene mutational spectrum, gene mutational rate, gene arrangements, DNA methylation, RNA expression, and signaling pathways analysis.
- Cytogenetic, molecular diagnostics and epigenetic biomarkers can be performed for diagnosis and prognosis of cancer and its epidemiologic studies.
- Circulating small noncoding RNAs (e.g. microRNAs), long noncoding RNAs and exosomal RNAs thus reflect the overall host–tumor cross-talks.
  - Exosomal RNAs induce angiogenesis in human cancers.
  - Biomarkers are analyzed on samples obtained from blood plasma/serum, urine, cerebrospinal fluid, saliva, and malignant tumor tissue.
- One or more cancer-specific molecular markers are analyzed to study genetic or epigenetic pathways regulating cellular proliferation and differentiation or apoptosis. Some biomarkers are specific and highly sensitive for detection of malignant tumors.
- Learning some basic facts about DNA, RNA, and proteins, it is essential to understand the importance of biomarkers in human malignant tumors. Biomarkers are analyzed on samples obtained from blood plasma/serum, urine, cerebrospinal fluid, saliva, and tumor tissue.
- Some biomarkers are specific and highly sensitive for detection of malignant tumor. Recently, our knowledge on biomarkers has evolved significantly for improving the detection and efficient management of cancer patients.
- Selected examples of molecular diagnostics in malignant tumors are given in Table 6.119. Molecular diagnostics in oncology is shown in Fig. 6.135. Kindly refer to Chapter 14: 'Cellular–Molecular Diagnostic Techniques in Clinical Practice'.

PURPOSE TO ANALYZE CANCER BIOMARKERS

In general cancer biomarkers are classified by their different functions. Even within the biomarker categories, molecules that can trigger abnormal cell growth

Table 6.119 Selected examples of molecular diagnostics in malignant tumors

Molecular Biomarker	Associated Cancers
Human papillomavirus (HPV)	Cervical carcinoma
BRCA1/BRCA2 mutation	Inherited breast carcinoma and ovarian carcinoma
CA125	Ovarian carcinoma
Prostate-specific antigen (PSA)	Prostatic carcinoma
HER2/neu mutation	Breast carcinoma
DNA mismatch repair (MLH1, MSH2, MSH3, MSH6, PMS1 and PMS2) mutations	Hereditary nonpolyposis colorectal carcinoma (HNPCC) also called Lynch syndrome
c-KIT mutation	Acute myelogenous leukemia (AML), gastrointestinal stromal tumors, seminoma, and sinonasal NK cell lymphoma
EFGR mutation	Head and neck cancers, and lung carcinoma
EGFR, EML4-ALK, ROS1, K-RAS mutations	Non-small cell lung carcinoma
BRAF mutation	Colorectal carcinoma, melanoma, thyroid carcinoma, lung carcinoma, brain gliomas and hairy cell leukemia
BCR-ABL1 mutation	Chronic myelogenous leukemia (CML), and B cell acute lymphoblastic leukemia (B-ALL)
IGH-BCL-2 mutation	B cell lymphoma
K-RAS, N-RAS mutation	Colorectal carcinoma
TP53 mutation	Li-Fraumeni
ATRX mutations	Brain gliomas, neuroendocrine tumors, osteosarcoma, liver angiosarcoma, leiomyoma

Molecular diagnostics are most performed on samples of blood, saliva, or tumor tissue.

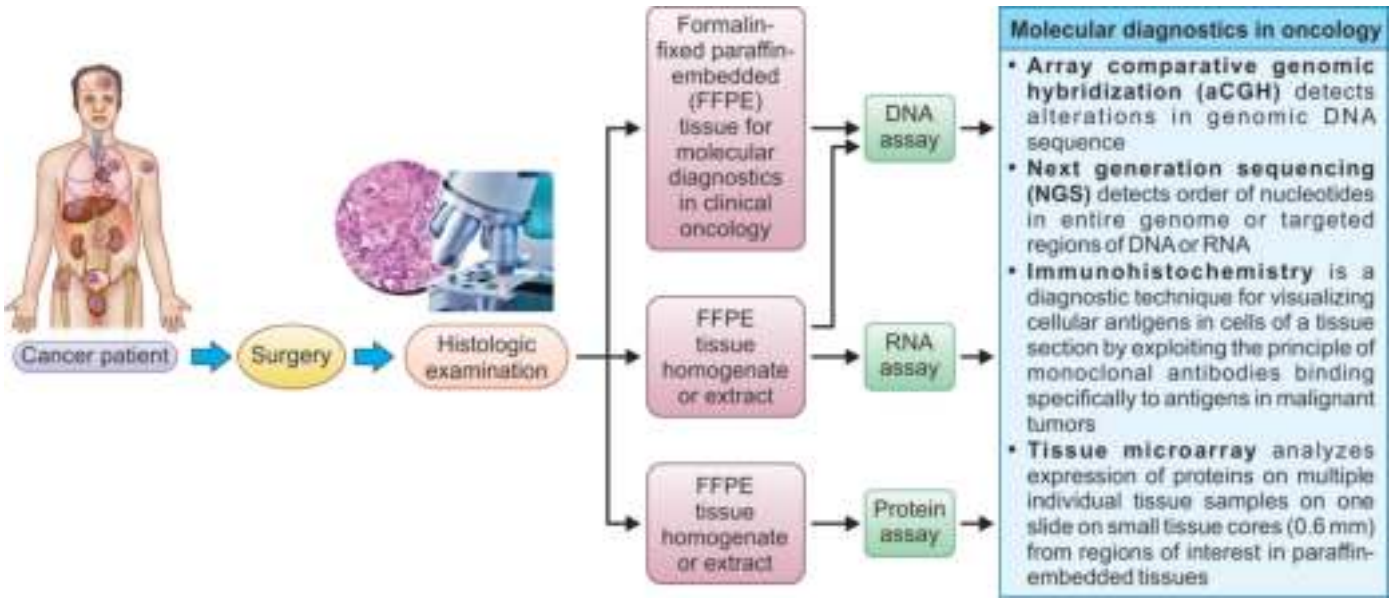


Fig. 6.135: Molecular diagnostics in oncology. There are multiple applications of molecular tests in clinical oncology. Mutation analysis is now routinely performed for the diagnosis of hereditary cancer syndromes and healthy carriers of cancer predisposing germline mutations. Mutation analysis is performed to detect somatic mutations. Tumors almost always shed their fragments (i.e. single cells or their clusters, DNA, RNA, and proteins) or some other tumor-derived molecules hold a great promise for non-invasive monitoring of cancer disease, analysis of drug-sensitizing mutations and early cancer detection through screening. Some tumor- or tissue-specific mutations and medically relevant DNA, RNA and protein-base markers expression can be efficiently utilized for the diagnosis of cancers of unknown primary origin.

and proliferation can come from a gene mutation or extra copies of an otherwise healthy gene within the tumor's DNA.

- **Analysis of unrestricted cell proliferation:** HER2/neu-positive breast cancer that rests positive for protein called epidermal growth factor receptor 2 (EGFR2, i.e. HER2) leading to unrestricted CSC proliferation and progressive disease. Targeted 'Herceptin therapy' is known to disrupt the HER2 signaling pathway, that inhibits cell growth, proliferation, and progression of disease.
- **Analysis of cellular changes in cancer:** SPARC (secreted protein, acidic, rich in cysteine) protein regulates interactions between cells and their surrounding extracellular matrix (ECM), and collagen in bones.
  - SPARC protein governs cell adhesion, proliferation, and differentiation. Cell migration and metastasis greatly contribute to the progression of cancers.
  - In highly malignant tumors (i.e. glioblastoma multiforme, melanoma, breast carcinoma and prostatic carcinoma), SPARC protein promotes bone metastasis and transforming growth factor-β (TGF-β) induced epithelial–mesenchymal transition (EMT).
- **Analysis of efficacy platinum-based chemotherapeutic agents:** Platinum-based chemotherapeutic drugs (**cisplatin, carboplatin** and **oxaliplatin**) are widely used for eradication of CSCs. However, there is a protein-encoded by **ERCC1** (excision repair 1, endonuclease non-catalytic unit) gene, that repairs tumor DNA. If cancer biomarker testing detects high levels of ERCC1 protein in a patient's malignant tumor, platinum-based chemotherapeutic agents are not likely to be very effective for that patient.

SPECIMEN REQUIREMENTS FOR MOLECULAR DIAGNOSTICS IN CANCER

Biomarkers are analyzed on samples obtained from blood plasma/serum, urine, cerebrospinal fluid, saliva, and tumor tissue.

- Fresh tissue is required for cell culture and subsequent G-banded metaphase cell preparations or metaphase FISH procedures and special karyotyping multicolor FISH techniques.
- DNA can be extracted from the fresh, frozen, or formalin-fixed paraffin-embedded tumor tissue for comparative genomic hybridization platforms.
- Cytologic touch imprints are prepared from fresh or frozen malignant tumor tissue. Formalin-fixed paraffin-embedded malignant tumor tissue is used to analyze interphase FISH.
- Blood and bone marrow samples should be drawn into anticoagulated tubes containing ethylene-diaminetetra-acetic acid (EDTA) and transported at ambient temperature for DNA sequencing.

MOLECULAR DIAGNOSTICS USES IN ONCOLOGY

In the field of oncology, biomarkers have several potential applications in oncology, including risk assessment, differential diagnosis, prognosis, prediction of treatment response, pharmacokinetics, monitoring treatment response and monitoring of disease progression and cancer recurrence.

- **Biomarker use to recognize genetic variations:** Genetic variations are nonpathogenic and present in 1% of healthy population. Term '**polymorphism**' is used to describe nonpathogenic genetic variation, and mutation is a change in DNA sequence from errors in DNA replication during cell division.
  - Conversion of a proto-oncogene to oncogene is called activation, which results from transduction, insertional mutagenesis, point mutation (single nucleotide substitution), deletions, insertions, amplification, copy number variations, and chromosomal rearrangements. Mutations can be classified according to their effects on structure of gene, i.e. gene promoters, splicing regions, and coding regions (missense, nonsense, and salient mutations). K-RAS, BRAF and HER2/neu gene mutations are common in lung cancers. ALK gene activated by point mutation in neuroblastoma, and chromosomal translocation in non-small cell lung carcinoma (NSCLC) and anaplastic large cell lymphoma.
  - Tumor suppressor genes inhibit cell proliferation and malignant tumor development. Tumor suppressor genes require two mutational hits, i.e. inactivation/biallelic loss to induce malignant tumors. Point mutations or deletions in tumor suppressor TP53 and CDKN2A genes are linked to many cancers.
- **Biomarker use in risk assessment of cancer:** Molecular diagnostics refers to molecular profiling, that can be used to assess whether an individual is at risk for development of certain histologic type of malignant tumor. Molecular testing can also be used to decide whether an individual should undergo more intensive screening or take preventive measures. For example, blood sample is used to analyze BRCA1 and BRCA2 genes in patient and close relatives (e.g. mother, aunt). BRCA1 and BRCA2 gene alterations can increase risk of breast carcinoma and ovarian carcinoma.

- **Biomarker use in differential diagnosis of cancer:** Molecular diagnostics plays pivotal role in clinical oncology in establish diagnosis, tumor origin and histologic subtypes, that affects the clinical course. The cancer's subtype may have implications for treatment.
  - Chromosomal translocations are one of the biomarkers for cancer diagnosis (e.g. BCR-ABL1 gene fusion in chronic myelogenous leukemia), and heavy immunoglobulin–Myc gene fusion in Burkitt's lymphoma.
- Molecular diagnostics is widely used to diagnose and determine clinical course of acute myelogenous leukemia (AML) and acute promyelocytic leukemia (APL).
  - Acute myelogenous leukemia (AML) is classified into poor, intermediate and favorable risk categories based on evaluation of chromosomes. Patients with intermediate risk of AML should undergo molecular testing for different gene mutations.
  - Karyotyping detects chromosomal translocations in various malignancies such as in papillary thyroid carcinoma (RET-PTC gene fusion), prostatic carcinoma (TMPRSS-ETS gene fusion) and other solid malignant tumors.
- **Biomarker use to assess prognosis in cancer patients:** Prognosis is defined as the natural course of disease in the absence of treatment or a predicted clinical outcome of cancer patients from medical treatment.
  - Some malignant tumors are naturally more aggressive than others, malignant tumors and knowing, this can help the clinician to select line of treatment. For example, alteration in FLT3 gene in AML is associated with aggressive clinical course. FLT3 inhibitor is administered to treat such AML cases. Molecular diagnostics can also be used to evaluate the response of AML to treatment in relation to its recurrence.
  - Several molecular diagnostics are available to predict the clinical course of breast carcinoma in female with early stage disease, lymph node negative, estrogen receptor (ER) positive, and treated with tamoxifen 'anti-estrogen' therapy. These molecular tests analyze multiple genes in CSCs obtained from a tissue sample of the breast carcinoma.
- **Biomarker use in prediction of treatment response in cancer patients:** Molecular diagnostics can be used to predict response to treatment. Molecular testing is done to analyze HER2/neu gene amplification, which directs CSCs to produce excess of human epidermal growth factor receptor 2 (EGFR2, i.e. HER2), leading to rapid cell proliferation and hence breast carcinoma. A drug known as 'trastuzumab' sold under the brand name 'Herceptin' is a monoclonal antibody, that inhibits the activity of HER2 protein.
- **Biomarker use in pharmacokinetics in cancer patients:** Pharmacokinetics is the aspect of pharmacology dealing with how drugs are absorbed, distributed, metabolized, and eliminated from the body.
  - Depending on the genetic constitution of individuals, therapeutic drug is metabolized at a faster rate in some individuals. Therapeutic drug '**irinotecan**' (topoisomerase 1 inhibitor) is used to treat colon carcinoma. Irinotecan is converted to an active metabolite SN-38, which is then inactivated, and detoxified by UDP-glucuronosyltransferase **(UGT)** enzyme encoded by the UGT1A1 gene in the body. UDP-glucuronosyltransferase (UGT) enzymes are responsible for glucuronidation, a process that transforms lipophilic metabolites into water-soluble metabolites that can be excreted from the body.
  - Patient of colon carcinoma with a genetic pattern designated 'UGT1A1-28' metabolize 'irinotecan' more slowly than those without this pattern. To prevent the accumulation of 'irinotecan' in the body, these persons must be administered a lower dose of therapeutic drug than normal.
- **Biomarker use in monitoring treatment response in cancer patients:** Molecular diagnostics monitors response to neoadjuvant chemotherapy by analyzing blood biomarkers at multiple times over the course of the treatment of many human cancers.
  - Patients with chronic myelogenous leukemia (CML) are treated by imatinib for years. Such CML patients can develop resistance to imatinib due to change in the sequence of genetic material over time.
  - Consequently, CML patients, who no longer respond to imatinib may undergo molecular diagnostic testing to determine whether the gene has changed. Successfully treated CML patients are monitored at regular intervals for signs of recurrence of disease. It is essential to develop better molecular diagnostics that can accurately monitor cancer recurrence, whose disease has been successfully treated.

Pathology Pearls: Molecular Diagnostics Applications in Oncology

There are multiple applications of molecular tests in clinical oncology, which utilizes molecular-based assays CTCs, ctDNA, RNA and proteins.

- **Herediatry cancer syndromes testing:** Mutational analysis is routinely utilized for the diagnosis of hereditary cancer syndromes for identification of persons at-risk, risk of second malignancy and for personalization of systemic treatment.

- Healthy carriers of cancer-predisposing mutations benefit from close medical surveillance and various preventable interventions.
- Cancers caused by germline mutations in corresponding genes most often require significant modification of treatment strategy.
- Germline mutations in BRCA-1 and BRCA-2 genes are associated with probability of cancers of breast and ovary.
- Analysis of mutation-related to breast cancer risk includes BRCA1, BRCA2, PALB2, TP53, CHEK2, ATM, BLM, NBS/NBN, PTENRAD51CC, RAD51D, RECQL, FNACC, FANCM, BRAD1, and BRIP1.
- Hereditary nonpolyposis colorectal carcinoma (**HNPCC**) syndrome, also known as Lynch syndrome, is caused by germline mutations in MLH1, MSH2, MSH6, PMS2, and EPCAM genes.
- Molecular testing detects recurrent mutations (PCR), single-gene analysis (Sanger sequencing), multigene analysis (next-generation sequencing), and whole exome sequencing.

- **Predictive molecular markers:** There are several predictive tests (DNA, RNA, proteins, cells, and tissue slices) involving either the analysis of individual drug targets (EGFR, BRAF, ALK, ROS1 and PARP inhibitors) or identification of specific tumor phenotypes such as high level microsatellite instability (**MSI-H**), BRCA gene and mutation burden, which aid the choice of anticancer drugs.
- **Circulating tumor fragments and molecular tests:** Malignant tumors almost always shed their fragments (single cells or in clusters, DNA, RNA, and proteins) into various body fluids.
  - Monitoring of malignant disease can be achieved through molecularly driven detection of residual tumor fragments. It is anticipated that liquid biopsy will serve as an instrument for early cancer diagnosis and screening in the future.
  - Liquid biopsy has many clinical applications in oncology by analyzing circulating free tumor DNA (ctDNA)/viral DNA (virus-related malignancies), circulating free nucleic acids (cfNA), extracellular vehicles (EVs) and tumor-educated platelets (TEPs).
- **Carcinomas of unknown origin at primary site:** Recent developments are in the mutation testing and RNA analysis novel tools for diagnosis of cancers of unknown primary site. Tissue specific markers (RNA and proteins) and genetic markers (point mutation, gene rearrangements and gene copy variants) are analyzed to detect carcinoma of unknown primary tumor.

MOLECULAR TECHNIQUES: METHODOLOGIES

Extraction of intact, moderately high quality DNA or RNA is essential for molecular assays. Depending on the type of molecular diagnostics, molecular testing is currently performed on the malignant tumor itself, by analyzing circulating tumor cells (CTCs) and circulating free tumor DNA (ctDNA), chromosomal translocations, and other structural chromosomal abnormalities, gene structure, gene amplification, gene copy number variation (gains or losses), single nucleotide base pair substitutions, small deletions/insertions, single nucleotide polymorphisms (SNPs), and epigenetic alterations in gene expression, which facilitate diagnosis, subclassification, prognosis and monitoring response to therapy. On receipt of specimen, pathologist reviews the specimen adequacy, extracts DNA or RNA, analyzes and interprets results.

- **Nucleic acid hybridization:** Nucleic acid hybridization is based on the ability of single-stranded nucleic acid sequence (either DNA or RNA) to specifically hybridize/anneal (reestablishment of hydrogen bonds) to a complementary strand.
  - **Southern blotting technique and Northern blotting technique:** Southern blotting technique and Northern blotting technique use a radioactive or fluorescent probe apply the principle of nucleic acid hybridization (DNA and RNA sequences). Probes are the key tools in the hybridization techniques used to identify the complementary sequence in question. The important steps involved in blotting techniques include: (a) digestion of DNA or RNA in small fragments using restriction enzymes, (b) separation of nucleic acid based on size by agarose gel electrophoresis, (c) denaturation of nucleic acids, (d) transfer of nucleic acid from agarose gel to nylon membrane, (e) hybridization of the single nucleic acid probe to the filter-bound nucleic acid, and (f) development of the membrane to visualize and analyze hybridized products.
  - **Polymerase chain reaction:** Another example of nucleic acid hybridization molecular technique is polymerase chain reaction (**PCR**) used to amplify a specific nucleic acid sequence such as template nucleic acid (DNA), primer pairs (forward and reverse primers set to hybridize the complementary sequences of template DNA—the portion of sequence flanked between forward and reverse primers is amplified).
- **DNA sequencing:** DNA sequencing determines the exact order of four chemical building blocks called nucleotide base pairs (e.g. adenine, guanine, cytosine and thymine) in DNA strand.
  - Sequencing strategies include whole genome sequencing (involving entire exons and introns), amplification-based polymerase chain reaction, transcriptome RNA sequencing, also known as RNA sequencing, and exon capture transcriptome sequencing.
  - Whole-genome sequencing is the most powerful form of DNA sequencing technology.
  - Shotgun (Sanger) sequencing is more traditional approach, which is designed for sequencing

Table 6.120 Strategies for detection of genomic alterations in cancers

Sequencing Strategies	Applications
Whole genome sequencing (involving entire exons and introns)	Gene point mutation, copy number and structural variants
Whole exome sequencing (involving 20,000 genes constituting 1% of the genome)	Gene point mutation and copy number
Amplification based polymerase chain reaction	Gene point mutation and deletion
Transcriptome RNA sequencing, also known as RNA sequencing	Gene expression, fusion, and splice variants
Exon capture transcriptome sequencing	Gene expression, fusion, and splice variants

entire chromosomes or long DNA strands with more than 1000 nucleotide base pairs by using a purified DNA polymerase enzyme to synthesize DNA chains of varying lengths.

- Strategies for detection of genomic alterations in cancers are given in Table 6.120.

Pathology Pearls: Southern Blot Hybridization Technique

- Southern blot hybridization is used when a DNA sequence variant is too large detected by conventional polymerase chain reaction (PCR) to detect mutations (i.e. deletions, insertions, or duplications) and polymorphisms. This technique requires a very large amount of high molecular weight genomic DNA as the start input.
- DNA is initially digested with one or more restriction enzymes, which are specific for individual, and the digested fragments are run on an agarose gel electrophoresis, which is transferred to a membrane, hybridized with a labeled probe.
  - The denatured single-stranded DNA is then bound to the membrane by a heat or ultraviolet source.
  - The membrane is subsequently hybridized with sequence specific, washed, and exposed on film for imaging.
- Southern blot hybridization technique may be used to detect clonal rearrangement of their receptor genes in T and B cells neoplasms, deletions in the dystrophin gene in Duchenne muscular dystrophy, and trinucleotide repeat diseases (repetitive duplication of three nucleotides of DNA) such as myotonic dystrophy and fragile X syndrome.

LIQUID BIOPSY: CELL-FREE DNA TECHNOLOGY

In recent years, medical oncologists opt for a liquid biopsy over a tissue biopsy for patients with advanced stage cancer disease.

- **Liquid biopsy** is minimally invasive, safe, quick, and accurate, and performed to obtain blood sample.
- **Tissue biopsy** is analyzed to diagnose fundamental histologic characterization of tumors and analysis of several molecular tests. Compared with tissue biopsy, liquid biopsy has broad potential applications for cancer diagnosis and treatment including screening of early diagnosis study of tumor heterogeneity, and clonal evolution detection of minimal residual disease (MRD). Liquid biopsy accurately detect all four classes genomic alterations in over 70 genes most relevant to solid tumors.
- Liquid biopsy can be repeated at different time points, and therefore it can complement both tissue biopsy and imaging techniques during disease. Moreover, liquid biopsy could anticipate disease progression even months before radiological progression of the disease.
- During cancer progression, liquid biopsy may help oncologists to stratify patients for treatment personalization and to monitor the treatment response and resistance development. It can also be used for the tumor molecular characterization, and its minimal invasive nature allows repeat sampling to monitor changes over time without the need for a tissue biopsy.
- During metastatic cascade malignant tumors shed some amount of their fragments into peritumoral space.
  - Tumor fragments may be represented by single/cluster of circulating tumor cells (CTCs), circulating tumor DNA (ctDNA), cell-fee nuclear DNA (cfDNA), mitochondrial DNA, viral DNA, methylated DNA, extracellular vehicles (EVs), exosomes protein-coding regions of genome, RNA, protein microRNA (MiRNA), and tumor-educated platelets (TEPs).
  - **Exosomes** are small stable vesicles released from the cell of origin and carry a plethora of biological molecules encompassing DNA, RNA, microRNA, and proteins. Consequently, these entities can be collected in various body fluids (blood plasma/serum, urine, cerebrospinal fluid, saliva) and serve as tumor markers evaluated during cancer progression.
- A liquid biopsy may be used to detect malignant tumor at an early stage. In the human body, most of the deoxyribose acid (DNA) in a genome is packed inside with the help of specific proteins, protecting it from being degraded.
  - **Circulating tumor DNA (ctDNA)** is a single- or double-stranded DNA released by the malignant tumors cells into the bloodstream and it harbors the

gene mutations of the original primary malignant tumors.
  - Circulating cell-free RNAs (cfRNAs) are cancer-related messenger RNAs or noncoding RNAs, including microRNAs (miRNAs).
  - Extracellular vesicles (EVs) are small membrane-bound vesicles, including microvesicles and exosomes, which carry cargo such as nucleic acids and proteins during tumor metastasis.
- Circulating tumor cell (CTC) tests may be performed to monitor metastatic tumors of breast, colorectal region, and prostate. CTC diagnostic test helps capture, identify, and count CTC in a blood sample.
  - CTCs are CSCs that detach from solid malignant tumors and enter bloodstream. CTC test may be performed prior to the initiation of therapy or during treatment.
  - Several methods have been developed to capture and analyze circulating tumor DNA (**ctDNA**) for specific molecular tumor alterations, including allele specific polymerase chain reaction (PCR), droplet digital PCR (ddPCR) or targeted next generation sequencing and are successful used in several cancer types to monitor genomic alterations in a dynamic way.
  - Cell-free DNA (**cfDNA**) can be detected in either plasma or serum via multiple mechanisms, including active secretion, necrosis, and apoptosis. Cell-free DNA (cfDNA) is an ideal biomarker for real-time monitoring cancer disease progression and therapeutic response.
- During metastatic cascade, different analytes are involved. Unrestricted CSC proliferation of primary malignant tumor releases DNA from necrotic/apoptotic cells. Extracellular vesicles (EVs) are involved in tumor angiogenesis. A test is performed on a sample containing free circulating pieces of DNA (ctDNA) to detect cancers. Circulating viral DNA can be used to identify virus-related cancers.
- During local invasion, detachment, and intravasation, CSCs acquire significant alterations to survive the physical interactions, and the mechanical forces in blood and tissues.
  - Cancer stem cells undergo epithelial–mesenchymal transition (EMT) to move within surrounding connective tissue, and then secrete exosomes that contribute to induce vascular endothelial permeability for intravasation.
  - During embolization and survival, CTCs can survive and undergo adaptation in the bloodstream by forming CTC clusters/microemboli, that display higher metastatic potential by increasing CSC survival and reducing apoptosis. Clustering of CTCs with neutrophils can also promote cell cycle progression and survival of CTCs. The CTCs also gain physical and immune system protection by interacting with tumor-educated platelets.
  - During arrest and extravasation in target organ/tissue, CTCs interact with vascular endothelial cells, mainly capillaries, where they become trapped. CTCs and platelets might release EVs that can modify the cytoskeleton of vascular endothelial cells and increase blood vessel permeability, and allow CTCs extravasation.
  - In micrometastases in organ/tissue, CTCs need favorable pragmatistic niche and exosomes play a key role in its preparation. CTCs form macrometastasis in distant organs/tissues such as liver, lung, bone, and brain.
- Liquid biopsy has many clinical applications in oncology by analyzing CTCs, ctDNA, cfDNA, mitochondrial DNA, viral DNA, methylated DNA, EVs, exosomes, protein-coding regions of genome, RNA, protein MiRNA, and tumor-educated platelets (TEPs).
- Liquid biopsy is used in detection of genetic alterations (i.e. point mutation, insertions, amplification, deletions, copy number variations (CNVs), chromosomal aberrations, chromosomal translocation, chromosomal fusion transcripts, and aberrant protein expression) in cancers.
- Multistep metastatic cascade and biomarkers analysis, and clinical applications of liquid biopsy for treatment strategy in various stages of cancer are shown in Fig. 6.136. Comparison of tissue biopsy and liquid biopsy is given in Table 6.121. Liquid biopsy to assess analytes during metastatic cascade is given in Table 6.122. Clinical applications of liquid biopsy are given in Table 6.123.

Pathology Pearls: Liquid Biopsy Protocol and Steps

- **Isolation of CTCs technique:** Immune-based methods use antibodies to selectively bind surface antigens that distinguishes cancer tumor cells (CTCs) from blood cells. These antibodies may be conjugated to magnetic nanoparticles or immobilized on the walls of microfluidic chips to isolate CTCs. A new generation of CTC antigen-based dual platforms combines immunomagnetic beads with microfluidics.
  - Size-dependent isolation techniques include filtration, microfluidics, centrifugation and inertial focusing.
  - Direct imaging detection methods use specific fluorescent tags to identify and count cancer tumor cells (CTCs) in blood circulation. Each of these techniques is unique in its sample preparation, detection algorithms and fluorophores.
  - Dielectrophoresis technique relies on particles with different polarization that move differently under a non-uniform electric fluid.

- **Enumeration technique:** Enumeration technique is used to count the number of CTCs detected in a sample include impedance, high-throughput imaging, flow cytometry and artificial intelligence.
- **Characterization technique:** Characterization technique is used to characterize CTCs include immunostaining, fluorescent *in situ* hybridization (FISH) sequencing, quantitative reverse transcription polymerase chain reaction (qrt-PCR), expression analysis and cell culture. The molecular techniques used to characterize CTCs include immunohistochemistry, fluorescence *in situ* hybridization (FISH), next generation sequencing, quantitative reverse transcription polymerase chain reaction (qRT-PCR) and cell culture.
  - **Circulating tumor DNA:** Circulating tumor DNA (ctDNA) is a single- or double-stranded DNA released by the tumor cells into the bloodstream and it harbors the gene mutations of the original tumor. In recent, liquid biopsy based on ctDNA analysis has enlightened on the molecular diagnosis and monitoring of cancer disease. Gene mutations in tumor are detected by droplet digital PCR, beads, emulsion, amplification, magnetic (BEAMing), next-generation sequencing-based approaches.
  - **Circulating cell-free DNA (cfDNA):** Circulating cell-free DNA (cfDNA) is degraded fragment released to body fluids such as bloodstream, urine, and cerebrospinal fluid. cfDNA exhibits the genetic and epigenetic alterations of cancers including mutations, copy number variations, chromosomal rearrangements, DNA hypomethylation. Gene mutations in tumor are detected by droplet digital PCR, BEAMing, next generation sequencing-based approaches. The profiling of epigenetic features of cfDNA, such methylation signatures, may provide information about the tissue of origin.
  - **Extracellular vesicles:** Extracellular vesicles (EVs) are small membrane-bound vesicles, including microvesicles and exosomes, which carry cargo such as nucleic acids and proteins during tumor metastasis. EVs detected by liquid biopsy lacks efficient procedures to obtain EVs with high purity. Strategies used to isolate EVs include centrifugation, polymer precipitation, ultrafiltration, size-exclusion chromatography, affinity isolation and microfluidics-based technique.
  - **Circulating cell-free RNA:** Circulating cell-free RNAs (cfRNAs) are cancer-related messenger RNAs or noncoding RNAs, including microRNAs (miRNAs). Profiling cfRNA offers unique opportunities to detect the molecular subtype. RNA-based liquid biopsy technique hinders clinical application due to lack of standardized protocols.

Pathology Pearls: Applications of Liquid Biopsy to Monitor Tumor Progression

- Early diagnosis through screening based on detection of predictive biomarker.
- Diagnosis—stratification and therapeutic intervention with tumor staging in metastatic disease based on detection of biomarkers.
- Monitoring—drug response and resistance in real-time.
- Tumor clonal evolution assessment.
- Minimal residual disease (MRD) detection, prognosis, recurrence, and metastasis and risk of relapse.
- Actionable therapeutic targets and resistance mechanism—tumor heterogeneity and characterization.
- Prognosis—prognosis and risk of recurrence, and metastasis.
- Immunotherapy—determination of microsatellite instability (MSI) status, mutational load and TCR profile-based next-generation sequencing.

Pathology Pearls: Clinical Applications of Liquid Biopsy

- Circulating free tumor DNA (ctDNA) can be exploited to detect the presence of cancer.
- Circulating viral DNA can be used identify virus-related cancers.
- After diagnosis ctDNA allows patients' stratification and can help guiding therapeutic intervention.
- During therapy ctDNA can be used to monitor and resistance in real time as well as to detect minimal residual disease.
- At progression, ctDNA analysis could reveal tumor molecular heterogeneity and actionable targets for further therapeutic interventions.
  - Also, ctDNA analysis could be helpful to monitor microsatellite instability (MSI) status and tumor mutational loads that are valuable parameters for immunotherapy.
  - In addition, analysis of peripheral blood mononuclear cell can be used to profile T cell receptors (TCRs).

Pathology Pearls: Mitochondrial Deoxyribonucleic Acid (DNA) Biomarkers

- Interestingly, besides nuclear DNA aberrations, mitochondrial DNA (mtDNA) alterations have been detected in patients with human cancers, hence mitochondrial DNA could serve as molecular markers for the disease.
- Mitochondrial DNA molecule is the small circular chromosome found inside mitochondria, which can replicate independently of nuclear DNA.
  - Mitochondrial DNA contains 37 genes, which encodes ribosomal RNAs, transfer RNAs and polypeptides.
  - Mitochondrial DNA has higher rate than nuclear DNA due to lack of DNA repair system and histone proteins; and due to its exposure to reactive oxygen species, which are generated during oxidative phosphorylation in the inner mitochondrial membrane.
- Somatic mitochondrial DNA mutations have been implicated in the process of carcinogenesis seen in all human cancers.
- Single gene mutation, insertion, deletion, and mitochondrial microsatellite instabilities have been demonstrated in the breast carcinoma, cervical carcinoma, urinary bladder carcinoma, and head and neck cancers.

TARGETED MUTATION ANALYSIS METHODS

Germline mutations, also called hereditary mutations, are passed on from parents to offspring leading to

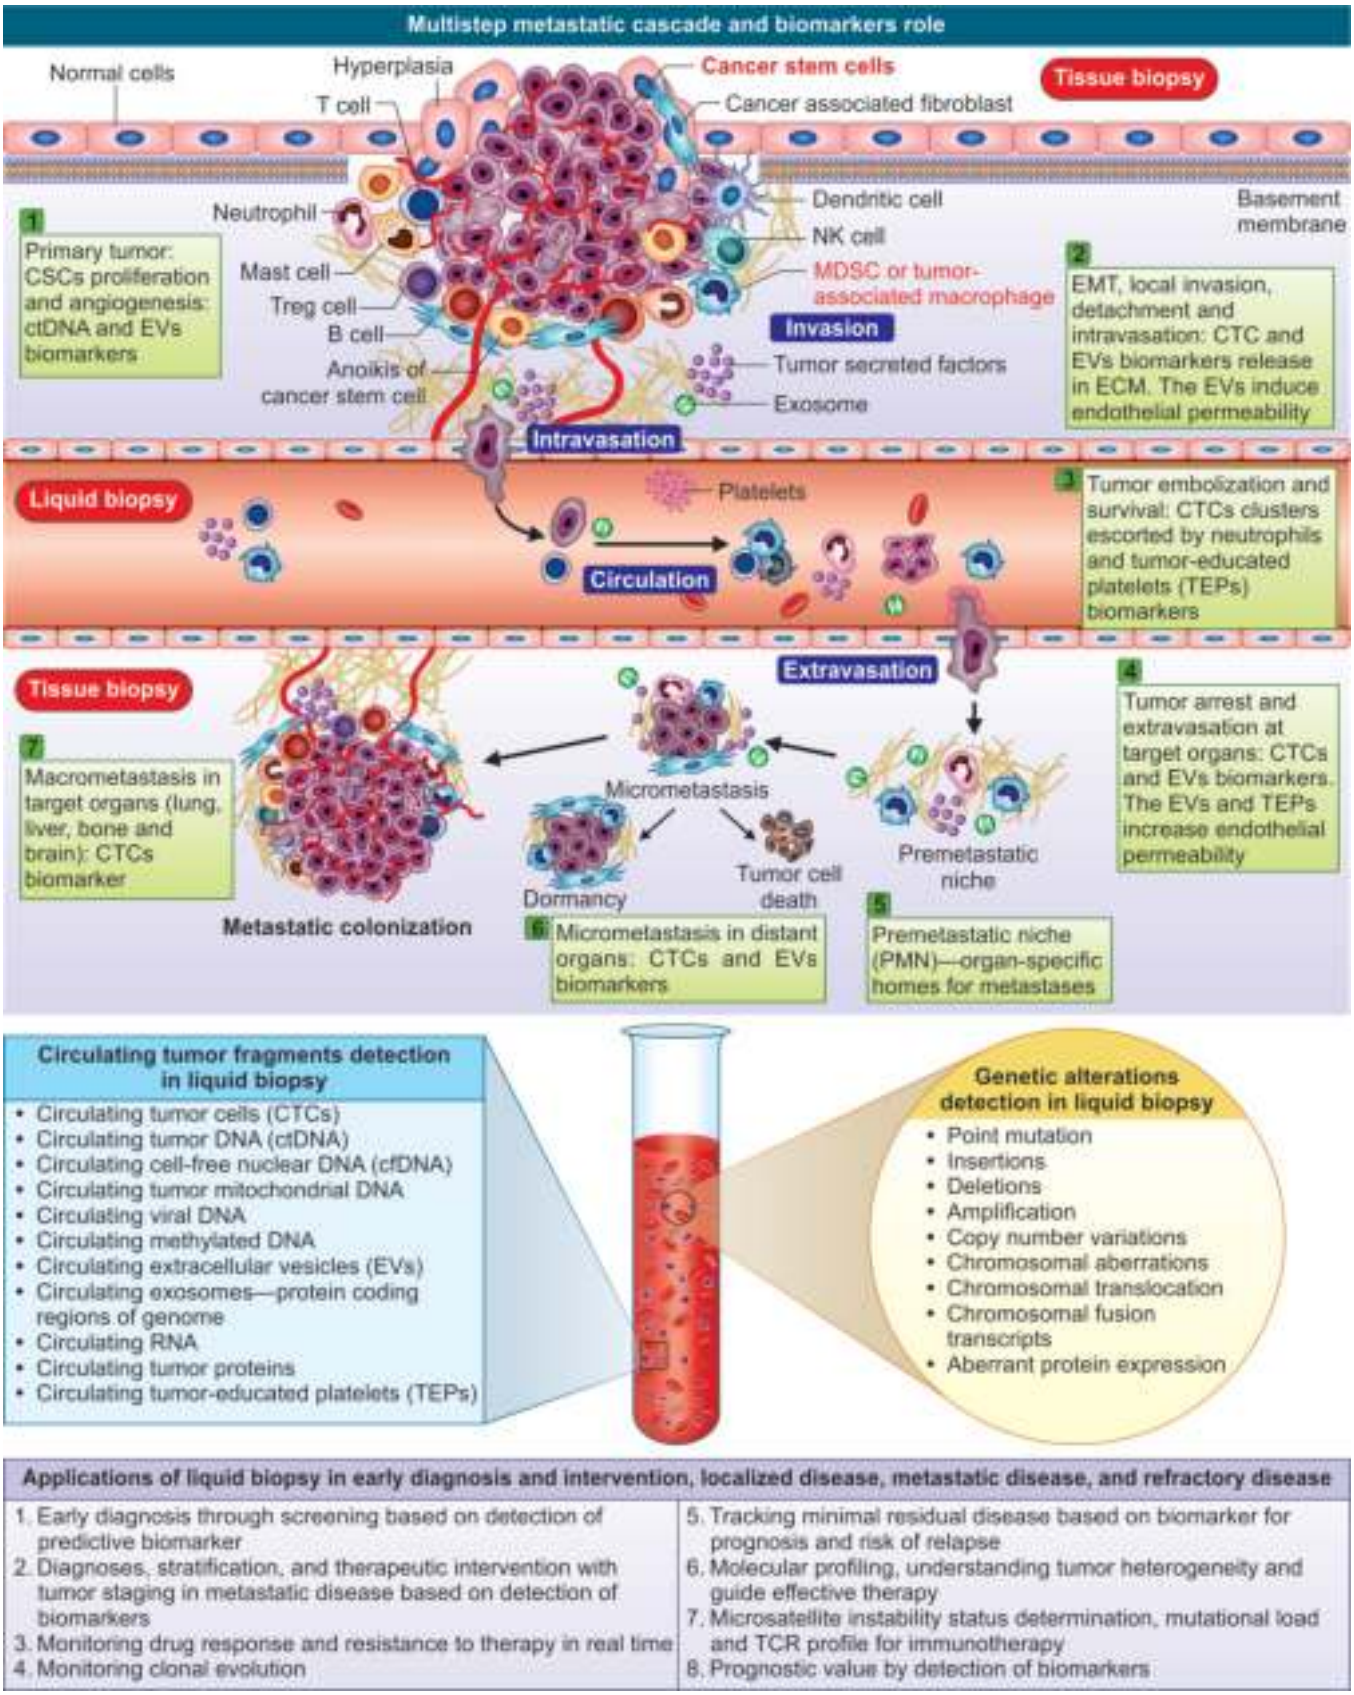

Fig. 6.136: Multistep metastatic cascade and biomarkers analysis, and clinical applications of liquid biopsy for treatment strategy in various stages of cancer. Liquid biopsy has broad potential applications for cancer diagnosis and treatment including early diagnosis through screening, study of tumor heterogeneity and clonal evolution, detection of minimum residual disease, and assessment of treatment response and development.

Table 6.121 Comparison of tissue biopsy and liquid biopsy

Liquid Biopsy	Tissue Biopsy
Liquid biopsy sampling requires venous blood—minimally invasive quick technique	Organ/tissue specific—tissue biopsy often difficult and invasive time-consuming
Liquid biopsy—easily repeatable and highly reproducible	Multiple tissue biopsy samplings—not always feasible
Liquid biopsy does allow tumor histologic type specification and staging of the disease	Tissue biopsy—allows histologic diagnosis and staging of the disease
Liquid biopsy—real-time monitoring of the disease, i.e. minimum residual disease (MRD) and progressive disease	Tissue biopsy—single snapshot, limited for localized cancer over time and space
Liquid biopsy does not provide histologic evaluation	Tissue biopsy provides histologic evaluation
Liquid biopsy—representative of the different localization of the malignant clones (i.e. tumor heterogeneity)	Tissue biopsy—not always representative for the entire variety of malignant clones (i.e. tumor heterogeneity)
Liquid biopsy—multiple real-time assessment and insight for tumor evolution and monitoring of the disease	Tissue biopsy—one-time assessment overtime and space and unable to assess into tumor evolution
Tissue biopsy—real-time monitoring of drug resistance	Tissue biopsy—treatment monitoring not possible without re-biopsy
Liquid biopsy—lacks standardization and it is still used mainly in translational research	Tissue biopsy—still the gold standard for tumor characterization, prognostic, and therapeutic prediction information

Table 6.122 Liquid biopsy to assess analytes during metastatic cascade

Metastatic Cascade	Molecular Events during Metastatic Cascade
Primary malignant tumor—unrestricted CSC proliferation	▪ Circulating tumor cell (CTC) DNA release ▪ Extracellular vesicles (EVs, i.e. apoptosis bodies) release
Primary malignant tumor—angiogenesis	Extracellular vesicles (EVs, i.e. apoptosis bodies) induced angiogenesis
Primary malignant tumor—EMT in some CSCs, local invasion, detachment and intravasation	▪ Tumor EVs induce endothelial permeability ▪ Circulating tumor cell (CTC) subsets survive in the bloodstream ▪ Crosstalk between CTCs and platelets for protection
Malignant tumor—embolization and survival	Higher metastatic and survival of CTC clusters escorted by neutrophils
Malignant tumor—circulating CSCs arrest extravasation at target organs	▪ Circulating tumor cell (CTC) interaction with endothelial cells ▪ Increased permeability of vessels
Malignant tumor—micrometastases in organs	Pre-metastatic niches prepared by exomes for CTCs being settle down in a favorable niche

Table 6.123 Clinical applications of liquid biopsy

Clinical Applications	Comments
Screening of disease	Screening is done to identify predictive biomarker, i.e. ctDNA for early detection of cancer; and circulating viral DNA in virus-related cancers
Diagnosis of disease	Circulating free tumor DNA (ctDNA) allows patients' stratification and can help guiding therapeutic intervention with staging of cancer
Monitoring of disease	Circulating free tumor DNA (ctDNA) can be used to monitor response and resistance to therapy in real time
Detection of minimal residual disease and progression	Circulating free tumor DNA (ctDNA) can be used to detect minimal residual disease (MRD), prognosis and risk of relapse
Actionable targets	At progression, ctDNA analysis could reveal tumor molecular heterogeneity and actionable targets for further effective therapeutic interventions
Immunotherapy	Circulating free tumor DNA (ctDNA) can be used to monitor microsatellite instability (MSI) status, mutational load for immunotherapy, and T cell receptor (TCR) profile for analysis of immune repertoire status to determine progression of cancer

cancer risk and susceptibility. Knowledge of these germline mutations in the DNA sequence can lead to the development of preventive measures to reduce the likelihood of developing malignant tumors. Somatic mutations may drive carcinogenesis and acquisition of subsequent mutations in the DNA sequence but are only present in specific cells. Oncogenes act in a dominant fashion: a gain-of-function mutation in a single copy of the cancer-critical gene can drive normal cell toward CSC. Tumor suppressor genes are recessive at the cellular level, with inactivation/loss of both alleles typically found in malignant tumors. Inheritance of a solitary mutant allele increases tumor susceptibility because only a single additional inactivating event is essential from complete loss of gene function. DNA biomarkers include mutation in single nucleotide, loss of heterozygosity, changes in gene copy number, and MSI.

- **Changes in single nucleotide base pair analysis:** Molecular testing is done to detect mutation in single nucleotide of genes responsible for human cancers such as BRCA1, BRCA2, and RAD1 genes in breast carcinoma, TP53, XRCC1 and ATM genes in head and neck carcinomas, and APC gene in colorectal carcinoma.
- **DNA copy number variation:** Most DNA diagnostics rely on DNA copy number variation analysis or DNA sequencing. Polymerase chain reaction (PCR) technique allows an exponential amplification of a DNA segment from genome, allowing multiple procedures on a single pure DNA sequence.
  - Microarray-based (e.g. oligonucleotide arrays, comparative genomic hybridization array) copy number variation analysis detects small abnormalities in the structure of chromosomes.
  - Copy number variation analysis for the human genome can pinpoint the location, number, gene content, frequency, and approximate breakpoints of numerous copy number variations in healthy population.
- **Loss of heterozygosity (LOH) in hereditary nonpolyposis colon cancer (HNPCC) and lung carcinoma:** Loss of heterozygosity (LOH) is a common genetic event in HNPCC and lung carcinoma, whereby one allele is lost, leading to part of the genome appearing homozygous in the malignant tumor, where heterozygous in matching DNA. Loss of one allele of a genetic locus can have multiple possible functional effects including loss of gene expression, **haploinsufficiency** (insufficient gene product), and being the 'second hit' that unmasks a recessive tumor suppressor gene.
  - Loss of heterozygosity (LOH) can be caused by mitotic errors, chromothripsis, gene conversion and inappropriate DNA repair breaks. LOH is associated with specific cancer (e.g. colorectal carcinoma and lung carcinoma), and significant in individuals, who have inherited a predisposition for cancer.
  - The molecular diagnostic methods for detection of LOH include microsatellite analysis, genome-wide assays, single-nucleotide polymorphism arrays and massively parallel DNA sequencing.
- **Microsatellite instability (MSI) analysis of mutations in mismatch repair genes:** Microsatellites (also called short tandem repeats (STRs) or simple sequence repeats (SSRs) are stretches of DNA with repetitive sequence of 1–6 nucleotides (e.g. AAAAA or CGCGCG) located near the coding and noncoding regions (introns), that are particularly susceptible to acquire errors when mismatch repair gene function is impaired. Microsatellite generation occurs due to DNA slippage in the process of DNA replication. The distribution of microsatellite differs from small satellite DNA consisting of 15–65 nucleotides tandem repeats present near the ends of chromosomes.
  - Normal DNA repair system, called mismatch repair system, can correct the errors during DNA replication. Cancer arising in cells with defective MMR gene's function exhibit an inconsistent number of microsatellite nucleotide base pair repeats when compared to normal tissue, a finding referred to microsatellite instability (MSI) with the possibility of gene mutation. It has been observed that microsatellite instability is an important factor in the occurrence and development of human malignant tumors.
  - Microsatellite instability (**MSI**) is caused by one or more mutations in DNA mismatch repair genes (e.g. MLH1, MSH2, MSH3, MSH6 PMS2) in microsatellite sequences due to the deletion or insertion of one or more microsatellite repeats that are associated with cancer.
  - The presence of microsatellite instability is a sign of mutations in DNA mismatch repair genes, that can be inherited caused by germline mutation in the MSH2 gene in hereditary nonpolyposis colon cancer (**HNPCC**) syndrome or sporadic colorectal cancer due to hypermethylation of the MLH1 promoter.
  - Microsatellite instability (MSI) is also demonstrated in endometrial carcinoma. MSI testing is performed to detect tumors caused by defective MMR genes by comparing the number of nucleotide base pair repeats in a panel of microsatellite markers (BAT25, BAT26, D2S123, D5S346 and D17S250) in the malignant tumor tissue, and normal tissue from the same individual. In the line with frequency of MSI, it can be MSI-high, MSI-low, and microsatellite-stable.

- Microsatellite instability is present if the same number of nucleotide base pair repeats are present in each marker in both malignant tumor and normal tissue. MSI is present if the number of nucleotide base pair repeats in the tumor and normal tissue differs.
- Molecular testing for MSI is most often performed using polymerase chain reaction (PCR) amplification of selected microsatellite repeats followed by capillary gel electrophoresis. Typically, DNA isolated from normal tissue and malignant tumor tissue is separately amplified by PCR technique with fluorescent-labeled primers and automated detection platforms. The gel electrophoretic patterns of PCR products from the normal tissue and malignant tumor are compared to identify insertions or deletions of repetitive units in the malignant tumor tissue sample. High-frequency microsatellite instability is defined as an instability in two or more of the five markers. Low-frequency microsatellite instability is defined as an instability in one of the five markers.

- Target mutation analysis is highly specific, sensitive, quick-turn around and cost effective, making it ideal diagnostic tool for detection of more than two mutations in germline and somatic malignancies and done in blood, saliva, and tissue samples.

Polymerase Chain Reaction Technique

Polymerase chain reaction technique is the backbone of molecular mutation analysis. PCR is crucial to amplify specific DNA sequences of nucleic acid of interest to generate thousands to millions of copies of a particular DNA sequence using pairs of short sequence specific oligonucleotide primers.

- Polymerase chain reaction (PCR) technique requires five basic reagents, e.g. DNA template, forward and reverse primers, thermostable DNA polymerase (i.e. Taq polymerase), deoxynucleotide triphosphates (dNTPs) and suitable buffer.
- Genomic DNA, forward and reverse primers, thermostable DNA polymerase (i.e. Taq polymerase), and deoxynucleotide triphosphates (dNTPs) are combined in a suitable buffer, and subjected to repeated cycles of alternating temperatures which denature the DNA template, allow for primer annealing to the template and finally extend the primer to create a new strand of DNA (DNA amplicons).
- The process of PCR begins by denaturation of the DNA template by heating sample at 94°C, which breaks the hydrogen bonds between the nucleotide base pairs of double-stranded DNA, and produces single-stranded DNA. Primers specific to the region of interest then anneal to the single-stranded DNA in the sample at specific temperature of 55–65°C.
- The temperature is then raised to 72°C, which allows DNA polymerase to extend the primers into full length product, from the forward primer to the reverse primer sequence thereby copying the sequence of interest.
- The primer extension occurs with DNA polymerase (i.e. Taq polymerase) incorporating dNTPs, and produces a final elongated double-stranded DNA product. This process is repeated 25–35 times to generate millions of copies of genetic material for downstream analysis by gel electrophoresis, sequenced, or cloned into vectors for further analysis.
- Flexible platforms permit detection of conserved specific hotspot mutations (i.e. nucleotide base pair substitutions, small length mutations—deletions, insertions) and chromosomal translocations. Polymerase chain reaction technique is highly sensitive to detect minimal residual disease (MRD).

Quantitative Real-time Polymerase Chain Reaction Technique

Quantitative real-time polymerase chain reaction (RT-PCR) is highly sensitive method, that allows amplification and quantification of a specific targeted nucleic acid sequences by incorporating a fluorescent probe.

- RT-PCR plays key roles in detection of minimal residual disease (MRD), i.e. circulating tumor cells (CTCs) in patients with hematolymphoid malignancies such as acute myelogenous leukemia (AML), acute lymphoblastic leukemia (ALL), and non-Hodgkin's lymphoma associated with poor prognosis.
- Similarly, quantitative RT-PCR has been used to quantify target chromosomal translocation fusion transcripts, i.e. BCR-ABL fusion protein with enhanced receptor tyrosine kinase activity in chronic myelogenous leukemia (CML).
  - Philadelphia chromosome is created by the tumor specific chromosomal translocation t(9;22) in CML.
  - Serial quantitative RT-PCR assays are typically used during targeted therapy of CML with a tyrosine kinase inhibitor (e.g. imatinib) to monitor tumor response.
- Quantitative real-time PCR has performed to detect mutations such as K-RAS, BRAF, and EGFR mutations in solid malignant tumors, and KIT D816V mutation in acute myelogenous leukemia (AML). Real-time PCR can also characterize CSCs burden, i.e. minimal residual disease (MRD) from blood samples of patients with malignant epithelial tumors.

Reverse Transcription Polymerase Chain Reaction Technique

Reverse transcription polymerase chain reaction (RT-PCR) technique is a modified PCR-based exponential amplification of specific DNA fragments, that uses ribonucleic acid (RNA), rather than deoxyribonucleic acid (DNA), as a template. This process uses **viral transcriptase** to catalyze the conversion of RNA into complimentary DNA (cDNA) that provides the possibility to assess gene transcription in several body fluids and tissues.

- Reverse transcription polymerase chain reaction (RT-PCR) technique can identify aberrant oncogenic fusion products produced by chromosomal translocations associated with follicular lymphoma and acute promyelocytic leukemia (APL).
- Follicular lymphoma is caused by chromosomal translocation t(14;18) that juxtaposes the BCL-2 with immunoglobulin locus leading to oncogenic IGH-BCL-2 fusion product.
- Acute promyelocytic leukemia (APL) results in oncogenic APL-RARA fusion gene product in the blood, bone marrow, or lymph node.
- Achieving molecular remission in follicular lymphoma and acute promyelocytic leukemia is a superior measure of prognosis over clinical assessments of remission.

Allele-specific Polymerase Chain Reaction

Allele-specific polymerase chain reaction is considered targeted mutation analysis for detection of a specific single nucleotide variants (SNVs). It is sensitive method that can detect mutant DNA if present even 1–5%.

- Real-time polymerase chain reaction (RT-PCR) with fluorescent reporter probes in which reporter probes for one wild type of nucleic acid, and another primer with homology to the mutant allele are added to the reaction mixture.
  - Following hybridization to the genomic DNA, polymerase chain reaction extends probes in a complimentary fashion, releasing the reporter molecule for detection.
  - Subsequently, polymerase chain reaction cycles using the reporter probes result in amplified signals, allowing for precise analysis of one or both alleles of interest.
- Alternately, routine fluorescent polymerase chain reaction is coupled with capillary electrophoresis for detection of allele-specific mutation. Similarly, the 3′ end of the mutant-specific primer-template pair will prevent DNA polymerase extension.

DNA Fragment Analysis Technique

DNA fragment analysis technique is a powerful research tool that provided relative quantitation, sizing and genotyping information and enables a wide array of genetic analysis applications.

- DNA fragment analysis workup consists of four general steps: (a) deoxyribonucleic acid (DNA) extraction and purification, (b) fluorescent dyes attached to the primers and DNA fragments, and PCR amplification, (c) capillary electrophoresis to detect fluorescent-labeled primers by a laser/camera system, and (d) data analysis.
- DNA fragment analysis technique can be used to analyze the DNA damage induced by chemotherapeutic agents. This technique has been used to analyze DNA methylation in the BRCA1 and RAD51C genes in pancreatic cancers.

Sanger Dideoxy Sequencing Technique

Sanger dideoxy sequencing technique is used to detect specific mutations, including single nucleotide variants (SNVs) and small duplications, insertions, and deletions. Sanger dideoxy sequencing is performed on polymerase chain reaction (PCR) products.

- Sequencing primers are hybridized to the PCR product and extended by using DNA polymerase, four dideoxynucleotide triphosphates (dNTPs), and a mixture of fluorescently labeled dNTPs.
- Each of four dye-labeled, chain-terminating dNTPs results in termination of strands at each location along the sequence. The reaction primers can be extended by up to about 1000 nucleotides.
- Capillary electrophoresis separates the strands by depending on size, and the terminating nucleotides are analyzed using fluorescence spectroscopy. In a clinical laboratory, both the forward and reverse strands are sequenced.

Pyrosequencing Technique

Pyrosequencing is a replication-based DNA sequencing technique used to detect specific mutations in a small targeted region of gene in cancer patients to help oncologists understand if a disease is progressing or treatment is efficacious in clinical oncology. It is quick and sensitive detection of mutant DNA at a level of 5%.

- In pyrosequencing technique, DNA strand of interest is split into smaller fragments of about 100 nucleotide base pairs, which are amplified using PCR technique and placed into wells; and fragments will not be mixed within the same well.
- Each well of pyrosequencing technique also receives ATP sulfurylase, luciferase, apyrase, adenosine 5′-phosphosulfate and luciferin. Next, one of the four

possible nucleotide base pairs is added to the wells. As DNA polymerase incorporates the nucleotides into the DNA strand, pyrophosphate is generated to be converted into ATP by the ATP sulfurylase.
- ATP helps to covert luciferin into oxyluciferin and light is released. The sequence can be determined from the order of the dNTP additions, and the intensity of the light produced with each addition and captured by camera.

DNA Methylation of CpG Island Analysis Technique

In mammalian genome, DNA methylation of CpG dinucleotides (CpG island) is an epigenetic mechanism involving the transfer of a methyl group onto the C5 position of the cytosine to form 5-methylcytosine.
- Unmethylated CpG islands are regions of DNA with a minimum of 200 nucleotide base pairs to roughly 1000–2000 nucleotide base pairs along with a high concentration of phosphate-linked cytosine-guanine nucleotide pairs present near promoters of gene.
- Recently, these unmethylated stretches of CpG dinucleotides (CpG islands) are detected by clustering methods.
- DNA methylation occurs almost exclusively in CpG dinucleotides. DNA methylation usually inhibits the transcription of genes, particularly when it occurs in the vicinity of the promoter region. DNA methylation plays important role in the silencing of tissue-specific genes to prevent them from being expressed in the wrong tissue.
- In molecular oncology, DNA methylation of CpG island of tissue DNA has emerged as a clinically useful diagnostic tool for malignant tumor detection, outcome prediction, and treatment selection, as well as for assessing efficacy of treatment with use of demethylation agents, and monitoring for tumor recurrence.

WHOLE GENOME SEQUENCING ANALYSIS

Chromosomes are the thread-like structures inside the nucleus of the cells that contain the genetic information from parents to offsprings or from one generation to another. Humans have 22 pairs of autosomes and one pair of sex chromosomes, i.e. XX in eggs of females and XY in sperms of males.
- Chromosomes are made up of DNA, and certain stretches of DNA make up genes. Hereditary (germline) mutations occur in the germ cells (eggs and sperm). Somatic (acquired) mutations occur in somatic cells.
- Deoxyribonucleic acid (DNA) is the molecule in chromosomes that contains the genetic information that is passed on from one generation to the next. DNA is made of two linked strands that wind round each other to resemble a twisted ladder shape known as a double helix. DNA molecule is three meters long and stable in pH range of 4–9.
  - Individual nucleotide base pairs form the rings of the ladder. DNA has four types of nucleotide base pairs: adenine (A) compliments with thymine (T) and contains two hydrogen bonds, guanine (G) compliments with cytosine (C) and contains three hydrogen bonds. Nucleotide base pairs are hydrophobic. Deoxyribose sugar and phosphate are hydrophilic in DNA. Nucleotide base pairs absorb maximum ultraviolet light at 260 nm.
  - Two DNA strands that can bind because they contain nucleotide base pairs throughout their entire length are said to be complementary. For example, the nucleotide base sequence of AAAGA is complementary to the nucleotide base sequence of TTTCT.
  - Each nucleotide base pair in DNA binds with only one nucleotide base pair: adenine (A) pairs with thymine (T), and guanine (G) pairs with cytosine (C). These nucleotide base pairs are essential for the DNA's double helix structure, which resembles a twisted ladder.
- Central dogma of molecular biology includes main steps: replication, transcription, and translation, in which genetic information flows only in one direction: DNA → RNA → specific protein.
  - DNA replication is semiconservative unidirectional (5′-3′) process by which the genome's DNA is copied in cells.
  - Transcription is the process of synthesis of RNA from DNA. During transcription process, only one strand of DNA is usually copied to form template strand, and the RNA molecules produced are single-stranded messenger RNAs (mRNAs). Different post-transcriptional modifications include capping, polyadenylation, and splicing. Transcription occurs when there is a requirement from a particular gene product at a specific time in specific tissue.
  - The process of synthesizing a polypeptide chain from mRNA codons is known as **translation**.
- Chromosomes are made up of DNA, and certain stretches of DNA make up genes.
  - Gene expression is the process by which a gene gets 'turned on' in a cell to make ribonucleic acid (RNA) and proteins. Proteins are biochemicals made up of individual amino acids.
  - Alterations in genes encoding cellular signaling molecules, especially receptor tyrosine kinases, can result in malignant tumors.

- Drugs targeting mutant receptor tyrosine kinases are efficacious in cancer patients. The sensitivity of such targeted drugs is related to the genetic makeup of individual cancers.
- Thus, mutation profiles of malignant tumor DNA help prioritize anti-cancer therapy in the management of cancer patients.

- Most cancer-causing DNA changes occur in genes, which are sections of DNA, that carry the instructions to make proteins resulting from acquired (somatic) mutations, germline mutations of oncogenes (mutated proto-oncogenes), inactivation/biallelic loss of tumor suppressor genes, and mutations in DNA repair genes.
  - **Single nucleotide variants:** Single nucleotide variants (SNVs), also known as point mutations, in which a nucleotide base pair may be missing or replaced by another nucleotide bae pair.
  - **Frameshift mutation:** A frameshift mutation is a genetic mutation caused by a deletion or insertion in a DNA sequence, that shifts the way the sequence is read. A DNA sequence is a chain of many smaller molecules called nucleotides.
  - **Changes in exon or gene copy number:** Changes in exon or gene copy number, resulting from deletions, duplications, or genomic rearrangements lead to loss or gain of genetic material regions, that might change of levels of gene expression included in the regions of variable copy number allowing transcription levels higher or lower than that can be achieved by control of transcription of single copies per haploid genome.
  - **Genomic structural variations in chromosomes:** Genomic structural variation in chromosomes consists of microscopic and submicroscopic variations such as deletions, duplication, copy number variants, insertions, inversions, and chromosome translocations. Fusion gene products, which can occur when parts of different chromosomal regions are joined, may drive the development of many malignant tumors. Genomic structural variation in chromosomes drives oncogenesis progression in both solid malignant tumors and hematopoietic malignancies.
- **Next-generation sequencing (NGS) technology** has enabled the detection of diverse patterns of genomic changes in somatic cells. Often, cancer-causing mutations cluster in '**hotspots**', where malignant tumors from different patients harbor the same recurrent mutation.
  - Some genomic structural variation in chromosomes may occur frequently such as BRAF V400E mutation occurs in 40% of all melanomas, while BRAF L697S mutation occurs in 1% of all melanomas. Determining the order of nucleotide base pairs is called 'whole genome sequencing'. Pathologist must ensure adequate malignant tumor content in the biopsy for reliable mutation detection.
  - Both malignant tumors and normal tissues are sequenced to distinguish germline from somatically acquired mutations in the malignant tumor. Sequence results are presented at a multidisciplinary malignant tumor board to determine clinical significance.
  - Scientists conduct whole genome sequencing by following four steps: (a) DNA shearing—DNA is cut into small pieces by using molecular scissors for the sequencing machine to analyze, (b) DNA bar coding—small pieces of DNA tags are coded to identify which pieces of sheared DNA belongs to which bacteria, (c) DNA sequencing—the bar-coded DNA from bacteria is combined and put in a DNA sequencer that identifies nitrogen bases: adenine, thymine, guanine, and cytosine, which make up each bacterial sequence, and (d) data analysis—scientists use computer analysis tools to compare sequences from multiple bacteria and identify differences.
- A targeted therapy is a medication or other substance that treats cancer by interfering with molecules that are specifically involved in cancer cell growth, spread, and progression.

Next-Generation Sequencing Technique

Next-generation sequencing (NGS) is a powerful molecular diagnostic tool used in genomics research NGS can sequence millions of DNA fragments at once to identify whole genome, genetic variations, entire gene or group of genes activity, and alterations in gene behavior.

- Genomic studies using **NGS** analyze DNA using various approaches such as whole genome sequencing, whole exome sequencing, and targeted sequencing.
- Targeted genome sequencing analysis focuses on several targeted regions of genes of interest such as K-RAS, TP53, BRAF and EGFR genes are screened in various solid malignant tumors.
- Germline and somatic mutations can be tested using targeted next-generation panels, which work on a simple approach of enrichment by amplification using pools of region-specific oligonucleotide primers. Specific libraries that are produced, then sequenced and analyzed bioinformatically.
- Examples of next-generation sequencing in oncology include small targeted panels (3–50 genes) for non-small cell lung carcinoma, colon carcinoma, melanoma, and acute myelogenous leukemia.
- Recently, the number of somatic mutations per megabase of next-generation sequencing, also known as malignant tumor mutation burden, is being evaluated

as a potential biomarker of response to immunotherapy in patients with various malignancies.

Next-Generation Sequencing: Whole Genome Sequencing Analysis Technique

Whole genome sequencing (WGS) is the process to determine complete DNA sequence in an individual's whole genome at a single time. Humans have a unique genetic code, or genome, that is composed of nucleotide base pairs: adenine (A), thymine (T), guanine (G), and cytosine (C).

- Knowing the sequence in nucleotide base pairs, one can identify DNA fingerprint, or pattern. Whole genome sequencing is a laboratory procedure that determines the order of nucleotide base pairs in the whole genome.
- Whole genome sequencing (WGS) can identify genetic variations, ranging from single-nucleotide polymorphisms (SNPs) to larger structural changes such as substitutions, deletions, insertions, gene copy number changes, and indels (insertion-deletion of nucleotide bases in whole genome), and chromosomal inversions and translocation across the entire genome. The information obtained through WGS offers a multitude of applications in various fields.

Next-Generation Sequencing: Whole Exome Sequencing Analysis Technique

Whole exome sequencing (WES) is widely used next-generation sequencing technique, that involves sequencing the protein-coding regions of genome to detect substitutions, duplications, insertions, deletions, and gene copy number changes.

- In humans, exome is the part of the genome composed of exons, that represents approximately 1–2% of the entire genome.
- Whole exome sequencing allows cancer researchers, which frequently contain mutations that affect malignant tumor progression.
- Whole exome sequencing can identify patient groups at higher risk for certain malignant tumors.
- Whole exome sequencing provides a clear picture of gene mutations that affect tumor progression such as microsatellite instability (MSI). Whole exome sequencing can also identify heritable mutations.

Next-Generation Sequencing Custom Panels and Amplicon Capture

Next-generation sequencing—custom panels, amplicon capture enables simultaneous detection of substitutions, duplications, insertions, deletions and indels (insertion-deletion of nucleotide base pairs in genome) in a single assay. Next-generation sequencing molecular tests are custom-designed to interrogate tissues for mutations of interest in specific genes, but unable to detect gene copy number changes.

Next-Generation Sequencing Custom Panels and Hybridization Capture Assay Technique

Next-generation sequencing—custom panels, hybridization capture enables simultaneous detection of substitutions, duplications, insertions, deletions, exon, gene copy number changes in many genes and select chromosomal translocation in a single assay.

- Hybridization captures the regions of interest, followed by next generation sequencing and specialized bioinformatics analysis.
- Genomic DNA fragments are hybridized in solution to sequence-specific capture probes corresponding to target regions of the genome.
- Probes can also be designed to capture select chromosomal translocation breakpoints in recurrently rearranged genes. Next-generation sequencing assays are sensitive to detect low abundant gene mutations. Compared to next-generation sequencing methods, custom panels can be cheaper or faster.

Genome Microarrays Analysis Technique

Among the many benefits of the '**Human Genome Project**', genome-wide hybridization is a powerful diagnostic technique known as **DNA microarray**, which determines mutation of BRCA1 and BRCA2 genes in individuals.

- The principal behind genomic microarrays is that complementary sequences will bind to each other. The unknown DNA molecules are cut into fragments by restriction endonucleases; and fluorescent markers are attached to these DNA fragments. These are then allowed to react with probes of the DNA microarray chip.
- DNA microarrays consist of known sequence specific long probes (i.e. PCR probes, cDNA clones or long oligonucleotides) covalently bonded to a microarray chip consisting of a small glass plate encased in plastic material.
  - The input nucleic acid sample is first fluorescently labelled and then hybridized to the microarray chip.
  - Probes that bind nucleic acid sample emit fluorescent and effectively genotype the nucleic acid for that sequence.

Array-based Comparative Genomic Hybridization Assay Technique

One of the most common clinical assays using microarrays is array-based 'comparative genomic hybridization (cCGH)' that allows for the widespread screening of DNA for copy number (gene dosage) differences between a control sample and a test sample.

- Structural variation in the genome (deletions and duplications, copy number variation, insertions, inversions, and chromosomal translocations) can be detected using array-based comparative genomic hybridization.
- Comparative genomic hybridization (CGH) method is used to detect copy number differences in sample of interest. CGH has multiple applications such as screening for deletions or insertions and gene amplifications.
- Advanced array-based approaches have enabled detection of the main forms of genomic variation: amplifications, deletions, insertions, rearrangement, and nucleotide base pair changes.
- A copy number neutral reference and a patient sample are fluorescently labeled with two different dyes and hybridized to the chip. Regions that are a 1:1 ratio of the two colors denote copy neutral regions. Regions that diverge from the 1:1 ratio of the two colors suggest deletions or duplication in the tested sample.

Gene Expression Panels Technology

Genomics is the study of multiple genes in genome (DNA), including interactions of those genes with each other and with the individual's environment. A major part of genomics is determining the sequence of molecules that make up the genomic deoxyribonucleic acid (DNA) content of an individual. The genome is the entire DNA content that is present within each cell of an organism.

- Genomics employs recombinant DNA, DNA sequencing methods and bioinformatics to sequence, assemble and analyze the structure and function of genome. It also involves the study of **intragenomic processes** (e.g. **epistasis, heterosis,** and **pleiotropy**) as well as the interactions between loci and alleles within the genome.
- Gene expression panels measure messenger RNA (mRNA), and microRNA transcriptome, which show the pattern of few hundred genes to whole expressed by a cell at the transcription level (transcription initiation, elongation, and termination), the post-translational level (RNA translocation, RNA splicing, RNA stability), and covalent modifications.
- Gene expression panels technology generates results from clinically relevant samples, such as formalin-fixed paraffin-embedded malignant tumor tissue to support biomarker discovery, drug targeting and diagnostics development.
- Panel gene names conform to the names curated in the **HUGO Gene Nomenclature**. Each gene expression panel consists of validated probes for over 1,000 genes.

Oncotype DX® 21 Genes Test for Breast Carcinoma

Oncotype DX® test is a tumor profiling genomic quantitative RT-PCR-based assay that measures the expression of **21 genes** in formalin-fixed paraffin-embedded tissue (FFPE) in breast carcinoma, and evaluation of its recurrence. Oncotype DX® test is also a part of breast carcinoma staging for some estrogen receptor positive, lymph node negative and HER2/neu negative tumors.

- Factors that affect prognosis and treatment of breast carcinoma include lymph node status, tumor size, tumor grade, histologic type, hormone receptor status, HER2/neu status, proliferative rate, Oncotype DX®, MammaPrint test score and breast carcinoma stage.
- In addition to Oncotype DX® tumor profiling genomic test, 'MammaPrint' and 'Prosigna PAM50' are also available in estrogen positive (ER positive), HER2/neu negative and lymph node negative breast cancers.
- Oncotype DX® test is designed for prediction of the potential benefit of chemotherapy in addition to hormone therapy and likelihood of distant metastasis and recurrence of breast carcinoma in women with lymph node negative, ER positive, HER2/neu negative and lymph node negative breast carcinoma.
- Oncotype DX® genomic testing scoring is done to manage breast carcinoma cases.
  - Oncotype DX® testing score <26 is associated with low-risk of metastasis and treated with only estrogen.
  - Oncotype DX® testing score ≥31 is associated with high-risk of metastasis and treated with both hormone and chemotherapy.

MammaPrint® Test and BluePrint® Test: Breast Carcinoma

The MammaPrint® test identifies the activity of 70 genes from a sample of the breast carcinoma tumor removed during a biopsy or mastectomy then calculate recurrence score that is low-risk or high-risk BluePrint® test identifies **80 genes** and then calculates a recurrence score that is either low-risk or high-risk.

PAM-50 (Prediction Analysis of Microarray 50) Test: Breast Carcinoma

PAM-50 test identifies the activity of **70 genes** from a sample of the breast carcinoma tumor removed during a biopsy or mastectomy then calculate recurrence score that is low-risk or high-risk.

Pathology Pearls: Gene Expression Panels: HTG Transcriptome Panel

- **HTG transcriptome panel:** Next-generation sequencing (NGS)-based HTG transcriptome panel (HTP) provides extensive coverage of most human mRNA transcripts and detect 19398 target genes using neoplastic and normal formalin-fixed paraffin-embedded (FFPE) extracted RNA. HTP provides sensitivity and dynamic range of next generation sequencing to generate reliable results suing limited sample amount.
- **HTG EdgeSeq microRNA whole transcriptome assay:** Next-generation sequencing (NGS)-based HTG EdgeSeq microRNA whole transcriptome assay analyzes the expression of 2083 human microRNA transcripts using next generation sequencing. HTG EdgeSeq microRNA whole transcriptome assay is compatible with formalin-fixed paraffin-embedded tissue samples, biofluids, and cell lines.
- **HTG EdgeSeq oncology biomarker panel:** Next-generation sequencing (NGS)-based HTG EdgeSeq oncology biomarker panel analyzes simultaneous, quantitative detection of 2083 human microRNA transcripts in plasma or serum and to identify therapeutic targets and drug response in cancers.
- **HTG EdgeSeq precision immuno-oncology panel:** Next-generation sequencing (NGS)-based HTG EdgeSeq precision immuno-oncology panel is designed to analyze immune response both inside malignant tumor and the surrounding microenvironment. This technique analyzes 1392 genes from a single section of formalin-fixed paraffin-embedded (FFPE) tissue extracted RNA and PAX gene sample.
- **HTG EdgeSeq immune response panel:** Next-generation sequencing (NGS)-based HTG EdgeSeq immune response panel analyzes 2002 immune response mRNA targets in a single RNA extraction-free panel. This technique detects genes from a single section of formalin-fixed paraffin-embedded (FFPE) tissue and PAX gene sample, implicated in the immune response to pathogens and many autoimmune diseases.
- **HTG EdgeSeq pan B cell lymphoma panel:** Next-generation sequencing (NGS)-based HTG EdgeSeq pan B cell lymphoma panel analyzes 298 genes expression of mRNA transcripts in a single analysis commonly associated with indolent and aggressive lymphomas to identify lymphoma subgroups to elucidate the transcription response of disease state and drug therapy.

RIBONUCLEIC ACID (RNA) BIOMARKERS

The '**Central Dogma of molecular biology**' suggests that primary role of RNA is to convert the genetic information stored in DNA into proteins. The messenger RNA (**mRNA**) carries genetic information out of the nucleus to the site of protein synthesis in the ribosomes present in cytoplasm. The transfer RNA (**tRNA**) transfers amino acids from the cytoplasm to the protein synthesizing machinery. Ribosomal RNA (**rRNA**) plays key role in the binding of messenger RNA to ribosomes and its translation. Presence of a reactive OH group present at 2'-position in the ribose makes RNA labile and easily degradable. RNAs are unstable at alkaline conditions.

- In the field of oncology, RNA biomarkers generally possess three types of relevance: clinical, diagnostic, and prognostic values.
  - Diagnostic values include early diagnosis of disease, determination of origin and classification of cancer subtypes.
  - Prognostic values include prediction of response to treatment.
- RNA biomarkers have more sensitivity and specificity. RNA has multiple copies in the cell, which delivers more information than DNA, RNA biomarkers provide dynamic insights into the cellular states and regulatory processes than DNA markers. Specific structure of some RNAs provides stability in the plasma and/or serum.
- RNA biomarkers are classified into coding (e.g. mRNA) and noncoding (e.g. incRNA, piwiRNA, snoRNA and circRNA). These can be analyzed on tumor tissue, blood (plasma, serum), saliva, bile juice, urine, and cerebrospinal fluid.
- RNA biomarkers are analyzed by quantitative reverse transcriptase-polymerase chain reaction (RT-PCR), RNA sequencing, microarray and microfluid card analysis. Pure RNA signature procurements can be analyzed by laser capture-based microarray in various stages and grades of cancer treatment. RNA expression comparative analysis is helpful in studying cell functional status, diagnosis, and prognosis of human cancers.
- Extracellular messenger RNA is unstable and easily degraded to small pieces by RNase in circulation. In some cases, circulating mRNA can form complexes with chaperones either protein or lipid binding partners, and persist in the circulation. Circulating mRNA can be a useful source of cancer biomarkers.
- Researchers have confirmed that mRNA remains at the same level for 24 hours after blood sampling. Unlike DNA, the RNA molecule can reflect events in the human body, which occurred within 24 hours leading to an early diagnosis of the disease. However, high degree of variability and turnover in circulating mRNA makes it a challenging candidate for precision molecular diagnostics.

Tissue-based RNA Biomarkers in Human Cancers

The first well-studied type of RNA as biomarker is the mRNA. Globally, perspective of the mRNA expression forms and deregulated pathways may provide a more exact cancer picture including its clinical outcome. Positive or negative expression of genes correlates with disease pathology. A panel of multiple genes is applied

as biomarkers to study the clinical outcome in various human cancer studies. Tissue-based RNA biomarkers in human cancers are discussed here.

Messenger RNA Biomarker Assay Technique

For example, PAM50 messenger RNA biomarker a **70-gene** panel has been used to analyze diagnosis and prognosis of breast carcinoma. A panel of 30-gene mRNA related to cell cycle progression is used to study prognosis, progression, and recurrence of prostatic carcinoma. Variable expression tissue-based mRNA profiling suggested to distinguish three histologic subtypes: renal cell carcinoma [e.g. clear cell, papillary (chromophil) and chromophobe variants].

MicroRNA Biomarkers Assay Technique

MicroRNAs are small noncoding RNAs, which can function as tumor promoters and tumor suppressors. Some microRNAs play key roles in cell proliferation, differentiation, and apoptosis. MicroRNA biomarkers analysis helps in classification of poorly differentiated cancers. Low expression of microRNA-21 indicates low hazard rate for pancreatic ductal carcinoma patients after adjuvant therapy. MicroRNA-21 has been reported as a potential therapy target.

- **IncRNA biomarkers:** Upregulation of incRNA biomarkers is used in diagnosis and prognosis many human cancers. Examples of incRNA biomarkers include: upregulation of PCA3 (prostatic carcinoma), HULC (pancreatic carcinoma), and HOTAIR (nasopharyngeal carcinoma).
- **Piwi-interacting RNA biomarker (piRNA):** Piwi-interacting RNA participates in transposon silencing via DNA methylation, cell proliferation and invasion. Low expression of piRNA-651 biomarker is linked to poor prognosis in lymphoma patients.
- **Small nucleolar RNA (snoRNA) biomarker:** Small nucleolar RNA regulates ribosomal maturation and its function. Upregulation of SORD33, SNORD66 and SNORD76 biomarkers is demonstrated in non-small cell lung carcinoma.
- **Circular RNA (circRNA) biomarker:** Non-coding circular RNA is generated from pre-mRNA with back-splice mechanism, that makes circular RNA more resistant to exonucleases. Hsa_circ_002059 biomarker is downregulated in gastric carcinoma associated with metastasis.

Extracellular Vesicle-derived RNAs Biomarkers Detected in Blood and Body Fluids in Cancers

In addition to RNAs present within tumor cells, many extracellular vesicle-derived RNAs released by cells (normal and tumor cells) have been detected in blood (plasma and serum), breast milk, saliva, cerebrospinal fluid, bile juice and urine.

- **Extracellular vesicle-derived RNAs** are released by cells in the form of microvesicles, exosomes, oncosomes and apoptotic bodies.
  - Microvesicles directly shed from the plasma membrane, whereby budding microdomains undergoing phosphatidylserine translocation and remodeling of the actin cytoskeleton.
  - The proto-oncogene SRC promotes the release of promigratory exosome by phosphorylating syndecans and syntenin.
  - Exosomes are endosomal membrane-derived vesicles released by the fusion of the multivesicular bodies with the cell membrane. Upon secretion into extracellular space, microvesicles and exosomes can bind to the recipient cell surface via ligand receptor and their interactions initiate cell signaling, transfer of functional messages resulting in cellular phenotype.
- Extracellular vesicle-mediated RNA in cancer plays important role in initiation, progression, metastasis, and cancer immunology. CSCs secreting extracellular vesicle-derived RNAs reach the adjacent cells, that alter local tumor microenvironment resulting in local invasion and multifocal tumor growth.
- Extracellular vesicle-derived RNAs from different cancer cell lines show distinct RNA profiles in coding mRNA and non-coding RNAs (e.g. tRNA, piwiRNA, IncRNA, SnoRNA and circRNA).
- Analysis of extracellular-vesicle derived RNAs are promising diagnostic and prognostic biomarkers including therapeutic targets for human cancers. Their analysis helps in the classification of tumors, when the solid tissue is not available.
- Tumor-promoting RNAs also disrupt vascular endothelial barriers and transform normal cells into niche cells in distant tissues/organs resulting in premetastatic niche generation and metastasis.
- Extracellular vesicle-derived miR-105 from breast CSCs disrupts vascular integrity by targeting tight junction protein ZO-1 resulting in enhanced vascular permeability and increased dissemination to lung and brain. Moreover, extracellular vesicle miR-122 from breast cell lines is delivered to premetastatic niches and inhibits glucose consumption in the lung fibroblasts and brain astrocytes by targeting PKM thereby resulting in metastasis to lungs and brain.
- Extracellular vesicle-derived miR-103 from hepatocellular (HCC) cells disrupts vascular endothelial barriers, promotes endothelial permeability, transendothelial invasion by targeting VE-cadherin, ZO-1

and p120, thereby resulting in cancer dissemination to liver and lungs.
- Extracellular vesicle-derived circRNA from pancreatic CSC lines promotes endothelial permeability and transendothelial transmigration of CSCs by targeting miR-122 leading to dissemination to distant organs.

PROTEINS AS BIOMARKERS

Proteins are biomolecules composed of individual amino acids. The body utilizes proteins to make up the body structures and perform cellular functions of life. Examples of body proteins include: immunoglobulins (e.g. IgG, IgA, IgM, IgD, IgE), enzymes, messenger proteins (e.g. hormones), structural component proteins and transport or storage proteins (e.g. amino acids and metal ions).
- Proteins are the main executioner biomolecules of cells, which affect the molecular pathways in normal and transformed cells. Protein biomarkers are commonly performed in clinical practice, which are more significant than RNA-based or DNA-based biomarkers.
- **Proteomics** encompasses the identification and quantitative analysis of differentially expressed proteins relative to healthy tissue counterparts of different stages of disease (e.g. transformation of normal cells to malignant cells). Proteomics of malignant tumors includes details on cellular processes that happen in CSCs, tumor microenvironment and cancer–host interaction. Protein markers are most common type of biomarkers analyzed by molecular diagnostics.
- Cancer stem cells (CSCs) can shed certain proteins, that enter the bloodstream. These proteins can then be analyzed by taking a blood sample and subjecting it to a molecular diagnostic test. Some of these proteins can finish up in the bloodstream and thus serve as potential serum biomarkers. Other proteins can be analyzed in malignant tumor tissue (e.g. estrogen receptors and HER2 proteins in breast carcinoma). Few crucial antigens of CSCs are analyzed for diagnostic and prognostic cancer biomarkers such as carcinoembryonic antigen (CEA), prostate-specific antigen (PSA), α-fetoprotein (AFP), and cancer antigen 125 (CA 125).
- Classically, protein-dependent signatures have been developed from the polyacrylamide gel electrophoresis and two-dimensional fluorescence difference gel electrophoresis analysis. Other protein-based molecular diagnostics include mass spectroscopy, matrix associated laser absorption/desorption ionization time of flight and reverse phase microarray surface enhanced laser absorption ionization time of flight. Recently nanoparticles and quantum dots have improved technologies usable to evaluate potential as cancer biomarkers.

Carcinoembryonic Antigen Biomarker Test

Carcinoembryonic antigen (CEA) is a protein that typically is not present in healthy adults. Though CEA is produced by CSCs, it may also be elevated in liver disease and inflammatory bowel disease.
- Blood levels of CEA is a protein biomarker, that is not performed for diagnostic purpose of many human cancers, but to monitor the treatment response in patients with already diagnosed cancers (e.g. colorectal carcinoma, gastric carcinoma, hepatocellular carcinoma, pancreatic carcinoma, ovarian carcinoma, breast carcinoma).
- Blood CEA can perform to determine the prognosis and staging of the cancer. Blood CEA molecular testing is performed along with other biomarkers to analyze whether metastasis has occurred or not.

Cancer Antigen 125 Serum Biomarker Test

Cancer antigen 125 (CA 125) test measures the amount of CA 125 protein in a patient's blood. CA 125 test may be used to monitor certain cancers during and after treatment.
- CA 125 is found in higher concentration in particularly in ovarian carcinoma. CA 125 concentration is high in cancers of endometrium, fallopian tube, pancreas, stomach, esophagus, colon, liver, breast, and lung.
- It is important to mention that conditions other than malignant tumors may cause higher levels CA 125, including uterine fibroids, endometriosis, lupus, liver diseases and pancreatitis.

Prostate-specific Antigen Serum Biomarker Test

Prostate-specific antigen (PSA) is a protein synthesized by normal cells and CSCs in the prostate gland. PSA is mostly found in the semen, but a small amount of PSA is also present in blood and expressed in units called nanograms per millimeter. There is no cut off point to diagnose prostatic carcinoma. PSA concentration may be high in prostatitis and benign nodular hyperplasia.

Flow Cytometry Technique

Flow cytometry is performed to quantify different types of cells according to their membrane antigen character and DNA content used in classification of **leukemias** and **lymphomas**, and to evaluate the risk of recurrence. This molecular test may be performed as a part of stem cell transplantation process. **Flow cytometry** measures the properties of size, granularity, and protein expression (immunophenotype) of individual cells in sample of blood, bone marrow and lymph nodes.

- There are four steps in most flow cytometry protocols: sample preparation, blocking, antibody specific to surface or intracellular proteins incubation and data collection.
  - Monoclonal antibodies are used to differentiate different hematopoietic cell lineages. Cells are made to flow in laminar flow in an isotonic fluid under pressure in front of a laser beam.
  - If monoclonal antibodies are attached to the cells, these emit light. Flow cytometry detects antigens on the surface of CSCs.
- Flow cytometry may also be performed to measure the amount of CSCs DNA. In cancer patients, CSCs are treated with special light-sensitive dyes that react with DNA. Presence of an abnormal amount of DNA indicates that patients have recurrence of malignant epithelial tumors of breast, lung, colorectal region, prostate, and urinary bladder. Comparison of immunohistochemistry and flow cytometry techniques is given in Table 6.124.

CHROMOSOMES ANALYSIS (KARYOTYPING TEST)

Chromosomes analysis, also known as karyotyping genetic test on peripheral blood sample may be clinically significant to diagnose genetic disorders and malignant tumors by looking structural and numerical chromosomal alterations at the metaphase stage of the cell cycle when chromatin is highly condensed, and the chromosome morphology is well-defined. Karyotyping that involves the pairing of homologous chromosomes.

- Chromosomes are thread-like structures made up of single molecular of deoxyribose nucleic acid (DNA) in the nucleus of each cell. Each chromosome contains several genes. **Gene** is defined as a segment of DNA that contains the instructions for making a particular protein.
- Humans have 23 pairs of chromosomes (i.e. 46 chromosomes in total). Twenty-two of these pairs, called autosomes, look the same in both males and females. The last 23rd chromosome pair is called the sex chromosome, that determines the genetic gender of the person. Females have two copies of the X chromosome (XX), while males have one X and one Y chromosome (XY). Chromosomal analysis test can provide information about structural and numerical abnormalities.

Cytogenetic Analysis

Cytogenetic analysis is the study of individual chromosomes, their structure, and inheritance patterns.

- Cytogenetic analysis can be utilized to diagnose solid malignant tumors and hematolymphoid malignancies including acute myelogenous leukemia (AML), acute lymphoblastic leukemia (ALL), chronic

Table 6.124 Comparison of immunohistochemistry and flow cytometry

Characteristics	Immunohistochemistry Technique	Flow Cytometry Technique
Definition	Microscopy-based technique that allows selective identification and localization of antigens in cells of a tissue	Laser-based technique that detects and measures the physical and chemical characteristics of a cell population
Cost of equipment needed	Less expansive equipment	Expensive equipment and additional technical staff
Specimen required	Formalin-fixed paraffin-embedded sections or frozen sections	Bone marrow, body fluids, fine needle aspirations, and fresh solid tissue
Technique utilizes	Monoclonal/polyclonal antibodies limited but gradually expanded	Abundant monoclonal antibodies
Instrument	Light microscopy or fluorescent microscope	Flow cytometer
Analysis (morphologic correlation)	Excellent morphologic correlation, viewed under a light microscope or fluorescence microscopy	No visual correlation, technique using a computer
Dual staining on same cells	Limited	5 to 6 color staining
Quantification	Estimation with imaging techniques	Accurate and reproducible
Distinction between surface and cytoplasmic staining	Difficult	Easy
Turnaround time	Four hours after hematoxylin and eosin-stained tissue section is examined	Three hours

Similarities between immunohistochemistry and flow cytometry are two techniques that use fluorescently-labeled antibodies to detect antigens on the cell surface or within cells to detect in cancers and infectious diseases.

myelogenous leukemia (CML) and lymphoma, determine appropriate therapy, and monitor the status of disease.

- After white blood cells or single-cell suspensions of CSCs are cultured in media, they are stimulated to divide with mitogens then arrested in cell metaphase. The chromosomes are released from the nucleus, fixed, and spread onto slides for staining and microscopic examination.
- In most banding methods, the individual chromosomes are identified by their size, chromosome short (p) and long (q) arms, the position of the centromere and patterns of transverse striations.
- Chromosomes are categorized based on their morphologic features, staining characteristics and placement of centromere: (a) acrocentric chromosomes have their centromere near one end of the chromosome and have satellite short arms encoding ribosomal RNA (rRNA), and (b) metacentric chromosomes have a centrally placed centromere.
- Chromosomal studies are indicated in cases for various reasons: developmental delay, dysmorphic features, malignant tumors, fertility-related issues, and pregnancy in women who are older than 35 years. Chromosome abnormalities include incorrect number of chromosomes (aneuploidy) and structural chromosome rearrangements.
- **Aneuploidy** refers to any number of chromosomes more or less than expected 26 (e.g. 47 in trisomy 21) and chromosome rearrangements occur when chromosomes break and constituent pieces reassemble abnormally (chromosome translocation). Balanced chromosome rearrangements may not be clinically evident because all the chromosomal material is intact. However, imbalanced chromosome translocations may result in aberrant expression of fusion genes leading to development of various lymphoid malignancies.

Chromosome Structural Alterations Analysis in Cancers

Chromosome structural alterations can be biomarkers for human cancers. Usually, chromosome structural alterations are not only biomarkers but also the underlying cause of the human cancer. Chromosomal translocation and exchange of sister chromatids give rise to structural abnormalities that can be easily marked by employing various banding techniques. Further, homogenously stained regions (**HSRs**) and double minute chromosomes (small fragments of extrachromosomal DNA) are frequently associated with gene amplification of a variety of human cancers (e.g. breast carcinoma, lung carcinoma, ovarian carcinoma, colon carcinoma and neuroblastoma), which can serve as biomarkers.

- **Cytogenetic analysis in chronic myelogenous leukemia (CML):** Philadelphia chromosome contains a BCR-ABL fusion gene that consists the amino portion of BCR on chromosome 22 and the carboxyl portion of ABL on chromosome 9. BCR-ABL fusion gene cannot '**turn off**' encodes abnormal protein, that results in cell growth, proliferation, and progression in unregulated manner.
  - BCR-ABL fusion gene is demonstrated in most patients with chronic myelogenous leukemia (CML) and some patients with acute lymphoblastic leukemia (ALL). Philadelphia chromosome can be detected by cytogenetic analysis.
  - Polymerase chain reaction (PCR) is performed to analyze DNA sequence that can find BCR-ABL fusion gene. PCR testing may be used to monitor a patient's clinical course. CML patients are treated by chemotherapeutic agent 'imatinib', that inhibits the activity of BCR-ABL fusion protein, thus prevents unrestricted leukemic cell proliferation and progression.
- **Cytogenetic analysis in acute myelogenous leukemia (AML):** Cytogenetic analysis plays a crucial role in the diagnosis on the bone marrow, classification, prognosis, and management of acute myelogenous leukemia (AML) patients.
  - Moreover, cytogenetic analysis assists in determining treatment response and overall prognosis. The t(8;21) is one of the most frequent chromosomal alterations associated with AML.
  - The chromosomal translocation which involves the AML1 gene (also called RUNX1) on chromosome 21 and the ETO gene (also called RUNX1T1 gene) on chromosome 8 generates AML1-ETO fusion gene that encodes leukemic inducing transcription factor leading to unrestricted cell proliferation, differentiation, and the viability of leukemia cells.
  - The disease can be diagnosed by cytogenetic analysis of AML blasts by G-banding technique and fluorescence *in situ* hybridization (FISH). Detection of AML1/ETO fusion gene can be detected by reverse transcriptase polymerase chain reaction (RT-PCR).
- **Cytogenetic analysis in acute promyelocytic leukemia (APL):** The PML-RARA fusion gene is the most critical event in the pathogenesis of acute promyelocytic leukemia (APL). Although APL is one of the most characterized forms of acute myelogenous leukemia (AML).
  - APL is defined by the PML-RARA rearrangement as a consequence of the translocation t(15;17) (q24;q21) resulting in the **PML RARA fusion gene**, that encodes an oncoprotein responsible for disruption

of myeloid distinction and abnormal proliferation of promyelocytes, life-threatening coagulopathy.
  - Rapid molecular testing is performed for fluorescence *in situ* hybridization (FISH) to detect RARA-PML fusion gene. APL patients are treated by all-*trans*-retinoic acid (ATRA) and arsenic trioxide (ATO) therapy.
- **Cytogenetic analysis in Burkitt's lymphoma:** The oncogenic transcription factor Myc is pathologically activated in many human cancers. A paradigm of Myc dysregulation is offered by Burkitt's lymphoma characterized by a high turnover rate of malignant B cells.
  - In Burkitt's lymphoma, reciprocal chromosomal translocation t(8;14) (q24;q32) involves the c-Myc gene (8q24) and immunoglobulin heavy-chain (IGH) locus (14q32).
  - Cytogenetic analysis performed on bone marrow and blood samples, most Burkitt's lymphoma cases show t(8;14) (q24;q32) (Myc-IGH), and less commonly t(8;22) (q24;q11) or t(2;8)(p12;24). The Myc breakpoints are diverse and distributed over a 2 Mb region. High quality metaphases are required to detect t(8;14) and t(8;22). Fluorescence *in situ* hybridization cannot detect all Myc rearrangements.
- **Cytogenetic analysis in Ewing sarcoma:** Reciprocal recurrent balanced chromosomal translocation between chromosome 11 and 22 results in fusion of the amino terminus of EWSR1 gene to the FLT1 gene and forming EWSR1/FLT1 fusion gene, which encodes a nuclear transcription factor resulting in cellular proliferation in about 85% of patients with Ewing sarcoma. **Diagnostic criteria of Ewing sarcoma**/primitive neuroectodermal tumor (PNET) includes (≥2 major features of neural differentiation): Homer Wright rosettes, MIC2 expression, vimentin expression, neuron-specific enolase (NSE), synaptophysin, and chromogranin. EWSR1/FLT1 fusion gene is detected by cytogenetic analysis.
- **Cytogenetic analysis in hematolymphoid malignancies:** The IGH/CCND1 gene has been reported in many B cell-derived hematolymphoid malignancies such as mantle cell lymphoma, chronic lymphocytic leukemia (CLL), prolymphocytic lymphoma, multiple myeloma, splenic lymphoma with villous morphology, and plasma cell leukemia. The chromosomal translocation juxtaposes the CCND1 gene located on chromosome 11q13 with IGH gene mapped on chromosome 14q32 results in formation of IGH-CCND1 fusion gene. Immunohistochemistry, cytogenetic analysis, fluorescence *in situ* hybridization (FISH), and flow cytometry play pivotal role in diagnosis and monitoring B cell-derived hematolymphoid malignancies.
- **Cytogenetic analysis in pediatric acute lymphoblastic leukemia (ALL):** The t(12;21) translocation generates the ETV6/RUNX1 (TEL-AML1) fusion gene is the most common chromosomal rearrangement in 25% pediatric acute lymphoblastic leukemia (ALL) between the ages of 2 and 10 years, with a median of 4 years, and is exclusively associated with B cell precursor acute lymphoblastic leukemia (BCP-ALL). **Real-time polymerase chain reaction (RT-PCR)** technique detects t(12;21) of the ETV6/RUNX1 (also called TEL/AML1) chimeric fusion transcript. Recently, fluorescence *in situ* hybridization (FISH) is also employed to detect t(12;21) of the ETV6/RUNX1 (also called TEL/AML1) chimeric fusion transcript.
- **Cytogenetic analysis in acute myelomonocytic leukemia (AMML)-AML-M4:** Researcher reported a related chromosomal 16 inversion in acute myelomonocytic leukemia (AMML) that shows evidence of both myeloid and monocytic differentiation.
  - **Bone marrow** contains myeloblasts and monoblasts constitute 20%. Monoblasts must be <80% of total nucleated cells.
  - **Cytogenetic analysis** detects chromosome 16 inversion. Flow cytometry will confirm the diagnosis.
- Monoblasts and promonocytes are CD45 bright and SSC slightly higher than myeloblasts; and these cells express CD11b, CD11c, CD13, CD14, CD64 and HLA-DR.

Chromosome Numerical Alterations Analysis in Cancers

Chromosomes are thread-like structures in which DNA is tightly packaged many times around associated histone proteins within the nucleus, that carries genetic information to the next generation. Human beings have 23 pairs of chromosomes for a total of 46 overall. Each cell contains 22 pairs chromosomes called autosomes and one pair of sex chromosomes: female has XX pattern and male has XY pattern.

- **Haploid cells versus diploid cells:** Somatic cells in human beings are diploid cells, which contain 23 pairs of chromosomes (46 total chromosomes) in each diploid cells, i.e. half come from the mother; and half come from the father.
  - The total number of chromosomes in diploid cells is described (2n), which is twice the number of chromosomes in a haploid cell (n). Diploid cells are produced by mitosis. Haploid cells contain only one set of chromosomes (n).

- Gametes are the most common types of haploid cells, which are produced by meiosis and are genetically diverse. When the haploid cells from male and female fertilize fuse together during fertilization, it forms a diploid cell. Diploid cells contain two sets of homologous (similar) copies of each chromosome.

- **Aneuploidy:** Chromosomal alterations involving addition or loss of chromosome in cell leading to unbalanced chromosome complement is termed aneuploidy. For example, human cell has 47 or 45 chromosomes instead of 46.
  - Trisomy and monosomy are examples of aneuploidy. Specific aneuploidy has been observed in various non-cancer genetic orders: Down syndrome with trisomy chromosome 21, Patau syndrome with trisomy 13, Edwards' syndrome with trisomy 18, Klinefelter syndrome with an extra X chromosome to normal male karyotype (XXY aneuploidy), and Turner syndrome with the absence of one X chromosome.
  - While, clonal aneuploidy is detected in some human cancers such as chronic lymphocytic leukemia (CLL) with trisomy 12 and acute myelogenous leukemia (AML) with trisomy 8.
  - Complete loss of chromosome 17 (monosomy of chromosome 17) has been detected in breast carcinoma.
  - Complete or partial loss of chromosome 7 (monosomy of chromosome 7) is associated with a variety of myeloid disorders including pediatric acute myelogenous leukemia (AML).

Fluorescence *in situ* Hybridization (FISH) Technique

Fluorescence *in situ* hybridization (FISH) is a cytogenetic diagnostic technique that uses fluorescent probes to hybridize with chromosomal DNA sequence fixed on slides to analyze gene amplification, gene fusions, and copy number of DNA segments and routine breast cancer studies (e.g. HER2/neu gene amplification, mitotic index with Ki-67, ER and PR) by FISH labeled with fluorescence dyes and fluorescence microscopy.

- The fluorescent staining pattern is then viewed at the appropriate wavelength of light to localize specific genes or chromosomes (e.g. to highlight red or green labels). Interphase fluorescence *in situ* hybridization uses a probe while cells are in the interphase, allowing for large number of nuclei to tested. Metaphase fluorescence *in situ* hybridization allows for specific localization of the probe-binding region within a specific region within a specific chromosome.
- Each probe is inserted to detect a unique sequence (e.g. HER2/neu) or specific portion of a chromosome. Sequence specific DNA probes permit unique DNA sequences to be analyzed for DNA insertions, deletions, and chromosome translocations.
  - Chromosomal paints are DNA probes for a mixed DNA from all or part of chromosome to visually inspect the chromosome for translocated fragments.
  - Multiple chromosomal paints may be used simultaneously to identify each metaphase chromosome with a unique color in a piece known as spectral karyotyping.

Pathology Pearls: DNA Probe Analysis

- Probes are copies of complementary DNA (cDNA). Two probes are prepared: one from the tumor and another from normal tissue. The tumor (cDNA) is now tagged with red color fluorochrome. Normal DNA probe is tagged with green color fluorochrome.
- DNA of the cells is digested by one or more restriction enzymes (bacterial enzymes). Nucleotide base pair of DNAs is identified and cut.
- DNA fragments are separated by gel electrophoresis, then denatured and transferred to nitrocellulose membrane and then DNA probe is applied resulting in hybridization.

CHAPTER 7

Nutritional and Infectious Diseases

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

NUTRITIONAL DISORDERS

- Protein-calorie malnutrition
  - Marasmus
  - Kwashiorkor (edematous malnutrition)
- Obesity
  - Pathogenesis
  - Obesity-associated health problems

VITAMINS DEFICIENCY

- Fat-soluble vitamins
  - Vitamins A, D, E and K
- Water-soluble vitamins
  - Vitamin C (ascorbic acid)
  - Vitamin B-complex
    - Thiamine (vitamin B_1)
    - Riboflavin (vitamin B_2)
    - Niacin (vitamin B_3)
    - Pantothenic acid (vitamin B_5)
    - Pyridoxine (vitamin B_6)
    - Biotin
    - Folate (folic acid)
    - Cyanocobalamin (vitamin B_{12})

BACTERIAL INFECTIONS

- Gram-positive bacterial infections
  - Gram-positive cocci
    - *Staphylococcus aureus*
    - *Staphylococcus epidermidis*
    - *Staphylococcus saprophyticus*
    - *Streptococcus pneumoniae*
    - *Streptococcus viridans*
    - *Streptococcus pyogenes*
    - Enterococci
  - Gram-positive bacilli
    - Anthrax (*Bacillus anthracis*)
    - Diphtheria (*Corynebacterium diphtheriae*)
    - Listeriosis (*Listeria monocytogenes*)
    - Nocardia
    - Erysipelothriosis (*Erysipelothrix rhusiopathiae*)
    - Actinomycosis (*Actinomyces israelii*)
- Gram-negative bacterial infections
  - *Neisseria meningitidis*
  - *Bordetella pertussis* (whooping cough)
  - Plague (*Yersinia pestis*)
  - Granuloma inguinale (*Klebsiella granulomatis*)
  - Chancroid (*Haemophilus ducreyi*)
  - *Salmonella typhi* infection
- *Mycobacterium tuberculosis*
- Mycobacterium leprosy (Hansen's disease)
- Spirochetes
  - Syphilis (*Treponema pallidum*)
  - Lyme disease
- Anaerobic bacteria
  - Anaerobic bacterial abscesses
  - Clostridial infections
    - Tetanus (*Clostridium tetani*)
    - Botulism (*Clostridium botulinum*)
    - Gas gangrene (*Clostridium perfringens*)
- Obligate intracellular bacteria
  - Chlamydial infection (*Chlamydia trachomatis*)
  - Rickettsial infections

VIRAL INFECTIONS

- Viral infections: overview
  - Pathogenesis
  - Protection of cells against viruses
- RNA viruses
  - Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) for COVID-19 pandemic
  - Poliovirus infection
  - Coxsackievirus infection
  - Hepatitis A virus infection
  - Norovirus (Norwalk virus) infection
  - Yellow fever virus infection
  - Rubella virus infection
  - Ebola virus and Marburg virus infection
  - Mumps virus (paramyxovirus family) infection
  - Measles virus (paramyxovirus family) infection
  - Rabies virus infection
  - Hepatitis C virus infection
  - Human T cell leukemia virus type 1 infection
  - Human rotavirus infection
- DNA viruses
  - Variola (smallpox) infection
  - Varicella-zoster virus (chickenpox) infection
  - Molluscum contagiosum virus 1 and 2 (MCV-1/MCV-2) infection
  - Herpes simplex virus (HSV-1/HSV-2) infection
  - Human papillomavirus infection
  - John Cunningham virus (JC virus) infection
  - Hepatitis B virus (HBV or Dane particle) infection
  - Parvovirus B19 infection
  - Human adenoviruses infection

FUNGAL DISEASES

- Ascomycota
  - Dermatophytes (*Epidermophyton flocossum, Microsporum canis, Trichophyton interdigitale, Trichophyton rubrum*)
  - Molds (*Aspergillus fumigatus, Aspergillus flavus, Aspergillus niger*)
  - Yeast (*Candida albicans, Candida glabrata, Candida krusei*)
  - Dimorphic fungi (*Blastomyces dermatitidis, Histoplasma capsulatum, Coccidioides immitis, Paracoccidioides brasiliensis*)
- Basidiomycota
  - *Cryptococcus neoformans*
  - *Malassezia furfur*
- Zygomycota
  - *Absidia corymbifera*
  - *Rhizomucor pusillus*
  - *Rhizopus oryzae*
- Dematiaceous fungi
  - Mycetoma (madura foot)
  - Phaeohyphomycosis
  - Chromoblastomycosis
- Other fungi causing skin and subcutaneous tissue infections
  - *Sporothrix schenckii*
  - Cladosporium

PARASITIC INFESTATIONS

- Protozoa
  - *Entamoeba histolytica, Giardia lamblia, Trichomonas vaginalis,* malarial parasite, Leishmaniasis, babesiosis, African trypanosomiasis, Chagas disease
- Metazoa (Helminths)
  - Strongyloidiasis, lymphatic filariasis, Cysticercosis—tapeworm (cestode), Hydatid cyst—tapeworm (cestode), *Ancylostoma duodenale* (nematode), *Enterobius vermicularis* (pinworm) nematode, trichinosis, schistosomiasis, onchocerciasis

NUTRITIONAL DISORDERS

Nutritional disorders occur when a person's dietary intake lacks the right amount of nutrients for normal functioning, or when a person is unable to absorb nutrients from food. Nutritional disorders can be caused by undernutrition, overnutrition leading to obesity or incorrect balance of nutrients.

- Nutrient deficiencies can occur due to poor dietary nutrient intake, acute or chronic diseases, medications, altered nutrient metabolism or a combination of these factors leading to alterations in energy metabolism, immune system function, growth and development, if the nutrient deficiency is present during fetal development and early childhood.
- Globally, both undernutrition and obesity are important public health problems. Interventions in the treatment of nutritional disorders may involve the use of therapeutic diets and the administration of dietary supplements.

PROTEIN-CALORIE MALNUTRITION

Protein-calorie malnutrition (PCM), or protein-energy malnutrition (PEM) refers to a form of malnutrition where there is inadequate calorie or protein intake or both. Protein-calorie malnutrition is accompanied by varying degrees of micronutrient deficiency such as vitamin A, vitamin E, folate, vitamin B_6, iron, copper, zinc and selenium. Protein-calorie malnutrition occurs in two forms: marasmus and kwashiorkor.

- Marasmus results from low calorie intake, which is characterized by growth failure and wasting.
- Kwashiorkor occurs due to protein deficiency, which is characterized by tissue edema and tissue damage. Protein-calorie malnutrition increases the risk of mortality from pneumonia, measles or chickenpox.
- Protein-calorie malnutrition is diagnosed by measurement of body weight for given height with standard tables (weight <80% of normal), evaluation of fat stores (thickness of skin folds), muscle mass (mid-arm circumference), serum proteins (albumin), decreased mid-arm circumference (marasmus) and decreased serum proteins (kwashiorkor). Comparison of kwashiorkor and marasmus is given in Table 7.1.

MARASMUS

Marasmus is caused by widespread deficiency of almost all nutrients, notably protein and calories, which often coexists with vitamin deficiencies. It typically occurs in children younger than 1 year of age who are not breast-fed and do not have an adequate intake of substitute nutrients. Chronic diarrhea is also underlying cause of marasmus. Weight for age is <60% of expected normal in marasmus.

Table 7.1 Comparison of kwashiorkor and marasmus

Characteristics	Kwashiorkor	Marasmus
Age group	2–5 years	Less than one year
Deficiency of nutrients	Protein deficiency is marked	Protein and calories deficiency
Loss of protein in compartment	Depletion of liver proteins stores	Depletion of protein stores in somatic tissues
Etiology	Weaning of child at early age without protein supplement	Weaning of child at early age without protein as well as carbohydrates, and chronic diarrhea
Skeletal muscle	Relatively spared	Loss of skeletal mass due to catabolism
Serum protein levels	Markedly reduced	Normal or slightly decreased
Immune status	Immunodeficiency with secondary infection	Immunodeficiency with secondary infection
Subcutaneous fat	Spared	Mobilized for energy purpose
Extremities	Edematous due to decreased serum albumin level	Emaciated
Skin folds and mid-arm circumference	Relative spared	Reduced skin fold, and decreased mid-arm circumference
Growth retardation	Present but less	Present but more severe
Skin lesions	▪ Skin-flaky paint appearance ▪ Hair loss of color, alternating bands of pale and dark hair, loss of scalp attachment	▪ No characteristics skin and hair changes ▪ No characteristics skin and hair changes

Contd...

Table 7.1 Comparison of kwashiorkor and marasmus (*Contd...*)

Characteristics	Kwashiorkor	Marasmus
Hepatomegaly	Fatty change present	Fatty change absent
Small bowel changes	Mucosa is atrophic, loss of villi, and decreased mitotic index in crypts of glands	No such change
Bone marrow	Hypoplastic with decreased erythropoiesis	Hypoplastic with decreased erythropoiesis
Thymic and lymphoid atrophy	More marked	Less marked
Brain changes	Usually, absent	Brain-cerebral atrophy, reduced number of neurons, impaired myelination of white matter
Associated nutritional deficiency	Present	Present

Clinical Features

Patient of marasmus presents with retarded growth due to depletion of protein stores in tissues and emaciated extremities. Loss of subcutaneous fat ('wasting away') due to mobilization of fat for energy purpose. Child is prone to recurrent infections due to immunosuppression. On clinical examination, patient does not show signs of edema. Schematic representation of marasmus child is shown in Fig. 7.1.

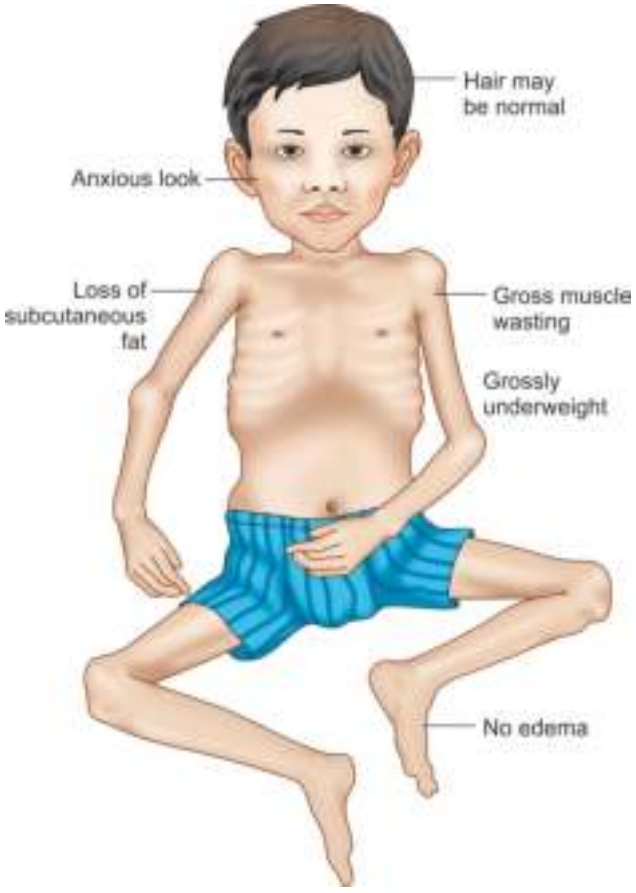

Fig. 7.1: Schematic representation of marasmus child. Marasmus is caused by lack of proteins and calories resulting in emaciated extremities, loss of subcutaneous fat, muscle wasting, retarded growth but no edema.

KWASHIORKOR (EDEMATOUS MALNUTRITION)

Kwashiorkor is caused by protein deficiency but with adequate caloric intake, which usually affects children older than 1 year of age who are no longer breastfed and receive a starch-rich and protein-poor diet. Serum proteins are markedly reduced. There is suppression of bone marrow and thymus. Child is underweight with edema having electrolyte abnormalities.

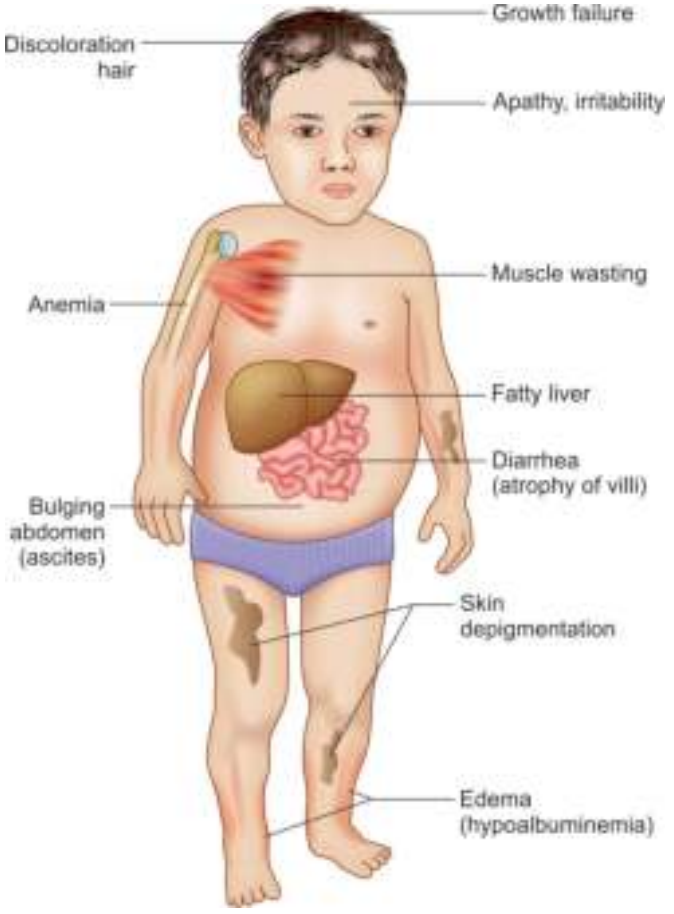

Fig. 7.2: Schematic representation of kwashiorkor in a child. It is caused by lack of proteins resulting in edema, ascites, anemia, skin pigmentation, muscle wasting, fatty liver and growth failure.

Clinical Features

Patient presents with retarded growth and muscle wasting due to inadequate protein intake, but with preservation of subcutaneous fat. Kwashiorkor is distinguished from marasmus by the presence of the following abnormalities: fatty liver, severe edema due to protein deficiency and decreased oncotic pressure, anemia, malabsorption as a result of atrophy of the small intestinal villi, depigmented bands with pale streaking in the hair or skin. Schematic representation of kwashiorkor in a child is shown in Fig. 7.2.

OBESITY

Obesity is defined as abnormal or excessive accumulation of fat that may impair health, which is independent risk factor for development of venous thromboembolic disease.

- Adipose tissue has endocrine role in synthesis of adipokines, which have been implicated in the development of inflammation, atherosclerosis, cancer and thrombosis. Obesity is also associated with increased risk of type 2 diabetes mellitus, hypertension, gallbladder stones, and osteoarthritis.
- As specific diagnostic tools such as magnetic resonance imaging or dual energy X-ray absorptiometry for assessment of obesity are not easily available, hence body mass index (**BMI**) is the most accepted definition of obesity, which is calculated by weight in kilograms divided by the square of the height in meters (kg/m^2).
- For adults, WHO defines overweight (BMI 25) and obesity (BMI 30). For children, age needs to be considered when defining overweight and obesity.
- For children under 5 years of age, WHO defines overweight as weight-for-height ≥2 standard deviations above WHO defined child growth standards median, while obesity is weight-for-height ≥3 deviations above WHO defined child growth standards.
- For children between 5 and 19 years of age, WHO defines overweight as BMI-for-age ≥1 standard deviation above WHO defined child growth standards median, while obesity is ≥2 standard deviation above WHO defined child growth standards median.
- World Health Organization classification system for BMI defines obesity as a BMI >30 with further subcategories given in Table 7.2.

Table 7.2 World Health Organization classification of obesity

BMI (kg/m^2)	Alternative Commonly used Terminology	WHO Classification
<18.50	Underweight	Underweight
18.50–24.99	Normal weight	Normal weight
25–29.99	Overweight	Overweight
≥30.00–34.99	Obese	Obese class I
35.00–29.99	Obese	Obese class II
≥40.00	Morbid obesity	Obese class III
≥50.00	Super-obesity	Obese class IV
≥60.00	Super-super-obesity	Obese class V

PATHOGENESIS

Obesity usually results from combination of causes and contributing factors such as family inheritance, lifestyle (e.g. unhealthy diet, physical inactivity), medical illnesses (e.g. Prader-Willi syndrome, Cushing's syndrome), medications (e.g. some antidepressants, antiepileptic medications, diabetes mellitus medications, antipsychotic medications, corticosteroids and β-blockers), pregnancy, lack of sleep, stress and microbiome. Obesity pathogenesis involves two related distinct processes: (a) sustained positive energy balance, i.e. energy intake > energy expenditure; and (b) resetting the body weight 'set point' at an increased value through changes of diet and/or lifestyle (Fig. 7.3).

Leptin Synthesis and Functions

Leptin is the adipocyte peptide hormone, which circulates at concentrations proportion to body weight, which regulates food intake, body mass and reproductive function. Leptin plays a key role in energy homeostasis, fetal growth, proinflammatory immune responses, angiogenesis and lipolysis. Leptin deficiency is linked to hyperphagia and obesity.

Leptin Structure and its Regulation

Leptin peptide hormone is the product of the '**obese (Ob) gene**'. Leptin molecule comprises 167 amino acids including a 21-amino acid sequence. Leptin exhibits the tertiary structure of globular protein.

- **Insulin regulates leptin:** Insulin is primary regulator of leptin production. Persistent hyperinsulinemia enhances plasma concentration of leptin via glucose metabolism, while short-term hyperinsulinemia does not affect plasma concentration of leptin.
  - The blockade of glucose transport or glycolysis in the presence of hyperinsulinemia suppresses the expression and secretion of leptin from adipocytes.
  - Leptin flows from adipocytes into the bloodstream passes through blood–brain barrier and reaches in regions of hypothalamus involved in regulation of energy balance.
- **Catecholamines regulate leptin:** Unlike insulin, catecholamines bind to β_2- and β_3-adrenergic receptors and suppress leptin synthesis from adipocytes, indicating a link between neuroendocrine and

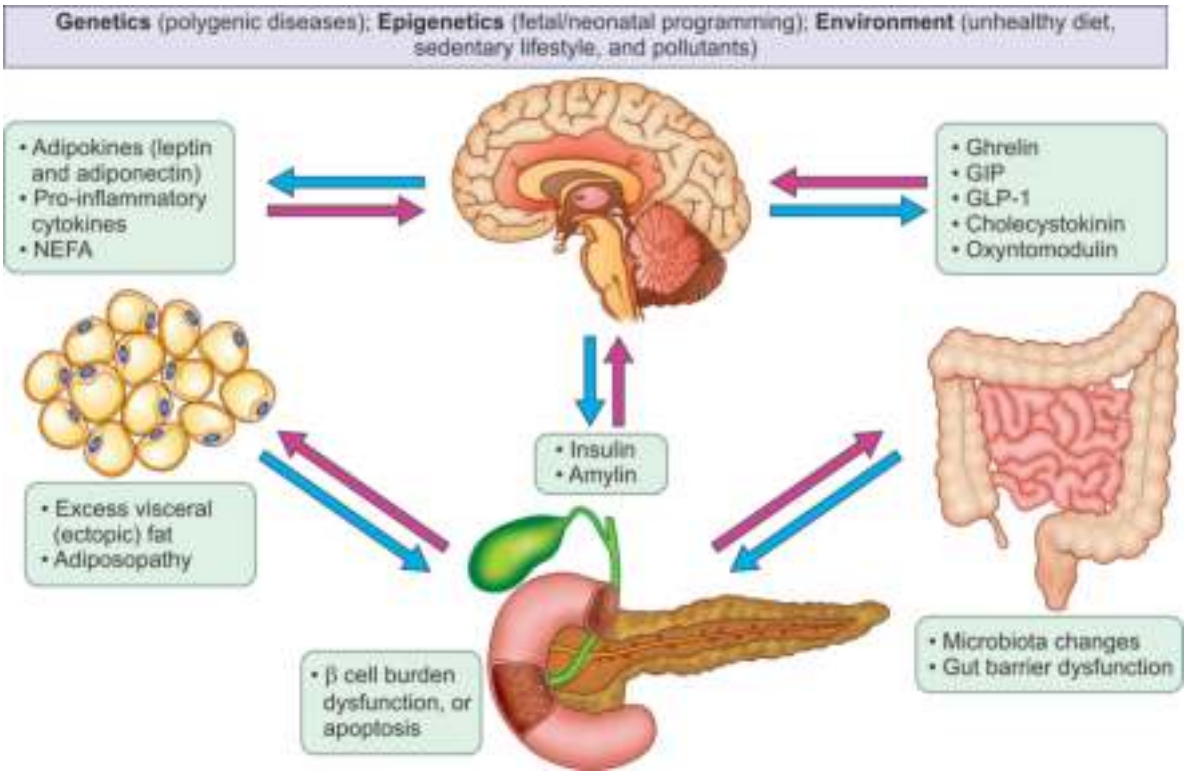

Fig. 7.3: Pathogenesis of obesity. Leptin gene is most often defective in obesity. Mutation of leptin gene inhibits leptin release by adiposities. Obesity is related to synthesis of leptin, an antiobesity hormone produced by adipocytes. Neuropeptide Y, pro-obesity is synthesized by the hypothalamus in response to leptin deficiency.

sympathetic regulation of adipose tissue endocrine function through negative feedback between brain and adipose tissue.

- **Corticosteroids and thyroid hormones regulate leptin:** Corticosteroids and tumor necrosis factor-α (**TNF-α**) enhance leptin synthesis, while thyroid hormones are likely to suppress its synthesis from adipocytes. Increased adipose tissue store enhances leptin synthesis. Leptin decreases food intake via hypothalamus and stimulates energy expenditure.
- **Adipose tissue store regulates leptin:** On the contrary, decreased adipose tissue store suppresses leptin synthesis from adipocytes, which increases food intake via hypothalamus and suppresses energy expenditure.

Leptin and its Cognate Receptors

Leptin receptor (LEP-R) exists in several alternatively spliced variants labeled as LEP-Ra, LEP-Rb, LEP-Rc, LEP-Rd, LEP-Re and LEP-Rf. Following leptin synthesis, and secretion from adipocytes in white adipose tissue binds to its cognate transmembrane leptin receptor (LEP-R).

- LEP-R distribution facilitates leptin's pleotropic effects by regulating body mass via a negative feedback mechanism between white adipose tissue and the hypothalamus.
- LEP-R exhibits structural similarity to the class I family of cytokine receptors, which include receptors for interleukins, colony stimulating factor 3 (CSF-3), growth hormone, prolactin, erythropoietin and leukemia inhibitory factor.

Leptin and Energy Homeostasis

Brain has dual-center: (a) satiety center in the ventromedial hypothalamic nucleus (VMH); and (b) hunger center in the lateral hypothalamic nuclei (LH). These centers in brain maintain energy input and energy expenditure.

- Leptin regulates appetite and metabolism by inhibiting the synthesis and its release of pro-obesity neuropeptide Y (**NPY**) in the arcuate nucleus (**ARC**) in brain leading to obesity.
- Subsequently, researchers discovered the LEP-Rb isoform in the ventromedial hypothalamic nucleus (**VMH**), arcuate nucleus (**ARC**), lateral hypothalamic nuclei (**LH),** and dorsomedial hypothalamic nucleus (**DMH**), which play an important role in the regulation of energy balance and body mass.

Leptin Hormone and Obesity

Obese gene mutation inhibits release of **antiobesity leptin hormone** synthesis from adipocytes.

- **Leptin expression in obesity:** Severe early obesity develops due to obese (ob) gene mutation as a result of either hereditary leptin deficiency or leptin resistance that affects leptin signaling pathways.
- **Leptin resistance in obesity:** Leptin resistance is characterized by reduced satiety, overconsumption of nutrients, and increased total body mass. Leptin resistance leads to obesity, which reduces the effectiveness of using exogenous leptin as a therapeutic agent. Thus, combining leptin therapies with leptin sensitization may assist to overcome leptin resistance and consequently obesity.

OBESITY-ASSOCIATED HEALTH PROBLEMS

Persons with obesity are more likely to develop a number of potentially serious health problems including heart diseases, cerebral stroke, type 2 diabetes mellitus, certain cancers, digestive problems, osteoarthritis, gynecological and sexual disorders. Schematic representation of obesity associated health problems is shown in Fig. 7.4.

Obesity-related Respiratory System Disorders

Obesity causes obstructive sleep apnea, obesity hypoventilation syndrome, bronchial asthma, cor pulmonale (pulmonary hypertension and right ventricular hypertrophy).

- **Obstructive sleep apnea:** Obstructive sleep apnea refers to recurrent episodes of apnea (interrupted airflow) due to obstruction of the upper airway during sleep followed by transient awakening to restore airway patency, which occurs due to accumulation of fat in neck region. Recurrent obstructive sleep apneas cause chronic alveolar hypoxia resulting in

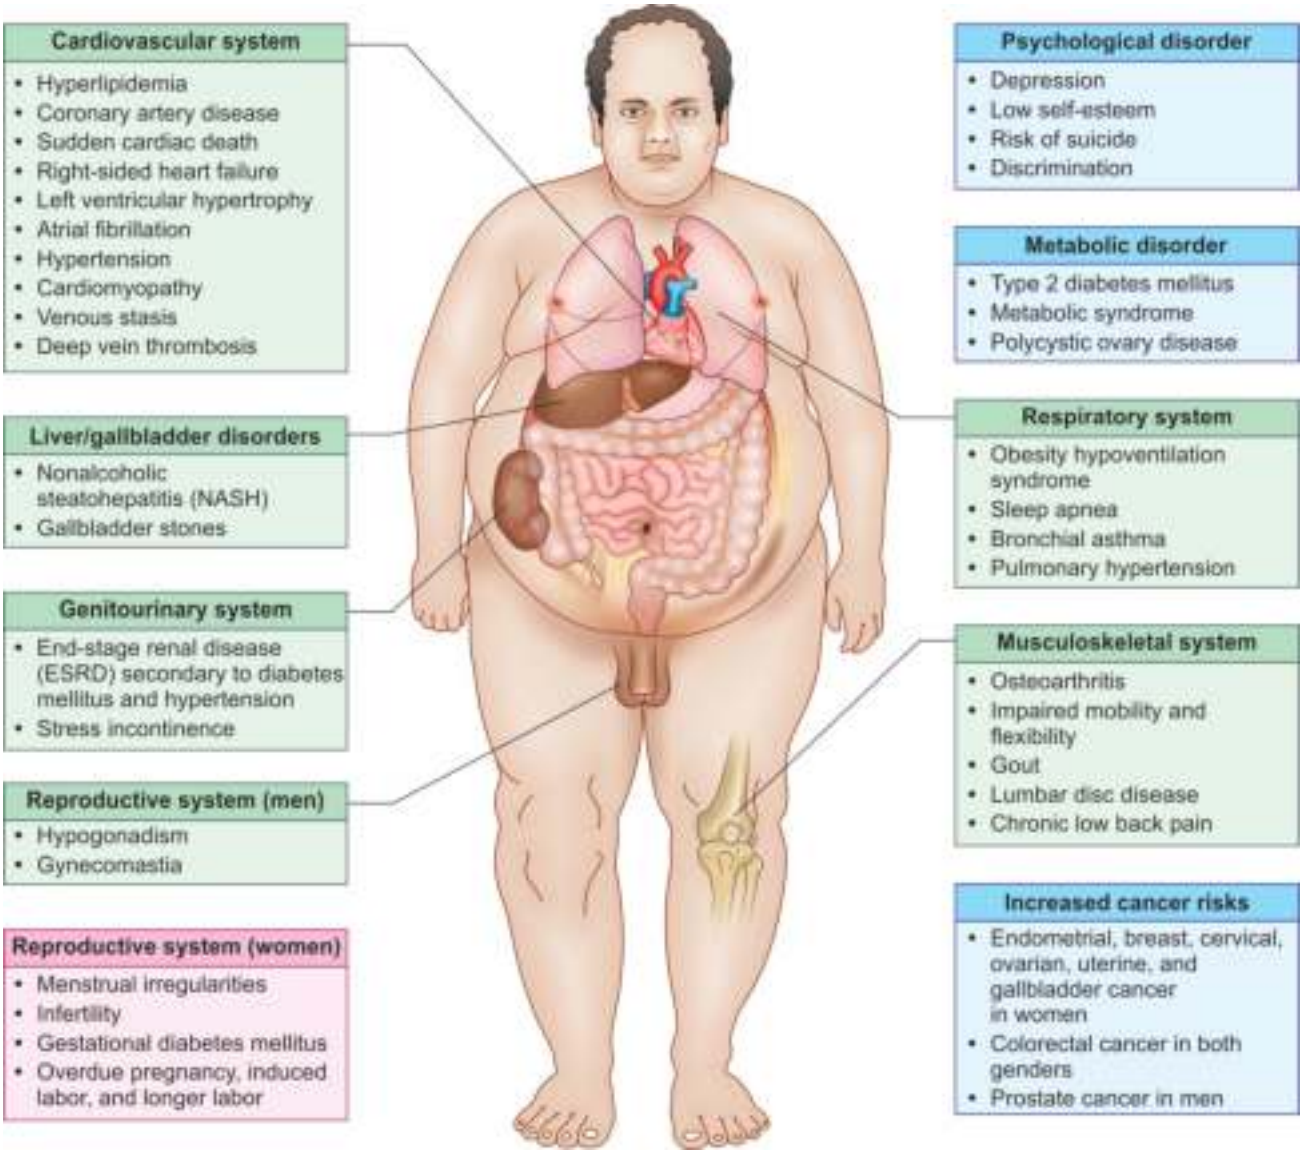

Fig. 7.4: Schematic representation of obesity-associated health problems.

pulmonary hypertension and cor pulmonale, which is confirmed by polysomnography. Obstructive sleep apnea is exacerbated by tobacco smoking, sedative drugs and alcohol consumption. Obstructive sleep apnea is independent risk factor for congestive heart failure, hypertension, myocardial infarction, cardiac arrhythmias and sudden cardiac death.

- **Obstructive hypoventilation syndrome:** Obstructive hypoventilation syndrome is also known as 'Pickwickian syndrome' comprising hypoventilation, daytime hypercapnia and hypoxemia ($paCO_2$ >45 mm Hg and paO_2 <10 mm Hg). The diagnostic test for obstructive hypoventilation syndrome is daytime arterial blood gas analysis. This disease has a high mortality rate due to leptin resistance resulting in central hypoventilation and impaired compensatory response to acute hypercapnia.

Obesity-related Cardiovascular System Disorders

Obesity contributes directly to cardiovascular system disorders related risk factors, including dyslipidemia, hypertension, type 2 diabetes mellitus and sleep disorders. Obesity also leads to the development of cardiovascular disease and cardiovascular disease mortality independently of other cardiovascular system risk factors.

- **Cardiomyopathy:** Obesity is directly responsible for alterations in the structure and function of the heart leading to cardiomyopathy, which is multifactorial involving metabolic disturbances (insulin resistance, increased free fatty acid levels, increased levels of adipokines), activities of angiotensin-aldosterone system, sympathetic nervous system, myocardial remodeling and small vessel disease. Increased plasma insulin increases sodium retention and expansion of plasma volume leading to cardiomyopathy. Thickness of left ventricle wall is >10 mm, which should be differentiated from a genetic disorder dilated cardiomyopathy with left ventricle wall thickness <10 mm.
- **Deep vein thrombosis:** Obesity is independent risk factor for development of deep vein thrombosis. Pathogenesis of thromboembolic phenomenon in obese is complex potentially involving a number of hormones, cytokines, growth factors and leptin synthesized by adipose tissue.
- **Coronary artery disease:** Obesity is independent risk factor for development of coronary artery disease. Proinflammatory state is caused by excess of deposition of fat in obese persons. Coronary artery disease occurs due to increased synthesis of **adipokines** such as **adiponectin** associated with inflammation and insulin resistance resulting in atherosclerosis.
- **Sudden cardiac death:** Obese persons have increased risk of development of cardiac arrhythmias and sudden cardiac death even in the absence of obvious cardiac pathology. There is prolonged QT interval in obese persons.

Obesity-related Hepatobiliary System Disorders

Obesity is associated with an increased risk of non-alcoholic fatty liver disease (**NAFLD**) and cholelithiasis.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) is characterized by an increase in intrahepatic triglyceride content (steatosis) with or without inflammation and fibrosis (i.e. steatohepatitis). NAFLD is so named because it closely resembles alcoholic fatty liver.

- The hallmark of nonalcoholic fatty liver disease (NAFLD) occurs when the rate of hepatic fatty acid uptake from plasm and *de novo* fatty acid synthesis is greater than the rate of fatty acid oxidation and export as triglyceride within very-low-density lipoproteins. Therefore, there is increased deposition of triglyceride within hepatocytes leading to adverse alterations in glucose, fatty acid and lipoprotein metabolism.
- There is increased risk of nonalcoholic steatohepatitis (NASH) in obese persons, which represents a spectrum of liver injuries that initially display steatosis, with or without hepatitis.
- Steatohepatitis may progress to bridging fibrosis and cirrhosis of the liver, which is consistently associated with metabolic syndrome (central obesity, type 2 diabetes mellitus, dyslipidemia, and microalbuminuria).

Cholelithiasis

Obese person is more to develop gallbladder stones as a result of supersaturation of fat. Obesity, particularly abdominal or centripetal obesity, is a well-established risk factor for gallbladder stone disease, which is associated with an increased activity of the rate-limiting step in cholesterol synthesis, the hepatic enzyme, 3-hydroxyl-3-methyl-glutaryl coenzyme A (**HMG-CoA**) reductase, leading to increased cholesterol synthesis in the liver, its secretion into bile and storage in the gallbladder.

Obesity-related Metabolic Disorders

According to WHO definition, obesity-related metabolic syndrome occurs due to insulin resistance, impaired glucose tolerance or diabetes mellitus together with at least two of the following: (a) hypertension, (b) obesity, (c) high triglycerides and/or low-high-density lipoproteins, and (d) macroglobulinemia.

Obesity-related metabolic syndrome increases risk for cardiovascular disease.

- Increased adipose tissue in the body downregulates insulin receptor synthesis resulting in increased concentration of serum insulin and thus diabetes mellitus. Weight reduction increases insulin receptor synthesis.
- Uncontrolled diabetes mellitus is associated with increased risk for life-threatening complications, i.e. macrovascular diseases (atherosclerosis) such as coronary artery disease, cerebral vascular disease, peripheral vascular disease (gangrene) and microvascular diseases like retinopathy, nephropathy and neuropathy.

Obesity-related Cancers' Risk

Obesity is associated with increased risk for development of several cancers of breast, endometrium, esophagus, gastric, colon, rectum, pancreas, liver, biliary tract, kidney, prostate and skin (melanoma). Insulin resistance, increased insulin level, increased insulin-like growth factor (IGF), increased steroid level as a result of aromatization of androgens to estrogens in adipose tissue, increased peptide level and systemic inflammation as a result of due to adipokine (leptin) and tumor necrosis factor α (TNF-α) participate in the development of malignant tumors in obese persons.

Obesity-related Reproductive System Disorders

Obese men present with gynecomastia and hypogonadism. Obese women are at risk for menstrual irregularities, infertility, gestational diabetes, overdue child birth, induced labor and prolonged labor.

Obesity-related Genitourinary System Disorders

Obese persons are more prone to develop end-stage renal disease as a result of hypertension and diabetes mellitus. End-stage renal disease refers to GFR <5% of normal, which is the terminal stage with uremic manifestations. Glomeruli are markedly sclerosed, tubular atrophy with thyroidization, intestinal fibrosis and vascular thickening.

Obesity-related Musculoskeletal System Disorders

Obese persons are at higher of osteoarthritis, impaired mobility, gout, prolapse lumbar intervertebral discs and chronic low back pain. Osteoarthritis is a slowly progressive destruction of the articular cartilage. Articular cartilage loses its elasticity results to fragmentation, which floats into synovial fluid. Floating cartilage erodes bone, which exhibits polished and ivory-like appearance (eburnation), which is accompanied by new bone formation (osteophytes) in subchondral region and at the margins of the affected joint.

VITAMINS DEFICIENCY

Vitamins are group of organic compounds essential for normal growth and functions. These are required in small quantities in the diet because they cannot be synthesized by the body. Vitamins are categorized into two groups: (a) fat-soluble vitamins include A, D, E and K; and water-soluble vitamins include thiamine (vitamin B_1), riboflavin (vitamin B_2), niacin (vitamin B_3), pantothenic acid (vitamin B_5), pyridoxine (vitamin B_6), biotin, folate/folic acid, cyanocobalamin (vitamin B_{12}) and vitamin C. Major functions of vitamins and deficiency syndrome are given in Table 7.3.

FAT-SOLUBLE VITAMINS

Vitamins A, D, E and K are called the fat-soluble vitamins, because these are soluble in organic solvents and insoluble in water. Fat-soluble vitamins are absorbed and transported in a manner similar to that of lipids.

VITAMIN A

Vitamin A is essential for the maintenance of normal mucous membranes, cell growth, reproduction, enhancement of immune system and for normal vision. Vitamin A is found in foods of animal origin, such as liver, fish, butter, whole milk and egg yolk. However, body converts certain carotenoids derived from plants especially β-carotene to vitamin A.

- Vitamin A occurs in two forms: (a) retinol is an active form of vitamin A found in animal liver, whole milk and some fortified foods; and (b) carotenoids are dark-colored pigments found in plant foods that can turn into active form of vitamin A. There are more than 500 known carotenoids. One such carotenoid is β-carotene that acts as an oxidant.
- β-Carotene is converted to retinol (steroid hormone essential for growth and development). Retinol is converted to retinal (Wald's visual cycle) and retinyl phosphate (glycoprotein synthesis).

Table 7.3 Major functions of vitamins and deficiency syndrome

Nutrient	Functions	Deficiency Syndrome
Fat-soluble vitamins		
Vitamin A	Visual pigment regulating cell growth	Nyctalopia (night blindness), xerophthalmia (conjunctival xerosis), Bitot's spots, keratomalacia, corneal scarring, infertility, delayed growth, metaplasia of columnar epithelium in ducts. Immune deficiency and recurrent infections
Vitamin D	Vitamin D facilitates calcium and phosphate absorption from small intestine, and maintains plasma calcium and phosphate levels	Rickets in children, osteomalacia in adults and hypocalcemic tetany
Vitamin E	Antioxidant maintaining nervous system	Spinocerebellar syndrome
Vitamin K	Acts as cofactor for hepatic carboxylation of prothrombin; VII, IX and X, protein C and protein S	Bleeding diathesis
Water-soluble vitamins		
Thiamine (B_1)	Thiamine pyrophosphate functions as a coenzyme essential for maintaining nervous system	Wet beriberi, dry beriberi and Wernicke-Korsakoff syndrome
Riboflavin (B_2)	Acts as cofactor for enzyme including FMN and FAD	Ariboflavinosis, cheilosis, glossitis, dermatitis, keratitis
Niacin (B_3)	Component of coenzyme NAD and NADP	Pellagra, dementia, diarrhea and dermatitis
Pantothenic acid (B_5)	Component of coenzyme A and acyl carrier proteins	Recognized only under experimental conditions: constitutional and gastrointestinal symptoms, paresthesia, cramps, impaired coordination
Pyridoxine (B_6)	Forms pyridoxal-5-phosphate, a coenzyme in many reactions	Cheilosis, glossitis, dermatitis and peripheral neuropathy
Biotin	Acting as cofactor in several carboxylation reactions	Deficiencies extremely rare. Patient presenting with anorexia, dermatitis, atrophic glossitis, myalgia, ECG changes, hypothermia and mild anemia
Folate (folic acid)	Acting as coenzyme in transfer and utilization of 1-carbon units, essential step in nuclei acid synthesis.	Megaloblastic anemia
Cyanocobalamin (B_{12})	▪ Participates in utilization of folate in nucleic acid synthesis ▪ Essential for maintenance of nervous system	▪ Megaloblastic anemia ▪ Subacute combined degeneration of spinal cord in midthoracic region
Vitamin C (ascorbic acid)	Acting as cofactor in hydroxylation and amination reactions	Scurvy

- Carotenoids are present in yellow and green, leafy vegetables and fruits (carrots, sweet potatoes, pumpkins, mango, spinach), which can turn into active form of vitamin A in the body. Biochemical functions of vitamin A are given in Table 7.4.

Vitamin A and Normal Vision

George Wald described the biochemical function of vitamin A in the process of vision, known as Wald's visual cycle or rhodopsin cycle. Two types of light receptors, rods and cones, exist in the retina of the eye. Rods are present in the periphery and are involved in dim light vision (e.g. cats and owls). **Cones** are present at the center are responsible for bright light vision and color vision in humans.

Wald's Visual Cycle

Retinol is type of retinoid also called vitamin A_1, which is produced from vitamin A. Oxidation of retinol leads to formation of aldehyde, retinal and retinoic acid compounds. Retinyl esters are storage form of vitamin A. Schematic representation of Wald's visual cycle is shown in Fig. 7.5.

- Retinol is a component of the photoprotective visual pigment rhodopsin present on cones, which is sensitive in reduced light. Iodopsins in cones are responsive in bright light. Retinol is transported to retina via circulation, which moves into retinal pigment epithelial cells, where it is esterified to form retinyl esters and then stored.

Table 7.4 Biochemical functions of vitamin A

Vitamin A is essential for maintenance of healthy epithelial tissue and normal vision
Vitamin A maintains proper immune system to fight against infections
Vitamin A is required for synthesis of cholesterol and glucocorticoids
Retinol and retinoic acid function almost like steroid hormones and regulate protein synthesis essential for cell growth and differentiation
Retinol and retinoic acid function in the synthesis of transferring the iron transport protein
Retinyl phosphate derived from retinol participates in synthesis of glycoproteins and mucopolysaccharide compounds, which are essential for cell growth and mucus secretion
Carotenoids (most important β-carotene) possess antioxidant property that reduce synthesis of oxygen-derived free radicals and thus reduce the risk for cancers

- When needed, retinyl esters are hydrolyzed and isomerized to form 11-*cis*-retinol, which shuttles to rod cells of retina, where it binds to protein called opsin to form visual pigment rhodopsin, also known as 'visual purple'. Rhodopsin is a conjugated protein in rods, which contains 11-*cis*-retinal and a protein opsin.
- The primary process in Wald's visual cycle is that on exposure to light, the isomerization of 11-*cis* retinal to 'all-*trans*-retinal' takes place, which results in conformational change in opsin responsible for the generation of electrical signal to optic nerves. The nerve impulse generated by optic nerve is transmitted to the brain, where it is interpreted.
- The all-*trans*-retinal is immediately isomerized by retinal isomerase to 11-*cis*-retinal, which combines with opsin to generate rhodopsin and completes the Wald's visual cycle.

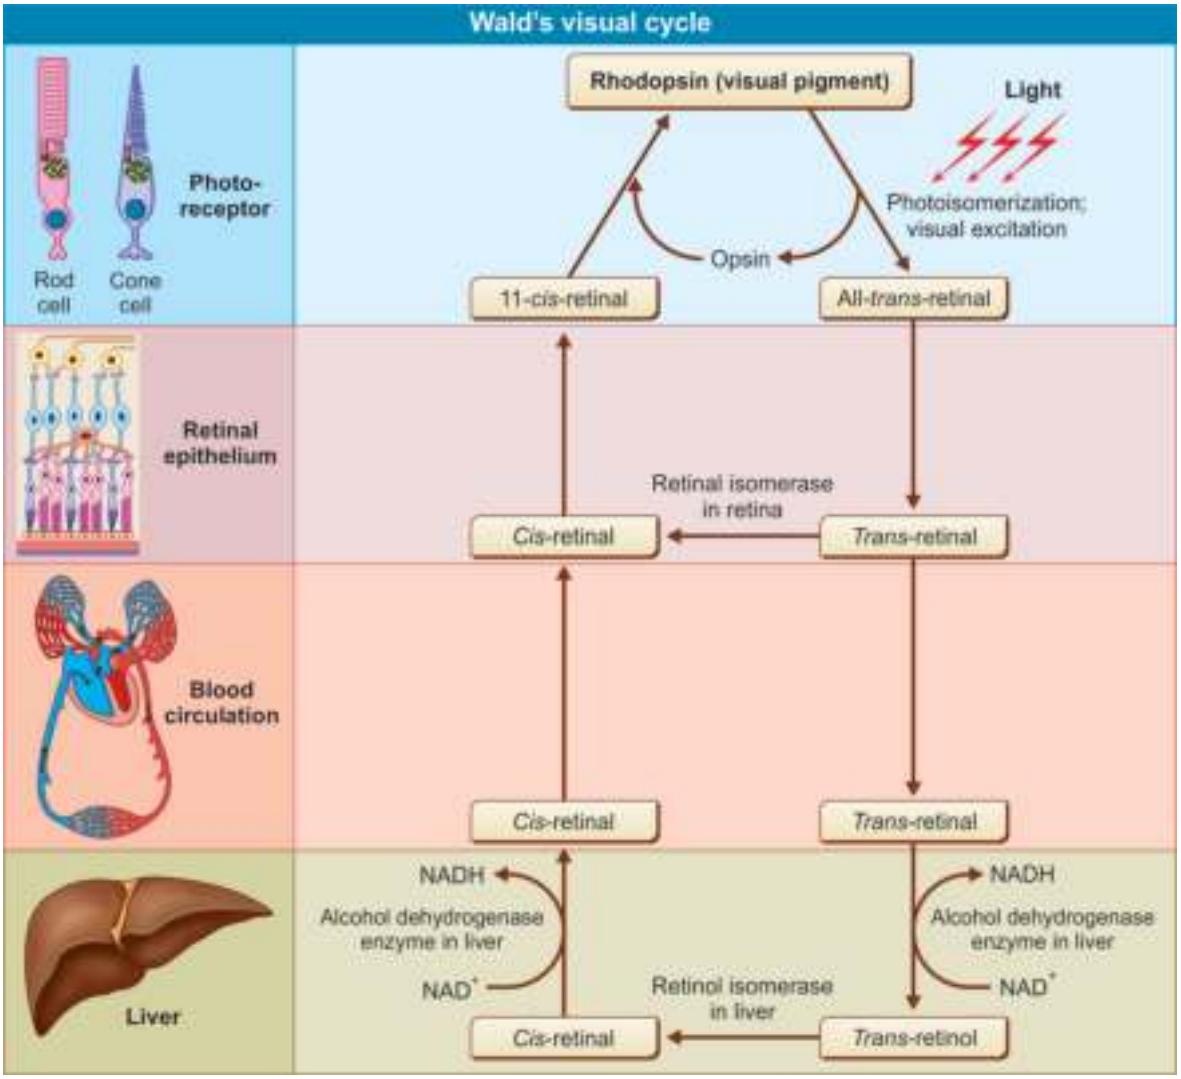

Fig. 7.5: Schematic representation of Wald's visual cycle. Oxidation of retinol leads to formation of aldehyde, retinal and retinoic acid compounds. A derivative, retinol, is a component of the photoprotective visual pigment rhodopsin. This visual pigment rhodopsin present on cones is sensitive in reduced light. Iodopsins in cones are responsive in bright light.

- However, the conversion of all-*trans*-retinal to 11-*cis* retinal is incomplete. Therefore, most of the 'all-*trans*-retinal' is transported to the liver and converted to 'all-*trans*-retinol' by alcohol dehydrogenase enzyme, which undergoes isomerization to '11-*cis*-retinol' which is then oxidized to 'all-*trans*-retinol' to participate in the Wald's visual cycle.

Wald's Visual Cycle and Color Vision

Cones are specialized for bright and color vision. Wald's visual cycle occurs in rods and also in cones. The color vision is governed by color sensitive pigments such as porphyropsin (red), idopsin (green) and cyanopsin (blue). All these pigments are retinal opsin complexes.

- When bright light strikes the retina, one of the color sensitive pigments is bleached depending on the particular color of light. When exposed to light, the color of rhodopsin changes from red to yellow by bleaching process. Bleaching occurs within milliseconds and many unstable intermediate products are formed during this process (Rhodopsin Prelumirhodopsin → Lumirhodopsin → Metarhodopsin I → Metarhodopsin II → All-*trans*-retinal + opsin).
- The color sensitive pigments dissociate to all-*trans*-retinal and opsin, as in case of rhodopsin. The bleaching process transmits nerve impulse to brain as a specific color red when porphyropsin splits, green when iodopsin splits, or blue for cyanopsin. The perception of different color in the brain occurs due to splitting of color sensitive pigments in different proportions (Fig. 7.6).

Clinical Features

Vitamin A deficiency can result from inadequate dietary intake, fat malabsorption or liver disorders.

- Night blindness (nyctalopia) is the earlier clinical symptom of vitamin A deficiency. Patient has difficulty to see in dim light since dark adaptation time is increased.
- Severe deficiency of vitamin A leads to xerophthalmia, which is characterized by dryness of conjunctiva and cornea; Bitot's spots and keratomalacia. Night blindness is prevented in children under five years of age by vitamin A supplementation. Clinical photograph of keratomalacia in vitamin A deficiency is shown in Fig. 7.7.
- Vitamin A deficiency results in growth retardation, keratinization of epithelial cells in gastrointestinal tract, respiratory tract, glandular ducts and urinary tract. Impairment of immune system results in infections in persons with vitamin A deficiency.
- Reproduction system is adversely affected due to vitamin A deficiency. Patients with vitamin A deficiency may develop gonadal dysgenesis. Clinical manifestations of vitamin A are given in Table 7.5.

Hypervitaminosis A

Both acute and chronic types of hypervitaminosis A are responsible for dermatitis, headache, hepatomegaly, weight loss, alopecia, bone changes and joint pains.

- Person with acute hypervitaminosis A may experience one or more of the symptoms such as irritability, drowsiness, nausea, vomiting and abdominal pain.

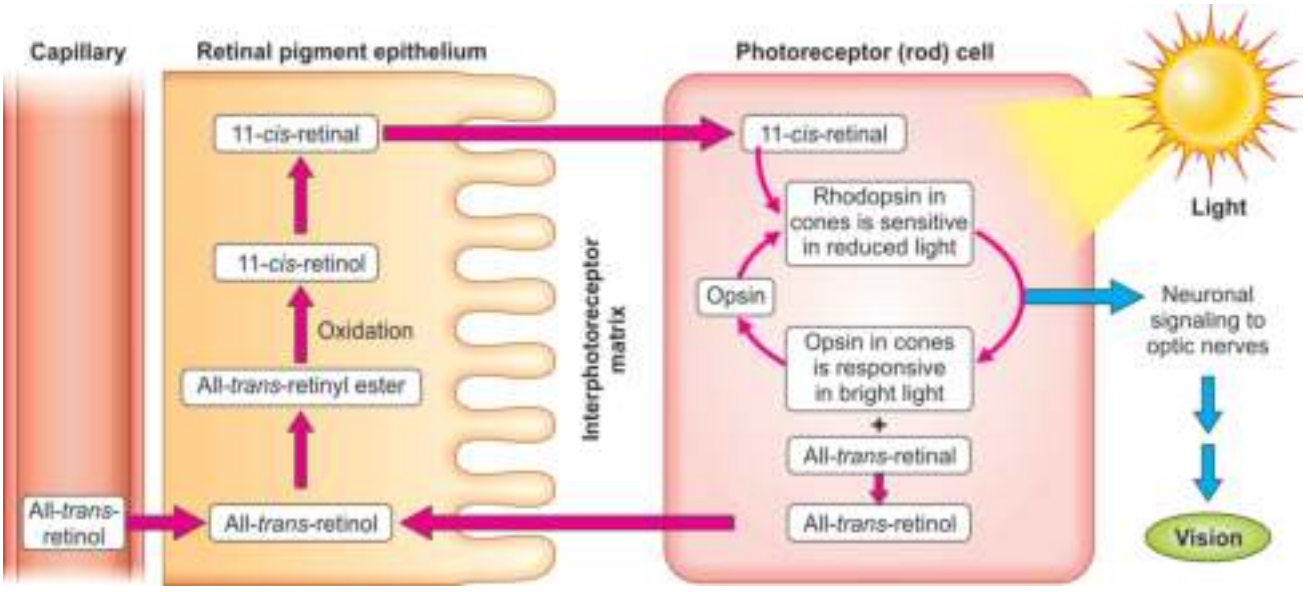

Fig. 7.6: Schematic representation of Wald's visual cycle. Oxidation of retinol leads to formation of aldehyde, retinal and retinoic acid compounds. A derivative, retinol, is a component of the photoprotective visual pigment rhodopsin. This visual pigment rhodopsin present on cones is sensitive in reduced light. Iodopsins in cones are responsive in bright light.

Fig. 7.7: Clinical photograph of keratomalacia in vitamin A deficiency. Vitamin A deficiency causes night blindness, Bitot's spots, corneal ulcer, keratomalacia and squamous metaplasia of epithelium lining bronchi, urinary system and glandular ducts. (*Courtesy:* Dr. JL Goyal, Director Professor, Department of Ophthalmology, Maulana Azad Medical College and Associated Guru Nanak Eye Centre, New Delhi).

- Person with chronic hypervitaminosis A may have symptoms such as mouth ulcers, swelling of the bones, cracked fingernails, anorexia, bone pain, cheilosis, blurred vision, dizziness, nausea, vomiting, sensitivity to light and rough, dry itchy skin and alopecia; jaundice, confusion and respiratory tract infections.

VITAMIN D

Vitamin D (also referred to as calciferol) is a fat-soluble vitamin derived from dietary supplement and endogenously when ultraviolet rays from sun triggering vitamin D. Schematic representation of vitamin D metabolism is shown in Fig. 7.8.

- Dietary vitamin D exist in two forms: (a) vitamin D_2 (ergocalciferol) found in plants such as trout, fortified cereals, broccoli, apple, banana, whole wheat, and sunflower seeds and mushrooms, and (b) vitamin D_3 (cholecalciferol) found in cod liver oil, milk products, tuna fish, salmon fish and egg yolk.
- Vitamins obtained from dietary and sun ultraviolet rays is biologically inert and must undergo two hydroxylations in the activation. Vitamin D which enters blood and reaches liver and kidneys.
  - First hydroxylation occurs in the liver converts vitamin D to 25-hydroxyvitamin D[25(OH)] by D-25 hydroxylase. The 25-hydroxyvitamin D[25(OH)] is also known as calcidiol.
  - Second hydroxylation occurs primarily in the kidney and forms physiologically active 1,25-dihydroxyvitamin D[1,25(OH)2D] by α_1-hydroxylase, also known as calcitriol.

Vitamin D Functions

Vitamin 1, 25$(OH)_2$ D acts on gastrointestinal tract and promotes absorption and maintains normal plasma levels of calcium and phosphorus. Calcium and phosphorus participate in bone mineralization.

- Vitamin D collaborates with parathormone in mobilization of calcium from bone, which facilitates parathormone dependent reabsorption of calcium in the distal renal tubules. Vitamin D is requisite for normal mineralization of cartilage and bone.
- Vitamin D plays other roles in the body, including reduction of inflammation as well as modulation of cellular processes such as cell growth, neuromuscular and immune function including glucose metabolism.
- Serum concentration of 25(OH)D is currently the main indicator of vitamin D status, which has a half-life of 15 days.

Table 7.5 Clinical manifestations of vitamin A deficiency

Organ Involvement	Clinical Manifestations
Ocular changes	▪ Nyctalopia (night blindness) ▪ Xerophthalmia (conjunctival xerosis) ▪ Bitot's spots ▪ Keratomalacia ▪ Corneal ulcer ▪ Xerophthalmic scarring ▪ Xerophthalmic fundus (white spotted fundus due to changes in outer segment of rods)
Growth	Delayed growth
Skin changes	Follicular hyperkeratosis
Bone changes	Failure of bone remodeling
Gonadal changes	Gonadal dysfunction (infertility and troubled conception)
Keratinization of lining epithelium	Metaplasia of columnar epithelium lining gastrointestinal tract, respiratory tract, respiratory tracts and ducts
Immune system	Immune deficiency and recurrent infections
Tissue healing	Poor wound healing

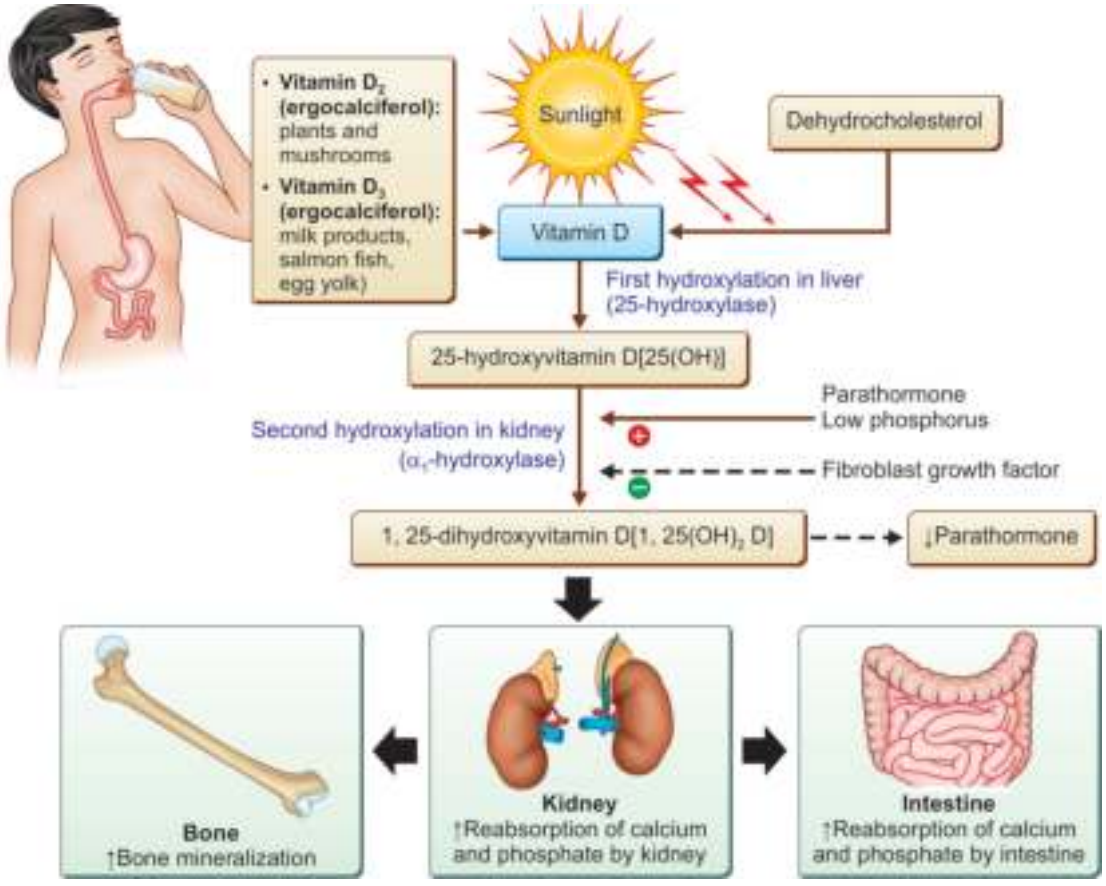

Fig. 7.8: Schematic representation of vitamin D metabolism. Vitamin D is synthesized from 7-dehydrocholesterol in the skin. Vitamin D is also derived from dietary source (vitamins D_2 and D_3). Vitamin D is metabolized by hydroxylation in the liver and kidney. The first hydroxylation, which occurs in the **liver** converts vitamin D to 25-hydroxyvitamin D[25(OH)] by vitamin D 25-hydroxylase. The 25-hydroxyvitamin D[25(OH)] is also known as '**calcidiol**. The second hydroxylation occurs primarily in the kidney and forms physiologically active 1,25-dihydroxyvitamin D[1,25$(OH)_2$D] by α_1-hydroxylase, also known as calcitriol.

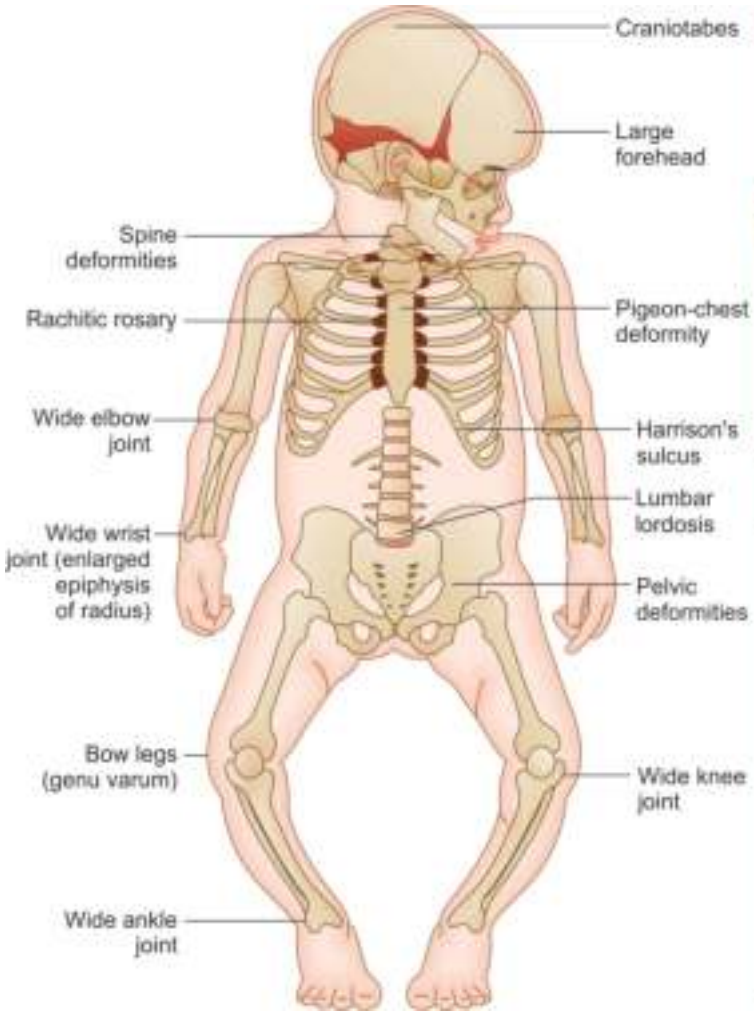
Vitamin D Deficiency-related Disorders

Persons can develop vitamin D deficiency when usual dietary intakes are lower over time that recommended, or exposure to sunlight is limited, the kidneys cannot convert 25(OH)D to its active form, or inadequate vitamin D absorption in gastrointestinal tract. Dietary vitamin D deficiency is more common in vegetarians and persons with milk allergy and glucose intolerance. Vitamin D deficiency leads to rickets in children, osteomalacia in adults and hypocalcemic tetany.

Rickets

Prolonged exclusive breastfeeding without vitamin D supplementation can cause rickets in infants. In children, vitamin D deficiency results in rickets, which is characterized by a failure of bone tissue to become properly mineralized, resulting in soft bones and skeletal abnormalities. Schematic representation of rickets is shown in Fig. 7.9.

- During infancy, head and chest sustain the greatest stresses. Child develops rickets and presents with craniotabes, frontal bossing, rachitic rosary, Harrison's groove, pigeon-shaped chest, deformities of pelvic bones and spine as a result of inadequate calcification of cartilage and replacement of cartilage by osteoid matrix on inadequately mineralized cartilaginous remnants. It leads to projection of distorted, irregular masses of cartilage into marrow cavity and enlargement and lateral expansion of the osteochondral junction.
- Radiograph of the wrists in rickets demonstrates irregular fraying and capping of metaphysis of the distal ends of radius and ulna with widening of growth plate. Further, there is evidence of a transverse lucency in the bilateral distal end of radius and ulna with irregular sclerotic margins suggestive pseudofractures (looser zones). All ossification centers expected for age have not appeared with looser zones. Radiograph of wrists in rickets is shown in Fig. 7.10.
- Fortification of milk and other staples, such as breakfast cereals and margarine, with vitamin D along with cod liver oil help in prevention of rickets.



Vitamin D sources

- Vitamin D synthesis in skin on exposure to sunlight
- Vitamin D_2 (ergocalciferol found in plants and mushrooms)
- Vitamin D_3 (ergocalciferol found in milk products, cod liver oil, salmon fish, tuna fish, egg yolk)

Vitamin D functions

- Regulation of calcium and phosphorus homeostasis
- Regulation of growth and bone mineralization
- Regulation of immune system
- Regulation of insulin secretion
- Regulation of cell proliferation and differentiation
- Regulation of calcium transport in muscles

Vitamin D deficiency: Clinical features of rickets in children

- **Craniotabes:** Thinning and softening of occipital and parietal bones occurs and late closure of fontanelles.
- **Frontal bossing:** Frontal bone is squared due to increased formation of osteoid tissue.
- **Rachitic rosary:** Thickening of costochondral junction occurs due to overgrowth of cartilage and osteoid tissue results in a string-of-beads-like appearance known as rachitic rosary.
- **Harrison's sulcus:** Depression along the line of insertion of the diaphragm into the rib cage occurs due to inward pull of diaphragm.
- **Pigeon-shaped chest:** Anterior protrusion of sternum occurs due to inward pull of metaphyseal areas of ribs by respiratory muscles
- **Pelvis bones:** Deformity of pelvic bones occurs
- **Spine deformity:** Lumbar lordosis occurs in ambulatory child.

Fig. 7.9: Schematic representation of rickets. Rickets child shows craniotabes, frontal bossing, rachitic rosary, Harrison's groove, pigeon-shaped chest, deformities of pelvic bones and spine as a result of inadequate calcification of cartilage and replacement of cartilage by osteoid matrix on inadequately mineralized cartilaginous remnants.

Clinical Pearls: Clinical Features of Rickets in Children

- **Craniotabes:** Thinning and softening of occipital and parietal bones occurs and late closure of fontanelles.
- **Frontal bossing:** Frontal bone is squared due to increased formation of osteoid tissue.
- **Rachitic rosary:** Thickening of costochondral junction occurs due to overgrowth of cartilage and osteoid tissue results in a string-of-beads-like appearance known as rachitic rosary.
- **Harrison's sulcus:** Depression along the line of insertion of the diaphragm into the rib cage occurs due to inward pull of diaphragm.
- **Pigeon-shaped chest:** Anterior protrusion of sternum occurs due to inward pull of metaphyseal areas of ribs by respiratory muscles.
- **Pelvis bones:** Deformity of pelvic bones occurs.
- **Spine deformity:** Lumbar lordosis occurs in ambulatory child.

Osteomalacia

In adults and adolescents, vitamin D deficiency can lead to osteomalacia, which means loss of skeletal mass or too little bone (osteopenia) leading to softening of bones.

- Osteomalacia is characterized by inadequate mineralization of osteoid matrix, excess of unmineralized osteoid resulting in weak bones vulnerable to fractures (vertebrae, hips, wrists and ribs) in 25% cases.
- Patient may develop kyphoscoliosis, apparent loss of bone density and cortical thickness, visualized on radiographs.

VITAMIN E

Vitamin E is a fat-soluble vitamin with several forms (tocopherol α, β, γ and δ). α-Tocopherol is the active form of vitamin E used by human body. Vitamin E is found in plant-based oils, nuts, seeds, fruits and vegetables.

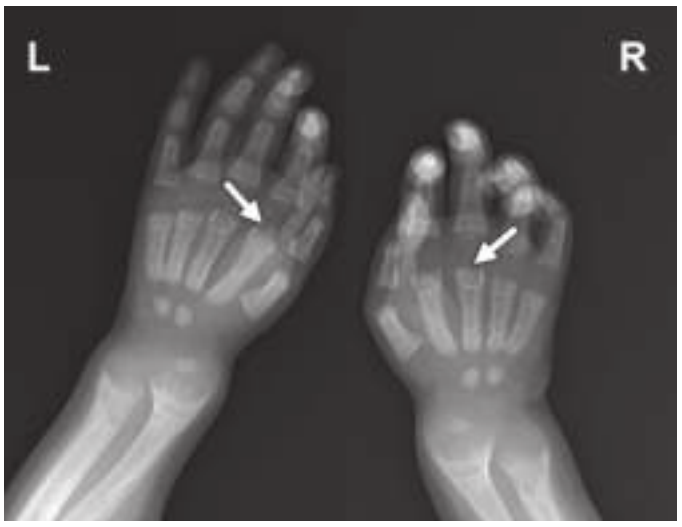


Fig. 7.10: Radiograph of wrists in rickets. Radiograph demonstrates irregular fraying and capping of metaphysis of the distal ends of radius and ulna with widening of growth plate. These findings are suggestive of rickets. Further, there is evidence of a transverse lucency in the bilateral distal end of radius and ulna with irregular sclerotic margins suggestive pseudofractures (looser zones). All ossification centers expected for age have not appeared with looser zones. These findings are suggestive of rickets with looser zones. (*Courtesy*: Dr. Vigyat, Dr. DY Patil Medical College, Pune.)

Vitamin E sources include wheat germ oil, sunflower oil, safflower oil, soybean oil, almonds, peanuts, peanut butter, beat greens, spinach, pumpkin, red bell pepper, mango, asparagus and avocado.

Vitamin E Functions

Vitamin E main function is to act as an antioxidant, scavenging loose electrons—so-called 'oxygen-derived free radicals'—that can cause damage to cells.

- Vitamin E intercepts oxygen-derived free radicals and prevents destruction of cell membrane by modulation of lipid peroxidation in certain situation. Vitamin E participates in maintenance of nervous system.
- Vitamin E protects the lipid in the LDL molecule from oxidation and thus prevents atheromatous plaque formation in large elastic and medium-sized arteries. Vitamin E inhibits platelets aggregation, but enhances vasodilatation.
- Vitamin E inhibits the activity of protein kinase C, which is involved in the function of other proteins through phosphorylation of hydroxyl groups of serine and threonine amino acid residues on proteins.

Clinical Features

Because vitamin E is found in a variety of foods and supplements. Deficiency of vitamin E occurs as a result of gastrointestinal disorders such as pancreatitis, cystic fibrosis and celiac disease.

- Patient with vitamin E deficiency develops retinopathy, peripheral neuropathy, spinocerebellar syndrome and impaired immune system.
  - Spinocerebellar syndrome is characterized by neurological symptoms (impaired coordination and muscle weakness due to degenerations of axons in posterior columns). There is loss in sensory nuclei of trigeminal, auditory and vagus nerves.
  - There is increased risk of cardiovascular diseases in adults, and hemolytic anemia (premature destruction of red blood cells) in children.
  - Vitamin E is administered to prevent of cardiovascular disease, diabetes mellitus, cancer, and dementia, and to boost immunity.

Vitamin E Hypervitaminosis

Hypervitaminosis E manifests primarily as an anticoagulant state by inhibiting vitamin K-derived coagulation factors (2, 7, 9 and 10), that may cause impaired blood clotting leading to increased risk for bleeding in some persons. This is due to its antagonism of vitamin K resulting in prolonged prothrombin time and therefore, increased international normalized ratio (INR). Prothrombin time–INR is used to monitor persons who are treated with anticoagulant therapy. It is recommended that vitamin E supplements to be stopped one month before elective surgery.

VITAMIN K

Vitamin K is one of the fat-soluble vitamins, that is divided into two main groups: vitamin K_1 (phylloquinone derived from plants) and vitamin K_2 (menaquinone derived from animal-based and fermented foods).

- Vitamin K is found in green leafy vegetables (spinach, broccoli, lettuce, parsley), vegetable oils, almonds, Avocado cereal grains. Small amounts can also be found in meat and dairy products. Bacteria in large intestine produce vitamin K_2 and 40–50% of human body. Vitamin K is absorbed in the small intestine and stored in adipose tissue and the liver.
- Vitamin K is essential for normal blood clotting and bone homeostasis. Vitamin K is a cofactor (coenzyme) for hepatic glutamyl carboxylation required for the synthesis of γ-carboxyglutamyl residues of active serine proteases (e.g. clotting factors II, VII, IX, and X); protein C and protein S.

Clinical Features

Vitamin K deficiency occurs due to cystic fibrosis, celiac disease, common bile duct obstruction and diabetes mellitus, that can cause bleeding diathesis. It is uncommon in adults, except in those with severe liver disease and on oral anticoagulants. Deficiency of vitamin K exclusively occurs in breastfed and premature

babies, because human milk is low in vitamin K, and their gut is not yet colonized with bacteria. Hemorrhagic disease of the newborn is a serious threat to life. Routine vitamin K administration is administered prophylactically.

WATER-SOLUBLE VITAMINS

The water-soluble vitamins include ascorbic acid (vitamin C), thiamine (B_1), riboflavin (B_2), niacin (B_3), pantothenic acid (B_5), pyridoxine (B_6), biotin, folate/folic acid, and cyanocobalamin (B_{12}).

- B complex vitamins (except vitamin B_{12}) are present in whole grain cereals, green leafy vegetables, fish, meat, and dairy foods. Vitamin B_{12} is derived from foods of animal origin only. Folic acid is derived from leafy vegetables, cereals, fruits, and a number of animal products. Vitamin C is derived from citrus fruits, tomatoes, vegetables, milk and meat. Biotin and pantothenic acid deficiencies are extremely rare, which are found in numerous foods and also are synthesized by intestinal bacteria. Biotin deficiency may occur with prolonged antibiotic therapy and ingestion of raw eggs.
- Water-soluble vitamins participate in the release and storage of energy especially in tissues with active metabolism.
- Water-soluble vitamins are not stored in the body except for vitamin B_{12}. That is the reason that regular intake of water-soluble vitamins is essential. Vitamin B_{12} is stored in the liver in large quantities.
- Toxicity from excessive intake is of vitamin B-complex rare, because excess of these vitamins is excreted in the urine. In general, deficiencies of vitamin B complex are often marked by glossitis, dermatitis, and diarrhea.

VITAMIN C (ASCORBIC ACID)

Ascorbic acid, also known as vitamin C, occurs naturally in foods such as citrus fruit, tomatoes, potatoes and leafy vegetables. It is not synthesized endogenously. It is stored in the body (normal range 1.5–4.0 g). Vitamin C is essential for the growth and development and repair of the body tissues.

Vitamin C Functions

Vitamin C plays important role in the synthesis of collagen and reticulin fibers from mucopolysaccharide ground substance in wound healing, absorption of iron needed for red blood cell production, the proper functioning of the immune system, and the maintenance of cartilages, bones and teeth.

- Vitamin C participates in the synthesis of collagen and reticulin fibrils from mucopolysaccharide ground substance in wound healing.
- Vitamin C is required for hydroxylation of proline and lysine, essential for collagen synthesis in coats of blood vessels. It is required for hydroxylation of dopamine in synthesis of norepinephrine.
- Vitamin C enhances maintenance of reduced state of other metabolic products such as iron and FH4 (activated tetrahydrofolate).
- L-ascorbic acid is converted to dehydroascorbic acid (DHA) that participates in oxidation and reduction reactions. Vitamin C accumulates in mitochondria where oxygen-derived free radicals are produced by entering dehydroascorbic acid (oxidized form) through glucose transporters, GLUT-10.
- Ascorbic acid protects the mitochondrial genome and membrane. Vitamin C has antioxidant property by scavenging oxygen-derived free radicals. Vitamin C acts indirectly by regenerating the antioxidant form of vitamin E.

Clinical Features

The most common causes of ascorbic acid (vitamin C) deficiency are poor diet, anorexia, alcoholism, tobacco smoking and hemodialysis/peritoneal dialysis.

- Ascorbic acid deficiency results in scurvy. While symptoms of severe vitamin C deficiency can take months to develop scurvy.
- Scurvy is characterized by defective formation of collagen fibers and osteoid matrix. Patient presents with bleeding gums, subperiosteal hemorrhage; and perifollicular petechial hemorrhages, defective wound healing; hemorrhagic phenomena. Hemorrhages and healing defects occur in both children and adults. Schematic representation of manifestations in scurvy is shown in Fig. 7.11.

Bleeding (Hemorrhages)

Defective connective tissue also leads to fragile capillaries, resulting in abnormal bleeding. Infants and children present with hemorrhages in mucocutaneous and skeletal muscles along fascial planes at mechanical stress points due to loosened vascular endothelial cells from capillaries especially in nail beds, subperiosteal hematomas, bleeding into joint spaces, retrobulbar region and subarachnoid, and intracerebral regions. In adults, ulceration and hemorrhage in gums occur due to loosening of teeth.

Skeletal Manifestations

Bone changes in scurvy are secondary to defective osteoid matrix formation. Insufficient production of osteoid matrix results in cartilaginous overgrowth, widening of epiphysis, bowing of the long bones and

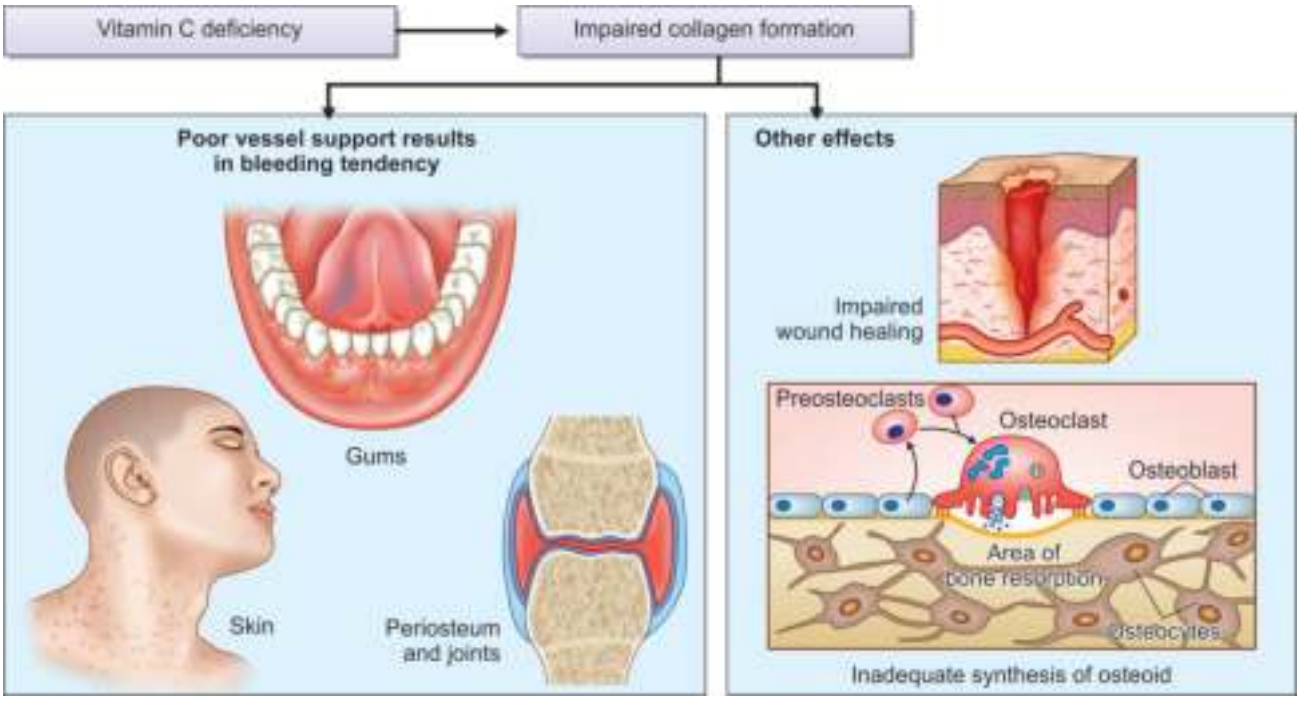

Fig. 7.11: Schematic representation of manifestations in scurvy. Vitamin C deficiency causes impaired synthesis of collagen fibers leading to bleeding gums, hemorrhages in mucocutaneous, muscles along fascial planes, retrobulbar, subarachnoid, and intracerebral regions and bone changes.

chest deformity. Osteoporosis is seen especially at the metaphyseal ends of bone.

Other Manifestations

Patient presents with gingival swelling and periodontal infection, impaired wound healing, impaired localization of focal infections and anemia.

VITAMIN B-COMPLEX

Vitamin B-complex includes thiamine (vitamin B_1), riboflavin (vitamin B_2), niacin (vitamin B_3), pantothenic acid (vitamin B_5), pyridoxine (vitamin B_6), biotin, folate (folic acid) and cyanocobalamin (vitamin B_{12}).

Thiamine (Vitamin B_1)

Thiamine is a water-soluble vitamin, also known as vitamin B_1. It is found in many foods, including cereals, whole grains, beans, nuts, yeast, pea and meat, which enables the body to use carbohydrates as energy. Dietary requirement of thiamine is proportional to the caloric intake of the diet and ranges from 1.0 to 1.5 mg/day for normal adults.

Thiamine Functions

Thiamine is essential for glucose metabolism, which plays a key role in nerve, skeletal muscle and cardiac function.

- Thiamine is rapidly converted into thiamine pyrophosphate (active form) in the brain and liver by thiamine diphosphotransferase enzyme.
- Thiamine pyrophosphate is essential as cofactor for the reactions of the pentose phosphate pathway for maintaining nervous system.

Thiamine Deficiency

Thiamine deficiency is most often associated with severe malnutrition and alcoholism. Other causes of thiamine deficiency include increased demand in disorders (malaria and AIDS) and excessive loss of thiamine (hemodialysis and diuretics). Anti-thiamine factors in diet such as tea and coffee retard thiamine absorption. Thiaminases are found in raw fish, raw shellfish and silkworms.

Clinical Features

Thiamine is used for treatment of congestive heart failure and Alzheimer's disease as well as in cancer prevention. Deficiency of thiamine causes dry beriberi, wet beriberi and Wernicke-Korsakoff syndrome.

- **Dry beriberi:** Patient presents with peripheral neuropathy with resultant atrophy of the skeletal muscles of the extremities. Peripheral neuropathy occurs due to fragmentation of myelin sheath, axons of extremities. There is also involvement of vagus nerve.
- **Wet beriberi:** It is characterized by congestive heart failure associated with dilated cardiomyopathy. Congestive heart failure occurs due to peripheral dilation of arterioles and capillaries.
- **Wernicke-Korsakoff syndrome:** It is characterized by impairment of symmetric motor and sensory reflexes,

involvement of extraocular muscles (ophthalmoplegia), confusion, ataxia and marked memory loss. Degenerative changes occur in the brainstem and diencephalon, with hemorrhagic lesions of cortical and bilateral paramedian masses of grey matter and the mammillary bodies.

Riboflavin (Vitamin B_2)

Riboflavin is water-soluble vitamin derived from milk, meat, eggs, nuts, enriched flour, green vegetables, which works with other B complex vitamins. Riboflavin acts as a cofactor in many cellular processes essential for normal growth and functions and also aids in the release of energy from metabolism of carbohydrates, proteins and lipids.

Riboflavin Functions

- In biochemistry, riboflavin synthesizes flavin adenine dinucleotide (**FAD**) and two molecules of ATP.
- Riboflavin is phosphorylated by ATP to give riboflavin 5′-phosphate (also called flavin mononucleotide—**FMN**).
- Flavin adenine dinucleotide acts as redox-active coenzyme associated with various proteins.
- Both FAD and FMN are essential for various cellular enzymatic oxidation-reduction reactions in metabolism.

Clinical Features

Deficiency of riboflavin occurs in alcoholic persons and newborn especially born to vegetarian mother. The signs and symptoms of riboflavin deficiency include glossitis, angular stomatitis, cheilosis (skin fissures, crust at angle of mouth), seborrheic dermatitis (nasolabial folds, scrotum, or vulva), keratitis (vascularization of cornea, photophobia), hair loss, reproductive system problems and pure red cell aplasia (PRCA).

Niacin (Vitamin B_3)

Niacin is one of the water-soluble vitamins. Niacin is a generic name for nicotinic acid (pyridine-3-carboxylic acid), nicotinamide (pyridine-3-carboxamide) and related derivative such as nicotinamide riboside.

- Niacin is naturally found in many foods such as yeast, rice, fortified cereal grains, green vegetables, beans, liver meat, eggs, chicken, tuna fish, salmon fish anchovies and beef.
- Niacin (nicotinic acid) can be synthesized from the essential amino acid tryptophan with the help of pyridoxine, which is a component of the nicotinamide adenine dinucleotides (NAD and NADP). Niacin is essential to glycolysis, the citric acid cycle, and other oxidative metabolic processes.
- Niacin deficiency occurs in alcoholic persons, Hartnup disease, malignant carcinoid syndrome and isoniazid therapy in tuberculosis.
- Excessive administration of niacin lowers plasma cholesterol levels, and elevates blood glucose and blood uric acid levels. So, it is not recommended in patients with diabetes mellitus and gout.

Clinical Features

Severe niacin deficiency results in pellagra and cause symptoms related to the skin, gastrointestinal tract and nervous system.

- Pellagra is characterized by the 'three **Ds**': dementia, dermatitis (keratotic scaly pigmented rashes on skin exposed to sunlight such as face, neck, dorsum of hands and feet), bright red tongue, and diarrhea.
- There is presence of red ulcerated oral mucosa, thickening of colon wall with atrophy of crypts and demyelination of posterior and lateral columns of spinal cord as well as cerebrum.

Pantothenic Acid (Vitamin B_5)

Pantothenic acid is one of the water-soluble vitamins, which is naturally present in some foods such as seafoods, organ meats, eggs, milk products, mushrooms, avocados, potatoes and broccoli, whole grains such as wheat, rice and oats, peanuts and sunflower seeds.

- The main function of pantothenic acid is in the synthesis of coenzyme A and acyl carrier protein.
- Pantothenic acid helps the body to break food and utilize its metabolic products for cell growth.

Clinical Features

Patient presents with fatigue, headache, irritability, insomnia, nausea, vomiting, numbness in hands or feet and muscle cramps.

Pyridoxine (Vitamin B_6)

Pyridoxine is one of the water-soluble vitamins, which forms pyridoxal-5-phosphate, which acts an essential cofactor for many series of reactions involved in amino acid and protein metabolism such as transamination, deamination, decarboxylation, phosphorylation, racemization and cleavage of cystathionine to cysteine in the methionine pathway. Pyridoxine also converts glutamic acid to γ-aminobutyric acid.

Pyridoxine Sources

Pyridoxine is naturally present in peanuts, soybeans, wheat grains, oat, banana, chicken, some fish and pork. Daily requirement of pyridoxine is 0.5–2.0 mg.

Pyridoxine Deficiency

Pyridoxine deficiency can occur in various disorders such as malnutrition, chronic alcoholism, sickle cell disease, celiac disease, rheumatoid arthritis, hepatitis, extrahepatic biliary obstruction and hepatocellular carcinoma. Pyridoxine deficiency can occur due to therapeutic administration of isoniazid and phenylamine. Isoniazid reacts as competitive inhibitor for pyridoxine binding sites.

Clinical Features

Patient presents with glossitis, cheilosis, dermatitis, pyridoxine-responsive microcytic anemia due to reduced heme synthesis, neonatal seizures, peripheral neuropathy and homocystinuria. Neonatal convulsions occur due to decreased activity of pyridoxal-dependent glutamate decarboxylase, which leads to deficient production of γ-aminobutyric acid (**GABA**), a neurotransmitter. Clinical manifestations are similar to those of vitamin B_2 (riboflavin) deficiency.

Biotin

Biotin is a water-soluble vitamin, which acts as a cofactor in several carboxylation reactions. Biotin is naturally present in whole grain bread, mushrooms, cauliflower, bananas, raspberries, avocados, eggs, sardines stored fish and salmon fish.

- In general, healthy diet provides sufficient amounts of biotin. Biotin deficiency is extremely rare. Biotin is used for hair loss and brittle nails.
- Patient with biotin deficiency may develop lassitude, anorexia, dermatitis, atrophic glossitis, myalgia, ECG changes, hypothermia and mild anemia.

Folate (Folic Acid)

Folate is one of the water-soluble vitamins. Folic acid is the synthetic form of folate. Folate is obtained from yeast, leafy vegetables and animal liver. Animals cannot synthesize folate; thus, it must be obtained from diet.

- Folate acts as a coenzyme in transfer and utilization of 1-carbon unit, an essential step in nucleic acid synthesis and cell division, which is also important for prenatal health. Folate deficiency during pregnancy can lead to neural tube defects such as spina bifida and anencephaly in the newborns. Folate is used for treatment of chronic hemolytic anemia.
- Deficiency of folate occurs due to inadequate intake, intestinal malabsorption, alcoholism, increased demand during pregnancy, hemolytic anemia, and chemotherapeutic agents containing folic acid antagonists.
- Megaloblastic anemia occurs due to deficiency of vitamin B_{12} or folate resulting in defective DNA synthesis, which is characterized by macrocytic anemia, leukopenia, hypersegmented neutrophils and thrombocytopenia in peripheral blood and megaloblastic erythropoiesis.

Clinical Features

Folate deficiency causes megaloblastic anemia that can cause a wide range of symptoms, which usually develop gradually, but can worsen if the condition goes untreated.

- Patient presents with fatigue, lethargy, breathlessness, headache and palpitations. Folic acid deficiency does not cause neurologic changes (in contrast to vitamin B_{12} deficiency). Folate deficiency causes megaloblastic anemia and neural tube defects *in utero*.
- Vitamin B_{12} and folate nutritional aspects are given in Table 7.6. Major functions of vitamin B_{12} and folate nutritional aspect are given in Table 7.7. Comparison between vitamin B_{12} and folate deficiency inducing megaloblastic anemia is given in Table 7.8.

Cyanocobalamin (Vitamin B_{12})

Cyanocobalamin (vitamin B_{12}) is an essential water-soluble vitamin derived from animal source and absorbed by small intestine by two-step processes. First hydrochloric acid in the stomach separates vitamin B_{12} from the protein that is attached to it. Second, the freed vitamin B_{12} then combines with a protein synthesized by the gastric parietal cells, called intrinsic factor, and the body absorbs them together.

Vitamin B_{12} Functions

Vitamin B_{12} acts as cofactor for enzymes required for the catabolism of fatty acids, and the conversion of homocysteine to methionine. High homocysteine in blood is a risk for ischemic heart disease and cerebral stroke. Vitamin B_{12} plays a key role in utilization of folate in nucleic acid synthesis, which is essential for maintenance of nervous system.

Vitamin B_{12} Deficiency

Vitamin B_{12} deficiency is common in strict vegetarians, pernicious anemia, Crohn's disease, blind loop syndrome, *Diphyllobothrium latum* (giant fish tapeworm) infestation and prolonged antibiotic treatment.

Clinical Features

Vitamin B_{12} deficiency causes megaloblastic anemia and demyelination of peripheral nerves leading to sensorimotor disturbances. Subacute combined degeneration of spinal cord occurs in midthoracic region.

- **Physiologic state:** Normally, methylcobalamin converts homocysteine to methionine, which acts as a donor in the synthesis of choline containing

Table 7.6 Vitamin B_{12} and folate nutritional aspects

Parameters	Vitamin B_{12} (Cobalamin)	Folate
Normal daily dietary intake	7–30 μg	200–250 μg
Minimal adult daily requirement	1–2 μg	100–150 μg
Main dietary foods	Animal (dairy) products	Liver, green raw leafy vegetables, yeast, fresh fruits, whole grain cereals
Cooking effect	Little effect	Easily destroyed
Absorption site	Ileum	Duodenum and jejunum
Mechanism of absorption	Vitamin B_{12} combines with intrinsic factor synthesized by gastric parietal cells	Folate converted to methyltetrahydrofolate
Limit of absorption	2–3 μg	50–80% of dietary content
Enterohepatic circulation	5–10 μg	80 μg
Transport in plasm	Most bound to haptocorrin (transcobalamin 1) essential for cell uptake	Folate weakly bound to albumin
Major intracellular physiological forms	Methyl carbylamine, deoxyadenosylcobalamin	Reduced polyglutamate derivatives
Storage sites	Liver (main site), kidney, heart and brain	Liver acts as a coenzyme in transfer and utilization of 1-carbon unit, an essential step in synthesis of nucleic acid
Functions	Vitamin B_{12} participates in utilization of folate in synthesis of nucleic acid; and essential for maintenance of nervous system	Folate acts as a coenzyme involving 1-carbon unit transfer resulting in the synthesis of nucleic acid
Usual therapeutic form	Hydroxocobalamin	Folic (pteroylglutamic) acid
Serum assays	Serum vitamin B_{12} (160–925 ng/L)	Serum folate (3–15 μg/L)

Table 7.7 Major functions of vitamin B_{12} and folate nutritional aspect

Vitamin B_{12} (Cyanocobalamin)
Vitamin B_{12} participates in utilization of folate in synthesis of nucleic acid and maintenance of nervous system. Its deficiency causes megaloblastic anemia and subacute combined degeneration of spinal cord in midthoracic region
Metformin blocks vitamin B_{12}. Hence, reticulocyte count is low in vitamin B_{12} deficiency
Vitamin B_{12} deficiency raises LDH and indirect bilirubin by destroying red blood cells early, as they come out of the bone marrow. This phenomenon is called 'ineffective erythropoiesis', that is why the reticulocyte count is low
After vitamin B_{12}, reticulocyte count improves first and neurological abnormalities improve last
Folate (Folic Acid)
Folate acts as a coenzyme in transfer and utilization of 1-carbon unit, an essential step in the synthesis of nucleic acid
Folic acid deficiency causes megaloblastic anemia without central nervous system involvement

phospholipids an important component of myelin. Normally, deoxyadenosylcobalamin converts methylmalonyl-CoA into succinyl-CoA. Deficiency of methylcobalamin results in decreased synthesis of choline required for myelin synthesis.

- **Pathologic state:** Vitamin B_{12} deficiency results in accumulation of methylmalonyl-CoA, which is converted into methylmalonate and propionate, which leads to increased production of abnormal fatty acids, which incorporate into neuronal lipids. Myelin sheath breakdown occurs. Posterior and lateral white columns of mid-thoracic spinal cord involved. Patient develops total paralysis of lower legs. Subacute combined degeneration of spinal cord occurs in mid-thoracic and cervical region.
  - **Morphology of spinal cord:** Spinal cord shows pale areas of demyelination in the posterior columns and the lateral corticospinal tracts. Spinal cord shows swollen myelin sheath with disintegration and axonal degeneration.
  - **Clinical features:** Patient develops spastic paraparesis, sensory ataxia and marked paresthesia leading to total paralysis of trunk and lower limbs. Associated lesions include optic atrophy and axonal peripheral neuropathy.

Table 7.8 Comparison between vitamin B_{12} and folate deficiency inducing megaloblastic anemia

Parameters	Vitamin B_{12} Deficiency	Folate Deficiency
Etiology	▪ Decreased dietary intake in vegetarians, impaired absorption, increased requirement and impaired utilization of vitamin B_{12} ▪ Failure to synthesize intrinsic factor by gastric parietal cells results in pernicious anemia	▪ Decreased dietary intake, impaired absorption, increased requirement and impaired utilization of folate ▪ Synthesis of intrinsic factor by gastric parietal cells is normal
Pathological findings	▪ Demyelization of the posterior and lateral columns of spinal cord in the midthoracic region ▪ Peripheral blood smear examination shows pancytopenia, macrocytes, hypersegmented neutrophils ▪ Bone marrow shows megaloblastic erythropoiesis ▪ Schilling test abnormal in pernicious anemia	▪ Spinal cord demyelization absent ▪ Peripheral blood smear examination shows pancytopenia, macrocytes, hypersegmented neutrophils ▪ Bone marrow shows megaloblastic erythropoiesis ▪ Schilling test normal
Clinical features	Neurological manifestations present, e.g. ataxia, impaired proprioception and vibrating sensations; anemia and glossitis	Neurological manifestations absent; but anemia and glossitis present
Serum assays	▪ Serum vitamin B_{12} assay decreased ▪ Anti-intrinsic factor autoantibodies demonstrated in pernicious anemia	▪ Red blood folate decreased ▪ Anti-intrinsic factor autoantibodies absent
Treatment	Vitamin B_{12} supplement and intrinsic factor administration in pernicious anemia caused by autoimmune gastritis	Folate supplement

Laboratory Diagnosis: Megaloblastic Anemia

Vitamin B_{12} and folic acid are essential for maturation of nuclei developing precursors in bone marrow. Deficiency of either of the two results in megaloblastic erythropoiesis due to decreased DNA synthesis. Abnormalities will be observed in all the developing cells in the bone marrow. Investigations that may be needed in patients with macrocytosis.

- Serum vitamin B_{12} assay
- Serum and red blood cell folate assay
- Liver and thyroid function tests
- Serum protein electrophoresis
- Reticulocytosis
- Vitamin B_{12} deficiency investigations: serum parietal cell and intrinsic factor antibodies, radioactive vitamin B_{12} adsorption with and without intrinsic factor (Schilling test), possibly serum gastrin concentration.
- Folic acid deficiency investigations: serum antigliadin, antiendomysial and antireticulin antibodies.
- Endoscopy: gastric biopsy (vitamin B_{12} deficiency) and duodenal biopsy (folate deficiency).
- Peripheral blood smear examination shows macrocytes, leukopenia, thrombocytopenia and hypersegmented neutrophils.
- Bone marrow examination shows megaloblastic erythropoiesis.

Peripheral Blood Smear

- Red blood cells show anisocytosis, poikilocytosis, macrocytes (macrocytes are oval with MCV >100 femtoliters in megaloblastic anemia, while round in shape in normoblastic anemias in hemolytic anemia and posthemorrhagic anemia). Macrocytosis and increased MCV may be seen in alcoholic patients.
- Reticulocytosis results in polychromasia. Presence of tear drop cells, Howell-Jolly bodies, basophilic stippling and Cabot's rings indicate dyserythropoiesis.
- White blood cells show leukopenia and hypersegmented neutrophils 8–9 lobes (>5/100 neutrophils).
- Moderate thrombocytopenia with giant platelets is present. Giemsa-stained peripheral blood smear in megaloblastic anemia is shown in Fig. 7.12.

Reticulocyte Count

Reticulocyte count is decreased as a result of dyserythropoiesis in megaloblastic anemia. Post-therapeutic response should be assessed by demonstration of increased reticulocyte count on the sixth day. Reticulocytes are round with polychromasia in peripheral blood smear.

Bone Marrow Smear Examination

- Bone marrow smear examination shows megaloblastic erythropoiesis. Bone marrow changes at all stages of RBCs development. Maturation of the nuclei of erythroid, myeloid and megakaryocytes lags behind and thus chromatin of these cells remains 'open sieve-like'.
- Bone marrow becomes hypercellular with reversal of myeloid to erythroid ratio (M:E ratio 1:1) due to erythroid hyperplasia. Normal myeloid to erythroid ratio is 4:1. Ineffective erythropoiesis leads to intramedullary hemolysis of erythroid precursors. Bone marrow iron store is increased due to dyserythropoiesis.
- Megaloblasts are extremely large erythroid precursors. Chromatin remains open and arranged in a fine reticular fashion to give stippled appearance. Although some of the

megaloblasts are well hemoglobinized, the nucleus is still present suggesting nuclear/cytoplasmic developmental asynchrony.

- Presence of giant band form of neutrophil and metamyelocytes in bone marrow give a clue of megaloblastic anemia.
- Megakaryocytes demonstrate nuclear hypersegmentation with open sieve-like nuclear chromatin. Maturation of the cytoplasm of these cells is normal. The size of these cells remains large. Most of these cells die within bone marrow.

Giemsa-stained bone marrow smear in megaloblastic anemia is shown in Fig. 7.13.

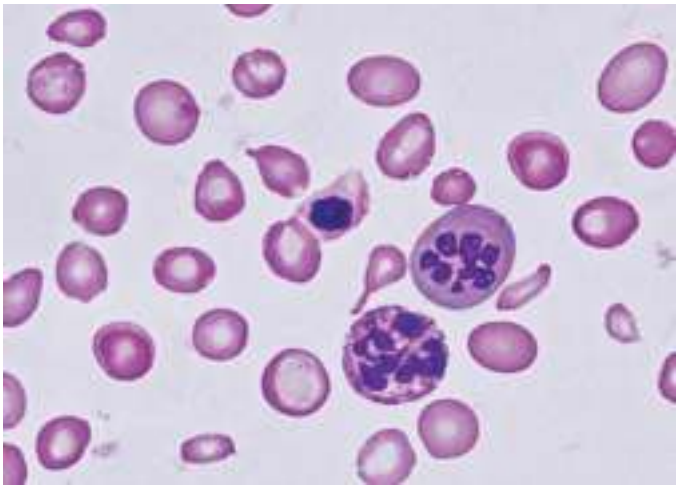

Fig. 7.12: Megaloblastic anemia: Giemsa-stained peripheral blood smear in megaloblastic anemia. It is showing anisocytosis with numerous macrocytosis and scattered tear drop cells (1000X).

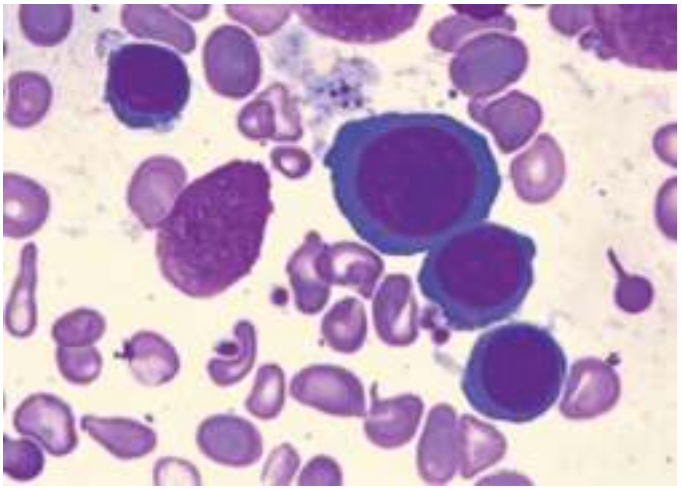

Fig. 7.13: Megaloblastic anemia: Giemsa-stained bone marrow smear in megaloblastic anemia. Bone marrow becomes hypercellular with reversal of myeloid to erythroid ratio (M:E ratio 1:1) due to erythroid hyperplasia. There is preponderance of early and intermediate normoblasts showing stippled nuclear chromatin (open sieve-like) on bone marrow smear examination (1000X).

BACTERIAL INFECTIONS

BACTERIAL INFECTIONS: OVERVIEW

A bacterial infection is a proliferation of a harmful strain of bacteria on body surface or inside the body. Bacteria are transmitted in human beings through direct contact, airborne, droplets and living vectors. Bacteria have circular double-stranded DNA (except in Mycoplasma) and cell walls. Examples of virulence factors produced by pathogenic bacteria are given in Table 7.9.

- Preventive measures such as personal hygiene, safe water intake, immunization and safe sexual practice have impact on morbidity and mortality. Examples of diseases caused by harmful bacteria are pneumonia, meningitis and food poisoning.

Table 7.9 Examples of virulence factors produced by pathogenic bacteria

Pathogenic Bacteria	Virulence Factor	Effect on Host
Vibrio cholerae	Cholera toxin (exotoxin)	Secondary diarrhea
Corynebacterium diphtheriae	Diphtheria toxin (exotoxin)	Inhibits protein synthesis
Clostridium botulinum	Botulinum toxin (exotoxin)	Neuroparalysis, inhibits acetylcholine release
Streptococcus pneumoniae	Pneumolysin (exotoxin)	Inhibition of respiratory ciliated and phagocytic cell function
Many gram-negative bacteria	Liposaccharide (endotoxin)	Fever, hypotension, shock
Staphylococcus aureus	Toxic shock toxin (enterotoxin)	Skin rash, vomiting, diarrhea, hepatitis
Neisseria gonorrhoeae	Pili (adherence)	Induces infection
Haemophilus influenzae	IgA protease	Inactivates antibody
Pseudomonas aeruginosa	Collagenase (invasive)	Penetration of tissue
Clostridium perfringens	Phospholipase (invasive)	Penetration of tissue

- Bacteria occur in three basic shapes: spherical cocci, rod-shaped (bacilli), or helical (spirilla). In clinical practice, bacteria can be broadly classified as gram-positive or gram-negative and anaerobes, mycobacteria, spirochetes, ureaplasma and obligate intracellular organisms and other organisms included in miscellaneous group. Gram-positive bacteria possess a thick cell wall while gram-negative bacteria lack a thick cell wall.
- Gram staining, bacterial culture with antibiotic sensitivity determination, chemical tests, and genetic analysis are used to identify bacterial strains and help to determine the appropriate course of treatment.
- Certain bacteria are encapsulated. The capsule inhibits phagocytosis of *Haemophilus influenzae*, pneumococcus and meningococcus. Bacteria such as Clostridium and Bacillus sporulate under unfavorable growth conditions. Antibacterial drugs are administered to destroy bacterial wall or inhibit their growth at their cellular processes such as protein systhesis.

GRAM-POSITIVE BACTERIAL INFECTIONS

Gram-positive bacteria are classified based on their color demonstrated in the gram staining method developed by Christian Gram in 1884. Gram staining method uses crystal violet dye, which is retained by the thick peptidoglycan cell wall found in gram-positive bacteria, which give a blue color when viewed under light microscope.

- It is worth mentioning that gram-negative organisms have a thin outer membrane consisting of thin peptidoglycan layer, which does not hold the blue color dye used in the initial staining process.
- Other information used to differentiate bacteria is their shape. Gram-positive bacteria comprise cocci, bacilli or branching filaments.
- It is important to identify patients with sepsis and order echocardiogram to detect endocarditis, blood cultures and various laboratory investigations such as complete blood counts and fluid examination.

GRAM-POSITIVE COCCI

Gram-positive cocci cause certain infections by *Staphylococcus aureus*, streptococci, enterococci and pneumococci.

Staphylococcus Aureus

Staphylococcus aureus is transmitted by touching infected blood or body fluids and contaminated hands, which can cause skin and soft tissue infections such as boils (abscesses in hair follicle or sebaceous gland), furuncles, impetigo, cellulitis and Staphylococcus scalded syndrome. *Staphylococcus aureus* can disseminate via bloodstream and cause serious infections such as pneumonia, osteomyelitis and arthritis.

Staphylococcus Epidermidis

Staphylococcus epidermidis is a gram-positive, catalase positive, coagulase negative arranged in clusters, which commonly infects prosthetic devices and intravenous catheters. *Staphylococcus epidermidis* is novobiocin sensitive.

Staphylococcus Saprophyticus

Staphylococcus saprophyticus is a normal flora of the genital tract and perineum that is novobiocin resistant, which accounts for the second most common cause of uncomplicated urinary tract infection (UTI).

Streptococci

Streptococci are gram-positive aerobic organisms transmitted through cough and sneezing. There are different types of streptococci related infections varying in severity from mild sore throat (pharyngitis) to pneumonia and sepsis in both children and adults. Streptococcal infections are primarily treated by antibiotics. Streptococci are divided into two groups: α-hemolytic streptococci and β-hemolytic streptococci. α-Hemolytic streptococci include *Streptococcus pneumoniae*, *Streptococcus viridans*, and *Streptococcus pyogenes*.

- ***Streptococcus pneumoniae:*** The bacterium resides on the skin surface and inside throat, which is transmitted through cough and sneezing. It causes sinusitis, middle ear infections, necrotizing fasciitis, pneumonia, bacteremia, meningitis and brain abscess in newborns, elderly and immunocompromised persons.
- ***Streptococcus viridans:*** The bacterium most often lives in the mouth, gastrointestinal tract and genital region, which disseminates via bloodstream to cause endocarditis.
- ***Streptococcus pyogenes:*** The organism can cause pyogenic infections (e.g. pharyngitis, cellulitis, impetigo and erysipelas), toxigenic infections (e.g. scarlet fever and necrotizing fasciitis) and immunogenic infections (e.g. rheumatic fever and glomerulonephritis). ASO (antistreptococcal-O) detects *Streptococcus pyogenes* infection.

Enterococci

Enterococci are gram-positive cocci that often occur in pairs (diplococci) or short chains, which cause urinary tract infections, endocarditis, bacteremia,

catheter-related infections, wound infections, intra-abdominal infection and pelvic inflammatory disease. Many strains originate from the patient's intestinal flora. It is difficult to distinguish enterococci from Streptococci on physical characteristics alone.

GRAM-POSITIVE BACILLI

Gram-positive bacilli cause certain infections by anthrax, diphtheria, listeriosis, Nocardia and erysipelothricosis.

Anthrax

Anthrax is a serious infectious disease caused by spore forming gram-positive, rod-shaped bacteria known as *Bacillus anthracis*.

- Bacteria anthracis are found in soil that commonly affects domestic and wild animals across world.
- People can become infected through inhaled bacteria spores, contaminated water or food or skin wounds.
- Certain persons are at great risk for bacillus anthrax infection in farmers, military persons, researchers and laboratory workers, veterinarians and workers in wool mill, tannery and slaughterhouse.

Clinical Pearls: Anthrax—Three Forms

Anthrax can occur in three forms: cutaneous (95%), pulmonary and gastrointestinal tract. Antibiotics are the first-line of treatment for this potentially deadly infection.

Cutaneous Anthrax

- Cutaneous anthrax is the most common form of anthrax infection that develops within 1–7 days after exposure. When anthrax spores gain entrance through a skin cut or scraping leading to cutaneous anthrax.
- Patient presents with a group of small itchy blisters, swelling around a painless skin ulcer on the face, neck, arms or hands.

Pulmonary Anthrax

- Inhalation of anthrax spores cause pulmonary anthrax, which do not cause pneumonia, but do cause pulmonary edema, hemorrhagic pleural effusions and mediastinitis.
- Pulmonary anthrax is the most severe form of the disease associated with bacteremia, lymphadenopathy and death even with treatment.
- Patient presents with flu-like symptoms such as sore throat, mild fever, fatigue and skeletal muscle ache.

Gastrointestinal Tract Anthrax

- Ingestion of anthrax spores may cause gastrointestinal tract anthrax involving oral cavity to the rectum regions.
- Patient presents with fever and chills, swelling neck, sore throat, painful dysphagia, hoarseness of voice, nausea, vomiting, hematemesis and bloody diarrhea and headache.

Diphtheria

Diphtheria is caused by *Corynebacterium diphtheriae* that affects mucous membranes of nose and throat, which can lead to breathlessness, loud barking cough, bluish skin, discomfort, dysphagia, slurred speech, signs of shock (i.e. pale cold skin, sweating and tachycardia) heart failure, paralysis and even death. Although, bacteria are transmitted from one person to another, diphtheria can be prevented through the use of vaccines. Untreated cases develop severe damage to kidneys, nervous system and heart leading to death in 3% of cases.

Listeriosis

Listeriosis is a serious infection caused by consumption of contaminated refrigerated foods such as meat, seafood, unpasteurized milk and milk products with the gram-positive rod-shaped bacterium *Listeria monocytogenes*. Patient presents with fever, chills, skeletal muscle aches. Central nervous system infection causes headache, stiff neck, confusion, loss of balance and convulsions. Disease is treated by oral antibiotics. If septicemia or meningitis develop, patient should be administered intravenous antibiotics for six weeks.

Nocardia

Nocardiosis is a disease caused by weakly staining gram-positive, and catalase-positive bacillus *Nocardia asteroides*. The bacillus forms partially acid-fast branching filaments (acting as fungi, but being true bacteria). Nocardia is found in soil and water, and transmitted through open wounds and skin cuts in persons working in soil. The organism can affect the lungs, brain and skin in immunocompromised persons. Pulmonary manifestations include fever, weight loss, night sweats, cough, chest pain and pneumonia.

Erysipelothricosis-Erysipeloid

Erysipelothricosis-erysipeloid is caused by gram-positive bacillus *Erysipelothrix rhusiopathiae*. The most common manifestation is erysipeloid, an acute slowly evolving localized cellulitis.

- Patient presents with raised, purplish red, indurated, slowly, localized itchy skin rash on hands within one week of infection.
- Dissemination may occur in rare cases causing endocarditis, meningitis, osteomyelitis and intra-abdominal infection.
- Disease is diagnosed by performing culture of a biopsy specimen or occasionally polymerase chain reaction testing. Patients are treated by antibiotics.

Actinomyces Israelii

Actinomyces israelii is a gram-positive anaerobic filamentous bacterium no longer classified as a fungus. It is a normal colonizer of the vagina, colon, and mouth. It is an opportunistic pathogen. Infection is established first by a breach of the mucosal barrier during various procedures (dental, gastrointestinal tract), aspiration, or diverticulitis.

- Patient develops chronic abscess with sinus tract formation in cervicofacial, pulmonary, abdominal (colon and appendix) and skin. Lower genital tract infection may be associated with intrauterine device.
- Histologic examination of lesion shows exudates containing sulfur granules, yellow clumps of the organism.

GRAM-NEGATIVE BACTERIAL INFECTIONS

Gram-negative bacilli are responsible for numerous diseases. Some are commensal organisms present among normal intestinal flora.

NEISSERIA MENINGITIDIS

Meningococcal infections are caused by the aerobic or facultative anaerobe bacterium *Neisseria meningitidis*, which affects persons of all ages.

- *Neisseria meningitidis* resides in the nasopharynx of normal persons, which is transmitted through inhalation of infected aerosolized particles. The incubation period varies and ranges from 1 to 14 days.
- The organism possesses several virulent factors that aid in its invasion and infection of human beings: capsule, pili, meningococcal serine protease, opacity proteins, human factor H-binding protein and oligosaccharide.
- *Neisseria meningitidis* is associated with fulminant meningococcemia and meningococcal meningitis in children and adults, including pneumonia, septic arthritis, pericarditis and urethritis. Manifestations of meningococcal meningitis include sudden onset of fever, headache, nausea, vomiting, severe myalgia, nonspecific rash, sore throat and symptoms related to upper respiratory tract.

BORDETELLA PERTUSSIS (WHOOPING COUGH)

Bordetella pertussis (whooping cough) is highly contagious disease caused by the bacterium *Bordetella pertussis* that adversely affects respiratory tract. There are three stages to clinical course of pertussis: catarrhal, paroxysmal and convalescent.

- *Bordetella pertussis* (whooping cough) is characterized by uncontrollable violent coughing and breathlessness due to difficulty in expelling thick mucus from the tracheobronchial tree.
- Long inspiratory effort is accompanied by a high-pitched 'whoop' at the end of the paroxysms. Patient develops cyanosis, vomiting and exhaustion.
- Whooping cough is diagnosed by medical history, physical examination, throat swab, blood test and chest radiograph. Vaccines are available that can help prevent *Bordetella pertussis* infection.

PLAGUE

Plague is an infectious disease caused by bacterium *Yersinia pestis*, usually found in small mammals and their fleas. Bacterium is transmitted to human beings through direct contact with infected fleas either by bite of fleas or inhalation of organisms. Plague can be very severe disease in human beings especially in its bubonic, septicemic and pneumonic forms, which may have fatal outcome.

- **Bubonic plague:** Patient presents with sudden onset of fever, headache, chills and weakness and one or more swollen, tender and painful lymph nodes (known buboes).
- **Septicemic plague:** Patient presents with fever, chills, weakness, abdominal pain, shock and possibly bleeding into the skin and other organs.
- **Pneumonic plague:** Patient presents with fever, headache and rapidly developing pneumonia associated with breathlessness, chest pain, cough and sometimes bloody or water sputum. The pneumonia progresses to respiratory failure and shock within 2–4 days.

GRANULOMA INGUINALE (DONOVANOSIS)

Granuloma inguinale is sexually transmitted disease caused by bacterium *Klebsiella granulomatis* (formerly known as *Calymmatobacterium granulomatis*). The disease is more prevalent in tropical and subtropical regions such as southeast India, Guyana and New Guinea. Patient presents with painless red lump on or near genitals or anus, which progresses to become painful genital ulcers. The disease slowly spreads and destroys genital tissue.

CHANCROID (SOFT CHANCRE)

Chancroid is caused by gram-negative, facultative anaerobic bacillus *Haemophilus ducreyi* transmitted by sexual contact. Incubation period is 4–7 days. Patient develops painful genital ulcers associated with painful suppurative inguinal lymphadenopathy. Genital ulcer has undermined edges, and is covered by a gray-yellow exudate.

Surgical Pathology: Chancroid

Light Microscopy

Histologic examination shows three zones: surface zone, intermediate zone and deep zone. Diagnosis is based on histologic features and histochemical staining (giving railroad track or alignment of short rods).

- **Surface zone of ulcer:** It consists of exudate, fibrin and neutrophils with debris at the base of the ulcer.
- **Intermediate zone of ulcer:** It consists of wide regions with prominent vascular proliferation and thromboses with vascular ectasia.
- **Deep zone of ulcer:** It consists of dense infiltration by lymphocytes and plasma cells.

SALMONELLA TYPHI INFECTION (TYPHOID FEVER)

Typhoid fever is a systemic disease caused by gram-negative *Salmonella typhi* bacilli, which has three antigenic structures: O antigens, H antigens and Vi antigens.

- The organism is transmitted by faecal–oral route. There is involvement of mononuclear phagocytic system with nodule formation in the Peyer's patches of lower ileum.
- Patient may present with **stepladder** rise of **fever** during first week and continued during second and third stage, relative bradycardia, headache, nausea, vomiting, abdominal tenderness, rose spots (2–4 mm on trunk) and hepatosplenomegaly.

MYCOBACTERIUM TUBERCULOSIS

Tuberculosis is worldwide health problem caused by mycobacterium tubercle bacilli (*Mycobacterium hominis* strain or *Mycobacterium bovine* strain). It is transmitted by inhalation of droplets (most common), ingestion of infected milk and skin inoculation (handling infected specimens). It may involve multiple systems.

MYCOBACTERIUM TUBERCULOSIS: OVERVIEW

Mycobacterium tubercle bacillus is strict aerobe and acid-fast due to presence of mycolic acid in its cell wall and stained by Ziehl-Neelsen staining (decolorized by 20% H_2SO_4).

- Mycobacterium tubercle bacilli contain large quantity of hydrophobic waxes and fatty acids of high molecular weight, which prevents entry of Gram's stain.
- Virulence of bacillus depends on presence of cord factor (a sulphated glycolipid), which prevents fusion of phagosomes with lysosomes and thus favors intracellular revival of AFB in macrophages. If cord factor is extracted, AFB becomes avirulent.
- Mycobacterium tubercle bacillus is viable for months in dry or wet sputum. Single AFB is potentially infective in immunocompromised persons. Virulence and bacterial factors in Mycobacterium tubercle bacilli are given in Table 7.10.

Predisposing Factors

There is increased risk for tuberculosis in persons, who have been in close contact with a newly diagnosed tuberculosis case (sputum smear positive), history of previous tuberculosis exposure, immunocompromised individuals (AIDS and corticosteroids therapy). History of silicosis, diabetes mellitus, malnutrition, cancer, Hodgkin's disease, or leukemia, gastrectomy, chronic renal failure and alcoholism increase the risk for tuberculosis.

Mode of Transmission

Mycobacterium tubercle bacilli are transmitted by droplet infection, ingestion of infected milk products, skin inoculation and vertical transmission.

- **Droplet infection:** Infection is most common contracted by droplet infection from open case of pulmonary tuberculosis (cavities formation in lung).

Table 7.10 Virulence and bacterial factors in Mycobacterium tubercle bacilli

Name	Functions
Virulence factors	
*Cord factor composed of glycolipids, mycolic acid and trehalose 6,6'-dimycolate	▪ Cord factor preventing fusion of phagosomes with lysosomes thus favoring intracellular revival of AFB in macrophages ▪ Cord factor eliciting granulomas formation
Catalase-peroxidase and lipoarabinomannan (LAM)	Resisting the host cell oxidative response
Sulfatides and trehalose 6,6'-dimycolate	Triggering toxicity in animal models
Lipoarabinomannan (LAM)	Induction of cytokines and resist host oxidative stress
Bacterial factors	
Nonreplicating persistent (NRP1) state	Under aerophilic conditions with increased glycine dehydrogenase activity
Nonreplicating persistent (NRP2) state	Under anaerobic conditions with decreased glycine dehydrogenase activity

**If cord factor is extracted, AFB becomes avirulent.*

- **Ingestion of unpasteurized milk containing AFB:** Ingestion of unpasteurized milk containing AFB produces Ghon's focus in tonsils and ileocecal region. Acid-fast bacilli produce circumferential ulcers perpendicular to long axis of small intestine. Fibrosis in this region is responsible for 'stricture formation'.
- **Skin inoculation by AFB:** Primary cutaneous inoculation with AFB occurs in person handling infected specimens. Patient develops painless non-healing papule (Ghon's focus) in 2–4 weeks after inoculation, which form cold abscess resulting to discharging sinuses after several weeks.
- **Vertical transmission:** Placental transmission of tuberculosis from mother to fetus shows lesions in liver and portal lymph nodes seen at birth.

Tubercular Infection and Disease

- **Tubercular infection:** Tubercular infection refers to a positive tubercular skin test (Mantoux test or tuberculin test or purified protein derivative test) with no evidence of active disease. Purified protein derivative (PPD) is injected by intradermal route on forearm. Area of induration is demonstrated after 48–72 hours in immunocompetent individuals after exposure to tubercle bacilli after 2–4 weeks. Positive tuberculin test does not distinguish infection (inactive disease) from active disease.
- **Tuberculous disease:** Tuberculous disease refers to cases that have positive acid-fast bacilli on smear or culture for *Mycobacterium tuberculosis* or radiographic and clinical presentation of tuberculosis. Children below 2 years of age are more susceptible. Patients with silicosis and with immunosuppression are also more susceptible to tuberculosis.

Tissue Susceptibility

Lungs are the most common site of tuberculosis in children and adults. Most common organs involved due to Mycobacterium tubercle bacilli in children include lungs, lymph nodes, spleen and meninges. Lungs, adrenal glands, kidneys, liver, spleen, bone, meninges, serous membranes, fallopian tubes, epididymis and lymph nodes are involved in adults. Tissues rarely involved include cardiac muscle, skeletal muscle, stomach, thyroid gland, and pancreas.

Pulmonary and Extrapulmonary Tuberculosis

Tuberculosis is divided into two categories: **pulmonary tuberculosis** (85% cases) and **extrapulmonary tuberculosis** (15% cases). Active disease develops in 5–15% of those infected with *M. tuberculosis*. Pulmonary tuberculosis has two distinct phases, i.e. primary tuberculosis (children) and secondary tuberculosis (adults). Organs involved in primary, secondary and miliary tuberculosis are shown in Figs 7.14 and 7.15.

Primary Tuberculous (Ghon's Complex)

Primary tuberculosis is also known as 'Ghon's complex' caused by Mycobacterium tubercle bacillus. 'Ghon's complex' consists of lesion involving organ, lymphatics and draining lymph node, which is demonstrated in lungs (hilar region), tonsils (cervical region), gastrointestinal tract (ileocecal region) and skin (cutaneous region), which usually does not progress to clinically evident disease. Epithelioid cell granuloma in tuberculosis is known as tubercle. Histologic examnation of tubercular lesion reveals caseous necrosis, epithelioid cell granulomas, Langhans' giant cells.

Secondary Tuberculosis

Secondary tuberculosis usually occurs due to reactivation of old tubercular lesions or gradual progression of primary tuberculosis to chronic form of tuberculosis. However, recent evidence suggests that reinfection is responsible for some form of the secondary tuberculosis. The granulomatous inflammation is much more florid and widespread. Typically, the upper lobes of the lung are most commonly affected and cavitation can occur. Disseminated tuberculosis can occur in which Mycobacterium tubercle bacilli have spread from the lungs to extrapulmonary organs such as bone, brain, adrenal glands, genital system and other organs of the body through the hematogenous or lymphatic system within one week of infection.

Miliary Tuberculosis

Miliary tuberculosis is potentially a life-threatening type of tuberculosis that occurs when numerous Mycobacterium tubercle bacilli travel through blood circulation and disseminate throughout the body. Miliary tuberculosis is so named because the innumerable tiny spots that form in the lungs, which are of the size of millet.

Multidrug-resistant Tuberculosis

Patient develops drug resistance used to treat tuberculosis due to spontaneous gene mutations in acid-fast bacilli involving mycolic acid, catalase and peroxidase enzyme. Catalase enzyme is required to activate isoniazid.

Pathology Pearls: Pathogenesis of Tuberculosis

Mycobacterium tubercle bacillus antigens play an important role in cell-mediated immunity and type 4 hypersensitivity reaction. To study the virulence of Mycobacterium tubercle bacilli, virulence and bacterial factors have been devised, which are associated with intracellular survival, and genotype differences in the community prevalence of clinical strains.

Tuberculosis Pathogenesis <3 Weeks Duration

- Mycobacterium tubercle bacilli's mannose capped glycolipid (lipoarabinomannan) binds to mannose receptors expressed on alveolar macrophages leading to engulfment of AFB.
- Cord factor synthesized by Mycobacterium tubercle bacilli prevents fusion of phagosomes with lysosomes.
- Hence, unchecked proliferation of tubercle bacilli continues inside alveolar macrophages.

Tuberculosis Pathogenesis >3 Weeks Duration

Macrophages are antigen presenting cells, which transmit Mycobacterium tubercle bacilli antigen to CD4+ helper T cells. Macrophages synthesize IL-12, which takes part in differentiation of T-helper cells in lungs and lymph nodes.

- **Bactericidal activity of immune system:** CD4+ helper T cells synthesize interferon-γ (IFN-γ), which stimulates 'nitrogen synthase' enzyme resulting to synthesis of 'nitrogen intermediates' (NO, NO_2 and HNO_3) and oxygen-derived free radicals causing oxidative destruction of AFB.
- **Formation of epithelioid granulomas:** Macrophages synthesize tumor necrosis factor α (TNF-α) and chemokines participate in recruitment of monocytes and sensitization of T cells. This process leads to formation of epithelioid granulomas comprised of macrophages and surrounded by lymphocytes. Granulomas prevent spread of infection by confining bacteria within a compact collection of activated macrophages and lymphocytes. Schematic representation of mechanism of epithelioid cell granuloma formation in tuberculosis is shown in Fig. 7.16.
- **Caseous necrosis:** CD8+ cytotoxic T cells cause destruction of macrophages by 'Fas-independent' mechanism. On the other hand, CD4+ helper T cells cause destruction of macrophages laden with Mycobacterium tubercle bacilli 'Fas-dependent' mechanism resulting in caseous necrosis. Histopathologic examination of tubercular lesion shows epithelioid cell granulomas, caseous necrosis and Langhans' giant cells (Fig. 7.17). Langhans' giant cells are demonstrated in a case of tuberculosis as shown in Fig. 7.18.

PULMONARY TUBERCULOSIS

Pulmonary tuberculosis occurs when Mycobacterium tubercle bacilli attack the lung. However, it can spread to other organs. Pulmonary tuberculosis is curable with an early diagnosis and treatment. Summary of patterns of tuberculous infection of the lungs are given in Table 7.11.

Primary Pulmonary Tuberculosis of Ghon's Complex

Primary pulmonary tuberculosis of Ghon's complex consists of Ghon's focus involving lung, lymphatic channels and draining lymph nodes. Primary pulmonary tuberculosis of Ghon's complex is shown in Fig. 7.19A and B.

- Primary tuberculosis produces a small mid-zone subpleural focus of consolidation near with interlobar fissure, involvement of lymphatic channels and hilar lymph nodes. Approximately 5% of immunocompromised children develop symptomatic infection (cavities in lung, bronchopneumonia, pleural effusion or miliary tuberculosis).
- The tubercular lesion most often heals by fibrosis and dystrophic calcification in 95% cases. The calcified lesion known as 'Ranke's complex' is often visible on radiography. Because, acid-fast bacilli persisting in dormant form in old necrotic calcified lesions is still capable of initiating lesion, and thus a nidus for secondary tuberculosis.
- Lymphatic channels are laden with Mycobacterium tubercle bacilli without producing lesion. Hilar lymph nodes draining pulmonary Ghon's focus become enlarged. Histologic examination of tubercular lesion shows caseous necrosis, epithelioid cell granulomas and Langhans' giant cells. Lymph node lesions of tuberculosis take longer time to regress hence remain a potential source of re-infection.

Post-primary Pulmonary (Secondary) Tuberculosis

Secondary tuberculosis is also known as post-primary pulmonary tuberculosis or reactivation disease. Pulmonary lesion in secondary tuberculosis is known as 'Simon's focus', which develops during adult life especially in immunocompromised persons. Secondary tuberculosis occurs either due to inhalation of Mycobacterium tubercle bacilli or reactivation of dormant lymph node and old calcified healed parenchymal lesion, which causes extensive tissue destruction (caseous necrosis) by the action of cytokines synthesized by memory T cells.

Clinical Features

Patient presents with cough, expectoration, hemoptysis (blood-tinged sputum), night sweats, and evening rise of temperature, anorexia, loss of weight, lassitude and chest pain. Fever is probably caused by the absorption of toxic products from the site of infection and synthesis of cytokines (i.e. **TNF-α and IL-1**) by macrophages.

Clinical Examination

On clinical examination, percussion note is dull over the affected area. On auscultation, one can hear bronchial breath sounds, crepitant crackles and wheeze. Sound is heard through stethoscope, when the patient whispers, it is known as **'whispered pectoriloquy'**.

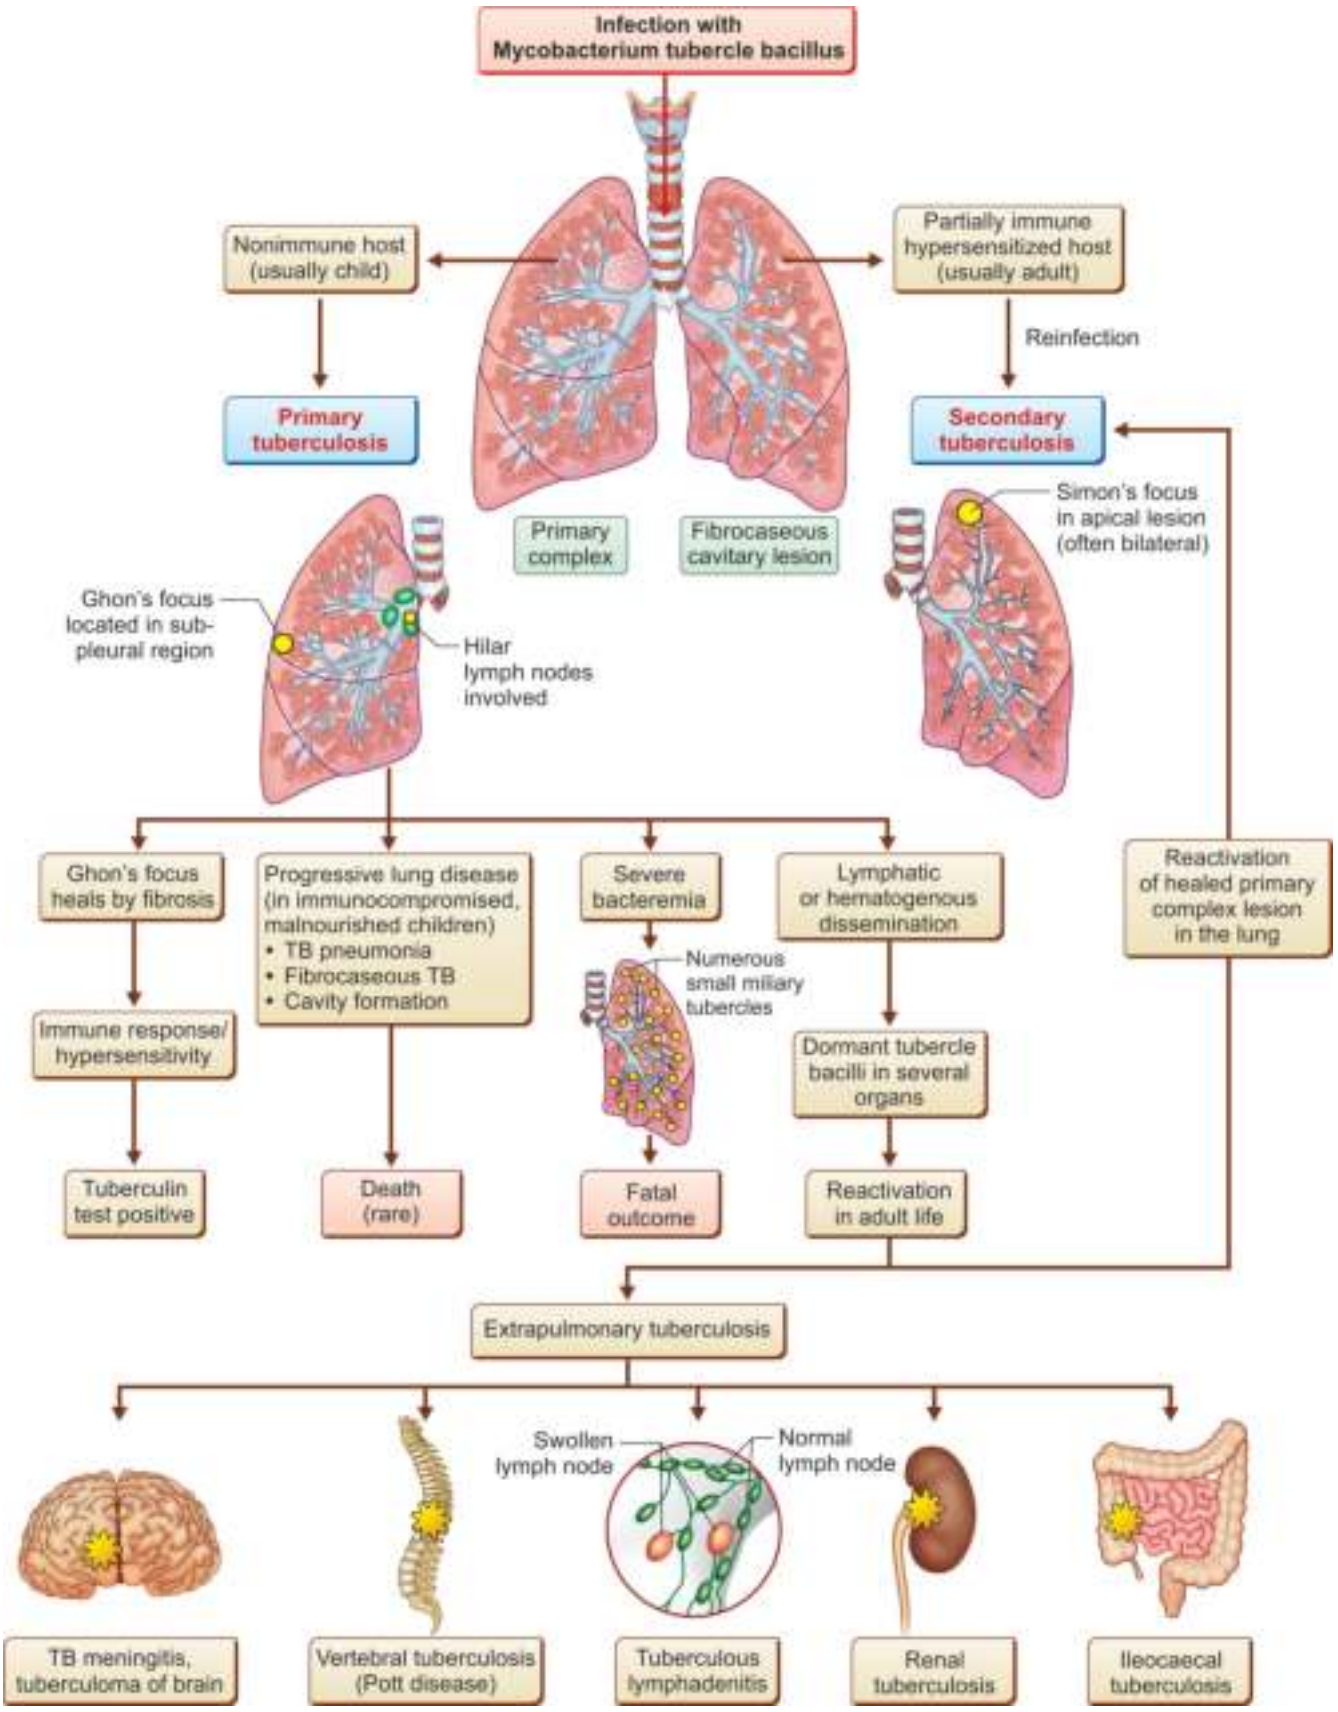

Fig. 7.14: Organs involved in primary, secondary and miliary tuberculosis.

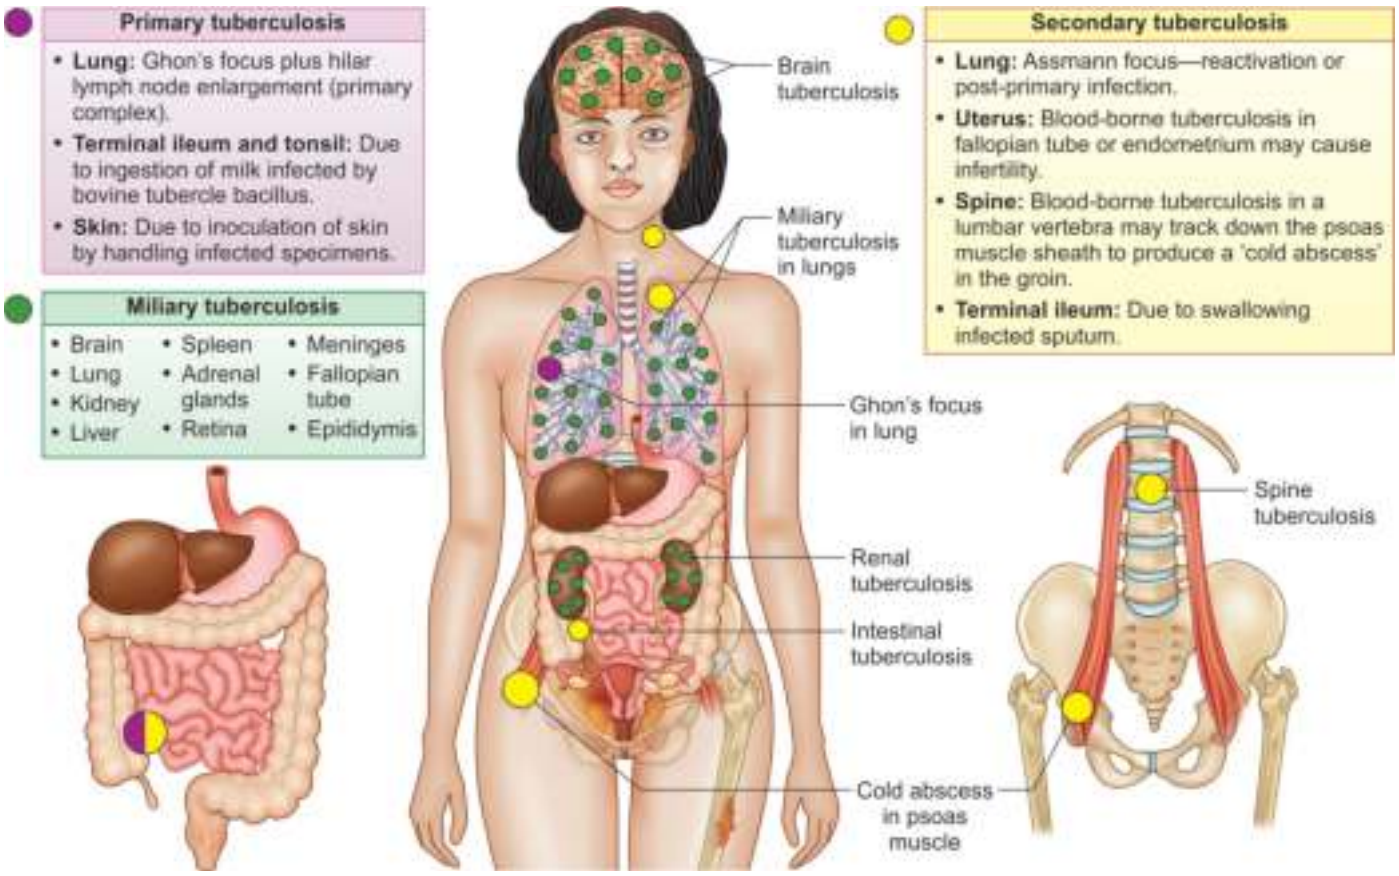

Fig. 7.15: Organs involved in primary, secondary and miliary tuberculosis. Primary tuberculosis produces a subpleural mid-zone lesion in lung. In secondary tuberculosis, lesion is located in apical region of lung. Miliary tuberculosis shows tubercles in various organs.

Pathology Pearls: Pulmonary Tuberculosis—Morphological Patterns

Morphological patterns in pulmonary tuberculosis are discussed below. Morphological patterns in a case of pulmonary tuberculosis are shown in Fig. 7.20A to F.

Primary Tuberculosis (Ghon's Complex)

Ghon's complex consists of three components: (a) midzonal subpleural tubercular focus in lung, (b) lymphatics involvement, (c) hilar lymph nodes involvement.

Simon's Focus in Lungs in Secondary Tuberculosis

- Initially, the tubercular lesion is 2 cm, diffuse solid, gray white to yellowish, with poorly defined margins and central areas of caseous necrosis.
- The lesion is located in the apical region of upper lobes of posterior segments, high oxygen tension and paucity of macrophages due to decreased blood supply.
- Growth of Mycobacterium tubercle bacilli is inhibited at pH <6.5. Some patients may develop tubercular cavities in lungs, which are highly contagious. Large cavities are associated with hemoptysis. Hilar lymphadenopathy is prominent. Pulmonary cavity lesion frequently ruptures into the bronchi.

Aspergilloma in Pulmonary Cavities in Tuberculosis

Aspergillus species may also grow in preexisting cavities caused by tuberculosis. They proliferate to form fungus balls, which are also referred to as aspergillomas.

Pulmonary Cavities in Tuberculosis

- Caseous material may liquefy resulting in cavity lesions is a characteristic of secondary, but not primary tuberculosis. The cavity is filled with yellow-grayish caseous material more or less surrounded by fibrous tissue.
- Acid-fast bacilli (AFB) can easily be demonstrated in open pulmonary cavities. Tubercular lesion may erode into airways.
- Patient may develop empyema and hemoptysis, and sputum becomes positive for AFB. Causes of hemoptysis are given in Table 7.12.

Pulmonary Consolidation in Tuberculosis

- Immunocompromised young children and elderly persons may develop tubercular bronchopneumonia or lobar pneumonia.
- These patients are very infectious. Patient presents with high fever and productive cough.

Tubercular Pleuritis and Pleural Effusion

- Tubercular pleuritis with effusion usually develops soon after initial infection. Tuberculous focus located at the edge of the

lung ruptures into the pleural space causing pleurisy and pleural effusion.
- Patient presents with dyspnea and sharp chest pain that worsens with a deep breath (pleurisy). Tuberculosis pleurisy generally resolves without treatment. Differences between primary and secondary pulmonary tuberculosis are given in Table 7.13. Differences between tuberculosis and sarcoidosis are given in Table 7.14.

Pathology Pearls: Pulmonary Tuberculosis—Consequences

Outcomes of pulmonary tuberculosis are lung fibrosis, lung cavitation, miliary tuberculosis and other lesions described as under.

Pulmonary Fibrosis

Healing of secondary pulmonary tuberculosis occurs by fibrosis in favorable conditions.

Pulmonary Lesions

In some patients, tubercular lesion continues to progress for months and years results in further pulmonary damage. It leads to cavity formation, lobar pneumonia, fibrocaseous tuberculosis and miliary tuberculosis. Lung cavity in a case of tuberculosis is shown in Fig. 7.21.

Airways Involvement

Endobronchial and endotracheal tuberculosis spread cause laryngeal (vocal cords) tuberculosis. Erosion of airways reveals AFB in sputum.

Miliary Tuberculosis

- Secondary tuberculosis may disseminate via hematogenous route resulting in multiple small innumerable small 'millet seed-like lesions' 'tubercular granulomas' known as miliary tuberculosis.
- Mycobacterium tubercle bacilli may disseminate via systemic circulation to seed distant organs such as bone marrow, liver, spleen, adrenal glands, retina, meninges, kidneys, fallopian tubes, and epididymis.
- Mycobacterium tubercle bacilli reach the lungs via pulmonary arteries. Chest radiograph reveals very small nodules throughout the lungs that look-like millet seeds. It occurs shortly after primary infection in immunocompromised persons. Miliary tuberculosis in lung is shown in Fig. 7.22.

Other Complications

Patient may develop tuberculous laryngitis, bronchopleural fistula, bronchiectasis, vertebral tuberculosis (Pott's disease), amyloidosis, scar carcinoma of the lung and granulomatous hepatitis.

TUBERCULOSIS IN HIV PATIENTS

Mycobacterium avium-intracellulare (MAC) complex is a progressive systemic disorder, often occurring in patients who have AIDS. Approximately 33% of all patients develop overt disease due to depletion of CD4+ helper T cells cripples the immune response.

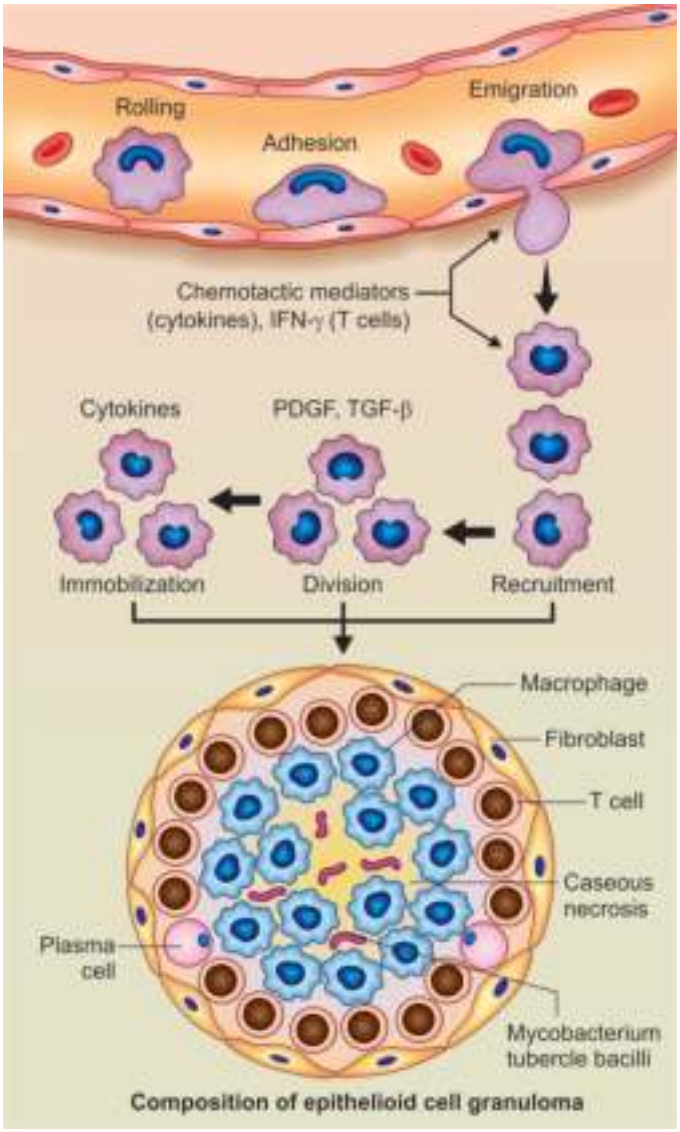

Fig. 7.16: Schematic representation of mechanism of epithelioid cell granuloma formation in tuberculosis.

CD4+ Helper T Cells Count <200/cu mm

Immunosuppression is more severe in HIV patients. Consolidation occurs in lower and middle lobe of lungs. Lymphadenopathy occurs in 50% of cases.
- Histologic examination of tubercular pneumonia lesion shows macrophages laden with numerous Mycobacterium tubercle bacilli, caseous necrosis but lack of epithelioid cell granulomas, which is called nonreactive tuberculosis due to poor immune response.
- Clinical presentation associated with *Mycobacterium avium-intracellulare* resembles that of tuberculosis.

CD4+ Helper T Cells Count >300/cu mm

Immunosuppression is less severe in HIV patients. Apical regions of lungs are affected. Extrapulmonary organs involvement occurs in 15% of cases.

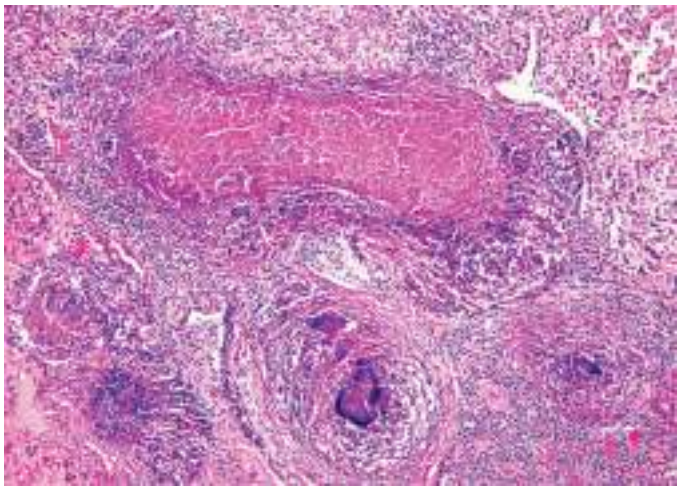

Fig. 7.17: Histologic examination of tubercular lesion shows epithelioid granulomas. Langhans' giant cells and caseous necrosis (400X).

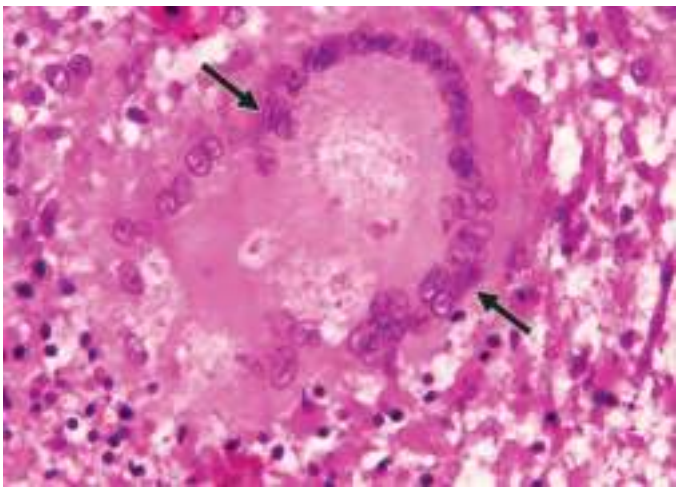

Fig. 7.18: Langhans' giant cells are demonstrated in a case of tuberculosis (arrows) (400X).

Table 7.11 Summary of patterns of tuberculous infection of the lungs

Primary Tuberculosis (Ghon's Focus + Regional Lymph Nodes = Primary Complex)
▪ Reparative mid-zone subpleural tubercular focus that usually heals by fibrosis and calcification
▪ Quiescent healed tubercular lesion (Mycobacterium tubercle bacilli present dormant in organs and lymph nodes)
▪ Progressive tubercular lesion • Pleural involvement (pleurisy/pleural effusion) • Airway dissemination of tubercular lesion (tuberculous laryngitis, tuberculous bronchopneumonia) • Tuberculosis involving lung segments (tubercular pneumonia) • Miliary tuberculosis (hematogenous dissemination to multiple organs)
Post-primary (Secondary) Tuberculosis
▪ Fibrocaseous apical cavitation due to high oxygen tension in apical region of lungs
▪ Reparative tubercular lesion that heals by fibrosis and calcification
▪ Quiescent lesion (Mycobacterium tubercle bacilli dormant)
▪ Progressive tubercular lesion • Local extension of tubercular lesion • Pleural involvement (pleurisy/pleural effusion) • Airway dissemination results in tubercular bronchopneumonia • Miliary tuberculosis (hematogenous dissemination to multiple organs)
Nonreactive Tuberculosis (Immunocompromised Persons)
▪ Tubercular lesion lacks epithelioid cell granulomas
▪ Ziehl-Neelsen stain demonstrates numerous Mycobacterium tubercle bacilli

EXTRAPULMONARY TUBERCULOSIS

Extrapulmonary tuberculosis occurs primarily in immunocompromised patients. Prominent examples of extrapulmonary tuberculosis include tuberculous meningitis, Pott's disease of the spine, paravertebral abscess, or psoas abscess. Other organs involved include kidney, adrenal glands, fallopian tubes, peritoneum, pericardium, breast, larynx and lymph node. Extrapulmonary tuberculosis in order of frequency is given in Table 7.15.

Tuberculous Meningitis

Tuberculous meningitis has insidious onset and may last for weeks or months, which is secondary to tuberculous infection occurring elsewhere in the body. It has a predilection for the base of the brain. Basal cisterns and the lateral sulci contain gelatinous whitish gray material. Inadequately treated tuberculous meningitis results in meningeal fibrosis, communicating hydrocephalus and vasculitis. Inflammation of striate arteries results in cerebral infarcts. Patient may develop focal mass in the brain is known as '**tuberculoma**'.

Pathogenesis

Tuberculous meningitis develops in two steps: (a) In the first step, Mycobacterium tubercle bacilli enter the host by droplet inhalation and escalate within the lungs, then disseminate to the regional lymph nodes, and via hematogenous route to meninges or brain parenchyma resulting in the formation of small subpial or subependymal foci disseminated caseous necrosis lesion, termed Rich foci, and (b) In the second step, development of tuberculous meningitis is an increase in the size of a Rich focus until it ruptures in the subarachnoid

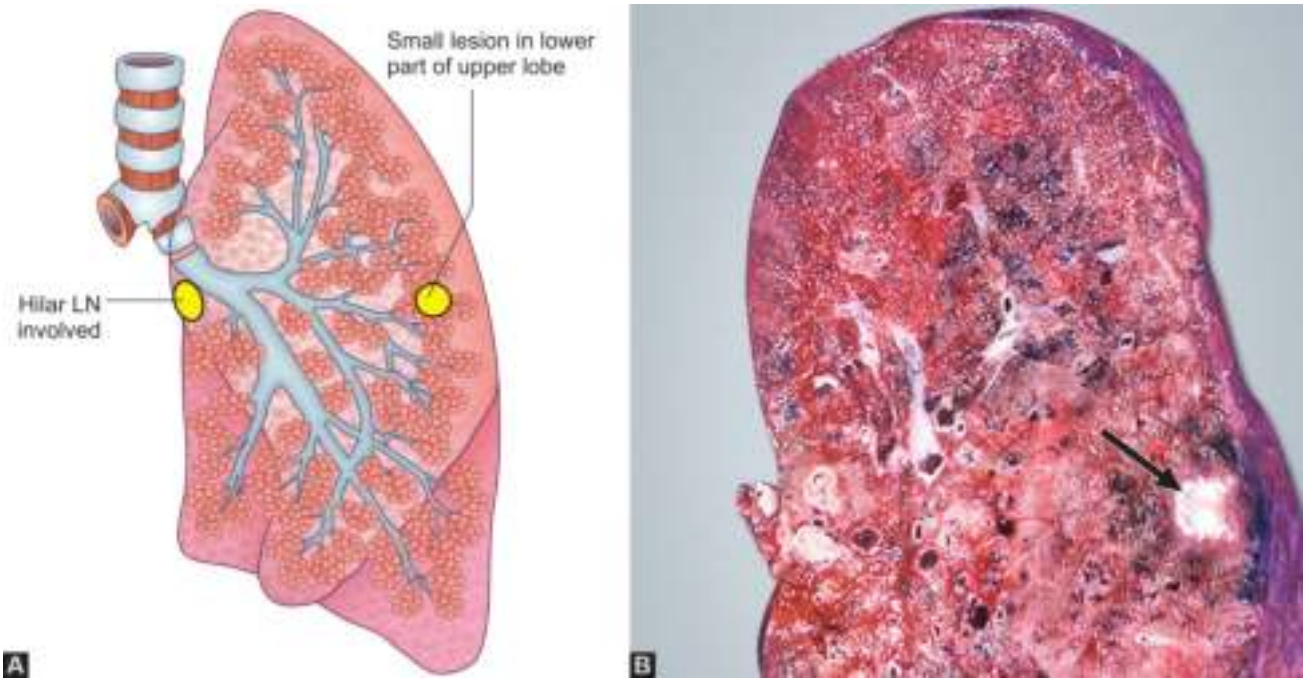

Fig. 7.19A and B: Primary pulmonary tuberculosis of Ghon's complex. It is showing subpleural mid-zonal Ghon's focus and hilar lymph node enlargement. Gross examination of lung showing subpleural mid-zonal Ghon's focus (arrow). (*Courtesy*: Department of Pathology, Dr. DY Patil Medical College, Pune, Maharashtra).

space of brain and spinal cord. Expansion of the tubercle '**Rich focus**' determines the type of central nervous system involvement.

Clinical Features

Tuberculous meningitis involves the central nervous system. Patient presents with headache, neck rigidity, drowsiness, vomiting, irritability, confusion and focal neurological symptoms possibly leading to coma.

Laboratory Diagnosis

Lumbar puncture reveals increased CSF pressure yielding straw-colored CSF. Proteins content is markedly increased. Light microscopy of CSF shows numerous lymphocytes. Acid-fast bacteria may be grown on culture media. Cerebrospinal fluid findings in tuberculous meningitis is given in Table 7.16.

Clinical Pearls: Brain Tuberculoma—Diagnosis

Brain tuberculoma is an important clinical entity. It is main challenge in the management to diagnose it.

- Computed tomography (CT) scan of brain demonstrates solitary or multiple ring-enhancing lesion with moderate perilesional edema, but these findings are not specific for brain tuberculoma.
  - Neurocysticercosis (NCC), coccidioidomycosis, toxoplasmosis, metastasis and few other diseases have identical appearance on CT scan of brain.
  - Cerebrospinal fluid examination is most often normal.
- Magnetic resonance imaging (MRI) of brain with magnetic resonance spectroscopy (MRS) have advantage over CT scan in diagnosis of brain tuberculoma.
- Magnetic resonance spectroscopy demonstrates a specific lipid peak in cases of brain tuberculoma, which is not seen in any other differential diagnosis of brain tuberculoma.
- Histologic examination of biopsy and tissue culture from tubercular lesion can establish the diagnosis. The tubercular lesion consists of epithelioid cell granulomas, caseous necrosis and Langhans' giant cells.

Intestinal Tuberculosis

Mycobacterium tubercle bacilli reach the intestine either ingestion of infected sputum or ingestion of unpasteurized milk. The tubercular lesion begins in the Peyer's patches (lymphoid follicles) and spread through lymphatic channels resulting in tubercular ulcer in terminal ileum especially in the **ileocecal region**.

Surgical Pathology: Intestinal Tuberculosis

Gross Morphology

- Intestinal tuberculosis produces circumferential ulcers perpendicular to long axis of small intestine.
  - Fibrosis in this region is responsible for 'stricture formation'.
  - Draining lymph nodes of small intestine are enlarged and matted with caseous necrosis known as 'tabes mesenterica', which most often heals by fibrosis and dystrophic calcification.

- Hyperplastic ileocecal tuberculosis is a variant of intestinal tuberculosis characterized by thickening of terminal ileum, caecum and ascending colon with mucosal ulceration. On clinical examination, hyperplastic ileocecal tuberculosis is palpable and mistaken for caecal carcinoma. Stricture formation in the intestine in tuberculosis is shown in Fig. 7.23.

Light Microscopy

Histologic examination of ileocecal tuberculosis lesion reveals caseating epithelioid granulomas with Langhans' giant cells.

Tuberculous Osteomyelitis

Tuberculous osteomyelitis is most commonly secondary to hematogenous extension from a primary tubercular focus in the lung, which principally targets the vertebral column, called Pott's disease and paraspinal cold abscess. Vertebral body destruction may result in impingement on the spinal cord. Tuberculosis also targets hip bone, long bones (femur, tibia) and small bones (hands, feet). Patient presents with fever, fatigue, bone pain, some tissue swelling and discharging sinuses.

Tuberculous Pyelonephritis

Kidneys are most common extrapulmonary site in tuberculosis, which can cause asymptomatic pyuria (white blood cells in the urine) and can spread to the reproductive organs and adversely affect reproduction. In men, tuberculous epididymitis (inflammation of the epididymis) may occur.

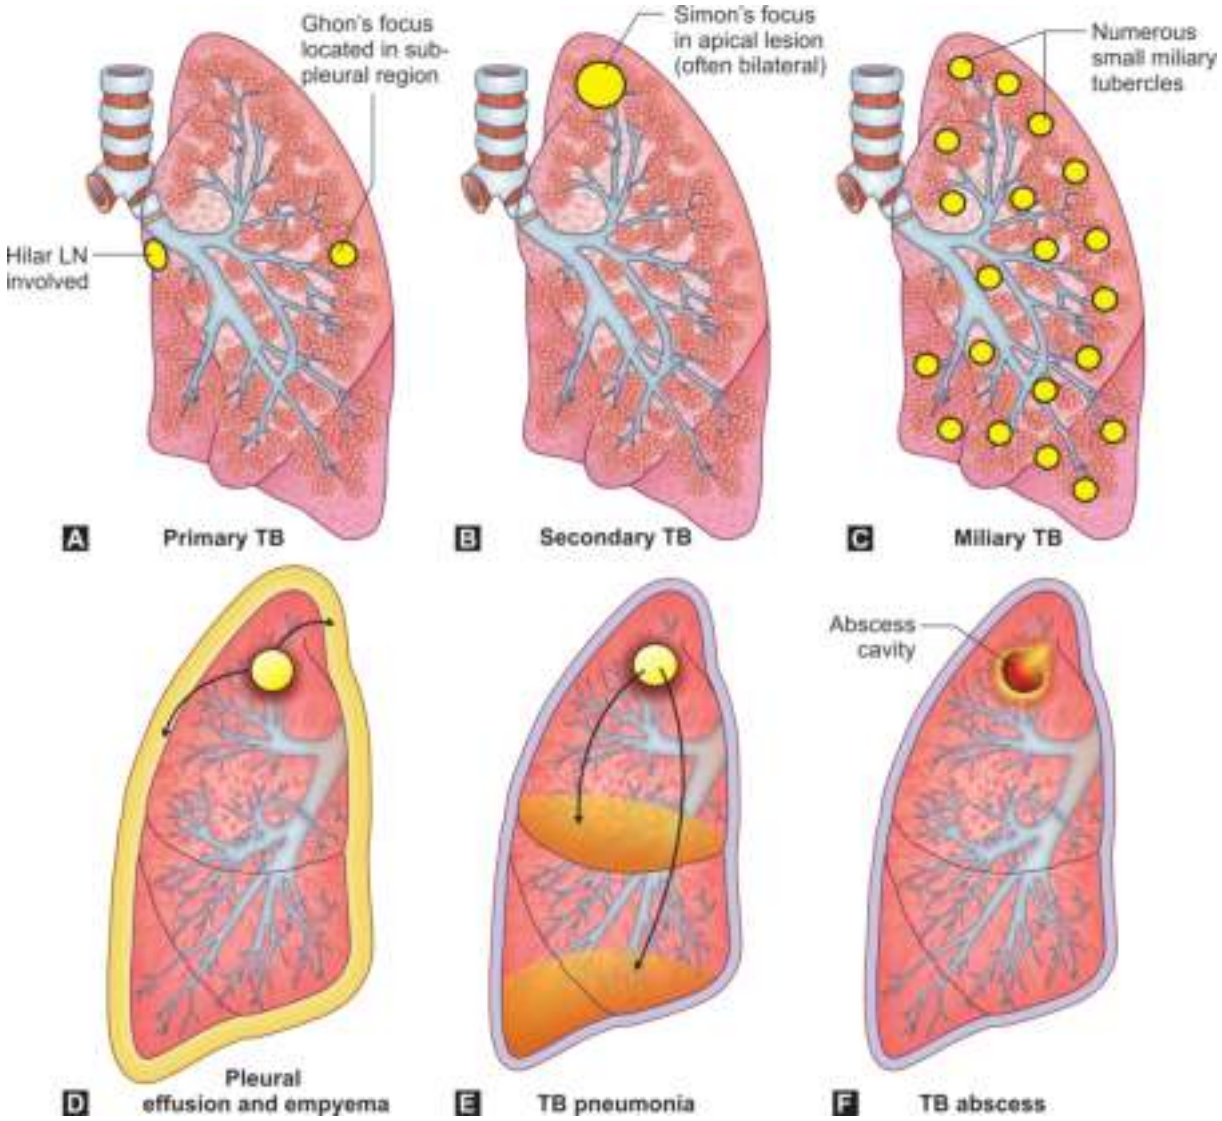

Fig. 7.20: Morphological patterns in a case of pulmonary tuberculosis. (A) Primary tuberculosis shows subpleural mid-zone and lesion hilar lymph node enlargement, (B) apical lesion is seen in secondary tuberculosis, (C) small miliary tubercles are demonstrated in lung, (D to F) pleural effusion, empyema, consolidation (pneumonia) and abscess are complications of tuberculosis.

Table 7.12 Causes of hemoptysis

Etiology	Disorders
Inflammatory lesions	▪ Tuberculosis* ▪ Bronchiectasis* ▪ Pneumonias*
Neoplastic lesions	▪ Primary lung cancers* ▪ Metastatic lung cancers* ▪ Bronchopulmonary adenoma
Other lesions	▪ Pulmonary embolism and infarction* ▪ Mitral stenosis ▪ Left ventricular failure ▪ Anticoagulant therapy ▪ Bronchial adenoma ▪ Idiopathic pulmonary hemosiderosis

**Most common causes of hemoptysis are tuberculosis, bronchiectasis, pneumonias, bronchogenic carcinoma, pulmonary embolism and infarction.*

Surgical Pathology: Tuberculous Pyelonephritis

Gross Morphology

Kidney is enlarged with hydronephrotic changes. Cut surface reveals fibrous-walled abscess cavities filled with caseous material filling the renal pelvis. Tuberculous pyelonephritis with hydronephrosis is shown in Fig. 7.24.

Light Microscopy

Histopathologic examination of tuberculous pyelonephritis shows caseous necrosis, epithelioid cell granulomas and Langhans' giant cells.

Adrenal Gland Tuberculosis

Tuberculosis of the adrenal glands can lead to adrenal insufficiency, which is the inability to increase steroid production in times of stress, causing weakness and collapse.

Table 7.13 Differences between primary and secondary (post-primary) pulmonary tuberculosis

Parameters	Primary Tuberculosis	Secondary Tuberculosis
Exposure to AFB	First time exposure	Reactivation of tubercular lesion
Age group	Children/younger age group	Any age group
Consolidation	Solitary lesion	Multifocal lesions (poorly defined)
Location	Mid-zone (Ghon's focus in subpleural lesion), other sites (tonsils, ileocecal region, skin)	▪ Upper lobes (apical region), Simon's focus in lungs: 2 cm gray white to yellowish well circumscribed consolidation in apical regions of one or both lungs ▪ Sputum for AFB is positive
Lymphadenopathy	Lymphadenopathy common	Lymphadenopathy rare
Severity of lesion	Less severe, healing by fibrosis and dystrophic calcification	More severe progressing to cavitation, lobar pneumonia, extension in lumen of bronchi, trachea, and larynx with vocal cord involvement
Pleural effusion	Pleural effusion common	Empyema common
Cavitation	Cavitation rare	Cavitation common
Miliary tuberculosis*	Miliary tuberculosis can involve organs	Miliary tuberculosis can involve organs

**Miliary tuberculosis can involve lung, liver, bone marrow, spleen, adrenal glands, meninges, kidneys, fallopian tubes, epididymis.*

Table 7.14 Differences between tuberculosis and sarcoidosis

Characteristics	Tuberculosis	Sarcoidosis
Etiology	Mycobacterium tubercle bacilli	Unknown etiology
Granuloma	Caseating granuloma	Noncaseating granulomas
Cytoplasmic inclusions in giant cells	Absence of Schaumann bodies, asteroid bodies and birefringent crystals	Presence of Schaumann bodies, asteroid bodies and birefringent crystals
Steroid therapy	Worsens the disease	Improves the disease
Diagnosis	Acid-fast bacilli present	Excluding causes of granulomatous lesions

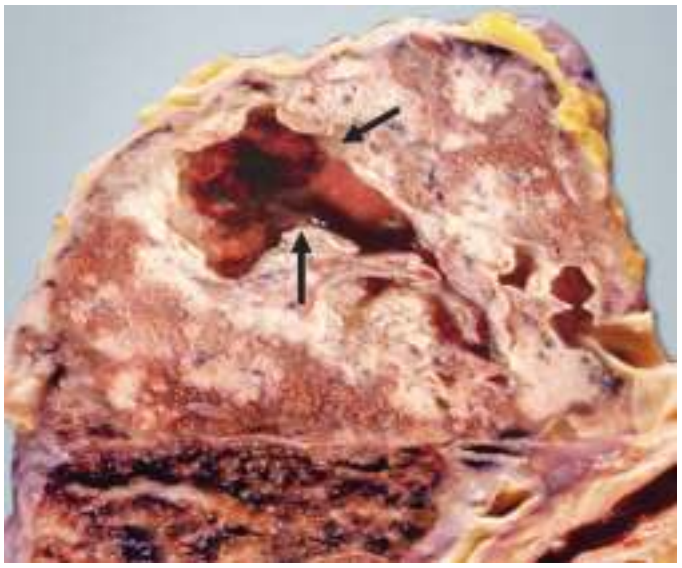

Fig. 7.21: Lung cavity in a case of tuberculosis. Cut surface of the lung shows a large cavity and pulmonary consolidation (arrows). (*Courtesy*: Department of Pathology, Dr. DY Patil Medical College, Pune.)

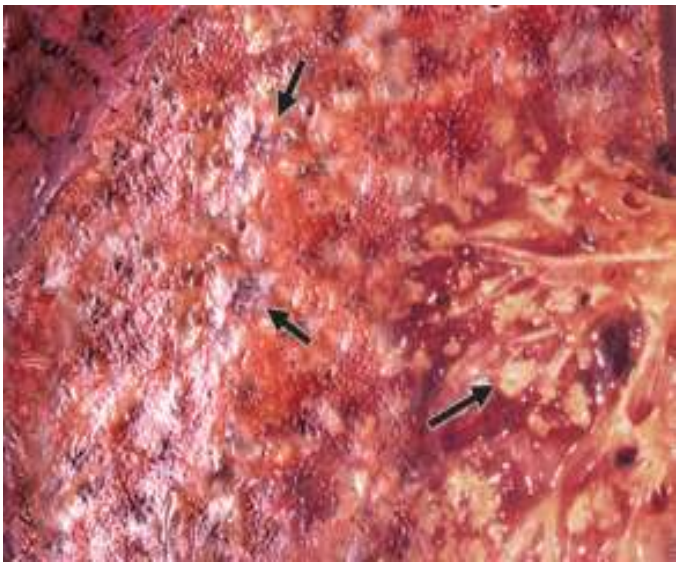

Fig. 7.22: Miliary tuberculosis in lung. Lung is showing millet-like seedlings in miliary tubercles (arrows). (*Courtesy*: Department of Pathology, Dr. DY Patil Medical College, Pune.)

Table 7.15 Extrapulmonary tuberculosis in order of frequency

Extrapulmonary Tuberculosis	Mechanism of Involvement	Comments
Tuberculous lymphadenitis	Hematogenous lymphatic spread	▪ Painless enlarged cervical lymph nodes in cervical and supraclavicular regions ▪ Cervical lymph node may form fistulous tract in skin
Pleural tuberculosis	Pleural tuberculosis can be part of pulmonary tuberculosis	▪ Pleural effusion ▪ Empyema ▪ Pleural fibrosis ▪ Restrictive lung disease
Tuberculosis of upper respiratory airways	Hematogenous spread	▪ Involvement of the larynx, pharynx and epiglottis in advanced secondary tuberculosis ▪ Symptoms, e.g. hoarseness, productive cough and dysphagia
Genitourinary tuberculosis	Hematogenous spread	▪ Tuberculous pyelonephritis ▪ Genital tuberculosis in females can affect the fallopian tube and endometrium causing infertility and menstrual abnormalities ▪ Genital tuberculosis in males affects epididymis producing a tender mass that may form a fistulous tract
Skeletal tuberculosis	Hematogenous or lymphatic spread	▪ Weight-bearing joints tuberculosis ▪ Spinal tuberculosis (Pott disease) may cause abscess formation that track along muscles and ligaments
Tuberculous meningitis and tuberculoma	Hematogenous spread or rupture of subependymal tubercle	▪ Tuberculous meningitis is more common in children than adults present with headache and altered sensorium and/or paresthesia ▪ Tuberculoma can cause seizures and focal symptoms
Intestinal tuberculosis	Swelling of infected sputum or ingestion of infected milk with *Mycobacterium bovis*	▪ *Mycobacterium bovis* trapped in the lymphoid follicles of intestinal mucosa causing bowel inflammation and ulceration ▪ Ileocecal tuberculosis
Tuberculous pericarditis	Progression of a pericardial focus or rupture of a nearby tubercular lymph node	▪ Tuberculous pericarditis may progress to constrictive pericarditis ▪ Tuberculous pericardial effusion
Miliary (disseminated) tuberculosis	Hematogenous spread to multiple organs	▪ Small yellow tubercles that may coalesce forming large areas of consolidation ▪ Nonspecific symptoms such as fever, night sweats and weight loss

Table 7.16 Cerebrospinal fluid findings in tuberculous meningitis

Features	Tuberculous Meningitis	Normal CSF
Causative organism	Mycobacterium tubercle bacillus	No organisms
CSF pressure	Increased	80–180 cm of H_2O (20 drops/minute)
Color	Straw colored	Clear, colorless
CSF proteins	Increased due to increased vascular permeability	Normal 15–40 mg%
CSF sugar	Normal range	50–80 mg%
White blood cells in CSF	Lymphocyte count is increased	0–4 Lymphocytes/mm^3
CSF culture	Bacterial growth on LJ medium	Sterile
Ziehl-Neelsen staining	Acid-fast bacteria demonstration	Organisms absent, hence insignificant

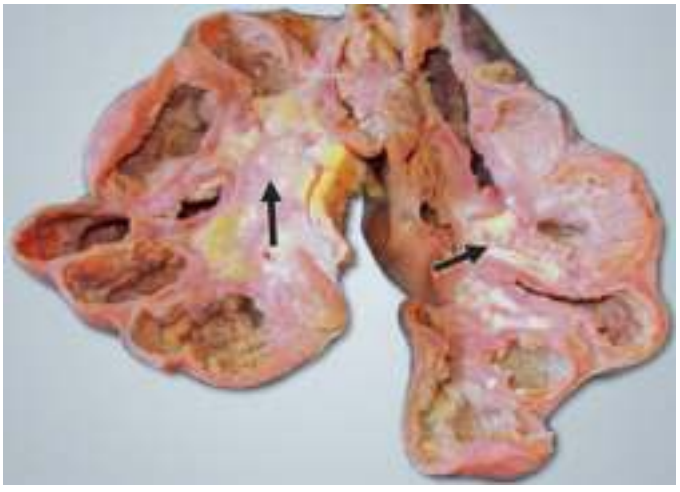

Fig. 7.24: Tuberculous pyelonephritis with hydronephrosis. Fibrous-walled abscess cavity filled with caseous material is shown on cut surface. This patient had a previous well-established history of pulmonary tuberculosis. Section from the patient's nephrectomy specimen shows a tuberculous granuloma, with central caseating necrosis and peripheral scarring. (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka.)

Mammary Tuberculosis

Mammary tuberculosis usually occurs due to extension from a rib in females. Patient presents with breast abscess and fever. Breast abscess contains caseous material. Light microscopy reveals epithelioid cell granulomas, caseous necrosis and Langhans' giant cells.

Laryngeal Tuberculosis

Laryngeal tuberculosis is extremely infectious as it affects larynx or the vocal cords. Patient presents with hoarseness (80–90%), odynophagia (50–70%), dysphagia, stridor, cough and hemoptysis.

Tuberculous Salpingitis

Tuberculous salpingitis occurs due to extension of tuberculous infection of endometrium through intraluminal route causes adhesions of lining epithelium, which is important cause of infertility. On histopathologic examination, fallopian tube shows epithelioid cell granulomas, Langhans' giant cells and caseous necrosis.

Tuberculous Peritonitis

Tuberculous peritonitis affects peritoneum leading to increased production of fluid (exudate) within the peritoneal cavity. Increased fluid leads to abdominal distension and pain. Patients are moderately ill and having fever.

Tuberculous Pericarditis

The pericardium membrane surrounding the heart is involved in tuberculosis. Excessive production of fluid in the pericardial cavity impairs normal cardiac functions.

Tuberculous Lymphadenitis

Lymph nodes contain macrophages that capture the Mycobacterium tubercle bacilli. Any lymph node can

Fig. 7.25: Gross morphology of tuberculous lymphadenitis. Cut surface tuberculous lymphadenitis shows cheesy appearance on cut surface (arrows). (*Courtesy*: Department of Pathology, Dr. DY Patil Medical College, Pune, Maharashtra.)

harbor uncontrolled replication of bacteria, causing the lymph node to become enlarged. The infection can develop a fistula (passage way) from the lymph node to the skin. Gross morphology of tuberculous lymphadenitis is shown in Fig. 7.25.

LABORATORY DIAGNOSIS

Tuberculosis is caused by Mycobacterium tubercle bacilli. Tuberculosis should be suspected in persons who present with unexplained weight loss, anorexia, night sweats, fever and fatigue.

- In addition to these symptoms, patient with pulmonary tuberculosis presents with cough for longer than three weeks, hemoptysis and chest pain. Extrapulmonary tuberculosis presents with symptoms based on the area affected.
- Clinicians should ask about the patient's history of tuberculosis exposure, infection or disease.
- A physical examination can provide valuable information about the patient's overall condition and other factors such as HIV infection or other illnesses that may adversely affect tuberculosis outcome.

Imaging Techniques

- **Chest X-ray:** It reveals cavitation, calcification (healed disease), and lymph nodes in the upper lobes, but cannot confirm the diagnosis.
- **Computed tomography (CT):** It is more sensitive than chest radiography for detection of pulmonary cavities, lymphadenopathy, miliary disease, bronchiectasis, bronchial stenosis, bronchopleural fistula, and pleural effusion.
- **Magnetic resonance imaging (MRI):** It is preferred for diagnosis of extrapulmonary disease such as skeletal and intracranial tuberculosis.

Sputum Smear Prepared from Samples

Smears are prepared from specimens, i.e. sputum for three consecutive days, laryngeal, bronchoalveolar and gastric lavage. Smears prepared are stained with Ziehl-Neelsen staining and 'auramine–rhodamine O' for examination by immunofluorescence microscopy.

- **Sputum collection:** Sputum should be collected for three consecutive days to demonstrate acid-fast bacilli.
- **Laryngeal swab:** By laryngoscope, two swabs are collected and put in 10% H_2SO_4 in test tube for 5 minutes for killing contaminants. Then transfer these swabs to another test tube containing 2% NaOH for 5 minutes to kill other bacilli. Laryngeal swab material is stained with Ziehl-Neelsen stain.
- **Bronchoalveolar lavage:** Smears are prepared and stained with Ziehl-Neelsen stain.
- **Gastric lavage:** It is indicated in children and older patients, who are unable to cough out sputum. Specimen is collected by Ryle's tube and processed immediately to avoid the effect of gastric secretions. Neutralize the gastric contents with N/10 NaOH and put in refrigerator for 15 minutes. Remove the supernatant and centrifuge at 3000 rpm for 15 minutes. Smears are made from deposits.

Sputum Smear Staining for Tubercular Acid-fast Bacilli

Tubercular acid-fast bacilli can be demonstrated by Ziehl-Neelsen stain and fluorescent-like stains such as auramine and rhodamine 'O' stain in sputum samples.

- No acid-fast bacilli in 100 oil immersion fields: negative
- <9 acid-fast bacilli in 100 oil immersion fields: 1+
- 10–99 acid-fast bacilli in 100 oil immersion fields: 2++
- 1–9 acid-fast bacilli in oil immersion fields: 3+++
- >10 acid-fast bacilli in oil immersion fields: 4++++

Fine Needle Aspiration Cytology

Fine needle aspiration cytology smears are stained with May-Grunwald-Giemsa stain. Microscopic examination reveals epithelioid cell granulomas, caseous necrosis and Langhans' giant cells. Mycobacterium tubercle bacilli are demonstrated by Ziehl-Neelsen staining.

Histologic Examination

Biopsy is done to establish diagnosis of tuberculosis. Histologic examination of the tissue consists of epithelioid cell granulomas, caseous necrosis and Langhans' giant cells. Noncaseating tuberculosis lacks epithelioid cell granulomas but numerous Mycobacterium tubercle bacilli show strong positivity with Ziehl-Neelsen stain.

Fluid Examination

Fluid examination is done in extrapulmonary tuberculosis, i.e. cerebrospinal fluid, pleural fluid, peritoneal fluid and synovial fluid.

Culture Techniques

Liquid media-based culture takes 2 weeks. **Löwenstein-Jensen** culture medium takes 10 weeks. Drain off excess of fluid and inoculate in two test tubes of Löwenstein-Jensen medium.

- Aeration is done for every week for more than 8 weeks to remove water of condensation. Growth starts appearing in 10–14 days.
- Human strains of Mycobacterium tubercle bacilli (eugonic) grow more than bovine strains (dysgonic).
- Addition of 0.75% glycerol promotes the growth of human strains without any effect on bovine strain. After culture, smears are made from colonies and stained with Ziehl-Neelsen stain.

Gas Chromatographic Method

Gas chromatographic method is useful diagnostic tool to demonstrate tuberculostearic acid, when AFB is not demonstrated.

Nucleic Acid Amplification Test (NAAT)

Direct tests of nucleic acid amplification (NAA) are rapid, widely available, and can be performed in a day (within 2–7 hours).

- The amplified *Mycobacterium tuberculosis* direct test (gene-probe) targets mycobacterial ribosomal RNA by transcription-mediated amplification. DNA probes are used, which are highly specific for *M. tuberculosis* species.
- The amplified *Mycobacterium tuberculosis* direct test (gene-probe) is best used (and only approved for use) in patients in whom Mycobacterium tubercle bacilli smears are positive. Nucleic acid amplification test is highly specific for *Mycobacterium tuberculosis*. Specificity is greater than 95% in either acid-fast bacilli smear negative or smear positive samples.

Polymerase Chain Reaction Technique

Polymerase chain reaction (PCR) technique amplifies even very small portions of a predetermined target region of *M. tuberculosis*-complex DNA. The test uses an automated system that can rapidly detect as few as one organism from sputum, bronchoalveolar lavage, blood, cerebrospinal fluid, pleural fluid, or other fluid and tissue samples and has shown sensitivity and specificity of nearly 90% in pulmonary disease.

MYCOBACTERIUM LEPROSY (HANSEN'S DISEASE)

Leprosy is an infectious disease caused by a bacillus, *Mycobacterium leprae*, which multiplies slowly. Mycobacterium is slender rod-shaped weakly acid-fast bacillus and cannot be grown on culture medium or cell culture.

- *Mycobacterium leprae* are transmitted from human body by nasal discharge and digital impregnation of skin, as bacilli can be carried under nails and are inoculated under the skin by scratching. The incubation period is usually 3–5 years. Skin and peripheral nerves are commonly involved.
- After entering body, *Mycobacterium leprae* spread through circulation and reach cooler parts of body such as skin of extremities, peripheral nerves, mouth and eyes. These organisms may be demonstrated in bone marrow, liver, spleen and lymph nodes.
- *Mycobacterium leprae* target Schwann cells (SCs) leading to injury of the nerve, demyelination, loss of axonal conductance and consequent disability. The pathogen can invade the Schwann cells by a specific laminin-binding protein known as phenolic-glycolipid 1 (**PGL-1**).
- Leprosy is curable with multidrug therapy (MDT). If leprosy is untreated, it can cause progressive and permanent damage to the skin, nerves, limbs, and eyes.

CLASSIFICATION

Based on clinical, histologic and immunological status, leprosy is classified within two poles of the disease with transition into five categories: tuberculoid polar leprosy (TT), borderline tuberculoid (BT), mid-borderline (BB), borderline lepromatous (BL), and lepromatous polar leprosy (LL). Schematic representation of Ridley-Jopling and WHO classification of leprosy is shown in Fig. 7.26.

Indian Leprosy Classification

According to Indian classification, leprosy is classified into five forms: indeterminate, tuberculoid, borderline, lepromatous and pure neuritic leprosy (PNL). It is essential to pay more attention to **pure neuritic leprosy** and diagnose and treat patients earlier to prevent deformities and sequelae of nerve damage.

Myrid Leprosy Classification

According to Myrid classification, leprosy is classified into two categories: (a) immunological stable (lepromatous and tuberculoid leprosy), and (b) immunological unstable (indeterminate and borderline leprosy).

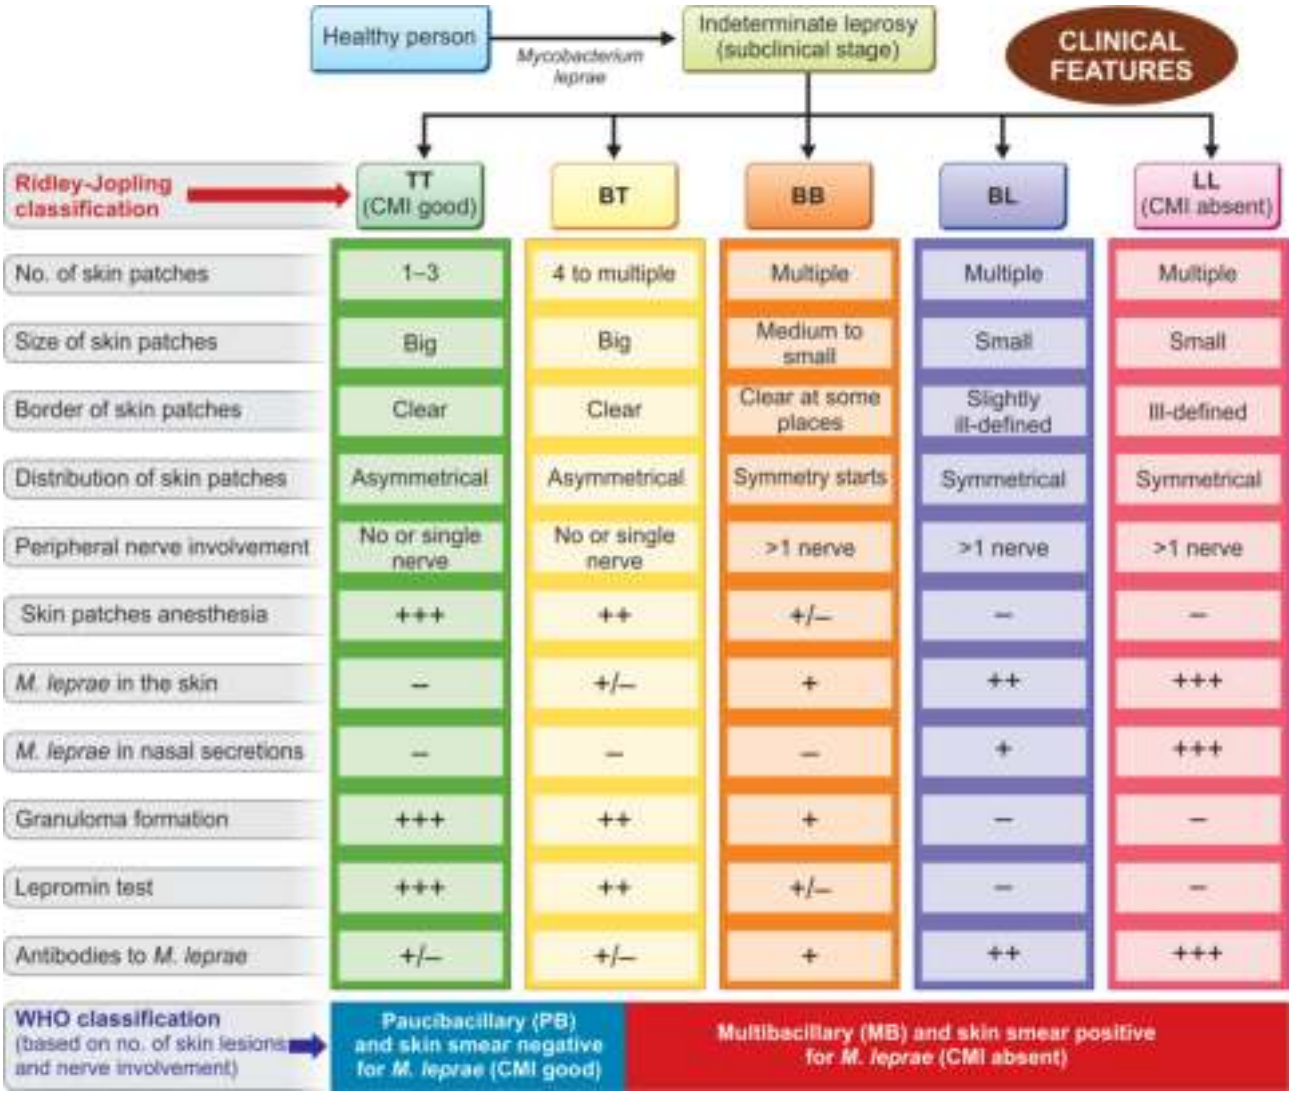

Fig. 7.26: Schematic representation of Ridley-Jopling and WHO classification of leprosy.

Clinical Pearls: Immune Status in Leprosy

- Cell-mediated and humoral immunity have been implicated in leprosy.
- CD4+ helper T cells participate in cell-mediated immunity. Increased titers of IgG, IgA and IgM have been demonstrated in these patients, which are not protective.
- Tuberculoid leprosy has good cell-mediated immunity with granulomatous reaction.
- Lepromatous leprosy has poor cell-mediated immune response without granulomatous reaction.
- Borderline leprosy is an intermediate form between tuberculoid and lepromatous leprosy.

High-immune Response (Indeterminate, TT and BT)

Patient presents with few well-defined skin lesions with regular borders with asymmetrically distribution pattern and nerve enlargement. Slit-skin smear may show scant *Mycobacterium leprae*. Lepromin test is positive.

Low-immune Response (BL and LL)

Patient presents with symmetrical distribution of numerous skin lesions ranging from macules–papules with ill-defined margins. These skin lesions may be hypoanesthetic.

Mid-immune Response (BB)

Patient shows features of both the spectrums of leprosy. This BB is immunologically unstable, and hence prone to reactions.

WHO Leprosy Classification

According to WHO system of working classification, leprosy is classified into paucibacillary (PB) or multibacillary (MB) because, they entail different treatment regimens.

- **Paucibacillary leprosy:** It is characterized by 1–5 skin lesions, one nerve involvement and slit-skin smear negative for AFB.

- **Multibacillary leprosy:** It is characterized by 6 or more skin lesions, involvement of more than two nerves and slit-skin smear positive for AFB.

Ridley-Jopling Leprosy Classification

The most widely accepted scheme of classification of leprosy is Ridley-Jopling classification based on a combination of clinical findings, bacteriological index (BI), immunological reactivity (lepromin test) and the histologic findings. Ridley-Jopling leprosy classification ranges from a spectrum of high- to low-resistance pattern.

Borderline Leprosy

Borderline leprosy includes borderline tuberculoid, mid-borderline and borderline lepromatous leprosy.

- **Borderline tuberculoid (BT) leprosy:** Patients present with multiple large anesthetics less-defined discrete; satellite papules similar to those seen in tuberculoid leprosy. Several peripheral nerve trunks are symmetrically enlarged and neuropathy often occurs. Bacterial index ranges from 0 to 2.
- **Mid-borderline (BB) leprosy:** Patient presents with numerous asymmetrical annular dimorphic plaques with poorly-defined outer borders and sharply defined central 'punched out' skin lesions, which exhibit both tuberculoid and lepromatous lesions. These patients may develop nerve hypertrophy and/or neuritis. Bacterial index ranges from 3 to 4.
- **Borderline lepromatous (BL) leprosy:** Majority of borderline lepromatous leprosy patients have variable immunological response. BL patients do not fall into polar group. BT (borderline tuberculoid) tends to be more towards TT (tuberculoid leprosy) and BL towards LL (lepromatous leprosy). Patient presents with dimorphic, symmetric bilaterally distributed lesions with widespread small macules, papules and nodules of variable sizes and shapes on skin including symmetric peripheral nerve involvement. Bacterial index is 4 or 5.

Tuberculoid Leprosy

Tuberculoid leprosy is characterized by presence of immunological response against *Mycobacterium leprae*. Patient develops large macular lesions on cooler parts especially nose, outer ears, testes and superficial nerve endings. There is presence of cell-mediated immune response. Infectivity is low in tuberculoid leprosy. Schematic representation of genesis of cell-mediated immunity in tuberculoid leprosy is shown in Fig. 7.27.

Lepromatous Leprosy

Lepromatous leprosy has least capacity to mount immunological response against *Mycobacterium leprae*. Patient develops extensive erythematous macules, papules or nodules with extensive destruction of skin. Immune response is severely depressed. There is high infectivity in lepromatous leprosy. Schematic representation of genesis of cell-mediated immunity in lepromatous leprosy is shown in Fig. 7.28.

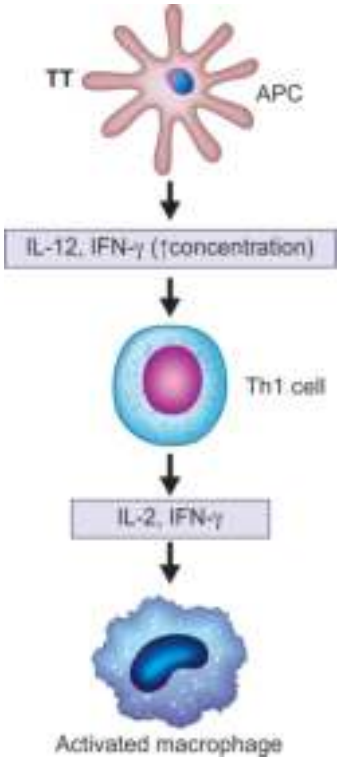

Fig. 7.27: Schematic representation of genesis of cell-mediated immunity in tuberculoid leprosy. It induces good immune response. Infectivity is low in tuberculoid leprosy.

Pure Neuritic Leprosy

Pure neuritic leprosy (**PNL**) constitutes a significant proportion of cases in India. It is essential to pay more attention to this form of leprosy and diagnose and treat patients earlier to prevent deformities and sequelae of nerve damage.

Pathology Pearls: Histology of Skin Biopsy in Leprosy

- Histologic examination reveals granulomatous inflammation and nerve inflammation and acid-fast bacilli on Ziehl-Neelsen staining.
- Langhans' giant cells are present in tuberculoid leprosy and borderline tuberculoid (BT) leprosy lesions.
- Noncaseating epithelioid cell granulomas are present in tuberculoid (TT) leprosy, mid-borderline (BB) leprosy lesions and to a lesser extent in borderline lepromatous (BL) leprosy.
- Histiocytes and foamy macrophages are present in borderline lepromatous leprosy and lepromatous leprosy (LL) lesions.
- Clear subepidermal zone is observed in mid-borderline, borderline lepromatous leprosy, and lepromatous leprosy lesions. Lamination of the perineum is more characteristic of borderline leprosy and lepromatous leprosy.

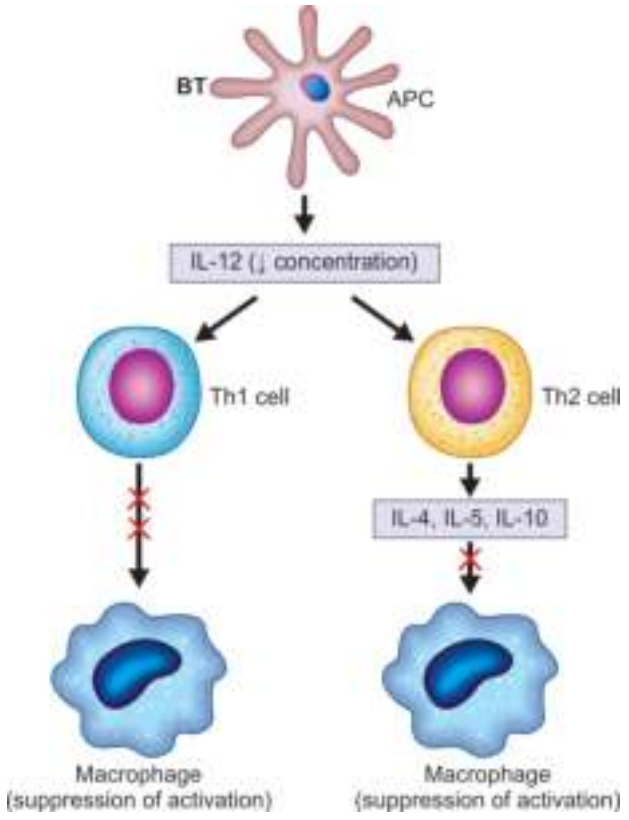

Fig. 7.28: Schematic representation of genesis of cell-mediated immunity in lepromatous leprosy (LL). It induces poor immune response. Infectivity is high in lepromatous leprosy.

CLINICAL FEATURES

Activity of leprosy disease is assessed by various signs: erythema/infiltration, extension or appearance of new lesions, extension/new appearance of anesthesia, paresis and paralysis, tenderness and pain in nerves, morphologic index and occurrence of reaction. Even though the nerves affected in leprosy are mixed nerves, the sensory loss is more marked compared to motor dysfunction.

Indeterminate Leprosy

The initial cutaneous manifestations of indeterminate leprosy are subtle and not specific. Initially erythematous patch, which in darker-skinned individuals appears pale; most cases resolve, some advance into more severe disease. It is most common type of leprosy in Indian children. Most cases resolve, but some advance into more severe disease.

- Patient presents with an ill-defined, bizarre hypopigmented macule(s) with a smooth or scaly surface. The sensations over the macule may or may not be impaired. The nerve proximal to the patch may or may not be thickened.
- Histologic examination of indeterminate leprosy shows scant lymphocytes and histiocytes in the superficial and deep in the dermis with some tendency to localize around skin appendages; and increased mast cells. Histology of indeterminate leprosy is shown in Fig. 7.29.

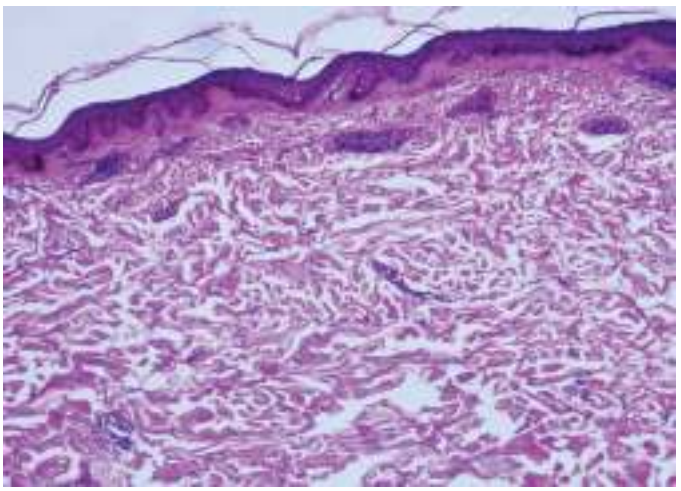

Fig. 7.29: Histology of indeterminate leprosy. Histologic examination of indeterminate leprosy shows scant lymphocytes and histiocytes around neurovascular bundles in the superficial and deep in the dermis with some tendency to localize around appendages; and increased mast cells (400X). (*Courtesy*: Dr. Geeta Pachori, Senior Professor and Head of Pathology, Jawahar Lal Nehru Medical College, Ajmer, Rajasthan.)

Borderline Leprosy

Borderline leprosy is an intermediate form between tuberculoid and lepromatous leprosy. Patient has hypopigmented macules and involvement of nerves exhibiting onion-skin appearance.

Borderline Tuberculoid Leprosy

Borderline tuberculoid leprosy (BT) is characterized by noncaseating epithelioid cell granulomas and numerous lymphocytes in dermis. Diagnosis of BT leprosy is achieved using real-time polymerase chain reaction (PCR) to amplify *Mycobacterium leprae* specific DNA sequence and to detect serum antibodies specific to *Mycobacterium leprae* antigens. Clinical photograph of borderline tuberculoid leprosy is shown in Fig. 7.30. Histology of borderline tuberculoid leprosy is shown in Fig. 7.31.

Borderline Lepromatous Leprosy

Majority of borderline lepromatous (BL) leprosy patients have variable immunological response. BL patients do not fall into polar group. Borderline tuberculoid (BT) leprosy tends to be more towards tuberculoid (TT) leprosy and borderline lepromatous leprosy (BL) towards lepromatous leprosy (LL). Patient presents with dimorphic, symmetric bilaterally widespread small macules, papules and nodules of variable sizes

Fig. 7.30: Clinical photograph of borderline tuberculoid leprosy. Clinical examination shows more widespread and less sharply defined lesions than in tuberculoid form. These lesions are usually symmetrical on trunk but may be asymmetric on face. Nerve involvement is less prominent. (*Courtesy*: Dr. Krishna Deb Barman, Director Professor of Dermatology, Maulana Azad Medical College and Associated Lok Nayak Hospital, New Delhi.)

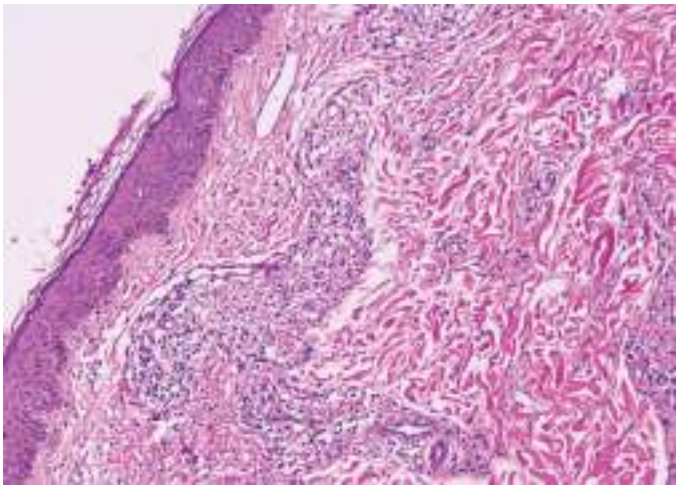

Fig. 7.31: Histology of borderline tuberculoid leprosy. Hematoxylin and eosin-stained section shows formation of noncaseating epithelioid cell granulomas (400X).

and shapes on skin including symmetric peripheral nerve involvement. Bacterial index is 4 or 5. Clinical photograph of borderline lepromatous leprosy is shown in Fig. 7.32. Histology of borderline lepromatous leprosy is shown in Fig. 7.33.

Tuberculoid Leprosy

Tuberculoid leprosy is a milder, less severe form of leprosy (called paucibacillary leprosy). It has robust cell-mediated immune response with prompts granulomatous inflammation and characterized by infiltration of dermis and subcutaneous fat by noncaseating granulomas predominantly centered

Fig.7.32: Clinical photograph of borderline lepromatous leprosy. Clinical examination shows symmetric bilateral widespread, well-defined, hypopigmented to erythematous hypoesthetic small macules, papules and nodules of variable sizes and shapes with downward slopping edges seen over the back. Small satellite lesion is also in the periphery of periphery. These skin lesions are mostly lepromatous in nature but also contain aspects of tuberculoid lesions. (*Courtesy*: Dr. Krishna Deb Barman, Director Professor of Dermatology, Maulana Azad Medical College and Associated Lok Nayak Hospital, New Delhi.)

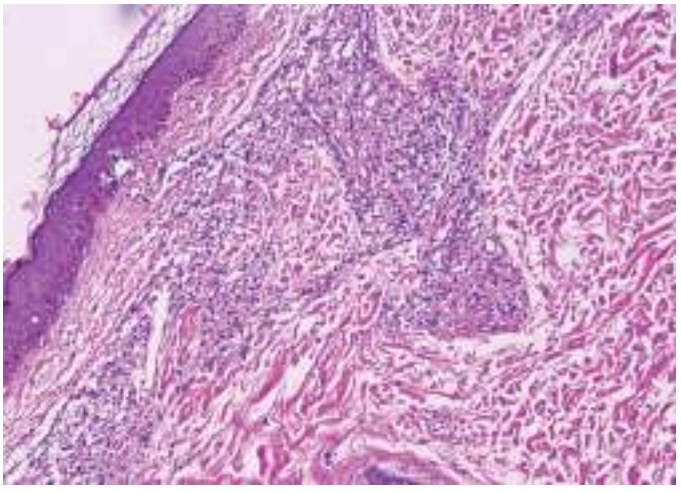

Fig. 7.33: Histology of borderline lepromatous leprosy. Hematoxylin and eosin-stained section shows formation of noncaseating epithelioid cell granulomas (400X).

around small cutaneous nerves. Nerves are completely destroyed in the process and replaced by noncaseating epithelioid cell granulomas. Cell-mediated hypersensitivity reaction eradicates bacteria from the lesion in

tissue. Therefore, *Mycobacterium leprae* bacilli are scarce and usually not identified with modified acid-fast stains (Wide-Fite stain).

- Patient presents with one or multiple erythematous or scaly, well-circumscribed macules or patches; usually hypoanesthetic or anesthetic on extremities, buttock and face, thickened nerves, loss of sensation and diminished sweating. All patients have nerve involvement. Inflammation of Schwann cells leads to thickening of peripheral nerves. Clinical course is generally benign.
- On histologic examination, tuberculoid leprosy demonstrates noncaseating epithelioid cell granuloma, Langhans' giant cells, CD4+ helper T cell infiltration, and involvement of peripheral nerve. The close association of granulomatous response with the cutaneous nerves is a helpful diagnostic feature in tuberculoid leprosy. Tuberculoid leprosy is less contagious than other forms. Histology of tuberculoid leprosy is shown in Fig. 7.34.

Lepromatous Leprosy

Patient presents with symmetrically distributed papular and nodular lesions on nose and ears; on cooler parts (face, ears, wrists, elbows, buttocks, and knees) sparing inguinal and axillary regions. These lesions often start on nose and ears, later involve hands, arms, buttocks. Facial lesions can be markedly swollen with loss of eyebrows (**Lucio sign**). Facial nerve involvement, hoarseness, loss of eyebrows and eyelashes, and nasal collapse (**saddle nose**) secondary to septa perforation may occur in advanced cases of disease. Nasal secretions are rich in organisms. Differences between tuberculoid and lepromatous leprosy are given in Table 7.17.

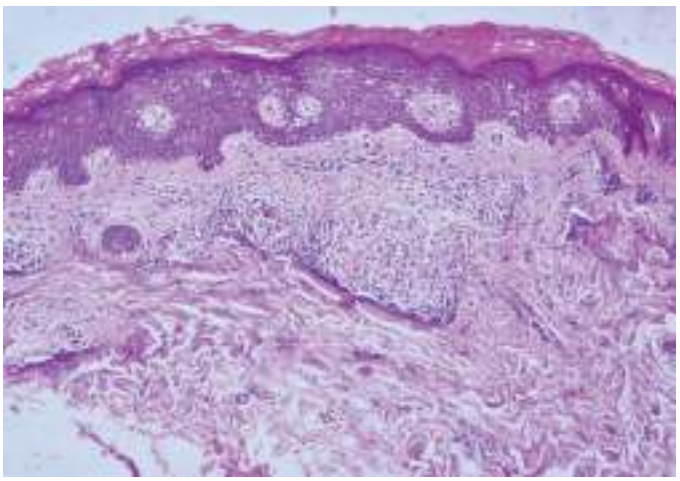

Fig. 7.34: Histology of tuberculoid leprosy. Hematoxylin and eosin-stained section shows noncaseating epithelioid granuloma, Langhans' giant cells, T-helper lymphocytic infiltration, and involvement of peripheral nerve (400X). (*Courtesy*: Dr. Geeta Pachori, Senior Professor and Head of Pathology, Jawahar Lal Nehru Medical College, Ajmer, Rajasthan.)

Surgical Pathology: Lepromatous Leprosy

Light Microscopy

- The predominant histologic feature in lepromatous leprosy is a diffuse histiocytic infiltrate in the dermis that is not necessarily centered around nerves.
- A grenz zone of sparing is usually present in the papillary dermis. There are no discrete granulomas in the dermis. The histiocytes are arranged in poorly circumscribed clusters.
- Lymphocytes are scarce and those are present usually CD8+ cytotoxic T cells. The histiocytes may demonstrate vacuolated or foamy cytoplasm with a grayish-blue tinge on hematoxylin and eosin-stained sections due to clusters of *Mycobacterium leprae* bacilli.
- With modified Ziehl-Neelsen (Wide-Fite) stain, *Mycobacterium leprae* bacilli can be visualized in large numbers in histiocytes surrounding cutaneous nerves, blood vessels and eccrine glands. In some cases of lepromatous leprosy, histiocytes are spindle-shaped and arranged in storiform pattern mimicking fibrous histiocytoma. This variant is referred to as histoid leprosy.
- Histology of lepromatous leprosy is shown in Fig. 7.35 and Ziehl-Neelsen (Wide-Fite) stained section demonstrates numerous *Mycobacterium leprae* bacilli as shown in Fig. 7.36.

Pathology Pearls: Histoid Leprosy—Rare Variant of Lepromatous Leprosy

- Histoid leprosy is a rare variant of lepromatous leprosy characterized by unique clinical, histopathologic, and morphological features.
- Patient presents with cutaneous and subcutaneous nodules. Histoid leprosy patients represent probable residual bacilli and a highly active lepromatous leprosy process. These cases may act as reservoirs of the disease and lead to further spread of leprosy.
- Continual occurrence of these cases does not bode well for eradication of leprosy. Histology of histoid leprosy is a type of lepromatous leprosy as shown in Fig. 7.37.

Erythema Nodosum Leprosum

Leprosy reactions are significant cause of morbidity in leprosy patients. Erythema nodosum leprosum (**ENL**) is an immunological complication affecting 50% of patients with lepromatous leprosy (LL) and affecting 10% of borderline lepromatous (BL) leprosy.

- Erythema nodosum leprosum is associated with clinical manifestations such as tender red plaques and nodules together with areas of erythema over skin, neuritis, orchitis, dactylitis, osteitis, lymphadenitis, facial mutilation, eye inflammation, neurotrophic ulcers, flexion contractures of hands, foot drop and nephritis.
- The eruption is generally widespread and accompanied by fever, malaise and arthralgia. Erythema

Table 7.17 Differences between tuberculoid and lepromatous leprosy

Characteristics	Tuberculoid Leprosy	Lepromatous Leprosy
Host resistance	Present	Absent
T cell immunity	Present	Absent
Lepromin test	Strongly positive	Negative
Fernandez reaction (24–48 hours)	Positive	Negative
Mitsuda reaction (3–4 weeks)	Positive	Negative
Skin lesions	▪ Macular lesions with central depressed areas and hypopigmented margins ▪ Asymmetrical lesions not involving both sides	▪ Macular/papular/nodular lesions on hand and face (leonine face) ▪ Symmetrical lesions involving both sides
Touch sensation	Hypoanesthetic/anesthetic lesions	Absent (anesthetic patches)
Clinical appearance	Disfigurement minimal	Disfigurement maximum (leonine facies, claw hands and pendulous ear lobes)
Nerves involved	Ulnar, facial and peroneal nerves	Ulnar and peroneal nerves
Other organs	Other organs not involved	Anterior chamber eye, upper respiratory tract, testes, lymph nodes, liver, spleen and gynecomastia in males
Infectivity	Low	Very high
Skin histology	▪ Epidermis nonatrophic ▪ Rete ridges present ▪ Dermal papillae normal ▪ Clear zone between epidermis and dermis is absent ▪ Epithelioid cell granulomas present ▪ CD4+ helper T cells: Present at the periphery of granulomas ▪ CD8+ cytotoxic T cells: Very few at the center of lesion ▪ Fite stain: AFB (*M. lepare* bacilli) few (4–5) in macrophages	▪ Epidermis atrophic ▪ Rete ridges absent ▪ Dermal papillae flattened ▪ Clear zone between epidermis and dermis is present ▪ Epithelioid cell granulomas absent ▪ CD4+ helper T cells are absent ▪ CD8+ cytotoxic T cells are present in large number in diffuse manner ▪ Fite stain: AFB (*M. lepare* bacilli) abundant in macrophages
Complications	These are related to nerve damage like paralysis, distinct sensory losses	Antigen–antibody complex mediated erythema nodosum leprosum, vasculitis, glomerulonephritis besides nerve related
Prognosis	Milder disease, hence good prognosis	Extensive progressive disease, hence poor prognosis

nodosum leprosum is treated mainly with corticosteroids. Prolonged administration of corticosteroids can cause morbidity and mortality. Clinical photograph of erythema nodosum leprosum is shown in Fig. 7.38.

- Histologic examination of hematoxylin and eosin-stained sections demonstrates an inflammatory neutrophilic infiltrate, vasculitis and/or panniculitis, immune-complex deposit and complement deposit associated with antigens of *Mycobacterium leprae*. Histology of erythema nodosum leprosum is shown in Fig. 7.39.
- The clinical course is prolonged with recurrent episodes of *Mycobacterium leprae* over a period of 12–24 months or even longer than seven years in some cases.

LEPROMIN TEST

Lepromin test is used to demonstrate immune status in leprosy patients. Antigenic extract obtained from *Mycobacterium leprae* is administered by intradermal route. The injection site is evaluated at 1–2 days and 3 weeks. Delayed hypersensitivity is demonstrated in tuberculoid leprosy (TT). Lepromin test is negative

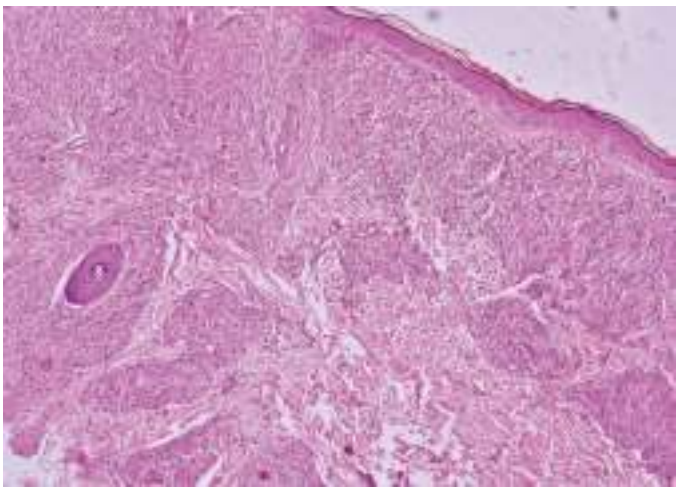

Fig. 7.35: Histology of lepromatous leprosy. Epidermis shows atrophy. There is loss of rete ridges of epidermis. Dermal papillae are flattened. There is loss of dermal appendages. The predominant histologic feature in lepromatous leprosy is a diffuse histiocytic infiltrate arranged in nodular or diffuse patterns. In the dermis that is not necessarily centered around nerves. Grenz zone (clear zone) is demonstrated at the junction of epidermis and dermis in lepromatous leprosy. There are no discrete granulomas in the dermis. The histiocytes are arranged in poorly circumscribed clusters (400X).

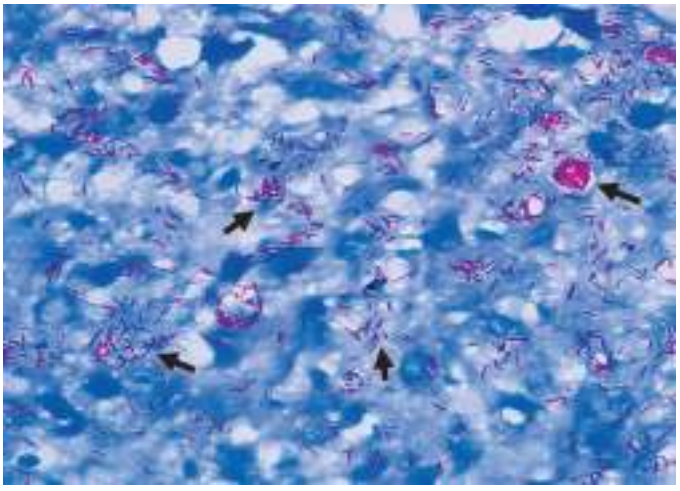

Fig. 7.36: Lepromatous leprosy. Modified Ziehl-Neelsen (Wide-Fite) stain is showing macrophages laden with *Mycobacterium leprae* bacilli (arrows) (400X). (*Courtesy*: Dr. Geeta Pachori, Senior Professor and Head of Pathology, Jawahar Lal Nehru Medical College, Ajmer, Rajasthan.)

in lepromatous leprosy (LL). Lepromin positive reaction is of two types: (a) Fernandez reaction, and (b) Mitsuda reaction.

Fernandez Reaction

Fernandez reaction occurs within first 2 days and represents a delayed-type of hypersensitivity reaction to intradermally injected heat-killed leprosy bacilli. Patient develops skin induration within 24–48 hours at the site of injection.

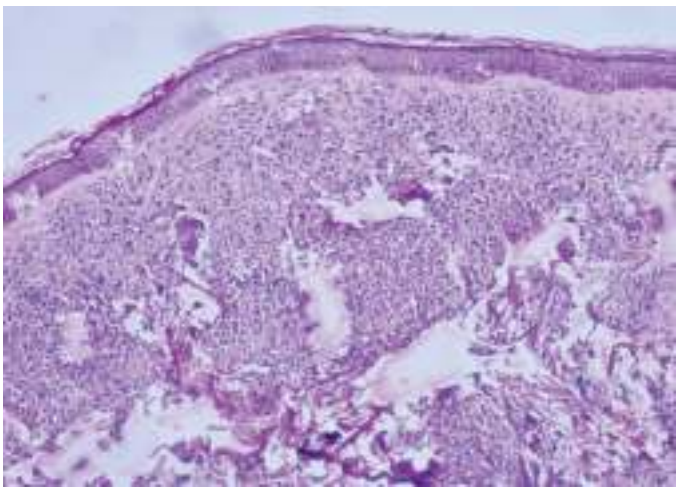

Fig. 7.37: Histology of histoid leprosy. It is a variant of lepromatous leprosy. In some cases of lepromatous leprosy, histiocytes are spindle-shaped and arranged in storiform pattern mimicking fibrous histiocytoma around blood vessels and adnexal structures (400X). (*Courtesy*: Dr. Geeta Pachori, Senior Professor and Head of Pathology, Jawahar Lal Nehru Medical College, Ajmer, Rajasthan.)

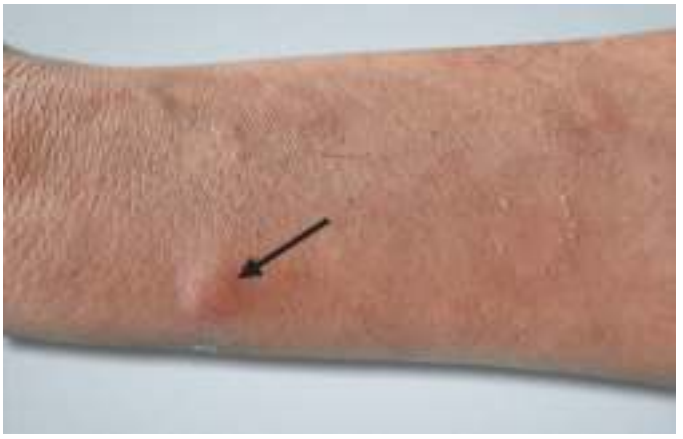

Fig. 7.38: Clinical photograph of erythema nodosum leprosum. The skin lesions are characterized clinically by tender red plaques and nodules together with areas of erythema. The eruption is generally widespread and accompanied by fever, malaise and arthralgia (arrow). (*Courtesy*: Dr. Krishna Deb Barman, Director Professor of Dermatology, Maulana Azad Medical College and Associated Lok Nayak Hospital, New Delhi.)

Mitsuda Reaction

Mitsuda reaction measures the granulomatous immune response to intradermally injected heat killed leprosy bacilli. A positive Mitsuda reaction is described as an indurated skin lesion of more than 4 mm that histologically shows noncaseating epithelioid cell granuloma formation after 3–4 weeks at the site of injection. A positive Mitsuda reaction corresponds to the acquisition of cell-mediated immunity against the *Mycobacterium leprae* and occurs in tuberculoid leprosy patients. Borderline leprosy patients show an indurated skin lesion of less than 3 mm.

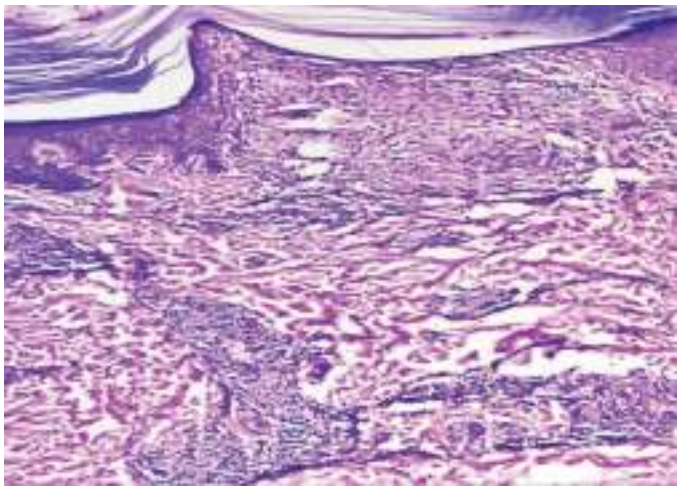

Fig. 7.39: Histology of erythema nodosum leprosum (ENL). Histologic examination of H&E-stained sections demonstrates an inflammatory neutrophilic infiltrate, vasculitis and/or panniculitis, immune-complex deposit and complement deposit associated with antigens of *Mycobacterium leprae* (400X). (*Courtesy*: Dr. Geeta Pachori, Senior Professor and Head of Pathology, Jawahar Lal Nehru Medical College, Ajmer, Rajasthan.)

DIAGNOSTIC APPROACH

Diagnostic approach includes clinical examination of skin patches with definite sensory impairment, peripheral nerves enlargement, skin biopsy and positive skin smears for AFB. Involvement of nerves is seen in 100% of patients. The type C fibers which mediate sensations towards heat and cold or different temperatures are lost first before loss of pain or light touch fibers.

Histologic Examination of Skin Biopsy: Tuberculoid (TT) Leprosy and Lepromatous Leprosy (LL)

Histopathologic examination of skin biopsy is performed. Fite stain is done to demonstrate leprae bacilli.

Tuberculoid (TT) Leprosy

- **Well-formed noncaseating epithelioid cell granulomas:** Skin biopsy from patient with tuberculoid leprosy shows discrete noncaseating epithelioid cell granulomas surrounded by zone of lymphocytes. Langhans' giant cells are demonstrated.
- **Absence of grenz zone (clear zone):** There is absence of clear zone at the junction of epidermis and dermis in tuberculoid leprosy. Clear zone is demonstrated in lepromatous leprosy.
- **Perineural inflammation:** Histopathologic examination of dermal nerve twigs shows infiltration by lymphocytes and macrophages, which indicates destruction of nerves responsible for sensory loss.
- **Fite stain:** *Mycobacterium leprae* is usually negative on Wade-Fite stain.

Lepromatous Leprosy (LL)

- **Epidermis and dermis:** Epidermis shows atrophy. There is loss of rete ridges of epidermis. Dermal papillae are flattened. There is loss of dermal appendages.
- **Grenz zone (clear zone):** Clear zone is demonstrated at the junction of epidermis and dermis in lepromatous leprosy.
- **Foamy macrophages:** Dermis shows collection of macrophages arranged in nodular or diffuse patterns.
- **Fite stain:** Macrophages in dermis are laden with *Mycobacterium leprae* on Wade-Fite staining.

TREATMENT

Many different agents available for treating leprosy. According to currently WHO recommendations, leprosy is treated based on tuberculoid or lepromatous leprosy:

- **Tuberculoid leprosy:** Dapsone 100 mg daily and rifampicin 600 mg monthly for 6–9 months are administered in these patients.
- **Lepromatous leprosy:** Dapsone 100 mg daily; clofazimine 150 mg, and rifampicin 600 mg monthly for 12–18 months are administered in these patients.

SPIROCHETES

Spirochetes are gram-negative, motile, spiral bacteria, which have axial filaments depending on the species. These cause syphilis. Lyme disease, relapsing fever and leptospirosis. Most of the spirochetes are characterized by their distinct shapes and unique motility.

SYPHILIS

Syphilis is a systemic bacterial disease caused by *Treponema pallidum* affecting persons across world. *Treponema pallidum* is the only organism that causes venereal disease transmitted through sexual contact, anogenital and orogenital contact.

- Primary and secondary syphilis during pregnancy lead to neonatal infection and adverse pregnancy outcomes if not timely treated. Vertical transmission occurs via transplacental route resulting in congenital syphilis. Sir Jonathan Hutchinson from England described a triad in late congenital syphilis consisting of notched incisors, interstitial keratitis and eighth cranial nerve deafness.
- The infection progresses through four stages that can affect many organs. There are many histopathologic features of syphilis such as interstitial chronic inflammatory lymphoplasmacytic infiltrate, endothelial swelling, irregular acanthosis, elongated rete ridges. Methenamine silver stain can detect spirochetes at any site in 30–70% of cases. Immunohistochemistry

has a sensitivity of 70% of accuracy in identification of the *Treponema pallidum*.

- Fortunately, spirochete *Treponema pallidum* is still sensitive to penicillin. The organism has a rich outer phospholipid membrane and slow metabolic rate as it takes an average of 30 hours to multiply.
- Syphilis is an important synergistic infection for human immunodeficiency virus (HIV) acquisition and has been closely linked with HIV. Untreated cases affect the course of HIV infection with higher virus replication and lowers CD4+ helper T cells counts and a rapid progression to late syphilis.

Pathophysiology

Treponema pallidum is a very tiny organism that is not visible on light microscopy. Thus, it can be identified by its distinct spiral movements on darkfield microscopy. The organism cannot survive outside the body.

Primary Syphilis

Patient presents with a solitary nontender genital chancre in response to invasion by the *Treponema pallidum*. However, patient can have multiple nongenital chancres on digits, nipples, oral mucosa and tonsils accompanied by nontender lymphadenopathy. The lesion primary syphilis may heal by scarring without scarring.

Secondary Syphilis

After 3–12 weeks from the resolution of a chancre, untreated primary syphilis can progress to secondary syphilis via hematogenous dissemination of the spirochetes, which has many clinical and histopathologic findings.

- Patient presents with condylomata lata (papulosquamous eruptions with central surface and a white ring of a scaling edge known as Biett's collarette) on hands and feet, macular rash and lymphadenopathy, headache, myalgia, malaise, arthralgia, pharyngitis, alopecia, and hepatosplenomegaly.
- The secondary lesion in secondary syphilis may heal without scarring. The infection can be detected at this stage with serological testing.

Tertiary Syphilis

Untreated patients in secondary syphilis stage progress to the tertiary syphilis stage, characterized by irreversible cardiovascular syphilis, neurosyphilis and latent benign syphilis. The incubation period is about 20–90 days.

- **Cardiovascular syphilis:** Cardiovascular syphilis can manifest as syphilitic aortitis, aortic valve regurgitation, cardiomegaly **'cor bovinum',** carotid **ostial stenosis** and granulomatous lesions (gummas) in various organs.
- **Meningovascular syphilis (neurosyphilis):** *Treponema pallidum* does not invade the central nervous system early, but symptoms appear late in tertiary syphilis, neurosyphilis can manifest as meningitis, cerebral stroke, cranial nerve palsies during early neurosyphilis or tabes dorsalis, dementia, general paresis during late neurosyphilis.
- **Latent benign syphilis:** It is the stage at which there are no clinical signs of syphilis and the cerebrospinal fluid is normal. Latent benign syphilis begins when the first attack of secondary syphilis passed and that persists for lifelong, which is usually detected by reactive serologic tests for syphilis.

Congenital Syphilis

Congenital syphilis occurs if *Treponema pallidum* spirochete is transmitted from the mother to the fetus. If vertical transmission of infection occurs within the first trimester of pregnancy, the consequences may be premature delivery, spontaneous abortion, stillbirth, nonimmune hydrops or perinatal mortality. If vertical transmission of infection during second to third trimesters of pregnancy, newborns appear healthy and develop clinical manifestations months to years later. Thus, congenital syphilis may be differentiated in early congenital syphilis (clinical manifestations ≤2 years of age) or late congenital syphilis (clinical manifestations ≥2 years of age).

- **Early congenital syphilis:** Clinical manifestations of early congenital syphilis include skin exfoliative rash (pemphigus syphiliticus), splenomegaly, lymphadenopathy, condylomata lata, chorioretinitis, cataracts, periostitis, osteochondritis, nephrotic syndrome, myocarditis, pancreatitis, malabsorption syndrome and hypopituitarism (diabetes insipidus).
- **Late congenital syphilis:** Clinical manifestations of late congenital syphilis include Hutchinson's triad (i.e. notched teeth, Mulberry molar teeth, interstitial keratitis), healed chorioretinitis, intellectual disability, hydrocephalus, seizures, optic nerve atrophy, cranial nerve palsies, juvenile general paresis, frontal bossing, saddle nose deformity, protuberant mandible, short maxilla, high palatal arch, saber shin, sternoclavicular joint thickening (Higouménakis' sign) and Clutton joints (swelling of synovial membrane).

Prognosis

Prognosis of syphilis depends on the stage and extent of organ involvement. Untreated cases have significant

morbidity and mortality. These patients usually develop cardiovascular syphilis and neurosyphilis, which can be fatal. Congenital syphilis is associated with miscarriage, stillbirth and fulminant pulmonary hemorrhage in neonates. Without treatment during pregnancy, syphilis is almost always transmitted to the fetus.

LYME DISEASE

Lyme disease is caused by four main species of bacteria *Borrelia burgdorferi* and *Borrelia mayoni* cause Lyme disease in the United States while *Borrelia afzelii* and *Borrelia garinii* cause Lyme disease in Europe and Asia. Lyme disease is transmitted by the bite of an infected black-legged tick, commonly known as a deer tick. Disease is more common in persons, who spend time in grassy and heavily wooded regions where blacklegged ticks bite the persons to cause Lyme disease.

Clinical Features

Initially patient presents with skin rash (erythema migrans) within 3–30 days after tick bite, fever, chills, fatigue, body aches, headache, neck stiffness, and lymphadenopathy. Skin rash may expand and attain 30 cm in size. Untreated cases develop symptoms within weeks to months such as skin rash (erythema migrans) on the other regions of body, migratory severe joint pain and swelling and neurological symptoms (e.g. meningitis and Bell's palsy).

Complications

Untreated Lyme disease can cause arthritis of the knee, neurological symptoms such as facial palsy and neuropathy, cardiac arrhythmia and cognitive defects such as impaired memory.

ANAEROBIC BACTERIA

Anaerobic bacteria do not grow in the presence of oxygen, which are most commonly found in gastrointestinal tract. They play a key role in pathogenesis of appendicitis, diverticulitis and perforation of the bowel. Anaerobes are classified as facultative, microaerophilic and obligate types.

- Facultative anaerobes preferentially utilize oxygen as terminal electron acceptor and metabolize in the absence of oxygen by reducing other compounds.
- Microaerophilic anaerobes can only proliferate in low concentration of oxygen (2–10%).
- Obligatory anaerobes are completely incapable of aerobic metabolism but they are variably tolerant to oxygen.

ANAEROBIC BACTERIAL ABSCESSES

Anaerobes can cause a perirectal abscess or facial abscess in children, or dental abscess.

- **Brain abscess:** Anaerobes are commonly isolated from brain abscesses, which result from a complication of sinusitis, otitis media and dental infections. Anaerobes commonly isolated are Fusobacterium, Bacteroides and Prevotella.
- **Intra-abdominal abscess:** It is caused by mixed anaerobic and aerobic organisms. Perforated appendix gives enteric anaerobic abscess leading to peritonitis. The common anaerobic bacteria implicated in abdominal infections are Bacteroides, Lactobacillus and *Clostridium* species.
- **Liver abscess:** The common anaerobic bacteria implicated in liver abscess include Bacteroides and *Fusobacterium* species.
- **Pelvic inflammatory disease:** Anaerobic bacteria are implicated in pelvic inflammatory disease (PID). Common anaerobe bacteria implicated in pelvic inflammatory disease are Prevotella, *Clostridium* species and Porphyromonas.
- **Pulmonary infections:** Pulmonary infections are common in children, who lack normal cough reflex, or they suffer from cerebral palsy and tracheoesophageal malformations. Aspiration results in pneumonia, which can develop into pulmonary abscess if untreated. The predominant pathogens involved in aspiration pneumonia are part of the oropharyngeal flora such as Fusobacterium, *Bacteroides fragilis* and Prevotella and Peptostreptococcus.
- **Skin and soft tissue infections:** Anaerobic bacteria can cause perirectal abscess or facial abscess in children. Perirectal abscess is caused by *Bacteroides fragilis* and *Clostridium* species. Oral infections are caused by Prevotella, Porphyromonas and Fusobacterium.

CLOSTRIDIAL INFECTIONS

Life-threatening soft tissue infections are caused by anerobic bacteria *Clostridium* species found in soil, which enter the human body via punctured wounds. Clostridium bacteria produce spores that can survive in the environment for a very long time and can cause diseases in human beings such as tetanus (*Clostridium tetani*), botulism (*Clostridium botulinum*) and **gas gangrene** (*Clostridium perfringens*).

Tetanus (Clostridium Tetani)

Tetanus is an infection caused by bacterium called *Clostridium tetani*. The incubation period is usually

between 3 and 21 days (average 10 days). Most cases acquire tetanus within 14 days of wound contaminated by *Clostridium tetani*. In general, tetanus has shorter incubation period due to heavily contaminated wounds, which is linked to serious disease with fatal outcome.

Mode of Transmission

Spores of *Clostridium tetani* are present in the environment such as soil, dust and manure. The spores can enter the body from contaminated objects through broken skin such as punctured wounds, burns, crush injuries, scraping of superficial wounds, surgical procedures, compound fractures and intravenous drug addicts. The spores of *Clostridium tetani* develop into bacteria.

Clinical Features

Clostridium tetani produce toxin that causes painful skeletal muscle contractions. The most common initial sign is spasms of the muscles of neck and jaw resulting in 'lockjaw' of patients.

- Patient presents with jaw cramping, sudden involuntary muscle spasms, painful skeletal muscle stiffness all over the body, difficulty in swallowing, jerking or seizures, headache, fever, sweating, changes blood pressure and tachycardia.
- Vaccines are recommended to infants, children, adolescents and adults to prevent tetanus.

Botulism (Clostridium Botulinum)

Clostridium botulinum is an anaerobic, rod-shaped spore forming bacterium, which synthesizes and releases potent neurotoxin (eight distinct toxins designated types A through H) that can cause food poisoning 'botulism' arising from improperly sterilized food products. Botulism is classified into various types: (a) food-borne botulism is associated with home-canned or fermented foods, (b) infant botulism is associated with honey ingestion, (c) wound botulism is associated with injection drug use of black-tar' heroin, (d) iatrogenic botulism occurs due to use of botulism toxins A and B for therapeutic and cosmetic purpose, and (e) botulism is a potent bioterrorism agent deployed by aerosol or ingestion.

Clinical Features

More than 90% of patients with botulism have 3–5 of the following signs and symptoms such as nausea, vomiting, dysphagia, skeletal muscle weakness, difficulty in breathing, diplopia (double vision), blurred vision, drooping of eyelids, dilated/fixed pupils, difficulty in moving eyes, and an extremely dry mouth.

Laboratory Diagnosis

Presumptive diagnosis of botulism is based on clinical presentation such as acute onset of bilateral cranial neuropathies with symmetrical descending weakness.

- Mouse bioassay is gold standard for demonstration of botulinum toxin, in which patient samples are injected intraperitoneally. The presence of botulinum toxin results in rapid development of disease symptom such as skeletal muscle weakness and respiratory failure within 1–5 days.
- Culture of serum, stool and environmental samples requires strict anaerobic conditions. Characteristic electrophysiological study findings are suggestive of botulism.

Gas Gangrene (Clostridium Perfringens)

Clostridium perfringens synthesizes and releases exotoxin that can cause gas gangrene (also called clostridial myonecrosis), enteritis necroticans and food poisoning in human beings.

Pathogenesis

As *Clostridium perfringens* grows inside the body, it produces gas and toxin that can damage body tissue cells and blood vessels. Gas gangrene develops suddenly at the site of trauma following surgery, most often in the gastrointestinal tract or biliary tract and following aseptic abortions. *Clostridium perfringens*, *Clostridium septicum* and *Clostridium histolyticum* are the principal causes of trauma-associated gas gangrene especially during wars, hurricanes, earthquakes and mass-casualty conditions.

Clinical Features

Gas gangrene can occur anywhere on the body, which most commonly affects arms or legs. Patient presents with fever, tachycardia, and air under the skin. The skin in the affected becomes pale and later changes to dark red or purple. These symptoms usually develop 6–48 hours after initial infection with *Clostridium perfringens* and progress rapidly.

Treatment

Patients are treated by administration of antibiotics and surgical removal of dead tissue. Surgery consists of debridement and sometimes amputation.

OBLIGATE INTRACELLULAR BACTERIA

Obligate intracellular bacteria cannot live outside the host cell. Examples of obligate intracellular bacteria are *Chlamydia trachomatis* and *Rickettsia*. Chlamydial cells are unable to carry out energy metabolism and lack biosynthetic pathways and therefore are dependent on

the host cell to supply them with adenosine triphosphate (ATP) and other intermediate products. The rickettsia is found in ticks, fleas, mites and mammals.

CHLAMYDIAL INFECTIONS

Chlamydia disease is sexually transmitted infection caused by bacterium *Chlamydia trachomatis* in men and women. Many persons, who have Chlamydia, do not develop symptoms, but they can still infect others through sexual contact. Untreated cases can develop serious complications later.

- *Chlamydia trachomatis* infection in women may induce genital pain, discharge from vagina, trachoma, lymphogranuloma venereum, cervicitis, salpingitis and pelvic inflammatory disease. On the contrary, men present with burning sensation during urination, yellow or green discharge from the penis, pain in lower abdomen and pain in the testes.
- *Chlamydia trachomatis* is treated by azithromycin in single dose. Doxycycline antibiotic is administered twice daily for about one week.

RICKETTSIAL INFECTIONS

Rickettsial infections are caused by unusual bacteria that can live and multiply only inside the cells of host and cannot survive on their own in the environment. Many species of these bacteria live in human beings, rats, cattle, sheep and goats. Most of Rickettsial infections are transmitted through bite of ticks, mites, fleas, or lice. Each species of rickettsiae and Rickettsia-like bacteria has its own host and usually vectors. Some of these bacteria occur across world.

- Human beings are the usual host for *Rickettsia prowazekii*, which causes epidemic typhus. Hosts may or may not be ill from the infection.
- Some of these bacteria infect vascular endothelial cells of small blood vessels causing occlusion or bleeding into the surrounding tissue.
- *Coxiella burnetii* reside in cattle, sheep or goats, which cause Q fever, which can be transmitted through the air or in contaminated food and water. The bacteria do not require a vector. Patient presents with severe headache and skin rash. The patients are treated by antibiotics.

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever is a bacterial infection caused by *Rickettsia rickettsii* and transmitted by a tick. The disease is most prevalent in Southeastern part of the United States and other parts of Canada, Mexico, Central America and South America.

- Initially patient presents with severe headache, high-grade fever, chills, muscle aches, nausea, vomiting, confusion and neurological symptoms. A few days later, a red, nonpruritic skin rash appears on the wrists and ankles.
- Rocky Mountain spotted fever responds to prompt treatment with antibiotics. Untreated cases can cause serious damage smallest blood vessels to internal organs such as heart, lungs, kidneys, brain.
- In addition to severe headache, it can cause encephalitis, which can cause confusion, seizures and delirium.
- It can cause inflammation of heart and lungs leading to cardiopulmonary failure in severe cases.
- It can damage small blood vessels supplying kidneys leading to renal failure.
- It can damage small blood vessels supplying fingers and toes. Amputation of fingers and toes would then be necessary. About 80% of untreated cases, who have fatal outcome.

Epidemic Typhus

Epidemic typhus is potentially lethal, louse-borne disease caused by *Rickettsia prowazekii*. Disease has also been called camp fever, jail fever, and war fever that occurs due to overcrowding and improper sanitation. Patient presents with prolonged high-grade fever, chills, intractable headache, rapid breathing, body and skeletal muscle aches, maculopapular rash, cough, nausea, and vomiting.

Ehrlichiosis

Ehrlichiosis is caused by several forms of the bacterium, which affects human beings through the bite of tick on skin surface. Rarely, blood transfusions or organ transplants infected with the bacterium have caused ehrlichiosis. Without treatment, this infection may cause serious complications.

- Patient develops symptoms a week or more after an infected tick bites a person. Severity of disease varies from mild to severe.
- Patient presents with flu-like symptoms such as fever, chills, muscle aches, skin rash, fatigue, diarrhea, nausea, vomiting, headache, confusion and red eyes (more in children).
- Severe ehrlichiosis may cause seizures, breathlessness, organ failure and superinfections from viruses and fungi. Patients are diagnosed by taking careful history, physical examination, biochemical tests and hemogram.

Anaplasmosis

Anaplasmosis is a disease caused by the bacterium *Anaplasma phagocytophilum* transmitted by tick bites

primarily from the blacklegged tick (*Ixodes scapularis*) and the Western blacklegged tick (*Ixodes pacificus*). Patient presents with fever, headache, chills and muscle aches within 1–2 weeks after the bite of an infected tick.

- Tick bites are usually painless. Persons with anaplasmosis will initially present with fever, chills, headache, skeletal muscle aches, nausea, vomiting, loss of appetite and diarrhea.
- Later, these patients can develop severe illness such as respiratory failure, organ failure, bleeding tendencies and fatal outcome.

Q Fever (Coxiella Burnetii) Infection

Q fever is a disease caused by the bacterium *Coxiella burnetii*, which is usually as mild disease with flu-like symptoms. Many persons remain asymptomatic. However, in a small percentage of persons, the infection can resurface years later.

- Patient presents with fever, chills, sweats, fatigue, headache, skeletal muscle aches, nausea, vomiting, diarrhea, chest pain and pain in gastric region.
- Q fever is diagnosed by indirect immunofluorescence antibody using *Coxiella burnetii* antigen to demonstrate a significant rise of antibody titer.

VIRAL INFECTIONS

VIRAL INFECTIONS:OVERVIEW

Viruses are infectious particles lacking organelles. A virus particle comprises nucleic acid core either DNA or RNA and not both and is surrounded by a protein shell, or capsid. Combination of nucleic acid and capsid is called **nucleocapsid**. Depending on the viral morphology, viruses can be categorized into complex, enveloped or naked. Basic types of viral morphology may be complex, enveloped or naked given in Table 7.18. Important human DNA and RNA virus-induced diseases are given in Table 7.19.

Table 7.18 Basic types of viral morphology

Basic Type of Virus	Examples
Complex viruses	▪ Poxvirus (large DNA virus) ▪ Flexible-tailed bacteriophage
Enveloped viruses	▪ With a helical nucleocapsid (e.g. mumps virus and rhabdovirus) ▪ With an icosahedral nucleocapsid (e.g. herpesvirus and HIV)
Naked viruses	▪ Helical capsid (e.g. plum poxvirus) ▪ Icosahedral capsid (e.g. poliovirus and papillomavirus)

Table 7.19 Important human DNA and RNA virus-induced diseases

Common Name of Genus Members	Name of Disease
DNA viruses	
Variola	Smallpox
MCV1 and MCV2	Molluscum contagiosum
Herpes simplex 1 (HSV-1)	Fever, blister, cold sores
Herpes simplex 2 (HSV-2)	Genital herpes
Varicella-zoster virus	Chickenpox
Human cytomegalovirus	CMV infections
Human adenovirus	Adenovirus infections
Human papillomaviruses	Several types of warts
JC virus (human polyomavirus 2)	Progressive multifocal leukoencephalopathy
Hepatitis B virus (HBV or Dane particle)	Serum hepatitis
Parvovirus B19	Erythema infectiosum (slapped cheek syndrome)
RNA viruses	
Poliovirus	Poliomyelitis
Coxsackievirus	Hand-foot-mouth disease
Hepatitis A virus	Short-term hepatitis
Human adenovirus	Common cold, bronchitis

Contd...

Table 7.19 Important human DNA and RNA virus-induced diseases (*Contd...*)

Common Name of Genus Members	Name of Disease
Norwalk virus	Viral diarrhea, Norwalk vial syndrome
Yellow fever virus	Yellow virus
Rubella virus	Rubella (German measles)
Dengue fever virus	Dengue
Ebola Marburg virus	Hemorrhagic fever
Human rotavirus	Rotavirus gastroenteritis
Influenza type A virus	Influenza or flu
Mumps virus	Mumps
Measles virus	Measles
Rabies virus	Rabies (hydrophobia)
Human T cell leukemia virus (HTLV)	T cell leukemia
HIV (human immunodeficiency virus 1 and virus 2)	Human immunodeficiency syndrome (AIDS)
SARS virus	Severe acute respiratory syndrome

Clinical Pearls: Viral Infections—Clinical Course

Depending on clinical course of viral diseases, viral infection can be acute, persistent and transforming viral infections.

Acute (Transient) Viral Infection

An acute viral infection is characterized by rapid onset of disease (common flu, respiratory tract infection), which persists for a brief period and resolves within days.

Persistent Viral Infection

Persistent viral infections occur when the virus is not cleared but remains in specific cells of infected persons. Persistent viral infections may involve stages of both silent and productive infection without rapidly fatal disease or even producing excessive damage of the host cell. There are three types of overlapping persistent virus–host interaction that may be defined as latent, chronic and slow viral infection.

- **Latent viral infection:** A latent viral infection occurs when the virus persists in the body in dormant or inactive state and does not replicate within the host.
- **Chronic viral infection:** Chronic viral infection underlies important diseases that either follow directly from primary infection or may require months, years, or even decades to develop. Pathogens associated with significant disease include hepatitis C virus, human immunodeficiency virus (HIV) and a number of herpesviruses.
- **Slow viral infection:** Slow viral infection is characterized by a prolonged incubation period followed by progressive disease.

Transforming Viral Infection

Transforming viral infections are also referred to as malignant tumor-forming viruses, which can be either cytotoxic (usually in the case of RNA viruses) or persistent (usually in the case of DNA viruses). Integration of HBV (hepatitis B virus), HPV (high-risk human papillomavirus) and MCV (Merkel cell polyomavirus) into the human genome induces cellular and viral responses and further contributes to carcinogenesis.

- **Hepatitis B virus (HBV):** HBV integrates into the host genome that results in elevated expression of cellular cancer-related genes such as TERT (telomerase reverse transcriptase), MLL4 (mixed-lineage) and CCNE1. Integrated HBV sequences encode HBx and/or truncated envelope pre-S2/S proteins. These cellular alterations cause genomic instability and cell cycle deregulation contributing to carcinogenesis.
- **Human papillomavirus (HPV):** HPV integrates into the host genome that results in disruption of E2 resulting in significantly increased expression of the E6 and E7 oncoproteins. These cellular alterations cause deregulated cellular proliferation, inhibition of apoptosis, and increased genomic instability.
- **Merkel cell polyomavirus (MCV):** MCV integrates into the host genome that results in clonal expansion of tumor cells contributing to Merkel cell carcinoma.

PATHOGENESIS

Virus enters human cell leading to formation of complete viral particles. Enveloped virus attaches to its host cell by specific binding of its spikes to cell receptors.

- The virus is engulfed into a vesicle leading to uncoating of its envelope and freeing the virus RNA into the cell's cytoplasm.
- Under the control of viral genes, the cell synthesizes the basic components of new viruses such as RNA molecules, capsomers and spike proteins. Nucleocapsid is formed from RNA and capsomers.
- Enveloped virus is released by budding of the cell membrane carrying away an envelope with spikes. This released complete virus is ready to infect another human cell.
- Released virus infects another human cell and induces cytopathic changes. Viral cytotoxicity is either direct or immunologically mediated.

- Major events in the multiplication cycle of an enveloped RNA virus in human are shown in Fig. 7.40. Cytopathic changes in selected virus infected cells are given in Table 7.20.

PROTECTION OF CELLS AGAINST VIRUSES

Both humoral and cellular arms of the immune system protect against the harmful effects of viral infections. Presentation of viral proteins to immune

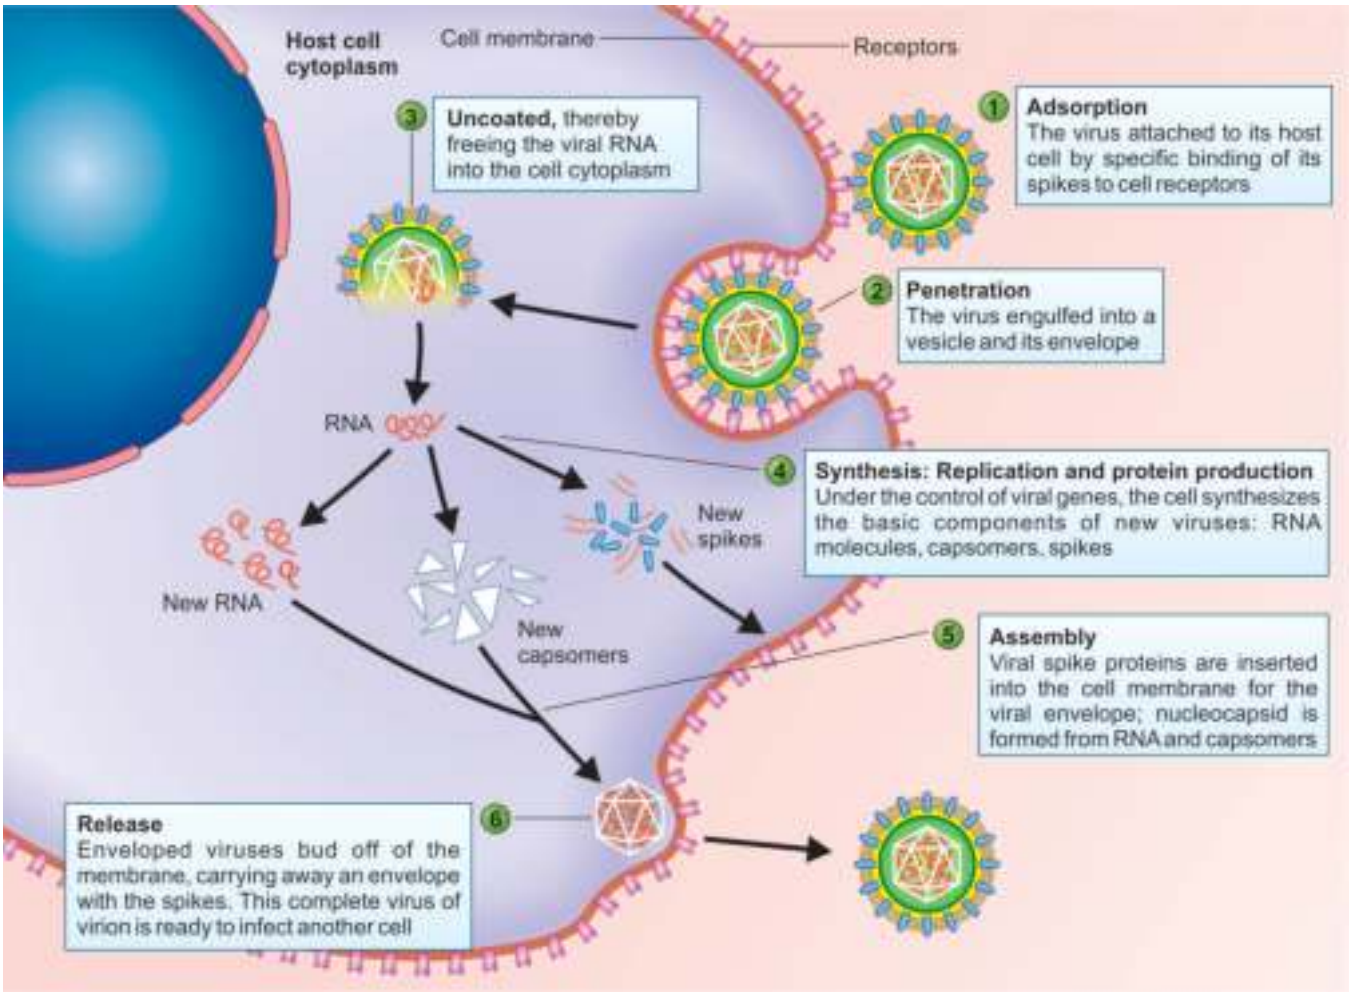

Fig. 7.40: Major events in the multiplication cycle of an enveloped RNA virus in human.

Table 7.20 Cytopathic changes in selected virus infected cells

Virus	Shape of Cell	Inclusions in Cytoplasm or Nucleus
Smallpox virus	Cell round	Cytoplasm
Herpes simplex virus	Cells fuse to form multinucleated syncytium	Nucleus
Adenovirus	Clumping of cells	Nucleus
Poliovirus	Cell enlarged	Absent
Influenza virus	Cell round	Absent
Rabies virus	No change in cell shape	Cytoplasm (Negri bodies)
Measles virus	Multinucleated cell forming syncytium	Absent
Cytomegalovirus	Cell enlarged	Nucleus (owl eye inclusion)

system immunizes the body against the invader and elicits natural killer cells and production of antiviral antibodies. Humoral and cellular arms of the immune system eliminate virus-infected cells by either inducing apoptosis or directing complement-mediated cytolysis.

RNA VIRUSES

RNA virus contains single-stranded RNA and double-stranded RNA as its genetic material. RNA viruses have high mutation rates when compared to DNA viruses, because viral RNA polymerases lack the proofreading ability of DNA polymerases.

- The genetic diversity of RNA viruses is the main reason why it is difficult to prepare effective vaccine against them.
- Human diseases caused by RNA viruses include hepatitis C virus, Ebola virus, Marburg virus. Severe acute respiratory syndrome (SARS) caused by coronavirus, influenza, polio, measles, orthomyxovirus, retrovirus including adult human T cell lymphotrophic type 1 (HTLV-1) and human immunodeficiency virus (HIV).

SEVERE ACUTE RESPIRATORY SYNDROME CORONAVIRUS 2 (SARS-COV-2) FOR COVID-19 PANDEMIC

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is the pathogen responsible for the coronavirus disease 2019 (COVID-19) disease across world, which has resulted in global healthcare crises and strained health resources. COVID-19 disease is now recognized as a multiorgan disease with a broad-spectrum of clinical manifestations.

- The spike protein (S) plays a key role in the receptor recognition and cell membrane fusion. The spike protein (S) of SARS-CoV-2 is composed of two subunits, S1 (receptor-binding domain) and S2 (viral cell membrane fusion domain). Most persons experience mild-to-moderate respiratory illness and recover without requiring special medical treatment.
- Elderly persons and those with underlying medical illness like diabetes mellitus, cardiovascular disease, chronic respiratory diseases, and cancer are more prone to develop serious illness.
- COVID-19 disease spreads primarily through droplets of saliva or discharge from the upper respiratory tract when an infected person coughs or sneezes on the surfaces.
- Best way to prevent and slow down transmission of COVID-19 by avoiding contact with these infected patients and washing hands or using an alcohol-based rub and not touching face.

SARS-CoV-2 Virus Genomic Arrangement

Single-stranded RNA genome of SARS-CoV-2 virus has ~3000 nucleotides and consists of two large genes: ORF1a and ORF1b. SARS-CoV-2 virus encodes 16 nonstructural proteins (NSP1–NSP16) and four structural proteins: (a) nucleocapsid (N) protein, (b) membrane (M) protein, (c) envelope (E) protein, and (d) spike (S) protein. Schematic genomic representation of the SARS-CoV-2 virus is shown in Fig. 7.41.

Structural Proteins

Structural genes of the SARS-CoV-2 virus encode structural proteins: (a) nucleocapsid (N) protein, (b) membrane (M) protein, (c) envelope (E) protein and (d) spike (S) protein.

- **Nucleocapsid (N) protein:** SARS-CoV-2 virus nucleocapsid (N) is a structural protein that forms complexes with genomic RNA, which interacts with the viral membrane (M) protein during virion assembly and plays a pivotal role in enhancing the efficiency of SARS-CoV-2 virus transcription and assembly in host cells. Recent studies have confirmed that nucleocapsid (N) protein is a multifunctional protein.
- **Membrane (M) protein:** The membrane protein plays a key role in virus assembly, turning cellular membranes into workshops where SARS-CoV-2 virus and host factors come together to produce new virus particles.
- **Envelope (E) protein:** The envelope protein is a small, integral membrane protein involved in several aspects of SARS-CoV-2 virus life cycle such as assembly, budding, envelope formation, pathogenesis, and virus release.
- **Spike (S) protein:** Spike protein consists of the S1 subunit (14–685 residues) and S2 subunit (686–1273 residues), which are responsible for receptor binding and membrane fusion, respectively. Spike protein is located on the surface of envelope by which spike protein binds to the receptor. S1 domain contains the RBD, which is mainly responsible for binding of the receptor on host cell, while S2 domain mainly contains the HR domain, including HR1 and HR2, which is closely related to virus.
  - **S1 subunit of spike protein:** The binding of SARS-CoV-2 virus particle with the help of spike protein S1 subunit to the cell ACE2 receptors on the surface of the host cell distributed on lung (alveolar type 2), heart and intestine, that results in the formation of endosomes, which triggers viral fusion activity under low pH. Therefore, receptor is an important determinant of viral entry and a drug design target for therapy.

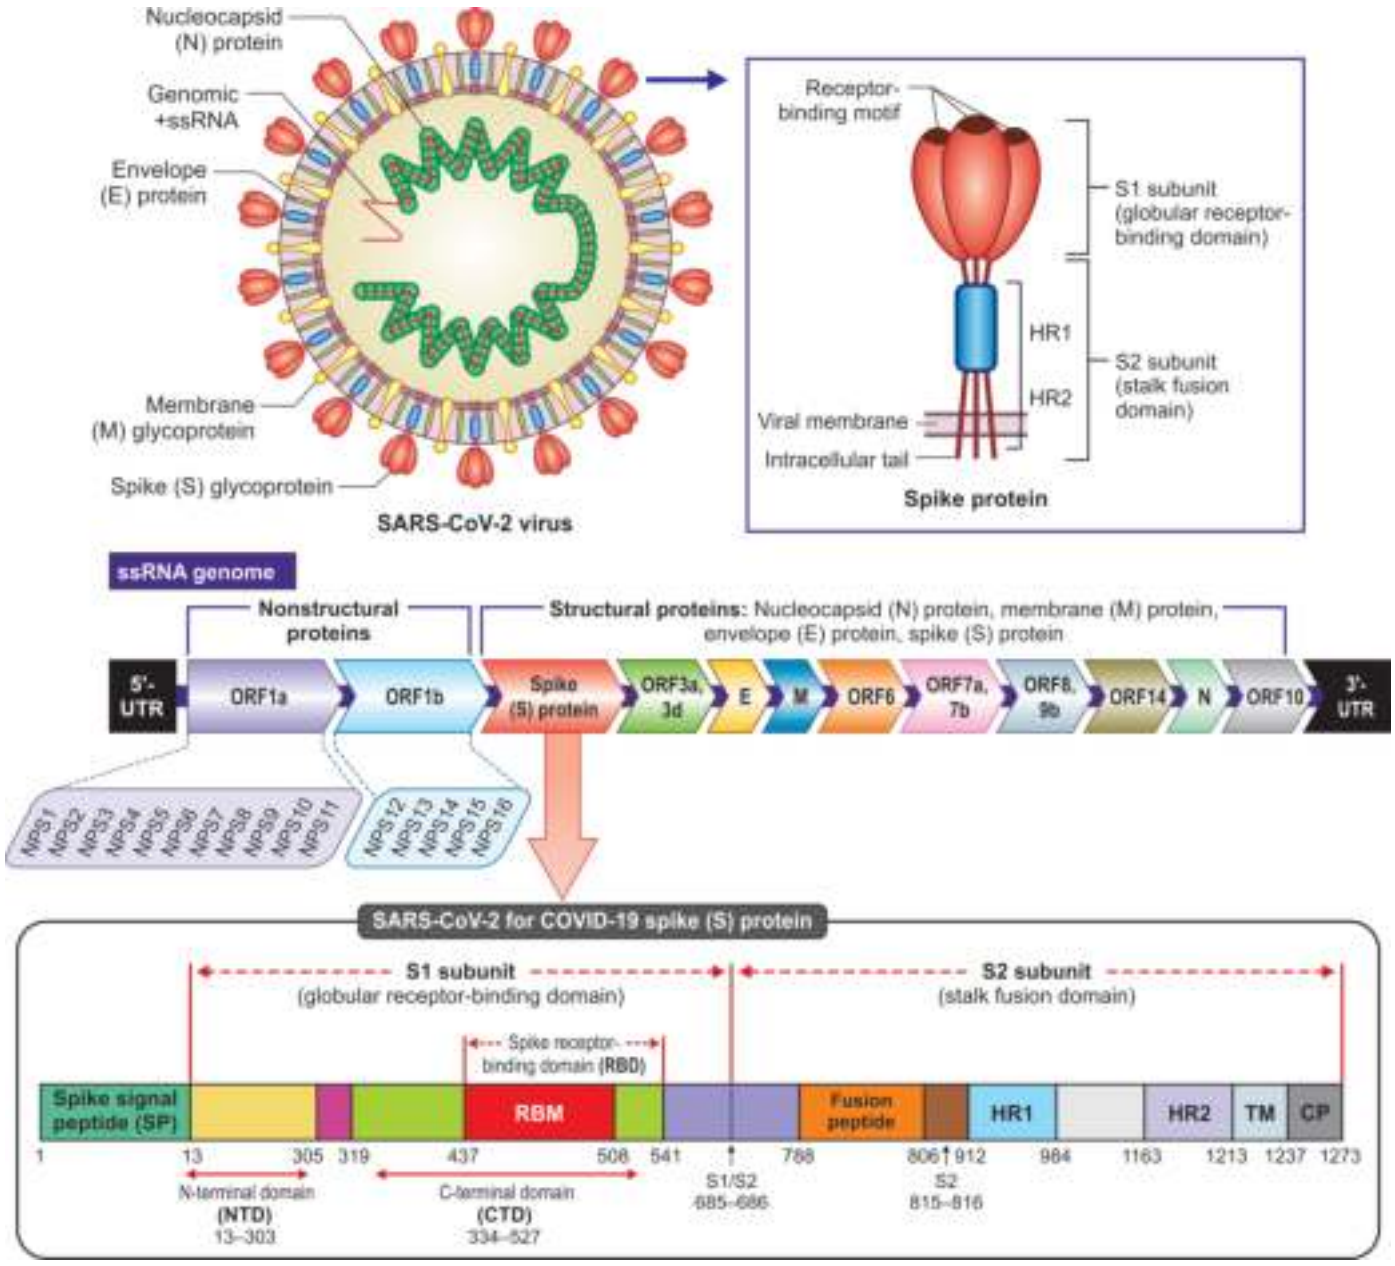

Fig. 7.41: Schematic genomic representation of the SARS-CoV-2 virus. The genomic organization of the SARS-CoV-2 demonstrates sequential arrangement of various structural, nonstructural and accessory genes as follows: 5'-cap-leader UTR-replicase spike (S), envelope (E), membrane (M), nucleocapsid (N)-3'UTR-poly(A) tail with accessory genes such as ORF3a, ORF3d, ORF6, ORF7a, ORF7b, ORF8, ORF9b, ORF14, and ORF10 interspersed among the structural genes preceding 3'end of the viral RNA genome. The spike (S) protein binds to the receptor ACE2 expressed on lung, heart and intestine, which mediates virus cell binding and its fusion with host cell fusion.

- **S2 subunit of spike protein:** Spike membrane S2 unit of virus is composed of a fusion peptide (FP), heptapeptide repeat sequence 1 (HR1), heptapeptide repeat sequence 2 (HR2), TM domain, and cytoplasmic domain fusion (CT) is responsible for viral fusion and entry.

Nonstructural Proteins (NSPs)

Apart from aforementioned structural proteins there are several nonstructural proteins in SARS-CoV-2 virus, namely NSP-1 to NSP-10 and NSP-12 to NSP-16 encoded by genes located within the 5'-region of viral RNA genome. Nonstructural proteins (NSPs) of severe acute respiratory distress syndrome (SARS)-CoV-2 virus for COVID-19 disease are given in Table 7.21.

Accessory Proteins

There are nine accessory proteins in SARS-CoV-2: ORF3a, ORF3b, ORF3d, ORF6, ORF7a, ORF7b and ORF8, ORF9b, ORF14 and ORF10 encoded by ORF

Table 7.21 Nonstructural proteins (NSPs) of severe acute respiratory distress syndrome (SARS)-CoV-2 virus for COVID-19 Disease

Nonstructural Proteins (NSPs)	Proteins	Comments
NSP1	N-terminal product of the viral replicase	SARS-CoV-2 NSP1, is also known as leader protein that binds the ribosomal mRNA channel to inhibit translation and also degrade host mRNA
NSP2	N-terminal product of the viral replicase	▪ NSP2 binds to two host proteins such as prohibitin 1 (PHB1) and prohibitin 2 (PHB2) and disrupts the host cell environment ▪ Normally, PHB1 and PHB2 play roles in cell cycle progression, cell migration, cellular differentiation, apoptosis and mitochondrial biogenesis
NSP3	Papain-like protease	NSP3 is responsible for release of NSP1, NSP2 and NSP3 from the N-terminal region of pp1a and pp1ab
NSP4	Membrane spanning protein containing trans-membrane domain 2	NSP4 plays key role in viral replication–transcription complex and helps modify endoplasmic reticulum membrane
NSP5	Proteinase	NSP5 cleaves at multiple distinct sites to yield mature and intermediate nonstructural proteins
NSP6	Putative transmembrane domain	▪ NSP6 generates autophagosomes from endoplasmic reticulum (ER) as well as double membrane vesicles ▪ Autophagosomes facilitate assemble of replicase proteins ▪ NSP6 limit autophagosome/lysosome expansion, which in turn prevents autophagosomes from delivering viral components for degradation in lysosomes
NSP7	RNA-dependent RNA polymerase	NSP7 is required to form a complex with NSP8 and NSP12 to yield the RNA polymerase activity of NSP8
NSP8	Multimeric RNA polymerase; replicase, single-stranded	NSP8 makes heterodimer with NSP8 and NSP12, which ultimately forms the RNA polymerase complex
NSP9	RNA-binding viral protein	NSP9 interacts with the DEAD-box RNA helicase 5 (DDX5) cellular protein and plays role in viral replication
NSP10	Growth factor protein consists of 13 amino acids and possesses two zinc-binding motifs	NSP10 interacts with NSP14 in SARS-CoV-2, which stimulates activity of NSP14
NSP11	Consists of 13 amino acids	Function unknown
NSP12	RNA-dependent RNA polymerase	NSP12 is the RNA-dependent RNA polymerase that copies viral RNA, which forms complex with NSP7-NSP8 and plays role in replication and methylation
NSP13	RNA-dependent RNA polymerase (RdRp)	▪ NSP13 has high concentration of ATP and has zinc binding domain involved in replication and transcription ▪ NSP13 possesses 5'-triphosphatase activity which is responsible for introducing the 5'-terminal caps of the viral mRNA
NSP14	3' to 5'-endonuclease, N7-methyltransferase	NSP14 has exoribonuclease activity acting in a 3'–5' direction and N7-guanine methyltransferase activity
NSP15	EndoRNAs; NSP15-A1 and NSP15-B-NeuroUEndoRNAase	NSP15 is Mn (2+)-dependent endoribonuclease activity
NSP16	2'-O-ribose-methyltransferase	NSP16 is methyltransferase that mediated mRNA cap 2'-O-ribose methylation to the 5'-cap structure of viral mRNAs

encoding accessory genes. These proteins along with above mentioned nonstructural proteins (NSPs) play important role in SARS-CoV-2 viral replication.

- **ORF3a and ORF3b proteins:** The accessory protein ORF3a of SARS-CoV-2 consists of 274 amino acid residues and is encoded by ORF3a located in between the spike (S) and envelope (E) genes.
  - The ORF3a accessory protein is an O-linked glycosylated possessing three transmembrane domains. ORF3a forms dimer and its six transmembrane

helices together create ion channel in the host cell membrane, which is highly conductive for Ca^{++}/K^{+} cations compared with Na^{+} ion. ORF3a also participates in the SARS-CoV-2 virus release, apoptosis and pathogenesis.
  - Similarly, ORF4d encodes ORF4d protein of SARS-CoV-2 which consists of 154 amino acids long polypeptide chain. ORF4d is located in the nucleolus and mitochondria.
- **ORF6 protein:** The accessory ORF6 protein is a long membrane associated protein comprising 61 amino acids located in endoplasmic reticulum (ER) and Golgi apparatus in virus infected host cells in lung and intestine of patients.
- **ORF7a and ORF7b proteins:** ORF7a and ORF7b accessory proteins are synthesized by SARS-CoV-2 bicistronic RNA-7. ORF7a protein is a type 1 of transmembrane protein, which consists of 15 amino acids signal peptide sequence, an 81-amino acid luminal domain, 21 amino acids transmembrane domain and a short C-terminal tail. On the other hand, ORF7b of SARS-CoV-2 consists of 44 amino acids, which is integral membrane protein expressed in virus infected host cells in the Golgi apparatus. Furthermore, patients develop anti-ORF7b antibody in their serum indicative of its expression in infected SARS-CoV-2 patients. In addition, ORF7b protein has been demonstrated to be closely associated with intracellular virus particles.
- **ORF8 protein:** ORF8 accessory protein of SARS-CoV-2 is encoded by ORF8 gene.
  - ORF8 protein consists of 121 amino acid residues. The 1–17 amino acid residues comprise N-terminal signal sequence, prerequisite for transport to endoplasmic reticulum (ER).
  - ORF8 has been demonstrated to interact with major histocompatibility complex I (MHC-I), thereby mediating their gradation in cell culture and therefore may help in immune evasion.
- **ORF9b protein:** ORF9b accessory protein of SARS-CoV-2 consists of 97 amino acid residues encoded by sgRNA of N gene. ORF9b protein tends to be associated with TOMP70 adaptor protein, which suppresses interferon 1 (INF-1)-mediated antiviral response. Analysis of ORF9b-IFN-1 interaction helps in designing therapeutic response.
- **ORF10 protein:** ORF10 accessory protein of SARS-CoV-2 is encoded by leaky scanning of sgRNA of N gene. ORF10 protein is detected in infected host cells.
- **ORF14 protein:** ORF10 accessory protein of SARS-CoV-2 is encoded by leaky scanning of sgRNA of N gene. ORF14 protein plays a key role in virus replication and evasion of virus from immune system. Researcher has demonstrated the association of ORF9b protein of SARS-CoV-2 to host mitochondrial import receptor subunit (TOMP70) and thereby suppresses type 1 interferon signaling.

Life Cycle of SARS-CoV-2

Life cycle of SARS-CoV-2 consists of invasion of virus into host cell, expression of viral genes, formation of progeny and eventual exit via exocytosis. Life cycle of virus can be divided into six steps: (a) attachment of SARS-CoV-2 to host cell surface ACE2 receptors, (b) SARS-CoV-2 fusion to host cell membrane, (c) viral penetration into host cell and uncoating, (d) replication–transcription complex (RTC) formation, (e) synthesis of viral RNA, and (f) molecular assembly and exit of SARS-CoV-2 through exocytosis. Schematic representation of life cycle of the SARS-CoV-2 in host cells is shown in Fig. 7.42.

Attachment of SARS-CoV-2 to Host Cell Surface

Life cycle of the SARS-CoV-2 begins by binding with the spike protein (RBD region of the S1 subunit mediating viral attachment to the host cells in the form of trimer) on the host cell ACE2 receptors expressed on nasal epithelium, lung alveolar type 2, kidney, heart and intestine. Nasal epithelium is one of the first sites of infection with SARS-CoV-2.
- The researchers probed for the expression of the cell surface enzyme angiotensin-converting enzyme 2 (ACE2), which have been proven to bind to SARS-CoV-2 spike (S) protein and promote internalization of the virus into the human cells.
- Numerous studies have highlighted the low-rates of SARS-CoV-2 infection and less severe symptoms in children compared with adults, it is because of to low expression of ACE2 receptors on the nasal epithelium in children.

Fusion of SARS-CoV-2 to Host Cell Membrane

Receptor binding of S1 subunit to ACE2 (angiotensin-converting enzyme 2) drives conformational change in the S2 subunit and thereby facilitating its fusion with the plasma membrane of the host cell resulting in release of the viral genome into the cell. Cleavage of the SARS-CoV-2 spike proteins S1 and S2 subunits is the basis of fusion. The spike protein is cleaved into two parts, the S1 subunit and S2 subunit, by host proteases, and the subunits exist if noncovalent form until viral fusion occurs.

Penetration of SARS-CoV-2 into Host Cell and Uncoating

After fusion of SARS-CoV-2 spike (S) protein with ACE2 receptors on host cells, there is subtle conformational alterations, releasing viral nucleocapsid (N) into the

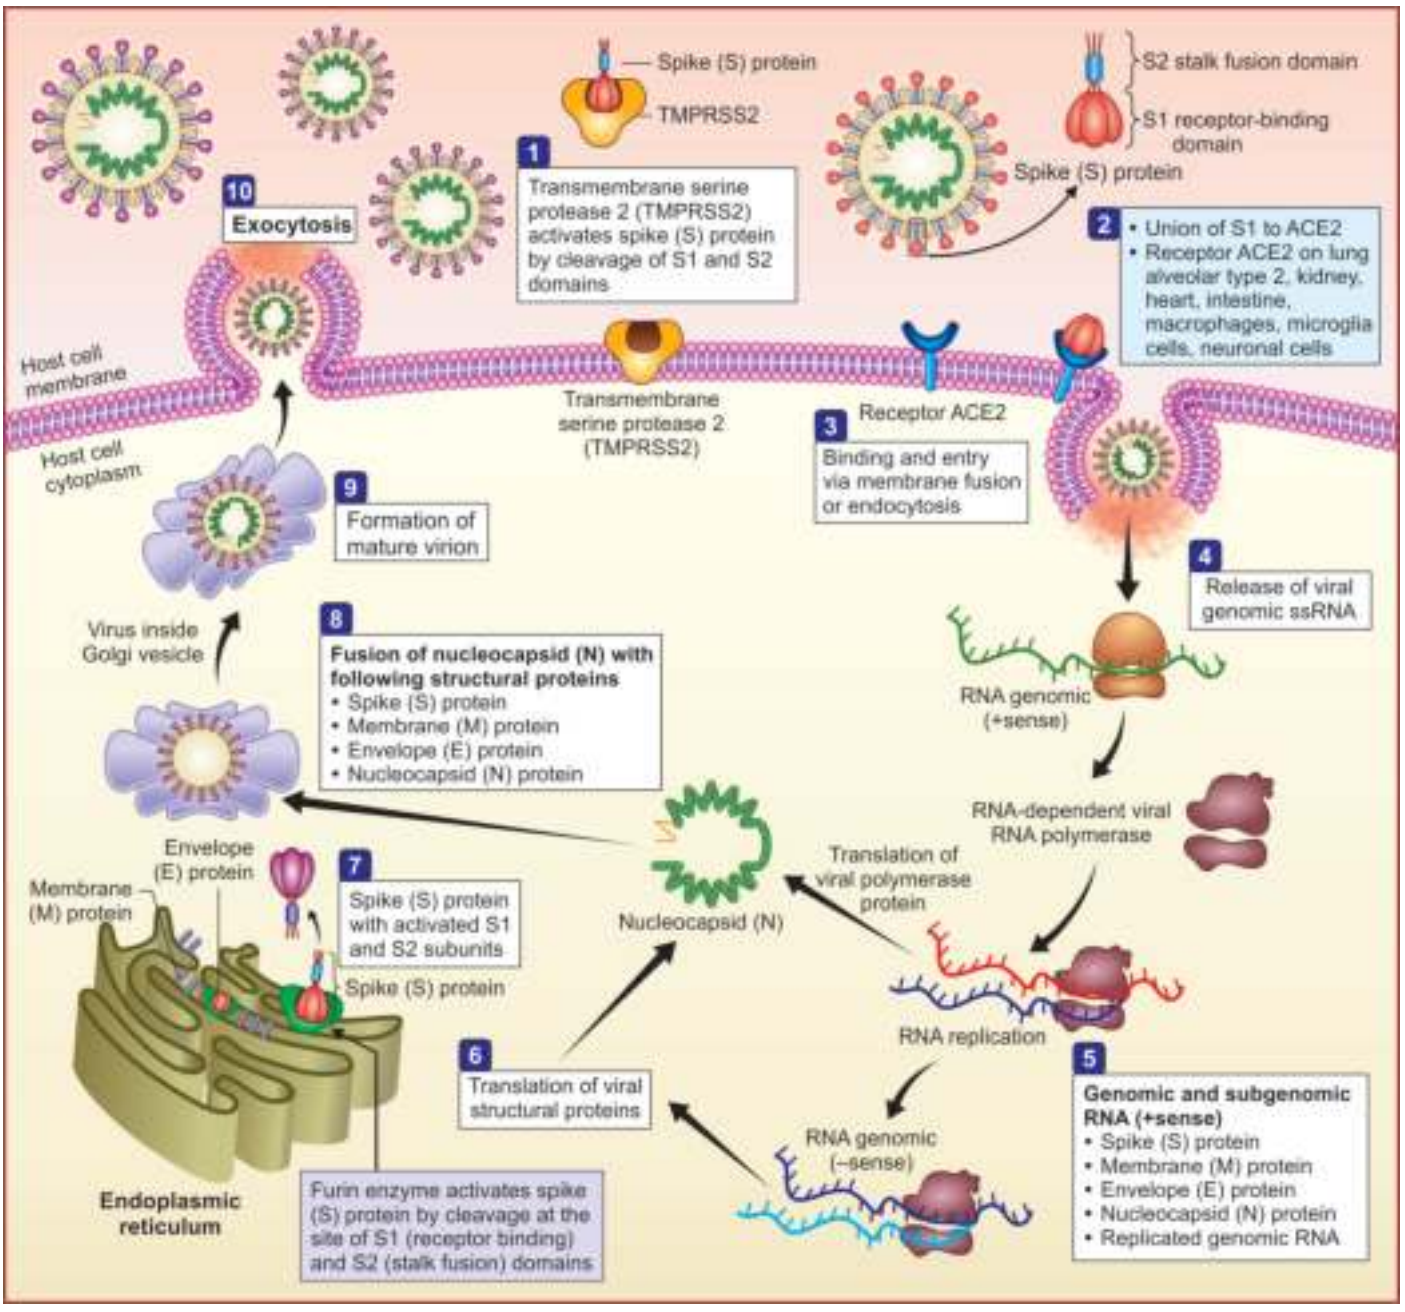

Fig. 7.42: Schematic representation of life cycle of the SARS-CoV-2 in host cells. Life cycle of virus can be divided into six steps: (a) attachment of SARS-CoV-2 to host cell surface ACE2 receptors, (b) SARS-CoV-2 fusion to host cell membrane, (c) viral penetration into host cell and uncoating, (d) replication–transcription complex (RTC) formation, (e) synthesis of viral RNA, and (f) molecular assembly and exit of SARS-CoV-2 through exocytosis.

host cell cytosol. This process is assisted by several host factors, including transmembrane, serine protease 2 (TMPRSS2) and cathepsin L.

Replication–Transcription Complex (RTC) Formation

Immediately, after release of viral nucleocapsid (N), single-stranded RNA (+ssRNA) serves as a functional messenger RNA (mRNA) with respect to ORF1a and ORF1b encoding **polyprotein pp1a** (440–500 kDA) and **pp1ab** (740–810 kDA) respectively.

- However, polyprotein pp1a is expressed more than pp1ab owing to differential efficiency of frameshift between ORF1a and ORF1b genes. These pp1a and pp1ab polyproteins undergo autoproteolytic cleavage yielding 16 nonstructural proteins (16 NSPs) which together form the 'replication–transcription complex' for viral RNA synthesis.
- This functional replication–transcription complex (**RTC**) leads to formation of a nested set of single guide RNA (**sgRNA**) via discontinuous transcription.

SARS-CoV-2 RNA Synthesis

The 'replication–transcription complex' sets molecular process in motion resulting in synthesis of multiple copies of SARS-CoV-2 virus into the host cell.

- The negative single-stranded RNA (**ssRNA**) serves as intermediate template, which is eventually replicated to form multiple copies of guide RNA (**gRNA**) as well as nested single guide RNA (**sgRNA**) by discontinuous transcription.
- Thereafter, they associate with ribosome that leads to synthesis of various structural and accessory proteins building multiple virus structure in the endoplasmic reticulum–Golgi intermediate compartment (**ERGIC**) and eventually exit cell via exocytosis.

Molecular Assembly and Virus Exit

Most of the structural and accessory proteins associated with membrane such as spike (S) protein, membrane (M) protein and envelope (E) protein are synthesized by endoplasmic reticulum (ER) bound ribosomes, whereas viral proteins, including nucleocapsid (N) protein, are translated by free cytosolic ribosomes of host cells.

- The structural (S) proteins also undergo post-translational modification that modulate their functions. Virions are assembled at endoplasmic reticulum–Golgi intermediate compartment.
- Membrane (M) protein interacts with other structural proteins, such as envelope protein (E) and facilitates virion morphogenesis.
- Further, membrane (M) protein–nucleocapsid (N) interactions mediate condensation of nucleocapsid (N) with the envelope (E) protein.
- Post-molecular assembly, progeny virions are transported in smooth-wall vesicle and using secretory pathway that are trafficked to plasma membrane of host cells eventually exit through exocytosis and spread to other regions of body.

Complications and Sequelae

Acute complications of SARS-CoV-2 usually persists until four weeks from the onset of symptoms affecting lungs, kidneys, heart and black fungal infection, known as mucormycosis.

- On the other hand, post-acute sequelae of SARS-CoV-2 is defined as persistent symptoms and/or long-term complications beyond four weeks from the onset of symptoms such as fatigue, dyspnea, chest pain, palpitations, muscular weakness, persistent oxygen requirement, anxiety/depression, sleep disturbances, cognitive disturbances, headache, arthralgia, thromboembolism, chronic renal disease, and alopecia; which adversely affect the quality of life.
- SARS-CoV-2 infection induces synthesis of inflammatory cytokines and procoagulant factors leading to cellular damage and sequelae. Therefore, holistic approach is essential for follow-up care and well-being of post-SARS-CoV-2 recovering patients. SARS-CoV-2 acute complications and sequelae in COVID-19 survivors are shown in Fig. 7.43.

Pathology Pearls: Severity of SARS-CoV-2 (COVID-19) Disease

Nonsevere Patients
