- Absence of signs of severe or critical disease
- Patients are managed by supportive measures

Severe Patients

- SpO_2 <90% on room air
- Respiratory rate >30 in adults
- Increased respiratory rate in children
- Signs of respiratory distress

Critically Ill Patients

- Patients require life-sustaining treatment
- Acute respiratory distress syndrome
- Sepsis
- Septic shock

Pulmonary Manifestations

Acute pulmonary complications of COVID-19 disease include pneumonia, acute respiratory distress syndrome (ARDS), dyspnea, decreased exercise capacity and hypoxia, pneumocyte damage and dyspnea, increased vascular permeability, thrombotic microangiopathy and oxygenation dysfunction.

- Follow-up COVID-19 disease survivors demonstrate persistent dyspnea and chest pain, reduced diffusion capacity, restrictive pulmonary physiology and ground-glass opacities and fibrotic changes on radiograph or high-resolution computed tomography imaging of the chest.
- Assessment of progression or recovery of pulmonary disease and functions is analyzed by home pulse oximetry, six-minute walk tests (6MWTs), pulmonary function tests (PFTs), high-resolution computed tomography imaging of the chest and computed tomography pulmonary angiogram as clinically appropriate.
- Pathophysiology of accumulation of fluid in the lungs in a patient of SARS-CoV-2 (COVID-19) disease is shown in Fig. 7.44. Computed tomography scan demonstrates lungs involvement in a patient of SARS-CoV-2 (COVID-19) disease is shown in Fig. 7. 45.

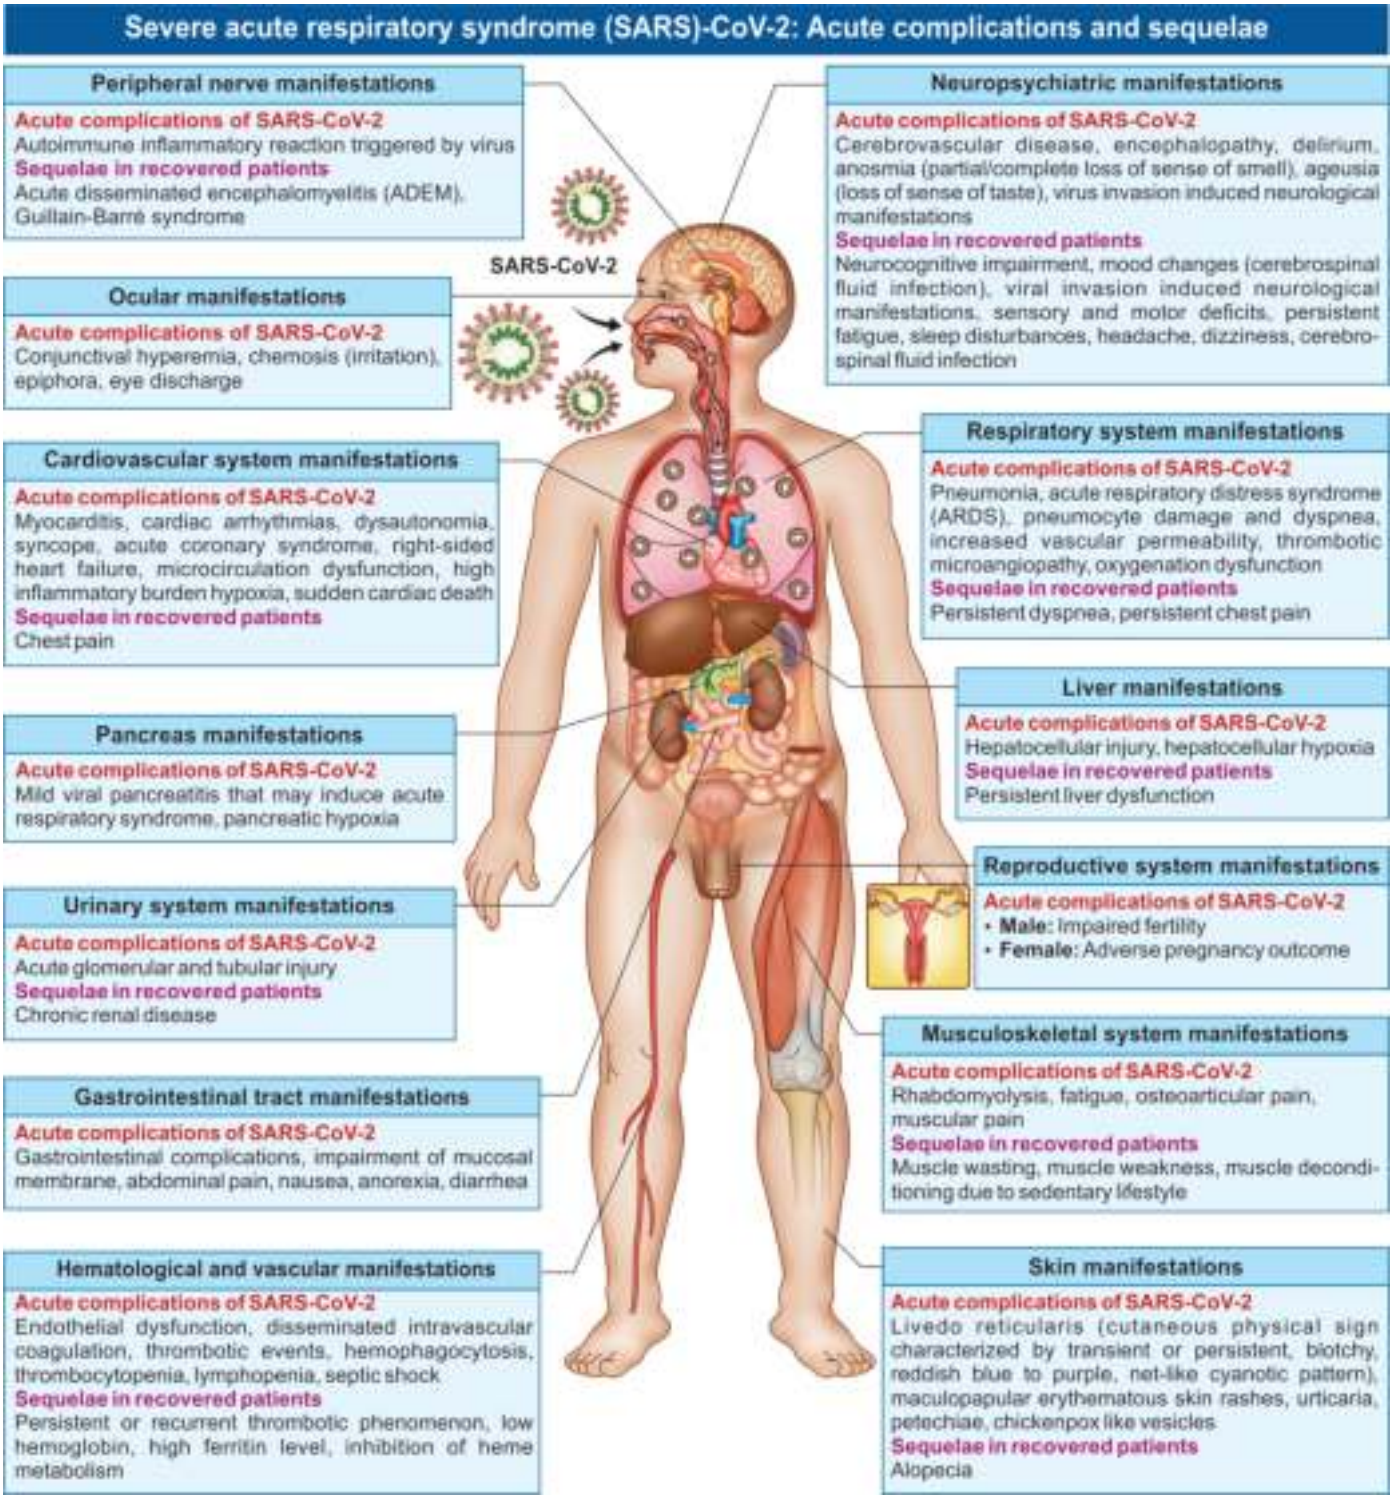

Fig. 7.43: SARS-CoV-2 acute complications and sequelae in COVID-19 survivors.

Cardiovascular System Manifestations

Acute cardiovascular system complications in COVID-19 disease patients include myocarditis, chest pain, cardiac arrhythmias, dysautonomia, syncope, acute coronary syndrome, right-sided heart failure, microcirculation dysfunction, high inflammatory burden hypoxia and sudden cardiac death.

- Long-term sequelae may include increased metabolic demand of heart, cardiac arrhythmias, persistent chest pain, autonomic dysfunction and myocardial fibrosis (detectable via cardiac MRI).
- Patients develop cardiovascular complications during acute COVID-19 infection. Those patients experiencing persistent cardiovascular system

SARS-CoV-2 (COVID-19): Autoimmune hemolytic anemia and pleural effusion

- Normal life span of red blood cells is around 120 days. SARS-CoV-2 (COVID-19) infection causes autoimmune leading to pleural effusion. At the time of autoimmune hemolytic anemia onset, all patients demonstrate elevated markers of inflammation (i.e. fibrinogen, D-dimers and C-reactive protein).
- Heme oxygenase is an enzyme that catalyzes the degradation of heme to produce biliverdin, ferrous ion and carbon monoxide.
- Biliverdin reductase (BVR) is an enzyme present in all tissues especially in reticuloendothelial cells in liver and spleen. Biliverdin reductase facilitates the conversion of biliverdin to bilirubin via the reduction of a double-bond between the second and third pyrrole ring into a single-bond.

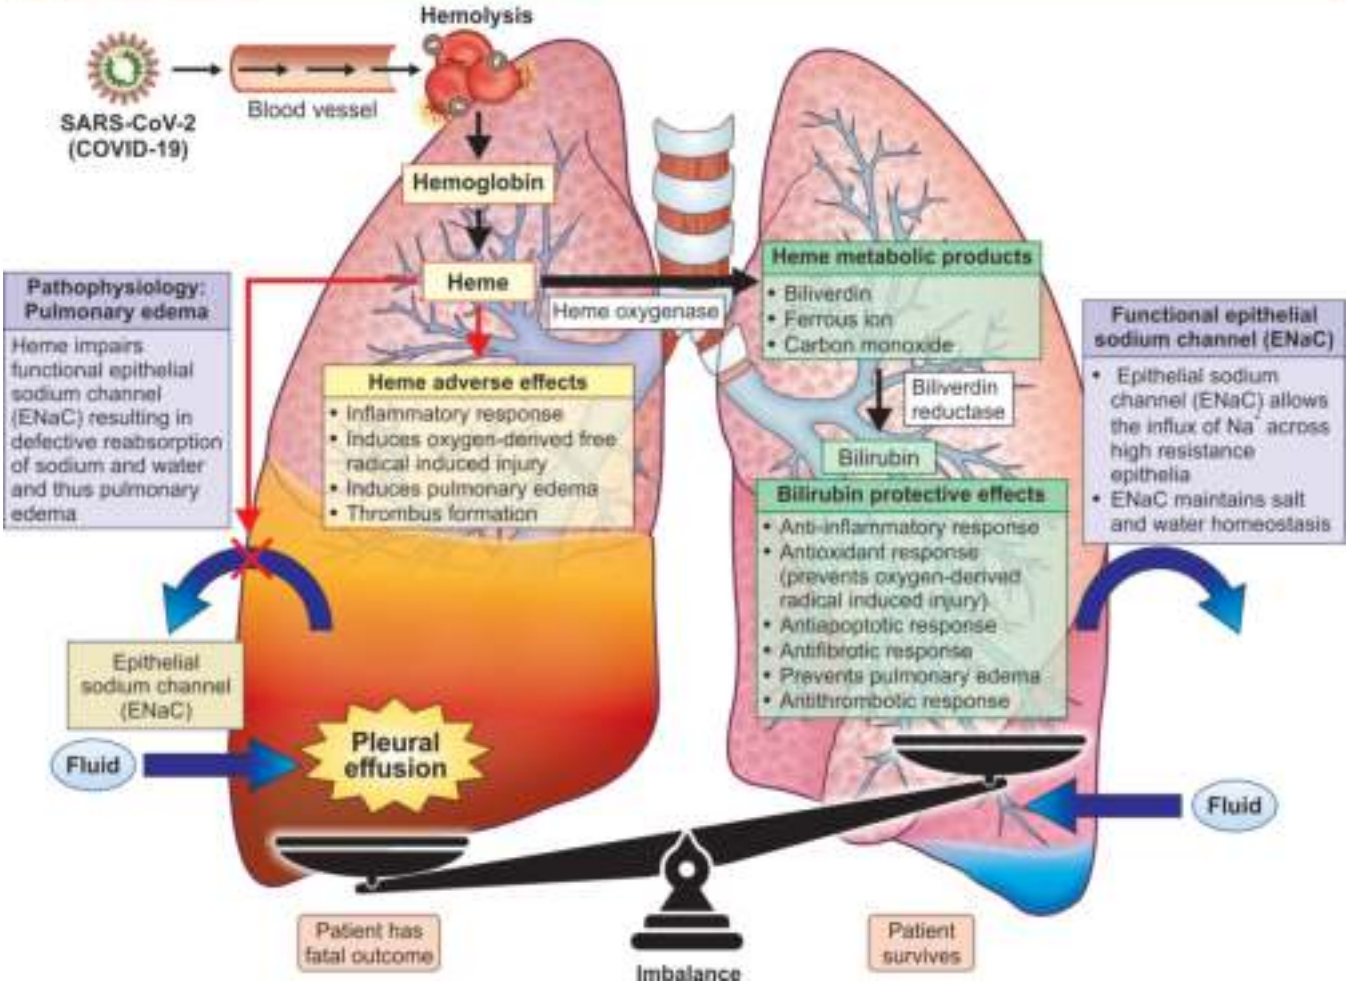

Fig. 7.44: Pathophysiology of accumulation of fluid in the lungs in a patient of SARS-CoV-2 (COVID-19 disease).

manifestations must be monitored with serial clinical echocardiogram and electrocardiogram follow-up.

Neuropsychiatric Manifestations

Acute neuropsychiatric complications of COVID-19 disease include cerebrovascular disease, encephalopathy, delirium, anosmia (partial/complete loss of sense of smell), ageusia (loss of sense of taste) and virus invasion induced neurological manifestations.

- Patients develop persistent neuropsychiatric manifestations such as neurocognitive impairment, mood changes, fatigue, myalgia, headache, dysautonomia, cerebrospinal fluid infection, viral invasion induced neurological manifestations, sensory and motor deficits, persistent fatigue, sleep disturbances, headache, dizziness and cerebrospinal fluid infection.
- About 30–40% of COVID-19 disease survivors develop anxiety, depression, sleep disturbances and post-traumatic stress disorder (PTSD).
- Neuropsychiatry manifestations occur due to immune dysregulation, inflammation, microvascular thrombosis, iatrogenic adverse effects of medications and psychological impacts of COVID-19 disease.

Peripheral Nervous System Manifestations

Acute peripheral nervous system complication of COVID-19 disease includes autoimmune inflammatory reaction triggered by virus. COVID-19 disease survivors

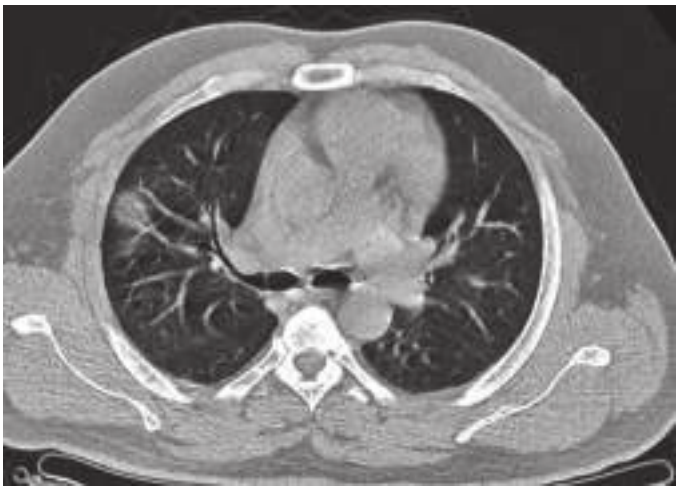

Fig. 7.45: Computed tomography scan demonstrates lungs involvement in a patient of SARS-CoV-2 (COVID-19 disease). (*Courtesy:* Dr. Vigyat, Dr. DY Patil Medical College, Pune, Maharashtra).

may develop acute disseminated encephalomyelitis (ADEM) and Guillain-Barré syndrome. The clinical presentation of COVID-19 associated Guillain-Barré syndrome is similar to non-COVID-19 cases. Patient presents with weakness and tingling sensations in extremities, which quickly progress to paralysis. Most patients with this disorder must be hospitalized to receive treatment.

Ocular Manifestations

Acute ocular complications of COVID-19 disease include conjunctival hyperemia, chemosis (irritation), epiphora and eye discharge.

Gastrointestinal Tract Manifestations

Prolonged viral fecal shedding can occur in COVID-19 disease even after negative nasopharyngeal swab testing. COVID-19 disease has potential to change the gut microbiome, including enrichment of opportunistic organisms and depletion of beneficial commensals. Acute gastrointestinal system complications of COVID-19 disease include impairment of mucosal membrane, abdominal pain, nausea, anorexia and diarrhea.

Hepatobiliary System Manifestations

Acute hepatobiliary system complications of COVID-19 disease include hepatocellular injury and hypoxia. COVID-19 disease survivors develop persistent liver dysfunction.

Pancreas Manifestations

Acute pancreas complications of COVID-19 disease include mild viral pancreatitis that may induce acute respiratory syndrome and pancreatic hypoxia.

Hematologic Manifestations

Acute hematologic complications of COVID-19 disease include endothelial dysfunction, disseminated intravascular coagulation, thromboembolic events, hemophagocytosis, thrombocytopenia, lymphopenia and septic shock.

- About 5% of post-COVID-19 disease cases may develop thromboembolic phenomenon in retrospective studies. Exact mechanism of persistent or recurrent thromboembolic event is not known. Therefore, the patients should be administered oral anticoagulants and low-molecular heparin to prevent thromboembolic phenomenon.
- D-dimer levels should be analyzed to predict severity of the disease. Elevated levels of D-dimer are demonstrated in severely infected COVID-19 disease patients.

Renal Manifestations

Acute renal complication of COVID-19 disease includes acute glomerular and tubular injury in majority of patients. These renal changes may resolve, however reduced glomerular filtration rate has been reported at months follow-up. COVID-19 disease survivors develop persistent impaired renal function. Collapsing glomerulopathy may be predominant pattern of renal injury in African descent.

Musculoskeletal System Manifestations

Acute musculoskeletal system complications in COVID-19 disease patients include rhabdomyolysis, fatigue, osteoarticular pain and muscular pain. Long-term sequelae in COVID-19 disease survivors include muscle wasting, muscle weakness and muscle deconditioning due to less physical activity.

Dermatologic Manifestations

Acute complications in COVID-19 disease patients include livedo reticularis (cutaneous physical sign characterized by transient or persistent, blotchy, reddish blue to purple, net-like cyanotic pattern, maculopapular erythematous skin rashes, urticaria, petechiae and chickenpox-like vesicles. Hair loss is the predominant symptom and has been reported in about 20% of COVID-19 disease survivors.

Endocrine System Manifestations

Endocrine system post-COVID-19 disease sequelae may include new or worsening control of diabetes mellitus, subacute thyroiditis and bone demineralization. Patients with newly diagnosed diabetes mellitus in the absence of risk factors for type 2 diabetes mellitus, suspected hypothalamic-pituitary-adrenal axis suppression or

hypothyroidism should undergo appropriate laboratory testing and should be referred to endocrinologists.

Reproductive System Manifestations

COVID-19 disease, men and women survivors may develop infertility. Women may have adverse pregnancy outcome.

Multisystem Inflammatory Syndrome in Children

Multisystem inflammatory syndrome in children (MIS-C) is a serious disorder linked to COVID-19 disease. Diagnostic criteria include: less than 21 years old presents with fever, elevated inflammatory markers, multiorgan dysfunction, recent SARS-CoV-2 infection and exclusion of other plausible diagnoses. It most often occurs in children less than seven years of age and disproportionately of African, Africa-Caribbean or Hispanic origin. These children may develop complications such as coronary artery aneurysm, headache, encephalopathy, cerebral stroke and seizures.

SARS-CoV-2 Genetic Mutations

SARS-CoV-2 virus has mutated overtime, leading to genetic variation in the population of circulating viral strains over the course of the COVID-19 pandemic.

- Molecular antigen, and serology tests are affected by viral mutations differently due to the inherent design differences of each test.
- Genetic mutation of the severe respiratory syndrome coronavirus 2 (SARS-CoV-2) is a change in the genetic sequence of the SARS-CoV-2 when compared with genetic sequence such as Wuhan-Hu1 (the first genetic sequence identified) or USA-WA1/2020 (the first identified genetic sequence in the United States).
- A new genetic variant of SARS-CoV-2 may have one or more mutations that differentiate it from the reference genetic sequence of predominant virus variants.
- New genetic variants of SARS-CoV-2 can have different characteristics. Some variants of SARS-CoV-2 may spread more easily or show signs of resistance to existing treatment options.

SARS-CoV-2 Delta Variant

SARS-CoV-2 Delta variant has K417 mutation in the spike (S) protein of the SARS-CoV-2 virus, and thus named delta virus by World Health Organization.

- SARS-CoV-2 Delta variant is highly contagious, which spreads faster than early forms of SARS-CoV-2, which virus strain drove the **second wave of infections** in India. The spike protein helps the virus enter and infect human cells.
- The K417 mutation in SARS-CoV-2 Delta variant has been associated with immune escape that makes the virus less susceptible to the vaccine or any form of drug therapy.
- Some data suggest the SARS-CoV-2 Delta variant causes more severe illness than previous strains in unvaccinated persons. Unvaccinated persons remain the greatest concern. Fully vaccinated persons with SARS-CoV-2 Delta variant breakthrough infections can spread the virus to others. However, vaccinated persons appear to be more infectious for a shorter period. It is essential to wear multilayered masks to prevent transmission of SARS-CoV-2.

SARS-CoV-2 Omicron (B.1.1.529) Variant

SARS-CoV-2 Omicron (B.1.1.529) variant was first reported to the World Health Organization from South Africa on 24 November 2021, which has a large number of genetic mutations, some of which are concerning. Current SARS-CoV-2 polymerase chain reaction (PCR) diagnostics continue to detect SARS-CoV-2 Omicron (B.1.1.529) variant except one of three genes, i.e. spike gene (32 mutations affect spike proteins). World Health Organization has designated SARS-CoV-2 (B.1.1.529) Omicron variant.

SARS-CoV-2 Vaccines

Vaccines are highly effective to prevent SARS-CoV-2 infections, including Delta variant in majority of persons. But these vaccines are not 100% effective and some fully vaccinated persons can become infected (called a breakthrough infection) and experience illness. For such persons, the vaccine still provides them strong protection against serious illness and death. There are three main approaches to design vaccine: (a) whole virus approach using whole pathogen, (b) subunit approach using very specific subunit of pathogen, and (c) genetic approach using nucleic acid.

- Whole virus vaccine: Whole SARS-CoV-2 virus is used to prepare vaccine by three methods: inactivation of virus, weakened version of virus and viral proteins.
- Subunit vaccine: A subunit vaccine is prepared by using the very specific subunit of a SARS-CoV-2 virus that the immune system needs to recognize.
- Genetic material vaccine: Genetic material vaccine provides the instructions for making specific proteins. The nucleic acid approach is a new way of developing vaccines against SARS-CoV-2 virus.

INFLUENZA VIRUS INFECTION

Influenza A viruses are single-stranded RNA viruses, which are three types of influenza viruses: A, B and C. Out of these influenza viruses, influenza A virus is most important to cause illness, whereas influenza types B and C produce minor illness. Researchers suggest that most adults have considerable immunity against influenza A virus.

- Influenza A virus is inhaled into respiratory tract, which evades the mucoprotein 'trap' and eviction by ciliated epithelium. Virus invades columnar ciliated cells and induces cell death due to virus replication and apoptosis. Spread of influenza virus infection to adjacent epithelial cells results in cell death producing areas of necrosis. Nonproductive influenza A virus infection of leukocytes, lymphocytes and monocytes compromises their function. There is increased risk of secondary bacterial infection, e.g. *Staphylococcus aureus*.
- Patient presents with flu-like symptoms within one to four days after exposure to the influenza A virus that resolve itself within five to seven days as the immune system fights it off.

POLIOVIRUS INFECTION

Human beings are the only known reservoir of polio RNA virus. The single-stranded RNA core is surrounded by a protein capsid without a lipid envelope, which makes poliovirus resistant to lipid solvents and stable at low pH. There are distinct serotypes of poliovirus, types 1, 2 and 3. The poliovirus is transmitted via droplets or aerosols from the throat and via fecal contamination of hands, utensils, water and food. Immunization against poliovirus infection represents one of the world's great medical achievements.

Clinical Features

Brain stem nuclei are affected by poliovirus resulting in poliomyelitis, which is characterized by degeneration and necrosis of anterior horn cells of the spinal cord. Poliomyelitis can lead to a spectrum of clinical presentations ranging from subclinical infection to paralysis and mortality. About 90–95% of all poliovirus infections remain asymptomatic. Paralytic poliomyelitis has been classified into spinal, bulbar and bulbospinal types, depending on the site of the affected motor neurons.

- **Spinal poliomyelitis:** Patient presents with meningitis followed by severe myalgia and localize sensory and motor symptoms leading to weakness and asymmetric and flaccid paralysis involving proximal skeletal muscles predominantly and distal muscles within 1–2 days.
- **Bulbar poliomyelitis:** Patient suffers from serious form of disease resulting from paralysis of the skeletal muscles innervated by cranial nerves. Patient presents with dysphagia, nasal speech, pooling of secretions and breathlessness. Rarely, patient can develop encephalitis. Bulbar poliomyelitis is linked to mortality in 5–15% of cases.
- **Post-polio syndrome:** It is poorly understood condition. Post-polio syndrome is characterized by the onset of fatigue, skeletal muscle weakness and wasting in patients, who have recovered from paralytic polio, starting several years after acute polio disease.

COXSACKIEVIRUS INFECTION

Coxsackievirus can spread from person-to-person contact, usually on unwashed hands and surfaces contaminated by feces, where Coxsackievirus can survive for several days to eight weeks. The incubation period lasts about 1–2 days. Patient presents with fever, anorexia, breathlessness, sore throat, cough, malaise and small blisters on the palms and feet. These skin blisters may undergo ulceration. The patients may shed virus for many days.

HEPATITIS A VIRUS INFECTION

Hepatitis A is an enteric picornavirus. Its HAV genome contains single-stranded RNA molecule that codes for a polyprotein which is processed to give rise to viral proteins **VP-1, VP-2, VP-3** and other proteins.

- Hepatitis A virus causes a highly contagious short-time mild to severe hepatitis A infection. Hepatitis A virus is primarily transmitted by fecal–oral route; and also, via close, physical contact (oral–anal sex) with an infected person.
- Incubation period of hepatitis A virus is usually 14–28 days. Patient presents with fever, malaise, loss of appetite, nausea, diarrhea, abdominal discomfort, dark-colored urine and jaundice. Hepatitis A virus infection is normally followed by recovery.

NOROVIRUS (NORWALK VIRUS) INFECTION

Norovirus survives acid barrier of the stomach, which invades terminal epithelial cells of the villi in the upper intestine and induces cell death due to replication and apoptosis.

- Norovirus replication spreads distally along the intestine. Villi remain intact, but are broadened and flattened. Villus function is compromised.
- Malabsorption of carbohydrates and fat leads to diarrhea. Autonomic signal to the stomach delays gastric emptying with associated projectile vomiting.

YELLOW FEVER VIRUS INFECTION

Yellow fever virus belongs to the genus Flavivirus, which is related to West Nile, Japanese encephalitis virus and St. Louis encephalitis virus. Yellow fever virus is transmitted to the persons through infected Aedes mosquitoes. The 'yellow' name refers to the jaundice that affects some patients. Yellow fever virus is endemic in tropical regions of Africa and Central America and South America due to heavily populated regions with high Aedes mosquito density.

Clinical Features

Patient presents with fever, headache, jaundice, skeletal muscle pain, abdominal pain, nausea, vomiting, fatigue, passage of dark colored urine. Bleeding can occur from the mouth, nose, eyes or gastric region. In most patients, symptoms disappear within 3–4 days. About half of the patients develop severe toxic symptoms and have fatal outcome with 7–10 days.

Laboratory Diagnosis

Polymerase chain reaction (**PCR**) analysis of blood and urine samples can sometimes detect the yellow fever virus in early stages of the disease. In the later stages, antibodies are demonstrated by enzyme-linked immunosorbent assay (**ELISA**) and plaque reduction neutralization test (**PRNT**) techniques.

Prevention

Yellow fever can be prevented by yellow fever vaccine, which is safe and affordable. Single dose of yellow fever vaccine gives lifelong immunity.

RUBELLA VIRUS INFECTION

Rubella is commonly called as German measles caused by rubella virus, which is more prevalent in China than across world. It is a contagious disease, that commonly affects skin and lymph nodes.

- Rubella virus is transmitted from person to person via coughing and sneezing of respiratory secretions such as mucus. Rubella is very dangerous for a pregnant woman and her developing baby transmitted via hematogenous route. It is essential to protect women from rubella virus before they become pregnant. Rubella virus infection causes the most severe damage when the mother is infected early in pregnancy, especially in the first 12 weeks (first trimester).
- Rubella virus is inhaled into respiratory tract, which invades the mucosa and lymphoid tissue of the nasopharynx, where replication occurs. Virus spreads directly to the regional lymph nodes or via a transient viraemia.
- With appearance of IgM and IgG antibodies, patents develop maculopapular rash. In the nonimmune mother in the first stage of pregnancy, rubella virus crosses the placenta, and replicates in a wide range of tissues of the fetus. There is a direct cytotoxic effect on cells of the myocardium, retinal epithelium and neural tissues.

Clinical Features

Most persons who get rubella virus infection usually present with low-grade fever, sore throat, skin rash progressing to generalized skin rashes, lymphadenopathy and joint pains. Children who have rubella recover within a week, but adults take longer time to recover.

Clinical Pearls: Congenital Rubella Syndrome (CRS)

- Congenital rubella syndrome occurs in a developing baby in the womb whose mother is infected with rubella virus.
- Pregnant women who contract rubella infection are at high risk for miscarriage or stillbirth, and their developing babies are prone to develop severe birth defects with devastating, lifelong consequences.
- The most common birth defects include cardiac defects, cataracts, deafness, intellectual disabilities, liver damage, spleen damage, low birth rate and skin rashes.
- Less common lifelong consequences include glaucoma, brain damage, endocrinopathies and inflammation of the lungs.
- It is essential to vaccinate women for rubella vaccine before they become pregnant. There is no definite cure of congenital rubella syndrome.
- The rubella test is done to detect antibodies in the blood that develop in response to a rubella or immunization. Rubella testing may be performed to confirm the presence of adequate protection against the rubella virus.

DENGUE VIRUS INFECTION

Dengue is a mosquito-borne human viral infection caused by dengue virus (DENV) between human beings and mosquito vector.

- Dengue virus (DENV) is transmitted by female mosquitoes mainly of the species *Aedes aegypti* and to a lesser extent, *Aedes albopictus*.
- Dengue virus infection occurs in tropical and subtropical regions across world. There are four serotypes of dengue virus: DENV-1, DENV-2, DENV-3 and DENV-4.

Clinical Features

Dengue virus infection produces acute flu-like illness that affects infants, young children and adults. Symptoms usually persists for 2–7 days and incubation period of 4–10 days after bite from an infected mosquito. Occasionally, patient develops potentially lethal complication, severe dengue infection associated with bleeding, organ impairment and/or plasma leakage.

- **Mild to moderate dengue fever:** Dengue fever should be suspected when patient presents with high-grade fever (40°C/104°F) accompanied by two of the symptoms during the febrile phase such as severe headache, myalgia, arthralgia, pain behind eyes, nausea, vomiting, skin rashes and lymphadenopathy.
- **Severe dengue fever**: Patient with severe dengue fever can progress to potentially severe disease due to plasma leaking, fluid accumulation, respiratory

distress, severe bleeding tendencies or organ impairment. Warning signs that medical professional should look for severe abdominal pain, persistent vomiting, rapid respiration, fatigue and hematemesis. These patients should be kept under close observation to prevent lethal complications.

Treatment

There is no specific treatment for dengue fever. Early detection of disease progression helps in prompt medical treatment. Dengue prevention and control depends on effective vector control measures.

EBOLA VIRUS AND MARBURG VIRUS INFECTION

Ebola and Marburg viruses are related filamentous filoviruses but distinct from each other that cause clinically similar diseases characterized by hemorrhagic fever and capillary leakage. Ebola virus infection is slightly more virulent than Marburg infection.

Mode of Transmission

Ebola is named for the river in **Africa** where the hemorrhagic fever disease was first recognized in 1976. Ebola virus has five species: (a) infectious viruses include Zaire Ebola virus, Sudan Ebola virus, Tai Forest Ebola virus, Bundibugyo Ebola virus, and (b) noninfectious Reston Ebola virus. Ebola virus outbreaks have been linked to consumption of meat and soup from wild animals like bats. Marburg virus has been identified in bats. Persons are exposed to bats in mines or caves.

Clinical Features

Patient develops abrupt hemorrhagic fever, chills, malaise, myalgia with 5–10 days of Ebola and Marburg virus infection. Over the time, symptoms increase in severity such as nausea, vomiting, bloody diarrhea, abdominal pain, weight loss, skin rashes, red eyes, cough, sore throat, and chest pain.

MUMPS VIRUS INFECTION

Mumps is caused by a Paramyxovirus, a member of the Rubulavirus family, that involves salivary glands. The incubation period ranges 12–25 days with average 16–18 days.

Clinical Features

Patient presents with pain, tenderness and swelling of unilateral or bilateral parotid salivary glands. Swelling usually peaks in 1–3 days and then subsides during the next week. Submandibular and sublingual glands may also be involved in 10% of cases. Nonspecific symptoms may precede parotitis such as low-grade fever, myalgia, anorexia, malaise and headache, that last within 5–10 days.

Complications

Patient with mumps can develop various complications that include orchitis, oophoritis, mastitis, meningitis, encephalitis, pancreatitis and hearing loss among adults than children.

MEASLES VIRUS INFECTION

Measles is a highly contagious serious disease caused by a virus in the Paramyxovirus family. Unvaccinated young children are at high risk of developing measles and its complications including mortality.

Mode of Transmission

Measles virus is transmitted by coughing and sneezing through inhalation of droplets, close personal contact or direct contact with infected nasal or throat infections. Virus remains active and contagious in the air and infected surface up to two hours.

Clinical Features

Patient presents with high-grade fever, which begins about an incubation period of 10–12 days and lasts for 4–7 days. Initially, patient presents with cough, runny nose, red and watery eyes, and small white spots inside the cheeks. After several days, skin rashes erupt usually on the face and upper region of neck. After three days, skin rashes appear on hands and feet, which last for 5–6 days and then fade away.

Complications

Most measles-related mortality occurs caused due to serious complications such as blindness, encephalitis, severe diarrhea related dehydration, otitis media and pneumonia in immunocompromised persons.

Prevention

Measles virus infects the respiratory tract, then spreads throughout the body. Accelerated immunization activities contribute to reduce morbidity and mortality in measles.

RABIES VIRUS INFECTION

Rabies virus is transmitted by the bite of animals as dogs, foxes and bats, whose saliva contains rabies virus, which enters a peripheral nerve and is transported by retrograde axoplasmic flow to the spinal cord and brainstem and spillage into the cerebellum and hypothalamus.

Clinical Features

Patient presents with hydrophobia (fear from water) characterized by violent muscle contractions and convulsions.

Histologic Examination

Histologic examination of brain shows eosinophilic intracytoplasmic inclusions (**Negri bodies**) in the hippocampus and Purkinje cells of the cerebellum. Brainstem and spinal cord shows neuronal degeneration, perivascular accumulations of mononuclear cells.

HEPATITIS C VIRUS INFECTION

Hepatitis C virus causes chronic liver inflammation, and is transmitted through blood-to-blood contact and sharing infected needles. If left untreated over many years, some patients can cause serious and potentially life-threatening cirrhosis and hepatocellular failure. Direct-acting antiviral medicines can cure >95% of persons with hepatitis C.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Human immunodeficiency virus (HIV) may affect the brain, spinal cord, or peripheral nervous system before the onset of immunodeficiency syndrome. Reticuloendothelial cells are vehicles for viral entry into the nervous system. HIV infection results in AIDS dementia complex and is characterized by impairment of memory, coordination of balance and motor functions with progressive dementia. Patient is prone to opportunistic bacterial and fungal infections. Refer to Chapter 4, immunopathology for human immunodeficiency virus (HIV) infection in details.

HUMAN T CELL LEUKEMIA VIRUS TYPE 1 INFECTION

Human T cell leukemia virus type 1 (HTLV-1) is a retroviral infection that affects T cells. Majority of persons have no signs and symptoms. However, some persons may develop T cell leukemia, HTLV-1 associated myelopathy/tropical spastic paraparesis (HAM/TSP) or other medical disorders.

Mode of Transmission

Human T cell leukemia virus type 1 is transmitted by blood transfusions, sharing infected needles and sexual contact. HTLV-1 can also be transmitted from mother to the newborn during birth or breastfeeding. Majority of persons remain asymptomatic throughout life.

Clinical Features

Majority of the persons with HTLV-1 infection remain asymptomatic. About 2–5% of infected persons develop adult T cell leukemia. Depending on the subtype of acute T cell leukemia, patients have a life span of 6 months to two years of diagnosis. Although chemotherapy can produce a complete remission, yet it cannot alter the life expectancy. About 2% of persons can develop HTLV-1 associated myelopathy/tropical spastic paraparesis (HAM/TSP) or other medical disorders. These persons are unable to walk and need wheelchair.

Laboratory Diagnosis

Human T cell leukemia virus type 1 is diagnosed by detection of antibodies to the HTLV-1 during screening of blood donation and testing in patients having family history of the infection or a work up for HTLV-1 related disorders.

HUMAN ROTAVIRUS INFECTION

Human rotaviruses are responsible for severe acute watery diarrhea with dehydration, vomiting, fever and/or abdominal pain among infants and young children.

- Persons who are infected with rotavirus shed virus in their stool. Viruses in the environment can infect other persons. Infants and children in contact with infected persons get rotavirus infection during winter and spring seasons (January to June).
- Rotavirus vaccination is the best way to protect infants and children from rotavirus. Handwashing and cleanliness are important to prevent transmission of the virus.

DNA VIRUSES

DNA viruses have DNA genomes that are replicated by either host or virally encoded DNA polymerases. Upon uncoating, the genomes of DNA viruses are transcribed to produce an "early" set of mRNAs required for viral genome replication. After genome replication another set of mRNAs, the "late" mRNAs are expressed. Late genes encode structural proteins and other proteins that are packaged within virions.

VARIOLA (SMALLPOX)

Before smallpox was eradicated, it had been an acute contagious, disfiguring and deadly disease caused by the variola virus, a member of the Orthopoxvirus family. Edward Jenner developed smallpox vaccine in 1796. World Health Organization launched an intensified plan to eradicate smallpox in 1967 and achieved the target in 1980. Patients developed pus-filled blisters all over the body. Because smallpox no longer occurs naturally, scientists are only concerned that it could emerge through bioterrorism.

VARICELLA-ZOSTER VIRUS (CHICKENPOX) INFECTION

Varicella (chickenpox) is an acute viral infection of childhood caused by the varicella-zoster virus. The varicella-zoster is a DNA virus that is a member of herpesvirus group. The average incubation period for varicella is 14–16 days after exposure to varicella-zoster virus.

- Infants, adolescents, adults, pregnant women and immunocompromised persons are at risk for more serious disease and acquiring complications.
- Patient presents with fever, malaise and generalized pruritic skin rashes such as macules, papules and vesicles.
- The skin rashes usually appear first on the chest, back, and face, then spread over the entire body. Recovery from primary varicella zoster virus infection usually provides lifelong immunity.
- Following overt varicella, the virus can remain latent for years in dorsal root ganglia. Reactivation of latent infection causes herpes zoster (Shingles).

MOLLUSCUM CONTAGIOSUM VIRUS 1 AND 2 (MCV1/MCV2) INFECTION

Molluscum contagiosum is viral infection of the keratinocytes caused by MCV1 (DNA poxvirus) in 98% of affecting children (2–5 years) and immunocompromised persons. **MCV1** is transmitted by direct skin-skin contact or sharing infected clothes. **MCV2** is transmitted via **sexual contact** in adults in human immunodeficiency virus (HIV). In contrast to most double-stranded DNA viruses, poxvirus replicates in the cytoplasm. Incubation period is 2 weeks to six months. Average incubation period is 6 weeks. Henderson-Paterson bodies also known as 'molluscum bodies' are large intracytoplasmic eosinophilic virion inclusions in keratinocytes.

Clinical Features

Patient presents with umbilicated, dome-shaped papules over body, arms, legs, thighs, neck, face, axilla, trunk, genitalia and perianal region. Umbilication of skin lesion occurs as a result of intracytoplasmic viral inclusions extruding infected cell on the surface with central pore.

Surgical Pathology: Molluscum Contagiosum

Gross Morphology

Molluscum contagiosum is dome-shaped flesh colored skin papule. Central umbilication may be present or absent.

Light Microscopy

- Epidermis grows deeper down into the dermis and form closely packed lobules.
  - Epidermal cells contain large intracytoplasmic eosinophilic stained inclusion bodies known as molluscum bodies.
  - Molluscum bodies displace the nuclei at the periphery of epidermal cells.
  - In the center of the lesion, stratum corneum disintegrates and release the molluscum bodies together with keratinous debris resulting to formation of central crater.
- Dermis shows prominent acute and chronic inflammatory infiltrate and foreign body giant cells. Histopathologic features of molluscum contagiosum are shown in Fig. 7.46.

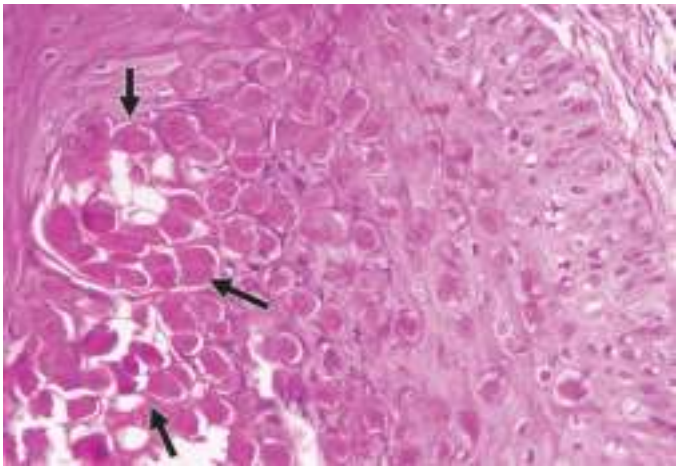

Fig. 7.46: Histopathological features of molluscum contagiosum. Epidermal cells contain large intracytoplasmic eosinophilic stained inclusion bodies known as molluscum bodies (arrows) (400X).

HERPES SIMPLEX VIRUS (HSV-1, HSV-2) INFECTION

The herpes simplex virus is categorized into two types: herpes simplex type 1 (HSV-1) and herpes simplex type 2 (HSV-2).

- **HSV-1** is mainly transmitted by oral-to-oral contact to induce oral herpes that presents as cold sores. HSV-1 can also induce genital herpes. **HSV-2** is sexually transmitted infection that induces genital herpes.
- Both HSV-1 and HSV-2 infections can occur throughout life. Most oral and genital herpes infections are asymptomatic and leading to painful blisters at the site of infection.
- Herpes infections are most contagious when in contact with symptomatic patients. However, herpes infections can be transmitted to others in the absence of symptoms. Infection with HSV-2 increases the risk for acquiring and transmitting human immunodeficiency virus (HIV) infection.
- Neonatal herpes simplex infection can occur when an infant is exposed to HSV-1 or HSV-2 in the genital tract during delivery.

Herpes Simplex Virus Type 1

Herpes simplex virus type 1 is inoculated onto mucosa of the mouth. Virus replication occurs in epidermis and dermis and the patient is usually asymptomatic.

- Virus enters sensory nerve endings and migrates via axon to cell bodies in the trigeminal ganglion. With high level replication in the ganglion, virus returns to the skin, and replicates there with herpetic vesicles developing. Immune response resolves skin lesions, but latent virus exists in the ganglion.
- Reactivation of latent HSV-1 and its traveling back to the skin manifests as new skin lesions. Oral herpes infection is most often asymptomatic.

- Patient with oral herpes simplex infection presents with painful blisters around the mouth with itching and burning sensation. Sores on the lips are commonly referred to cold sores.
- Neonatal herpes infection can occur when an infant is exposed to HSV-1 or HSV-2 in the genital tract during delivery.
- In immunocompromised persons, HSV-1 can induce more severe infection involving brain (encephalitis) and eye (keratitis). Herpes simplex virus targets the temporal lobes by binding on the plasma membranes of central nervous system cells. Herpes simplex virus 1 (HSV-1) has ability to remain latent or selective replication in distinct intracellular microenvironments. Patient presents with headache, hyperactivity, and/or general weakness.

Herpes Simplex Virus Type 2

Herpes simplex virus type 2 (HSV-2) is exclusively sexually transmitted infection inducing genital herpes across world. Genital herpes infection remains asymptomatic in 66% of cases lifelong and incurable.

- About one-third of genital herpes may have symptoms such as one or more blisters on genitalia and anal region. Patient presents with fever, body aches, sensations of mild tingling or shooting pain in the legs, hips and buttocks before appearance of genital ulcers and lymphadenopathy.
- HSV-2 infection increases the risk of acquiring a new human deficiency virus (HIV) infection in immunocompromised persons by approximately three-fold.
- Neonatal herpes infection can occur when an infant is exposed to HSV-2 or HSV-1 in the genital tract during delivery.
- HSV-2 infection can cause complications such as meningoencephalitis, esophagitis, hepatitis, pneumonitis, retinal necrosis or disseminated infection.

CYTOMEGALOVIRUS INFECTION

Cytomegalovirus (CMV) affects lungs, kidneys (tubules and glomerular endothelial cells), gastrointestinal tract (epithelial lining), brain (neurons) and eye, which is transmitted via droplets, saliva, sexual contact (vaginal discharge) and transplacental route (mother to fetus).

- **Congenital cytomegalovirus infection:** Vertical transmission of cytomegalovirus (mother to fetus) causes intrauterine growth retardation. Lesion in proximity to third ventricle and aqueduct cause hydrocephalus. Neonate presents with jaundice, hepatosplenomegaly, encephalitis, chorioretinitis, anemia, and thrombocytopenia.
- **Postnatal cytomegalovirus infection:** Postnatal CMV infection most often occurs in immunocompromised persons, which causes encephalomyelitis and affects lungs, kidneys, liver and salivary glands.
- **Cytomegalovirus infection in immunocompetent persons:** Cytomegalovirus infection in immunocompetent person is generally asymptomatic or may present as cytomegalovirus mononucleosis syndrome, which is characterized by long duration of fever but has less cervical lymphadenopathy.
- **Cytomegalovirus infection in immunocompromised persons:** Cytomegalovirus infection in immunocompromised persons cause substantial morbidity and mortality especially in persons with human immunodeficiency virus (HIV) infection and among transplant recipients.

Surgical Pathology: Cytomegalovirus Involving Organs

Light Microscopy

- The organ affected shows mononuclear cells infiltration with mild edema.
- The infected cells are large with prominent deep blue inclusion in nuclei surrounded by a clear space giving an 'owl eye appearance'.
- Necrosis and calcification are seen.

Histochemistry

Cytomegalovirus is highlighted by PAS and silver methenamine stain.

Immunohistochemistry

Monoclonal antibodies to cytomegalovirus are used for diagnosis.

HUMAN PAPILLOMAVIRUS INFECTION

Human papillomavirus (6, 11) causes vulvar wart known as 'condyloma acuminatum' on vagina and cervix. Koilocytes (intracytoplasmic vacuolation) are indicative of HPV-infected epithelial cells, which are apparent in cytopathologic (Papanicolaou smear) and histopathologic preparations. High-risk human papillomavirus (16, 18, 31, 33, 35, 39, 45) may contribute to the pathogenesis of squamous cell carcinoma of vulva and vagina. Oncogenic risk for anogenital human papillomavirus is given in Table 7.22. Papanicolaou smear prepared from cervical squamous cell infected by human papillomavirus (HPV) is shown in Fig. 7.47.

JOHN CUNNINGHAM VIRUS (JC VIRUS) INFECTION

John Cunningham virus (JC virus) or also called human polyomavirus 2 infects the white matter of the brain and attacks the cells responsible for producing

Table 7.22 Oncogenic risk for anogenital human papillomavirus

Oncogenic Risk for Cervical Cancer	Human Papillomavirus	Histologic Features	
High-risk anogenital human papillomavirus	16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 68, 59, 66	▪ HSIL (high-grade squamous intra-epithelial lesion) ▪ Koilocytosis occasional present ▪ Aneuploidy usually	▪ Abnormal mitoses frequent ▪ Undifferentiated cells and mitoses in upper two-thirds of cervical epithelium
Low-risk anogenital human papillomavirus	6, 11, 42, 43, 44, 53	▪ LSIL (low-grade squamous intra-epithelial lesion) ▪ Koilocytosis frequently present ▪ Diploid or polyploid (most often)	▪ Abnormal mitoses absent ▪ Undifferentiated cells and mitoses in lower third of cervical epithelium

Medium risk human papillomavirus includes 33, 35, 39, 51, 52, 56, 57, 58, 59, 68.

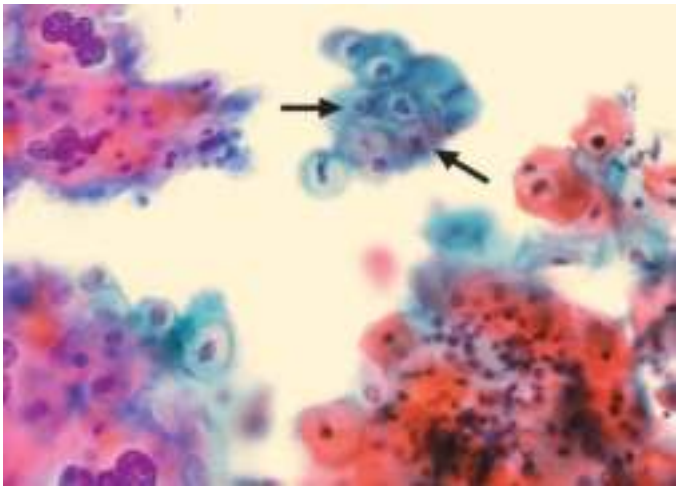

Fig. 7.47: Papanicolaou smear prepared from cervical squamous cell infected by human papillomavirus (HPV). It shows koilocytosis, the typical appearance. There is a 'halo' of cleared cytoplasm surrounding an enlarged nucleus (arrows) (400X).

myelin, the protective coating that covers and protects nerve cells. Imaging of the head and a spinal tap are performed.

Mode of Transmission

John Cunningham virus (JC virus) is transmitted via urine-oral route. The virus remains latent in the renal tubular epithelial cells, bone marrow hematopoietic stem cells (HSCs), tonsillar lymphoid cells and brain. Antibodies formed against JC virus cannot control JC virus reactivation and replication.

Clinical Features

Patient presents with clumsiness, weakness, progressing to dementia, partial vision loss and progressive multifocal leukoencephalopathy (**PML**) in immuno-compromised persons associated with fatal outcome within nine months.

HEPATITIS B VIRUS (HBV OR DANE PARTICLE) INFECTION

Hepatotropic viruses infecting liver include HAV, HBV, HCV, HDV and HEV. Acute viral hepatitis shows similar morphology irrespective of their precise etiology. HAV infection has a direct cytopathic effect. Hepatitis B is a potentially life-threatening liver infection caused by hepatitis B virus (HBV). Acute hepatitis has three phases: preicteric phase (prodromal phase), icteric phase (jaundice) and recovery phase (convalescence phase).

Pathogenesis

Hepatocellular injury occurs due to attack by CD8+ cytotoxic T cells and natural killer cells followed by antibodies formed against viral neoantigens expressed on virally infected hepatocytes. The mechanisms of hepatocellular injury have been most closely studied in HBV. It is thought that the extent of inflammation and necrosis depends on the person's immune response.

- **Prompt immune response:** A prompt immune response during the acute phase of HBV infection may cause hepatocellular cell injury but at the same time eliminate the virus.
- **Marginal immune response:** People with marginal immune response and fewer symptoms are less likely to eliminate the HBV, and hepatocytes expressing the viral antigens persist, leading to the chronic or carrier state.
- **Accelerated immune response:** It can be explained in terms of an accelerated immune response of HBV inducing severe hepatocellular necrosis.

Clinical Course

Patient may remain asymptomatic and can develop acute hepatitis without jaundice (anicteric hepatitis), acute hepatitis with jaundice (anicteric hepatitis), chronic hepatitis, chronic carrier stage and massive liver necrosis with acute hepatocellular failure.

PARVOVIRUS B19 INFECTION

Parvovirus B19 infects only human beings, that spreads from person to person. It most commonly causes classic 'slapped cheek' skin rash of erythema infectiosum (fifth disease), that mainly affects children. However, it may be observed in adults. Parvovirus B19 can also cause severe anemia.

Clinical Features

Patient presents with mild skin rash (erythema infectiosum), fatigue, low-grade fever, headache, and swollen and painful joints (more common in adults). Clinical course can vary in intensity and usually vanishes in 7–10 days, but it can come and go for several weeks. There is no vaccine available for Parvovirus B19.

HUMAN ADENOVIRUS INFECTION

Human adenoviruses are small nonenveloped DNA viruses with linear, double-stranded genome. In human, there are 88 human adenoviruses in seven species (human adenovirus A, B, C, D, E, F, G).

Mode of Transmission

Human adenoviruses are transmitted by two routes: (a) respiratory tract infections via contact with infectious material from another person, and (b) gastrointestinal tract infection occurs via fecal–oral route due to intake of contaminated food or water. Symptoms appear 1–2 days after exposure of children to adenovirus infection may persist for 1–2 weeks. Patient presents with abrupt onset of watery diarrhea, fever, abdominal tenderness and vomiting.

Clinical Features

Human adenoviruses are associated with common cold, croup, bronchitis or pneumonia, conjunctivitis and gastrointestinal tract infections. Adenovirus infection may occur at any age. Symptoms appear 2–14 days after infection. Patient presents with runny nose, sore throat, fever, severe cough, lymphadenopathy, headache, pink eyes.

Laboratory Diagnosis

Human adenovirus infection is diagnosed by complete medical history, physical examination, complete blood counts, nasal swab culture, stool culture and chest radiograph.

Complications

Complications of human adenoviruses infection include pneumonia, chronic obstructive pulmonary disease and intussusception.

FUNGAL DISEASES

Important fungal diseases include Candida, mucormycosis, Aspergillus, Cryptococcus, histoplasmosis, chromomycosis and rhinosporidiosis. Rhinosporidiosis mainly involves the mucosa of nose, nasopharynx and conjunctiva. Classification of pathogenic fungi and diseases is given in Table 7.23. Classification of pathogenic fungi is given in Table 7.24.

ASCOMYCOTA

Ascomycota are fleshy unicellular or multicellular fungi. Most of ascomycetes have reproductive structure called ascus. The ascus contains microscopic sexual reproductive cells are called **ascospores**. The mycelium is made up of chitin. Ascomycota has members such as **dermatophytes, molds, yeasts** and **dimorphic fungi**.

DERMATOPHYTES (SUPERFICIAL FUNGAL INFECTIONS)

Dermatophytes grow in the soil and on animals, which are often confined to the stratum corneum, hair and nails. The genera most often causing dermatophytosis include *Epidermophyton flocossum, Microsporum canis, Trichophyton interdigitale, Trichophyton rubrum*, which can produce a number of diverse and characteristic clinical lesions according to the area involved.

Cutaneous Dermatophytosis

Dermatophytes cause cutaneous dermatophytosis involving scalp, beard, skin and nails. Cutaneous dermatophytes and lesions are given in Table 7.25.

- **Tinea corporis:** It is commonly referred to as '**ringworm**', a term used by laypersons, to describe practically any annular or ring-like eruption on non-hairy regions of the trunk, but any region may be affected. Active site of growth of fungi occurs in the periphery of lesion, which may spread from other infected humans, or it may be autoinoculated from other regions of the body that are infected by tinea such as tinea pedis or tinea capitis.
- **Tinea capitis (scalp ringworm):** Dermatophyte fungal infection causes scalp and hair-shaft lesions. Patient presents with itchy, scaly bald (loss of hair) patches on scalp. Tinea capitis is highly contagious infection most often observed in toddlers and school-age children.

Table 7.23 Classification of pathogenic fungi and diseases

Fungus	Diseases
Ascomycota	
Dermatophytes	Dermatophytes (*Epidermophyton flocossum, Microsporum canis, Trichophyton interdigitale, Trichophyton rubrum*) cause cutaneous dermatophytosis: scalp, beard, skin and nails
Molds	*Aspergillus fumigatus, Aspergillus flavus, Aspergillus niger* cause allergic bronchopulmonary aspergillosis, fungal balls in damaged lungs, invasive disease of lung, sinuses, brain in neutropenic patients
Yeast	Yeast (*Candida albicans*, *Candida glabrata*, *Candida krusei*, *Candida parapsilosis*) causes oropharyngeal, mucocutaneous candidiasis
Dimorphic fungi	Dimorphic fungi cause pneumonia and disseminated infection involving organs ▪ *Blastomyces dermatitidis:* Skin, bone and genitourinary system ▪ *Coccidiodes immitis:* Central nervous system and bone ▪ *Histoplasma capsulatum:* Liver, spleen, spleen and bone marrow demonstrated in macrophages in immunocompromised states like HIV infection, corticosteroid therapy and immunosuppression therapy ▪ *Paracoccidioides brasiliensis:* Mucosa of mouth and nose
Basidiomycota	
Cryptococcus neoformans	*Cryptococcus neoformans* causes lung infections involving meninges in immunocompromised persons
Malassezia furfur	*Malassezia furfur* causes pityriasis of skin
Zygomycota*	
Absidia corymbifera	*Absidia corymbifera* causes rhinocerebral, thoracic and systemic infections in poorly controlled diabetes mellitus, burns and immunocompromised persons
Rhizomucor pusillus	*Rhizomucor pusillus* causes disseminated infections in immunocompromised persons
Rhizopus oryzae	*Rhizopus oryzae* invades and occlude blood vessels resulting in organ infarcts and hematogenous dissemination in immunocompromised persons
Dematiaceous fungi (pigmented fungi)	
Mycetoma	Mycetoma is chronic granulomatous disease of the skin and subcutaneous tissue, which sometimes involves skeletal muscle, bone and neighboring organs leading to tumefaction, abscess formation and fistulae in the lower extremities of farm workers
Phaeohyphomycosis	Phaeohyphomycosis is a clinical syndrome caused by melanized or dematiaceous fungi characterized by the presence of brown mycelial structures
Chromoblastomycosis	Chromoblastomycosis is a chronic fungal infection involving skin and subcutaneous tissue following traumatic injury and inoculation of the organism
Other fungi causing skin and subcutaneous infections	
Sporothrix schenckii	Sporotrichosis is also known as rose gardener disease caused by *Sporothrix schenckii* fungus
Cladosporium	*Cladosporium* species have been reported to cause infections of the skin and toenails as well as sinuses and lungs

* ***Zygomycota phylum members:*** *Absidia corymbifera, Rhizomucor pusillus and Rhizopus oryzae cause rhinocerebral, thoracic and systemic infections in poorly controlled diabetes mellitus, burns and immunocompromised persons.*

- **Tinea unguium:** It is common type of dermatophyte fungal infection called onychomycosis. The fungus causes infections in nails more commonly toe-nails, which become thickened and brittle. It is more common in older men, who have diabetes mellitus, peripheral vascular disease or immunocompromised persons.
- **Tinea cruris (jock itch):** Dermatophyte fungal infection causes skin lesions in moist areas such as upper thighs and genitalia. The disease is diagnosed by clinical manifestations and demonstration of fungus in potassium hydroxide wet mounted slide preparations.

Table 7.24 Classification of pathogenic fungi

Categories	Species
True pathogens	
Cutaneous infective fungi also called dermatophytosis	▪ *Epidermophyton flocossum* ▪ *Microsporum canis* ▪ *Trichophyton interdigitale* ▪ *Trichophyton rubrum*
Subcutaneous infective fungi (acquired through traumatic injury)	▪ *Actinomedura medurae* ▪ Cladosporium ▪ *Madurella grisea* ▪ *Sporothrix schenckii*
Fungi causing systemic infections	▪ *Blastomyces dermatitidis* ▪ *Coccidioides immitis* ▪ *Histoplasma capsulatum* ▪ *Paracoccidioides brasiliensis*
Opportunistic pathogens in immunocompromised persons	
Invading multiple organs	▪ *Aspergillus fumigatus* ▪ *Cryptococcus neoformans* ▪ *Candida albicans* ▪ *Absidia corymbifera* ▪ *Rhizomucor pusillus* ▪ *Rhizopus oryzae*

- **Tinea pedis (athlete foot):** It is a dermatophyte fungal infection that begins between the toes, which spreads to nails, which commonly occurs in persons whose feet become very sweaty while confined within tight-fitting shoes. Patient presents with scaly rash that usually causes itchy, stinging and burning sensations.

Laboratory Diagnosis

A scraping with KOH mount can be utilized to identify these fungi. Fungal cell walls are rich in mucopolysaccharides and stained with periodic acid-Schiff (PAS) stain resulting in bright pink to red appearance. Involved regions of skin and nails may fluoresce under ultraviolet light.

MOLDS

Molds (*Aspergillus fumigatus, Aspergillus flavus, Aspergillus niger*) cause allergic bronchopulmonary aspergillosis, fungal balls in damaged lungs, invasive disease of lung, sinuses, brain in neutropenic patients.

Aspergillus Fumigatus

Aspergillus fumigatus grows and invades blood vessels and produces organ infarcts, which may also grow in preexisting cavities caused by tuberculosis or bronchiectasis. Invasive form of aspergillosis has predilection for growth into blood vessels, with consequent widespread hematogenous dissemination.

- The fungus proliferates to form fungus balls, which are also referred to as aspergillomas or mycetomas in patients with a previous history of **cavitating** pulmonary disease such as pulmonary tuberculosis.
- The fungus generally does not invade the lung parenchyma. Lung shows focal yellow areas of consolidation. There are three different types of pulmonary aspergillosis, namely allergic bronchopulmonary aspergillosis, aspergillomas, and invasive aspergillosis.

Aspergillus Flavus

Aspergillus flavus is an opportunistic pathogen of crops, which is important because *Aspergillus flavus* produces a variety of secondary metabolites such as aflatoxins, cyclopiazonic acid, aflavinin, aflatrem, kojic acid, aspergillic acid, neoaspergillic acid, β-nitropropionic acid and paspalinine in the seeds of crops before and

Table 7.25 Cutaneous dermatophytes and lesions

Disease	Fungi Responsible	Cutaneous Lesions
Tinea pedis (athlete foot)	▪ *Trichophyton rubrum* ▪ *Trichophyton mentagrophytes* ▪ *Epidermophyton flocossum*	Area between toes spreading to nails
Tinea corporis (ringworm)	▪ *Epidermophyton flocossum* ▪ *Trichophyton* species ▪ Microsporum	▪ Most often on nonhairy areas of the trunk, but any area may be affected ▪ Active site of growth of fungi in the periphery of lesion
Tinea capitis (scalp ringworm)	▪ *Trichophyton* species ▪ Microsporum	Scalp lesions with hair loss
Tinea cruris (jock itch)	▪ *Epidermophyton flocossum* ▪ *Trichophyton rubrum*	Skin lesions in moist areas such as upper thighs and genitalia
Tinea unguium	*Trichophyton rubrum*	Nails thickened and brittle

after harvests. Aflatoxin B1 is one of the highly toxic metabolites of *Aspergillus flavus*, which can cause hepatocellular carcinoma.

Aspergillus Niger

Aspergillus niger causes a disease called '**black mold**' on certain fruits and vegetables such as grapes, onions, apricots and peanuts, which is a common contaminant of food. Some strains of *Aspergillus niger* secrete ochratoxins-mycotoxins, which can cause nephrotoxicity and renal tumors on consumption of contaminated fruits and vegetables.

YEAST

Yeast (*Candida albicans, Candida glabrata, Candida krusei, Candida parapsilosis* is unicellular fungus, which is reproduced by budding and causes oropharyngeal, mucocutaneous candidiasis. Yeast can be demonstrated in tissues or exudates if cultured in an incubator at 37°C.

Candida Albicans

Candida albicans causes vulvovaginitis affecting 10% of women, which is a normal vaginal flora. *Candida albicans* infection is commonly associated with pregnancy, diabetes mellitus, broad-spectrum antibiotic therapy, oral contraceptive use, and immunosuppression resulting in fungal growth.

- In immunocompromised patients, invasive form of *Candida albicans* produces blood-borne dissemination leading to abscess formation in lungs, kidneys, renal liver and endocardium.
- Patient presents with white curd-like vaginal discharge that may cause intense itching. Per vaginal examination shows white patches on the mucosal surface of vagina covered with vaginal discharge. Diagnosis is best made microscopically on wet mounts on Pap smear showing fungal hyphae.

Candida Glabrata

Candida glabrata is an opportunistic human fungal infection that causes superficial mucosal and life-threatening bloodstream infections in immunocompromised persons.

Candida Krusei

Candida krusei is a human fungal infection of patients with hematologic malignancies and transplant recipients. The fungus causes invasive candidiasis in hospitalized patients mainly due to its natural resistanceto fluconazole.

DIMORPHIC FUNGI

Some fungi occur in both the yeast and mycelial forms, which are called dimorphic fungi, which cause pneumonia and disseminated infection. Dimorphic fungi causing systemic infections involving multiple organs are given in Table 7.26.

- *Blastomyces dermatitidis* causes disseminated infection that involves skin, bone and genitourinary system.
- *Histoplasma capsulatum* causes systemic infection that involves liver, spleen, spleen and bone marrow demonstrated in macrophages in immunocompromised states such as human immunodeficiency virus (HIV) infection, corticosteroid therapy and immunosuppression therapy.
- *Coccidioides immitis* can involve central nervous system and bone.
- *Paracoccidioides brasiliensis* produces mucosal lesions in mouth and nose.

Blastomyces Dermatitidis

Blastomyces dermatitidis resides in moist soil and decomposed wood and leaves, which causes blastomyosis involving skin, bone and genitourinary system. Patient presents with fever, cough, night sweats, musculoskeletal pain, weight loss, chest pain and fatigue.

Histoplasma Capsulatum

Histoplasma capsulatum infection occurs in immunocompromised states like human immunodeficiency virus (HIV) infection, corticosteroid therapy and immunosuppression therapy. Fungus causes multiple pulmonary lesions with late calcification.

- Disseminated form of *Histoplasma capsulatum* is marked by multisystem involvement (liver, spleen and bone marrow, lymph nodes, skin) with infiltrates of macrophages filled with fungal yeast forms.

Table 7.26 Dimorphic fungi causing systemic infections involving multiple organs

Systemic Fungi	Possible Sites of Infection
Blastomyces dermatitidis	Skin, bone and genitourinary system
Coccidioides immitis	Central nervous system and bone
*Histoplasma capsulatum**	Lungs, Liver, spleen and bone marrow
Paracoccidioides brasiliensis	Lung, mucosa of mouth and nose; dissemination to central nervous system

**Histoplasma capsulatum infection occurs in immunocompromised states like HIV infection, corticosteroid therapy and immunosuppression therapy. Histoplasma capsulatum is demonstrated in reticuloendothelial cells of liver, spleen and bone marrow.*

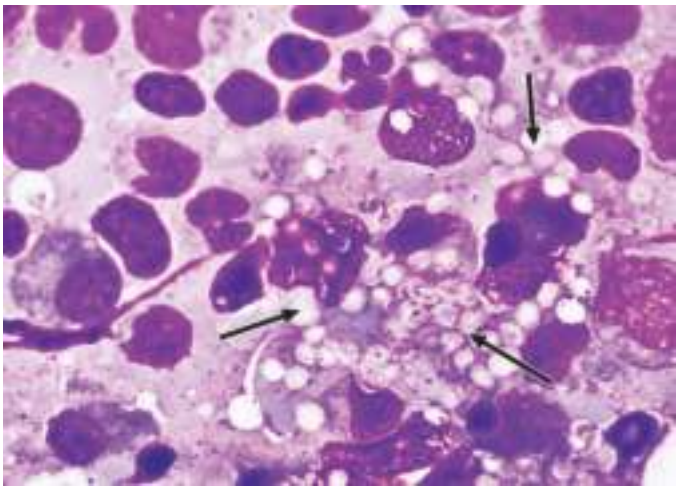

Fig. 7.48: Bone marrow demonstrates *Histoplasma capsulatum* as empty spaces in the reticuloendothelial cells in immunocompromised state (arrows) (1000X).

- *Histoplasma capsulatum* may remain clustered beyond the death of their host cells. It is difficult to identify the fungus on hematoxylin and eosin-stained sections, which appear as retracted artifact.
- Gomori methenamine silver stain and periodic acid–Schiff (PAS) stains are helpful to highlight organisms.
- Bone marrow demonstrates *Histoplasma capsulatum* as small, uniform, oval narrow-based yeasts appear as empty spaces in the reticuloendothelial cells in immunocompromised state is shown in Fig. 7.48.

Coccidioides Immitis

Coccidioides immitis occurs in primary and disseminated forms involving central nervous system and bone. Fungal spherules contain endospores found within granulomas.

Paracoccidioides Brasiliensis

Paracoccidioides brasiliensis is dimorphic human fungus endemic in subtropical regions of Mexico and Central and South America. The fungus infects lungs, oral mucosa and nasal cavity. Initial lesion occurs in lung, that disseminates to involve central nervous system.

BASIDIOMYCOTA

Basidiomycota are filamentous fungi composed of hyphae except its yeast form, which reproduce by sexual reproduction via formation of specialized club-shaped end cells called basidia that normally bear external meiospores (usually four). These specialized spores are called **basidiospores**.

CRYPTOCOCCUS NEOFORMANS

Pneumonia results from the inhalation of spores of *Cryptococcus neoformans*, which has a proteoglycan capsule responsible for its pathogenicity.

- *Cryptococcus neoformans* almost exclusively affects persons with impaired cell-mediated immune response, which has a proteoglycan capsule, which is essential for pathogenicity.
- The fungus primarily affects the meninges and lungs in immunocompromised persons, which appears as faintly stained, basophilic yeast with a clear, 3–5 μm thick mucinous capsule. *Cryptococcus neoformans* stains positively with a mucicarmine stain or Indian ink due to presence of polysaccharides in its capsule.
- Endobronchial ultrasound (EBUS) bronchoscopy demonstrates *Cryptococcus neoformans* is shown in Fig. 7.49. Mucicarmine stain demonstrates *Cryptococcus neoformans* is shown in Fig. 7.50. Silver methenamine stain demonstrates *Cryptococcus neoformans* is shown in Fig. 7.51.

MALASSEZIA FURFUR

Malassezia furfur is a fungus that resides on the superficial layers of the dermis, that causes tinea versicolor, catheter-related fungemia and sometimes pneumonia.

ZYGOMYCOTA

Zygomycota are usually rapid growing fungi characterized by **primitive coenocytic hyphae (mostly aseptate)**.

- Asexual reproduction in the zygomycetes results in nonmotile spores are called sporangiospores contained in sporangia borne on simple or branched sporangiophores.

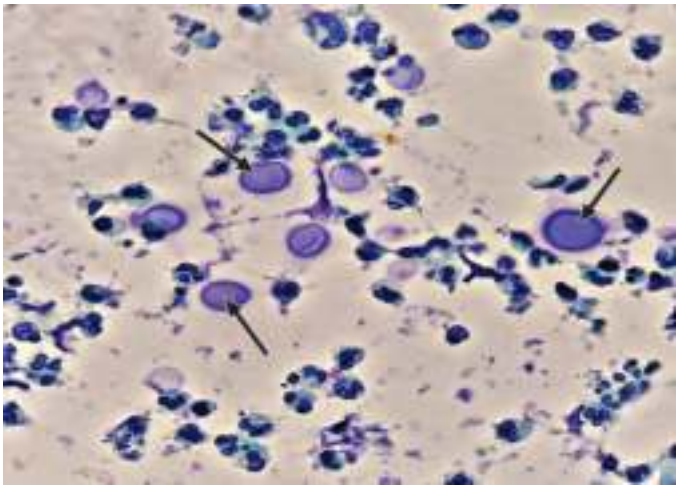

Fig. 7.49: Endobronchial ultrasound (EBUS) bronchoscopy demonstrates *Cryptococcus neoformans* (arrows) (400X).

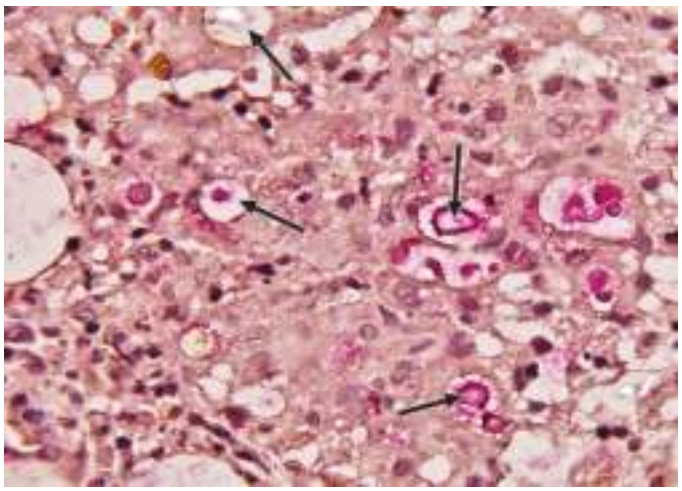

Fig. 7.50: Mucicarmine stain demonstrates *Cryptococcus neoformans* (arrows) (400X). (*Courtesy:* Dr. Vikram Raj Gopinathan, Postgraduate from Maulana Azad Medical College, New Delhi and presently working as Assistant Professor of Pathology, Christian Medical College, Vellore, Tamil Nadu.)

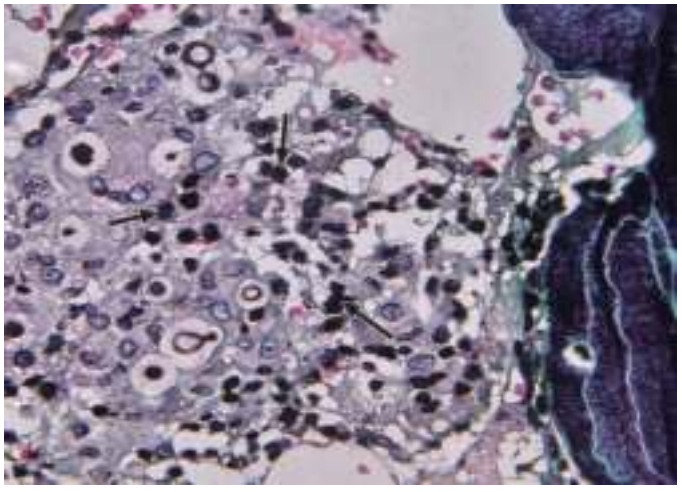

Fig. 7.51: Silver methenamine stain demonstrates *Cryptococcus neoformans* (arrows) (400X). (*Courtesy:* Dr. Vikram Raj Gopinathan, Postgraduate from Maulana Azad Medical College, New Delhi and presently working as Assistant Professor of Pathology, Christian Medical College, Vellore, Tamil Nadu.)

- Sexual spores are produced when two morphologically similar gametangia of opposite mating types fuse.

Pathology Pearls: Zygomycota—Members
Zygomycota members such as *Absidia corymbifera*, *Rhizomucor pusillus* and *Rhizopus oryzae* cause rhinocerebral, thoracic and systemic infections in poorly controlled diabetes mellitus, burns and immunocompromised persons.
Absidia corymbifera
Absidia corymbifera causes rhinocerebral, thoracic and systemic infections in poorly controlled diabetes mellitus, burns and immunocompromised persons.
Rhizomucor pusillus
Rhizomucor pusillus causes disseminated infections in immunocompromised persons.
Rhizopus oryzae
Rhizopus oryzae invades and occlude blood vessels resulting in organ infarcts and hematogenous dissemination in immunocompromised persons.

MUCORMYCOSIS

Mucormycosis has been previously called zygomycosis, which is also known as 'black fungus' which usually adversely affects immunocompromised persons.

- Symptoms depend on where in the body the infection occurs. There are three principal forms of mucormycosis, namely rhinocerebral, pulmonary, and cutaneous.
- Mucormycosis can produce necrotizing opportunistic infections that begin in the nasal sinuses or lungs.
- Histologic examination shows a purulent arteritis with thrombi composed of broad nonseptate hyphae branching at 90° accompanied by numerous neutrophils and histiocytes. Histologic characteristics of mucormycosis are prominent organ infarct, angioinvasion and perineural invasion.
- Mucormycosis should be suspected in patients who present with a paranasal sinusitis unresponsive to antibiotic treatment, particularly those who also have an underlying chronic disease (e.g. diabetes or leukemia). Histopathologic features of mucormycosis are shown in Fig. 7.52.

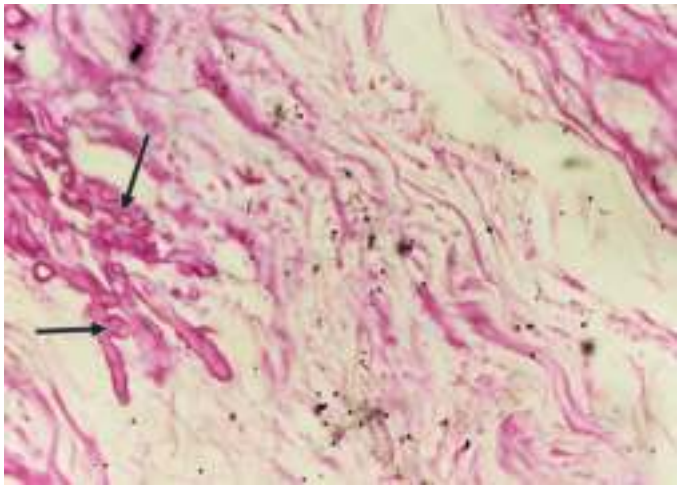

Fig. 7.52: Histopathologic features of mucormycosis. It demonstrates broad nonseptate hyphae branching at 90° accompanied by numerous neutrophils and histiocytes. Histopathologic characteristics of mucormycosis are prominent tissue infarct, angioinvasion and perineural invasion (arrows) (400X).

Pathology Pearls: Mucormycosis—Clinical Manifestations

Rhinocerebral Mucormycosis

- Pulmonary mucormycosis is usually fatal. The hard palate or nasal cavity is typically covered by a black crust, and the underlying tissues become friable and hemorrhagic.
- The fungal hyphae grow into arteries, causing devastating and rapidly progressive septic embolic infarctions also called zygomycosis.
- Rhinocerebral mucormycosis is caused by filamentous fungus that involves the nose, paranasal sinuses and brain in immunocompromised persons.

Pulmonary Mucormycosis

- Pulmonary mucormycosis is usually fatal. The hard palate or nasal cavity is typically covered by a black crust, and the underlying tissues become friable and hemorrhagic.
- The fungal hyphae grow into arteries, causing devastating and rapidly progressive septic embolic infarctions.

Subcutaneous Mucormycosis

- Subcutaneous mucormycosis is caused by opportunistic fungal infection in immunocompromised persons. Infection is acquired by direct inoculation through trauma.
- Patient presents with an indurated, localized, firm, nontender and mobile swelling, that rapidly evolved to necrosis is common pathologic finding.
- Diagnosis is established on histologic examination and culture.

DEMATIACEOUS FUNGI

Dematiaceous fungi are characterized by dark pigmentation of hyphae, which can cause diseases by direct inoculation or spore inhalation in human beings.

- Dematiaceous fungi are unique owing to the presence of melanin pigment in their walls, which imparts the characteristic dark color to their spores and hyphae.
  - Melanin may also be a virulence factor. Melanin production in hyphae scavenges oxygen-derived free radicals and inhibits phagocytosis.
  - Acute inflammatory cells fail to clear fungal infection leading to pyogranulomatous inflammation, which shows neutrophils and mononuclear cells.
  - Pigmentation may be faint on histologic examination; Masson-Fontana stain for melanin may prove helpful.
- Dematiaceous fungi can invade subcutaneous tissue, lungs, central nervous system and systemic or dissemination in immunocompromised patients.

Pathology Pearls: Dematiaceous Fungi

Examples of human diseases caused by dematiaceous fungi include mycetoma, phaeohyphomycosis and chromoblastomycosis. Mycetoma and chromoblastomycosis are prevalent in tropical and subtropical regions.

- **Mycetoma:** It is chronic subcutaneous collection of pigmented hyphae (fungus ball) that expands within the tissues and form tumor-like growth.
- **Phaeohyphomycosis:** It occurs due to trauma characterized by widely disseminated infection in immunocompromised patients. Its pigmented hyphae invade within skin, lung and brain.
- **Chromoblastomycosis:** It is chronic subcutaneous infection characterized by pigmented round structures termed 'copper pennies' within skin but no hyphae present.

Clinical Pearls: CARD19 (Caspase Recruitment Domain Family Member 19) Deficiency

- CARD19 is a protein encoding gene, that regulates apoptosis and inflammation through modulation of signals from pro-inflammatory to anti-inflammatory cytokines.
- Deficiency of CARD19, an autosomal recessive disorder, is associated with increased susceptibility to fungal infections especially phaeohyphomycosis, dermatophytes and *Candida albicans*.

MYCETOMA (MADURA FOOT)

Mycetoma (madura foot) is a chronic granulomatous subcutaneous infection caused by fungi (eumycetoma) or aerobic filamentous actinomycetoma. Mycetoma is commonly prevalent in tropical and subtropical countries like Central America, South America, Africa and India. Men especially agricultural workers are more susceptible.

- Mycetoma involves lower extremities, hands, back and buttocks.
  - Mycetoma starts with as a painless lump under the skin involving underlying fascia, which progresses to open infection, discharging sinuses with 'small grains' containing fungal spores leading to swollen, disfigured body regions such as lower extremities, hands, head and neck, chest, shoulder, arms, back and buttocks. Rare sites for eumycetoma include abdominal wall, face involving bones, paranasal sinuses, orbit or eyelid, and genitalia involving vulva or scrotum.
  - Madura foot shows suboptimal response to a wide range of antibiotics.
  - Untreated cases have no other option but to undergo amputation that consequently results in lifelong disability.

Fig. 7.53: Gross morphology of mycetoma. Cut surface of mycetoma foot demonstrates black granules. (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka.)

- Histologic examination of mycetoma shows black mycotic granules or grains surrounded by dense extracellular matrix. Pigmentation may be faint; **Fontana-Masson stain for melanin** may prove helpful. Gross morphology of mycetoma is shown in Fig. 7.53.

Actinomycetoma Madurae

Actinomadura madurae is one of the most frequent actinomycetes. Actinomycetoma occurs more often on chest or abdominal wall as compared to the extremities and mycetoma involving both limbs also have been reported.

Madurella Grisea

Madurella grisea causes **'black grain' mycetoma** in India, Africa, Central America and South America. Granules are black, round to lobed and soft to firm in consistency, which measure 0.3–0.6 mm in diameter with two distinct zones, hyaline to weakly pigmented central zone and deeply pigmented periphery. Diagnosis is established by examination of tissue sample under light microscope.

PHAEOHYPHOMYCOSIS

Phaeohyphomycosis refers to infections due to dematiaceous fungi, that can invade subcutaneous tissue, lungs, central nervous system and systemic or dissemination in immunocompromised patients.

- Dematiaceous fungal hyphae contain black melanin pigment in their walls, which likely act as virulence factor. Virtually, every person is exposed to dematiaceous fungi through inhalation, as these are ubiquitous in the environment.
- The highly virulent fungi implicated in causing brain abscess include *Cladophialophora bantiana* (neutropic; immunocompetent), *Exophiala dermatitidis* (neutropic; black yeast), *Lomentospora prolificans* (resistant to all antifungal drugs), *Rhinocladiella mackenziei*, *Verruconis gallopava*, *Chaetomium strumarium*, *Fonsecaea monophora*, *Wangiella dermatitidis*, *Bipolaris specifera*, *Curvularia lunata* and *Exserohilum heteropogonicola* (outbreak associated with corticosteroid injections).

Clinical Features

Patients present with invasive sinusitis, subcutaneous nodules or abscess, keratitis, pulmonary masses, brain abscesses, osteomyelitis, mycotic arthritis, endocarditis and disseminated infection.

Laboratory Diagnosis

Phaeohyphomycosis can frequently be discerned in tissue specimens stained with conventional hematoxylin and eosin and examined under light microscope, which appears as brownish, pigmented and septate hyphae, reflecting their high melanin content. Masson-Fontana staining for melanin confirms the diagnosis. Phaeohyphomycosis is distinguished from mycetoma and chromoblastomycosis by the absence of specific histopathologic findings such as sclerotic bodies or grains in the tissue. Culture is required to identify the causative species. Phaeohyphomycosis in brain (pigmented fungus) is shown in Figs 7.54 and 7.55.

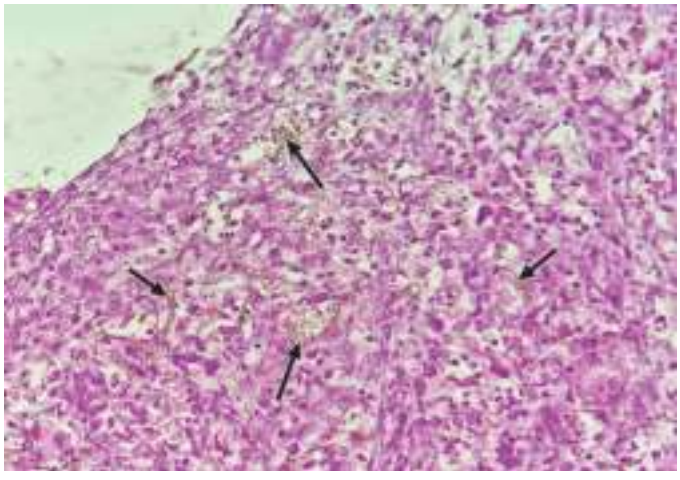

Fig. 7.54: Phaeohyphomycosis in brain (pigmented fungus). Phaeohyphomycosis is a clinical syndrome caused by melanized or dematiaceous fungi characterized by the presence of brown mycelial structures. The fungus has caused black, necrotic brain tissue, black pus, and black cerebrospinal fluid. Histologic examination of lesion demonstrates brown-walled septate hyphae (arrows) (400X). (*Courtesy*: Dr. Tushar Kalonia and Dr. Neha Kumari.)

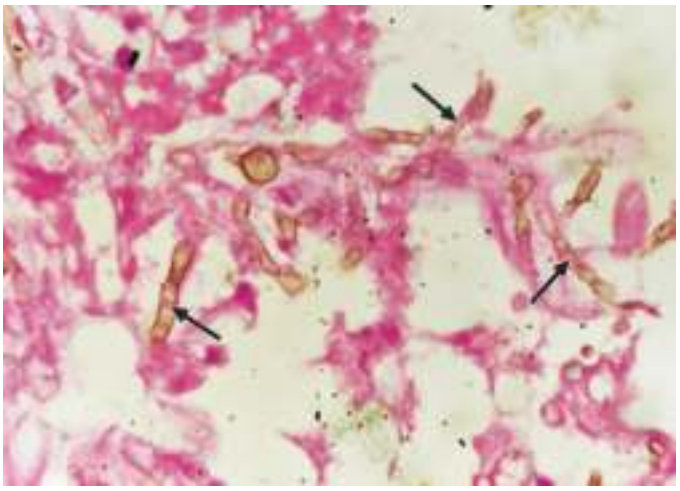

Fig. 7.55: Phaeohyphomycosis in brain (pigmented fungus). The fungus has caused black, necrotic brain tissue, black pus, and black cerebrospinal fluid. Histologic examination of lesion demonstrates brown-walled septate hyphae (arrows) (400X). (*Courtesy*: Dr. Neha Kumari and Dr. Tushar Kalonia.)

CHROMOBLASTOMYCOSIS

Chromoblastomycosis is a chronic fungal infection, which most often affects and subcutaneous tissue of upper and lower limbs at the inoculation site by a minor injury such as a cut with a splinter in barefooted person. Examples of chromoblastomycosis include *Phialophora verrucosa*, *Fonsecaea compacta*, *Fonsecaea pedrosi*, *Rhinocladiella aquaspersa* and *Cladophialophora carrionii*. Chromoblastomycosis is found in soil and plant debris mainly in tropical and subtropical regions. It is transmitted by traumatic inoculation.

Clinical Features

Patient presents with slowly progressive raised hyperkeratotic crusted warty looking lesion within 1.5 years over foot or hands of adult men engaged in outdoor work. The affected limb can enlarge generally that mimics elephantiasis. Satellite new primary lesions can develop. Rarely, squamous cell carcinoma of skin develops within long-standing chromoblastomycosis.

Laboratory Diagnosis

Histologic examination of chromoblastomycosis demonstrates dark typical thick-walled dark brown sclerotic bodies with thick-walled septations. It is dark colored fungus due to presence of melanin in its walls. Culture of fungus in Sabouraud medium with antibiotics at 25–30°C grows olive-green to black colonies after one or two weeks.

OTHER FUNGI CAUSING SKIN AND SUBCUTANEOUS TISSUE INFECTIONS

Sporothrix schenckii and Cladosporium fungi can cause skin and subcutaneous infections by direct inoculation following minor injury or inhalation. Other fungi causing skin and subcutaneous infections through traumatic injury are given in Table 7.27.

SPOROTHRIX SCHENCKII

Sporothrix schenckii causes sporotrichosis, which is a chronic infection of the skin and subcutaneous tissue. The fungus lives in soil, decaying plants and hay; and other living plants. *Sporothrix schenckii* usually enters the body through traumatic implantation of soil, plants and organic matter contaminated with fungus.

CLADOSPORIUM

Cladosporium is a genus of mold that includes more than 40 individual species of fungus, which can be found in indoor (basements, bathrooms, under sinks, carpets, curtains) and outdoor (decaying trees, dead plants and tree trunks) places. Most kinds of Cladosporium are not harmful to human beings. *Cladosporium* species have been reported to cause infections of the skin and toe-nails as well as sinuses and lungs including bronchial asthma.

Table 7.27 Other fungi causing skin and subcutaneous infections through traumatic injury

Fungus	Clinical Manifestations
Sporothrix schenckii	▪ Granulomatous ulcer at punctured site ▪ Secondary lesions along draining lymphatics
Cladosporium species	▪ Wart nodules ▪ Crusty abscess along draining lymphatics

PARASITIC INFESTATIONS

Parasites need another living host to get the nutrients they need to survive. Parasitic diseases are caused by protozoa and helminths, which can be spread through contaminated water, food, waste, soil, and blood. Cysticercosis, malaria, filariasis and hydatid cysts are common in India. Clinically important protozoa are given in Table 7.28. Clinically important metazoa (helminths) are given in Table 7.29.

Table 7.28 Clinically important protozoa

Pathogenic Protozoa	Mode of Locomotion	Site of Infection
Intestinal protozoa		
Entamoeba histolytica (amoeba)	Move by cytoplasmic projections	▪ Colon and secondary liver involvement ▪ Cysts demonstrated in stool
Giardia lamblia (flagellates)	Move by rotating whip-like flagella	▪ Duodenum (infection with drinking contaminated water) ▪ Foul smelling watery diarrhea ▪ Trophozoites and cysts demonstrated in stool
Cryptosporidium parvum (sporozoan)	Nonmotile adult form	▪ Parasite is intracellular in intestinal villus epithelium ▪ Infection by drinking contaminated water ▪ Duodenum involved (foul smelling diarrhea) ▪ Stool examination showing trophozoites and cysts
Urogenital system		
Trichomonas vaginalis (flagellates)	Move by rotating whip-like flagella	▪ Vagina, vulva and cervix in women ▪ Urethra, seminal vesicle and prostate in men ▪ Higher than normal pH favoring growth
Blood and tissues protozoa		
Plasmodium species (sporozoan)	Nonmotile adult form	Sporozoites introduced by mosquito bite
Toxoplasma gondii (sporozoan)	Nonmotile adult form	Sporozoites entering liver becoming merozoites infecting red blood cells
Trypanosoma species (flagellates)	Move by rotating whip-like flagella	▪ Cardiomyopathy in Americans by *Trypanosoma cruzi* ▪ CNS by *Trypanosoma brucei* and *Trypanosoma gambiense*
Leishmania species (flagellates)	Move by rotating whip-like flagella	▪ Phlebotomus (sand fly) bite ▪ Liver, spleen, lymph nodes and bone marrow (parasite infecting macrophages and migrating to these organs) ▪ Leishman-Donovan (LD) bodies demonstrated in tissue

Table 7.29 Clinically important helminths

Groups	Examples
Cestodes (tapeworms)	▪ *Echinococcus granulosus* (dog tapeworm) produces hydatid cyst in liver, lung and brain ▪ *Taenia solium* (pork tapeworm) produces cysticercosis diagnosed by CT and histopathologic examination ▪ *Taenia saginata* (beef tapeworm) ▪ *Diphyllobothrium latum* (broad fish tapeworm)
Trematodes (flukes)	▪ *Schistosoma haematobium* (blood fluke) ▪ *Schistosoma mansoni* (blood fluke) ▪ *Clonorchis sinensis* (Chinese or oriental liver fluke) ▪ *Paragonimus westermani* (lung fluke)
Nematodes (roundworms)	▪ *Ancyclostoma duodenale* (hookworm in intestine) ▪ *Ascaris lumbricoides* (giant roundworm in intestine) ▪ *Enterobium vermicularis* (small roundworm or threadworm in intestine) ▪ *Trichinella spiralis* (worm in intestine) ▪ *Trichuris trichiura* (whipworm in intestine) ▪ *Wuchereria bancrofti* (filarial worm) causing tissue infection ▪ *Oncocerca volvulus* (filarial worm) causing tissue infection ▪ *Loa-loa* (filarial worm or African eye worm) causing tissue infection ▪ *Brugia malayi* causing tissue infection ▪ *Dracunculus medinensis* causing tissue infection ▪ *Toxocara canis* (dog worm) causing tissue infection

PROTOZOA

Protozoa are eukaryotic, unicellular and lacking cell wall. The organelles of protozoa have similar functions to the organelles of higher animals. Protozoa reproduce primarily by asexual means, although some can reproduce by sexual mode.

ENTAMOEBA HISTOLYTICA

Entamoeba histolytica in the colon of infected persons in the form of infective cyst and trophozoites in the vegetative form. *Entamoeba histolytica* is transmitted by fecal–oral contact.

- **Cyst** of *Entamoeba histolytica* is the infective stage of parasite, which is surrounded by specific membrane. Cyst measures 10–20 × 12–50 µm in diameter, which contains 1, 2, 3, or 4 nuclei with a karyosome. Cyst can be demonstrated by **Lugol's iodine** stain or **Gomori-Wheatley stain**.
- **Trophozoite** form of parasite with a diameter of 12–50 µm is surrounded by cell membrane that creates amoeboid pseudopodia that participates in endocytosis of food particles.
  - Trophozoite contains a nucleus in which DNA is concentrated in the form of small dense karyosome and evenly distributed chromatin in the peripheral region.
  - Trophozoite invades submucosal veins of the colon, enters the portal circulation, and gains access to the liver leading to amoebic liver abscess.

Pathophysiology

Entamoeba histolytica can cause two types of clinical forms or amoebiasis: (a) acute or chronic intestinal amoebiasis, and (b) amoebic liver abscess.

Intestinal Amoebiasis

Acute intestinal amoebiasis is caused by trophozoites of *Entamoeba histolytica*. Trophozoites adhere to the epithelial cells of the colon, and synthesize proteolytic enzymes such as hyaluronidase, cysteine proteinase, cathepsin B, which produce a local inflammatory reaction, congestion and degradation.

- Trophozoites further invade the intestinal submucosal tissue and induce cyclooxygenase 2 enzyme leading to increased secretion of prostaglandin E_2 (PGE_2), which contribute to inflammatory process.
- Acute intestinal amoebiasis manifests with persistent diarrhea containing mucus and blood in the stool, and accompanied by abdominal pain, flatulence, vomiting and fever. Severe diarrhea results in hemorrhages and ulcers in the colon, dehydration, electrolyte water imbalance, cardiovascular instability and collapse.
- Untreated cases lead to chronic intestinal amoebiasis, which is characterized by alternating bloodless diarrhea and constipation of varying severity, ulcerative colitis, liver enlargement, low-grade fever and anemia.

Amoebic Hepatitis and Abscess

In some persons, amoeba trophozoites may travel through the bloodstream from the large intestine to the liver.

- Amoebic hepatitis can develop as a consequence of acute intestinal amoebiasis, which is characterized by liver hepatomegally, fever, chills and perspirations. Biochemical analysis reveals elevated liver enzymes ALT and AST.
- Amoebic liver abscess is dangerous complication of acute intestinal amoebiasis, which is filled with a dark brown material that resembles anchovy paste. Patient presents with abrupt onset of fever, anorexia and dull aching abdominal pain in the right upper quadrant or epigastrium, usually lasting less than 10 days. Jaundice is unusual.
- An amoebic liver abscess can rupture and extend into the peritoneal cavity. Trophozoites of *Entamoeba histolytica* in the mucosa and submucosa of large intestine are shown in Fig. 7.56.

Other Organs Involved due to Amoebiasis

Amoebic liver abscess can create an abscess in the various organs such as lungs, pericardium, spleen, brain, kidneys and urinary bladder in immunocompromised persons. Sometimes amoebic abscesses require surgical removal. *Entamoeba histolytica* can cause asymptomatic infestations (subclinical disease) as trophozoites do not cause damage to the mucosa of large intestine.

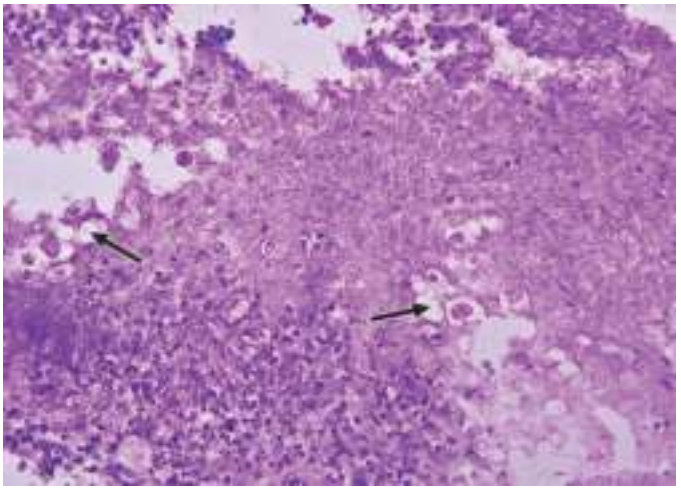

Fig. 7.56: Trophozoites of *Entamoeba histolytica* in the mucosa and submucosa of large intestine. *Entamoeba histolytica* is a protozoan of human large intestine, which is a causative agent of amoebiasis (arrows) (400X).

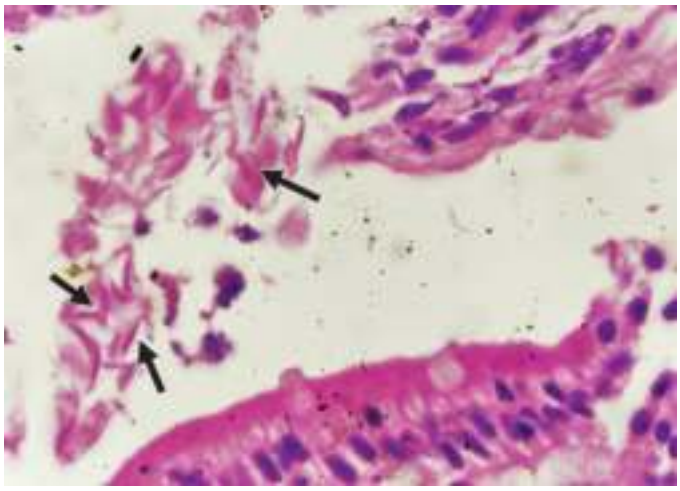

Fig. 7.57: Giardia lamblia parasites are seen on the mucosal side of intestine (arrows) (400X).

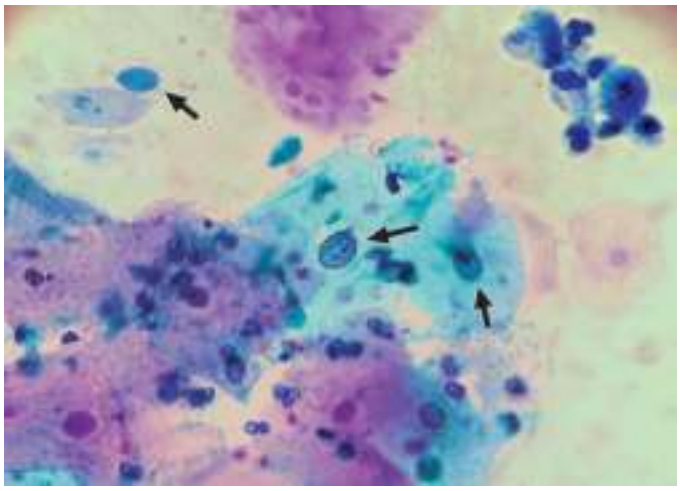

Fig. 7.58: *Trichomonas vaginalis*. Pap smear demonstrates *Trichomonas vaginalis* (arrows) (400X).

GIARDIA LAMBLIA

Giardiasis is an infestation of the small intestine by the flagellated protozoan *Giardia lamblia*. Parasite can be acquired from contaminated water or food.

- Patient presents with abdominal cramping and non-bloody diarrhea. The gastrointestinal symptom usually resolves in 1–4 weeks, but chronic giardiasis may lead to malabsorption, weight loss, and growth retardation. *Giardia lamblia* does not induce significant villus architectural changes.
- The *Giardia lamblia* are recovered from stool specimens, duodenal aspirates, or luminal surface of normal appearing mucosa of intestinal biopsies. The parasite is mistaken as cytoplasmic debris. Giemsa stain and Masson trichrome stain highlight the parasite. *Giardia lamblia* parasites are seen on the mucosal side of intestine are shown in Fig. 7.57.

TRICHOMONAS VAGINALIS

Trichomonas vaginalis is the second most common cause of vaginitis commonly transmitted by sexual contact. Patient presents with a profuse opaque or creamy colored frothy vaginal discharge with fishy smell.

- Vaginal discharge may cause vulvar irritation and burning micturition due to urethral inflammation. *Trichomonas vaginalis* is best diagnosed in freshly prepared wet mounts (i.e. smears of unfixed vaginal discharge in which the flagellated protozoa keep moving).
- *Trichomonas vaginalis* is also demonstrated as flagellated motile organisms in wet mounted smear. *Trichomonas vaginalis* is shown in Fig. 7.58.

MALARIAL PARASITE

Plasmodium is a wide distribution in many tropical or subtropical regions of the world. *Plasmodium* species known to cause malaria in human beings are *Plasmodium vivax*, *Plasmodium falciparum*, *Plasmodium ovale* and *Plasmodium malariae*. *Plasmodium* species infect erythrocytes. Unlike those of other *Plasmodium* species, gametocytes of *Plasmodium falciparum* are elongated and crescent-shaped by which they are identified.

- *Plasmodium falciparum* causes 'blackwater fever' and hemoglobinuria. Red blood cell hemolysis releases hemoglobin into the urine leading to renal failure. Ischemic injury to the brain leads to range of symptoms such as somnolence, hallucinations, behavioral changes, seizures, and even coma. The liver, spleen, and lymph nodes are darkened by macrophages that are filled with hemosiderin and malaria pigments.
- Timely identification of the infecting *Plasmodium* species is important, as *Plasmodium falciparum* can be fatal and is often resistant to chloroquine treatment. Peripheral blood smear demonstrates infected red blood cells with *Plasmodium falciparum*.

Life Cycle

Asexual life cycle of *Plasmodium falciparum* occurs in human and sexual life cycle in mosquito. Infected mosquito bites and injects sporozoites, which infect the hepatocytes resulting in release of merozoites.

- The **merozoites** infect red blood cells and develop into trophozoites, schizont and gametocytes. The trophozoites multiply and produce merozoites, which infects other red blood cells.

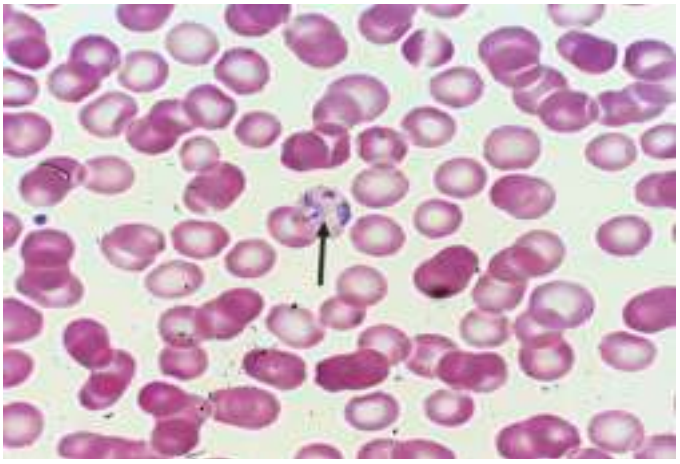

Fig. 7.59: *Plasmodium vivax*. Peripheral blood smear examination shows infected red blood cells and Schuffner's dots and amoeboid trophozoite (arrows) (1000X).

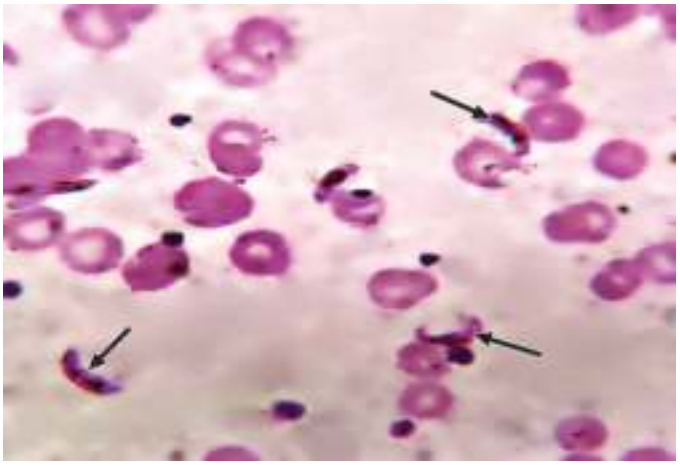

Fig. 7.60: *Plasmodium falciparum* in peripheral blood smear. Unlike those of other *Plasmodium* species, gametocytes of *Plasmodium falciparum* are elongated and crescent-shaped by which they are identified (arrows) (1000X).

- Rupture of infected red blood cells liberate gametocytes. The female mosquito picks up gametocytes from an infected human. Sexual cycle occurs in the mosquito leading to formation of sporozoites.
- *Plasmodium vivax* and **Schuffner's dots** and amoeboid trophozoite in infected red blood cells are shown in Fig. 7.59. *Plasmodium falciparum* in peripheral blood smear is shown in Fig. 7.60.

LEISHMANIASIS

Leishmania parasites are intracellular protozoans, which are transmitted to humans through insect bites of Phlebotomus sandflies, which acquire infections from feeding on infected animals. They cause a spectrum of clinical syndromes, ranging from indolent self-resolving cutaneous ulcers to fatal disseminated disease.

- Amastigote form is present in the human body, which measures 1–2 × 3–6 micron in diameter and ovoid in shape. Amastigote form is composed of intercalated ring of DNA, which serves key metabolic functions and possible drug target.
- Amastigote form is detectable within the reticuloendothelial cells (macrophages/monocytes). Kinetoplast looks like a small nucleus and helpful feature for identification. Culture and polymerase chain reaction are diagnostic modalities.

Clinical Features

Three distinct clinical entities are recognized: localized cutaneous leishmaniasis, mucocutaneous leishmaniasis, and visceral leishmaniasis.

- **Cutaneous leishmaniasis (localized/diffuse):** Cutaneous leishmaniasis is caused by *Leishmania major*, *Leishmania tropica*, *Leishmania guinensis*. Patient with small, erythematous and pruritic papule leading to formation of round and ring-shaped ulcer and local lymphadenopathy, which may regress spontaneously with scar formation although recurrences may occur.
- **Mucocutaneous leishmaniasis:** Mucocutaneous leishmaniasis is caused by *Leishmania brasiliensis* and *Leishmania guinensis*. Patient presents with disfigurement of nasopharynx, pharynx and perioral skin.
- **Visceral leishmaniasis (kala azar):** Visceral leishmaniasis is caused by *Leishmania donovani* (India, East Africa), *Leishmania infantum*, *Leishmania tropica* and *Leishmania chagasi*.
  - Amastigote form of parasite involves reticuloendothelial cells. Patient presents with persistent fever, progressive weight loss, hepatosplenomegaly and hematopoietic suppression (anemia, thrombocytopenia, and leukopenia).
  - Light-skinned persons develop darkening of the skin, which is usually fatal if untreated. Histology of visceral leishmaniasis is shown in Fig. 7.61. Bone marrow involvement by leishmaniasis is shown in Fig. 7.62.

BABESIOSIS

Babesiosis is caused by microscopic parasite 'Babesia' that infects red blood cells. Babesia parasitic infection is transmitted by certain tick especially during warm months in North East and upper Mid-East regions.

- The parasite grows and reproduces inside the red blood cells of the infected persons and often causes intense pain due to red blood cells rupture.
- Many persons infected with Babesia remain asymptomatic. Disease can be prevented if steps are taken to reduce exposure to ticks.

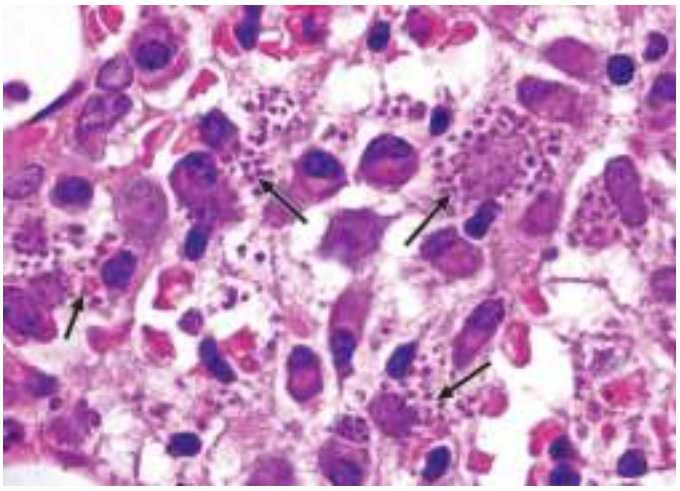

Fig. 7.61: Histology of visceral leishmaniasis demonstrates amastigote stage of *Leishmania donovani* in reticuloendothelial cells (arrows) (400X).

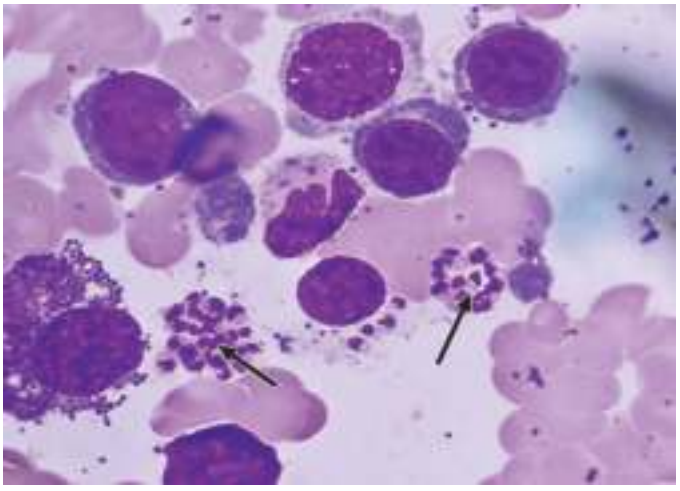

Fig. 7.62: Bone marrow involvement by leishmaniasis demonstrates amastigote stage of *Leishmania donovani* in reticuloendothelial cells (arrows) (1000X).

Clinical Features

Severity of the symptoms of babesiosis can vary from slight flu-like to life-threatening complications.

- Patient presents with high fever, chills, muscular joint aches and fatigue. Less common manifestations include severe headache, abdominal pain, nausea, jaundice and skin bruising.
- Disease progression may cause chest or hip pain, breathlessness and drenching sweats. Patient may develop complications such as hypotension, hemolytic anemia, liver dysfunction, renal failure and heart failure.

AFRICAN TRYPANOSOMIASIS

Human African trypanosomiasis is also known as **sleeping sickness**. It is transmitted by the bite of tsetse fly (Glossina genus) to persons from infected persons with protozoan parasite and residing in sub-Saharan Africa. Trypanosoma can cross the placenta and infect the fetus. Human African trypanosomiasis takes two forms, depending on the subspecies of the parasite involved: (a) *Trypanosoma brucei gambiense* (95%), and (b) *Trypanosoma brucei rhodesiense* (5%). Without treatment, disease is considered fatal.

Clinical Features

- **Hemolymphatic stage of disease:** In the first stage, trypanosomes multiply in the subcutaneous tissues, blood and lymph. It is also called hemolymphatic stage. Patient presents bouts of fever, headache, lymphadenopathy, arthralgia and itching.
- **Meningoencephalic stage of disease:** In the second stage, trypanosomes cross the blood–brain barriers to infect the central nervous system. This is known as meningoencephalic stage. Patient presents with behavioral changes, confusion, sensory disturbances, poor coordination and sleeping sickness.

CHAGAS DISEASE

Chagas disease is known as American trypanosomiasis. When the persons become infected by the parasite *Trypanosoma cruzi*, they can suffer of Chagas disease. The feces of the vector 'Tryptominae', or 'kissing bugs', transmits the parasites to the persons. Other routes of transmission include oral route, blood/blood products transfusion, mother–fetus transmission and organ transplantation. Symptoms change over the course of the infection. *Trypanosoma cruzi* infection is curable if patients are treated.

Clinical Features

Patient of Chagas disease presents itself in two phases: (a) initial acute phase of infestation in Chagas disease, and (b) chronic phase of infestation in Chagas disease patients are at risk for severe acute respiratory syndrome CoV-2 (SARS-CoV-2) manifestions and should be a priority group to be vaccinated.

- **Initial acute phase of infestation** in Chagas disease persists for two months after infection, in which numerous parasites circulate in the bloodstream but persons are usually asymptomatic in 50% of cases. Rest 50% of persons may present with skin lesion, purple swelling of the lids of unilateral eye, fever, headache, lymphadenopathy, pallor, muscular pain, breathlessness, chest pain and abdominal pain.
- **During chronic phase of infestation** in Chagas disease patients have hidden parasites in the cardiac muscle and muscular coat of gastrointestinal tract (i.e. esophagus and colon) and nervous system leading to cardiac arrhythmias, megaesophagus, megacolon and neurological manifestations.

METAZOA (HELMINTHS)

Metazoa (helminths) are multicellular eukaryotic organisms in biological animal kingdom. Metazoa include *Strongyloides stercoralis*, *Wuchereria bancrofti*, *Taenia solium*, *Taenia saginata* and *Taenia asiatica*, *Ancylostoma duodenale*, *Enterobius vermicularis*, Trichinosis and Schistosoma.

STRONGYLOIDIASIS

Strongyloidiasis is a human disease caused by nematode round worm called *Strongyloides stercoralis*, which most often infects small intestine and rarely colon. The parasite is diagnosed by demonstration of larvae, eggs and adult worms embedded in the crypts. Eosinophils, sometimes with Charcot-Leyden crystals may be present. Gastric strongyloidiasis may occur in association with human T-lymphotropic virus causing adult T cell lymphoma. *Ascaris lumbricoides* causing small intestine gangrene is shown in Fig. 7.63.

LYMPHATIC FILARIASIS

Infective form is third stage larva of *Wuchereria bancrofti* responsible for lymphatic filariasis, which enters through skin inoculation by mosquito bite and localizes in the lymphatic system especially inguinoscrotal region. Microfilariae are demonstrated in small number in circulating blood during the day and peak density at night between 10 pm and 2–4 am due to feeding habit of mosquitoes at night. In subperiodic form, microfilariae are demonstrated between noon and 8 pm due to feeding habit of mosquitoes during daytime.

Fig. 7.63: *Ascaris lumbricoides* causing small intestinal gangrene. *Strongyloides stercoralis* (roundworm nematode) causing gangrene of small intestine (arrows).

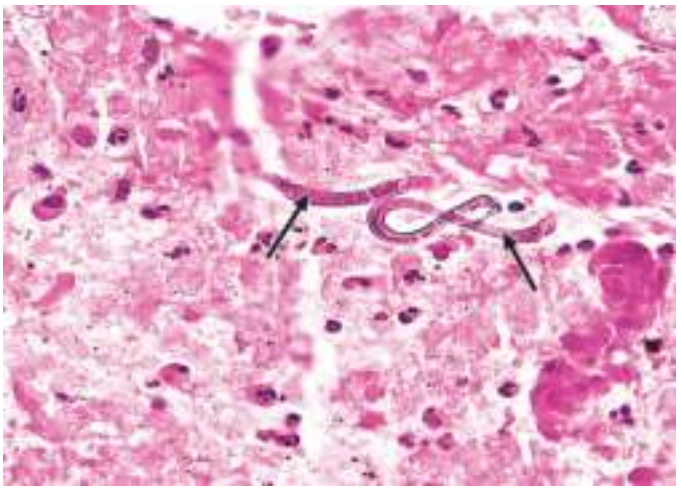

Fig. 7.64: *Wuchereria bancrofti* adult worms in endometrial curettings. Histologic examination of endometrial curettings shows adult *Wuchereria bancrofti* adult worms, necrotic endometrial fragments and inflammatory cells (arrows) (400X). (*Courtesy*: Dr. Tushar Kalonia.)

Pathogenesis

Adult worm and developing larva incite an inflammatory reaction in the lymphatic system lymphangitis. The reaction products of growing larvae are highly allergenic producing urticaria, 'fugitive swellings' and lymphedema. Intensity and type of host immune response may reflect range of clinical manifestations. Immune response varies by stage of infection.

- Elephantiasis is relatively a late complication of filariasis and characterized by swelling of limbs, scrotum, breasts or vulva with dermal hypertrophy. Impairment of the circulation leads to secondary bacterial and fungal infections in the regions.
- Chronic lymphedema leads to hyperplasia of connective tissue, infiltration by eosinophils, macrophages and plasma cells. *Wuchereria bancrofti* adult worms in endometrial curettings are shown in Fig. 7.64.

Clinical Features

Initially, patient is asymptomatic. Later patient presents with fever and symptoms due to inflammation and obstruction of lymphatic channels (limbs, breasts, and scrotum), lymphadenitis (femoral, inguinal, axillary and epitrochlear nodes), orchitis, lymphocele, hydrocele and **elephantiasis**.

Laboratory Diagnosis

Diagnosis of filariasis is frequently made on clinical grounds in endemic regions but demonstration of microfilariae in circulating blood is the key. Where more than one species of filarial infection occurs, it needs well stained slides for morphological identification of microfilariae.

- **Conventional method:** Thick stained peripheral blood smear is examined to demonstrate microfilariae.
- **Concentration techniques:** It is done by nucleopore filtration or Knott's concentration, detection of circulating filarial antigen by rapid format card test/immunochromatographic card test (ICT).
- **Serodiagnosis:** Filariasis is diagnosed by polymerase chain reaction (PCR) based assays for DNA.
- **Imaging studies:** High frequency ultrasound, lymphoscintigraphy is performed to diagnose filariasis.
- **Light microscopy:** Adult worm lodges in the lymph node leading to lymphangitis and lymph varices. The vascular endothelium of the vessels is occupied by the parasite leading to obliterative endolymphangitis and occlusion of the lymphatic channels. There is infiltration of monocyte, macrophage and giant cells killing the worm and replacing the lymph node with fibrous tissue eventually.

CYSTICERCOSIS—TAPEWORM (CESTODE)

Three species of cestodes in human include: *Taenia solium, Taenia saginata* and *Taenia asiatica*. Out of these Taenia solium causes major health problems, *Taenia solium* taeniasis is acquired by human beings through the ingestion of the parasite's larval cysts (cysticerci) in undercooked and infected pork.

- **Tissue infection** caused by ingestion of contaminated food, water or faces with larva cysts of the cestode *Taenia solium* (cysticercus cellulose). In cysticercosis, the human represents an intermediate host and the parasite develops cysticerci in various organs.
- The term **taeniasis** refers to intestinal infection with cestodes (adult tapeworms), which occurs from ingestion of larvae in undercooked pork. Cysticerci are larva forms or tapeworms found within a fluid-filled cyst.

Life Cycle

- Human beings are carriers of cestode (tapeworm), who excrete eggs in their feces and contaminate the environment when they defecate in open areas.
- Human beings can also become infected with *Taenia solium* eggs due to poor hygiene (via the fecal–oral route) or ingestion of contaminated water and food. Ingested *Taenia solium* eggs develop to larvae (called **cysticerci**) in nervous system, heart, skeletal muscle, subcutaneous tissue and eyes of the human body. When eggs enter the central nervous system and produce **neurocysticercosis**, which can cause neurological symptoms such as severe headache, blindness, convulsions and epileptic seizures.
- *Taenia solium* is the cause of epilepsy in 30–70% of population in endemic areas where people live in proximity to roaming pigs.

Laboratory Diagnosis

Clinical history, biopsy, serology, cerebrospinal fluid examination, cytological examination and imaging can aid in the proper diagnosis of cysticercosis.

- Ultrasonography can reveal cystic lesions. Computed tomography scan can reveal hyperdense lesions in the tissue with or without calcification.
- Cytological examination reveals fibrillary stroma interspersed nuclei and a honeycomb pattern infiltrated by mixed inflammatory infiltrate.
- The treatment of taeniasis by *Taenia solium* is important to prevent neurocysticercosis and as a tool to assist in controlling the parasite transmission cycle.

Surgical Pathology: Cysticercosis

Gross Morphology

Gross morphology of lesion reveals circumscribed, white to tan, cystic nodules measuring 1 mm to 2 cm in diameter containing clear fluid. Larva forms are identified within the cyst cavity.

Light Microscopy

- Histologic examination of cysticercosis lesion reveals larva form in the cystic cavity, scolex with hooklets and two pairs of suckers.
- The larva form is composed of duct-like invaginations and lined by a double-layered eosinophilic structure. Its body exhibits a myxoid matrix and calcified bodies. Birefringent hooklets may be identified.
- There is presence of granulomatous reaction, inflammatory infiltrate with lymphocytes and eosinophils, fibrosis and calcification. Histopathologic examination of cysticercosis lesion is shown in Fig. 7.65.

HYDATID CYST—TAPEWORM (CESTODE)

Hydatid cyst is caused by *Echinococcus granulosus*, a tapeworm (cestode). Adult parasites are found in dogs and sheep. Humans are infected after ingestion of eggs. Right lobe of liver is the commonest site of hydatid cyst followed by lung.

- When the lungs are affected, protoscolices might be found in sputum or bronchial washings.
- Liver contains multiple cysts of variable size invading surrounding tissue. Color of the cysts resembles white of boiled egg.
- Echinococcosis is diagnosed mainly with imaging techniques such as ultrasonography, radiology, magnetic resonance imaging (MRI) or CT scanning, supported by serology. Hydatid cyst of spleen is shown in Fig. 7.66.

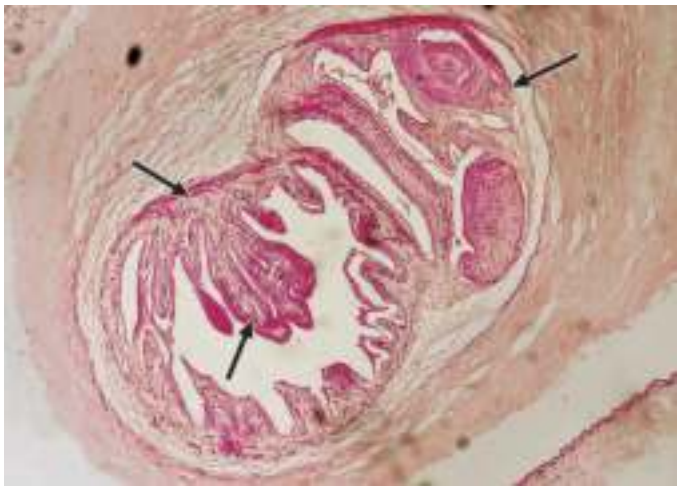

Fig. 7.65: Histopathologic examination of cysticercosis lesion reveals larva form in the cystic cavity, scolex with hooklets and two pairs of suckers. The larva form is composed of duct-like invaginations and lined by a double-layered eosinophilic structure. Its body exhibits a myxoid matrix and calcified bodies. There may be presence of granulomatous reaction, inflammatory infiltrate with lymphocytes and eosinophils, fibrosis and calcification (arrows) (400X).

Fig. 7.66: Hydatid cyst of spleen. The outer, thick fibrotic wall of the cyst is clearly seen and the cyst is filled with multiple daughter cysts of varying sizes (arrow).

Cytological Smear Examination

Cytological smear examination shows laminated membranous structures resembling ectocyst of hydatid cyst.

- Periodic acid–Schiff (PAS) stain highlights the laminated membranous structures as magenta-colored structures.
- Gomori methenamine stain stains laminated membranous structures black.
- Claw-like refractile hooklets are demonstrated in the background by Ziehl-Neelsen stain as bright purple. Accidental spillage during fine needle aspiration may cause anaphylactic shock.

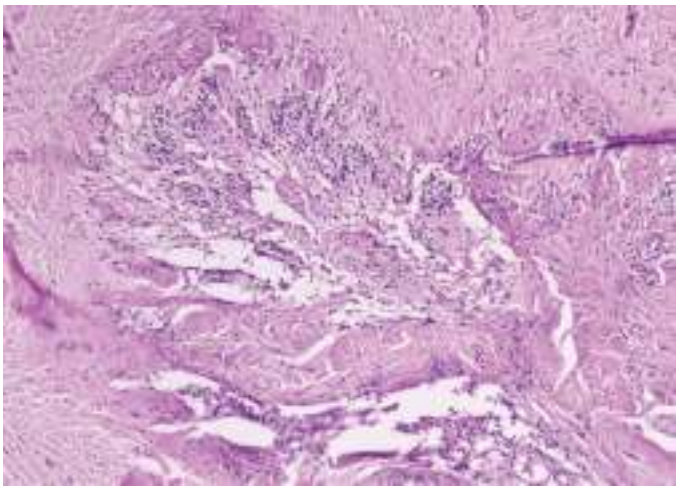

Fig. 7.67: Histology of hydatid cyst involving liver. The cyst wall shows an inner germinal layer (endocyst), outer chitinous (fibrous lamina) ectocyst layer surrounded by either granulation tissue or a fibrous capsule (pericyst) (400X).

Histologic Examination

On histologic examination, hydatid cyst wall consists of endocyst and ectocyst surrounded granulation tissue (pericyst). Serological tests used in humans include enzyme-linked immunosorbent assays (ELISAs), indirect immunofluorescence, indirect hemagglutination, immunoblotting and latex agglutination. Histology of hydatid cyst involving liver is shown in Fig. 7.67.

ANCYLOSTOMA DUODENALE (NEMATODE)

The adult worm of *Ancylostoma duodenale* (hookworm) lives in the small intestine of human beings in the jejunum less often in the duodenum and rarely in the ileum. Freshly passed adult worm is small greyish white, cylindrical and curved shape and reddish-brown color due to the ingested blood in the intestinal tract. Life cycle of *Ancylostoma duodenale* is completed in human beings. No intermediate host is required.

Mode of Transmission

Human feces are the only source of infection. Infective filariform larva is transmitted either by penetration of skin or fecal–oral route or rarely via breastfeeding by mothers to infants.

Clinical Features

The infective filariform larvae at the site of the penetration of the skin, produce a local reaction called **ground itch**.

- The migration of large number of filariform larvae, through the lung produces minute hemorrhages and infiltration of leukocytes resulting in the entrapment of the larva in the lung tissue associated with

low-grade fever, mild cough, dizziness, pneumonia with pulmonary consolidation. Both eosinophilia and leukocytosis occur at this stage.
- Intestinal infection manifests as abdominal pain, nausea, vomiting, hemorrhagic diarrhea, blood loss and iron deficiency anemia associated with pallor, fatigue, and breathlessness on exertion. Hypoproteinemia associated edema.

ENTEROBIUS VERMICULARIS ('PINWORM') NEMATODE

Enterobius vermicularis ('pinworm') is an intestinal nematode encountered worldwide and more common in temperate zones. Individuals can be infected at any age, but parasitism is more common in children. Most people complain of pruritus due to migration of *Enterobius vermicularis*.

TRICHINOSIS

Trichinosis is a type of roundworm infestation, which primarily induce disease in bears, foxes and pigs. The infestation is acquired eating trichinella roundworm larvae in raw or undercooked meat. Trichinella larvae mature into adult worms in the small intestine over several weeks. The adult roundworms then produce larvae that travel through various tissues including skeletal muscle. Trichinosis is most widespread in rural regions across world.

Clinical Features

Severity of clinical manifestations of trichinosis infection depend on the number of larvae consumed in the infected meat. Patient presents with diarrhea, abdominal pain, fatigue, nausea and vomiting within 1–2 days after infestation. Other symptoms usually start 3–8 weeks after infestation such as high-grade fever, skeletal muscle pain and tenderness, swelling of eyelids and face, weakness, headache, photophobia and conjunctivitis.

SCHISTOSOMIASIS

Schistosomiasis, also called as bilharzia, or snail fever or Katayama fever is an acute and chronic disease caused by trematode parasitic flatworms of the genus Schistosoma. The parasite may infect intestine or urinary tract. Lack of proper hygiene, swimming or fishing in infested water make the persons vulnerable to infection. Parasite species and geographical distribution of schistosomiasis are given in Table 7.30.

Life Cycle

Person becomes infected, when larva form of the parasite is released by fresh water snails. The larva form of parasite penetrates skin during contact with infected water.
- Transmission occurs when persons suffering from schistosomiasis contaminate fresh water sources with their excreta containing larva form of parasite, which hatch in water. The larva then develops into adult schistosomiasis in the body.
- Adult worms reside in the blood vessels, where the female adult worms release eggs. Some of the eggs are excreted in the feces or urine to continue the parasite's life cycle. Other eggs become trapped in body tissues, causing immune reactions and progressive damage to organs.

Clinical Features

Within 1–2 months of infestation, patient presents with fever, chills, cough and muscular aches. Without treatment, schistosomiasis can persist for years and the patients present with abdominal pain, hepatomegaly, diarrhea, bloody stool or blood in the urine.

ONCHOCERCIASIS

Onchocerciasis is also known as river blindness, because the blackflies that transmit *Onchocerca volvulus*, which breed in rapidly flowing streams mostly near remote rural villages. It is the second most cause of blindness after trachoma.

Table 7.30 Parasite species and geographical distribution of schistosomiasis

Species	Geographical Distribution
Intestinal schistosomiasis	
Schistosoma mansoni	Africa, the Middle East, the Caribbean, Brazil, Venezuela and Suriname
Schistosoma japonicum	China, Indonesia, Philippines
Schistosoma mekongi	Columbia and Lao People's Democratic Republic
Schistosoma guineensis and related *Schistosoma intercalatum*	Rain forest regions of Central Africa
Urinary bladder	
Schistosoma haematobium	Africa, Middle East, Corsica (France)

- Onchoerciasis is caused by parasitic filarial worm *Onchocerca volvulus* transmitted through repeated bites by female blackflies of the genus Simulium of an infected person.
- These female blackflies exist mainly in Africa and some parts of Central and South America. In the human body, adult worms produce embryonic larvae (microfilariae) that migrate to the skin, subcutaneous tissue, eyes and other organs.

Life Cycle

The life cycle of *Onchocerca volvulus* begins inside human host, which consists of the following four stages.

- **Stage I:** Young parasitic worms called microfilariae move toward the skin of human host. Female blackfly bites the human host, and ingest the microfilariae.
- **Stage II:** While inside the female blackfly, the microfilariae develop into larvae within a week.
- **Stage III:** The infected female blackfly bites a person, transferring the worm larvae into the human host. Here the larvae develop into adult worms in a process that takes about 6–12 months. Swollen nodules are formed around the adult worms.
- **Stage IV:** Adult worms reside inside the human body for up to 15 years. Most of the microfilariae inside the human body, trigger the inflammatory immune response. Depending on the location of the worms within human body, the inflammatory response may cause damage to skin or eye.

Clinical Features

Patient with *Onchocerca volvulus* infestation presents with severe itching, skin rashes over hands, feet, buttocks and shoulders, lumps under the skin undergoing into blisters due to presence of worms, and eye damage. Untreated onchocerciasis may also result in permanent skin damage and blondness.

Red Blood Cell Disorders

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

HEMATOPOIESIS

- Hematopoiesis: overview
  - Site of hematopoiesis
    - Hematopoiesis during intrauterine life
    - Hematopoiesis during postnatal period
  - Hematopoietic microenvironment
    - Hematopoietic cells
    - Nonhematopoietic cells
- Regulation of hematopoiesis
  - Hematopoietic transcription factors
  - Hematopoietic growth factors in clinical practice
  - Role of hormones in hematopoiesis
- Pathways involved in hematopoiesis
  - Erythropoiesis
    - Development of red blood cells
    - Metabolic pathways in the red blood cells
  - Leukopoiesis
    - Granulocytes
    - WBCs: qualitative anomalies
    - Agranulocytes
  - Thrombopoiesis
- Bone marrow aspiration
  - Bone marrow aspiration needles
  - Bone marrow aspiration sites
  - Bone marrow aspiration procedure
  - Bone marrow aspirate smear staining
  - Bone marrow aspirate smears: avaluation
- Bone marrow trephine biopsy
  - Bone marrow trephine biopsy needles
  - Bone marrow trephine biopsy procedure
  - Bone marrow trephine biopsy fixation
  - Bone marrow trephine biopsy section staining technique

RED BLOOD CELL, HEMOGLOBIN, ANTICOAGULANTS AND ANEMIAS

- Red blood cell
  - Red blood cell indices
  - Reticulocyte count
- Hemoglobin
- Anticoagulants used in laboratory
  - Ethylenediaminetetra-acetic acid (EDTA) and trisodium citrate
  - Heparin
- Anemias
  - Causes of anemia
  - Diagnostic approach of anemia

IRON METABOLISM AND IRON DEFICIENCY ANEMIA

- Iron metabolism
- Iron deficiency anemia
  - Etiopathogenesis
  - Clinical features
  - Laboratory diagnosis
  - Response to iron therapy
  - Iron overload

MEGALOBLASTIC ANEMIA, FOLIC ACID AND VITAMIN B_{12} DEFICIENCY

- Megaloblastic anemia
- Megaloblastic anemia: classification
- Megaloblastic anemia due to folic acid deficiency
- Vitamin B_{12} deficiency
  - Role of vitamin B_{12} and folic acid in DNA synthesis
- Pernicious anemia

RED BLOOD CELLS DESTRUCTION AND CLASSIFICATION OF HEMOLYTIC ANEMIA

- Hemolytic anemia: overview
  - Clinical features
  - Compensatory mechanisms of hemolytic anemia
- Extravascular hemolysis involving RBCs destruction
- Intravascular hemolysis involving RBCs destruction

HEREDITARY SPHEROCYTOSIS, OVALOCYTOSIS AND STOMATOCYTOSIS: RBC MEMBRANE DEFECTS

- Hereditary spherocytosis
- Hereditary ovalocytosis
- Hereditary stomatocytosis

THALASSEMIAS

- Thalassemias: overview
- β-Thalassemias
  - β-Thalassemia major
  - β-Thalassemia minor (trait)
  - β-Thalassemia intermedia
- α-Thalassemias
  - Silent carrier of α-thalassemia
  - α-Thalassemia trait
  - Hemoglobin H disease (β_4)
  - Hydrops fetalis
- Hereditary persistence of fetal hemoglobin

SICKLE CELL DISORDERS AND OTHER HEMOGLOBINOPATHIES

- Sickle cell disease
- Sickle cell trait
- Sickle cell thalassemia syndrome
- Hemoglobin C disorder
- Hemoglobin D disorder
- Hemoglobin E disorder

G6PD DEFICIENCY AND PYRUVATE KINASE DEFICIENCY DISORDERS

- G6PD deficiency disorder
- Pyruvate kinase deficiency disorder

IMMUNE-MEDIATED HEMOLYTIC ANEMIA

- Autoimmune hemolytic anemia
  - Warm antibody-mediated hemolytic anemia
  - Cold agglutinin disease
  - Paroxysmal cold hemoglobinuria
- Alloimmune hemolytic anemia
  - Hemolytic disease of newborn

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

RED BLOOD CELL FRAGMENTATION SYNDROMES

- Cardiac hemolytic anemia
- Microangiopathic hemolytic anemia
- Hemolytic uremic syndrome
- Thrombotic thrombocytopenic purpura
- March hemolytic anemia

DIAGNOSTIC APPROACH OF HEMOLYTIC ANEMIA

BONE MARROW FAILURE SYNDROMES

- Aplastic anemia
- Pure red cell aplasia (erythroblastopenia)
- Sideroblastic anemia
- Congenital dyserythropoietic anemia
- Anemia of chronic disease
- Myelophthisic anemia
- Fanconi anemia

HEMATOPOIESIS

HEMATOPOIESIS: OVERVIEW

Process of formation of blood cells is called hematopoiesis, which occurs within bone marrow microenvironment (niche), where hematopoietic stem cells (HSCs) come in contact with many other cells.

- Cell-to-cell communication occurs in bone marrow by binding via cell surface receptors, adhesion molecules, cytokines and hematopoietic growth factors. Binding of hematopoietic growth factor to its receptor activates the JAK/STAT. MAPK and phosphatidylinositol 3-kinase (PI3K) pathways, which l ead to transcriptional activation of specific genes resulting in cell proliferation, differentiation and inhibition or activation of apoptosis.
- Apoptosis occurs by activation of caspases by DNA damage, release of 'cytochrome c' from mitochondria and by FAS ligand.
  - Apoptosis is inhibited by BCL-2. E2F is a transcription factor needed for cell cycle transition from G1/S phase. ET2 is inhibited by tumor suppressor retinoblastoma protein (pRB), which can be indirectly activated by p53 tumor suppressor protein.
  - The synthesis and degradation of different cyclins stimulate the cell to pass through the different phases of cell cycle.
  - The growth factors may also suppress apoptosis by activating AKT (protein kinase B). Hematopoiesis during intrauterine life and postnatal life is shown in Fig. 8.1 and Table 8.1.

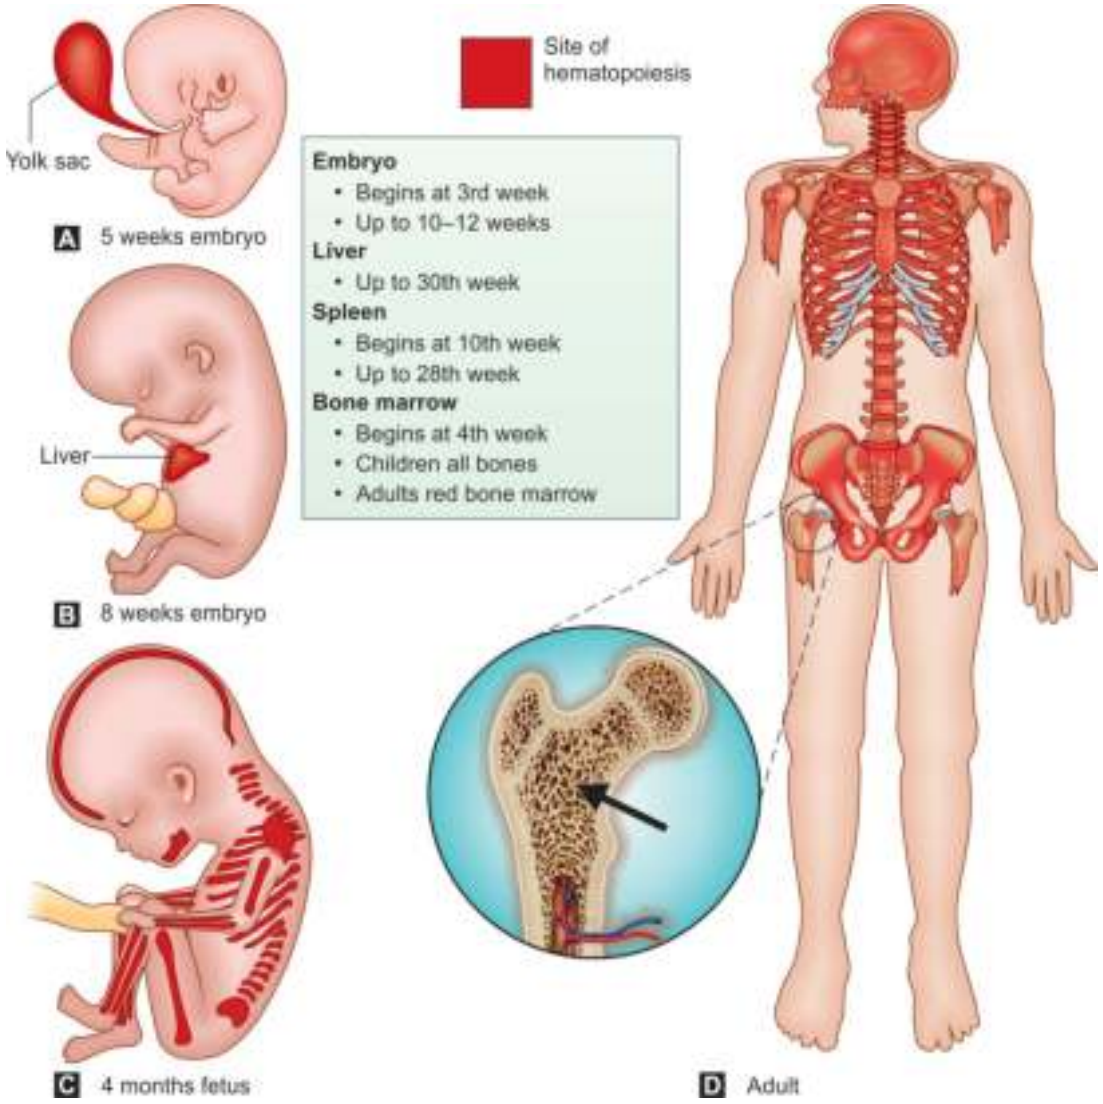

Fig. 8.1: Hematopoiesis during intrauterine life and postnatal period.

Table 8.1 Sites of hematopoiesis and bone marrow cellularity during intrauterine and postnatal life

Age Group	Sites of Hematopoiesis	Type of Hemoglobin and Globin Chains	Bone Marrow Cellularity
Embryonic development			
2–8 weeks	Aorta gonad mesonephros (AGM)/yolk sac	▪ Hemoglobin Gower I ($\zeta_2\varepsilon_2$) ▪ Hemoglobin Gower II ($\alpha_2\gamma_2$) ▪ Hemoglobin Portland ($\zeta_2\gamma_2$)	Nil
Fetus			
2–7 months	Liver, spleen, bone marrow, thymus, lymph nodes during 2–7 months of age	▪ HbA ($\alpha_2\beta_2$) small quantity ▪ HbA_2 ($\alpha_2\delta_2$) small quantity	100%
5–9 months	Bone marrow (main site during 5–9 months)	▪ HbF ($\alpha_2\gamma_2$) 90–95% just before birth	100%
Infants to childhood age group			
Newborn to 3 months and children	Bone marrow (all bones rich in red bone marrow in newborn)	▪ HbA ($\alpha_2\beta_2$) 25% ▪ HbA_2 ($\alpha_2\delta_2$) 1% ▪ HbF ($\alpha_2\gamma_2$) 75%	100% and then decreased to 60–80% during childhood
Adults age group			
22–40 years, 40–70 years and >70 years (bone marrow cellularity decrease as age advances)	▪ Red bone marrow in vertebrae, ribs, sternum, skull, sacrum, pelvis; proximal end of femur and humerus. ▪ Red bone marrow is gradually replaced by yellow bone marrow in most bones except bones mentioned as site of hematopoiesis	▪ HbA ($\alpha_2\beta_2$) >95% ▪ HbA_2 ($\alpha_2\delta_2$) <3.5% ▪ HbF ($\alpha_2\gamma_2$) 1%	▪ 60–70% ▪ 40–50% ▪ 30–40%

SITE OF HEMATOPOIESIS

Hematopoiesis during Intrauterine Life

During embryonic life, hematopoiesis begins in the 2 weeks embryo. Liver takes over hematopoiesis function in 8 weeks embryo and continues until a few weeks before birth. Spleen starts hematopoiesis during 3–7 months of intrauterine period. Thymus gland and lymph nodes participate in production of lymphocytes. Bone marrow also participates in hematopoiesis during intrauterine life.

Hematopoiesis during Postnatal Period

At birth until first 2–3 years after birth, all bones contain red marrow involved in hematopoiesis. During adult life by the age of 18–22 years, hematopoiesis occurs in cranial bones, vertebrae, sternum and ribs, iliac bones and upper ends of femur and humerus.

HEMATOPOIETIC MICROENVIRONMENT

Hematopoietic microenvironment comprises two types of cells: hematopoietic stem cells and nonhematopoietic cells. Hematopoietic microenvironment is shown in Fig. 8.2 and Table 8.2.

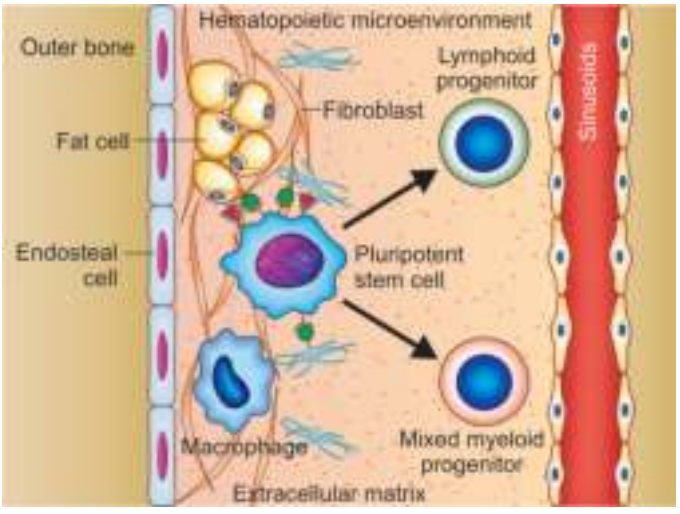

Fig. 8.2: Hematopoietic microenvironment in bone marrow: Adipocytes, endothelial cells, fibroblasts, osteoblasts, T cells and macrophages participate in expression of homing receptors and synthesis of soluble growth factors, soluble differentiation factors, extracellular matrix components; and integral membrane proteins that function as juxtacrine regulators (SCF, FL, SCI). Cytokines and growth factors synthesized by extracellular component participate in regulation of hematopoietic stem cell/progenitor cell differentiation and expansion. Collagen gives structural strength. Extracellular components such as glycosaminoglycans participate in cell-to-cell interactions and localization of growth factors; while cytoadhesion molecules participate in adhesion of hematopoietic precursors to ECM proteins.

Table 8.2 Hematopoiesis depends on hematopoietic microenvironment (i.e. stromal cells and extracellular matrix)

Hematopoietic Components	Functions
Hematopoietic cells	
Hematopoietic stem cells (HSCs)	CD34+ (potential to self-replicate and differentiate to progenitor cells)
Progenitor cells (committed cells)	Myeloid progenitor cells, lymphoid progenitor cells, i.e. colony forming units resulting in production of red blood cells, white blood cells and platelets
Cellular stroma	
Macrophages, fibroblasts, reticulum cells, adipocytes, endothelial cells, and T cells	▪ Expression of homing receptors ▪ Synthesis of soluble growth and differentiating factors ▪ Synthesis of integral membrane proteins that function as juxtacrine regulators (stem cell factor) ▪ Synthesis of extracellular matrix components
Extracellular microenvironment	
Soluble factors (cytokines and growth factors)	Regulation of hematopoietic stem cell/progenitor cell differentiation and expansion
Extracellular matrix (ECM) and collagen fibers	Structural support
ECM glycosaminoglycans (heparan, chondroitin, dermatan sulfate)	Cell-cell interactions; localization of growth factors
Cytoadhesion molecules	Adhesion of hematopoietic precursors to extracellular matrix proteins

The hematopoietic stem cell (HSC) attaches to bone marrow stromal cells via specific receptors and ligands. The HSC is then influenced by both positive and negative regulatory growth factors.

Hematopoietic Cells

Hematopoietic cells are composed of hematopoietic stem cells (CD34+), progenitor cells (committed cells) and mature cells (RBCs, WBCs and platelets). Self-renewal is an important property of hematopoietic stem cells. Some of the hematopoietic stem cell disorders are given in Table 8.3.

Hematopoietic Stem Cell Lineages

Hematopoietic stem cells (HSCs) have the potential to self-replicate and differentiate into committed progenitors of trilineage myeloid and lymphoid cells (B cells, T cells and NK cells).

- Trilineage myeloid cell gives rise to erythroid/megakaryocytic, eosinophilic, and granulocytic/macrophage.
- Progenitor cells are multipotent stem cells derived from hematopoietic stem cells. These are committed to one cell lineage such as myeloid, erythroid, megakaryocyte or lymphoid cells.
- Late progenitor cells differentiate and undergo maturation forming red blood cells (RBCs), white blood cells (WBCs), platelets and lymphocytes.

Colony Forming Units

Committed stem cells have been grown *in vitro* by cell culture techniques on semisolid media of agar or methylcellulose, with the production of colonies of differentiated progeny. Colony consists of 40 to a few hundred cells.

- Thus, the committed stem cells have been called colony forming units (CFU), e.g. CFU-G/M, CFU-Eo and CFU-E/M. Cluster consists of 3–40 cells.

Table 8.3 Hematopoietic stem cell disorders

Hematopoietic Stem Cell (HSC)	Hematopoietic Stem Cell Disorders
Proliferation and differentiation of HSC	▪ Chronic myelogenous leukemia ▪ Essential thrombocythemia ▪ Polycythemia vera
Proliferation with nil or minimal differentiation of HSC	▪ Acute myelogenous leukemia ▪ Acute lymphoblastic leukemia
Failure of proliferation with somatic mutation of HSC	▪ Paroxysmal nocturnal hemoglobinuria
Proliferation with abnormal differentiation and apoptosis of HSC	▪ Myelodysplastic syndrome
Failure of proliferation of HSC	▪ Aplastic anemia

- During bone marrow transplantation, administration of G-CSF, GM-CSF and IL-1 acts on bone marrow microenvironment and causes migration of bone marrow stem cells to peripheral blood. Colony forming units are shown in Fig. 8.3 and Table 8.4.

Nonhematopoietic Cells

Nonhematopoietic cells comprise stromal cells, macrophages, fibroblasts and vascular endothelial cells. These cells synthesize growth factors, which stimulate hematopoiesis.

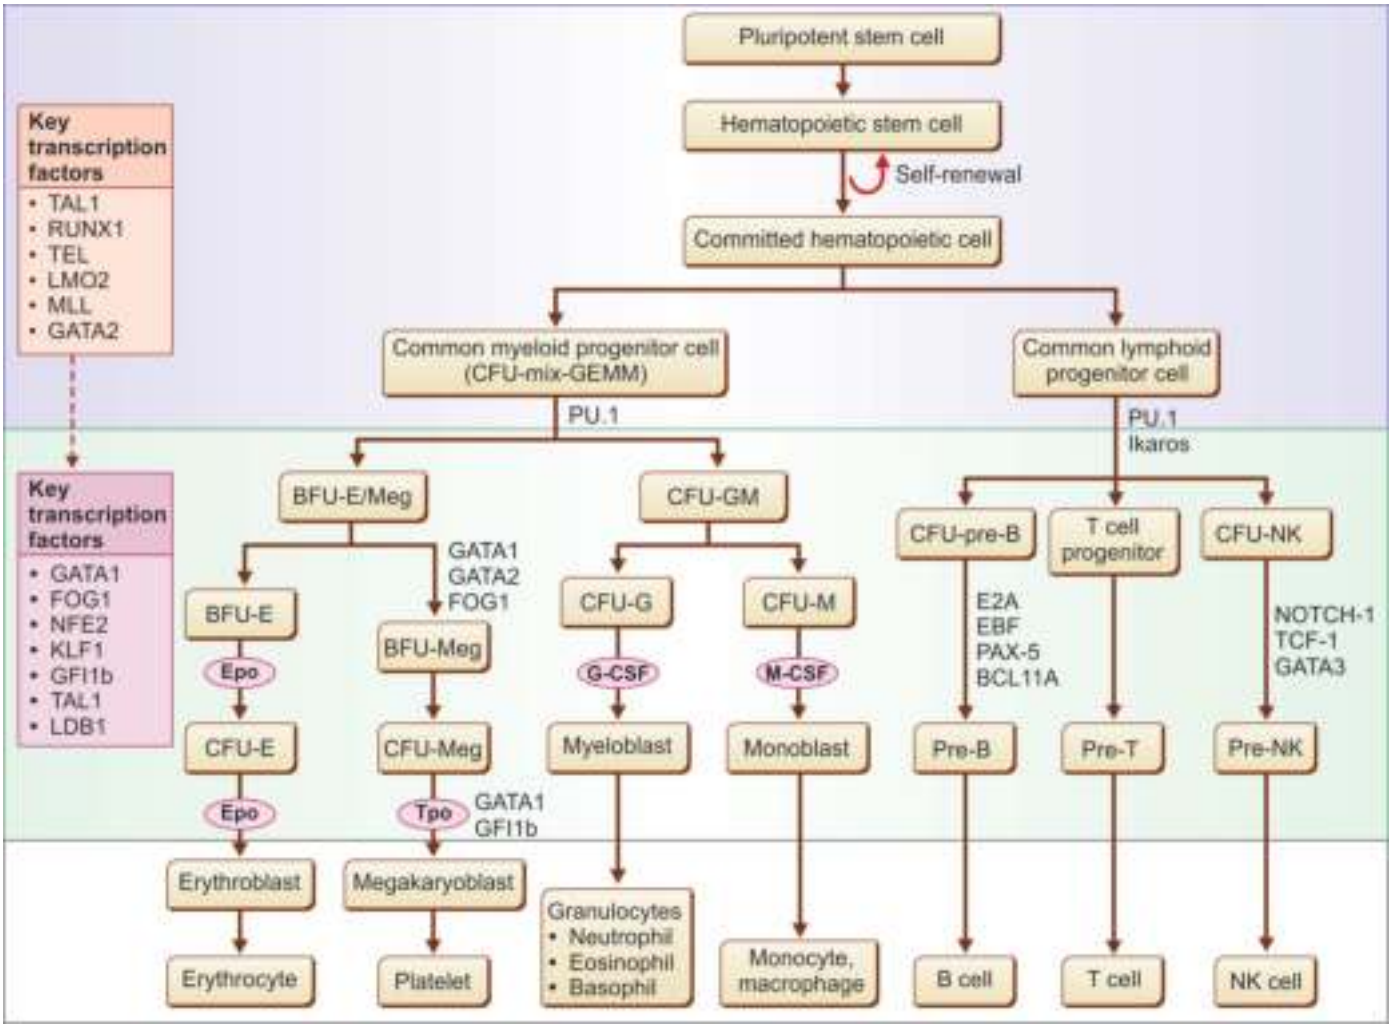

Fig. 8.3: Hematopoiesis shows stages of development of blood cells.

Table 8.4 Colony forming units in bone marrow microenvironment

Colony Forming Unit	Production of Cells in Bone Marrow
CFU-GEMM or CFU-MIX	Earliest units giving rise to granulocytic, erythroid, monocytic and megakaryocytic cells
CFU-GM	Unit of progenitor cells giving rise to granulocytic–monocytic series
CFU-Eo	Colonies of eosinophilic myeloid cells
CFU-Baso	Colonies of basophilic myeloid cells
CFU-MG	Colonies of megakaryocytic myeloid cells
BFU-E (burst-forming unit-erythroid)	Earliest progenitor erythroid cells
CFU-E	More differentiated cells of erythroid progenitors

REGULATION OF HEMATOPOIESIS

- Hematopoiesis is regulated by hematopoietic growth factors, inhibitory mechanisms and apoptosis. Negative regulators of hematopoiesis include TGF-β, TNF-α, interferons, PGEs, lactoferrin, CD8+ cytotoxic T cells and natural killer cells, vitamin D_3 (1,25-dihydroxyvitamin D_3), acidic isoferritins and macrophage inflammatory protein-1α (MIP-1α).
- Kit-ligand and FLT-3 ligand and vascular endothelial growth factor (VEGF) stimulate pluripotent hematopoietic stem cells.
- Erythropoietin (EPO) regulates eythropoiesis and production of erythroid cells, their differentiation and survival by inhibiting apoptosis.
- Thrombopoietin (TPO) is synthesized by liver and kidneys, that stimulates megakaryopoiesis.
- Hematopoietic growth factors are the cytokines that stimulate bone marrow stromal cells to synthesize colony-forming units. GM-CSF stimulates granulocytes, monocytes, eosinophils, erythroid cells, megakaryocytes, hematopoietic progenitor cells (HPCs) and dendritic cells. G-CSF regulates granulocytes and hematopoietic progenitor cells (HPCs). M-CSF regulates monocyte/macrophage and osteoclast cells.
- IL-3 is multi-CSF growth factor for the trilineage myeloid stem cells; thus, stimulate the more committed precursor cells. Many interleukins (IL-1, IL-2, IL-4, IL-5, IL-7, IL-8, IL-9, IL-10, IL-11, IL-12, IL-13) regulate lymphopoiesis. Hematopoietic growth factors (HGFs) regulating hematopoiesis are given in Table 8.5. Selected hematopoietic growth factors and their source are given in Table 8.6.

Table 8.5 Hematopoietic growth factors (HGFs) regulating hematopoiesis

Hematopoietic Growth Factor	Chromosome	Source	Major Target Cells/Actions
Kit-ligand	–	Bone marrow stromal cells	Pluripotent hematopoietic stem cell
FLT-3 ligand	–	T cells	Pluripotent hematopoietic stem cell
Erythropoietin (EPO)	7	Kidney (liver)	Erythroid cells, their differentiation and survival by inhibiting apoptosis
Thrombopoietin (TPO)	3	Bone marrow stromal cells, hepatocytes, kidney	Megakaryopoiesis, hematopoietic stem cells
IL-3 (multi-CSF)	5	Activated T cells, mast cells	Hematopoietic trilineage progenitor cells and more committed cells, mast cells
GM-CSF	5	Activated T cells, bone marrow stromal cells, endothelial cells	Granulocytes, monocytes, eosinophils, erythroid cells, megakaryocytes, hematopoietic progenitor cells (HPCs), dendritic cells
G-CSF	17	Monocytes, macrophages, bone marrow stromal cells	Granulocytes, hematopoietic progenitor cells (HPCs)
M-CSF	1	Monocytes, macrophages, bone marrow stromal cells	Monocytes, macrophages, osteoclasts
IL-1	2	Monocytes, macrophages, dendritic cells	Monocytes, endothelial cells, fibroblasts, lymphocytes, polymorphonuclear cells and early hematopoietic progenitor cells
IL-2	4	Activated Th1 cells	Activation and proliferation of T cells, B cells and natural killer cells
IL-4	5	Activated Th2 cells	Stimulates Th2 cells, suppresses Th1, mast cells, basophils
IL-5	5	Activated Th2 cells, mast cells	Eosinophil, B cells, cytotoxic T cells
IL-6	7	Macrophages, Th2 cells, fibroblasts	Early hematopoietic progenitor cells, B cells, T cells, megakaryocytes and myeloma cells
IL-7	8	Bone marrow stromal cells, dendritic cells, hepatocytes, keratinocytes, neurons, epithelial cells and thymus stromal cells	Pre-T cells, pre-B cells, natural killer cells
IL-8	4	Monocytes, macrophages, endothelial cells	Chemotaxis of granulocytes (chemokine)

Contd...

Table 8.5 Hematopoietic growth factors (HGFs) regulating hematopoiesis (*Contd...*)

Hematopoietic Growth Factor	Chromosome	Source	Major Target Cells/Actions
IL-9	5	Activated Th2 cells	T cells, B cells, early erythroid cells, mast cells
IL-10	1	Activated Th2 cells, monocytes, macrophages, B cells	B cells, mast cells, Th2 and inhibits Th1
IL-11	19	Bone marrow stromal cells	B cells, megakaryocytes and natural killer cells
IL-12	3.5	Monocytes, macrophages, B cells, T cells	Th1 cells, natural killer cells
IL-13	5	Activated Th2 cells, basophils	▪ Isotype switching of B cells ▪ Inhibition of cytotoxic and inflammatory functions of monocytes and macrophages
IL-14	16	T cells	Activated B cells
IL-15	4	Monocytes, macrophages, endothelial cells, fibroblasts	▪ CD8+ cytotoxic T cells ▪ Natural killer cells ▪ Costimulator of B cells
IL-16	15	T cells, eosinophil, epithelial cells	Chemotactic for CD4+ helper T cells
IL-17	2	Activated Th17 cells	Induces cytokine production by bone marrow stromal cells
IL-18	7	Macrophages, keratinocytes	Induces interferon production by Th1 cells, natural killer cells
Stem cell factor/KL (SCF/KL)	12	Fibroblasts, monocytes, macrophage, T cells	▪ Stem cells ▪ Early hematopoietic progenitor cells ▪ Basophils, mast cells ▪ Melanocytes ▪ Germ cells
FLT3 (fetal liver tissue 3) ligand	19	Bone marrow stromal cells, hepatocytes, kidney	▪ Hematopoietic stem cells ▪ Hematopoietic progenitor cells ▪ Dendritic cells

Table 8.6 Selected hematopoietic growth factors and their source

Source of Hematopoietic Growth Factors	Hematopoietic Growth Factors
Kidney, liver	Erythropoietin, thrombopoietin
Monocytes/macrophage	IL-1, IL-6, G-CSF, M-CSF
Lymphocytes	IL-2, IL-3, IL-4, IL-5, IL-6, GM-CSF
Endothelial cells	IL-6, GM-CSF, M-CSF

G-CSF—granulocyte-colony stimulating factor; GM-CSF—granulocyte-macrophage colony stimulating factor; and M-CSF—macrophage-colony stimulating factor.

ERYTHROPOIETIN

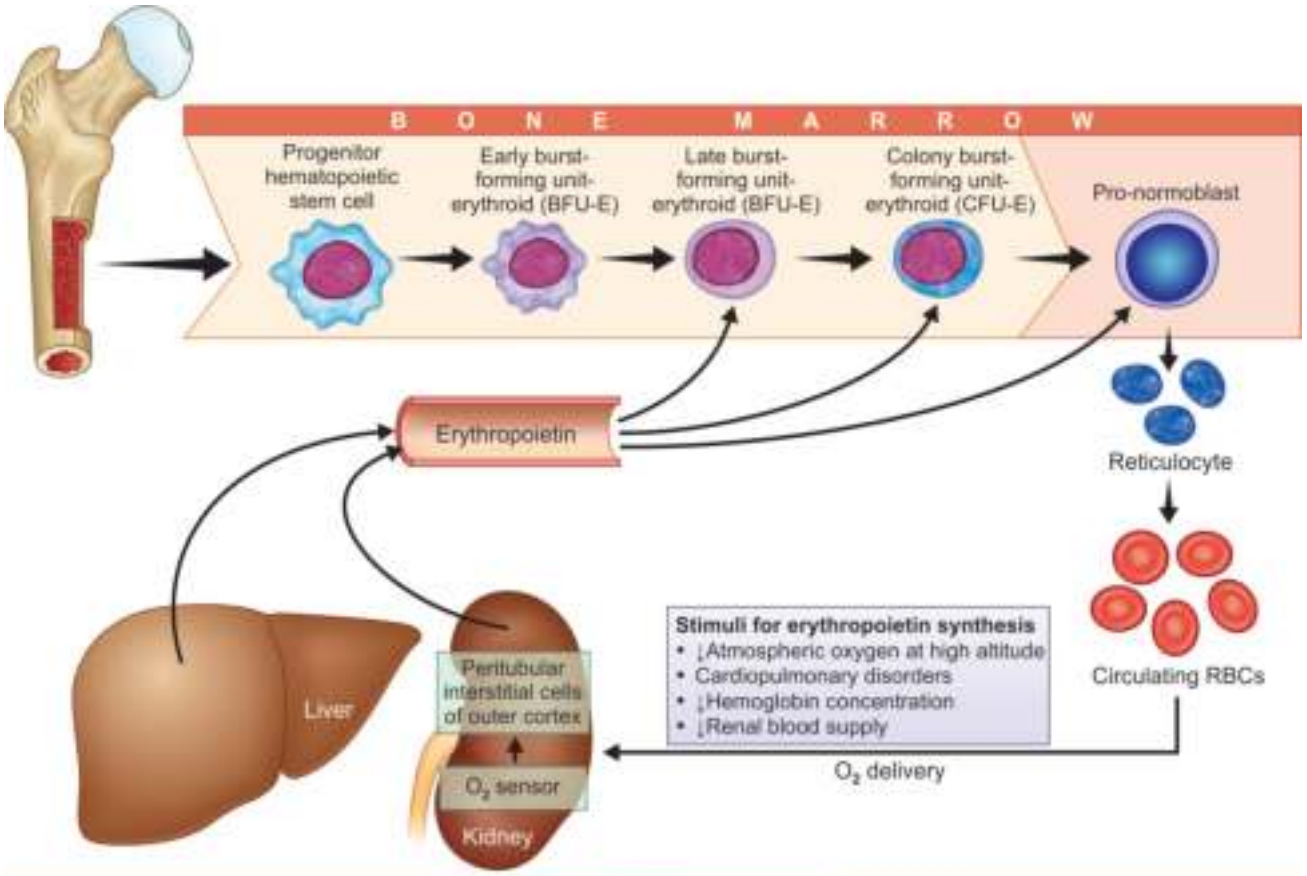
Erythropoietin (EPO) is glycoprotein synthesized by peritubular cells of **kidney** and **liver** regulates erythroid cells, their differentiation and survival by inhibiting default apoptosis. Hematopoietic stem cells are sensitive to oxygen tension in the blood.

- A heme containing protein senses oxygen need and triggers the synthesis of erythropoietin and its release in the bloodstream.
- Erythropoietin interacts with receptor-bearing cells in the bone marrow, where physiologic oxygen demands are translated into increased red blood cell production.
- Under normal conditions, the plasma erythropoietin level is maintained between 2 and 25 IU/L. Red blood cell production is also regulated by serum erythropoietin levels (Fig. 8.4).
- Characteristics and functions of erythropoietin are given in Table 8.7. Conditions associated with increased erythropoietin production are given in Table 8.8.

HEMATOPOIETIC TRANSCRIPTION FACTORS

Hematopoietic transcription factors play major role in the regulation of formation, survival, proliferation and differentiation of multipotent stem cells, as they undergo the transition to erythroid cells/megakaryocytes.

- Key hematopoietic transcription factors known to be involved in the specification and maintenance of hematopoietic stem cell (HSC) include GATA binding protein 2 (GATA 2), runt-related transcription factor 1 (RUNX1), T cell acute



Characteristics of erythropoietin

General characteristics	Functions	Response to anemia
• Erythropoietin is a glycoprotein • Cellular hypoxia stimulates erythropoietin synthesis • Erythropoietin synthesis occurs in kidneys (80–90%) and liver (<15%) • Normal range of plasma erythropoietin is 2–25 IU/L	• Stimulates BFU-E and CFU-E to divide and mature • Increases rate of mRNA and protein (hemoglobin synthesis) • Decreases normoblast maturation time • Increases rate of enucleation (extrusion of nucleus) • Stimulates early release of bone marrow reticulocytes (shift)	Generally increased except in anemia of renal disease

Fig. 8.4: Red blood cell production is also regulated by serum erythropoietin levels. Erythropoietin is synthesized by the kidney (85%) and liver (15%), which senses blood oxygen levels. Stimuli for erythropoietin synthesis include decreased atmospheric oxygen at high altitude, cardiopulmonary disorders, decreased hemoglobin concentration, and decreased renal blood supply. Erythropoietin promotes survival of BFU-E, CFU-E, and normoblasts in the bone marrow resulting in formation of reticulocytes and mature red blood cells.

lymphoblastic leukemia 1 (TAL1), translocation Ets leukemia (TEL), LIM domain only 2 (LMO2) and mixed lineage leukemia (MLL).

- Later on, other transcription factors known to be involved in hematopoiesis include GATA binding protein 1 (GATA 1), friend of GATA1 (FOG1), nuclear factor erythroid 2 (NFE2), Kruppel-like factor 1 (KLF1), growth factor independent 1B (GFI1B) and T cell acute lymphoblastic leukemia 1 (TAL1).
- During normal development of erythroid lineage, GATA2 initiates the programming of erythroid lineage and plays key role in the expansion and maintenance of hematopoietic progenitors, it is replaced by GATA1 during the terminal maturation of erythroid cells. At this stage, the level of GATA2 keeps on declining and GATA1 keeps on increasing. GATA1 is first expressed in megakaryocyte-erythroid progenitor cells (MEPs), and thus essential for the terminal differentiation of both erythroid and megakaryocytes. Transcription factors in hematopoietic lineage differentiation are given in Table 8.9. Molecular regulators of hematopoietic stem cell (HSC) fate are given in Table 8.10.

HEMATOPOIETIC GROWTH FACTORS IN CLINICAL PRACTICE

Hematopoietic growth factors are essential components for hematopoiesis. Recombinant DNA technology and availability of hematopoietic growth factors have

Table 8.7 Characteristics and functions of erythropoietin

Characteristics of Erythropoietin	
Composition	Glycoprotein
Stimulus for synthesis	Cellular hypoxia
Site of synthesis	▪ Kidneys (80–90%) ▪ Liver (<15%)
Normal range	Plasma 2–25 IU/L
Functions of Erythropoietin	
▪ The production of erythropoietin by kidney (80–90%) and liver (<15%) in response to its oxygen supply. Erythropoietin stimulates erythropoiesis and so increases oxygen delivery. Hypoxia induces hypoxia-inducible factors (HIFs) α and β, which stimulate erythropoietin production. von Hippel-Lindau (vHL) protein breaks down HIFs. Prolyl hydroxylase 2 (PHD2) hydroxylates HIFs-2α allowing vHL binding to HIFs. ▪ Stimulates BFU-E and CFU-E to divide and mature cells ▪ Increases rate of mRNA and protein (hemoglobin) synthesis ▪ Decreases maturation time of normoblasts ▪ Increases rate of extrusion of nucleus from normoblasts ▪ Stimulates early release reticulocytes from bone marrow	
Erythropoietin Synthesis Response to Anemia	
Erythropoietin synthesis occurs in anemias except anemia of chronic renal disease	

Table 8.8 Conditions associated with increased erythropoietin production

Chronic Hypoxia	
▪ Pulmonary disease ▪ Congenital heart disease	▪ Heavy tobacco smokers ▪ High altitude
Tumors	
▪ Renal cell carcinoma ▪ Hepatocellular carcinoma ▪ Cerebellar hemangioma	▪ Pheochromocytoma ▪ Adrenal adenoma with Cushing's syndrome
Tumor-like Disorder	
Adult polycystic disease of kidney	
Therapeutic Administration	
Androgens therapy	

significantly altered care of patients with bone marrow disorders and hematologic malignancies.

Table 8.9 Transcription factors in hematopoietic lineage differentiation

Hematopoietic Lineage	Transcription factors
Erythroid/megakaryocytic lineage	▪ GATA1 ▪ FOG1 ▪ GFI1B ▪ FLI1 (friend leukemia integration 1 also known as ERGB)
Myeloid lineage	▪ PU-1 ▪ C/EBPα ▪ C/EBPε_2 ▪ GFI1 ▪ EGR1 (early growth response 1) ▪ RARα
Lymphoid lineage	▪ PU-1 ▪ Ikaros family of hematopoietic-specific zinc finger proteins ▪ E2A ▪ EBF ▪ PAX-5 ▪ NOTCH-1 ▪ GATA3

- Erythropoietin (EPO) administration stimulates erythropoiesis in chronic renal disease. G-CSF, GM-CSF, IL-3, Flt3 ligand (FL) are administered for priming of bone marrow for donation used for bone marrow transplantation.
- G-CSF, GM-CSF, erythropoietin, IL-13 are administered to treat myelodysplastic syndrome and stimulate bone marrow recovery in bone marrow transplantation. IL-2 enhances killing of CSCs. IL-2 and IL-15 are administered to enhance immune system. Clinical application of hematopoietic growth factors is given in Table 8.11. Dietary requirements for red blood cell production are given in Table 8.12.

ROLE OF HORMONES IN HEMATOPOIESIS

TSH, thyroid hormones, ACTH, corticosteroids and human growth hormone also stimulate erythropoietin synthesis. Polycythemia is often a feature of Cushing's syndrome. However, very high doses of steroid

Table 8.10 Molecular regulators of hematopoietic stem cell (HSC) fate

HSC Receptor Proteins	Osteoblast Ligands	Functions
NOTCH proteins	Jagged, delta proteins	Promote HSC self-renewal and blockade of differentiation
Frizzled proteins (Wnt receptors)	Wnt proteins	Promote HSC self-renewal and expansion
Patched proteins (Shh receptors)	Sonic hedgehog (Shh)	Promote mitosis and initiation of differentiation
Tie-2	Angioprotein 1	Promote HSC quiescence
CXCR4	SDF1/CXCL12	Promote survival and proliferation of HSC

Table 8.11 Clinical application of hematopoietic growth factors

Hematopoietic Growth Factors	Indications in Clinical Practice
Erythropoietin (EPO)	Stimulation of erythropoiesis in chronic renal disease
G-CSF and GM-CSF	Recovery from treatment-induced myelosuppression
GM-CSF, erythropoietin, IL-3	Treatment of myelodysplastic syndromes
IL-2	Enhanced killing of cancer stem cells (CSCs)
G-CSF, GM-CSF, IL-3, FL	Priming of bone marrow for donation used for transplantation
IL-1, IL-6	Enhancement of the acute phase response
IL-2, IL-15	Enhancement of the immune system
G-CSF, GM-CSF, erythropoietin, IL-13	Stimulation of bone marrow recovery in bone marrow transplantation
G-CSF, GM-CSF, IL-3	Treatment of bone marrow failure

G-CSF—granulocyte-colony stimulating factor, GM-CSF—granulocyte-macrophage colony stimulating factor.

Table 8.12 Dietary requirements for red blood cell production

Dietary Element	Role in Red Blood Cell Production
Amino acids	Synthesis of chains of globin
Iron	Hemoglobin synthesis
Vitamin B_{12} and folic acid	Nucleic acid synthesis of erythroid precursors
Vitamin B_6	Functions as coenzyme in amino acid metabolism and synthesis of ALA in heme synthesis
Vitamin C	Required for folate metabolism and to facilitate the absorption of iron
Vitamin E	Maintenance of red blood cell integrity
Copper	Participates in transfer of iron for maintenance of red blood cell integrity
Thyroid hormones, corticosteroids, human growth hormone and androgens	Stimulate erythropoietin synthesis

hormones seem to inhibit erythropoiesis. Androgens stimulate estrogen production, which depress the erythropoiesis.

PATHWAYS INVOLVED IN HEMATOPOIESIS

Bone marrow hematopoietic stem cells give rise to myeloid, lymphoid and erythroid precursor cells, which differentiate to form mature cells under the influence of colony stimulating factors, cytokines and erythropoietin.

- Bone marrow stromal cells can synthesize local hormones participating in hemopoiesis.
- Erythrocytes normally lose their nuclear material prior to entering the blood circulation. Platelets are formed from megakaryocytes. Pathways involved in hematopoiesis are shown in Fig. 8.5.
- Human blood is composed of plasma (55%) and formed elements (45%). Blood formed elements include RBCs, WBCs and platelets.
- Plasma contains water and solutes such as plasma proteins, nutrients, vitamins, hormones, glucose, respiratory gases O_2 and CO_2, bilirubin, inorganic constituents such as sodium, potassium, calcium chloride, carbonate, and bicarbonate; and waste products like urea and creatinine (Fig. 8.6).

ERYTHROPOIESIS

The production of RBCs is referred to as erythropoiesis. Hemocytoblasts give rise to erythrocytes. Erythropoietin synthesized by juxtaglomerular cells of kidneys participates in erythropoiesis, which is essential for the differentiation of erythroid precursors. Erythropoietin is released in response to hypoxia in renal arterial blood supply. Patients suffering from erythropoietin secreting tumors, e.g. leiomyoma, renal cell carcinoma, hepatocellular carcinoma, and cerebral hemangioblastoma develop secondary polycythemia.

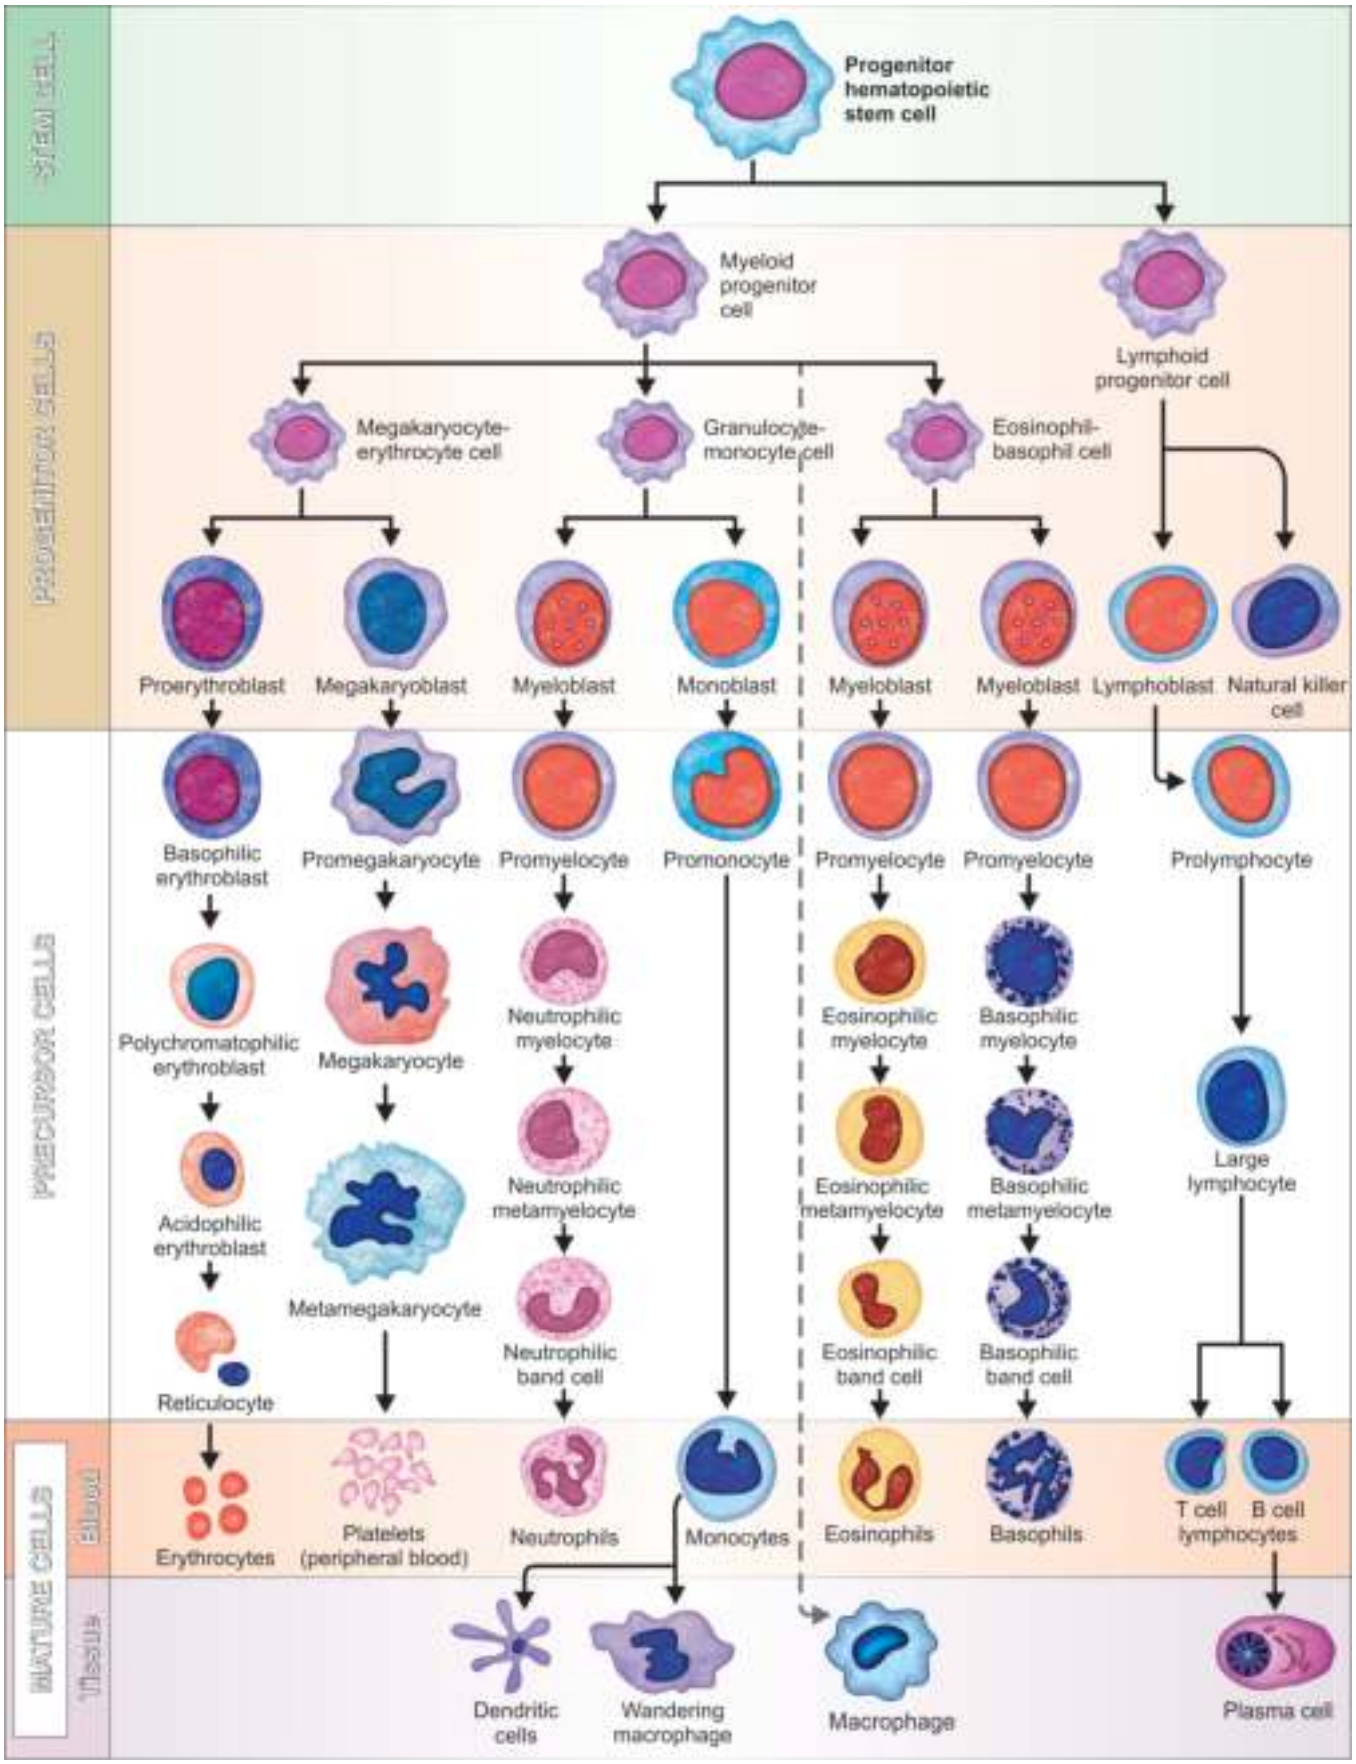


Fig. 8.5: Pathways involved in hematopoiesis.

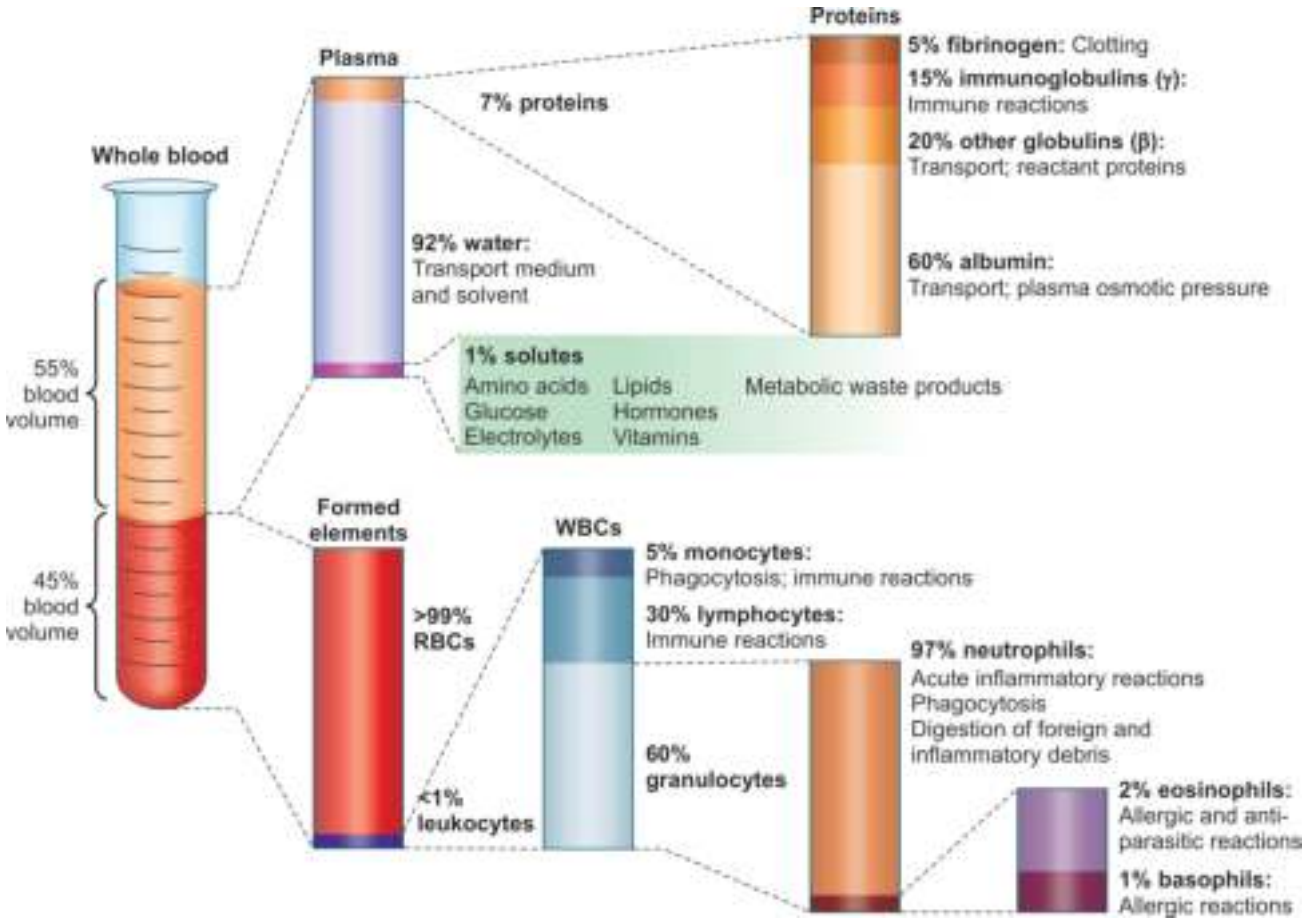

Fig. 8.6: Composition of blood shows plasma and formed elements.

Dyserythropoiesis and Ineffective Erythropoiesis: Terms

Dyserythropoiesis

- The term dyserythropoiesis refers to production of abnormal cells resulting in their destruction in the bone marrow prior to their release into blood circulation.
- The developing normoblasts may show nuclear budding, abnormal mitosis, fragmentation of nuclei, basophilic stippling and Howell-Jolly bodies.
- Howell-Jolly bodies may also be demonstrated in the red blood cells.

Ineffective Erythropoiesis

- The term ineffective erythropoiesis refers to erythroid hyperplasia in the bone marrow, but the patient is anemic. Ineffective erythropoiesis occurs in megaloblastic anemia and myelodysplastic syndrome.
- Reticulocyte count is normal or low in these cases.
- Erythroid hyperplasia in hemolytic anemia is associated with increased reticulocyte count.

Development of Red Blood Cells

During red blood cells (RBCs) development, there is gradual reduction in size of cells, loss of mitochondria, disappearance of ribonucleic acid (RNA), extrusion of nuclei and gradual appearance of hemoglobin. Stages of development of RBCs are given in Table 8.13.

Red Blood Cells: Stages of Development

- Proerythroblasts undergo 3–4 mitotic cell divisions, so that each stem cell gives rise to 8 or 16 cells of basophilic, polychromatic and orthochromatic erythroblasts in about 7 days. Iron is required for heme synthesis.
- Vitamin B_{12} and folic acid are needed for maturation of nucleus of erythroid precursors.
- Comparison of the DNA and RNA content, their distribution in the bone marrow and peripheral blood of the erythroblast (normoblast) reticulocyte and mature red blood cell is given in Table 8.14.

Reticulocyte

- Reticulocyte, a young RBC contains network of ribonucleic acid (reticulum) in cytoplasm. It normally takes about 4 days to mature into an erythrocyte in blood circulation.
- Supravital stains used for reticulocyte count include new methylene blue, and acridine orange. When stained with new methylene blue, the RNA precipitates as bluish filaments and their cytoplasm.
- Newborn baby has 2–6% circulating reticulocytes. Reticulocyte count is 0.5–1.5% in adults.

Mature Red Blood Cells

- RBCs are biconcave discs, anucleate, and essentially without organelles, and filled with water and 97% hemoglobin (Hb), a protein that functions in O_2 and CO_2 transport. Biconcave shape of RBCs possesses huge surface area to volume, and thus contributes to its gas transport function.
- Cytoskeleton proteins present in RBC membrane give erythrocytes, their flexibility, and allows them to change shape as necessary.
- ATP is generated anaerobically, so the erythrocytes do not consume the oxygen, during transport. RBCs contain carbonic anhydrase enzyme, which catalyzes reaction between CO_2 and H_2O and helps in transport of CO_2 from tissues to the lungs. The life span of an erythrocyte is 100–120 days.

Metabolic Pathways in the Red Blood Cells

The metabolic pathways in the red blood cells (RBCs) are given in Table 8.15.

- Glycolytic metabolic signaling pathway in phosphofructokinase and pyruvate kinase (PK) enzymes participate in production of ATP accounting for 90% of glucose consumption in RBC.
- Hexose-monophosphate shunt signaling pathway provides NADPH and glutathione to reduce oxidants that would shift the balance of oxyhemoglobin to methemoglobin.
- Rapoport-Luebering metabolic signaling pathway in mature red blood cells of 2,3-bisphosphoglycerate (2,3-BPG) by 2,3-bisphosphoglyceric acid synthase, which regulates oxygen release from hemoglobin and delivery to tissues.
- Methemoglobin reductase metabolic signaling pathway protects hemoglobin from oxidation via NADPH (from glycolytic pathway) and methemoglobin reductase.

LEUKOPOIESIS

White blood cells are composed of granulocytes and agranulocytes. Granulocyte is the collective name designated to neutrophils, eosinophils and basophils derived from myeloblast. Agranulocytes comprise monocytes and lymphocytes. Characteristics of leukocytes are given in Table 8.16.

Granulocytes

Granulocytes are derived from myeloblast and progenitor committed cells. During development through various stages such as myeloblast, promyelocyte, myelocyte, metamyelocyte, band form and mature granulocyte (Table 8.17).

- There is progressive condensation and lobulation of nuclei, development of cytoplasmic granules, loss of RNA and mitochondria. Red bone marrow also contains a large reserve of mature granulocytes.

Table 8.13 Stages of development of red blood cells (RBCs)

Cell	Size (μm)	Nucleus	Cytoplasm
Proerythroblast	15–20	Large with immature chromatin, usually a single nucleolus	Blue
Early erythroblast	12–16	Fine chromatin clumps, nucleolus barely visible	Deep blue due to high RNA
Intermediate erythroblast	12–15	Smaller size, chromatin clumps	Polychromatic due to beginning of hemoglobinization
Late erythroblast	8–12	Small, dense, pyknotic and eccentric	Polychromatic
Reticulocytes	8–10	No nucleus	Polychromatic, remnants of RNA visible as a network on supravital staining
Erythrocyte	7–8	No nucleus	Pink

Table 8.14 Comparison of the DNA and RNA content, their distribution in the bone marrow and peripheral blood of the erythroblast (normoblast), reticulocyte and mature red blood cell

Parameters	Erythroblast (Normoblast)	Reticulocyte	Mature Red Blood Cell
Nuclear DNA	Present	Absent	Absent
RNA in cytoplasm	Present	Present	Absent
Bone marrow	Present	Present	Absent
Peripheral blood	Absent	Present	Present

Table 8.15 Metabolic pathways in the red blood cells

Metabolic Pathways in RBC	Key Enzymes in Metabolic Pathway	Functions	Abnormality in Metabolic Pathways and Associated Hematologic Disorders
Glycolytic pathway	▪ Phosphofructokinase ▪ Pyruvate kinase (PK)	This pathway participates in production of ATP accounting for 90% of glucose consumption in red blood cell (RBC)	Hereditary pyruvate kinase deficiency (hemolytic anemia)
Hexose-monophosphate shunt pathway	▪ Glucose-6-phosphate dehydrogenase (G6PD) ▪ Glutathione reductase	This pathway provides NADPH and glutathione to reduce oxidants that would shift the balance of oxyhemoglobin to methemoglobin	▪ Hereditary G6PD deficiency (hemolytic anemia) ▪ Glutathione reductase deficiency (hemoglobinopathies)
Rapoport-Luebering metabolic pathway	2,3-Bisphosphoglyceric acid synthase	The pathway controls the amount of 2,3-bisphosphoglycerate (2,3-BPG), which in turn affects the oxygen affinity of hemoglobin	Tissue hypoxia
Methemoglobin reductase metabolic pathway	Methemoglobin reductase	This pathway protects hemoglobin from oxidation via NADPH (from glycolytic pathway) and methemoglobin reductase	▪ Tissue hypoxia ▪ Hemolytic anemia

Table 8.16 Characteristics of leukocytes

Cell Type	Prevalence	Morphology	Primary Function	Comments
Neutrophil (12–15 µm)	50–70%	▪ Nucleus 2–5 lobed ▪ Cytoplasm contains small purple granules rich in digestive enzymes	Essential blood phagocytes, engulf and kill bacteria	Life span of 2 days with only 4–10 hours in the circulation
Eosinophil (12–15 µm)	1–4%	Bilobed nucleus with large coarse orange-colored granules containing toxic proteins, inflammatory mediators and digestive enzymes	▪ Destroys worms and fungi ▪ Participates in allergies and other inflammatory reactions	Found in much large numbers in the spleen and bone marrow
Basophil (10–12 µm)	0–1%	Constricted nuclei with dark blue to black granules in cytoplasm	Participates in inflammatory and allergic reactions	Cytoplasmic granules contain histamine, prostaglandins and other chemical mediators of allergic response
Monocyte (12–20 µm)	2–8%	Largest size cells with large nuclei often indented. Granules are not visible on light microscopy	▪ Participates in phagocytosis followed by final differentiation into macrophages and dendritic cells ▪ Dendritic cells are relatives of macrophages responsible for processing foreign matter and presenting to lymphocytes	Monocytes also secrete several chemical mediators that moderate the functions of the immune system
Lymphocyte (7–10 µm) or (10–14 µm)	20–40%	Small spherical cells with uniformly staining dark round nuclei	Participates in specific acquired immunity	▪ T cells are responsible for cell-mediated immunity and assisting B cells ▪ B cells differentiate into plasma cells and participate in humoral immunity ▪ Natural killer cells are related to T cells but display no antigen specificity. These cells are active against cancer cells and virally infected cells

Table 8.17 Stages of maturation of myeloid cells

Cell	Size (μm)	Nucleus	Cytoplasm
Myeloblast	15–20	Nucleus is large, immature, fine dispersed chromatin with 2–5 nucleoli	Cytoplasm is scanty, light blue
Promyelocyte	16–20	Similar to myeloblast	Azurophil granules appear
Myelocyte	14–16	Chromatin condensed, no nucleoli	▪ Specific and azurophil granules present ▪ Specific granules predominate
Metamyelocyte	14–18	Indented or kidney-shaped; peripheral clumping of chromatin	Specific numerous pink granules and fine faint pink azurophil granules
Band form	14–16	U-shaped or band-like nucleus with heavily clumped chromatin	Specific numerous pink granules and fine faint pink azurophil granules
Neutrophil	12–15	2–5 lobes joined by chromatin strands	Specific numerous pink granules and fine faint pink azurophil granules

- Mature granulocytes pass actively across endothelial lining of bone marrow sinusoids. Turn out of granulocytes is very high. Stages of maturation of myeloid cells are shown in Fig. 8.7. Myelocytes in the bone marrow differentiate to form neutrophils, eosinophils and basophils.

Neutrophils

Neutrophils measure 12–15 μm in diameter, which constitute 50–70% of leukocytes. These cells have 2–5 lobed nucleus. Cytoplasm contains small purple granules rich in digestive enzymes. Neutrophils remain in circulation for 4–10 hours. Life span of neutrophils is 2 days. Neutrophils are recruited to the site of injury within first 24 hours of inflammation.

Eosinophils

Eosinophils measure 12–15 μm in diameter, which constitute 1–4% of leukocytes. These cells have bilobed nucleus. Cytoplasm contains large coarse orange-colored granules. Eosinophilic granules contain highly cationic major basic protein (MBP) that kills only invasive

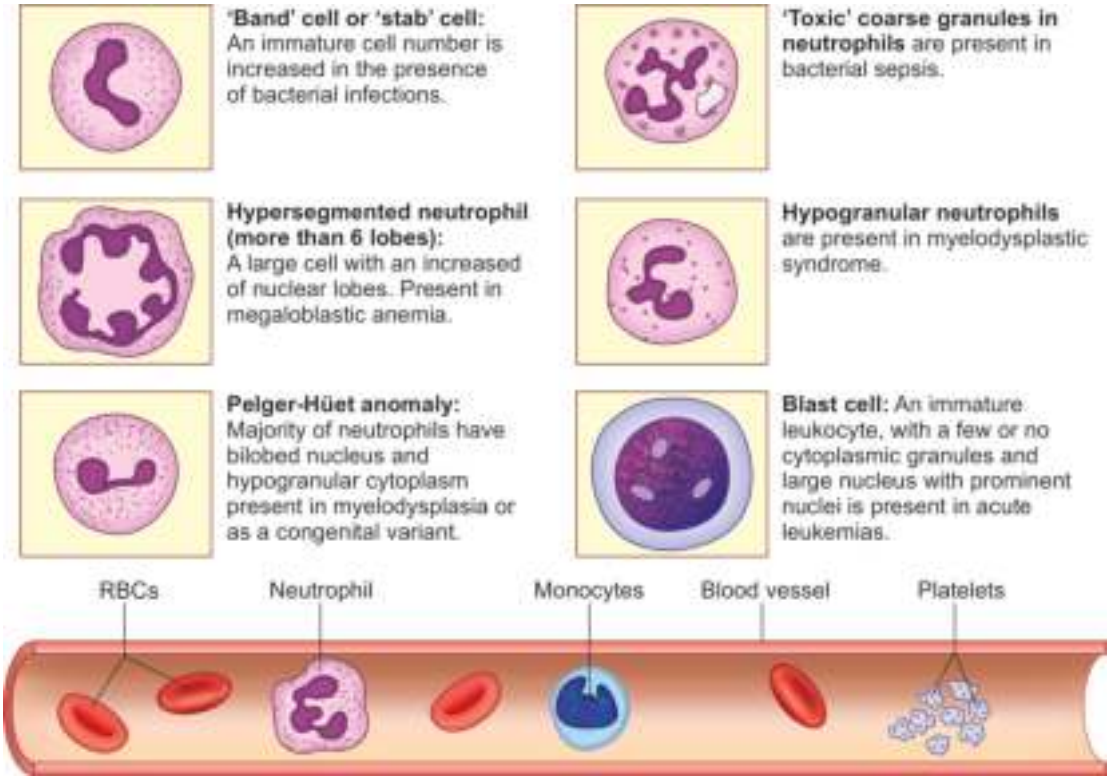

Fig. 8.7: WBCs qualitative anomalies.

helminthes. Eosinophils are recruited by chemokine (eotaxin) at injury site in IgE-mediated allergic reactions. Eosinophilic red granules contain crystalline material in cytoplasm, which becomes Charcot-Leyden crystals in the sputum of bronchial asthmatic patients.

Basophils

Basophils measure 10–12 µm in diameter, which constitute 0–4% of leukocytes. These cells have pale staining constricted nucleus. Cytoplasm contains dark blue to black granules. Basophils possess coarse granules rich in histamine.

White Blood Cells: Qualitative Anomalies

- **May-Hegglin anomaly:** May-Hegglin anomaly is autosomal disorder due to mutation of MYH9 gene. The disorder is characterized by basophilic inclusions (Döhle body-like) in neutrophils, anemia, thrombocytopenia and giant platelets.
- **Alder-Reilly anomaly:** It is autosomal recessive disorder associated with several genetic mucopolysaccharidoses. There is deficiency of lysosomal enzymes required forbreakdown of mucopolysaccharides. There is presence of liliac inclusions with clear halo in neutrophils stained with Giemsa stain. These granules are also demonstrated with toluidine blue.
- **Pelger-Hüet anomaly:** Pelger-Hüet anomaly is autosomal dominant disorder due to mutation of lamin B receptor (LBR) gene. It is characterized by lack of segmentation of neutrophils. Nuclei are dumbbell-shaped in >70% of neutrophils. Chromatin is coarse. Two lobes of the nuclei are joined by thin chromatin bridge.

Agranulocytes

Agranulocytes comprise monocytes and lymphocytes. Monocytes differentiate into tissue macrophages. Bone marrow participates in production of B and T cells. B cells mature in the bone marrow. T cells migrate to thymus gland for maturation. Multiple subtypes of lymphocytes are given in Table 8.18. Comparison between B cells and T cells is given in Table 8.19.

Monocytes

Monocytes are derived from monoblasts in the bone marrow. These have life span of 12 hours. Monocyte contains reinform, lobulated or indented nuclei with open chromatin without nucleoli. Cytoplasm is pale blue. Monocytopoiesis is regulated by GM-CSF.

Lymphocytes

Markers of B cell, T cell and natural killer cells are given in Table 8.20.

- **B cells:** B cells, when stimulated with antigen, become plasma cells and secrete immunoglobulins (e.g. IgG, IgA, IgM, IgD and IgE).
  - Plasma cells participate in humoral immunity. Plasma cell has amphophilic cytoplasm and an eccentric nucleus with heterochromatin in a characteristic cartwheel or clockface arrangement.
  - On electron microscopy, cytoplasm of plasma cell contains a pale zone containing extensive Golgi apparatus, centrioles and abundant rough endoplasmic reticulum, ribosomes, mitochondria, lysosomes and the plasma membrane.
- **T cells:** T cells participate in cell-mediated immunity. Activated macrophages display antigens to T cells. Macrophages synthesize IL-12 that stimulates T cell responses. Activated T cells recruit monocytes from the circulation with IFN-γ, a powerful activator of macrophages.
- **Natural killer cells:** Natural killer cells (NK cells) kill tumor cells and virus infected cells by lysing or damaging plasma membranes.

THROMBOPOIESIS

Platelets are produced in the bone marrow by a process termed thrombopoiesis. Platelets production is regulated by thrombopoietin synthesized from **liver**. Megakaryocytes are derived from the bone marrow stem cells known as megakaryoblasts, which mature in about 10 days.

Table 8.18 Multiple subtypes of lymphocytes

Lymphocytes	Subtype	Actions
B cell	Plasma cell	Synthesis of antibodies either against persistent antigen to injury site or against altered tissue components in chronic inflammation
T cell	▪ Effector T cells	▪ Delayed hypersensitivity ▪ Showing mixed lymphocytic reactivity ▪ Cytotoxic killer cells (K cells)
	▪ Regulatory T cells	▪ Helper T cells ▪ Suppressor T cells
Natural killer cell (NK cell)	Cytotoxic cells	▪ Kill tumor cells ▪ Virus infected cells by lysing or damaging plasma membranes

Table 8.19 Comparison between B cells and T cells

Parameters	B Cells	T Cells
Origin	Stem cells in bone marrow	Stem cells in bone marrow
Site of maturation	Bone marrow and lymphoid cells	Thymus gland
Distribution in lymph node	Cortex (germinal follicles and medullary cords) of lymph nodes	Paracortical areas of lymph nodes
Distribution in spleen	Germinal centers of follicles	Periarteriolar lymphoid sheaths
Differentiation (product of antigenic stimulation)	Plasma cells and memory cells	CD4+ helper T cells, CD4+ regulatory T cells, CD8+ cytotoxic T cells and memory T cells
Circulation in blood	Low numbers (10–20%)	High numbers (60–70%)
Life span	Short-lived (weeks to a few months)	Long lived (2–4 years)
Fc receptors	Present	Absent
Electron microscopy	Microvilli present	Smooth surface
Requires antigen presenting cells with MHC	No	Yes required APCs with MHC
General functions	Production of antibodies to inactivate, neutralize target antigens	Cell function in regulating immune functions killing foreign cells, hypersensitivity, synthesize cytokines
MHC molecules	MHC I and MHC II	MHC I and MHC II
Immune surface marker	Immunoglobulin	T cell receptor
Immunological markers	CD19 to CD22	CD1 to CD8

Table 8.20 Markers of B cell, T cell and natural killer cells

B Cell Markers	
▪ CD19 (pan B cell marker)	▪ κ light chain
▪ CD20 (pan B cell marker)	▪ λ light chain
▪ CD22	
T Cell Markers	
▪ CD2	▪ CD5
▪ CD3 (pan T cell marker)	▪ CD7
▪ CD4 (helper T cell marker)	▪ CD8 (cytotoxic T cell marker)
Natural Killer Cell Marker	
CD56	

Megakaryoblast

Megakaryoblast measures 15–30 µm in diameter. It has high nucleus to cytoplasmic ratio. It contains basophilic cytoplasm with granules.

Promegakaryocyte

Promegakaryocyte measures 20–30 µm in diameter, which contains oval lobulated and elongated nucleus with basophilic cytoplasm.

Platelets

Platelets are 3–4.5 microns in diameter, which possess 2 membrane glycoproteins. Normal platelet count is 150,000–400,000/cu mm.

- Platelets are formed by pinching off cytoplasm of megakaryocytes situated close to bone marrow sinusoids circulation. It is known as **platelet budding**.
- Platelets have normal life span of 8–10 days. Platelets are destroyed by macrophages, mainly in the spleen and also in the liver.
- Platelet consists of dense granules and α-granules. These contain primary inflammatory chemical mediators. Platelets regulate vascular endothelial permeability and proliferation of mesenchymal cells in chronic inflammation.
- Platelets participate in surveillance of blood vessel continuity, formation of primary and secondary hemostatic plugs, and healing of injured tissue. Structure and functions of platelets are shown in Fig. 8.8 and Table 8.21.

BONE MARROW ASPIRATION

Bone marrow is composed of network of blood vessels, hematopoietic stem cells, stroma, nerves and reticulo-endothelial cells.

- Bone marrow venous sinusoids are lined by endothelial cells. Bone marrow stroma is composed of cells such as fibroblasts, stromal cells, fat cells, endothelial cells and macrophages and extracellular matrix.
- Extracellular matrix comprises collagen, laminin, fibronectin and proteoglycans.
- Bone marrow examination gives more information and morphologic characteristics are better defined in stained blood films. Indications of bone marrow aspiration are given in Table 8.22.

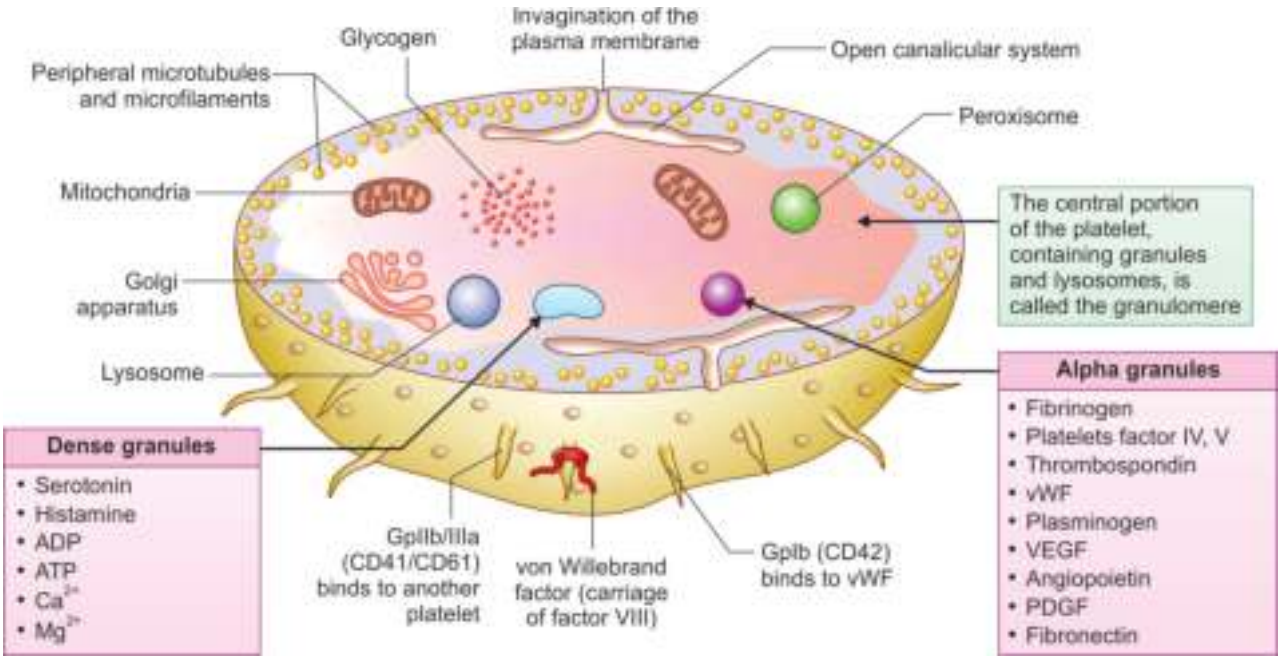

Fig. 8.8: Structure of platelet. Platelet consists of outer glycocalyx layer and inner plasma membrane. Cytoskeleton maintains discoid shape. It consists of dense and α-granules.

Table 8.21 Structure and functions of platelets

Parameters	Functions
Platelet membrane	
▪ Glycocalyx ▪ Plasma membrane	▪ Outermost coat comprising glycolipids, glycoproteins and mucopolysaccharide ▪ Negative charge due to sialic acid residue of proteins and lipids ▪ Composed of glycolipids, cholesterol and glycoproteins ▪ Lipoprotein layer containing platelet factor III involved in blood coagulation
Membrane glycoproteins (acting as receptors for cell-cell and ligand-cell interaction)	
▪ Glycoprotein IIb/IIIa ▪ Glycoprotein Ib–IX	▪ Cross-linking of IIb/IIIa to vWF and fibrinogen leading to platelets aggregation ▪ Deficiency of GpIb–IX results in Bernard-Soulier syndrome (bleeding diathesis)
Cytoskeleton	
▪ Short actin filament ▪ Actin microfilament network ▪ Microtubules	▪ Present under plasma membrane involved in maintaining discoid shape ▪ Present in cytoplasm ▪ Present in peripheral part of cytoplasm involved in maintaining discoid shape
Dense granules	
▪ ADP ▪ ATP ▪ Calcium ▪ Serotonin	▪ Recruits platelets and activates new platelets result in aggregation of platelets ▪ Agonist for cells other than platelets ▪ Extracellular source for hemostatic reactions ▪ Vasoconstrictor
α-Granules	
▪ Fibrinogen ▪ Platelets factor IV ▪ Thrombospondin ▪ Factor V ▪ vWF binds factor VIII ▪ Plasminogen ▪ PDGF	▪ Causes aggregation of platelets and itself gets converted to fibrin ▪ Binds with heparin ▪ Promotes aggregation of platelets ▪ Promotes aggregation of platelets ▪ Participates in adhesion of platelets and aggregation of platelets ▪ Inhibits fibrinolysin ▪ Plasminogen gets converted to plasmin. Plasmin participates in fibrinolysis ▪ Promotes repair of smooth muscle cells

Table 8.22 Indications of bone marrow aspiration

Diagnostic Purposes

- Unexplained leukopenia, thrombocytopenia, undefined anemia, monoclonal hypergammaglobulinemia, lasts or other abnormal cells in the blood suggestive of bone marrow pathology
- Diagnosis of hematopoietic neoplasms
- Evaluation of storage diseases (Gaucher's disease, Niemann-Pick disease), amyloidosis and mastocytosis
- Work up of fever of unknown etiology, monoclonal gammopathy, splenomegaly or other organomegaly

Staging for Hematopoietic Malignant Disorders

- Diagnosis of metastatic tumor to bone marrow, solitary metastatic bone disease (lung carcinoma, renal cell carcinoma, well-differentiated thyroid carcinoma) or multifocal metastatic bone disease (mammary adenocarcinoma, gastric carcinoma, colorectal carcinoma, neuroblastoma)
- Staging of lymphomas

Monitoring the Follow-up Cases

- Follow-up after induction of chemotherapy for acute leukemia and maintenance of chemotherapy
- Monitoring toxicity and antineoplastic effects of antineoplastic therapy
- Restaging of malignant lymphoma after treatment
- Follow-up after hematopoietic stem cell transplantation
- Follow-up of patients with aplastic anemia, paroxysmal nocturnal hemoglobinuria and Fanconi's anemia for the development of myelodysplastic syndrome

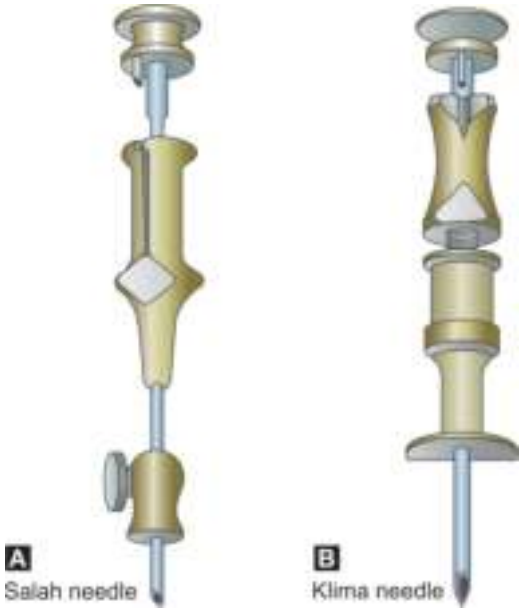

Fig. 8.9A and B: Bone marrow aspiration needles.

BONE MARROW ASPIRATION NEEDLES

Klima needle and **Salah needle** are most often used to aspirate bone marrow. **Islam needle** is used in patients either with osteosclerotic bone, or osteoporotic bone. The needles are stout wide bore, short bevel, stellate and adjustable guard that prevents overpenetration. Bone marrow aspiration needles must be sterilized in a hot air oven or autoclaved before being used (Fig. 8.9A and B). Diagnostic significance of bone marrow examination is given in Table 8.23.

Table 8.23 Diagnostic significance of bone marrow aspiration

Disorders	Examples
Red blood cell disorders	▪ Megaloblastic anemia ▪ Iron deficiency anemia to assess iron stores in bone marrow ▪ Pure red cell aplasia ▪ Sideroblastic anemia to assess iron in sideroblasts
White blood cell disorders	▪ Subleukemic leukemia ▪ Acute myelogenous leukemia ▪ Acute lymphoblastic leukemia
Myeloproliferative disorders	▪ Chronic myelogenous leukemia ▪ Polycythemia rubra vera ▪ Idiopathic thrombocythemia
Megakaryocytic disorders	▪ Idiopathic thrombocytopenic purpura ▪ Other thrombocytopenic purpura
Plasma cell disorders	▪ Multiple myeloma ▪ Waldenström's macroglobulinemia
Storage disorders	▪ Gaucher's disease ▪ Niemann-Pick disease
Metastases in bone marrow	▪ **Adults:** Cancers of prostate, urinary bladder, breast, lung (small cell type), kidney, gastrointestinal tract and thyroid gland. Hodgkin's disease involves bone marrow in stage IV. Non-Hodgkin's lymphoma also involves bone marrow ▪ **Children:** Neuroblastoma, embryonal rhabdomyosarcoma, and retinoblastoma
Parasites	▪ *Leishmania donovani* bodies in kala-azar ▪ Malarial parasites
Histiocytic disorders	▪ Langerhans' histiocytosis ▪ Hemophagocytic syndrome

BONE MARROW ASPIRATION SITES

Posterior superior iliac crest site is preferred in adults and older children. **Calcaneum bone** is site of choice in infants. In children under 2 years of age, bone marrow aspiration may be done from medial aspect of tibia below tibial tubercle.

- **Midline of sternum** at the height of the second intercostal space provides best representative material in adults. But the patient is more apprehensive when bone marrow aspiration is done from this site.
- No attempt should be made to aspirate bone marrow from below the second intercostal space, because if the inner cortical layer is perforated, the great vessels and the right atrium located below this space may be damaged.

BONE MARROW ASPIRATION PROCEDURE

Under aseptic conditions and local anesthesia by adjusting guard the needle is inserted with a boring and slight rotating motion in bone marrow by applying a strong vacuum pressure via an attached syringe.

BONE MARROW ASPIRATE SMEAR PREPARATION

Bone marrow fragments are aspirated and smears are prepared, stained with Romanowsky stains and examined under low power.

- The ideal area for examination of bone marrow aspirate smear is one in which the hematopoietic stem cells constitute a monocellular layer and the red blood cells exhibit pink stained morphology.
- The cellularity of bone marrow varies with the age of the patient. In early childhood, the bone marrow contains red marrow and little fat. In adults, bone marrow has about 50% of fat cells, while 75% of fat cells are present in elderly persons.

BONE MARROW ASPIRATE SMEAR STAINING

Bone marrow aspirate smears are stained with Romanowsky stain. One bone marrow aspirate smear is used for iron stain. CD markers used for hematolymphoid neoplasms are given in Table 8.24. Special tests on bone marrow cells to diagnose hematologic malignant disorders are given in Table 8.25.

Table 8.24 CD markers used for hematolymphoid neoplasms

Hematology Cells	Immunophenotyping Markers on Flow Cytometry
RBCs	Glycophorin A
Megakaryocytes	CD41, CD61
WBCs	CD45 (leukocyte common antigen)
Blasts	CD34, TdT, HLA-DR
Myeloid cells	Anti-MPO, CD13, CD33, CD14, CD117
B cells	CD19, CD20, CD10, FMC7, CD23, CD79a, Ig, IgM

Table 8.25 Special tests on bone marrow cells to diagnose hematologic malignant disorders

Special Tests on Bone Marrow Cells	Comments
Conventional chromosomal analysis	Diagnosis and classification of leukemia and myelodysplastic syndrome
Fluorescence *in situ* hybridization (FISH)	Analysis of chromosomal deletion, duplication, translocation, inversion
DNA analysis	Diagnosis and classification of leukemias, myeloproliferative disease, lymphoproliferative disease and detection of minimal residual disease
Immunophenotype analysis	Diagnosis and classification of leukemias, lymphoproliferative disease and detection of minimal residual disease
Flow cytometry	Analysis and quantification of cells in leukemia, i.e. diagnosis and minimal residual disease
Polymerase chain reaction (PCR)	▪ Performed by amplification of a DNA segment digested by a restriction enzyme and fractioned by size using gel electrophoresis. ▪ Performed to detect point mutation of JAK2 in hematologic disorders, minimal residual disease, and diagnosis of inherited mutations of hemoglobin and coagulant proteins
Second generation sequencing technique of whole genome	To detect new clonal point mutations in hematologic malignancies, e.g. acute myelogenous leukemia (AML), myelodysplastic syndrome (MDS), chronic lymphocytic leukemia (CLL)
Northern blot technique	▪ Gene expression studied by analyzing RNA extracted from fresh cells by gel electrophoresis ▪ Gene can be semiquantified by using the enzyme reverse transcriptase to generate a DNA copy and then applying a modified PCR technique
DNA microarray analysis	DNA microarray analysis used to analyze expression of multiple cellular genes. Microarrays can also be used to detect small deletions or gains in DNA

Bone Marrow Aspirate Smears: Evaluation

Bone marrow smears are screened for bone marrow fragments under scanner objective. Most of the bone marrow particles are present in the tail of smears.

- **Cellularity:** Cellularity of bone marrow is assessed by visualization of bone marrow particles. Number, cellularity of fragments and cellular details are observed. Bone marrow is more cellular in children than adults. Bone marrow is reported as hypercellular, hypocellular or normocellular. Bone marrow cellularity ranges for various groups are given in Table 8.26.
- **Erythropoiesis:** Type of erythropoiesis, normoblastic or megaloblastic. Activity and maturity of erythroid precursors are observed. Largest number of bone marrow cells is erythroid cells.
- **Leukopoiesis:** Maturity, abnormal granules, atypical cells, lymphocytes and plasma cells are observed.
- **Myeloid to erythroid ratio:** At least 500 bone marrow cells are counted. Ratio of normal fat cells to hematopoietic cells is 1:1 in adults. Ratio of normal myeloid cells to erythroid cells is 3:1 in adults. Ratio of normal fat cells to erythroid cells is 4:1 in adults.
- **Megakaryopoiesis:** Megakaryocytes are examined in bone marrow particles near tail of bone marrow smears. It is important to look for budding of platelets from megakaryocytes. Relative number of promegakaryoblasts and megakaryocytes is also observed.
- **Other bone marrow cells:** Plasma cells, lymphocytes and reticulum cells are observed. Differential cell count in adult bone marrow aspirate is given in Table 8.27.
- **Abnormal cells:** One must look for metastases, LD bodies, malarial parasite and *Histoplasma capsulatum*. Granulomas are demonstrated in bone marrow due to tuberculosis, sarcoidosis, *Histoplasma capsulatum* and *Cryptococcus neoformans*, systemic lupus erythematosus and infectious mononucleosis. Microorganisms demonstrated in bone marrow smear are given in Table 8.28.

Bone Marrow Iron Content

By means of a cytochemical stain, the amount of stainable iron in the bone marrow can be visualized and quantitatively assessed. It has diagnostic role in diagnosing iron deficiency anemia, β-thalassemia, and sideroblastic anemia.

Perls Prussian Blue Staining: Principle

The bone marrow iron content test is based on the Perls Prussian blue reaction. Ionic iron reacts with acid potassium ferricyanide solution (2% potassium ferricyanide + N/5 HCl) to produce a blue color. Bone marrow aspirate smears are counterstained by 0.33% neutral red to stain nuclei as red.

Normal Bone Marrow Iron Stores: Interpretation

- Iron granules appear as bright blue or blue-green aggregates not exceeding 1 µm in diameter in the cytoplasm of nucleated (sideroblasts) or non-nucleated (siderocytes) precursors contrasting sharply with the pink stained background.
- Normally, 25–50% of normoblasts contain 1–4 small iron granules. Often, iron granules can also be seen in the reticuloendothelial cells of the bone marrow, and they may be spherical or irregularly shaped.
- When the granules surround the erythroid nuclei, they constitute the so-called ring sideroblasts.
- Grading of iron stores on bone marrow aspirate is given in Table 8.29.

Bone Marrow Iron Stores in Pathologic Disorders

- Bone marrow is deficient in iron deficiency anemia. Bone marrow iron is increased in thalassemia. Iron granules scattered throughout cytoplasm surrounding nuclei occur in sideroblastic anemia.
- Excess of iron is deposited in reticuloendothelial cells in dyserythropoietic anemia and anemia of chronic inflammation.
- Demonstration of iron granules in normoblasts under oil immersion lens is given in Table 8.30.

Table 8.26 Bone marrow cellularity ranges for various groups

Age Group	Bone Marrow Cellularity
Newborn to 3 months	80–100%
Children	60–80%
Adults (20–40 years)	60–70%
Adults (>40–70 years)	40–50%
Adults (>70 years)	30–40%

Table 8.27 Differential cell count in adult bone marrow aspirate

Bone Marrow Cells	Percentage of Cells
Myeloid cells*	
Myeloblasts	0–3
Promyelocytes	3–10
Neutrophilic myelocytes	4–10
Metamyelocytes	3–8
Neutrophils including band form	25–45
Erythroid cells	
Proerythroblasts	0–1
Early/basophilic normoblasts	1–5
Intermediate/polychromatic normoblasts	5–20
Late/orthochromatic normoblasts	5–15
Lymphoid cells	
Lymphocytes	5–10
Plasma cells	0–2
Monocyte/macrophages	
Monocytes	1–3
Macrophages	0–1
Megakaryocytic cells	
Megakaryocytes	0–2

**Normal myeloid to erythroid ratio ranges 3:1–15:1.*

Table 8.28 Microorganisms demonstrated in bone marrow

Microorganisms Demonstrated in Bone Marrow in Immunocompromised Persons		
Parasites	▪ *Leishmania donovani* bodies (LD bodies)	▪ Malarial parasite
Bacteria	▪ *Mycobacterium tuberculosis* bacilli	▪ *Mycobacterium leprae* bacilli
Fungi	▪ *Cryptococcus neoformans*	▪ *Histoplasma capsulatum*
Virus	Cytomegalovirus	

Table 8.29 Grading of iron stores on bone marrow aspirate

Grade	Interpretation	Iron Content in Bone Marrow Cells
Grade 0	▪ Iron stores—nil	▪ Absence of iron granules
Grade 1	▪ Diminished iron stores	▪ Small granules in reticulum cells observed under oil immersion lens
Grade 2	▪ Normal iron stores	▪ Presence of iron granules with low power lens
Grade 3	▪ Normal iron stores	▪ Numerous small granules present in all marrow particles
Grade 4	▪ Increased iron stores	▪ Presence of large granules in clumps
Grade 5	▪ Increased iron stores	▪ Presence of dense clumps of granules
Grade 6	▪ Increased iron stores	▪ Very large granules present obscuring marrow cells

Table 8.30 Demonstration of iron granules in normoblasts under oil immersion lens

Erythroid Cells	Iron Granules
Late normoblasts	1–3 pinpoint granules
Abnormal sideroblasts (late and intermediate normoblasts) seen in megaloblastic anemia	1–10 pinhead granules
Ring sideroblasts (sideroblastic anemia)	>5 coarse granules surrounding nucleus

BONE MARROW TREPHINE BIOPSY

Bone marrow trephine biopsy should be performed when the bone marrow obtained by bone marrow aspiration is inadequate for examination in cases of aplastic anemia or myelofibrosis. Comparison between bone marrow aspiration and bone marrow trephine biopsy is given in Table 8.31.

BONE MARROW TREPHINE BIOPSY NEEDLES

Bone marrow trephine biopsy procedure is done with a biopsy needle such as Jamshidi-Swaim needle or Islam needle or Osgood biopsy needle. The preferred site is the posterior superior iliac spine. Sternal site is always avoided due to danger of penetrating heart.

BONE MARROW TREPHINE BIOPSY PROCEDURE

Under aseptic conditions and anesthetizing the area, the sterile trephine biopsy needle is inserted into bone marrow by to and fro rotation clockwise and anticlockwise at least 10 times. Bone marrow trephine biopsy processing technique is given in Table 8.32.

BONE MARROW TREPHINE BIOPSY FIXATION

The material is aspirated by bone marrow trephine biopsy and put in 2 ml of **Helly's fluid for fixation**. Helly's fluid consists of potassium dichromate (2.5 g); mercuric chloride (5.0 g); 40% formaldehyde (5 ml); dissolved in 100 ml of water. The section is stained with hematoxylin and eosin. The preparation allows for optimal evaluation of bone marrow cells with bony trabeculae. It is helpful in evaluation of metastatic tumor or bone marrow fibrosis.

Bone Marrow Trephine Biopsy: Indications

Bone marrow trephine biopsy is performed in diagnosing of following disorders:

- Aplastic anemia
- Metastases in bone marrow
- Myelofibrosis
- Aleukemic leukemia
- Hypoplastic acute myelogenous leukemia M7 (AML-M7)
- Miliary tuberculosis involving bone marrow
- Malignant lymphomas
- Myelodysplastic syndrome
- Chronic lymphoproliferative disorders

Table 8.31 Comparison between bone marrow aspiration and bone marrow trephine biopsy

Parameters	Bone Marrow Aspiration	Bone Marrow Trephine Biopsy
Site of procedure	Posterior iliac crest, sternum in adults and tibia in infants	Posterior iliac crest in adults
Staining techniques	▪ Romanowsky stains ▪ Perls Prussian blue for iron	▪ Hematoxylin and eosin ▪ Silver methenamine stain for demonstration of reticulin
Advantages/ disadvantages	▪ Bone marrow aspiration is simple, reliable, rapid method providing cytologic features of bone marrow cells suited for cytogenetics, molecular and flow cytometric analysis provides excellent appreciation of spatial relationship between cells and overall bone marrow structure ▪ Bone marrow aspiration has low sensitivity in detection of granulomas, solid malignant tumor metastases and lymphoma involvement	▪ Bone marrow trephine biopsy provides excellent appreciation of spatial relationship between cells and overall bone marrow structure ▪ Bone marrow trephine biopsy is required in inadequate or failed bone marrow aspirate, assessment of cellularity, bone marrow architecture, suspected granulomas, detection of micrometastases, lymphoma deposits and bone marrow fibrosis
Results available	Within 1–2 hours	Within 1–7 days depending on decalcification method used for specimen
Indications	▪ Unexplained pancytopenia (anemia, leukopenia, thrombocytopenia) ▪ Suspected bone marrow failure (leukemia, myelodysplastic syndrome, lymphoma, multiple myeloma, metastatic bone disease, Gaucher's disease, Niemann-Pick disease) ▪ Suspected infection (leishmaniasis, tuberculosis)	▪ Aplastic anemia ▪ Malignant disorders (multiple myeloma, lymphoma, metastatic bone disease) ▪ Dry tap on bone marrow aspiration ▪ Miscellaneous (splenomegaly, pyrexia of unknown origin, amyloid deposit)
Special investigations	▪ Cytogenetic analysis ▪ Fluorescence *in situ* hybridization (FISH) ▪ Flow cytometry ▪ DNA, RNA analysis ▪ Microarrays ▪ Progenitor cell culture ▪ Microbiological culture	Immunocytochemistry (*refer* to Table 8.35)

Bone marrow trephine biopsy is required for unexplained pancytopenia or suspected bone marrow infiltration by malignant tumors, storage disorders and infections.

Table 8.32 Bone marrow trephine biopsy processing technique

Fixatives for Bone Marrow Trephine Biopsy

- Neutral buffered formalin (18–24 hours)
- Bouin's fluid
- Buffered formalin
- Zinc formalin
- Schaffer's solution

Decalcification of Bone Marrow Trephine Biopsy

- Ethylenediaminetetra-acetic acid (EDTA) (14%): Excellent preservation of cell morphology, antigens and nucleic acid, but time-consuming process
- Nitric acid (time 6–8 hours): Routinely used in laboratory
- Formic acid (time 12–24 hours): Routinely used in laboratory
- Rapid decalcifier: TBD-1 Shandon decalcifier (15–60 minutes)

- **Combined Fixatives and Decalcifier Agents**
  - **Acetic acid zinc formaldehyde** (rapid technique with excellent preservation of cell morphology and antigens, but poor preservation of nucleic acid)
- **Microwave Assisted Fixation and Decalcification**
  - Microwave assisted fixation and decalcification (rapid process): Bone marrow trephine biopsy specimen should be fixed in 10% neutral formalin and then washed in water before decalcification in 5% nitric acid
- **Paraffin-embedding of Bone Marrow Trephine Biopsy**
  - Histologic sections are obtained by microtome and stained with hematoxylin and eosin stain: Technique is routinely done in histopathologic laboratories. Immunohistochemistry, fluorescence *in situ* hybridization (FISH) and polymerase chain reaction (PCR) are easily feasible.

BONE MARROW TREPHINE BIOPSY SECTION STAINING TECHNIQUE

Bone marrow trephine biopsy sections are stained by hematoxylin and eosin, Perls Prussian blue stain for iron, reticulin stain and Masson trichrome stain. Stains performed on bone marrow and bone marrow trephine biopsy are given in Table 8.33. Galle's iron-grading system in bone marrow trephine biopsy is given in Table 8.34. Lineage associated CD antigens and cellular expression commonly analyzed in bone marrow trephine biopsy by routine flow cytometry are given in Table 8.35.

Table 8.33 Stains performed on bone marrow and bone marrow trephine biopsy

Stain	Comments on Stain Used
Stains on bone marrow smears	
Romanowsky stain	Study of bone marrow cellularity, myelopoiesis, erythropoiesis and myeloid to erythroid ratio; megakaryopoiesis, Gaucher's cells, Niemann-Pick cells, malarial parasite
Perls Prussian blue stain for iron	Evaluation of storage iron and ring sideroblasts
Periodic acid–Schiff (PAS) stain	Visualization of megakaryocytes and fungi
Ziehl-Neelsen stain	Demonstration of acid-fast bacilli
Bone marrow trephine biopsy	
Hematoxylin and eosin stain	Evaluation of histologic features
Perls Prussian blue stain for iron	▪ Evaluation of storage iron but less sensitive than performed on bone marrow aspirate ▪ Ring sideroblasts may be demonstrated in non-decalcified bone sections
Reticulin stain	Evaluation of reticulin fibers in the bone marrow in a case of myelodysplastic syndrome
Masson trichrome stain	Evaluation of collagen fibrosis in bone marrow indicating an advanced disease
Immunohistochemistry	Immunohistochemistry results may be different from non-decalcified bone sections

Table 8.34 Galle's iron-grading system in bone marrow trephine biopsy

Galle's Iron-grading System	Iron Content	Iron Demonstration under Light Microscope
Grade 0	None	No visible iron high-power magnification (X1000)
Grade 1	Very slight	Small iron particles just visible in few reticulum cells under high-power magnification (X1000)
Grade 2	Slight	Small spersely distributed iron granules just visible under low-power magnification (X100)
Grade 3	Moderate	Numerous small iron granules present in the reticulum cells throughout the bone marrow fragments visible under low power magnification (X100)
Grade 4	Moderate heavy	Large iron granules throughout the bone marrow fragments with tendency to aggregate into clumps visible under low-power magnification (X100)
Grade 5	Heavy	Dense large clumps of iron granules visible under low-power magnification (X100)
Grade 6	Very heavy	Very large deposits of iron granules both intracellular and extracellular regions obscuring cellular details in the bone marrow fragments visible under low-power magnification (X100)

Table 8.35 Lineage associated CD antigens and cellular expression commonly analyzed in bone marrow trephine biopsy by routine flow cytometry

Lineage	Immunophenotype Markers on Flow Cytometry	
Hematopoietic stem cells	▪ CD34 (hematopoietic stem cells) ▪ CD117 (c-KIT) (hematopoietic stem cells) ▪ Terminal deoxynucleotidyl transferase (TdT)	▪ CD10 ▪ CD3 ▪ CD19
Myeloid lineage	▪ MPO ▪ CD13 ▪ CD33	▪ CD10 ▪ HLA-DR
Erythroid lineage	▪ CD71 ▪ Glycophorin A (encoded by GYPA gene) ▪ Glycophorin C	▪ Hemoglobin ▪ Spectrin (cytoskeleton protein)
Megakaryocytic lineage	▪ CD41 ▪ CD42b	▪ CD61 ▪ von Willebrand factor (factor VIII RA)
Monocytic lineage	▪ CD14 ▪ CD68 (KP-1 and PGM-1)	▪ CD163

Fluorescently tagged antibodies can be used to determine cell lineage in characterizing patient immunophenotype by flow cytometry. CD55 and CD59: Decay-accelerating factor (DAF) and membrane inhibitor of reactive lysis (MIRL).

RED BLOOD CELL, HEMOGLOBIN, ANTICOAGULANTS AND ANEMIAS

RED BLOOD CELL

Red blood cell measures 7–8 µm in diameter with life span of 100–120 days, which contains hemoglobin. Normal red blood cell membrane cytoskeleton proteins of RBCs comprise spectrin, ankyrin, actin, protein 4.1 and protein 3. Together, these cytoskeleton proteins maintain the normal biconcave shape of RBCs. Patient develops hereditary spherocytosis due to deficiency of any of these RBCs membrane cytoskeleton proteins.

RED BLOOD CELL INDICES

Hematocrit values are basically the measures of red blood cells size and their hemoglobin content, which give valuable information in diagnosing anemia. Automated cell counters provide these data on each sample. These values vary slightly in different laboratories. Mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH) and mean corpuscular hemoglobin concentration (MCHC) are calculated as discussed under.

Mean Corpuscular Volume

Mean corpuscular volume (MCV) is the index used to measure the average volume of red blood cell. MCV categorizes RBCs according to their size. RBCs with normal size are called normocytic cells. Smaller RBCs are termed microcytes, and larger red blood cells are referred to as macrocytes. Normal MCV is 82–96 femtoliters. MCV is decreased in iron deficiency anemia (<80 femtoliters). **MCV** is increased in megaloblastic anemia (>100 femtoliters).

Mean Corpuscular Hemoglobin

Mean corpuscular hemoglobin (MCH) is the index used to measure average hemoglobin content per red blood cell. MCH is calculated by dividing hemoglobin concentration (g/dl) by red blood cells concentration/liter. Normal value of MCH is 26–33 pg. MCH is decreased in iron deficiency anemia and increased in megaloblastic anemia.

Mean Corpuscular Hemoglobin Concentration

Mean corpuscular hemoglobin concentration (MCHC) measures the average concentration of hemoglobin in a given packed cell volume of red cells. Normal MCHC value is 33–37 g/dl. MCHC is decreased in iron deficiency anemia and increased in hereditary spherocytosis. MCHC remains normal in megaloblastic anemia.

Red Blood Cell Distribution Width

Red blood cell distribution width (RDW) is the index to measure degree of anisocytosis (various in size of red blood cells). Normal value of RDW is 11.5–14.5%. RDW is increased in iron deficiency anemia, megaloblastic anemia and immune-mediated hemolytic anemia. RDW remains within normal range in thalassemia.

Hematocrit or Packed Cell Volume

Packed cell volume (PCV) is the index to measure blood volume proportion occupied by red blood cells. Normal PCV range in males is 40–52% and 36–48% in females.

- Increase in number of red blood cells will increase hematocrit or packed cell volume except in thalassemia and megaloblastic anemia.
- Hemolysis in thalassemia increases production of number of red blood cells, but with small size red blood cells and decreased hematocrit value.
- Patient of megaloblastic anemia shows macrocytic red blood cells size but decreased hematocrit value. Cut off points for anemia according to WHO are given in Table 8.36.

RETICULOCYTE COUNT

Approximately 50,000 reticulocytes are produced daily, which circulate for about one day to form mature red blood cells. Reticulocyte count is used to assess the capacity of the bone marrow to increase RBC production in response to increased demand.

Supravital New Methylene Blue Stain

Reticulocytes are demonstrated by supravital stains such as new methylene blue (best stain) and brilliant cresyl blue. Heinz bodies are demonstrated by supravital stains (Table 8.37).

Conditions Associated with Increased or Decreased Reticulocyte Count

Reticulocyte count is increased following massive bleeding, acute hemolysis, and response to specific therapy in nutritional anemia and even after voluntary blood donation. Peripheral blood smear examination under these conditions shows red blood cell polychromasia and increased reticulocyte count. Reticulocyte count is decreased in aplastic anemia, pernicious anemia, bone marrow metastases and congenital dyserythropoietic anemia. Factors impairing the normal reticulocyte response are given in Table 8.38.

Table 8.36 Cut off points for anemia according to WHO

Subject	Hemoglobin (%)	MCHC
Children (6 months to 6 years)	11 g/dl	34%
Children (>6–14 years)	12 g/dl	34%
Women (during pregnancy)	11 g/dl	34%
Women (nonpregnant)	12 g/dl	34%
Men	13 g/dl	34%

Table 8.37 Composition of new methylene blue reagent

Stain Constituents	Quantity
New methylene blue	0.5 g
Potassium oxalate	0.6 g
Distilled water	100 ml

Table 8.38 Factors impairing the normal reticulocyte response

Bone Marrow Disorders	
▪ Hypoplasia/Aplasia of bone marrow	▪ Lymphoma
▪ Metastatic bone disease	▪ Tuberculosis
▪ Acute leukemia	
Lack of Erythropoietin Synthesis	
Chronic renal disease	
Ineffective Erythropoiesis	
▪ Thalassemia major	▪ Megaloblastic anemia
▪ Myelodysplastic syndrome (MDS)	▪ Myelofibrosis
Reduced Tissue Oxygen Consumption	
▪ Myxedema	▪ Protein malnutrition
Miscellaneous Disorders	
▪ Iron deficiency anemia	▪ Malignant tumors
▪ Chronic inflammatory disease	

HEMOGLOBIN

Normal adult hemoglobin is a tetramer protein composed of four globin (peptide) chains (α_1, α_2, β_1, β_2), each with its own heme molecule. These peptide chains undergo conformational change and move with respect to each other when binding of O_2, CO_2, and 2,3-diphosphoglycerate (2,3-DPG) between β-chains reduce affinity for O_2 and permit O_2 release to the tissues.

- Hemoglobin synthesis occurs in the developing red blood cell. The mitochondria are the primary sites of porphyrin synthesis. Iron is supplied from circulating transferrin; globin chains are synthesized on ribosomes.
  - Embryonic hemoglobin exists up to 8 weeks of intrauterine life.
  - Fetal hemoglobin (HbF) is synthesized after 8 weeks of intrauterine life. Fetal hemoglobin level is attained <2% by 7 months of intrauterine life. HbA_2 synthesis begins by 35 weeks of intrauterine life. Switch over from fetal to adult hemoglobin starts at 30 weeks of intrauterine life.
  - Adult hemoglobin synthesis (HbA) is completed by 38 weeks at the time of birth of newborn. Significant time for switching over synthesis from fetal hemoglobin to adult hemoglobin starts at 30 weeks of intrauterine life. Adult hemoglobin synthesis is completed by 38 weeks at the time of birth of newborn. After one year of life and in adults, normal fetal hemoglobin (HbF) is <1% and HbA_2 is <3%. Adult hemoglobin (HbA) constitutes >95%. Steps of heme synthesis are shown in

Fig. 8.10. Steps of hemoglobin synthesis are shown in Fig. 8.11.

Nomenclature of Hemoglobin

The various forms of hemoglobin are named according to the types of globin chains present. Some of these hemoglobins are present in adults, while others may be found only *in utero* or early in infancy.

- Embryonic hemoglobin exists up to 8 weeks of intrauterine life.
- Fetal hemoglobin is synthesized after 8 weeks of intrauterine life. Normal types of hemoglobin according to developmental stage are given in Table 8.39.

Genetic Control

Hemoglobin consists of pairs of globin chains. A variety of globin chains can be present. Normally, α- and β- and to a lesser extent δ-globin chains form adult hemoglobin. In fetal life (γ, ε, and ζ) chains are present. The globin chains of hemoglobin are synthesized independently under separate genetic control. The α-chain and ζ-chain are under genetic control on chromosome 16. Rest globin chains (β-chain, γ-chain, δ-chain, and ε-chain) are under genetic control on chromosome 11. Globin chains and their locus on chromosomes are given in Table 8.40.

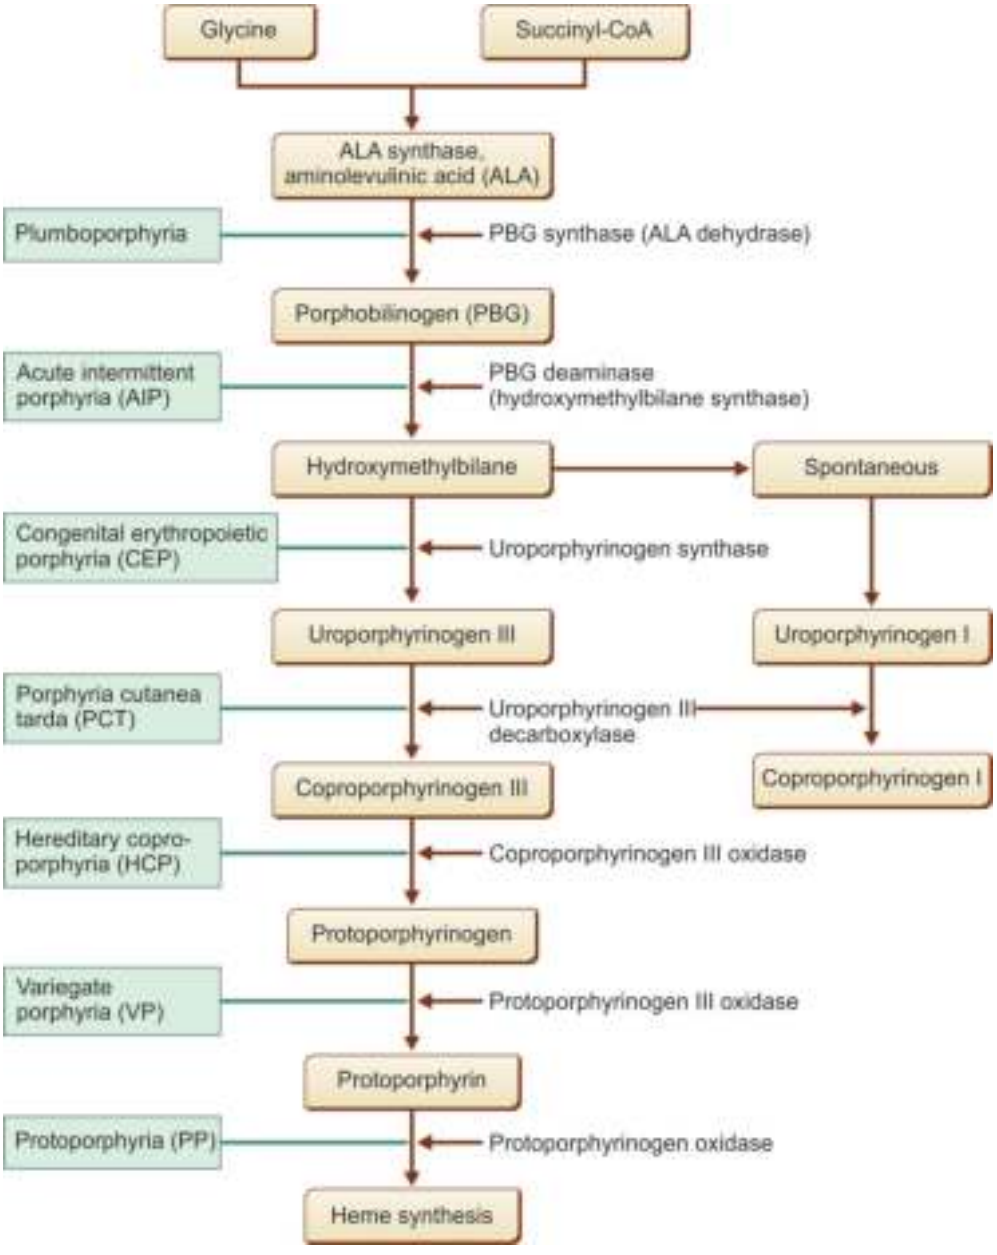

Fig. 8.10: Steps in heme synthesis.

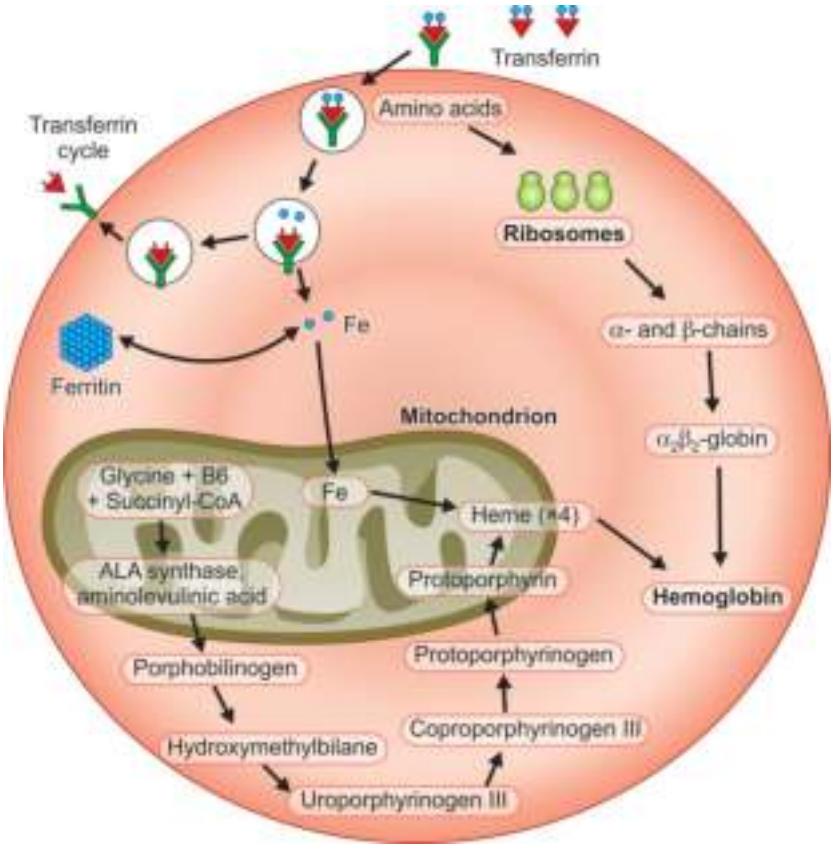

Fig. 8.11: Steps of hemoglobin synthesis

Table 8.39 Normal types of hemoglobin according to developmental stage

Developmental Stage	Site of Hematopoiesis	Type of Hemoglobin	Globin Chains	Reference Interval
Embryonic stage	2–8 weeks	▪ Gower I ▪ Gower II ▪ Portland	▪ $\zeta_2\varepsilon_2$ ▪ $\alpha_2\varepsilon_2$ ▪ $\zeta_2\gamma_2$	▪ Small quantity ▪ Small quantity ▪ Small quantity
Fetal stage	Liver, spleen, bone marrow	▪ HbA ▪ HbA_3 ▪ HbF	▪ $\alpha_2\beta_2$ ▪ $\alpha_2\delta_2$ ▪ $\alpha_2\gamma_2$	▪ Small quantity ▪ Small quantity ▪ 90–95% before birth
Newborn >1-year-old stage	Bone marrow (all bones containing red marrow), liver, spleen	▪ HbA ▪ HbA_2 ▪ HbF	▪ $\alpha_2\beta_2$ ▪ $\alpha_2\delta_2$ ▪ $\alpha_2\gamma_2$	▪ 25% ▪ 1% ▪ 75%
Adult stage	Cranial bone, vertebrae, sternum, ribs, upper end of femur and humerus	▪ HbA ▪ HbA_2 ▪ HbF	▪ $\alpha_2\beta_2$ ▪ $\alpha_2\delta_2$ ▪ $\alpha_2\gamma_2$	▪ >95% ▪ <3.5% ▪ 1%

Hemoglobin Disorders

Hemoglobin disorders are of two types—qualitative and quantitative hemoglobinopathies. These hemoglobin disorders lead to hemolytic anemias.

- Qualitative hemoglobinopathies occur due to defect in abnormal structure of hemoglobin without change in their quantity of synthesis (HbS, HbC, HbD and HbE).
- Quantitative hemoglobinopathies occur due to decreased synthesis of hemoglobin affecting quantity of chains without defect in structure of hemoglobin. Examples are α-thalassemia and β-thalassemia. Hemoglobinopathies associated with microcytosis are given in Table 8.41.

Acquired Abnormal Hemoglobins

Abnormal acquired hemoglobins include methemoglobin, sulfhemoglobin and carboxyhemoglobin. Characteristics of acquired abnormal hemoglobins are given in Table 8.42.

Table 8.40 Globin chains and their locus on chromosomes

Globin Chain	Location of Gene
α-Chain	Chromosome 16
β-Chain	Chromosome 11
γ-Chain	Chromosome 11
δ-Chain	Chromosome 11
ε-Chain	Chromosome 11
ζ-Chain	Chromosome 16

Hemoglobin α-chain and ζ-chain are under genetic control on chromosome 16. Rest hemoglobin globin chains (β-, γ-, δ-, ε-chains) are under genetic control on chromosome 11.

ANTICOAGULANTS USED IN LABORATORY

Most often blood is collected by venepuncture into collection tubes containing anticoagulant. Most commonly used anticoagulants are tripotassium and trisodium salts of ethylenediaminetetra-acetic acid (EDTA), trisodium citrate and heparin. Anticoagulants, mechanism of action and uses are given in Table 8.43.

Table 8.41 Hemoglobinopathies associated with microcytosis

Hemoglobinopathies Associated with Microcytosis
β-Thalassemia major (homozygous)
β-Thalassemia trait (heterozygous)
α-Thalassemia trait
α-Thalassemia trait and hemoglobin constant spring
HbC homozygous and heterozygous
HbD disease
HbO Arab disease
Hb Lepore homozygous and heterozygous
δβ-Thalassemia homozygous and heterozygous
γδβ-Thalassemia homozygous and heterozygous
Hereditary persistence of fetal hemoglobin (HPFH) homozygous
Hereditary persistence of fetal hemoglobin (HPFH); special types of heterozygous

ETHYLENEDIAMINETETRA-ACETIC ACID AND TRISODIUM CITRATE

Ethylenediaminetetra-acetic acid (EDTA) and trisodium citrate remove calcium, which is essential for the

Table 8.42 Characteristics of acquired abnormal hemoglobins

Abnormal Acquired Hemoglobin	Acquired Change	Abnormal Function	Laboratory Detection
Methemoglobin	Hemoglobin iron (Fe^{+++}) oxidized to ferric (Fe^{++}) state in methemoglobin	Methemoglobin cannot combine with oxygen	▪ Maximal absorption band at 630 nm ▪ Chocolate brown-colored blood
Sulfhemoglobin	Sulfur combined with hemoglobin	Sulfhemoglobin has 1/100 oxygen affinity of HbA	▪ Maximal absorption band at 620 nm ▪ Sulfhemoglobin, only hemoglobin not analyzed by cyanmethemoglobin method
Carboxyhemoglobin	Normal hemoglobin combines with carbon monoxide to form carboxyhemoglobin	Carboxyhemoglobin has higher affinity for oxygen	Absorption band at 541 nm

Table 8.43 Anticoagulants, mechanism of action and uses

Anticoagulant	Mechanism of Action	Uses
EDTA	Chelates calcium and removes thus prevents blood coagulation	Hb estimation, platelet count, RBCs count, absolute eosinophil count, estimation of HbF, Hb electrophoresis
Trisodium citrate	Binds with calcium and forms complex	▪ ESR estimation by Westergren's pipette method, blood to anticogulant ratio (4:1) ▪ Prothrombin time done to assess coagulation study, blood to anticoagulant ratio (9:1)
Heparin	Acts against thrombin	Assess osmotic fragility for spherocytosis, RBC enzymes, G6PD and pyruvate kinase
Ammonium–potassium mixture (2:3)	Ammonium causes swelling of RBCs, whereas potassium leads to shrinkage of RBCs resulting in maintaining size of RBCs	Used instead of EDTA
Sodium fluoride	Inhibits glycolysis	Best anticoagulant to estimate blood sugar

initiation of coagulation. EDTA is often used for blood counts, as it causes minimal morphologic and physical effects on the blood cells. Trisodium citrate is the preferred anticoagulant for erythrocyte sedimentation rate (ESR), packed cell volume (PVC), platelets and coagulation studies.

HEPARIN

Heparin acts by forming complex with antithrombin III in the plasma to prevent thrombin formation. Heparin causes a bluish coloration of the background when a smear is stained with Wright-Giemsa stain. Heparin is often used for red blood cell testing, osmotic fragility testing and functional or morphologic analysis of leukocytes.

Hematology Pearls: Romanowsky Stains

Routine stain for peripheral smear and bone marrow examination is a family of Romanowsky stains: May-Grunwald stain, Leishman stain, Giemsa stain, Wright's stain and Jenner's stain. Romanowsky stains also highlight Howell-Jolly bodies, basophilic stippling and Cabot's ring. Romanowsky stain cannot stain Heinz bodies. Comparison between Leishman and Giemsa stains is given in Table 8.44. Composition of buffered water (Sorenson's phosphate buffer) is given in Table 8.45.

ANEMIAS

The criteria for anemia depend upon age, gender, ethnicity, and pregnancy status. World Health Organization has defined anemia as the hemoglobin level below 13 g/dl (hematocrit <39%) in adult males and below 12 g/dl (hematocrit <36%) in adult females. In newborns, hemoglobin level averages 16.5 g/dl (anemia <12.0 g/dl). Hemoglobin level in the age group between six months to two years average 12 g/dl (anemia <10 g/dl). Hemoglobin must be analyzed with a reliable method such as cyanmethemoglobin method. Maintenance of normal level of hemoglobin requires good nutrition, normal gastrointestinal function and absence of chronic diseases. World Health Organization definition of anemia is given in Table 8.46.

Table 8.44 Comparison between Leishman and Giemsa stains

Parameters	Leishman Stain	Giemsa Stain
Stain powder	Leishman powder: 1 g	Giemsa stain powder: 1 g
Methanol	Methanol (acetone-free): 500 ml	Methanol (acetone-free): 66 ml
Glycerol	Nil	Glycerol: 66 ml

Table 8.45 Composition of buffered water (Sorenson's phosphate buffer)

Solution	Salt
Solution A	Potassium dihydrogen phosphate: 9.08 g/L
Solution B	Dibasic hydrogen phosphate: 9.47 g/L

Preparation of buffer water with 6.8 pH: Solution A 50.8 ml + Solution B 49.2 ml = 100 ml.

Table 8.46 World Health Organization definition of anemia

Group	Hemoglobin Level
Adult males	<13.0 gm/dl
Adult nonpregnant females	<12.0 gm/dl
Pregnant females	<11.0 gm/dl
Infants and children (6 months to 6 years)	<12.0 gm/dl
Children (>6 to 14 years)	<11.0 gm/dl

- Clinical manifestations of anemia depend on the rate of onset and degree of anemia. Patient presents with weakness, pallor, exertional breathlessness, dizziness and tachycardia. Diminished tissue oxygenation may provoke the compensatory mechanisms of increased heart rate and force of ventricular contraction.
- Physical examination reveals pallor of conjunctiva, face and palms. Flat spoon-shaped nails (**koilonychia**) are observed in severe iron deficiency anemia. Smooth painful tongue is seen in macrocytic anemia. **Jaundice** and **anemia** are seen in hemolytic anemia.
- Anemias are classified based on morphologic features (size and shape of red blood cells) or mechanism of reduction of hemoglobin (i.e. decreased red blood cells production or increased red blood cells destruction).
- Normal red blood cells are biconcave in shape with a little variation in size and shape. Any deviation from normal morphology is associated with reduced life span of red blood cells.
- Morphologic scheme divides anemia into three groups, based on mean corpuscular volume of red blood cells into microcytic anemia (MCV 50–82 fl), normocytic normochromic anemia (MCV >82–98 fl) and macrocytic anemia (MCV >100 fl). Classification of anemia based on mean corpuscular volume (MCV) is given in Table 8.47.

Table 8.47 Classification of anemias based on mean corpuscular volume (MCV)

Microcytic Anemias (MCV 50–82 fl)		
Disorders of iron metabolism	▪ Iron deficiency anemia ▪ Anemia of chronic disease ▪ Hereditary atransferrinemia	▪ Shahidi-Nathan-Diamond syndrome characterized by congenital microcytic hypochromic anemia with iron overload
Disorders of porphyrin and heme synthesis	▪ Acquired sideroblastic anemias ▪ Hereditary sideroblastic anemia ▪ X chromosome-linked sideroblastic anemia	▪ Idiopathic refractory sideroblastic anemia, complicating other diseases associated with drug (isoniazid) or toxins (ethanol, lead)
Disorders of globin synthesis	▪ Thalassemia (α or β) ▪ Hemoglobinopathies (HbS, HbC, HbD, HbE, HbG)	
Normocytic Normochromic Anemias (MCV >82–98 fl)		
Anemia with appropriate bone marrow response	▪ Acute post-hemorrhagic anemia ▪ Hemolytic anemia with pronounced reticulocytosis (hereditary spherocytosis, hereditary ovalocytosis, paroxysmal nocturnal hemoglobinuria, G6PD deficiency, pyruvate kinase deficiency, hemolytic disease of newborn, blood transfusion reactions, autoimmune hemolytic anemia)	
Anemia with impaired bone marrow response	▪ Bone marrow aplasia (aplastic anemia, pure red cell anemia) ▪ Bone marrow failure (metastatic bone disease, myelofibrosis, Gaucher's disease, Niemann-Pick disease) ▪ Decreased erythropoietin production due to renal disease, liver disease, endocrinal deficiency, malnutrition, anemia of chronic disease	
Macrocytic Anemias (MCV >100 fl)		
Vitamin B_{12} (cobalamin) deficiency	▪ Inadequate dietary intake ▪ Impaired absorption (pernicious anemia, ileal resection, gastric partial or total resection, celiac disease, malabsorption syndrome, intestinal lymphoma, scleroderma) ▪ Competitive consumption of vitamin B_{12} (*Diphyllobothrium latum*—fish tapeworm) ▪ Increased requirement of vitamin B_{12} (pregnancy, neoplasms, hyperthyroidism, chronic pancreatic disease) ▪ Impaired utilization of vitamin B_{12} (transcobalamin II deficiency, abnormal serum cobalamin-binding protein, enzyme deficiencies, nitrous oxide administration)	
Folate deficiency	▪ Decreased dietary intake ▪ Impaired absorption (steatorrhea, celiac disease, anticonvulsant drugs, tropical sprue, intrinsic intestinal disease) ▪ Increased requirement (pregnancy, infancy, neoplasms, hypothyroidism, hyperactive hematopoiesis)	
Unresponsive to vitamin B_{12} and folate in cases of metabolic inhibitors	▪ Purine synthesis metabolic inhibitors (6-mercaptopurine, 6-thioguanine, azathioprine) ▪ Pyrimidine synthesis metabolic inhibitors (6-azauridine) ▪ Thymidylate synthesis metabolic inhibitor (methotrexate, 5-fluorouracil) ▪ Deoxyribonucleotide synthesis metabolic inhibitor (hydroxyurea, cytarabine, severe iron deficiency anemia)	
Inborn errors of cobalamin and folate	▪ Cobalamin deficiency, e.g. Imeslund-Gräsbeck disease, congential deficiency of intrinsic factor, transcobalamin deficiency, cobalamin mutant syndromes with homocysteinemia and or methylmalonic acidemia ▪ Folate deficiency, e.g. congenital folate malabsorption, dihydrofolate reductase deficiency, N5-methyltetrahydrofolate homocysteine methyltransferase deficiency	
Inborn errors related disorders	▪ Lesch-Nyhan syndrome ▪ Hereditary otitic aciduria ▪ Deficiency of formiminotransferase ▪ Deficiency of methyltransferase	▪ Congenital dyserythropoietic anemia ▪ Refractory megaloblastic anemia ▪ Erythroleukemia

CAUSES OF ANEMIA

Anemia may be caused by two major mechanisms: decreased production and destruction of red blood cells (hemolytic anemia). Iron plays role in heme synthesis. Vitamin B_{12} and folic acid are essential for DNA synthesis during hematopoiesis. Decreased RBC production results from damage to hematopoietic stem cells or deficiency of nutrients such as iron, vitamin B_{12} and folic acid. Classification of anemia is shown in Figs 8.12 and 8.13.

DIAGNOSTIC APPROACH OF ANEMIA

Anemia is diagnosed by incorporating information obtained from the clinical history, physical examination and laboratory evaluation.

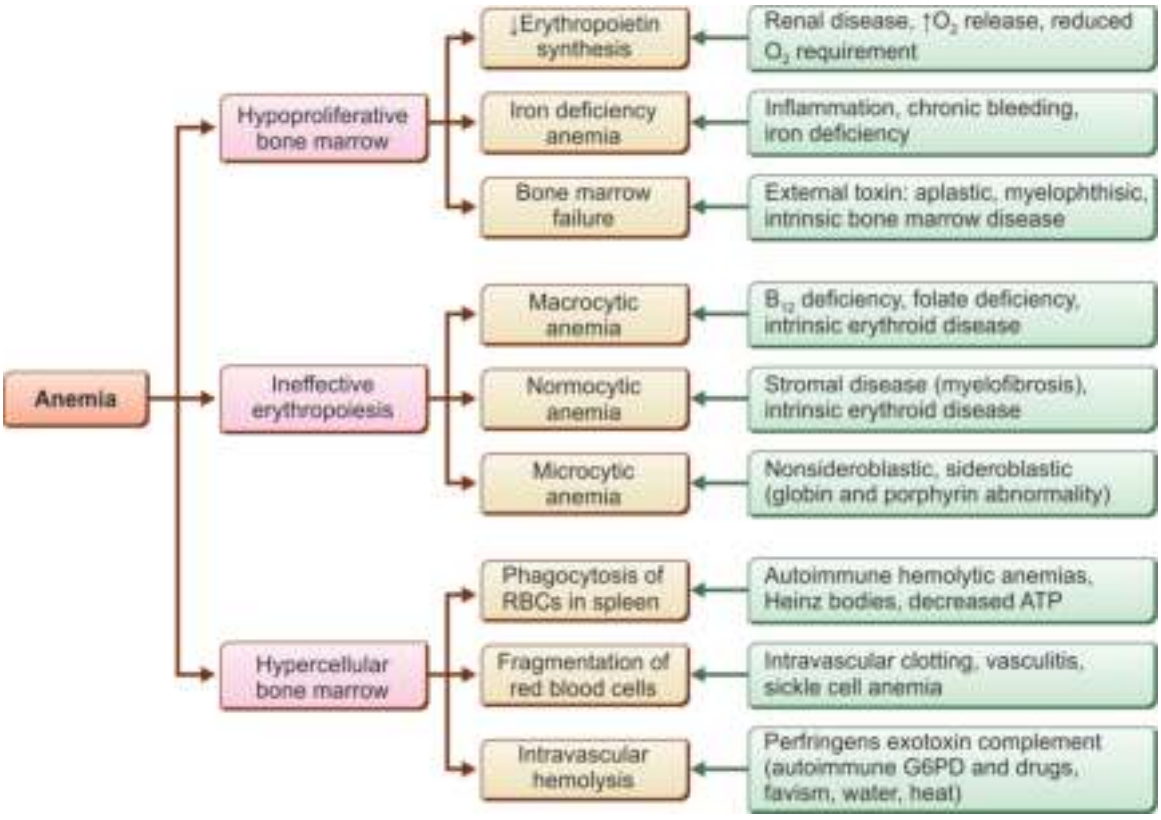

Fig. 8.12: Classification of anemia according to hypoproliferative, ineffective or hypercellular (hemolytic process) erythropoiesis.

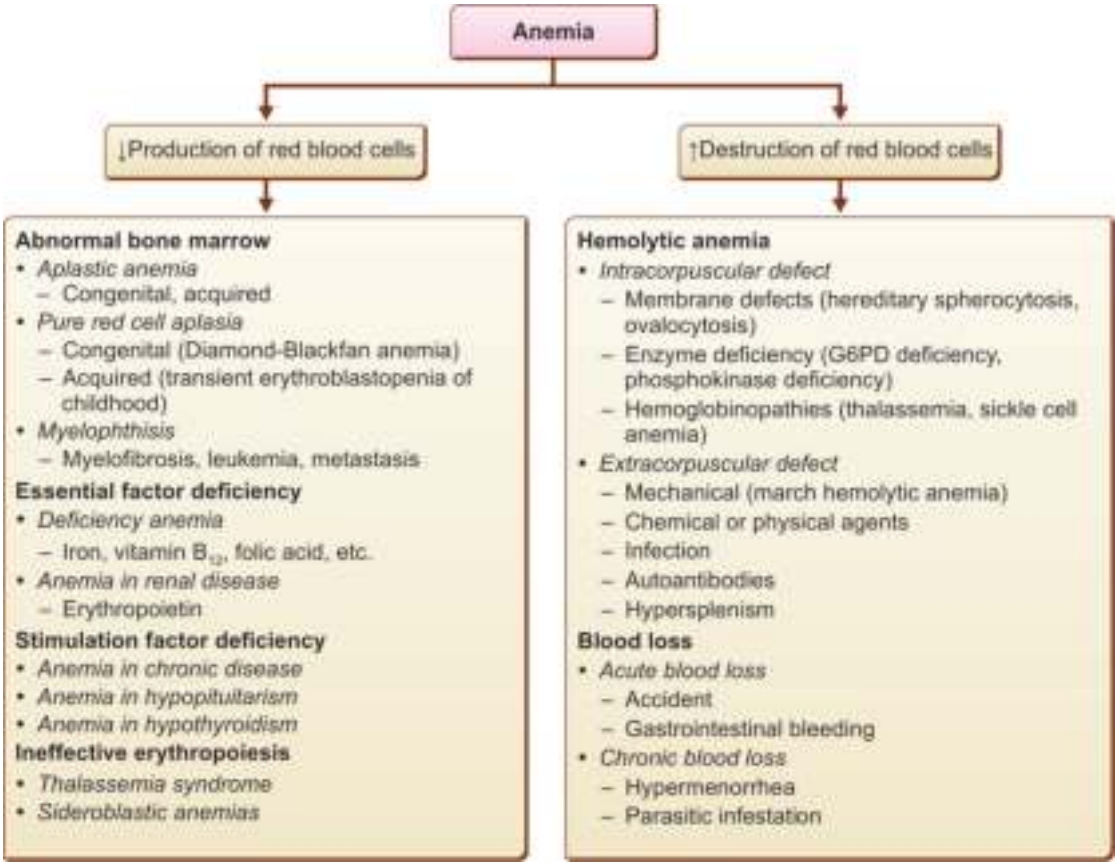

Fig. 8.13: Classification of anemia according to decreased production or increased destruction of red blood cells.

- Diseases with clinical presentations similar to anemia include hypoxia, carbon monoxide poisoning, methemoglobinemia and ischemic heart disease. Best initial diagnostic test for anemia is complete blood count especially MCH, MCHC and peripheral blood smear examination.
- Additional initial tests include reticulocyte count, haptoglobin, lactic dehydrogenase, serum bilirubin, iron stores, serum vitamin/B_{12}/folic acid, serum TSH/T4 and complete urine examination.

Clinical History

Anemia in poorly nourished infants suggests a nutritional cause. Clinical history of jaundice suggests a possible hemolytic process. Ingestion of certain drugs and exposure to chemical agents may also predispose to anemia.

- History of chronic blood loss in females and males is most important cause of anemia.
- Family history, ethnic and geographical considerations provide valuable information in diagnosis anemias.

Physical Examination

Physical examination provides important information such as pallor, bruising, shock, palpable spleen, lymphadenopathy and jaundice. Leg ulcers may occur in sickle cell anemia and thalassemia. Residual neurological abnormalities are seen in sickle cell disease and vitamin B_{12} deficiency.

Evaluation of Basic Hematologic Studies

Basic blood studies include hemoglobin, PCV, reticulocyte count and examination of peripheral blood smears. MCV, MCH and MCHC are measured by blood cell count. Main hematologic parameters are given in Table 8.48.

Biochemical Parameter Studies

Biochemical parameter studies include analysis of serum ferritin, serum iron and serum total iron binding capacity.

Peripheral Blood Smear Examination

Peripheral blood smear examination provides valuable information in studying anemias, leukemias and platelets disorders and demonstration of parasites (e.g. microfilaria, Plasmodium and trypanosomes).

- Scanning for nucleated red blood cells and abnormal white blood cells can be done under high power (40X). In a normal well-prepared peripheral blood smear, one may see 1–3 leukocytes, 10–15 platelets and 200 red blood cells in each high power field.
- Finally, peripheral blood smear should be examined under oil immersion to study the morphology of red blood cells, white blood cells and platelets. Presence of malarial parasites and spirochetes should be carried out.

Table 8.48 Main hematologic parameters

Hematologic Parameter	Calculations	Normal Range	Interpretations
Hematocrit	▪ The ratio of RBC to serum expressed in percentage ▪ It is measured by centrifuging whole blood in a calibrated capillary tube	▪ Men (39–49%) ▪ Women (33–43%)	▪ Hematocrit value is low ▪ Hematocrit value is high in polycythemia
MCV of RBCs	The average calculated volume of a single RBC (hematocrit/erythrocyte count)	82–96 femtoliters	▪ MCV is decreased in iron deficiency anemia (<80 femtoliters) ▪ MCV is increased in megaloblastic anemia (>100 femtoliters)
MCH	The average content of hemoglobin in each RBC (hemoglobin/RBC count)	26–33 pg	MCH is decreased in iron deficiency anemia and increased in megaloblastic anemia
MCHC	The average concentration of hemoglobin in a given volume of packed RBCs (hemoglobin/hematocrit)	33–37 g/dl	▪ MCHC is decreased in iron deficiency anemia and increased in hereditary spherocytosis ▪ MCHC remains normal in megaloblastic anemia
Red blood cell distribution width (RDW)	RDW is the index to measure degree of anisocytosis (various in size of red blood cells)	11.5 to 14%	▪ RDW is increased in iron deficiency anemia, megaloblastic anemia and immune hemolytic anemia ▪ RWD remains within normal range in thalassemia

Diagnostic Approach of Anemia

Red Blood Cells: Morphologic Changes

- One should look for anisocytosis, poikilocytosis of RBCs, hypochromia, polychromasia, presence of abnormal cells like target cells, burr cells, acanthocytes, fragmented red blood cells (schistocytes), sickle cells, spherocytes.
- One should also look for red blood cell inclusions like nuclear fragments (Howell-Jolly bodies), aggregated ribosomes (stippling) or malarial parasites. Abnormal RBCs morphology and interpretations are given in Table 8.49 and Fig. 8.14.

Inclusions in Red Blood Cells

- **Howell-Jolly bodies:** Howell-Jolly bodies are nuclear remnants (aggregates of chromatin material) present in the RBCs and intermediate normoblasts. These are demonstrated by examination of Romanowsky stained smear in postsplenectomy/hyposplenism, megaloblastic anemia and acute hemolytic anemia.
- **Basophilic stippling:** Basophilic stippling is also known as punctate basophilia due to precipitated ribosomal RNA. Periphery of RBCs display small blue-black dots in Romanowsky stained blood films. These are demonstrated by examination of Romanowsky stained smear in lead poisoning, β-thalassemia, megaloblastic anemia, myelodysplastic syndrome and alcoholism.
- **Siderotic nodules/Pappenheimer bodies:** Siderotic nodules are aggregates of ferritin located close to the red blood cell membrane appear as pale blue; which can be demonstrated by examination of Perls Prussian blue stained smear in sideroblastic anemia, megaloblastic anemia, hemolytic anemia and postsplenectomy.
- **Hemoglobin H inclusions:** Hemoglobin H inclusions are β-chains appearing as golf ball-shaped inclusions in red blood cells. These are demonstrated by supravital stains on peripheral blood smear in α-thalassemia and some cases of myelodysplastic syndrome.
- **Heinz bodies:** Heinz bodies are denatured globin located close to the red blood cell membrane. These are demonstrated by examination of supravital stained.
- **Cabot's ring:** Cabot's ring is circular or figure of eight probably formed as a result of damage to RBCs stromal lipoproteins. These are demonstrated in megaloblastic anemia and lead poisoning.
- **Hemoglobin C inclusions:** Hemoglobin C inclusions are tetragonal in shape and are birefringent in a polarized light seen as a result of crystallization of hemoglobin C in 10% of RBCs following splenectomy in homozygous hemoglobin C disease. Red blood cell inclusions in hematologic disorders are given in Table 8.50.

Other Abnormalities of RBCs

- **Rouleaux formation:** RBCs are aggregated resembling a stack of coins known as rouleaux as a result of increased gamma globulins in cases of multiple myeloma, kala-azar, Waldenstörm macroglobulinemia and chronic inflammatory disease.
- **Polychromasia:** Reticulocytes appear as bluish red in Romanowsky stained blood film. These appear as fine reticular network in supravital staining in cases of hemorrhage, hemolysis and response to hematinic replacement.

Table 8.49 Abnormal RBCs morphology and interpretations

Abnormal Red Blood Cells	Interpretations
Macrocytes	Megaloblastic anemia, liver disease, myelodysplasia
Microcytes	Iron deficiency anemia, thalassemia, sideroblastic anemia
Microspherocytes	Hereditary spherocytosis, immune hemolytic anemia, HbC disease, splenectomy, stored blood, burns
Ovalocytes (elliptocytes)	Hereditary elliptocytes, thalassemia, pernicious anemia, iron deficiency anemia, myelofibrosis
Sickle cells (drepanocytes)	Hb sickle cell disease (HbSS), other sickle cell disorders
Target cells	Hemoglobinopathy, liver disease, iron deficiency anemia, splenectomy
Schistocytes (fragmented red blood cells)	Microangiopathic hemolytic anemia, thalassemia, drug-induced hemolytic anemia, mechanical hemolytic anemia, disseminated intravascular coagulation
Hypochromia	Iron deficiency anemia, thalassemia, sideroblastic anemia, chronic renal failure (sometimes)
Polychromasia	Hemolytic anemia, hypoxia, megaloblastic anemia, acute blood loss
Acanthocytes (spiny projections of the surface due to defect within the lipid bilayer of the red cell membrane may be associated with hemolysis)	Chronic liver disease (increased free cholesterol is deposited within the cell membrane), abetalipoproteinemia, splenectomy
Poikilocytes (tear-shaped red cells)	Megaloblastic anemia, thalassemia, myelosclerosis, microangiopathic hemolytic anemia, iron deficiency anemia

Contd...

Table 8.49 Abnormal RBCs morphology and interpretations (*Contd...*)

Abnormal Red Blood Cells	Interpretations
Burr cells (ethinocytes)	Uremia (chronic renal disease), liver disease, MDS, pyruvate kinase deficiency, disseminated malignancy
Stomatocytes (slit- or mouth-like area)	An artifact, alcoholism, stomatocytosis
Leptocytes (RBCs with thin ring of membrane due to grossly deficient hemoglobin)	Iron deficiency anemia, thalassemia
Helmet cells	Disseminated intravascular coagulation, thrombotic thrombocytopenic purpura
Bite cells	G6PD deficiency

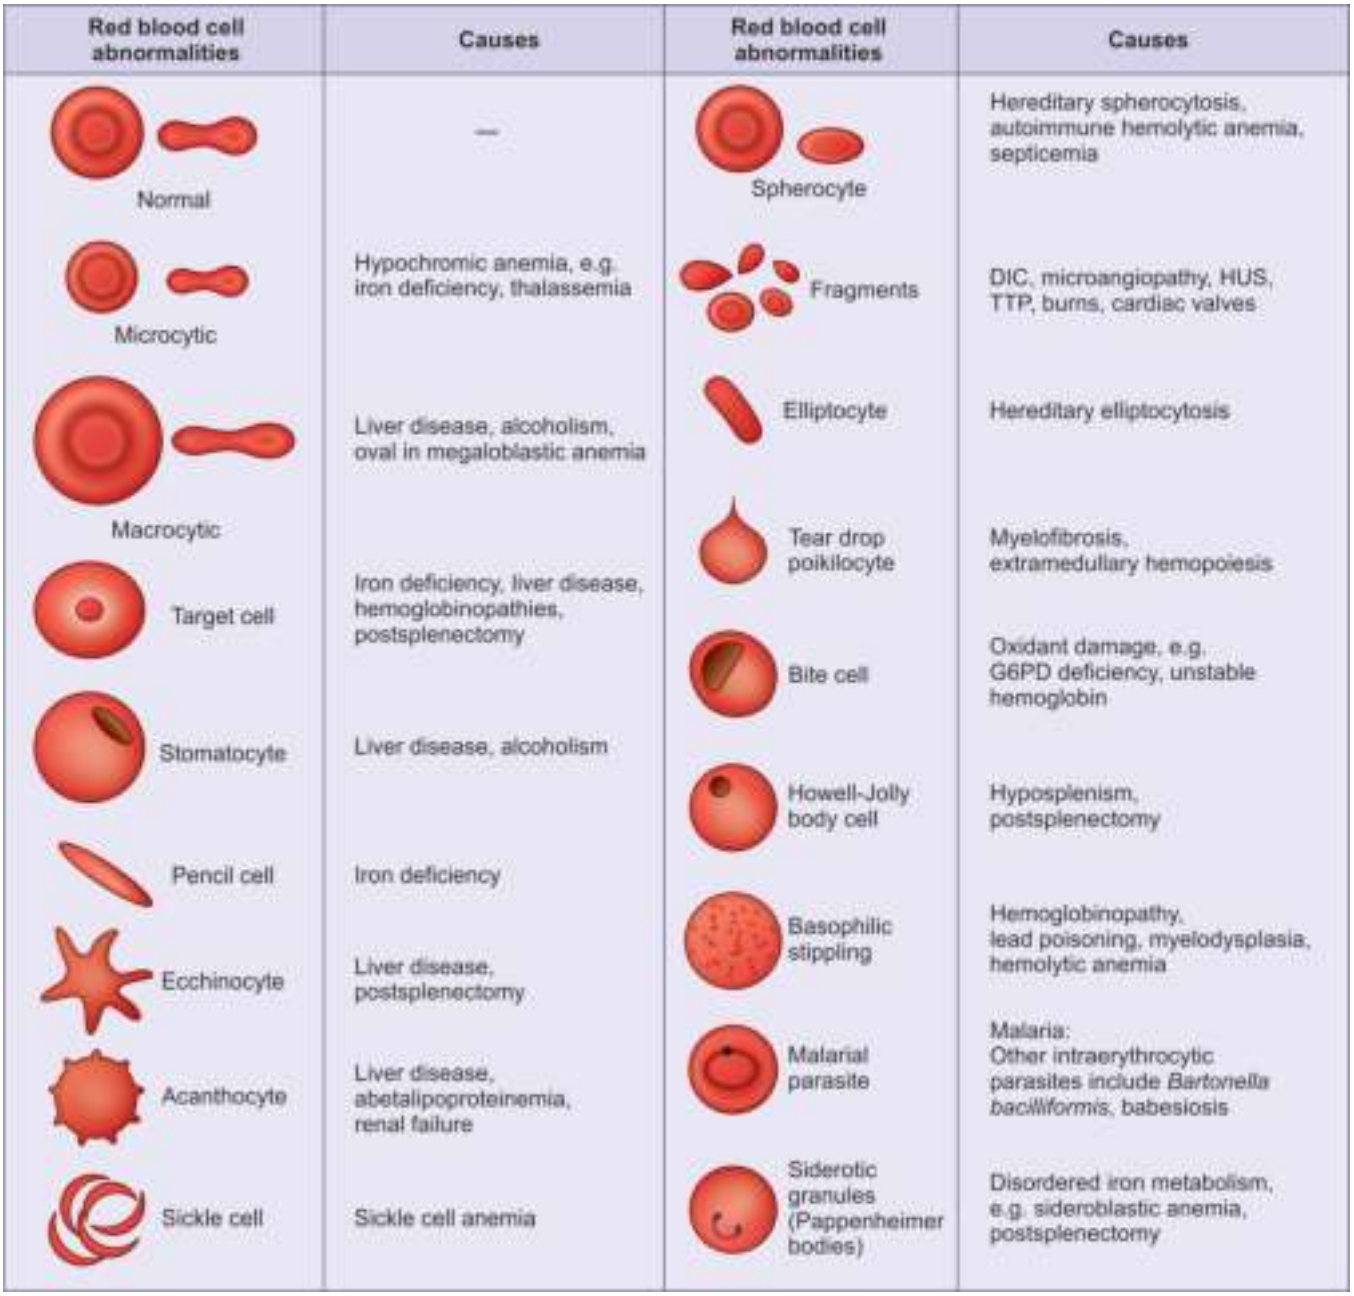

Fig. 8.14: Abnormal RBCs morphology and interpretations.

Table 8.50 Red blood cell inclusions in hematologic disorders

RBC Inclusion	Comment	Staining Technique	Hematologic Disorders	
Howell-Jolly bodies	DNA nuclear remnants	Romanowsky stains	▪ Postsplenectomy state ▪ Hypersplenism	▪ Megaloblastic anemia ▪ Acute hemolytic process
Basophilic staining	Ribosomal RNA	Romanowsky stains	▪ β-Thalassemia major and trait ▪ Megaloblastic anemia ▪ Myelodysplastic syndrome (MDS) ▪ Sideroblastic anemia	▪ Pyrimidine 5'-nucleosidase deficiency ▪ Heavy metal poisoning (coarse basophilic stippling in RBCs seen due to lead, zinc, arsenic, silver, mercury)
Pappenheimer body	Iron (siderotic) nodule	Perls Prussian stain	▪ Sideroblastic anemia ▪ Hemolytic anemia ▪ Megaloblastic anemia	▪ Postsplenectomy state ▪ Myelodysplastic syndrome
HbH inclusions	β-Globin tetramers (β4)	Supravital stain	▪ α-Thalassemia	▪ Myelodysplastic syndrome (some cases)
Heinz bodies	Denatured hemoglobin	Supravital stain	▪ G6PD deficiency ▪ Drugs and poisons with oxidative action	▪ Hypersplenism ▪ Unstable hemoglobin ▪ Postsplenectomy
Hemoglobin C crystals	Hemoglobin C homozygous state	Polarizing microscope	▪ Hemoglobin C homozygous state	▪ Postsplenectomy state
Cabot's rings (figure of 8)	Mitotic spindle remnants	Romanowsky stain	▪ Megaloblastic anemia	▪ Lead poisoning

Bone Marrow Aspirate Smear Examination

Bone marrow aspiration is usually performed on the back of hip bone or posterior iliac crest. Bone marrow aspirate smear examination gives more information and morphologic characteristics, better defined in Romanowsky stained bone marrow aspirate blood smears. Bone marrow examination is done to diagnose iron deficiency anemia, megaloblastic anemia, leukemias, ITP, multiple myeloma, Gaucher's disease, Niemann-Pick disease, metastatic deposits and parasites, e.g. LD bodies and malarial parasite. Iron content is demonstrated by Perls Prussian blue stain.

IRON METABOLISM AND IRON DEFICIENCY ANEMIA

Iron deficiency is the most common nutritional disorder across world, it is frequent cause of microcytic hypochromic anemia. Decreased dietary iron, increased demand, decreased iron absorption, or blood loss lead to iron deficiency anemia.

IRON METABOLISM

Iron participates in various chemical reactions and maintains homeostasis of iron at both the systemic and cellular levels. A well-balanced diet contains sufficient iron. Normal diet contains 10–20 mg of iron each day. Iron present in the ferrous form (Fe^{2++}) is mainly absorbed in the duodenum and upper jejunum. This is sufficient to balance the 1.0–2.0 mg daily loss from desquamation of epithelia of gastrointestinal tract and skin. Iron absorption is enhanced by citrate and ascorbate present in citrus fruits; and acidic pH, while decreased by tannates present in tea, phytates, tetracycline, milk and alkaline pH. Factors favoring and reducing iron absorption are given in Table 8.51.

REGULATION OF IRON METABOLISM

Heme iron derived from animal products such as liver and meat is more readily absorbed. Non-heme iron (inorganic iron) derived from raw vegetables and cereals is first reduced to ferrous (Fe^{2++}) form inside enterocytes of duodenum via cytochrome B. Regulation of iron metabolism is shown in Fig. 8.15.

Binding of Fe^{2++} with DMT1

Ferrous (Fe^{2++}) binds to apical transporter is called DMT1 (divalent metal transporter 1) encoded by **SLC11A2**

Table 8.51 Factors favoring and reducing iron absorption

Factors Favoring Iron Absorption	Factors Reducing Iron Absorption
Heme iron	Inorganic iron
Ferrous iron (Fe^{2+})	Ferrous iron (Fe^{3+})
Acids—HCl, vitamin C	Alkalis—antacids, pancreatic secretions
Stabilizing agents—sugars, amino acids	Iron precipitating agents—phytates, phosphates
Ineffective erythropoiesis	Tea consumption
Pregnancy	Infection
Hereditary hemochromatosis	Decreased erythropoiesis
Increased expression of DMT1 and ferroportin in duodenal enterocytes	Decreased expression of DMT1 and ferroportin in duodenal enterocytes
Decreased hepcidin concentration	Increased hepcidin concentration

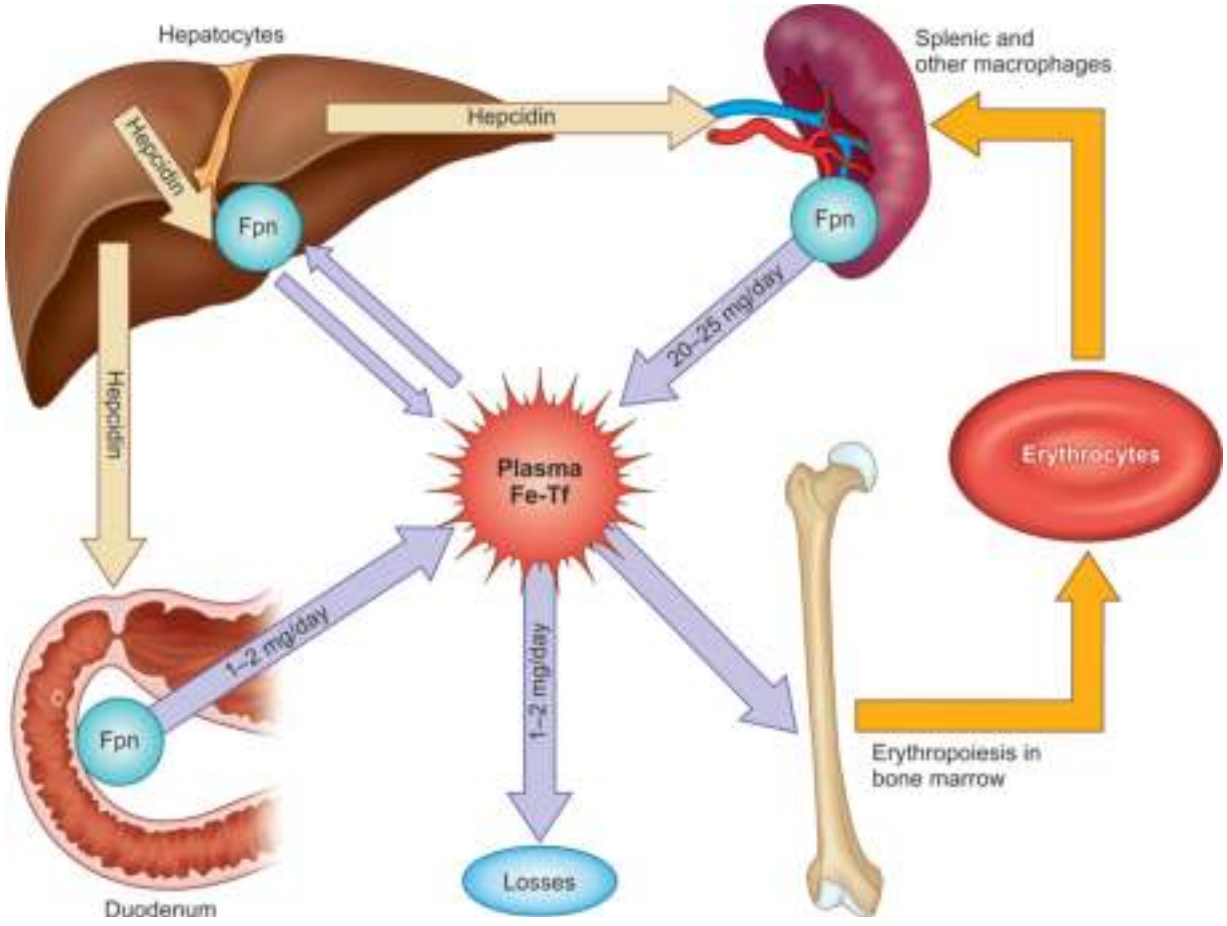

Fig. 8.15: Regulation of iron metabolism. Hepcidin (also known as LEAP1) encoded by HAMP gene is the main regulator of iron metabolism. It degrades ferroportin (protein involved in iron absorption). It blocks ferroportin carrying iron to spleen. It blocks iron release from macrophages required for heme synthesis during erythropoiesis.

gene. DMT1 participates in transfer of iron from endosomes into the cytosol of developing erythroid precursors. Mutation of SLC11A2 gene encoding DMT1 (divalent metal transporter 1) causes severe microcytic hypochromic anemia in newborns. Serum ferritin level in newborns is decreased due to defective release of iron into the blood. Patient's transferrin saturation percentage is increased.

Iron Transport Across Enterocytes

Absorbed iron is transported by transporter proteins such as ferroportin and hephaestin across basolateral membrane of enterocytes. These transporter proteins convert ferrous (Fe^{2++}) to ferric (Fe^{3+++}) form. Intracellular mucosal ferritin in the enterocytes is subsequently lost during sloughing of epithelia. Iron absorption in enterocytes in duodenum is shown in Fig. 8.16.

Hepcidin: Master Regulator of Iron Absorption

- Hepcidin is main regulator of iron absorption also known as liver expressed antimicrobial peptide or LEAP1, encoded by the HAMP gene.
- Hepcidin inactivates ferroportin 1 (iron-regulated transporter 1 protein encoded by SLC40A1 gene), prevents reabsorption of iron from duodenum.
- Decrease in hepcidin level increases expression of ferroportin 1 resulting in increased iron absorption by duodenum.
- Hepcidin also blocks the release of important source of iron from reticuloendothelial cells in bone marrow required for heme synthesis during erythropoiesis.
- Hepcidin also prevents excessive deposition of iron in liver, heart, pancreas, joints, skin and pituitary gland.
- Iron is demonstrated by Perls Prussian blue stain. Iron level >22 mg/g of liver dry weight carries increased risk of cirrhosis.

Transport of Iron in Plasma

Absorbed iron is carried in the bloodstream by the glycoprotein named transferrin. Normally, about 20–45% of transferrin binding sites are saturated with iron termed as the percent saturation. Familial atransferrinemia causes microcytic hypochromic anemia.

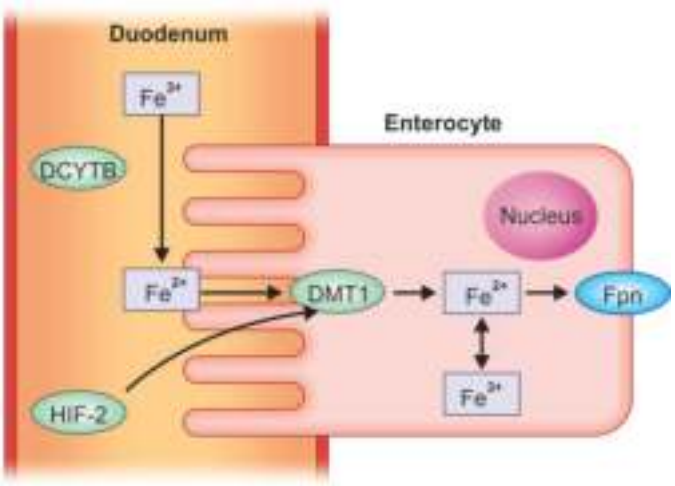

Fig. 8.16: Iron absorption in enterocytes in duodenum.

Storage of Iron

Serum iron (Fe^{3++}) is mainly stored in the liver (33%), spleen (33%), bone marrow (33%) and skeletal muscle. Iron is initially stored as ferritin. However, ferritin can be incorporated by phagolysosomes to form hemosiderin. Distribution of body iron in average adult male and female is given in Table 8.52. Differences between ferritin and hemosiderin are given in Table 8.53.

Utilization of Iron

Most absorbed iron (Fe^{3++}) is utilized in the bone marrow for erythropoiesis. About 10–20% of absorbed iron goes into a storage pool, which is also being recycled for erythropoiesis, so there is a balance of storage and use.

Table 8.52 The distribution of body iron in average adult male and female

Distribution of Iron Form	Distribution of Iron in Adult Male	Distribution of Iron in Adult Female	Percentage of Total Body Iron
Hemoglobin (functional iron)	2.4 gm	1.7 gm	65%
Heme enzymes for cellular respiration: functional iron (e.g. cytochromes, catalase, peroxidase, flavoproteins)	0.02 gm	0.015 gm	0.5%
Myoglobin (functional iron)	0.15 gm	0.12 gm	3.5%
Ferritin and hemosiderin (storage iron in bone marrow, liver and spleen)	1.0 gm (0.3–1.5 gm)	0.3 gm (0–1.0 gm)	30%
Transferrin-bound iron in plasma	0.004 gm	0.003 gm	0.1%

Table 8.53 Differences between ferritin and hemosiderin

Parameters	Ferritin	Hemosiderin
Color	Colorless (unstained smear)	Golden yellow (unstained smear)
Solubility in water	Water soluble	Water insoluble
Iron content	Contains less iron	Contains more iron
Storage sites	Bone marrow, liver and spleen	Storage: Bone marrow, liver and spleen

IRON DEFICIENCY ANEMIA

Iron deficiency anemia occurs due to dietary iron deficiency, increased iron demand during reproductive period in women, decreased absorption and chronic blood loss.

ETIOPATHOGENESIS

Dietary Iron Deficiency

Dietary iron deficiency is rare except in infants, because human milk is low in iron. Newborn iron stores are depleted within first 6 months of postnatal life unless it is replaced by dietary supplementation. Iron deficiency anemia is common in infants within the first 2 months of life, who are non-breastfed and supplemented with cow's milk, rather than iron-fortified formula. Other uncommon causes of iron deficiency anemia include poor economic status, anorexia in pregnancy, poor dentition and financial constraints.

Increased Iron Demand

During reproductive period, women require more iron due to menstrual blood loss. During pregnancy 0.5 g of extra iron is needed for growing fetus. Growth spurt during childhood requires more iron.

Decreased Iron Absorption

Diseases that could impair iron absorption include celiac disease, achlorhydria, partial or total gastrectomy. Absorption of iron is decreased by tannates present in tea, phytates, tetracycline, milk and alkaline pH.

Chronic Blood Loss

Chronic blood loss is most common cause of iron deficiency anemia in adults due to pathological disorders. Gastrointestinal tract bleeding may occur due to peptic ulcer disease, GIT carcinomas, hemorrhoids, chronic use of aspirin, hookworm disease.

- Bleeding from respiratory tract occurs due to hemoptysis and recurrent epistaxis. Renal pathology may lead to hematuria and hemoglobinuria.
- Chronic blood loss in women may occur due to dysfunctional uterine bleeding, early onset of menarche, postmenopausal bleeding and cervical carcinoma. Of course, hemorrhage will increase the iron need to replace lost RBCs. Hookworm infestation is a common cause of iron deficiency anemia.

CLINICAL FEATURES

Patient presents with pallor, fatigue, or dyspnea on exertion. Fatigue appears first than abnormal laboratory findings. Latent iron deficiency refers to deficient iron stores but hemoglobin remains within normal range. In severe iron deficiency anemia, associated features may include glossitis, gastritis, koilonychia (spooning of the nails) due to loss of essential iron containing enzymes (Fig. 8.17 and Table 8.54).

Plummer-Vinson Syndrome

Plummer-Vinson syndrome also known as Paterson-Kelly syndrome is a triad, i.e. chronic iron deficiency anemia, dysphagia due to partially obstructing postcricoid webs in esophagus and glossitis. Postcricoid esophageal web may undergo esophageal squamous cell carcinoma.

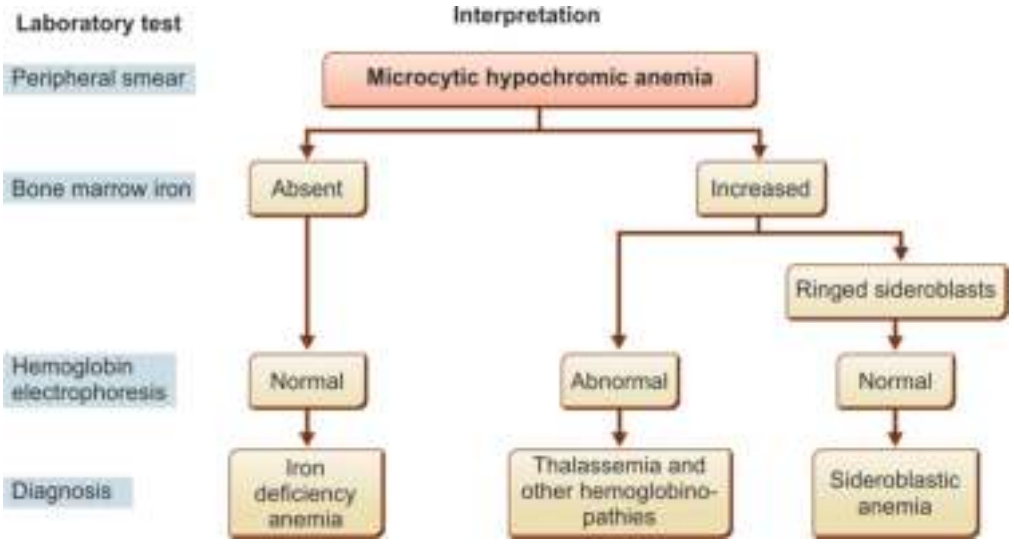

Fig. 8.17: Scheme for investigating patients with microcytic hypochromic anemia. This figure represents a convenient approach to the diagnosis of this form of anemia.

Table 8.54 Laboratory investigations of iron deficiency anemia

Laboratory Method	Reference Range	Iron Deficiency Anemia
Complete blood count and peripheral smear examination		
RBC count	▪ Male: 4.6–6 million/mm^3 ▪ Female: 4.2–5 million/mm^3	Decreased
Hemoglobin	▪ Male: 13–16 g/dl ▪ Female: 12–15 g/dl	▪ Male: <13 g/dl ▪ Female: <12 g/dl
MCV	80–98 femtoliter (fl)	<79 femtoliter (fl)
MCH	27–32 pg	<26 pg
MCHC	32–36 g/dl	<30 g/dl
RDW-CV = (standard deviation of MCV ÷ MCV) × 100	11.5–14.5%	Increased
Mentzer index in children: It is used as a rough guide to differentiate between iron deficiency anemia (>13) and thalassemia trait (<13)	<13	>13
RBC morphology	Normocytic normochromic anemia	Microcytic hypochromic cells, anisocytosis, poikilocytosis (ring cells, target cells, pencil cells, elliptical cells)
Serum ferritin	▪ Male: 12–300 ng/ml ▪ Female: 12–150 ng/ml	▪ <12 ng/ml ▪ <12 ng/ml
Serum iron	50–150 µg/dl	<30 µg/dl
Serum TIBC (total iron-binding capacity)	250–435 µg/dl	>400 µg/dl
Serum TIBC % saturation: It is calculated by serum iron 100/TIBC	20–45%	<16%
Bone marrow iron stores: Iron is graded by Galle's bone marrow aspirate smear iron grading (0–6+). Iron is demonstrated by Prussian blue reaction/Perls reaction	1–3 grade	0 grade in severe iron deficiency anemia
Bone marrow sideroblasts percentage	40–60%	<10%
RBC-free protoporphyrin level	30–50 µg/dl	>200 µg/dl (increased)
Serum soluble transferrin receptor (sTfR)	4–9 µg/L	Increased

Flow cytometric analysis of reticulocytes: Reticulocyte hemoglobin content (CHr) and percentage of hypochromic reticulocytes.

LABORATORY DIAGNOSIS

If during initial evaluation of peripheral blood smear, pathologist finds microcytic hypochromic picture, one must consider common causes of microcytic hypochromic anemia such as iron deficiency anemia, thalassemia and abnormalities of iron metabolism.

- **PCV analysis:** Extent of morphological abnormalities depend on the level of hemoglobin or PCV.
- **Laboratory diagnostic tools:** Laboratory diagnostic tools are hemoglobin estimation, complete blood count, peripheral smear examination, bone marrow aspiration, hematocrit values, packed cell volume, erythrocyte sedimentation rate, serum iron, serum iron-binding capacity, percentage saturation, serum ferritin, bone marrow biopsy and liver biopsy. Bone marrow iron is deficient in iron deficiency anemia.
- **Bone marrow iron:** Bone marrow iron is increased in β-thalassemia major and other hemoglobinopathies.

In sideroblastic anemia, bone marrow evaluation reveals sideroblasts and increased iron. Hemoglobin electrophoresis is normal in iron deficiency and sideroblastic anemia.

Laboratory Diagnosis of Iron Deficiency Anemia

Peripheral Blood Smear Examination

- RBCs show anisocytosis, poikilocytosis, microcytes, hypochromic red blood cells with central pallor area greater than half, ring cells, target cells, pencil cells, elliptical cells.
- Complete blood count gives an indirect measure of iron stores, because the mean corpuscular volume (MCV) is decreased in iron deficiency anemia.
- Microcytic hypochromic anemia is also observed in thalassemia major, thalassemia trait, thalassemia intermedia, HbE thalassemia and HbH disease. RDW is <15% in thalassemia trait and >15% in iron deficiency anemia (Fig. 8.18A to C).

Bone Marrow Smear Examination

Bone marrow smear examination is a diagnostic tool for differentiating iron deficiency from other causes of hypochromic anemia. By definition, iron deficiency anemia means that the bone marrow has no iron stores.

Iron store is most often determined by Perls Prussian blue iron stain. Iron granules appear as bright blue or blue-green aggregate contrasting sharply with pink stained background. Bone marrow smear shows following features (Fig. 8.19):

- **Cellularity:** Bone marrow smear examination shows hypercellular marrow as a result of erythroid hyperplasia.
- **Erythroid series:** Erythroid hyperplasia shows micronormoblastic erythropoiesis. Predominant cells are polychromatic (late) normoblasts with fraying of cell borders.
- **Myeloid series:** Myelopoiesis is normal.
- **Myeloid/erythroid ratio:** Myeloid/erythroid ratio is decreased due to erythroid hyperplasia.
- **Megakaryocytic series:** Megakaryopoiesis is normal.

Bone Marrow Iron

- Bone marrow store study is another reliable method for estimating iron stores, but drawback is invasive technique.
- The amount of storage iron for erythropoiesis can be quantified by performing an iron stain Perls Prussian blue stain) on a bone marrow aspiration. Potassium ferrocyanide combines with iron forming potassium ferrocyanide–ferricyanide complex giving bluish coloration.
- Iron stores are depleted in iron deficiency anemia. Excessive iron stores can be determined by bone marrow and by liver biopsies.

Biochemical Markers of Iron Deficiency Anemia

Biochemical markers of iron deficiency anemia comprise serum ferritin, serum iron, TIBC, % saturation of transferrin and serum transferrin receptors.

- **Serum iron:** Serum iron test gives indirect indication of iron stores. Normal serum iron concentration is the range of 60–150 μg/dl. Serum iron concentration is below normal in iron deficiency anemia. Serum iron concentration is increased in cases of β-thalassemia major, hemoglobinopathy, sideroblastic anemia and history of multiple blood transfusions.
- **Total iron-binding capacity:** Total iron-binding capacity (TIBC) measurement may provide useful in information about iron stores. Normal range of TIBC is 250–450 μg/dl and its saturation is 33%. Measurement of TIBC is based on saturating plasma with iron and removal of excess of unbound iron by adsorbing onto chemical agent and then estimation of iron in the iron-saturated serum.
- **Hemoglobin electrophoresis:** HbA_2 and HbF determinations are very useful for differentiating thalassemia from abnormal use of iron. HbA_2 and HbF are increased in patients with β-thalassemia. Hemoglobin electrophoresis is not useful in α-thalassemia. Therefore, demonstration of HbH in RBCs on peripheral blood smear stained by brilliant cersyl blue is useful in α-thalassemia.
- **Other hematological tests:** RBCs protoporphyrin level is increased due to nonavailability of iron for synthesis of heme (normal range 20–40 μg/dl). Osmotic fragility is increased.

Differential Diagnosis

Iron deficiency anemia must be distinguished from other causes of microcytic hypochromic anemia such as β-thalassemia major/minor and anemia of chronic disease.

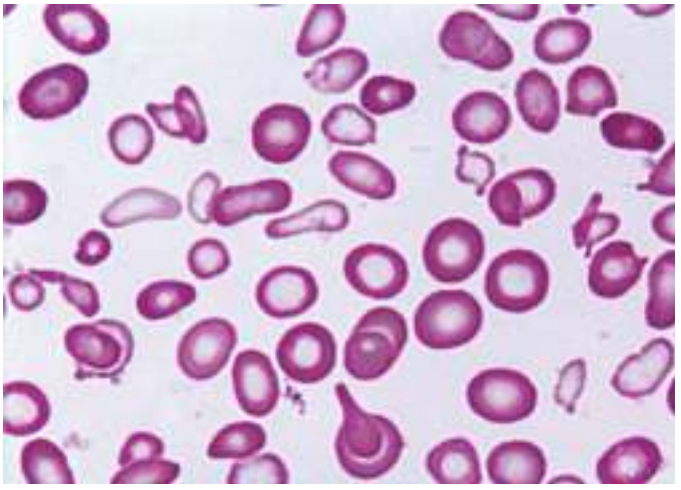

Fig. 8.18A: Peripheral blood smear examination shows microcytic hypochromic anemia. There is central pallor area of erythrocytes. Erythrocytes show anisocytosis and poikilocytosis. RBCs are elongated known as pencil cells.

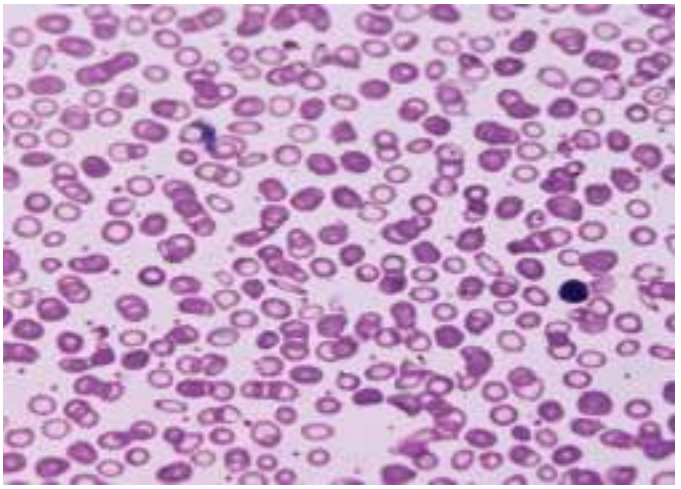

Fig. 8.18B: Peripheral blood smear examination in iron deficiency anemia. It shows marked anisocytosis, poikilocytosis of red blood cells, microcytic hypochromic picture with numerous target cells and a few pencil cells.

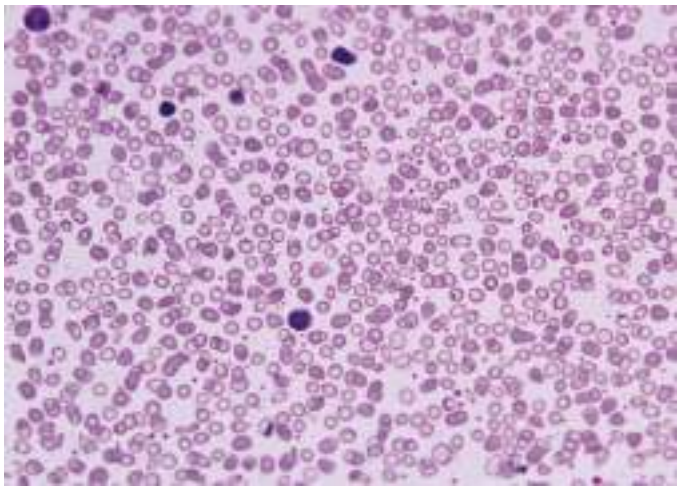

Fig. 8.18C: Peripheral blood smear examination in iron deficiency anemia. It shows microcytic hypochromic picture, target cells and nemerous target cells.

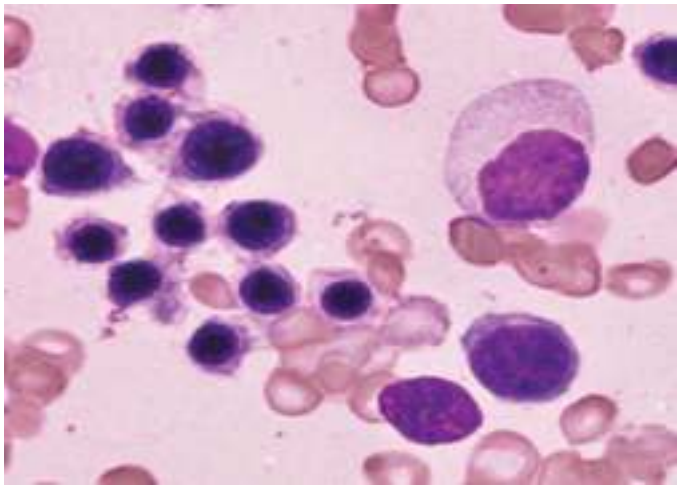

Fig. 8.19: Bone marrow aspiration shows micronormoblastic erythropoiesis in iron deficiency anemia.

- Free erythrocyte protoporphyrin level is increased in iron deficiency anemia and anemia of chronic disease; but normal in β-thalassemia major.
- In iron deficiency anemia, serum ferritin is markedly reduced (<15 µm/L). Bone marrow iron is very low or absent. In β-thalassemia major/minor, serum ferritin and bone marrow iron are increased along with increased HbF (20–90%). In β-thalassemia minor, the HbA_2 is increased.
- In anemia of chronic disease, the serum iron is low in iron deficiency anemia, but the TIBC is also low. Ratio of serum transferrin receptors (sTfR) to ferritin is important parameter to distinguish iron deficiency anemia and anemia of chronic disease. Ratio of serum transferrin receptors to ferritin >1.5 indicates iron deficiency anemia and ratio <1.5 indicates anemia of chronic inflammation.

RESPONSE TO IRON THERAPY

Oral iron preparations in the form of ferrous salts containing 100–200 mg of elemental iron is given per day for 3–6 months in severe iron deficiency anemia. Patients may be treated by administering injectable iron–dextran or iron–sorbitol citrate.

- **Subjective symptoms:** Iron supplement therapy leads to improvement in symptoms due to synthesis of iron containing enzymes and globin. Iron containing enzymes are cytochrome B, catalase, ferrochelatase countase and ribonucleotide reductase.
- **Reticulocyte count:** Response to iron therapy is evaluated by reticulocyte count on day 7 of therapy. There is increase in the reticulocyte count within 7–10 days after iron therapy.
- **Hemoglobin content:** Hemoglobin estimation is the most accurate measure of degree of iron deficiency anemia. Hemoglobin level achieves normal range within 2 months after iron therapy. Atrophic gastritis disappears. Koilonychia (spooning of the nails) due to loss of essential iron containing enzymes disappears by 3–6 months after iron therapy.

IRON OVERLOAD

Excessive iron can accumulate and induce either acute iron poisoning or chronic iron overload.

Acute Iron Poisoning

Acute iron poisoning is mainly seen in children following ingestion of 20 mg of elemental iron per kg of body weight, which occurs when free iron not bound to transferrin appears in the blood. Free iron can damage blood vessels resulting in vasodilation with increased vascular permeability, hypotension and metabolic acidosis.

- In addition, excessive iron damages mitochondria and causes lipid peroxidation, and manifest mainly as renal damage and hepatocellular damage.
- Early signs of acute iron poisoning include vomiting and diarrhea, fever, hyperglycemia, and leukocytosis.
- Later signs of acute iron poisoning include hypotension, metabolic acidosis, lethargy, seizures, and coma. Hyperbilirubinemia and elevated liver enzymes suggest hepatocellular injury, while proteinuria and appearance of tubular cells in urine suggest renal tubular injury.

Chronic Iron Overload

Chronic iron overload can occur in patients who receive multiple blood transfusions for anemias caused by anything other than blood loss. Patients with congenital anemias may require numerous blood transfusions for many years. Each unit of blood bag has 250 mg of iron.

MEGALOBLASTIC ANEMIA, FOLIC ACID AND VITAMIN B_{12} DEFICIENCY

MEGALOBLASTIC ANEMIA

The megaloblastic anemias are a group of disorders characterized by macrocytic anemia picture in peripheral blood and megaloblastic erythropoiesis in bone marrow. Megaloblastic anemia occurs due to deficiency of vitamin B_{12} or folate resulting in defective DNA synthesis. Vitamin B_{12} is not required directly for DNA synthesis; however, it is required as methylcobalamin to convert 5-methyltetrahydrofolate (methyl-THF), which enters cells from plasma into other folate coenzyme forms through its involvement in the methionine synthase reaction in which homocysteine gets methylated to methionine. Vitamin B_{12} participates in utilization of folate in synthesis of nucleic acid; and essential for maintenance of nervous system. Folate acts as coenzyme involving one carbon unit transfer resulting in the synthesis of nucleic acid. Major functions of folate and vitamin B_{12} deficiency syndrome are given in Table 8.55. Differences between vitamin B_{12} and folate nutritional aspects are given in Table 8.56.

MEGALOBLASTIC ANEMIA: CLASSIFICATION

MACROCYTIC ANEMIA WITH MEGALOBLASTIC ERYTHROPOIESIS

Megaloblastic macrocytic anemia occurs due to deficiency of vitamin B_{12} and/or folic acid, which is characterized by decreased DNA synthesis, with a consequent delay in DNA replication and nuclear division.

Table 8.55 Major functions of folate and vitamin B_{12} deficiency syndrome

Nutrient	Functions	Deficiency Syndrome
Folate	Acts as a coenzyme in transfer and utilization of 1-carbon unit, an essential step in nucleic acid synthesis	Megaloblastic anemia
Cyanocobalamin (vitamin B_{12})	▪ Participates in utilization of folate in nucleic acid synthesis ▪ Essential for maintenance of nervous system	▪ Megaloblastic anemia ▪ Subacute combined degeneration of spinal cord in midthoracic region

Table 8.56 Differences between vitamin B_{12} and folate nutritional aspects

Parameters	Vitamin B_{12} (Cyanocobalamin)	Folate
Normal daily dietary intake	7–30 µg	200–250 µg
Minimal adult daily requirement	1–2 µg	100–150 µg
Main dietary foods	Animal (dairy) products	Liver, green raw leafy vegetables, yeast, fresh fruits, whole grain cereals
Cooking effect	Little effect	Easily destroyed
Absorption site	Ileum	Duodenum and jejunum
Mechanism of absorption	Vitamin B_{12} combines with intrinsic factor synthesized by gastric parietal cells	Folate converted to methyltetrahydrofolate
Limit of absorption	2–3 µg	50–80% of dietary content
Enterohepatic circulation	5–10 µg	80 µg
Transport in plasma	Most bound to haptocorrin (transcobalamin 1) essential for cell uptake	Folate weakly bound to albumin
Major intracellular physiologic forms	▪ Methylcarbylamine ▪ Deoxyadenosylcobalamin	Reduced polyglutamate derivatives
Storage sites	Liver (main site), kidney, heart and brain	Liver acts as a coenzyme in transfer and utilization of 1-carbon unit, an essential step in synthesis of nucleic acid
Functions	Participates in utilization of folate in synthesis of nucleic acid; and essential for maintenance of nervous system	Folate acts as a coenzyme involving one carbon unit transfer resulting in the synthesis of nucleic acid
Usual therapeutic form	Hydroxocobalamin	Folic acid (pteroylglutamic acid)
Serum assays	Serum vitamin B_{12} (160–925 ng/L)	Serum folate (3–15 µg/L)

- Cytoplasmic maturation is relatively unimpeded. Bone marrow examination shows megaloblastic erythropoiesis and manifests as nuclear-cytoplasmic asynchrony of large erythroid precursor cells with an open, loose sieve-like appearing chromatin pattern.
- Peripheral blood smear examination shows oval macrocytes, leukopenia, hypersegmented neutrophils, and thrombocytopenia.

MACROCYTIC ANEMIA WITH NORMOBLASTIC ERYTHROPOIESIS

Normoblastic macrocytic anemia occurs due to liver disease, alcoholism, hypothyroidism, postsplenectomy, pregnancy, hemolytic anemia, posthemorrhagic anemia, aplastic anemia, hypothyroidism, cytotoxic therapy, chronic myeloproliferative neoplasm (erythroleukemia), myelodysplastic syndrome and chronic obstructive pulmonary disease. Causes of macrocytic anemia (MCV >100 fl) with megaloblastic erythropoiesis are given in Table 8.57. Causes of macrocytosis other than megaloblastic anemia are given in Table 8.58. Vitamin B_{12} and folate nutritional aspects are given in Table 8.59. Comparison between vitamin B_{12} and folate deficiency inducing megaloblastic anemia is given in Table 8.60. Causes of macrocytic anemia due to congenital disorders are given in Table 8.61.

Table 8.57 Causes of macrocytic anemia (MCV >100 fl) with megaloblastic erythropoiesis

Vitamin B_{12} (Cobalamin) Deficiency	
Decreased dietary intake of vitamin B_{12}	Vegetarians
Impaired absorption of vitamin B_{12}	▪ Gastric causes (pernicious anemia, partial or total gastrectomy, Zollinger-Ellison syndrome) ▪ Intestinal causes (ileal resection, celiac disease, malabsorption syndrome, intestinal lymphoma, competitive consumption of vitamin B_{12} by *Diphyllobothrium latum*—fish tapeworm) ▪ Pancreatic insufficiency
Increased requirement of vitamin B_{12}	Pregnancy, neoplasms, hyperthyroidism, chronic pancreatic disease
Impaired utilization of vitamin B_{12}	Impaired utilization of vitamin B_{12} (transcobalamin II deficiency, abnormal serum cobalamin-binding protein, enzyme deficiencies, nitrous oxide administration)
Folate Deficiency	
Decreased dietary intake of folate	Malnutrition, premature infants, old persons, alcoholic persons, goat's milk anemia, hemodialysis
Impaired absorption of folate	Steatorrhea, celiac disease, anticonvulsant drugs, tropical sprue, intrinsic intestinal disease, Whipple disease, scleroderma
Increased requirement of folate	Pregnancy, infancy, neoplasms, hypothyroidism, hyperactive hematopoiesis, exfoliative dermatitis
Increased utilization of folate	▪ Physiologic state, e.g. pregnancy, lactation, premature infants ▪ Pathologic state: (a) chronic hemolytic anemia, e.g. sickle cell disease, β-thalassemia major and myelofibrosis; (b) malignant disorders, e.g. leukemias, lymphomas, multiple myeloma and carcinoma; (c) inflammatory disorders, e.g. tuberculosis, Crohn's disease, psoriasis, malaria and exfoliative dermatitis
Antifolate drugs	Anticonvulsant drugs, e.g. phenytoin, barbiturates and pyrimidine; methotrexate potent inhibitor of dihydrofolate, sulfasalazine, trimethoprim, omeprazole and oral contraceptives
Inborn errors	▪ Lesch-Nyhan syndrome ▪ Hereditary otitic aciduria ▪ Deficiency of formiminotransferase ▪ Deficiency of methyltransferase
Unresponsive to Vitamin B_{12} and Folate in Cases of Metabolic Inhibitors	
Purine synthesis metabolic inhibitors	6-Mercaptopurine, 6-thioguanine, azathioprine
Pyrimidine synthesis metabolic inhibitors	6-Azauridine
Thymidylate synthesis metabolic inhibitors	Methotrexate, 5-fluorouracil
Deoxyribonucleotide synthesis metabolic inhibitors	Hydroxyurea, cytarabine, severe iron deficiency anemia

Contd...

Table 8.57 Causes of macrocytic anemia (MCV >100 fl) with megaloblastic erythropoiesis (*Contd...*)

Inborn errors of cobalamin and folate	▪ Cobalamin deficiency, e.g. Imeslund-Gräsbeck disease, congenital deficiency of intrinsic factor, transcobalamin deficiency, cobalamin mutant syndromes with homocysteinemia and/or methylmalonic acidemia ▪ Folate deficiency, e.g. congenital folate malabsorption, dihydrofolate reductase deficiency, N5-methyltetrahydrofolate homocysteine methyltransferase deficiency
Other inborn errors	▪ Hereditary otitic aciduria ▪ Lesch-Nyhan syndrome ▪ Deficiency of formiminotransferase ▪ Deficiency of methyltransferase
Unexplained mechanism	▪ Congenital dyserythropoietic anemia ▪ Refractory megaloblastic anemia ▪ Erythroleukemia

Table 8.58 Causes of macrocytosis other than megaloblastic anemia

Macrocytosis in Other Disorders
Liver disease
Alcohol
Pregnancy
Aplastic anemia
Chronic myeloproliferative neoplasm (e.g. erythroleukemia)
Myelodysplastic syndrome (MDS)
Cytotoxic drugs
Hemolytic anemia
Reticulocytosis
Multiple myeloma
Paraproteinemias due to other disorders
Chronic obstructive pulmonary disease
Neonates

Table 8.59 Major functions of folate and vitamin B_{12} deficiency syndrome

Vitamin B_{12} (Cyanocobalamin)
Vitamin B_{12} participates in utilization of folate in synthesis of nucleic acid and maintenance of nervous system. Its deficiency causes megaloblastic anemia and subacute combined demyelination of posterolateral columns of spinal cord in midthoracic region.
Metformin blocks vitamin B_{12}. Hence, reticulocyte count is low in vitamin B_{12} deficiency.
Vitamin B_{12} deficiency raises LDH and indirect bilirubin by destroying red blood cells early, as they come out of the bone marrow. This phenomenon is called 'ineffective erythropoiesis. That is why the reticulocyte count is low.
After vitamin B_{12}, reticulocyte count improves first and neurological abnormalities improve last.
Folate (Pteroylglutamic Acid)
Folate acts as a coenzyme in transfer and utilization of 1-carbon unit, an essential step in the synthesis of nucleic acid.
Folic acid deficiency causes megaloblastic anemia without central nervous system involvement.

Table 8.60 Comparison between vitamin B_{12} and folate deficiency inducing megaloblastic anemia

Parameters	Vitamin B_{12} Deficiency	Folate Deficiency
Etiology	▪ Decreased dietary intake in vegetarians, impaired absorption, increased requirement and impaired utilization of vitamin B_{12} ▪ Failure to synthesize intrinsic factor by gastric parietal cells results in pernicious anemia	▪ Decreased dietary intake, impaired absorption, increased requirement and impaired utilization of folate ▪ Synthesis of intrinsic factor by gastric parietal cells is normal
Pathologic findings	▪ Demyelination of the posterior and lateral columns of spinal cord in the midthoracic region ▪ Peripheral blood smear examination shows pancytopenia, macrocytes, hypersegmented neutrophils ▪ Bone marrow shows megaloblastic erythropoiesis ▪ Schilling test abnormal in pernicious anemia	▪ Spinal cord demyelination absent ▪ Peripheral blood smear examination shows pancytopenia, macrocytes, hypersegmented neutrophils ▪ Bone marrow shows megaloblastic erythropoiesis ▪ Schilling test normal
Clinical features	Neurologic manifestations present, e.g. ataxia, impaired proprioception and vibrating sensations; anemia and glossitis	Neurologic manifestations absent; but anemia and glossitis present
Serum assays	▪ Serum vitamin B_{12} assay decreased ▪ Anti-intrinsic factor autoantibodies demonstrated in pernicious anemia	▪ Red blood folate decreased ▪ Anti-intrinsic factor autoantibodies absent
Treatment	Vitamin B_{12} supplement and intrinsic factor administration in pernicious anemia caused by autoimmune gastritis	Folate supplement

Table 8.61 Causes of macrocytic anemia due to congenital disorders

Congenital Disorders	Bone Marrow Findings	Comments
Diamond-Blackfan syndrome	Isolated profound decrease in erythroid elements, defective erythroid cells maturation and increased hematogone (multiparameter analysis of bone marrow precursor cells)	Autosomal dominant disorder (40%) associated with short stature, abnormalities of head, upper limbs and mild to moderate macrocytic anemia
Congenital dyserythropoietic anemia type 1 (CDA I), HEMPAS (hereditary erythroblastic multinuclearity with positive acidified serum)	Megaloblastic erythropoiesis, 1–3% of erythroid cells show intranuclear chromatin bridges or nuclear budding	▪ Autosomal recessive disorder ▪ CDN1 gene mutation (15q15.1–q15.3) ▪ Mild to moderate macrocytic anemia
Congenital dyserythropoietic anemia type 2 (CDA II)	Normoblastic to megaloblastic erythropoiesis, 10–40% erythroid precursor cells show binucleation or multinucleation, and karyorrhexis	▪ Autosomal recessive disorder ▪ CDN2 gene mutation (20q11.2) ▪ Mild to moderate macrocytic anemia
Congenital dyserythropoietic anemia type 3 (CDA III)	Megaloblastic erythropoiesis, 10–40% erythroid precursor cells show multinucleation, including giant erythroblasts (up to 12 nuclei), and karyorrhexis	▪ Autosomal dominant disorder ▪ CDN3 gene mutation (15q21–25) ▪ Mild to moderate anemia

MEGALOBLASTIC ANEMIA DUE TO FOLIC ACID (PTEROYLGLUTAMIC ACID) DEFICIENCY

Megaloblastic anemia due to folate deficiency is similar to vitamin B_{12} deficiency. But no neurological abnormalities and gastric atrophy occur due to folate deficiency in contrast to vitamin B_{12} deficiency.

- Folate deficiency results in megaloblastic anemia in approximately 20 weeks.
- Deficiency of vitamin B_{12} and folic acid occurs due to less intake, intestinal malabsorption and alcoholism, increased demand during pregnancy and hemolytic anemia; and chemotherapeutic agents containing folic acid antagonists.
- Causes of megaloblastic anemia due to folic acid deficiency are given in Table 8.62.

FOLIC ACID METABOLISM

Folates are derived from leafy vegetables, fresh fruits, whole grain cereals, and dairy products. Heating and boiling of foodstuffs destroy 90–95% of folic acid.

- Goat's milk is lower in folate than cow's milk. Daily requirement is 50–100 µg.
- Daily intake is 500–800 µg. During cooking, 70–100% of folates are lost. Folate is present in diet in the form of polyglutamate. It is broken down to monoglutamate. It is absorbed in duodenum and jejunum and stored in the liver (capacity of 5–10 mg).

FOLIC ACID FUNCTIONS

Under physiologic state, folate acts as a coenzyme in transfer and utilization of 1-carbon unit, an essential step in nucleic acid synthesis. Folate is taken into cells in the form of N5-methyltetrahydrofolate (N5-methyl-THF). Reduction to tetrahydrofolate derivative is essential for folate to participate in metabolic reactions. Tetrahydrofolate must be demethylated before conjugation can occur. Demethylation is mediated by cobalamin.

PATHOGENESIS

If cobalamin supply is inadequate, demethylation does not occur. If N5-methyl-THF is not conjugated, it will leak out of the cell again. Normally, deoxyuridine monophosphate (dUMP) is entirely converted to deoxythymidine monophosphate (dTMP). Deoxyuridine gets converted to deoxyuridylate and then thymidylate. Thymine is necessary for DNA synthesis. Due to folate deficiency, dUMP is not converted to dTMP. As a consequence, dUTP concentration rises and begins to replace dTTP in DNA synthesis, which leads to impairment of DNA synthesis.

CLINICAL FEATURES

Folic acid deficiency does not cause neurological changes in contrast to vitamin B_{12} deficiency, which causes megaloblastic anemia and neural tube defects in fetus *in utero*. Folic acid is used for treatment of chronic hemolytic anemia.

LABORATORY DIAGNOSIS

Peripheral blood smear examination shows oval macrocytes, leukopenia, hypersegmented neutrophils, and decreased platelets. Normal Schilling test (vitamin B_{12} absorption) indicates folic acid deficiency. Serum folate assay may be variable and should be carried out with a RBC folate assay. Bone marrow examination reveals megaloblastic erythropoiesis.

Table 8.62 Causes of megaloblastic anemia due to folic acid deficiency

Mechanism	Etiology
Decreased intake	Malnutrition, elderly persons
Increased demand	Pregnancy, infancy, cancers, hemolytic anemia (hyperplasia of bone marrow)
Impaired absorption	Malabsorption syndrome, oral contraceptives, diphenylhydantoin (antiepileptic drug), alcoholism and cirrhosis
Impaired utilization	Folic acid antagonists such as anticancer drug (methotrexate, 6-mercaptopurine, 5-fluorouracil, cytosine arabinoside and vinca alkaloids)
Increased loss	Steatorrhea or tropical sprue, hemodialysis

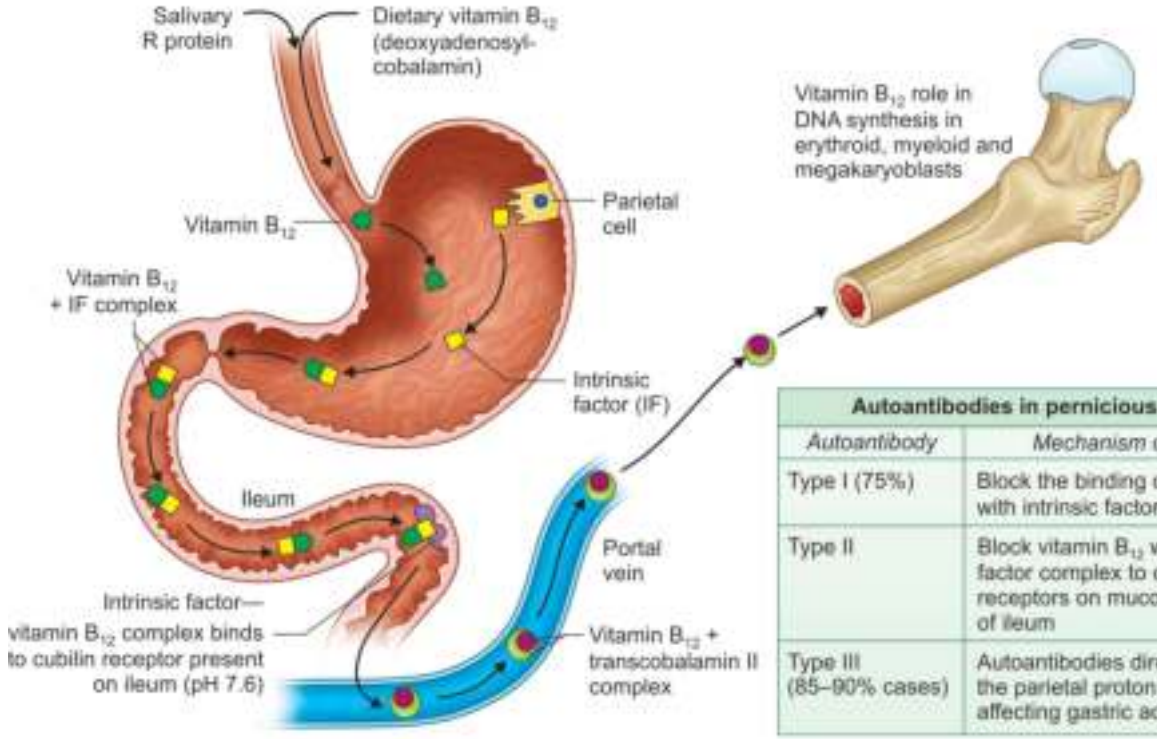
VITAMIN B_{12} DEFICIENCY

Vitamin B_{12} deficiency is reflected by impaired DNA synthesis in developing precursors in the bone marrow and defective fatty acid degradation leading to excessive demyelination. Vitamin B_{12} therapeutic administration gives excellent response. Vitamin B_{12} occurs in three forms: dehydroxyadenosylcobalamin forms in diet, methylcobalamin forms in plasma and hydroxocobalamin used for therapeutic purpose (Fig. 8.20).

VITAMIN B_{12} METABOLISM

Dietary dehydroxyadenosylcobalamin is mostly derived from animal products. Peptic digestion releases cobalamins from the dietary vitamin B_{12}.

- **Binding of vitamin B_{12} to salivary R protein:** Deoxyadenosylcobalamin binds with salivary R protein is known as haptocorrin temporarily.
- **Release of vitamin B_{12} by pancreatic enzymes:** Cobalamin is liberated in duodenum by pancreatic enzymes.
- **Binding of vitamin B_{12} with intrinsic factor (IF):** Cobalamin combines with intrinsic factor synthesized by parietal cells of stomach, which becomes resistant to proteolysis.
- **Absorption of vitamin B_{12}:** Intrinsic factor (IF) synthesized by parietal cells of stomach is required for absorption of vitamin B_{12}. IF vitamin B_{12} complex binds to IF receptors (cubilin) on mucosal epithelium of ileum. Vitamin B_{12} is absorbed in ileum, which is facilitated by calcium at pH >6.
- **Transport of vitamin B_{12}:** Vitamin B_{12} is present in the form of methylcobalamin in plasma. It is transported by transcobalamin II (β-globulin) synthesized by liver. Congenital deficiency of transcobalamin II results in severe megaloblastic anemia.
- **Storage sites of vitamin B_{12}:** Vitamin B_{12} is mainly stored in liver. Other storage sites are kidneys, heart and brain.



Autoantibodies in pernicious anemia

Autoantibody	*Mechanism of action*
Type I (75%)	Block the binding of vitamin B_{12} with intrinsic factor
Type II	Block vitamin B_{12} with intrinsic factor complex to cubilin (IF) receptors on mucosal surface of ileum
Type III (85–90% cases)	Autoantibodies directed against the parietal proton pump proteins affecting gastric acid synthesis

Fig. 8.20: Vitamin B_{12} absorption. It also shows autoantibodies demonstrated in pernicious anemia.

CAUSES OF VITAMIN B_{12} DEFICIENCY

Deficiency of vitamin B_{12} most often occurs in strict vegetarian and chronic alcoholism and impaired absorption. Most common cause of vitamin B_{12} deficiency is impaired absorption. Causes of megaloblastic anemia due to vitamin B_{12} deficiency are given in Table 8.63.

- **Increased demand of vitamin B_{12} deficiency:** Vitamin B_{12} deficiency may also occur due to increased demand during pregnancy or disseminated malignant tumor; and decreased absorption due to gastrectomy or malabsorption syndromes affecting terminal ileum.
- **Gastric causes of vitamin B_{12} deficiency:** In achlorhydria, vitamin B_{12} is not released from salivary R binding proteins.
  - Gastrectomy causes loss of synthesis of intrinsic factor by parietal cells in the gastric fundus, the clinical picture is the same as in pernicious anemia.
  - Pernicious anemia is the most common form of vitamin B_{12} deficiency megaloblastic anemia. It is immune-mediated disorder associated with formation of autoantibodies against intrinsic factor essential for vitamin B_{12} absorption.
- **Intestinal causes of vitamin B_{12} deficiency:** Vitamin B_{12} is not absorbed in patient, who has undergone resection of ileum. Bacterial overgrowth in a surgically induced intestinal blind loop results in the depletion of vitamin B_{12}.
  - Broad-spectrum antibiotic therapy can result in intestinal bacterial overgrowth with vitamin B_{12} depletion.
  - The giant fish tapeworm (*Diphyllobothrium latum*) infestation in man is acquired by ingestion of freshwater fish. The parasite inhabits the intestine and causes vitamin B_{12} depletion.

ROLE OF VITAMIN B_{12} AND FOLIC ACID IN DNA SYNTHESIS

Vitamin B_{12} and folic acid are essential for maturation of nuclei of developing precursors in bone marrow. Deficiency of vitamin B_{12}/folic acid causes megaloblastic erythropoiesis due to decreased DNA synthesis. The nuclear maturation of developing precursors lags behind than maturation of cytoplasm. All the developing precursors in the bone marrow show abnormalities.

- Peripheral blood smear examination shows macrocytosis, hypersegmented neutrophil and thrombocytopenia.
- Patient with vitamin B_{12} deficiency develops subacute combined demyelination of posterolateral columns of spinal cord in midthoracic region. Role of vitamin B_{12} and folic acid in DNA synthesis is shown in Fig. 8.21.

Role of Vitamin B_{12} in DNA Synthesis

Vitamin B_{12} (methylcobalamin) is indirectly required for DNA synthesis, which converts homocysteine to methionine and forms tetrahydrofolate, which is then converted to polyglutamate used for DNA synthesis. Vitamin B_{12} is also required for conversion of methylmalonyl-CoA to succinyl-CoA. Due to deficiency of vitamin B_{12}, these chemical reactions do not take place.

Role of Folic Acid in DNA Synthesis

5,10-methylene TH_4 is required for conversion of deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP). Thus, deficiency of folic acid hinders synthesis of DNA.

- **Physiologic state:** Histidine is metabolized to form formiminoglutamic acid (FIGLU), which combines with tetrahydrofolate.

Table 8.63 Causes of megaloblastic anemia due to vitamin B_{12} deficiency

Mechanism	Etiology
Decreased intake	Dietary deficiency, strict vegetarians
Increased demand	During pregnancy, disseminated malignancies
Impaired absorption	▪ Achlorhydria (vitamin B_{12} not released from salivary R binding proteins) ▪ Pernicious anemia (autoantibodies against intrinsic factor essential for vitamin B_{12} absorption) ▪ Partial gastrectomy (loss of parietal cells synthesizing intrinsic factor) ▪ *Diphyllobothrium latum* parasite (inhibiting vitamin B_{12} absorption) ▪ Blind loop syndrome (depletion of vitamin B_{12} due to overgrowth of bacteria) ▪ Surgical resection of ileum ▪ Broad-spectrum antibiotic therapy (depletion of vitamin B_{12} due to bacterial overgrowth)

Neurologic symptoms develop in vitamin B_{12} deficiency, secondary to degeneration of the posterior and lateral columns of the spinal cord.

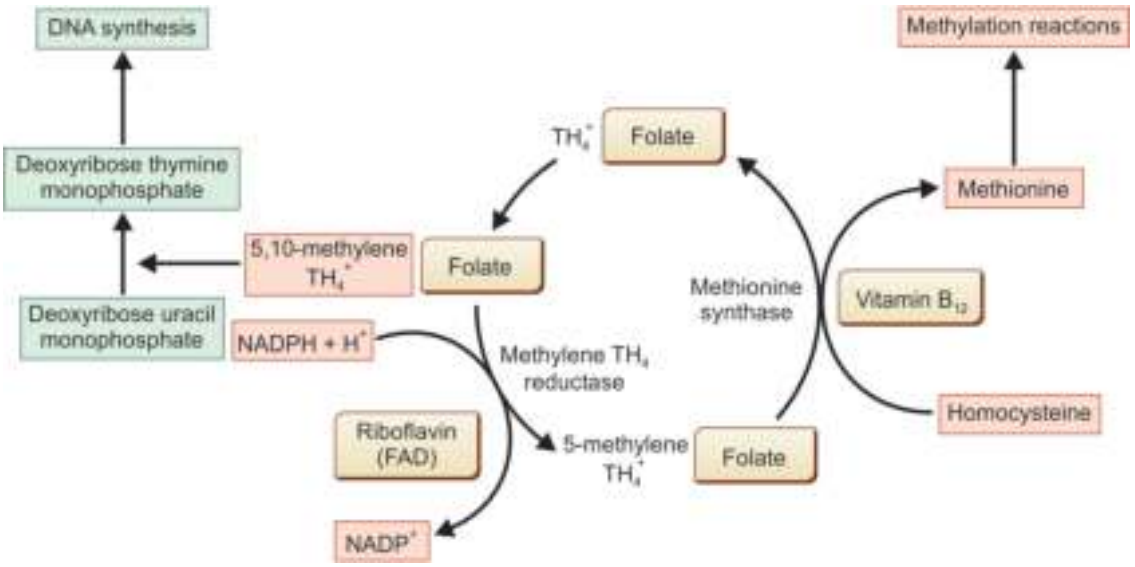


Fig. 8.21: Role of vitamin B_{12} and folic acid in DNA synthesis. 5,10-methylenetetrahydrofolate (TH_4) is required for the formation of methionine from homocysteine. Methionine, in the form of S-adenosylmethionine is required for many biological reactions including DNA methylation. Methylene TH_4 reductase is a flavin-dependent enzyme required to catalyze the reduction of 5,10-methylene TH_4 to 5-methylene TH_4.

- **Pathologic state:** Deficiency of folic acid leads to accumulation of formiminoglutamic acid and excreted in urine. FIGLU test is performed to diagnose folic acid deficiency.

PATHOPHYSIOLOGY OF MEGALOBLASTIC ANEMIA DUE TO VITAMIN B_{12} DEFICIENCY

Megaloblastic anemia occurs due to decreased DNA synthesis, ineffective erythropoiesis and mild hemolysis as a result of intramedullary death of bone marrow erythroid precursors. Patient may have mild jaundice due to increased serum bilirubin.

Clinical Features

Patient presents with pallor, glossitis, central nervous system manifestations and peripheral neuropathy. Clinical manifestations of peripheral neuropathy include spastic paraparesis, sensory ataxia and marked paresthesia leading to total paralysis of trunk and lower limbs. CNS results in ataxic gait, hyperreflexia with extensor plantar reflexes, and impaired position and vibration sensation. There may also be associated with optic atrophy and axonal peripheral neuropathy. Mechanism of neuropathy is described as under.

Peripheral Neuropathy in Vitamin B_{12} Deficiency

- **Physiologic state:** Methylcobalamin converts homocysteine to methionine, which acts as a donor in the synthesis of choline containing phospholipids, an important component of myelin. Normally deoxyadenosylcobalamin converts methylmalonyl-CoA into succinyl-CoA.
- **Pathologic state:** Deficiency of methylcobalamin results in decreased synthesis of choline required for myelin sheath synthesis. Vitamin B_{12} deficiency leads to accumulation of methylmalonyl-CoA, which is converted into methylmalonate and propionate. It leads to increased production of abnormal fatty acids like methylmalonic acid and propionic fatty acids. These fatty acids incorporate into neuronal lipids resulting in breakdown of myelin sheath.

Subacute Combined Demyelination of Spinal Cord in Midthoracic Region due to Vitamin B_{12} Deficiency

Subacute combined demyelination of spinal cord occurs in midthoracic and cervical regions. Spinal cord shows pale areas of demyelination in the posterior columns and the lateral corticospinal tracts. On histopathologic examination, spinal cord shows swollen myelin sheath with disintegration and axonal degeneration.

Laboratory Diagnosis of Megaloblastic Anemia

Main laboratory tests performed in diagnosing megaloblastic anemia include serum vitamin B_{12}, serum and RBCs folate level, autoantibodies to intrinsic factor, lactate dehydrogenase (LDH), homocysteine and methylmalonic acid in urine. Patient with macrocytic anemia should be investigated by examination of peripheral blood smear, bone marrow, reticulocyte count and therapeutic response (Fig. 8.22). Laboratory investigations needed in patient with macrocytic anemia are given in Table 8.64.

Peripheral Blood Smear Examination

Peripheral blood smear examination reveals macrocytic anemia, leukopenia and mild to moderate thrombocytopenia. Hypersegmented neutrophils may be demonstrated (Fig. 8.23A to D).

- **Red blood cells:** Large number of oval macrocytes with MCV >100 femtoliters are present. RBCs are normochromic and show polychromasia, anisocytosis and poikilocytosis. Macrocytes are oval in megaloblastic anemia, while round macrocytes in normoblastic macrocytic anemia. Presence of tear drop cells, Howell-Jolly bodies, basophilic stippling and Cabot's rings indicate dyserythropoiesis.
- **White blood cells:** Total leukocyte count is decreased. Hypersegmented neutrophils constitute >5% of all neutrophils, which should have >5 lobes and even >6 lobes. This finding indicates shift-to-the-right in megaloblastic anemia.
- **Platelets:** Moderate thrombocytopenia with giant platelets is seen.

Reticulocyte Count

- Reticulocyte count is decreased as a result of dyserythropoiesis in megaloblastic anemia.
- Post-therapeutic response should be assessed by demonstration of increased reticulocyte count on the sixth day.
- Reticulocytes are round with polychromasia in peripheral blood smear.

Bone Marrow Smear Examination

Vitamin B_{12} and folic acid are essential for maturation of nuclei developing precursors in bone marrow. Deficiency of either of the two results in megaloblastic erythropoiesis due to decreased DNA synthesis. Abnormalities will be observed in all the developing precusors in the bone marrow. Bone marrow smears show changes at all stages of RBCs development. Maturation of the nuclei of erythroid, myeloid and megakaryocytes lags behind and thus chromatin of these cells remains open sieve-like. Megaloblastic erythropoiesis in vitamin B_{12} deficiency is shown in Fig. 8.24.

- **Cellularity and M:E ratio:** Bone marrow becomes hypercellular with reversal of myeloid to erythroid ratio (M:E ratio 1:1) due to erythroid hyperplasia. Normal myeloid to erythroid ratio is 4:1. Ineffective erythropoiesis leads to intramedullary hemolysis of erythroid precursors. Bone marrow iron store is increased due to dyserythropoiesis.
- **Erythropoiesis:** Bone marrow shows dyserythropoiesis. Erythroid precursors show hyperplasia. Erythroid precursors are extremely large called megaloblastic cells. Early megaloblasts do not mature to late normoblasts. Intermediate and late erythroid precursors (megaloblasts) undergo ineffective apoptosis in the bone marrow. It is known as dyserythropoiesis.
  - Promegaloblasts and basophilic megaloblasts constitute 50% of population indicate maturation arrest. Polychromatic megaloblasts are well marked, while orthochromatic megaloblasts are less common.
  - Megaloblasts show nuclear budding, irregular dumbbell-shaped nuclei, irregular mitosis and Howell-Jolly bodies.
  - Megaloblasts are extremely large erythroid precursors. Chromatin remains open and arranged in a fine reticular fashion to give stippled appearance.
  - Although some of the megaloblasts are well hemoglobinized, the nucleus is still present suggesting nuclear/cytoplasmic developmental asynchrony. Oval macrocytes may also be demonstrated.
- **Leukopoiesis:** Presence of giant band form of neutrophil and metamyelocytes in bone marrow give a clue of megaloblastic anemia. Many myeloid precursor cells die within bone marrow and rest develop into giant stab forms and hypersegmented neutrophils.
- **Megakaryopoiesis:** Megakaryocytes demonstrate nuclear hypersegmentation with open sieve-like nuclear chromatin. Maturation of the cytoplasm of these cells is normal. The size of these cells remains large. Most of megakaryocytes die within bone marrow.

Other Laboratory Tests

- **Serum bilirubin:** Serum bilirubin is increased due to short life span of macrocytes. Imbalanced nuclear and cytoplasmic maturation of erythroid precursors result in hemolysis.
- **Serum vitamin B_{12} assay:** Normal serum vitamin B_{12} is 160–925 ng/L. Serum vitamin B_{12} is decreased to <100 ng/L in vitamin B_{12} deficiency.
- **Serum folate assay:** Serum folate level is decreased in folic acid deficiency. It is determined by isotope dilution and microbial chemiluminescence methods.
- **Striking reticulocyte response to vitamin B_{12} therapy:** Reticulocyte count is increased in megaloblastic anemia due to vitamin B_{12} deficiency, when the patient is given vitamin B_{12}.
- **Striking neurological improvement to vitamin B_{12} therapy:** Patient shows neurological improvement in response to vitamin B_{12} therapy.
- **Urinary analysis:** Methylmalonic acid level is raised in vitamin B_{12} deficiency.
- **FIGLU excretion in urine:** FIGLU test is performed to diagnose folic acid deficiency. Normally, histidine is metabolized to form FIGLU, which combines with tetrahydrofolate. Deficiency of folic acid leads to accumulation of FIGLU and excreted in urine.

TREATMENT

Shotgun therapy may be used where the etiology is unclear. Folate, then vitamin B_{12} must be attempted to make the patient well. Intramuscular hydroxycobalamin is administered daily for a week. Regime will depend on the cause of megaloblastic anemia.

Vitamin B_{12} and Folic Acid Deficiency: Therapeutic Response

Therapeutic response to vitamin B_{12} and folic acid in patients with megaloblastic anemia is dramatic described as under. Patient starts recovering from sore throat and glossitis in a day or two after therapy. Tongue becomes normal within 2 weeks.

- **Hemoglobin:** Hemoglobin starts increasing within one week after the therapy.

- **Peripheral blood smear:** Macrocytic anemia picture returns to normocytic morphology within 4–8 weeks after therapy. Platelet count returns to normal within a week.
- **Reticulocyte count:** Decreased platelet count in megaloblastic anemia returns to normal within 2–3 weeks after therapy.
- **Bone marrow:** Megaloblastic erythropoiesis returns to normal within 24 hours of therapy.

PERNICIOUS ANEMIA

Pernicious anemia, an autoimmune disorder causes megaloblastic anemia. Immunoreactive T cells cause autoimmune gastritis. Autoantibodies are formed against intrinsic factor that is essential for vitamin B_{12} absorption. Demonstration of autoantibodies against intrinsic factor is highly specific for pernicious anemia. Atrophic glossitis is common finding in pernicious anemia characterized by shiny red and glazed tongue.

EPIDEMIOLOGY

Pernicious anemia is more prevalent in European persons and rare in India and South Asia. Females are more affected than males.

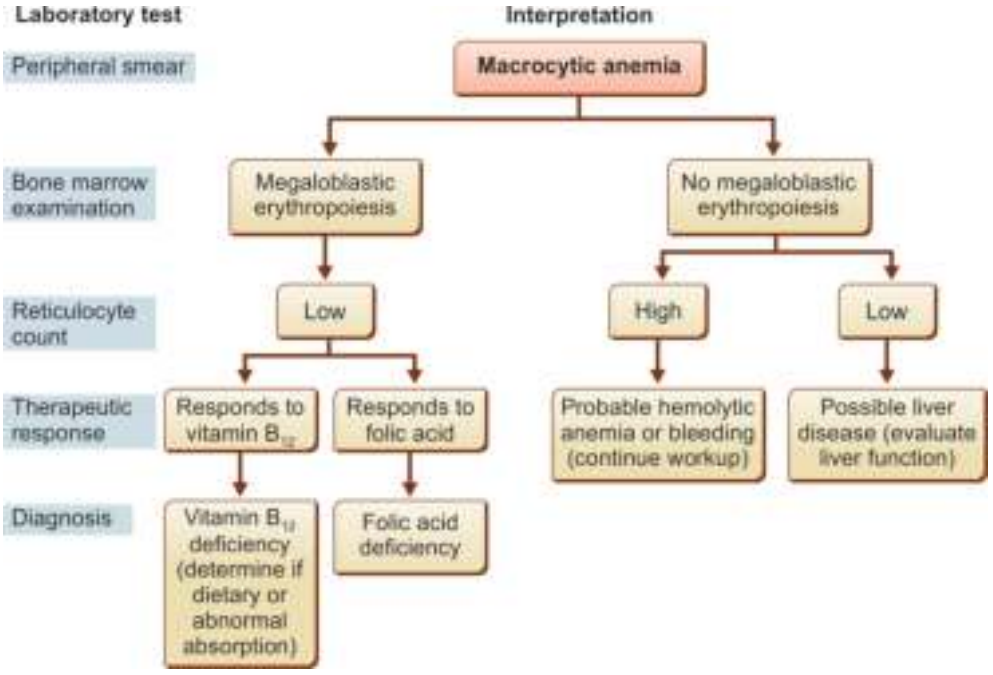

Fig. 8.22: Scheme for investigating patients with macrocytic anemia. It represents a convenient approach to this form of anemia by peripheral blood smear and bone marrow examination, reticulocyte count, therapeutic response to administration of vitamin B_{12} or folic acid.

Table 8.64 Laboratory investigations needed in patient with macrocytic anemia

Laboratory Investigations in Macrocytic Anemia
Liver function tests
Thyroid function tests
Endoscopy for gastric biopsy for vitamin B_{12} deficiency; or duodenal biopsy for folate deficiency
Peripheral smear examination
Reticulocyte count
Bone marrow examination shows megaloblastic erythropoiesis suggestive of vitamin B_{12} or folate deficiency or alternative diagnoses, e.g. myelodysplastic syndrome, aplastic anemia and myeloma
Serum protein electrophoresis
For vitamin B_{12} deficiency such as serum parietal cell antibodies and intrinsic factor antibodies, radioactive vitamin B_{12} absorption with or without intrinsic factor (Schilling test), possibly serum gastrin concentration
For folate deficiency such as FIGLU test, serum and red blood cell folate assay antigliadin antibody, anti-endomysial antibody and anti-reticulum antibody

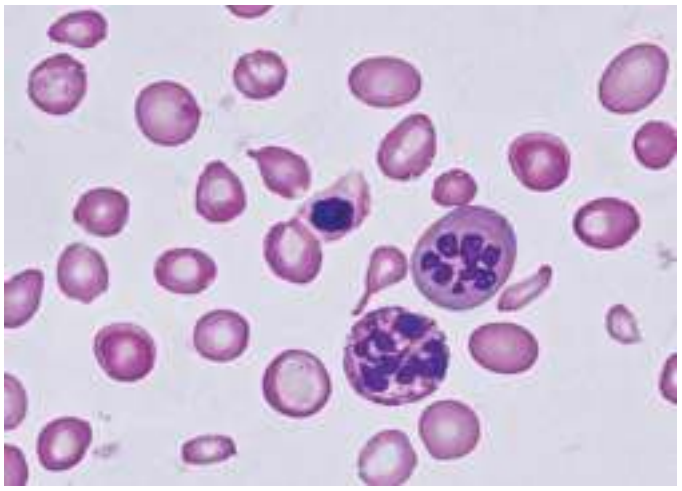

Fig. 8.23A: Peripheral blood smear examination in megaloblastic anemia. It shows anisocytosis, poikilocytosis with macrocytosis and a tear drop cell. Hypersegmented neutrophils with >5 lobes are also present.

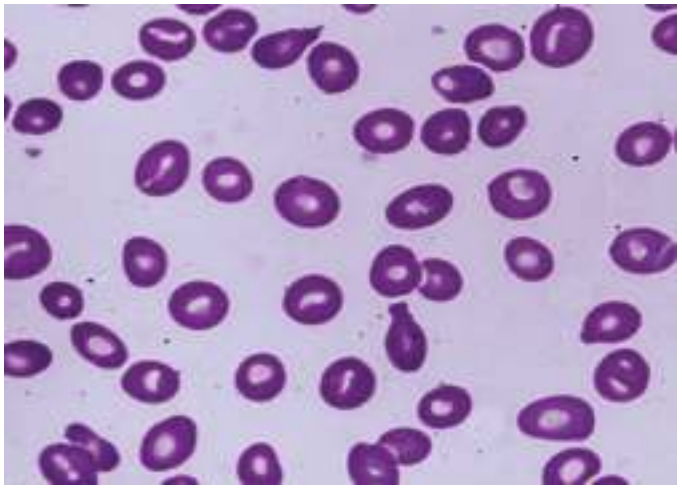

Fig. 8.23B: Peripheral blood smear examination in megaloblastic anemia It shows anisocytosis with numerous macrocytosis and scattered tear drop cells.

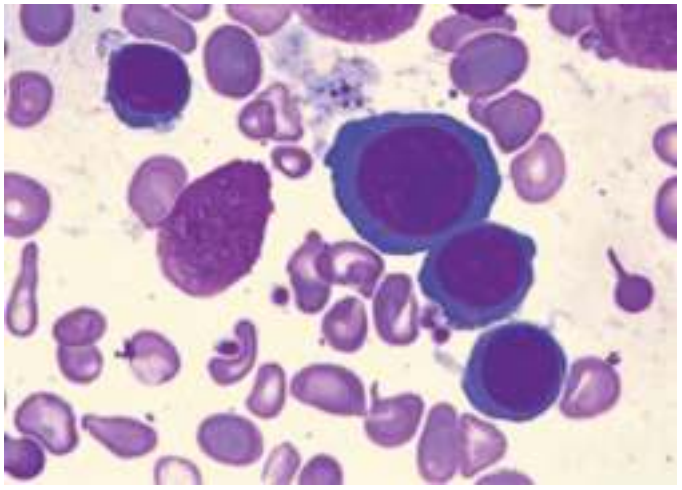

Fig. 8.24: Megaloblastic erythropoiesis in vitamin B_{12} deficiency. There is preponderance of early and intermediate normoblasts showing stippled nuclear chromatin (open sieve-like) on bone marrow smear examination.

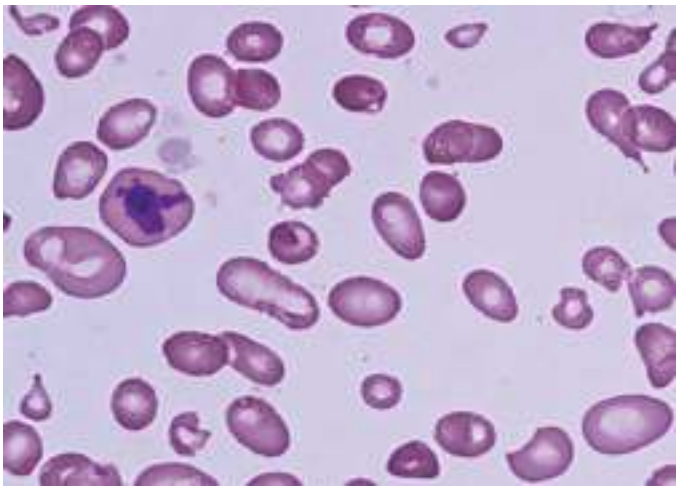

Fig. 8.23C: Peripheral blood smear examination in megaloblastic anemia It shows anisocytosis with numerous macrocytosis and scattered tear drop cells. Howell-Jolly body in red blood cell is seen.

Fig. 8.23D: Peripheral blood smear examination in megaloblastic anemia. It shows anisocytosis with numerous macrocytes and scattered tear drop cells. Giant band form of neutrophil is seen.

PATHOGENESIS

Pernicious anemia is considered autoimmune disorder, which may be associated with Hashimoto's thyroiditis and type 1 diabetes mellitus and Addison's disease. Three types of autoantibodies in pernicious anemia are given in Table 8.65.

CLINICAL FEATURES

Patient presents with anemia, paresthesia, glossitis, recurrent diarrhea, anorexia, weight loss, abdominal pain, mental disturbance and visual disturbance.

- **Atrophic glossitis:** Tongue becomes shiny red and glazed in pernicious anemia.
- **Chronic atrophic gastritis:** Sections from gastric biopsy of fundus region show features of chronic atrophic gastritis due to antiparietal autoantibodies.

Table 8.65 Autoantibodies in pernicious anemia

Autoantibody	%	Mechanism of Action
Type 1 blocking autoantibodies	75–80	Block binding of vitamin B_{12} with intrinsic factor
Type 2 autoantibodies	50	Block vitamin B_{12} with intrinsic factor complex to cubilin receptors on mucosal surface of ileum
Type 3 autoantibodies	85–90	Autoantibodies directed against the parietal proton pump proteins affecting gastric acid synthesis

Replacement of parietal cells by mucin-secreting goblet cells is known as gastric intestinalization.

- **Central nervous system:** Central nervous system is most commonly involved in >75% cases of pernicious anemia. Due to incorporation of methylmalonic acid and propionic fatty acids into neuronal lipids, there is breakdown of myelin sheath of posterior and lateral white columns of mid-thoracic spinal cord involved. Patient develops spastic paraparesis, sensory ataxia and marked paresthesia leading to total paralysis of trunk and lower limbs.

Laboratory Diagnosis of Pernicious Anemia

Peripheral Blood Smear Examination

Peripheral blood smear examination shows oval macrocytes, leukopenia, hypersegmented neutrophils and moderate thrombocytopenia.

- **Red blood cells:** Large number of oval macrocytes with MCV >100 femtoliters are present. RBCs are normochromic picture with polychromasia, anisocytosis and poikilocytosis. Macrocytes are oval in megaloblastic anemia, while round macrocytes in normoblastic macrocytic anemia. Presence of tear drop cells, Howell-Jolly bodies, basophilic stippling and Cabot's rings indicate dyserythropoiesis.
- **White blood cells:** Total leukocyte count is decreased. Hypersegmented neutrophils constitute >5% of all neutrophils, which should have >5 lobes and even has >6 lobes. This finding indicates shift-to-the-right in megaloblastic anemia.
- **Platelets:** Moderate thrombocytopenia with giant platelets is seen.

Reticulocyte Count

Reticulocyte count is decreased as a result of dyserythropoiesis in megaloblastic anemia.

Bone Marrow Smear Examination

- Vitamin B_{12} and folic acid are essential for maturation of nuclei developing precursors in bone marrow. Deficiency of either of the two results in megaloblastic erythropoiesis due to decreased DNA synthesis.
- Pernicious anemia is one of the causes of vitamin B_{12} deficiency of megaloblastic anemia. Autoantibodies are formed against intrinsic factor synthesized by gastric parietal cells, which is essential for vitamin B_{12} absorption.
- Abnormalities will be observed in all the developing cells in the bone marrow. Bone marrow smears show changes at all stages of RBCs development. Maturation of the nuclei of erythroid, myeloid and megakaryocytes lags behind and thus chromatin of these cells remains open sieve-like.
  - **Cellularity and M:E Ratio:** Bone marrow becomes hypercellular with reversal of myeloid to erythroid ratio (M:E ratio 1:1) due to erythroid hyperplasia. Normal myeloid to erythroid ratio is 4:1. Ineffective erythropoiesis leads to intramedullary hemolysis of erythroid precursors. Bone marrow iron store increased due to dyserythropoiesis.
  - **Erythropoiesis:** Bone marrow shows megaloblastic erythropoiesis.
  - **Leukopoiesis:** Presence of giant band form of neutrophil and metamyelocytes in bone marrow give a clue of megaloblastic anemia. Many myeloid precursor cells die within marrow and rest develop into giant stab forms and hypersegmented neutrophils.
  - **Megakaryopoiesis:** Megakaryocytes demonstrate nuclear hypersegmentation with open sieve-like nuclear chromatin. Maturation of the cytoplasm of these cells is normal. The size of these cells remains large. Most of these cells die within bone marrow.

Serum Assays

Serum B_{12} levels are low. Due to diminished thymidine and methionine synthesis, serum concentration of homocysteine and methylmalonic acid is increased.

Therapeutic Response

Diagnosis of pernicious anemia is confirmed by increased reticulocyte count, following parenteral administration of vitamin B_{12}.

Schilling Test

- Schilling test is done to establish the diagnosis of pernicious anemia. Injectable dose of vitamin B_{12} is given to saturate body vitamin B_{12} stores.
- Oral dose of radioactive vitamin B_{12} is given. If intrinsic factor is intact, then vitamin B_{12} is absorbed otherwise not. Its excretion is estimated in urine.
- Normally, >8% of oral radioactive vitamin B_{12} is demonstrated in urine.
- But in pernicious anemia and malabsorption syndrome, its excretion will be decreased depending upon the severity of the disease.
- Now oral dose of radioactive vitamin B_{12} combined with intrinsic factor is given to the patient with pernicious anemia, its excretion is within normal range.
- In patient with chronic renal failure not suffering from pernicious anemia, Schilling test is false positive due to impaired renal functions.

RED BLOOD CELLS DESTRUCTION AND CLASSIFICATION OF HEMOLYTIC ANEMIA

HEMOLYTIC ANEMIA: OVERVIEW

Hemolytic anemia is produced by an increased rate of destruction of red blood cells that cannot be compensated by hematopoiesis in bone marrow. RBC destruction may be due to intrinsic defects within red blood cells or extrinsic etiology.

- Intravascular hemolytic anemia is marked by intrinsic defects, most often genetically determined, in the red blood cell itself.
- Extracorpuscular hemolytic anemia is marked by extrinsic defects, most often acquired such as circulating antibodies against RBCs or splenomegaly.
- Normal life span of RBCs is 100–120 days. But in hemolytic anemia, life span of red blood cells may be reduced to as low as 15 days. Classification of inherited hemolytic anemia is given in Table 8.66. Acquired causes of hemolytic anemia are given in Table 8.67. Differences between extravascular hemolysis and intravascular hemolysis are given in Table 8.68.

Table 8.66 Classification of inherited hemolytic anemia

Disorder	Gene Mutation and Inheritance	RBC Morphology	Laboratory Diagnosis
Red blood cell membrane defects			
Hereditary spherocytosis	▪ ANK1 (autosomal dominant/ autosomal recessive disorder) ▪ SPTB (autosomal dominant disorder) ▪ SPTA1 (autosomal recessive disorder) ▪ SLC4A1 (autosomal dominant disorder) ▪ EPB42 (autosomal recessive disorder)	▪ Microspherocytosis ▪ Microspherocytosis ▪ Microspherocytosis ▪ Microspherocytosis ▪ Microspherocytosis	▪ RBC morphology ▪ RBC morphology ▪ RBC morphology ▪ RBC morphology ▪ RBC morphology
Hereditary ovalocytosis (elliptocytosis)	▪ SPTA1 (autosomal dominant disorder) ▪ SPTB (autosomal dominant disorder) ▪ EPB41 (autosomal dominant disorder)	▪ Elliptocytosis >25% ▪ Elliptocytosis >25% ▪ Elliptocytosis >25%	▪ Coombs' test negative ▪ Coombs' test negative ▪ Coombs' test negative
Southeast Asian ovalocytosis	RHAG (autosomal dominant disorder)	↑Ovalocytosis with transverse bars or single longitudinal slit	RBC morphology
Dehydrated hereditary stomatocytosis	▪ PIEZOI (autosomal dominant disorder) ▪ KCN4 (autosomal dominant disorder)	▪ Macrocytosis, stomatocytosis, target cells, schistocytes, spiculated cells ▪ Macrocytosis, stomatocytosis, target cells, schistocytes, spiculated cells	▪ RBC morphology ▪ RBC morphology
Dehydrated hereditary stomatocytosis	PIEZOI (autosomal dominant disorder)	Macrocytosis, stomatocytosis, target cells, schistocytes, spiculated cells	RBC morphology
Overhydrated hereditary stomatocytosis	RHAG (autosomal dominant disorder)	Spiculated cells	RBC morphology
Hereditary pyropoikilocytosis	▪ EPB4 (autosomal recessive disorder) ▪ SPTA1 (autosomal recessive disorder) ▪ SPTB (autosomal recessive disorder)	▪ Bizarre RBC fragments ▪ Bizarre RBC fragments ▪ Bizarre RBC fragments	▪ RBC morphology ▪ RBC morphology ▪ RBC morphology
Red blood cell enzyme disorders			
G6PD deficiency	G6PD (X-linked recessive disorder)	Usually normal, occasional bite cells	G6PD enzyme measurement
Pyruvate kinase deficiency	Pyruvate kinase (autosomal recessive trait)	Usually normal	Pyruvate kinase measurement
Sickle cell disease, HbC, HbD, HbE and HbG			
Sickle cell disease	▪ Change in 6th amino acid of the β-globin chain from glutamate to valine (β_6 glutamine → valine)	▪ Sickle cells in peripheral blood smear	▪ Hemoglobin electrophoresis

Contd...

Table 8.66 Classification of inherited hemolytic anemia (*Contd...*)

Disorder	Gene Mutation and Inheritance	RBC Morphology	Laboratory Diagnosis
	▪ Sickle cell trait (A/S) ▪ Sickle cell disease (S/S)	▪ Sickle cells in peripheral blood smear ▪ Sickle cells in peripheral blood smear	▪ Hemoglobin electrophoresis ▪ Hemoglobin electrophoresis
Hemoglobin C (HbC) disease	▪ Change in 6th amino acid of the β-globin chain from glutamate to valine (β_6 glutamine → lysine) ▪ Hemoglobin C trait (A/C) ▪ Hemoglobin disease (C/C)	▪ Target cells in peripheral blood smear ▪ Target cells in peripheral blood smear ▪ Target cells in peripheral blood smear	▪ Hemoglobin electrophoresis ▪ Hemoglobin electrophoresis ▪ Hemoglobin electrophoresis
Hemoglobin D (HbD) disease (affects East Indian population)	Change in 121st amino acid of the β-globin chain from glutamate to glutamine (β_{121} glutamine → glutamine)	Mild hemolytic anemia	Hemoglobin electrophoresis (HbD migrates with HbS at pH 8.6)
Hemoglobin E (HbE) disease (affects South East Asian population)	▪ Change in 26th amino acid of the β-globin chain from glutamate to lysine (β_{26} glutamine → lysine) ▪ Hemoglobin E trait (A/E) ▪ Hemoglobin E disease (E/E)	▪ Microcytic hypochromic picture ▪ Microcytic hypochromic picture ▪ Microcytic hypochromic picture	▪ Hemoglobin electrophoresis (HbE migrates with HbC and HbA_2 at pH 8.6) ▪ Hemoglobin electrophoresis (HbE migrates with HbC and HbA_2 at pH 8.6) ▪ Hemoglobin electrophoresis (HbE migrates with HbC and HbA_2 at pH 8.6)
Hemoglobin G (HbG) disease	Change in 68th amino acid of the α-globin chain from asparagine to lysine (α_{68} asparagine → lysine)	Mild hemolytic anemia	Hemoglobin electrophoresis
α-Thalassemia (in a normal person, α-gene synthesizes α-globin chains)			
Silent carrier	–α/αα due to HBA gene mutation	Normal hematologic findings	Genetic testing
α-thalassemia minor/trait	–α/–α or –/αα due to HBA gene mutation	▪ Hemoglobin normal ▪ Mild microcytic hypochromic picture	▪ Hemoglobin electrophoresis ▪ Genetic testing
Hemoglobin H disease	–α/– due to HBA gene mutation	▪ Hemolytic anemia picture ▪ HbA (70–90%) ▪ HbH (5–30%)	Genetic testing
Hydrops fetalis	–/– (loss of all four α-globin alleles due to HBA gene mutation)	▪ Hb Bart (>80%) ▪ HbH (10–20%) ▪ HbA (nil) ▪ Severe disease not compatible with life	Genetic testing
β-Thalassemia (in a normal person, β-gene synthesizes β-globin chains)			
Thalassemia major	β^0/β^0 due to HBB gene mutation	▪ Microcytic hypochromic picture, numerous target cells, basophilic stippling ▪ HbA (nil) ▪ HbA_2 (3.8%) ▪ HbF (>90%)	▪ Hemoglobin electrophoresis ▪ Genetic testing ▪ High performance liquid chromatography (HPLC) ▪ Genetic testing

Contd...

Table 8.66 Classification of inherited hemolytic anemia (*Contd...*)

Disorder	Gene Mutation and Inheritance	RBC Morphology	Laboratory Diagnosis
Thalassemia minor/trait	β^0/β due to HBB gene mutation	▪ Microcytic hypochromic picture, target cells, basophilic stippling ▪ HbA (90%) ▪ HbA_2 (3.8%) ▪ HbF (+/–)	▪ High performance liquid chromatography (HPLC) ▪ Genetic testing
Thalassemia intermedia	β^+/β^+ due to HBB gene mutation	▪ Mild microcytic hypochromic picture ▪ HbA (50–70%) ▪ HbA_2 (3.8%) ▪ HbF (20–40%)	No definite investigations
δβ-Thalassemia			
δβ-Thalassemia major	$\delta\beta^0/\delta\beta^0$	▪ HBA (absent) ▪ HbA_2 (absent) ▪ HbF (100%)	High performance liquid chromatography (HPLC)
δβ-Thalassemia minor	$\delta\beta^0/\delta\beta$	HBA (80–90%)	High performance liquid chromatography (HPLC)

Table 8.67 Acquired causes of hemolytic anemia

Immune-mediated Hemolytic Anemia

- Autoimmune hemolytic anemia
  - Warm autoantibody mediated hemolytic anemia (at 37°C)
  - Cold autoantibody mediated hemolytic anemia (at <37°C)
- Alloimmune hemolytic anemia
  - Hemolytic disease of newborn
  - Hemolytic blood transfusion reactions
  - Allografts especially stem cell transplantation
- Paroxysmal nocturnal hemoglobinuria (PNH)
- Drug-induced hemolytic anemia
  - α-methyldopa
  - Penicillin
  - Oxidant drugs
  - Primaquine
  - Dapsone

Red Blood Cell Fragmentation Syndromes

- Cardiac hemolysis
  - Prosthetic cardiac valves
  - Severe aortic valvular diseases
  - Grafts used in vessels
  - Perivascular leaks
- March hemoglobinuria
- Arteriovenous malformations
- Microangiopathic hemolytic anemia
  - Thrombotic thrombocytopenic purpura
  - Hemolytic uremic syndrome
  - Disseminated intravascular coagulation (DIC)
  - Malignant hypertension
  - Polyarteritis nodosa (PAN)
  - Pre-eclampsia/eclampsia of pregnancy
  - HELLA syndrome (life-threatening pregnancy associated complication during later half of pregnancy or sometimes after childbirth)
  - Renovascular disorders
  - Cyclosporine immunosuppressive drug
  - Homograft rejection

Severe Infections induced Hemolytic Anemia

- *Clostridium welchii*
- *Vibrio cholerae*
- Malarial parasite
- Bartonella gram-negative bacteria

Chemicals and Physical Agents induced Hemolytic Anemia

- Industrial chemical: Naphthalene
- Domestic substances: Nitrites and nitrates
- Thermal injury: Severe burns

Secondary Causes induced Hemolytic Anemia

- Liver disease
- Renal disease

Miscellaneous Causes induced Hemolytic Anemia

- Hypersplenism
- Snake venom
- Celiac disease
- Vitamin E deficiency

Contd...

Table 8.68 Differences between extravascular hemolysis and intravascular hemolysis

Features	Extravascular Hemolysis	Intravascular Hemolysis
Site of hemolysis	Reticuloendothelial cells (spleen, bone marrow)	Inside blood circulation
Examples	Red blood cell membrane defect, HbS, thalassemia	Fragmentation syndrome, mismatched blood transfusion, *Clostridium welchii* sepsis, paroxysmal nocturnal hemoglobinuria
Clinical features	Anemia, jaundice	Anemia, jaundice
Splenomegaly	Present	Absent
Serum bilirubin (unconjugated)	Increased (++)	Increased (+)
Serum haptoglobin	Normal or reduced	Decreased
Serum methemalbumin	Absent	Present
Plasma hemoglobin	Absent	Present
Serum LDH	Increased (+)	Increased (++)
Urine hemoglobinuria	Absent	Present
Urine hemosiderin	Absent	Present
Body iron stores in spleen, bone marrow, liver	Increased	Decreased

Morphologically changes in both types of hemolysis are identical, except for the fact that erythrophagocytosis in extravascular hemolysis causes hypertrophy of the mononuclear phagocytic system, and this may lead to splenomegaly.

- Red blood cell destruction may occur in the extravascular or intravascular compartments. Clinical data of the patient gives clue to the diagnosis, which includes a family history of hemoglobinopathies or hereditary spherocytosis, a recent blood transfusion, malaria or splenectomy or malignant tumor.
- In addition to the basic symptoms of anemia, splenomegaly and jaundice may be present. There is presence of reticulocytes higher than normal in the blood, which cannot carry as much as oxygen as the fully developed red blood cells.

CLINICAL FEATURES

Clinical features of hemolytic anemia depend on duration and severity of red blood cell destruction. Patient presents with anemia, jaundice, cholelithiasis, leg ulcers, dark or red-colored urine, cortical bone thinning, extramedullary hematopoiesis and splenomegaly. Main features of hemolytic anemia are given in Table 8.69.

- **Pallor:** Depending on the severity of hemolysis, patient presents with anemia. Pallor is demonstrated in conjunctiva and tongue.
- **Jaundice:** Hemolytic jaundice occurs due to rapid destruction of red blood cells resulting in production of excess of bilirubin. Liver is not able to conjugate excess of bilirubin. Most hemoglobinopathies are characterized by mild jaundice. Patient with hereditary spherocytosis or G6PD deficiency may develop moderate to severe jaundice.
- **Splenomegaly:** In chronic hemolytic anemia, patient presents with vague abdominal discomfort. Splenomegaly is appreciated on clinical examination.
- **Gallbladder pigment stones:** Chronic intravascular hemolysis is the most common cause of gallbladder pigment stones, which are commonest and associated with hemolysis and cirrhosis. Pigment stones are confined to the gallbladder. Bile juice is sterile.
  - Gallbladder pigment stones consist of large amounts of polymerized degradation product of oxidized bilirubin.
  - Patient presents with sudden pain in right upper quadrant that may radiate to scapular region, lasting for 2–4 hours following ingestion of fatty meals, alcohol, and caffeine. Pain is associated with nausea and vomiting.
- **Skeleton abnormalities:** Skeleton abnormalities occur in congenital hemolytic anemia such as β-thalassemia major. Erythroid hyperplasia leads to widening of diploë of skull bones (parietal and frontal bones) and maxilla. Physical examination reveals frontal bossing, eminent cheek bones and widening of teeth. Radiograph of skull shows crewcut appearance as a result of widening of diploë and formation of new bone especially in young patients.
- **Chronic leg ulcers:** Patient suffering from hereditary spherocytosis or β-thalassemia major may develop leg ulcers as a result of thrombosis of small blood vessels and necrosis of skin. Leg ulcers are demonstrated on medial and lateral malleoli.

Table 8.69 Main features of hemolytic anemia

Features	Comments
Evidence of increased extravascular and intravascular red blood cell destruction	
Hyperbilirubinemia	▪ Mild, moderate or severe jaundice (yellow discoloration of sclera) depending on extent of hemolysis ▪ Increased risk of gallbladder stones
Physical examination	▪ Anemia depends on extent of hemolysis ▪ Jaundice (yellow discoloration of sclera) ▪ Frontal bossing, eminent cheek and widening of teeth as a result of widening of skull bones ▪ Splenomegaly due to extravascular hemolysis
Laboratory findings	▪ Decreased serum haptoglobin level ▪ Decreased serum hemopexin level ▪ Increased urinary urobilinogen ▪ Increased fecal stercobilinogen ▪ Increased body iron stores ▪ Extravascular hemolytic anemia (increased body iron store) ▪ Intravascular hemolytic anemia (hemoglobinemia, hemoglobinuria, hemosiderinuria, methemoglobinemia and decreased iron stores)
Compensatory mechanisms of red blood cell hemolysis	
Bone marrow findings	Evidence of erythroid hyperplasia as a result of expansion of bone marrow and decreased myeloid to erythroid ratio
Peripheral blood smear findings	▪ Polychromasia and reticulocytosis ▪ Macrocytosis due to increased requirement of folate

COMPENSATORY MECHANISMS OF HEMOLYTIC ANEMIA

Hematopoiesis is increased as a consequence of hemolytic process to compensate RBCs destruction. Compensatory mechanisms include erythroid hyperplasia and reticulocytosis.

Evidence of Erythroid Hyperplasia

Increased erythropoiesis compensates in part for the shortened red blood cell survival in hemolytic anemia. Bone marrow examination shows normoblastic erythroid hyperplasia.

- There is increased number of circulating reticulocytes (newly formed red blood cells identified by residual stainable RNA). Because reticulocytes are larger than mature red blood cells, the MCV may be moderately increased (up to about 105 fl).
- Peripheral blood smear examination shows nucleated red blood cells, polychromasia and leukocytosis.

Reticulocytosis

Reticulocyte count is increased following massive bleeding, acute hemolysis, and response to specific therapy in nutritional anemia and even after voluntary blood donation.

- Reticulocyte count is used to assess the capacity of the bone marrow to increase RBC production in response to increased demand.
- Reticulocytes are demonstrated by supravital stains such as new methylene blue (best stain) and brilliant cresyl blue.

Peripheral Blood Smear Examination

Peripheral blood smear examination provides valuable information about hemolytic anemia.

- Red blood cells exhibit polychromasia and increased reticulocyte count.
- Normoblasts are demonstrated in peripheral blood smear following moderate to severe hemolysis.
- One must look for spherocytes, sickle cells, target cells, fragmented red blood cell and acanthocytes.
- Neutrophilia with shift to left with myelocytes and metamyelocytes is seen. Thrombocytosis is demonstrated in acute hemolysis.

EXTRAVASCULAR HEMOLYSIS INVOLVING RBCs DESTRUCTION

After 100–120 days, RBCs are destroyed by reticuloendothelial system and liberate hemoglobin, which dissociates to form heme (porphyrin, iron and globin).

- Iron goes to iron storage sites for further utilization. Globin goes to amino acid pool. Iron goes to iron storage sites (e.g. bone marrow, spleen and liver) for reutilization.
- Metabolic products of porphyrin such as urobilinogen and stercobilinogen are excreted via urine and stool

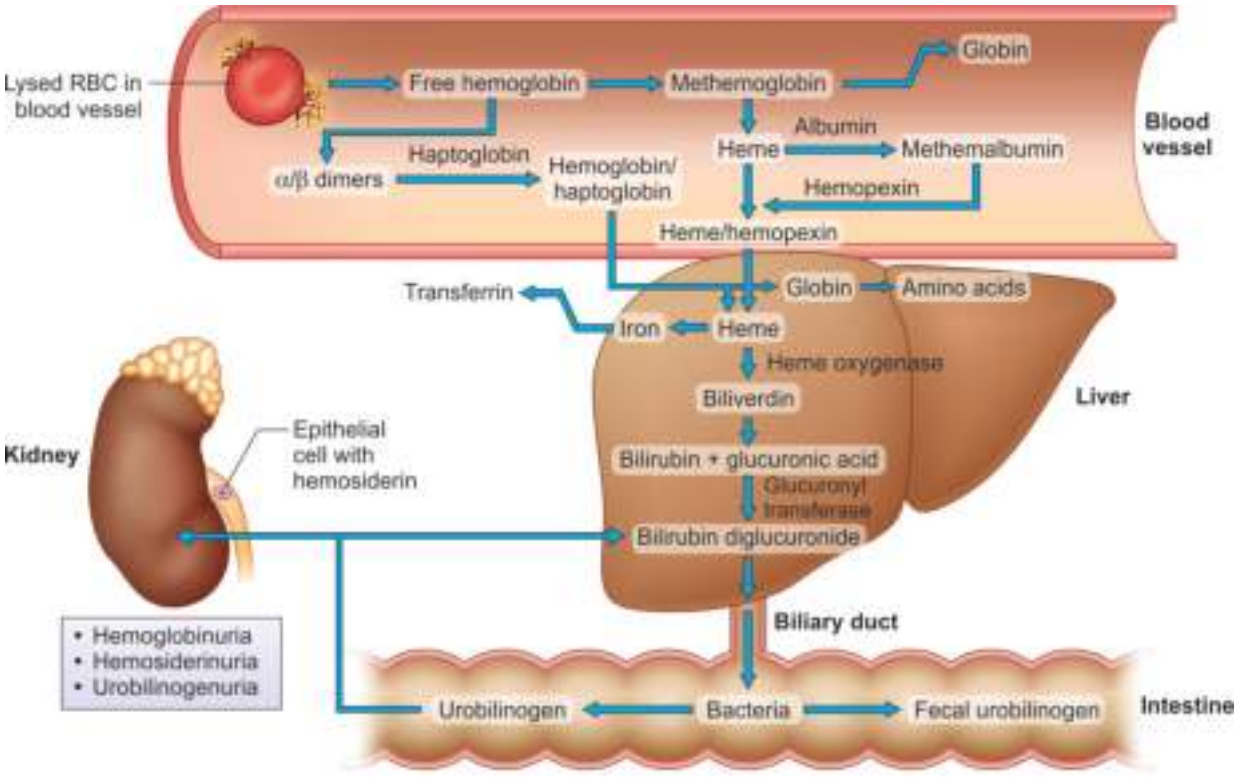

Fig. 8.25: Simplified pathway of bilirubin metabolism. Hemolytic anemia leads to increased biliary excretion of bilirubin.

respectively. Total normal bilirubin level is 0.3–1.0 mg/dl. Simplified pathway of bilirubin metabolism is shown in Fig. 8.25.

BIOCHEMICAL ALTERATIONS

Increased Serum Bilirubin

Absence of jaundice does not exclude hemolytic anemia. Increased red blood cell destruction results in liberation of hemoglobin or its degradation products. Hemolytic anemia is not accompanied with pruritus. Hyperbilirubinemia may lead to pigment-containing gallbladder stones as a late complication.

- Clinical jaundice is not apparent until the serum bilirubin exceeds 40 µmol per liter. Urine contains increased level of urobilinogen. Aqueous diazotized sulphanilic acid reacts only with conjugated bilirubin, giving red color.
- Addition of alcohol (methanol) frees the albumin, hence, rest of the unconjugated bilirubin reacts with the reagent. Bilirubin is destroyed by direct sunlight or ultraviolet light including fluorescent light.

Increased Excretion of Urobilinogen

Extravascular hemolysis involving red blood cell destruction leads to increased excretion of urobilinogen in urine giving high-colored urine.

Increased Excretion of Stercobilinogen

Extravascular hemolysis involving red blood cell destruction leads to increased excretion of stercobilinogen exhibiting dark-colored stool.

Increased Iron Stores in Tissues

Hemolytic anemia due to extravascular etiology leads to excess release and deposition of iron in tissues.

INTRAVASCULAR HEMOLYSIS INVOLVING RBCs DESTRUCTION

Estimation of serum haptoglobin, hemopexin and methemalbumin provides good indicators of severity of intravascular hemolytic process. Indicators of intravascular hemolytic anemia are shown in Fig. 8.26. Causes of intravascular hemolysis are given in Table 8.70. Biochemical alterations in intravascular hemolysis destruction are discussed below.

BIOCHEMICAL ALTERATIONS

Hemoglobinemia

Normal free hemoglobin in plasma is 0.6 mg/dl. When free hemoglobin is markedly raised, the color of the plasma becomes pink or red. When rise of free hemoglobin is moderate, plasma color is lacking due to

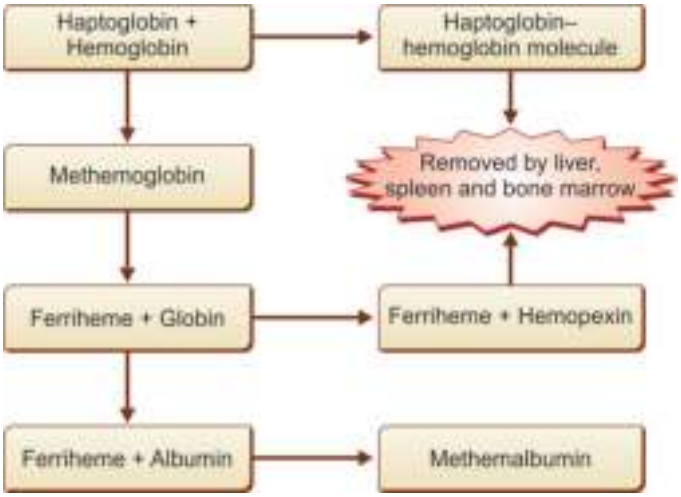

Fig. 8.26: Indicators of intravascular hemolytic anemia.

Table 8.70 Causes of intravascular hemolysis

Mismatched blood transfusion
G6PD deficiency with oxidative stress
Paroxysmal nocturnal hemoglobinuria (PNH)
Unstable hemoglobin
Drug-induced hemolytic anemia (e.g. α-methyldopa, penicillin, oxidant drugs, primaquine, dapsone)
Infection-induced hemolytic anemia (*Clostridium welchii*, *Vibrio cholerae*, malarial parasite, Bartonella gram-negative bacteria)
Red cell fragmentation syndromes (march hemoglobinuria, prosthetic cardiac valves, thrombotic thrombocytopenic purpura, hemolytic–uremic syndrome, malignant hypertension, pre-eclampsia/eclampsia of pregnancy, HELLP syndrome associated with pregnancy, disseminated intravascular coagulation (DIC), homograft rejection and ciclosporin immunosuppressive drug)

low hemoglobin concentration. Hemoglobin in plasma is detected by **benzidine test**.

- Presence of other pigments such as bilirubin gives yellow color.
- **Methemoglobin** is dark brown in acidic urine, while **oxyhemoglobin** is bright red in alkaline urine.

Hemoglobinuria

Hemoglobinuria occurs in severe intravascular hemolysis. Hemoglobin in urine is demonstrated by spectroscopy in bright day light. Oxyhemoglobin appears in the yellow-green, while methemoglobin in the red by spectroscopy, which must be distinguished from hematuria. In hematuria, intact RBCs are seen in freshly voided specimens. *In vitro* lysis of the red blood cells in hematuria results in artificial hemoglobinuria.

Hemosiderinuria

Hemosiderinuria is a valuable sign for chronic hemolytic process, which persists for several weeks after a hemolytic episode. Examination of urinary sediment stained by **Perls Prussian blue** stain demonstrates iron-containing renal tubular cells.

Plasma Haptoglobin

Haptoglobin is α_2 glycoprotein synthesized by liver, which combines with any hemoglobin in plasma and prevents its excretion in urine. Haptoglobin–hemoglobin molecule is removed by liver, spleen and bone marrow. Hence, plasma haptoglobin levels are decreased with each episode of hemolysis, which come to normal within 3 days. Decreased level of plasma haptoglobin is very sensitive indicator of mild hemolytic process (normal range 0.5–1.5 g/L).

Plasma Hemopexin

Hemopexin is a glycoprotein synthesized by liver, which does not bind to hemoglobin rather binds only to ferriheme. When hemolysis occurs, hemoglobin liberated is reduced to methemoglobin, which splits into ferriheme and globin.

- Globin goes to amino acid pool for further utilization, while ferriheme combines with hemopexin and cleared by liver. Hemopexin value is decreased only in severe degree of hemolysis.
- Plasma hemopexin level is a good index of sensitivity of the hemolytic process as it is not reduced by minor degrees of hemolysis. Decreased plasma hemopexin levels indicate severe hemolytic process (normal range 0.5–1.0 g/dl).

Plasma Methemalbumin

Methemalbumin occurs in hemolytic anemia, especially when hemolysis is intravascular. Methemoglobin consists heme and albumin, which gives brown color to plasma in intravascular RBCs hemolysis.

- Schumm's test is performed to differentiate intravascular hemolysis from extravascular hemolysis in a case of hemolytic anemia.
- Methemalbumin has a characteristic absorption in the red band (at 624 nm), which may be seen by means of spectroscope. Now cover the sample with a layer of ether, and add 1/10th of saturated yellow ammonium sulfide and mix, which leads to formation of an ammonium hemochromatogen, a more intense band can be seen in the green part of the spectrum (588 nm). This is called Schumm's test.

HEREDITARY SPHEROCYTOSIS, OVALOCYTOSIS AND STOMATOCYTOSIS: RBC MEMBRANE DEFECTS

HEREDITARY SPHEROCYTOSIS

Hereditary spherocytosis is an autosomal disorder caused by deficiency of cytoskeleton isolated or combined proteins resulting in reduced RBC membrane stability and loss of RBCs membrane lipid bilayer.

- Red blood cells assume shape, i.e. microspherocytes having small surface area for the given volume.
- Life span of red blood cells is reduced to 10–20 days against a normal 100–120 days.
- Spectrin cytoskeleton protein deficiency linked to hereditary spherocytosis is more common.
- Combined deficiency of spectrin and ankyrin cytoskeleton proteins is demonstrated in majority of hereditary spherocytosis cases.
- Band 3 cytoskeleton protein deficiency occurs in 25% of cases.
- Band 4.2 cytoskeleton protein deficiency linked to hereditary spherocytosis is more common in Japan.

Pathology Pearls: Hereditary Spherocytosis

Physiologic State

Normal biconcave shape and flexibility of red blood cells are maintained by the presence of cytoskeleton proteins composed of spectrin, ankyrin, actin, protein 4.1 and protein 3 (Fig. 8.27).

Pathologic State

- Hereditary deficiency of cytoskeleton proteins in red blood cells leads to reduced membrane stability, loss of lipid bilayer membrane and microspherocytes formation.
- The microspherocytes fail to pass through interendothelial fenestrations of sinusoids and get trapped in the spleen.
- Due to accumulation of lactic acid in microspherocytes disrupts sodium pump resulting in sequestration in the spleen and chronic extravascular hemolysis. Life span of red blood cells is decreased to 10–20 days.
- Hereditary spherocytosis is autosomal dominant (more common and less severe) or recessive disorder (less common but more severe). Pathophysiology of hereditary spherocytosis is shown in Fig. 8.28.

GENE MUTATIONS

Isolated or combined mutation in spectrin and ankyrin genes account for most cases. Isolated mutation occurs in band 3 or band 4.2. Glycophorin is not involved in the pathogenesis of hereditary spherocytosis. Hereditary spherocytosis (HS) and inherited defects of cytoskeleton proteins are given in Table 8.71.

Spectrin Proteins

Approximately, 65% of hereditary spherocytosis/autosomal dominant cases are due to SPTAI gene mutation

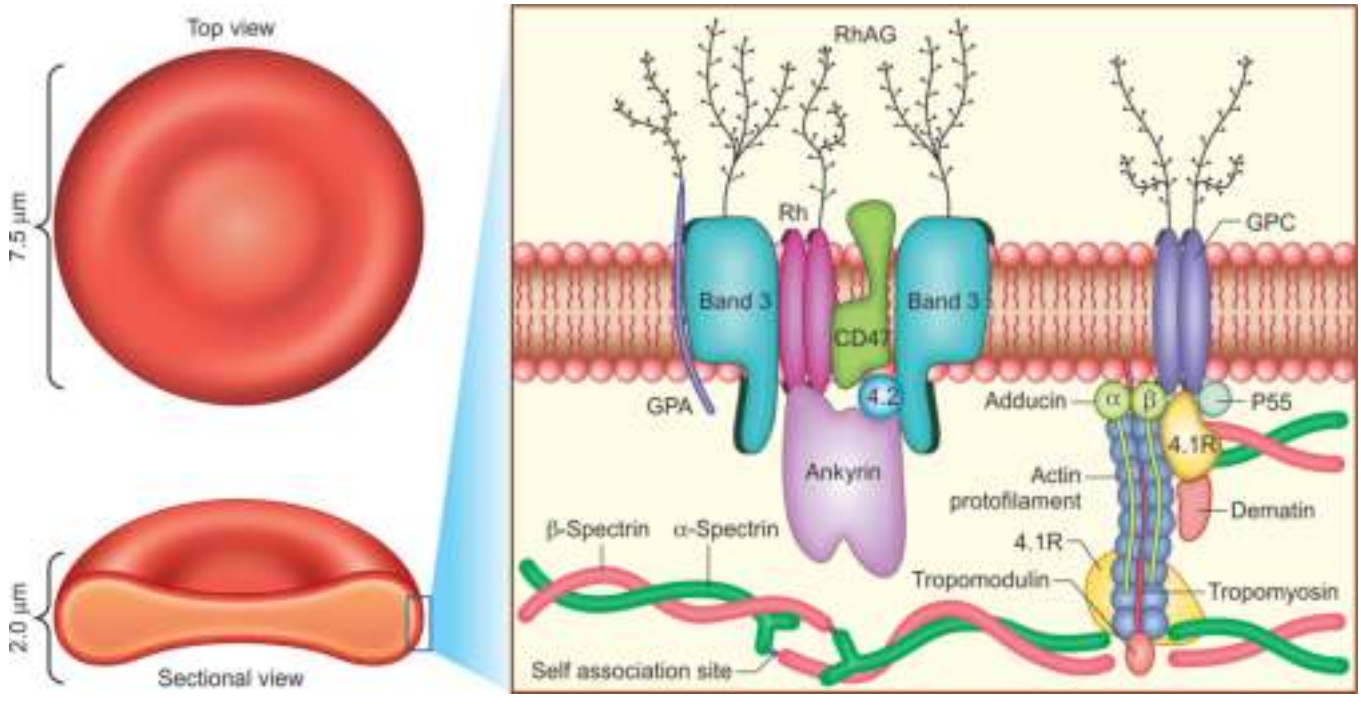

Fig. 8.27: Cross-sectional side view of the biconcave structure of red blood cell. Diagram shows cytoskeleton and flexible spectrin, ankyrin, actin, protein 4.1 and protein 3. Vertical interaction proteins include spectrin, ankyrin, protein 4.2 and band 3. Horizontal interaction proteins include actin, protein 4.1 and adducin.

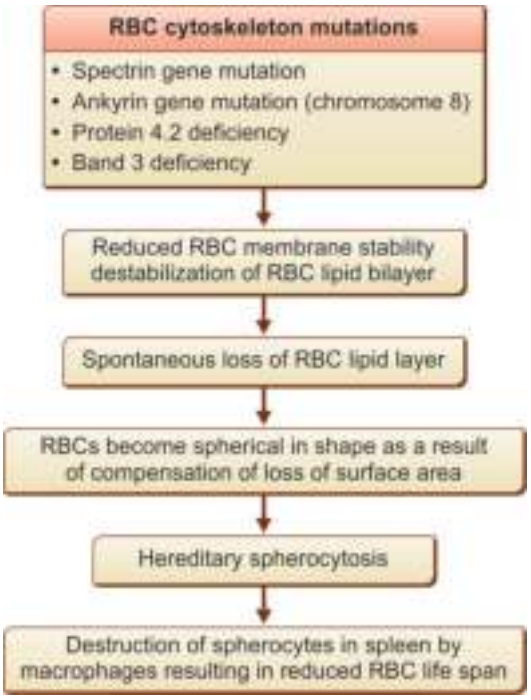

Fig. 8.28: Pathophysiology of hereditary spherocytosis.

located on chromosome 1q22–q23 encoding spectrin protein, and 30% cases due to SPTB gene mutation located on chromosome 14q23–q24.1 encoding spectrin protein. α-Spectrin mutation correlates with severity of hemolysis and osmotic fragility.

Ankyrin Protein

ANK1 gene mutation located on chromosome 8p11.2 encoding ankyrin protein is associated with majority of hereditary spherocytosis (as autosomal dominant disorder). It is most common mutation in hereditary spherocytosis.

Band 3 (Anion Channel) Protein

Band 3 is anion transport protein. SLC4A1 gene mutation located on chromosome 17q21 encoding band 3 (anion channel) protein accounts for 25% of hereditary spherocytosis is an autosomal dominant disorder.

Band 4.2 Protein (Pallidin)

EPB42 gene mutation located on chromosome 15q15–q21 encoding mutant band 4.2 protein accounts for 3% of hereditary spherocytosis an autosomal recessive disorder. Protein 4.2 deficiency is common in Japan.

CLINICAL FEATURES

Due to chronic hemolysis of microspherocytes in the spleen, patient presents with intermittent jaundice, splenomegaly, pigmented gallstones in 50% of cases, mild to moderate anemia and chronic leg ulcers. The severity of the disease is quite variable among individuals.

- Patient may develop aplastic crisis due to bone marrow depression by Parvovirus B19 infection. Splenectomy is the treatment of choice.
- Splenectomy cures the anemia caused by hereditary spherocytosis by removing the site of extravascular hemolysis.
- Genetic defect is incurable. Microspherocytes persist in blood circulation in postsplenectomy patients.

Age and Sex

Hereditary spherocytosis manifests in neonates, children and adults affecting both sex groups.

Anemia

Patient presents with mild to moderate anemia. Severe anemia rarely occurs. Aplastic crisis occurs due to bone marrow depression caused by Parvovirus B19 infection. Majority of patients present with moderate anemia showing 15–30 microspherocytes/HPF and splenomegaly.

Jaundice

Intermittent jaundice is the most common presentation in children. Pregnancy, fatigue and infection may aggravate jaundice.

Splenomegaly

Mild to moderate splenomegaly is most common clinical finding in hereditary spherocytosis as a result

Table 8.71 Hereditary spherocytosis (HS) and inherited defects of cytoskeleton proteins

Encoding Proteins	Gene	Location on Chromosome	Autosomal Dominant/Recessive Hereditary Spherocytosis	Percentage
Spectrin	▪ SPTAI gene ▪ SPTB gene	▪ 1q22–q23 ▪ 14q23–q24.1	▪ Autosomal dominant ▪ Autosomal dominant	▪ 65% of cases ▪ 30% of cases
Ankyrin	ANK1 gene	8p11.2	Autosomal dominant	Majority of cases
Band 3 (anion channel)	SLC4A1	17q21	Autosomal dominant	25% of cases
Band 4.2 (pallidin)	EPB42	15q15–q21	Autosomal recessive	3% of cases (common in Japan)

of trapping of microspherocytes in the red pulp of the spleen.

Gallbladder Pigment Stones

Gallbladder pigment stones are most often demonstrated during first to second decade in 50–75% cases of hereditary spherocytosis.

Leg Ulcers

Patient with hereditary spherocytosis may rarely develop leg ulcers.

Laboratory Diagnosis of Hereditary Spherocytosis

- **Hemoglobin:** Hemoglobin is low depending on degree of hemolysis.
- **Reticulocyte count:** Reticulocyte count is increased (>8%).
- **Hematocrit values:** MCHC is often increased. MCH is within normal range. MCV is decreased.

Peripheral Blood Smear Examination

- Peripheral blood smear examination shows round, slightly smaller than normal red blood cells. The microspherocytes lack central pallor area. Nucleated and polychromatic red blood cells are demonstrated.
- To demonstrate microspherocytes properly, it is important to visualize in the area of the peripheral blood smear, where red blood cells are nearly touching each other but not stretched out.
- Normal red blood cells when stretched, as at the tail or thin end of the peripheral blood smear have an artificial spherical appearance.
- Platelet count is within normal range. Peripheral blood smear showing hereditary spherocytosis is shown in Fig. 8.29A to C.
- Hereditary spherocytosis should be differentiated from other disorders showing spherocytes, which include immune hemolytic anemia (Coombs' test positive), paroxysmal nocturnal hemoglobinuria, G6PD deficiency, blood transfusion reactions, *Clostridium perfringens* sepsis, snakebites, microangiopathic hemolytic anemia and malarial parasitic infection.

Bone Marrow Smear Examination

Bone marrow is hypercellular due to normoblastic erythroid hyperplasia. Myelopoiesis and megakaryopoiesis are within normal range.

Serum Bilirubin

- There is increase in indirect unconjugated serum bilirubin, but not direct (conjugated).
- The jaundice is acholuric (no bilirubin in the urine, so bilirubinuria would not be expected).

Incubation Osmotic Fragility

Osmotic fragility is **most reliable diagnostic test** for hereditary spherocytosis. Incubation increases sensitivity of osmotic fragility test by enhancing loss of surface area of red blood cells. It is performed to measure the erythrocyte's resistance to hemolysis by osmotic stress. It mainly depends on volume of the cell, surface area and membrane function. Osmotic fragility test on human red blood cells in hereditary spherocytosis is shown in Fig. 8.30.

- **Physiologic state:** Normal red blood cells begin to hemolyze at 0.5% NaCl concentration. Hemolysis is complete at about 0.3%. There is increased RBCs osmotic fragility in hypotonic saline.
- **Pathologic state:** Red blood cells are incubated in varying concentrations of hypotonic NaCl solution. The erythrocytes take in water in an effort to achieve osmotic equilibrium. Further uptake of water by red blood cells results in rupture of membrane. Osmotic fragility curve demonstrates a shift-to-the-right in hereditary spherocytosis, and autoimmune hemolytic anemia.

Coombs' Test

- Presence of microspherocytes in the peripheral blood smear and along with family history, strongly suggest a diagnosis of hereditary spherocytosis.
- Spherocytes are also observed in warm antibody autoimmune hemolytic anemia and G6PD deficiency. Coombs' test is negative in hereditary spherocytosis, but positive in autoimmune hemolytic anemia.

Flow Cytometry Test

Flow cytometric analysis is done by binding eosin-5-maleimide to red blood cells for identifying deficient band 3 protein in hereditary spherocytosis.

Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis (SDS-PAGE)

SDS-PAGE is performed to detect abnormalities of cytoskeleton proteins, e.g. spectrin, ankyrin, band 4.2 (pallidin) and band 3 (anion channel).

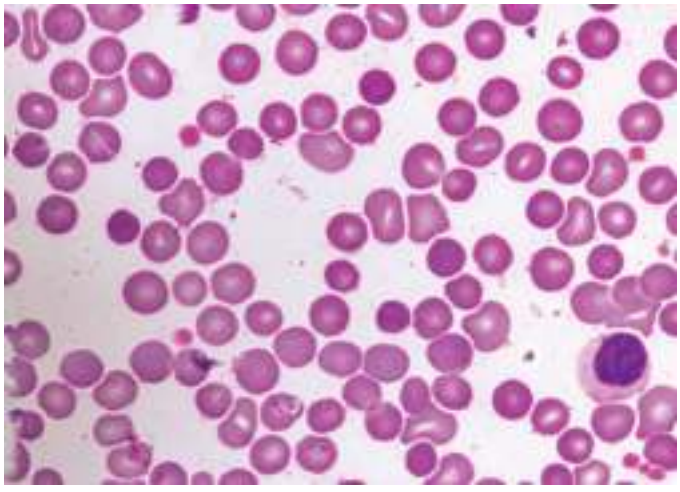

Fig. 8.29A: Peripheral blood smear examination in hereditary spherocytosis shows darkly stained microspherocytes lacking central pallor.

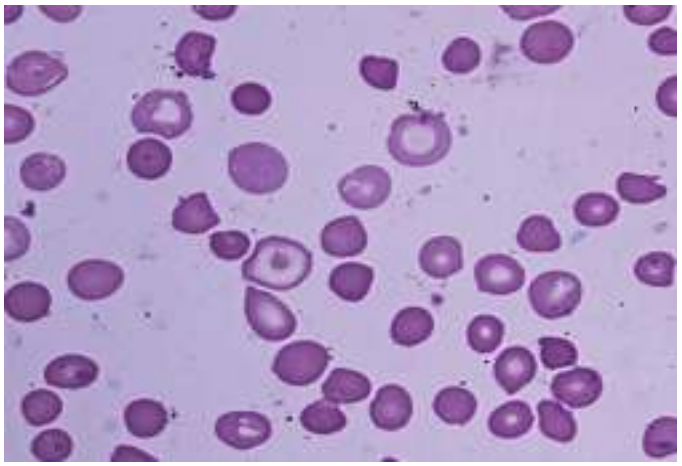

Fig. 8.29B: Peripheral blood smear in hereditary spherocytosis. It shows darkly stained microspherocytes.

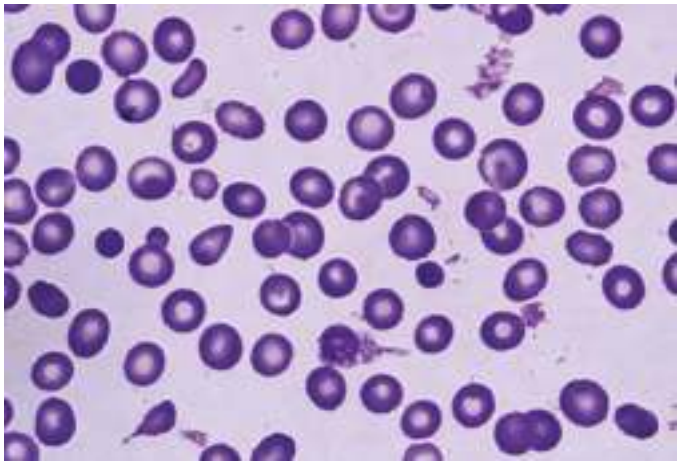

Fig. 8.29C: Peripheral blood smear in hereditary spherocytosis shows many spherocytes.

HEREDITARY OVALOCYTOSIS

Hereditary ovalocytosis (elliptocytosis) is an autosomal dominant disorder affecting assembly of membrane associated cytoskeleton horizontal proteins band 3 (anion channel) and band 4.1.

- Hereditary ovalocytosis is characterized by elongated, oval red blood cells in peripheral blood smears in some populations residing in Melanesia.

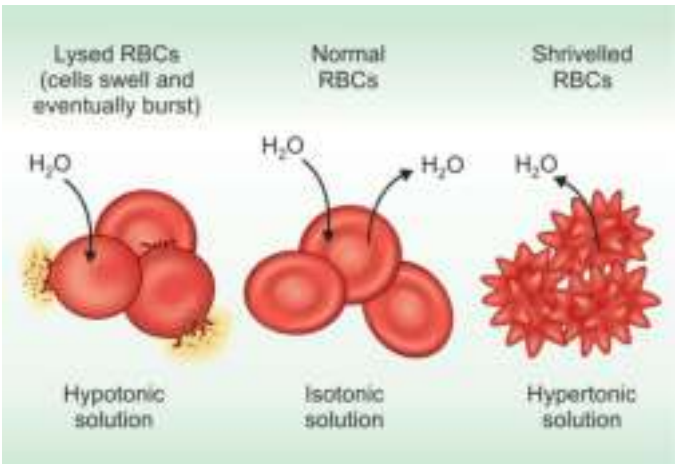

Fig. 8.30: Osmotic fragility test on human red blood cells in hereditary spherocytosis.

- There may be mild hemolysis during infancy. Homozygous persons may rarely develop chronic hemolytic anemia, which does not cause anemia in most of the cases.

GENE MUTATIONS

Hereditary ovalocytosis occurs due to gene mutations encoding cytoskeleton horizontal proteins band 3 or band 4.1. Hereditary ovalocytosis and inherited defects of cytoskeleton proteins are given in Table 8.72.

- **Band 3 (anion channel) protein:** SLC4A1 gene mutation (polymorphic mutation-deletion of 9 amino acids) located on chromosome 17q21 encoding band 3 (anion channel) is associated with autosomal dominant ovalocytosis in South-East Asia. The patients are clinically symptomatic and resistant to *Plasmodium falciparum.*
- **Band 4.1 protein:** EPB41 gene mutation located on 1p33–p34.2 encoding band 4.1 accounts for 5% of cases.

CLINICAL FEATURES

Most patients are occasionally symptomatic. Patient may present with pallor, jaundice, anemia and gallbladder stones.

Table 8.72 Hereditary ovalocytosis and inherited defects of cytoskeleton proteins

Encoding Proteins	Gene	Location on Chromosome	Disorder	Percentage and Comments
Band 3 (anion channel)	SLC4A1	17q21	Autosomal dominant	▪ Polymorphic deletion of 9 amino acids ▪ South-East Asian persons are asymptomatic and resistant to *Plasmodium falciparum*
Band 4.1	EPB41	1p33–p34.2	Autosomal dominant	▪ 5% of cases ▪ Severe hemolysis in homozygotes ▪ No hemolysis in heterozygotes

Laboratory Diagnosis of Hereditary Ovalocytosis

- **Hematocrit values:** MCH, MCHC and MCV are within normal range.
- **Hemoglobin value:** Hemoglobin value is most often within normal range.
- **Peripheral blood smear:** Peripheral blood smear examination shows ovalocytes constituting 20–90% of red blood cells (Fig. 8.31).

RBC Autohemolysis Test

Autohemolysis is increased in hereditary ovalocytosis. It can be corrected by addition of glucose.

Molecular Genetic Testing

The confirmatory test to diagnose hereditary ovalocytosis is based on molecular genetic testing for the presence of gene mutations in the specific protein molecules of the RBCs.

HEREDITARY STOMATOCYTOSIS

Hereditary stomatocytosis is an autosomal dominant disorder, which affects the red blood cells, in which the membrane of RBCs leaks sodium and potassium ions. It is caused by SLCA4A-I gene mutation located on chromosome 17q21 encoding RBCs membrane cytoskeleton band 3 protein. Hereditary stomatocytosis and inherited defects of cytoskeleton proteins are given in Table 8.73.

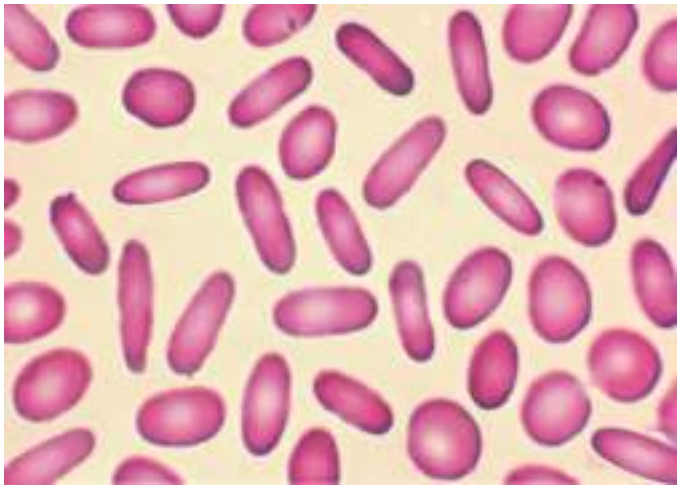

Fig. 8.31: Hereditary ovalocytosis shows large number of ovalocytes.

PATHOPHYSIOLOGY

Normally, ion exchanger pump on RBCs membrane pumps out sodium out cell and potassium inside cell. This action is balanced by 'the passive leak'. Due to SLCA4A-1 gene mutation encoding band 3 protein, the passive leak is increased resulting in swelling of red blood cells as a result of accumulation of salt and water. RBCs lyse and hemolytic anemia results. Stomatocytes are trapped and consequently hemolyzed in the

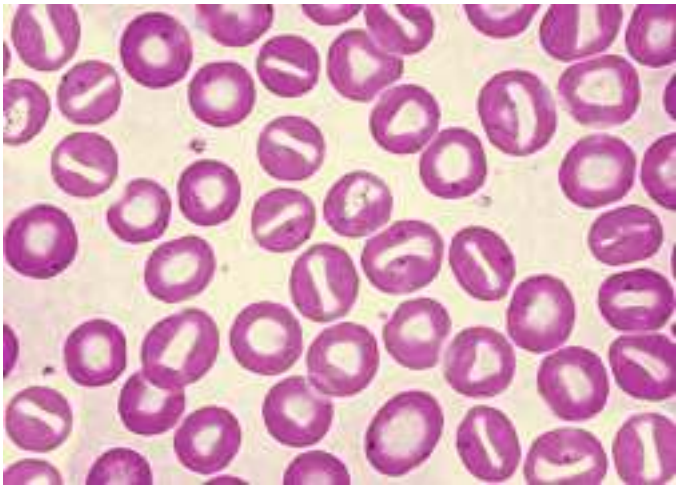

Fig. 8.32A: Peripheral blood smear in hereditary stomatocytosis. It shows stomatocytes with central slit-shaped area. These stomatocytes are also demonstrated in liver disease.

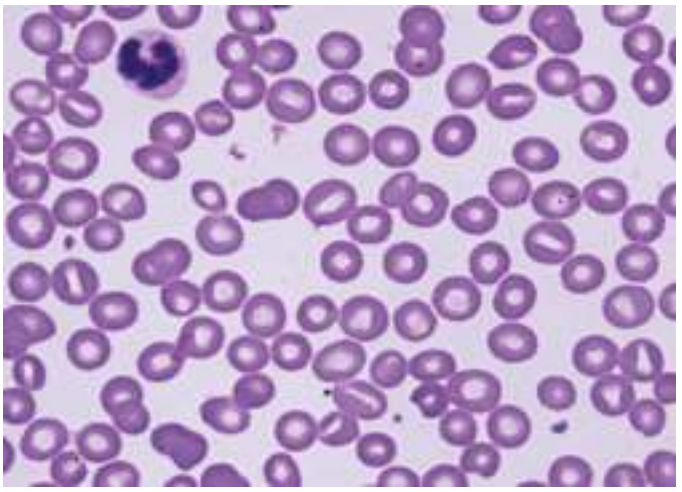

Fig. 8.32B: Peripheral blood smear in hereditary stomatocytosis.

Table 8.73 Hereditary stomatocytosis and inherited defects of cytoskeleton proteins

Encoding Proteins	Gene	Location on Chromosome	Disorder	Percentage and Comments
Band 3 (anion channel)	SLC4A1	17q21	Hereditary stomatocytosis	Certain specific missense mutations shift protein function from anion exchanger to cation conductance

microvasculature of spleen and other organs. Patient with hereditary stomatocytosis is protected against malarial parasite infection.

CLINICAL COURSE

Many patients present with hereditary stomatocytosis with hemolytic anemia in the neonatal period. Other patients remain asymptomatic throughout their lifetime.

Laboratory Diagnosis of Hereditary Stomatocytosis

Peripheral Blood Smear Examination

Peripheral blood smear examination shows many stomatocytes with a slit-like central pallor giving them the appearance of 'coffee beans'. In three dimensions, stomatocyte has lost its biconcave morphology due to membrane defect (Fig. 8.32A and B).

THALASSEMIAS

THALASSEMIAS: OVERVIEW

Thalassemia is a heterogenous group of inherited blood disorders affecting the hemoglobin genes coding for α- and β-chains of hemoglobin resulting in ineffective erythropoiesis. Hemoglobin serves as the oxygen-carrying component of red blood cells. Patients present with anemia in early childhood, who require frequent blood transfusions to maintain hemoglobin levels throughout life.

- **Physiologic state:** A normal hemoglobin molecule contains four globin chains, consisting of two α- and two β-chains. Three normal variants of hemoglobin are encountered, based on the nature of the non-α-chains. Hemoglobin A ($\alpha_2\beta_2$) accounts for 95–98% of the total hemoglobin in adults; only minor amounts of HbF ($\alpha_2\gamma_2$) and HbA_2 ($\alpha_2\delta_2$) are present.
- **Pathologic state:** Thalassemia is group of genetic disorders characterized by complete or deficient synthesis of either α- or β-globin chains of structurally normal hemoglobin chains. It is worth mentioning that heme synthesis is not affected. Thalassemias occur across world with high frequency in Africa, India, South-East Asia, and the Mediterranean area.

CLASSIFICATION

Thalassemias are classified according to the type of chains that are missing.

- If the α-chains are not synthesized, it is called α-thalassemia; if the β-chains are missing, it is called β-thalassemia.
- Homozygous β-thalassemia is a more serious disease, and silent carrier of α-thalassemia is asymptomatic.
- Thalassemia intermedia is double heterozygotes and less severe. Classification of α-, β- and δβ-thalassemias is shown in Fig. 8.33 and Table 8.74.

β-THALASSEMIAS

β-THALASSEMIA MAJOR

β-Thalassemia major is also known as Mediterranean anemia or Cooley's anemia. In transfusion-dependent anemia, morbidity and mortality occur due to cardiac failure as a result of expansion of plasma volume and iron overload. It is a serious disease which often results in death during childhood unless frequent blood transfusions are given. Life expectancy is 15–25 years with or without treatment death occurs by 5 years of age.

Pathophysiology

The lack of β-chains leads to accumulation of unpaired α-chains (which are free and uncombined) within developing red blood cells.

- These α-chains aggregate and result in premature destruction of maturing erythroblasts within bone marrow (ineffective erythropoiesis) and premature destruction of abnormal mature red blood cells in the spleen (hemolysis).
- Serum ferritin and serum iron levels are increased. Excess of iron is deposited in liver, heart, spleen, hypothalamus and endocrine glands (pituitary, islets of Langerhans' and parathyroid glands). Pathophysiology of β-thalassemia major is shown in Fig. 8.34.

Point Mutations of Globin Gene Clusters

β-Thalassemia major occurs due to various point mutations of the globin gene clusters. Suppression of β-globin occurs as a consequence of single nucleotide base pair substitution in the promoter region or messenger RNA processing region.

- Gene mutation at terminator region causes β-thalassemia characterized by absence of synthesis of β-chains.

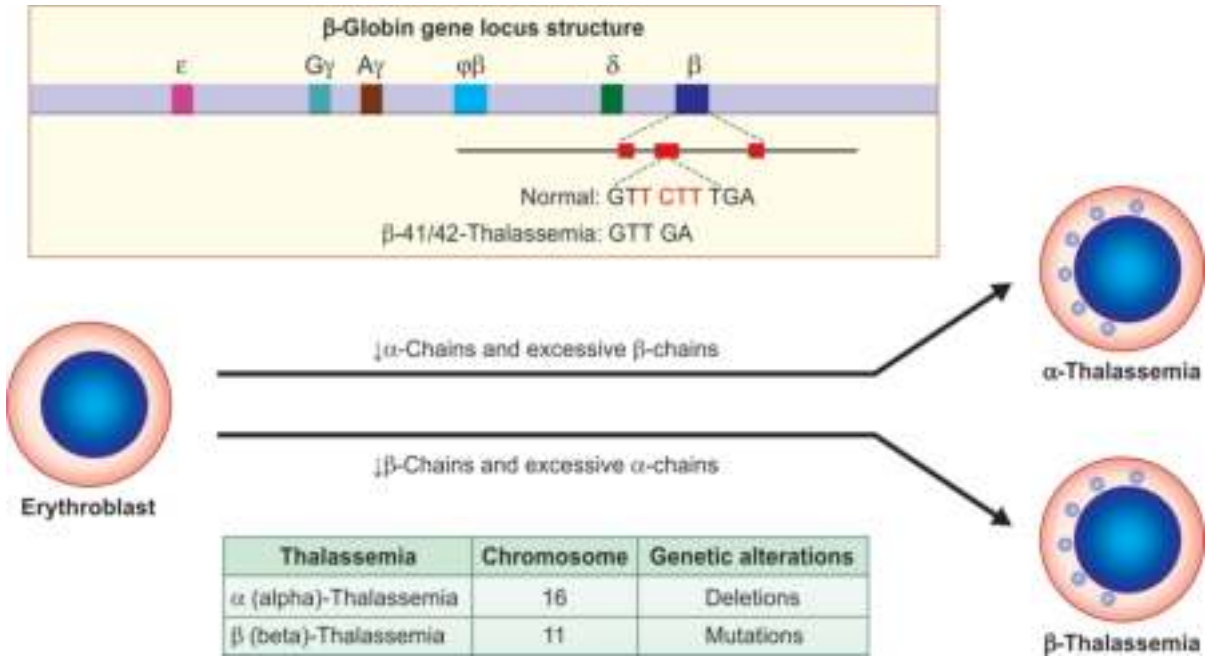

Fig. 8.33: Classification of thalassemias.

Table 8.74 Classification of α-, β- and δβ-thalassemias

Phenotype of Thalassemia	Globin Chain Synthesis Affected	Hemoglobin Synthesis in Patient	Peripheral Blood Smear, Bone Marrow, Hematocrit Values and Serum Assays	Clinical Features
β-Thalassemias				
Thalassemia major	β^0/β^0 due to total HBB gene mutation and absence of β-globin chain synthesis (homozygous state)	▪ HbA (nil) ▪ HbA_2 (3.8%) ▪ HbF (>90%)	▪ Peripheral blood smear examination shows microcytic hypochromic picture, numerous target cells, basophilic stippling ▪ Bone marrow shows erythroid hyperplasia and increased bone marrow iron due to hemolysis and repeated blood transfusion (generalized hemosiderosis) ▪ Serum iron increased ▪ Serum ferritin increased ▪ MCH, MCHC and MCV decreased ▪ Hemoglobin electrophoresis diagnostic significance ▪ High-performance liquid chromatography (HPLC) diagnostic significance	▪ Pallor due to severe anemia since childhood and failure to thrive ▪ Mongoloid face and other skeletal abnormalities ▪ Marked splenomegaly ▪ Hepatomegaly moderate ▪ Septicemia ▪ Transfusion-dependent disease
Thalassemia minor/trait	β^0/β due to HBB gene mutation (heterozygous state)	▪ HbA (90%) ▪ HbA_2 (3.8%) ▪ HbF (+/–)	▪ Peripheral blood smear examination shows mild microcytic and hypochromic picture, few target cells and basophilic stippling ▪ Hemoglobin electrophoresis diagnostic ▪ High-performance liquid chromatography diagnostic significance	Usually asymptomatic and mild pallor

Contd...

Table 8.74 Classification of α-,β- and δβ-thalassemias (*Contd...*)

Phenotype of Thalassemia	Globin Chain Synthesis Affected	Hemoglobin Synthesis in Patient	Peripheral Blood Smear, Bone Marrow, Hematocrit Values and Serum Assays	Clinical Features
Thalassemia intermedia	β^0/β^+ due to HBB gene mutation (double heterozygous state)	▪ HbA (50–70%) ▪ HbA_2 (3.8%) ▪ HbF (20–40%)	▪ Peripheral blood smear shows microcytic hypochromic picture ▪ Bone marrow shows erythroid hyperplasia and increased iron stores ▪ MCH, MCHC and MCV decreased	Anemia manifests during third to fourth decade of life
α-Thalassemias				
Silent carrier	α/αα due to HBA gene mutation (deletion of single α-globin chain located on chromosome 16)	Normal findings	Minority of patients show reduced mean cell volume and mean corpuscular hemoglobin	Asymptomatic
α-Thalassemia minor/trait	α/–α or –/αα due to HBA gene mutation (deletion of two α-globin chains located on chromosome 16)	Normal findings	▪ Hemoglobin is normal or slightly reduced decreased mean corpuscular volume and corpuscular hemoglobin ▪ Peripheral blood smear shows mild microcytic and hypochromic picture	Usually asymptomatic
Hemoglobin H disease	–α/– due to HBA gene mutation (deletion of three α-globin chains located on chromosome 16)	▪ HbA (70–90%) ▪ HbH (5–30%)	▪ Formation of unstable nonfunctional hemoglobin, i.e. failure to transport oxygen ▪ Moderate microcytic hypochromic hemolytic anemia	Anemia proportional to concentration of hemoglobin
Hydrops fetalis	–/– (loss of all four α-globin alleles due to HBA gene mutation)	▪ Hb Bart (>80%) ▪ HbH (10–20%) ▪ HbA (nil)	Severe disease not compatible with life. Intrauterine death or stillborn at 25–40 weeks or dies after birth	Intrauterine death of fetus
δβ-Thalassemias				
δβ-Thalassemia major	$\delta\beta^0/\delta\beta^0$	▪ HBA (absent) ▪ HbA_2 (absent) ▪ HbF (100%)	▪ Mild anemia (microcytic hypochromic picture and target cells) ▪ Recent onset of jaundice	▪ Pallor ▪ Palpable spleen
δβ-Thalassemia minor	$\delta\beta^+/\delta\beta^0$	▪ HBA (80–90%) ▪ HbA_2 (3%) ▪ HbF (100%)	▪ Mild anemia (microcytic hypochromic picture and target cells) ▪ Recent onset of jaundice	▪ Pallor ▪ Palpable spleen

β: *Normal β-globin gene and normal synthesis of β-globin chain.*
β^0: *Total depletion of β-globin gene and absence of synthesis of β-globin chain.*
β^+: *Partial depletion of β-globin gene and reduced synthesis of β-globin chain.*

- On the other hand, gene mutation in the splicing region causes β_1-thalassemia characterized by some synthesis of β-chains. Possible effects of point mutation of globin gene point and functional consequences (β-thalassemia) (Table 8.75).

Bone Marrow Changes

Development of hemolytic anemia stimulates erythropoietin synthesis resulting in erythroid hyperplasia in bone marrow. Expansion of bone marrow leads to widening of diploë of the skull and other bones. Skull radiograph shows hair-end-on appearance.

Extramedullary Hematopoiesis

Extramedullary hematopoiesis occurs in liver and spleen.

Fetal Hemoglobin (HbF) Synthesis

Synthesis of γ-chains continues even after 6 months of age. These γ-chains combine with α-chains resulting in synthesis of HbF ($\alpha_2\gamma_2$) varying from 20 to 90%.

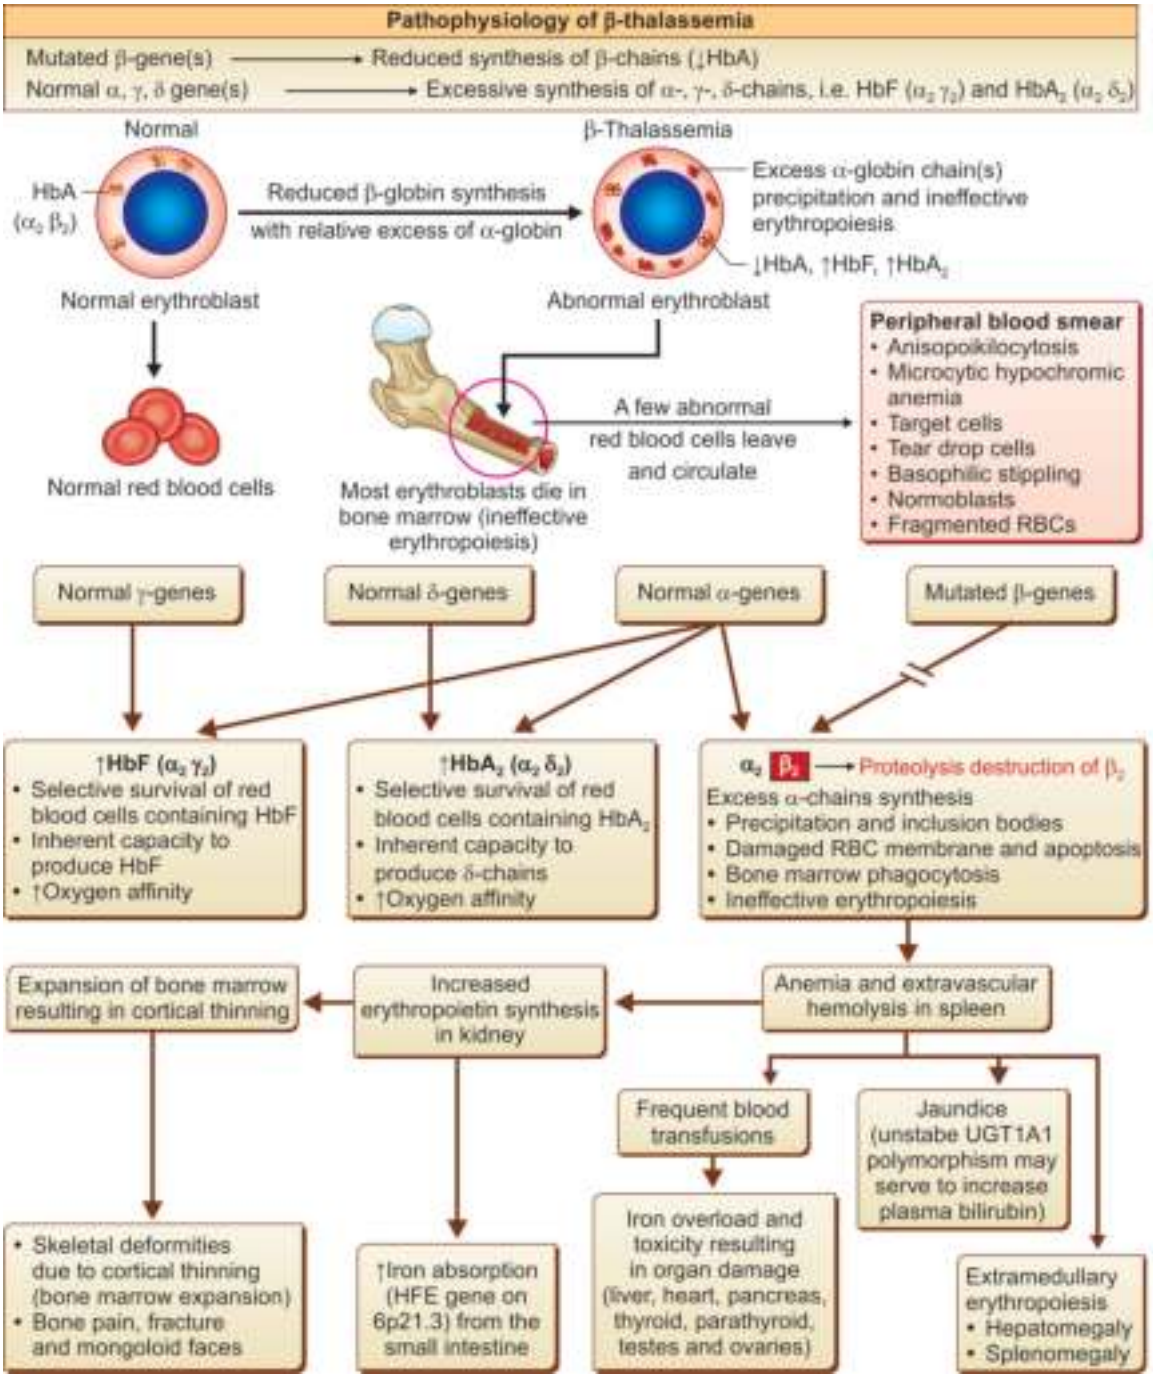

Fig. 8.34: Pathophysiology of β-thalassemia major. In β-thalassemia major, the decreased synthesis of β-globin chains reduces the production of HbA, and increases the synthesis of non-β-globin chain containing HbA_2 and HbF. Excess α-globin chains form insoluble precipitates inside red blood cells, damaging the red blood cell membrane and reducing their life span through splenic sequestration and ineffective erythropoiesis. All these factors contribute to a reduced oxygen delivery to the body tissues resulting in anemia and hypoxia. The compensatory erythroid hyperplasia in the bone marrow expands the bone marrow cavity by increased synthesis of erythropoietin, resulting in pathological fracture and mongoloid facial features.

Clinical Features

Clinical features begin during childhood after attaining 6–9 months of age as hemoglobin synthesis switch from HbF to HbA. Bone marrow transplantation is the only curative therapy. Clinical features of β-thalassemia major are shown in Fig. 8.35.

Severe Anemia

Anemia becomes within first year of life due to decrease in hemoglobin synthesis, marked shortening of RBC life span due to aggregation of insoluble excess α-chains, ineffective erythropoiesis and relative folate deficiency. Severe anemia impairs cardiac functions.

Table 8.75 Possible effects of point mutation of globin gene point and functional consequences (β-thalassemia)

Site of Point Mutation of Globin Chain	Possible Effects of Globin Gene Mutation	Example of Functional Consequences
Promoter site	Reduced transcription	β^+-Thalassemia
Initiation codon site	Methionine not encoded, hence absence of transcription	β^0-Thalassemia
Splice site	Absence of normal transcription	β^0-Thalassemia
Consensus site	Reduced transcription	β^+-Thalassemia
Intron site	Creation of false spice	β^+-Thalassemia
STOP codon site	STOP codon is converted to a coding sequence	α-Thalassemia due to elongation of globin chain and decreased synthesis at a reduced rate

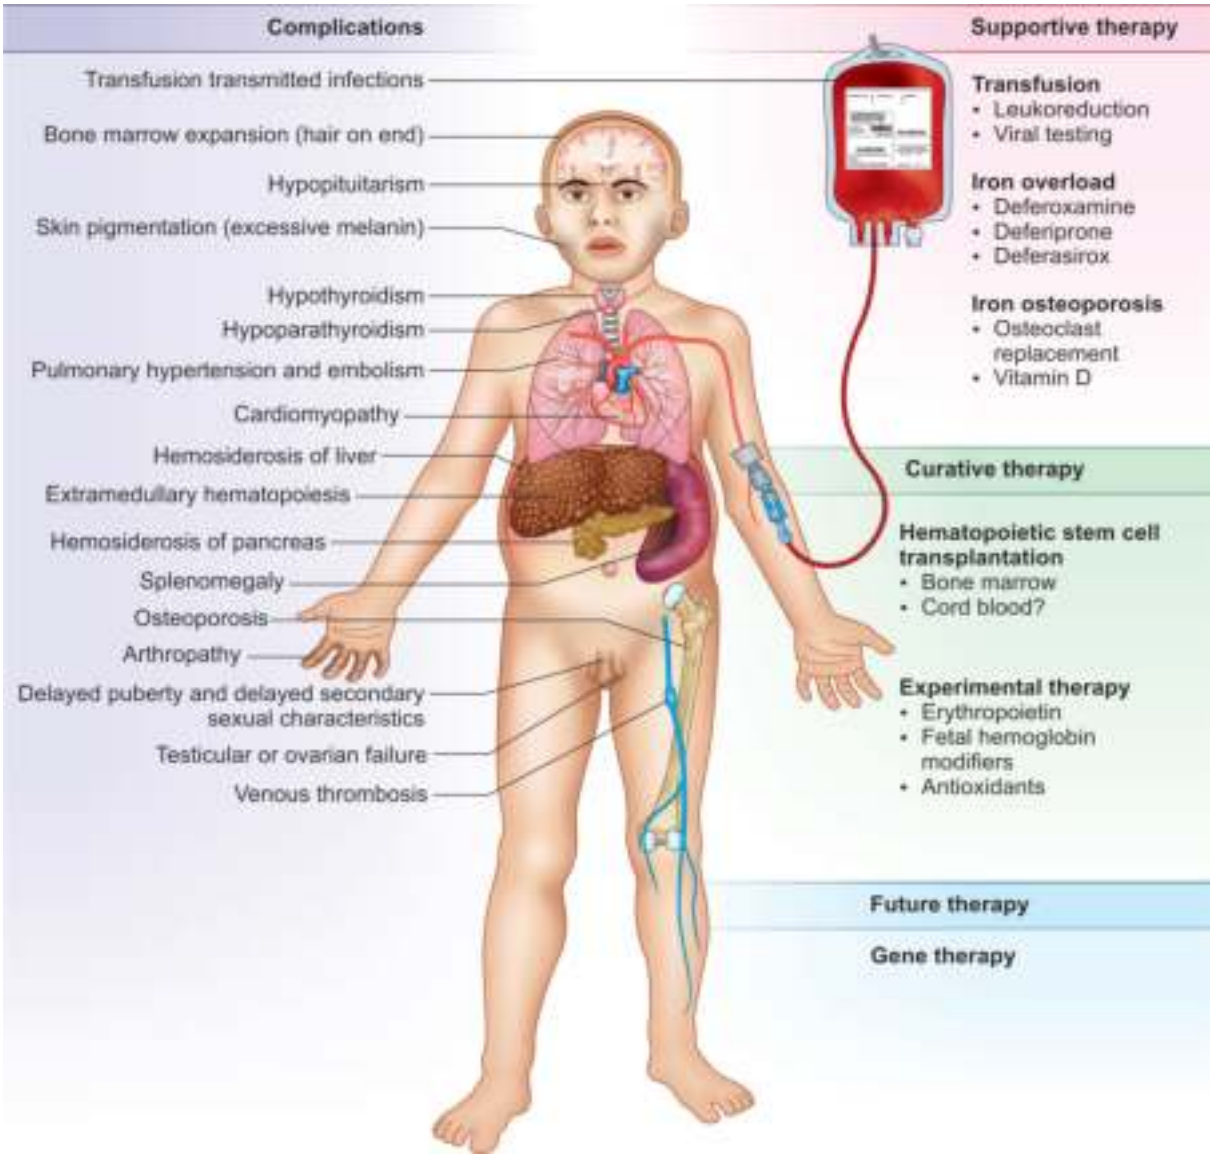

Fig. 8.35: Clinical features of β-thalassemia major.

Failure to Thrive

If untreated, the β-thalassemia major often results in failure to thrive. Impairment of growth results in short stature, diarrhea and recurrent infections.

Bone Marrow Expansion

Increased oxygen affinity of hemoglobin F (HbF) and the underlying anemia impair oxygen delivery and resulting in marked bone marrow erythroid hyperplasia.

Expansion of bone marrow causes facial and cranial bone deformities resulting in mongoloid face. These bone changes are demonstrated by X-rays in skull, long bones, small bones of hands and feet. Pathological fractures and bone pain may occur.

Marked Splenomegaly

Child develops marked splenomegaly by attaining age of 3 years due to sequestration, intramedullary destruction of red blood cells and extramedullary hematopoiesis.

Hepatomegaly

Child develops moderate to marked hepatomegaly as a result of iron overload and extramedullary hematopoiesis. Excessive absorption of iron due to ineffective erythropoiesis and repeated blood transfusions cause iron overload.

Spinal Cord Compression

Extramedullary hematopoiesis can occur in patients with β-thalassemia major, which can lead to spinal cord compression.

Generalized Hemosiderosis

Excess iron deposition in tissues is a major cause of morbidity and mortality in these patients. Extravascular hemolysis together with repeated blood transfusions creates iron overload. Excessive iron is deposited in bone marrow, liver (Kupffer's cells), myocardium, pituitary gland, hypothalamus, pancreas (islets of Langerhans) and parathyroid glands. Hemochromatosis is rare, if it occurs, patient may develop bronze diabetes comprising of cirrhosis, diabetes mellitus and skin pigmentation.

Septicemia

Septicemia is one of the leading causes of mortality in patients with β-thalassemia major.

Laboratory Diagnosis of β-Thalassemia Major

Hemoglobin

Patient suffers from moderate to severe anemia. Hemoglobin level ranges between 3 and 8 g/dl.

Routine Investigations

Hemoglobin, MCH, MCHC and MCV are decreased. Serum bilirubin is slightly increased. Reticulocyte count is increased. Osmotic fragility is decreased.

Peripheral Blood Smear Examination

Peripheral blood smear findings are shown in Fig. 8.36A and B.

- **RBCs morphology:** RBCs show marked anisocytosis, poikilocytosis with microcytic hypochromic picture.
  - Presence of target cells is characteristic finding.
  - **Basophilic stippling** is constant findings. Normoblasts range between 5 and 40/100 WBCs.
  - There is presence of tear drop cells, inclusion bodies in red blood cells due to aggregation of α-chains, and fragmented red blood cells. Target cells in various disorders are given in Table 8.76.
- **WBCs morphology:** TLC normal or increased. DLC shows slight shift-to-the-left with presence of some myelocytes and metamyelocytes.
- **Platelets:** Platelet count is normal but may be decreased due to sequestration of platelets in cases showing splenomegaly.

Reticulocyte Count

Reticulocyte count is increased 3–10%. Brilliant cresyl blue stain is used for reticulocyte count.

Bone Marrow Smear Examination

Bone marrow of β-thalassemia major is shown in Fig. 8.37A and B.

- **Cellularity:** Bone marrow is hypercellular as a result of erythroid hyperplasia.
- **Erythroid series:** Erythroid hyperplasia with micronormoblastic erythropoiesis (e.g. basophilic and polychromatic normoblasts) is seen.
  - Siderotic nodules are commonly seen in developing normoblasts.
  - Some normoblasts demonstrate dyserythropoiesis with irregular nuclear borders.
- **Myeloid series:** Myeloid precursors are within normal range. Myeloid hyperplasia occurs due to infection.
- **Myeloid–erythroid ratio:** M:E ratio is decreased.
- **Megakaryocytes:** Megakaryocytes are normal.

Bone Marrow Iron

Iron stores are increased in bone marrow due to hemolysis and multiple blood transfusions, demonstrated by Perls reaction/ Prussian blue reaction. Iron study in iron deficiency and β-thalassemia major is given in Table 8.77.

Naked Eye Single Tube Red Cell Osmotic Fragility Test (NESTROFT)

NESTROFT is most common screening test for thalassemia in India and across world. Normal saline (0.35%) is added to the test tube containing blood sample. Keep it for 30 minutes. A plain white paper with a black line is placed behind the test tube. Black line is visible in normal person as a result of hemolysis. On the other hand, black line is not visible in blood sample of thalassemia patient, because red blood cell membranes are relatively stable and resistant to hemolysis.

Fetal Hemoglobin (HbF) Estimation

Fetal hemoglobin is high ranging between 30 and 90% especially in β-thalassemia major estimated by alkali denaturation test. HbF may also be demonstrated by acid elution test. RBCs containing HbF are well stained. Red blood cells containing HbA appear as ghost cells.

Hemoglobin Electrophoresis

Diagnosis of β-thalassemia major is confirmed by hemoglobin electrophoresis with increased level of HbF in range of 30–90%. HbA_2 is also increased in these patients. Synthesis of HbF ($\alpha_2\gamma_2$) continues throughout life even after 6 months of age. The γ-chains combine with α-chains result in formation of fetal hemoglobin. In β-thalassemia, HbF and HbA_2 are present but no HbA.

High Performance Liquid Chromatography (HPLC)

HPLC is one of the commonest laboratory investigations performed for the identification of abnormal hemoglobin.

Molecular Genetic Alterations

DNA analysis is carried out to demonstrate gene mutations.

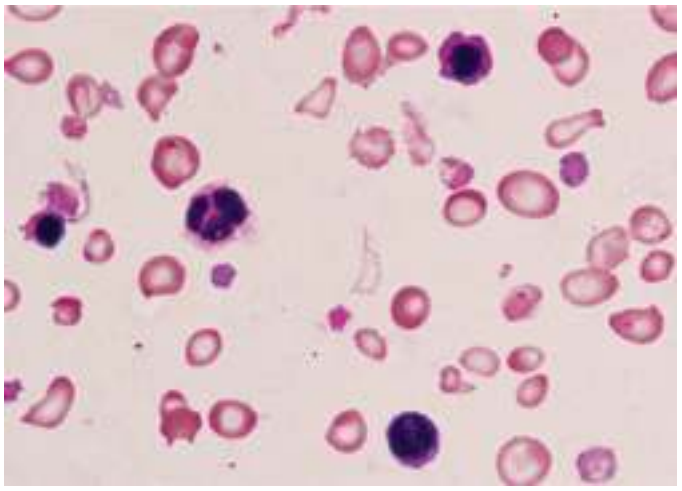

Fig. 8.36A: β-Thalassemia major of peripheral blood smear shows anisopoikilocytosis, many target cells and a few normoblasts.

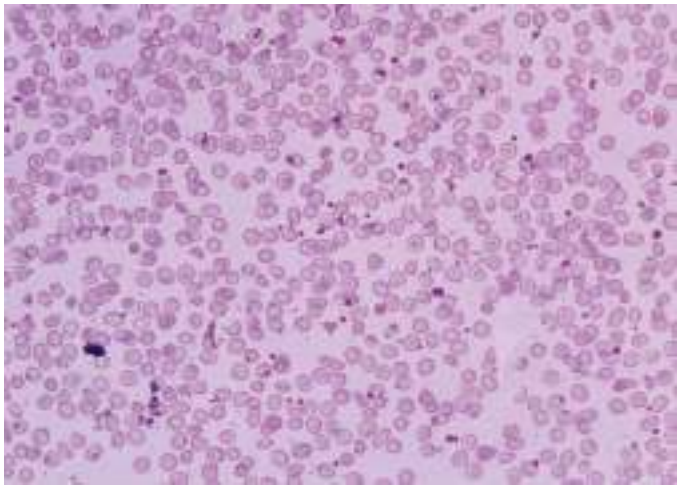

Fig. 8.36B: Peripheral blood smear examination in β-thalassemia major shows anisocytosis and poikilocytosis of red blood cell, microcytic hypochromic picture and numerous target cells.

β-THALASSEMIA MINOR (TRAIT)

In β-thalassemia minor (trait), a single aberrant β-globin gene is present on chromosome 11. The disorder may result in mild anemia, or no anemia at all. Heterozygotes are usually asymptomatic due to sufficient synthesis of β-globin. These patients have protection against malaria. Differences between β-thalassemia minor and iron deficiency anemia are given in Table 8.78.

Table 8.76 Target cells in various disorders

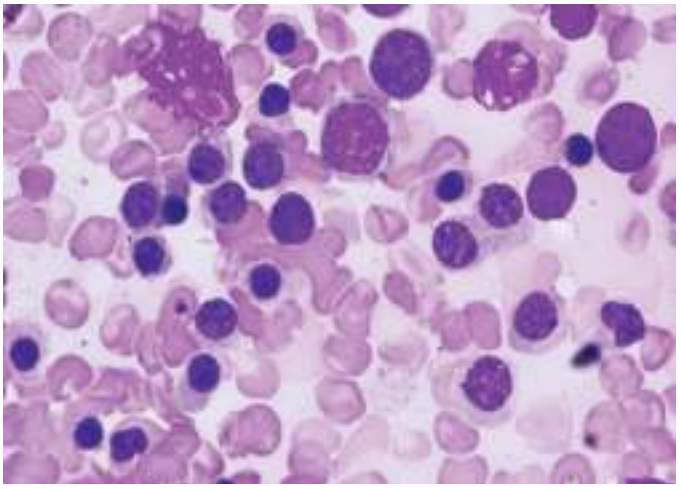

Fig. 8.37A: β-Thalassemia major. Bone marrow shows erythroid hyperplasia. Some normoblasts demonstrate dyserythropoiesis with irregular nuclear borders.

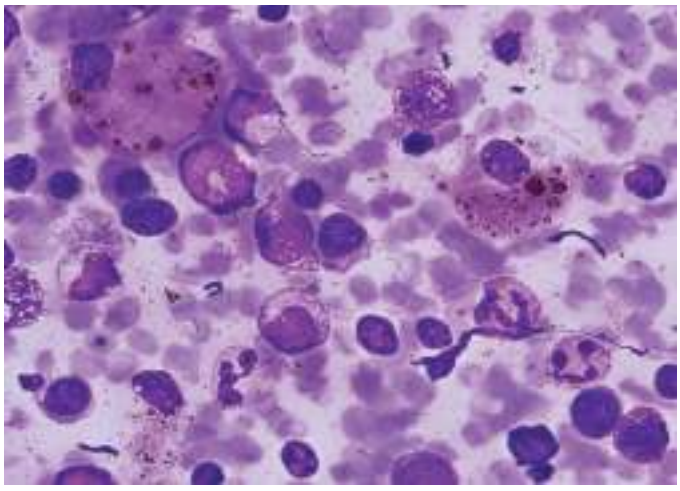

Fig. 8.37B: Bone marrow in β-thalassemia major shows erythroid hyperplasia with decreased myeloid to erythroid ratio. Bone marrow iron is increased. Iron can demonstrated by Perls Prussian blue stain.

Table 8.77 Iron study in iron deficiency and β-thalassemia major

Iron Staudy	Iron Deficiency	β-Thalassemia Major
Serum iron	Decreased	Normal/increased
Serum ferritin	Decreased	Normal/increased
TIBC	Increased	Normal/increased
Percent saturation	Decreased	Increased
Storage iron	Absent	Increased
FEP (free erythrocyte protoporphyrin)	Increased	Normal

Laboratory Diagnosis of β-Thalassemia Minor

- **Peripheral blood smear:** Peripheral blood smear examination shows minimal hypochromic microcytic anemia, target cells, and basophilic stippling.
- **Hematocrit values:** RBCs have reduced MCV and MCH.
- **Hemoglobin electrophoresis:** Increased HbA_2 ($\alpha_2\delta_2$) level between 3 and 6% is diagnostic for β-thalassemia minor. It demonstrates double the normal amount of hemoglobin A_2 ($\alpha_2\delta_2$), about 3–6%, and up to 5% fetal hemoglobin ($\alpha_2\gamma_2$). This finding is useful in distinguishing β-thalassemia minor from iron deficiency anemia and the anemia of chronic disease.

β-THALASSEMIA INTERMEDIA

β-Thalassemia intermedia is of less severity due to sufficient quantity of HbA. Insoluble α-globin chain aggregates are absent. These patients are anemic, who become blood transfusion-dependent later during adulthood.

- Complications of β-thalassemia intermedia are not as severe as for β-thalassemia major. These patients are diagnosed between 15 and 30 years of age. Hemolysis and increased iron absorption result in increased body iron stores.
- β-Thalassemia intermedia is double heterozygotes due to interaction of α, β with HbD, HbE, HbS and HbE.
- The clinical presentation of β-thalassemia intermedia is intermediate between β-thalassemia major and β-thalassemia minor.
- Hemolysis and increased iron absorption result in increased body iron stores.

Clinical Features

Patient presents with pallor, mild to moderate splenomegaly, skeleton changes (many cases), leg ulcers and infections.

Laboratory Diagnosis of β-Thalassemia Intermedia

- **Peripheral blood smear:** Peripheral blood smear shows microcytic hypochromic anemia, moderate degree of anisocytosis, poikilocytosis, target cells and tear drop cells.
- **Hemoglobin and hematocrit values:** Hemoglobin varies between 7 and 10 g/dl. MVC, MCH, and MCHC are decreased.
- **Bone marrow:** Bone marrow examination shows erythroid hyperplasia with increased iron stores.
- **Fetal hemoglobin:** HbF ranges between 10 and 30% in comparison to thalassemia major with HbF 40–90% (usually >90%).

α-THALASSEMIAS

α-Thalassemia is caused by α-globin gene deletion, which results in reduced or absent synthesis of α-globulin chains. Alpha-globin gene consists of 4 alleles and disease severity ranges from mild to severe disorders depending on the number of deletions of the alleles. Four alleles deletion is most severe disorder in which no α-globins are synthesized and the excess γ-chains form tetramers during intrauterine.

Table 8.78 Differences between β-thalassemia minor and iron deficiency anemia

Parameters	β-Thalassemia Minor	Iron Deficiency Anemia
Peripheral blood smear examination	Microcytic hypochromic picture	Microcytic hypochromic picture
RDW	Normal	Increased
Mentzer's index calculated by dividing MCV by RBCs	<13	>13

It is incompatible with life and results in hydrops fetalis. One allele deletion is the mildest form and is mostly clinically silent.

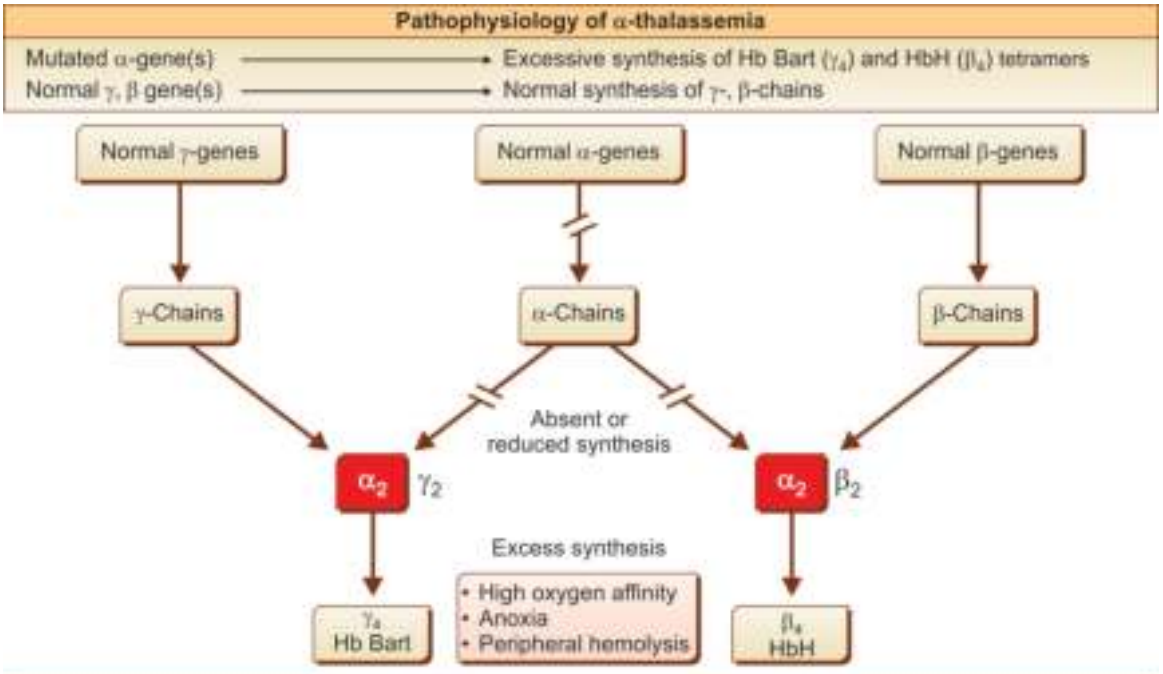
- α-Thalassemias are most common disorders in South-East Asia. Deletions of single or more α-globin genes on chromosome 16 result in reduced or deficient synthesis of α-globin.
- Clinical manifestations occur due to imbalanced synthesis of α- and non-α-chains such as γ-chain during infancy and β- and δ-chains at 6 months of age. Pathogenesis of α-thalassemia is shown in Fig. 8.38.
- α-Thalassemias are classified on the basis of the number and position of the α-globin genes deletion: silent carrier, α-thalassemia trait, hemoglobin H disease (β_4) and hydrops fetalis.

SILENT CARRIER OF α-THALASSEMIA

Silent carrier of α-thalassemia occurs due to deletion of single α-gene on chromosome 16. These silent carrier of α-thalassemia patients are asymptomatic without development of anemia.

α-THALASSEMIA TRAIT

α-Thalassemia trait occurs due to deletion of two α-genes on chromosome 16 (Asians) or two α-genes (one each on chromosome) in Africans. Peripheral blood smear examination shows absence or minimal anemia, and some microcytic red blood cells. These patients are asymptomatic without physical signs, and clinical findings remain identical to β-thalassemia minor showing microcytic hypochromic picture.



α-Thalassemia syndrome	Hematologic findings	Electrophoresis findings
Silent carrier (–α/αα) one gene deletion	No anemia or microcytosis	1–2% Hb Bart (γ_4) tetramers
Thalassemia trait (–α/–α) two genes deletion	Mild anemia and microcytosis	3–10% Hb Bart
HbH disease (–/–α) three genes deletion	Moderate microcytic, hypochromic hemolytic anemia and increased reticulocytes	20–40% Hb Bart
Hb Bart's hydrops syndrome (–/–) four genes deletion	Severe microcytic hypochromic anemia (lethal)	80% Hb Bart, 20% HbH (β_4) tetramers

Where αα/αα is normal (that is, 4 α-genes) and –α represents deletion of one α-gene on a chromosome
Only three genes deletion α-thalassemia has high reticulocytes

Fig. 8.38: Pathogenesis of α-thalassemia

HEMOGLOBIN H DISEASE (β_4)

Hemoglobin H disease occurs due to deletion of three α-genes on chromosome 16, which leads to formation of unstable tetramers of β-globin (β_4) known as HbH. These unstable tetramers are nonfunctional in oxygen transport, so anemia is disproportionate to hemoglobin level. Patient presents with moderate hemolytic anemia, which resembles β-thalassemia intermedia.

Laboratory Diagnosis of Hemoglobin H Disease

- Hemoglobin level is decreased.
- Peripheral blood smear examination shows microcytic hypochromic picture, target cells and Heinz bodies with anisocytosis and poikilocytosis.
- Hematocrit values (MCV, MCH, and MCHC) are decreased. Reticulocyte count is increased.

HYDROPS FETALIS

Hydrops fetalis disorder occurs due to deletion of all four α-globin chains. Due to absence of α-chains, fetus synthesizes excess of γ-globin chains forming tetramers known as hemoglobin Bart (γ_4). During intrauterine life, hemoglobin Bart (γ_4) is unable to deliver the oxygen to tissues. Without intrauterine transfusions, the fetus invariably dies. Newborn is either stillborn or death occurs immediately after birth due to pulmonary hypoplasia or cardiac failure. Hydrops fetalis, the most common, occurs in persons of South-East Asian ancestry.

Clinical Features

In hydrops fetalis, fetus shows pallor, generalized edema and massive hepatosplenomegaly.

Laboratory Diagnosis of Hydrops Fetalis

- **Peripheral blood smear:** Peripheral blood smear examination shows macrocytic hypochromic anemia, marked anisocytosis, poikilocytosis, with numerous normoblasts. MCV is more than 110 femtoliter. MCH is decreased.
- **Reticulocyte count:** Reticulocyte count is increased.
- **Hemoglobin electrophoresis:** Hemoglobin electrophoresis will reveal affected fetuses or neonates to have about 80% hemoglobin Bart (γ_4, a tetramer of γ-chains) and about 20% hemoglobin Portland ($\gamma_2\zeta_2$) or sometimes hemoglobin Gower 1 ($\zeta_2\varepsilon_2$) normally present only in embryonic life in the first trimester. There is absence of adult hemoglobin.

HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN

Hereditary persistence of fetal hemoglobin (HPFH) is characterized by continuous synthesis of fetal hemoglobin (HbF) in significant quantity since postnatal to adulthood life due to mutation of β-globin gene cluster. Fetal hemoglobin concentration ranges between 10 and 100%. These patients are most often asymptomatic and detected during screening.

SICKLE CELL DISORDERS AND OTHER HEMOGLOBINOPATHIES

Every person has combination of 2α genes and 2β genes responsible for adult hemoglobin A (HbA) synthesis.

- Persons having one normal adult hemoglobin A (HbA) gene and one sickle (HbS) gene known as heterozygous (sickle cell trait) having HbA (60%) and HbS (20–40%). These patients remain asymptomatic because sufficient HbA prevents polymerization of HbS.
- Persons having both sickle cell genes are known as *homozygous*. Such person has 85–95% of HbS. Sickle cells are demonstrated in the peripheral blood smear in sickle cell anemia in contrast to sickle cell trait. Double heterozygote state occurs as a result of interaction of HbS with thalassemia (α, β), HbC, HbD and HbE. Sickle cell disorders are given in Table 8.79.
- Structural gene mutations involving β-globin chain in HbS, HbC, HbD, HbE and α-globin chain in HbG are given in Table 8.80.

Table 8.79 Sickle cell disorders

HbSS (sickle cell anemia)	HbS/C-Harlem
HbSC disease	HbS/S Antilles
HbS/B^+ thalassemia	HbS/Lepore
HbS/B^0 thalassemia	HbC/C-Harlem
HbSD disease	HbS-Antilles (heterozygous)
HbSO-Arab	HbS-Oman (heterozygous)

- Sickle cell disease (homozygous HbS) and sickle cell trait (HbA and HbS) are given in Table 8.81.

SICKLE CELL DISEASE

Sickle cell disease is an autosomal recessive disorder, which most often affects African and Mediterranean populations. Approximately 7% of African Americans

Table 8.80 Structural gene mutations involving β-globin chain in HbS, HbC, HbD, HbE and α-globin chain in HbG

Disorder	Globin Gene Mutation and Inheritance	RBC Morphology	Laboratory Diagnosis
Sickle cell disease (HS)	▪ Change in 6th amino acid of the β-globin chain from glutamate to valine (β_6 glutamine → valine) ▪ Hemoglobin S trait (A/S) ▪ Hemoglobin S disease (S/S)	Sickle cells in peripheral blood smear	Hemoglobin electrophoresis
Hemoglobin C (HbC) disease	▪ Change in 6th amino acid of the β-globin chain from glutamate to valine (β_6 glutamine → lysine) ▪ Hemoglobin C trait (A/C) ▪ Hemoglobin C disease (C/C)	Target cells in peripheral blood smear	Hemoglobin electrophoresis
Hemoglobin D (HbD) disease (affects East Indian population)	Change in 121st amino acid of the β-globin chain from glutamate to glutamine (β_{121} glutamine → glutamine)	Mild hemolytic anemia	Hemoglobin electrophoresis (HbD migrates with HbS at pH 8.6)
Hemoglobin E (HbE) disease (affects South-East Asian population)	▪ Change in 26th amino acid of the β-globin chain from glutamate to lysine (β_{26} glutamine → lysine) ▪ Hemoglobin E trait (A/E) ▪ Hemoglobin E disease (E/E)	Microcytic hypochromic picture	Hemoglobin electrophoresis (HbE migrates with HbC and HbA_2 at pH 8.6)
Hemoglobin G (HbG) disease	Change in 68th amino acid of the α-globin chain from asparagine to lysine (α_{68} asparagine → lysine)	Mild hemolytic anemia	Hemoglobin electrophoresis

Table 8.81 Sickle cell disease (homozygous HbS) and sickle cell trait (HbA and HbS)

Sickle Cell disease (Homozygous HbS)	Sickle Cell Trait (HbA and HbS)
Red blood cells contain ≥80% HbS (rest is fetal hemoglobin)	Red blood cells contain <50% of HbS and rest HbA
Sickled red blood cells may be present in peripheral blood film: Sickling occurs at oxygen tension found in venous blood; cyclic sickling episodes	Renal papillary necrosis may occur in occasional case
Reticulocytes: Raised to 10–20%	Older persons are unable to concentrate urine
Variable hemolysis	Red blood cells do not sickle unless oxygen saturation <40% (rarely reached in venous blood)
Hand and foot syndrome (dactylitis)	Painful crises and splenic infarction have been reported in severe hypoxia such as unpressurized aircraft, anesthesia
Intermittent episodes characterized by bone pain, worsening anemia, or pulmonary or neurological disease	Sickling is more severe where HbS is present with another β-globin chain abnormality—such as HbS and HbC (HbSC) or HbS and HbD (HbSD)
Chronic leg ulcers common	Chronic leg ulcers absent
Gallbladder stones	Present

carry the hemoglobin S gene, which confers resistance to *Plasmodium falciparum* malarial infection. Prenatal diagnosis of HbS can be performed on amniotic cells or on chorionic villus samples. Hemoglobin percentage in normal adult person is given in Table 8.82.

Table 8.82 Hemoglobin percentage in normal adult person

Hemoglobin Type	Chains	Percentage
Hemoglobin A	$\alpha_2\beta_2$	97%
Hemoglobin A_2	$\alpha_2\delta_2$	1–3%
Hemoglobin F	$\alpha_2\gamma_2$	<1%

BASIC GENETIC DEFECT IN SICKLE CELL DISEASE

Sickle cell disease occurs due to partial missense point mutation in codon 6 of the **β**-globin gene resulting in substitution of valine for glutamic acid in the **β**-globin gene (Fig. 8.39A and B). Consequently, sickle cell hemoglobin (HbS) replaces normal adult HbA in the red blood cells. HbS causes polymerization of hemoglobin leading to formation of needle-like insoluble crystals within RBCs. Therefore, RBCs take shape of crescentic or holly leaf-like or boat shape, which are called sickle cells or drepanocytes. Solubility of HbS is altered by nonpolar (water insoluble) valine without affecting its structure, function and/or stability.

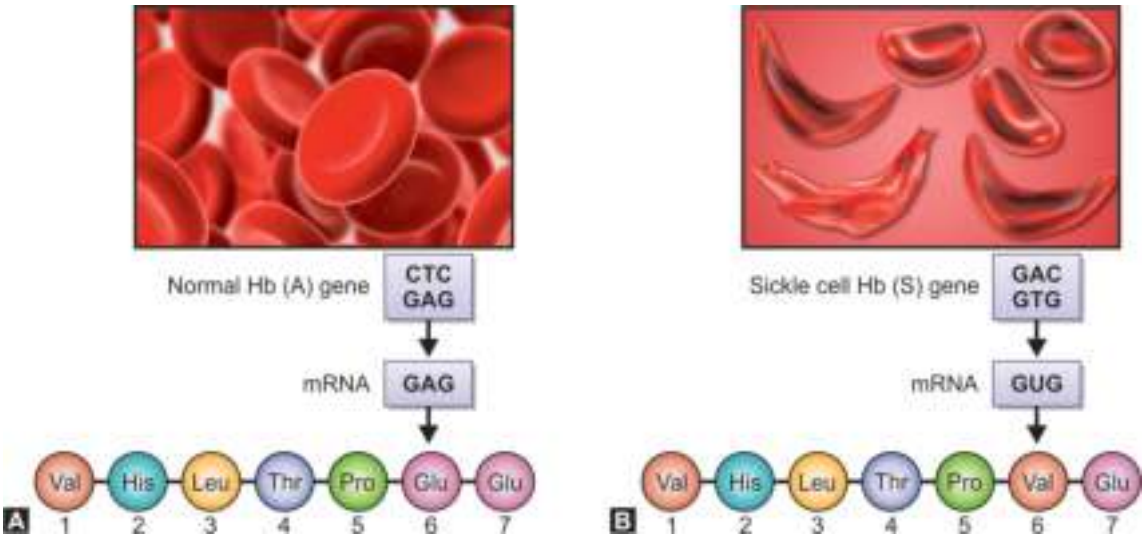


Fig. 8.39: (A) HbA peptide shows synthesis of normal hemoglobin; (B) HbS peptide shows synthesis of HbS as a result of replacement of glutamic acid (polar) by valine (nonpolar) in codon 6 of the β-globin gene.

CLINICAL FEATURES

Systemic complications of sickle cell disease are given in Table 8.83 and clinical features of sickle cell disease are shown in Fig. 8.40.

Severe Hemolytic Anemia

Deoxygenated HbS is 50 times less soluble in blood than deoxygenated HbA.

Table 8.83 Systemic complications of sickle cell disease

Systemic Complications	Comments
Hand and foot syndrome	Hand and foot syndrome occurs in infancy; painful swelling of digits
Painful crisis	Painful crisis occurs later in life, generalized bone pain; precipitated by cold, dehydration, self-limited clinical course over a few days
Aplastic crisis	Bone marrow temporarily becomes hypoplastic and may follow Parvovirus B19 infection, patient has profound anemia and reduced reticulocyte count
Splenic sequestration crisis	Splenic sequestration crisis occurs most often in infancy; progressive anemia; and splenomegaly; later autosplenectomy
Hepatic sequestration crisis	Hepatic sequestration crisis similar to splenic sequestration crisis but with sequestration of red blood cells in liver
Gallbladder stones	Pigment gallbladder stones due to hemolysis
Ischemic retinopathy	Blindness due to occlusion of retinal veins by sickle cells
Brain syndrome	Blockage of cerebral circulation and endothelial damage by sickle cells
Lung syndrome	Blockage of pulmonary circulation and endothelial damage by sickle cells
Renal function impairment	Papillary necrosis occurs due to occlusion of vasa recta by sickle cells
Infections	▪ *Streptococcus pneumoniae* ▪ *Haemophilus influenzae*
Progressive renal failure	Blockage of renal vessels by sickle cells cause progressive renal failure
Recurrent priapism	Blockage of renal vessels by sickle cells
Aseptic necrosis of humerus/femoral head	Occlusion of vessel by sickle cells supplying humerus or femur
Chronic osteomyelitis	*Salmonella typhi* in some cases
Impaired immune system	Autosplenectomy or hyposplenism increases susceptibility to infection
Chronic leg ulcers	Chronic leg ulcers around the malleoli around bilateral ankle joints due to stagnant blood flow due to occlusion of blood vessels by sickle cells
Priapism	Prolonged painful erection of penis due to venous occlusion by sickle cells

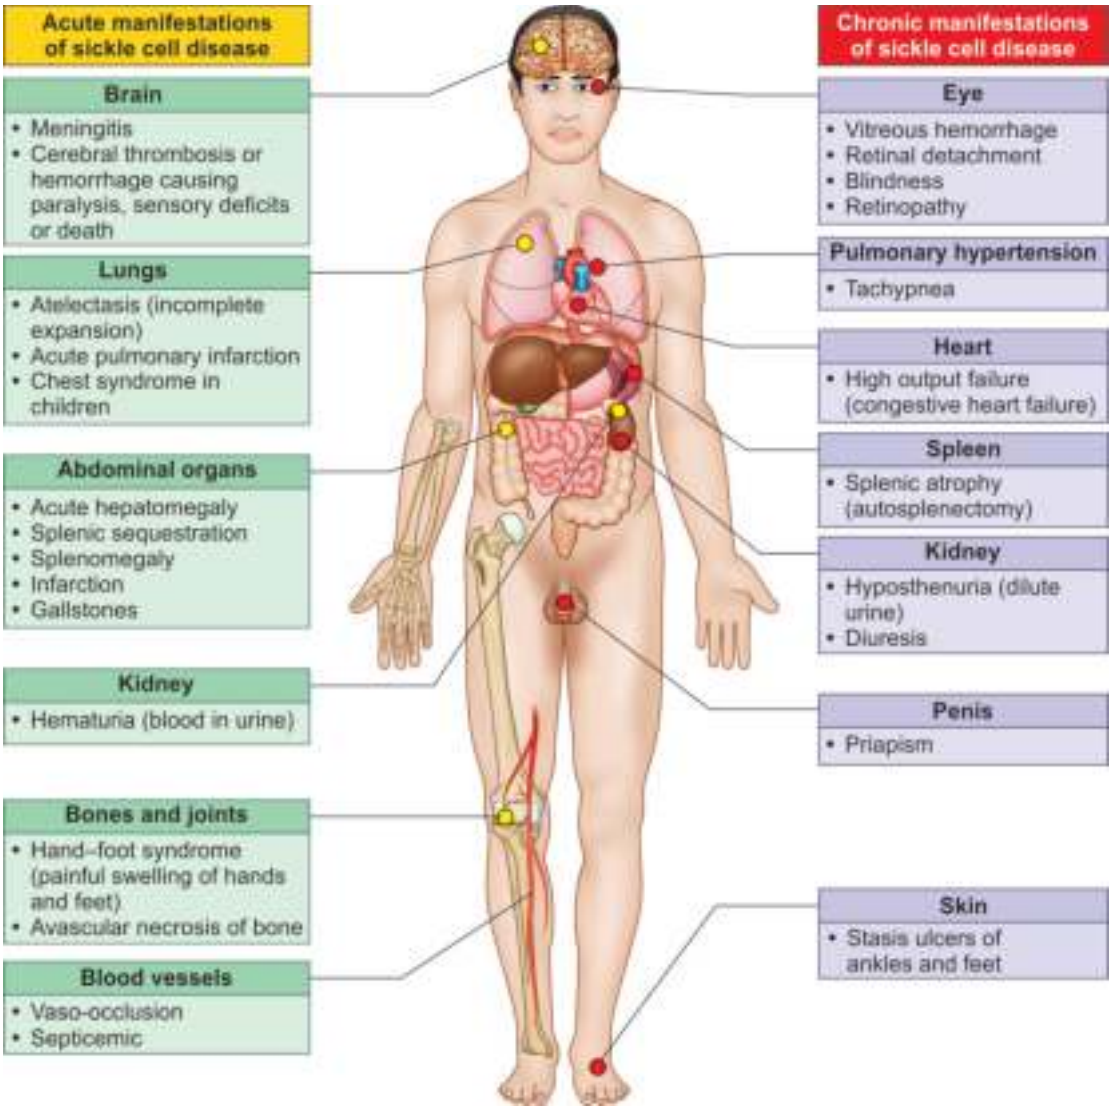

Fig. 8.40: Clinical features of sickle cell disease.

- Under low oxygen tension in capillaries, deoxygenated HbS comes out of solution forming long parallel fibers (needle-like insoluble crystals) called tactoids which distort the red blood cells to assume sickle or crescent shaped.
- Repeated episodes of red blood cell sickling lead to intravascular hemolysis and obstruction of the microvasculature.
- The life span of sickle cell becomes 10–20 days as opposed to a normal life span of red blood cell of 120 days. Sickle cell disease results in chronic hemolytic anemia with hemoglobin of around 5–8 g/dl.

Sickle Cell Crisis

Sickle cell disease leads to cell death and tissue infarction at the site of obstruction, which is termed a sickle cell crisis. Apart from hypoxia, acidosis irrespective of the prevailing oxygen tension is important reason for most sickling of red blood cells occurring in the venous circulation. Therapeutic agent is administered to increase HbF levels in these patients. Sickle cell crises are given in Table 8.84.

Vaso-occlusive Crisis

Vaso-occlusive crisis occurs at about 6 months of age after the reduction in fetal hemoglobin (HbF), which initially acts as a protective mechanism. Vaso-occlusive phenomenon is often precipitated by infection or dehydration. Patient develops infarction of bones, lungs, brain, renal papillae, spleen, and liver resulting in pain lasting for few minutes or several days.

- **Hand and foot syndrome:** Patient develops hand and foot syndrome characterized by dactylitis of small bones of hands and feet in first 2 years of life.

- **Avascular necrosis of femoral head:** Avascular necrosis of the femoral head often occurs in sickle cell patients. Aseptic necrosis is also referred to as osteonecrosis. Pain, tenderness and disability are frequently signs of avascular necrosis of femoral head.
- **Bone and joint crises:** Vascular occlusion of vertebrae, long bones such as femur, tibia, fibula and humerus undergo infarction. This can cause permanent damage to hips, shoulders or knees. Fish mouth vertebrae are demonstrated due to vaso-occlusive phenomenon. Skull shows crewcut appearance on radiographs due to expansion of bone marrow leading to bone resorption and new bone formation.
- **Acute chest syndrome:** Repeated vascular occlusive episodes result in pulmonary infarction and impaired lung functions. Patient presents with classical features of the acute chest syndrome characterized by dyspnea, cough, pleuritis (chest pain) and hemoptysis.
- **Renal papillary necrosis:** The relative hypoxia and hyperosmolarity in the renal medulla create an environment for sickling of red blood cells in the vasa recta, which leads to destruction of long loops of Henle resulting in renal papillary necrosis and renal failure. The kidney loses its ability to concentrate urine. Hematuria is also a complicating feature.
- **Priapism:** Prolonged painful penile erection occurs due to venous occlusion as a result of sickling of red blood cells is common, often requiring surgical decompression.
- **Liver manifestations:** Liver becomes congested with sickle cells. The liver is often firm and can become tender. Hepatocellular failure may supervene as a result of multiple infarcts or hemosiderosis from frequent blood transfusions. Patient may develop jaundice (yellow discoloration of sclera) and gall-bladder stones as a consequence of chronic hemolysis.
- **Autosplenectomy:** Spleen becomes congested and enlarged during childhood. Blood circulation in spleen is slow. Deoxygenation promotes sickling of red blood cells resulting in blockage of capillaries in spleen, and thus causing ischemic infarcts. Later, spleen becomes progressively smaller through repeated multiple tiny infarcts and fibrosis resulting in autosplenectomy. In autosplenectomy patients, peripheral blood smear shows numerous target cells, Howell-Jolly bodies, marked anisocytosis, poikilocytosis and thrombocytosis.

Aplastic Crisis

Patients with sickle cell anemia may undergo an aplastic crisis in 80% of cases due to infection of the bone marrow by human Parvovirus B19, which suppresses erythropoiesis leading to precipitous fall in hemoglobin concentration. Bone marrow failure (aplastic crisis) also occurs associated with a high mortality.

Splenic Sequestration Crisis and Autosplenectomy

Splenic sequestration crisis is most severe crisis in infants and children. Sudden pooling of blood in the spleen known as splenic sequestration results in severe anemia, shock, loss of consciousness with fatal outcome.

- Repeated RBCs sickling in spleen impairs blood supply, which results in autosplenectomy. Impairment of the normal function of the spleen increases the risk of infection.
- Patient presents with painful splenomegaly and hypovolemic shock. There is acute fall in hemoglobin usually secondary to infection induced hemolysis or an acute sequestration syndrome in the spleen. Blood transfusion is often essential.
- Gamna-Gandy bodies are demonstrated in the spleen due to organization of splenic hemorrhages. There is deposition of calcium and hemosiderin in Gamna-Gandy bodies.

Table 8.84 Sickle cell crises

Crisis	Comments
Vaso-occlusive crisis	Vaso-occlusive phenomenon in any tissue but especially, bone, chest and abdomen (e.g. splenic infarcts); in cerebral vessels resulting in cerebral stroke
Aplastic crisis	Aplastic crisis due to Parvovirus B19 infection
Sequestration crisis	Sequestration crisis especially occurs in infants and young children; massive pooling of red blood cells in spleen and other organs, e.g. liver resulting in precipitous drop in hemoglobin
Hemolytic crisis	Hemolytic crisis further reduces life span of red blood cells resulting in worsening anemia and features of hemolysis
Acute chest syndrome	Chest syndrome characterized by pleuritic pain and fever may mimic pneumonia or pulmonary embolism; progressive respiratory failure

Treatment of sickle cell crises includes vigorous intravenous hydration, adequate analgesia (e.g. intravenous opiates), broad spectrum antibiotics, oxygen therapy and consideration of exchange of blood transfusion.

Chronic Leg Ulcers

Patient of sickle cell disease is susceptible to chronic leg ulcers particularly around the malleoli of ankles and both sides of lower legs due to stagnant blood flow caused by sickled red blood cells. The leg ulcers are often complicated by trauma and poor hygiene.

Osteomyelitis

Damage to the spleen with increased susceptibility to bacterial infections occurs with age. Patient with autosplenectomy is prone to Salmonella infections. Salmonella is most often implicated in osteomyelitis.

Lobar Pneumonia and Meningitis

Lobar pneumonia is extremely common in children with sickle cell anemia. Patient with poor functioning of spleen is prone to *Streptococcus pneumoniae* infection. These children frequently develop meningitis due to pneumococci and *Haemophilus influenzae* bacteria.

Gallbladder Pigment Stones

Accumulated bilirubin in the liver can concentrate into crystals that build up in the gallbladder resulting in cholelithiasis.

Neurological Manifestations

Acute brain syndrome is rare but serious, complication of sickle cell disease characterized by confusion with variable neurological defects. There is an increased risk of subarachnoid hemorrhage, retinal hemorrhage (partial or complete blindness) and deafness.

Laboratory Diagnosis of Sickle Cell Disease

Following tests are useful to complement the clinical history and examination.

Hemoglobin

Normal hemoglobin level excludes sickle cell disease.

Peripheral Blood Smear Examination

- Person with sickle cell disease has mostly HbS. Peripheral blood smear examination shows sickle cells, some target cells, nucleated red blood cells, Howell-Jolly bodies and sideroblasts.
- Patients with sickle trait are usually fit and healthy. Peripheral blood film may show a few sickle cells in sickle cell trait (Figs 8.41 to 8.44).

Erythrocyte Sedimentation Rate

ESR is most often increased in all anemias in except sickle cell disease. Rouleaux formation does not occur in sickle cell anemia.

Serum Bilirubin

Unconjugated bilirubin may be raised in the blood as a result of the hemolytic anemia.

Sickling Test

- Sickling test is a screening test for sickle cell anemia. Mixing blood with the reducing agent, sodium metabisulphite on a sealed slide, will induce sickling of red blood cells.
- Sickling test is simple and quick. The results can be viewed under light microscope after 20 minutes.
- The sickle cell preparation is positive whenever hemoglobin S is present (e.g. sickle cell anemia, sickle cell trait, sickle C disease, sickle cell thalassemia). Sickling test in sickle cell disease is shown in Fig. 8.45.

High Performance Liquid Chromatography (HPLC)

HPLC is one of the commonest laboratory investigations performed for the identification of globin chain synthesis. It estimates quantity of normal and abnormal hemoglobins. It is the investigation of choice to confirm diagnosis of sickle cell anemia.

Hemoglobin Electrophoresis

- Hemoglobin electrophoresis is the second best method for diagnosing sickle cell disease. HbA moves faster than HbS towards anode.
- HbS moves faster than HbA towards cathode. Formation of 1 band indicates sickle cell anemia. Formation of 2 band is suggestive of sickle cell carrier.
- Hemoglobin moves in the S region on hemoglobin electrophoresis in alkaline pH. HbD, HbG, HbQ India and HB Lepore are also demonstrated in the same S region on hemoglobin electrophoresis. It differentiates between homozygous and heterozygous conditions.
- In the absence of electrophoresis, a positive sickling test associated with normal hemoglobin concentration indicates a patient with sickle cell disease.

Kidney Function Tests

Blood urea, serum creatinine and electrolytes are analyzed to assess renal function to rule out renal papillary necrosis.

Cardiovascular System Evaluation

ECG is performed to look for evidence of cardiac damage.

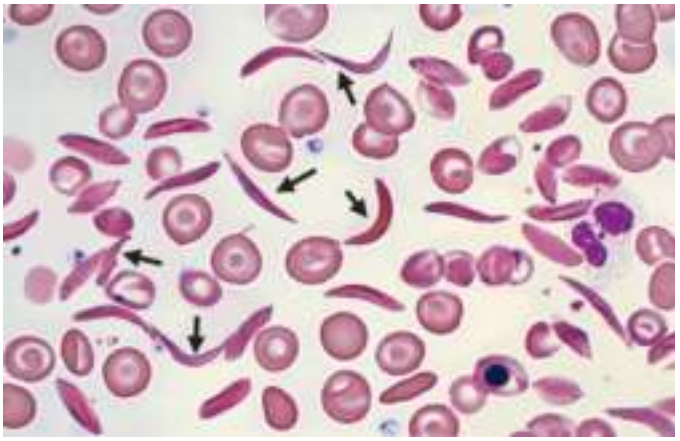

Fig. 8.41: Peripheral blood smear examination shows sickling (arrows).

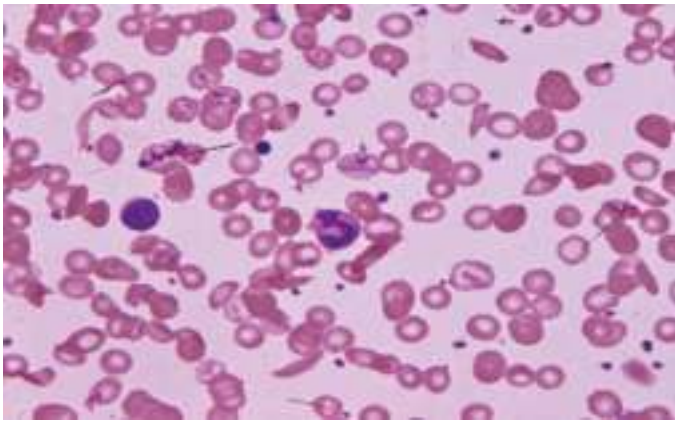

Fig. 8.42: Peripheral blood smear examination shows normocytic normochromic picture and many sickle red blood cells.

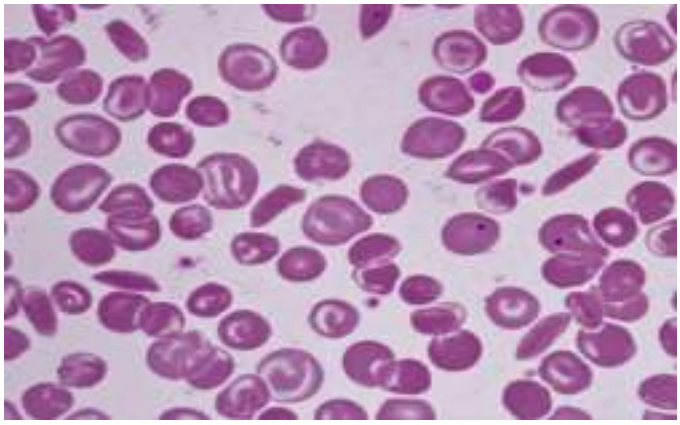

Fig. 8.43: Peripheral blood smear examination shows normocytic normochromic picture. Classic sickle red blood cells are demonstrated.

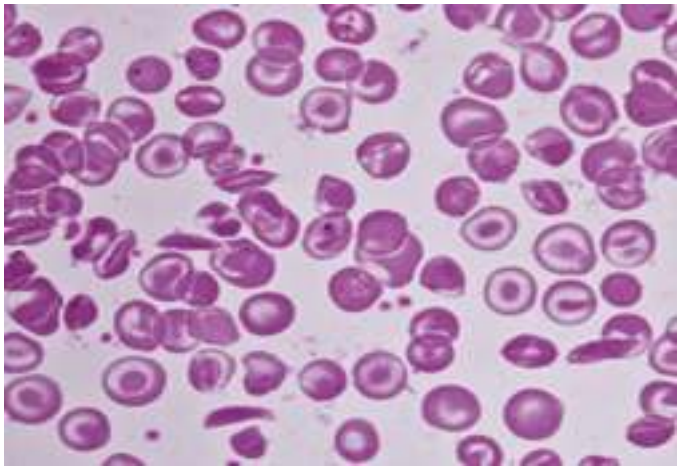

Fig. 8.44: Peripheral blood smear examination shows normocytic normochromic picture and many sickle red blood cells.

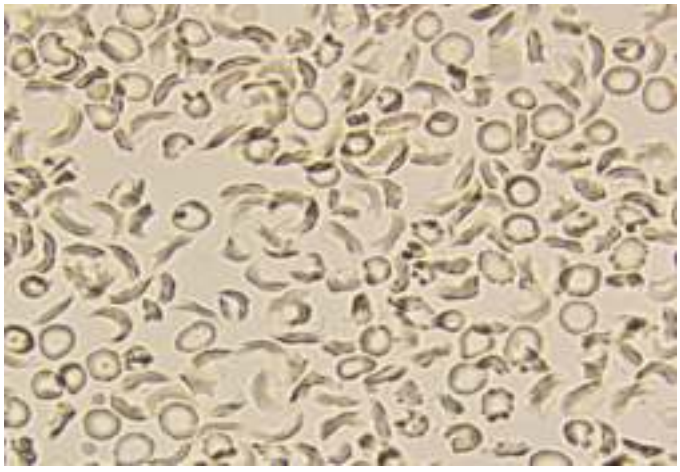

Fig. 8.45: Sickling test in sickle cell disease performed by mixing blood with the reducing agent, sodium metabisulphite on a sealed slide.

SICKLE CELL TRAIT

Sickle cell trait (HbAS) is benign disorder, which shows no hematological manifestations. It is associated with normal growth and life expectancy. It reduces the risk of falciparum malaria.

- Ratio of HbA to HbS is 60:40. Sickle cell trait affects 25–30% of the population in West Africa.
- Patients may have impaired urine concentration ability and hematuria. Pregnant women are at risk of development of urinary tract infection. There is risk of splenic infarction at high altitude and sudden death during exercise. Elevated plasma myeloperoxidase and RBC sickling have been observed during exercise with fluid restriction in sickle celltrait.
- Plasma levels of VCAM-1 are higher following exercise in sickle cell trait suggestive of subtle microcirculatory dysfunction. Anoxia, hyperosmolarity and low pH of the renal medulla predisposes to sickling of RBCs.
- Risk of venous thromboembolism is also increased in these patients.

Laboratory Diagnosis of Sickle Cell Trait

- Sickle cell trait is characterized by a laboratory profile of evidence of hemolytic anemia, hemoglobin between 5 and 11 gm/dl with increase in lactic dehydrogenase (LDH), indirect bilirubin and reticulocyte count, and decrease in plasma haptoglobin. Red blood cell density is increased with normal MCHC. Serum erythropoietin level is decreased.
- Sickle cell trait can be accurately diagnosed by high-performance liquid chromatography (HPLC) and isoelectric focusing. Polymerase chain reaction is the method of choice for prenatal diagnosis.

Peripheral Blood Smear Examination

- Peripheral blood smear examination shows normocytic normochromic picture. A few sickle red blood cells are demonstrated in sickle cell trait disease (Fig. 8.46).
- Elevated neutrophil count is observed in persistent low-grade inflammation.

Bone Marrow Smear Examination

Bone marrow smear examination shows erythroid hyperplasia.

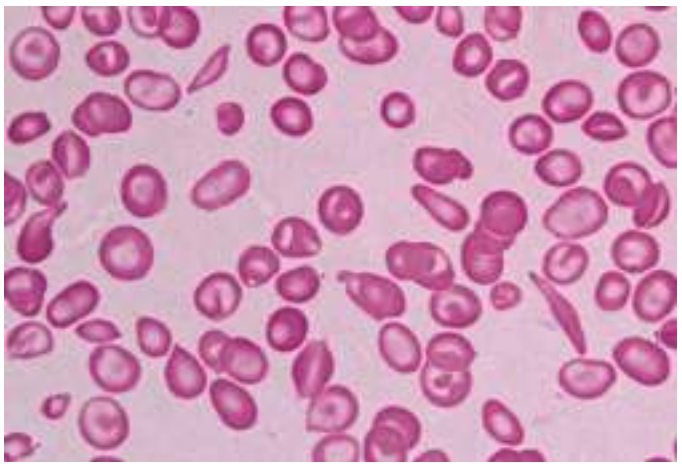

Fig. 8.46: Peripheral blood smear examination shows normocytic normochromic picture. A few sickle red blood cells are demonstrated in sickle cell trait disease.

SICKLE CELL THALASSEMIA SYNDROME

Sickle cell thalassemia syndrome results from coinheritance of hemoglobin S gene and thalassemic variant of the β-globin gene mutation (compound heterozygosity). Its clinical picture resembles thalassemia intermedia. Prognosis is better than sickle cell anemia and thalassemia.

HEMOGLOBIN C DISORDER

Hemoglobin C disorder primarily affects 2–3% of African lineage, which occurs due to point mutation in codon 6 of the β-globin gene on chromosome 11 resulting in substitution of lysine for glutamic acid in the β-globin gene. Consequently, hemoglobin C replaces normal adult hemoglobin (HbA) in the red blood cells. But it does not lead to sickling of red blood cells, but produces target cells.

HOMOZYGOUS HEMOGLOBIN C DISORDER

Homozygous person with mutation of two β-globin genes on chromosome 11 develops clinical manifestations such as anemia varying in severity, episodes of abdominal and joint pain, splenomegaly, and mild jaundice.

Laboratory Diagnosis of Homozygous HbC Disorder

- Serum bilirubin (indirect) concentration is increased.
- Peripheral blood smear examination shows numerous target cells and occasionally elongated hexagonal crystals in red blood cells particularly in splenectomized persons.
- Hemoglobin electrophoresis reveals 80–90% of HbC and 1–7% HbF. When hemoglobin C is present, the amount of hemoglobin A_2 is difficult to assess, as these two hemoglobins are difficult to distinguish by hemoglobin electrophoresis.

HETEROZYGOUS (HbS/HbC) DISORDER

Heterozygous (HbS/HbC) person develops disorder, when HbC and HbS are inherited together. Patients present with complications at about half the rate of patients with homozygous sickle cell disease. The patients are prone to avascular necrosis of the bone and proliferative retinopathy.

HEMOGLOBIN D DISORDER

Hemoglobin D is an autosomal recessive disorder that occurs when a person inherits two genes coding for the hemoglobin D, one from each parent. Parents of the affected children with hemoglobin D are usually not affected and remain healthy carriers. The parents have one copy of the hemoglobin D gene and are said to have hemoglobin D trait.

- Hemoglobin D disorder is seen most frequently among people of Asiatic Indian heritage and European descent: however, anyone can have the disorder.
- Homozygous hemoglobin D does not typically cause clinically significant symptoms. Occasionally, disorder can cause mild hemolytic anemia and mild splenomegaly. Anemia usually occurs in the first few months as fetal hemoglobin decreases (HbF) and hemoglobin D increases.
- Hemoglobin disorder-Punjab becomes significant when it is co-inherited with HbS and β-thalassemia. Genetic counseling is recommended for family planning during future pregnancies.
- Persons with hemoglobin D trait have red blood cells that contain normal hemoglobin A (HbA) more than an abnormal hemoglobin D.
- Hemoglobin D (HbD) trait is inherited from one's parent. If one parent has HbD trait and the other parent has normal hemoglobin, there is 50% chance with each pregnancy of having a child who has HbD trait. There are the possible outcomes of HbD disorder with each pregnancy: 50% of children have HbD trait and rest 50% without HbD trait.

HEMOGLOBIN E DISORDER

Hemoglobin E disorder is prevalent in South-East Asia. Clinical and laboratory manifestations are similar to those of hemoglobin C disorder. HbE disorder occurs due to point mutation in codon 26 of the β-globin gene on chromosome 11 resulting in substitution of lysine for glutamic acid in the β-globin gene. Consequently, hemoglobin E replaces normal adult HbA in the red blood cells. But it does not lead to sickling of red blood cells, but produces microcytosis.

HOMOZYGOUS HEMOGLOBIN E DISORDER

Homozygous HbE disorder in person having mutation of two β-globin genes on chromosome 11 develops mild anemia. Peripheral blood smear examination shows mild microcytic anemia with lower MCV. Hemoglobin electrophoresis demonstrates 90–95% hemoglobin E, 3–5% hemoglobin A_2, and 1–5% hemoglobin F.

HETEROZYGOUS HEMOGLOBIN E DISORDER

Heterozygous HbE disorder in person having mutation of single β-globin gene on chromosome 11 has no clinical manifestations. Peripheral blood smear examination shows microcytes with decreased MCV. Hemoglobin electrophoresis demonstrates 30–40% hemoglobin E and 60–70% hemoglobin A.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY AND PYRUVATE KINASE DEFICIENCY DISORDERS

GLUCOSE-6-PHOSPHATE DEHYDROGENASE (G6PD) DEFICIENCY DISORDER

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an X-linked recessive disorder affecting exclusively males that causes a hemolytic anemia characterized by abnormal sensitivity of red blood cells to oxidative stress (Fig. 8.47).

- Most G6PD deficient persons are clinically well until exposed to excessive oxidant stress induced by ingestion of fava beans and drugs (e.g. primaquine, chloroquine, phenacetin, nitrofurantoin, sulfonamides drugs) and infection (e.g. viral hepatitis, pneumonia and typhoid fever).
- G6PD deficiency disorder is the most common form of enzyme deficiency hemolytic anemia. Major hemolysis is of extravascular type, while minor component as intravascular hemolysis. G6PD should not be assessed during hemolytic episode, because reticulocytes contain normal G6PD. It should be assessed when reticulocyte count is within normal range.
- World Health Organization classification of G6PD deficiency disorder is given in Table 8.85.

EPIDEMIOLOGY

Full expression of G6PD deficiency disorder is seen only in males. Females are being asymptomatic carriers. Affected persons are also more prone to infection.
The highest prevalence of G6PD deficiency disorder is in Africa and the Mediterranean region in 10% of population. G6PD deficiency gives protection against malarial parasitic infection.

PATHOPHYSIOLOGY

Physiologic State

Under physiologic state, G6PD enzyme is involved in the hexose monophosphate shunt pathway. G6PD reduces nicotinamide adenine dinucleotide phosphate (**NADP**) to **NADPH**, which reduces glutathione within RBCs. Reduced glutathione aids in protecting red blood cells against oxidant injury.

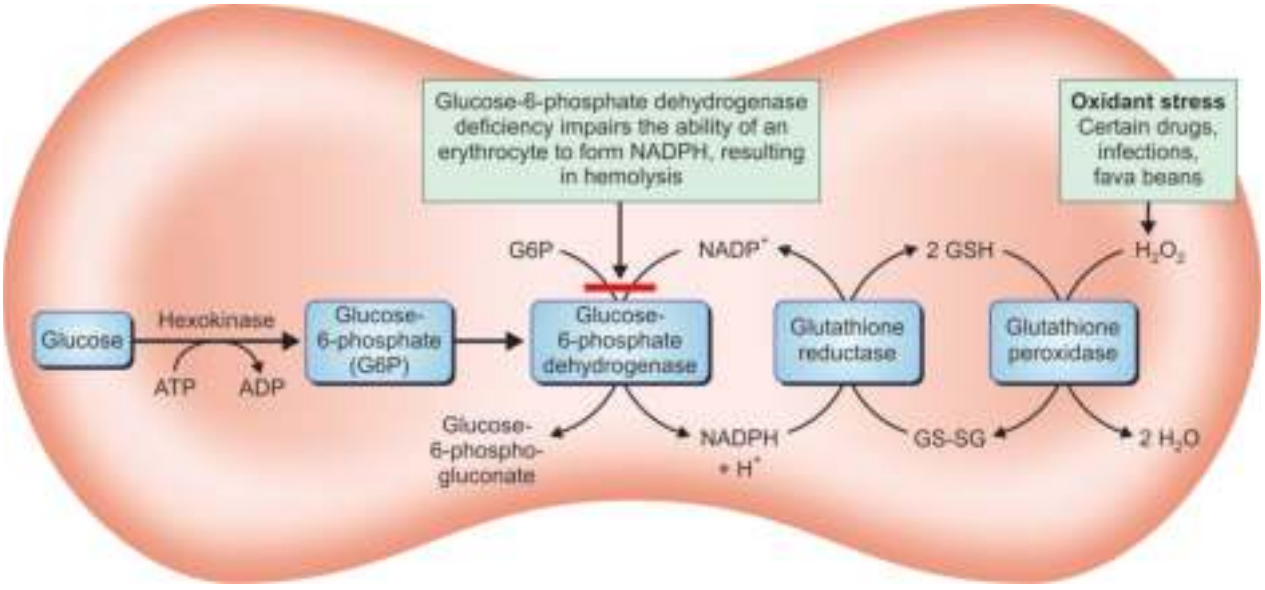

Fig. 8.47: Pathogenesis of glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Table 8.85 World Health Organization classification of G6PD deficiency

Class of G6PD Deficiency Disorder	G6PD Enzyme Activity (% of Normal)	Examples	Clinical Consequences
Class I G6PD deficiency disorder	▪ Severe disease ▪ G6PD activity <2% of normal	Santigo de Cuba (Gly447Arg)	Congenital nonspherocytic hemolytic anemia
Class II G6PD deficiency disorder	G6PD activity <10% of normal	▪ Mediterranean Ser188Phe) Orissa (Ala44Gly)	▪ Favism and drug-induced acute intravascular hemolysis ▪ Neonatal jaundice
Class III G6PD deficiency disorder	G6PD activity >10% and >60% of normal	▪ A (Val68Met) ▪ Asn126Asp	Acute intravascular hemolysis (drug-induced), neonatal jaundice
Class IV G6PD deficiency disorder	G6PD activity 100% of normal	▪ B-Wild type ▪ A (Ana126Asp)	Nonclinical consequences
Class V G6PD deficiency disorder	G6PD activity 150% of normal	▪ B-Wild type ▪ A (Ana126Asp)	Nonclinical consequences

Table 8.86 WHO classification of mutant G6PD isoenzymes

Class	G6PD Deficiency	Hemolysis
I	Severely deficient G6PD seen in African American population (<10%)	Chronic hemolysis is self-limited course because younger RBCs are not affected
II	Mediterranean form with severely deficient G6PD	More severe acute episode of hemolysis. Patients are protective against *Plasmodium falciparum*
III	Mild to moderate deficient (10–60%)	Acute hemolysis (episodic)
IV	Mild to normal deficient	Hemolysis absent
V	Increased G6PD	Hemolysis absent

Pathologic State

- **Gene mutations:** Red blood cells deficient in G6PD are less resistant to oxidant injury.
  - Mutant gene on X chromosome results in either impaired G6PD enzyme synthesis or impaired enzyme stability due to loss of normal folding of G6PD proteins. The unfolding form of G6PD proteins undergo proteolytic degradation.
  - Any exposure to oxidants results in hemolysis, which mainly occurs in the older red blood cells due to reduced amount of G6PD, hence prone to hemolysis. WHO classification of mutant G6PD isoenzymes is given in Table 8.86.
- **Oxidant stress:** Under oxidant stress, inadequate G6PD activity leads to oxidation of sulfhydryl groups of hemoglobin resulting in precipitation of denatured hemoglobin is known as Heinz bodies.
  - Heinz bodies can cause direct injury to RBCs. Cell rigidity and increased membrane permeability cause erythrocyte injury leading to intravascular and extravascular hemolysis in spleen.
  - Splenic macrophages remove Heinz bodies and form bite cells demonstrated in peripheral blood smear.

CLINICAL FEATURES

Red blood cells are more prone to hemolysis in G6PD deficiency disorder. Patient presents with acute self-limited intravascular hemolytic anemia with intravascular hemoglobinemia and hemoglobinuria caused by oxidative stress. Patient may present with malaise, severe lethargy, nausea, vomiting, abdominal pain, fever with chills. Due to intermittent hemolysis, there is no splenomegaly and cholelithiasis. Characteristic features of hemolytic episode in G6PD deficiency disorder are given in Table 8.87.

Laboratory Diagnosis of G6PD Deficiency Disorder

Peripheral Blood Smear Examination

- Peripheral blood smear examination shows bite cells, Heinz bodies and polychromasia, fragmented RBCs.
- When RBCs containing Heinz bodies pass through the spleen, reticuloendothelial cells of spleen take a bite of red blood cells and remove Heinz bodies and result in formation of bite cells (Fig. 8.48).

Supravital Staining

- Heinz bodies are inclusions of denatured hemoglobin present near red blood cell membrane demonstrated by supravital

staining (brilliant cresyl blue or methylene blue) and not with Romanowsky stains.
- Failure of disposal of oxygen-derived free radicals converts hemoglobin to methemoglobin resulting in condensation to form Heinz bodies.

Fluorescent Spot Test

Principle of the fluorescent spot test is based on generation of NADPH by normal G6PD in the lysate of red blood cells to fluorescence under ultraviolet light. In G6PD deficiency, no fluorescence spot is observed as a result of lack of generation of NADPH.

Reticulocyte Count

Reticulocyte count is increased (8–10%).

Serum Bilirubin

Serum bilirubin is increased (indirect bilirubin) due to hemolysis.

Serum Haptoglobin

- Haptoglobin is α_2 glycoprotein synthesized by liver, which combines with any hemoglobin in plasma and prevents its excretion in urine.
- Haptoglobin–hemoglobin molecule is removed by liver, spleen and bone marrow. Hence, plasma haptoglobin levels are decreased with episode of hemolysis, which come to normal within 3 days.

Serum Lactic Dehydrogenase

Values of plasma lactic dehydrogenase are increased in hemolytic anemia (normal range is 125–270 microliter).

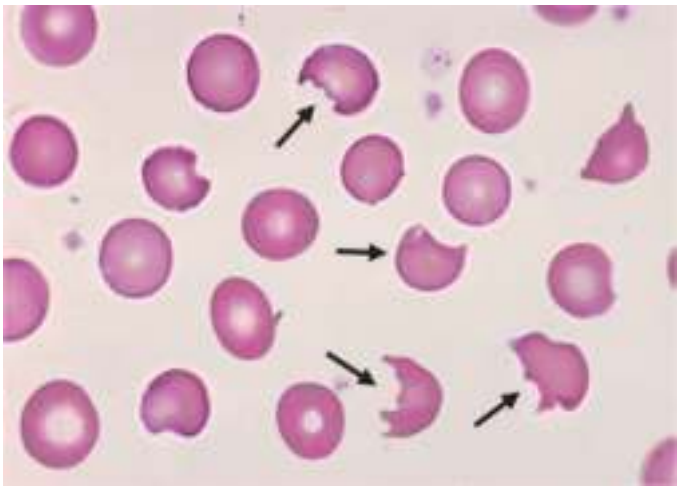

Fig. 8.48: Peripheral blood smear examination shows bite cells (arrows).

PYRUVATE KINASE DEFICIENCY DISORDER

Pyruvate kinase deficiency disorder is the second most common enzyme deficiency hemolytic anemia. Pyruvate kinase deficiency disorder is an autosomal recessive disorder characterized by hereditary nonspherocytic hemolytic anemia. In contrast to the more common G6PD deficiency disorder, in which the anemia is episodic and self-limited, the anemia in pyruvate kinase deficiency disorder is chronic and sustained. Peripheral blood smear examination shows acanthocytes in pyruvate kinase deficiency (Fig. 8.49A and B).

Table 8.87 Characteristic features of hemolytic episode in G6PD deficiency

Clinical Manifestations	Hematologic Findings
Acute phase of hemolysis	
▪ Abrupt onset of jaundice, pallor, malaise and prostration ▪ Abdominal pain, fever and passage of dark-colored urine (hemoglobinuria) and may progress to renal failure	▪ Peripheral blood smear examination shows features of anemia, and Heinz bodies ▪ Reticulocyte count increased and peak level in 5–8 days ▪ Hemoglobinemia ▪ Methemalbuminemia ▪ Hemoglobinuria ▪ Serum bilirubin increased ▪ Serum haptoglobin decreased/absent ▪ Serum creatinine increased ▪ Blood urea increased
Recovery phase	
▪ Gradual but rapid cessation of hemolysis ▪ Urine clears in a few days ▪ Jaundice clears in 1–2 weeks	Concentration of G6PD increases but rarely to normal range

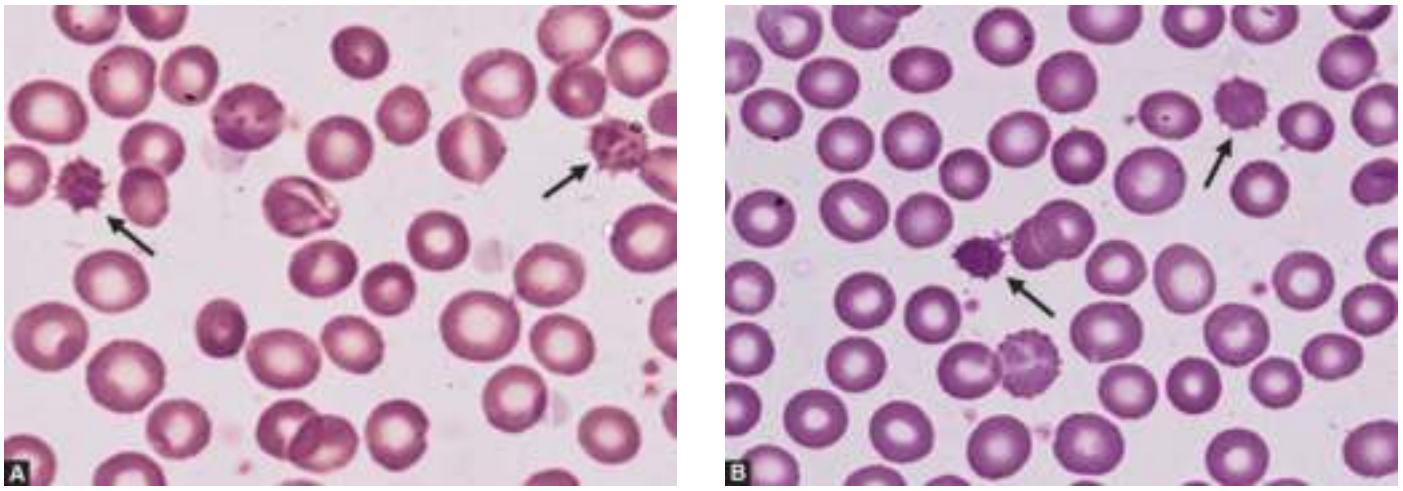

Fig. 8.49A and B: Peripheral blood smear examination shows acanthocytes in pyruvate kinase deficiency (arrows).

IMMUNE-MEDIATED HEMOLYTIC ANEMIA

In immune-mediated hemolytic anemias, hemolysis of red blood cells is mediated by autoantibodies or alloantibodies, which occurs in both intravascular and extravascular compartments. Autoantibodies produced by the patient's immune system are directed against antigens expressed on red blood cells leading to their premature destruction. These patients are diagnosed by demonstration of antibodies and/or complement by Coombs' test. Classification of immune hemolytic anemia is given in Table 8.88.

Table 8.88 Classification of immune hemolytic anemia

Immune Hemolytic Anemia	Mechanism	Causes
Autoimmune hemolytic anemia		
Warm antibody-mediated immune hemolytic anemia	RBCs coated by IgG (most common) or IgM autoantibodies bind to Fc receptors of macrophages in spleen at 37°C leading to RBCs hemolysis in spleen	▪ Primary or idiopathic (50%) ▪ Chronic lymphocytic leukemias ▪ Systemic lupus erythematosus ▪ Viral infections ▪ Drug-induced hemolysis (benzylpenicillin, α-methyldopa and quinidine)
Cold agglutinin disease	IgM class antibody agglutinate RBCs at 0°–4°C (<37°C) leading to extravascular destruction of RBCs in spleen by macrophages	▪ It is primary disorder ▪ Lymphoma-related disorder ▪ *Mycoplasma pneumoniae* ▪ Paroxysmal cold hemoglobinuria ▪ Infectious mononucleosis (EB virus)
Drug-induced (benzylpenicillin) autoimmune hemolytic anemia	Antibodies directed against surface antigens on RBCs. Opsonization and phagocytosis of RBCs and platelets	Benzylpenicillin, cephalosporins and quinidine
Alloimmune hemolytic anemia		
Hemolytic disease of newborn	Antibodies directed against RBCs membrane proteins (Rh blood group antigen, I antigen) leading to opsonization and phagocytosis and destruction of red blood cells in newborn	Hemolytic disease of newborn (rhesus incompatibility)
Hemolytic mismatch blood transfusion	IgG or IgM antibodies attach to the foreign cells of donor, resulting in complement fixation leading to formation of membrane attack complex lysing the donor cells	Hemolytic transfusion reactions

AUTOIMMUNE HEMOLYTIC ANEMIA

Two types of autoantibodies (warm and cold) react with antigens expressed on red blood cells leading to their destruction by spleen.

- Warm autoantibodies (IgG) being active at 37°C bind to antigens expressed on red blood cells without activation of complement system leading to their destruction by splenic macrophages.
- On the other hand, cold autoantibodies (IgM) being active at 30°C bind to antigens expressed on red blood cells and activates complement system leading to RBCs destruction by splenic macrophages. These splenic macrophages possess Fc receptor for Fc fragment of immunoglobulin. Clinical features and laboratory findings in a case of autoimmune hemolytic anemia are given in Table 8.89. Pathogenesis of immune hemolytic anemia is shown in Fig. 8.50.

Pathology Pearls: Autoimmune Hemolytic Anemias

- Warm autoimmune hemolytic anemia (WAIHA) is mediated by IgG autoantibodies that optimally bind red blood cells at body timperature (37°C).
- Cold autoimmune hemolytic anemia (CAIHA), also called cold agglutinin disease, is mediated by IgM autoantibodies that bind red blood cells at lower temperature ranges (<30°C).
- Drug-induced immune hemolytic anemia occurs through several pathophysiologic mechanisms: (a) drug absorption (hapten) induced extravascular hemolysis, (b) immune-complex mediated intravascular hemolysis, and (c) autoimmune hemolytic anemia by drug-induced extravascular hemolysis.
- If a pregnant woman has antibodies against a fetal antigen, the fetus is at risk for hemolytic disease of newborn.

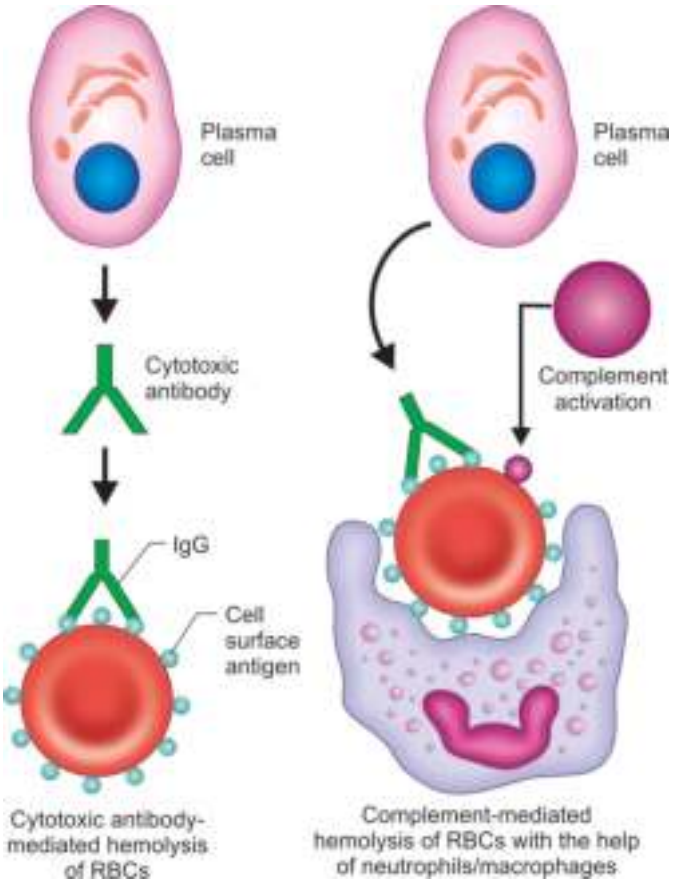

Fig. 8.50: Pathogenesis of immune hemolytic anemia by type 2 hypersensitivity reaction complement-mediated phagocytosis by macrophage resulting in RBCs destruction by spleen.

WARM ANTIBODY-MEDIATED HEMOLYTIC ANEMIA

Warm antibody-mediated hemolytic anemia is the most common form of immune hemolytic anemia. Disorder is mediated by IgG class antibodies that react with red blood cell surface antigens (often Rh antigens) at 37°C. IgM autoantibody is active at 4°C, which becomes less active at higher temperature; but is still

Table 8.89 Clinical features and laboratory findings in a case of autoimmune hemolytic anemia (AIHA)

Parameters	Warm Autoimmune Hemolytic Anemia (AIHA)	Cold Autoimmune Hemolytic Anemia (AIHA)
Onset of disease	Sudden onset	Gradual onset
Jaundice	Present	Usually absent
Splenomegaly	Present	Absent
Immunoglobulin-mediated	IgG-mediated AIHA (rarely IgM or IgA)	IgM-mediated (except PCH-IgG)
Temperature at which antibody reacts	Antibody reacts at 37°C	Antibody reacts below 30°C
Red blood cells morphology	Spherocytes	Agglutinated RBCs
Clinical association	Usually associated with autoimmune disorders	Usually due to infections
Direct antiglobulin test (DAT)	IgG-mediated positive test	C3-mediated positive test
Mechanism of hemolysis	Extravascular hemolysis by reticuloendothelial system	Intravascular hemolysis mediated by complement system

able to bind complement and agglutinate red blood cells at 30°C temperature of the peripheral tissues (e.g. hands, feet, nose and ears). Sometimes, disorder is mediated by IgA.

Pathophysiology

Immune-mediated hemolytic anemia disorder is idiopathic (primary) in majority of patients. Secondary immune-mediated hemolytic anemia is associated with systemic lupus erythematosus, rheumatoid arthritis, chronic lymphocytic leukemia, Hodgkin disease, or non-Hodgkin lymphoma and drug-induced hypersensitivity.

- RBCs coated by IgG or IgM autoantibodies bind to receptors on macrophages because they have receptors for the Fc fragments of immunoglobulins.
- Once activated, the complement system cascade leads to the destruction of the RBCs through formation of C5b–C9 membrane attack complex (MAC).
- IgM antibodies, which are powerful agglutinins, may agglutinate red blood cells (RBCs) in the red pulp of the spleen, resulting in RBCs destruction. IgM may also activate complement system cascade, resulting in RBCs lysis. Such autoantibodies are detected by Coombs' test (agglutination test).

Clinical Features

Patient presents with progressive anemia, jaundice and mild splenomegaly. History of drug intake such as benzylpenicillin, cephalosporins, methyldopa and quinidine should be taken into consideration.

Laboratory Diagnosis of Warm Antibody-mediated Hemolytic Anemia
Hemoglobin
Hemoglobin and PCV become low.
Peripheral Blood Smear Examination
Peripheral blood smear examination shows polychromasia and spherocytes due to progressive loss of membrane protein by serial passage of antibody-coated red cells through the spleen (Fig. 8.51).
Reticulocyte Count
Reticulocyte count is increased between 5 and 20%. Higher reticulocyte count is demonstrated in acute hemolytic process.
Serum Bilirubin
There is mild to moderate increase in unconjugated serum bilirubin.
Serum Lactic Dehydrogenase (LDH)
Hemolysis of red blood cells increases serum LDH level.
LE Cell Phenomenon
LE cell test is significant in immune hemolytic anemia induced by systemic lupus erythematosus.

Coombs' Test

Positive direct Coombs' test (also known as direct antiglobulin test or DAT) is reflecting the binding of IgG autoantibody to the red cell surface (Table 8.90).

- **Direct Coombs' test (direct antiglobulin test):** In direct Coombs' test, RBCs are coated *in vivo* and washed to remove unbound globulins. Addition of anti-human globulin (AHG) promotes agglutination after centrifugation.
  - Direct Coombs' test (DAT) is performed for the demonstration *in vivo* sensitization of red blood cells with immunoglobulin and/or complement. It can occur after antigen–antibody complexes have been formed in certain diseases such as autoimmune hemolytic anemia or hemolytic disease of the fetus and newborn.
  - Direct Coombs' test (DAT) may also be positive following blood transfusion of antigen-positive, to which the recipient possesses the antibody.
- **Indirect Coombs' test (indirect antiglobulin test):** In indirect Coombs' test (DAT), serum with specific antibody is mixed with reagent red blood cells.
  - Anti-human globulin (AHG) is added to promote agglutination on centrifuge. Indirect antiglobulin test (IAT) is performed for the detection of antibodies of the IgG class. In spin-tube techniques, unbound immunoglobulins or other proteins are washed from the test system and anti-human globulin (AHG) is added to the sensitized red blood cells. During centrifugation, anti-human globulin (AHG) promotes agglutination and thus visible hemagglutination.
  - Indirect antiglobulin test (IAT) is used for identification of antibody in the serum/plasma of a potential transfusion recipient or as part of antenatal testing, to help assess the likelihood of the antibody promoting fetal red blood cell destruction. It can also be used with known antibodies for typing antigens on the red blood cells.

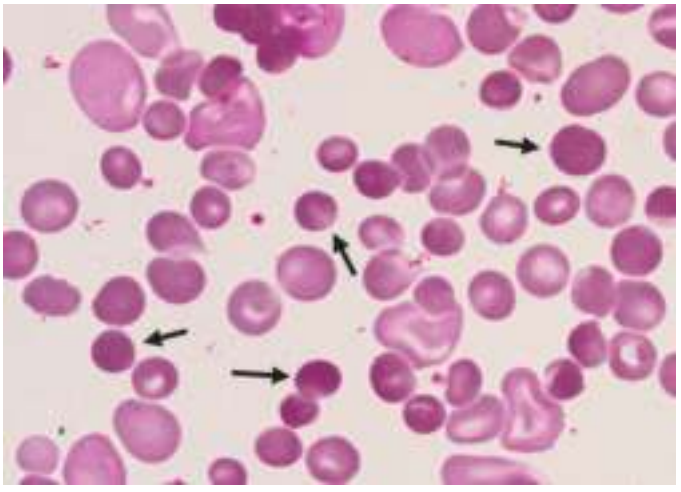

Fig. 8.51: Peripheral blood smear examination from a case of autoimmune hemolytic anemia showing polychromasia and spherocytes (arrows).

Table 8.90 Direct and indirect Coombs' test (Antiglobulin test)

Parameters	Coombs' Test	
	Direct Coombs' Test (Direct Antiglobulin Test)	Indirect Coombs' Test (Indirect Antiglobulin Test)
Principle	Detects antibodies or complement bound to surface of RBCs antigens *in vivo*	Detects *in vitro* antigen–antibody reactions or antibodies in serum
Utility in clinical practice	▪ Immunomediated hemolytic anemia ▪ Drug-induced hemolytic anemia ▪ Hemolytic disease of newborn ▪ ABO hemolytic disease of newborn ▪ Mismatched blood transfusion	▪ Detection of low concentration of antibodies in patient's blood prior to blood transfusion ▪ Detection of antibodies in antenatal women that may cause hemolytic disease of newborn ▪ Compatibility testing in blood banking ▪ RBC phenotyping ▪ Identification of antibody in mother's serum ▪ Titration studies

COLD AGGLUTININ DISEASE

Cold agglutinin disease is caused by IgM antibodies, which agglutinate RBCs at low temperature (0°–4°C). Cold agglutinin disease is mediated by IgM antibodies optimally active at low temperatures at 4°C against the red blood cells I antigen.

- IgM antibodies cause agglutination of red blood cells at low temperature at especially during winter season in the capillaries of nose and fingers.
- Complement coated RBCs are phagocytozed by macrophages in spleen leading to extravascular hemolysis.

Pathophysiology

Cold agglutinin disease disorder occurs due to formation of anti-I antibodies in EB virus associated infectious mononucleosis. These anti-I antibodies frequently complicate *Mycoplasma pneumoniae* infection. This disorder also occurs in patient with HIV infection. Chronic hemolysis may be primary or associated with B cell neoplasms.

Clinical Features

Patient with cold agglutinin disease presents with chronic hemolytic anemia exacerbated by cold weather, episodes of jaundice, sometimes with hemoglobinemia and hemoglobinuria. Disorder has self-limited course, which rarely induces significant extravascular hemolysis.

Laboratory Diagnosis of Cold Agglutinin Disease

Peripheral Blood Smear Examination

- The peripheral blood smear from this patient shows clumped RBCs caused by cold agglutinins during especially winter.
- During winter, it is difficult to prepare peripheral blood smear, because agglutination occurs at low temperature (Fig. 8.52).

Hematocrit Values

MCH and MCHC values are very high due to agglutination of red blood cells. Red blood cell value is very low.

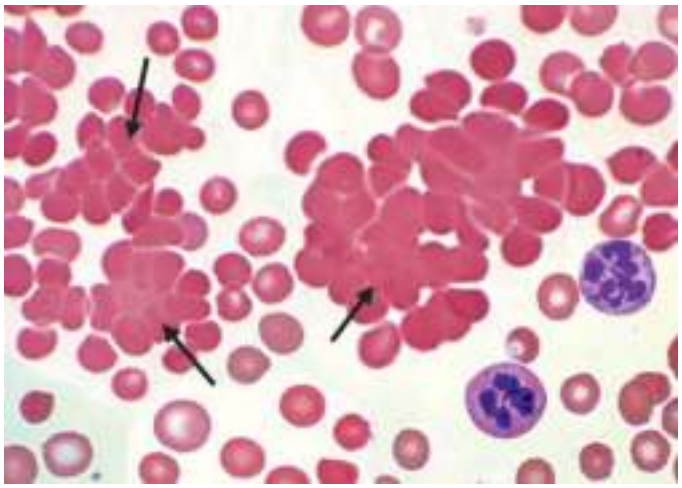

Fig. 8.52: Cold agglutinin disease. Peripheral blood smear examination shows agglutination of red blood cells (arrows).

PAROXYSMAL COLD HEMOGLOBINURIA

Paroxysmal cold hemoglobinuria (PCH) most often occurs in children associated with viral infections. IgG autoantibodies are formed against P antigen on surface of RBCs at low temperature. These antibodies fix complement and induce intravascular hemolysis. IgG antibodies are also known as Donath-Landsteiner antibody.

- **Hemoglobinuria:** Hemoglobin in urine is demonstrated by benzidine test.
- **Hemosiderinuria:** Hemosiderin is demonstrated by Perls Prussian blue reaction.
- **Hemoglobinemia:** Presence of hemoglobin in the plasma gives red discoloration. Hemoglobinemia is demonstrated by hemoglobin blood test.

DRUG-INDUCED HEMOLYTIC ANEMIA

Most antigens have high molecular weight in excess of 10,000. Small molecules cannot act as antigen by

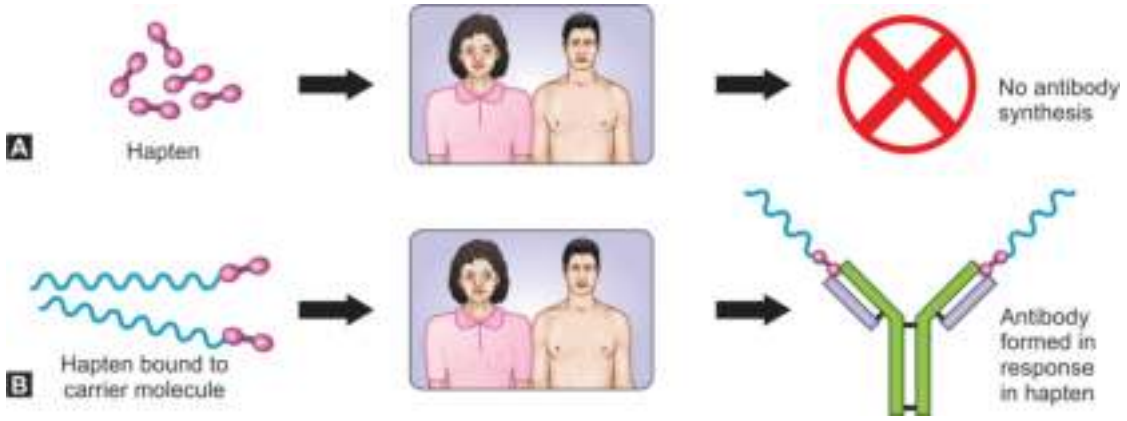

Fig. 8.53: The hapten-carrier phenomenon. (A) Hapten molecule is too small to trigger an immune response, (B) binding of hapten with carrier triggers an immune response.

themselves. Binding of antigen with small carrier hapten molecule, which induces immune response.

- Hapten molecule is too small (MW <1000) to trigger an immune response alone but can be immunogenic when it attaches to a larger carrier molecule such as host serum protein.
- Drug-induced hemolytic anemia occurs by two mechanisms: antigenic drugs and tolerance-breaking drugs. The hapten-carrier phenomenon is shown in Fig. 8.53A and B.
  - Antigenic drugs are benzylpenicillin, cephalosporins and quinidine, which bind to the surface of RBCs leading to formation of antibodies against drug. These antibodies react with drugs and form complex on the surface of RBCs leading to hemolysis.
  - Example of tolerance breaking drug is α-methyldopa drug, which induces antibodies against intrinsic antigens.

ALLOIMMUNE HEMOLYTIC ANEMIA

Alloimmune hemolytic anemia occurs when immune system produces antibodies against foreign or non-self antigens, which include hemolytic disease of newborn and hemolytic blood transfusion reactions.

HEMOLYTIC DISEASE OF NEWBORN

Hemolytic disease of newborn most commonly occurs with Rh blood group incompatibility between mother and fetus. It occurs when the mother is Rh –ve and baby is Rh +ve, having inherited an allele for one of the Rh antigens from the father (Fig. 8.54).

- **During first pregnancy:** At birth, a small quantity of fetal blood usually leaks across the placenta into the maternal bloodstream. Upon exposure to Rh antigen, the mother's immune system responds by making anti-Rh antibodies. Because the baby is already born, it suffers no damage.
- **During subsequent pregnancy:** The maternal antibodies cross the placenta into the fetal blood. If the second fetus is Rh +ve, the ensuring antigen–antibody reaction causes hemolysis of fetal RBCs. The result is hemolytic disease of newborn (HDN).

Clinical Features

Newborn develops anemia, jaundice, hepatosplenomegaly, cardiac failure and kernicterus (staining of the basal ganglion and other structures of CNS by unconjugated bilirubin). Kernicterus with resultant neurological damage is the most significant long-term consequence of hemolytic disease of newborn. In addition, consequences include stillbirth or in hydrops fetalis, fetal heart failure with massive generalized edema.

Management

Administration of anti-D antiserum to D-negative mother at the time of delivery of D-positive child prevents maternal alloimmunization by removing fetal red blood cells from the maternal circulation.

Preventive Measures

Routine administration of anti-D IgG antiserum to D-negative mothers at 28 weeks gestation and at the time of first delivery (or at the time of termination of pregnancy) of D-positive child results in the antibody-mediated removal of fetal red blood cells from

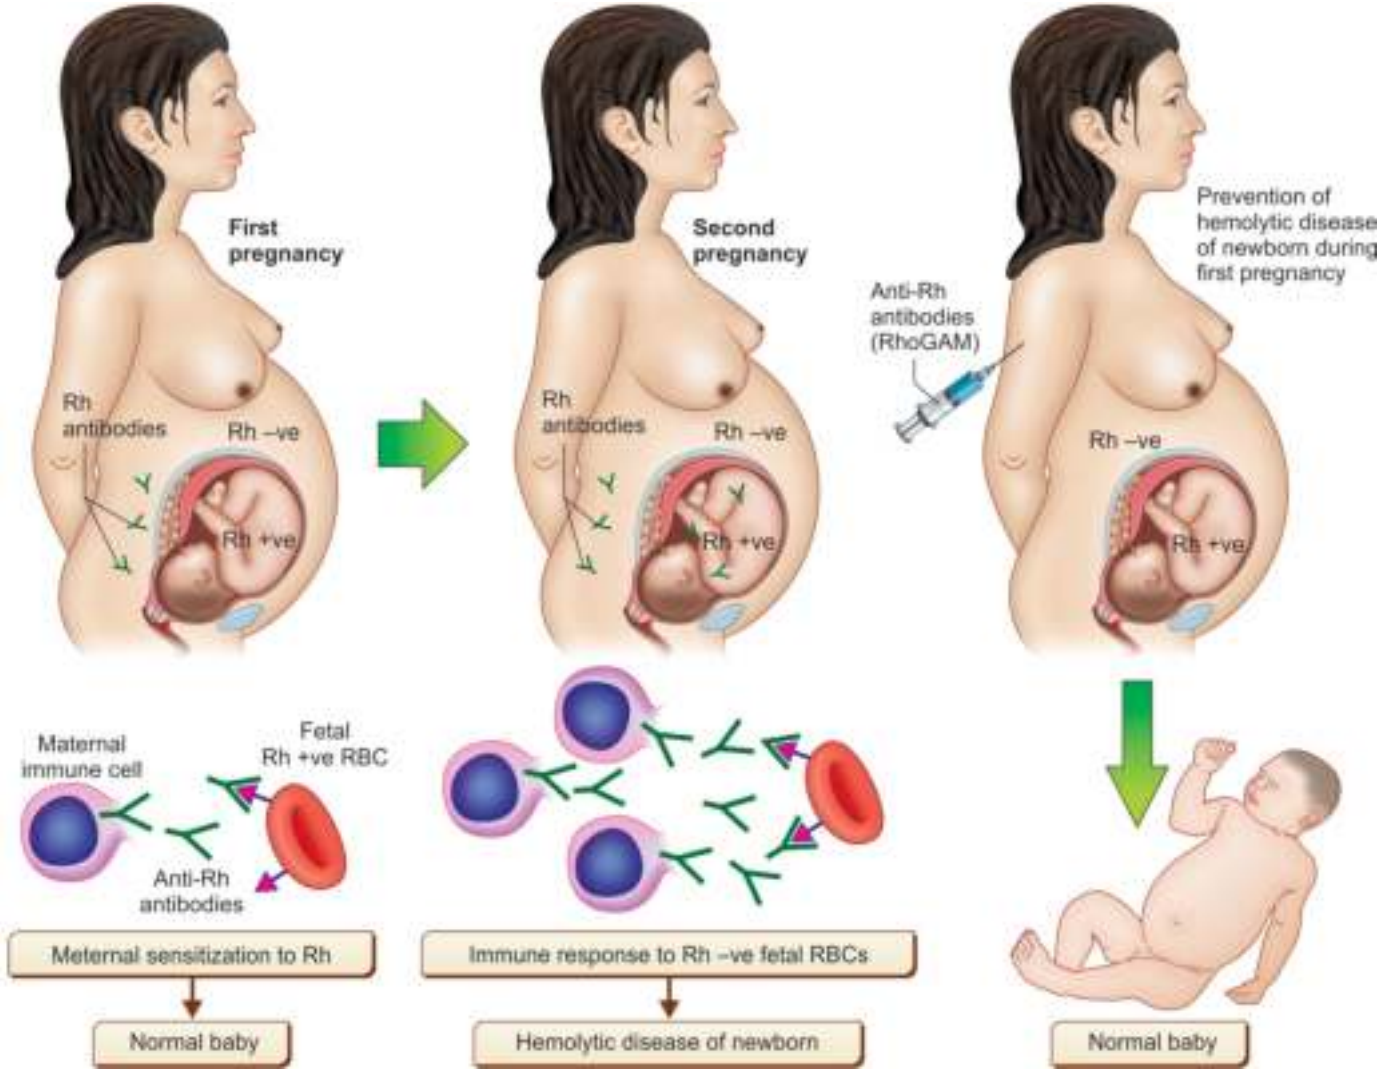

Fig. 8.54: Hemolytic disease of newborn. Rh factor incompatibility can cause lysis of red blood cells. A naturally occurring red blood cell incompatibility results when a fetus Rh +ve develops within Rh –ve mother. Initial sensitization of the maternal immune system occurs when fetal blood passes the placental barrier. In most cases, the fetus develops normally. However, a subsequent pregnancy with Rh +ve fetus results in a severe fetal red blood cells hemolysis. Control of incompatibility is done by administration of anti-Rh antibodies (RhoGAM) to Rh –ve mothers during pregnancy to inactivate and remove any Rh factor that may be transferred from the fetus in maternal circulation. In some cases, anti-Rh antibody (RhoGAM) is administered before sensitization occurs.

the maternal circulation, preventing maternal alloimmunization.

Laboratory Diagnosis of Hemolytic Disease of Newborn

- Hemolytic disease of newborn (HDN) can be diagnosed during pregnancy or after the baby is born by amniocentesis, blood and percutaneous umbilical cord blood sampling to analyze serum bilirubin, anemia, and Rh +ve antibodies (direct antiglobulin test/direct Coombs' test).
- Peripheral blood smear examination shows evidence of hemolysis such as anemia and erythroid percursors.

HEMOLYTIC BLOOD TRANSFUSION REACTIONS

Hemolytic blood transfusion reactions occur immediately or within days of a red blood cell transfusion. The transfusion recipient is exposed to a foreign red blood cell antigen on the donor red blood cells, which stimulates an immune response.

In ABO mismatch blood transfusion, preformed IgM antibodies present in the serum of recipient are active at 37°C. These antibodies and complement coated red blood cells and activate complement system resulting in intravascular hemolysis.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA: OVERVIEW

Paroxysmal nocturnal hemoglobinuria may develop as a primary disorder or evolve from preexisting etiology.

- Paroxysmal nocturnal hemoglobinuria (PNH) occurs due to an acquired (somatic) mutation in the PIG-A gene of a hematopoietic stem cell, the major consequence of which is decreased synthesis of glycosylphosphatidylinositol (GPI) anchor proteins. PNH is characterized by passage of hemoglobin in urine, pancytopenia and mild jaundice due to complement mediated recurrent bouts of intravascular hemolysis.
- During hemolytic episodes, patient develops normocytic or macrocytic anemia accompanied by an appropriate increased reticulocyte response.
- Patient may develop acute myelogenous leukemia (AML), or myelodysplastic syndrome or aplastic anemia.
- Thrombosis in portal and hepatic veins is the most common cause of death in these cases.

PATHOPHYSIOLOGY

Physiologic State

PIG-A gene located on X chromosome encodes GPI (glycosylphosphatidylinositol) anchor regulatory proteins, which bind to various red blood cell membrane proteins like membrane inhibitor of reactive lysis (MIRL) (CD59), decay accelerating factor (DAF) (CD55), CD8, CD14, CD16a and CD52 required for the protection of red blood cells, granulocytes, and platelets from complement-mediated lysis. DAF cleaves C3b. MIRL participates in cleaving C5–C9. These complement regulatory proteins are required for the protection of red blood cells, granulocytes, and platelets from complement-mediated lysis.

Pathologic State

Paroxysmal nocturnal hemoglobinuria occurs due to PIG-A gene located on X chromosome resulting in deficient cytoskeleton anchoring proteins, i.e. GPI (glycosylphosphatidylinositol), MIRL (CD59), DAF (CD55) and CD8, CD16a and CD52.

- Normally, these cytoskeleton anchoring proteins are expressed on red blood cells, granulocytes and platelets from complement-mediated lysis.
- Acidic pH causes uncontrolled activation of complement pathway to form membrane attack complex (C5b–C9), which attacks RBCs, granulocytes and platelets leading to recurrent bouts of complement-mediated intravascular hemolysis.
- In normal persons, membrane attack complex (C5b–C9) formation is neutralized by C-reactive protein (CPR). Pathogenesis of paroxysmal nocturnal hemoglobinuria is shown in Fig. 8.55A and B.

CLINICAL FEATURES

Paroxysmal nocturnal hemoglobinuria (PNH) is often marked by the passage of hemoglobin-containing urine on awakening. Patient presents with recurrent bouts of complement-mediated intravascular hemolysis, mild jaundice, abdominal pain and pancytopenia. There is increased risk of thrombosis in the portal vein, hepatic veins and cerebral veins. Most common cause of death is thrombosis in portal vein and hepatic veins. PNH may be associated with aplastic anemia and myelodysplastic syndrome progressing to acute myelogenous leukemia.

Laboratory Diagnosis of Paroxysmal Nocturnal Hemoglobinuria (PNH)

Diagnostic tests commonly used in detection of paroxysmal nocturnal hemoglobinuria include hematologic analysis (hemoglobin, hematocrit values, reticulocyte count, peripheral blood smear and bone marrow examination; NAP score), serum bilirubin and serum haptoglobin levels, flow cytometric analysis for decay accelerating factor DAF (CD55) and MIRL (CD55) expressed on RBCs, granulocytes and platelets; modified gel diffusion analysis, fluorescein labeled proaerolysin (FLAER) test, Ham's test *in vitro*, and sucrose hemolysis test. Markers for paroxysmal nocturnal hemoglobinuria testing by flow cytometry are given in Table 8.91.

Hematologic Findings

- Hemoglobin and hematocrit values are decreased.
- Reticulocyte count is increased.
- Peripheral blood smear examination shows normocytic normochromic picture with polychromasia.
- Bone marrow examination shows hypercellular marrow due to erythroid hyperplasia.
- Neutrophil alkaline phosphatase (NAP) score is decreased.

Biochemical Alterations

- Serum bilirubin level is increased.
- Serum haptoglobin level is decreased.
- Hemoglobinemia is present.
- Hemoglobinuria is demonstrated by benzidine test.

Flow Cytometric Analysis

Flow cytometry is **most sensitive** diagnostic technique to demonstrate diminished DAF (CD55) and MIRL (CD59) expressed on red blood cells, ganulocytes and platelets.

Modified Gel Diffusion Analysis

Modified gel diffusion analysis by using gelcard demonstrates deficient DAF (CD55) and MIRL (CD59) expressed on red blood cells.

Fluorescein-labeled Proaerolysin (FLAER) Test

- FLAER test is a diagnostic tool to demonstrate clones on neutrophils and monocytes.
- FLAER binds to GPI-AP and increases the detection accuracy of flow cytometry for paroxysmal nocturnal hemoglobinuria, granulocyte and monocyte clones.

Ham Test *in vitro*

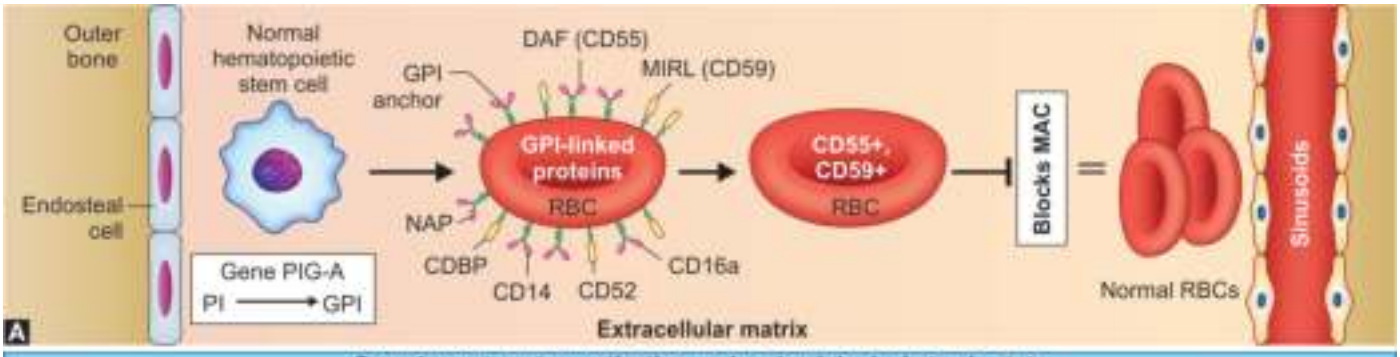
The Ham test is used in the diagnosis of paroxysmal nocturnal hemoglobinuria (PNH) by using acidified serum. Acidic pH of serum activates complement by alternate pathway resulting in hemolysis of red blood cells. This is now an obsolete test for diagnosis of PNH due to its low sensitivity and specificity.

Sucrose Hemolysis Test *in vitro*

Sucrose hemolysis test is a screening test for paroxysmal nocturnal hemoglobinuria (PNH). Sucrose reduces pH and thus activates complement pathway resulting in hemolysis of red blood cells. Hemolysis of RBCs >10% is diagnostic of PNH.

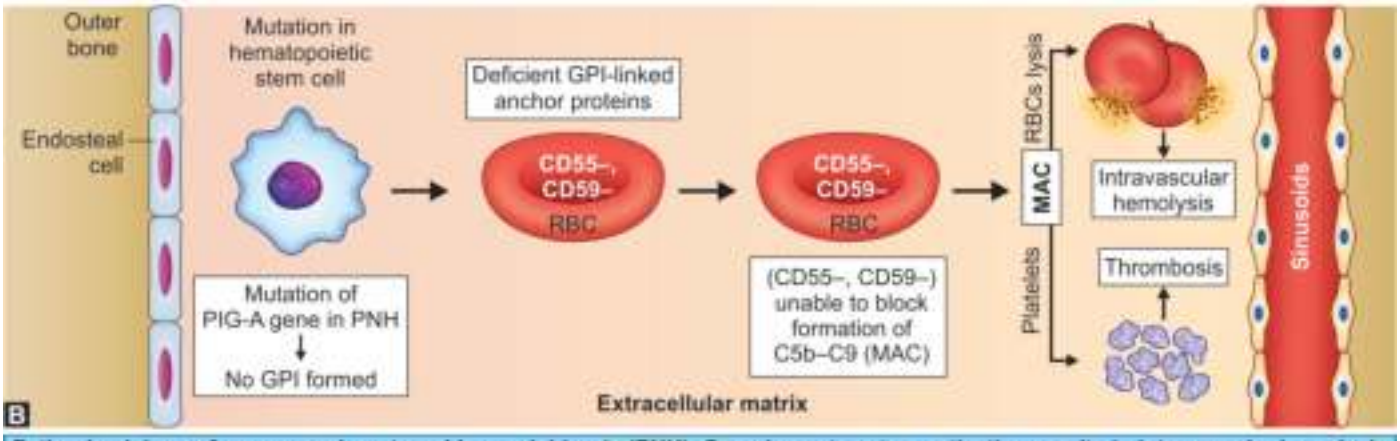
MANAGEMENT

Paroxysmal nocturnal hemoglobinuria patients are managed by blood transfusions, oral anticoagulants and antibiotics. Bone marrow transplantation is curative of disorder.



Complement system activation under physiological steady state

- Normal red blood cells (CD55+, CD59+) can withstand the hazard of complement system activation.
- Under physiological state, alternative, classic and lectin pathways of complement system activation, C3 convertase enzyme takes over that converts C3 to C3b. Then C3b is attached to red blood cells (CD55+, CD59+).
- The C3b + C3 convertase + C5 convertase participate in conversion of C5 to C5b. Then C5b activates C6, C7, C8, C9 and forms C5b–C9 (MAC—membrane attack complex).
- Red blood cells (CD55+, CD59+) block the action of membrane attack complex (MAC) and thus prevent intravascular hemolysis.



Pathophysiology of paroxysmal nocturnal hemoglobinuria (PNH): Complement system activation results in intravascular hemolysis

- Abnormal paroxysmal nocturnal hemoglobinuria (PNH) red blood cells (CD55–, CD59–) will undergo intravascular hemolysis sooner or later by activated complement system (C5b–C9 membrane attack complex).
- In paroxysmal nocturnal hemoglobinuria patient with PIG-A gene mutation, alternative, classic and lectin pathways of complement system activation, C3 convertase enzyme takes over that converts C3 to C3b. Then C3b is attached to red blood cells (CD55–, CD59–).
- The C3b + C3 convertase + C5 convertase participate in conversion of C5 to C5b. Then C5b activates C6, C7, C8, C9 and forms C5b–C9 (MAC—membrane attack complex).
- Red blood cells (CD55–, CD59–) are unable to block the action of membrane attack complex (MAC) and thus leading to intravascular hemolysis sooner or later.

Fig. 8.55: Pathogenesis of paroxysmal nocturnal hemoglobinuria. (A) Under physiologic state, PIG-A gene encoding GPI membrane anchoring proteins, which bind to CD55, CD59, CD8, CD14, CD16a and CD52 resulting in maintenance of red blood cell membrane, (B) under pathologic state, PIG-A gene mutation causes deficiency of membrane anchoring proteins leading to red blood cell destruction.

Table 8.91 Markers for paroxysmal nocturnal hemoglobinuria testing by flow cytometry

Study of Cells	Lineage Defining Markers	Glycosylphosphatidylinositol (GPI) Markers	Other Markers Used
Red blood cells	CD235a (glycophorin)	CD59	CD55
Granulocytes	CD15	▪ FLAER* (fluorescein-labeled proaerolysin) test ▪ CD24	▪ CD16 ▪ CD66b
Monocytes	CD64	▪ FLAER* (fluorescein-labeled proaerolysin) test ▪ CD157	CD14

**FLAER (fluorescein-labeled proaerolysin) test increases the detection accuracy of flow cytometry for paroxysmal nocturnal hemoglobinuria to demonstrate clones on neutrophils and monocytes.*

RED BLOOD CELL FRAGMENTATION SYNDROMES

Turbulent blood flow over prosthetic cardiac valves or synthetic vascular graft can cause shearing of red blood cells (RBCs) leading to intravascular hemolysis, hyperbilirubinemia and mild to moderate anemia.

- Red blood cell fragmentation syndromes occur in the settings of are prosthetic heart valves or synthetic vascular graft, disseminated intravascular coagulation and thrombotic thrombocytopenic purpura, malignant hypertension, vasculitis syndrome, hemolytic uremic syndrome, long distance running or walking and prolonged vigorous exercise. Vascular endothelial alterations in capillaries cause generalized thrombosis of capillary vessels leading to turbulent blood flow.
- These conditions can cause repetitive trauma to red blood cells in the microcirculation leading to intravascular hemolysis. Causes of red blood cell fragmentation syndrome are given in Table 8.92. Red blood cell fragmentation syndromes with or without thrombocytopenia is given in Table 8.93.

CARDIAC HEMOLYTIC ANEMIA

Hemolytic anemia occurs due to prosthetic valve, aortic stenosis, mitral valvular disease, coarctation of aorta and ruptured chordae tendineae. Turbulence of blood flow within cardiac chambers induces mechanical injury to red blood cells resulting in anemia.

Laboratory Diagnosis of Cardiac Hemolytic Anemia

- **Peripheral blood smear examination:** Periheral blood smear examination shows fragmented triangular-shaped red blood cells known as schistocytes or helmet cells (Fig. 8.56).
- **Reticulocyte count:** Reticulocyte count is increased.
- **Serum bilirubin:** Serum bilirubin level is increased.

MICROANGIOPATHIC HEMOLYTIC ANEMIA

Red blood cells undergo destruction, when these pass through arterioles, capillaries and venules in cases of hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, mucin secreting metastatic carcinoma, eclampsia and cavernous hemangioma. Cancers associated with microangiopathic hemolytic anemia are given in Table 8.94.

HEMOLYTIC UREMIC SYNDROME

Hemolytic uremic syndrome (HUS) is a triad characterized by acute renal failure, microangiopathic hemolytic anemia and thrombocytopenia. Bacterial toxins

Table 8.92 Causes of red blood cell fragmentation syndrome

Categories	Causes	
Microangiopathic hemolytic anemia	▪ Thrombotic thrombocytopenic purpura (TTP) ▪ Hemolytic uremic syndrome (HUS) ▪ Disseminated intravascular coagulation (DIC) ▪ Eclampsia of pregnancy	▪ Metastatic mucin-secreting carcinoma ▪ Hemolysis with elevated liver enzymes and low platelets (HELLP)
Cardiac hemolytic anemia	▪ Prosthetic valve ▪ Aortic stenosis ▪ Mitral valvular disease	▪ Coarctation of aorta ▪ Ruptured chordae tendineae
March hemoglobinuria	Athletes and soldiers	

Table 8.93 Red blood cell fragmentation syndrome with or without thrombocytopenia

Red Blood Cell Fragmentation with Thrombocytopenia
Disseminated intravascular coagulation (DIC)
Thrombotic thrombocytopenic purpura (TTP)
Hemolytic uremic syndrome (HUS)
Pre-eclampsia/eclampsia of pregnancy
HELLP syndrome occurs during later stage of pregnancy characterized by hemolysis, elevated liver enzymes and low platelet count
Malignant hypertension
Disseminated mucin secretory carcinoma
Systemic lupus erythematosus (SLE)
Sepsis
Antiphospholipid antibody crisis
Vascular corporeal circulation device
Red Blood Cell Fragmentation without Thrombocytopenia
Damaged cardiac valves
Renal transplant rejection
Renal cortical necrosis
Vasculitis
Drugs (cyclosporine, tacrolimus)

play role in the pathogenesis of HUS, which cause vascular endothelial damage resulting in activation of coagulation system. Patient presents with bloody diarrhea, anemia, jaundice, oliguria, hemoglobinuria and proteinuria.

Laboratory Diagnosis of Hemolytic Uremic Syndrome
Hematologic Findings
Hematologic findings are low hemoglobin, microcytic hypochromic picture with fragmented red blood cells, increased serum bilirubin, increased blood urea and serum creatinine.
Urine Analysis
Urine analysis shows oliguria, hemoglobinuria and proteinuria.

THROMBOTIC THROMBOCYTOPENIC PURPURA

Thrombotic thrombocytopenic purpura (TTP) may affect young adults. There is widespread thrombi formation in arterioles, capillaries and venules. Patient presents with fever, central nervous system manifestations and renal failure. There are three variants of TTP: congenital, primary and secondary. Schistocytes are demonstrated in peripheral blood smear examination.

- **Pathogenesis:** Congenital and primary TTP occur due to deficiency of ADAMTS 13 enzyme. The disorder is initiated as a result of vascular endothelial injury resulting in release of von Willebrand factor (vWF) and other procoagulant substances. Deficient cleaving protease activity leads to accumulation of vWF multimers resulting in platelets aggregation and microthrombi formation in microcirculation.
- **Management:** Thrombotic thrombocytopenic purpura is treated by plasma exchange. Corticosteroids are commonly administered in these patients. In cases of thrombocytic thrombocytopenic purpura refractory to plasma exchange, administration of anti-CD20 monoclonal antibody rituximab resolves acute disease and prolongs remission.

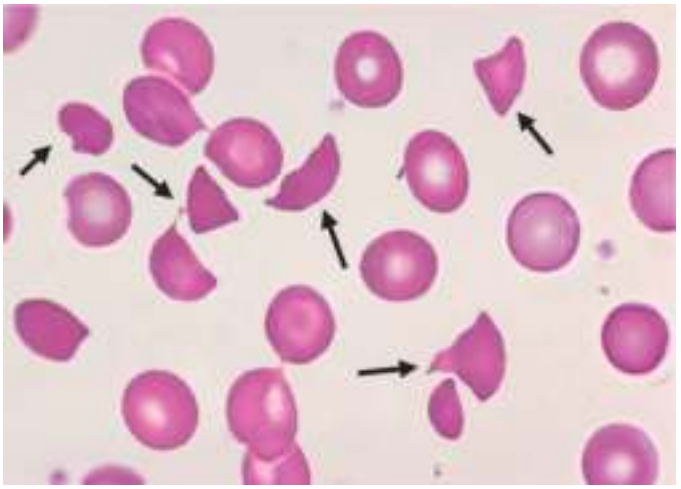


Fig. 8.56: Peripheral blood smear examination shows fragmented red blood cells (arrows) in a case of mitral valvular disease.

Table 8.94 Cancers associated with microangiopathic hemolytic anemia

Organs	Malignant Tumor
Gastrointestinal tract	▪ Gastric adenocarcinoma (55%) ▪ Colon adenocarcinoma
Breast	Breast carcinoma (13%)
Lung	▪ Lung adenocarcinoma (10%) ▪ Small cell lung carcinoma
Gallbladder	Gallbladder adenocarcinoma
Liver	Hepatocellular carcinoma
Pancreas	Pancreatic adenocarcinoma
Male genital system	Prostatic carcinoma
Female genital system	Ovarian carcinoma
Thymus	Thymoma
Oropharynx	Squamous cell carcinoma
Hematology	Erythroleukemia
Skin and other sites	Melanoma

MARCH HEMOLYTIC ANEMIA

March hemolytic anemia is seen in athletes and soldiers following strenuous exercise and marching. Mechanical destruction of red blood cells occurs in the microvessels of the feet. There is transient hemoglobinemia and hemoglobinuria, which persist for a few days.

DIAGNOSTIC APPROACH OF HEMOLYTIC ANEMIA

HEMOLYTIC ANEMIA: LABORATORY DIAGNOSIS

Hemolytic anemia is produced due to increased red blood cell destruction that cannot be compensated by bone marrow. RBCs destruction may be due to defects within red blood cells or due to extrinsic causes. Family history of hemoglobinopathy or hereditary spherocytosis, recent blood transfusions, malaria and drug intake provide clues to proper diagnosis. Diagnostic approach of hemolytic anemia is shown in Fig. 8.57.

PERIPHERAL BLOOD SMEAR EXAMINATION

Peripheral blood smear should be examined for the presence of microspherocytes, fragmented red blood cells and malarial parasite. Hemolytic anemia in which spherocytes are not present includes G6PD deficiency, hemoglobinopathies (other than HbC and thalassemia), unstable hemoglobin, drugs, snakebite and malaria. RHAG gene located on chromosome 6p21.1–p11 encodes rhesus antigen. RHAG gene mutation causes total loss of rhesus antigens leading to chronic nonspherocytic hemolytic anemia.

- Microspherocytes appear small dense and spherical. These are demonstrated in hereditary spherocytosis and immune hemolytic anemia. These are also demonstrated in HbC and hypersplenism. When hereditary spherocytosis is considered as a possible cause, peripheral blood smear obtained from family members supports the diagnosis.
  - Presence of microspherocytes and numerous target cells are highly suggestive of hemoglobin C disease. Hemoglobin electrophoresis should be performed to establish hemoglobin C.
  - Hereditary spherocytosis is diagnosed by osmotic fragility and acidified glycerol tests.
- Ovalocytes are demonstrated in hereditary ovalocytosis.
- Acanthocytes are demonstrated in pyruvate kinase deficiency disorder.
- Fragmented RBCs: Presence of fragmented red blood cells (burr cells, schistocytes and helmet cells) indicate microangiopathic hemolytic anemia.
- Sickle cells are demonstrated in cases of sickle cell disease and trait.
- Bite cells are demonstrated in peripheral blood smear of G6PD deficiency disorder. The diagnosis of G6PD deficiency disorder is done by methemoglobin reduction test and fluorescent assay.

PLASMA HAPTOGLOBIN

Haptoglobin is a glycoprotein that is synthesized in the liver, which consists of two pairs of α-chains and β-chains. With hemolysis, free hemoglobin readily dissociates into dimers of α- and β-chains, which bind with haptoglobin in plasma or serum. The complex is removed by liver. Plasma haptoglobin level is decreased in hemolytic anemia.

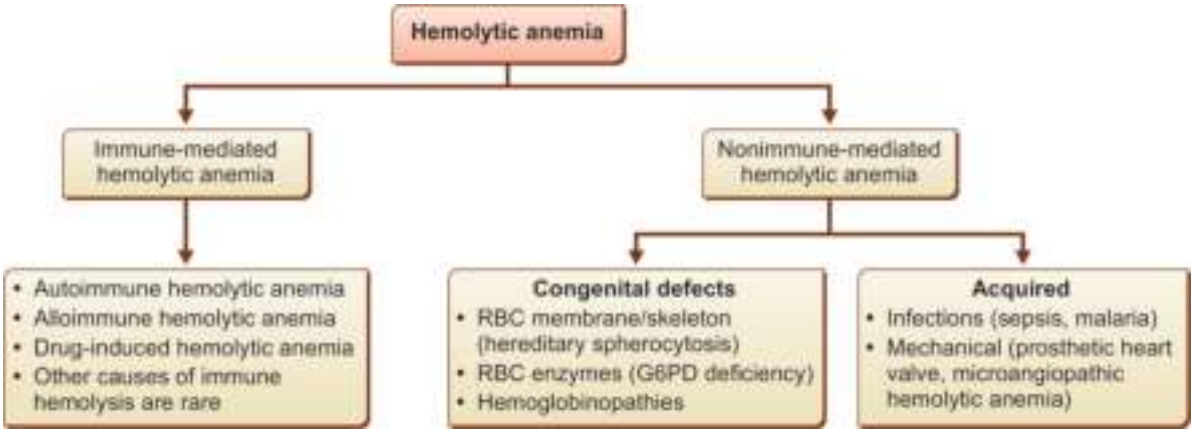

Fig. 8.57: Diagnostic approach of hemolytic anemia.

PLASMA HEMOPEXIN

Hemopexin is a β_1-glycoprotein of molecular weight 70,000 synthesized in the liver, which directly binds to ferriheme rather hemoglobin. In severe intravascular hemolysis, when haptoglobin is depleted, hemopexin is low or absent and elevated plasma methemalbumin. With less severe hemolysis, although haptoglobin is likely to be reduced or absent, hemopexin may be normal or only slightly lowered.

PLASMA HEMOGLOBIN

In plasma hemoglobin analysis, the catalytic action of heme-containing proteins brings about the oxidation of benzidine by H_2O_2 to give a green color, which changes to blue and finally to reddish violet. The intensity of reaction may be compared in a spectrophotometer with that produced by solutions of known hemoglobin. When the plasma hemoglobin is >50 mg/L, it can be measured as hemoglobin cyanide (HiCN) or oxyhemoglobin by a spectrometer at 540 nm.

HEMOSIDERINURIA

Hemosiderinuria is a sequel to the presence of hemoglobin in the glomerular filtrate. Hemosiderinuria is a valuable sign of intravascular hemolysis because the urine will be found to contain iron-containing granules even if there is no hemoglobinuria at the time.

- However, hemosiderinuria is not found in the urine at the onset of a hemolytic attack even if this is accompanied by hemoglobinemia and hemoglobinuria. Because the hemoglobin has first to be absorbed by renal tubular cells.
- The intracellular breakdown of hemoglobin liberates iron, which is then re-excreted. Hemosiderinuria may persist for several weeks after a hemolytic episode.

SICKLING TEST

Hemoglobin S is less soluble in a reducing agent than other forms of hemoglobin. Mixing blood with the reducing agent, sodium metabisulphite on a sealed slide, will induce sickling in susceptible sickle cells.

- Sickling test is simple and quick. The results can be viewed under light microscope after 20 minutes.
- Sickling test is positive whenever hemoglobin S is present (e.g. sickle cell anemia, sickle cell trait, sickle C disease, sickle cell thalassemia).
- False positivity of sickling test is seen in exceptionally high hematocrit, unstable hemoglobin, elevated plasma proteins and lipids.

ANTIHUMAN GLOBULIN TEST (COOMBS' TEST)

Direct Coombs' Test

Direct Coombs' test also known as antihuman globulin test is performed to detect autoantibodies.

- Patient's RBCs are mixed with antibodies directed against human immunoglobulin or complement. Presence of RBCs agglutination indicates positive direct Coombs' test.
- Direct Coombs' test detects antibodies or complement bound to surface of RBCs antigens *in vivo* in immune-mediated hemolytic anemia, hemolytic disease of newborn, mismatched blood transfusion.
- Drug-induced hemolytic anemia may also be associated with direct positive Coombs' test. If direct Coombs' test is negative in the presence spherocytes, one should consider hereditary spherocytosis as a possible cause of hemolysis.

Indirect Coombs' Test

Indirect Coombs' test is performed to detect *in vitro* antigen–antibody reactions, which detects low concentration of antibodies in patient's blood prior to blood transfusion and antenatal Rh –ve with Rh +ve fetus. Direct and indirect Coombs' test is also performed for compatibility testing in blood banking, and RBCs phenotyping (Fig. 8.58A and B).

HEMOGLOBIN ELECTROPHORESIS

Hemoglobin electrophoresis is a diagnostic tool to measure different types of hemoglobin in the blood in suspected disorder associated with abnormal hemoglobin such as sickle cell anemia and thalassemia.

Principle

The principle behind hemoglobin electrophoresis is that when proteins are exposed to charge gradient, they separate from each other by forming bands that separate toward one end or the other end in the electric field. Cellulose acetate membrane, starch gel, agarose gel, citrate agar gel and filter paper are the commonly used. Cellulose acetate electrophoresis is performed at alkaline pH of 8.2–8.6. Citrate agar or agarose gel electrophoresis is done in acidic pH of 6.0–6.2. High-performance liquid chromatography (**HPLC**) is rapidly taking its place in many laboratories.

Blood Sampling

Blood transfusions given within the previous 12 weeks may alter hemoglobin electrophoresis test results. Hemoglobin electrophoresis is performed on venous

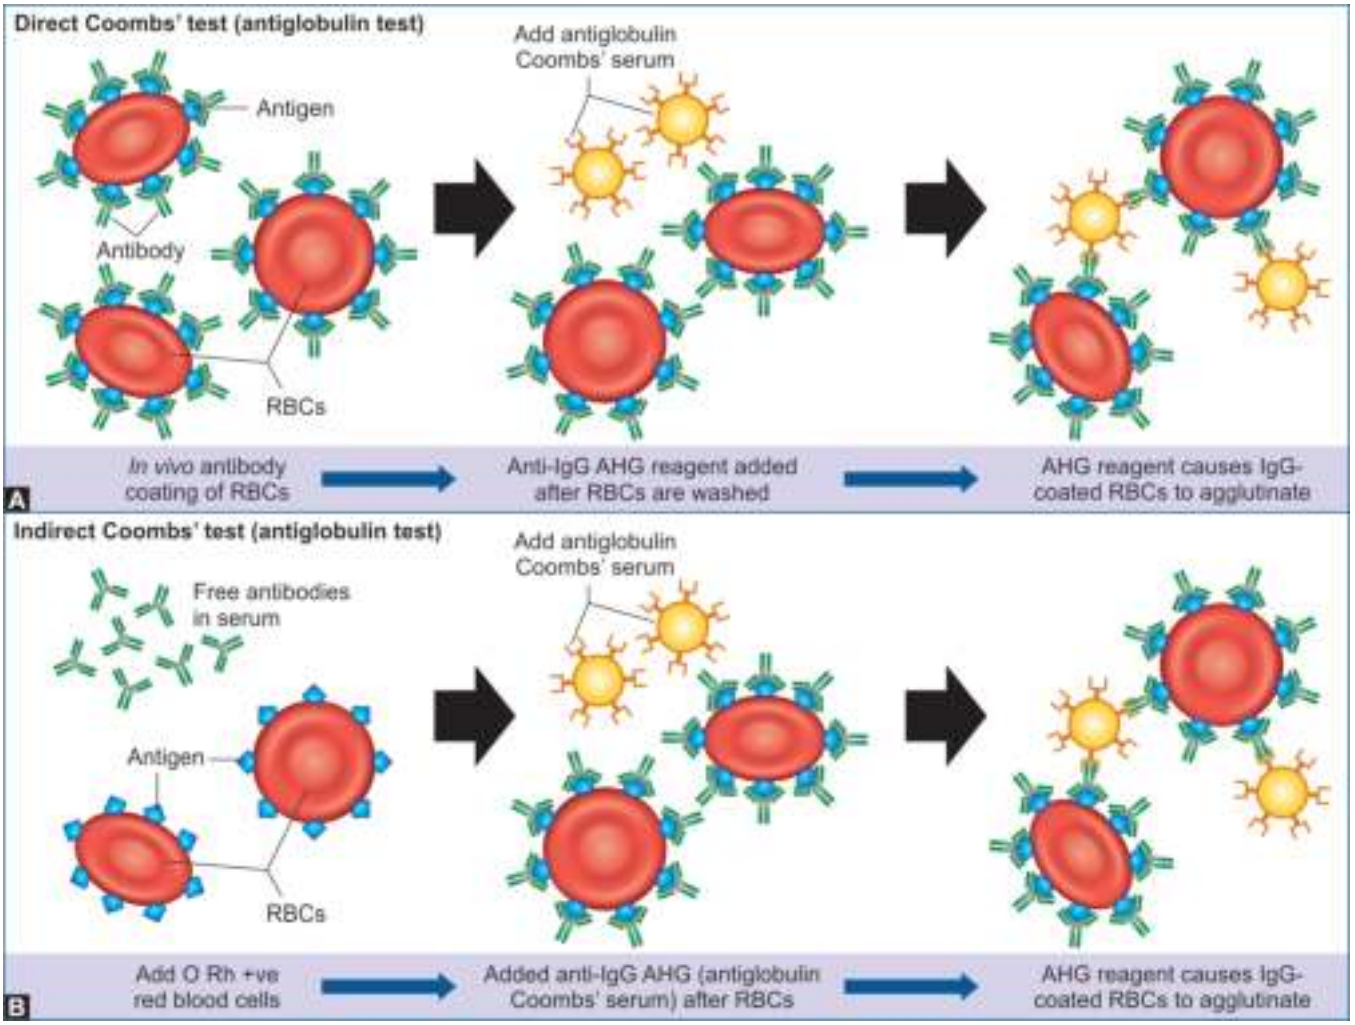

Fig. 8.58A and B: Direct and indirect Coombs' test.

blood samples taken in anticoagulant EDTA container. Red blood cell lysate is prepared using a lysing reagent (Na_4EDTA and KCN).

Interpretation

Each of the major hemoglobin types has an electrical charge of a different degree. Hemoglobin electrophoresis separates and measures normal and abnormal hemoglobin. The components then move away from each other at different rates, and when separated from a series of distinctly pigmented bands.

- These pigmented bands are then compared with those of a normal sample. Each band is further assessed as a % of the total hemoglobin, thus indicating the severity of any abnormality.
- Description of hemoglobin (Hb) is comprising of many different types, the most common being HbA_1, HbA_2, HbF, HbS, and HbC. Normal reference values can vary by laboratory but are generally within the following ranges.

Hemoglobin Electrophoresis Patterns

In normal adults, HbA_1 is the major component of hemoglobin in the normal red blood cell. HbA_2 is a minor component of normal hemoglobin, comprising approximately 2–3% of the total hemoglobin levels.

- In children, HbF is the major hemoglobin component in the fetus, but usually exists only in minimal quantities in the normal adult.
- Levels of fetal hemoglobin (HbF) greater than 2% in patients over three years of age are considered abnormal. Hemoglobin electrophoresis pattern in normal persons and hemoglobin disorders is given in Tables 8.95 and 8.96.

HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

High-performance liquid chromatography (HPLC) is one of the commonest laboratory investigations performed for the identification of globin chain synthesis.

Table 8.95 Hemoglobin electrophoresis pattern in normal persons

Age Group	Hemoglobin	Percentage
Adults	▪ HbA_1 ▪ HbA_2 ▪ HbF ▪ HbS ▪ HbC	▪ 95–98% ▪ 2–3% ▪ 0.8–2.0% ▪ 0% ▪ 0%
Children	▪ HbF (newborn) ▪ HbF (6 months age) ▪ HbF (>6 months age)	▪ 50–80% ▪ 8% ▪ 1–2%

Principle

Cation exchange HPLC is a process by which mixture of hemoglobins with net positive charge are separated by their adsorption onto a negatively charged stationary phase in a chromatography column. This process is then followed by their elution by a liquid mobile phase containing increasing concentrations of cations flowing through the column. Hemoglobins separated by this process are optically identified in the elute. The quantification is done by computing the area under the corresponding peak in the elution profile.

Interpretation

Different hemoglobins have different affinity for the stationary phase. Hemoglobin with strong positive charge has higher affinity for stationary phase and appears in elute later than other hemoglobins. Retention time is the time taken by normal and variant hemoglobin to appear in the elute. Retention time of normal and variant hemoglobins is given in Table 8.97.

Advantages

High performance liquid chromatography is performed on very small venous sample, which estimates quantity of normal and abnormal hemoglobins. HPLC is used to estimate quantity of HbA_2 in diagnosing β-thalassemia trait. Overall, HPCL has more advantages than hemoglobin electrophoresis and routinely performed in many laboratories.

Disadvantages

HPLC instrument and its reagents are very costly.

ISOELECTRIC FOCUSING

Isoelectric focusing (IEF) is a technique for separating different molecules by differences in their isoelectric point.

- Hemoglobins in isoelectric focusing (IEF) are separated in agarose gel according to their isoelectric points at which these have no net charge.
- Bands in IEF are sharper as compared to electrophoresis. But this diagnostic tool is more expensive than electrophoresis.

MICROCOLUMN CHROMATOGRAPHY

Microcolumn chromatography is an anion exchange chromatography used to estimate quantity of **HbA_2 in α-thalassemia**.

Table 8.97 Retention time of normal and variant hemoglobins

Window	Retention Time (Minutes)	Hemoglobins that Appear in the Window
H	Peak within first minute	HbH, Bart's hemoglobin, bilirubin, acetylated HbF
F	1.10	HbF
A	2.50	HbA, glycosylated S
A_2	3.60	HbA_2, D-Iran, E-Lepore
D	4.10	D-Punjab
S	4.50	S
C	5.10	C-constant spring

Table 8.96 Hemoglobin electrophoresis pattern in hemoglobin disorders

Hemoglobin	Hemoglobin Disorder	Percentage
HbA_2	▪ β-thalassemia ▪ HbH disease	▪ 4.00–5.8% ▪ <2%
HbF	▪ β-thalassemia major ▪ β-thalassemia minor ▪ Homozygous hereditary persistence of fetal hemoglobin (HPFH) ▪ Heterozygous hereditary persistence of fetal hemoglobin (HPFH) ▪ Heterozygous HbS	▪ 10–90% ▪ 2–5% ▪ 100% ▪ 5–35% ▪ 15%
HbS	Sickle cell disease (homozygous)	70–98%
HbC	Hemoglobin C disease (homozygous)	90–98%

IMMUNOASSAY

Immunoassay is used to evaluate various hemoglobins by commercially available kits such as hemocards for specific hemoglobins.

KLEIHAUER-BETKE TEST

Kleihauer test (acid elution test) is a blood test to measure the amount of fetal hemoglobin transferred from a fetus to a mother's bloodstream. Test is based on principle that red blood cells containing HbF become resistant to lysis as compared to red blood cells containing HbA. It is most often performed on Rh –ve mothers to determine the required dose of Rho (D) immune globulin (RhIg) to inhibit formation of Rh antibodies in the mother and prevent Rh disease in future Rh positive children.

FLOW CYTOMETRY TECHNIQUE

Flow cytometry technique is done by using fluorochrome conjugated monoclonal antibody to HbF (kindly *refer* to flow cytometry technique disscuss in detail in Ch 14: Cellular–Molecular Diagnostic Techniques in Clinical Practice).

2,6-DICHLOROPHENOLINDOPHENOL TEST

Hemoglobin E is an abnormal hemoglobin with a single point mutation in the β-chain due to change in the amino acid, from glutamic acid to lysine at position 26. HbE disorder is very common in South-East Asia but has a low frequency amongst other ethnicities HbE can be detected on electrophoresis. 2,6-dichlorophenolindophenol (**DCIP**) test is used to screen patient with HbE.

SUPRAVITAL STAINING

Supravital staining is used to demonstrate HbH inclusions. Peripheral blood smears are stained with brilliant cresyl blue stain, that acts as a mild oxidant and precipitates HbH.

GLOBIN CHAIN ELECTROPHORESIS

In globin chain electrophoresis DL-dithiothreitol and urea added to red blood cell lysate to dissociate heme and globin chains. Globin chain electrophoresis is then carried out on cellulose acetate membrane with both acid and alkaline buffer systems, which method permits the distinction between α- and β-chain abnormalities.

BONE MARROW FAILURE SYNDROMES

Bone marrow participates in hematopoiesis. Bone marrow failure is characterized by marrow hypoplasia leading to pancytopenias (erythroid, myeloid and megakaryocytes) and decreased reticulocyte count as a result of failure of bone marrow to produce precursor cells. Bone marrow failure occurs due to inherited or acquired causes. Summary of inherited bone marrow failure syndrome is given in Table 8.98.

Table 8.98 Summary of inherited bone marrow failure syndrome

Inherited Disorder	Inheritance	Cellular Pathway Abnormality	Associated Risk of Malignant Neoplasms
Fanconi syndrome	Autosomal recessive disorder (except X-linked FNCB)	DNA repair abnormality	▪ Myelodysplastic syndrome ▪ Acute myelogenous leukemia
Diamond-Blackfan anemia	Autosomal dominant (except GATA1 related X-linked disorder)	Ribosomal biogenesis abnormality	▪ Myelodysplastic syndrome ▪ Acute myelogenous leukemia ▪ Colon adenocarcinoma ▪ Osteosarcoma
Shwachman-Diamond syndrome	Autosomal recessive disorder	Ribosomal assembly abnormality	▪ Myelodysplastic syndrome ▪ Acute myelogenous leukemia ▪ Acute lymphoblastic leukemia
Congenital dyserythropoietic anemia (CDA)	▪ Autosomal recessive disorder (CDA I, CDA II) ▪ Autosomal dominant (CDA III, CDA IV)	Abnormality of unfolded protein response, cytokinesis and erythroid transcription factor	Multiple myeloma related to CDA III
Congenital amegakaryocytic thrombocytopenia	Autosomal recessive disorder	Abnormality of megakaryopoiesis	▪ Myelodysplastic syndrome ▪ Acute lymphoblastic leukemia

Contd...

Table 8.98 Summary of inherited bone marrow failure syndrome (*Contd...*)

Inherited Disorder	Inheritance	Cellular Pathway Abnormality	Associated Risk of Malignant Neoplasms
Thrombocytopenia with absent radii	Autosomal recessive disorder	Abnormality of mRNA processing	▪ Acute myelogenous leukemia ▪ Acute lymphoblastic leukemia
Severe congenital neutropenia with ELANE gene mutation	Autosomal dominant disorder	Abnormality of unfolded protein response	▪ Myelodysplastic syndrome (MDS) ▪ Acute myelogenous leukemia
Dyskeratosis congenita	X-linked disorder, autosomal dominant disorder, autosomal recessive disorder	Abnormality of maintenance of telomere	▪ Myelodysplastic syndrome (MDS) ▪ Acute myelogenous leukemia ▪ Squamous cell carcinoma ▪ Other malignant tumors
GATA deficiency	Autosomal dominant disorder	Abnormality of hematopoietic stem cell differentiation	▪ Myelodysplastic syndrome (MDS) ▪ Acute myelogenous leukemia
Familial platelet disorder with a propensity to myeloid malignancy (RUNX-1)	Autosomal dominant disorder	Abnormality of hematopoietic stem cell differentiation	▪ Myelodysplastic syndrome (MDS) ▪ Acute lymphoblastic leukemia

APLASTIC ANEMIA

Aplastic anemia is pluripotent stem cell disorder results in bone marrow failure, which adversely affects erythroid, myeloid and megakaryocytic series.

- Bone marrow shows variably reduced cellularity, depending on the clinical stage of the disease.
- Severe aplastic anemia is characterized by <25% cellularity of bone marrow, platelet count <20,000/cu mm and increased fat spaces in the bone marrow.
- Bone marrow pluripotent stem cell failure occurs due to primary or secondary causes. Causes of aplastic anemia are given in Table 8.99.

PATHOGENESIS

Primary aplastic anemia occurs in 65% of cases. Four inherited aplastic anemia syndromes include Fanconi anemia, dyskeratosis congenita, Shwachman-Diamond syndrome and congenital megakaryocytic thrombocytopenia. Fanconi anemia is characterized by pancytopenia, congenital abnormalities and increased risk of cancers. Secondary aplastic anemia may be caused by total body irradiation, drugs, chemical agents, viral infections, and Fanconi anemia.

- **Physical agent:** Ionizing radiation causes aplastic anemia.
- **Exposure to chemical agents:** Bone marrow suppression due to drugs and chemicals may be dose related (e.g. benzene, alkylating agents, vincristine).
- **Exposure to drugs:** Drugs causing bone marrow suppression in unpredictable manner (idiosyncrasy) are streptomycin, chloramphenicol and chlorpromazine.

Table 8.99 Causes of aplastic anemia

Primary/Idiopathic Aplastic Anemia	
Constitutes 70% cases of aplastic anemia	
Secondary Aplastic Anemia	
▪ **Cytotoxic drugs** • Anti-inflammatory drugs (e.g. phenylbutazone, indomethacin) • Antibiotics (e.g. chloramphenicol) • Anticonvulsants (e.g. carbamazepine, phenytoin, valproic acid)	
▪ **Exposure to industrial chemical agents** • Benzene	• Pesticides
▪ **Exposure to radiation** • Therapeutic radiation	• Accidental radiation
▪ **Viral infections** • Parvovirus B19 • Hepatitis virus A • Hepatitis virus B • Cytomegalovirus	• Human immunodeficiency virus (HIV) syndrome • Epstein-Barr virus
▪ **Immune including autoimmune disorders** • Systemic lupus erythematosus (SLE) • Graft-versus-host disease	• Transfusion related graft-versus-host disease • Eosinophilic fasciitis
▪ **Miscellaneous disorders** • Paroxysmal nocturnal hemoglobinuria (PNH) • Pregnancy	• Thymoma • Thymic carcinoma

- **Viruses:** Aplastic anemia may be caused by human Parvovirus B19 or HCV.
- **Hematologic disorders:** Aplastic anemia can occur in the course of hereditary spherocytosis or sickle cell anemia. Some cases of paroxysmal nocturnal

hemoglobinuria are associated with aplastic anemia, while some may progress to myelodysplastic syndrome resulting in acute myelogenous leukemia. Fanconi anemia is inherited disease due to defects in telomerase activity.

Laboratory Diagnosis of Aplastic Anemia

Diagnostic Criteria

Diagnosis and assessment of severe aplastic anemia defined by Camitta's criteria include as bone marrow cellularity <30% and severe pancytopenia with at least two of the following peripheral blood count findings:

- Absolute neutrophil count is $<0.5 \times 10^9$/L
- Platelet count is $<20 \times 10^9$/L
- Corrected reticulocyte count is <1%

Reticulocyte Count

The lack of an appropriate reticulocyte response to the anemia indicates ineffective hematopoiesis as the mechanism for the pancytopenia.

Bone Marrow Smear Examination

Hematopoietic elements are replaced by fat cells lacking normal hematopoietic activity. There is relative increase in lymphocytes and plasma cells. As bone marrow cellularity decreases, there is a corresponding increase in bone marrow fat. One must look for metastatic deposits in bone marrow (Fig. 8.59).

CLINICAL FEATURES

Patients with aplastic anemia present with weakness, fatigue, progressive anemia, recurrent infections due to neutropenia, and bleeding tendencies as a result of thrombocytopenia. Withdrawal of potential inciting agent may sometimes lead to recovery. Bone marrow transplantation is recommended in these cases.

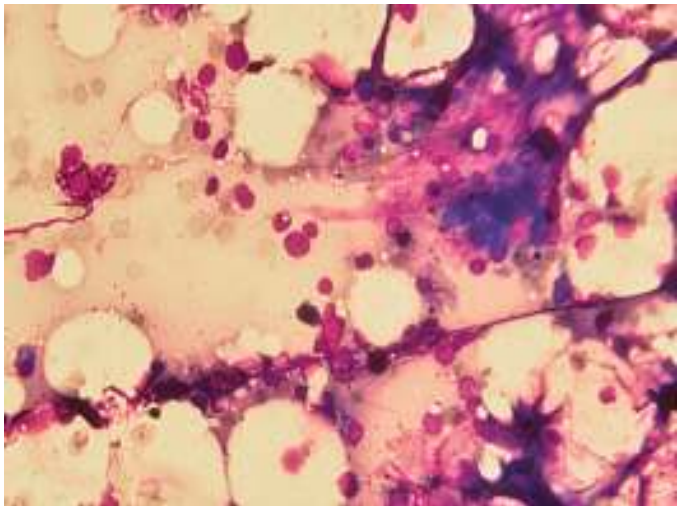

Fig. 8.59: Bone marrow in aplastic anemia shows marked reduction in the erythroid, myeloid and megakaryocytic precursor cells with increased adipose cells.

PURE RED CELL APLASIA (ERYTHROBLASTOPENIA)

Pure red cell aplasia (PRCA) is an uncommon disorder in which maturation arrest occurs in the formation of red blood cells. Erythroblasts are virtually absent in the bone marrow. Bone marrow shows normal myelopoiesis and megakaryopoiesis.

CLASSIFICATION

Pure red cell aplasia may be congenital or acquired. Congenital pure red cell aplasia may be inherited (Diamond-Blackfan anemia) or nonherited (Pearson syndrome). Diamond-Blackfan anemia belongs to one of the rare group of genetic disorders known as the inherited bone marrow failure syndromes (IBMFSs). These disorders share a predilection to bone marrow failure, birth defects, and cancer are characterized by proapoptotic hematopoiesis. Classification of pure red cell aplasia (erythroid hypoplasia) is given in Table 8.100.

PATHOGENESIS

In some cases, the IgG seems to be cytotoxic to CFU-E in the presence of complement; in others, its inhibitory activity is independent of the presence of complement but its presence is continuously required during the 7-day period of maturation of CFU-E to erythroblasts.

Table 8.100 Classification of pure red cell aplasia (erythroid hypoplasia)

Inherited Pure Red Cell Aplasia
Diamond-Blackfan syndrome
Thymoma (T cell-mediated suppression of erythropoiesis)
Acquired Transient Pure Red Cell Aplasia
Transient erythroblastopenia of childhood
Parvovirus infection cytotoxic to CFU-E in children usually transient affects erythroid precursors in bone marrow showing few giant proerythroblasts with basophilic cytoplasm, intranuclear inclusions in sieve-like nucleus
Acquired Sustained Pure Red Cell Aplasia
Thymoma (T cell-mediated suppression of erythropoiesis)
Large granular lymphocytic T cell leukemia
Chronic lymphocytic leukemia
Clonal myeloid disease especially 5q syndrome
Viral infection other than Parvovirus
Solid malignant tumors
Drugs (phenytoin, procainamide, isoniazid)
Collagen vascular diseases

- The bone marrow arrest occurs at any level between CFU-E and basophilic erythroblasts.
- The stage of erythropoiesis at which the bone marrow arrest occurs has been studied by assaying PRCA bone marrow cells in semisolid media for erythroid progenitors.

CLINICAL FEATURES

Adult patients of inherited pure red cell aplasia present with symptoms of anemia that may be quite severe at the time of diagnosis. Complete arrest of erythropoiesis in bone marrow leads to a decline in red cell count averaging about 1% per day, so the development of anemia is slow and progressive, allowing for physiologic compensatory changes. Physical examination in primary pure red cell aplasia (PRCA) is usually negative except for pallor and signs of anemia. In secondary pure red cell aplasia cases, patients may have physical findings related to the underlying disease. Hepatosplenomegaly and lymphadenopathy findings are not consistent with primary PRCA.

Laboratory Diagnosis of Pure Red Cell Aplasia (PRCA)

Peripheral Blood Smear Examination

- Peripheral blood smear examination shows normochromic and normocytic.
- The white cell count and the differential leukocyte count are normal. Occasionally, mild leukopenia, lymphocytosis, and/or eosinophilia may be present.
- There is a complete absence of polychromatophilic red blood cells on the peripheral blood smear, and the reticulocyte count is between 0 and 1%.

Bone Marrow Smear Examination

- The hallmark of PRCA is the absence of erythroblasts from an otherwise normal bone marrow.
- The cellularity of the bone marrow is normal or slightly increased. High cellularity with elimination of fat spaces should lead away from the diagnosis of PRCA. In typical cases, the erythroblasts are either totally absent, or these constitute <1% on the marrow differential count.
- The myeloid cells and the megakaryocytes in the bone marrow are normal and exhibit full maturation.
- An increased number of lymphocytes on bone marrow smear, or an increased number of lymphoid aggregates in bone marrow trephine biopsy, or a mild increase in plasma cells, eosinophils, or mast cells may be seen.

Bone Marrow Iron Stores

Bone marrow iron stores are increased and normally distributed, but during recovery or the phase of ineffective erythropoiesis, a few ring sideroblasts may be seen.

SIDEROBLASTIC ANEMIA

Sideroblastic anemias (SA) are heterogeneous group of disorders characterized by presence of ring sideroblasts in the bone marrow, ineffective erythropoiesis, increased levels of tissue iron and microcytic hypochromic picture. Sideroblastic anemia may be hereditary or secondary (more common). Classification of sideroblastic anemia is given in Table 8.101.

- Sideroblasts are erythroblasts containing aggregates of iron which are demonstrable by Perls Prussian blue reaction. There are three types of sideroblasts: normal sideroblast, abnormal sideroblast and ring sideroblast (Fig. 8.60). Types of sideroblastic anemia according to WHO are given in Table 8.102.
- Under physiologic state, iron present in mitochondria combines with protoporphyrin to synthesize heme in erythroid precursors. Under pathologic state, iron present in mitchondria fails to bind with protoporphyrin affecting heme synthesis. Iron remains in the mitochondria of developing erythroblasts and forms ring sideroblasts, which do not mature into RBCs leading to sideroblastic anemia. Ineffective erythropoiesis increases iron overload.

HEREDITARY SIDEROBLASTIC ANEMIA

Hereditary sideroblastic anemia may be X-linked affecting males or autosomal recessive disorder, which occurs due to defective ALA synthatase resulting in defective synthesis of hemoglobin. Patient presents with anemia, hepatomegaly, splenomegaly, failure to thrive and cardiac arrhythmias.

Laboratory Diagnosis of Hereditary Sideroblastic Anemia

Peripheral Blood Smear Examination and Other Hematological Tests

- Peripheral blood smear examination shows anisopoikilocytosis and microcytic hypochromic anemia. Leukocytes and platelets are within normal ranges.
- Hematocrit values (MCH and MCHC) are decreased.
- Serum iron and ferritin levels are increased.

Bone Marrow Examination

- Bone marrow examination shows erythroid hyperplasia and dyserythropoiesis. Megakaryocytes are normal.
- Bone marrow iron stores are increased demonstrated by Perls Prussian blue reaction.

Table 8.101 Classification of sideroblastic anemia

Sideroblastic Anemia: Classification	Comments
Genetic sideroblastic anemia	
X-linked sideroblastic anemia (XLSA)	▪ Erythroid δ-aminolevulinic acid synthase (ALAS2) gene mutation inactivates hematopoietic component resulting in mild anemia ▪ Sideroblastic anemia with ataxia (ABCB7, an ATP-binding cassette protein)
Mitochondrial DNA genetic sideroblastic anemia	▪ Mitochondrial amino acid carrier protein SIC25A38, MCV low, severe transfusion dependent anemia ▪ Mitochondrial respiratory enzyme mutations, e.g. Pearson syndrome*; Kearns-Sayre syndrome* ▪ YARS2 gene encoding for mitochondrial tyrosyl-tRNA synthase
Autosomal genetic sideroblastic anemia	▪ Glutaredoxin 5 (GLRX5) gene mutation, MCV low, rarely transfusion dependent anemia ▪ Erythropoietic protoporphyria (EPP) congenital sideroblastic anemia (ferrochelatase gene mutation), mild anemia in children with photosensitivity ▪ Thiamine-responsive megaloblastic anemia and sideroblastic anemia [SLC19A2 gene encoding the thiamine transporter THTR-1, DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness) syndrome]
Acquired sideroblastic anemia	
Primary genetic sideroblastic anemia	Myelodysplastic syndrome (MDS)
Secondary genetic sideroblastic anemia	▪ Hematological disorders • Acute myelogenous leukemia (AML) • Multiple myeloma • Polycythemia vera • Myelofibrosis • Porphyria • Megaloblastic anemia • Hemolytic anemia ▪ Vitamin deficiency • Pyridoxine deficiency ▪ Autoimmune disorders • Systemic lupus erythematosus • Rheumatoid arthritis ▪ Drugs • Isoniazid • Pyrazinamide • Chloramphenicol • Cycloserine • Penicillamine • Fusidic acid ▪ Gastrointestinal disorder • Celiac disease

**Pearson syndrome (neutropenia, thrombocytopenia, sideroblastic anemia, exocrine pancreatic dysfunction and hepatic dysfunction); Kearns-Sayre syndrome (neutropenia, thrombocytopenia, sideroblastic anemia, exocrine pancreatic dysfunction and hepatic dysfunction, and involvement of brain, spinal cord and peripheral nerve).*

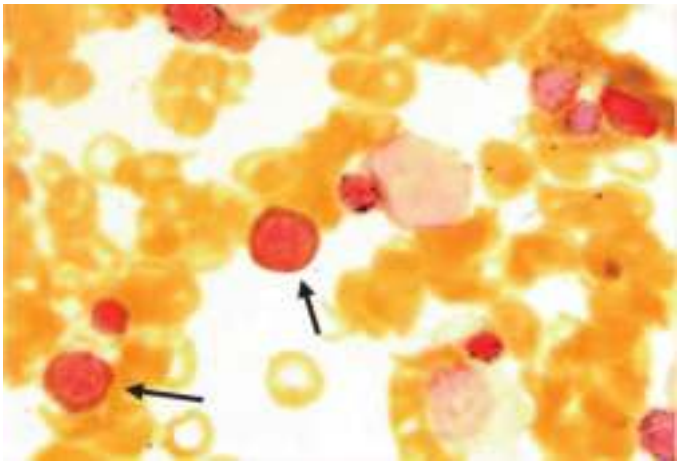

Fig. 8.60: Bone marrow aspirate in sideroblastic anemia shows ring sideroblasts (arrows).

ACQUIRED SIDEROBLASTIC ANEMIA

Acquired sideroblastic anemia occurs more frequently affecting adults than hereditary type. Ineffective erythropoiesis leads to iron overload. Patient presents with progressive anemia, signs of congestive heart failure and mild hepatosplenomegaly.

Laboratory Diagnosis of Acquired Sideroblastic Anemia

Peripheral Blood Smear Examination

- Peripheral blood smear examination shows dimorphic picture (microcytic hypochromic and macrocytic anemia).
- RBCs show basophilic stippling and target cells.
- RBCs also show iron deposits known as Pappenheimer bodies demonstrated by Perls Prussian blue reaction. Red blood cell distribution width (RDW) is increased.

Bone Marrow Smear Examination

- Bone marrow smear examination is hypercellular showing ringed sideroblasts demonstrated by Perls Prussian blue reaction.
- Dyserythropoiesis is characterized by nuclear budding.
- Howell-Jolly bodies are demonstrated in the normoblasts.
- Megakaryopoiesis is normal.

Biochemical Tests

- Serum iron, serum ferritin, % transferrin saturation and free protoporphyrin are increased.
- TIBC is decreased.

CONGENITAL DYSERYTHROPOIETIC ANEMIA

Congenital dyserythropoietic anemia is a heterogeneous disorder characterized by markedly ineffective erythropoiesis with dysplastic multinucleated erythroblasts and reduced reticulocyte count.

- Congenital dyserythropoietic anemias are designated as types 1 to 3 defined by the presence of distinctive morphologic abnormalities in erythroblasts demonstrated by light and electron microscopy.
- Dyserythropoiesis refers to abnormalities in the morphology or function or both of erythroid precursors. Features of congenital dyserythropoietic anemia (CDA) are given in Table 8.103.
  - Congenital dyserythropoietic anemia type 1 is characterized by moderate to severe macrocytic anemia in neonates or intrauterine growth retardation.
  - Congenital dyserythropoietic anemia type 2 is characterized by moderate anemia, splenomegaly and hepatomegaly.
  - Congenital dyserythropoietic anemia type 3 is characterized by mild anemia and retinal degeneration.
  - Congenital dyserythropoietic anemia type 4 is characterized by severe anemia at birth.

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE 1

Congenital dyserythropoietic anemia (CDA) type 1 is an autosomal recessive disorder characterized by megaloblastic erythropoiesis due to CDAN1 or C150RF41 gene mutation (15q15).

Table 8.102 Types of sideroblastic anemia according to World Health Organization

Type of Sideroblastic Anemia	Bone Marrow	Iron Contents Demonstrated by Prussian Blue Reaction
Type 1	Intermediate or late normoblasts	1–2 pinpoint size iron granules in normoblasts randomly distributed
Type 2	Intermediate or late normoblasts	1–5 pinpoint size iron granules in normoblasts seen in megaloblastic anemia and thalassemia
Type 3	Intermediate or late normoblasts	Nonferritin iron, pinpoint-sized granules forming partial or complete ring seen in primary/secondary sideroblastic anemia

Table 8.103 Features of congenital dyserythropoietic anemia (CDA)

CDA Type	Gene Mutation	Inheritance	Bone Marrow Findings	Associated Clinical Findings
CDA type 1	▪ CDAN1 gene mutation (15q15) ▪ CD150RF4 gene mutation	Autosomal recessive	Megaloblastic erythropoiesis, erythroblasts with internuclear bridging	Skeletal abnormalities
CDA type 2	▪ CDAN2 gene mutation ▪ SEC23B gene mutation (20p11.2)	Autosomal recessive	Numerous binucleated erythroblasts and occasional multinucleated erythroblasts	Variable clinical findings
CDA type 3 (sporadic)	Unknown	Unknown	Giant multinucleated normoblasts containing 12 nuclei	Variable
CDA type 3 (familial)	KIF23 gene mutation (19p13.13)	Autosomal dominant	Giant multinucleated normoblasts	Plasma cell dyscrasias and angioid streaks
CDA type 4	KLF1 gene mutation (p13.12)	Autosomal dominant	Erythroblasts with internuclear bridging	Mild to moderate splenomegaly
CDA other variants	▪ KLF1, GATA1 gene mutation ▪ XLR gene mutation	▪ Autosomal dominant ▪ X-linked disorder	▪ Erythroblasts with internuclear bridging to numerous binucleated erythroblasts ▪ Erythroblasts with internuclear bridging to numerous binucleated erythroblasts	▪ Not applicable ▪ Not applicable

- On electron microscopy, erythroblasts in bone marrow show spongy nuclear chromatin giving Swiss cheese appearance.
- A few patients with CDA type 1 have been treated with interferon-α_2, with a good response.

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE 2

CDA type 2 is most common autosomal recessive disorder due to mutation of CDAN2 gene located on chromosome 20q11.2. Geographic distribution—higher frequency of the gene mutation in North-West Europe, Italy and North Africa. Both sexes are equally affected. CDA type 2 patients suffer from lifelong anemia.

- **Pathogenesis:** CDA type 2 disorder results from a combination of the death of erythroblasts in the bone marrow (ineffective erythropoiesis) and hemolysis of red blood cells is known as peripheral hemolysis. The red blood cell glycosylation defects are responsible for both mechanisms.
- **Clinical features:** Patient during infancy or early childhood presents with anemia, jaundice and hepatosplenomegaly. There may be evidence of extramedullary hematopoiesis.
- **Laboratory diagnosis:** CDA type 2 is defined by serological abnormalities. It is also known as hereditary erythroblastic multinuclearity with a positive acidified serum lysis test (HEMPAS), because RBCs most often show positive HEMPAS result on the acidified serum lysis test. RBC membrane shows marked reduction in membrane glycoprotein and band 3 detected by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE). On electron microscopy, RBCs show double cytoplasmic membrane.

CONGENITAL DYSERYTHROPOIETIC ANEMIA TYPE 3

CDA type 3 is an autosomal dominant disorder in which erythroblasts show multiple nuclei up to 12 due to KIF23 gene mutation mapped on 19p13.13.

ANEMIA OF CHRONIC DISEASE

Anemia of chronic disease can be secondary to acute and chronic inflammation, viral infections including HIV, hematologic solid malignant tumors, autoimmune diseases (rheumatoid arthritis, systemic lupus erythematosus, inflammatory bowel disease, and sarcoidosis), chronic rejection of solid organ transplantation and chronic renal disease.

- Anemia of chronic disease is second in incidence to iron deficiency anemia, which occurs due to impaired utilization of iron from macrophage stores in the bone marrow.

Table 8.104 Causes of anemia of chronic inflammation, autoimmune and malignant disorders

Infectious Causes	
▪ Tuberculosis	▪ Pneumonia
▪ Pulmonary abscess	▪ Bacterial endocarditis
Noninfectious Causes	
▪ Systemic lupus erythematosus (SLE)	▪ Sarcoidosis
▪ Rheumatoid arthritis	▪ Crohn's disease
	▪ Gaucher's disease
Malignant Tumors	
▪ Carcinoma	▪ Lymphoma
▪ Sarcoma	

- Anemia of chronic disease is a functional iron deficiency, although storage iron is either normal or even increased. Causes of anemia of chronic inflammation, autoimmune and malignant disorders are given in Table 8.104.

PATHOGENESIS

In chronic inflammation, activated macrophages synthesize cytokines like IL-6, IL-1 and TNF-α. IL-6 activates synthesis of master regulator of iron protein hepcidin by liver.

- Hepcidin inhibits release of iron from storage sites resulting in decreased erythropoiesis.
- The cytokines inhibit CFU-E (colony forming units-erythroid) resulting in decreased production of red blood cells.
- Anemia in chronic kidney disease shares some of the characteristics of anemia of chronic disease. Anemia in chronic kidney disease occurs due to decreased production of erythropoietin, renal insufficiency and circulating the antiproliferative effects of accumulating uremic toxins.
- Interleukin 1 (IL-1) cytokine synthesized by activated macrophages inhibits synthesis of erythropoietin by kidney. IL-1 also increases uptake of iron by reticuloendothelial cells.
- Tumor necrosis factor α (TNF-α) cytokine synthesized by activated macrophages participates in phagocytosis and degradation of red blood cells.
- Interferon γ (IFN-γ) cytokine synthesized by lymphocytes inhibits erythropoiesis and increases uptake of iron by reticuloendothelial cells.
- Erythropoiesis may be decreased by infiltration of bone marrow by microorganisms and cancer stem cells. Tumor cells can produce proinflammatory cytokines and oxygen-derived free radicals that damage developing erythroid progenitor cells in the bone marrow.

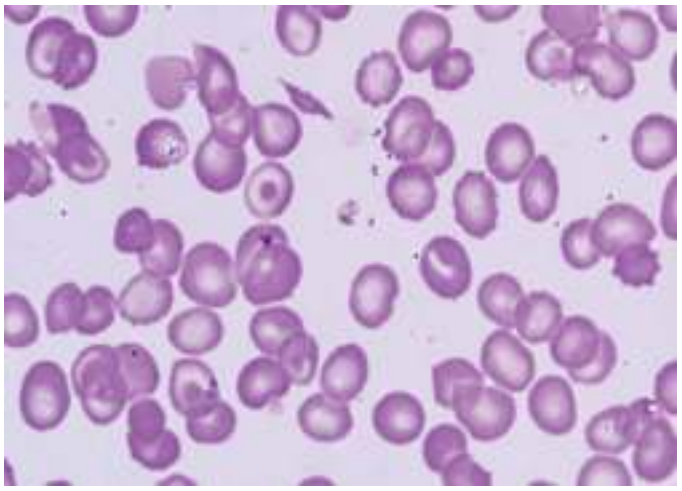

Fig. 8.61: Anemia of chronic disease. Peripheral blood smear examination shows mild to moderate microcytic hypochromic picture.

Laboratory Diagnosis of Anemia of Chronic Disease

Peripheral Blood Smear Examination

- Peripheral blood smear examination shows mild normocytic or mild to moderate microcytic hypochromic anemia.
- In chronic renal disease, anemia is most often normocytic and normochromic.
- Anemia in liver disease is moderately macrocytic. Peripheral blood smear findings are shown in Fig. 8.61.

Bone Marrow Smear Examination

- Increased iron is demonstrated in reticuloendothelial cells, e.g. bone marrow
- Defective iron transfer to red blood cell precursors
- Iron is reduced in red blood cell precursors
- Increased red cell protoporphyrin is observed
- Hematologic findings in anemia of chronic disease are given in Table 8.105.

MYELOPHTHISIC ANEMIA

Myelophthisic anemia is caused by bone marrow infiltration by metastatic tumor (e.g. lymphoma, breast, prostate, lung, stomach, kidney, thyroid gland) or extracellular material, bone marrow fibrosis (e.g. hairy cell leukemia, myelodysplastic syndrome), granulomatous disease, storage disease (e.g. Gaucher's disease, Niemann-Pick disease), and bone marrow necrosis.

Myelophthisic anemia is most often accompanied by a leukoerythroblastic peripheral blood picture characterized by increased dacrocytes (tear drop cells), nucleated red blood cells (normoblasts) and granulocyte precursors (shift to the left). Disorders causing myelophthisic anemia are given in Table 8.106.

- **Clinical features:** Patient presents with anemia and symptoms related to underlying cause, abdominal pain and massive splenomegaly.

Laboratory Diagnosis of Myelophthisic Anemia

Peripheral Blood Smear Examination

Peripheral blood smear examination shows severe anemic picture with leukoerythroblastic picture.

- Peripheral blood smear examination also shows increased dacrocytes (tear drop cells), nucleated red blood cells (normoblasts) and precursor granulocytic picture (shift to left).

Bone Marrow Smear Examination

- Bone marrow may demonstrate findings related to underlying etiology such as metastatic deposits (carcinomas, lymphoma), granulomatous disease, Gaucher's cells, Niemann-Pick cells.
- Bone marrow may show necrosis.

- **Prognosis and treatment:** Patient should be treated the underlying cause of myelophthisic anemia. Prognosis of myelophthisic anemia depends on underlying pathology.

Table 8.105 Hematologic findings in anemia of chronic disease

Features	Results
Peripheral blood smear examination	Mild normocytic or mild to moderate microcytic hypochromic anemia
Serum iron	Decreased
Serum total iron binding capacity (TIBC). In contrast to iron deficiency anemia, total iron binding capacity is decreased	Decreased
Transferrin saturation	Decreased
Serum ferritin	Normal or increased
Iron deposition in reticuloendothelial cells of bone marrow	Increased
Iron transfer to red blood cell precursors	Defective
Iron in red blood cell precursors	Decreased
Red blood cell protoporphyrin level	Increased

Table 8.106 Disorders causing myelophthisic anemia

Metastatic Solid Malignant Tumors and Lymphoma
▪ Breast carcinoma ▪ Prostatic carcinoma ▪ Lung carcinoma ▪ Gastric carcinoma ▪ Renal cell carcinoma ▪ Thyroid carcinoma ▪ Lymphomas
Granulomatous Inflammation
Tuberculosis
Hematologic Disorders
▪ Myeloproliferative neoplasms causing myelofibrosis ▪ Hairy cell leukemia causing myelofibrosis
Storage Disorders
▪ Gaucher's disease ▪ Niemann-Pick disease
Bone Marrow Necrosis
▪ Sickle cell disease crisis ▪ Infective etiology/sepsis ▪ All-*trans* retinoic acid therapy of acute promyelocytic leukemia
Disseminated Intravascular Coagulation (DIC)
▪ Blood transfusion reactions ▪ Infection by bacteria or fungi ▪ Liver disease ▪ Pregnancy-related complication due to retained placenta after delivery
Pulmonary Hypertension causing Myelofibrosis
Persistent pulmonary hypertension
Hematophagocytic Syndrome
Triggered by viral infections, e.g. Epstein-Barr virus or cytomegalovirus

FANCONI ANEMIA

Fanconi anemia (FA) is a rare autosomal recessive disorder characterized by bone marrow suppression (pancytopenia), multiple congenital anomalies, e.g. hypoplasia of bones of thumbs, radius, kidney or spleen, developmental delay and hyperpigmentation.

- **Molecular genetics:** Fanconi anemia occurs due to defects in a cluster of proteins responsible for DNA repair via homologous recombination.
  - Cells lack ability to excise UV-induced pyrimidine dimers from cellular DNA.
  - At least 13 gene mutations are known to cause Fanconi anemia, e.g. FANCD1/BRCA2, GANCG (XRCC9), FANCI, FANCJ, FANCL, FANCM and FANCN.
  - Patient with BRCA2 gene mutation is move prone to develop breast carcinoma.
- **Clinical features:** Fanconi anemia affects all bone marrow elements. Patient develops pancytopenia, bone marrow failure and growth retardation. There is increased risk for development of myelodysplasia (MDS), acute myelogenous anemia (AML) and solid tumors, e.g. brain tumors, hepatocellular carcinoma and breast carcinoma.

Laboratory Diagnosis of Fanconi Anemia (FA)

Peripheral Blood Smear Examination

- After attaining 10 years of age, patient develops pancytopenia defining abnormalities in two or more blood cell lineages in contrast to Diamond-Blackfan anemia, which affects only erythrocytes.
- Peripheral blood smear examination shows pancytopenia and thrombocytopenia.

Bone Marrow Smear Examination

- Bone marrow aspiration and trephine biopsy are essential to assess cellularity and morphology of residual marrow cells.
- Bone marrow shows a few hematopoietic cells replaced by fat cells, stromal cells and lymphocytes. Residual erythroid precursors may show evidence of dysplasia with nuclear-cytoplasmic maturation dissociation.

- **Treatment:** Hematopoietic stem cell (HSC) transplantation is curative. After bone marrow transplantation, patient may still develop myelodysplasia, acute myelogenous leukemia, brain tumors, hepatocellular carcinoma, and head and neck cancers. Surveillance for early detection of cancer is essential in these patients.

CHAPTER 9

White Blood Cell Disorders

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

LEUKOPOIESIS, QUANTITATIVE AND QUALITATIVE DISORDERS OF LEUKOCYTES

- Leukopoiesis
- Leukocytes: granulocytes and agranulocytes
  - Neutrophils
  - Eosinophils
  - Basophils
  - Monocytes
  - Lymphocytes
- Quantitative variations in leukocytes
  - Leukocytosis
  - Leukopenia
- Qualitative variations in leukocytes
  - Alder-Reilly anomaly
  - Chédiak-Higashi syndrome
  - May-Hegglin anomaly
  - Pelger-Hüet anomaly
  - Chronic granulomatous disease of the childhood
  - Myeloperoxidase deficiency
  - Leukocyte adhesion deficiency disorder
- Infectious mononucleosis
  - Mode of transmission
  - Clinical features
  - Pathophysiology
  - Complications
  - Laboratory diagnosis

LEUKEMIAS

- Leukemias: overview
  - Classification of leukemia
    - French-American-British (FAB) classification of leukemias
    - Revised 2024 WHO classification of leukemias
  - Pathogenesis
  - Laboratory diagnosis

ACUTE LYMPHOBLASTIC LEUKEMIA

- Acute lymphoblastic leukemia: overview
  - Predisposing factors
  - Molecular pathogenesis
  - Clinical features
  - Life-threatening complications of ALL and management
  - Laboratory diagnosis
    - Lymphoblast morphology in ALL subtypes
    - Immunophenotying in ALL subtypes
    - Cytogenetic/molecular genetic alterations in acute lymphoblastic leukemia
  - Prognosis
  - Treatment
  - Minimal residual disease

ACUTE MYELOGENOUS LEUKEMIA

- Acute myelogenous leukemia: overview
  - Pathogenesis
  - Clinical features
    - French-American-British (FAB) and revised 2024 WHO classification of acute myelogenous leukemia
  - Laboratory diagnosis
- Acute myelogenous leukemia: entities
  - AML-M0 with minimal differentiation
  - AML-M1 without maturation
  - AML-M2 with maturation
  - Acute promyelocytic leukemia (AML-M3, FAB)
  - Acute myelomonocytic leukemia (AMML/ AML-M4, FAB)
  - Acute monoblastic/monocytic leukemia (AML-M5A and AML-M5B, FAB)
  - Acute erythroid leukemia (AML-M6)
  - Acute megakaryoblastic leukemia (AMKL-M7)
- Myeloid sarcoma
- Acute myelogenous leukemia, not otherwise specified (AML-NOS)
  - Diagnostic approach
  - Prognostic factors
  - Treatment

MYELODYSPLASTIC SYNDROMES

- Myelodysplastic syndromes: overview
  - French-American-British (FAB) and revised 2024 WHO classification of myelodysplastic syndrome (MDS)
  - Pathogenesis
    - Molecular genetic alterations
    - Cytogenetic abnormalities
  - Clinical features
  - Laboratory diagnosis
  - Prognostic criteria
  - Treatment

MYELODYSPLASTIC/MYELOPROLIFERATIVE NEOPLASMS

- Myelodysplastic/myeloproliferative neoplasms: entities
  - Chronic myelomonocytic leukemia (CMML)
  - Juvenile myelomonocytic leukemia (JMML)
  - Atypical chronic myelogenous leukemia (aCML), BCR-ABL1 negative

CHRONIC MYELOPROLIFERATIVE NEOPLASMS

LEUKOPOIESIS, QUANTITATIVE AND QUALITATIVE DISORDERS OF LEUKOCYTES

LEUKOPOIESIS

Hematopoiesis occurs from a succession of anatomic sites during embryonic and fetal development, beginning outside the embryo in the yolk sac. Soon afterward, hematopoiesis begins in the embryo proper, then in the fetal liver, spleen and finally the fetal bone marrow. With each change of anatomic site, the range of hematopoiesis becomes more complex and similar to that of the adult.

- Hematopoietic growth factors may stimulate proliferation of early bone marrow cells, direct differentiation to one or other cell type, stimulate cell maturation, suppress apoptosis, or affect the function of mature non-dividing cells. Hematopoietic growth factors can act on stromal cells, pluripotent stem cells, multipotential progenitor cells and committed progenitor cells.
- Hematopoietic cells comprise hematopoietic stem cells (HSCs; CD34+), progenitor cells (committed cells) and mature red blood cells, white blood cells and platelets.
- Leukocytes originate from pluripotent hematopoietic stem cells (CD34+) in the bone marrow common myeloid and lymphoid hematopoietic stem cells.
- Hematopoietic stem cells (HSCs) possess self-renewal property. Hematopoietic growth factors are a family of regulatory molecules that play important roles in the growth, and differentiation of blood progenitor cells, as well as functional activation of mature cells.
- Granular leukocytes (neutrophils, eosinophils, basophils) have their origin in the myeloid stem cells and develop through a sequence involving myeloblast, promyelocyte, myelocyte, metamyelocyte, band forms and mature granular cells such as neutrophils, eosinophils, and basophils.
- Neutrophils are predominant cells in the first few weeks in the newborn. Lymphocytes are predominant cells in the postnatal period between 4 weeks and 4 years. After 4 years of age, neutrophils are predominant cells.
- Monocytes like granulocytes have their origin from myeloid stem cell, but develop along a pathway involving monoblast, promonocyte and monocytes. The monocytes migrate to tissues and become tissue macrophages (called reticuloendothelial cells). Monocyte-macrophages phagocytose bacteria and particulate material and play a pivotal role in the inflammatory reactions.
- Lymphocytes originate from lymphoid stem cell lineage, which develop through sequence involving

Table 9.1 Hematopoietic growth factors and their actions on bone marrow cells

Hematopoietic Growth Factors	Actions on Bone Marrow Cells
TNF (tumor necrosis factor), IL-1	Stromal cells
SCF (stem cell factor), FLT3-L (FLT-ligand), VEGF (vascular endothelial growth factor)	Pluripotent stem cells
IL-3, GM-CSF (granulocyte-macrophage colony-stimulating factor), IL-6, G-CSF (granulocyte colony-stimulating factor), Thrombopoietin	Multipotential progenitor cells
G-CSF (granulocyte colony-stimulating factor), M-CSF (macrophage colony-stimulating factor), IL-5 (maturation and release of eosinophils), erythropoietin, thrombopoietin	Committed progenitor cells

Hematopoietic growth factors also act synergistically with early acting growth factors on pluripotential progenitors.

Table 9.2 Normal percentage and differential white blood cell count

White Blood Cells	Percentage
Neutrophils	50–70%
Eosinophils	1–4%
Basophils	0–1%
Lymphocytes	20–40%
Monocytes	2–10%

lymphoblasts, prolymphocytes, lymphocytes, which undergo further differentiation in the lymphoid organs. T progenitor cell migrates to thymus. B progenitor cell is transformed into plasma cell. Natural killer progenitor cell gives rise to natural killer cell.

- Life span of leukocytes is relatively short, so the constant renewal is essential to maintain normal blood levels. Any conditions that decrease the availability of hematopoietic stem cells or hematopoietic growth factors lead to decrease in white blood cells.
- Hematopoietic growth factors and their actions on bone marrow cells are given in Table 9.1. Normal percentage and differential white blood cell count are given in Table 9.2.

LEUKOCYTES: GRANULOCYTES AND AGRANULOCYTES

Leukocytes are the major cellular components of the inflammatory and immune response that protect against infection and neoplasia and assist in the tissue repair.

- Like all blood cells, leukocytes are produced primarily in the bone marrow, which develop from hematopoietic stem cells that mature into one of the five major types of white blood cells (i.e. neutrophils, lymphocytes, monocytes, eosinophils, and basophils).
- Normally, persons produce approximately 100 billion white blood cells. The number of white blood cells in a given volume of blood is expressed as cells per microliter of blood. The total leukocyte count normally ranges between 4,000 to 11,000 cells per microliter (**4×10^9/L to 11×10^9/L**).

NEUTROPHILS

Neutrophils are the dominant circulating myeloid-lineage phagocytes involved in self-defense in humans, which constitute 50–70% of leukocytes.

- Neutrophils measure 12–15 µm in diameter and have 2–5 lobed nucleus. Cytoplasm contains small purple azurophilic and specific granules rich in hydrolytic enzymes and other potentially toxic oxygen-derived free radicals leading to elimination of pathogens.
- Neutrophils are recruited to the site of tissue injury within first 24 hours of acute inflammation and provide essential defense against acute bacterial infections. Following bacterial infections, neutrophils are attracted by chemotactic factors. Neutrophils eliminate injurious agent by phagocytosis of antibody and complement-coated bacteria and degradation occurs through activation of hydrolytic proteases and other potentially toxic oxygen-derived free radicals.
- Neutrophils are derived from hematopoietic stem cell (HSC). The development of neutrophils occurs in the bone marrow in 14 days. Subsequent differentiation of myeloid stem cell occurs through the stages of myeloblast, promyelocyte, myelocyte, metamyelocyte, band form neutrophil and mature neutrophil. Neutrophils are terminally differentiated, which neither divide nor alter their morphologic phenotype after their release from the bone marrow.
- Several myeloid factors are required for the transcription regulation of neutrophils including lymphoid enhancer-binding factor 1 (LEF1), growth factor independent 1 (GFI-1) and CCAAT/enhancer-binding proteins (C/EBPs).
- Principal among the hematopoietic growth factors/cytokines regulating granulopoiesis is granulocyte colony-stimulating factor (G-CSF) derived from monocyte-macrophage, T cells, fibroblasts, vascular

endothelium. G-CSF binds to its cognate G-CSFR participates in myeloid differentiation, proliferation of granulocyte precursors, and release of mature neutrophils from the bone marrow. Other hematopoietic cytokines such as **IL-6** and **IL-3** also contribute to granulopoiesis.

- Mature neutrophils exit the bone marrow through the pores of sinusoidal endothelium and enter in blood circulation, a process called transcellular migration. Neutrophils released from the bone marrow have a bloodstream half-life of 4–10 hours and tissue half-life of two days.
- Neutrophils undergo apoptosis through soluble signaling molecules such as tumor necrosis factor (TNF) and FAS (CD95) ligand.
- Recently, the SDF-1/CXCR4 has been implicated in clearance of neutrophils. Mature neutrophils have low levels of CXC chemokine receptors. As neutrophils undergo aging, these alter their phenotype and upregulate CXCR4.

EOSINOPHILS

Eosinophil is a specialized cell of the innate immune system linked with allergic state and parasitic infections. It constitutes 1–4% of leukocytes. This pro-inflammatory white blood cell measures 12–15 µm in diameter and has a nucleus with two lobes and large coarse, orange-colored granules in cytoplasm.

- Eosinophil arises from the hematopoietic stem cells (HSCs) in the bone marrow and take about 8 days to mature through various stages such as myeloblast, eosinophilic myelocyte, metamyelocyte, band form cell and mature eosinophil. The eosinophil migrates from the bone marrow into blood circulation and target tissues/organs. The migration and movement of eosinophils is promoted by **c**hemokines such as CCL11, CCL24 and CCL26 and chemokine receptors such as CCR3.
- Eosinophils are terminally differentiated, which neither divide nor alter their morphologic phenotype after their release from the bone marrow.
- Eosinophilic granulopoiesis appears to be regulated by T cells through the secretion of hematopoietic growth factors such as granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-5 and IL-3. GM-CSF and IL-3 also increase the production of other myeloid cells. Interleukin-5 increases eosinophil production exclusively. These proteins and cytokines are involved in the maturation, survival and persistence of eosinophils. Eosinophils are recruited by chemokine (eotaxin) at injury site in IgE-mediated allergic reactions.
- Eosinophilic granules contain four major proteins: major basic protein (**MBP**), eosinophilic cationic protein (**ECP**), eosinophil peroxidase (**EPO**) and eosinophil-derived neurotoxin **(EDN)**. These proteins are involved in phagocytosis, killing invasive helminths, antigen presentation to other cells and platelet interaction. The action of eosinophil peroxidase (EPO) also leads to oxidative burst, a crucial step in phagocytosis.
- Eosinophils may modulate immediate hypersensitivity reactions by degrading or inactivating chemical mediators released by mast cells such as histamine, leukotrienes (which may induce vasoconstriction and bronchoconstriction), lysophospholipids and heparin.
- Eosinophilic granules contain crystalline material in cytoplasm, which become 'Charcot-Leyden crystals' demonstrated in the sputum of bronchial asthmatic patients.

BASOPHILS

Basophils are the least abundant circulating granulocytes, which account for less than 1% of circulating leukocytes. The basophil measures 14–16 µm in diameter and contains large cytoplasmic dark blue to black granules which obscure the cell nucleus in Romanowsky stained peripheral blood smears examined by light microscopy. However, when unstained nucleus of basophil is visible, and it usually has two lobes.

- The cytoplasmic granules inside the basophils contain histamine, heparin and tryptase. Histamine is a vasodilator near site of infection, which prevents blood coagulation at the site of infection.
- Basophils, like other blood cells, arise from hematopoietic stem cells in the bone marrow, develop, differentiate and mature under the influence of hematopoietic growth factors such as IL-3 through various stages including myeloblast, basophilic myelocyte, metamyelocyte, band form cell and mature basophil.
- Basophils are released from the bone marrow into the blood circulation as mature basophil. Mature basophils have an estimated life span of 60–70 hours.
- Basophils play a role in immediate hypersensitivity disorders as well as atopy, allergic contact dermatitis and possibly autoimmune disorders such as systemic lupus erythematosus. Basophils bind to and may trigger production of immunoglobulin E (IgE), an antibody that helps in protection against parasites.

MONOCYTES

Monocytes are the largest cells of the blood with average 15–18 µm in diameter and make up 2–8% of the leukocytes. The nucleus is relatively big and tends to be indented and reniform (kidney) shape with open

chromatin without nucleoli. The cytoplasm contains large number of fine granules, which often appear to be more numerous near the cell membrane of the monocyte.

- Primary stimulators of monocytopoiesis and granulopoiesis are granulocyte colony-stimulating factor (G-CSF), IL-1, IL-3, IL-6 and granulocyte-macrophage colony-stimulating factor (GM-CSF). In general, hematopoietic growth factors and cytokines are produced by various inflammatory cells, with or without contribution from stromal cells. Monocytes are derived from monoblasts in the bone marrow, which have life span of 12 hours.
- Monocytes are actively motile and phagocytic capable of ingesting infectious agents, red blood cells and other large particles. Monocytes cannot replace the function of neutrophils in the removal and destruction of bacteria, which usually reach the site of inflamed tissue later than the granulocytes. Monocytes are found at the sites of chronic inflammation.

LYMPHOCYTES

Lymphopoiesis is a tightly regulated sequence of events that leads to expression of a functional antigen receptor on the surface of lymphocytes. B cell expresses cell surface immunoglobulin receptors (BCRs) and T cell receptors (TCRs) are expressed on T cells.

- Lymphopoiesis begins in the bone marrow with committed lymphoid stem cells. The initial step of differentiation of the committed lymphoid stem cells appears to be the separation of B progenitor cells from T progenitor cells, and natural killer T cells.
- Several hematopoietic regulatory cytokines including IL-1, IL-2, IL-4, IL-10 and interferon-γ (IFN-γ) influence the development of B progenitor cells. T cells are derived from the precursor lymphoid cells in the bone marrow under the influence of several hematopoietic cytokines including IL-1, IL-2 and IL-9 and migrate to the thymus gland for further maturation.
- Natural killer cells (NK cells), large granular lymphocytes, appear to share a common progenitor cell with T cells in the bone marrow. Natural killer cells production is under the influence of regulatory cytokine IL-5. NK cells demonstrate HLA non-restricted cytotoxicity and release a variety of hematopoietic regulatory cytokines, such as IL-1, IL-2, IL-4 and interferons.
- Some of lymphocytes enter bloodstream and most move through lymphatic system, which is the group of tissues and organs, like tonsils, lymph nodes, spleen, and mucosa-associated lymphoid tissue (MALT) organs that provide protection from infection.
- About 25% of the newly formed lymphocytes remain in the blood marrow and become B cells. The remaining 75% of lymphocytes travel to thymus and become T cells. It is well established that the earliest progenitor cells enter the thymus gland receives critical signals delivered through the NOTCH1 receptor, which leads to specification and commitment toward the T cell fate.
- There are different kinds of B cells and T cells, which include: (a) effector cells that are activated by antigens to fight an active infection, and (b) memory cells that recognize and remember past infections and go into action quickly on reinfection with an antigen. B cells and T cells work together to fight infection.

Pathology Pearls: Different Types of Lymphocytes and their Functions

B Cells

- B cells recognize antigens and become plasma cells that produce immunoglobulins (e.g. IgG, IgA, IgM, IgD and IgE) to fight infections.
- B cells are distinguished by the presence of cell surface immunoglobulin receptors. Plasma cells are terminally differentiated B cells that produce immunoglobulins.

T Cells

- T cells migrate from bone marrow and mature in the thymus gland. T cells differentiate into CD8+ cytotoxic T cells, CD4+ helper T cells and CD4+ regulatory T cells, natural killer T cells and memory T cells.
- Once T cells are released into the blood circulation, they have a long life. T cells can discern between healthy and abnormal cells. healthy cells have abundant peptide major histocompatibility complex on their surface.
- T cells participate in cell-mediated immunity. T cells possess cell surface receptors (TCR), that bind antigens prepared by antigen-presenting cells (APCs). Activated T cells recruit monocytes from the circulation with IFN-γ, a powerful activator of macrophages. Each of these cells performs different functions.
  - **CD4+ regulatory T cells:** CD4+ regulatory T cells suppress immune system to keep its immune response in check through the transcription factor FOXP3, so that it does not overreact, as does in autoimmune disorders. Mutations in FOXP3 gene can cause the autoimmune disorder (X-linked immunodysregulation polyendocrinopathy, enteropathy).
  - **CD4+ helper T cells:** CD4+ helper T cells express glycoproteins on their cell surface, which activate in the presence of peptide antigens on the surface of invading pathogens. These cells respond immediately to protect the immune system by recruiting other immune cells. These cells secrete different cytokine proteins according to the immune response.

- **CD8+ cytotoxic T cells:** CD8+ cytotoxic T cells express CD8 glycoproteins on their cell surface, which activate in the presence of antigens that bind to MHC class I molecules present on all nucleated cells. These cells patrol the immune system and become memory T cells upon battle with invading pathogens. These cells find and directly attack cells infected with an antigen, cancer stem cells and foreign cells like transplanted organs.
- **Memory T cells:** Memory T cells are antigen-specific T cells that remain long-term after an infection has been eliminated, which remember markers on the surface of bacteria, viruses or cancer cells that have seen before. Memory T cells are quickly converted into large numbers of effector T cells upon re-exposure to specific invading antigen, thus providing a rapid immune response to past infection.
- **Natural killer T cells:** Natural killer T cells bridge the adaptive immune system to the innate immune system that recognizes pathogens with the glycolipid antigen molecule CD1d protein, which is human antigen encoded by CD10 gene. Natural killer T cells kill a variety of infected and cancer cells by lysing their cell membrane in the absence of prior exposure or priming.

QUANTITATIVE VARIATIONS IN LEUKOCYTES

Causes of quantitative variations (increase or decrease in number) in normal leukocytes include: bone marrow dysfunction, premature destruction of leukocytes in the circulation, and alterations in leukocytes that originate in the circulation or lymphoid organs in response to invasion by infectious microorganisms.

- Leukocytosis is defined as increase in the white blood cell count to more than 11,000 per microliter of blood (11×10^9/L) in adults. It is most often a normal protective response of physiologic stressors involving specific subtype of leukocyte. Leukocytosis occurs in pathologic conditions like leukemias.
- Leukopenia is defined as decrease in the white blood cells to fewer that 4000 cells per microliter (4×10^9/L), which frequently makes persons most susceptible to infections.
  - Leukopenia can be caused by radiation, certain chemotherapeutic agents, immunodeficiency states and autoimmune disease (i.e. systemic lupus erythematosus).
  - Neutropenia is abnormally low number of neutrophils. Lymphopenia is abnormally low number of lymphocytes.

LEUKOCYTOSIS

Leukocytosis is defined as increase in the white blood cell count to more than 11,000 per microliter of blood (11×10^9/L) in adults. It is most often caused by normal response to the body to help fight an infection or some drugs such as corticosteroids.

- Neutrophil leukocytosis is an abnormally high number of neutrophils. Lymphocyte leukocytosis is an abnormally high number of lymphocytes.
- However, an increase in the number of leukocytes can also occur in leukemias with the release of immature or atypical leukocytes from the bone marrow into the blood circulation.

Neutrophilia

Neutrophilia refers to neutrophil count that exceeds the reference range for age on a complete and differential blood count. The absolute neutrophil count (ANC) is not measured directly, but calculated by multiplying the total number of WBC count by the percentage of neutrophils dividing by 100. The percentage of neutrophils consists of the mature segmented neutrophils and band form neutrophils. The normal range of absolute neutrophil count is 1.5×10^9/L to 8×10^9/L.

- During established bacterial infection, absolute neutrophil count and band form neutrophils remain elevated with equal numbers in the marginal and circulatory granulocyte pool. During the recovery phase, the flow of neutrophils from the bone marrow decreases, with a resultant in the number of neutrophils in the circulation. During pregnancy and parturition, neutrophil count is raised.
- Neutrophilia may result from a shift of neutrophils from the marginal pool to the circulating pool or because of increase in number of neutrophils.
- Some bacterial infections do not cause neutrophilia, rather induce neutropenia in the settings of typhoid fever, tuberculosis, and brucellosis.
- Pathologic disorders induced neutrophilia are given in Table 9.3. Polymorphonuclear leukocytosis in Giemsa-stained peripheral blood smear is shown in Fig. 9.1. Reactive neutrophilia in Giemsa-stained bone marrow aspirate smear is shown in Fig. 9.2.

Eosinophilia

Eosinophilia is defined as a peripheral blood eosinophil count exceeding 500 per microliter of blood (>0.5×10^9/L). Peripheral eosinophilia is characterized as mild: 500–1500 per microliter of blood (0.5 to 1.5×10^9/L, moderate: 1500–5000 per microliter of blood (1.5 to 5×10^9/L) and severe: more than 5000 per microliter of blood (>5 to 10×10^9/L).

- Peripheral blood eosinophil count may be increased above 30×10^9/L in allergic disorders. Persistent eosinophilia may cause organs damage because of tissue inflammation and reaction to the cytokines and chemokines released by eosinophils as well as immune cells that are recruited to the site tissue injury.

Table 9.3 Pathologic disorders induced neutrophilia

Acute Bacterial Infections
▪ Lobar pneumonia ▪ Bronchopneumonia ▪ Pyogenic meningitis ▪ Acute appendicitis ▪ Infected burns ▪ Diphtheria
Acute Stress State
▪ Acute myocardial infarction ▪ Posthemorrhagic state ▪ Post-surgery state
Myeloproliferative State
▪ Chronic myelogenous leukemia, BCR-ABL1 positive ▪ Polycythemia vera (PV)
Miscellaneous Disorders
▪ Leukemoid reactions ▪ G-CSF therapy induction ▪ Corticosteroid therapy ▪ Rheumatoid arthritis ▪ Gout

Although any organ may be involved including heart, lungs, spleen, skin and nervous system.

- Eosinophilia may be primary or secondary. Primary eosinophilia is a clonal proliferation of eosinophils associated with hematologic disorders such as leukemias and myeloproliferative neoplasms. Secondary eosinophilia is associated with nonclonal and non-hematologic disorders.
- Eosinophilia in Giemsa-stained peripheral blood smear is shown in Fig. 9.3. Causes of primary and secondary eosinophilia are given in Table 9.4.

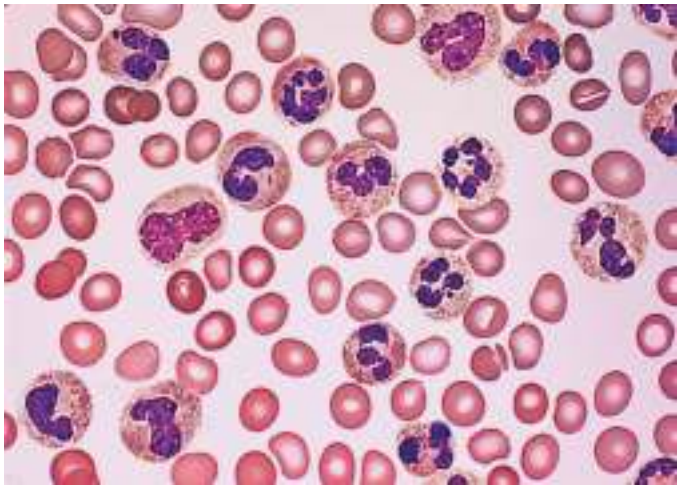

Fig. 9.1: Polymorphonuclear leukocytosis in Giemsa-stained peripheral blood smear. Polymorphonuclear leukocytosis is characterized by increased levels of polymorphonuclear leukocytes in the blood above 11,000 WBCs in a cubic millimeter of blood in the settings of infections, tissue damage, inflammatory diseases and diabetic ketoacidosis (1000X).

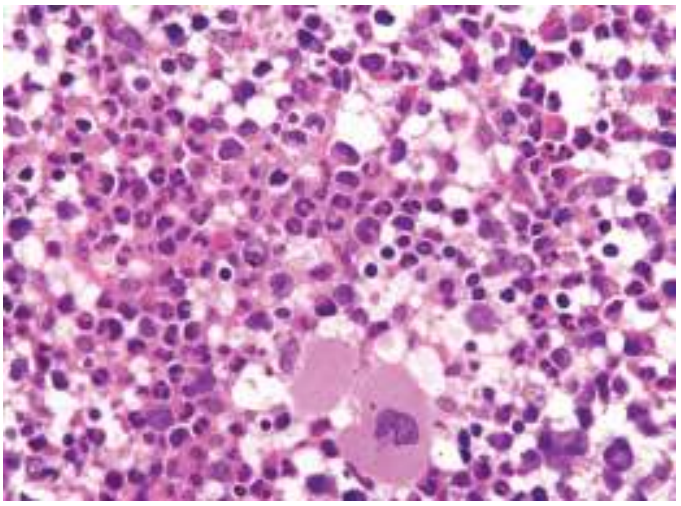

Fig. 9.2: Reactive neutrophilia in Giemsa-stained bone marrow aspirate smear. Bone marrow aspirate smear examination shows increased cellularity and replaced by numerous neutrophils (1000X).

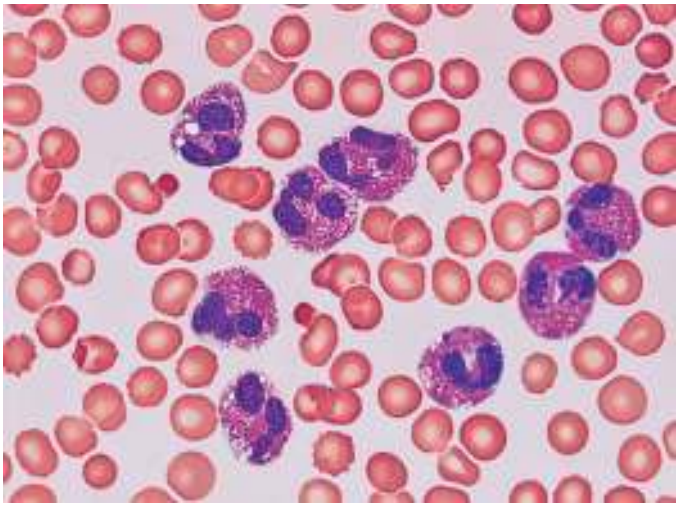

Fig. 9.3: Eosinophilia in Giemsa-stained peripheral blood smear. Eosinophilia is an increase in the number of eosinophils in the blood circulation in the setting of response to some allergens, drugs and parasites and in some types of leukemia. Eosinophils release granules of enzymes to fight some foreign substances and infections (1000X).

Clonal Hypereosinophilic Syndrome

- Hypereosinophilic syndrome is defined as peripheral blood eosinophilia more than 1500/cu mm ($\geq 1.5 \times 10^9$/L) persisting ≥6 months, which most often affects persons of 20–50 years of age.
- Only some patients with persistent eosinophilia develop organ dysfunction (heart, lungs, spleen, skin, bone marrow and nervous system).
- Cardiac involvement can cause significant morbidity and mortality.
- Two categories of clonal hypereosinophilic syndrome include myeloproliferative and lymphoproliferative variants are as follows.

Table 9.4 Causes of primary and secondary eosinophilia

Primary Clonal Eosinophilia Associated with Clonal Disorders		
Myeloid neoplasms	▪ Chronic myelogenous leukemia (BCR-ABL1 positive) ▪ Acute myelogenous leukemia with inv(16) (p13.1q22) or t(16;16) (p13.1; q22) ▪ Acute myelogenous leukemia with t(8;21) (p22; q22.1) ▪ Chronic myelomonocytic leukemia (CMML)	
Myeloid and lymphoid neoplasms associated with rearrangement and fusion genes	▪ Myeloid and lymphoid neoplasms associated with PDGFRA, PDGFRB, or FGFR1 rearrangements ▪ Myeloid and lymphoid neoplasms associated with PCM1-JAK2, ETV6-JAK2, or BCR-JAK2 fusion genes	
Lymphoid neoplasms	▪ T cell lymphoma ▪ Hodgkin disease (mixed cellularity variant) ▪ ALL (acute lymphoblastic leukemia) ▪ Lymphoproliferative variant of hypereosinophilic syndrome	
Other disorders	▪ Eosinophilic granuloma ▪ Mastocytosis	
Eosinophilia Associated with Nonclonal Reactive Disorders		
Allergic state	▪ Bronchial asthma ▪ Urticaria	▪ Hay fever ▪ Allergic rhinitis
Parasitic infections	▪ *Ancylostoma duodenale* ▪ *Necator americanus*	▪ *Ascaris lumbricoides* ▪ *Wuchereria bancrofti*
Skin disorders	▪ Eczema ▪ Pemphigus vulgaris ▪ Psoriasis	▪ Bullous pemphigoid ▪ Dermatitis herpetiformis
Collagen vascular diseases	▪ Churg-Strauss disease ▪ Wegener granulomatosis	
Pulmonary diseases	▪ Idiopathic acute or chronic eosinophilic pneumonia	▪ Tropical pulmonary eosinophilia ▪ Allergic bronchopulmonary aspergillosis
Miscellaneous disorders	▪ Gastroenteritis ▪ Adrenal insufficiency	▪ Immunologic disorders

Myeloproliferative variant of clonal hypereosinophilic syndrome

- The myeloproliferative variant of hypereosinophilic syndrome is most often associated with a small interstitial deletion of chromosome at the **CHIC2 site** that induces the FIP1L1/PDGFRA-associated fusion gene, which possess receptor tyrosine kinase activity that can transform hematopoietic stem cells. Other cytogenetic abnormalities include rearrangement of the gene for fibroblast growth factor 1 (FGFR1) or Janus kinase 2 (PCM1-JAK2).
- Patients present with splenomegaly, thrombocytopenia, anemia, elevated serum vitamin B_{12} levels, hypogranular or vacuolated eosinophils and myelofibrosis, who often develop endomyocardial fibrosis, but rarely develop acute myelogenous leukemia or acute lymphoblastic leukemia. Patients are treated by imatinib and other receptor tyrosine kinase inhibitors.

Lymphoproliferative variant of clonal hypereosinophilic syndrome

- The lymphoproliferative variant of hypereosinophilic syndrome is associated with a clonal population of T cells with aberrant phenotype.
- Clonal T cell receptor rearrangement is demonstrated by polymerase chain reaction (PCR) in lymphoproliferative variant of hypereosinophilic syndrome.
- Patient presents with angioedema, skin abnormalities or both, hypergammaglobulinemia (especially IgE), circulating immune complexes (sometimes with serum sickness) and rarely T cell lymphoma.

Basophilia

Basophilia is defined as an absolute increase in the number of basophils in blood. Reference values of basophilia vary from laboratory, but an absolute count

of basophils greater than 0.2×10^9/L in blood is considered a true basophilia.

- Basophilia is associated with chronic myelogenous leukemia BCR-ABL1 positive, basophilic leukemia, Hodgkin's disease, polycythemia vera, hypothyroidism, IgE-mediated allergic reactions, ulcerative colitis, mastocytosis and tuberculosis.
- Elevated basophil count (>20%) in the peripheral blood in a patient with chronic myelogenous leukemia BCR-ABL1 positive, often indicates a transition of chronic myelogenous leukemia BCR-ABL1 chronic phase to CML blast phase.
- Polycythemia vera is also associated with mild basophilia. A subset of acute myelogenous leukemias are associated with basophilia including acute myelogenous leukemia with t(6;9) (p23;q34); DEK-NUP214 and acute basophilic leukemia.
- Conditions associated with reactive basophilia include IgE-mediated allergic and type 1 hypersensitivity reactions, collagen vascular disorders, myxedema, irradiation, tuberculosis, and certain viral infections.

Lymphocytosis

Lymphocytosis is defined as an increase in absolute lymphocyte count (ALC) to $>4 \times 10^9$/L in adult patients, $>7 \times 10^9$/L in children and $>9 \times 10^9$/L in neonates. Lymphocytes constitute around 20–40% of white blood cells (WBCs).

- Absolute lymphocyte count calculates total white blood cell (WBC) multiplied by the percentage of lymphocytes in the peripheral blood. Different lymphocyte subsets (B cells, T cells or natural killer cells) may be elevated depending on the etiology.
- The definition of relative lymphocytosis refers to an increase in WBC count >40% in the presence of a normal absolute white blood cell count. Distinguishing reactive lymphocytosis from malignant lymphocytosis can be challenging and may vary depending on the age and other demographics.
- Reactive lymphocytosis may be caused by viruses (EBV, HIV, influenza, hepatitis, mumps, rubella, HTLV-1, measles, chickenpox, adenovirus), bacteria (*Bartonella henselae*, *Bordetella pertussis*, *Brucellosis*, *Treponema pallidum*, Mycobacterium bacilli), and parasites (mlarial parasite, *Toxoplasma gondii*).
- Lymphocytosis occurs in lymphoproliferative disorders (chronic lymphocytic leukemia, NHL-mantle cell lymphoma, marginal zone lymphoma, hairy cell leukemia, follicular lymphoma, Sézary syndrome, large granular lymphocytic leukemia).
- Congenital B cell lymphocytosis occurs due to germline heterozygous missense mutation in CARD11 gene that encodes a scaffolding protein required for nuclear factor kappa B (NF-κB) in both B and T lymphocytes. This entity typically progresses to chronic lymphocytic leukemia (CLL) by the fourth decade of life.
- Persistent B cell polyclonal lymphocytosis is characterized by binucleated lymphocytes predominantly in young tobacco smoker women, and associated with IgM polyclonal gammopathy and HLA-DR7, which exhibits a stable clinical and biological course. Lymphocytosis may also occur in post-splenectomy patients, that persists stable over years. Lymphocytosis in peripheral blood smear is shown in Fig. 9.4. Causes of lymphocytosis are given in Table 9.5.

Monocytosis

Monocytosis is defined by an absolute circulating monocyte count exceeding upper limit of the reference range of $\geq 1.0 \times 10^9$/L (1000/cu mm) in adults and $\geq 3.5 \times 10^9$/L (3500/cu mm) in neonates.

- Monocytosis usually occurs in the setting of chronic inflammation resulting from infections like tuberculosis, syphilis, brucellosis or subacute bacterial endocarditis, autoimmune disorders, granulomatous diseases, and sarcoidosis. Monocytosis is often the first sign of recovery after myelosuppression.
- Monocytosis is severe in chronic myelomonocytic leukemia, juvenile myelomonocytic leukemia. Monocytosis may be mild to moderate in acute monocytic leukemia.
- Monocytosis, especially monocyte : lymphocyte ratio greater than 0.8–1.0, may indicate active progression of tuberculosis and poor prognosis. Normal monocyte : lymphocyte ratio of ≤0.3 is restored when tissue healing process is complete. Causes of monocytosis are given in Table 9.6.

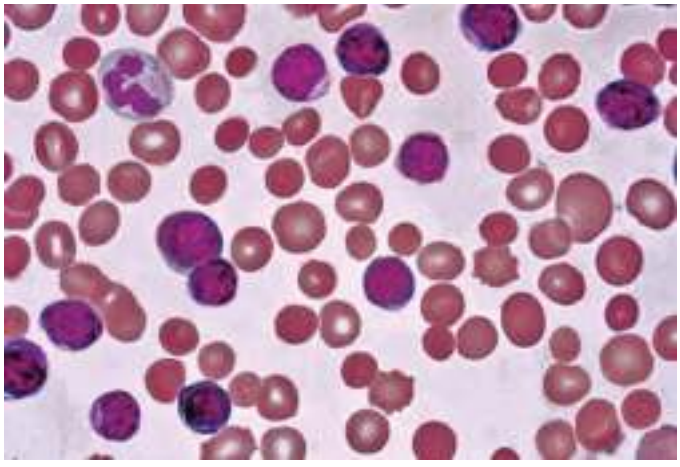

Fig. 9.4: Lymphocytosis in peripheral blood smear. Lymphocytosis is an increase in number of lymphocytes in blood higher than 5000 lymphocytes in a microliter of blood circulation (1000X).

Table 9.5 Causes of lymphocytosis

Bacterial Infections	
▪ Mycobacterium bacilli	▪ *Bartonella henselae*
▪ *Treponema pallidum*	▪ *Bordetella pertussis*
▪ Brucellosis	
Viral Infections	
▪ Infectious mononucleosis (Epstein-Barr virus)	▪ Adenovirus
▪ Hepatitis B virus (HBV)	▪ Mumps virus
▪ Hepatitis C virus (HCV)	▪ Measles virus
▪ Rubella virus	▪ Chickenpox virus
	▪ Cytomegalovirus
Parasitic Infestations	
▪ Malarial parasite	▪ *Toxoplasma gondii*
Hematological Malignancies	
▪ Chronic lymphocytic leukemia (CLL)	▪ NHL spillover
▪ Adult T cell leukemia/ lymphoma	▪ Hairy cell leukemia (HCL)
▪ Prolymphocytic leukemia (PML)	▪ Sezary syndrome
	▪ Large granular lymphocytic leukemia

Table 9.6 Causes of monocytosis

Bacterial Infections	
▪ Tuberculosis	▪ Bacterial endocarditis
▪ Syphilis	▪ Brucellosis
Parasitic Infestations	
▪ Kala-azar	▪ Trypanosomiasis
Hematologic Malignancies	
▪ Acute myelogenous leukemia (AML-M4 and AML-M5)	
▪ Hodgkin's disease	
▪ Chronic myelogenous leukemia, BCR-ABL1 positive	
▪ Chronic myelomonocytic leukemia (CMML)	
▪ Myelodysplastic syndrome (MDS)	
Autoimmune Disorders	
▪ Ulcerative colitis	▪ Systemic lupus erythematosus (SLE)
▪ Crohn's disease	
▪ Sarcoidosis	▪ Rheumatoid arthritis (RA)

LEUKOPENIA

Leukopenia refers to the decrease in the number of white blood cells in blood due to exposure to certain chemical agents, certain drugs (antiepileptic sodium valproate, immunosuppressive cyclosporin, antithyroid thiouracil, and interferon), chemotherapy and radiation for cancer treatment leading to bone marrow failure or suppression.

- Leukopenia can be caused by certain hematologic disorders such as myelodysplastic syndrome, myeloproliferative syndrome, myelofibrosis, aplastic anemia, and megaloblastic anemia.
- Cancers metastasizing to bone marrow result in leukopenia. Leukopenia is demonstrated in systemic lupus erythematosus (SLE). Hypersplenism is caused by splenomegaly, that destroys the red blood cells and white blood cells leading to anemia and leukopenia. Leukopenia leads to decreased immunity.

Pancytopenia

Pancytopenia is defined as deficiency of all three cellular components of the red blood cells, white blood cells and platelets leading to simultaneous presence of anemia, leukopenia and thrombocytopenia. Therefore, pancytopenia exists when hemoglobin is less than 13.5 g/dl in males or 11.5 g/dl in females, the leukocyte count is less than 4000 per microliter and platelet count is less than 1,500,000 per microliter.

- Most common cause of pancytopenia is megaloblastic anemia followed by acute myelogenous leukemia and aplastic anemia. Pancytopenia is induced by infections, some drugs, chemotherapeutic agents, radiation therapy, and exposure to radiation, arsenic and benzene.
- Patients present with fever, pallor, fatigue, dizziness, weight, anorexia, night sweats, bleeding tendencies and organomegaly.
- Bone marrow examination is a single useful investigation, which reveals the underlying etiology in patients with pancytopenia. Severity of pancytopenia and underlying pathology determine the management and prognosis. Thus, pancytopenia of the correct cause will help in implementing appropriate therapy. Pancytopenia in Giemsa-stained peripheral blood smear is shown in Fig. 9.5.

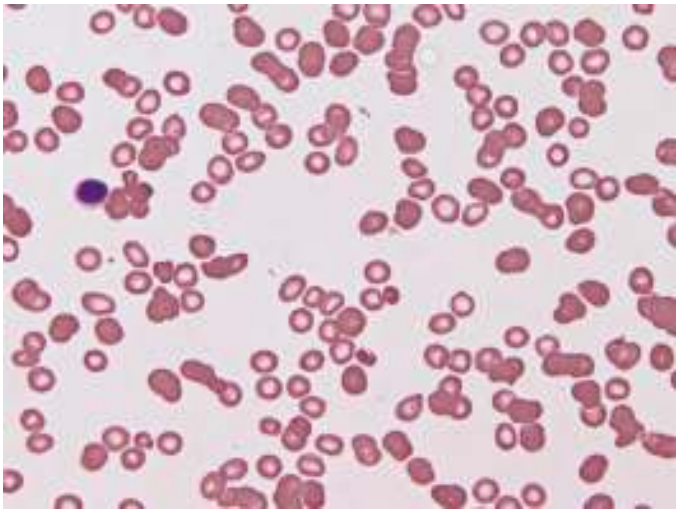

Fig. 9.5: Pancytopenia in Giemsa-stained peripheral blood smear. Pancytopenia is defined as deficiency of all three cellular components of the red blood cells, white blood cells and platelets (1000X).

Neutropenia (Agranulocytosis)

Neutropenia is defined as decrease in the neutrophil count $<1.5 \times 10^9$/L in adults and $<2.5 \times 10^9$/L in children. Neutropenia occurs due to suppression of myelopoiesis, destruction of neutrophils in the peripheral blood or pooling of neutrophil in the peripheral regions. Patient with neutropenia presents with sore throat, recurrent infections and delayed wound healing.

- Most bacterial infections cause neutrophilia with increased band forms exceeding reference range.
  - Some bacterial infections do not cause neutrophilia but result in neutropenia. Typhoid fever causes leukopenia or neutropenia or both.
  - Other causes of neutropenia include *Mycobacterium tuberculosis*, leishmaniasis, Rickettsia, brucellosis, tularemia, ehrlichiosis and *Staphylococcus aureus*.
  - Infants and preterm infants have small storage pools of neutrophils in the bone marrow. Therefore, neutropenia develops in severe or chronic infections in these infants because the demand of neutrophils is greater than the supply.
- After chemotherapy, radiation, bone marrow transplant, the absolute neutrophil count is usually depressed and then slowly rises, reflecting the fact the bone marrow is recovering and new blood cells are beginning to produce and undergoing maturation. Causes of neutropenia are given in Table 9.7.

Table 9.7 Causes of neutropenia

Bacterial Infections	
▪ Typhoid fever	▪ Endotoxic shock (gram-negative bacteria)
▪ Tuberculosis	
Viral Infections	
▪ Human immune deficiency virus	▪ Epstein-Barr virus (EBV)
▪ Parvovirus B19	▪ Hepatitis B virus (HBV)
Drug-induced Neutropenia	
▪ Anti-inflammatory drugs (phenylbutazone, ibuprofen)	
▪ Antithyroid drugs (thiouracil, carbimazole)	
▪ Antibacterial drugs (penicillin, gentamicin, doxycycline, ciprofloxacin, cephalosporins, cotrimoxazole)	
▪ Antiepileptic drugs (phenytoin, trimethadione, valproic acid)	
Autoimmune Disorders	
▪ Systemic lupus erythematosus (SLE)	▪ Blood transfusion reactions
	▪ Felty syndrome
Congenital Disorders	
▪ Severe congenital neutropenia	▪ Cyclic neutropenia
▪ Chronic benign neutropenia	
Hematological Disorders	
▪ Hypersplenism	▪ Myelodysplastic syndrome
▪ Splenomegaly	▪ Aplastic anemia
▪ Megaloblastic anemia	▪ X-ray irradiation induced neutropenia
▪ Chronic autoimmune neutropenia	

Lymphocytopenia

Lymphocytopenia is defined as decrease in the lymphocyte count less than 1,000/cumm ($<1 \times 10^9$/L) in adults and less than 2000/cumm ($<2 \times 10^9$/L) in the children in peripheral blood. It is observed in patients following therapeutic administration of corticosteroid and cytotoxic drugs; radiation and viral infections. Causes of lymphocytopenia in pathological state are given in Table 9.8.

Table 9.8 Causes of lymphocytopenia in pathological state

Bacterial Infections	
▪ Miliary tuberculosis	
Inherited Disorder	
▪ Ataxia-telangiectasia	
Inherit Drug-induced Lymphocyte Destruction ed Disorder	
▪ Cytotoxic drugs	▪ Antithymocyte globin administration
▪ Corticosteroid therapy	
Autoimmune Disorders	
▪ Systemic lupus erythematosus (SLE)	▪ Sarcoidosis
▪ Rheumatoid arthritis	▪ Myasthenia gravis
Immunodeficiency Disorders	
▪ Acquired immune deficiency syndrome	▪ Severe combined immune deficiency
Miscellaneous Disorders	
▪ Radiation therapy	▪ Malnutrition

Monocytopenia

Monocytopenia may be observed in patients receiving corticosteroid therapy or on hemodialysis, Epstein-Barr viral infection, aplastic anemia, and sepsis with splenomegaly. Profound monocytopenia is associated with hairy cell leukemia (HCL) and considered to be a diagnostic hallmark of disease.

QUALITATIVE VARIATIONS IN LEUKOCYTES

Qualitative inherited disorders of leukocytes include Alder-Reilly anomaly, Chédiak-Higashi anomaly, May-Hegglin anomaly (MHA), Pelger-Hüet anomaly, chronic granulomatous disease (CGD), myeloperoxidase deficiency and leukocyte adhesion deficiency (LAD).

Qualitative acquired defects of leukocytes include toxic granules in neutrophils, hypersegmented neutrophils, hyposegmented neutrophils, Auer rods, myeloid shift to left, smudge cells, variant lymphocytes with increased size in peripheral blood, lupus erythematosus (LE) cell phenomenon, Tart cells and leukemic cells (e.g. myeloblast, lymphoblast, monoblast, promyelocyte). Leukocyte inherited and acquired abnormalities and associated disorders are given in Table 9.9.

Table 9.9 Leukocyte inherited and acquired abnormalities and associated disorders

Disorder	Morphologic and Functional Defects	Clinical Features and Associated Disorder
Inherited leukocyte abnormality		
Alder-Reilly anomaly	▪ Defect involves protein–carbohydrate complexes within lysosomes ▪ Large, purplish cytoplasmic granules present in all mature leukocytes ▪ Leukocytes function normally	Associated with hereditary mucopolysaccharidosis such as Hurler syndrome
Chédiak-Higashi anomaly	▪ Autosomal recessive disorder due to LYST gene mutation ▪ Giant fused granules in neutrophils and lymphocytes ▪ Neutrophils phagocytose but do not kill microorganisms	▪ Serious, often fatal disorder with recurrent pyogenic infections ▪ Partial albinism ▪ Patchy gray hair ▪ Chédiak-Higashi anomaly accelerated phase associated with poor outcome due to multiorgan failure (85%)
May-Hegglin anomaly (MHA)	▪ Blue, Dohle-like cytoplasmic inclusions (RNA) in all leukocytes with giant platelets ▪ Leukocytes function normally	Bleeding tendency from associated thrombocytopenia and giant platelets
Pelger-Hüet anomaly	▪ Inherited disorder occurs due to lamin B receptor (LBR) gene mutation ▪ Hyposegmented neutrophils with hyposegmented bilobed nucleus, but normal granulation of neutrophils and eosinophils; coarse chromatin and pink cytoplasm; however, the neutrophil functions are normal ▪ Lamin B receptor (LBR) gene mutation, inherited disorder with hyposegmented but normal granulation of neutrophils and eosinophils	Hereditary myelogenous leukemia
Chronic granulomatous disease (CGD)	Defective respiratory burst	Recurrent infections, especially in childhood
Myeloperoxidase deficiency	Low or absent myeloperoxidase (MPO) enzyme in neutrophils with normal cell morphology	Usually benign disorder; recurrent infections occur due to decreased or absent bactericidal activity of neutrophils
Leukocyte adhesion deficiency (LAD)	Absence of cell-surface adhesion proteins affecting multiple cell functions but normal cell morphology	Serious disorder with recurrent infections and high mortality
Acquired leukocyte anomalies		
Toxic granules in neutrophils	Neutrophils contain black or purple granules in cytoplasm	Increased susceptibility to bacterial infections occurs due to inflammatory disease, burns and patient on chemotherapy
Hypersegmented neutrophils	Neutrophils contain >5 distinct lobes	Megaloblastic anemia due to vitamin B_{12} and folate deficiency; and hereditary constitutional hypersegmented of neutrophils
Hyposegmented neutrophils	Neutrophils with bilobed nuclei due to lamin B receptor (LBR) gene mutation	Pelger-Hüet anomaly, and pseudo-Pelger-Hüet anomaly in AML and AIDS

Contd...

Table 9.9 Leukocyte inherited and acquired abnormalities and associated disorders (*Contd...*)

Disorder	Morphologic and Functional Defects	Clinical Features and Associated Disorder
Auer rods	Rod-like long, red purple, refractile inclusions in neutrophils resulting from an abnormal fusion of azurophilic granules	Acute myelogenous leukemia (AML) or acute myelomonocytic leukemia (AMML)
Myeloid shift to left	Presence of band form neutrophils, myelocytes, metamyelocytes or promyelocytes in peripheral blood	Infections, tissue necrosis, chronic myelogenous leukemia, myeloproliferative syndrome and hyposplenism
Smudge cells	Disintegrated nucleus of a ruptured lymphocytes	Chronic lymphocytic leukemia
Variant lymphocytes with increased size in peripheral blood	Epstein-Barr viral infection causes cervical lymphadenopathy	Infectious mononucleosis and other viruses
Lupus erythematosus (LE) cell phenomenon	Neutrophil with a homogenous red-purple inclusion that distends the cytoplasm of cell	Systemic lupus erythematosus, other collagen disorders, chronic hepatitis, drug reactions and mechanical trauma *in vitro*
Tart cells	Neutrophil with phagocytosed nucleus of a granulocyte that retains some nuclear structure	Drug reactions (e.g. penicillin, procainamide) or actual phagocytosis
Leukemic cells (e.g. myeloblast, lymphoblast, monoblast, promyelocyte)	Presence of myeloblasts or lymphoblast or monoblasts and promyelocytes in peripheral blood	Acute leukemia, leukemoid reactions, severe infections, inflammatory disorders, malignancies, and recovery from bone marrow suppression

ALDER-REILLY ANOMALY

Alder-Reilly anomaly is an autosomal recessive disorder characterized by presence of large azurophilic granules in the cytoplasm of neutrophils, lymphocytes, and monocytes.

- Granulocytes show metachromatic and darkly staining inclusions (Alder-Reilly bodies) containing partially digested mucopolysaccharides because of deficient lysosomal enzymes.
- Alder-Reilly bodies, that resemble toxic granules can be demonstrated in the bone marrow and peripheral blood smear stained with Giemsa stain and toluidine stain.
- Leukocyte function is not impaired in Alder-Reilly anomaly. Alder-Reilly anomaly is associated with syndromes such as Hunter syndrome, Hurler syndrome, Tay-Sachs disease and Maroteaux-Lamy polydystrophic dwarfism. These clinical entities result in different clinical manifestations.
- Physical findings associated with Alder-Reilly anomaly include gargoylism (deformities of head, trunk, and limbs; mental retardation and hepatosplenomegaly) and dwarfism.

CHÉDIAK-HIGASHI SYNDROME

Chédiak-Higashi syndrome is an autosomal recessive disorder due to mutation in LYST gene (lysosomal trafficking regulator gene).

- LYST gene located on chromosome 1q42 encodes protein essential for assembly of microtubules in the cytoplasm. LYST gene mutation leads to defect in assembly of microtubules in neutrophils.
- Chédiak-Higashi syndrome is characterized by defective degranulation of neutrophils, impaired microbial killing, and recurrent bacterial infections due to *Staphylococcus aureus* forming soft tissue abscess. Neutrophils contain giant granules due to aberrant organelles. In Chédiak-Higashi syndrome, there are severe immunologic defects including recurrent bacterial infections, impaired chemotaxis, and abnormal natural killer function with fatal outcome.
- Basic defect in Chédiak-Higashi syndrome is in the formation of giant phagosomes within all white blood cells and defective granulation. Neutrophils phagocytose but do not kill microorganisms. Patient presents with partial albinism, patchy gray hair, increased susceptibility to pyogenic infections due to defective degranulation of neutrophils. Accelerated phase of Chédiak-Higashi syndrome is associated with fatal outcome due to multiorgan failure in 85% of cases. Neutrophils containing giant granules due to aberrant organelles in Chédiak-Higashi syndrome are shown in Fig. 9.6.

MAY-HEGGLIN ANOMALY

May-Hegglin anomaly (MHA) is an autosomal dominant disorder due to mutation in MYH9 gene. Disorder is characterized by basophilic cytoplasmic inclusions resembling Döhle body (RNA) within neutrophils, anemia, bleeding manifestations, thrombocytopenia, and giant platelets.

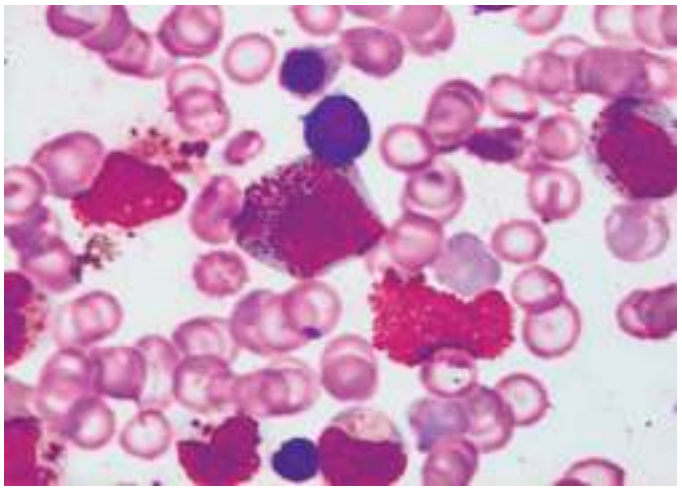

Fig. 9.6: Chédiak-Higashi syndrome. Neutrophils contain giant granules due to aberrant organelles in peripheral blood in Chédiak-Higashi syndrome. Chédiak-Higashi syndrome is characterized by oculocutaneous albinism, which causes abnormally light coloring (pigmentation) of the skin and eyes, vision problems such as reduced sharpness, rapid involuntary eye movements (nystagmus) and increased sensitivity to light (photophobia). Affected persons have fair skin and light-colored hair often with a metallic sheen (polished metal) (1000X).

PELGER-HÜET ANOMALY

Pelger-Hüet anomaly is an autosomal dominant disorder due to lamin B receptor (LBR) gene mutation. Disorder is characterized by hyposegmented nuclei with coarse chromatin and normal granulation in >70% of neutrophils and eosinophils. Neutrophils have normal functions. Two lobes of the nuclei of neutrophils are joined by thin chromatin bridge. Pelger-Hüet anomaly is associated with hereditary myelogenous leukemia.

CHRONIC GRANULOMATOUS DISEASE OF THE CHILDHOOD

Chronic granulomatous disease of the childhood is X-linked disorder characterized by defective respiratory burst due to defect in NADPH oxidase activity in neutrophils.

- Phagocytic cells (neutrophils) phagocytose microorganisms but fail to kill them resulting in recurrent infections, especially in childhood.
- Nitroblue tetrazolium (NBT) slide test is used for screening defects in NADPH oxidase. Positive NBT slide test means neutrophils turn blue, while negative NBT slide test means neutrophils color remains yellow.
  - The number of neutrophils with dark cytoplasmic granules of reaction product is counted.
  - Normally >95% of the neutrophils containing NADPH oxidase are positive for nitroblue tetrazolium. In chronic granulomatous disease, nitroblue tetrazolium test is negative due to the lack of NADPH oxidase activity in neutrophils.

MYELOPEROXIDASE DEFICIENCY

Myeloperoxidase deficiency is a benign disorder due to low or absent myeloperoxidase (MPO) enzyme in neutrophils. Cell morphology of neutrophils is normal.

- Myeloperoxidase deficiency is associated with recurrent infections due to decreased or absent bactericidal activity of neutrophils.
- Persons with myeloperoxidase deficiency have a respiratory burst with a normal nitroblue tetrazolium (NBT) test because they still have NADPH oxidase activity, but do not form HClO (bleach) due to lack of myeloperoxidase activity in neutrophils.

LEUKOCYTE ADHESION DEFICIENCY DISORDERS

Leukocyte adhesion deficiency (LAD) is a primary immunodeficiency autosomal recessive disorder that involves phagocytic cell defects due to absence of cell-surface adhesion proteins resulting in dysfunctional granulocytes and both T cells and B cells. The clinical picture of LAD deficiency is characterized by marked leukocytosis and bacterial recurrent infections in soft tissue and high mortality. Cell morphology of the leukocytes is normal.

Leukocyte Adhesion Deficiency Type 1 Disorder

Leukocyte adhesion deficiency type 1 (LAD-1) disorder is characterized by delay in detachment of the umbilical cord stump after birth. In normal infants, the umbilical cord stump falls off within the first two weeks of life, but in infants with LAD 1 disorder, separation of umbilical cord stump usually occurs at three weeks or later. Delayed separation of umbilical cord stump may also be observed in patients with IL-1 receptor-associated kinase 4 (IRAK4) deficiency or neutropenia.

- Bacterial and fungal infections most commonly occur in skin and mucous membranes lining nose and mouth.
- Life expectancy in persons with leukocytes adhesion deficiency type 1 is most often severely shortened. Due to recurrent infections, affected individuals may not survive past infancy.

Leukocyte Adhesion Deficiency Type 2 Disorder

Leukocyte adhesion deficiency type 2 (LAD-2) is a rare inherited disorder characterized by recurrent infections, persistent leukocytosis, and severe mental retardation.

- In LAD-2, neutrophils are deficient in expression of selectin ligand activity.
- In LAD-2, patients exhibit a deficiency in the expression of cell surface fucosylated glycan structures that

include the Hh and Lewis blood group determinants and the Sialyl Lewis X epitope.
- The molecular defect in LAD-2 has been localized to the pathway that synthesizes GDP-fucose from GDP-mannose.

INFECTIOUS MONONUCLEOSIS

Epstein-Barr virus (EBV), also known as human herpesvirus 4, is a member of the herpes family. It is one of the most common human viruses. EB virus spreads most commonly through body fluids, primarily saliva. EB virus can cause infectious mononucleosis (also called kissing disease and glandular fever) and other illnesses. Onset of infectious mononucleosis disease is abrupt, which most often occurs between 5 and 30 years of age. Salient features of infectious mononucleosis are given in Table 9.10.

MODE OF TRANSMISSION

Epstein-Barr virus (EB virus) spreads most commonly through body fluids, especially through oropharyngeal secretions (saliva). However, EB virus can also be transmitted through blood and semen during sexual contact, blood transfusions, and organ transplantations. EB virus can spread by using toothbrush or drinking glass that an infected person has recently used. Incubation period of EB virus infection is 1–2 months.

CLINICAL FEATURES

Infectious mononucleosis has been recognized as a clinical syndrome in teenagers/young adults consisting of fever, pharyngitis (sore throat), cervical lymphadenopathy in the first week, skin rash and splenomegaly. On clinical examination, enlarged lymph nodes are discrete and slightly tender. The enlarged lymph nodes gradually subside in the second week. Peripheral blood smear examination shows transformed atypical lymphocytes (CD8+ cytotoxic T cells).

PATHOPHYSIOLOGY

Epstein-Barr virus is transmitted via intimate contact with primarily oropharyngeal secretions. EB virus may also be shed from the uterine cervix, implicating the role of genital transmission in some cases. EB virus can be contracted via blood transfusion in occasional case. EB virus infects B cells in the oropharyngeal lining epithelium.
- Circulating B cells spread the infection throughout the reticuloendothelial cells in peripheral lymph nodes, spleen and liver.
- Epstein-Barr virus (EBV) infection of the B cells induces humoral and cellular response. The humoral response directed against EB virus structural proteins is the basis for technique used to diagnose infectious mononucleosis.
- However, T cell cellular response is essential in the control of EBV infection by CD8+ cytotoxic T cells and natural killer cells. CD8+ cytotoxic T cells control proliferating B cells infected by EB virus. T cell cellular response is critical in determining the clinical expression of EB virus infection.
- T cell cellular response determines clinical expression of EB virus infection. Efficient and quick T cell cellular response control primary EB virus infection and lifelong suppression of EB virus infection.
- Ineffective T cell response can lead to excessive and uncontrolled B cell proliferation resulting in B cell lymphoma.
- Cytokine release consequent to B cell immune response results in fever in EB virus infection.
- Proliferation of EB virus infected B cells leads to lymphocytosis.
  - Pharyngitis observed in EB virus-induced infectious mononucleosis occurs due to proliferation of EB virus-infected B cells in the oropharyngeal tissue.
  - EB virus transforms resting human B cells into indefinitely proliferating lymphoblastoid cell lines.

Table 9.10 Salient features of infectious mononucleosis

Parameters	Comments
Etiology	Epstein-Barr virus
Clinical features	Fever (38.3–38.9°C), tonsillitis/ severe pharyngitis (exudative or nonexudative), cervical lymphadenopathy (anterior, posterior, axillary, epitrochlear, mediastinal and mesenteric regions), fatigue, generalized nonpruritic skin rashes, petechiae on hard and soft palate (30%), bilateral palpebral edema, splenomegaly (50%), hepatomegaly (10%)
Diagnostic findings	Positive heterophile antibody test (monospot test) but false negative in 25% of cases during first week of illness, atypical lymphocytosis, transient hepatitis, increased alanine transaminase (ALT) and aspartate transaminase (AST)
Complications	Autoimmune hemolytic anemia and thrombocytopenia due to cross-reactivity of EB virus induced antibodies against red blood cells and platelets. Splenic rupture can occur due to trauma within three weeks of symptoms appear
Management	Avoid contact sports for ≥3 weeks due to risk of splenic rupture

COMPLICATIONS

In some cases, Epstein-Barr virus infection can lead to mild to serious complications such as immune hemolytic anemia, immune-mediated thrombocytopenia, hemophagocytic syndrome, secondary bacterial sore throat, hepatitis, myocarditis, conditions affecting central nervous system (meningoencephalitis, Guillain-Barré syndrome), and splenic rupture in rare cases. EB virus associated disorders are Burkitt's lymphoma, nasopharyngeal carcinoma, Hodgkin's disease, body cavity lymphoma (HIV/AIDS patients) and X-linked lymphoproliferative disease (Duncan's syndrome).

Pathology Pearls: Epstein-Barr Virus-induced Disorders

- Immune hemolytic anemia
- Immune-mediated thrombocytopenia
- Hemophagocytic syndrome
- Secondary bacterial sore throat and hepatitis
- Viral myocarditis
- Meningoencephalitis
- Guillain-Barré syndrome
- Burkitt's lymphoma
- Nasopharyngeal carcinoma
- Hodgkin's disease
- Body cavity lymphoma (HIV/AIDS patients)
- X-linked lymphoproliferative disease (Duncan's syndrome)

LABORATORY DIAGNOSIS

Diagnosing Epstein-Barr virus (EB virus)-induced infectious mononucleosis is challenging because clinical manifestations are like other illnesses.

- Lymph nodes should not be biopsied as diagnosis is established by clinical features and detection of antibodies by serologic tests.
- About 90% of adults have antibodies that demonstrate that they have a current or past EB virus infection.
- Potential EB virus infections are often diagnosed without any blood testing. However, blood tests can detect the presence of antibodies associated with EB virus infection.

Paul and Bunnell Test

Paul and Bunnell originally described that heterophilic antibodies are present in 90–95% of adults in recent or past EB virus infections in the second to third weeks of infection.

- However, heterophilic antibody responses are not most often detected in infants and children under the age of four years.
- The heterophilic antibodies agglutinate horse red blood cells. Heterophilic antibodies are IgM antibodies, which agglutinate erythrocytes from sheep, goat, horse and camel.
- Epstein-Barr virus-induced heterophilic antibodies have no reactivity against guinea pig kidney cells in contrast to natural occurring antibodies (Forssman antibodies) or antibodies present in patients with serum sickness and other conditions. Heterophilic antibodies may be present in serum in response to microbial infections in patients.

Monospot Test

Several laboratory tests have been developed to aid in the diagnosis of infectious mononucleosis. Currently, serum testing for EB virus infection-specific antibodies is considered the gold standard for diagnosis, but rapid results are most often obtainable. Therefore, monospot test has been developed for rapid diagnosis.

- Principle of the monospot test is erythrocytes agglutination, much like Paul-Bunnell test which was developed prior to the monospot test.
- Monospot test is a latex agglutination test which utilizes equine erythrocytes as the primary substrate used to detect specific heterophilic antibodies produced by the human immune system in response to EB virus infection. When specific heterophilic antibodies are present in the patient's blood sample, exposure to equine erythrocytes will result in clumping of erythrocytes thus indicating a positive agglutination reaction, which is considered a positive test and therefore a diagnostic confirmation of the clinically suspected infectious mononucleosis especially in adult patients.
- The monospot test is **not indicated** for patients under the age of four years old children as the false-negative test results are unacceptably high.

Epstein-Barr Virus Specific Antibodies Assay

In addition to the monospot test, there are other blood tests to demonstrate more specific antibodies to EB virus infection: (a) viral capsid antigen (VCA), (b) early membrane antigen and (c) EB virus nuclear antigen.

- Antibodies to viral capsid antigen (VCA) appear early in the acute EB virus infection. One type of antibodies (anti-IgM) disappears after several weeks while another (anti-IgG) persists throughout life.
- Antibodies to early membrane antigen appear during an active EB virus infection. These antibodies are not detectable after several months, although these antibodies may persist for longer in some cases.
- Antibodies to EB virus nuclear antigen appear slowly in months following EB virus infection and can be detected throughout person's life.

Solid-phase Enzyme-linked Immunosorbent Assay

Solid-phase enzyme-linked immunosorbent assay is a reliable method to diagnose infectious mononucleosis by demonstration of IgM and IgG by complement fixation test and the indirect immunofluorescence test.

Molecular Techniques

Molecular techniques have become an important tool in Epstein-Barr virus in diagnostics.

- In the recent years, novel real-time polymerase chain reaction (RT-PCR) and *in situ* hybridization techniques have been developed to analyze EB virus DNA in specimens such as tissues, body fluids and peripheral blood, that offer increased time efficiency, reduced cross-contamination, high reproducibility, high sensitivity and allow determination of EB virus viral loads.
- Currently, monitoring of Epstein-Barr virus viral loads in different tissue compartments is used to assess the treatment response or prognosis in patients with oncological disorders or immunosuppression.

Laboratory Diagnosis of Infectious Mononucleosis

Routine Hematologic Findings

Total leukocyte count (TLC) is increased >15–30 × 10^9/L with absolute lymphocytosis. Morphology of transformed lymphocytes in infectious mononucleosis is given in Table 9.11.

Peripheral Blood Smear Examination

- Peripheral blood smear shows >10% transformed polyclonal T cells (CD8+ cytotoxic T cells). The indentation of cytoplasm of the lymphocyte by red blood cells gives rise to classic 'Dutch skirt' appearance of the T cell border.
- Differential white cell count shows lymphocytosis (>50%). Platelet count is within normal range.
- Morphologic variations of lymphocytes in infectious mononucleosis. Infectious mononucleosis in Giemsa-stained peripheral blood smear is shown in Fig. 9.7.

Bone Marrow Examination

- Bone marrow is performed to rule out leukemia.
- Bone marrow shows infiltration by transformed lymphocytes.

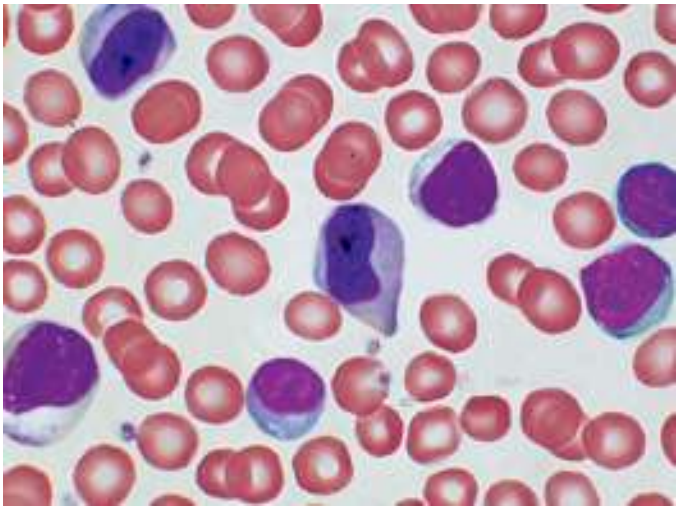

Fig. 9.7: Morphologic variations of lymphocytes in infectious mononucleosis in Giemsa-stained peripheral blood smear. It shows morphological variations in lymphocytes. Lymphocytes are large and irregular typical lymphocytes with indentation of the cytoplasm by red blood cells giving rise to the classic 'Dutch skirt' appearance of the border of lymphocytes (1000X).

Table 9.11 Morphology of transformed lymphocytes in infectious mononucleosis

Parameters	Plasmacytoid Cells (Type 1)	Monocytoid Cells (Type 2)	Blastoid Cells (Type 3)
Nuclear chromatin	Condensed chromatin giving cartwheel appearance with basophilic cytoplasm	Kidney-shaped nucleus with open chromatin	Open chromatin with thin cytoplasm

LEUKEMIAS

LEUKEMIAS: OVERVIEW

Hematopoietic stem cells (HSCs) and their progenitors maintain normal hematopoiesis during life-time of an individual. HSCs may differentiate into myeloid and lymphoid cell lineages.

- Leukemia is progressive disease due to clonal proliferation of HSCs either lymphoid or myeloid cell lineages resulting in accumulation of immature and nonfunctional HSCs in the bone marrow and blood circulation. Peripheral blood smear examination shows leukemic blasts with large nuclei, prominent nucleoli and few other distinguishing features.
- The leukemia cells show increased proliferation and/or decreased programmed cell death (apoptosis).
- Failure of normal production of red blood cells, leukocytes and platelets results in anemia, recurrent infection and thrombocytopenia. The net result is expansion of the leukemic clones and decrease in the normal HSCs in the bone marrow.

CLASSIFICATION OF LEUKEMIAS

Leukemias have been classified according to French-American-British classification and revised 2024 WHO classification. Acute leukemias consist of predominantly immature cells; chronic leukemias are composed of more mature cells.

- Four broad subtypes of leukemias most likely to be encountered by physicians are acute lymphoblastic leukemia (ALL), acute myelogenous leukemia (AML), chronic lymphocytic leukemia (CLL) and chronic myelogenous leukemia (CML).
- Acute lymphoblastic leukemia (ALL) occurs more often in children, whereas other subtypes of leukemias affect adults. Risk factors for leukemias include a genetic predisposition and environmental factors, such as ionization radiation.
- Patient presents with nonspecific symptoms such as fever, fatigue, weight loss, bone pain, bleeding, and bruising.
- The two major categories of acute leukemias are classified according to origin of the cell with the primary defect: acute myelogenous leukemia (AML) and acute lymphoblastic leukemia (ALL).
  - If the defect primarily affects the maturation and differentiation and common myeloid progenitor cell, the leukemia is classified as AML.
  - If the defect primarily affects the common lymphoid progenitor cell, the leukemia is classified as acute lymphoblastic leukemia. Leukemic cells infiltrate liver, spleen, lymph nodes and other organs. In acute lymphoblastic leukemia, leukemic cells may cross blood–brain barrier and involve central nervous system.
- In subleukemic leukemia, blast cells are fewer in peripheral blood, and ≥20% in bone marrow. Aleukemic leukemia refers to low total leukocytes count ($<4 \times 10^9$/L) with absence of blasts in the peripheral blood smear. However, bone marrow shows ≥20% blasts.
- Hematopoietic stem cell-derived hematopoietic and lymphoid neoplasms found in the bone marrow, peripheral blood, lymph nodes and spleen are shown in Fig. 9.8. Origin of AML, ALL, CLL, B cell prolymphocytic leukemia (B-PLL), hairy cell leukemia (HCL), multiple myeloma (MM), Waldenström's macroglobulinemia is shown in Fig. 9.9.
- Characteristics of major subtypes of leukemia are given in Table 9.12. Immunophenotype markers for myeloblasts, B and T lymphoblasts are given in Table 9.13.

French-American-British (FAB) Classification of Leukemias

Leukemias were originally termed acute or chronic based on the life expectancy, but now are classified according to cell maturity. Leukemias are classified into acute myelogenous leukemia (AML-M0 to AML-M7), acute lymphoblastic leukemia (ALL-L1, ALL-L2, ALL-L3), chronic myelogenous leukemia (CML), and chronic lymphocytic leukemia (CLL). Other leukemias include hairy cell leukemia, prolymphocytic leukemia and T cell leukemia/lymphoma.

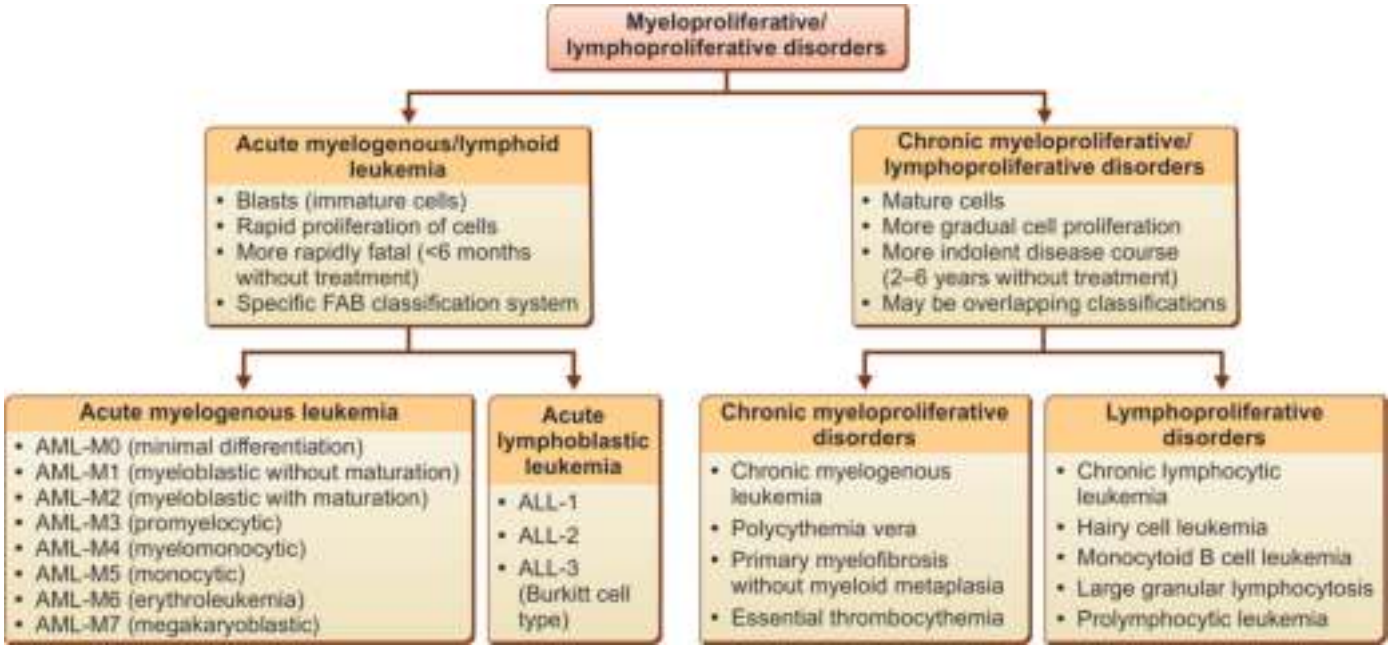

Fig. 9.8: Schematic representation of hematopoietic stem cell (HSC)-derived myeloid and lymphoid neoplasms. A neoplasm arising from hematopoietic stem cells are found in the bone marrow, peripheral blood, lymph nodes and spleen. HSC-derived neoplasms can also involve central nervous system and gastrointestinal tract either by metastasis, direct tumor infiltration or neoplastic transformation of extranodal lymphoid tissues.

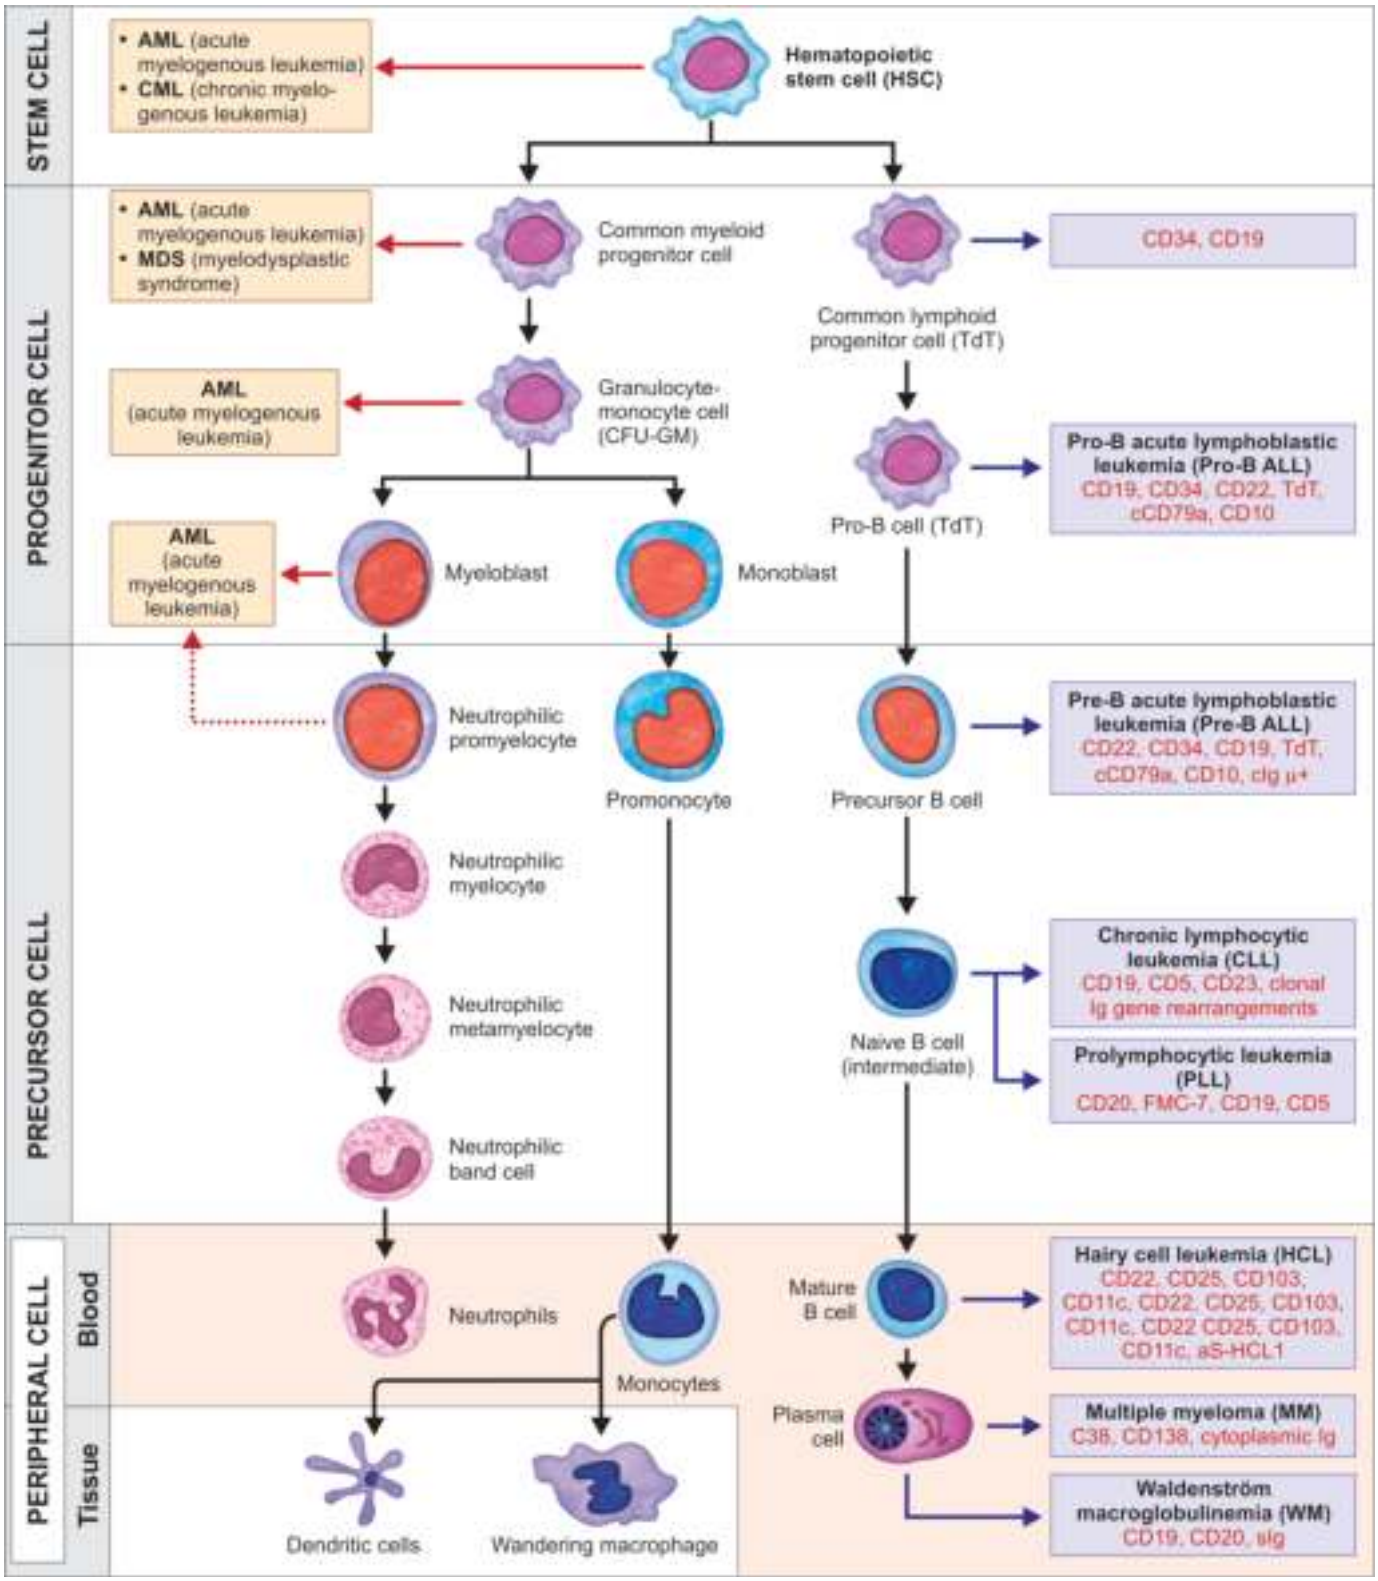

Fig. 9.9: Schematic representation of origin of acute myelogenous leukemia (AML), acute lymphoblastic leukemia (ALL), chronic lymphocytic leukemia (CLL), prolymphocytic leukemia (PLL), hairy cell leukemia (HCL), multiple myeloma (MM), Waldenström heavy chain disease. AML and ALL may originate from any of the hematopoietic cells that fall within the pathways of the downward arrows. Importantly, the AML cell of origin acquires the capacity for self-renewal and maturation arrest.

Table 9.12 Characteristics of major subtypes of leukemia

Leukemia Subtype	Description	Age Group Affected	Clinical Features
Acute lymphoblastic leukemia (ALL)	Lymphoblasts on peripheral blood smear or bone marrow aspirate	Children 2–5 years and young adults in persons <20 years	Patient presents with fever, weakness, bleeding, musculoskeletal pain, or dysfunction. Clinical examination reveals hepatosplenomegaly and lymphadenopathy
Acute myelogenous leukemia (AML)	▪ Myeloblasts on peripheral blood smear or bone marrow aspirate ▪ Auer rods in myeloblasts on peripheral blood	Adults	Patient presents with fever, weakness, weight loss, bleeding, or bruising. Clinical examination reveals hepatosplenomegaly. Lymphadenopathy may occur in rare case
Chronic lymphocytic leukemia (CLL)	Clonal expansion of at least 5000 B lymphocytes per μl (5×10^9/μl) in the peripheral blood	Elderly adults >65 years	About 50% of patients remain asymptomatic
Chronic myelogenous leukemia (CML), BCR-ABL1 positive	Marked leukocytosis with myelocyte bulge and Philadelphia chromosome (BCR-ABL1 fusion transcript)	Adults	About 50% of patients remain asymptomatic. Clinical examination reveals massive splenomegaly, hepatomegaly and lymphadenopathy

Table 9.13 Immunophenotype markers for myeloblasts, B and T lymphoblasts

Lineage-specific Immunophenotype Markers	Expression
Myeloblast	
CD13, CD15, CD33, CD11b	Positive
CD34, c-KIT, HLA-DR	Positive/negative
Pro-B lymphoblast	
CD19	Positive
CD34	Positive
CD22	Positive
TdT (terminal deoxynucleotidyl transferase)	Positive
Cytoplasmic CD79a	Positive
CD10	Positive
Pre-B lymphoblast	
CD22	Positive
CD19	Positive
TdT (terminal deoxynucleotidyl transferase)	Positive
Cytoplasmic CD79a	Positive
CD10	Positive
Cytoplasmic mu	Positive
CD20, CD34, CD10, HLA-DR	Positive/negative
T lymphoblast	
CD3	Positive
TdT (terminal deoxynucleotidyl transferase)	Positive
CD5	Positive
CD7	Positive
CD1a	Positive
CD34, CD10	Positive/negative
HLA-DR, c-KIT (CD117)	Negative/positive (rarely)

- According to French-American-British (FAB) classification, in acute leukemias (AML or ALL) bone marrow and peripheral blood contain ≥30% blasts. FAB classification of ALL is based on cell size, cytoplasm, nuclear chromatin, nuclear shape, nucleoli, color and vacuolation of cytoplasm.
- Acute lymphoblastic leukemia (ALL) has three types: ALL-L1, ALL-L2 and ALL-L3. AML most often affects young adults and ALL is a disorder of children. Both ALL and AML more commonly affect males than females. ALL is most often seen in White population.
- Revised 2024 WHO classification of acute myelogenous and lymphoblastic leukemias and their features is given in Table 9.14. Revised 2024 WHO classification of acute myeloid and lymphoid leukemias and their features is given in Table 9.15.

Table 9.14 Revised 2024 WHO classification of acute myelogenous and lymphoblastic leukemias

Acute Myelogenous Leukemias	
▪ AML-M0:	Acute myelogenous leukemia with minimal evidence of myeloid differentiation
▪ AML-M1:	Acute myelogenous leukemia without maturation
▪ AML-M2:	Acute myelogenous leukemia with maturation
▪ AML-M3:	Acute promyelocytic leukemia
▪ AML-M4:	Acute myelomonocytic leukemia
▪ AML-M5:	Acute monocytic/monoblastic leukemia
▪ AML-M6:	Acute erythroleukemia
▪ AML-M7:	Acute myelogenous leukemia
Acute Lymphoblastic Leukemias

▪ ALL-L2:	Acute lymphoblastic leukemia L2
▪ ALL-L3:	Acute lymphoblastic leukemia L3

Revised 2024 WHO Classification of Acute Leukemias

According to revised 2024 WHO classification of acute leukemias (acute myelogenous/acute lymphoblastic leukemia), diagnostic criteria are the presence of ≥20% blast cells as the cut off percentage in bone marrow and peripheral blood.

Table 9.15 Revised 2024 WHO classification of acute myeloid and lymphoid leukemias and their features

Leukemia Subtype	Description
Acute myelogenous leukemias	
AML-M0	▪ AML-M0 with minimally differentiation expressing myeloid lineage accounts for 2–3% ▪ AML-M0 is associated with poor prognosis
AML-M1	▪ AML-M1 without maturation demonstrates <10% promyelocytes or more mature myeloid cells ▪ Prognosis is favorable in AML-M1
AML-M2	▪ AML with maturation and differentiation into neutrophilic lineage ▪ AML-M2 is associated with favorable prognosis
AML-M3	▪ AML with promyelocytic differentiation (APL) in most cases demonstrate promyelocytes with heavy granulation and bilobed folded (cottage-loaf) nuclei (commonly associated with disseminated intravascular coagulation (DIC) due to release of thromboplastin-like substance); rarely microgranular variant with inconspicuous granules, accounts for 5–10% of leukemias ▪ Acute promyelocytic leukemia now represents most curable leukemia treated by administration of nontoxic cytotoxic chemotherapeutic drugs such as all-*trans* retinoic acid (ATRA) and arsenic trioxide (ATO)
AML-M4	▪ Acute myelomonocytic leukemia (AMML) shows myelocytic and monocytic differentiation (>20% monocytoid cells involving gums, skin or CNS) ▪ AML-M4E0 variant contains >5% abnormal eosinophils; associated with the inv(16) cytogenetic abnormality associated with favorable prognosis
AML-M5A	▪ Acute monoblastic/monocytic leukemia (AML-M5A) shows monoblasts without differentiation, extramedullary disease involving gums, skin, lymph node and central nervous system ▪ AML-M5A is associated with extramedullary disease, abnormalities of chromosome 11q23 and poor prognosis.
AML-M5B	▪ Acute monoblastic/monocytic leukemia (AML-M5B) showing more than 80% monoblasts with differentiated monocytes, or promonocytes ▪ Extramedullary AML-5B disease has poor prognosis
AML-M6A	▪ In acute erythroid leukemia (AML-M6A), bone marrow shows dysplastic nucleated erythroblasts (>50%) and myeloblasts (>20%) ▪ AML-M6A is associated with poor prognosis
AML-M6B	▪ In acute erythroid leukemia (pure erythroid leukemia) (AML-M6B), bone marrow shows dysplastic nucleated erythroblasts (>80%) ▪ AML-M6B is associated with poor prognosis
AML-M7	▪ Acute megakaryoblastic leukemia (AML-M7), bone marrow shows micromegakaryoblasts (common in Down's syndrome and myelofibrosis) ▪ AML-M7 accounts for <1% of leukemias ▪ AML-M7 is associated with poor prognosis
Acute lymphoblastic leukemias	
ALL-L1	▪ In acute lymphoblastic leukemia L1 (ALL-L1), lymphoblasts are uniform, homogenous with scant cytoplasm with regular nuclei and inconspicuous nucleoli ▪ ALL-L1 accounts for >80% of leukemias ▪ Children are affected associated with good prognosis
ALL-L2	▪ Acute lymphoblastic leukemia L2 (ALL-L2) demonstrates lymphoblasts, which are large, heterogenous with round to oval nuclei showing indentation or clefts with prominent nucleoli ▪ ALL-L2 accounts for 10–50% of leukemias ▪ Adults are affected associated with poor prognosis
ALL-L3	▪ Acute lymphoblastic leukemia L3 (ALL-L3) demonstrates lymphoblasts, which are large homogenous with round to oval nuclei, finely stippled chromatin, prominent nucleoli and abundant basophilic vacuolated cytoplasm ▪ ALL-L3 accounts for 3–4% of leukemias ▪ Adults are affected associated with poor prognosis

CD: Cluster of differentiation.

- Revised 2024 WHO classification of leukemias represents presence of ≥20% blast cells in bone marrow and peripheral blood. Presence of ≥30% blast cells were considered as a cut off percentage of diagnostic criteria of leukemia in bone marrow and peripheral blood as per original guidelines of French-American-British (FAB) classification of leukemias.
- PML-RARA molecular abnormality is the diagnostic feature of AML-M3. Revised 2024 WHO classification of acute leukemias and related neoplasm is discussed under AML and ALL entities.

PATHOGENESIS

Various predisposing factors are believed to participate in the pathogenesis of acute leukemias. Inherited genetic predisposition, ionizing radiation, chemotherapeutic agents (e.g. cyclophosphamide, chlorambucil, nitrosoureas, β-propiolactone, dimethyl sulfate, and dexproxibutene), tobacco smoke and benzene, pre-existing hematologic disorders (myelodysplastic dysplastic syndrome, paroxysmal nocturnal hemoglobinuria, familial aplastic anemia and acquired somatic mutations) associated with aging process play an important role in the development of acute myelogenous leukemia. Certain disorders predispose to acute lymphoblastic leukemia, most notably trisomy 21 (Down syndrome), in which the relative risk of ALL is increased 10- to 30-fold.

Chemical Agents

Benzene is widely used to prepare plastics, resins, synthetic fibers, dyes, detergents, drugs and pesticides. Natural source of benzene includes emissions from fires. Benzene is also a component of crude oil, gasoline and cigarette smoke.

- Prolonged exposure to benzene can lead to hematotoxicity and genomic toxicity that contribute to leukemogenic process leading to acute myelogenous leukemia.
- Benzene metabolites such as 1,4-benzoquinone (1,4-BQ) and hydroquinone (1,4-HQ) cause oxidative DNA damage through H_2O_2 generation in cells, preceding internucleosomal DNA damage leading to apoptosis or mutation.
- The outcome of the transformed cells to undergo apoptosis or mutation might be dependent on the intensity of DNA damage and ability to repair DNA.

Chemotherapeutic Agents

Chemotherapeutic agents such as cyclophosphamide, chlorambucil, nitrosoureas, β-propiolactone, dimethyl sulfate, and dexproxibutene, administered in patients with Hodgkin disease, NHL and ovarian carcinoma may cause somatic and cytogenetic mutations (monosomy 5, monosomy 7, 5p and 11q23) and evoke second form of cancer such as acute myelogenous leukemia (AML).

Ionizing Radiation

Ionizing radiation poses a potential worldwide threat in this nuclear age. Low doses of ionizing radiation can cause DNA mutations and chromosomal abnormalities leading to acute leukemias. Large doses of radiation can inhibit cell division. Survivors of atomic blasts in Hiroshima and Nagasaki develop acute myelogenous leukemia (AML) or chronic myelogenous leukemia (CML), but not ALL and CLL. Radiologists may develop acute myelogenous leukemia.

Human T-Lymphotropic Virus 1 (HTLV-1)

Human T-lymphotropic virus 1 (HTLV-1) can cause adult T cell leukemia or non-Hodgkin lymphoma (NHL) in Japan. HTLV-1 activates TAX gene that causes proliferation of T cells by neutralizing growth inhibitory signals by TP53 and CDKN2A genes. Additional gene mutations result in development of T-adult leukemia and non-Hodgkin lymphoma (NHL).

Bone Marrow Failure Syndrome

Bone marrow failure syndrome increases the risk for developing leukemia in patients with Fanconi syndrome, Diamond-Blackfan, ataxia-telangiectasia, familial aplastic anemia, and Bloom syndrome. Germline TP53 gene mutations, a cause of cancer-predisposing Li-Fraumeni syndrome, are present in 40% of acute lymphoblastic leukemia (ALL) patients with low hypodiploid chromosomes (32–39 chromosomes).

Genetic Disorders

Down syndrome, Bloom syndrome, Fanconi syndrome, dyskeratosis congenita, ataxia-telangiectasia, Li-Fraumeni syndrome, Kostmann syndrome, Klinefelter syndrome, osteogenesis imperfecta, Wiskott-Aldrich syndrome, leukemia in siblings and Diamond-Blackfan syndrome, increase the risk for developing acute myelogenous leukemia (AML).

Molecular Genetic Alterations

Molecular analysis has increased our understanding the role of Philadelphia chromosome in the pathogenesis of chronic myelogenous leukemia (CML).

- Philadelphia chromosome (Ph) is an acquired chromosomal translocation that results in a fusion gene called BCR-ABL1. Once the Philadelphia chromosome is detected, its rise and fall reflects the tumor burden; and hence can be used as a measure of the disease progression, remission and relapse. All the three cell lineages of the hematopoietic stem cells are involved in CML, the original transformed cell is pluripotent hematopoietic stem cell (HSC).

Table 9.16 Hereditary and acquired disorders associated with increased risk for acute leukemia/lymphoma

Predisposing Factors	Disorders and Causes	
Genetic susceptibility	▪ Down's syndrome (↑ risk of AML or ALL) ▪ Fanconi syndrome (↑ risk of AML) ▪ Ataxia-telangiectasia (↑ risk of ALL or NHL) ▪ Bloom syndrome ▪ Klinefelter's syndrome	▪ Osteogenesis imperfecta ▪ Leukemia in siblings ▪ Diamond-Blackfan syndrome ▪ Li-Fraumeni syndrome ▪ Xeroderma pigmentosum
Predisposing hemato-logical disorders	▪ Myeloproliferative syndrome (↑ risk of AML) ▪ Chronic myeloproliferative disorders (↑ risk of AML) ▪ Aplastic anemia	▪ Paroxysmal nocturnal hemoglobinuria (↑ risk of AML or rarely ALL)
Somatic mutations	▪ Chronic exposure to benzene ▪ Alkylating agents (chlorambucil, melphalan) ▪ Prolonged exposure to radiation	▪ Chronic exposure to benzene ▪ Alkylating agents (chlorambucil, melphalan)
Viral infection	▪ HTLV1 (↑ risk of adult T cell leukemia/ lymphoma)	▪ HIV infection
Immunologic disorders	▪ Wiskott-Aldrich syndrome ▪ Bruton's type X-linked agammaglobulinemia	▪ Immunosuppressive therapy
Chemical agents	▪ Prolonged benzene exposure	▪ Alkylating agents (chlorambucil, melphalan)

- On the other hand, chronic lymphocytic leukemia (CLL) is a disease of clonal B cells that have low proliferative rate and defect in the apoptosis of leukemic cells. CLL leukemic B cells appear mature but are actually arrested during early development resulting in less capable of differentiating into antibody-synthesizing plasma cells.
- Hereditary and acquired disorders associated with increased risk for acute leukemia/lymphoma are given in Table 9.16. Schematic representation of pathogenesis of acute leukemia is shown in Fig. 9.10. Schematic representation of pathogenesis of acute myelogenous leukemia showing class I and class II mutations is shown in Fig. 9.11.

LABORATORY DIAGNOSIS

A complete hemogram examination usually reveals leukocytosis and abnormally elevated or depressed cell lineages in leukemias.

- Coagulation studies reveal elevated prothrombin time–INR, decreased fibrinogen level and the presence of fibrin degradation products in acute promyelocytic leukemia also known as AML-M3 associated with disseminated intravascular coagulation (DIC).
- The diagnosis is confirmed by further examination of peripheral blood smear, bone marrow aspirate and bone marrow trephine biopsy.
- Cytogenetic analysis, molecular testing and immunophenotyping are performed to establish diagnosis of leukemias. Common laboratory tests for the evaluation of leukemias are given in Table 9.17.

Peripheral Blood Smear Examination

Examination of Romanowsky stained peripheral blood smear is an inexpensive but powerful reliable and diagnostic tool of hematologic disorders in both children and adults.

- In leukemias, malignant transformation and uncontrolled proliferation of an abnormally differentiated, long-lived myeloid progenitor cell results in high number of immature blood cells and replacement of normal bone marrow by leukemic cells.
- Changes in the number and the appearance of different types of blood cells such as anemia and thrombocytopenia of variable degrees are helpful in diagnosing leukemias.

Bone Marrow Smear Examination

Bone marrow smear examination is performed to obtain greater concentration of hematopoietic stem cells for identification of blast cells in acute myelogenous leukemia and acute lymphoblastic leukemia.

- Extent of bone marrow involvement is correlated with prognosis in chronic lymphocytic leukemia. It is essential to diagnose chronic myelogenous leukemia, BCR-ABL1 positive in its chronic, accelerated and blast phase.
- Bone marrow aspiration smears should be stained with May-Grunwald-Giemsa or Wright-Giemsa stain for optimal visualization of cytoplasmic granules and nuclear chromatin. It is recommended to count at least 500 nucleated cells on bone marrow cellular

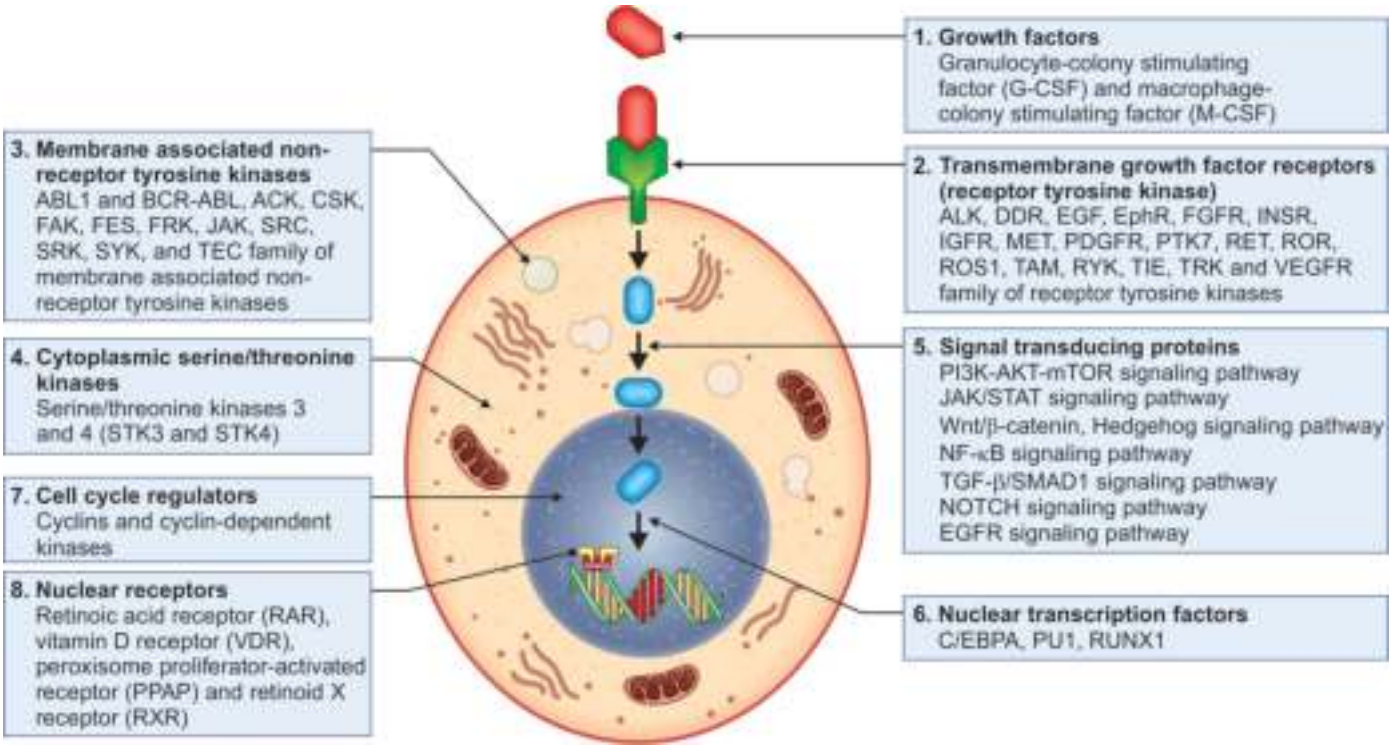

Fig. 9.10: Schematic representation of pathogenesis of acute myelogenous leukemia. It depicts mutations in growth factors, growth factor receptors, signaling transduction pathways leading to development of acute myelogenous leukemia as a consequence of a series of genetic changes in the hematopoietic precursor cell. These changes alter normal hematopoietic cell growth and differentiation resulting in an accumulation of large number of abnormal, immature myeloid cells in the bone marrow and peripheral blood.

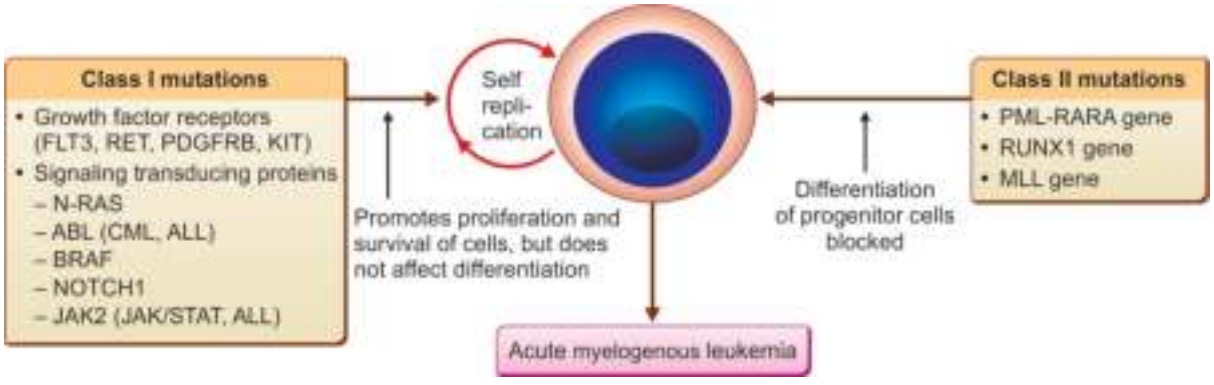

Fig. 9.11: Schematic representation of pathogenesis of acute myelogenous leukemia showing class I and II mutations. Class I mutations of growth factors and signaling transducing proteins act on hematopoietic stem cell that replicates. Class II mutations block the differentiation of progenitor cells. PML-RARA molecular abnormality is the diagnostic feature of AML-M3.

aspirate smears as close to the particle and undiluted with blood as far as possible.

- The cells to be counted in bone marrow aspirate smears include blasts, promyelocytes, myelocytes, metamyelocytes, band neutrophils, segmented neutrophils, eosinophils, basophils, lymphocytes, plasma cells, erythroid precursors, megakaryocytes, and mast cells. Comparison of acute and chronic leukemias is given in Table 9.18.

Bone Marrow Trephine Biopsy Examination

Bone marrow trephine biopsy examination is performed to obtain greater concentration of hematopoietic stem cells for identification of blast cells in acute myelogenous leukemia and acute lymphoblastic leukemia.

- Bone marrow trephine biopsies of suspected myeloid neoplasms should be ≥1.5 cm in length and obtained at right angles to the cortical bone,

Table 9.17 Common laboratory tests for the evaluation of leukemias

Laboratory Test	Characteristics	Clinical Application
Peripheral blood smear	Examination of peripheral blood smear under light microscope	Identification of Auer rods in myeloblasts in acute myelogenous leukemia
Bone marrow aspirate and/or bone marrow trephine biopsy examination	Examination of greater concentration of hematopoietic cells	▪ Identification of blast cells in acute myelogenous leukemia and acute lymphoblastic leukemia ▪ Extent of bone marrow involvement correlated with prognosis in chronic lymphocytic leukemia
Cytogenetic analysis	Examination of whole chromosomes through karyotyping or fluorescence *in situ* hybridization (FISH)	▪ Detection of the Philadelphia chromosome (BCR-ABL1 fusion gene) for the diagnosis of chronic myelogenous leukemia ▪ Identification of chromosomal abnormalities to diagnose leukemia subtype ▪ Cytogenetic analysis can be used to guide treatment and determine prognosis
Flow cytometry with immunophenotyping	Sorting and counting cell by specific markers, samples obtained from blood and/or bone marrow	▪ Counting cloned cells of lymphoid lineage for the diagnosis of chronic lymphocytic leukemia ▪ Identification of certain cell surface markers to diagnose leukemia subtypes
Molecular analysis	Analysis of specific mutations at the DNA level through polymerase chain reaction testing	▪ Detection of the Philadelphia chromosome (BCR-ABL1 fusion gene) for the diagnosis of chronic myelogenous leukemia ▪ Diagnosis of leukemia subtypes, monitoring response to therapy and prognosis

Table 9.18 Comparison of acute and chronic leukemias

Features	Acute Leukemia	Chronic Leukemia
Age group	All age groups	Adults
Clinical onset	Sudden onset	Insidious onset
Clinical course of disease (untreated cases)	Weeks to months	Months to years
Predominant cells	Blasts, some mature forms	Mature forms
Anemia	Mild to severe	Mild
Thrombocytopenia	Mild to severe	Mild
WBCs count	Variable	Increased

which provide information regarding overall cellularity, cytomorphologic details, proportion and maturation of hematopoietic stem cells, evaluation of bone marrow stroma and cancellous bone structure. Bone marrow trephine biopsy provides material for immunohistochemical studies that may have diagnostic and prognostic significance.

- Bone marrow trephine biopsy is essential whenever, one suspect myelofibrosis. Bone marrow trephine biopsy should be well fixed. Tissue sections should be 3–4 μm and stained with hematoxylin and eosin.
- Gomori silver methenamine stain is used for evaluation of collagen and reticulin fibers in myelofibrosis. Periodic acid–Schiff stain (PAS) may be used to detect megakaryocytes.

Cytochemistry

Cytochemistry is commonly performed to diagnose leukemias. In principle, it identifies differences in the cellular content of different cytoplasmic enzymes such as myeloperoxidase (MPO) stain, nonspecific esterase (NSE) stain, periodic acid–Schiff (PAS) stain, Sudan black stain and acid phosphatase (AP) stain.

- Cytochemical stains are sometimes difficult to interpret even in the most experienced hands, especially when leukemic blasts are undifferentiated enough to make a morphologic diagnosis difficult.
- Cytochemical staining techniques in hematology are given in Table 9.19. Cytochemistry in acute myelogenous leukemia (AML) and acute lymphoblastic leukemia (AML) is given in Table 9.20.

Table 9.19 Cytochemical staining techniques in hematology

Cytochemical Stain	Element Stained	Positive Staining Reaction	Negative Staining Reaction	Diagnostic Utility
Myeloperoxidase (MPO) stain	MPO present in primary granules of granulocytic cells	▪ Myeloblasts and promyelocytes (strong staining) ▪ Monocytes (weak staining)	Lymphoblasts	▪ Differentiating AML versus ALL ▪ AML positive ▪ ALL negative
Sudan black B (SBB) stain	Lipids present in primary, secondary granules and lysosomes of monocytes	▪ Myeloblasts and promyelocytes (strong staining) ▪ Monocytes (weak staining)	Lymphoblasts	▪ Differentiating AML versus ALL ▪ AML positive ▪ ALL negative
Leukocyte esterase AS-D chloroacetate esterase stain	Specific esterase enzyme present in neutrophils	Myeloblasts	Lymphoid cells	Demonstration of cells of myeloid origin
Leukocyte esterase (alpha-naphthyl esterase) stain	Nonspecific esterase enzyme present in monocytes	▪ Monoblasts ▪ Monocytes	▪ Granulocytes ▪ Lymphoid cells	Differentiating myeloid versus monocytic origin
Tartrate-resistant acid phosphatase (TRAP) stain	Isoenzymes of acid phosphatase	Hairy cell lymphocytes (isoenzyme 5 of acid phosphatase is not inhibited with the addition of tartrate, thus positive reaction)	All cells except hairy cell lymphocytes	Positive staining and diagnosis of hairy cell leukemia
Periodic acid–Schiff (PAS) stain	▪ Glycogen ▪ Mucoproteins ▪ High molecular weight carbohydrates	Multiple cell types	Normal erythroblasts	▪ AML of erythroid (coarse granular staining) or megakaryocytic origin ▪ ALL (some cases)
Leukocyte alkaline phosphatase (LAP)	LAP present in the secondary granules of mature neutrophils	Neutrophils (activity of LAP is demonstrated in mature band cells and segmented neutrophils and scoring done on a 0–4 rating scale)	Not applicable	▪ Differentiation of CML versus leukemoid reaction ▪ CML (low activity) ▪ Leukemoid reaction (high activity)
Terminal deoxynucleotidyl transferase (TdT)	DNA polymerase in cell nuclei	Lymphoblasts	▪ Myeloblasts ▪ Monoblasts	Demonstration of lymphoblasts

AML: Acute myelogenous leukemia, ALL: Acute lymphoblastic leukemia, CML: Chronic myelogenous leukemia.

Table 9.20 Cytochemistry in acute myelogenous leukemia (AML) and acute lymphoblastic leukemia (ALL)

Cytochemical Stain	Acute Myelogenous Leukemia (AML)	Acute Lymphoblastic Leukemia (ALL)
Myeloperoxidase	Positive	Negative
Sudan black B	Positive	Negative
Nonspecific esterase	Positive (AML-M4, AML-M5)	Negative
PAS	Positive diffuse staining (AML-M6)	Positive
Acid phosphatase	Negative	Positive (T cell ALL)

Pathology Pearls: Cytochemical Stains used Diagnosing Leukemias

Leukocyte Myeloperoxidase Stain

- Leukocyte myeloperoxidase is present in the myeloblasts, that plays a role in killing bacteria. Myeloblasts show positivity for myeloperoxidase.
- Myeloperoxidase (MPO) is positive in myeloblast of acute myelogenous leukemia and negative in lymphoblast of acute lymphoblastic leukemia.
- Myeloperoxidase enzyme stain negativity in lymphoblasts in acute lymphoblastic leukemia 2 (ALL-L2) is shown in Fig. 9.12. Myeloperoxidase enzyme stain positivity in myeloblasts in a case of acute myelogenous leukemia M2 (AML-M2) is shown in Fig. 9.13.

Leukocyte Esterase Stain

- Leukocyte esterases are found in monocytes and neutrophils in different concentrations.
- α-Naphthyl esterase is strongly positive in monocytes and weakly positive in neutrophils.
- Reverse expression is true of naphthol AS-D chloroacetate esterase, i.e. weakly positive in macrophages and strongly positive in neutrophils.
- Leukocyte esterases are useful to differentiate the monocytic from granulocytic precursors in acute myelogenous leukemia.
- Nonspecific esterase stain (α-naphthyl-acetate-esterase) positivity in a case of T cell lineage acute lymphoblastic leukemia (T-ALL) is shown in Fig. 9.14. Nonspecific esterase stain positivity in a case of acute myelogenous leukemia M3 (AML-M3) is shown in Fig. 9.15.

Periodic Acid–Schiff Stain

- Periodic acid–Schiff (PAS) stain demonstrates the presence of polysaccharides. Neutrophilic granules stain with PAS stain technique.
- Lymphocytes may have PAS positive granules.
- PAS stain is negative in acute myelogenous leukemia blasts, but acute lymphoblastic leukemia lymphoblasts may demonstrate variable positivity.
- Periodic acid–Schiff (PAS) stain positivity in blasts in a case of acute lymphoblastic leukemia L2 (ALL-L2) is shown in Fig. 9.16.

Acid Phosphatase Stain

- Acid phosphatase is present in macrophages and osteoblasts.
- T cell acute lymphoblastic leukemia (T-ALL) and hairy cell leukemia (HCL) are also positive for acid phosphatase.
- Acid phosphatase is tartrate resistant in hairy cell leukemia.
- Acid phosphatase staining on bone marrow aspirate smear is shown in Fig. 9.17.

Leukocyte Alkaline Phosphatase Stain

- Leukocyte alkaline phosphatase is present in the more mature cells of the myeloid lineage, band form and neutrophils.
- Leukocyte alkaline phosphatase is useful for the differential diagnosis between chronic myelogenous leukemia (CML), where alkaline phosphatase is low from leukemoid reactions, where alkaline phosphatase is normal.

Sudan Black Stain

- Sudan black is a lipid stain positive in neutrophilic granules of precursors and mature granulocytes.
- Sudan black is also present in myeloblast of acute myelogenous leukemia but not in lymphoblast of acute lymphoblastic leukemia.

Terminal Deoxynucleotidyl Transferase

- Terminal deoxynucleotidyl transferase (TdT) is present in thymocytes and thymocyte precursors. TdT is positive in most patients with acute lymphoblastic leukemia except the rare B cell acute lymphoblastic leukemia.
- TdT is absent in acute myelogenous leukemia (AML).

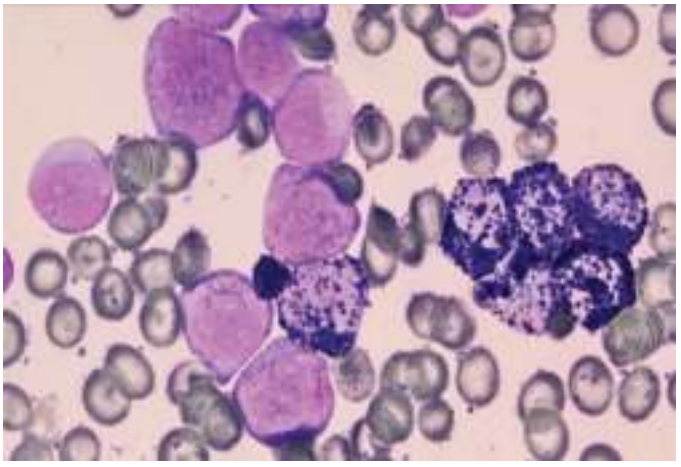

Fig. 9.12: Myeloperoxidase (MPO) enzyme stain in acute lymphoblastic leukemia 2 (ALL-L2). Blasts are showing negative results with myeloperoxidase stain and the neutrophils and eosinophils are showing positivity in the form of dense greenish blue granules in the cytoplasm (1000X).

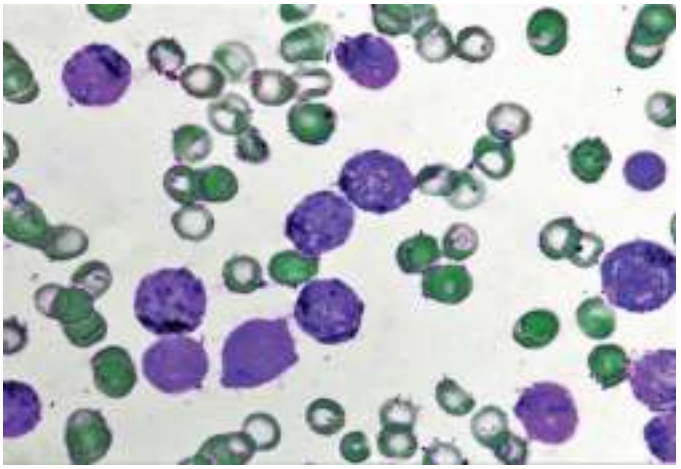

Fig. 9.13: Myeloperoxidase (MPO) enzyme stain positivity in myeloblasts in a case of acute myelogenous leukemia M2 (AML-M2). Myeloperoxidase is the hallmark enzyme of the myeloid lineage. It can be detected by cytochemistry, flow cytochemistry or immunohistochemistry. The diagnosis of acute myeloblastic leukemia (AML) is easy if more than 3% of myeloblast cells are confirmed to be cytochemically myeloperoxidase positive (1000X).

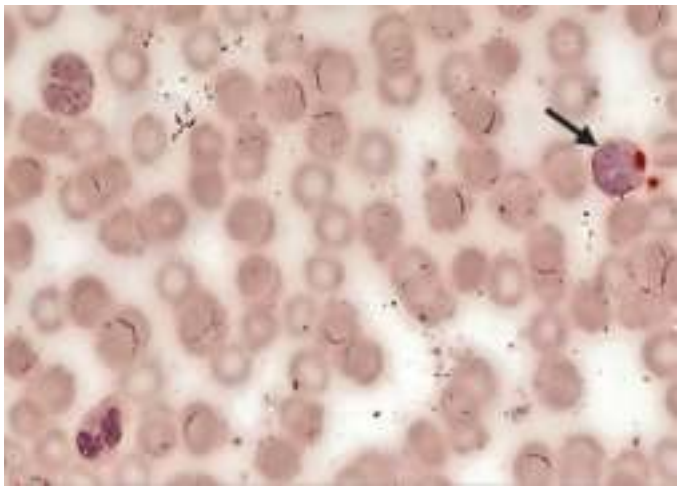

Fig. 9.14: Nonspecific esterase stain (α-naphthyl-acetate-esterase) positivity in a case of T cell lineage acute lymphoblastic leukemia (T-ALL). Bone marrow trephine biopsy section is showing reddish brown focal positivity in the blast (marked by arrow). On immunophenotyping this case turned out to be of T-lineage acute lymphoblastic leukemia (1000X).

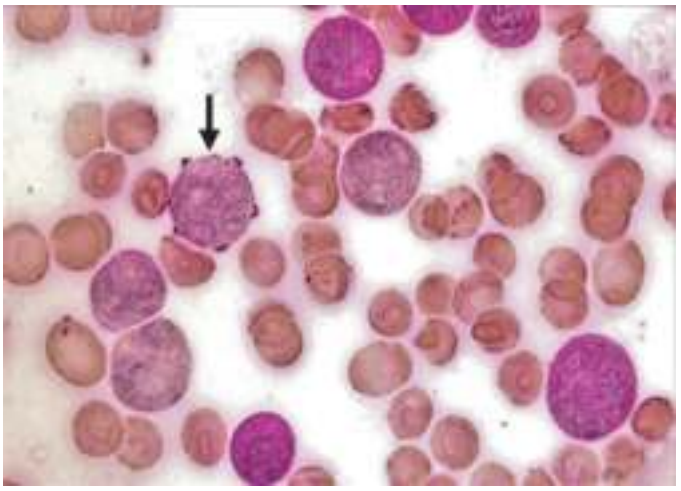

Fig. 9.16: Periodic acid–Schiff (PAS) stain positivity in blasts in a case of acute lymphoblastic leukemia L2 (ALL L2). Periodic acid–Schiff (PAS) stain of the same case as above showing granular magenta positivity in the blast cell (marked by arrow) and neutrophils are showing dense confluent positivity (acting as positive control) (1000X).

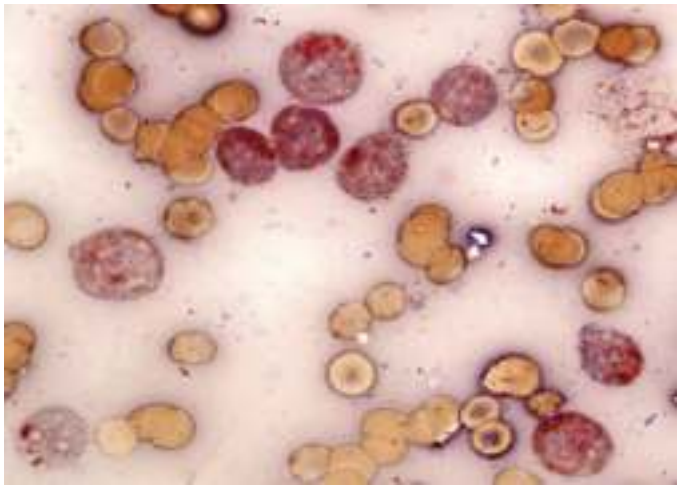

Fig. 9.15: Nonspecific esterase stain positivity in a case of acute myelogenous leukemia M3 (AML-M3) (1000X).

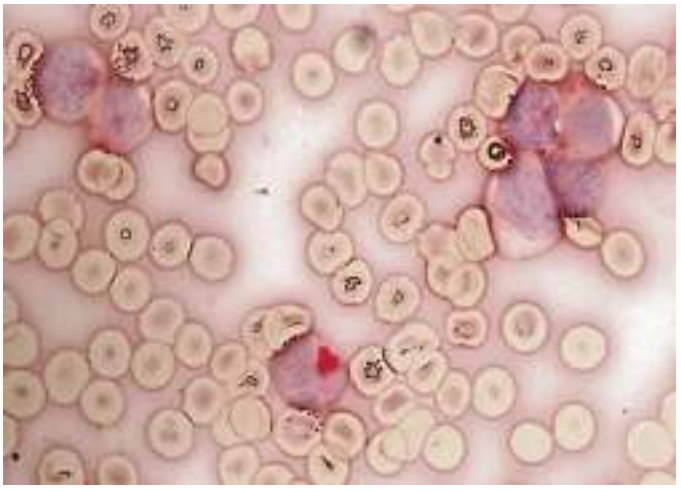

Fig. 9.17: Acid phosphatase stain on bone marrow aspirate smear shows polar magenta colored positivity in the blast cells. This case was of T-ALL on immunophenotyping (1000X).

Immunophenotyping

Flow cytometry is performed for immunophenotyping for sorting and counting cell by specific surface markers to diagnose leukemias on samples obtained from blood and/or bone marrow.

- Monoclonal antibodies are useful to differentiate acute myelogenous leukemia (AML) from acute lymphoblastic leukemia (ALL) in cases inconclusive on cytochemistry.
- Patients with AML express HLA-DR, cytoplasmic anti-MPO, CD13, CD33 and CD65. HLA-DR, CD10, CD19, CD20 are positive in acute lymphoblastic leukemia (ALL). B-ALL and T-ALL cases are positive with CD2, CD3, CD5 and CD7.
- Monocyte is positive with CD14. AML-M6 is positive with glycophorin A. AML-M7 is positive for CD33, CD61, vWF, GpIIb/IIIa and glycophorin A.
- Immunophenotyping of AML and B-ALL, T-ALL, chronic lymphocytic leukemia, B-prolymphocytic leukemia and hairy cell leukemia is given in Table 9.21. Expression of markers for diagnosis of AML and mixed phenotype acute leukemia (MPAL) is shown in Fig. 9.18.

Cytogenetic Analysis

Cytogenetic analysis is study of whole chromosomes through karyotyping or fluorescence *in situ* hybridization. Cytogenetic analysis is done to detect the Philadelphia

Table 9.21 Immunophenotyping of acute myelogenous leukemia (AML) and B cell acute lymphoblastic leukemia (B-ALL), T cell acute lymphoid leukemia (T-ALL), chronic lymphocytic leukemia, B-prolymphocytic leukemia and hairy cell leukemia

Leukemia	Expression
Acute myelogenous leukemia (AML)	HLA-DR+, CD13+, CD33+, CD65+, cAnti-MPO+
B-lineage acute lymphoblastic leukemia	CD19+, CD210+, CD22+, CD24+, CD79a+
Pro-B acute lymphoblastic leukemia	CD19+, CD34+, CD22+, TdT+, cytoplasmic CD79a+, CD10+
Pre-B acute lymphoblastic leukemia	CD22+, CD34+, CD34+, CD19+, TdT+, cytoplasmic CD79a+, CD10+, cytoplasmic Ig mu+
Cortical/thymic T cell acute lymphoblastic leukemia (T cell-ALL)	TdT+, CD10+, CD1a+, CD2+. CD3+. CD5+. CD7+
Chronic lymphocytic leukemia (CLL)	CD19+, CD5+, CD23+ clonal Ig gene rearrangements+
B cell-prolymphocytic leukemia (B-PLL)	CD20+, FMC-7+, CD19+, CD5+
Hairy cell leukemia (HCL)	CD19+, CD20+, CD200+, monoclonal surface immunoglobulin-aS-HCL1+, CD22+ CD25+, CD103+, CD11c+

CD1 is specific marker for Langerhans cells; TdT: Terminal deoxynucleotidyl transferase.

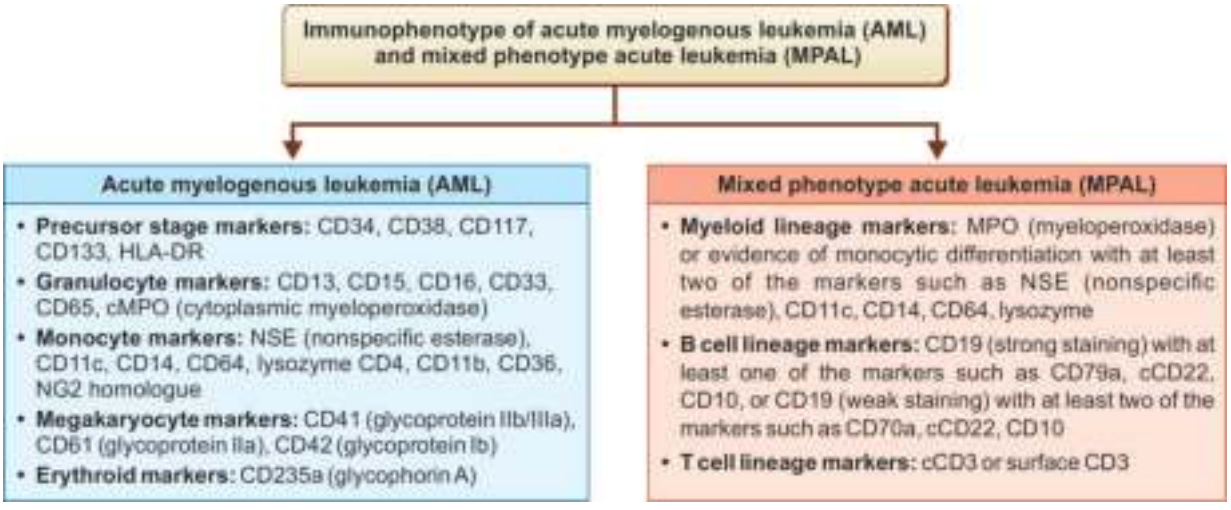

Fig. 9.18: Schematic representation of immunophenotype of acute myelogenous leukemia (AML) and mixed phenotype acute leukemia (MPAL).

chromosome (BCR-ABL1 fusion gene) for the diagnosis of chronic myelogenous leukemia. It can be used to guide treatment and determine prognosis. Cytogenetic abnormalities in acute and chronic leukemias are given in Table 9.22.

Molecular Genetic Analysis

Molecular genetic analysis is performed to identify specific mutations at the DNA level through polymerase chain reaction to detect the Philadelphia chromosome (BCR-ABL1 fusion gene) for the diagnosis of chronic myelogenous leukemia. Molecular genetic analysis also aids in the diagnosis of leukemia subtypes, can also be used to guide treatment and determine prognosis.

TREATMENT

Treatment of leukemias are treated by targeted therapy, chemotherapy, radiotherapy, monoclonal antibodies, or hematopoietic stem cell transplantation.

- Complications of leukemias treatment include tumor lysis syndrome and serious infections from immunosuppression in leukemic patients.
- Leukemic patients should be monitored closely for development of secondary malignancies, cardiac complications, and endocrinal disturbances such as metabolic syndrome, hypothyroidism and hypogonadism.

PROGNOSIS

Five-year survival rates are highest in the younger patients and patients with chronic lymphocytic leukemia (CLL) and chronic myelogenous leukemia (CML).

- Prognosis in patients with acute myelogenous leukemia (AML) ranges from mortality within a few days of initiating treatment.
- Acute lymphoblastic leukemia (ALL) is the second most common in children and adults. In adults, 75% of ALL cases develop from B cell lineage with

Table 9.22 Cytogenetic abnormalities in acute and chronic leukemias

Tumor	Chromosomal Abnormalities	Fusion Transcript, Involved Genes
Acute myelogenous leukemia (AML)		
AML-M1 (CD13+, CD15+, CD64+)	t(9;22)	BCR-ABL
AML-M2	t(8;21) favorable prognosis	CBa-ETO
AML-M3 (acute promyelocytic leukemia)	▪ t(15;17) (q22;q21) ▪ t(11;17) (q22;q21) ▪ t(5;17) (q35;q21) ▪ t(11;17) (q13;q21)	▪ RARA/PML (transcriptional factor in 95%) ▪ PLZF-RARA (<5%) ▪ NPM-RARA (<1%) ▪ NuMA-RARA (<1%)
AML-M4 eosinophil	inv(16) (p13'q22) favorable prognosis	CBFb/MYH1
Acute lymphoblastic leukemia (ALL)		
ALL-B cell lineage (good prognosis)	t(12;21)	CBFa-ETV6
ALL pre-B cell lineage (cytoplasmic Ig positive) with poor prognosis	t(1;19)	PBX1-E2A (transcription factor)
Chronic myelogenous leukemia (CML)		
Chronic myelogenous leukemia (CML), BCR-ABL1 positive	t(9,22) (q34,q11)	BCR-ABL
Chronic lymphocytic leukemia (CLL)		
Chronic lymphocytic leukemia (CD19+, CD20+, CD23+, CD5+)	▪ Trisomy 12 ▪ Deletions of 11q,13q and 17p	Not applicable

the remainder ALL cases develop from clonal T cell lineage.

- Despite advances in management, the backbone of therapy in leukemias remains multi-agent chemotherapy with vincristine, corticosteroids and an anthracycline with allogeneic hematopoietic stem cell transplantation for eligible candidates.

Clinical Pearls: Uses of Hematopoietic Growth Factors in Oncology Practice

- **Hematopoietic growth factors:** These belong to family of regulatory molecules that play important roles in the growth, and differentiation of blood progenitor cells, as well as functional activation of mature cells.
- **Recombinant growth factors:** The commercial availability of recombinant hematopoietic growth factors/cytokines (G-CSF, GM-CSF, EPO, IL-11, darbepoetin-α) has led to their wide clinical application in oncology clinical practice for prophylactic and therapeutic purpose.
  - **Prophylactic use:** It refers to administration of hematopoietic growth factor to prevent febrile neutropenia in patients receiving chemotherapy or subsequent cycles of chemotherapy.
  - **Therapeutic use:** It refers to administration of a hematopoietic growth factor at the time, when neutropenia or neutropenic fever is documented in a patient who had not been receiving colony-stimulating factors (CSF) previously.

Leukemia Disease Burden Impact

Leukemia disease burden refers to the number of leukemic cells, the size of the tumor or amount of cancer in the body. Tumor mutation burden (TMB) is defined as the total number of nonsynchronous mutations per coding are of tumor genome.

- TMB has been determined using whole exome sequencing, but due to the high costs, targeted panel sequencing is currently being explored to measure tumor mutation burden.
- Leukemic disease burden of 10^{12} leukemic clones is believed to be sufficient for recognizable signs and symptoms.
- Lethal levels of leukemic disease burden occur, when there is presence of 10^{13-14} leukemic clones. The classic triad of anemia, recurrent infections and bleeding manifestations in cases of acute leukemias occur as a result of replacement of normal hematopoietic stem cells by leukemic cells.

ACUTE LYMPHOBLASTIC LEUKEMIA

ACUTE LYMPHOBLASTIC LEUKEMIA: OVERVIEW

Acute lymphoblastic leukemia (ALL) represents the most common pediatric malignancy, accounting for approximately 25% of childhood cancer. ALL is derived from lymphoid precursor B cell (80%), lymphoid precursor T cell (20%) and mature B cells in the bone marrow.

- According to revised 2024 WHO classification of acute myelogenous leukemia (AML) or acute lymphoblastic leukemias diagnostic criteria is the presence of **≥20% blast cells** as the cut off percentage in bone marrow and peripheral blood. It represents a change from original guidelines as per French-American-British (FAB) classification of leukemias, where **≥30%** blast cells were considered as the cut off percentage diagnostic criteria in bone marrow and peripheral blood.
- Clonal lymphoblasts continuously multiply in the bone marrow and cause damage to normal progenitor cells of different cell-lineages (i.e. erythroid, myeloid and megakaryocytes) resulting in anemia, neutropenia (recurrent infection) and thrombocytopenia (bleeding tendencies).
- Acute lymphoblastic leukemia involves bone marrow (100%), peripheral blood and distant organs such as anterior mediastinal mass (10%), central nervous system (5%), testes (5%) and other sites such as eye, skin, pericardium, pleura, kidney, breast, ovary, penis (priapism, and gastrointestinal tract intussusception) in <5% of cases. Disease is most common during childhood with a peak at 4–5 years of age (85%) and adulthood (50%) with peak in old age.
- Acute lymphoblastic leukemia (ALL) patients are more responsive to therapy associated with long-term disease-free survival.
  - Rapid progression of the disease can be fatal in weeks to months, if left untreated.
  - Patients present with hepatosplenomegaly, fever, fatigue, cervical lymphadenopathy, bone pain, bleeding manifestations, anorexia and abdominal pain.
- Revised 2024 WHO classification of acute lymphoblastic leukemia/lymphoma is given in Table 9.23. French-American-British classification of acute lymphoblastic leukemias and their features is given in Table 9.24.

Table 9.23 Revised 2024 WHO classification of acute lymphoblastic leukemia/lymphoma

B Cell Derived Acute Lymphoblastic Leukemia/Lymphoma
B-lymphoblastic leukemia/lymphoma, not otherwise specified (NOS)
B-lymphoblastic leukemia/lymphoma with t(9;22) (q34.1;q11.2); BCR-ABL1
B-lymphoblastic leukemia/lymphoma with t(v;11q23.3); KMT2A-rearrangement
B-lymphoblastic leukemia/lymphoma with t(12;21) (p13.2;q22.1); ETV6-RUNX1
B-lymphoblastic leukemia/lymphoma with hyperdiploidy
B-lymphoblastic leukemia/lymphoma with hypodiploidy
B-lymphoblastic leukemia/lymphoma with t(5;14) (q31.1; q32.1);IGH/IL3
B-lymphoblastic leukemia/lymphoma with t(1;19) (q23;p13.3); TCF3-PBX1
Provisional entity: B cell acute lymphoblastic leukemia/lymphoma with BCR-ABL1 like
Provisional entity: B cell acute lymphoblastic leukemia/lymphoma with iAMP21 (intrachromosomal amplification of chromosome 21)
T Cell Derived Acute Lymphoblastic Leukemia/Lymphoma
T cell lymphoblastic leukemia/lymphoma
Early T cell precursor lymphoblastic leukemia/lymphoma
NK Cell Derived Acute Lymphoblastic Leukemia/Lymphoma
Adapted from revised 2024 WHO classification of acute lymphoblastic leukemia

Table 9.24 French-American-British (FAB) classification of acute lymphoblastic leukemias and their features

Leukemia Subtype	Description
ALL-L1	▪ ALL-L1 accounts for >80% of leukemias and affects children ▪ In ALL-L1, lymphoblasts are uniform, homogenous with scant cytoplasm with regular nuclei and inconspicuous nucleoli ▪ ALL-L1 is associated with good prognosis
ALL-L2	▪ ALL-L2 accounts for 10–50% and affects adults ▪ In ALL-L2, lymphoblasts are large, heterogenous with round to oval nuclei showing indentation or clefts with prominent nucleoli ▪ ALL-L1 is associated with poor prognosis
ALL-L3	▪ ALL-L3 accounts for 3–4% of leukemias and affects adults ▪ In ALL-L3, lymphoblasts are large homogenous with round to oval nuclei, finely stippled chromatin, prominent nucleoli and abundant basophilic vacuolated cytoplasm ▪ ALL-L3 is associated with poor prognosis

CD: Cluster of differentiation.

PREDISPOSING FACTORS

Acute lymphoblastic leukemia (ALL) accounts for 80% of all childhood leukemia. ALL is most common in children 2–8 years of age (85%), and another peak at 50 years of age.

- Only a small proportion of patients with childhood ALL have an underlying genetic abnormality in less than 5% of cases.
- Acquired chromosomal abnormalities such as aneuploidy (hyperploidy) and/or translocations are demonstrated in >90% of ALL cases. Such chromosomal abnormalities may be prenatal in origin in some cases.
- The genes involved in leukemogenesis are frequently transcription factors expressed in the hematopoietic tissues in bone marrow.
- Genetic disorders and environmental factors associated with acute lymphoblastic leukemia (ALL) are given in Table 9.25.

Molecular Genetic Alterations

Recent technical advances in next generation sequencing have shed light on genetic abnormalities in the hematopoietic stem cells and progenitor cells as the prerequisite to molecular genesis of acute lymphoblastic leukemia. Hyperdiploid ALL also occurs before birth, but these cases require postnatal events for full malignant transformation. Polymorphism at six genomic loci is associated with increased risk of ALL in genetic alterations: ARID5B, IKZF1, CEBPE, GATA3, CDKN2A, CDKN2B, BMI-PIP4K2A, TP53. The IKZF1 deletion is associated with poor prognosis in ALL patients. Loss of CDKN2A or CDKN2B increases the risk of ALL.

Congenital Disorders

Certain disorders predispose to acute lymphoblastic leukemia (ALL), most notably trisomy 21 (Down syndrome), in which the relative risk is increased 10- to 30-fold. Other predisposing factors for development of ALL include Fanconi anemia, Bloom syndrome and ataxia-telangiectasia.

Congenital Immunodeficiencies

There is no definite evidence of an association between leukemia and congenital immunodeficiencies such as X-linked agammaglobulinemia (Bruton agammaglobulinemia) and severe combined immunodeficiency (SCID) syndrome.

Germline TP53 Gene Mutations

Germline TP53 gene mutations, a cause of cancer-predisposing Li-Fraumeni syndrome, are present in 40% of ALL patients with low hypodiploid (32–39 chromosomes).

Fraternal (Dizygotic) Twins and Siblings

There is increased risk for development of ALL during the first decade of life in affected fraternal twins and siblings.

- Fraternal (dizygotic) twins produced derived from two separate fertilized eggs, which develop two separate amniotic sacs and placentae.
- In the case of identical twins, when leukemia affects a twin, there is increased risk for development of leukemia in another twin owing to ALL transfer *in utero* via the shared placental circulation before the age of one year.
  - In identical twins with t(4;11)/MIL-AF4, the concordance rate is nearly 100% within a week to few months period.
  - In identical twins with ETV6-RUNX1 fusion gene or T cell phenotype is lower in postnatal latency period. These cases require additional genetic alterations for development of acute lymphoblastic leukemia.

Environmental Factors

Acute lymphoblastic leukemia may be induced by environmental factors such as prolonged exposure to ionization radiation and chemical agents (benzene) in some cases.

Table 9.25 Genetic disorders and environmental factors associated with acute lymphoblastic leukemia (ALL)

Categories	Disorders
Genetic disorders	Down syndrome, Fanconi anemia, Bloom syndrome, ataxia-telangiectasia
Germline mutations in TP53 gene	Li-Fraumeni syndrome: ALL (40% cases) with low hypodiploid (32–39 chromosomes)
Fraternal twins and siblings	Increased risk of ALL during first decade
Identical twins	Increased risk of ALL in identical twins t(4;11)/MIL-AF4 and identical twins with ETV6-RUNX1 fusion
Loss of CDKN2A or CDKN2B	Increased risk of ALL
Environmental factors	Ionization radiation and chemical agent (benzene)

- Patients treated for other cancers with ionizing radiation and chemotherapy often develop leukemias. But clear etiological factors for ALL cannot be demonstrated in a majority of cases.
- *In utero* exposed to diagnostic X-rays increases the risk for developing ALL. Human T cell leukemia virus 1 (HTLV-1) endemic in Japan, which is the etiological agent for developing an aggressive adult T cell leukemia/lymphoma.

MOLECULAR PATHOGENESIS

Recent studies revealed genomic landscape of evolution of childhood acute lymphoblastic leukemia (ALL) prior to diagnosis, except for mixed-lineage leukemia (MLL)-rearranged involving fusions of 11q23 with one of more than 80% different genes in infant ALL, in which a single genetic mutation is likely to be initiating event in pathogenesis of ALL.

- All other subtypes of childhood ALL occur due to series of genetic events within cell that have acquired an initiating gene mutation during intrauterine life.
- A recurring leukemia associated chromosomal abnormality is demonstrated by karyotyping, fluorescence *in situ* hybridization (FISH) or molecular techniques in about 80% cases in children.
- High hyperdiploidy and ETV6-RUNX1-carrying cells are demonstrated at low levels in 1% of cord blood samples from normal neonates. Out of these, only 1% of neonates develop ALL after several years, thus these rearrangements are not sufficient to cause ALL.
- The initiating mutations drive transcriptional and epigenetic dysregulation and aberrant self-renewal and disrupt lymphoid development resulting in maturation arrest. Additional genetic mutations disrupt multiple molecular pathways such as cell cycle regulation and apoptosis.
- Normally hematopoietic stem cell (HSC) transforming to pre-B cell/pro-B cell and then mature B cell are regulated by various genes (e.g. ARID5B, IKZF1, CEBPE, GATA3, CDKN2A, CDKN2B, BMI-PIP4K2A and TP53). Predisposition of hematopoietic stem cell to pre-/pro-B cell occurs due to mutations of genes.
  - Initial gene mutations and ETV6/RUNX1 transform hematopoietic stem cell to pre-/pro-B cell pre-leukemic clone.
  - Further mutations in B cell transcriptional factor PAX2 gene leads to developmental arrest of B cell development.
- Now the pre-B cell/pro-B cell leukemic clone with the cooperation of mutations in CRLF2, JAK2, IZKF1, PDGFRB result in increased proliferation of clonal cells and their decreased apoptosis. Heterologous clones are demonstrated at ALL diagnosis. Basic aim of treatment of ALL to eradicate clones. Failure to treatment results in relapse.
- Schematic representation of molecular pathogenesis of acute lymphoblastic leukemia (ALL) is shown in Fig. 9.19. Schematic representation of immunophenotype of B cell and T cell lineage acute lymphoblastic leukemias is shown in Fig. 9.20.

CLINICAL FEATURES

Presenting signs and symptoms in acute lymphoblastic leukemia (ALL) are always caused by lymphoblast infiltration in the bone marrow with resultant involvement of peripheral blood and distant organs such as lymph nodes (75%), spleen, liver, anterior mediastinal mass (10%), central nervous system (5%), testes (5%), eye, skin, pericardium, pleura, kidney, breast, ovary, penis, priapism, and gastrointestinal tract intussusception in <5% of cases. The lymph nodes that are immobile and painless are commonly malignant. Painful lymphadenopathy is usually inflammatory in nature.

- Clonal lymphoblasts continuously multiply in the bone marrow and cause damage to normal progenitor cells of different cell lineages in bone marrow (erythroid, myeloid and megakaryocytes) resulting in anemia, neutropenia (recurrent infections) and thrombocytopenia (bleeding tendencies).
- Patients present with cervical lymphadenopathy (75%), hepatosplenomegaly (70%), and anterior mediastinal mass in the decreasing frequency. On clinical examination, enlarged lymph nodes are discrete and firm in consistency.
- Generalized lymphadenopathy is associated with high white blood cell count and fatal outcome. T cell ALL usually presents with bulky lymphadenopathy, mediastinal mass, pleural effusion, and/or hyperleukocytosis. Patient presenting with mediastinal mass has poor prognosis.
- Painless enlargement of scrotum may be due to a testicular infiltration by leukemic cells or hydrocele resulting from lymphatic obstruction in 1–2% of cases.
- Ocular involvement is more common during ALL relapse involving the retina, ocular nerve, orbit, cornea, or anterior chamber with hypopyon.
- Central nervous system involvement is usually leptomeningeal rather than parenchymal and may present with cranial nerve palsies in 5% of cases.
- Involvement of organs/tissues in acute lymphoblastic leukemia (ALL) and common presenting signs and symptoms are given in Table 9.26.

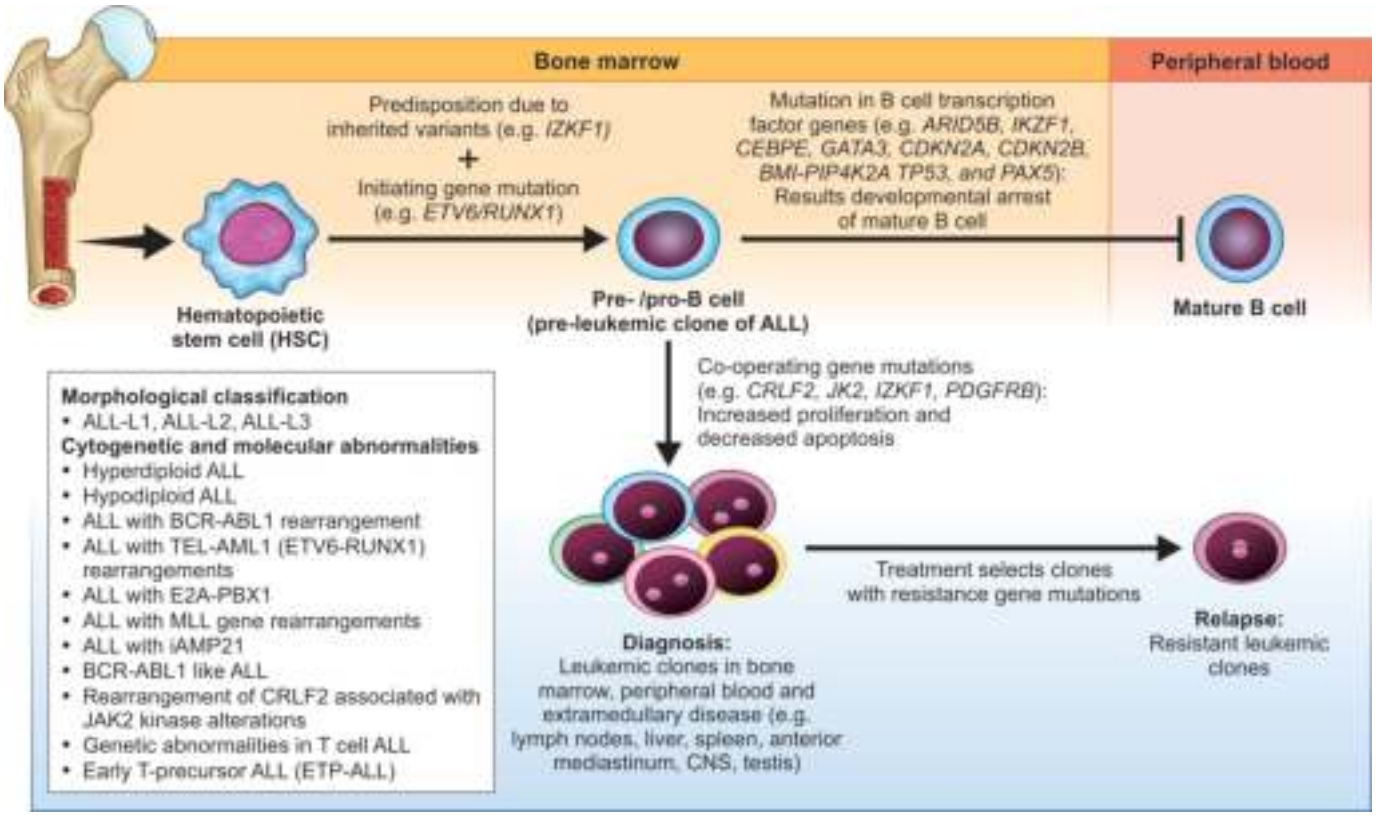

Fig. 9.19: Schematic representation of molecular pathogenesis of acute lymphoblastic leukemia (ALL). It shows morphological classification and cytogenetic and molecular abnormalities; and clinical course. Molecular pathogenesis of acute lymphoblastic leukemia involves a number of abnormal gene expression including TEL-AML1, BCR-ABL1, RAS and PI3K leading to dysregulated cell cycle. Risk factors such as parvovirus B19 infection, environmental toxins, high birth weight can induce abnormal DNA methylation and DNA damage leading to development B-ALL.

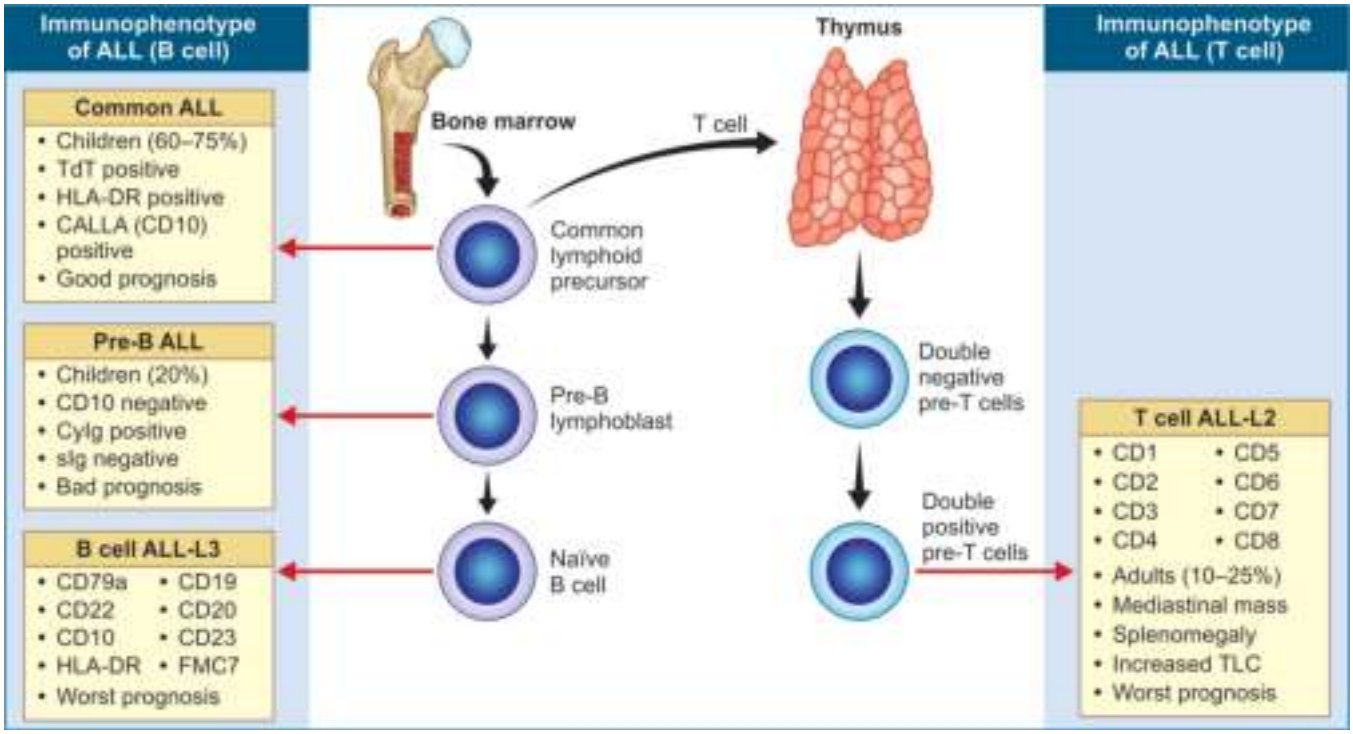

Fig. 9.20: Schematic representation of immunophenotype of B cell and T cell lineage acute lymphoblastic leukemias.

Table 9.26 Involvement of organs/tissues in acute lymphoblastic leukemia (ALL) and common presenting signs and symptoms

Organs/Tissues Involvement
▪ Bone marrow (100%)
▪ Cervical lymphadenopathy (75%)
▪ Mediastinal mass in anterior compartment (10%)
▪ Central nervous system (5%)
▪ Painless involvement of testes (1–2%)
▪ Involvement of organs in <5% of cases (eye, skin, pericardium, pleura, kidney, breast, ovary, priapism, intussusception)
Common Presenting Signs and Symptoms
▪ Hepatosplenomegaly (70%)
▪ Fever (50%)
▪ Fatigue (50%)
▪ Generalized lymphadenopathy (50%)
▪ Bleeding manifestations (40%)
▪ Bone or joint pains (40%)
▪ Anorexia (20%)
▪ Abdominal pain (10%)

- Petechial hemorrhages on the abdomen of a child in acute lymphoblastic leukemia (ALL) are shown in Fig. 9.21. Mediastinal lymph nodes in acute lymphoblastic leukemia (ALL) on CT scan are shown in Fig. 9.22. Abdominal lymph nodes in acute lymphoblastic leukemia (ALL) patient on CT scan are shown in Fig. 9.23.

Fig. 9.21: Petechial hemorrhages on the abdomen of a child in acute lymphoblastic leukemia (ALL).

LIFE-THREATENING COMPLICATIONS OF ALL AND MANAGEMENT

There are several life-threatening emergent clinical complications of ALL, that require emergent intervention.

- Hyperleukocytosis is treated by cytoreduction, leukapheresis and low-dose radiotherapy.
- Broad spectrum antibiotics should be administered in neutropenia with fever manifestations.
- Thrombocytopenia is treated by platelet transfusion.
- Disseminated intravascular coagulation (DIC) is treated by fresh frozen plasma or cryoprecipitate. Tumor lysis syndrome is treated by supportive measures.
- Airway obstruction, superior vena cava syndrome, central nervous system manifestations and spinal cord compression are treated by corticosteroids and/or radiation.

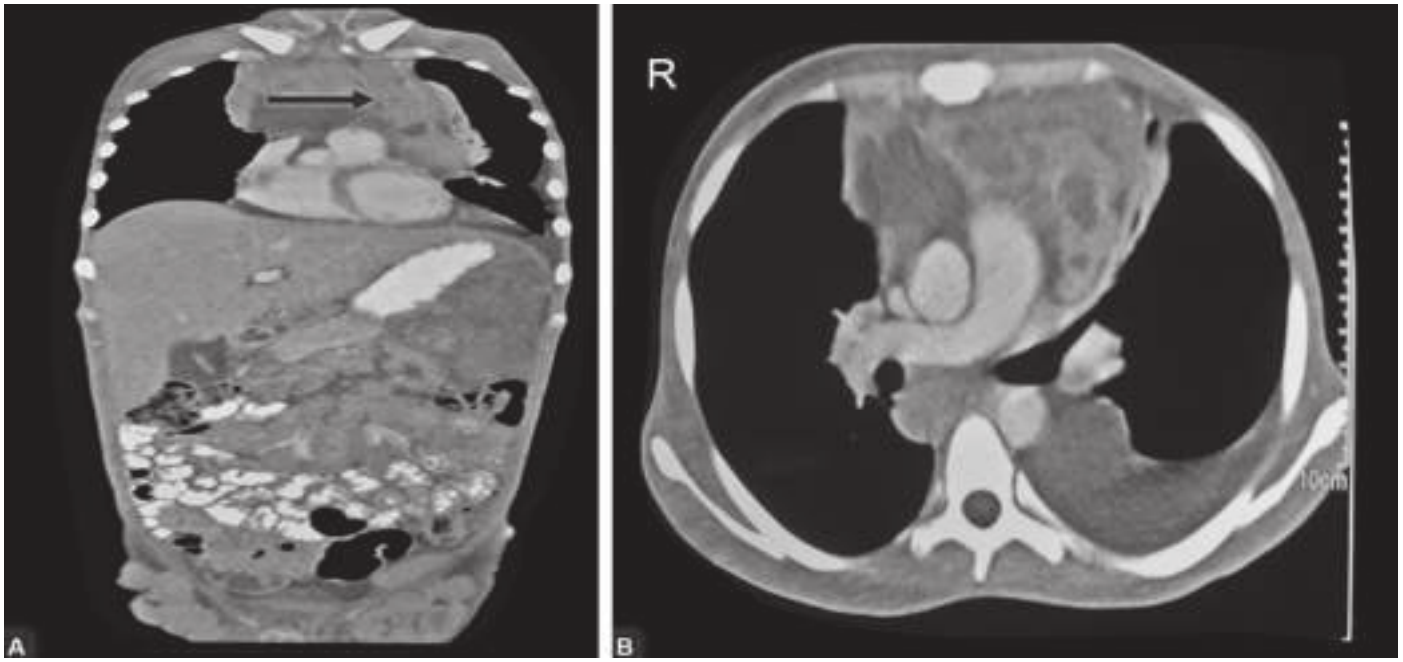

Fig. 9.22: Mediastinal lymph nodes in acute lymphoblastic leukemia (ALL) on CT scan. Coronal image (A) and transverse image (B) on CT scan shows mediastinal mass in a case of T-ALL.

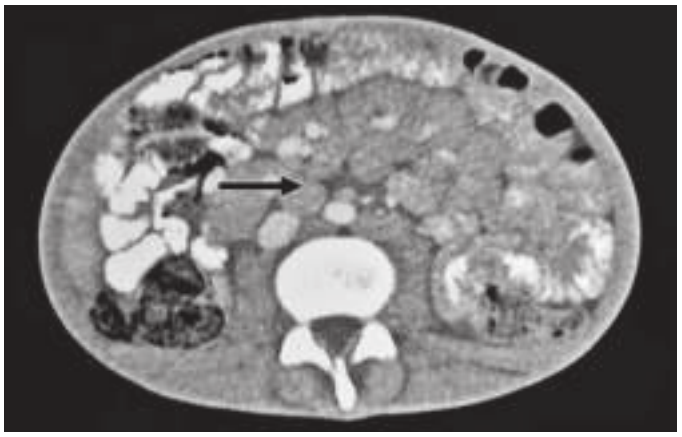

Fig. 9.23: Abdominal lymph nodes in acute lymphoblastic leukemia (ALL) patient on CT scan. Transverse image on CT scan is showing lymph nodes (shown by arrow) in the abdomen.

- Ocular involvement is treated by radiation. Pericardial tamponade is treated by pericardiocentesis and corticosteroids.
- Emergency clinical presentations and management of acute lymphoblastic leukemia (ALL) are given in Table 9.27.

LABORATORY DIAGNOSIS

Diagnosis of acute lymphoblastic leukemia is confirmed by the demonstration of lymphoblasts in the blood and/or bone marrow. Routine hematological analysis, immunophenotype, flow cytometry, cytogenetics, and molecular studies are performed to define ALL subtypes and further identify the prognostic factors.

- Approximately 80% of ALL cases are derived from pro-B cell (pre-B) with immunophenotype (CD19+, CD34+, CD22+, TdT+, cytoplasmic CD79a+, CD10+). precursor B cell (pre-B) with immunophenotype (CD22+, CD34+, CD19+, TdT+, cytoplasmic CD79a+, CD10+, cytoplasmic mu+), and 10–20% is of T cell origin with immunophenotype (TdT+, CD10+, CD1a+, CD2+, CD3+, CD5+, CD7+).
- Certain cytogenetic abnormalities are not apparent on routine karyotyping, thus molecular testing should be performed to demonstrate t(12;21) in 25% of ALL cases in children.
- Lumbar puncture is performed to evaluate the possibility of meningeal leukemia. Central nervous system involvement by ALL leads to cranial nerve palsies.
- According to revised 2024 WHO classification of acute leukemias (lymphoblastic/myelogenous leukemia), diagnostic criteria is the presence of ≥20% blast cells as the cut off percentage in bone marrow and peripheral blood, which represents a change from original guidelines where ≥30% blast cells were considered as the cut off percentage of diagnostic criteria in bone marrow and peripheral blood as per French-American-British (FAB) classification of leukemias.
- Morphology subtyping of various forms of ALL have been used according to French-American-British (FAB) classification: ALL-L1 (small uniform lymphoblasts), ALL-L2 (variable size lymphoblasts) and ALL-L3 (large lymphoblasts with vacuoles—bubble-like appearance as seen in Burkitt lymphoma).
- The revised 2024 WHO international panel recommends that FAB classification be abandoned, since the morphologic classification has no clinical or prognostic relevance. Revised 2024 WHO international panel instead advocates the use of the immunophenotypic classification. Each ALL subtype is then further classified by determining the surface markers of the leukemic lymphoblasts, called immunotyping. There are two main immunologic types of ALL:

Table 9.27 Emergency clinical presentations and management of acute lymphoblastic leukemia (ALL)

Emergent Clinical Presentation	Intervention/Management
Hyperleukocytosis (high leukocyte count)	Cytoreduction by leukapheresis; low dose of chemotherapy
Airway obstruction	Oxygen, corticosteroids administration, and/or radiation therapy
Superior vena cava syndrome	Corticosteroids and/or radiation therapy
Pericardial tamponade	Pericardiocentesis, corticosteroids administration
Neutropenia with fever and superadded infections	Broad spectrum antibiotics
Thrombocytopenia	Platelet transfusion
Disseminated intravascular coagulation (DIC)	Fresh frozen plasma, cryoprecipitate administration
Tumor lysis syndrome	Intravenous hydration, allopurinol and supportive measures, clinically indicated hemodialysis
Central nervous system manifestations such as increased intracranial pressure and nerve palsies	Corticosteroids and/or radiation therapy
Spinal cord compression	Corticosteroids and/or radiation therapy
Ocular involvement	Radiation

pre-B cell lineage ALL and pre-T cell lineage ALL. The mature B cell ALL-L3 is now classified as Burkitt leukemia/lymphoma. Subtyping helps to determine the prognosis and most appropriate therapy in ALL patients.

Laboratory Diagnosis of Acute Lymphoblastic Leukemias

- ALL-L1 usually affects children and young adults with peak incidence during 4–5 years of age and constitutes 75–80% of ALL cases.
- ALL-L2 most often affects children and young adults with peak incidence during 4–5 years of age constitutes 20–30% of ALL cases.
- ALL-L3 is now classified as Burkitt leukemia/lymphoma type. It constitutes 1–2% of ALL cases.

Biochemical Investigations

- Elevated uric acid and phosphorus levels may be demonstrated due to rapid tumor proliferation in patients with high tumor burden in acute lymphoblastic leukemia (ALL).
- Raised liver enzymes are detected due to infiltration of liver by leukemic cells in 10–20% of patients.
- A minority of patients develop mild cholestatic jaundice due to lymph nodes compression at the portal hepatic or portal tract infiltration by leukemic cells.

Peripheral Blood Smear Examination

White blood cells

- In acute lymphoblastic leukemia (ALL), initial total leukocyte count is markedly elevated ranging between 20×10^9/L and 200×10^9/L with ≥20% lymphoblasts and mean 40–95%. Higher the white blood cell count, there is decreased chance of remission of disease.
- Low white blood cell count is associated with good prognosis. In subleukemic/ aleukemic leukemia, peripheral blood smear demonstrates a few lymphoblasts.
- Reactive hypereosinophilia with pulmonary infiltration and cardiomyopathy is a feature of B cell lineage ALL subtype.
- ALL with t(5;14)(q3;q32), which results in activation of IL-3 gene on chromosome 5 by the enhancer of the Ig gene on chromosome 14.
  - **ALL-L1 (B cell or T cell):** Lymphoblasts are small with high nucleocytoplasmic ratio and containing large nucleus with homogenous chromatin, regular nucleoli, and scanty cytoplasm. Lymphoblasts are positivity for PAS stain. Prognosis is good in these patients. Acute lymphoblastic leukemia L1 (ALL-L1) in Giemsa-stained peripheral blood smear is shown in Figs 9.24 and 9.25.
  - **ALL-L2 (mostly T cell):** Lymphoblasts are of variable size with high nucleocytoplasmic ratio and containing irregular indented nuclei with slightly opened chromatin, prominent nucleoli and mild to moderate cytoplasm. Lymphoblasts are negative for PAS stain. ALL-L2 is associated with poor prognosis. Acute lymphoblastic leukemia L2 (ALL-L2) in Giemsa-stained peripheral blood smear is shown in Fig. 9.26.
  - **ALL-L3 (mature B cell):** Lymphoblasts are of large size containing large nucleus with homogenous chromatin with prominent nuclei and vacuolated basophilic cytoplasm giving bubble-like appearance. ALL-L3 lymphoblasts are like those seen in Burkitt's lymphoma. ALL-L3 lymphoblasts are positive for Sudan black B stain. Acute lymphoblastic leukemia L3 (ALL-L3) in Giemsa-stained peripheral blood smear is shown in Fig. 9.27.

Red blood cells

Peripheral blood smear examination shows normocytic normochromic picture.

Platelets

Platelet count is lower in acute lymphoblastic leukemia (<30,000/μl) than normal range (1,50,000–4,00.000/μl).

Bone Marrow Smear Examination

- Bone marrow is highly cellular with nearly absence of adipocytes. Lymphoblasts range between **≥20%,** which replace or suppress normal hematopoiesis in acute lymphoblastic leukemia in 100% of cases.
- In aleukemic leukemia, lymphocytes are absent in peripheral blood, but bone marrow shows ≥20% lymphoblasts.
- In subleukemic leukemia, a few lymphoblasts are present in peripheral blood and bone marrow shows ≥20% lymphoblasts. Erythroid and megakaryocytic series are suppressed.
- Morphologic features in acute lymphoblastic leukemia are described below:
  - **ALL-L1 (B cell or T cell):** Lymphoblasts are small with high nucleocytoplasmic ratio and containing large nucleus with homogenous chromatin, regular nucleoli, and scanty cytoplasm. Lymphoblasts are positive for PAS stain. Prognosis is good in these patients. Acute lymphoblastic leukemia L1 (ALL-L1) in Giemsa-stained in bone marrow aspirate smear is shown in Fig. 9.28.
  - **ALL-L2 (mostly T cell):** Lymphoblasts are of variable size with high nucleocytoplasmic ratio and containing irregular indented nuclei with slightly opened chromatin, prominent nucleoli and mild to moderate cytoplasm. Lymphoblasts are negative for PAS stain. ALL-L2 is associated with poor prognosis.
  - **ALL-L3 (mature B cell):** Lymphoblasts are of large size containing large nucleus with homogenous chromatin with prominent nuclei and vacuolated basophilic cytoplasm giving bubble-like appearance. These lymphoblasts are like those seen in Burkitt's lymphoma. Lymphoblasts are positive for Sudan black B cytochemical stain. Acute lymphoblastic leukemia L3 (ALL-L3) in Giemsa-stained bone marrow aspirate smear is shown in Fig. 9.29.

Cytochemistry

- Lymphoblasts in ALL-L1 and ALL-L2 subtypes are positivity for PAS stain.
- Whereas lymphoblasts in ALL-L3 subtype are positivity for Sudan black or Oil red O stains.

Bone Marrow Trephine Biopsy Examination

Acute lymphoblastic leukemia L1 (ALL-L1) in hematoxylin and eosin-stained section is shown in Fig. 9.30. Acute lymphoblastic leukemia L3 (ALL-L3) in hematoxylin and eosin-stained section is shown in Fig. 9.31. Bone marrow fibrosis in childhood acute lymphoblastic leukemia in hematoxylin and eosin-stained bone marrow trephine biopsy section is shown in Fig. 9.32. Bone marrow fibrosis in adult acute lymphoblastic leukemia patient in silver-stained bone marrow trephine biopsy is shown in Fig. 9.33.

Immunophenotyping

- B cell lineage ALL markers are CD19, CD20, CD22, CD24, CD79a, PAX5, BOB1, OCT2, PU1, HLA-DR and terminal deoxynucleotidyl transferase (TdT).
- T cell lineage ALL markers are cCD1, CD2, cCD3, CD4, CD5, CD7 and TdT. CD10 positivity is demonstrated in all subgroups except for some B cell lineage ALL.
- CD10 is expressed in childhood B cell ALL (80%) and T cell ALL (20%). ALL with CD10 positivity is amenable to chemotherapy. Thus, CD34 positivity in ALL is associated with better prognosis.
- Flow cytometry or immunohistochemistry can be used to demonstrate terminal deoxynucleotidyl transferase (TdT) in lymphoblasts in ALL.
- TdT was thought to be a lymphoid specific marker. But TdT is also demonstrated on more immature hematopoietic cells, sometimes including those of myeloid lineage.
- Therefore, TdT cannot be the sole determinant of lymphoid lineage.

Markers	Expression
B cell markers in ALL	
CD10	Positive (80%)
CD19	Positive
CD20	Positive
CD22	Positive
CD24	Positive
CD79a	Positive
PAX5	Positive
BOB1	Positive
OCT2	Positive
PU1	Positive
HLA-DR	Positive
TdT	Positive
T cell markers in ALL	
cCD1	Positive
CD2	Positive
cCD3	Positive
CD4	Positive
CD5	Positive
CD7	Positive
TdT	Positive

Acute lymphoblastic leukemia with CD10 positivity is amenable to chemotherapy. Thus, CD10 positivity is a favorable prognostic marker.

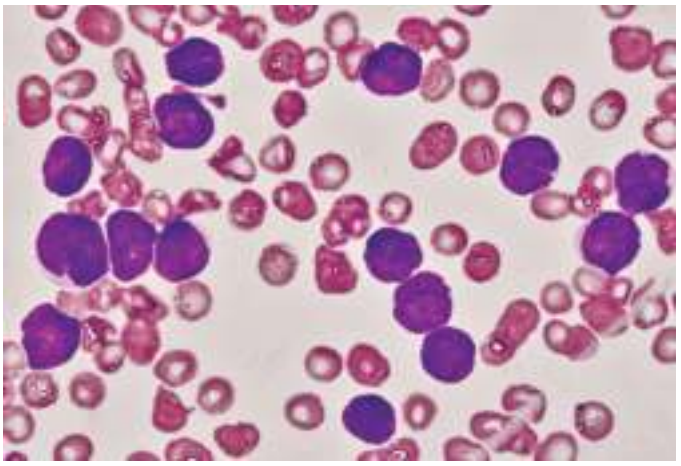

Fig. 9.24: Acute lymphoblastic leukemia L1 (ALL-L1) in Giemsa-stained peripheral blood smear. Peripheral blood smear examination shows small, uniform lymphoblasts with high nucleocytoplasmic ratio, coarse chromatin, inconspicuous nucleoli and scant cytoplasm (1000X).

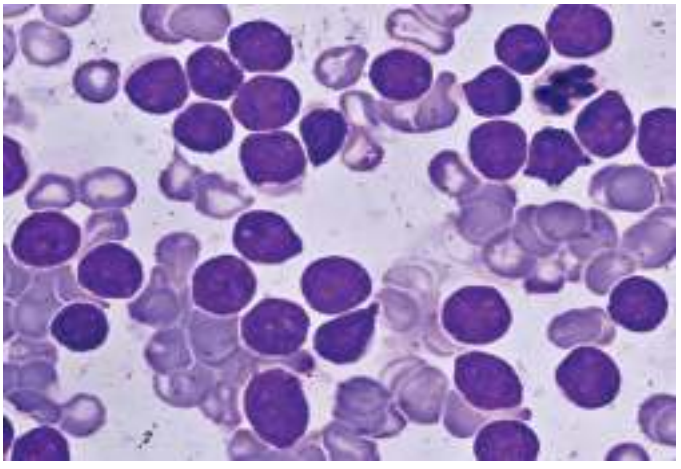

Fig. 9.25: Acute lymphoblastic leukemia L1 (ALL-L1) in Giemsa-stained peripheral blood smear. Peripheral blood smear is showing uniform population of lymphoblasts with high nucleocytoplasmic ratio, coarse chromatin, inconspicuous nucleoli and all of them showing nuclear notching. There is a minimal amount of cytoplasm in lymphoblasts (1000X).

Pathology Pearls: Terminal Deoxynucleotidyl Transferase

- Flow cytometry or immunohistochemistry can be used to demonstrate terminal deoxynucleotidyl transferase (TdT) in cells. TdT was thought to be a lymphoid specific marker.
- However, TdT is also demonstrated in more immature hematopoietic stem cells, sometimes including those of myeloid lineage.
- Therefore, TdT cannot be the sole determinant of lymphoid lineage.

Lymphoblast Morphology in ALL Subtypes

According to French-American-British (FAB) classification, three morphological subtypes of acute lymphoblastic leukemia have been defined: ALL-L1,

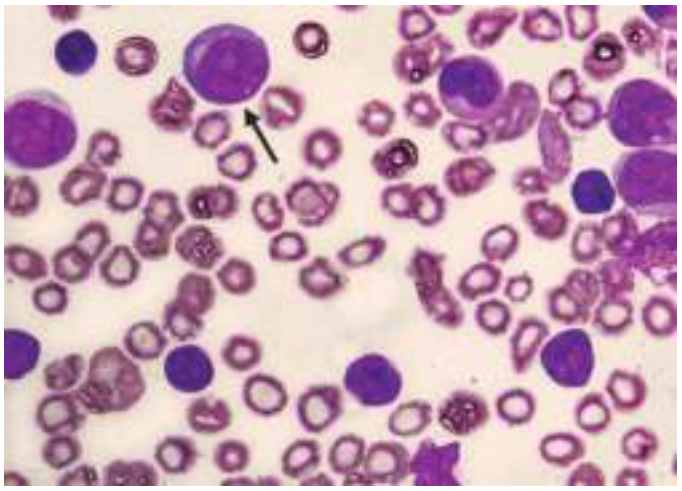

Fig. 9.26: Acute lymphoblastic leukemia L2 (ALL-L2) in Giemsa-stained peripheral blood smear. Peripheral blood smear examination shows variable sized lymphoblasts with high nucleocytoplasmic ratio, slightly opened up chromatin, prominent nucleoli and mild to moderate cytoplasm (arrow) (1000X).

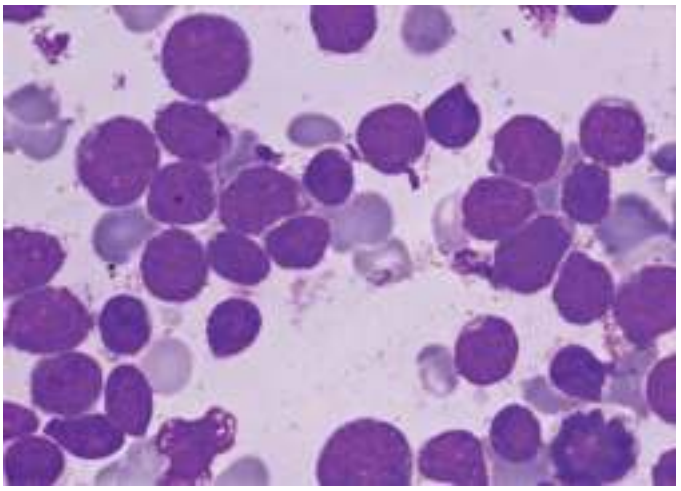

Fig. 9.28: Acute lymphoblastic leukemia L1 (ALL-L1) in Giemsa-stained in bone marrow aspirate smear. Bone marrow aspirate smear is showing ALL-L1 morphology lymphoblasts, with high N:C ratio, coarse chromatin, inconspicuous nucleoli, scant agranular cytoplasm and mild variation in the cell size, completely replacing the hematopoietic elements (1000X).

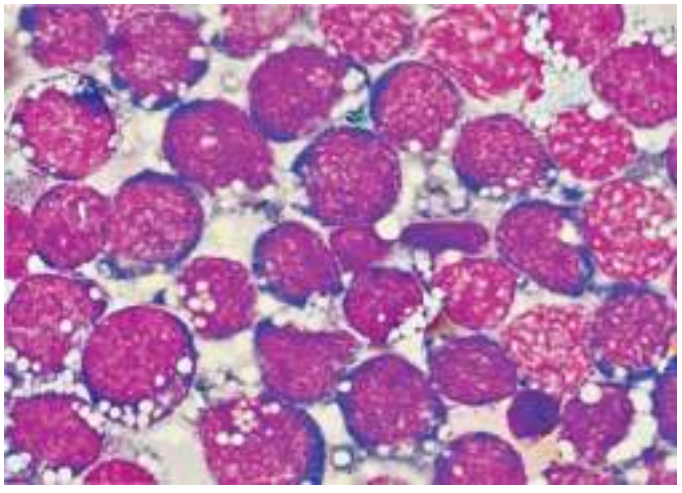

Fig. 9.27: Acute lymphoblastic leukemia L3 (ALL-L3) in Giemsa-stained peripheral blood smear. Peripheral blood smear examination shows large size lymphoblasts with large nucleus with homogenous chromatin with prominent nuclei and vacuolated basophilic cytoplasm giving bubble-like appearance. These lymphoblasts are similar to those seen in Burkitt's lymphoma (1000X).

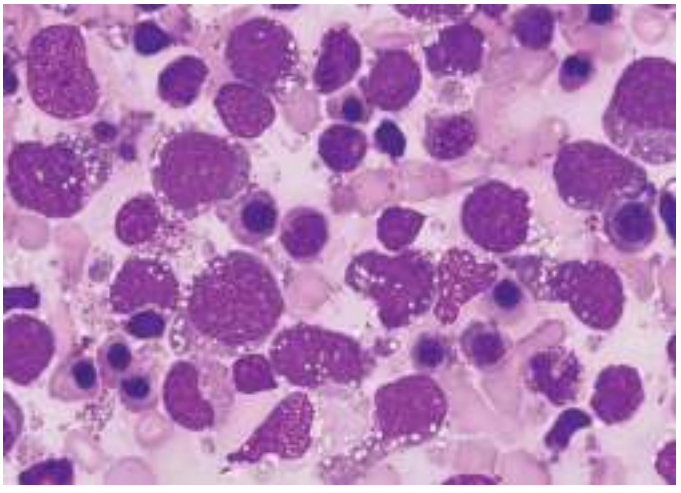

Fig. 9.29: Acute lymphoblastic leukemia L3 (ALL-L3) in Giemsa-stained bone marrow aspirate smear. Bone marrow examination shows large size lymphoblasts with basophilic vacuolated cytoplasm. These lymphoblasts are similar to those seen in Burkitt's lymphoma (1000X).

ALL-L2 and ALL-L3. Distinction between ALL-L1 and ALL-L2 morphology has no clinical significance.

- However, detection of ALL-L3 is of clinical and prognostic relevance. ALL-L3 subtype has been observed in ≤5% of adult patients, which is indicative of mature B cell neoplasm usually termed Burkitt's leukemia with different treatment options. ALL-L3 should be confirmed by demonstration of antigenic cell surface markers.
- Further French-American-British (FAB) classification and revised 2024 WHO classification of ALL/lymphomas categorized into number of subgroups based on morphological features, cytogenetic abnormalities, antigen cell surface markers and rearrangement of the immunoglobulin heavy chain or T cell receptor genes.
- Morphological subtypes of acute lymphoblastic leukemia according to French-American-British (FAB) classification is given in Table 9.28. Revised 2024 WHO classification of ALL/lymphomas is given in Table 9.29.

Immunophenotyping in ALL Subtypes

A series of monoclonal antibodies are employed to demonstrate antigens expressed on the surface of

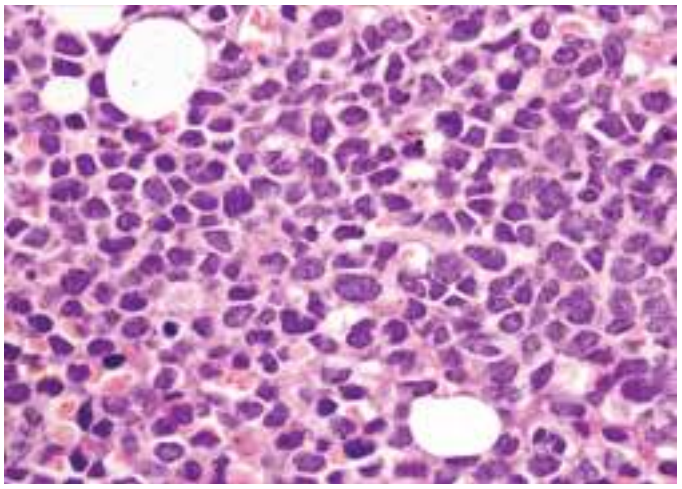

Fig. 9.30: Acute lymphoblastic leukemia L1 (ALL-L1) in hematoxylin and eosin-stained section. Bone marrow trephine biopsy section is showing a hypercellular marrow. The bone marrow is replaced by sheets of lymphoblasts having high N:C ratio, clumped chromatin, no nucleoli and minimal eosinophilic cytoplasm—ALL-L1 morphology (1000X).

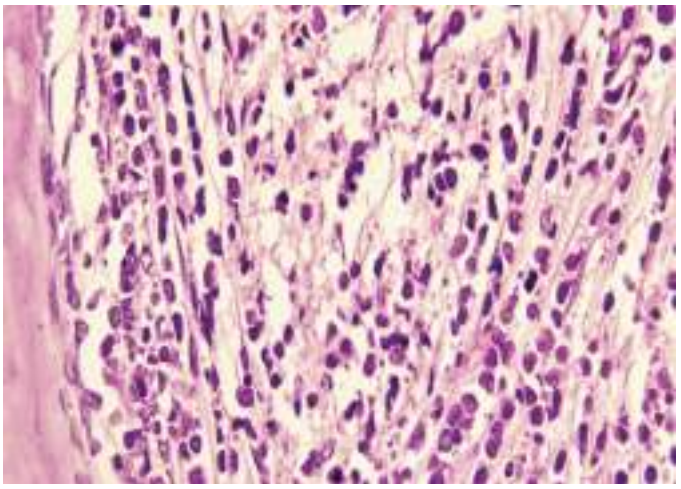

Fig. 9.32: Bone marrow fibrosis in childhood acute lymphoblastic leukemia in hematoxylin and eosin-stained bone marrow trephine biopsy section. It is showing bone marrow fibrosis with streaming of the lymphoblasts and absence of hematopoietic precursors (400X).

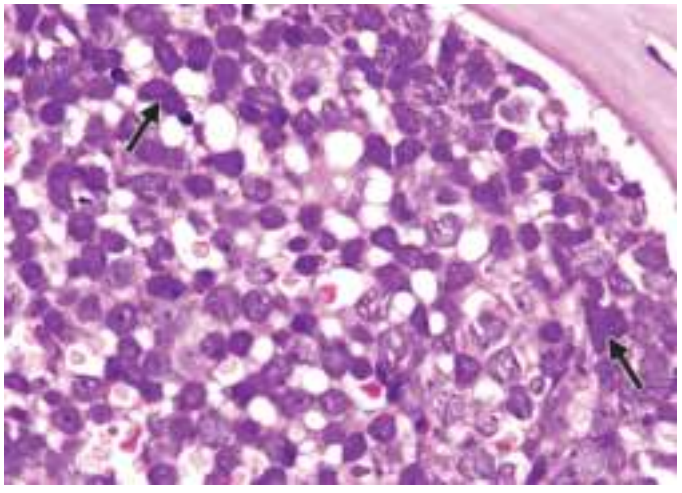

Fig. 9.31: Acute lymphoblastic leukemia L2 (ALL-L2) in hematoxylin and eosin-stained bone marrow trephine section. Bone marrow trephine biopsy section examination is hypercellular marrow, which is showing sheets of lymphoblast with high nucleocytoplasmic ratio and clumped chromatin, eosinophilic cytoplasm with indistinct margins. Some of the blasts are showing prominent nucleoli and occasional mitotic figure (marked by arrow)—ALL-L2 (1000X).

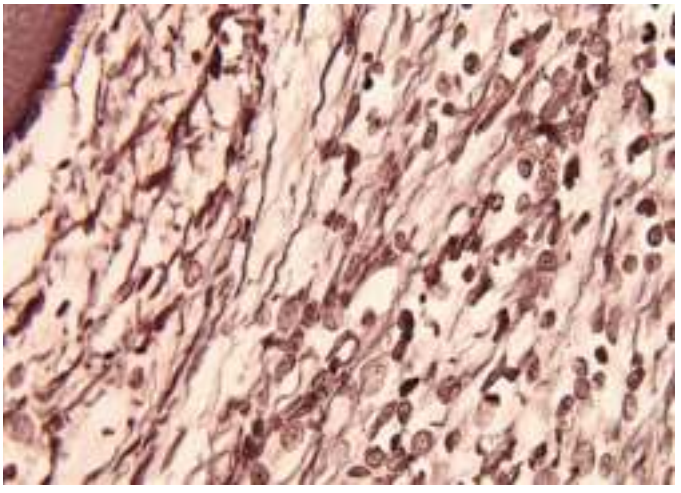

Fig. 9.33: Bone marrow fibrosis in adult acute lymphoblastic leukemia patient in silver-stained bone marrow trephine biopsy. It is showing replacement of bone marrow by dense reticulin fibers with streaming of the lymphoblasts and absence of hematopoietic precursors corresponding to grade 2 marrow fibrosis (400X).

normal lymphoid cells and leukemic lymphoblasts. The basic aim of the immunological classification is to subdivide acute lymphoblastic leukemias according to presence or absence of B cell or T cell markers, or B-phenotypic/hybrid acute leukemia. A marker is positive if ≥20% of leukemic lymphoblasts are stained with monoclonal antibodies.

- Terminal deoxynucleotidyl transferase is a specialized DNA polymerase expressed by immature, pre-B lineage lymphoid cells, pre-T lineage lymphoid cells and acute lymphoblastic leukemia/lymphoma cells in >95% of ALL cases.
- Demonstration of terminal deoxynucleotidyl transferase (TdT) activity suggests that a leukemic lymphoblast is derived from lymphoid lineage rather of myeloid lineage. Comparison of acute lymphoblastic leukemia derived from B cell and T cell lineage is given in Table 9.30.

Table 9.28 Morphological subtypes of acute lymphoblastic leukemia (ALL) according to French-American-British (FAB) classification

Features	ALL-L1	ALL-L2	ALL-L3
Epidemiology and immunophenotype class			
Frequency	70–75%	20–30%	1–2%
Age group	Children	Adults	Adults
Immunophenotype class	B-ALL, T-ALL	Adult T cell ALL	B cell ALL (equivalent to Burkitt's type ALL)
Prognosis	Good prognosis	Worse prognosis	Poor prognosis
Lymphoblast cell morphology			
Cell size	Small size lymphoblasts	Mixture of small and large lymphoblasts (heterogenous population)	Large size lymphoblasts
Nuclear shape	Regular shape with occasional clefting or indentation	Irregular shape with clefting or indentation common	Regular round to oval in shape
Nuclear chromatin	Homogenous chromatin	Heterogenous chromatin	Finely stippled and homogenous
Nucleoli	Nucleoli small or inconspicuous	Nucleoli (≥1) prominent	Nucleoli (≥1) prominent
Amount of cytoplasm	Scanty	Moderate	Moderate to abundant
Cytoplasmic basophilia	Slight or moderate cytoplasmic basophilia	Variable cytoplasmic basophilia	Very deep cytoplasmic basophilia
Cytoplasmic vacuolation	Absent or few cytoplasmic vacuoles	Variable cytoplasmic vacuolation	Prominent cytoplasmic vacuolation
Cytochemistry			
PAS stain	Positive	Negative	Negative
Acid phosphatase stain	Positive/negative	Positive/negative	Positive/negative
Oil red O stain	Negative	Negative	Positive

Table 9.29 Revised 2024 WHO classification of ALL/lymphomas

B Cell or T Cell ALL/Lymphoma	Recurrent Genetic Abnormalities
B cell ALL/lymphoma, not otherwise specified (NOS)	No recurrent genetic abnormalities
B cell ALL/lymphoma with recurrent genetic abnormalities	B cell ALL/lymphoma with recurrent genetic abnormalities ▪ t(9;22) (q34.1;q11.2);BCR-ABL1 ▪ t(v;11q23.3); KMT2 rearranged ▪ t(12;21) (p13.2;q22.1); ETV6-RUNX1 ▪ Hyperploidy >50 chromosomes ▪ Hypoploidy <45 chromosomes ▪ t(5;14) (q31.1;q32.3) IL3-IGH ▪ t(1;19) (q23;p13.3); TCF3-PBX1 ▪ Provisional entity B-ALL/lymphoma with BCR-ABL1-like
T-ALL/lymphoma	Provisional entity early T cell precursor lymphoblastic leukemia/lymphoma
Natural killer cell (NK cell) lymphoblastic leukemia/ lymphoma	Provisional entity natural killer cell lymphoblastic leukemia/lymphoma

Hematology Pearls: Immunophenotyping of Acute Lymphoblastic Leukemia

- Terminal deoxynucleotidyl transferase (TdT) is demonstrated in all subgroups of acute lymphoblastic leukemia (ALL).
- CD10 positivity is demonstrated in all subgroups except some B cell lineage ALL. HLA-DR is demonstrated in all subgroups of ALL.
- Common ALL (frequency 70–75% in children associated with good prognosis) express TdT, HLA-DR and CD10+ (CALLA).
- Pre-B cell-derived ALL (frequency 20% in children associated with poor prognosis) expresses cytoplasmic Ig, but negative for surface Ig and CD10.

B Cell and T Cell Lineage and Biphenotypic Acute Lymphoblastic Leukemias

More than 70% of adults ALLs are derived from B cell, i.e. precursor B cell (80%), and mature B cell in the bone marrow. B cell lineage ALLs demonstrate immunoglobulin gene rearrangement.

- Terminal deoxynucleotidyl transferase (TdT) is a specialized DNA polymerase expressed only by pre-B and pre-T lymphoblasts in >95% of ALL cases.
- Demonstration of TdT activity suggests that a leukemic blast is of lymphoid rather than myeloid lineage.

Table 9.30 Comparison of acute lymphoblastic leukemia (ALL) derived from B cell and T cell lineage

Parameters	B Cell Lineage ALL	T Cell Lineage ALL
Age group	2–10 years	13–17 years
Frequency in Indian population	80%	20%
Tumor load	Low tumor load	High tumor load
Clinical features	Extensive involvement of bone marrow and peripheral blood	Mediastinal lymphadenopathy, splenomegaly, marked leukocytosis
Molecular genetic alterations	▪ t(9;22)(q34;q11.2); BCR-ABL1 (Philadelphia chromosome) ▪ t(v;11q23.3); translocation between MLL (also called KMT2A), i.e. MLL rearrangement ▪ t(12;21)(p13;q22); TEL-AML1 ▪ Hyperploidy >50 chromosomes ▪ Hypoploidy <45 chromosomes ▪ t(5;14) (q31;q32); IL3-IGH ▪ t(1;19)(q23p13.3); E2A-PBX1	– ▪ t(v;11q23.3); translocation between MLL (also called KMT2A), i.e. MLL rearrangement – – ▪ Hypoploidy <45 chromosomes – –
Immunophenotype lineage markers	CD10(CALLA), CD19, CD20, CD22, CD24, CD79a, BOB1, OCT2, PU1, TdT, HLA-DR, monoclonal surface immunoglobulin, TCR gene rearrangement	cCD1, CD2, CD4, CD5, CD7, TdT
Treatment response	Responsive to therapy	Unresponsive to therapy
Prognosis	Good prognosis	Poor prognosis

T-lineage ALL shows TCR gene rearrangement and presents with mediastinal mass.

Common Acute Lymphoblastic Leukemia

Common ALL is characterized by the presence of ALL antigen, a glycoprotein (gp100/CD10). Common ALL lymphoblasts do not express markers of mature B cells such as cytoplasmic immunoglobulins or surface immunoglobulins.

Early Pre-B Cell Lineage Acute Lymphoblastic Leukemia

The lymphoblasts of early pre-B cell lineage ALL resemble B cell precursors in normal bone marrow, which show positivity for CD19, cCD22, CD79a, CD10 (90%), TdT (90%), CD34 (>75%) and CD2 (50%). These cells lack expression of surface and cytoplasmic immunoglobulins.

- ALL with rearrangement of the myeloproliferative leukemia gene (MPL gene) has immunophenotype of early pre-B cell ALL, which expresses CD15, CD65 and chondroitin proteoglycan sulfate, and lack expression of CD10 and CD22.
- Hyperploidy (chromosome number >50) is typically associated with weak or undetectable CD45 expression in ALL cases. It should be noted that myeloproliferative leukemia gene (MPL gene) encodes thrombopoietin receptor protein, which promotes cell growth and cell division of megakaryocytes, which produce platelets involved in blood clotting.

Pro-B Cell Lineage Acute Lymphoblastic Leukemia

Pro-B cell lineage ALL is also termed early B-precursor ALL, which constitutes about 11% of adult ALL. This variant of ALL was formerly termed non-B ALL, non-T ALL or null ALL; as neither of B cell nor T cell features could be demonstrated. The leukemic lymphoblasts express terminal deoxynucleotidyl transferase (TdT) and CD19.

Pre-B Cell Lineage Acute Lymphoblastic Leukemia

Pre-B cell lineage ALL immunophenotype is defined by the accumulation of cytoplasmic immunoglobulin μ heavy chains (cIgM) without detectable surface immunoglobulins (sIgM), that accounts for 25% of cases.

- Expression of both heavy chains cIgM and sIgM without kappa or lambda light chains in pre-B cell ALL is a rare finding, and such cases are designated transitional pre-B cell lineage ALL.
- Pre-B cell lineage ALL expresses CD19, CD22, CD79a, CD10 and TdT. CD34 is expressed in 66% of cases. CD34 is weakly expressed in some cases.

Mature B Cell Lineage Acute Lymphoblastic Leukemia

Mature B cell lineage ALL accounts for 3–4% of childhood ALL patients. The lymphoblasts express surface immunoglobulin μ (mu) heavy chains (sIgM) plus κ or λ light chains, which may express common ALL antigens and occasionally cytoplasmic immunoglobulin.

- Commonly, lymphoblasts have morphology according to the FAB classification. The lymphoblasts

express CD19, CD22, CD20 and CD10. The leukemic cells lack CD34 expression.

- The less common subtype of B cell lineage ALL demonstrates lymphoblasts with ALL-L1 and ALL-L2 morphology and express terminal deoxynucleotidyl transferase (TdT) and/or CD34.
- These patients should be treated as for stage IVB non-Hodgkin lymphoma (Burkitt type), if these cases have rearrangement of the c-Myc gene.
- B cell lineage acute lymphoblastic leukemia (B-ALL) in hematoxylin and eosin-stained bone marrow trephine biopsy section is shown in Fig. 9.34.

T Cell Lineage Acute Lymphoblastic Leukemia

T cell lineage acute lymphoblastic leukemia (T-ALL) usually affects 15% of children and young persons. Incidence is lower in children and higher with advancing age.

- In T cell lineage ALL, lymphoblasts express T cell antigen (gp40, CD7) and cytoplasmic or surface CD3. The leukemic lymphoblasts also express CD2, CD5 and TdT; CD1a, surface CD3, CD4, CD8, CD10 and/or CD21 in 45% of cases. HLA-DR expression is uncommon.
- T-lineage ALL has been divided into three stages of immunophenotypic differentiation: early, mid or common and late stages.
- T cell acute lymphoblastic leukemia (T-ALL) in Giemsa-stained peripheral blood smear is shown in Fig. 9.35. Expression of the immunohistochemical memory marker CD45 RO in cytoplasm of helper T cell lineage lymphoblast population in childhood acute lymphoblastic leukemia in bone marrow trephine biopsy is shown in Fig. 9.36. CD10 positivity in

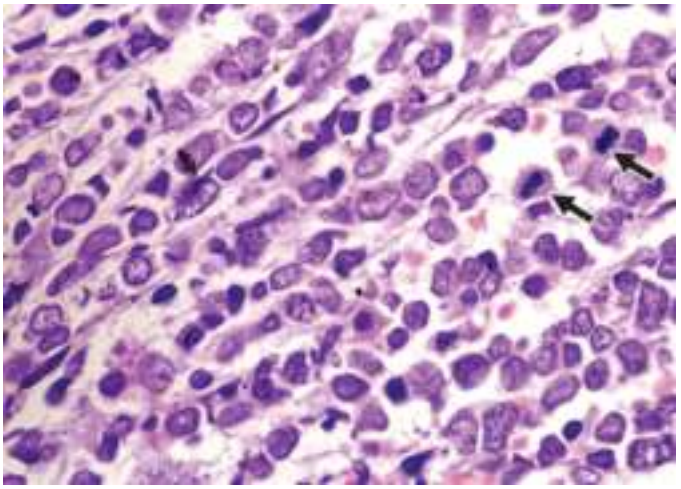

Fig. 9.34: B cell lineage acute lymphoblastic leukemia (B-ALL) in hematoxylin and eosin-stained bone marrow trephine biopsy section. Bone marrow trephine biopsy is showing sheets of blasts, with high mitosis (shown by arrows) and streaming of cells, replacing the hematopoietic elements in a case of B-ALL (1000X).

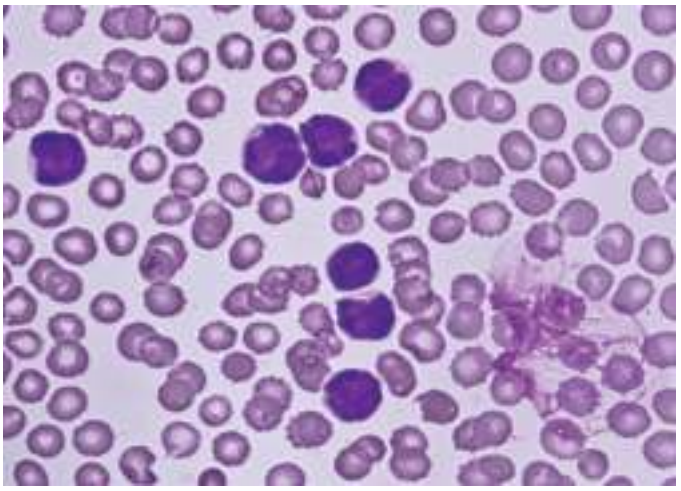

Fig. 9.35: T cell lineage acute lymphoblastic leukemia (T-ALL) in Giemsa-stained peripheral blood smear. T-ALL is a hematological malignancy characterized by the clonal proliferation of immature T cell precursors. In the acute variant, the leukemic cells are medium-sized to large lymphoid cells with irregular nuclei and basophilic cytoplasm. The characteristics of T cell ALL have been described as 'flower cells, with many nuclear convolutions and lobes. It is worth mentioning that T cell ALL in the chronic variant is generally small, with slight nuclear abnormalities such as notching and indentations (1000X).

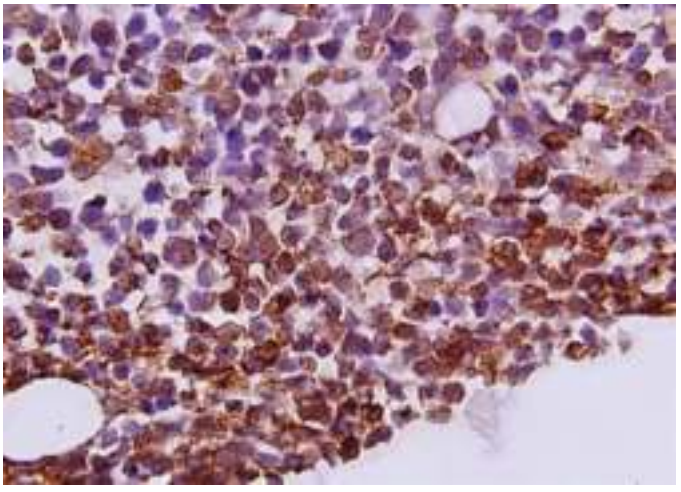

Fig. 9.36: Expression of the immunohistochemical memory marker CD45 RO in cytoplasm of T cell lineage lymphoblast population in childhood acute lymphoblastic leukemia in bone marrow trephine biopsy (400X).

T cell lineage acute lymphoblastic leukemia (T-ALL), also known as common acute lymphoblastic antigen (ALL antigen), is shown in Fig. 9.37. CD10 positive lymphoblasts from acute lymphoblastic leukemia (T-ALL) in bone marrow trephine biopsy section is shown in Fig. 9.38.

Biphenotypic Mixed Lineage Acute Leukemias

Biphenotypic mixed lineage leukemias are defined by the coexpression of markers of lymphoid and myeloid cell lineages on blast cells without typical phenotype

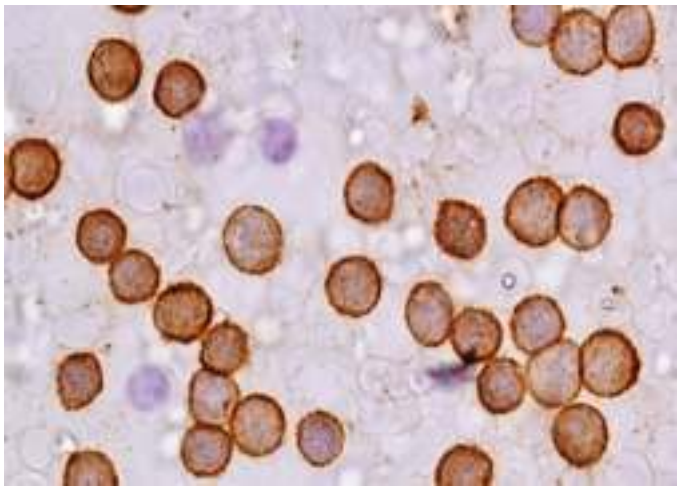

Fig. 9.37: CD10 positivity in T cell acute lymphoblastic leukemia (T-ALL), also known as common acute lymphoblastic antigen (ALL antigen). CD10 is a zinc metallopeptidase expressed in early lymphoid progenitors and normal germinal center cells. CD10 is almost expressed on the surface of precursor B cell lineage acute lymphoblastic leukemia (80%) and Burkitt lymphoma and much less frequently precursor of T cell lineage lymphoblastic leukemia (20%)/lymphoma. Acute lymphoblastic leukemia with CD10 positivity is amenable to chemotherapy. Thus, CD10 positivity is a favorable prognostic marker (1000X).

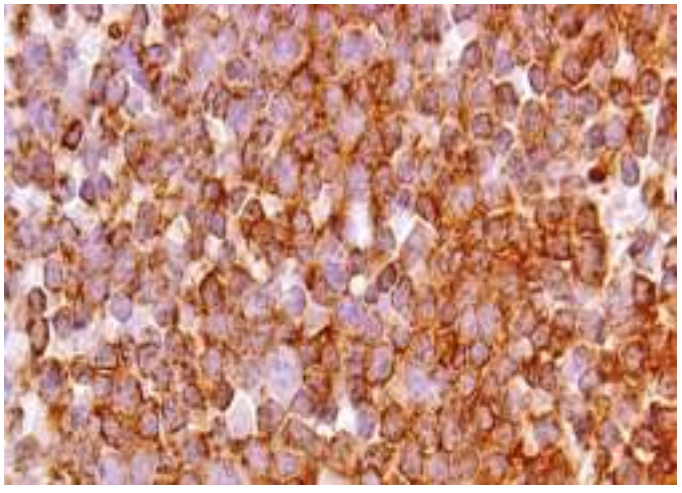

Fig. 9.38: CD10 positive lymphoblasts from acute lymphoblastic leukemia (T-ALL) in bone marrow trephine biopsy section. It shows CD10 positivity in lymphoblasts (400X).

of either acute lymphoblastic leukemia (ALL) or acute myelogenous leukemia (AML).

- Bilineage leukemias are those with two population of blast cells expressing either lymphoid or myeloid antigens.
- Bilineage leukemias should be differentiated from ALL by coexpression of myeloid markers and from AML by coexpression of lymphoid markers.
- Stages of immunophenotypic differentiation of T cell lineage acute lymphoblastic leukemia (ALL) are given in Table 9.31.

Table 9.31 Stages of immunophenotypic differentiation of T cell lineage acute lymphoblastic leukemia (ALL)

Stage of T Cell Lineage ALL	Immunophenotypic Differentiation	Expression
Early stage T cell lineage ALL	▪ CD7 ▪ cCD3 ▪ sCD3 ▪ CD4 ▪ CD8	▪ Positive ▪ Positive ▪ Negative ▪ Negative ▪ Negative
Mid or common stage T cell lineage ALL	▪ cCD3 ▪ CD4 ▪ CD8 ▪ CD1a ▪ sCD3	▪ Positive ▪ Positive ▪ Positive ▪ Positive ▪ Negative
Late stage T cell lineage ALL	▪ sCD3 ▪ CD4 or CD8 ▪ CD1a	▪ Positive ▪ Positive ▪ Negative

cCD3: cytoplasmic CD3; sCD3: surface CD3.

Molecular Genetic Alterations in Acute Lymphoblastic Leukemia

Both acute lymphoblastic leukemias/lymphoblastic lymphomas (ALL/lymphoma) have overlapping clinical presentations.

- Broadly ALL/lymphoma is divided into tumors of B cell and T cell lineage, and rarely NK cell lineage. Immunophenotyping is required to determine the lineage of ALL/lymphoma because different subtypes are morphologically indistinguishable.
- Most cases of ALL/lymphoma have cytogenetic and/or molecular abnormalities that are associated with distinctive phenotypes prognostic features and/or influence the choice of treatment.
- The World Health Organization (WHO) classification system uses immunophenotype and cytogenetic/molecular features to define specific categories of ALL/lymphoma.
- Cytogenetic analysis must be performed in all patients suffering from acute lymphoblastic leukemias. The demonstration of a specific karyotype is performed for the confirmation of the diagnosis.
- Demonstration of chromosomal abnormalities is important independent prognostic variables for disease-free survival or selection of patients to a specific targeted therapy.
- B cell lineage ALL/lymphoma with recurrent genetic abnormalities are given in Table 9.32. Salient features of B cell acute lymphoblastic leukemia/lymphoma with recurrent genetic abnormalities are given in Table 9.33. Cytogenetic alterations in acute lymphoblastic leukemia (ALL) are given in Table 9.34.

Table 9.32 B cell lineage ALL/lymphoma with recurrent genetic abnormalities

▪ A translocation between 9 and 22, i.e. t(9; 22), known as Philadelphia chromosome occurs in 5% in pediatric cases and about 20% of adults in ALL. It is associated with poor prognosis
▪ A translocation between chromosomes 4 and 11 occurs in about 4% of cases in infants under 12 months of age
▪ Cytogenetic abnormality such as hyperdiploidy (>50 chromosomes) is associated with good prognosis
▪ Other cytogenetic abnormalities include t(12; 21), t(4;11), TEL-AML1, t(1;19), 11q23 rearrangements, polyploidy and hypodiploidy. These cytogenetic abnormalities sometimes predict poor prognosis

Prognostic significance of cytogenetic findings in acute lymphoblastic leukemia are given in Table 9.35.

- Acute lymphoblastic leukemia (ALL) is a neoplastic disorder characterized by clonal expansion of leukemic cells in the bone marrow, lymph nodes, spleen or thymus gland. Majority of the ALL—patients harbor acquired somatic mutations that contribute to the unrestricted cell proliferation, prolonged survival and/or impaired differentiation of the lymphoid hematopoietic progenitors. Cytogenetic/molecular genetic alterations in acute lymphoblastic leukemia are discussed below.

Hyperdiploid Acute Lymphoblastic Leukemia

Hyperdiploid acute lymphoblastic leukemia (51–65 chromosomes) is the most common genetic abnormality observed in 35% of children and 10% of adults; and associated with favorable outcome related to sensitivity to methotrexate. Some patients with hyperdiploidy and trisomies of chromosomes 4, 10 and 17 have a favorable prognosis.

Hypodiploid Acute Lymphoblastic Leukemia

Hypodiploid ALL (<45 chromosomes) is demonstrated in less than 2% of ALL and associated with unfavorable prognosis especially for patients with near haploid (<30 chromosomes) or low hypodiploid (30–39 chromosomes) karyotype.

Acute Lymphoblastic Leukemia with BCR-ABL1 Rearrangement

The translocation t(9;22) (q34;q11) encodes a chimeric gene (BCR-ABL fusion gene) consisting of 3′ portion of ABL1 on chromosome 9 joins to the 5′ portion of BCR gene on chromosome 22. In ALL, chromosomal breaks tend to occur in the minor breakpoint cluster regions forming a 190 kDa BCR-ABL fusion gene.

- Genomic analysis of BCR-ABL fusion gene in ALL demonstrates deletions of IKZF1 in 85% of cases. Moreover, deletion of IKZF1 appears to be acquired

Table 9.33 Salient features of B cell acute lymphoblastic leukemia/lymphoma with recurrent genetic abnormalities

Genomic Abnormality	Age Group	Clinical Features	Immunophenotype (Positive Expression)	Aberrant Antigen Expression	Prognosis
t(9;22) (q34;q11.2); BCR-ABL1 (Philadelphia chromosome)	Adults	Organomegaly	CD10, CD19, TdT, CD25	CD13, CD33	Worst prognosis
t(v;11q23.3); translocation between MLL (also called KMT2A), i.e. MLL rearrangement	Infants <1 year	Marked leukocytosis and CNS involvement	CD19, CD15, CD10, neural/glial antigen 2 (NG2), melanoma associated chondroitin sulfate proteoglycans (MCSP)	Not applicable	Poor prognosis
t(12;21)(p13;q22); TEL-AML1	Children	Similar to other ALL features	CD19, CD10, CD34	CD13	Favorable prognosis
Hyperploidy >50	Children	Similar to other ALL features	CD19, CD10, CD34	Not applicable	Favorable prognosis
Hypoploidy <45 chromosomes	Children and adults	Similar to other ALL features	CD19, CD10	Not applicable	Poor prognosis
t(5;14)(q31;q32); IL3-IGH	Children and adults	Asymptomatic eosinophilia	CD19, CD10	Not applicable	Unpredictable prognosis
t(1;19)(q23p13.3); E2A-PBX1	Children	Similar to other ALL features	CD19, CD10, CD9, cytoplasmic μ (cμ) heavy chain	Not applicable	Better prognosis with intensive therapy

In hyperploidy state, each cell contains one or more extrachromosomes. In hypoploidy state, each cell contains one or more fewer chromosomes than normal.

Table 9.34 Cytogenetic alterations in acute lymphoblastic leukemia (ALL)

ALL Type	Cytogenic Findings	Frequency
ALL-B cell type	▪ t(2;8) ▪ t(8;22)	>90%
ALL pre-B cell (cytoplasmic Ig of mu, heavy chain)	▪ t(1;19) (q23;p13) ▪ t(9;22) in adults	25%
ALL-T cell	▪ t(14q11)	25%
Mixed lineage ALL	▪ t(11p23) ▪ t(14q32) ▪ t(9;22) (q34;q11)	Unknown

Table 9.35 Prognostic significance of cytogenetic findings in acute lymphoblastic leukemia

Cytogenetic Abnormalities	Prognosis
Hypodiploidy in 100% of chromosomes	Unfavorable prognosis
Hyperdiploidy in >50% of chromosomes	Favorable prognosis
Hyperdiploidy in 47–50% of chromosomes	Intermediate prognosis

lesion at the time of transformation from chronic myelogenous leukemia to lymphoid blast phase.

- BCR-ABL1 ALL is refractory to standard chemotherapy. These patients respond to first generation receptor tyrosine kinase inhibitor (RTKI) such as imatinib as well as second and third generation RTKIs such as nilotinib, dasatinib and bosutinib.

Acute Lymphoblastic Leukemia with ETV6-RUNX1 Rearrangements

The chromosomal translocation, t(12;21) (p13; q22) is the most prevalent translocation in pediatric ALL resulting in ETV6-RUNX1 chimeric fusion gene (formerly TEL-AML1). Children with ETV6-RUNX1 chimeric fusion protein have excellent prognosis with very low rates of relapses related to optimal asparaginase therapy.

Acute Lymphoblastic Leukemia with E2A-PBX1 Fusion Gene

About 20–25% of pre-B cell ALL cases demonstrate t(1;19) (q23;p13) chromosomal translocation abnormality that juxtaposes the E2A (TCF3 transcriptional factor 3) gene on chromosome 19 and the PBX1 gene on chromosome 1 resulting in E2A-PBX1 fusion transcription protein.

- Another fusion gene is created by t(17;19) (q22;p13) chromosomal translocation in which E2A is fused to the gene that encodes the transcription factor, i.e. hepatic leukemic factor (HLF).
- Chromosomal translocation t(1;19) (q23;p13) is demonstrated by conventional cytogenetics, fluorescence *in situ* hybridization (FISH) or reverse transcriptase polymerase chain reaction (RT-PCR).
- Patients usually presents with hypercalcemia and coagulopathy associated with poor prognosis.
- Acute lymphoblastic leukemia demonstrates MLL gene rearrangements. Structural cytogenetic alterations involving band 11q23 of chromosome 11 are frequently demonstrated in ALL affecting infants and children. The targeted therapy is administered in mixed-lineage leukemia (MLL) gene.
  - Chromosomal translocation t(4;11) (q21;q23) involving band 11q23 in ALL produces a chimeric protein that contains the N-terminal portion of MLL linked to the C-terminal portion of AFF1 (AF4/FMR2 family member) and other more than 50 genes.
  - MLL gene encodes DNA binding protein that regulates the expression of numerous genes including multiple HOX genes. Protein produced by normal MLL gene regulates hematopoiesis. In contrast MLL fusion protein transforms hematopoietic stem cells into leukemia-initiating cells. Prognosis of ALL in infants is poor.

Acute Lymphoblastic Leukemia with iAMP21 Alterations

Intrachromosomal amplification of a region of chromosome 21 (iAMP21); three or more extra copies of RUNX1 on an abnormal chromosome 21 is recently identified recurrent genomic abnormality associated with poor outcome in children with ALL. The patients have a common/pre-B cell immunophenotype of ALL.

BCR-ABL1-like Acute Lymphoblastic Leukemia

Out of B-lineage ALL, 10–20% of cases demonstrate a gene expression profile like that of BCR-ABL1; but lacks BCR-ABL1 rearrangement. The frequency of BCR-ABL1 like ALL is 10% in children and 25–30% in young adults.

- BCR-ABL1 like ALL cases usually demonstrate IKZF1 alteration, overexpression of CLRF2, and tyrosine kinase activating rearrangements involving ABL1, JAK2, PDGFRB and several others. These ALL patients are associated with worse outcome.
- About 50% of BCR-ABL1 like ALL cases demonstrate CRLF2 rearrangements and JAK2 mutations. Next-generation sequencing such as transcriptome and whole-genome sequencing has demonstrated that the remaining cases harbor a diverse range of rearrangements, deletions and sequence mutations that activate cytokine receptor and RTK signaling involving ABL1, JAK2, IL7R and PDGFR.
- BCR-ABL1 like ALL patients are treated by targeted therapy directed at the underlying genetic pattern with BCR-ABL inhibitors (e.g. dasatinib) or JAK2 inhibitors (e.g. ruxolitinib).

B Cell Lineage Acute Lymphoblastic Leukemia with CRLF2 Rearrangement and JAK2 Kinase Alterations

Approximately 8% of B-lineage ALL cases harbor a genomic rearrangement of CRLF2: a translocation of the immunoglobulin heavy chain gene on 14q32 to CRLF2 in the pseudoautosomal region 1 of Xp22.3/Yp11.3.

- CRLF2 encodes cytokine-like factor 2, the receptor for thymic stromal lymphopoietin (TSLP). CRLF2 rearrangement is commonly seen in ALL associated with Down syndrome.
- Approximately 50% of cases with CRLF2 rearrangement harbor concomitant activating mutations in Janus kinase genes JAK1 or JAK2 and associated with poor prognosis.

T Cell Lineage Acute Lymphoblastic Leukemia with Genetic Abnormalities

Cytogenetic alterations in T cell acute lymphoblastic leukemia include SCL (TAL1), LMO1 (TTG1), LMO2 (TTG2) and HOX11. An additional genetic alterations demonstrated in T cell lineage ALL is the deletion from chromosome 9p21 of the CDKN2A and CDKN2B genes, which encode $p16^{INK4a}$ and $p16^{INK4b}$ including cyclin-dependent kinase inhibitors. NOTCH1 mutation has been implicated in the pathogenesis of T cell lineage ALL.

Early T-Precursor Acute Lymphoblastic Leukemia

Early T-precursor ALL (ETP-ALL) is a recently described subtype of aggressive acute lymphoblastic leukemia of unknown genetic basis, which originates from early T cell precursors (ETPs), the subset of thymocytes that retain stem cell-like features. Early T-precursor ALL lacks CD1 and CD8 expression, and weak CD5 expression. Patients respond poorly to lymphoid cell-directed therapy.

- Genetic sequencing of ETP-ALL analysis reveals somatic mutations in genes regulating cytokine receptor and RAS signaling (K-RAS, N-RAS, FLT3, IL7R, JK3, JK1, SH2B3 and BRAF), inactivating lesions disrupting hematopoietic development (GATA3, ETV6, RUNX1, IKZF1 and EP300); and recurrent mutations of DNM2, ECT21 and RELN.
- Mutational spectrum of these cases is similar to myeloid tumors. These findings suggest that addition of myeloid-directed therapies might improve the poor outcome of ETP-ALL.

Hematology Pearls: Diagnostic Cytogenetic/Molecular Techniques for Acute Lymphoblastic Leukemia

- The diagnostic techniques for acute lymphoblastic leukemia (ALL) include standard cytogenetics, fluorescence *in situ* hybridization (FISH), and reverse transcriptase polymerase chain reaction (RT-PCR). These techniques allow the detection of Philadelphia chromosome positive acute lymphoblastic leukemia, with the chromosomal translocation t(9;22)(q34;q11) and demonstration of the corresponding BCR-ABL1 gene rearrangement.
- Further ALL entities that have been detected include t(5;14)(q31;q32)/IL3-IGH, t(1;19)(q23p13.3)/PBX-E2A, t(12;21)(p13;q22); TEL-AML1, t(4;11)(q21;q23)/MLL-AFA4, abnormalities 11q23/MLL, hyperploidy and hypoploidy.
- Gene expression profiling, single nucleotide polymorphism array analysis, array-comparative genomic hybridization. Next generation sequencing recognizes newly defined ALL entities with fatal outcome: Philadelphia chromosome like ALL and early T-precursor ALL.

PROGNOSIS

Age of the patient is a strong prognostic determinant in ALL. Prognosis is good in children and poor in infants and children. A higher initial total leukocyte count and presence of central nervous system involvement by leukemic cells also determine high-risk disease.

- Early response to post-induction therapy is measured by persistence or absence of minimal residual disease (MRD). Recently, genomic analysis has revealed molecular alterations and profiles have been associated favorable or unfavorable prognosis.
- Common B cell precursor subset of ALL cases expressing CD10, hyperdiploidy, and t(12;21)/TEL-AML1 rearrangement have been associated with good prognosis. The t(12;21)/TEL-AML1 generates TEL-AML1 (ETV6-RUNX1) fusion gene. Patient has poor prognosis showing chromosomal t(9; 22), t(1;19), 11q23 rearrangements and hypodiploidy. Prognostic factors in acute lymphoblastic leukemia (ALL) are given in Table 9.36.

TREATMENT

Approximately >90% cases of ALL achieve complete remission with treatment. Relapse is common in 75% of cases without prophylactic intrathecal chemotherapy. ALL in adults has worse prognosis and requires bone marrow transplantation as well as chemotherapy.

- Most infants under one year at diagnosis harbor rearrangements in the KMTT2A (formerly MLL) gene have a poor prognosis. These infants should be treated on age and weight specific protocols with certain agents to reduce the risk of severe toxicity.
- T-ALL patients are treated and are benefited by administration of high-dose methotrexate, dexamethasone and asparaginase.
- Philadelphia chromosome positive ALL patients are treated by receptor tyrosine kinase inhibitor. Patients with CNS involvement require CNS sterilization by administration of intrathecal chemotherapy

Table 9.36 Prognostic factors for acute lymphoblastic leukemia (ALL)

Features	Favorable Prognosis in ALL Patients	Unfavorable Prognosis in ALL Patients
Age group	2–10 years	<1 year or >10 years
Gender predilection	Girls	Boys
Racial predilection	White population	Black population
FAB classification	ALL-L1 subtype	ALL-L2, ALL-L3 subtypes
ALL derived from cell type	▪ ALL (early pre-B cell) ▪ Common acute lymphoblastic leukemia antigen (common ALL antigen)	▪ ALL (pre-B cell) ▪ ALL (B cell) ▪ ALL (pre-T cell)
Extramedullary involvement (testes and central nervous system)	Testis and CNS not involved	Testis and CNS involved
Total white blood cell count	Low white blood cell count (<30,000/ml)	High white blood cell count (>50,000/ml)
Hemoglobin	>10 g/dl	<7 g/dl
Platelet count	>100,000/ml	30,000/ml
Molecular genetics	▪ Hyperploidy involving >50% chromosomes (favorable) ▪ t(12;21) (p13;q22); TEL-AML1 ▪ t(1;19) (q23p13.3); E2A-PBX1	▪ Hypoploidy involving 100% chromosomes ▪ t(9;22) (q34;q11.2); BCR-ABL1 (Philadelphia chromosome) ▪ 11p23 ▪ t(14q;11) ▪ t(8;14) ▪ t(1;19) ▪ 11q23 rearrangement
Immunophenotype	CD10+ (amenable to therapy)	CD10 negative (not amenable to therapy)
Response to therapy	Rapid early responder	Slow early responder
Time to clear lymphoblasts from peripheral blood	<1 week	>1 week
Time of remission	<4 weeks	>4 weeks
Post-induction minimal residual disease (MRD)	Minimal residual disease negative after one month therapy in children and 3 months therapy in adults	Minimal residual disease persisting for 3–6 months after therapy

Hyperploidy involving 47–50% of chromosomes has intermediate prognosis. Translocation (9;22) in ALL is cytogenetically identical but distinct from demonstrated in CML/minor breakpoint region is more commonly involved in ALL. But in CML, major breakpoint region is typically involved in childhood ALL, a BCR/ABL fusion protein P190 is produced.

in combination with systemic chemotherapeutic agents such as dexamethasone and high-dose methotrexate.

- Radiation is most often reserved for those ALL cases with meningeal leukemia or CNS relapse. Testicular involvement resolves completely during the induction phase of therapy.
- Administration of molecular targeted agents has improved outcome in ALL patients. BCR-ABL receptor tyrosine kinase inhibitors (RTKIs) such as imatinib mesylate (Gleevec), dasatinib, and nilotinib have been successfully utilized in combination with chemotherapy to improve the survival in Philadelphia chromosome positive ALL patients.
- Monoclonal antibody-based therapies that target differentiation antigens expressed on the surface of lymphoblasts (e.g. CD19, CD20, CD22, CD52) have also been used in the setting of ALL. Rituximab combined with conventional chemotherapy has improved survival in adults with CD20 positive Philadelphia chromosome negative ALL.
- For adult patients with relapsed ALL, allogeneic stem cell transplantation with HLA-matched sibling donor has improved the survival of ALL patients.

MINIMAL RESIDUAL DISEASE

Minimal residual disease (MRD) is the detection of residual leukemic cells, not recognizable by light microscopy. Bone marrow of ALL patients in morphologic complete remission may contain up to 1010 residual leukemic cells.

- Molecular quantitation of MRD of ALL is analyzed by using real-time polymerase chain reaction (RT-PCR).
- Methods are based on the demonstration of leukemia-specific aberrant immunophenotypes by flow cytometry, analysis of leukemia-specific rearranged immunoglobulin or T cell receptor sequences by real-time quantitative polymerase chain reaction (RT-PCR), or the detection of fusion genes associated with chromosomal abnormalities (e.g. BCR-ABL, MLL-AF4).

ACUTE MYELOGENOUS LEUKEMIA

ACUTE MYELOGENOUS LEUKEMIA: OVERVIEW

Acute myelogenous leukemia (AML) is a hematopoietic stem cell (HSC) disorder characterized by unrestricted proliferation of myeloblasts in the bone marrow. It may originate from any of the cells that fall within the downward pathways.

- Importantly, AML cell of origin acquires capacity for self-renewal and maturation arrest, which results in accumulation of immature nonfunctional leukocytes in the bone marrow and blood circulation.
- Failure of normal production of red blood cells, leukocytes and platelets results in anemia, recurrent infections and thrombocytopenia.
- AML accounts for 15–20% in children and adolescents; and 85% in adults. The incidence of AML rises rapidly after the age of 60 years and the median age at diagnosis is 67 years.
- Clinical course of acute myelogenous leukemia (AML) is short and marked by anemia, neutropenia, recurrent respiratory tract infection, fever, and hemorrhage, and death occurs within 6–12 months. These patients are less responsive to therapeutic intervention.

PATHOGENESIS

Inherited genetic predisposition, environmental mutagens such as radiation, drugs (e.g. alkylating agents, topoisomerase II inhibitors:), tobacco smoke and benzene; preexisting hematological disorders; and acquired somatic mutations associated with aging process play a role in the development of AML.

- Genetic causes are suggested by the increased incidence of AML in identical twins as well as known association of AML with various congenital disorders.
- Genetic predisposition plays important role in the development of AML in children and young adults. Risk factors for development of acute myelogenous leukemia are given in Table 9.37.

CLINICAL FEATURES

Patients usually present with bone marrow failure that causes anemia, bleeding manifestations from

Table 9.37 Risk factors for development of acute myelogenous leukemia (AML)

Categories	Etiology and Disorders
Environmental factors	Benzene, ioniting radiation, tobacco smoking
Genetic disorders	Down syndrome, Bloom syndrome, Fanconi syndrome, dyskeratosis congenita, ataxia-telangiectasia, Li-Fraumeni syndrome, Kostmann syndrome, Klinefelter syndrome, osteogenesis imperfecta, Wiskott-Aldrich syndrome, leukemia in siblings, Diamond-Blackfan syndrome
Pre-existing hematological disorders	Myelodysplastic syndrome (MDS), myeloproliferative disorders, familial aplastic anemia, paroxysmal nocturnal hemoglobinuria (PNH)
Treatment-induced acute myelogenous leukemia (AML)	▪ **Alkylating agents (chlorambucil, melphalan):** Acute myelogenous leukemia (AML) usually arises from myelodysplastic syndrome (**MDS**), after 3–10-year latency period and is associated with deletions involving chromosomes 5 or 7 ▪ **Topoisomerase II inhibitors:** Acute myelogenous leukemia (AML) arises without preceding myelodysplastic syndrome. AML involves chromosome 11q23, chromosome 11q23, exhibits monocytic morphology ▪ **Radiotherapy alone or in combination chemotherapy:** Patients may develop acute myelogenous leukemia (AML)

thrombocytopenia and neutropenic recurrent infections of upper respiratory tract.

- Tissue infiltration with leukemic blasts involving gums, meninges, skin, liver, spleen, lymph nodes are most often associated with monocytic morphology.
- Striking bruising and life-threatening hemorrhage raise suspicion of disseminated intravascular coagulation (DIC) frequently seen in acute promyelocytic leukemia (AML-M3).
- Leukostasis and hyperviscosity syndrome cause organ dysfunction with blast cell counts and symptoms of decreased tissue perfusion.

Bone Marrow Failure

Symptoms and signs on presentation due to bone marrow failure include fatigue, breathlessness, fever, focal bacterial infections, petechiae, bruising and bleeding. Severe bleeding suspects acute promyelocytic leukemia (AML-M3).

Leukemic Blasts Infiltration in Multiple Organs

Leukemic blasts in patients with AML-M4 or AML- M5 or AML-M7 can infiltrate into gums, liver, spleen, lymph nodes, skin (diffuse erythematous skin rashes) and central nervous system (meninges, Vth and VIIth cranial nerves) and visual changes such as retinal involvement, intracranial hemorrhage, and papilledema. AML-M4, AML-M5 and AML-M7 result in pancytopenia and bone marrow fibrosis.

Leukostasis and Hyperviscosity Syndrome

Leukostasis and hyperviscosity syndrome cause organ dysfunction in AML cases with high blast cell counts more than 1,00,000 µl.

- Leukostasis is more common in acute myelogenous leukemia than in acute lymphoblastic leukemia, because the blast cells of AML have a larger cell volume than blast cells in ALL. Leukostasis is a medical emergency in patients with AML and in the CML blast phase in which blast cells are accumulated in small blood vessels.
- Skin rash with neutrophilic infiltrates in dermis and chloromas are rare findings in AML.
- Extramedullary AML disease pretends a poor prognosis.
- Bone marrow failure usually occurs in AML. Intracranial hemorrhage often associated with hyperviscosity is studied by CT scan. MRI demonstrates thickened nerve sheaths. Lung infiltrates are demonstrated by CT scan.

Chloroma

Chloroma is a rare malignant tumor solid mass formation in acute myelogenous leukemia composed of granulocyte precursor cells such as myeloblasts, promyelocytes and myelocytes. Children seem to more affected than adults. In many cases, chloroma does not cause major symptoms.

- About 50% of chloroma cases are diagnosed only during autopsy. The symptoms are caused by tumor mass itself located into the tissue/organ.
- Chloroma in the central nervous system is associated with symptoms such as cauda equina syndrome or radiculopathy.

Sweet Syndrome

Sweet syndrome, also called acute febrile dermatosis, is a rare finding in acute myelogenous leukemia, that typically presents with acute-onset tender plaques or nodules, fever, arthralgia, ophthalmic manifestations and headache. Diagnosis is established on clinical manifestations and histologic examination of plaque.

Hematology Pearls: French-American-British (FAB) and Revised 2024 WHO Classification of Acute Myelogenous Leukemia (AML)

- The classification of AML has evolved from the morphology-based French-American-British (FAB) to the more comprehensive revised 2024 WHO classification. AML has been categorized into eight subtypes (AML-M0–AML-M7) according to FAB classification based on morphology, cytochemical staining, and immunophenotype of the predominant cells.
- Revised 2024 WHO classification of acute myelogenous leukemia and acute lymphoblastic leukemia and their features is given in Table 9.38. Revised 2024 WHO classification of acute myelogenous leukemias is given in Table 9.39.
- Revised 2024 WHO classification of acute leukemias integrates new clinical, prognostic, morphologic, immunophenotyping and genetic data. Latest 2024 WHO classification also includes myeloid neoplasms with germline predisposition. Family history is essential to establish diagnosis of AML.
- According to revised 2024 WHO classification of acute leukemias (myelogenous/ lymphoblastic leukemia), diagnostic criterion is the presence of ≥20% lymphoblast cells as the cut off percentage in bone marrow and peripheral blood.
- According to French-American-British (FAB) classification of acute leukemias (myelogenous/lymphoblastic leukemia), original diagnostic criterion was the presence of ≥30% lymphoblast cells as the cut off percentage in bone marrow and peripheral blood.
- AML group with recurrent genetic abnormalities has prognostic significance. Most common ones such as t(8;21) and t(16;10) are considered acute myelogenous leukemia even if blast cell count in the bone marrow is ≤20%.

LABORATORY DIAGNOSIS

The most common laboratory findings in acute myelogenous leukemia are anemia, neutropenia and thrombocytopenia and myeloblasts in the bone marrow and peripheral blood.

Table 9.38 Revised 2024 WHO classification of acute myelogenous leukemia and acute lymphoblastic leukemia and their features

Leukemia Subtype	Description
Acute myelogenous leukemias	
AML-M0	▪ AML-M0 with minimally differentiation expressing myeloid lineage accounts for 2–3% ▪ Myeloperoxidase stain is positive in <3% of cases ▪ Two or more myeloid markers by flow cytometry: CD34+, HLA-DR+, CD33+/–; CD13+/– ▪ Frequent complex cytogenetic abnormalities such as 11q13 are present ▪ AML-M0 is associated with poor prognosis
AML-M1	▪ AML-M1 without maturation: less than 10% promyelocytes or more mature myeloid cells ▪ AML-M1 accounts for 20% of leukemias ▪ Myeloblast contains faint granules, distinct nucleoli and occasional Auer rod ▪ Myeloperoxidase stain positive (>3%) ▪ Two or more myeloid markers by flow cytometry: CD34+, HLA-DR +, CD33+/–; CD13+/– ▪ Frequent complex cytogenetic abnormalities: –6, –7, –17, del 3p, +21, +8 ▪ Prognosis is favorable
AML-M2	▪ AML with maturation and differentiation into neutrophilic lineage ▪ Myeloblast contains faint granules, distinct nucleoli and occasional Auer rods ▪ AML-M2 accounts for 30–40% of leukemias ▪ Myeloperoxidase stain positive (>10%) ▪ Subset of patients demonstrate cytogenetic abnormality: t(8;21) ▪ Two or more myeloid markers by flow cytometry: CD34–, HLA-DR+, CD33+, CD13+ ▪ AML-M2 is associated with favorable prognosis
AML-M3	▪ In AML-M3, AML with promyelocytic differentiation (APL), promyelocytes show heavy granulation and bilobed folded (cottage-loaf) nuclei (commonly associated with disseminated intravascular coagulation (DIC) due to release of thromboplastin like substance); rarely microgranular variant with inconspicuous granules in majority of cases ▪ AML-M3 accounts for 5–10% of leukemias ▪ Myeloperoxidase stain is positive ▪ Two myeloid markers by flow cytometry include: CD33+, CD13+, CD34–, HLA-DR– ▪ Most cases have t(15–17) chromosomal translocation associated with favorable prognosis ▪ Bruising and life-threatening hemorrhage raises suspicion of disseminated intravascular coagulation (DIC) associated with overall good prognosis ▪ AML-M3 is treated by targeted therapy directed against the leukemogenic event, t(15.17) PML-RARA fusion transcript, lead to improved outcome ▪ Acute promyelocytic leukemia now represents most curable leukemia treated by administration of nontoxic cytotoxic chemotherapeutic drugs such as all-*trans* retinoic acid (ATRA) and arsenic trioxide (ATO)
AML-M4	▪ AML-M4 (acute myelomonocytic leukemia—AMML) shows myelocytic and monocytic differentiation (>20% monocytoid cells involving gums, skin or central nervous system) ▪ AML-M4 accounts for 15–20% of leukemias ▪ Myeloperoxidase stain is positive in leukemic cells ▪ Nonspecific esterase stain is positive ▪ Complex cytogenetic abnormalities: inv(16), t(16;16), –5, –7, t(6;9) ▪ Two or more myeloid markers by flow cytometry: CD34–, HLA-DR+, CD33+, CD13+, CD14/CD64+ ▪ AML-M4E0 variant contains >5% abnormal eosinophils; associated with the inv(16) cytogenetic abnormality associated with favorable prognosis
AML-M5A	▪ AML-M5A (acute monoblastic/monocytic leukemia—AMoL) shows monoblasts without differentiation, extramedullary disease involving gums, skin, lymph node and central nervous system ▪ AML-M5A accounts for 5% of leukemias ▪ Nonspecific esterase (NSE) stain is positive ▪ AML-M5A is associated with extramedullary disease, abnormalities of chromosome 11q23 and poor prognosis
AML-M5B	▪ AML-M5B (acute monoblastic/monocytic leukemia—AMoL) shows more than 80% monoblasts with differentiated monocytes, or promonocytes ▪ AML-M5B accounts for 5% of leukemias ▪ Nonspecific esterase (NSE) stain is positive

Contd...

Table 9.38 Revised 2024 WHO classification of acute myelogenous leukemia and acute lymphoblastic leukemia and their features (*Contd...*)

Leukemia Subtype	Description
AML-M6A	▪ In AML-M6A (acute erythroid leukemia), bone marrow shows dysplastic nucleated erythroblasts (>50%) and myeloblasts (>20%) ▪ Erythroblasts are strongly positive for periodic acid–Schiff (PAS) stain and glycophorin. PAS highlights the abundant glycogen in the tumor cells, the staining will disappear after diastase treatment ▪ Complex cytogenetic abnormalities include: –5q, –7, –3, +8 ▪ AML-M6A is associated with poor prognosis
AML-M6B	▪ In AML-M6B (acute erythroid leukemia is known as pure erythroid leukemia), bone marrow shows dysplastic erythroblasts (>80%) ▪ Erythroblasts are strongly positive for periodic acid–Schiff (PAS) positive and glycophorin ▪ Complex cytogenetic abnormalities include: –5q, –7, –3, +8 ▪ AML-M6B is associated with poor prognosis
AML-M7	▪ In AML-M7 (acute megakaryoblastic leukemia), bone marrow shows micromegakaryoblasts (common in Down syndrome and myelofibrosis) ▪ AML-M7 accounts for <1% of leukemias ▪ Complex cytogenetic abnormalities: +8, +21, inv or del 3p are present ▪ Platelet peroxidase is positive ▪ Diagnosis is confirmed by immunophenotyping (CD41, CD61, platelet peroxidase) or electron microscopy ▪ AML-M7 is associated with poor prognosis
Acute lymphoblastic leukemias	
ALL-L1	▪ In ALL-L1, lymphoblasts are uniform, homogenous with scant cytoplasm with regular nuclei and inconspicuous nucleoli ▪ ALL-L1 accounts for >80% of leukemias ▪ Children are affected associated with good prognosis
ALL-L2	▪ In ALL-L2, lymphoblasts are large, heterogenous with round to oval nuclei showing indentation or clefts with prominent nucleoli ▪ ALL-L2 accounts for 10–50% of leukemias ▪ Adults are affected associated with poor prognosis
ALL-L3	▪ In ALL-L3, lymphoblasts are large homogenous with round to oval nuclei, finely stippled chromatin, prominent nucleoli and abundant basophilic vacuolated cytoplasm ▪ ALL-L3 accounts of 3–4% of leukemias ▪ Adults are affected associated with poor prognosis

CD: Cluster of differentiation.

- According to revised 2024 WHO classification of acute myelogenous leukemia and acute lymphoblastic leukemia, diagnostic criteria are the presence of ≥20% blast cells as the cut off percentage in bone marrow and peripheral blood, which represents a change from original guidelines where blasts ≥30% were considered as diagnostic criteria in bone marrow and peripheral blood as per French-American-British classification.
- The myeloblasts have distinct immunophenotype detected by flow cytometry. In aleukemic leukemia, myeloblasts are detected only in bone marrow.
- Coagulopathy is resulting from disseminated intravascular coagulation (DIC).
- Hyperuricemia is related to increased to high cell turnover and chemotherapy in AML. Rapidly rising serum concentrations of uric acid, potassium phosphate with decreased calcium level herald a tumor lysis syndrome that can cause acute renal failure.
- Muramidase released by leukemic myeloblasts can cause renal tubular dysfunction and electrolyte abnormalities. Lactic acidosis tends to occur due to anerobic glycolysis by leukemic cells.
- Blood biochemical investigations reveal hyperuricemia, elevated blood urea nitrogen and creatinine, high lactic dehydrogenase (LDH), hypokalemia (tubular dysfunction), spurious hypoglycemia and

Table 9.39 Revised 2024 WHO classification of acute myelogenous leukemias (AML) and related precursor neoplasms

AML and Recurrent Genetic Abnormalities	
▪ AML with t(8,21) (q22;q22.1); RUNX1-RUNX1T1	▪ AML with megakaryoblastic leukemia and t(1;22) (p13.3;q13.3); RBM15-MKL1
▪ AML with inv (16) (p13.1q22) or t(16;16) (p13.1;q22); CBFB-MYH11	▪ AML with BCR-ABL1 (provisional entity)
▪ Acute promyelocytic leukemia (APL) with PML-RARA	▪ AML with mutated NPM1
▪ AML with t(9;11) (p21.3;q23.3); KMT2A-MLLT3	▪ AML with biallelic mutations of CEBPA
▪ AML with t(6;9) (p23;q34.1); DEK-NUP214	▪ AML with mutated RUNX1 (provisional entity)
▪ AML with inv(3)(q21.3q26.2) or t(3;3) (q21.3;q26.2); GATA2, MECOM	
AML with Myelodysplasia-related Changes	
Therapy-related Myeloid Neoplasms	
AML, not otherwise specified (NOS)	
▪ AML with minimal differentiation	▪ Pure erythroid leukemia (AML-M6B)
▪ AML without maturation	▪ Acute megakaryoblastic leukemia (AML-M7)
▪ AML with maturation	▪ Acute basophilic leukemia
▪ Acute myelomonocytic leukemia	▪ Acute panmyelosis with myelofibrosis
▪ Acute monoblastic/monocytic leukemia	
Myeloid Sarcoma	
Myeloid Proliferations Related to Down syndrome	
▪ Transient abnormal myelopoiesis (TAM)	▪ Acute myelogenous leukemia of Down syndrome (AML-DS) contains acquired GATA1 mutation
Acute Leukemias of Ambiguous Neoplasms	
▪ Acute undifferentiated leukemia	▪ Mixed-phenotype acute leukemia, NOS (not otherwise specified), rare types
▪ Mixed-phenotype acute leukemia with t(9;22) (q34.1;q11.2); BCR-ABL1	▪ Mixed-phenotype acute leukemia of ambiguous lineage, NOS (not otherwise specified)
▪ Mixed-phenotype acute leukemia with t(v;11q23.3); KMT2A-rearranged	
▪ Mixed-phenotype acute leukemia, B/myeloid, NOS (not otherwise specified)	
▪ Mixed-phenotype acute leukemia, T/myeloid, NOS (not otherwise specified)	

Adapted from revised 2024 WHO classification of myeloid neoplasms and acute myelogenous leukemia.

hypoxemia. Increased serum lactic dehydrogenase (LDH) is associated with central nervous system involvement. Increased number of myeloblasts in circulation can cause spurious hypoglycemia, hypokalemia and other abnormalities result from cellular metabolic activity *in vitro*.

- Hematologic findings reveal increased white blood cell count with myeloblasts in the peripheral blood smear, anemia, granulocytopenia, thrombocytopenia and disseminated intravascular coagulation.
- Imaging techniques such as radiograph, CT scan and MRI scan are performed according to symptoms related to leukemic blasts infiltration in various organs.

ACUTE MYELOGENOUS LEUKEMIA: ENTITIES

Acute myelogenous leukemia (AML) is more common in adults although it may affect any age groups. Diagnostic features, incidence, cytochemistry, immunophenotype and cytogenetics of acute myelogenous leukemia according to French-American-British classification are given in Table 9.40.

AML-M0 WITH MINIMAL DIFFERENTIATION

Acute myelogenous leukemia (AML) with minimal differentiation (AML-M0) accounts for <5% of AML cases. It is thought to be originating from hematopoietic stem cell at the earliest stage of myeloid differentiation. AML-M0 typically occurs in infants and older adults.

- AML-M0 exhibits no morphologic or cytochemical evidence of myeloid differentiation. Myeloblasts in a case of AML-M0 resemble lymphoblasts, with scant, granular cytoplasm, which show block-like periodic acid–Schiff (PAS) positivity, as is typically observed in acute lymphoblastic leukemia, but has also been reported in cases of acute myelogenous leukemia.
- In AML-M0, flow cytometric immunophenotypic analysis reveals evidence of myeloid differentiation based on expression of at least two myeloid markers such as CD13 and CD117, including CD33, HLA-DR and CD34.
- Terminal deoxynucleotidyl transferase (**TdT**) is a DNA polymerase and its positivity typically seen in cases of acute lymphoblastic leukemia (ALL).

Table 9.40 Diagnostic features, incidence, cytochemistry, immunophenotype and cytogenetics of acute myelogenous leukemias according to French-American-British classification

Feature	Cytochemistry	Immunophenotype by Flow Cytometry with Monoclonal Antibodies	Cytogenetics	Comments
AML-M0 with minimal differentiation (<5%)				
Minimal evidence of myeloid differentiation (without maturation with agranular cytoplasm)	▪ Myeloperoxidase + (<3% of blasts) ▪ Sudan black B + (<3% of blasts) ▪ Specific esterase –	▪ CD34++ ▪ HLA-DR+ ▪ CD117+++ ▪ CD33+ ▪ CD13+ ▪ CD11b+/– ▪ CD14–	No unique chromosomal abnormality	AML-M0 originates from hematopoietic precursor cell at the earliest stage associated with poor prognosis
AML-M1 without maturation (20%)				
High % of blasts without significant maturation to more mature neutrophils, blasts demonstrate Auer rods	▪ Myeloperoxidase + (<3% of blasts) ▪ Sudan black B + (<3% of blasts) ▪ Specific esterase +	▪ CD34++ ▪ HLA-DR+++ ▪ CD117+++ ▪ CD33+ ▪ CD13+ ▪ CD14+ ▪ CD11b+/–	–6, –7, –17, del 3p, +21, +8	Favorable prognosis
AML-M2 with maturation (30–40%)				
All stages of neutrophil maturation, pseudo-Pelger-Hüet anomaly, hypogranulation	▪ Myeloperoxidase + (>10%) ▪ Sudan black B + ▪ Specific esterase +	▪ CD34– ▪ HLA-DR+ ▪ CD33+ ▪ CD13+	t(8;21), del 3p, or inv 3, –5, –7,+8, t(6;9)	Favorable prognosis
AML-M3 (5–10%)				
Acute promyelocytic leukemia (APL) with hypergranular with bilobed heavy contour	Myeloperoxidase +	▪ CD34– ▪ HLA-DR– ▪ CD33+ ▪ CD13+	t(15,17)	Disseminated intravascular coagulation associated with poor prognosis
AML-M3m (5–10%)				
Acute promyelocytic leukemia (APL) with microgranular variant	Myeloperoxidase ++	▪ CD34– ▪ HLA-DR– ▪ CD33+ ▪ CD13+	t(15,17)	Favorable prognosis
AML-M4 (5–10%)				
Acute myelomonocytic leukemia (monocytes and promonocytes in the bone marrow exceed 20%)	▪ Myeloperoxidase + ▪ Esterase +	▪ CD34– ▪ HLA-DR+ ▪ CD33+ ▪ CD13+ ▪ CD14/CD64+	Inv16, t(16;16), –5, –7, t(6;9)	Favorable prognosis
AML-M4Eo (5–10%)				
Acute myelomonocytic leukemia with abnormal eosinophils (>5%)	▪ Myeloperoxidase + ▪ Esterase +	▪ CD34– ▪ HLA-DR+ ▪ CD33+ ▪ CD13+ ▪ CD11+ ▪ CD14+	Inv16	Favorable prognosis

Contd...

Table 9.40 Diagnostic features, incidence, cytochemistry, immunophenotype and cytogenetics of acute myelogenous leukemias according to French-American-British classification (*Contd...*)

Feature	Cytochemistry	Immunophenotype by Flow Cytometry with Monoclonal Antibodies	Cytogenetics	Comments
AML-M5A, acute monoblastic/monocytic leukemia-5A (5%)				
Monoblasts/monocytes dominance (≥80%), hemophagocytosis, nuclear lobulation	▪ Myeloperoxidase – ▪ Specific esterase + ▪ Nonspecific esterase +/–	▪ CD34– ▪ HLA-DR+ ▪ CD33+ ▪ CD13+/– ▪ CD11+ ▪ CD14+	t(9,11) (p21–23)	Extramedullary disease associated with poor prognosis
AML-M5B, acute monoblastic leukemia-5B (5%)				
Monoblasts/monocytes dominance	▪ Myeloperoxidase – ▪ Specific esterase + ▪ Nonspecific esterase +/–	▪ CD34– ▪ HLA-DR+ ▪ CD33+ ▪ CD13+/– ▪ CD11+ ▪ CD14+	t(9,11) (p21–23)	Extramedullary disease associated with poor prognosis
AML-M6, acute erythroid leukemia (uncommon)				
▪ >50% erythroid precursors ▪ >20% myeloblasts in the nonerythroid cell population ▪ Megakaryoblastoid morphology, ▪ Auer rods+/–	▪ PAS ++ (erythroblasts) ▪ Myeloperoxidase – ▪ Sudan black B + ▪ Nonspecific esterase –	▪ Glycophorin A+ ▪ Hemoglobin A+ ▪ CD33+++	–5, –7, –3, +8	Poor prognosis
AML-M7, acute megakaryoblastic leukemia (<5%)				
Cytopenia with or without thrombocytopenia, basophilic agranular blasts with pseudopods, micromegakaryocytes	▪ Platelet peroxidase + ▪ Myeloperoxidase – ▪ Sudan black B – ▪ PAS +/–	▪ HLA-DR+ ▪ CD117+ ▪ CD34+ ▪ CD13+ ▪ CD33+++ ▪ CD41+ ▪ CD42+ ▪ CD61+ ▪ CD11b+ ▪ Electron microscopy	+8. +21, inv/del 3p	Poor prognosis

MPO: Myeloperoxidase; PAS: Periodic acid–Schiff; CD: Cluster of differentiation; Myeloid markers: CD13, CD33; Monocyte markers: CD11, CD14.

TdT positivity is observed in 50% of cases of AML-M0, but myeloblasts are negative for B cell and T cell markers. AML-M0 may exhibit complex karyotypes and unbalanced abnormalities such as –5, del(5q), –7, del(7q), +8 and del(11q).

- Myeloblasts in AML-M0 do not express more than one cell membrane marker for myeloid lineage. Myeloblasts in AML-M0 are negative for myeloperoxidase (MPO).
- It is important to recognize that AML-M0 is of myeloid cell lineage origin, so that patients may be treated with appropriate therapy for AML. Patient presents with evidence of bone marrow failure usually associated with poor prognosis.

Laboratory Diagnosis of Acute Myelogenous Leukemia M0 (AML-M0, FAB)	
Peripheral Blood Smear	
Myeloblasts in AML-M0 are medium in size with round or slightly indented nuclei and one or two nucleoli and agranular cytoplasm. Peripheral blood smear findings in acute myelogenous leukemia M0 (AML-M0) are shown in Fig. 9.39.	
Bone Marrow Smear Examination	
Bone marrow aspirate smear is hypercellular. Myeloblasts in AML-M0 are medium in size with round or slightly indented nuclei and one or two nucleoli and agranular cytoplasm.	
Cytochemistry	
Less than 3% of myeloblasts in AML-M0 are positive for myeloperoxidase and Sudan black B stains.	
Immunophenotyping	
▪ Myeloblasts in AML-M0 demonstrate myeloid differentiation by flow cytometry for myeloid lineage (CD13 and CD33). Most AML-M0 cases are also positive for HLA-DR, CD34 and CD38. ▪ No unique chromosomal abnormalities are observed in this subcategory. Because myeloblasts in AML-M0 have no morphological differentiating features, immunophenotyping should be performed to exclude the lymphoid lineage.	
Markers	**Expression**
▪ CD34 ▪ CD38 ▪ HLA-DR ▪ CD117 ▪ CD13 ▪ CD33	▪ Positive ▪ Positive ▪ Positive ▪ Positive (some cases) ▪ Positive (some cases) ▪ Positive (some cases)
Myeloid and monocytic maturation associated antigens are not expressed such as CD11b, CD15, CD14, CD64 and CD65 in AML-M0 cases.	

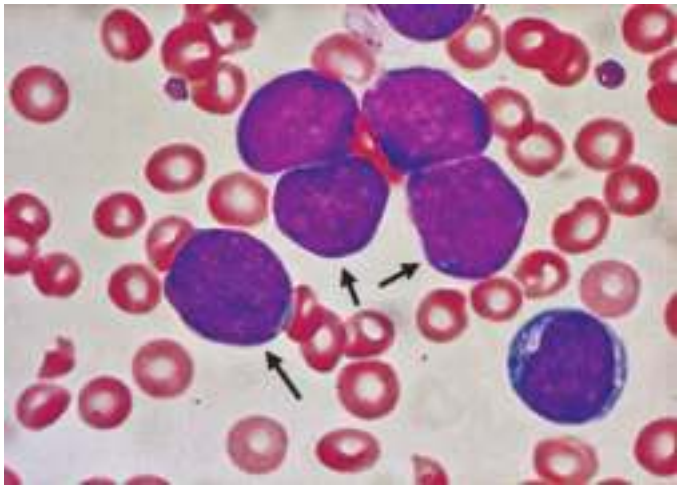

Fig. 9.39: Acute myelogenous leukemia M0 (AML-M0, FAB) in Giemsa-stained peripheral blood smear. It shows blasts in AML with minimal differentiation. The blasts are large with scant amount of cytoplasm, high nucleocytoplasmic ratio, fine nuclear chromatin and 2–4 prominent nucleoli (arrows) (1000X).

AML-M1 WITHOUT MATURATION

Acute myelogenous leukemia (AML) without maturation (AML-M1) is characterized by a high percentage (>90%) of bone marrow myeloblasts without significant evidence of maturation to more mature neutrophils.

- AML-M1 can affect any age group but most commonly in adult persons, which accounts for 5–10% of AML cases.
- Patients develop features of bone marrow failure such as anemia, thrombocytopenia and neutropenia. More than 3% of myeloblasts show myeloperoxidase (MPO) or Sudan black B positivity.
- The myeloblasts may contain azurophilic granules, Auer rods and vacuoles. Myeloblasts lacking azurophilic granules or Auer rods can resemble lymphoblasts, hence immunophenotyping helps to differentiate these blasts. Myeloblast in AML-M1 is positive for CD34, HLA-DR, CD33 and CD13. Prognosis in patients with AML-M1 is usually favorable.

Laboratory Diagnosis of Acute Myelogenous Leukemia M1 (AML-M1, FAB)	
Peripheral Blood Smear Examination	
Blasts resemble myeloblasts in some cases show azurophilic granules and Auer rods. In some cases, blasts resemble lymphoblasts. Acute myelogenous leukemia M1 (AML-M1, FAB) with minimal differentiation in Giemsa-stained peripheral blood smear is shown in Fig. 9.40.	
Bone Marrow Smear Examination	
In bone marrow aspirate smear examination, myeloblasts show presence of azurophilic granules and Auer rods. In some cases, myeloblasts resemble lymphoblasts.	
Cytochemistry	
More than 3% of myeloblasts in AML-M1 show positivity for myeloperoxidase (MPO) or Sudan black B.	
Immunophenotyping	
Myeloblasts in AML-M1 show positivity for CD13, CD33, CD117, HLA-DR and CD34.	
Markers	**Expression**
CD13 CD33 CD117 HLA-DR CD3	▪ Positive ▪ Positive ▪ Positive ▪ Positive ▪ Positive

AML-M2 WITH MATURATION

Acute myelogenous leukemia (AML) with maturation (AML-M2) is characterized by presence of ≥20% myeloblasts with evidence of maturation to more neutrophils (>10% of cells at different stages of maturation comprising of myeloblasts, promyelocytes, myelocytes

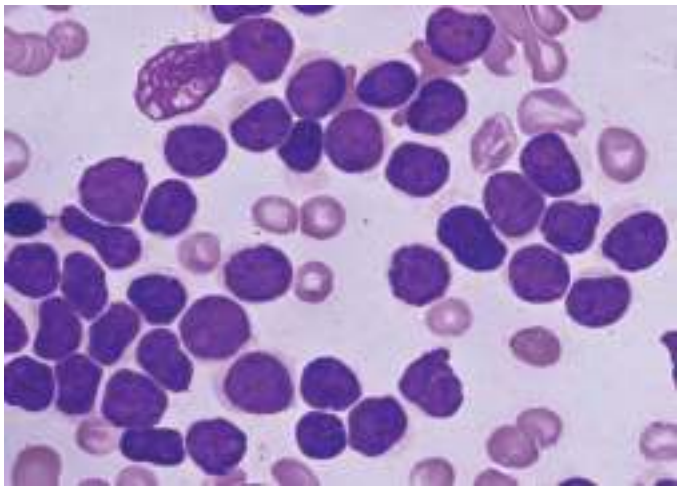

Fig. 9.40: Acute myelogenous leukemia M1 (AML-M1, FAB) with minimal differentiation in Giemsa-stained peripheral blood smear. It shows blasts with maturation with opened up chromatin with high nucleocytoplasmic ratio, 2–4 prominent nucleoli and moderate amount of cytoplasm (1000X).

and metamyelocytes) in the peripheral blood and bone marrow. Monocytes and their precursors constitute <20% of bone marrow cells.

- AML-M2 affects all age groups. It accounts for 30–40% of AML cases. Patients present with anemia, neutropenia, and thrombocytopenia.
- Myeloblasts frequently contain Auer rods. Pseudo-Pelger-Hüet anomaly and hypogranulation and binucleated cells may be present.
- About 10% of myeloblasts are positive for myeloperoxidase and Sudan black B cytochemical stain. Myeloblasts are positive for CD13, CD33 and HLA-DR, but negative for CD34.

Laboratory Diagnosis of Acute Myelogenous Leukemia M2 (AML-M2, FAB)

Peripheral Blood Smear

- Myeloblasts with Auer rods and azurophilic granules are seen along with promyelocytes, myelocytes and mature neutrophils comprising up to 10% of bone marrow cells.
- Acute myelogenous leukemia M2 (AML-M2, FAB) with maturation in Giemsa-stained peripheral blood smear is shown in Fig. 9.41.

Bone Marrow Smear Examination

In bone marrow aspirate smear examination, myeloblasts with Auer rods and azurophilic granules are seen along with promyelocytes, myelocytes and mature neutrophils comprising up to 10% of bone marrow cells.

Cytochemistry

Myeloblasts show positivity with myeloperoxidase stain. Peripheral blood smear showing MPO (myeloperoxidase) positivity in AML with maturation (AML-M2).

Immunophenotyping

Myeloblasts express positivity for CD13, CD33, CD65, CD11b and CD15.

Markers	Expression
▪ CD13	▪ Positive
▪ CD33	▪ Positive
▪ CD65	▪ Positive
▪ CD11b	▪ Positive
▪ CD15	▪ Positive

ACUTE PROMYELOCYTIC LEUKEMIA (AML-M3, FAB)

Acute promyelocytic leukemia (AML-M3) can be either hypergranular or microgranular/hypogranular, which accounts for 5–8% of AML cases. Median age of AML-M3 is 35–40 years but can occur at any age. Hypergranular variant of AML-M3 shows abnormal promyelocytes with numerous coarse azurophilic granules, folded nuclei resembling cottage loaf. Leukocyte count is decreased.

Diagnostic Criteria

Acute promyelocytic leukemia (AML-M3) is diagnosed by demonstration of >50% abnormal myelocytes with heavy cytoplasmic granules that may obscure the nuclear cytoplasmic margin, often reniform or bilobed nucleus, cells with multiple Auer rods. Abnormal promyelocytes show strong positivity for myeloperoxidase stain.

Clinical Features

Senescent leukemic cells degranulate and release thromboplastin-like substance into the peripheral blood and can cause disseminated intravascular coagulation (**DIC**) and hemorrhage before or during induction of

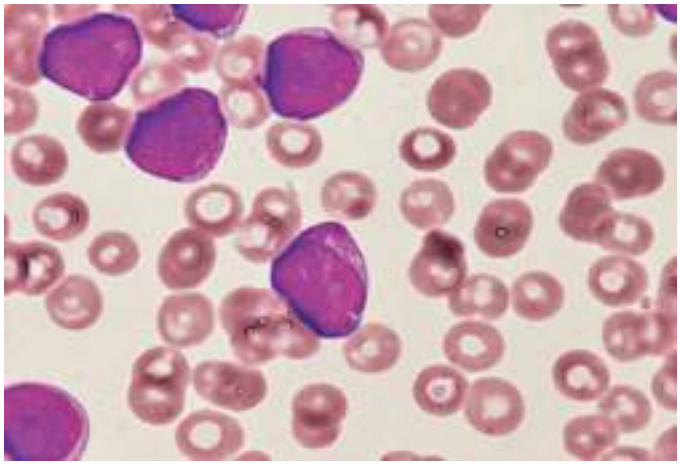

Fig. 9.41: Acute myelogenous leukemia M2 (AML-M2, FAB) with maturation in Giemsa-stained peripheral blood smear. It shows myeloblasts with promyelocyte, myelocyte and band forms of polymorphonuclear cells are showing evidence of maturation (1000X).

chemotherapy, which may cause early death. Organomegaly and extramedullary disease and skin involvement rarely occur.

Molecular Genetic Alterations

Acute promyelocytic leukemia (AML-M3) is associated with the translocation t(15;17) (q22;q21), which disrupts the retinoic acid receptor-α (RARA) gene on chromosome 17q21 and the PML gene on chromosome 15q22 and results in the formation of hybrid mRNA, that produces abnormal retinoic acid receptor leading to blockage of myeloid differentiation at the promyelocytic stage.

- Hybrid mRNA transcript is demonstrated by fluorescence *in situ* hybridization (FISH). Currently AML-M3 is classified under AML with recurrent genetic abnormalities.
- Cases without Auer rods in leukemic cells usually demonstrate additional chromosomal abnormalities. Cytogenetic abnormalities in acute promyelocytic leukemia are given in Table 9.41.

Treatment and Remission

Remission of AML-M3 is achieved by administration of oral all-*trans* retinoic acid variant of vitamin A analogue (ATRA), a form of differentiating therapy that overcomes the maturation arrest. Arsenic trioxide (ATO) for ATRA-refractory patients; induces differentiation at low doses, but higher doses cause bone marrow necrosis. All variants of AML except promyelocytic leukemia are treated by continuous infusion of cytarabine for 7 days and a 3-day course of daunorubicin followed by autologous hematopoietic stem cell transplant (HSCT) and allogeneic HSCT.

Laboratory Diagnosis of Acute Myelogenous Leukemia M3 (AML-M3,FAB)

Routine Hematologic Tests

Hemoglobin and hematocrit values (MCH, MCHC, MCV, RDW) are decreased. Total leukocyte count and erythrocyte sedimentation rate are increased.

Hemostatic Function Tests

Hemostatic function tests include prothrombin–INR time, activated partial thromboplastin time, fibrinogen levels, fibrinogen degradation products (**FDPs**), platelet count, plasma LDH level and plasma and urine lysozyme levels.

Peripheral Blood Smear Examination

- Acute myelogenous leukemia M3 (AML-M3, FAB), also called acute promyelocytic leukemia with hypergranular variant is diagnosed by demonstration of >50% abnormal promyelocytes with heavy cytoplasmic granulation that may obscure the nuclear cytoplasmic margin, often reniform or bilobed nucleus, cells with multiple Auer rods.
- Peripheral blood smear examination in AML-M3 shows either hypergranular (AML-M3, FAB) or hypogranular (AML-M3V) picture, normocytic and normochromic anemia, nucleated red blood cells, neutropenia and monocytosis.
- Acute myelogenous leukemia M3 (AML-M3, FAB), also called acute promyelocytic leukemia with hypergranular variant in Giemsa-stained peripheral blood smear is shown in Fig. 9.42.
- Acute myelogenous leukemia M3 (AML-M3V, FAB), also called acute promyelocytic leukemia with hypogranular variant in Giemsa-stained peripheral blood smear is shown in Fig. 9.43.

Bone Marrow Smear Examination

Bone marrow examination shows hypercellular marrow with high myeloid to erythroid ratio and predominant promyelocytes.

Bone Marrow Trephine Biopsy Examination

- Bone marrow trephine biopsy obtained section demonstrates numerous abnormal hypergranular promyelocytes containing abundant cytoplasm and round/oval eccentric nuclei with occasional clefts or indentations/reniform nuclei with moderate condensed chromatin and indistinct nuclei; and heavy red/purple cytoplasmic granules that may obscure nuclear borders.
- About 90% of abnormal promyelocytes contain multiple Auer rods.
- Acute myelogenous leukemia M3 (AML-M3, FAB) in hematoxylin and eosin-stained bone marrow trephine biopsy is shown in Fig. 9.44.

Cytochemistry

Leukemic promyelocytes in AML-M3 show strong positivity for myeloperoxidase stain.

Immunophenotyping

Acute promyelocytic leukemia (AML-M3) shows positivity for CD9, CD11a and CD11b.

Markers	Expression
▪ CD9	▪ Positive
▪ CD11a	▪ Positive
▪ CD11b	▪ Positive

ACUTE MYELOMONOCYTIC LEUKEMIA (AMML/AML-M4, FAB)

Acute myelomonocytic leukemia (AMML/AML-M4) is characterized by proliferation of myelocytic and monocytic precursors in the bone marrow and peripheral blood, which usually affects elderly persons. Some patients have family history of AMML.

- The cell of origin of AMML is believed to be a hematopoietic precursor cell, that has potential to differentiate into neutrophil and monocytic lineage.
- Bone marrow in AMML is hypercellular, which shows ≥20% lymphoblasts, neutrophils and their precursors, and monocytes and their precursors. Each lineage is composed of ≥20% of bone marrow cells. AMML/AML-M4 accounts for 5–10% of AML cases.

Table 9.41 Cytogenetic abnormalities in acute promyelocytic leukemia

Chromosomal Translocation	Genes Involved	All-*trans* Retinoic Acid Response
t(15;17) (q21;q11)	PML-RARA	Yes
t(11;17) (q13;q11)	NuMA-RARA	Yes
t(5;17) (q31;q11)	NPM-RARA	Yes
t(11;17) (q13;q11)	PLZF-RARA	No

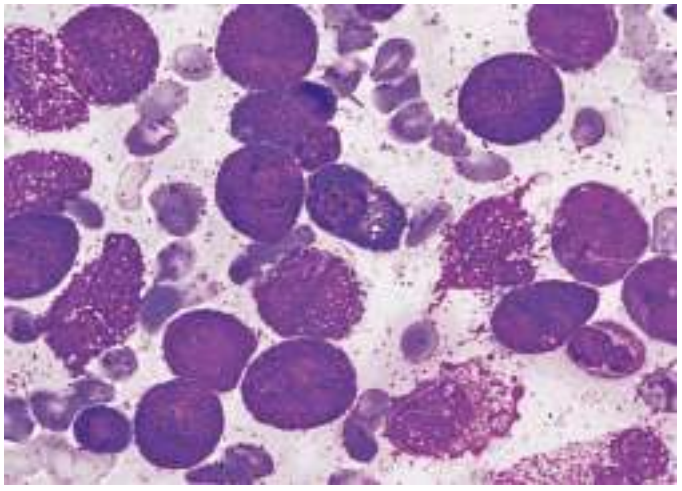

Fig. 9.42: Acute myelogenous leukemia M3 (AML-M3, FAB), also called acute promyelocytic leukemia with hypergranular variant in Giemsa-stained peripheral blood smear examination. It shows numerous promyelocytes, which contain an irregularly shaped nucleus and numerous azurophilic granules (1000X).

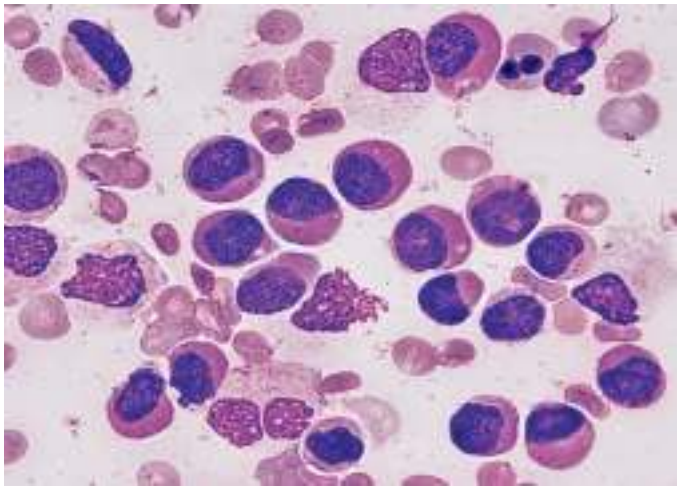

Fig. 9.43: Acute myelogenous leukemia M3 (AML-M3, FAB) also known as acute promyelocytic leukemia with hypogranular variant in Giemsa-stained peripheral blood smear examination. It shows abnormal promyelocytes, which show bilobed nuclei and absence of granules to fine granules (1000X).

- In AML-M4, extramedullary involvement is most often demonstrated. Cytogenetic analysis demonstrates inversion of 16, t(16;16), t(6;9) and loss of chromosomes 5 and 7.

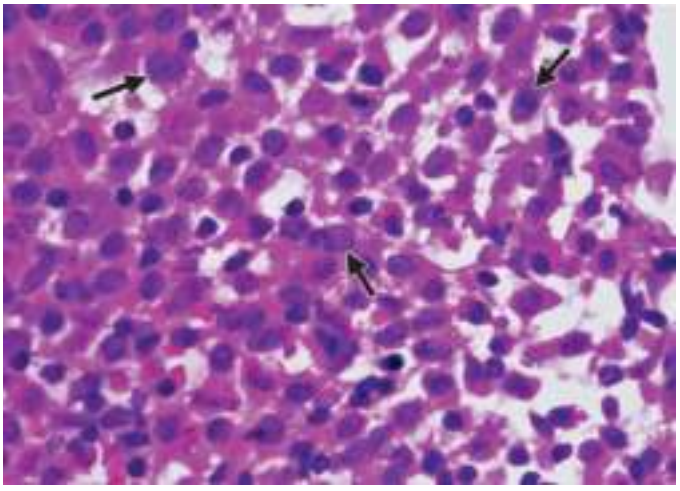

Fig. 9.44: Acute myelogenous leukemia M3 (AML-M3, FAB) in hematoxylin and eosin-stained bone marrow trephine biopsy. It shows hypercellularity and abnormal promyelocytes with moderate amount of cytoplasm and round to oval nuclei (arrows) (400X).

- Serum and urinary levels of muramidase (lysozyme) are most often elevated as a result of monocytic proliferation. Prognosis is favorable in AMML/AML-M4.
- Additional laboratory investigations of AML-M4 are essential when the bone marrow findings are as previously described, but the peripheral blood monocyte count is either $<5\times10^9$/L; or the peripheral blood monocyte count is $\geq5\times10^9$/L. In these cases, serum muramidase levels and cytochemical stains can be performed to establish AMML diagnosis.

Laboratory Diagnosis of Acute Myelomonocytic Leukemia (AMML/AML-M4, FAB)

Peripheral Blood Smear Examination

- Peripheral blood leukocyte count in acute myelomonocytic leukemia (AMML/AML-M4) is most often elevated. Monocytic lineage cells such as monoblasts, promonocytes and monocytes are elevated to $\geq5\times10^9$/dl.
- Anemia and thrombocytopenia are present in almost all cases. Myeloblasts are also present.
- Monoblasts are large cells with round to convoluted nucleus with delicate chromatin and one or more nucleoli; and abundant bluish-gray cytoplasm showing pseudopods. Monoblasts may demonstrate azurophilic granules and vacuoles.

- If peripheral blood smear examination shows monocyte count <5 × 10⁹/L; increased serum muramidase levels and cytochemical stains can be performed to establish the diagnosis of AML-M4.
- Acute myelogenous leukemia M4 (AML-M4, FAB), also known as acute myelomonocytic leukemia in Giemsa-stained peripheral blood smear examination is shown in Fig. 9.45.

Bone Marrow Smear Examination

- Bone marrow in acute myelomonocytic leukemia (AMML/AML-M4) is hypercellular and showing **≥20%** myeloblasts; neutrophils and their precursors; and monocytes and their precursors.
- Bone marrow can demonstrate hemophagocytosis by monocytes.

Cytochemistry

AMML/AML-M4 shows positivity for myeloperoxidase and non-specific esterase.

Immunophenotyping

AMML (AML-M4) demonstrates positivity for HLA-DR, CD33, CD34, CD13, CD14.CD68 and CD64.

- In normal circumstances, CD34 is a transmembrane glycoprotein expressed on 1–2% of the total bone marrow lymphohematopoietic stem cells and progenitor cells. About 40% of AMLs and ≥50% of ALLs express CD34. CD34 is also expressed in variety of nonhematopoietic neoplasms. CD34 expression in acute myelogenous leukemia M4 (AML-M4, FAB) in bone marrow trephine biopsy section is shown in Fig. 9.46.
- CD68, a hematopoietic differentiation marker of the monocytic-macrophage lineage is expressed in AML and CML. CD68 expression in acute myelogenous leukemia M4 (AML-M4, FAB) in bone marrow trephine biopsy section is shown in Fig. 9.47.

Markers	Expression
HLA-DR	Positive
CD33	Positive
CD13	Positive
CD14	Positive
CD64	Positive
CD34	Positive
CD68	Positive

ACUTE MONOBLASTIC/MONOCYTIC LEUKEMIA (AML-M5A AND AML-M5B, FAB)

Acute monoblastic/monocytic leukemia (AML-M5A, AML-M5B) is characterized by ≥80% of the leukemic cells comprising monoblasts, promonocytes, monocytes. Neutrophil component in AML-M5A/AML-M5B constitutes <20% of neutrophils.

- The majority of the monocytic cells (>80%) demonstrated in AML are monoblasts. The majority of monocytic cells in AML are promonocytes.

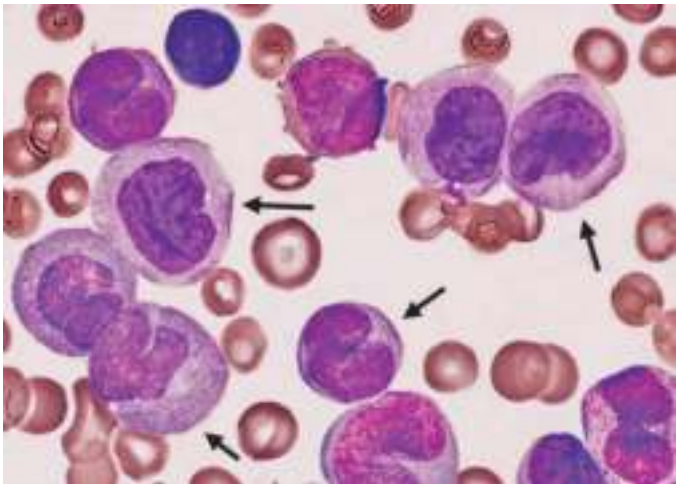

Fig. 9.45: Acute myelogenous leukemia M4 (AML-M4, FAB), also known as acute myelomonocytic leukemia in Giemsa-stained peripheral blood smear examination. It shows atypical cells of monocytic lineage (arrows) (1000X).

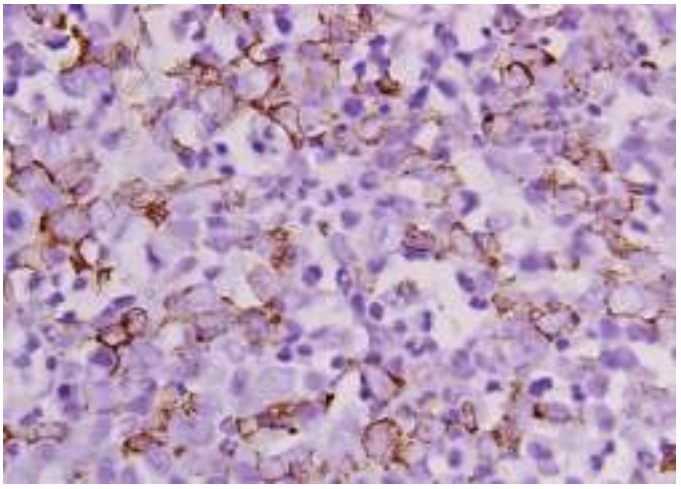

Fig. 9.46: CD34 expression in acute myelogenous leukemia M4 (AML-M4, FAB) in bone marrow trephine biopsy section. In normal circumstances, CD34 is a transmembrane glycoprotein expressed on 1–2% of the total bone marrow lymphohematopoietic cells and progenitor cells. About 40% of AMLs and over 50% of ALLs express CD34. CD34 is also expressed in variety of nonhematopoietic neoplasms (400X).

- Acute monoblastic leukemia accounts for 5–8% of AML cases. Acute monocytic leukemia accounts for 3–6% of AML cases. The disease usually affects children and young adults.
- There are two subtypes of AML-M5: (a) AML-M5A (monoblastic type with >80% blasts), and (b) AML-M5B (monocytic type with <80% blasts). AML-M5A is more common in young individuals, whereas AML-M5B commonly in adults.

Molecular Genetic Alterations

Molecular genetic alterations of the long arm of chromosome 11 with translocations or deletions are most often demonstrated in acute monocytic leukemias.

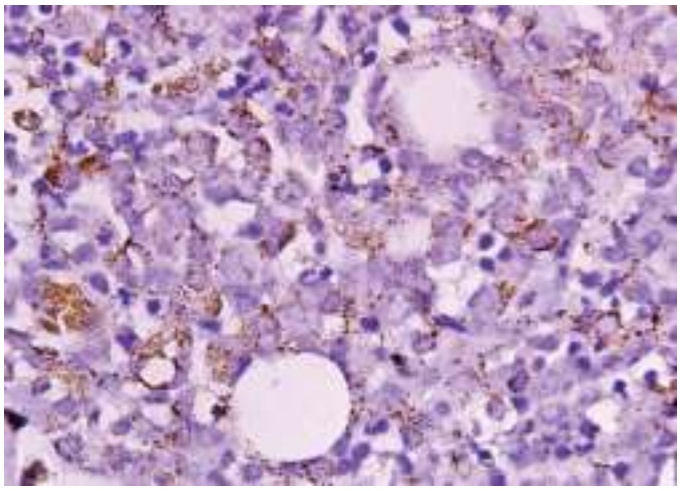

Fig. 9.47: CD68 expression in acute myelogenous leukemia M4 (AML-M4, FAB) in bone marrow trephine biopsy section (1000X). CD68, a hematopoietic differentiation marker of the monocytic-macrophage lineage is expressed in various human malignancies including acute myelogenous leukemia and chronic myelogenous leukemia (400X).

- The chromosomal t(8;16) abnormality is associated with hemophagocytosis. The expression of c-Fos proto-oncogene on chromosome 14 appears to be increased in acute leukemias with monocytic lineage.
- The expression of c-Fos proto-oncogene on chromosome 14 has been linked to normal monocyte-macrophage differentiation. The cell of origin for AML-M5 subtype is believed to be a hematopoietic stem cell committed to monocytic differentiation (CFU-M).

Clinical Features

Patient presents with weakness, bleeding gums and diffuse erythematous skin rash. In extramedullary disease, leukemic cells infiltrate gums, skin, lymph nodes, lungs and central nervous system. Extramedullary disease is associated with poor prognosis.

Laboratory Diagnosis of Acute Monoblastic/Monocytic Leukemia (AML-M5A and AML-M5B, FAB)

Biochemical Tests

Serum and urine muramidase are moderately elevated.

Peripheral Blood Smear Examination

- **AML-M5A:** In acute monoblastic/monocytic leukemia, peripheral blood smear shows increased number of monoblasts and monocytes in AML-M5A.
  - Monoblasts are large cells with round or oval nucleus with delicate chromatin and one or more nucleoli and abundant basophilic cytoplasm with pseudopod formation and scattered fine azurophilic granules and vacuoles. Auer rods are not demonstrated in leukemic cells.
  - Promonocytes contain more irregular and convoluted nucleus and nucleoli; and less basophilic cytoplasm than that of monoblasts giving ground glass appearance. Acute myelogenous leukemia (AML-M5A), also known as acute monoblastic and monocytic leukemia in Giemsa-stained peripheral blood smear examination is shown in Fig. 9.48.
- **AML-M5B:** In acute monoblastic/monocytic leukemia more mature forms of monocytic series are demonstrated in peripheral blood smear in AML-M5B. Promonocytes predominate with delicately convoluted nucleus, less basophilic cytoplasm and more obvious azurophilic granules. In Giemsa-stained peripheral blood smear examination is shown in Fig. 9.49.

Bone Marrow Smear Examination

- It is essential to evaluate both peripheral blood smear and bone marrow examination for AML-M5A and AML-M5B.
- Bone marrow aspirate smear examination shows ≥80% monoblasts and promonocytes.

Bone Marrow Trephine Biopsy Examination

- Hematoxylin and eosin-stained bone marrow trephine biopsy section shows sheets of more mature forms of monocytic series with delicately convoluted nucleus.
- Acute monoblastic/monocytic leukemia M5B (AML-M5B) in hematoxylin and eosin-stained bone marrow trephine biopsy section is shown in Fig. 9.50.

Cytochemistry

Leukemic cells in AML-M5 are positivity for specific esterase and nonspecific esterase. These cells are negative for myeloperoxidase stain.

Immunophenotyping

AML-M5 leukemic cells variably express CD13, CD33, CD15 and CD65. At least two markers of monocytic differentiation are positive such as CD14, CD11b, CD64, CD68, CD36 and lysozyme.

Markers	Expression
CD13	Positive
CD33	Positive
CD15	Positive
CD65	Positive
CD14	Positive
CD11b	Positive
CD64	Positive
CD68	Positive
CD36	Positive
Lysozyme	Positive
CD34	Negative

ACUTE ERYTHROID LEUKEMIA (AML-M6, FAB)

Acute erythroid leukemia (AML-M6, FAB) is defined as a subtype of AML-NOS with predominance of erythroid precursors. The vast majority (>90%) are of erythroid/myeloid (AML-M6A) subtype. AML-M6 is predominantly a disease of adult persons.

- Acute erythroid leukemia (AML-M6A) subtype with predominance of erythroid precursors (or acute

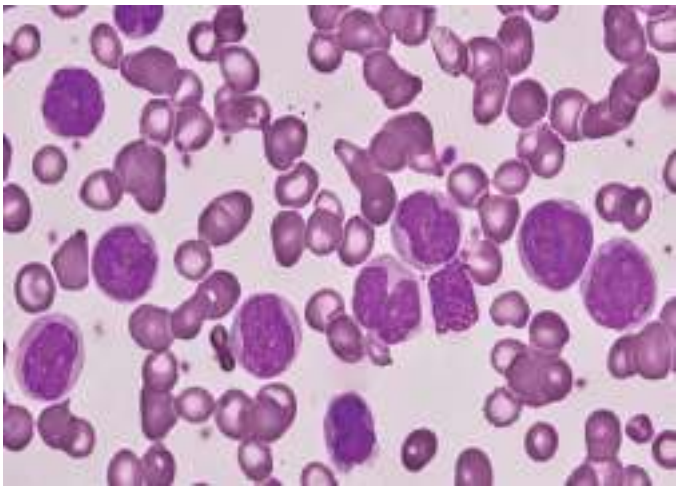

Fig. 9.48: Acute myelogenous leukemia M5A (AML-M5A), also known as acute monoblastic/monocytic leukemia in Giemsa-stained peripheral blood smear examination. It shows numerous monoblasts with round to oval nuclei with delicate chromatin, 1–2 prominent nucleoli, abundant basophilic cytoplasm with pseudopod formation and scattered fine azurophilic granules and vacuoles. Auer rods are not demonstrated in leukemic cells. Promonocytes contain more irregular and convoluted nucleus and nucleoli; and less basophilic cytoplasm than that of monoblasts giving ground glass appearance (1000X).

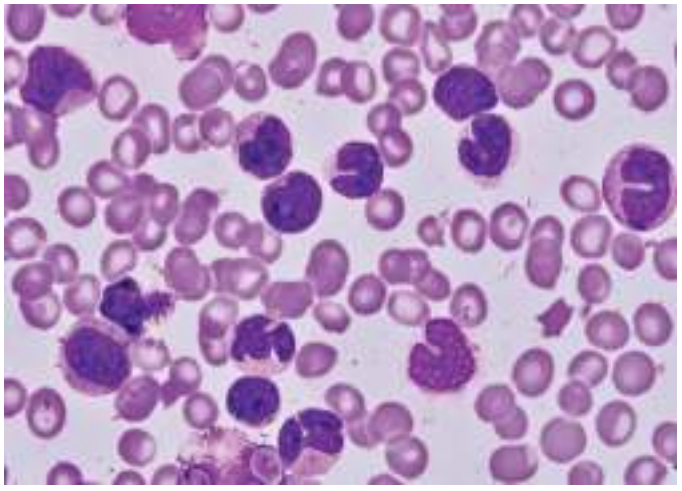

Fig. 9.49: Acute myelogenous leukemia M5B (AML-M5B), also known as acute monoblastic/monocytic leukemia in Giemsa-stained peripheral blood smear examination. It shows more mature forms of monocytic series, i.e. promonocytes and monoblasts. Promonocytes predominate with delicately convoluted nucleus, less basophilic cytoplasm and more obvious azurophilic granules; and monoblasts (1000X).

Di Guglielmo syndrome) is defined as the presence of ≥50% erythroid precursors and ≥20% lymphoblasts in the nonerythroid component affecting adults.

- The pure erythroid leukemia (AML-M6B) subtype is composed of ≥80% of more immature erythroblasts affecting any age group.
- Occasional case of CML can transform into AML-M6. Patient presents with profound anemia resulting in poor survival.

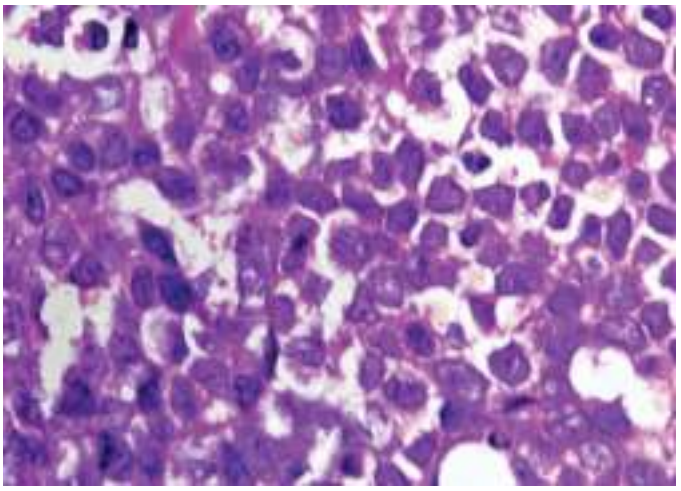

Fig. 9.50: Acute myelogenous leukemia M5B (AML-M5B), also known as acute monoblastic/monocytic leukemia in hematoxylin and eosin-stained bone marrow trephine biopsy section. It shows sheets of more mature forms of monocytic series with delicately convoluted nucleus (400X).

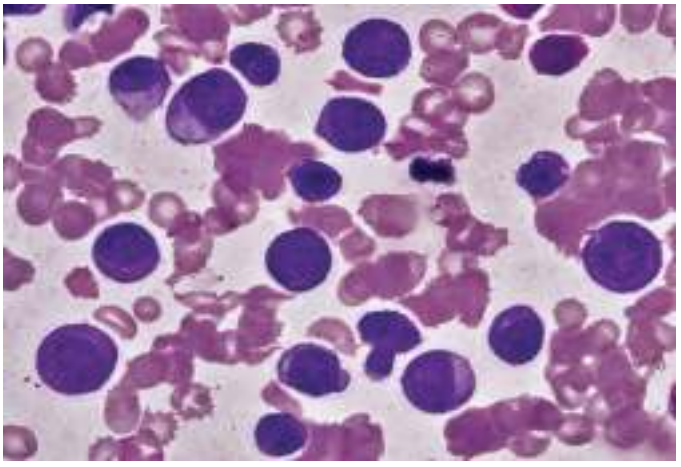

Fig. 9.51: Acute erythroid leukemia (AML-M6, FAB) in Giemsa-stained peripheral blood smear. It shows profound anemia with anisocytosis and poikilocytosis with a large number of nucleated red blood cells, that are extremely dysplastic with megaloblastoid nuclei and/or binucleated or multinucleated cells in the immature stages with vacuoles in the cytoplasm. Cytoplasmic pseudopods leukemic erythroid cells similar to those of acute megakaryocytic leukemia M7 (AMKL-M7) are demonstrated (1000X).

Laboratory Diagnosis of Acute Erythroid Leukemia (AML-M6, FAB)

Peripheral Blood Smear Examination

- Peripheral blood smear examination shows profound anemia with anisocytosis and poikilocytosis with many nucleated red blood cells, that are extremely dysplastic with megaloblastoid nuclei and/or binucleated or multinucleated cells in the immature stages with vacuoles in the cytoplasm.
- Cytoplasmic pseudopods leukemic erythroid cells similar to those in acute megakaryoblastic leukemia (AML-M7) may be present. Acute erythroid leukemia (AML-M6, FAB) in Giemsa-stained peripheral blood smear is shown in Fig. 9.51.

Bone Marrow Smear Examination

- Bone marrow examination demonstrates leukemic erythroid blasts distinctly abnormal bizarre morphologic features such as giant multilobular or multinucleated forms in AML-M6.
- Other morphologic features of leukemic erythroid blasts include nuclear budding and fragmentation, cytoplasmic vacuoles, Howell-Jolly bodies.
- Ring sideroblasts with megaloblastoid nuclei are demonstrated. Myeloblasts in mixed lineage variant contain Auer rods. Dysmegakaryopoiesis with mononuclear forms or micromegakaryoblasts are present.
- Neutrophils can demonstrate hypogranularity and pseudo-Pelger-Hüet anomaly. Leukocytes and platelets are decreased. Acute erythroid leukemia (AML-M6, FAB) in Giemsa-stained bone marrow aspirate smear is shown in Fig. 9.52.

Cytochemistry

- The leukemic erythroid blasts are myeloperoxidase (MPO) negative, but often positive for nonspecific esterase. Leukemic erythroid cells are PAS positive and forming positive lakes.
- Periodic acid–Schiff (PAS) positive erythroblasts are occasionally demonstrated in myelodysplastic syndrome (MDS), other subgroups of AML, thalassemia, iron deficiency anemia, severe hemolytic anemia and sometimes in megaloblastic anemia. Periodic acid–Schiff (PAS) stain positivity in various hematologic disorders is given in Table 9.42.
- Myeloblastic component in acute erythroleukemia demonstrates reactions similar to those found in other subtypes of AML in both morphological features and chromosomal aberrations.

Immunophenotyping

- Flow cytometry is performed to diagnose AML-M6 cases. Erythroblasts usually react positively with monoclonal antibodies to glycophorin A (CD71), hemoglobin A and CD33.
- The erythroid component in AML-M6 lacks myeloperoxidase (MPO), CD34, CD45 and pan-myeloid markers. CD117 and CD43 are often positive, when myeloblasts are present.
- AML-M6A (mixed lineage) cell of origin is thought to a primitive progenitor cell committed to the erythroid lineage (BFU-E or CFU-E).

Markers	Expression
▪ Glycophorin A	▪ Positive
▪ Hemoglobin A	▪ Positive
▪ CD33	▪ Positive

ACUTE MEGAKARYOBLASTIC LEUKEMIA (AMKL-M7, FAB)

Acute megakaryoblastic leukemia (AMKL-M7), subgroup of AML is defined by presence of 50% of the leukemic blasts of megakaryoblastic lineage, which accounts for <5% of AML cases. It occurs in adults and children.

- Acute megakaryoblastic leukemia (AMKL-M7) excludes AML with myelodysplasia-related changes such as AML with t(1;22) (p13;q13), inv(3)(q21;q26), t(3;3)(q21;q26.2), and Down syndrome-related cases. Patient presents with cytopenia, thrombocytopenia and sometimes with increased platelet count.
- There is no significant hepatosplenomegaly. Neutrophils and platelets can demonstrate dysplastic features. AML-M7 is associated with poor prognosis.

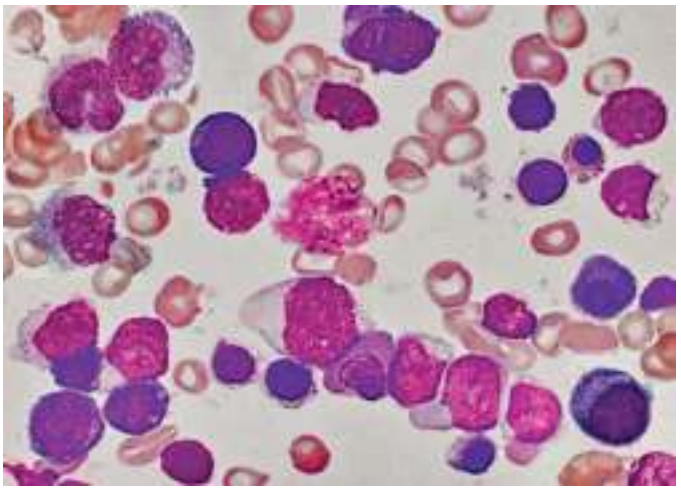

Fig. 9.52: Acute erythroid leukemia (AML-M6, FAB) in Giemsa-stained bone marrow aspirate smear. It shows myeloblast, promyelocyte and normoblasts with evidence of dyserythropoiesis (1000X).

Table 9.42 Periodic acid–Schiff (PAS) stain positivity in various hematologic disorders

Acute erythroid leukemia (AML-M6)
Myelodysplastic syndrome (MDS)
Acute myelogenous leukemia of other subgroups
Iron deficiency anemia
Thalassemia
Severe hemolytic anemia
Megaloblastic anemia (some case)

Laboratory Diagnosis of Acute Megakaryoblastic Leukemia (AMKL-M7, FAB)

Peripheral Blood Smear Examination

- On careful examination of the peripheral blood smear shows micromegakaryocytes and undifferentiated blasts.
- Demonstration of cytoplasmic blebs suggests that these cells are megakaryocytes. Megakaryocytic fragments can also be present.
- Acute megakaryoblastic leukemia (AMKL-M7, FAB) in Giemsa-stained bone marrow aspirate smear is shown in Fig. 9.53.

Bone Marrow Smear Examination

- Bone marrow smear examination shows medium to large size megakaryoblasts with basophilic often agranular cytoplasm, which usually exhibit distinct pseudopod formation. Small size megakaryoblasts can also be demonstrated.

- Morphology of megakaryoblasts is highly pleomorphic varying from small to large in size.
- Small megakaryoblasts are round in shape containing scanty cytoplasm and nucleus with dense chromatin resembling lymphoblasts.
- Large megakaryoblasts contain moderate amount of basophilic cytoplasm and nucleus with fine chromatin and prominent nucleoli. Some megakaryoblasts show cytoplasmic blebs.
- Dysplasia of all cell lineages is a common finding. No unique chromosomal abnormality is associated with acute megakaryoblastic leukemia in adults.

Cytochemistry

Megakaryocytes are positive for periodic acid–Schiff (PAS) and peroxidase stains; and negative for myeloperoxidase (MPO) and Sudan black B stains.

Bone Marrow Trephine Biopsy Examination

- Bone marrow aspiration usually results in dry tap due to bone marrow fibrosis associated with an expanded megakaryocyte lineage.
- In these cases, bone marrow trephine biopsy is performed to demonstrate increased fibroblasts and/or reticulin as well as ≥20% blasts.
- It has been proposed that those megakaryocytes synthesize a number of mitogenic factors that stimulate proliferation of fibroblasts.
- Hematoxylin and eosin-stained bone marrow trephine biopsy section shows extensive infiltration by blasts with sparse cytoplasm, frequent convoluted nuclei with fine chromatin and distinct nucleoli. Megakaryoblasts may be difficult to identify in bone marrow trephine biopsy, which may be present in small or large clusters surrounded by a network of reticulin fibers (Fig. 9.54).

Immunophenotyping

Monoclonal antibodies (CD41, CD42, CD61, HLA-DR, CD117, CD34, CD13, CD33, CD11b) are most commonly used to demonstrate megakaryoblasts by flow cytometry.

Markers	Expression
▪ CD41	▪ Positive
▪ CD42	▪ Positive
▪ CD61	▪ Positive
▪ HLA-DR	▪ Positive
▪ CD117	▪ Positive
▪ CD34	▪ Positive
▪ CD13	▪ Positive
▪ CD33	▪ Positive
▪ CD11b	▪ Positive

MYELOID SARCOMA

Myeloid sarcoma, also known as extramedullary myeloid tumor, that arises from hematopoietic stem cell affecting adults in 5–15% cases of AML.

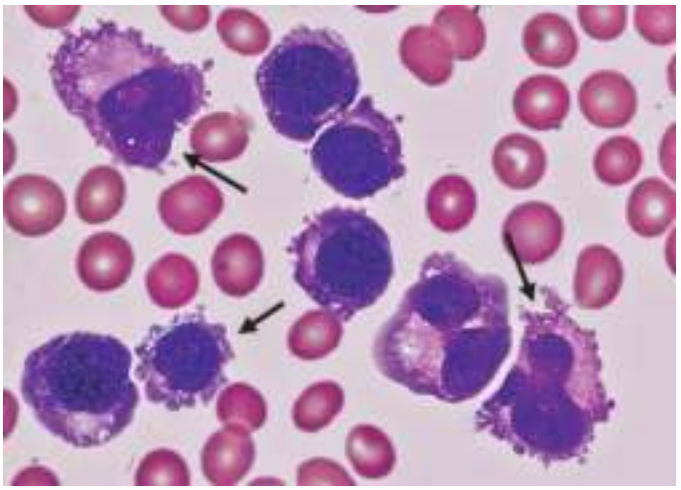

Fig. 9.53: Acute megakaryoblastic leukemia M7 (AMKL-M7, FAB) in Giemsa-stained bone marrow aspirate smear. It shows megakaryoblasts of variable in size. Some megakaryoblasts show cytoplasmic budding (arrows) (1000X).

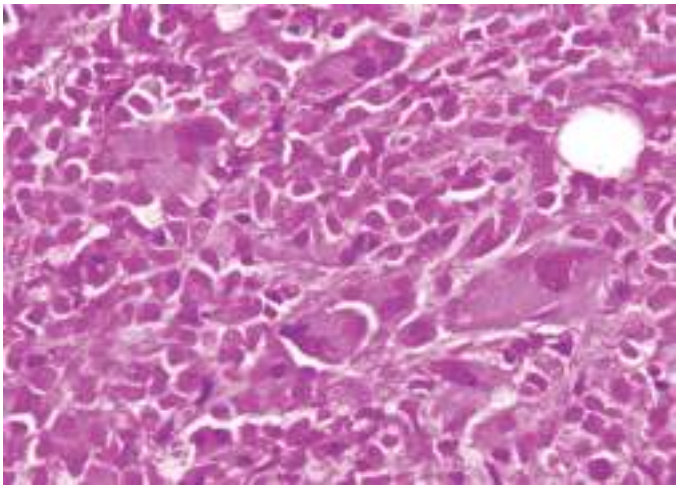

Fig. 9.54: Acute megakaryoblastic leukemia M7 (AMKL-M7, FAB) in hematoxylin and eosin-stained bone marrow trephine biopsy section. It shows extensive infiltration by blasts with sparse cytoplasm, frequent convoluted nuclei with fine chromatin and distinct nucleoli. Megakaryoblasts may be difficult to identify in bone marrow trephine biopsy. These may be present in small or large clusters surrounded by a network of reticulin fibers (400X).

- Cell of origin of myeloid sarcoma is believed to be the common myeloid progenitor cell. Cytogenetic abnormalities include t(8;21), inv(16), t(19;11)(p21;q23) and trisomy 8.
- Myeloid sarcoma tumor mass is composed of myeloblasts with or without maturation present in tissues outside bone marrow such as bone (periosteum) orbit, paranasal sinuses, skin, breast, gastrointestinal tract, mediastinum, pleura, ovary and lymph nodes.
- Myeloid sarcoma can occur *de novo* or initial manifestation of relapse in a patient previously diagnosed

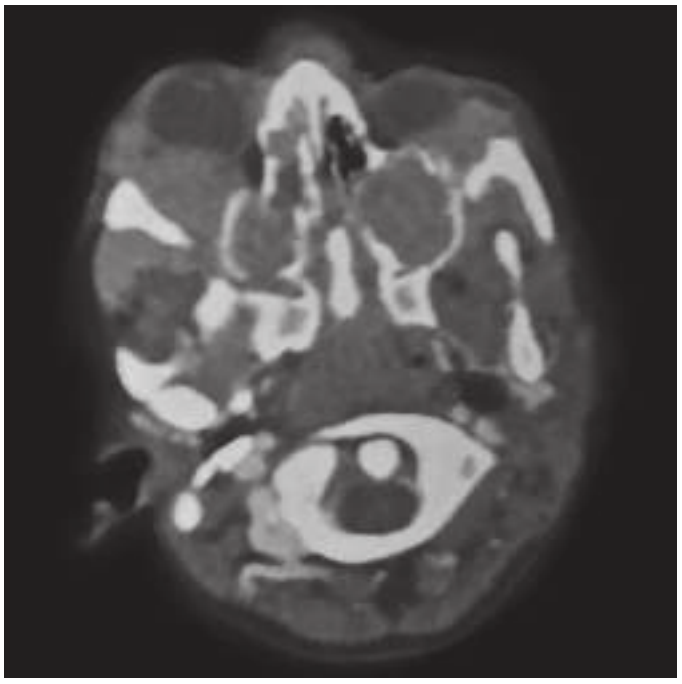

Fig. 9.55: Myeloid sarcoma involving nose and paranasal sinuses on CT scan. Axial contrast enhanced computed tomography (CECT) of the nose and paranasal sinuses reveals an enhancing soft tissue mass in bilateral nasal cavities and maxillary sinus with erosion of walls of maxillary sinus, extension into ethmoid sinuses, retroconal space of bilateral orbits and premaxillary space.

as AML, or chronic myelogenous leukemia (CML) with blast phase and/or other myelodysplastic/myeloproliferative disorders. It has varied clinical presentation depending on site involved.

- Diagnosis of myeloid sarcoma is challenging, that relies on radiology, histology, immunophenotyping and molecular analysis. Myeloid sarcoma involving nose and paranasal sinuses on CT scan is shown in Fig. 9.55.
- Patients of myeloid sarcoma are treated by surgery and radiotherapy. Allogeneic hematopoietic stem cell transplantation is beneficial in patients who achieve complete remission with AML-induction protocols.

Laboratory Diagnosis of Myeloid Sarcoma

Light Microscopy

Myeloid sarcoma tumor mass is composed of sheets of tumor cells arranged in cords admixed with or without promyelocytic or neutrophilic maturation that effaces the tissue architecture. Myeloid sarcoma in bone marrow trephine biopsy section from orbit is shown in Fig. 9.56.

Cytochemistry

Myeloperoxidase (MPO) positivity in myeloid sarcoma in bone marrow trephine biopsy is shown in Fig. 9.57.

Immunophenotyping

Panel of monoclonal antibodies is used to demonstrate tumor cells of myeloid sarcoma, which include cMPO, CD68, CD117, CD99, CD34, lysozyme, TdT, CD13, CD14, CD15, and CD33.

Markers	Expression
▪ cMPO	▪ Positive
▪ CD68	▪ Positive
▪ CD117	▪ Positive
▪ CD99	▪ Positive
▪ CD34	▪ Positive
▪ Lysozyme	▪ Positive
▪ TdT	▪ Positive
▪ CD13	▪ Positive
▪ CD14	▪ Positive
▪ CD15	▪ Positive
▪ CD33	▪ Positive

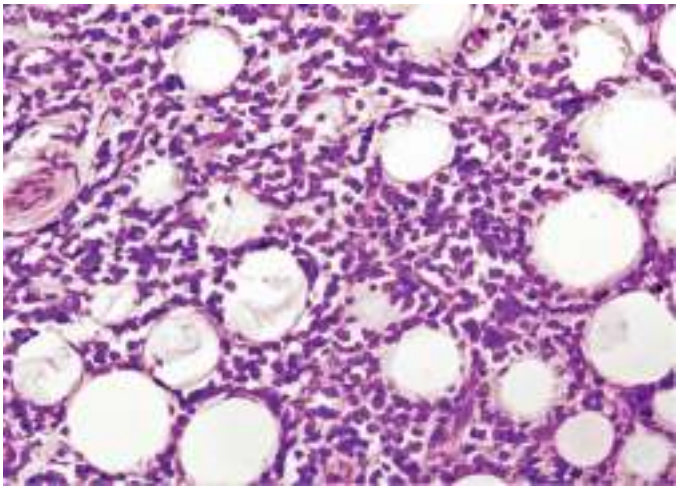

Fig. 9.56: Myeloid sarcoma. Bone marrow trephine biopsy section from orbit. It shows sheets of atypical cells infiltrating into surrounding adipose tissue (hematoxylin and eosin, 400X).

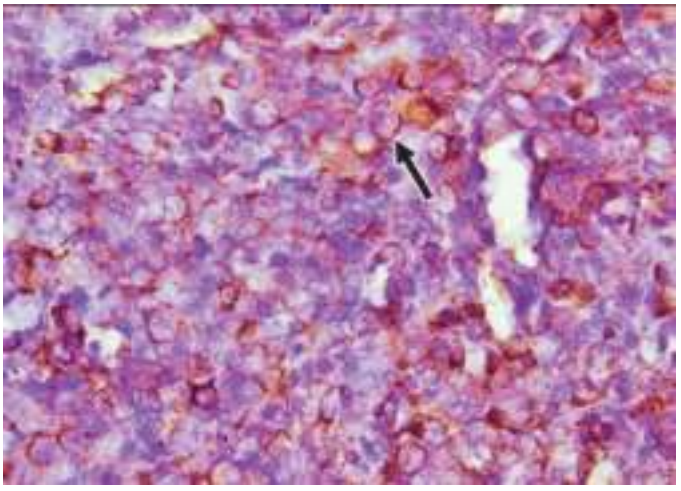

Fig. 9.57: Myeloperoxidase (MPO) positivity in myeloid sarcoma in bone marrow trephine biopsy (arrow) (300X).

ACUTE MYELOGENOUS LEUKEMIA, NOT OTHERWISE SPECIFIED (AML-NOS)

Leukemic myeloblasts in acute myelogenous leukemia, not otherwise specified (AML-NOS) are usually demonstrated on the Wright-Giemsa or May-Grünwald-Giemsa-stained peripheral blood smear, bone marrow aspirate smear; and hematoxylin and eosin-stained sections of bone marrow trephine biopsy. The results can be particularly informative, and attempts should be made to secure these records.

- A comprehensive clinical history should be taken of antecedent hematologic disorders including cancer diagnosis in the patient or family together, with history of occupational exposure to radiation, medication in treatment of cancer such as chemotherapy, radiation, or immunosuppressive drugs. The clinical history of the patient should be communicated to the pathologist together with results of relevant examination, laboratory, radiographic and other findings.
- Immunophenotyping by multiparameter flow cytometry, karyocyte (metaphase cytogenetics +/–FISH), molecular analysis (including NPM1, FLT3, KIT, CEBPA, TP53, RUNX1).
- Lumbar puncture should be performed if CNS symptoms appear. Immunophenotyping with a panel of monoclonal antibodies is particularly useful for distinguishing acute myelogenous leukemia from acute lymphoblastic leukemia (ALL) and for identification of acute myelogenous leukemia (AML) subtypes.
- Morphologic diagnosis of AML can be supported by the presence of Auer rods in the cytoplasm of myeloblasts, positive cytochemistry with Sudan black, and staining for myeloperoxidase and nonspecific esterase.
- Cytogenetic and molecular genetic alterations associated with the morphologic subtypes of acute myelogenous leukemia (AML) can further support the diagnosis and assist predict treatment outcomes.

Laboratory Diagnosis of Acute Myelogenous Leukemias, Not Otherwise Specified (AML-NOS)

Hematologic investigations of acute myelogenous leukemia include hemoglobin, total leukocyte count, differential leukocyte count, peripheral blood smear and bone marrow aspiration and trephine bone marrow biopsy. The quality of bone marrow specimen is critical for all subsequent analysis of molecular genetic alterations.

Hemoglobin and Blood Counts

- Hemoglobin is low. Total leukocyte count is 20×10^9/dl in acute myelogenous leukemia (AML) except in subleukemic leukemia.
- Platelet count is markedly reduced.

Peripheral Blood Smear Examination

Red blood cells

- Red blood cells are decreased, and hemoglobin <10 g/dl is common finding.
- Peripheral blood smear shows macrocytic picture because of their inability to successfully compete with the leukemic cells for folate or cobalamin and /or early release of reticulocytes.
- Red blood cell distribution (RDW) is usually elevated.
- Red blood cells demonstrate Howell-Jolly bodies.
- Pappenheimer bodies and basophilic stippling are indicative of red blood cell maturation defects.
- Nucleated red blood cells can be present in proportion to the anemia or bone marrow damage.

White blood cells

- Peripheral blood picture is quite variable in AML. Although, it is traditional to describe leukemias having increased white blood cells. About 50% of AML cases demonstrate decreased leukocyte count within the reference interval at the diagnosis.
- Leukocyte count ranges $<1 \times 10^9$/L to $>100 \times 10^9$/L. Regardless of the total leukocyte count, the presence of myeloblasts in the peripheral blood is suggestive of acute leukemia.
- The revised 2024 WHO classification of acute leukemia requires ≥20% blasts in the bone marrow or peripheral blood smears. These AML cases must be classified based on morphologic features, cytogenetic, molecular genetic diagnostic techniques.
- Myeloblasts in AML measure 20 µm in diameter and contain large nucleus composed of dispersed chromatin (euchromatin or transcriptionally active) with prominent 3–5 nucleoli.
- Myeloblasts contain linear Auer rods composed of crystallized azurophilic granular material that form elongated needles in the cytoplasm demonstrated under light microscopic examination. Auer rods are composed of fused lysosomes and contain lysosomal enzymes, peroxidase and larger crystalline inclusions. Auer rods are demonstrated in AML-M2, AML-M3 and CML with blast phase. The presence of Auer rods in myeloblasts in AML cases excludes ALL.
- Buffy coat should be prepared to demonstrate blasts in cases with low leukocyte count $<2 \times 10^9$/L.

Platelets

- Peripheral blood picture shows thrombocytopenia. Hypogranular platelets and occasional giant platelets can be present.
- As the disease advances, more immature platelets such as megakaryocytic fragments can be demonstrated.
- The platelet count might not correlate with the potential complication of bleeding because of the presence of qualitative platelet defects.

Other abnormal hematologic findings

Other abnormal hematologic findings demonstrated on the peripheral blood smear include monocytosis and neutropenia. Monocytosis usually precedes overt leukemia.

- Neutrophils can exhibit signs of dysplasia including hypo-segmentation, hypogranulation and small nuclei increased condensed chromatin. Signs of myelodysplasia are especially demonstrated in acute promyelocytic leukemia. There can be mild to moderate increase in the eosinophils and basophils.
- Presence of basophil differentiates AML from leukemoid reactions. Absolute basophil is absent in leukemoid reactions.
- Blast of chronic myelogenous leukemia (CML) should be excluded by evaluating BCR-ABL1.

Bone Marrow Smear Examination

Bone marrow analysis should include bone marrow aspiration and trephine bone marrow biopsy. The quality of bone marrow specimen is critical for all subsequent analysis such as cytogenetic and molecular genetic analysis.

- **Cellularity:** Bone marrow is hypercellular with high myeloid to erythroid ratio; and with decreased fat content. Bone marrow contains predominant myeloblasts and sometimes an increase in fibrosis.
- **Myeloid lineage:** Bone marrow demonstrates predominance of blasts. According to revised 2024 WHO classification, cut off percentage of blasts is ≥20%, which represents a change from original guidelines where ≥30% blast cells were considered as per FAB classification criteria. Frequently the blast count is close to 100%. Auer rods are demonstrated in bone marrow myeloblasts in 50% of cases. Differentiating features of myeloblast and lymphoblast in acute leukemias are given in Table 9.43.
- **Erythroid lineage:** Erythroid precursors are reduced as a result of increase in number of myeloblasts or suppression of hematopoietic stem cell.
- **Megakaryocytic lineage:** Megakaryopoiesis is markedly reduced.

Bone Marrow Trephine Biopsy Examination

- Bone marrow trephine biopsy is performed in patients with dry tap in bone marrow aspiration in acute myelogenous leukemia, not otherwise specified (AML-NOS) with pancytopenia. It demonstrates clumps of myeloblasts, occasionally forming sheets of infiltrate that disturb the usual bone marrow architecture.
- Bone marrow fibrosis is demonstrated by reticulin stain. In addition to the light microscopic morphologic evaluation, bone marrow samples should be analyzed for flow cytometry, cytogenetic and molecular genetic alterations analysis.
- Immunophenotyping is performed using anti-MPO, CD13, CD33, CD15, CD11b, and HLA-DR to confirm diagnosis.

DIAGNOSTIC APPROACH

A diagnosis of acute myelogenous leukemia, not otherwise specified (AML-NOS) requires the presence of at least ≥20% blasts in the bone marrow or peripheral blood. It is important to recognize that promonocytes are considered blast equivalents for the purpose of defining an acute myelogenous leukemia. Diagnostic tools for diagnosing acute myelogenous leukemia include cytomorphologic study, cytochemistry, immuno-phenotyping, cytogenetic and molecular alterations analysis.

Cytochemistry

The common cytochemical stains used in diagnosing AML-NOS include the myeloperoxidase (MPO), Sudan black B (SBB), naphthol AS-D chloroacetate esterase (specific esterase) and α-naphthyl acetate esterase (nonspecific esterase).

- Granulocytic cells are positivity for myeloperoxi-dase and with Sudan black B stain, whereas lympho-blasts are negative. Thus, cytochemical stains help in differentiating acute myelogenous leukemia from acute lymphoblastic leukemia.
- The esterase stains help in differentiating precursor granulocytic cells from precursor monocytic cells. Granulocytic cells stain positive with naphthol AS-D chloroacetate esterase (specific esterase), and cells of monocytic lineage stain positive with α-naphthyl acetate esterase (nonspecific esterase).
- Cytochemical stains are useful in cases not defined by immunophenotyping and cytogenetic analysis being used as first-line tests to define cell lineage. Cytochemistry in acute myelogenous leukemia according to French-American-British classification is given in Table 9.44.

Immunophenotyping

Immunophenotyping by low cytometry or immuno-histochemistry can be used to demonstrate terminal deoxynucleotidyl transferase (TdT) in cells. TdT was thought to be specific marker for lymphoid cell lineage. But TdT is also demonstrated on more immature hematopoietic stem cells, sometimes including those of myeloid lineage. Therefore, TdT cannot be the sole determinant of lymphoid lineage.

- Immunophenotyping by flow cytometry is an essential diagnostic tool in acute leukemia classification by using a specific sequence of testing with monoclonal antibodies. Commonly cell markers used in identification include CD2, CD3, CD4, CD5, CD10, CD13, CD14, CD15, CD16, CD19, CD22, CD33, MPO, HLA-DR, CD34, CD45, CD56, CD64 and CD117.
- The first panel of monoclonal antibodies used in flow cytometry should differentiate AML from ALL, and ALL-B cell origin from ALL-T cell origin.
- Monoclonal antibodies (CD19, CD20, CD22, CD79a) used in flow cytometry demonstrate B lymphoid cell antigens.

Table 9.43 Differentiating features of myeloblast and lymphoblast in acute leukemias

Parameters	Myeloblast in AML	Lymphoblast in ALL
Morphologic features		
Size of blast	Large size	Small size
Cytoplasm	Scant to moderate	Scant basophilic cytoplasm
Cytoplasmic granules	Cytoplasmic granules present	▪ Cytoplasmic granules rarely present ▪ Negative for myeloperoxidase stain and toluidine
Nuclear chromatin	Fine chromatin, delicately dispersed	▪ Fine chromatin, with dispersed ▪ Very condensed in small lymphoblasts
Nuclear membrane	Fine	Relatively dense
Nucleoli number	3–5	1–2
Auer rods	Present, especially in acute promyelocytic leukemia (hypergranular form)	Always absent
Cytochemistry		
Myeloperoxidase	Positive	Negative
Sudan black B (SBB)	Positive	Negative
Periodic acid–Schiff stain	Negative	Positive
Acid phosphatase	Negative	Positive
Nonspecific esterase	Negative, positive in AML-M4, AML-M5	Negative
Lineage markers		
Cluster of differentiation	CD13, CD15, CD33, CD11b, TdT	▪ B cell: CD10, CD19, CD79a, TdT ▪ T cell: CD3
Therapeutic response		
Chemotherapeutic agents	Cytosine, arabinoside, anthracycline, 6-thioguanine	Vincristine, anthracycline, prednisone, L-asparaginase
Response to therapy	Remission of short duration	Remission of long duration
Median survival	12–18 months	Children with CNS involvement for 5 years; and adults for 8–12 years

Table 9.44 Cytochemistry in acute myelogenous leukemia according to French-American-British classification

FAB Class and Features	Morphologic Features	Cytochemistry
AML-M0 minimal differentiated	Minimal evidence of myeloid differentiation (without maturation with agranular cytoplasm)	Myeloperoxidase stain positive (<3%)
AML-M1 without maturation	▪ High percentage of myeloblasts without significant maturation to more mature neutrophils, blasts demonstrate ▪ Auer rods are present in myeloblasts	Myeloperoxidase stain positive (>3%)
AML-M2 with maturation	All stages of neutrophil maturation, pseudo-Pelger-Hüet anomaly, hypogranulation	Myeloperoxidase stain positive (>10%)
AML-M3	Acute promyelocytic leukemia (APL) with hypergranular cytoplasm with bilobed heavy contour	Myeloperoxidase stain positive
AML-M3m	Acute promyelocytic leukemia (APL) with microgranular variant	Myeloperoxidase stain positive
AML-M4	Acute myelomonocytic leukemia (monocytes and promonocytes in the bone marrow exceed 20%)	▪ Myeloperoxidase stain positive ▪ Nonspecific esterase stain positive

Contd...

Table 9.44 Cytochemistry in acute myelogenous leukemia according to French-American-British classification (*Contd...*)

FAB Class and Features	Morphologic Features	Cytochemistry
AML-M4Eo	Acute myelomonocytic leukemia with abnormal eosinophils (>5%)	▪ Myeloperoxidase stain positive ▪ Nonspecific esterase stain positive
AML-M5A (acute monoblastic leukemia without differentiation)	Monoblasts/monocyte dominance (≥80%), hemophagocytosis, nuclear lobulation	Nonspecific esterase (NSE) stain positive
AML-M5B (acute monoblastic leukemia with differentiation)	Monoblasts/monocyte dominance	Nonspecific esterase (NSE) stain positive
AML-M6 (acute erythroid leukemia)	▪ >50% erythroid precursors ▪ >20% myeloblasts in the nonerythroid cell population ▪ Megakaryoblastoid morphology ▪ Auer rods +/– in leukemic blasts	▪ Periodic acid–Schiff (PAS) positive ▪ Glycophorin positive
AML-M7 (acute megakaryocytic leukemia)	Cytopenia with or without thrombocytopenia, basophilic agranular blasts with pseudopods, micro-megakaryocytes	Platelet peroxidase positive

MPO: Myeloperoxidase; PAS: Periodic acid–Schiff; CD: Cluster of differentiation; Myeloid markers: CD13, CD33; Monocyte markers: CD11, CD14.

- T lymphoid cell antigens are demonstrated by using monoclonal antibodies (CD2, CD3, CD5, CD7). Human leukocyte antigen DR (HLR-DR) antigens are present on both myeloid and lymphoid cells.
- Several aberrant antigens are sometimes demonstrated on the leukemic myeloid cells in AML (CD7, lymphoid cell antigen). CD34 marker is also demonstrated on the least differentiated myeloid cells and early lymphoid cells.
- The monoclonal antibodies that react with most cases of AML include CD13, CD15, CD33, CD64 and CD117.
- In addition, monoclonal antibody that identifies myeloperoxidase (MPO) is employed especially when cytochemistry for MPO is negative.
- Differentiation of acute myelogenous leukemia from acute lymphoblastic leukemia using immunophenotyping with selected monoclonal antibodies is given in Table 9.45. Expression of cell-surface and cytoplasmic markers for the diagnosis of acute myelogenous leukemia and mixed-phenotype acute leukemia are given in Table 9.46.

Cytogenetic Analysis

About 66% of AML patients have detectable cytogenetic abnormalities that include aneuploidies (variation in number of chromosomes) and chromosomal translocation. Commonly demonstrated aneuploidies include trisomy 8, trisomy 21, monosomy 7, and loss of an X or Y chromosome.

- Chromosomal translocations result in fusion genes, that are either beneficial for proliferation and survival of cells or disrupting differentiation and maturation of myeloid cells. Additional genetic abnormalities can develop in subclones as the disease progresses.
- Characteristics of nonrandom cytogenetic abnormalities are demonstrated in the revised 2024 WHO classification of acute myelogenous leukemia with recurrent genetic alterations and in therapy-related myeloid neoplasms. These genetic abnormalities are analyzed by cytogenetic analysis, fluorescence *in situ* hybridization (FISH) or molecular genetic studies.

Table 9.45 Differentiation of acute myelogenous leukemia from acute lymphoblastic leukemia using immunophenotyping with selected monoclonal antibodies

Leukemia Type	Cell Marker				
	HLA-DR	CD13, CD33, CD15, CD11b	CD19, CD20, CD22, CD79a	CD10	CD2, CD3, CD5, CD7
AML	+	+	–	–	–
ALL-B cell origin	+	–	+	+	–
ALL-T cell origin	–	–	–	+/–	+

Flow cytometry or immunohistochemistry can be used to demonstrate terminal deoxynucleotidyl transferase (TdT) in cells. TdT was thought to be a lymphoid specific marker. But TdT is also demonstrated on more immature hematopoietic cells, sometimes including those of myeloid lineage. Therefore, TdT cannot be the sole determinant of lymphoid lineage.
AML: Acute myelogenous leukemia; ALL: Acute lymphoblastic leukemia.

Table 9.46 Expression of cell-surface and cytoplasmic markers for the diagnosis of acute myelogenous leukemia and mixed-phenotype acute leukemia

Cell Lineage	Expression of Marker
Diagnosis of acute myelogenous leukemia	
Precursor cells	CD34, CD38, CD117, CD133, HLA-DR
Granulocytic markers	CD13, CD15, CD16, CD33, CD65, cytoplasmic myeloperoxidase (cMPO)
Monocytic markers	CD11b, CD11c, CD14, CD64, CD4, CD36, NG2 homologue, lysozyme, nonspecific esterase (NSE)
Megakaryocyte markers	CD41 (glycoprotein IIb/IIIa), CD61 (glycoprotein IIIa), CD42 (glycophorin Ib)
Erythroid cell markers	CD235a (glycophorin A member of glycoprotein family)
Diagnosis of mixed-phenotype acute myelogenous leukemia (MPAL)	
Myeloid lineage markers	MPO or evidence of monocytic differentiation (at least two of the following: NSE, CD11c, CD14, CD64, lysozyme)
B cell lineage markers	CD19 (strong positivity) with at least one of the following: CD79, cCD22, CD10
T cell lineage markers	cCD3, or surface CD3

- Molecular genetic alterations and morphologic features used to classify acute myelogenous leukemia (AML) with recurrent cytogenetic abnormalities are given in Table 9.47. Morphologic features in AML with t(8;21) (q22;q22) are given in Table 9.48. Salient features for laboratory diagnosis of acute myelogenous leukemia (AML) with inv (16) (p13q22) or t(16;16(p13; q22) are given in Table 9.49.

Table 9.47 Cytogenetic and morphologic features used to classify acute myelogenous leukemia (AML) with recurrent cytogenetic abnormalities

AML with Recurrent Molecular Genetic Alterations	Morphologic Features, Cytogenetics, Immunophenotypes	Comments
AML with t(8;21)(q22;q22); RUNX1-RUNX1T1 fusion gene involved in activation of other genes and cellular proliferation	▪ Similarity to FAB AML-M2 affecting children and adults <60 years ▪ Subcategory accounts for 5–10% of AML cases ▪ Maturation in the neutrophilic lineage (promyelocytes, myelocytes and mature neutrophils) with dysplasia in bone marrow ▪ Auer rods in myeloblasts ▪ Pseudo-Pelger-Hüet nuclear abnormality ▪ Immunophenotyping: CD34+, CD30+, HLA-DR+, MPO++, CD15+, CD33+ ▪ Aberrant markers: CD19+, PAX5+, cCD79a+	▪ Secondary genetic defects: deletion of Y chromosome and 9q ▪ Young persons may present with myeloid sarcoma ▪ Good response to chemotherapy ▪ Poor prognosis with KIT mutations
AML with inv(16) (13; q22) or t(16;16)(p13;q22) or t(16;16)(p13.1;q22); CBFβ-MYH11	▪ Similarity to FAB AML-M4 ▪ Subcategory accounts for 7% of AML cases ▪ CBFβ-MYH11 fusion proteins binds to RUNX1 and represses its function as transcription factor ▪ Maturation in both neutrophil and monocytic lineage, abnormal eosinophils (AMMLE0) ▪ Eosinophils ≥5% with abnormal eosinophilic granules present in promyelocyte or myelocyte stage ▪ Immunophenotyping: blasts with granulocyte differentiation: CD13, CD33, CD65+, MPO+ ▪ Immunophenotyping: blasts with monocytic differentiation: CD14, CD11b, CD11c, CD64, CD36, lysozyme ▪ Aberrant marker: CD2	▪ Secondary genetic defects: +22, +8, 21+ deletion 7q ▪ Young persons may present with myeloid sarcoma ▪ Good prognosis with +22 ▪ Poor prognosis with KIT mutations

Contd...

Table 9.47 Cytogenetic and morphologic features used to classify acute myelogenous leukemia (AML) with recurrent cytogenetic abnormalities (*Contd...*)

AML with Recurrent Molecular Genetic Alterations	Morphologic Features, Cytogenetics, Immunophenotypes	Comments
AML with t(9;11) (p22;q23); MLLT3-MLL	▪ Similarity to FAB AML-M4, AML-M5 usually associated with monocytic features usually affecting children and any age group ▪ MLL gene (11q23) protein, a DNA binding protein that interacts with other nuclear proteins and help other transcription factors ▪ Monoblasts and promonocytes predominate, can demonstrate granules and vacuoles ▪ Immunophenotyping: CD34+ CD33+, CD65, HLA-DR++, CD13+, CD14+/– ▪ Aberrant marker: CD2	▪ Secondary genetic defect: +8 ▪ Children present with gingival infiltration by leukemic cells and clinical manifestations of disseminated intravascular coagulation ▪ Intermediate prognosis
Acute promyelocytic leukemia with t(15;17) (q22;q12);PML-RARA and various chromosomal translocations	▪ Similarity to FAB AML-M3, AML-3v associated with abnormal promyelocytes ▪ Hypergranular variant with predominant promyelocytes and multiple Auer rods in one cell ▪ Microgranular variant with bilobed nuclei without visible granularity ▪ Immunophenotyping in homozygous: CD33+ CD13+; and heterozygous ▪ Immunophenotyping in heterozygous: HLA-DR+, CD34–	▪ Secondary genetic defect: chromosome 8+, FLT3-ITD ▪ Adult persons present with clinical manifestations of disseminated intravascular coagulation such as bleeding treated by heparin therapy
AML with t(6;9)(p23;q34); DEK-NUP214	▪ Resembles FAB AML-M2, AML-M4 ▪ With or without monocytic features and often associated with basophilia and multilineage dysplasia ▪ Immunophenotyping: MPO+, CD13+, CD33+, CD38++, HLA-DR ▪ Aberrant marker: TdT	▪ Secondary genetic defects: FLT3-ITD ▪ Children and adults present with pancytopenia or anemia with thrombocytopenia ▪ Poor prognosis
AML with inv(3)(q21;q26) or t(3;3) (q21;q26.2); RPN1-EV11	▪ Resembles FAB AML-M1, AML-M4, AML-M7 ▪ Associated with elevated platelets and atypical megakaryocytes (monolobed or multilobed nuclei) with multilineage dysplasia ▪ Immunophenotyping: CD34+, HLA-DR+, CD13+, CD33+, CD41, CD61+ ▪ Aberrant marker: CD7	▪ Secondary genetic defect: monosomy 7, deletion 5q ▪ Disorder in adults arises *de novo* or MDS presents with hepatosplenomegaly with aggressive clinical course
AML with t(1;22)(p13;q13); RBM15-MLK1	▪ Resembles FAB AML-M7 ▪ Megakaryocytic lineage with maturation (small and large size) ▪ Immunophenotyping:CD34++, HLA-DR, CD41+, CD61+, CD42+, CD13+, CD45– ▪ Aberrant marker absent	▪ Secondary genetic defects: absent ▪ Infants and young children in <3 years present with hepatosplenomegaly ▪ Patients respond to intensive chemotherapy
AML with mutation in nucleophosmin 1 (NPM1) associated with other gene abnormalities, FLT-ITD	Myelomonocytic or monocytic features present in older people with high blood counts and a normal karyocyte	Secondary genetic defects: chromosome 8+, 4+, 21+, loss of Y, deletion of 9q
AML with biallelic CEBPα mutation, tumor suppressor gene encodes transcription factor involved in granulopoiesis	Myeloid leukemia with or without maturation, can demonstrate myelomonocytic or monoblastic features	Prognosis favorable

Table 9.48 Morphologic features in acute myelogenous leukemia (AML) with t(8;21) (q22;q22)

French-American-British (FAB) AML-M2 morphology
Mature and immature myeloid cells contain abundant Auer rods
Myeloid cells contain salmon-colored granules in the cytoplasm and a rim of basophilic cytoplasm
Pseudo-Chédiak-Higashi anomaly present
Cells contain pink, waxy cytoplasmic globules
Large size blasts with prominent Golgi area
Cells contain cytoplasmic vacuoles
Bone marrow eosinophilia (>5%)

PROGNOSTIC FACTORS

Powerful prognostic factors established over decades include age over 60 years, cytogenetic abnormalities, prior myelodysplastic syndrome, and treatment-related AML supplemented by molecular genetic abnormalities. Prognostic factors variable associated with treatment outcomes include age of the patient, AML arising from pre-existing MDS, treatment related-AML, performance status, extramedullary disease, and comorbid conditions. Prognostic factors of acute myelogenous leukemia according to French-American-British classification are given in Table 9.50.

- The best pretreatment prognostic predictors of long-term outcome, together with age include chromosomal and molecular genetic alterations in the leukemic cells in AML cases.
- Cytogenetic analysis is the basis of stratification of AML patients into three risk categories with different response to chemotherapy and long-term outcomes. Stratification of acute myelogenous leukemia (AML) patients into three risk groups based on molecular genetic alterations is given in Table 9.51.

Table 9.49 Salient features for laboratory diagnosis of acute myelogenous leukemia (AML) with inv(16)(p13;q22) or t(16);16(p13;q22)

Karyotypic Analysis AML with inv(16)(p13;q22) or t(16);16(p13;q22)
Molecular Characterization of CBFb-MYH11 Fusion Gene by Following Techniques ▪ Fluorescence *in situ* hybridization (FISH) ▪ Real-time reverse transcriptase (RT-PCR)
Bone Marrow ▪ Myeloblasts and monoblasts ≥20% in the bone marrow; <20% acceptable when typical karyotype or molecular pattern is demonstrated ▪ Eosinophils >5% in the bone marrow, absence of eosinophilia; and eosinophils with abnormality in cytoplasmic granules and cytochemical stain

Contd...

Immunophenotyping by Flow Cytometry	
Leukemic Cells	**Markers**
Myelomonocyte markers	▪ CD13+ ▪ CD33+ ▪ CD14+ ▪ CD11b+ ▪ CD11c+ ▪ Myeloperoxidase (MPO)+
Immature cell markers	▪ CD34+ ▪ CD117+
Marker expressed by myeloid and T cell	CD2+

Table 9.50 Prognostic factors of acute myelogenous leukemia according to French-American-British classification

Characteristics	Favorable Prognosis	Poor Prognosis
Age group	<40 years	<2 years and >60 years in AML-M0, AML-M6, AML-M7
Sex distribution	Females	Males
Origin	*De novo*	Therapy-induced or in MDS
Infections	Absent	Present (AML-M5)
Total leukocyte count	<25000/cumm	>100,000/cumm
Serum LDH	<400 IU/L	>400 IU/L
Extramedullary involvement	Absent	Present
CNS involvement	Absent	Present
Cytogenetics	▪ AML-M2; t(8.21) ▪ AML-M3; t(15;17) ▪ AML-M4; inversion (16)	▪ AML-M2; t(6;9) ▪ AML-M5; translocation or deletion of chromosome 5

Contd...

Table 9.50 Prognostic factors of acute myelogenous leukemia according to French-American-British classification (*Contd...*)

Characteristics	Favorable Prognosis	Poor Prognosis
Molecular genetics	▪ NPM1 gene mutation (5q35) ▪ Biallelic CEBPA gene mutation (19q13.1)	▪ FLT3 gene mutation (13q12) ▪ WT1 gene mutation (11p13) ▪ KIT mutation (4q11, q12) ▪ BALLC overexpression (8q22.3) ▪ ERG overexpression (21q22.3) ▪ EVI1 overexpression (3q;26) ▪ MN1 overexpression (22q.12.1)
Immunophenotype	▪ CD34 negative ▪ CD14 negative ▪ HLA-DR negative	▪ CD34 positive ▪ HLA-DR positive

Immunophenotype markers are studied in bone marrow smears and bone marrow trephine biopsy specimens. Other parameters such as angiogenesis and proliferative index are also studied.

Table 9.51 Stratification of acute myelogenous leukemia patients into three risk groups based on molecular genetic alterations

Risk Status	Molecular Genetic Alterations in AML
Favorable prognosis	▪ AML with inv(16)(p13.1;q22) or t(16;16)(p13.1;q22);CBFB-MYH11 ▪ AML with t(8;21)(q22;q22); RUNX-RUNX1T1 ▪ AML with t(15;17) ▪ AML with NPM1 mutation in absence of FLT3-ITD ▪ AML with isolated biallelic CEBPα mutation
Intermediate prognosis	▪ AML with normal cytogenetics ▪ AML with chromosome +8 ▪ AML with t(9;11) ▪ AML with t(8;21), inv(16), t(16;16) with c-KIT mutation ▪ AML with not defined as better- or poor-risk status ▪ AML with NPM1 and FLT3-ITD (normal karyotype) and wild-type NPM1 ▪ AML with FLT3-ITD (normal karyotype) and wild type NPM1 without FLT3-ITD
Adverse prognosis	▪ AML with complex karyotype (≥ clonal chromosomal abnormalities) ▪ AML with monosomal karyotype ▪ AML with complex karyotype –5, del(5q)–7,17q ▪ AML with 11p23-non t(9;11) ▪ AML with inv(3)(q21;q26.2) or t(5,3)(q21;q26.2); RPN1-EVI1 ▪ AML with t(6;9)(p23;q34); DEK-NUP214 ▪ AML with t(v;11)(v;q23); MLL rearranged ▪ AML with t(0;22) ▪ AML with normal cytogenetics with FLT3-ITD mutation ▪ AML with TP53 mutation

NPM1: Nucleophosmin 1; FLT3-ITD: Fms-like tyrosine 5-internal tandem duplications; c-KIT; CD117 receptor tyrosine kinase; CEBPA or CCAAT/enhancer binding protein α.

- About 40–50% of AML cases demonstrate a normal karyotype at the time of diagnosis. Absence of NPM1 or FLT3-ITD or isolated biallelic CEBPA gene mutations, is linked to intermediate risk group. Frequency and prognostic impact of gene mutations in acute myelogenous leukemia (AML) is given in Table 9.52. These gene mutations provide substantial insights into the pathogenesis of AML and assist in identification of molecular targets for treatment of these patients.

TREATMENT

Basic aim of management of AML patients is to achieve remission after initial therapy. Except for acute

Table 9.52 Frequency and prognostic impact of gene mutations in acute myelogenous leukemia (AML)

Gene Mutation	Frequency	Comments
Favorable prognosis		
NPM1*	25–30%	Favorable prognosis in natural killer cell-based immunotherapy for AML
CEBPα (biallelic)*	≤5%	Favorable prognosis in isolated biallelic CEBPA mutation in AML
Intermediate prognosis		
KIT	≤5%	Intermediate prognosis when AML is associated with t(8;21), inv(16) karyotype
Poor prognosis		
FLT3-ITD*	20–25%	Poor prognosis in natural killer cell-based immunotherapy for AML but no prognostic significance in acute promyelocytic leukemia (APL)
TP53	≤6%	Poor prognosis in natural killer cell-based immunotherapy for AML
WT1	≤6%	Resistant AML disease associated with poor prognosis
RUNX1	9–10%	Resistant AML disease associated with poor prognosis
Undefined prognosis		
DNMT3A	18–25%	Unclear prognostic significance in AML, and may be demonstrated in healthy persons
IDH1 and IDH2	17–20%	Prognosis of AML varies based on combinations of genotypes (DNMT3 mutations)
TET2	≤10%	Co-mutated with NPM1, chromatin-spliceosome genes in AML

**Mutations of genes are already demonstrated within clinical guidelines.*
CEBPA or CCAAT/enhancer binding protein alpha; FLT3-ITD: Fms-like tyrosine 5-internal tandem duplications; IDH1/2: Isocitrate dehydrogenase 1 and 2; NPM1: Nucleophosmin 1; RUNX1: Runt-related transcription factor 1; CEBPA or CCAAT/enhancer binding protein alpha; TET2: ten-eleven-translocation 2; WT1: Wilms' tumor 1, DNMT3 alpha; DNA-methyltransferase 3A.

promyelocytic leukemia, it is challenge for the clinician to determine if the patient is candidate for intensive cytotoxic therapeutic agents. The patients are treated in two phases: remission induction and post-remission therapy.

- The goal of remission induction phase is to achieve a hematologic complete remission with incomplete hematologic recovery currently defined as meeting response criteria for at least four weeks, i.e. <5% of blasts in the bone marrow, no blasts with Auer rods, normal maturation of all cellular components in the bone marrow and absence of extramedullary disease.
- Acute promyelocytic leukemia M3 (AML-M3) is a well-defined disease with characteristic morphology and potentially life-threatening coagulopathy, i.e. disseminated intravascular coagulation (DIC) at presentation, but overall better prognosis than another AML subgroup.
- AML-M3 is treated by targeted therapy directed against the leukemogenic event, t(15.17) PML-RARA fusion transcript to improved outcome. Acute promyelocytic leukemia now represents most curable leukemia treated by administration of nontoxic cytotoxic chemotherapeutic drugs such as all-*trans* retinoic acid (ATRA) and arsenic trioxide (ATO).

Initial Management

The early management of AML patients should be organized and implemented by an experienced team. Tests/procedures in the initial management of acute myelogenous leukemia are given in Table 9.53.

Newer Treatment Modalities

The traditional chemotherapy for AML is designated to reduce the tumor load as rapidly as possible. Most commonly used therapeutic agents in patients <60 years include a combination of cytarabine by intravenous infusion over 7 days with 3 days of an anthracycline (daunorubicin or idarubicin) regimen. Complete remission is achieved in 60–85% in patients younger than 60 years. However, complete remission varies depending on subtype of AML.

- Newer treatment modalities for AML patients include molecular targeted therapies (e.g. ATRA), epigenetic-targeted therapies (demethylating agents, histone deacetylase inhibitors), and autologous or allogeneic hematopoietic stem cell (HSC) transplantation and infusion of donor lymphocytes with total body irradiation to enhance leukemic cell destruction. Current research is being focused on novel therapies

Table 9.53 Tests/procedures in the initial management of acute myelogenous leukemia

Tests to Establish Diagnosis
Complete blood counts and differential blood counts
Examination of peripheral blood smear
Bone marrow aspiration for morphology, cytochemistry, cytogenetics, molecular genetics and flow cytometry
Bone marrow trephine biopsy for pretreatment leukemic bone marrow sample and mandatory with a dry bone marrow aspirate
Immunophenotyping
Cytogenetic abnormalities such as RUNX1-RUNX1T1, CRFB-MYH11, PML-RARA or other fusion gene screening should be performed if chromosome morphology is of poor quality
Additional Tests/Procedures at Diagnosis
History and clinical examination
Performance status (ECOG/WHO score)
Analysis of comorbidities
Serum biochemistry includes glucose, sodium, potassium, calcium, uric acid, total glycerides, creatinine phosphokinase (CPK)
Evaluation of renal and kidney function tests: urea, creatinine, aspartate aminotransferase (AST), alanine aspartate transferase (ALT), alkaline phosphatase, lactic dehydrogenase, bilirubin, total serum proteins
Coagulation tests include prothrombin time, international normalized ratio (INR), activated partial thromboplastin time (APTT), fibrinogen, D-dimer
Urine analysis includes pH, glucose, proteins, red blood cells, leukocytes, nitrite
Serum pregnancy test in women with childbearing age
Information on oocyte and sperm cryopreservation: cryopreservation to be performed in accordance with consent of the patient
Human leukocyte antigen (HLA) typing and cytomegalovirus of patients eligible for allogeneic hematopoietic stem cell transplantation: ▪ Hepatitis A, B, C, herpes simplex virus (HSV), cytomegalovirus and HIV-1 testing ▪ Chest radiograph ▪ Electrocardiogram
Lumbar puncture in extramedullary disease in patients at high risk of CNS involvement (symptoms of intracranial bleeding, leptomeningeal disease, and mass lesion) especially in FAB AML-M4 or AML-M5
Biobanking should be performed in general practice
Prognostic/Predictive Marker Assessment
NAM1, CEBPA, FLT3 gene mutation: strongly encouraged in AML with normal karyotype
WT1, RUNX1, MLL, KIT, RAS, TP53, TET2, IDH1 gene mutation
ERG, MN1, EV11, BAALC gene expression
Detection of minimal residual disease (MRD)

including the use of monoclonal antibodies and gene therapy and destruction of the bone marrow cellular matrix that supports the leukemic cells.

- Peripheral blood smear examination is essential for blood counts such as leukocytes and platelets during chemotherapy.
- Patients treated by chemotherapeutic agents, development of pancytopenia, severe granulocytopenia and/or thrombocytopenia should be monitored, so that early intervention can be initiated by blood transfusions and administration of hematopoietic growth factors to induce hematopoiesis.
- Allogeneic or autologous HSC transplantation remains the only therapeutic choice that currently provides the prolonged ≥10 years disease-free survival for most of AML patients.

MYELODYSPLASTIC SYNDROMES

MYELODYSPLASTIC SYNDROMES: OVERVIEW

Myelodysplastic syndromes (MDSs) are considered primary neoplastic, pluripotent hematopoietic stem cell (HSC) disorders of the bone marrow, which most often involve the myeloid progenitor lineage cells; however, the lymphoid lineage cells are rarely affected.

- Myelodysplastic syndrome (MDS) is characterized by one or more peripheral blood cytopenias, with prominent maturation abnormalities (dyspoiesis or dysplasia) in the bone marrow and genetic instability.
- Peripheral blood cytopenias result from ineffective erythropoiesis and increased apoptosis of hematopoietic cells as evidenced by an accompanying bone marrow hyperplasia. Morphologic dysplastic changes can be demonstrated in the erythroid cells, myeloid cells and megakaryocytes with genetic instability.
- Myelodysplastic syndromes most affect middle-aged and elderly persons. However, these are diagnosed occasionally in children.
- The term myelodysplasia is more appropriate until the patient actually develops overt leukemia. Approximately 30–50% cases of myelodysplastic syndrome may develop acute myelogenous leukemia (AML).
- Myelodysplastic changes may be detected in healthy persons during aging process. Some persons may show persistent cytopenia without dysplastic change due to unknown etiology, which are considered as pre-phases of MDS. These persons may later develop hematologic neoplasms in life.
- Recently, molecular, genetic and flow cytometry-based techniques may help in the delineation of these cases. Some authors proposed classification of pre-phase of MDS cases with minimum diagnostic criteria to delineate from myelodysplastic syndrome and myelodysplastic neoplasms.
- Revised 2024 WHO classification of myelodysplastic syndromes and myelodysplastic neoplastic disorders is given in Table 9.54.
- Diagnostic criteria of myelodysplastic syndrome are based on consideration of pre-requisite criteria, major criteria, and co-criteria. Diagnostic criteria of myelodysplastic syndrome are given in Table 9.55.

FRENCH-AMERICAN-BRITISH (FAB) AND REVISED 2024 WHO CLASSIFICATION OF MDS

Chronic myelomonocytic leukemia (CMML), a clonal hematopoietic stem cell malignancy has been included in the category of myelodysplastic syndrome according to WHO classification 2024.

- Chronic myelomonocytic leukemia is stratified into myelodysplastic (white blood cell count $<13\times10^9$/L) and proliferative (white blood cell count $>13\times10^9$/L).
- Diagnostic criteria for myelodysplastic syndrome (MDS) entities according to revised 2024 WHO classification of hematologic neoplasms are given in Table 9.56.

Table 9.54 Revised 2024 WHO classification of myelodysplastic syndromes and myelodysplastic neoplastic disorders

Myelodysplastic Syndromes
Myelodysplastic syndrome with single lineage dysplasia (MDS-SLD)
Myelodysplastic syndrome with ring sideroblasts (MDS-RS) and single lineage dysplasia (MDS-RS-SLD)
Myelodysplastic syndrome with ring sideroblasts and multilineage dysplasia (MDS-RS-MLD)
Myelodysplastic syndrome with multilineage dysplasia (MDS-MLD)
Myelodysplastic syndrome with excess blasts (MDS-EB) and erythroid predominance or fibrosis
Myelodysplastic syndrome with isolated del(5q)
Myelodysplastic syndrome unclassifiable
Childhood myelodysplastic syndrome: refractory cytopenia of childhood
Myelodysplastic/Myeloproliferative Neoplasms
Chronic myelomonocytic leukemia (CMML)
Atypical chronic myelogenous leukemia, BCR-ABL1 negative
Juvenile myelomonocytic leukemia
Myelodysplastic/myeloproliferative neoplasm with ring sideroblasts and thrombocytosis
Myelodysplastic/myeloproliferative neoplasms, unclassifiable

Adapted from revised 2024 WHO classification of hematologic neoplasms.

Myelodysplastic Syndrome with Single Lineage Dysplasia

Myelodysplastic syndrome with single lineage dysplasia (MDS-SLD) presents with unexplained anemia, cytopenia or bicytopenia, with 10% dysplastic cells in one myeloid lineage. Some patients present with persistent unexplained neutropenia or thrombocytopenia. Peripheral blood and bone marrow are the principal sites of involvement.

Table 9.55 Diagnostic criteria of myelodysplastic syndrome

Pre-requisite Diagnostic Criteria of Myelodysplastic Syndrome must be Fulfilled
Persistent (for 4 months duration) peripheral blood cytopenia/s in 1–3 cell lineages (erythroid, neutrophils and megakaryocytes). There is presence of abnormal phenotype of bone marrow cell 1–3 lineages analyzed by flow cytometry
Exclusion of hematopoietic and nonhematopoietic disorders of primary cytopenia/dysplasia
Major Diagnostic Criteria of Myelodysplastic Syndrome (at least one of the following major diagnostic criteria must be fulfilled)
Dysplasia in at least 10% of cells in 1–3 cell lineages (erythroid, neutrophils and megakaryocytes) in the bone marrow. Bone marrow is usually hypercellular
Presence of ≥15% ring sideroblasts (Perl Prussian blue stain positivity for iron) in bone marrow or ≥5% ring sideroblasts in the presence of SF3B1 gene mutation
Presence of 5–19% myeloblasts in the bone marrow or 2–19% myeloblasts in peripheral blood
Presence of cytogenetic abnormalities in chromosome (3, 5 and del 5q, 7 and del 7q, and trisomy 8) demonstrated by conventional karyotyping or fluorescence *in situ* hybridization (FISH)
Diagnostic Co-criteria of Myelodysplastic Syndrome
Patients fulfill pre-requisite diagnostic criteria, but not fulfill major diagnostic criteria of MDS. Clinical manifestations include macrocytic anemia and transfusion-dependent clinical course
Trephine bone marrow biopsy and immunohistochemical analysis show clonal population of cell lineage. Molecular sequencing studies demonstrate MDS-related gene mutations

Myelodysplastic Syndrome with Multilineage Dysplasia

Myelodysplastic syndrome with multilineage dysplasia is characterized by one or more cytopenias and dysplastic changes in two or more of the hematopoietic stem cell lineages (erythroid, granulocytic and megakaryocytic).

- Peripheral blood smear examination shows **<1% blasts** and $<1 \times 10^9$/L monocytes. Bone marrow demonstrates <5% blasts. Auer rods are absent in cytoplasm of myeloid cells.
- The recommended values for defining cytopenias are those suggested in the International Prognostic Scoring System (**IPSS**): (a) hemoglobin concentration <10 g/dl, (b) platelet count $<100 \times 10^9$/L and (c) absolute neutrophil count **$<1.8 \times 10^9$/L.** Blood and bone marrow are involved.
- Patient presents with evidence of bone marrow failure. Most patients have unicytopenia or bicytopenia. Some patients present with pancytopenia or milder cytopenias above the levels in the International Prognostic Scoring System (IPSS).

Myelodysplastic Syndrome with Ring Sideroblasts

Myelodysplastic syndrome (MDS) with ring sideroblasts (MDS-RS) is characterized by cytopenias, morphologic dysplasia and ring sideroblasts most often constituting ≥15% of erythroid precursor cells in bone marrow. Secondary causes of ring sideroblasts must be excluded.

- MDS-RS is associated with SF3B1 gene mutation in majority of cases. MDS-RS diagnosis is established by presence of ≥5% ring sideroblasts in bone marrow.

Table 9.56 Diagnostic criteria for myelodysplastic syndrome (MDS) entities according to revised 2024 WHO classification of hematologic neoplasms

MDS Entities	Number of Dysplastic Lineage	Number of Cytopenias	Ring Sideroblasts as % of Bone Marrow Erythroid Elements	Molecular Genetic Alterations	Myeloblasts in Bone Marrow and Peripheral Blood
MDS with single lineage dysplasia (MDS-SLD)	1	1–2	<15%	SF3B1 gene (<5%)	▪ Bone marrow <5% ▪ Peripheral blood <1% ▪ Auer rods (absent)
MDS with multilineage dysplasia (MDS-MLD)	2–3	1–3	<15%	SF3B1 gene (<5%)	▪ Bone marrow <5% ▪ Peripheral blood <1% ▪ Auer rods (absent)
MDS with ring sideroblasts and single lineage dysplasia (MDS-RS-SLD)	1	1–2	≥15%	SF3B1 gene (<5%)	▪ Bone marrow <5% ▪ Peripheral blood <1% ▪ Auer rods (absent)
MDS with ring sideroblasts and multilineage dysplasia (MDS-RS-MLD)	2–3	1–3	≥15%	SF3B1 gene (<5%)	▪ Bone marrow <5% ▪ Peripheral blood <1% ▪ Auer rods (absent)

Contd...

Table 9.56 Diagnostic criteria for myelodysplastic syndrome (MDS) entities according to revised 2024 WHO classification of hematologic neoplasms (*Contd...*)

MDS Entities	Number of Dysplastic Lineage	Number of Cytopenias	Ring Sideroblasts as % of Bone Marrow Erythroid Elements	Molecular Genetic Alterations	Myeloblasts in Bone Marrow and Peripheral Blood
MDS with isolated del(5q)	1–3	1–2	None or any	del(5q)	▪ Bone marrow <5% ▪ Peripheral blood <1% ▪ Auer rods (absent)
MDS with excess blasts and erythroid predominance (MDS-EB1)	1–3	1–3	None or any	Not applicable	▪ Bone marrow 5–9% ▪ Peripheral blood 2–4% ▪ Auer rods (absent)
MDS with excess blasts and fibrosis (MDS-EB2)	1–3	1–3	None or any	Not applicable	▪ Bone marrow 10–19% ▪ Peripheral blood 5–9% ▪ Auer rods (present)
MDS-U with 1% blood blasts	1–3	1–3	None or any	Not applicable	▪ Bone marrow <5% ▪ Peripheral blood 1% ▪ Auer rods (absent)
MDS unclassifiable with single lineage dysplasia and pancytopenia	1	3	None or any	Not applicable	▪ Bone marrow <5% ▪ Peripheral blood 1% ▪ Auer rods (absent)
MDS unclassifiable based on defining cytogenetic abnormality	0	1–3	15%	*Complex karyotype (three or more abnormalities)	▪ Bone marrow <5% ▪ Peripheral blood 1% ▪ Auer rods (absent)
Refractory cytopenia of childhood			None	Not applicable	▪ Bone marrow <5% ▪ Peripheral blood <2% ▪ Auer rods (absent)

Complex karyotype (three or more abnormalities), unbalanced abnormalities such as 7/del(7q), dl(5q)/5t(5q), i(17q)t(17q), –13/del(13q), and del(11q) and balanced abnormalities such as t(11;16(q23.3;p13/3), t(3;21)(q26.2;q22.1) and 5(1;3)(p36.3;q21.2).

- Myeloblasts account for **<5%** of the nucleated bone marrow cells and <1% of peripheral blood leukocytes. Auer rods are absent in myeloblasts.
- MDS with ring sideroblasts (MDS-RS) is of two types: (a) MDS with single lineage dysplasia, and (b) MDS with multilineage dysplasia. The peripheral blood and bone marrow are the principal sites of involvement.
- Patient presents with anemia (most often), neutropenia or thrombocytopenia.

Myelodysplastic Syndrome with Excess Blasts

Myelodysplastic syndrome (MDS) with excess blasts is characterized by 5–19% myeloblasts in the bone marrow or 2–19% blasts in the peripheral blood (but <20% in both bone marrow and peripheral blood).

- Two subtypes of MDS with excess blasts include MDS-EB1 and MDS-EB2. MDS-EB1 is defined by 5–8% myeloblasts in the bone marrow or 2–4% myeloblasts in peripheral blood and MDS-EB2 is defined by 10–19% blasts in the bone marrow or 5–19% myeloblasts in the peripheral blood.
- The presence of **Auer rods in myeloblasts** designates any MDS case as MDS-EB2 irrespective of myeloblast percentage.

Myelodysplastic Syndrome with Isolated Deletion of Chromosome 5q

Myelodysplastic syndrome with isolated del(5q) is characterized by anemia (with or without cytopenias and/or thrombocytosis), which most often occurs in elderly women.

- Cytogenetic abnormality del(5q) in myelodysplastic syndrome occurs in isolation or with monosomy 7 or del(7q). Myeloblasts constitute <5% of the nucleated cells in bone marrow and <1% nucleated cells in the peripheral blood. Auer rods are absent in myeloblasts. Peripheral blood and bone marrow are affected.
- Peripheral blood smear examination shows severe macrocytic anemia and elevated platelet count. Thrombocytosis is demonstrated in 50% of cases. Thrombocytopenia and pancytopenia are rare.
- It is recommended that cases otherwise fulfilling the MDS criteria, but with pancytopenia (hemoglobin

concentration <10 g/dl, platelet count $<100 \times 10^9$/L and absolute neutrophil count $<1.8 \times 10^9$/L) be categorized as MDS, unclassifiable, because their clinical course is uncertain.

Myelodysplastic Syndrome Unclassifiable

Myelodysplastic syndrome unclassifiable (MDS-U) lacks appropriate findings for classification into any other MDS category. The peripheral blood and bone marrow are affected. Patient presents with symptoms similar to those seen in other MDS such as anemia, neutropenia or thrombocytopenia induced clinical manifestations.

PATHOGENESIS

Myelodysplastic syndromes are considered pluripotent hematopoietic stem cell disorders of the bone marrow, which most often involves the myeloid progenitor cells. Lymphoid lineage is rarely affected.

- Many of the afflicted hematopoietic stem cells do differentiate into mature cells but exhibit ineffective progression so that their number decrease in the peripheral blood; and phenomenon is known as 'ineffective hematopoiesis'.
- In addition to decreased number of cells, the myelodysplastic cells develop into abnormal morphologic features with compromised functions.
- Gradually pluripotent hematopoietic stem cells lose their ability to differentiate; and in some persons, dysplastic cells undergo acute myelogenous leukemia. About 50% of MDS patients with normal chromosomes present with genetic instability of the myeloid precursor cell contributing to the development of MDS.
- Primary myelodysplastic syndrome originates in *de novo*.
- Secondary myelodysplastic syndrome most often occurs as a result of administration of chemotherapeutic alkylating drugs or radiotherapy in treating various cancers after 5–7 years.
  - Exposure to tobacco smoke, benzene or viruses may cause secondary MDS.
  - Other predisposing factors for developing secondary MDS include paroxysmal nocturnal hemoglobinuria (PNH), aplastic anemia, neurofibromatosis type 1, Shwachman-Diamond syndrome, Kostmann agranulocytosis type 3, Down syndrome, Fanconi syndrome, ataxia-telangiectasia, and gene mutations in N-RAS gene, TP53 gene, IRF gene and BCL-2 gene.
  - Predisposing factors and epidemiologic associations of myelodysplastic syndromes are given in Table 9.57.

Table 9.57 Predisposing factors and epidemiologic associations of myelodysplastic syndromes (MDSs)

Hereditary Predisposition to MDS*
Constitutional genetic disorders [Down syndrome (trisomy 21), trisomy 8 mosaicism, familial monosomy]
Diamond-Blackfan anemia
Neurofibromatosis type 1 (NF1)
Germ cell tumors (embryonal dysgenesis)
Congenital neutropenia (Kostmann syndrome, Shwachman-Diamond syndrome)
Germline gene mutations (GATA2 gene mutation, germline predisposing mutations in RUNX1, ANKRD26, or ETV6 genes with pre-existing platelet disorder, germline predisposing mutations in CEBPA or DDX41 genes without pre-existing condition or organ dysfunction)
DNA repair deficiencies and telomere biology disorders (ataxia-telangiectasia, Bloom syndrome, Fanconi anemia, xeroderma pigmentosum, dyskeratosis)
Acquired Causes of MDSs
Therapeutic chemotherapy in cancers (alkylating agents, DNA topoisomerase II inhibitors)
Radiation exposure to hematopoietic bone marrow, β-emitters (phosphorus 32)
Autologous pluripotent stem cell transplantation
Exposure to environmental agents (benzene, tobacco smoke, viruses)
Stem cell disorders [paroxysmal nocturnal hemoglobinuria (PNH), aplastic anemia]
Gene mutations (N-RAS gene, TP53 gene, BCL-2 gene, IRF2 gene)

**Primary myelodysplastic syndrome (MDS) originates in de novo.*

Molecular Genetic Alterations

Molecular genetic alterations, epigenetics and single gene mutations contribute to pathogenesis of myelodysplastic syndrome (MDS). *In vitro* studies reveal that excessive premature intramedullary death of hematopoietic stem cells via apoptosis leads to ineffective hematopoiesis and peripheral blood cytopenias in early MDS. Increased levels of tumor necrosis factor α (TNF-α) in MDS patients have been linked to increased apoptosis of MDS clone as well as normal hematopoietic stem cells. Progression of MDS to AML is associated with a reduction in apoptosis, therefore permitting the expansion of the neoplastic clone.

- Nearly every chromosome exhibits genomic aberrations in MDS.
- MDS clone is characterized by altered function of genes because of chromosomal abnormalities, gene silencing or single gene mutation.

- Unbalanced molecular genetic alterations are responsible for ineffective hematopoiesis. Most encountered abnormal karyotypes in MDS are the loss of 5/del (5q), loss of 7/del(7q), trisomy 8, del(20q), and loss of Y chromosome suggesting that genes located in these regions play an important role in the pathogenesis of MDS.
- Examples of molecular genetic alterations in myelodysplastic syndrome and prognosis are given in Table 9.58. Abnormal karyotyping in myelodysplastic syndrome (MDS) is given in Table 9.59. Molecular genetic alterations in primary and therapy-related myelodysplastic syndrome with approximate frequency are given in Table 9.60. Common somatic gene mutations in at least 5% cases of myelodysplastic syndrome are given in Table 9.61. Significant gene mutations in myelodysplastic syndrome are given in Table 9.62.

Table 9.58 Examples of cytogenetic abnormalities in myelodysplastic syndrome and prognosis

Prognosis	Cytogenetic Abnormalities
Very good prognosis	Loss of Y chromosome or del(11q)
Good prognosis	Normal or del(5q)
Intermediate prognosis	del(7q) or double independent clones
Poor prognosis	inv(3) or double loss including 1 and 7 del(7q)
Very poor prognosis	Complex: >3 abnormalities

Table 9.59 Abnormal karyotyping in myelodysplastic syndrome

MDS Associated with Chromosome 5 and Deletion (5q)
Chromosome 5 and del(5q) is most frequent acquired genetic abnormality demonstrated in 10–20% of MDS cases. Three commonly deleted regions (CDRs) on chromosome 5q31–33 include EGR1 gene (early growth response gene 1), NPM1 gene (nucleophosmin 1) and RPS14 (ribosomal subunit)
Normally, EGR1, NPM1 and RPS14 genes encode proteins, that control cell signaling, transcription, cell cycle and apoptosis.
Loss of commonly deleted regions (CDRs) on chromosome 5 plays significant role in the pathogenesis of MDS. Whole or partial losses of chromosome 5 are somatically acquired.
These patients are treated with radiotherapy, alkylating agents, or DNA topoisomerase II antagonists. 5q syndrome manifests as anemia, with or without mild neutropenia and platelet counts either preserved or elevated
The prognosis is relatively good. Several cytokines, growth factors, and their receptors are found at the 5q locus
MDS Associated with Chromosome 7 and Deletion (7q)
Chromosome 7 and del(7q) genetic abnormality is most frequently demonstrated ≤20% of MDS cases. Three commonly deleted regions (CDRs) are demonstrated on chromosome 7 at 7q22, 7q31–32 and 7q36
This cytogenetic abnormality is most often demonstrated in children
Impaired neutrophilic function is associated with recurrent infections
MDS Associated with Trisomy 8
Trisomy 8 is demonstrated in about 10% of MDS cases. In contrast to chromosome 5 and del(5q) and chromosome 7 and del(7q), trisomy 8 in MDS and AML is not associated with prior treatment with radiation, alkylating agents or DNA topoisomerase II antagonists
It has been suggested that effect of trisomy is influenced by the overexpression of the proto-oncogene Myc located on chromosome 8q24
MDS Associated with Chromosome Deletion (20q)
L3MBTL1 gene is located on chromosome 20q12.13, that encodes a transcriptional repressor
Deletion of chromosome in the region has been demonstrated in 5% of cases
Loss of L3MBTL1 gene is likely to be involved in the neoplastic state of MDS
MDS Associated with Loss of Y Chromosome
Loss of the Y chromosome is variable in MDS as well as healthy aging persons
Loss of chromosomal Y is likely an age-related abnormality, independent of a neoplastic process
MDS Associated with Complex Karyotype
Complex karyotype (involving >3 chromosomal abnormalities such as whole or partial deletions of chromosome 5 and chromosome 7) is demonstrated in 20% of primary MDS cases and 90% of treatment related MDS patients

Table 9.60 Molecular genetic alterations in primary and therapy-related myelodysplastic syndrome (MDS) with approximate frequency

Molecular Genetic Alterations	Primary Myelodysplastic Syndrome	Therapy-related Myelodysplastic Syndrome
Complex karyotype	15–20%	80–90%
Deletion (5q) monosomy 5 (favorable prognosis)	15–20%	30–40%
Deletion (7q) monosomy 7 (unfavorable prognosis)	10–15%	40–50%
Trisomy 8 (intermediate prognosis)	10–15%	10–15%
Deletion (20q) (favorable prognosis)	5–10%	Nil
Loss of Y chromosome	5%	Nil
Deletion (11q)	<5%	Nil
Deletion (12p)	<5%	Nil
Deletion (17q)	<5%	Nil
Deletion (9q)	1–2%	Nil
Idic(X)(q13)	1–2%	Nil

Table 9.61 Common somatic gene mutations in at least 5% cases of myelodysplastic syndrome

Gene Mutation	Pathway	Frequency	Prognosis
RNA splicing factors			
SF3B1	RNA splicing factor	20–30%	Favorable prognosis
SRSF2	RNA splicing factor	≤15	Adverse prognosis
U2AF1	RNA splicing factor	5–10%	Adverse prognosis
ZRSR2	RNA splicing factor	5–10%	Adverse prognosis
Transcriptional factors			
N-RAS	Transcription factor	≤5%	Adverse prognosis
BCOR1	Transcription factor	≤5%	Adverse prognosis
RUNX1	Transcription factor	≤10	Adverse prognosis
ETV6	Transcription factor	<5%	Adverse prognosis (transformation to chronic myelomonocytic leukemia)
TP53 (tumor suppressor gene)	Transcription factor	5–10%	Adverse prognosis
GATA2	Transcription factor	<5%	Adverse prognosis (recurrent infection)
Growth factor signaling			
N-RAS/K-RAS	Growth factor signaling	5–10%	Adverse prognosis
JAK2	Growth factor signaling	<5%	Adverse prognosis
CBL*	Growth factor signaling	≤5%	Adverse prognosis
Epigenetic regulators			
TET2*	Epigenetic regulator (DNA methylation)	20–30%	Either neutral prognostic impact or conflicting data
DNMT3A*	Epigenetic regulator (DNA methylation)	≤10	Adverse prognosis
ASXL*	Epigenetic regulator (histone modification)	15–20%	Adverse prognosis
EZH2	Epigenetic regulator (histone modification)	5–10%	Adverse prognosis
STAG2	Cohesion complex	5–7%	Adverse prognosis
IDH1/IDH2	DNA methylation	≤5%	Either neutral prognostic impact or conflicting data

**Clonal hematopoiesis of indeterminate potential.*

Table 9.62 Significant gene mutations in myelodysplastic syndrome (MDS)

Gene	Locus on Chromosomes	Normal Function of Protein	Gene Mutation Frequency in MDS	Significance
ASXL1 (additional sex combs like 1) gene	20q11.1	Gene product regulates the expression of many genes, that play important role before birth	≤11%	Gene mutation causes myeloproliferation (prevalent in MDS/MPN)
EGR1 (early growth response 1) gene	5q31	Gene product regulates the transcription of numerous target genes, thereby regulating the response to growth factors, which regulate cell proliferation, survival and apoptosis	5–10%	Putative tumor suppressor gene, initial event in MDS
NPM1 (nucleoplasmin 1) gene	5(q35)	NPM1 gene protein 'nucleophosmin functions as tumor suppressor gene	5%	Putative proto-oncogene that inactivates p53
EVI1 (ecotropic viral integration site 1) gene	3q26.2	EVI1 gene product regulates normal development of hematopoietic cells and leukemogenesis	≤5%	Putative tumor suppressor signaling and apoptosis
JAK2V617F (Janus kinase 2) gene	9p	JAK2 gene protein tyrosine kinase controls production of blood cells from hematopoietic stem cells	5%	JAK2 gene mutation causes hypersensitivity to cytokines
N-RAS (neuroblastoma rat sarcoma) gene	1p13.2	N-RAS protein regulates cell division	≤15%	Activating gene mutations stimulate MARK signaling
RUNX1 (runt-related transcription factor 1) gene	21q22.12	RUNX1 gene protein activates genes that regulates hematopoiesis	20%	Important for differentiation of hematopoietic cells
K-RAS (Kristen rat sarcoma) gene	12p12.1	K-RAS protein regulates controlled cell proliferation	≤40% in advanced MDS	Associated with a worse prognosis and increased risk of progression to AML
FLT3 (Fms-related tyrosine kinase 3) gene encodes tyrosine kinase, that regulates proliferation, differentiation, apoptosis of hematopoietic stem cells	13.q12	FLT3 protein transmits signals from the cell surface into the cell through signal transduction	5–10%	FLT3 gene mutation associated with progression of AML
TP53 gene	17p13.1	p53 gene protein regulates cell cycle	20% and 25% in secondary MDS	Encodes a checkpoint protein (p53), rapid progression to AML with poor prognosis

CLINICAL FEATURES

Patient presents with fatigue and weakness related to anemia, that is nonresponsive to treatment. Less commonly symptoms are bleeding tendencies and related to thrombocytopenia and recurrent infections related to neutropenia $<1\times10^9$/L) as a result of apoptosis of hematopoietic precursor cells. Bleeding and recurrent infection are most common causes of death in MDS patients.

- Many patients are asymptomatic and detected on routine hematologic investigations. Splenomegaly and hepatomegaly are uncommon.
- Synthesis of transforming growth factor-β (TGF-β) and platelet-derived growth factor (PDGF) cause bone marrow fibrosis resulting in pancytopenia, extramedullary hematopoiesis in spleen and liver. MDS patient may develop acute myelogenous leukemia (AML) in about 40–50% of cases.

LABORATORY DIAGNOSIS

Patient with MDS presents with a range of abnormal morphologic features demonstrated on stained peripheral blood and bone marrow.

- Laboratory investigations performed to diagnose myelodysplastic syndrome include peripheral blood smear examination, bone marrow trephine biopsy examination, bone marrow aspiration, biochemical investigations, molecular diagnostics and immunophenotyping.
- Salient features of myelodysplastic syndrome are given in Table 9.63. Hematologic abnormalities in

Table 9.63 Salient features of myelodysplastic syndrome
Peripheral blood picture of cytopenia in 1–3 cell lineages
Dysplasia in 1–3 cell lineages demonstrated in peripheral blood and bone marrow
Bone marrow usually hypercellular
Increased ring sideroblasts
Increase in myeloid precursor antigens (CD34, CD117, HLA-DR) and immature granulocytic antigens (CD13, CD33)
Decrease in mature granulocytic antigens (CD10, CD11b, CD16, CD64)
Aberrant expression of nonmyeloid markers (CD7, CD19, CD56)
Identification of cell lineage and distribution by immunohistochemistry
Cytogenetic abnormalities as discussed in this chapter

myelodysplastic syndrome are given in Table 9.64. Characteristics of flow cytometric analysis of myelodysplastic syndrome are given in Table 9.65.

PROGNOSTIC CRITERIA

Accurate classification and prognosis of MDS is essential to plan therapy. MDS is categorized into three risk groups on the basis of survival time and evolution to AML. The comprehensive cytogenetic prognostic scoring system for myelodysplastic syndrome is given in Table 9.66.

MOLECULAR DIAGNOSTICS

Fluorescence *in situ* hybridization (FISH) provides diagnostic and prognostic information and monitor response to therapy in MDS cases. Specific FISH probes demonstrate commonly encountered abnormal karyotypes. Molecular diagnostic testing includes gene expression analysis by microarray, next generation sequencing and whole genome analysis to elucidate the complicated genetic profile of MDS.

Table 9.65 Characteristics of flow cytometric analysis of myelodysplastic syndrome (MDS)
Decreased granulocytic side scanner as a result of hypogranularity of granulocyte cytoplasm
Reduced expression of CD15, CD10, CD16, CD11b and CD13 on myeloid progenitors and maturing myeloid cells
Loss of synchronized expression on granulocytes including the failure of CD64/CD33, CD16/CD13, and CD16/CD11b antigens to co-express as expected
Characteristics lymphoid antigens such as CD2, CD5, CD7, CD19 and CD56 inappropriately expressed on granulocytes and/or monocytes
Decreased or absent CD4, CD13, and HLA-DR antigen expression on monocytes
Retention of an abnormally immature phenotype as a result of expansion of CD34+ and CD117+ immature cells

Table 9.64 Hematologic abnormalities in myelodysplastic syndrome

Erythroid Series	Myeloid Series	Thrombopoietic Series
Peripheral blood smear findings		
Red blood cell changes	**White blood cell changes**	**Platelet changes**
▪ Anemia ▪ Anisocytosis ▪ Poikilocytosis ▪ Macrocytes, oval macrocytes ▪ Basophilic stippling ▪ Nucleated RBCs ▪ Howell-Jolly bodies ▪ Sideroblasts ▪ Reticulocytopenia	▪ Neutropenia ▪ Hypogranulation, abnormal granulation ▪ Shift to the left ▪ Nuclear abnormalities (pseudo-Pelger-Hüet, ring nuclei) ▪ Monocytosis	▪ Thrombocytopenia or thrombocytosis ▪ Giant forms ▪ Hypogranulation ▪ Micromegakaryocytes ▪ Functional abnormalities
Bone marrow		
Erythropoiesis	**Myelopoiesis**	**Megakaryopoiesis**
▪ Megaloblastoid erythropoiesis ▪ Nuclear fragmentation and budding ▪ Nuclear karyorrhexis ▪ Multiple nuclei in erythroid cells ▪ Defective hemoglobinization ▪ Vacuolization in erythroid cells ▪ Ring sideroblasts	▪ Abnormal granules in promyelocytes ▪ Increase in granular and agranular blats ▪ Absence of secondary granules ▪ Nuclear abnormalities ▪ Decreased myeloperoxidase ▪ Auer rods in myeloblasts	▪ Micromegakaryocytes ▪ Megakaryocytes with multiple separated nuclei ▪ Large mononuclear megakaryocytes ▪ Hypogranular or large abnormal granules in megakaryocytes

Table 9.66 The comprehensive cytogenetic prognostic scoring system and recommended values for defining cytopenias are those suggested in the International Prognostic Scoring System (IPSS) for myelodysplastic syndrome

Parameters	Very Good Prognosis	Good Prognosis	Intermediate Prognosis	Poor Prognosis	Very Poor Prognosis
The recommended values for defining cytopenias are those suggested in the International Prognostic Scoring System (IPSS)					
Myeloblasts (%)	≤2%	>2–<5%	5–10%	>10%	>10%
Hb (g/dl)	≥10 g/dl	8–<10 g/dl	–	–	–
Platelet count	$\geq 100 \times 10^9$/L	$\leq 50–100 \times 10^9$/L	–	–	–
Absolute neutrophil count	$\geq 1.8 \times 10^9$/L	–	–	–	–
Defining cytogenetic abnormalities and prognostic significance					
Cytogenetic abnormalities	▪ Loss of Y chromosome ▪ del(11q)	▪ del(5q) ▪ del(12p) ▪ del(20q) [single/ double deletion including del(5q)]	▪ del(7q) ▪ Gain(8,19) ▪ Isochromosome 17q ▪ Single or double abnormalities, not specified in other subgroups ▪ Two or more independent non-complex clones	▪ Loss (7) ▪ inv(3), t(3q) or del(3q) ▪ Double including loss of chromosome 7 or del(7q) ▪ Complex (>3) cytogenetic abnormalities	▪ Complex (>3) cytogenetic abnormalities

Laboratory Diagnosis of Myelodysplastic Syndrome (MDS)

Biochemical Investigations

- Serum iron and serum ferritin levels are normal or increased.
- Total iron binding capacity (TIBC) is normal or decreased, a feature distinguishing MDS from iron deficiency anemia.
- Serum vitamin B_{12} and folic acid levels are normal or increased, a feature distinguishing MDS from megaloblastic anemia.
- Lactic dehydrogenase and uric acid levels are increased as a result of ineffective hematopoiesis.

Peripheral Blood Smear Examination

- Peripheral blood smear examination demonstrates cytopenias and dysplasia. In cytopenias, patient has hemoglobin <10 g/dl, absolute neutrophil count,1.8×10^9/L and platelets $<100 \times 10^9$/L.
- Anemia is most consistent finding in >80% of cases. Bicytopenia is demonstrated in 30% and pancytopenia in 15% of cases. Functional abnormalities of hematologic cells are common.
- Dysplastic features of one or more cell lineages are demonstrated. Higher degree and number of cytopenias are associated with poor prognosis.
- Peripheral blood smears should be prepared within two hours of anticoagulated blood. Morphologic changes from prolonged exposure to anticoagulant in blood sample can easily be confused with dysplastic changes in hematopoietic cells.

Red blood cells

Peripheral blood smear shows macrocytic picture with oval cells similar to those seen in megaloblastic anemia. Dimorphic anemia is also common finding. In addition to anemia, qualitative abnormalities indicative of dyserythropoiesis is demonstrated such as anisocytosis, poikilocytosis, basophilic stippling, Howell-Jolly bodies and nucleated erythrocytes.

Leukocytes

Neutropenia accompanied by shift to the left with myelocytes and metamyelocytes is the second most common cytopenia demonstrated in 50% MDS cases.

- Abnormalities in granulocytes indicative of dysgranulopoiesis is the hallmark finding in MDS, in which the granulocytes are agranular or hypogranular with persistent basophilic cytoplasm and hyposegmentation (pseudo-Pelger-Hüet abnormality).
- Neutrophils show decreased myeloperoxidase and leukocyte alkaline phosphatase (LAP). In some MDS cases, neutrophils show severe functional impairment including defective bactericidal, phagocytic or chemotactic properties.
- Absolute monocytosis is a constant finding even in leukemic conditions.
- MDS-related pancytopenia in Giemsa-stained peripheral blood smear is shown in Fig. 9.58. MDS-related band form segmented neutrophils in Giemsa-stained peripheral blood smear is shown in Fig. 9.59. MDS-related Pelger-Hüet cell abnormality in Giemsa-stained peripheral blood smear is shown in Fig. 9.60. MDS-related abnormal monocytoid cells in Giemsa-stained peripheral blood smear is shown in Fig. 9.61.

Platelets

- Qualitative and quantitative platelet abnormalities are demonstrated in MDS. About 25–50% of patients present with mild to moderate thrombocytopenia.
- Peripheral blood smear examination shows giant platelets, hypogranular platelets and platelets with large, fused platelets. Qualitative abnormalities include abnormal platelets adhesion and aggregation.
- Sometimes, peripheral blood smear examination shows micromegakaryocytes in MDS.
  - Micromegakaryocytes represent abnormal megakaryocytes with reduced ability to undergo endomitosis.

- Micromegakaryocytes contain single-lobed nucleus with attached one or more platelets. Nuclear structure of micromegakaryocytes is variable with dense clumped chromatin demonstrated by Wright-Giemsa stain.

Bone Marrow Smear Examination

Bone marrow smear examination is essential to demonstrate dyshematopoiesis, cellularity and diagnosing of myelodysplastic syndrome. Bone marrow shows increased iron demonstrated by Perls' Prussian blue stain. Myelodysplastic syndrome related iron overload demonstrated by Perls' Prussian blue reaction in bone marrow aspirate smear is shown in Fig. 9.62.

- **Cellularity:** Hypercellular bone marrow with peripheral blood picture of cytopenia occurs because of premature hematopoietic cells apoptosis and ineffective erythropoiesis. Bone marrow contains <20% myeloblasts. At least 10% of hematopoietic lineage cells should be dysplastic to establish diagnosis.
- **Dyserythropoiesis:** Nuclear-cytoplasmic asynchrony similar to megaloblastic erythropoiesis is the most common finding in MDS.
  - However, the chromatin of dyserythropoietic cells show hypocondensation of chromatin. Patients with MDS are unresponsive to vitamin B_{12} or folic acid therapy. Giant multinucleated erythroid precursors can be demonstrated.
  - Cytoplasm of erythroid precursor cells shows defective hemoglobinization, basophilic staining and vacuoles. Ring sideroblasts reflecting the abnormal erythrocyte metabolism are commonly demonstrated.
  - Ring sideroblasts contain at least five mitochondrial iron deposits encircle at least one-third or more of the circumference of the nucleus.
- **Dysgranulopoiesis:** Abnormal granulocyte maturation is almost always demonstrated.
  - In dysgranulopoiesis, bone marrow examination shows abnormal staining of granules in the promyelocytes and myelocytes. Sometimes, granules may be larger than normal.
  - Secondary granules are absent in myelocytes and mature neutrophils resulting in hypogranular neutrophils with irregular cytoplasmic basophilia demonstrated in the bone marrow.
- **Dysmegakaryopoiesis:** Bone marrow examination may show decreased, normal or increased megakaryocytes.
  - Presence of micromegakaryocytes, mononuclear megakaryocytes and megakaryocytes with abnormal nuclear configurations such as hyperlobulated or hypolobulated and multiple widely separated nuclei reflect abnormalities in maturation.
  - Dysplastic micromegakaryocytes containing single eccentric nucleus are demonstrated in MDS with chromosome del(5q) and abnormality of chromosome 3.
  - MDS-related dysmegakaryopoiesis in hematoxylin and eosin-stained bone marrow trephine biopsy section is shown in Fig. 9.63.

Bone Marrow Trephine Biopsy Examination

- Bone marrow trephine biopsy is helpful in diagnosing MDS in difficult cases. Abnormal localization of immature precursors can be demonstrated in bone marrow trephine biopsy before an increase in number of myeloblasts is demonstrated in bone marrow smears. ALIP has been associated with increased risk of AML in MDS cases.
- Presence of <5% of myeloblasts and abnormal localization of immature precursors (ALIP) indicates evolution to a more aggressive MDS.
- Bone marrow trephine biopsy provides a better assessment of cellularity and amount of bone marrow fibrosis. Reticulin stain demonstrates slight increase in reticulin fibers.
- Bone marrow trephine biopsy also shows the ring sideroblasts, nuclear fragmentation and budding. Auer rods, irregular cytoplasmic basophilia and abnormal granules in promyelocytes are more easily demonstrated in bone marrow smears.
- Thus, bone marrow aspiration and bone marrow trephine biopsy preparations are essential for accurate diagnosis of MDS.

Immunophenotyping

- Immunophenotyping is used in diagnosing and predicting prognosis of MDS patients. It is most useful in MDS cases, where bone marrow aspiration, bone marrow trephine biopsy and cytogenetics are inconclusive. It helps in distinguishing MDS cases with hypoplastic bone marrow morphology from other cause of bone marrow failure disorder such as aplastic anemia.
- Aberrant antigenicity demonstrated in MDS includes lymphoid antigens on myeloid cells, increased or decreased expression of expected antigens, the presence of immature antigens on mature cells, and expression of mature antigens on immature cells.

Fig. 9.59: Myelodysplastic syndrome related band form segmented neutrophils in Giemsa-stained peripheral blood smear. It shows band form segmented neutrophils (1000X).

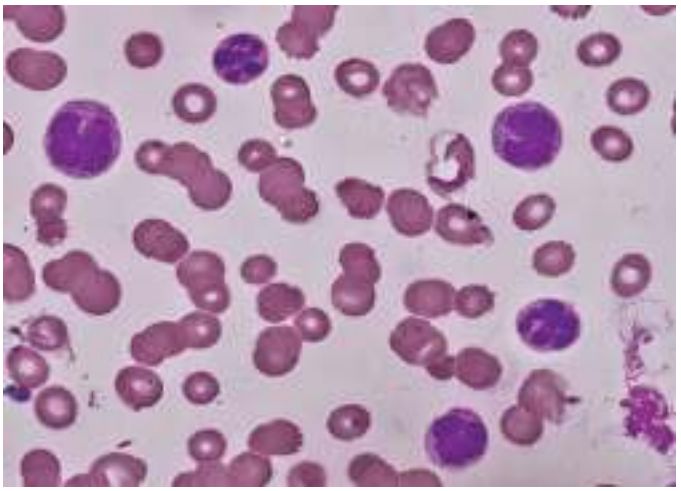

Fig. 9.61: Myelodysplastic syndrome related abnormal monocytoid cells in Giemsa-stained peripheral blood smear (1000X).

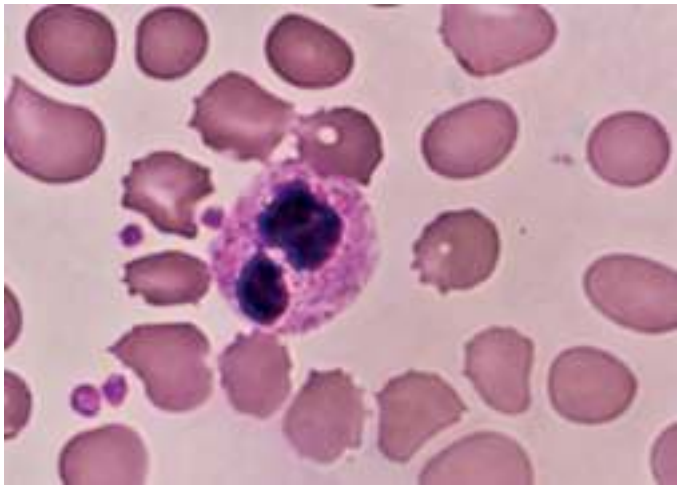

Fig. 9.60: Myelodysplastic syndrome related Pelger-Hüet cell abnormality in Giemsa-stained peripheral blood smear. It shows MDS related Pelger-Hüet cell abnormality (1000X).

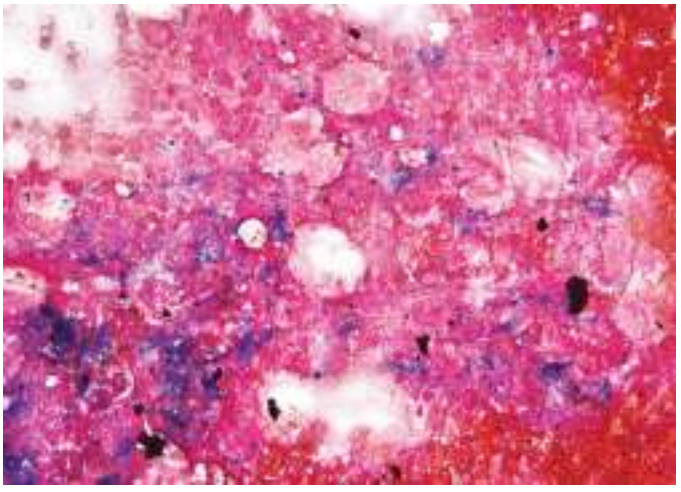

Fig. 9.62: Myelodysplastic syndrome related iron overload demonstrated by Perls' Prussian blue reaction in bone marrow aspirate smear (1000X).

TREATMENT

Therapeutic strategies of myelodysplastic syndrome (MDS) include supportive care, suppression of MDS clone and its leukemia progeny, improvement bone marrow function and curative allogeneic hematopoietic stem cell transplantation. It is essential to segregate patients into low-risk and high-risk before making therapeutic decision in these cases.

Supportive Care

Cytopenias-related recurrent infections cause death in MDS patients. Recurrent infections in the setting of neutropenia must be treated aggressively by administration of granulocyte-colony stimulating factor **(G-CSF)** and erythropoietin. These therapeutic agents do not hasten leukemic process. Thrombopoietin administration may hasten leukemic process. Recently, thrombopoietin receptor agonist 'Eltrombopag' agent is promising therapeutic agent.

Allogeneic Hematopoietic Stem Cell Transplantation

Allogeneic hematopoietic stem cell transplantation is the only curative in MDS. Decision for hematopoietic stem cell transplantation demands balancing the probability of disease progression and procedural abnormality and mortality. Favorable outcomes of hematopoietic stem cell transplantation are seen in younger patients with HLA-identical siblings.

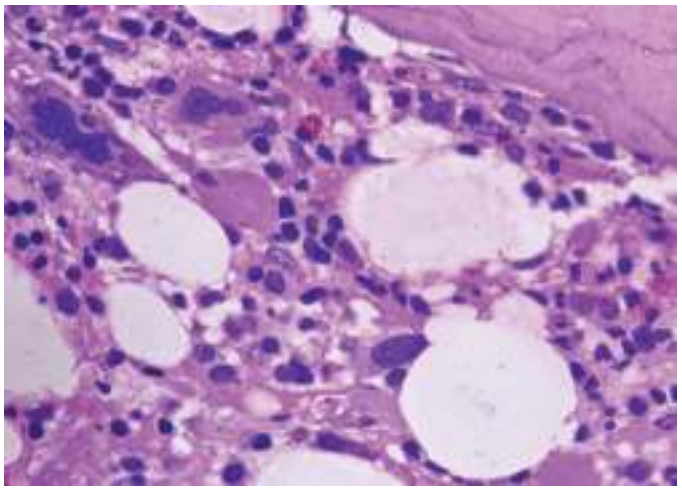

Fig. 9.63: Myelodysplastic syndrome (MDS) related dysmegakaryopoiesis in hematoxylin and eosin-stained bone marrow trephine biopsy. It shows dysmegakaryopoiesis (1000X).

Disease-modifying Hypermethylation Agents (DNA Methyltransferase Inhibitors)

DNA methyltransferases participate in hypermethylation of CpG promoter regions of many tumor suppressor genes resulting in decreased gene expression without changing the DNA sequence. Acquired hypermethylation of tumor suppressor genes downregulates expression and increasing the potential for dysplastic growth. '**Azacytidine**' is currently approved therapeutic agent to treat patients with all MDS subtypes.

Immunomodulatory Agents and Immunosuppression

Lenalidomide is an oral analog of thalidomide with greater potency and established efficacy. It is superior, and safe in treating MDS. Lenalidomide is administered in MDS patients with chromosome deletion 5q, with or without other cytogenetic abnormalities.

MYELODYSPLASTIC/MYELOPROLIFERATIVE NEOPLASMS

MYELODYSPLASTIC/MYELOPROLIFERATIVE NEOPLASMS: ENTITIES

Myelodysplastic/myeloproliferative neoplasms have features of both myelodysplastic/myeloproliferative neoplasms.

- Normally, bone marrow makes enough healthy red blood cells, white blood cells and platelets.
- In myelodysplastic/myeloproliferative neoplasms, hematopoietic stem cells do not mature into healthy red blood cells, white blood cells and platelets. Majority of these immature cells die within the bone marrow or soon after they enter in the blood circulation. As a result, there is presence of fewer healthy red blood cells, white blood cells and platelets in the blood.
- In myeloproliferative neoplasms (MPNs), bone marrow produces excessive cells in one or more types of the cell lineages. Some of these cells may show morphologically and/or functionally dysplastic features.
- Cytopenia may be demonstrated due to ineffective cell production in one or more of cell lineages in the bone marrow. The blast percentage in the bone marrow and peripheral blood is always <20%.
- A myeloblastic/myeloproliferative neoplasm may develop into acute myelogenous leukemia (AML).
- There are three types of myelodysplastic/myeloproliferative neoplasms: (a) chronic myelomonocytic leukemia (**CMML**), (b) juvenile myelomonocytic leukemia (**JMML**), and (c) atypical chronic myelogenous leukemia (**aCML**).
- Schematic representation of origin of bone marrow myeloproliferative neoplasms is shown in Fig. 9.64. Features of myelodysplastic/myeloproliferative neoplasms are given in Table 9.67.

CHRONIC MYELOMONOCYTIC LEUKEMIA

Chronic myelomonocytic leukemia (CMML) is a clonal hematopoietic stem cell neoplasm associated with persistent relative >10% of absolute monocytosis with monocyte count ($>1 \times 10^9$/L) in the peripheral blood. In bone marrow, some of monoblasts do not develop into mature monocytes, and persists for >3 months. CMML has features of both myeloproliferative neoplasm and myelodysplastic syndrome.

- The monocytes and immature cells (promonocytes and monoblasts) crowd out the other lineage precursor cells in the bone marrow with suppression of erythroid cells and megakaryocytes.
- Although the peripheral blood finding of absolute monocytosis is essential for CMML diagnosis, yet other hematologic findings are remarkably variable such as leukocytosis, neutrophilia or neutropenia.
- Dyshematopoiesis can range from minimal expression in single cell lineage to marked dysplasia in all the lineages. Blood and bone marrow are invariably involved in CMML.
- Spleen, liver, skin and lymph nodes are the most common extramedullary sites of involvement, CMML as inherent risk for transformation to acute myelogenous leukemia.

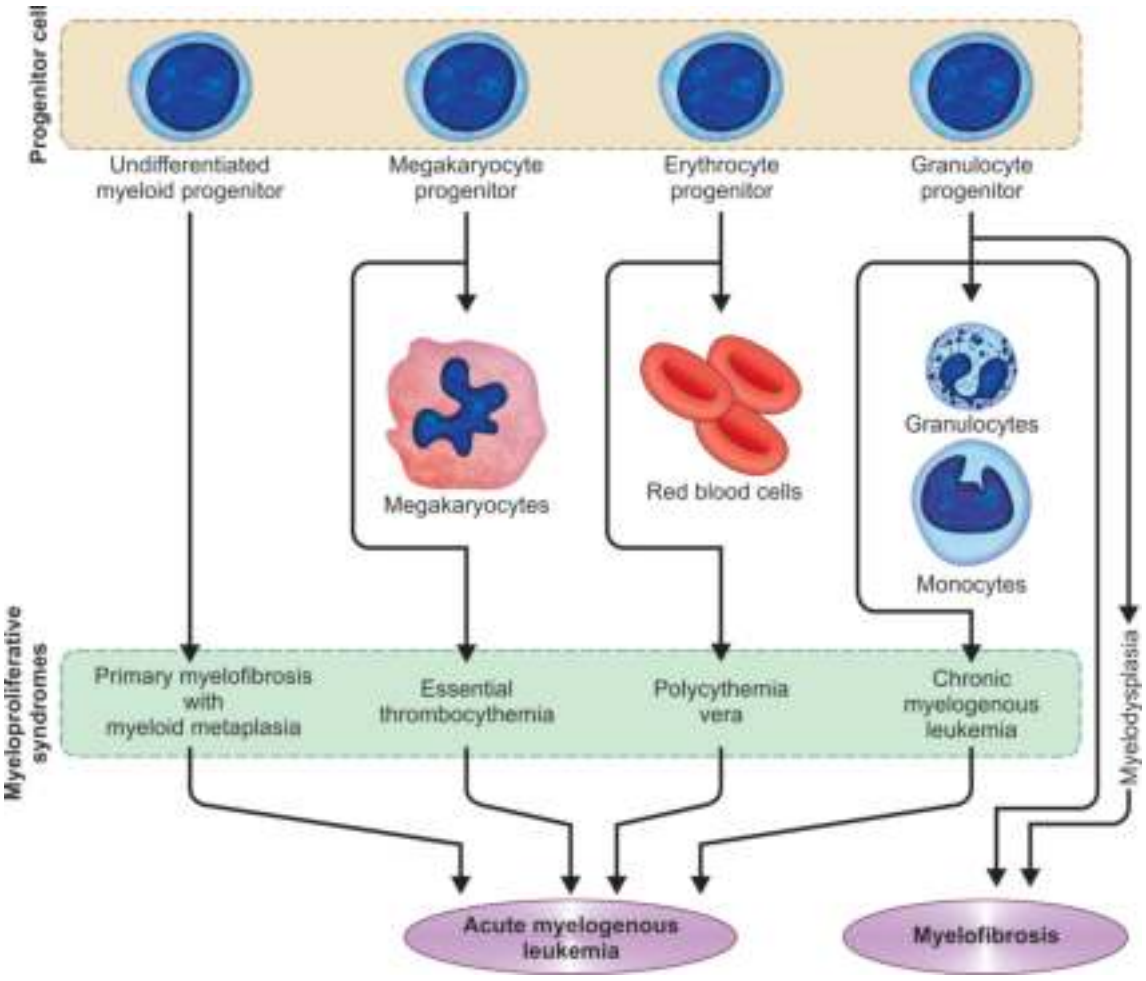

Fig. 9.64: Schematic representation of origin of bone marrow myeloproliferative neoplasms. Each malignant disorder is derived from particular type of myeloid progenitor cells. The myeloproliferative neoplasms are clonal hematopoietic disorders characterized by an overproduction of differentiated hematopoietic cells.

- CMML most often occurs in persons over 60 years of age, which is more common in men than in women. About 20–40% of persons have changes in certain chromosomes.

Molecular Genetic Alterations

The cell of origin of chronic myelomonocytic leukemia (CMML) is believed to be the hematopoietic stem cell (HSC). The clonal molecular genetic alterations are demonstrated in 20–40% of patients, however, none of these clonal molecular genetic alterations is specific.

- Most frequently molecular genetic alterations include chromosome +8, –7/del(7q), del(12p), del(20p), isochromosome 17q, and complex karyotype.
- Mutations in N-RAS/K-RAS, RUNX1, TET2, CBL, or ASX1 genes are demonstrated in 40% of patients.

Diagnostic Criteria

Diagnostic criteria for chronic myelomonocytic leukemia according to revised 2024 World Health Organization (WHO) recommendations are given below:

- Peripheral blood smear examination shows monocytosis $>1 \times 10^9$/L, and <20% of cells (e.g. myeloblasts, monoblasts and promonocytes) in the peripheral blood for at least 3 months including exclusion of all other reactive causes of monocytosis.
- Bone marrow examination shows monoblasts and monocytes, that constitute <20% including dysplasia in one or more myeloid lineages.
- Molecular genetic study shows absence of Philadelphia chromosomal abnormality or BCR-ABL1 fusion gene, and without rearrangement of PDGFRA and PDFGRB genes.
- Some CMMLs are more myeloproliferative in nature with white blood cell count 13×10^9/L, whereas others demonstrate more dysplastic characteristics with white blood cell count $<13 \times 10^9$/L. Diagnostic criteria of chronic myelomonocytic leukemia are given in Table 9.68.

Table 9.67 Features of myelodysplastic/myeloproliferative neoplasms

Classification	Peripheral Blood Smear Examination	Bone Marrow Examination	Genetics	Immunophenotyping
Chronic myelomonocytic leukemia (CMML-1)	▪ Monocytosis >1 × 10^9/L ▪ Blasts <5% including monocytes	▪ Blasts <10% including promonocytes ▪ Dysplasia of ≥1 myeloid lineage	BCR-ABL1 negative	▪ CD33+ ▪ CD13+ ▪ CD14 variable ▪ CD68 variable ▪ CD64 variable ▪ Lysozyme +
Chronic myelomonocytic leukemia (CMML-2)	▪ Monocytosis >1 × 10^9/L ▪ Blasts 5–19% including monocytes	▪ Blasts <10–19% including promonocytes or ▪ When Auer rods present, regardless of blast/promonocyte count	BCR-ABL1 negative	▪ CD33+ ▪ CD13+ ▪ CD14 variable ▪ CD68 variable ▪ CD64 variable ▪ Lysozyme +
Juvenile myelomonocytic leukemia (JMML)	▪ Monocytosis >1 × 10^9/L ▪ Blasts <20%	▪ Bone marrow hypercellular ▪ Blasts <20%, dysgranulopoiesis (occasional dyserythropoietic cell)	BCR-ABL1 negative	▪ CD33+ ▪ CD13+ ▪ CD14 variable ▪ CD68 variable ▪ CD64 variable ▪ Lysozyme +
Atypical chronic myelogenous leukemia (aCML, BCR-ABL1 negative)	▪ Leukocytosis >13 × 10^9/L ▪ Blasts <5% ▪ Promyelocytes, myelocytes, metamyelocytes: 10–20%	▪ Bone marrow hypercellular ▪ Blasts <20%; dysgranulopoiesis, occasional dyserythropoiesis	BCR-ABL1 negative	▪ CD33+ ▪ CD13+ ▪ Myeloperoxidase +
Myelodysplastic/ myeloproliferative neoplasm, unclassifiable (MDS/MPN, U)	▪ Anemia ▪ Leukocytosis and/or thrombocytosis ▪ Blasts <20%	▪ Bone marrow hypercellular ▪ Proliferation in any or all myeloid lineages	BCR-ABL1 negative	Nondiagnostic

Table 9.68 Diagnostic criteria of chronic myelomonocytic leukemia (CMML)

Peripheral Blood Smear Examination

- Persistent peripheral monocytosis >1 × 10^9/L for at least 3 months, monocyte count ≥10% of the leukocytes; and exclusion of all other reactive causes of monocytosis
- Monoblasts and monocytes constitute <20% containing Auer rods
- CMML-0 shows <2% monoblasts
- CMML-1 shows <5% monoblasts
- CMML-2 shows 5–19% monoblasts or Auer rods

Bone Marrow Examination

- Monoblasts and monocytes constitute <20%
- CMML-0 shows <2% monoblasts
- CMML-1 shows <10% monoblasts
- CMML-2 shows <20% monoblasts or Auer rods
- Dysplasia in one or more of myeloid lineages (if dysplasia is absent or minimal, diagnosis of CMML can still be made if the other requirements are met and an acquired cytogenetic or molecular abnormality is present)

Not Meeting WHO Criteria

- BCR-ABL1 positivity as demonstrated in chronic myelogenous leukemia
- Primary myelofibrosis
- Polycythemia vera
- Essential thrombocythemia

No Evidence of Gene Mutation

- PDGFRA
- PDFGRB
- PCM1-JAK2
- EGFR1 rearrangement

Table 9.69 Revised 2024 WHO subclassification for chronic myelomonocytic leukemia (CMML)

CMML Variants in Comparison to AML	Peripheral Blood Smear Examination	Bone Marrow Examination
CMML-0	<2% blasts	<2% blasts
CMML-1	<5%blasts	5–9% blasts
CMML-2	5–19% blasts or Auer rods	10–19% blasts or Auer rods
Acute myelogenous leukemia	≥20% blasts	≥20% blasts

CMML Subcategories

Currently, chronic myelomonocytic leukemias (CMMLs) can be divided into three subcategories (CMML-0, CMML-1 and CMML-2) depending on the number of blasts present in the peripheral blood and bone marrow.

- **Chronic myelomonocytic leukemia 0 (CMML-0):** It is defined by the presence of <2% blasts in peripheral blood and <2% blasts in the bone marrow.
- **Chronic myelomonocytic leukemia 1 (CMML-1):** It is defined by the presence of <5% blasts (i.e. 2–4 blasts) in the peripheral blood and <10% blasts (i.e. 5–9% blasts) in the bone marrow.
- **Chronic myelomonocytic leukemia 2 (CMML-2):** It is defined by the presence of 5–19% blasts (i.e. 5–19) or Auer rods in the peripheral blood and <20% (i.e. 10–19) blasts in the bone marrow or whenever Auer rods are present in blasts. Revised 2024 WHO subclassification for chronic myelomonocytic leukemia is given in Table 9.69.

Clinical Features

Patient presents with fever, weight loss, pallor, generalized weakness, recurrent infections, shortness of breath, easy bruising, and hepatosplenomegaly. Certain factors affect the prognosis and treatment options, which include: the number of white blood cells or platelets produced in the bone marrow or blood, presence or absence of anemia, percentage of blasts in the bone marrow or blood, the amount of hemoglobin in the red blood cells and certain alterations in the chromosomes.

Prognostic Factors

Prognosis of CMML is poor, with a median overall survival of 2–3 years.

- Approximately 15–30% of CMML cases have increased risk of transformation to acute myelogenous leukemia (AML) associated with high white blood cell count, thrombocytopenia, ASXL1 (frameshift or nonsense mutations) and certain molecular genetic alterations including trisomy 8, alterations of chromosome 7 and a complex karyotype.
- Allogeneic hematopoietic stem cell transplantation remains the only curative treatment option to treat CMML.

Laboratory Diagnosis

The various tests are performed to diagnose or rule out myelodysplastic/myeloproliferative neoplasms, which include: (a) complete blood count to assess the number and quality of white blood cells (leukocytosis or leukopenia with relative monocytosis and neutrophilia or neutropenia), red blood cells (anemia) and platelets (thrombocytopenia or rarely thrombocytosis), (b) blood biochemistry tests to know how well certain organs are functioning (increased serum lactate dehydrogenase), (c) bone marrow aspiration, and bone marrow trephine biopsy to confirm whether or not person has myelodysplastic/myeloproliferative neoplasm, (d) molecular genetic tests on a sample of blood or bone marrow cells to look for certain changes to chromosomes, and (e) fluorescence *in situ* hybridization (FISH) to analyze specific alterations in chromosomes and some abnormalities that are too small for standard molecular cytogenetic testing to find chromosomal alterations.

Laboratory Diagnosis of Chronic Myelomonocytic Leukemia

Peripheral Blood Smear Examination

- Giemsa-stained peripheral blood smear examination shows relative and absolute monocytosis, variable increased immature monocytes (promonocytes and monoblasts), which may show neutrophilia or neutropenia with variable dysplastic neutrophils (hypogranular, hyperlobated).
- There may be left shift of granulocytes accounting for <10% of leukocytes and blasts are <20% by definition. There may be presence of variable anemia and thrombocytopenia.
- Chronic myelomonocytic leukemia (CMML) in Giemsa-stained peripheral blood smear is shown in Fig. 9.65.

Cytochemistry

Myeloperoxidase (MPO) stain positivity in chronic myelomonocytic leukemia (CMML) in Giemsa-stained peripheral blood smear is shown in Fig. 9.66.

Bone Marrow Smear Examination

- Giemsa-stained bone marrow examination shows hypercellular marrow and myelomonocytic proliferation resulting in increased myeloid:erythroid ratio but an increased erythroid precursor cells in some cases.

- Monocytic proliferation and dysgranulopoiesis are always present. Dysmegakaryopoiesis is observed in ≤80% of cases. Bone marrow shows mild to moderate reticulin fibrosis.

Histopathologic Examination

Splenic red pulp is usually infiltrated by leukemic cells in cases of chronic myelomonocytic leukemia.

JUVENILE MYELOMONOCYTIC LEUKEMIA

Juvenile myelomonocytic leukemia (JMML) is an aggressive childhood myeloproliferative hematopoietic stem cell disorder affecting younger children of >4 years of age.

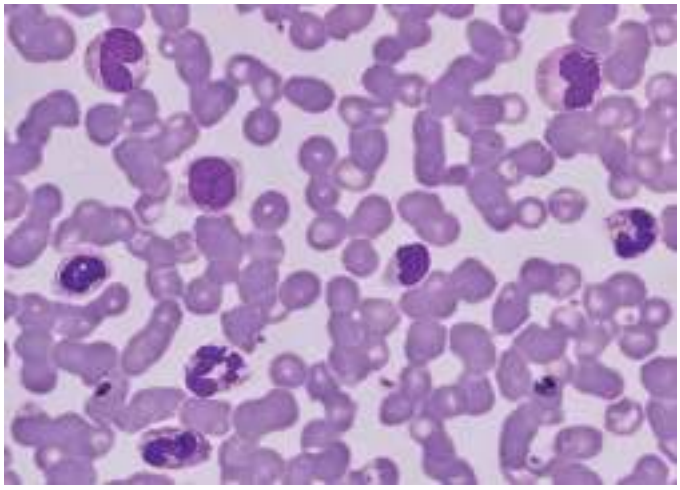

Fig. 9.65: Chronic myelomonocytic leukemia (CMML) in Giemsa-stained peripheral blood smear. It shows persistent peripheral monocytosis >1 × 10⁹/L for at least 3 months, monocyte count ≥10% of the leukocytes; and exclusion of all other reactive causes of monocytosis. Although the peripheral blood finding of absolute monocytosis is essential for diagnosis, yet other hematologic findings are remarkably variable. Dyshematopoiesis can range from minimal expression in a single lineage to marked dysplasia in all the lineages (1000X).

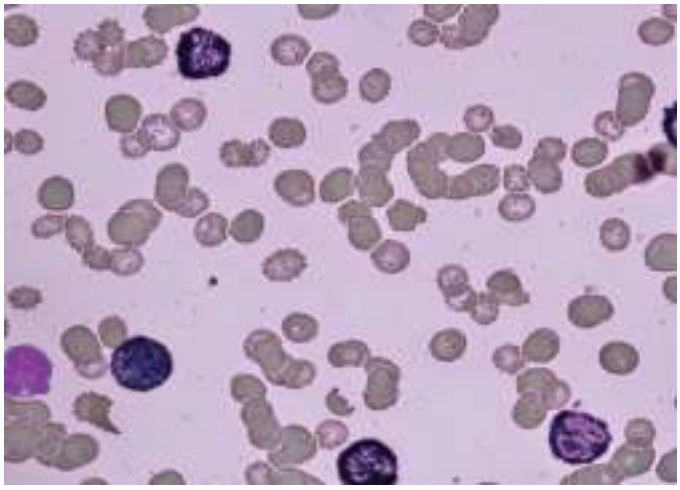

Fig. 9.66: Myeloperoxidase (MPO) stain positivity in chronic myelomonocytic leukemia in Giemsa-stained peripheral blood smear (1000X).

- JMML is characterized by proliferation and immaturity of the granulocytic and monocytic lineages in the peripheral blood and bone marrow.
- Bone marrow examination demonstrates dysmyelopoiesis and dyserythropoiesis; and rarely dysmegakaryopoiesis. JMML patient presents with anemia and thrombocytopenia.

Molecular Genetic Alterations

The cell of origin of juvenile myelomonocytic leukemia (JMML) is believed to be the hematopoietic stem cell (HSC). The gain-of-function mutations in N-RAS and K-RAS genes and disruption of tumor suppressor genes like NF1 are essential in the pathogenesis of JMML.

- Moreover, somatic **PTPN11 gene mutation** is demonstrated in 30–40% of JMMC. PTPN11 proto-oncogene encodes Src homology tyrosine phosphatase with a role in RAS/MAPK signal transduction and hematopoiesis. These molecular changes have been included in the diagnostic criteria of JMML.
- A significant association with neurofibromatosis type 1 (NF1) occurs in JMML. Overall prognosis of JMML is poor due to leukemic infiltration in organs.

Diagnostic Criteria

Salient features for diagnosis of juvenile myelomonocytic leukemia include: (a) peripheral blood smear shows monocytosis (>1 × 10⁹/L), <20% blasts (monoblasts and promonocyte) in peripheral blood and bone marrow; (b) absence of Philadelphia chromosome or BCR-ABL1 fusion gene, (c) increase in fetal hemoglobin for age, (d) immature granulocytes, leukocyte count >10 × 10⁹/L, (e) clonal chromosomal abnormality, and (f) GM-CSF hypersensitivity of myeloid progenitors *in vitro*. Recent WHO diagnostic criteria for juvenile myelomonocytic leukemia are given in Table 9.70.

Clinical Features

Patient presents with hemorrhagic tendencies, lymphadenopathy and skin rashes. Marked splenomegaly is less frequent finding. Patient has a poor response to therapy with fatal outcome.

Laboratory Diagnosis of Juvenile Myelomonocytic Leukemia (JMML)

Peripheral Blood Smear Examination

- Peripheral blood smear examination shows leukocytosis (>10 × 10⁹/L), monocytosis, absolute monocyte count (>1 × 10⁹/L) and thrombocytopenia unlike adult chronic myelogenous leukemia.

- Monoblasts and promonocytes constitute <20% of white blood cells.
- Neutrophil alkaline phosphatase score is low. Juvenile myelomonocytic leukemia (JMML) in a 10-month-old boy in Giemsa-stained peripheral blood smear is shown in Fig. 9.67.

Bone Marrow Smear Examination

Bone marrow is hypercellular. Monoblasts and promonocytes constitute <20% of cells. Megakaryocytes are decreased.

Prognostic Factors

Certain factors affect prognosis and treatment options of juvenile myelomonocytic leukemia. Prognosis depends on the age of the child at diagnosis, number of platelets in the blood and the amount of certain type of hemoglobin in the red blood cells. Poor prognostic factors for juvenile myelomonocytic leukemia include thrombocytopenia and increased fetal hemoglobin.

ATYPICAL CHRONIC MYELOGENOUS LEUKEMIA (aCML), BCR-ABL1 NEGATIVE

Atypical chronic myelogenous leukemia (aCML), BCR-ABL1 negative is a rare myelodysplastic syndrome/myeloproliferative neoplasm for which no current standard of management exists. Peripheral blood smear examination shows prominent immature granulocytosis and granulocytic dysplasia.

Table 9.70 Recent WHO diagnostic criteria for juvenile myelomonocytic leukemia with absence of BCR-ABL-1

Clinical and Hematologic Features (All Mandatory)
Peripheral monocytosis ($\geq 1 \times 10^9$/L)
Peripheral blood and bone marrow demonstrate <20% blasts (monoblasts and promonocyte)
Splenomegaly
Absence of Philadelphia chromosome (BCR-ABL1 rearrangement)
Genetic Analysis (One Finding Sufficient)
Somatic mutation in PTPN11 (35%) or K-RAS or N-RAS
Clinical diagnosis of neurofibromatosis type 1 due to NF1 gene mutation
Germline CBL gene mutation and loss of heterozygosity of CBL.
For Patients without Genetic Features, besides Clinical and Hematologic Features (Criteria must be fulfilled)
Monosomy 7 or any other chromosomal abnormality or at least two of the following mentioned below:
Hemoglobin F increased for age
GM-CSF hypersensitivity of myeloid progenitors *in vitro*
Hyperphosphorylation of STAT5
Presence of myeloid or erythroid precursors in the peripheral blood

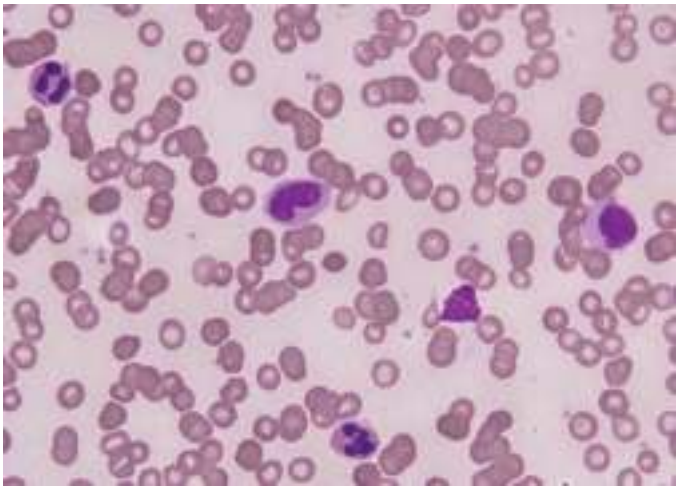

Fig. 9.67: Juvenile myelomonocytic leukemia (JMML) in a 10-month-old boy in Giemsa-stained peripheral blood smear. Complete blood count showed WBC of 10×10^9/L with 28% monocytes and significant myeloid left-shift. Molecular analysis showed evidence of a somatic PTPN11, N-RAS or K-RAS or NF1 gene mutations, all of which encode components of RAS dependent pathways in 30–40% of juvenile myelomonocytic leukemia and atypical chronic leukemia (aCML)(1000X).

- The cell of origin of atypical chronic myelogenous leukemia (aCML), BCR-ABL1 negative is believed to be the common myelogenous progenitor (CMP) cell. Molecular genetic alterations in aCML are similar as demonstrated in chronic myelomonocytic leukemia.
- Atypical chronic myelogenous leukemia shares clinical and laboratory features of chronic myelogenous leukemia but lacks the BCR-ABL1 fusion.
- Molecular genetic analysis reveals mutation of SETBP1 gene encoding Gly870Ser. Patient with SETBP1 gene mutation has higher total leukocyte count associated with poor prognosis.
- Atypical chronic myelogenous leukemia affects elderly persons with male predominance. Majority of patients die due to bone marrow failure.

Molecular Genetic Alterations

Molecular genetic alterations and molecular genetic studies are essential in the diagnosis of atypical myelogenous leukemia, to exclude t(9;22) or BCR-ABL1 positive chronic myelogenous leukemia. No definite molecular genetic alteration is known in atypical chronic myelogenous leukemia, but del(20p) (q11), del(12p), del(12p), trisomy 8 and 13, and i(17q); and complex karyotype have been reported. Mutations of the N-RAS/K-RAS, RUNX1, TET2, CBL, or ASX1 proto-oncogenes are demonstrated in about 30% of patients.

Revised 2024 WHO Diagnostic Criteria for Atypical CML (BCR-ABL1 Negative)

Recent 2024 WHO diagnostic criteria for atypical chronic myelogenous leukemia, BCR-ABL1 negative include the peripheral white blood cells (WBCs) count must be $>13 \times 10^9/L$ with increased dysplastic neutrophils and their precursors. Blasts constitute <20%; and promyelocytes, myelocytes and metamyelocytes together constitute >10% in the peripheral blood.

- Absolute monocytosis and basophilia are absent. Dysplasia and ineffective hematopoiesis in other cell lines frequently result in anemia and thrombocytopenia. Prognosis of aCML is very poor ranging between 11 and 25 months.
- Revised 2024 WHO diagnostic criteria for atypical chronic myelogenous leukemia, BCR-ABL1 negative are given in Table 9.71.

Clinical Features

Patients with atypical chronic myelogenous leukemia have some features of usual chronic myelogenous leukemia, BCR-ABL1 positive with splenomegaly, an elevated white blood cells count of predominantly granulocytic cells, anemia and normal or decreased platelet count.

- Atypical chronic myelogenous leukemia, BCR-ABL1 negative appears to be more aggressive disease than usual chronic myelogenous leukemia with progression occurring within two years.
- Patients may develop acute myelogenous leukemia or bone marrow failure secondary to marked bone marrow fibrosis. Majority of patients die due to bone marrow failure.

Table 9.71 Recent 2024 WHO diagnostic criteria for atypical chronic myelogenous leukemia, BCR-ABL1 negative

Peripheral Blood Leukocytosis
Peripheral blood leukocytosis occurs due to increased neutrophils number and their precursors (i.e. promyelocytes, myelocytes, metamyelocytes) constituting >10% of leukocytes
Number of blasts <20%
Dysgranulopoiesis, which may include abnormal chromatin clumping
No or minimal absolute basophils; basophils constitute usually <2% of leukocytes
No or minimal absolute monocytosis; monocytes constitute <10% of leukocytes
Hypercellular Bone Marrow Associated with Findings
▪ Myeloid to erythroid ratio is about 10:1
▪ Granulocytic proliferation and granulocytic dysplasia, with or without dysplasia in the erythroid and megakaryocytic lineages
▪ Blasts <20%
Absence of the Following Molecular Genetic Alterations
▪ PDGFRA
▪ PDGFRB
▪ FGFR1 rearrangement
▪ PCM1-JAK2
Not Meeting WHO Criteria for Following
▪ Chronic myelogenous leukemia, BCR-ABL1 positive
▪ Polycythemia vera (PV)
▪ Essential thrombocythemia (ET)
▪ Primary myelofibrosis (PMF)

CHRONIC MYELOPROLIFERATIVE NEOPLASMS

Chronic myeloproliferative neoplasms are heterogenous group of disorders, which include polycythemia vera (PV), chronic myelogenous leukemia, BCR-ABL1 positive, chronic myelomonocytic leukemia (CMML), chronic neutrophilic leukemia, chronic eosinophilic leukemia (CEL), not otherwise specified, chronic basophilic leukemia (CBL), primary myelofibrosis (PMF), essential thrombocytosis, mast cell disease (mastocytosis), and chronic myeloproliferative neoplasm (MPN) unclassifiable. Classification of chronic myeloproliferative neoplasms by prominent cell type is given in Table 9.72. The revised 2024 WHO classification of myeloproliferative neoplasms is given in Table 9.73. Chronic myeloproliferative neoplasms associated with gene mutation/rearrangement of receptor tyrosine kinase genes are given in Table 9.74. Genetic assessment of chronic myeloproliferative neoplasms is given in Table 9.75.

CHRONIC MYELOGENOUS LEUKEMIA, BCR-ABL1 POSITIVE

Chronic myelogenous leukemia (CML), BCR-ABL1 positive is myeloproliferative neoplasm characterized by clonal proliferation of granulocytes. CML arises from pluripotent hematopoietic stem cell in the bone marrow with 9(9;22) (q34.1;q11.2) chromosomal translocation and formation of the Philadelphia chromosome, containing the BCR-ABL1 fusion gene. Myeloid lineage is most often affected with elevation of granulocytes in the peripheral blood. Erythroid and megakaryocytic cell lineages as well as B cells can also expand, without T cells.

Table 9.72 Classification of chronic myeloproliferative neoplasms by prominent cell type

Involved Cell Line	Chronic Myeloproliferative Neoplasms
Erythroid cell lineage	Polycythemia vera (PV)
Myeloid cell lineage	▪ Chronic myelogenous leukemia (CML), BCR-ABL1 positive ▪ Chronic myelomonocytic leukemia (CMML) ▪ Chronic neutrophilic leukemia (CNL) ▪ Primary myelofibrosis (sometimes)
Megakaryocyte cell lineage	Essential thrombocythemia (ET)
Eosinophil cell lineage	Chronic eosinophilic leukemia (CEL)
Basophil cell lineage	Chronic basophilic leukemia (CBL)
Mast cell lineage	Mast cell disease (mastocytosis)
Variable cell lineage	Myeloproliferative disease, unclassified (MPD-U)
Fibroblasts*	Chronic idiopathic myelofibrosis (CIMF) with extramedullary hematopoiesis

**The fibroblast in chronic idiopathic myelofibrosis is not a part of neoplastic process but is increased due to reactive process.*

- Natural clinical course of CML disease occurs in three different phases: chronic phase (CP), accelerated phase (AP) and blast phase (BP). In chronic phase involves blood, bone marrow, spleen and liver. Chronic phase of CML progresses to accelerated phase. In blast phase, spleen, liver, lymph nodes, skin and soft tissues are the most common extramedullary sites of involvement.

Table 9.73 The revised 2024 World Health Organization classification of chronic myeloproliferative neoplasms

Chronic myelogenous leukemia (CML), BCR-ABL1 positive
Chronic neutrophilic leukemia (CNL)
Polycythemia vera (PV)
Primary myelofibrosis (PMF) ▪ Primary myelofibrosis prefibrotic/early stage ▪ Primary myelofibrosis overt fibrotic stage
Essential thrombocythemia (ET)
Chronic eosinophilic leukemia (CEL), NOS
Chronic myeloproliferative neoplasm (MPN) unclassifiable

Adapted from revised 2024 World Health Organization (WHO) classification of hematopoietic neoplasms.

- Chronic phase of CML responds well to therapy, which maintains normal health for many months and years. Majority of cases progress from chronic phase to accelerated phase then to blast phase (acute myelogenous leukemia or acute lymphoblastic leukemia) in 3–5 years.
- CML accounts for 15–20% of all leukemias, which can affect any age group with male predominance. Peak incidence is observed between 35 and 90 years of age. Incidence of CML increases with median age of diagnosis at 65 years. Disease is relatively rare in pediatric age group. Disease has an insidious onset. Ionizing radiation is the only known etiological factor. CML usually occurs within 6–8 years of radiation exposure.

Table 9.74 Chronic myeloproliferative neoplasms associated with gene mutation/rearrangement of receptor tyrosine kinase genes

Disorder	Gene Mutation	
Chronic myelogenous leukemia	BCR-ABL1	
Polycythemia vera (PV)	▪ JAK2 V617 (97%) ▪ JAK exon 12 ▪ CALR (0%)	▪ MPL (<1%) ▪ Triple negative: JAK2 V617, CALR, MPL
Chronic neutrophilic leukemia (CNL)	CSF3R T6181	
Primary myelofibrosis (PMF)	▪ JAK2 V617 (55–65%) ▪ CALR (20–25%) ▪ MPL (7%)	▪ Triple negative: JAK2 (V617F), CALR, MPL in 5–10%
Essential thrombocythemia (ET)	▪ JAK2 V617 (50–60%) ▪ CALR (20–25%) ▪ MPL (3–5%)	▪ Triple negative: JAK2 (V617F), CALR, MPL in 10–15%
Mastocytosis	KIT D816V	
Myeloid neoplasms with eosinophilia	▪ PDGFRA ▪ PDGFRB	▪ FGFR1 ▪ PCM1-KAK2

1. JAK2 V617 gene mutation is demonstrated in polycythemia vera, primary myelofibrosis, essential thrombocythemia, acute myelogenous leukemia, myelodysplastic syndrome, chronic myelomonocytic leukemia and myelodysplastic syndrome/myeloproliferative neoplasms.
2. JAK exon 12 mutation is demonstrated only in polycythemia vera.

Table 9.75 Genetic assessment of chronic myeloproliferative neoplasms

Unique 'Driver Molecular Genetic Alterations*	Comments	Most Frequent Molecular Genetic Alterations	Cytogenetic Alterations
Chronic myelogenous leukemia (CML) BCR-ABL1 positive			
BCR-ABL1	BCR-ABL1 fusion product demonstrated in CML	▪ TP53 ▪ RB1 ▪ RAS ▪ Myc ▪ AML1 ▪ EVI1 ▪ CDKN2A	▪ +8 ▪ +9 ▪ Philadelphia duplication ▪ Iso(17q) +
Chronic neutrophilic leukemia (CNL)			
CSF3R T6181 or CSF3R activating mutations positive	▪ Activating mutation in gene encoding the receptor for the colony stimulating factor (CSF3R) ▪ Patient carrying JAK activating CSF3R has marked improvement after administration of the JAK1/JAK2 inhibitor ruxolitinib	▪ Chromatin modifiers (ASXL1, EZH2) ▪ Spliceosome (SRSF2, SF3B1)	▪ +8 ▪ +9 ▪ del(20q) ▪ del(13q) ▪ del(5q)
Polycythemia vera (PV)			
▪ JAK2 V617F positive (>97%) ▪ JAK2 exon 12 (3%) ▪ MPL (1%) ▪ Triple negative (0–1%)	JAK2 allele burden is linked to transformation to acute leukemia (100% cases)	DNA methylation (TET2, DNMT3A, IDH1, IDH2, TP53)	▪ 7/del(7q) ▪ Complex karyotype ▪ del(17p)
Primary myelofibrosis (PMF)			
JAK2 (V617F) positive (60–65%)	JAK2 positivity has relatively low survival rate in comparison to CALR positivity	Activating signaling pathways (RAS, CBL)	No cytogenic aberration
CALR exon 9 positive (20–25%)	CALR positivity occurs in younger age with indolent clinical course and better survival than JAK2 positive	Activating signaling pathways (RAS, CBL)	No cytogenic aberration
MPL exon 10 positive (5–8%)	MPL exon 10 positivity has greater risk of thrombosis in JAK2 positive cases of primary myelofibrosis	Activating signaling pathways (RAS, CBL)	No cytogenic aberration
Triple negative: JAK2 (V617F), CALR, MPL (5–10%)	Triple negative status linked to inferior outcome and increase risk for transformation to acute leukemia	Activating signaling pathways (RAS, CBL)	No cytogenic aberration
Essential thrombocythemia (ET)			
JAK2 (V617F) positive (50–60%)	Higher rate of thrombosis in JAK2 positive patients	No molecular mutations	No cytogenic aberration
CALR exon 9 positive (20–25%)	Higher platelet count and high rate of fibrotic transformation in CALR positive essential thrombocytosis patients	No molecular mutations	No cytogenic aberration
MPL exon 10 positive (3–5%)	Survival rate is short in MPL negative mutated patients	No molecular mutations	No cytogenic aberration
Triple negative: JAK2 (V617F), CALR, MPL (10–15%)	Survival rate is longest for triple negative	No molecular mutations	No cytogenic aberration

Contd...

Table 9.75 Genetic assessment of chronic myeloproliferative neoplasms (*Contd...*)

Unique 'Driver Molecular Genetic Alterations*	Comments	Most Frequent Molecular Genetic Alterations	Cytogenetic Alterations
Mastocytosis			
c-KIT positive (frequent)	Abnormal growth and accumulation of atypical mast cells in the bone marrow and viscera	No molecular mutations	No cytogenic aberration
Chronic eosinophilic leukemia (CEL)			
No distinctive genotype	Persistent increase in eosinophils in peripheral blood, bone marrow and tissues	No molecular mutations	No cytogenic aberration
Myeloproliferative neoplasia unclassifiable			
No distinctive genotype	MPN unclassifiable with ring sideroblasts	No molecular mutations	No cytogenic aberration

**Some molecular genetic alterations can precede the 'driver' mutation or acquired during disease progression. Some cytogenetic abnormalities are associated with accelerated phase and/or leukemic transformation.*

- Children and young adults tend to have a more aggressive clinical presentation than older adults, more frequent in accelerated or blast phase. Prognosis is very poor in transformation of accelerated phase to blast phase and associated with survival of <6 months by using traditional chemotherapy.
- Three different phases, approximate length of phase and treatment status of chronic myelogenous leukemia (CML) BCR-ABL1 are given in Table 9.76.

PATHOPHYSIOLOGY

Molecular genetic analysis has increased our understanding the role of Philadelphia chromosome in the pathogenesis of chronic myelogenous leukemia (CML) BCR-ABL1 positive.

- Philadelphia chromosome (Ph) is an acquired chromosomal translocation that results in fusion gene called BCR-ABL1. Reciprocal chromosomal translocation t(9;22)(q34;q11) leads to the formation of the BCR-ABL1 chimeric fusion gene, which is

Table 9.76 Three different phases, approximate length of phase and treatment status of chronic myelogenous leukemia (CML), BCR-ABL1 positive

CML Phases and Features	Approximate Length of Phase	Treatment Status with Chemotherapy
CML chronic phase		
▪ Presence of blasts <10% in bone marrow and peripheral blood ▪ Massive splenomegaly (>90% of cases)	2–5 years	Highly treatable phase
CML accelerated phase		
▪ Presence of blasts 10–19% in bone marrow and peripheral blood ▪ Progressive splenomegaly ▪ Associated with additional chromosomal and molecular abnormalities	6–18 months	Resistance to chemotherapy develops
CML blast phase		
▪ Presence of blasts ≥20% in the bone marrow and peripheral blood ▪ Proliferation of blasts in extramedullary sites such as lymph nodes, skin, nervous system and other sites ▪ Blasts are present in clusters in bone marrow trephine biopsy ▪ Associated with additional chromosomal and molecular abnormalities	3–4 months	Generally unresponsive to chemotherapy

responsible for production of the oncoprotein BCR-ABL1. BCR-ABL1 oncoprotein has unrestricted tyrosine kinase activity, making abnormal pluripotent hematopoietic stem cell initiate excessive production of all myeloid cell lineages.

- Once the Philadelphia chromosome is detected, its rise and fall reflects the tumor burden; and hence can be used as measure of the disease progression, remission and relapse.
- All the three cell lineages of the hematopoietic stem cells are involved in CML, the original neoplastic cell is pluripotent hematopoietic stem cell (HSC). Pathogenesis of chronic myelogenous leukemia (BCR-ABL1 positive) is shown in Fig. 9.68.

Pathology Pearls: CML, BCR-ABL1 Positive Pathogenesis

First Hypothesis

According to first hypothesis, the acquisition of BCR-ABL1 may occur in a pluripotent hematopoietic stem cell with little or no T cells differentiation capacity in chronic myelogenous leukemia.

Second Hypothesis

- According to second hypothesis, T cells bearing BCR-ABL1 may be systematically eliminated.
- Unregulated proliferation of BCR-ABL1 positive pluripotent hematopoietic stem cell is responsible for massive expansion, primarily in granulocyte production, which leads to leukocytosis.
- Extramedullary granulocytic proliferation in the spleen and liver induces splenomegaly and hepatomegaly respectively, that reflects progression of disease.

Philadelphia Chromosome

Philadelphia chromosome is formed by balanced reciprocal translocation between long arms of chromosomes 9 and 22, t(9;22) (q34;q11.2) in CML,BCR-ABL1 positive. Lengthened Philadelphia chromosome is chromosome 22. Chronic myelogenous leukemia exhibiting balanced reciprocal translocation 9/22 known as Philadelphia chromosome is shown in Fig. 9.69. Exon maps of the normal BCR-ABL1 genes, formed by the Philadelphia chromosome translocation in CML and *de novo* acute leukemias are shown in Fig. 9.70.

Pathology Pearls: BCR-ABL1 Fusion Gene in Chronic Myelogenous Leukemia (CML)

- Exon maps of the normal BCR-ABL1 genes, formed by the Philadelphia chromosome translocation in CML and *de novo* acute leukemias.
- Philadelphia chromosome is formed by balanced reciprocal translocation between long arms of chromosomes 9 and 22, t(9;22) (q34;q11.2) in CML.
- Chromosome 22 is known as Philadelphia chromosome. Normally, ABL1 gene is located on chromosome 9 and BCR gene is located on chromosome 22. Due to reciprocal chromosomal translocation, BCR-ABL1 fusion gene is formed in CML and *de novo* acute leukemias.
- Breakpoints in the ABL1 gene occur upstream of exon 2 (e2 downstream arrow). Breakpoints in major breakpoint cluster region (**M-BCR**) of the BCR gene occur in exon 13 (e13) and exon 14 (e14).
- Breakpoints can also take place in the minor breakpoint cluster region (M-BCR, 3' of exon 1) in acute lymphoblastic leukemia. Following BCR-ABL1 fusion gene, the resulting protein of 210 (p210; e13a2 or e14a2) or 190 (p190; e1a190; e1a2) kilodalton is formed.

- **Normal ABL1 and BCR gene:** Normally, **ABL1 gene** is located on chromosome 9 and **BCR gene** is located on chromosome 22. Breakpoints in major breakpoint cluster region (M-BCR) of the BCR gene occur in exon 13 (e13) and exon 14 (e14), in which receptor tyrosine kinase domains reside. BCR-ABL1 fusion gene is formed by Philadelphia chromosome contain BCR-ABL1 fusion gene due to reciprocal chrosomal translocation found in CML and *de novo* acute leukemias.
- **Breakpoints in the ABL1 gene and BCR gene:** Breakpoints in the ABL1 gene occur upstream of exon 2 (a2 downstream arrow) in major breakpoint cluster region (M-BCR) of the BCR gene in exon 13 (e13) and exon 14 (e14). Breakpoints can also take place in the minor breakpoint cluster region (M-BCR, 3' of exon 1) in acute lymphoblastic leukemia. Following BCR-ABL1 fusion gene, the resulting protein of 210 (p210; e13a2 or e14a2) or 190 (p190; e1a190; e1a2) kilodalton is formed.
- **Formation of new BCR-ABL1 fusion gene:** Formation of new BCR-ABL fusion gene coding for the BCR-ABL fusion putative oncoprotein has increased receptor tyrosine protein kinase activity, which is presumably involved in the pathogenesis of CML.
  - BCR-ABL fusion putative oncoprotein binds ATP then transfers phosphate groups to receptor tyrosine kinase residues on various substrate proteins forming phosphorylated substrate within cells that activates intracellular signal transduction pathways involved in unrestricted cell proliferation, maturation, and resistance to apoptosis, ultimately resulting in the leukemic phenotype.
  - Administration of receptor tyrosine kinase inhibitor blocks ATP binding to BCR-ABL, so the substrate cannot be phosphorylated, hence proliferation of the leukemic cells cannot occur.
  - Levels of detection of disease include analysis of morphologic features, cytogenetic alterations and

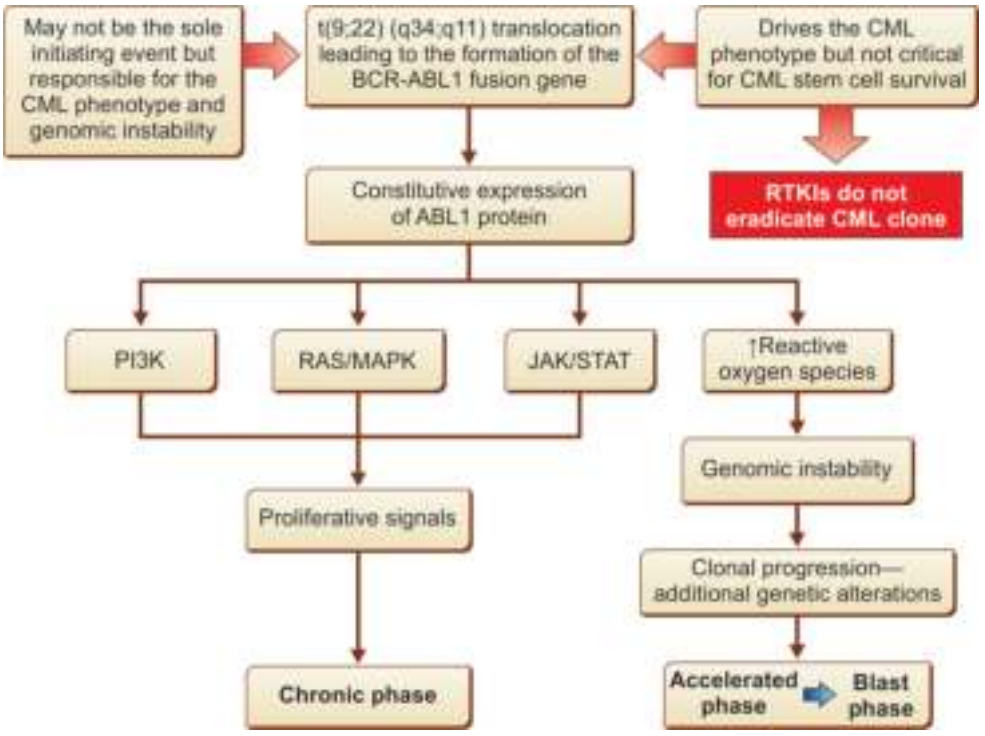

Fig. 9.68: Schematic representation of pathogenesis in chronic myelogenous leukemia (CML), BCR-ABL1 positive.

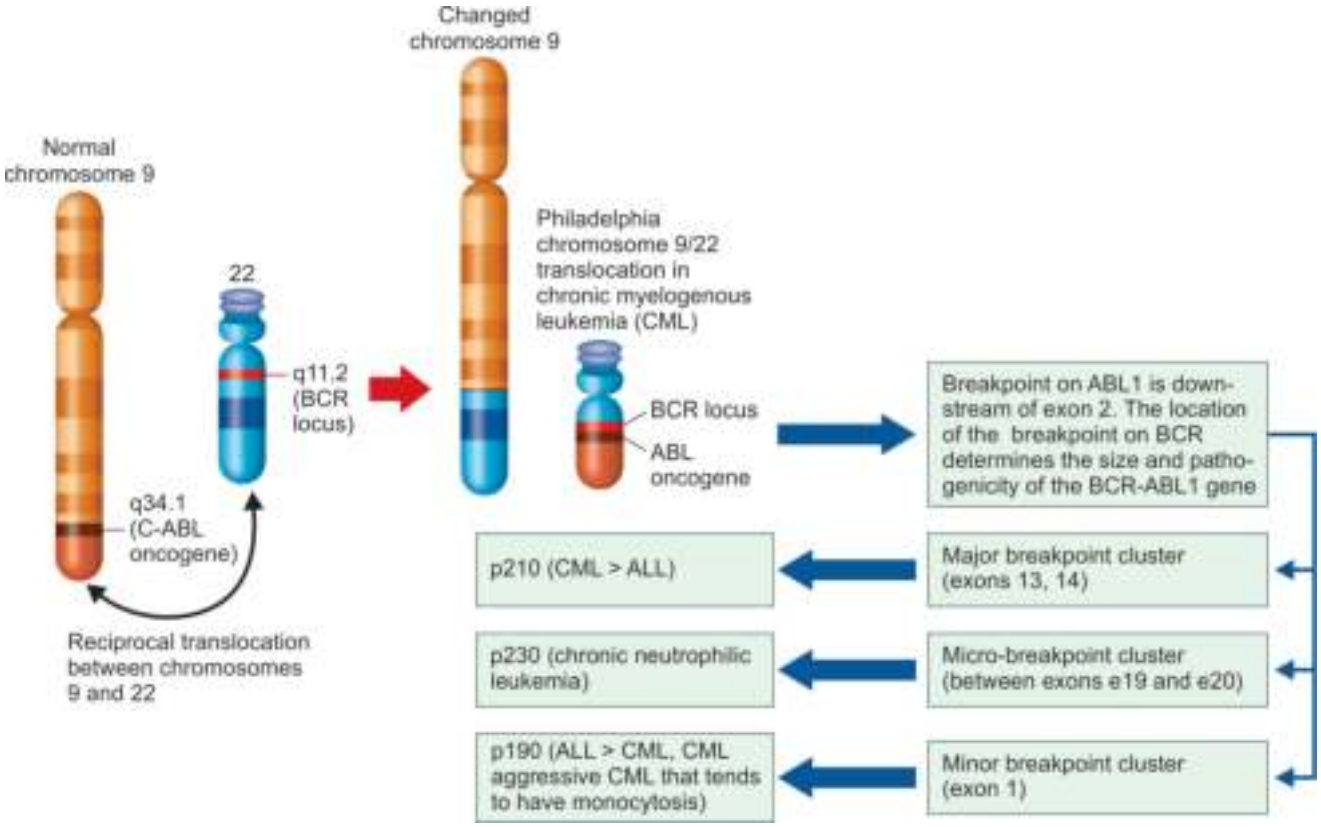

Fig. 9.69: Schematic representation of chronic myelogenous leukemia (CML), BCR-ABL1 positive. It shows balanced reciprocal translocation 9/22 known as Philadelphia chromosome. A reciprocal translocation involves two nonhomologous chromosomes, with exchange of the acentric segment. There is exchange of a segment between two nonhomologous chromosomes. Balanced reciprocal translocation 9/22 known as Philadelphia chromosome is seen in chronic myelogenous leukemia. Positivity of this Philadelphia chromosome indicates good prognosis. In interstitial translocation, a segment of a chromosome is lost and reattaches to nonhomologous chromosome.

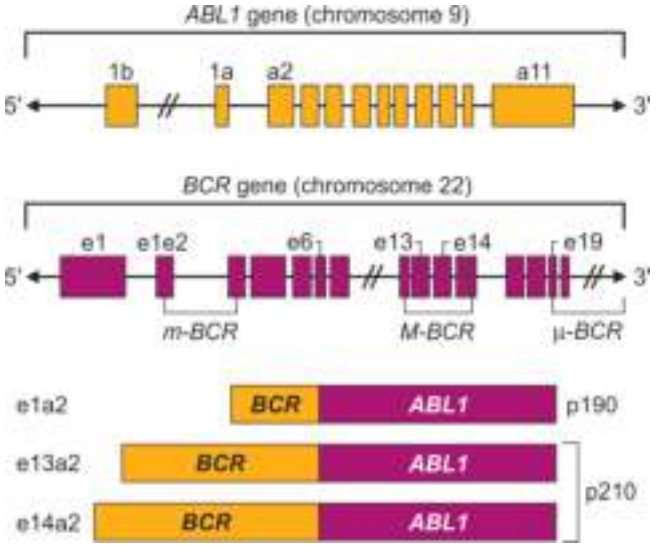

Fig. 9.70: Schematic representation of CML, BCR-ABL1 fusion gene in CML, BCR-ABL1 positive. It depicts exon maps of the normal BCR gene on chromosome 22 and ABL1 on chromosome 9 gene, and the BCR-ABL1 fusion gene formed by the Philadelphia chromosome translocation found in CML and *de novo* acute leukemias. Breakpoints in the ABL1 gene occur upstream of exon 2. Breakpoints in the major breakpoint cluster region (M-BCR) of the BCR gene occur in exon 13 and exon 14 in CML; breakpoints in the minor breakpoint cluster region (m-BCR,3' of exon 1) in acute leukemias. Following BCR-ABL1 fusion gene, the resulting protein of 210 or 190 is formed.

reverse transcriptase (RQ)-PCR following receptor tyrosine kinase inhibitor (RTKI) therapy. Detection of the BCR gene rearrangement has diagnostic and prognostic significance in CML cases.

Additional Chromosomal/Molecular Genetic Alterations in Progression of CML

Untreated cases of chronic myelogenous leukemia (CML) progressing from chronic phase to accelerated phase and blast phase, are accompanied by development of additional chromosomal abnormalities in 80% of patients.

- Frequent additional chromosomal/molecular genetic alterations in blast phase of CML include mutations in RUNX1, ASXL1, IKZF1, TP53, RB1, RAS, Myc, AML-1, EVI-1, CDKN2A, frequent cytogenetic aberrations (Philadelphia chromosome duplication, trisomy 8, isochromosome 17q, loss of Y chromosome), rare cytogenetic alterations (translocation (15;17), translocation (3;21) (p26; q22) and translocation (3;3), inv(3). Thus, repeated chromosome analysis can be useful in predicting progression of CML disease.
- Mutation of TP53 gene is rare in CML chronic phase. Additional molecular genetic alterations in the progression of chronic myelogenous leukemia (CML), BCR-ABL1 positive is given in Table 9.77.

Table 9.77 Additional molecular genetic alteration in the progression of CML, BCR-ABL1 positive

Molecular Genetic Alterations	Examples
Molecular most frequent mutations	TP53, RB1, RAS, Myc, AML-1, EVI-1, CDKN2A
Cytogenetic frequent aberrations	Philadelphia chromosome duplication, trisomy 8, trisomy 19, isochromosome 17q, loss of Y chromosome
Cytogenetic rare aberrations	Translocation (15;17), translocation (3;21) (p26;q22), translocation (3;3)/inv (3)

MOLECULAR GENETIC ANALYSIS

Molecular genetic analysis is the gold standard diagnostic test for CML, BCR-ABL1 positive. Diagnostic and prognostic significance of molecular genetic analysis of BCR/ABL1 gene rearrangement in CML is given in Table 9.78.

- Diagnostic tests for CML include genomic polymerase chain reaction (PCR) and Northern blot analysis that can determine the exact breakpoints of DNA fusion products. Reverse transcriptase PCR (RT-PCR) and Northern blot analysis demonstrate BCR-ABL1 transcription at the RNA level.
- Immunoprecipitation and Western blot analysis demonstrate BCR-ABL1 protein by using antibodies against N-terminal region of BCR and the C-terminal region of ABL1.
- Molecular genetic analysis of gene arrangements involving the BCR-ABL1 genes is clinically useful for confirmation of Philadelphia positive or negative cases of CML, diagnosis of blast phase, monitoring of patients by using receptor tyrosine kinase inhibitor therapy and after for detection of residual disease,

Table 9.78 Diagnostic and prognostic significance of molecular analysis of BCR-ABL1 gene rearrangement in chronic myelogenous leukemia

Differential diagnosis of CML
Diagnosis of CML with negative Philadelphia chromosome
Differential diagnosis of CML in blast phase from *de novo* acute lymphoblastic leukemia (ALL), when Philadelphia chromosome is positive
Establishment of diagnosis of CML when the patient develops blast phase in the course of disease
Monitoring of CML cases on tyrosine kinase inhibitor (TKI) therapy to determine therapeutic response, resistance to (TKI) therapy or relapse
Detection of minimal residual disease (MRD) in post-bone transplant patients

confirmation of remission and early detection of relapse.

CLINICAL FEATURES

Most chronic myelogenous leukemia patients are diagnosed in the chronic phase of the disease. About 50% of patients are asymptomatic and diagnosed during a routine examination. Disease is insidious onset with leukocytosis, anemia, fatigue, weight loss and night sweats.

- Majority of patients have massive splenomegaly with dragging sensation in the left upper quadrant.
- Rarely, patients present with marked thrombocytosis without leukocytosis, mimicking essential thrombocythemia.
- About 5% of patients present with fever, bone pain and bleeding in the accelerated phase of the blast phase.
- Criteria distinguishing CML, BCR-ABL1 positive at different stages of evolution are given in Table 9.79.

Table 9.79 Criteria distinguishing CML, BCR-ABL1 positive at different stages of evolution

Parameters	CML Chronic Phase	CML Accelerated Phase	CML Blast Phase
Approximate length of CML phases			
Duration of CML phase	2–5 years	6–18 months	3–4 months
Blasts and basophils in the bone marrow and peripheral blood			
Blasts in the peripheral blood	<10%	10–19%	≥20% (patients can develop AML-M1, AML-M2, AML-M4, AML-M6, AML-M7, ALL-L1, ALL-L2)
Blasts in the bone marrow	<10%	10–19%	≥20% (AML-M1, AML-M2, AML-M4, AML-M6, AML-M7, ALL-L1, ALL-L2)
Basophils	<20%	>20%	>20%
CML response to first tyrosine kinase inhibitors (TKIs)			
Therapeutic response to tyrosine kinase inhibitors (TKIs)	High response to chemotherapy	Development of resistance to chemotherapy due to failure of response to tyrosine kinase inhibitors	Failed complete hematologic/molecular remission of CML treated with ≥1 tyrosine kinase inhibitor
Two or more BCR-ABL mutations	Absent	Present	Present
Karyotype at diagnosis			
Chromosomal mutations by cytogenetic study	Philadelphia chromosome	▪ Philadelphia chromosome duplication ▪ Trisomy 8 ▪ Trisomy 19 ▪ Isochromosome 17q	▪ Philadelphia chromosome duplication ▪ Trisomy 8 ▪ Trisomy 19 ▪ Isochromosome 17q ▪ Chromosome Y loss
Molecular mutations			
Gene mutations	Absent	RUNX1 (33%), ASXL1 (21%), IKZF1 (20%), TP53, RB1, RAS, Myc, AML-1, EVI-1, CDKN2A	RUNX1 (33%), ASXL1 (21%), IKZF1 (20%), TP53, RB1, RAS, Myc, AML-1, EVI-1, CDKN2A
Bone marrow megakaryocyte's dysplasia			
Megakaryocyte's dysplasia	No dysplasia in megakaryocyte	Atypical megakaryocytes	Atypical megakaryocytes
Bone marrow fibrosis			
Reticulin/collagen	Absent	Reticulin/collagen deposition present	Reticulin/collagen deposition present
White blood cells escape from control			
White blood cells escape from control	Absent	Persistent increase in white blood cells $>10\times10^9$/L	Persistent increase in white blood cells $>10\times10^9$/L
Platelets			
Thrombocytosis	Absent	$>1{,}000\times10^9$/L	$>1{,}000\times10^9$/L
Thrombocytopenia	Absent	$<100\times10^9$/L	$<100\times10^9$/L

Contd...

Table 9.79 Criteria distinguishing CML, BCR-ABL1 positive at different stages of evolution (*Contd...*)

Parameters	CML Chronic Phase	CML Accelerated Phase	CML Blast Phase
Spleen size			
Splenomegaly	Present	Persistent splenomegaly/unresponsive to therapy	Persistent splenomegaly/unresponsive to therapy
Extramedullary sites involved			
Extramedullary blasts	Absent	Absent	Present
Bone marrow trephine biopsy			
Large foci of blasts in the bone marrow	Absent	Absent	Present

Pathology Pearls: Splenomegaly in Chronic Myelogenous Leukemia, BCR-ABL1 Positive

- The gross appearance of the spleen is solid and deep red, although areas of infarction may appear as light-colored regions.
- The red pulp distribution of the leukemic infiltrate usually compresses and obliterates the white pulp. Leukemic cells are present in the splenic cords and sinuses.
- Leukemic cells are shifted towards immature forms. It is essential to assess the maturity of the leukemic cells in the splenectomy specimens, because splenomegaly particularly in the face of receptor tyrosine kinase inhibitor (RTKI), may be associated with progression of the disease.

CML, BCR-ABL1 Positive in Chronic Phase

In CML, BCR-ABL1 positive in chronic phase, the leukemic cells are minimally invasive and mostly confined to the bone marrow, peripheral blood, spleen and liver.

- Patient presents with weakness, malaise, unexplained fever, night sweats, weight loss, sternal tenderness, dragging sensation in the left upper quadrant of abdomen due to massive splenomegaly. Occasionally, patient may have bleeding from mucocutaneous surface (gastrointestinal tract, skin) and retina.
- Clinical examination reveals pallor, tenderness over the lower sternum and massive splenomegaly, and occasionally hepatomegaly.
- Splenomegaly correlates with magnitude of leukocytosis. The gross appearance of spleen is solid and uniformly deep red, although areas of splenic infarcts may appear as light-colored regions. Leukemic cells infiltrate into the red pulp of spleen. The red pulp distribution of the leukemic infiltrate usually compresses and obliterates the white pulp.
- Hepatomegaly also correlates magnitude of leukocytosis. Leukemic cells can also infiltrate into the hepatic sinusoids and portal areas. Any organ can be infiltrated by leukemic cells. However, extramedullary involvement other than spleen and liver is uncommon in CML chronic phase.
- Sternal tenderness over lower sternum is reliable sign of the disease. Presence of petechiae and ecchymoses reflects quantitative or qualitative platelet abnormalities.
- Demonstration of Philadelphia chromosome or molecular BCR-ABL1 fusion gene analysis can establish the diagnosis of chronic myelogenous leukemia associated with bone marrow fibrosis, which differentiates it from primary myelofibrosis.
- Presence of micromegakaryocytes arranged in large clusters or sheets associated with marked reticulin bone marrow fibrosis demonstrated by bone marrow trephine biopsy may be considered presumptive evidence of CML in accelerated phase. Increasing splenomegaly and patient not responding to receptor tyrosine kinase inhibitor (RTKI) also suggest the progression of CML in chronic phase to accelerated phase and finally to blast phase.

Laboratory Diagnosis of Chronic Myelogenous Leukemia BCR-ABL1 Positive in Chronic Phase

Biochemical Investigations

- Granulocytes synthesize cobalamin and haptocorrin resulting in increase in total serum cobalamin and unsaturated cobalamin binding capacity; and haptocorrin levels.
- Uric acid and lactate dehydrogenase are elevated secondarily to increased cell turnover.
- Serum muramidase is within normal range or slightly increased.

Peripheral Blood Smear Examination

Chronic myelogenous leukemia (CML), BCR-ABL1 positive in chronic phase with basophilia in Giemsa-stained peripheral blood smear is shown in Figs 9.71 and 9.72.

White blood cells

- Extreme leukocytosis and neutrophilic cells at various stages of maturation and basophilia are the most striking abnormality. White blood cell count is usually >100 × 10^9/L with a median of 170 × 10^9/L.
- Peripheral blood smear exhibits a shift to the left with all stages of granulocyte maturation.

- The predominant cells are myelocytes and segmented neutrophils (myelocyte bulge 15–30%). Blasts and promyelocytes usually do not exceed 20% of leukocytes in the peripheral blood. Eosinophils and basophils are most often increased in both relative and absolute terms.
- The hallmark of CML is basophilia with basophil count often exceeding 1×10^9/L.
- Monocytes are moderately increased. Signs of myeloid dysplasia including pseudo-Pelger-Hüet anomaly (hyposegmentation of neutrophil nucleus) and deceased neutrophil alkaline phosphatase (NAP) score are frequent.
- Low or absent NAP is characteristic finding in CML but not specific.
- Monocytosis, myeloid dysplasia and micromegakaryocytes are overlapping features in both chronic myelogenous leukemia (CML) and chronic myelomonocytic leukemia (CMML). Philadelphia chromosome is demonstrated in CML but absent in CMML.
- Differential white blood cell count in CML, BCR-A BL1 positive in chronic phase includes myeloblasts (<10%), promyelocytes (2–8%), myelocytes (15–30%), metamyelocytes (15–25%), band forms (5–15%), neutrophils (40–70%), basophils (2–10%), eosinophils (>4% in few cases) and monocytes (2–10%).
- Differential white blood cell counts in chronic myelogenous leukemia (CML), BCR-ABL1 positive in chronic phase are given in Table 9.80.

Red blood cells

- At the time of diagnosis, peripheral blood smear shows mild to moderate normocytic normochromic picture with hemoglobin concentration in the range of 9–13 g/dl.
- Severity of anemia is proportional to the increase in the leukocytes due to suppression of erythroid cells by proliferating leukemic cells in the bone marrow.
- Nucleated red blood cells may be demonstrated. Reticulocyte count is usually within normal range or slightly increased.

Platelets

- Platelet count can exceed 1000×10^9/L with variation in platelet shape in 50% of cases.
- Platelet function is frequently abnormal.
- Megakaryocyte fragments and micromegakaryocytes can be demonstrated in 25% of cases.

Bone Marrow Smear Examination

Chronic myelogenous leukemia (CML), BCR-ABL1 positive in chronic phase in Giemsa-stained bone marrow aspirate smear is shown in Figs 9.73 and 9.74.

- **Cellularity:** Bone marrow is hypercellular with a striking increase in the myeloid to erythroid ratio (10:1 to 50:1) reflective of the myelopoiesis. The active red bone marrow can extend into the long bones. Cortical thinning and erosion of the trabeculae can be demonstrated.
- **Myeloid lineage:** The hematopoietic cells in bone marrow are primarily immature granulocytes with <20% blasts by revised 2024 WHO classification of hematopoietic and lymphoid neoplasms, an important characteristic that distinguishes CML from all forms of acute leukemias. Auer rods can be demonstrated in the myeloblasts in blast phase, but this is an unusual finding.
- **Erythroid lineage:** Bone marrow shows normoblastic erythropoiesis because the increased tyrosine kinase activity does not directly affect erythropoiesis, however, normoblasts can be decreased.
- **Megakaryocytic lineage:** Bone marrow shows increased micromegakaryocytes smaller than normal megakaryocytes (dwarf megakaryocytes) with frequent immature and atypical forms, hyposegmented nuclei in CML. Sometimes, micromegakaryocytes can be demonstrated in accelerated phase of chronic myelogenous leukemia. On the other hand, macromegakaryocytes are demonstrated in myelodysplastic syndrome (MDS).
- **Gaucher-like cells:** Gaucher-like cells are present in bone marrow due to overload of cerebrosides caused by increased cell turnover, and not due to lack of β-glucocerebrosidase enzyme.
- **Bone marrow fibrosis:** The bone marrow can become fibrotic, late in the clinical course of the disease.

Bone Marrow Trephine Biopsy Examination

Bone marrow trephine biopsy is performed only if the findings in the peripheral blood are atypical or if a cellular bone marrow aspirate cannot be obtained.

Neutrophil Alkaline Phosphatase (NAP) Scoring System

- Neutrophil alkaline phosphatase (NAP) is present in specific granules of neutrophils. NAP scoring system is a useful test to differentiate CML from leukemoid reactions.
- NAP score is low in CML but high in leukemoid reactions. Based on the number of granules and intensity of staining of neutrophils are scored 0–4. At least 100 consecutive neutrophils are counted and the sum of their scores is determined.
- Normal range of neutrophil alkaline phosphatase (NAP) score in adults is 25–100, and 150–300 in children. NAP scoring system is given in Table 9.81. NAP scoring system in various hematological disorders is given in Table 9.82.

Cytogenetic and Molecular Genetic Alterations Analysis

Philadelphia chromosome t(9;22) is demonstrated by cytogenetic analysis in CML patients. BCR-ABL1 is demonstrated by molecular technique (RT-PCR) in CML. Molecular genetic monitoring for patients with chronic myelogenous leukemia, BCR-ABL1 positive in chronic phase are given in Table 9.83.

Immunophenotyping

Immunophenotyping has a limited role in the diagnosis of chronic myelogenous leukemia. It is being used in CML cases with blast phase.

- Determination of the cell lineage of blast transformation is clinically important, because the patients with lymphoblast transformation have a better response to chemotherapy and better survival span than those with blast transformation of other lineages.

- Philadelphia chromosome positive immunophenotyping shows positivity for CD33, cCD11, CD36, CD117, CD15 and anti-myeloperoxidase (anti-MPO).

Markers	Expression
▪ CD33	▪ Positive
▪ cCD11	▪ Positive
▪ CD36	▪ Positive
▪ CD117	▪ Positive
▪ CD15	▪ Positive
▪ Anti-myeloperoxidase (anti-MPO)	▪ Positive

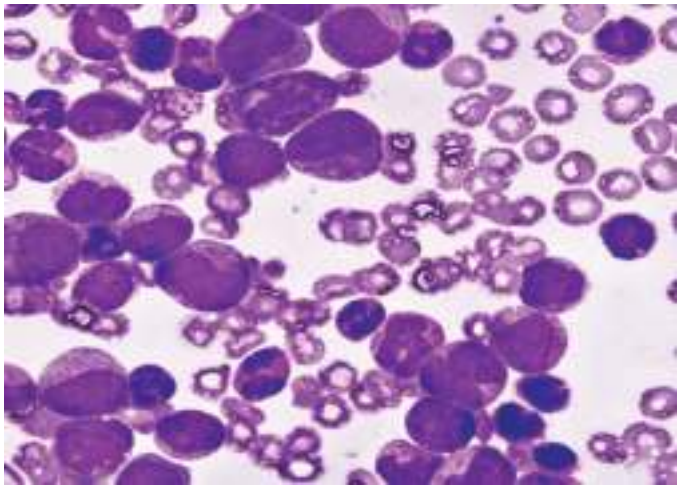

Fig. 9.71: Chronic myelogenous leukemia (CML), BCR-ABL1 positive in chronic phase with basophilia in Giemsa-stained peripheral blood smear. It shows hypercellular bone marrow with a striking increase in the myeloid to erythroid ratio (10:1 to 50:1) reflective of the myelopoiesis. The active red bone marrow can extend into the long bones. Cortical thinning and erosion of the trabeculae can be demonstrated. The hematopoietic bone marrow cells are primarily immature granulocytes with <20% blasts by revised 2024 WHO classification of hematopoietic and lymphoid neoplasms, an important characteristic that distinguishes CML from all forms of acute leukemias. Auer rods can be demonstrated in the myeloblasts in blast phase, but this is an unusual finding (1000X).

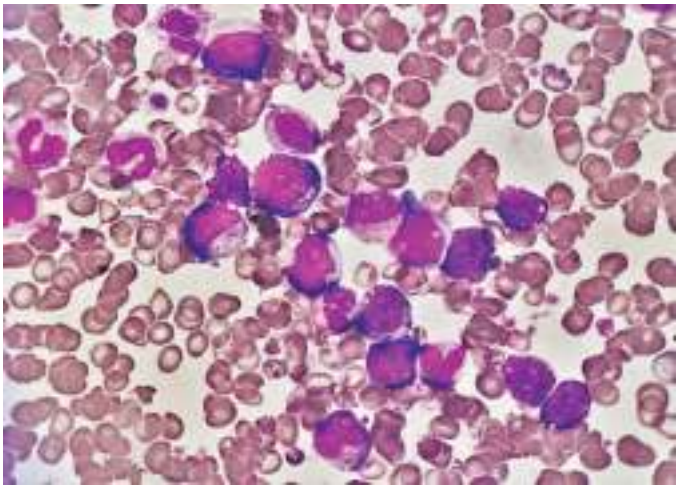

Fig. 9.72: Chronic myelogenous leukemia (CML), BCR-ABL1 positive in chronic phase in Giemsa-stained peripheral blood smear.

Table 9.80 Differential white blood cell counts in chronic myelogenous leukemia (CML), BCR-ABL1 positive in chronic phase

Differential White Blood Cells	Percentage
Myeloblasts	<10%
Promyelocytes	2–8%
Myelocytes	15–30%
Metamyelocytes	15–25%
Band cells (immature form of neutrophils)	5–15%
Neutrophils	40–70%
Basophils	2–10% (often $>1 \times 10^9$/L)
Eosinophils	>4% (few cases)
Monocytes	2–10%

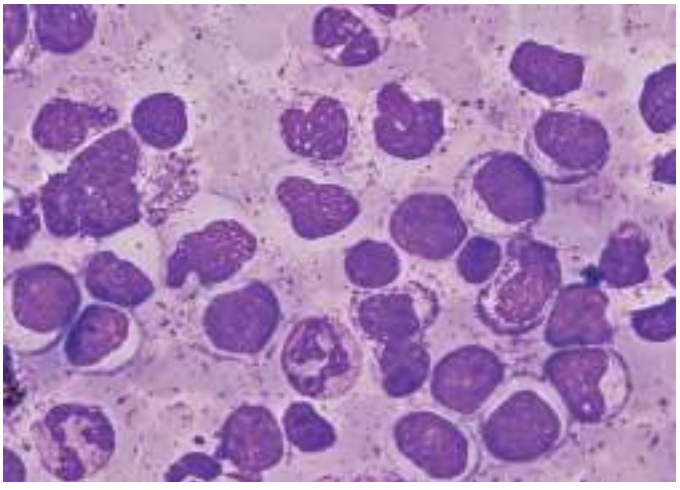

Fig. 9.73: Chronic myelogenous leukemia (CML), BCR-ABL1 positive in chronic phase in Giemsa-stained bone marrow aspirate smear. It shows hypercellular bone marrow with a striking increase in the myeloid to erythroid ratio (10:1 to 50:1) reflective of the myelopoiesis. The active red bone marrow can extend into the long bones. Cortical thinning and erosion of the trabeculae can be demonstrated. The hematopoietic bone marrow cells are primarily immature granulocytes with <20% blasts by revised 2024 WHO classification of hematopoietic and lymphoid neoplasms, an important characteristic that distinguishes CML from all forms of acute leukemias. Auer rods can be demonstrated in the myeloblasts in blast phase, but this is an unusual finding (1000X).

CML, BCR-ABL1 Positive in Accelerated Phase

In untreated patients, CML, BCR-ABL1 positive in chronic phase progresses to the CML accelerated phase in approximately 3–5 years of diagnosis.

- Presence of micromegakaryocytes arranged in large clusters or sheets associated with marked bone marrow fibrosis demonstrated by trephine bone marrow biopsy may be considered presumptive evidence of accelerated phase of CML.

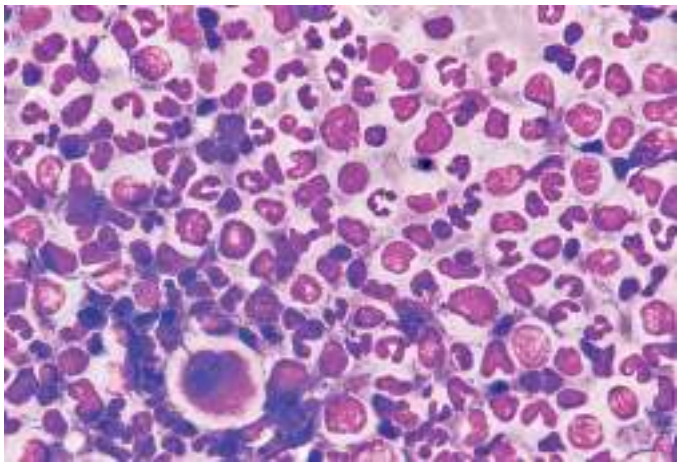

Fig. 9.74: Chronic myelogenous leukemia (CML), BCR-ABL1 positive in chronic phase in Giemsa-stained bone marrow aspirate smear.

Table 9.81 Neutrophil alkaline phosphatase (NAP) scoring system

NAP Score	Individual Neutrophil Cell Staining Scoring
Score 0	Negative staining
Score 1	Diffuse pale cytoplasm with occasional granules
Score 2	Moderate blue granules
Score 3	Cells with uneven distribution of blue granules
Score 4	Cells with uniform blue granules (strong positivity)

Normal range of neutrophil alkaline phosphatase (NAP) score in adults is 25–100, and 150–300 in children.

Table 9.82 Neutrophil alkaline phosphatase (NAP) scoring system in various hematologic disorders

Neutrophil Alkaline Phosphatase (NAP): Low Scores	Neutrophil Alkaline Phosphatase (NAP): High Scores
▪ Chronic myelogenous leukemia, BCR-ABL1 positive	▪ Leukemoid reactions
▪ Atypical myeloid leukemia	▪ Chronic neutrophilic leukemia (CNL)
▪ Juvenile CML	▪ Myelofibrosis
▪ Paroxysmal nocturnal hemoglobinuria (PNH)	▪ Polycythemia vera (PV)
▪ Hereditary hypophosphatasia	▪ Essential thrombocythemia (ET)

Table 9.83 Molecular genetic monitoring for patients with chronic myelogenous leukemia (CML), BCR-ABL1 positive

Period of Treatment	Comments
At the time of diagnosis of CML	▪ Karyotype of bone marrow cell metaphases ▪ Fluorescence *in situ* hybridization to variant, cryptic translocations ▪ Qualitative polymerase chain reaction to identify transcript type
During treatment of CML	Real-time QRT-PCR (real-time quantitative polymerase chain reaction) is done to determine BCR-ABL1 transcript levels, every three months until major molecular response (MMR) and then every six months and/or karyotype of bone marrow cell metaphases at 3, 6, and 12 months until elimination of the Philadelphia chromosome in bone marrow metaphases (CCyR) treated with tyrosine kinase inhibitor (TKI)
At the time of progression of CML disease	Real-time QRT-PCR, mutational analysis, karyotype of bone marrow cell metaphases; immunophenotype

- Patient presents with fever, night sweats, weight loss, weakness, malaise, bone pain and lymphadenopathy.
- Approximately 30% of those patients with CML in accelerated phase die before developing blast phase.
- CML in accelerated phase involves organs outside bone marrow, peripheral blood and spleen. Defining criteria of CML, BCR-ABL1 positive in accelerated phase (AP) are given in Table 9.84.

Laboratory Diagnosis of Chronic Myelogenous Leukemia (CML), BCR/ABL1 Positive in Accelerated Phase

Peripheral Blood Smear Examination

- Peripheral blood smear examination shows anemia, persistent thrombocytopenia (platelet count $<100 \times 10^9$/L), increasing WBCs ($>10 \times 10^9$/L), immature granulocytes (10–19% blasts), absolute eosinophilia and basophilia (basophil count ≥20%). Chronic myelogenous leukemia (CML), BCR-ABL1 positive in accelerated phase in Giemsa-stained peripheral blood smear is shown in Figs 9.75 and 9.76.

Bone Marrow Smear Examination

- Bone marrow aspirate smear examination shows hypercellular marrow and immature granulocytes (>10 × 10⁹/L).
- Myelofibrosis may develop and sideroblasts.

Bone Marrow Trephine Biopsy Examination

- Presence of micromegakaryocytes arranged in large clusters or sheets associated with marked reticulin bone marrow fibrosis demonstrated by bone marrow trephine biopsy may be considered presumptive evidence of CML, BCR-ABL1 positive in accelerated phase.
- Increasing splenomegaly and patient not responding to RTKI therapy also suggest the progression of chronic phase to accelerated phase and finally to blast phase in CML patients.

Molecular Genetic Alterations

- Evolution of the neoplastic clone in CML, BCR-ABL1 positive may be associated with development of new abnormal karyotypes, often an extra chromosome 8 or 9 (trisomy 8 or 9) or isochromosome 17q[i(17q)].
- Diagnosis is confirmed by finding the Philadelphia chromosome in samples examined with cytogenetic or molecular studies.
- The classic Philadelphia chromosome cytogenetic abnormality may be absent in 5% of CML patients, but the use of fluorescence *in situ* hybridization (FISH) or reverse transcription polymerase chain reaction (RT-PCR) can confirm the diagnosis.
- Molecular studies can demonstrate mutations in RUNX1 (33%). ASXL1 (21%), IKZF1 (20%), TP53, RB1, RAS, Myc, AML-1, EVI-1, CDKN2A genes in CML patients.

Frequent chromosomal changes	▪ Philadelphia chromosome duplication + ▪ Trisomy 8+ ▪ Trisomy 19+ ▪ Isochromosome 17q+ ▪ Loss of Y chromosome
Rare chromosomal changes	▪ Translocation (15;17)+ ▪ Translocation (3;21) (p26; q22)+ ▪ Translocation (3;3), inv(3)+
Very rare chromosomal changes	▪ Deletion of chromosome 5 (–5) or deletion of 5q ▪ Deletion of chromosome 7 (–7) or deletion of 7q
Additional molecular genetic mutations (genes involved)	RUNX1 (33%). ASXL1 (21%), IKZF1 (20%), TP53, RB1, RAS, Myc, AML-1, EVI-1, CDKN2A

CML, BCR-ABL1 Positive in Blast Phase

In majority of cases, CML, BCR-ABL1 positive in chronic phase progresses to accelerated phase, that terminates into blast phase. Without intervention of CML, in accelerated phase symptoms worsen over next 3–5 years with onset of blast phase. Clinical features of CML BCR-ABL1 positive in blast phase are similar to those of acute leukemia.

Table 9.84 Defining criteria of CML, BCR-ABL1 positive in accelerated phase

Hematologic Molecular Genetic Alterations: Diagnostic Criteria of CML, BCR-ABL1 Positive in Accelerated Phase
▪ Persistent or increasing high white blood cell count (>10 × 10⁹/L), unresponsive to RTKI therapy ▪ Persistent or increasing splenomegaly unresponsive to RTKI therapy ▪ Persistent thrombocytosis (>1000 × 10⁹/L) unresponsive to RTKI therapy ▪ Persistent thrombocytopenia (<100 × 10⁹/L) ▪ Presence of ≥20% basophils in the peripheral blood ▪ Presence of 10–19% blasts in peripheral blood and/or bone marrow ▪ Additional clonal chromosomal abnormalities in Philadelphia chromosome positive at diagnosis include duplication of Philadelphia chromosome, trisomy 8, trisomy 19, isochromosome 17 and loss of Y chromosome does not present in the CML chronic phase. Molecular mutations include RUNX1(33%). ASXL1(21%), IKZF1(20%), TP53, RB1, RAS, Myc, AML-1, EVI-1, CDKN2A ▪ Any new clonal chromosomal abnormality occurs in Philadelphia chromosome positive cells during tyrosine kinase therapy
Provisional Response to Receptor Tyrosine Kinase Inhibitors Therapy
▪ Hematologic resistance or failure to achieve a complete hematologic response. Any hematologic, cytogenetic, or molecular indications resistance to two sequential RTKIs. Occurrence of two or more mutations in the BCR-ABL1 fusion gene during RTKI therapy ▪ Complete hematological response is defined as total white blood cell count <10 × 10⁹/L, platelet count <450 × 10⁹/L, absence of immature granulocytes in the differential white blood cell count, and spleen not palpable ▪ Observation of lymphoblasts even <10% in the peripheral blood and/or bone marrow indicates lymphoblastic transformation and warrants further clinical, cytogenetic or molecular analysis ▪ Presence of ≥20% blasts in the peripheral blood and/or bone marrow, or infiltrative proliferation of blasts in an extramedullary site is diagnostic of CML blast phase ▪ Large clusters or sheets of small, abnormal megakaryocytes associated with marked reticulin or collagen fibrosis in bone marrow trephine biopsy specimens may be considered presumptive evidence of accelerated phase of chronic myelogenous leukemia, although these findings are usually associated with one or more of the diagnostic criteria listed above

Chronic myelogenous leukemia (CML), BCR-ABL1 positive in accelerated phase is defined by the presence of ≥1 of the following hematological/cytogenetic criteria or provisional criteria concerning response to receptor tyrosine kinase inhibitor (RTKI) therapy.

- Patient presents with refractory leukocytosis, extramedullary masses (chloromas), increasing splenomegaly, sudden onset of bone pain, central nervous system involvement and lymphadenopathy.
- Unusual manifestations include spinal cord compression, visual disturbance, cerebral stroke and priapism

(erection of penis). With the onset of blast phase, response to poor with fatal outcome in <6 months using traditional chemotherapy.

- Extramedullary proliferation of blasts most often occurs in the lymph nodes, skin, bone and central nervous system, and any other sites.
- Formation of tumor mass in these sites is known as 'chloroma'. On fresh incision of the extramedullary masses appear green, presumably due to the presence of the myeloperoxidase (MPO) enzyme in the myeloid cells. Greenish discoloration of tumor mass has been known as '**chloroma**'. The green color of chloroma fades to a dirty yellow color, on exposure of the tumor to surrounding air.

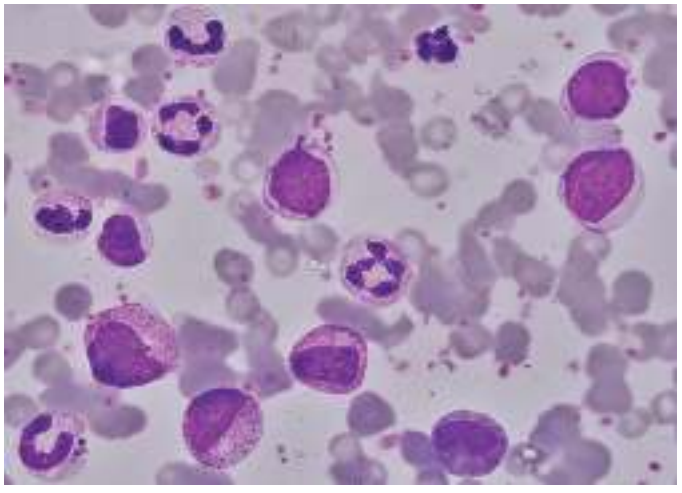

Fig. 9.75: Chronic myelogenous leukemia (CML), BCR-ABL1 positive in accelerated phase in Giemsa-stained peripheral blood smear. CML accelerated phase is defined by the presence of ≥1 of the following hematological/cytogenetic criteria or provisional criteria concerning response to tyrosine kinase inhibitor (TKI) therapy: (a) persistent or increasing high white blood cell count (>10 × 10^9/L), (b) unresponsive to tyrosine kinase inhibitor (TKI) therapy or (c) persistent or increasing splenomegaly unresponsive to tyrosine kinase inhibitor (TKI) therapy, (d) persistent thrombocytosis (>1000 × 10^9/L) unresponsive to tyrosine kinase inhibitor (TKI) therapy, (e) persistent thrombocytopenia (<100 × 10^9/L), (f) presence of ≥20% basophils in the peripheral blood; and (g) presence of 10–19% blasts in peripheral blood and/or bone marrow.

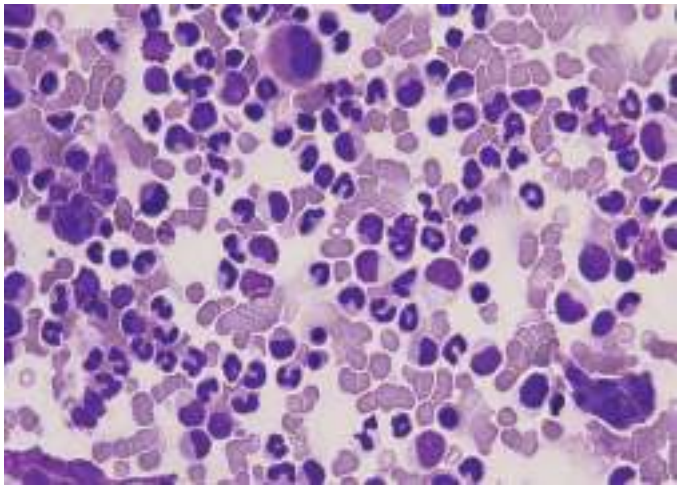

Fig. 9.76: Chronic myelogenous leukemia (CML) in accelerated phase with hemophagocytosis, BCR-ABL1 positive in Giemsa-stained peripheral blood smear (1000X).

Laboratory Diagnosis of Chronic Myelogenous Leukemia (CML), BCR-ABL1 Positive in Blast Phase

- Hematologic diagnostic criteria for CML, BCR-ABL1 positive in blast phase include moderate to marked diffuse bone marrow fibrosis and presence of ≥20% blasts in the bone marrow and peripheral blood of a patient previously diagnosed as suffering from CML.
- Characteristics of chronic myelogenous leukemia, BCR-ABL1 positive in blast phase are given in Table 9.85. Termination of CML, BCR-ABL1 positive in chronic phase via accelerated phase into blast phase and development of acute myelogenous leukemias (AML-M1, AML-M2, AML-M4, AML-M4E0, AML-M6, AML-M7) including their features, cytochemistry and immunophenotyping is given in Table 9.86. Peripheral blood smear CML, BCR-ABL1 positive in blast phase (*see* Fig. 9.31).

Peripheral Blood Smear and Bone Marrow Examination

- Chronic myelogenous leukemia, BCR-ABL1 positive is a clonal pluripotent hematopoietic stem cell disorder. Any type of blast involvement is possible including myeloblasts, lymphoblasts, erythroblasts or megakaryoblasts in CML, BCR-ABL1 positive in blast phase. Bone marrow and blood demonstrate blasts ≥20%.
- Cytochemistry, ultrastructural and immunophenotyping analysis are essential to identify type of blasts.
- About 60–70% of patients with blast phase demonstrate myeloblasts (AML-M1, AML-M2, AML-M4, AML-M6, AML-M7), approximately 25–35% of cases show lymphoblasts (ALL-L1, ALL-L2 of B cell origin) with positivity for CALLA+/CD10+ and elevated terminal deoxynucleotidyl transferase (TdT). Acute megakaryoblastic leukemia (AML-M7) may be associated with bone marrow fibrosis.
- Erythroblastic and megakaryoblastic blast phases are uncommon.
- Acute myelogenous leukemia with expression of lymphoid-related antigens is rare.
- Extramedullary proliferation of blasts forming tumor mass known as 'chloroma' in skin, lymph node, bone, central nervous system, or any organs.
- Cytochemistry and immunophenotyping of blasts are essential to analyze expression of antigens in more than one cell lineages.
- Chronic myelogenous leukemia, BCR-ABL1 positive in blast phase in Giemsa-stained peripheral blood smear is shown in Figs 9.77 to 9.79.
- Chronic myelogenous leukemia, BCR-ABL1 positive in blast phase in Giemsa-stained bone marrow aspirate smear is shown in Fig. 9.80.

Bone Marrow Trephine Biopsy Examination

- Bone marrow trephine biopsy examination shows ≥20% blasts arranged in clusters associated with marked collagen or reticulin fibrosis.
- Chronic myelogenous leukemia, BCR-ABL1 positive in blast phase in hematoxylin and eosin-stained bone marrow trephine biopsy is shown in Fig. 9.81.
- Bone marrow fibrosis grade 2 or 3 demonstrated by reticulin stain in CML, BCR-ABL1 positive in blast phase in bone marrow trephine biopsy section is shown in Fig. 9.82.

Lymph Node Biopsy and Histologic Examination

Chronic myelogenous leukemia, BCR-ABL1 positive in blast phase in hematoxylin and eosin-stained lymph node biopsy section is shown in Fig. 9.83. Myeloperoxidase (MPO) stain positivity in a case of CML blast phase, BCR-ABL1 positive in hematoxylin and eosin-stained lymph node biopsy section is shown in Fig. 9.84.

Additional Chromosomal Alterations in CML, BCR-ABL1 Positive in Blast Phase

Frequent chromosomal changes	▪ Philadelphia chromosome duplication+ ▪ Trisomy 8+ ▪ Trisomy 19+ ▪ Isochromosome 17q+ ▪ Loss of Y chromosome
Rare chromosomal changes	▪ Translocation (15;17)+ ▪ Translocation (3;21) (p26; q22)+ ▪ Translocation (3;3), inv(3)+
Very rare chromosomal changes	▪ Deletion of chromosome 5 (–5) or deletion of 5q ▪ Deletion of chromosome 7 (–7) or deletion of 7q
Genes involved	RUNX1 (33%), ASXL1 (21%), IKZF1 (20%), TP53, RB1, RAS, Myc, AML-1, EVI-1, CDKN2A

Table 9.85 Characteristics of chronic myelogenous leukemia (CML), BCR-ABL1 positive in blast phase

- Blast phase of CML is characterized by the presence of one or more of the following findings:
  - Presence of ≥20% myeloblasts in the bone marrow or nucleated cells in the peripheral blood
  - Extramedullary blast proliferation is known as chloroma.
  - Presence of blasts arranged in larger clusters demonstrated in trephine bone marrow biopsy
  - Additional clonal molecular genetic alterations include duplication of Philadelphia chromosome, trisomy 8, trisomy 19, isochromosome 17, and loss of Y chromosome does not present in the CML chronic phase

CLINICAL COURSE

In the absence of treatment, chronic myelogenous leukemia (CML) has a triphasic or biphasic clinical course as it progresses from chronic phase to an accelerated phase and then to blast phase (acute phase). Sometimes, CML goes from chronic phase to blast phase when blast phase is of lymphoid lineage. Summary of the clinical course of CML, BCR-ABL1 positive in chronic phase is given in Table 9.87. Summary of the clinical course of CML, BCR-ABL1 positive in accelerated phase is given in Table 9.88. Summary of the clinical course of CML, BCR-ABL1 positive in blast phase is given in Table 9.89.

Table 9.86 Termination of chronic myelogenous leukemia (CML), BCR-ABL1 positive in chronic phase via accelerated phase into blast phase and development of acute leukemias (AML-M1, AML-M2, AML-M4, AML-M4EO, AML-M6, AML-M7) including their features, cytochemistry and immunophenotyping

FAB Class	Features	Cytochemistry	Immunophenotype by Flow Cytometry
AML-M1	Acute myeloblastic leukemia without maturation (contains <10% promyelocytes or more mature myeloid forms)	Myeloperoxidase + (>3%)	▪ CD34+ ▪ CD33+ ▪ HLA-DR+ ▪ CD13+
AML-M2	Acute myeloblastic leukemia with maturation	Myeloperoxidase + (>10%)	▪ CD34+ ▪ CD13+ ▪ HLA-DR+ ▪ CD15+ ▪ CD33+
AML-M4	Acute myelomonocytic leukemia (monocytes and promonocytes in the bone marrow exceed 20%)	▪ Myeloperoxidase + ▪ Esterase +	▪ CD34– ▪ CD13+ ▪ HLA-DR+ ▪ CD14+ ▪ CD33+ ▪ CD64+
AML-M4Eo	Acute myelomonocytic leukemia with abnormal eosinophils (>5%)	▪ Myeloperoxidase + ▪ Esterase +	▪ CD34– ▪ CD13+ ▪ HLA-DR+ ▪ CD11+ ▪ CD33+ ▪ CD14+

Table 9.86 Termination of chronic myelogenous leukemia (CML), BCR-ABL1 positive in chronic phase via accelerated phase into blast phase and development of acute leukemias (AML-M1, AML-M2, AML-M4, AML-M4E0, AML-M6, AML-M7) including their features, cytochemistry and immunophenotyping (*Contd...*)

FAB Class	Features	Cytochemistry	Immunophenotype by Flow Cytometry
AML-M6	Acute erythroleukemia (shows >50% nucleated bone marrow cells are erythroid, often severely dyserythropoietic)	▪ Erythroblast shows strong positivity with periodic acid–Schiff (PAS) stain ▪ Esterase negative	▪ Glycophorin A+ ▪ Hemoglobin A+
AML-M7	Acute megakaryocytic leukemia may have micromegakaryoblasts	PAS +/–	▪ CD41+ ▪ CD61+ ▪ Platelet peroxidase + ▪ Electron microscopy

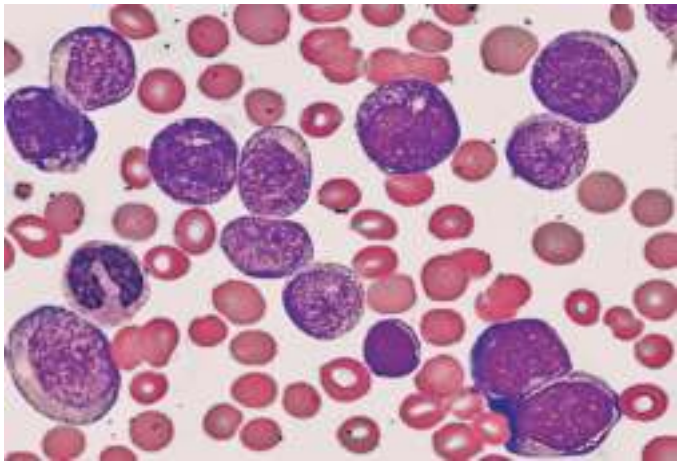

Fig. 9.77: Chronic myelogenous leukemia (CML), BCR-ABL1 positive in blast phase in Giemsa-stained peripheral blood smear. In majority of cases, CML chronic phase terminates in accelerated phase followed by blast phase. Without intervention of CML, symptoms worsen over next 3–5 years with onset of blast phase. Clinical findings in blast phase are similar to those of acute leukemia. Hematologic diagnostic criteria for CML blast phase include moderate to marked diffuse bone marrow fibrosis and ≥20% blasts in the peripheral blood and bone marrow of a patient previously diagnosed as suffering from CML (1000X).

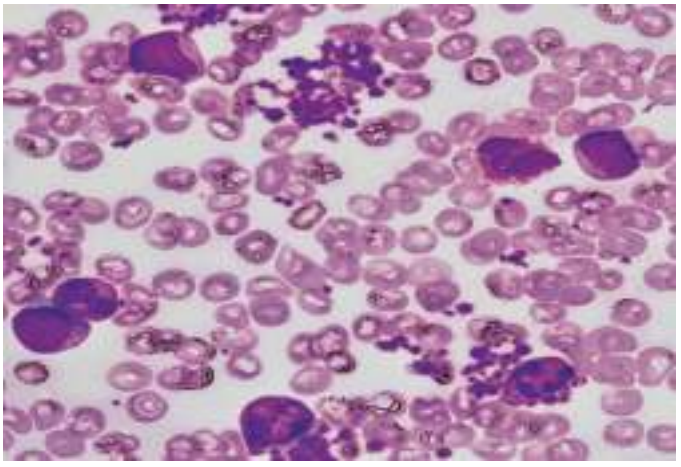

Fig. 9.79: Chronic myelogenous leukemia, BCR-ABL1 positive in blast phase in Giemsa-stained peripheral blood smear shows abundant platelets (1000X).

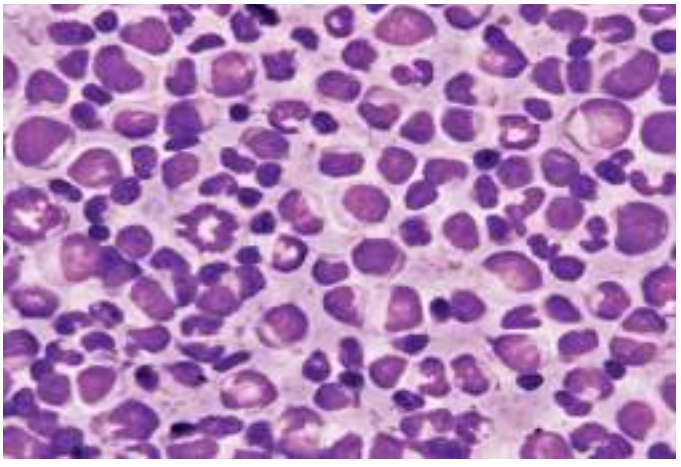

Fig. 9.80: Chronic myelogenous leukemia, BCR-ABL1 positive in blast phase in bone marrow aspirate smear. In majority of cases, CML chronic phase terminates in accelerated phase followed by blast phase. Without intervention of CML, symptoms worsen over next 3–5 years with onset of blast phase. Clinical features in blast phase are similar to those of acute leukemia. Hematologic diagnostic criteria for blast phase include moderate to marked diffuse bone marrow fibrosis and ≥20% blasts in the peripheral blood and bone marrow of a patient previously diagnosed as suffering from CML (1000X).

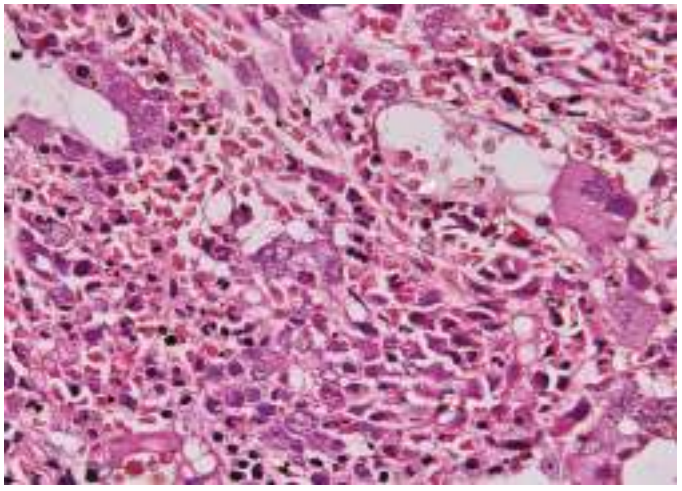

Fig. 9.81: Chronic myelogenous leukemia, BCR-ABL1 positive in blast phase in hematoxylin and eosin-stained bone marrow trephine biopsy. It shows ≥20% blasts arranged in clusters associated with marked collagen or reticulin fibrosis. In majority of cases, CML chronic phase progresses to accelerated phase and terminates into blast phase. Without intervention of CML, symptoms worsen over next 3–5 years with onset of blast phase. Clinical features in blast phase are similar to those of acute leukemia. Hematologic diagnostic criteria for blast phase include moderate to marked diffuse bone marrow fibrosis and ≥20% blasts in the peripheral blood and bone marrow of a patient previously diagnosed as suffering from CML.

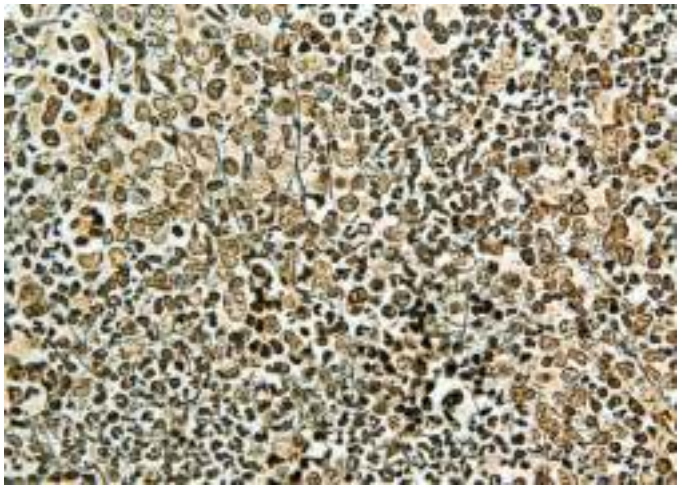

Fig. 9.82: Bone marrow fibrosis grade 2 or 3 demonstrated by reticulin stain in chronic myelogenous leukemia blast phase, BCR-ABL1 positive in bone marrow trephine biopsy section (1000X).

DIFFERENTIAL DIAGNOSIS

Chronic myelogenous leukemia (CML), BCR-ABL1 positive should be differentiated from leukemoid reactions and chronic neutrophilic leukemia. Comparison of CML, BCR-ABL1 positive in chronic phase and leukemoid reaction is given in Table 9.90. Comparison of CML, BCR-ABL1 positive and atypical chronic myelogenous leukemia (aCML), BCR-ABL1 negative is given in Table 9.91. Major characteristics

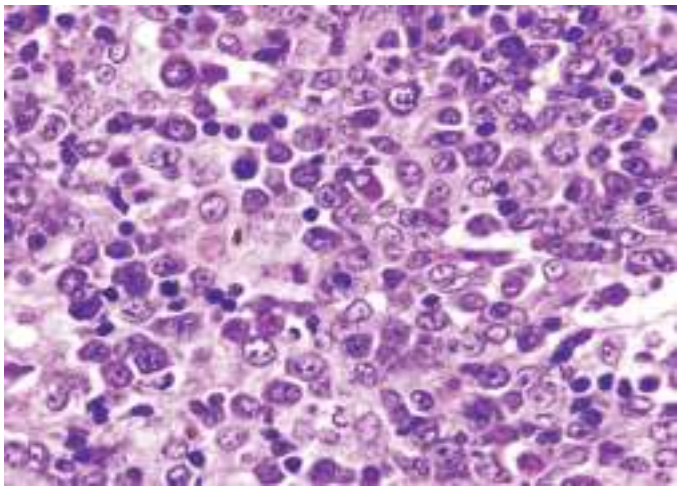

Fig. 9.83: Chronic myelogenous leukemia, BCR-ABL1 positive in blast phase in hematoxylin and eosin-stained lymph node biopsy section (400X).

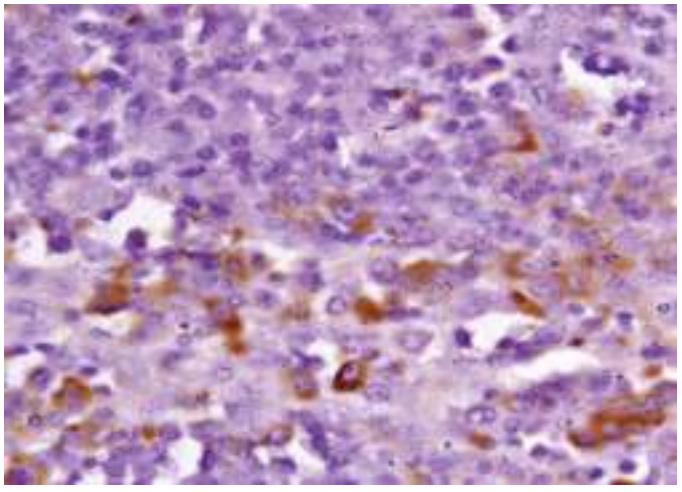

Fig. 9.84: Myeloperoxidase (MPO) stain positivity in a case of chronic myelogenous leukemia (CML) blast phase, BCR-ABL1 positive in hematoxylin and eosin-stained lymph node biopsy section (1000X).

of CML, BCR-ABL1 positive in atypical chronic myelogenous leukemia (aCML), BCR-ABL1 negative and chronic neutrophilic leukemia are given in Table 9.92.

TARGETED THERAPY

Basic aim of CML, BCR-ABL1 positive therapy is to reduce the leukocyte burden, restore bone marrow function, reduce splenomegaly and abolish clinical manifestations.

- Leukapheresis is sometimes performed initially to reduce the leukocyte burden with a purpose in reduction of blood hyperviscosity.
- Supportive measures during therapeutic management include blood transfusions to treat severe anemia and antibiotics to treat infections.

Table 9.87 Summary of the clinical course of chronic myelogenous leukemia (CML), BCR-ABL1 positive in chronic phase

Clinical Features and Laboratory Diagnosis	Hematologic Molecular Genetic Alterations
Clinical features	
Signs and symptoms	Anemia, sternal tenderness, discomfort in left upper quadrant, massive splenomegaly (>90%) and hepatomegaly, weight loss, night sweats, priapism, visual disturbances, gout and headache
Abdominal findings	▪ Massive splenomegaly because of infiltration of mature and immature granulocytes, i.e. leukemia cells in the red pulp of spleen ▪ Hepatomegaly because of infiltration of mature and immature granulocytes, i.e. leukemia cells in the hepatic sinusoids and portal tracts
Progression of CML chronic phase	Increasing splenomegaly and not responding to treatment suggests progression of chronic phase to accelerated and/or blast phase disease
Peripheral blood smear examination	
Total leukocyte count	$>100 \times 10^9$/L with a median of 170×10^9/L
Myeloblasts	<10%
Myelocytes	15–30%
Promyelocytes	2–8%
Metamyelocytes	15–25%
Band forms	5–15%
Neutrophils	40–70%
Basophilia	2–10% (often exceeding 1×10^9/L)
Eosinophilia	>4% (few cases)
Monocytes	<3% except in rare case with the p190 BCR-ABL1 isoform, which often mimics chronic myelomonocytic leukemia (CMML)
Platelet count	Normal or increased $\geq 1000 \times 10^9$/L, or marked thrombocytopenia uncommon
Bone marrow examination	
Cellularity	Hypercellular bone marrow with marked expansion at myelocytic stage
Myeloid precursors	Increased
Erythroid precursors	Significantly decreased
Myeloid to erythroid ratio	Increased
Myeloblasts	<10% (blast count increases as CML progresses to accelerated phase and terminates in blast phase)
Myelocytes	Markedly increased
Basophil count	Increased
Eosinophil count	Increased
Megakaryocytes	▪ Megakaryocyte number may be normal or slightly decreased. But 40–50% of cases exhibit moderate to marked megakaryocytic proliferation ▪ Size of megakaryocytes is smaller than normal and containing hyposegmented nuclei termed as 'dwarf' megakaryocytes
Pseudo-Gaucher cells	Common with foamy cytoplasm and derived from the neoplastic clone
Bone marrow trephine biopsy examination	
Bone marrow trephine biopsy is performed, only if the findings in the peripheral blood are atypical or if aspiration is not obtained due to cellular bone marrow	
Molecular genetic alterations	
Philadelphia chromosome t(9;22)	Cytogenetic alterations
BCR-ABL1 fusion protein	Molecular genetic alterations

Most cases of CML (hematopoietic stem cell disorder) are diagnosed based on peripheral blood findings and/or BCR-ABL1 by cytogenetic and molecular genetic techniques

Table 9.88 Summary of the clinical course of chronic myelogenous leukemia (CML), BCR-ABL1 positive in accelerated phase

Diagnostic criteria of chronic myelogenous leukemia, BCR-ABL1 positive in accelerated phase	
▪ Most cases of CML (pluripotent stem cell disorder) are diagnosed based on peripheral blood findings and/or BCR-ABL1 by cytogenetic and molecular genetic techniques	
▪ Diagnostic criteria of CML, BCR/ABL1 positive in accelerated phase: one or more (≥1) of the following findings: • Persistent increase in white blood cell counts >10 × 10⁹/L • Progressive increasing splenomegaly and unresponsive to tyrosine kinase inhibitor (TKI) therapy • Persistent increase in platelets >1000 × 10⁹/L • Increase in basophil count in peripheral blood >20% • Presence of 10–19% blasts in peripheral blood and/or bone marrow • Presence of additional clonal Philadelphia chromosome, trisomy 8, trisomy 19, isochromosome 17q • Presence of molecular mutations TP53, RB1, RAS, Myc, AML-1, EVI-1, CDKN2A • Bone marrow trephine biopsy is associated with marked collagen or reticulin fibrosis	
Peripheral blood smear examination	
White blood cell count	Persistent increase in white blood cell counts >10× 10⁹/L
Myeloblasts	10–19%
Basophils	>20%
Platelet count	<100 × 10⁹/L unrelated to therapy
Persistent thrombocytosis	>1000 × 10⁹/L unresponsive to therapy
Clonal genetic aberrations	Present in accelerated phase of CML, but not demonstrated in chronic phase
Bone marrow examination	
Cellularity	Hypercellular bone marrow with marked expansion
Myeloid series	Increased
Erythroid series	Significantly decreased
Myeloid to erythroid ratio	Increased
Myeloblasts	10–19% blasts (blast count increases as CML progresses and terminates in blast phase)
Myelocytes	Markedly increased
Additional cytogenetic alterations	
Frequent chromosomal alterations	▪ Duplication of Philadelphia chromosome ▪ Trisomy 8 ▪ Trisomy 19 ▪ Isochrome 17q ▪ Loss of Y chromosome
Rare chromosomal alterations	▪ Translocation (15;17) ▪ Translocation (3;21) (p26; q22) ▪ Translocation (3;3)/inv (3)
Very rare chromosomal alterations	▪ Deletion of chromosome 5 (–5) or the long arm (5q–) ▪ Deletion of chromosome 7 (–7) or the long arm (7q–)
Additional molecular genetic alterations	
Gene mutations	RUNX1 (33%). ASXL1 (21%), IKZF1 (20%), TP53, RB1, RAS, Myc, AML-1, EVI-1, CDKN2A

Table 9.89 Summary of the clinical course of chronic myelogenous leukemia (CML), BCR-ABL1 positive in blast phase

Laboratory Investigations	Hematologic Molecular Genetic Alterations
Peripheral blood smear examination	
Blasts number	≥20% blasts
Type of blasts	Myeloblasts (70–80%) or lymphoblasts (20–30%)
Bone marrow examination	
Blasts number	≥20% blasts

Contd...

Table 9.89 Summary of the clinical course of chronic myelogenous leukemia (CML), BCR-ABL1 positive in blast phase (*Contd...*)

Laboratory Investigations	Hematologic Molecular Genetic Alterations
Myeloblast proliferation	Extramedullary region forming blast chloroma in skin, lymph node, bone, central nervous system or any organ
Type of blast cells in CML blast phase	▪ CML is pluripotent stem cell disorder capable of differentiating along myeloid, lymphoid and megakaryocytes ▪ Myeloblasts are demonstrated in 70–80% of cases ▪ Lymphoblasts of B cell origin are demonstrated in 20–30% of cases
Bone marrow trephine biopsy examination	
Myeloblasts or lymphoblasts are arranged in clusters	Presence of large number of myeloblasts ≥20% in clusters in the bone marrow trephine biopsy is associated with marked collagen or reticulin fibrosis
Additional chromosomal alterations	
Frequent chromosomal changes	▪ Duplication of Philadelphia chromosome ▪ Trisomy 8 ▪ Trisomy 19 ▪ Isochrome 17q ▪ Loss of Y chromosome
Rare chromosomal changes	▪ Translocation (15;17) ▪ Translocation (3;21) (p26; q22) ▪ Translocation (3;3), inv(3)
Very rare chromosomal changes	▪ Deletion of chromosome 5 (–5) or deletion of 5q ▪ Deletion of chromosome 7 (–7) or deletion of 7q
Additional molecular genetic alterations	
Gene mutations	RUNX1 (33%). ASXL1 (21%), IKZF1 (20%), TP53, RB1, RAS, Myc, AML-1, EVI-1, CDKN2A

Most cases of CML (pluripotent stem cell disorder) are diagnosed based on peripheral blood findings and/or BCR-ABL1 by cytogenetic and molecular genetic techniques
Loss of response to tyrosine kinase inhibitor (TKI) therapy is characterized by loss of a complete hematologic response within 3 months, loss of a major cytogenetic response within 12 months (>37% Philadelphia metaphases present) and increasing levels of BCR-ABL as assessed by real-time PCR.

Table 9.90 Comparison of chronic myelogenous leukemia (CML), BCR-ABL1 positive in chronic phase and leukemoid reaction

Parameters	CML, BCR-ABL1 Positive in Chronic Phase	Leukemoid Reaction
Age group, etiology and clinical features		
Age group	Peak 35–45 years	Any age group
Etiology	Clonal disorder of pluripotent stem cell	Infections
Clinical features	Patient presents with weight loss, night sweats, itching, left hypochondrial pain, massive splenomegaly (>90%) gout, priapism, visual disturbances and headache	Patient presents with fever without splenomegaly
Peripheral blood smear examination		
Total leukocyte count	TLC >100 × 10^9/L with a median of 170 × 10^9/L	TLC <50 × 10^9/L (moderate increase)
Differential WBC count	Myeloblasts (<10%), myelocytes (15–30%), promyelocytes (2–8%), metamyelocyte (15–25%), band form (5–15%), neutrophils (40–70%)	Proportion of immature myeloid cells in small to moderate in number, myeloblasts seldom exceed 5% and myelocytes seldom exceed 15–30%
Basophils	2–10% (often exceeding 1 × 10^9/L)	Basophil count within normal range

Contd...

Table 9.90 Comparison of chronic myelogenous leukemia (CML), BCR-ABL1 positive in chronic phase and leukemoid reaction (*Contd...*)

Parameters	CML, BCR-ABL1 Positive in Chronic Phase	Leukemoid Reaction
Toxic granules in neutrophils	Absent	Present
Neutrophil alkaline phosphatase (NAP) score	Low score	High score
RBC morphology	Normocytic normochromic picture, anemia (30%)	Normocytic normochromic picture
Platelets number	Normal or increased $\geq 1000 \times 10^9$/L or marked thrombocytopenia uncommon	Platelet count normal
Dohle bodies (cytoplasmic inclusions in neutrophils, thought to be remnant of rough endoplasmic reticulum)	Absent	Present
Bone marrow smear examination		
Cellularity	Hypercellular bone marrow	Slightly increased cellularity in bone marrow
Myeloid cell lineage	Myeloid precursor cells at different stages of maturation	Normal
Erythroid cell lineage	Suppressed showing normoblastic erythropoiesis	Normal
Myeloid to erythroid ratio	10:1 to 50:1	Normal to slightly increased
Megakaryocyte morphology	Micromegakaryocytes (dwarf megakaryocytes) with hyposegmented nuclei	Megakaryocytes morphology normal
Molecular genetic alterations		
Philadelphia chromosome (balanced translocation 9;22)	Positive	Absent
BCR-ABL1 fusion transcript	Positive	Absent
Biochemical alterations		
Serum cobalamin synthesized by granulocytes	Increased	Normal
Serum haptocorrin synthesized by granulocytes	Increased	Normal
Total serum cobalamin	Increased	Normal
Serum unsaturated cobalamin binding capacity	Increased	Normal
Serum uric acid	Increased secondarily to increased cell turnover	Normal
Serum lactic dehydrogenase	Increased secondarily to increased cell turnover	Normal
Management and clinical course		
Tyrosine kinase inhibitor (TKI) imatinib drug	Indicated with good hematologic and cytogenetic response	Underlying cause treated (TKI never indicated)
Allogeneic hematopoietic stem cell transplantation	Indicated with good clinical course	Never done
Clinical course	Progressive from chronic to accelerated and blast phase	Transient

Table 9.91 Comparison of chronic myelogenous leukemia (CML), BCR-ABL1 positive and atypical chronic myelogenous leukemia (aCML), BCR-ABL1 negative

Features	Chronic Myelogenous Leukemia (CML), BCR-ABL1 Positive in Chronic Phase	Atypical Chronic Myelogenous Leukemia (aCML), BCR-ABL1 Negative
Cytogenetic and molecular genetic alterations		
Philadelphia chromosome t(9;22)	Positive	Negative
Other cytogenetic abnormalities	Absent	Trisomy 8, t(5;12), t(5;10)
BCR-AML1 fusion transcript	Positive	Negative
Age group and clinical findings		
Age group	Elderly persons (mean 55 years)	Elderly persons (65–72 years)
Anemia, thrombocytopenia	Less common	More common
Peripheral blood smear examination		
Total leukocyte count	$>100\times10^9$/L with a median of 170×10^9/L	$\geq13\times10^9$/L
Blasts	<10%	<10%
Immature granulocytes	>20%	10–20%
Basophils	2–10% (often exceeding 1×10^9/L)	<2%
Eosinophils	>4% (few cases)	<4%
Monocytes	<3% except in rare case with the p190 BCR-ABL1 isoform, which often mimics chronic myelomonocytic leukemia (CMML)	>3%
Platelet	Normal or increased $\geq1000\times10^9$/L, or marked thrombocytopenia uncommon	$\geq450\times10^9$/L
Bone marrow smear examination		
Cellularity	Hypercellular bone marrow	Hypercellular bone marrow
Myeloid to erythroid ratio	>10:1	<10:1
Blasts	<10%	<10%
Megakaryocytes	Normal or increased	Decreased
Dysplasia	Absent	Present

Both chronic myelogenous leukemia (CML) and atypical chronic myelogenous leukemia (aCML) have similar clinical features and progress to accelerated phase to blast phase. Neutrophil alkaline phosphatase (NAP) score is low in both disorders.

Table 9.92 Major characteristics of chronic myelogenous leukemia (CML), BCR-ABL1 positive in atypical chronic myelogenous leukemia (aCML), BCR-ABL1 negative and chronic neutrophilic leukemia

Specimen Tested	Observation	CML, BCR-AML1 Positive in Chronic Phase	aCML, BCR-AML1 Negative	Chronic Neutrophilic Leukemia
Peripheral blood smear examination	▪ Total leukocyte count ▪ Myeloblasts ▪ Promyelocytes, myelocytes, metamyelocytes ▪ Neutrophils and band forms ▪ Basophilia	▪ Not determined ▪ <2% ▪ ≥10% ▪ Not determined ▪ Present	▪ $>13\times10^9$/L ▪ <20% ▪ ≥10% ▪ Not determined ▪ Minimal or <2% of leukocytes	▪ $>25\times10^9$/L ▪ <1% ▪ <10% ▪ >80% ▪ Not determined
Bone marrow examination	▪ Granulocytic hyperplasia ▪ Granulocytic dysplasia ▪ Megakaryocytic dysplasia	▪ Present ▪ Minimal or absent ▪ Usually, present	▪ Present ▪ Prominent ▪ May or may not be present	▪ Present ▪ Minimal or absent ▪ Minimal or absent
Molecular studies	BCR-ABL or variant transcripts	Present	Absent	Absent

Table 9.93 Commonly used drugs to treat chronic myelogenous leukemia (CML), BCR-ABL1 positive

Indication	Therapeutic Agents
Intervention during clinical presentation	
Cytoreduction at clinical presentation	Hydroxyurea
White blood cells 100×10^9/L	Allopurinol or alternative control of high white blood cell count by busulfan
CML, chronic phase treated by first-line of tyrosine kinase inhibitors	
Tyrosine kinase inhibitor (TKI)	Imatinib, dasatinib, nilotinib
CML, chronic phase resistant to first-line or second-line of tyrosine kinase inhibitors	
Tyrosine kinase inhibitors (TKIs)	Bosutinib
Tyrosine kinase inhibitors (TKIs) in patients with T3151 mutation	Ponatinib

Interferon-α is used in clinical trials with tyrosine kinase inhibitor (TKI).

- Prior to the discovery of molecular targeted therapy, Interferon-α (IFN-α) plus cytarabine have been considered standard therapy for CML patients, who have not been candidates for an allogeneic hematopoietic stem cell (HSC) transplantation.
- Interferon-α (IFN-α), a glycoprotein, has a myelosuppressive effect by inhibiting myeloid progenitor cells, which induces a remission in 55–75% of CML cases. In some cases, interferon-α (IFN-α) eliminates the Philadelphia chromosome. CML patients treated in the early stage has favorable cytogenetic response.

Therapeutic Drugs and their Genetic Target

Currently, tyrosine kinase inhibitor (TKI) imatinib mesylate (**Gleevec**) is considered the first line of treatment option except in pregnant CML patients.

- Imatinib competitively binds to the ATP binding site of receptor tyrosine kinase of ABL1 (BCR-ABL1 and TEL/ABL1) stem cell receptor (c-KIT), and platelet-derived growth factor receptor resulting in inhibiting receptor tyrosine kinase activity and prevention of cell signal transduction. CML patients tolerate well imatinib with side effects of gastrointestinal tract and skin.
- Approximately, 85% of CML patients achieve complete hematologic response by 12 months. Imatinib therapy also improves molecular genetic alterations and delays progression of the disease to blast phase in CML patients.
- Some patients may develop primary resistance to imatinib therapy. Patients initially responsive to imatinib treatment can develop secondary resistance related to development of additional mutations in the tyrosine kinase domain of BCR-ABL1. A specific ABL1 protein mutant T3151, in which threonine is mutated to isoleucine at the gatekeeper position of receptor tyrosine kinase domain in 15% of CML patients.
- Prior to initiating imatinib therapy, baseline analysis should be performed by real-time polymerase chain reaction (RT-PCR) to evaluate bone marrow morphologic analysis and cytogenetic study of BCR-ABL1 transcripts. It is essential to perform real-time polymerase chain reaction (RT-PCR) at least every three months to analyze BCR-ABL1 transcripts. A complete cytogenetic response with absence of Philadelphia chromosome and BCR-ABL1 transcripts indicate good response in CML cases.
- Commonly used drugs to treat CML, BCR-ABL1 positive are given in Table 9.93. Therapeutic drugs, their genetic target in chronic myelogenous leukemia, BCR-ABL1, positive are given in Table 9.94. Hematologic, cytogenic and molecular responses in CML, BCR-ABL1 positive are given in Table 9.95. Development of resistance to imatinib (tyrosine kinase inhibitor) in CML, BCR-ABL1 positive patients is given in Table 9.96.

Table 9.94 Therapeutic drugs, their genetic target in chronic myelogenous leukemia (CML), BCR-ABL1 positive

Generic Name	Trade Name	Genetic Target
Imatinib	Gleevec	▪ BCR-ABL1 ▪ PDGFRA ▪ c-KIT
Nilotinib	Tasigna	▪ BCR-ABL1 ▪ PDGFRA ▪ c-KIT
Laptinib	Tykerb	▪ HER2/neu ▪ EFGR
Soratinib	Nexavar	▪ EGFR ▪ VEGFR ▪ PDGFRA ▪ BRAF

Table 9.95 Hematologic, cytogenetic and molecular responses in chronic myelogenous leukemia (CML), BCR-ABL1 positive

Response	Characteristics
Hematologic response	
Peripheral blood smear and clinical examination	▪ TLC 10×10^9/L ▪ Basophils <5% ▪ Absence of myelocytes, promyelocytes and blasts ▪ Platelet count $<450 \times 10^9$/L ▪ Nonpalpable spleen
Cytogenetic response	
Major cytogenetic response	▪ Complete response: absence of Philadelphia positive metaphases or <1% BCR-ABL positive nuclei of ≥200 cells demonstrated by fluorescence *in situ* hybridization (FISH) ▪ Partial response: 1–35% Philadelphia positive metaphases
Minor cytogenetic response	36–65% Philadelphia positive metaphases
Minimal cytogenetic response	66–95% Philadelphia positive metaphases
Cytogenetic response none	>95% Philadelphia positive metaphases
Molecular response	
Molecular response 4, 5	Ratio of BCR-ABL1 to ABL1 (or other housekeeping gene) ≤0.0032% (≥4.4 log reduction) on international scale
Molecular response 4	Ratio of BCR-ABL1 to ABL1 (or other housekeeping gene) ≤0.01% (≥4 log reduction) on international scale
Molecular response 3	Ratio of BCR-ABL1 to ABL1 (or other housekeeping gene) ≤0.1% (≥43 log reduction) on international scale
Molecular response 2 (corresponds to complete cytogenetic response)	Ratio of BCR-ABL1 to ABL1 (or other housekeeping gene) ≤0.1% (≥2 log reduction) on international scale

Table 9.96 Development of resistance to imatinib (tyrosine kinase inhibitor) in chronic myelogenous leukemia (CML), BCR-ABL1 positive patients

Primary Resistance to Imatinib (Tyrosine Kinase Inhibitor) in CML
Complete hematologic response is not achieved by 3–6 months
Cytogenetic response is not achieved by 6 months in >95% of patients and persistence of Philadelphia chromosome metaphases
Partial cytogenetic response is not achieved by 12 months in >56% of patients and persistence of Philadelphia chromosome metaphases
Secondary Resistance to Imatinib (Tyrosine Kinase Inhibitor) in CML
Absence of complete hematologic response
Loss of a partial or complete cytogenetic response
Increasing levels of BCR-ABL1 as analyzed by real-time polymerase chain reaction (RT-PCR)

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Allogeneic hematopoietic stem cell (HSC) transplantation can be performed in CML, BCR-ABL1 positive patients, who meet the bone marrow transplant criteria.

- Limitations of allogeneic hematopoietic stem cell transplantation are based on availability of a compatible (HSC) donor and age of the CML patients <65 years.
- Prior to allogeneic HSC transplantation, high-dose chemotherapy or imatinib drug should be administered.
- Allogeneic HSC transplantation is most successful, when performed during the chronic phase of CML. About 85% of CML patients receiving HLA-matched hematopoietic stem cells, have survival rate more than three years.
- Indications for allogeneic HSC transplantation in CML, BCR-ABL1 positive are given in Table 9.97.

Table 9.97 Indications for allogeneic hematopoietic stem cell (HSC) transplantation in chronic myelogenous leukemia (CML), BCR-ABL1 positive

CML Phase	Indications for Allogeneic HSC Transplantation
CML chronic phase	▪ Intolerance to tyrosine kinase inhibitor therapy ▪ After first-line failure of tyrosine kinase inhibitor therapy and the T3151 mutation in Philadelphia chromosome ▪ After second-line failure of tyrosine kinase inhibitor therapy
CML accelerated phase	▪ After failure of tyrosine kinase inhibitor therapy in newly diagnosed case ▪ Development of accelerated phase while on tyrosine kinase inhibitor therapy ▪ Development of accelerated phase while on tyrosine kinase inhibitor therapy
CML blast phase	Indication of allogeneic bone marrow transplantation in patients with blast phase

Best outcome of allogeneic HSC transplantation is seen in CML in the chronic phase.
Chronic phase CML patients should always be started on tyrosine kinase inhibitor and should not be considered for allogeneic HSC transplantation.

CHRONIC NEUTROPHILIC LEUKEMIA

Chronic neutrophilic leukemia (CNL) is a rare myeloproliferative neoplasm, that always involves bone marrow, peripheral blood, spleen and liver. CNL is predominantly seen in older patients with median age 65 years at diagnosis with slight male predominance.

- Chronic neutrophilic leukemia is characterized by persistent neutrophilia with a slight shift to the left in peripheral blood without Philadelphia chromosomal abnormality and BCR-ABL1 fusion transcript, hypercellular bone marrow and hepatosplenomegaly. Basophilia and monocytosis are absent.
- Bone marrow becomes hypercellular due to increased proliferation of neutrophilic granulocyte without dysplastic changes. It is essential to rule out etiology of reactive neutrophilia, CML, BCR-ABL1 positive, aCML, polycythemia vera, primary myelofibrosis or myelodysplastic/myeloproliferative neoplasm.
- Chronic neutrophilic leukemia must be distinguished from reactive leukemoid reactions that can be seen in association with infections or inflammatory processes or as a paraneoplastic phenomenon secondary to plasma cell neoplasms, lymphomas and some carcinomas.
- Revised 2024 WHO diagnostic criteria for chronic neutrophilic leukemia are given in Table 9.98.

Table 9.98 Revised 2024 WHO diagnostic criteria for chronic neutrophilic leukemia (CNL)

Peripheral Blood Smear
Peripheral blood shows leukocytosis with total WBCs count $\geq 25 \times 10^9$/L
Band and segmented neutrophils ≥80% white blood cell count
Myeloid precursors such as promyelocytes, myelocytes, and metamyelocytes constitute <10% of white blood cells
Myeloblasts constitute <1% of WBCs
Monocyte count $<1 \times 10^9$/L
Absence of dysgranulopoiesis
Hypercellular Bone Marrow
Increased neutrophils in percentage and number
Normal neutrophil maturation
Myeloblasts constitute <5% of nucleated cells
Not Meeting WHO Criteria for Following Myeloproliferative Neoplasms
Chronic myelogenous leukemia (CML), BCR-ABL1 positive
Polycythemia vera (PV)
Essential thrombocythemia (ET)
Primary myelofibrosis (PMF)
Absence of the Following Gene Mutations
PDGFRA
PDFGRB
FGFR1
PCM1-JAK2
Presence of the Following Molecular Mutations
CSF3R T6181 mutation common
Other activating CSF3R mutation
Or in the absence of a CSF3R mutation, persistent neutrophilia (≥3 months), splenomegaly, and/or, if present, demonstration of clonally myeloid cells by cytogenetic or molecular studies
CNL lacks BCR-ABL1 gene arrangement, which distinguishes CNL from CML, BCR-ABL1 positive

Hepatosplenomegaly is demonstrated in chronic neutrophilic anemia. Adapted from revised 2024 WHO classification of hematopoietic neoplasms.

PATHOPHYSIOLOGY

In chronic neutrophilic leukemia, neutrophilic proliferation may be related to abnormal cytokine production, which most probably a clonal bone marrow HSC with limited myeloid potential.

- In chronic neutrophilic leukemia, normal apoptotic signal may be disrupted. Cytogenetic study is normal

in 25% of patients. However, about 25% of patients can demonstrate abnormalities of chromosome 20q–, 21+, 11q–, 6 and 9.
- Philadelphia chromosome and BCR-ABL1 fusion transcript is not demonstrated in chronic neutrophilic leukemia. If a plasma cell proliferation is demonstrated, clonality of the neutrophils should be established by cytogenetic and molecular studies for diagnosing chronic neutrophilic leukemia.

CLINICAL FEATURES

Majority of chronic neutrophilic leukemia patients are symptomatic at the time of diagnosis.
- Patient presents with fatigue, weight loss, night sweats, easy bruising and bone pain.
- Clinical examination reveals hepatosplenomegaly as a result of leukemic infiltration. However, leukemic infiltration can be demonstrated in any tissue/organ.

LABORATORY DIAGNOSIS

The most notable feature of chronic neutrophilic leukemia is neutrophilia (25×10^9/L). Mature segmented forms and band forms of neutrophils predominate.
- Peripheral blood smear examination shows more immature cells such as promyelocytes, myelocytes, and metamyelocytes that constitute <10% of white blood cells.
  - Neutrophils can have toxic granules, however, lack dysplastic features. Both the red blood cell and platelet have normal morphology.
  - Platelet count is usually within normal range, but thrombocytopenia can develop as the disease progresses and the spleen enlarges. Neutrophilic alkaline phosphatase score is usually increased.
- Bone marrow smear examination shows hypercellular bone marrow, because of granulocytic hyperplasia with myeloid to erythroid ratio 20:1 or even higher. There is no increase in the number of myeloblasts. Auer rods are absent in myeloblasts. Bone marrow examination demonstrates excessive proliferation of erythroid cells and megakaryocytes.

Laboratory Diagnosis of Chronic Neutrophilic Leukemia

Peripheral Blood Smear Examination

- The most notable feature of chronic neutrophilic leukemia is neutrophilia ($\geq 25 \times 10^9$/L).
- Band and segmented neutrophils constitute >80% white blood cell count.
- Promyelocytes, myelocytes, and metamyelocytes constitute <10% of WBCs.
- Myeloblasts constitute <1% of WBCs.
- Monocyte count is $<1 \times 10^9$/L.
- Absence of dysgranulopoiesis is observed
- Neutrophils can have toxic granules with absence of dysplastic features.
- Morphology of red blood cell and platelet morphology is normal.
- Platelet count is usually within normal range, but thrombocytopenia can develop as the CNL disease progresses associated with increased in size of spleen.
- Chronic neutrophilic leukemia in Giemsa-stained peripheral blood smear is shown in Fig. 9.85.

Neutrophilic Alkaline Phosphatase Score

Neutrophilic alkaline phosphatase score is usually increased. Neutrophil alkaline phosphatase (NAP) stain positivity in chronic neutrophilic leukemia in Giemsa-stained peripheral blood smear is shown in Fig. 9.86.

Bone Marrow Smear Examination

- Bone marrow becomes hypercellular as a result of granulocytic hyperplasia with myeloid to erythroid ratio 20:1 or higher. There is no increase in the number of myeloblasts. Auer rods are absent in myeloblasts.
- Increased neutrophils in percentage and number
- Normal neutrophil maturation is observed
- Myeloblasts constitute <5% of nucleated cells in bone marrow
- Bone marrow demonstrates excessive proliferation of erythroid cells and megakaryocytes.
- Chronic neutrophilic leukemia in Giemsa-stained bone marrow smear is shown in Fig. 9.87.

Bone Marrow Trephine Biopsy Examination

- Chronic neutrophilic leukemia (CNL) in hematoxylin and eosin-stained bone marrow trephine biopsy section is shown in Fig. 9.88.

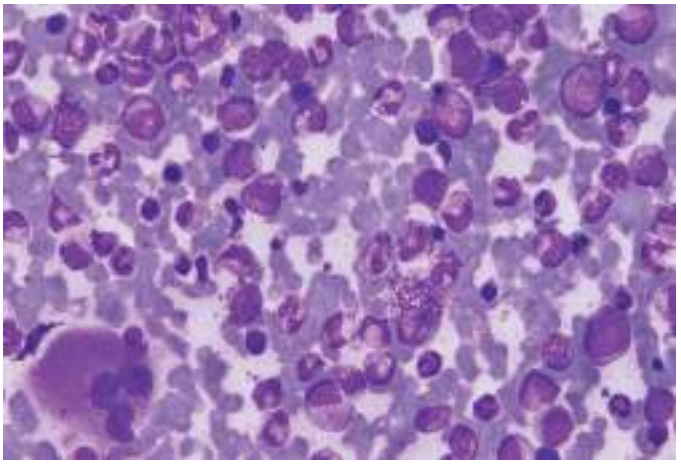

Fig. 9.85: Chronic neutrophilic leukemia in Giemsa-stained peripheral blood smear. The most notable feature of CNL is neutrophilia ($\geq 25 \times 10^9$/L). Band and segmented neutrophils constitute >80% white blood cell count. Neutrophils can have toxic granules, however, lack dysplastic features. Promyelocytes, myelocytes, and metamyelocytes constitute <10% of white blood cells. Myeloblasts are <1% of WBC. Monocyte count is $<1 \times 10^9$/L and absence of dysgranulopoiesis. Both the red blood cell and platelet have normal morphology (1000X).

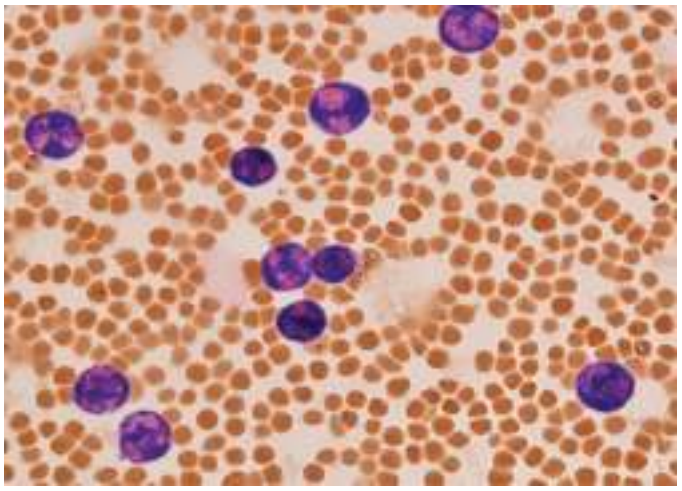

Fig. 9.86: Neutrophil alkaline phosphatase stain positivity in chronic neutrophilic leukemia in Giemsa-stained peripheral blood smear (1000X).

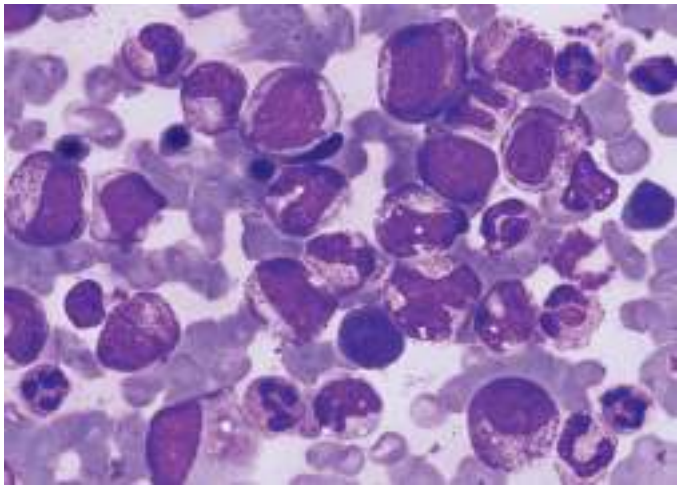

Fig. 9.87: Bone marrow aspirate smear examination shows hypercellular marrow, because of granulocytic hyperplasia with myeloid to erythroid ratio 20:1 or even higher. There is no increase in the number of myeloblasts. Auer rods are absent in myeloblasts. Bone marrow demonstrates excessive proliferation of erythroid cells and megakaryocytes (1000X).

TARGETED THERAPY

Hydroxyurea is the first-line targeted therapy for chronic neutrophilic leukemia. Hematologic response lasts for one year. Interferon-α (IFN-α) is the second line of therapy. Allogeneic HSC transplantation is potentially curative treatment for those eligible cases.

CLINICAL COURSE

Median survival of chronic neutrophilic leukemia is 2.5 years. The patients can develop accelerated phase in CML characterized by progressive neutrophilia unresponsive to treatment, anemia, thrombocytopenia, and splenomegaly. Peripheral blood smear examination can demonstrate myeloblasts and other immature myeloid cells.

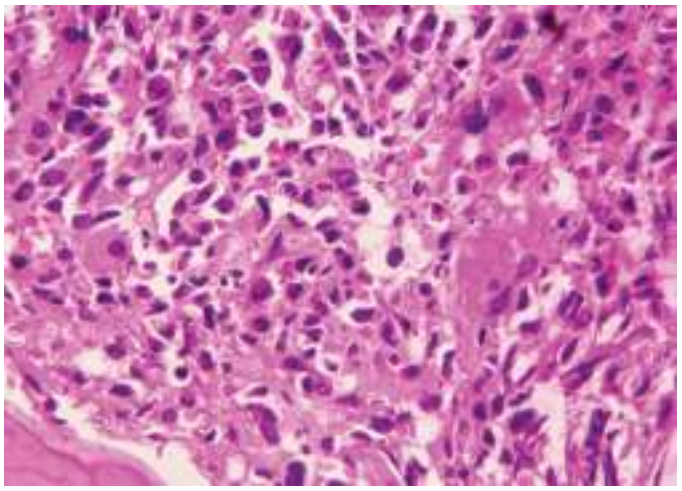

Fig. 9.88: Chronic neutrophilic leukemia in hematoxylin and eosin-stained bone marrow trephine biopsy section (400X).

DIFFERENTIAL DIAGNOSIS

Chronic neutrophilic leukemia (CNL) must be differentiated from CML, BCR-ABL1 positive and reactive neutrophilia due to infection or inflammation. Differential diagnosis from other myeloid neoplasms requires an absence of circulating blast cells, absolute monocytosis, eosinophilia and basophilia.

ESSENTIAL THROMBOCYTHEMIA

Essential thrombocythemia (ET) is a myeloproliferative neoplasm affecting primarily megakaryocytic lineage, which demonstrates sustained proliferation of megakaryocytes in the bone marrow and extreme thrombocytosis in the peripheral blood with qualitative disorder of platelets (thrombocytopathy).

- Thrombocytosis is a component of CML, primary myelofibrosis and polycythemia vera. However, it is now well established that essential thrombocythemia is a hematologic neoplasm with distinct clinical manifestations and complications.
- Most essential thrombocythemia (ET) patients have somatic mutation in Janus kinase 2 (JAK2), calretinin (CALR) or myeloproliferative leukemia (MPL) oncogene with subsequent dysregulation of the JAK2/STAT5 pathway.
- About 65% of ET patients demonstrate JAK2 (V617F) mutation associated with increased risk for thrombosis.
- Approximately 20–30% of ET patients demonstrate **CALR exon 9 mutation** associated with bone marrow fibrosis.
- About 3–5% of patients demonstrate **MPL exon 10 mutation** associated short survival.

Table 9.99 Diagnostic criteria for essential thrombocythemia must meet all three major and both minor criteria

Major Diagnostic Criteria of Essential Thrombocythemia (must Fulfill all Three Criteria)
Persistent elevation of platelets (≥450 × 10⁹/L) in the peripheral blood
Presence of acquired JAK2 (V617F), CALR, or MPL gene mutations (DNA testing)
Trephine bone marrow biopsy shows proliferation of megakaryocytic lineage with increased in number of mature large megakaryocytes with hyperlobulated nuclei, left shift in neutrophil granulopoiesis or erythropoiesis. Increase in reticulin fibrosis (grade I) may be rarely demonstrated.
Not meeting WHO diagnostic criteria for CML, polycythemia vera, primary myelofibrosis, myeloproliferative dysplasia or other myeloproliferative neoplasms
No evidence of reactive thrombocytosis and normal iron stores
Minor Diagnostic Criteria (must Fulfill Both Criteria)
Demonstration of clonal hematopoietic stem cell disorder
No evidence for reactive thrombocytosis such as inflammation

Diagnosis of essential thrombocythemia requires meeting all major and two minor criteria.

- About 5–10% of patients with triple negative mutations, i.e. JAK2 (V617F), CALR exon 9, and MPL have longest survival rate.
- Synonyms of ET include primary thrombocythemia, primary thrombocytosis, hemorrhagic thrombocythemia and idiopathic thrombocytosis. Diagnostic criteria for essential thrombocythemia are given in Table 9.99.

PATHOPHYSIOLOGY

Essential thrombocythemia (ET) is a clonal disorder of pluripotent HSC affecting all three lineages, but in some ET cases involving only the megakaryocytic lineage.

- Clonal population of HSC are hypersensitive to cytokines such as IL-3 and IL-6, and not to GM-CSF. Sensitivity to inhibitory effects of TGF-β to clonal population of cells is decreased, minimizing inhibition of thrombopoiesis.
- Thus, a combination of increased sensitivity to IL-3 and IL-6, and decreased sensitivity to negative regulators promote unrestricted proliferation of megakaryocytes resulting in increased production of platelets. Serum levels of thrombopoietin are normal or slightly elevated.

JAK2 (V617F) Gene Mutations

Janus Kinase 2 (JAK2) (V617F) is located on chromosome band 9p24 encodes JAK2 protein, i.e. receptor tyrosine kinase activator of cell signal transducers. JAK2 protein is cytoplasmic domain of receptor tyrosine kinase closely associated with cytokine receptors and distributed near the cell membrane.

- When a receptor tyrosine kinase binds cytokine, JAK2 protein gets transphosphorylated and activated. In turn, JAK2 phosphorylates signal transducers and activators of transcription STAT5 proteins. JAK2/STAT5 activation pathways are suppressed by negative regulators.
- Gain-of-function mutation in the JAK2 (V617F) tyrosine kinase gene is most often demonstrated in essential thrombocythemia, which results in autonomous cell signal transduction leading to unrestricted proliferation of the megakaryocytic lineage and production of platelets. Presence of the JAK2 (V617F) mutation is associated with thrombosis in these patients.

MPL Gene Mutations

Essential thrombocythemia (ET) is caused due to myeloproliferative leukemia (MPL) gene mutation that results in the replacement of the amino acid serine with the amino acid asparagine at position 505 in the protein (written as Ser505Asn or S505N).

- MPL (myeloproliferative leukemia) gene encodes thrombopoietin receptor protein also known as CD110, that participates in maintenance of hematopoietic stem cells, cell growth and proliferation of megakaryocytes leading to formation of platelets. Binding of thrombopoietin-to-thrombopoietin receptor leads to 'turning on' the thrombopoietin receptor, activation of JAK/STAT signaling pathway, resulting in maintenance of HSC and regulates megakaryocytes cell growth and proliferation with production of platelets.
- MPL gene mutations (MPLW5151 and MPLW515K) have been demonstrated in 4% of essential thrombocythemia patients. MPL gene mutation leads to cytokine-independent growth and constitutive downstream signaling pathways.
- MPL gene (exon 10) mutation is associated with short survival in 3–5% of ET patients.

Pathology Pearls: Essential Thrombocythemia

- About 65% of patients demonstrate mutation in JAK2 (V617F) associated with increased risk of thrombosis.
- Approximately 20–30% of patients demonstrate mutation CALR exon 9 and associated with increased rate of bone marrow fibrosis.
- About 3–5% of patients demonstrate mutation in MPL exon 10 and associated with short survival.
- About 5–10% of patients with triple negative mutations, i.e. JAK2 (V617F), CALR exon 9, and MPL associated with longest survival rate.

CLINICAL FEATURES

Essential thrombocythemia most often affects 50–60 years of age. It may also affect 20–30 years of age. Clinical manifestations of ET are variable. Extreme thrombocytosis is frequently demonstrated in these patients. Symptomatic patients present with symptoms related to thrombi formation in the microvasculature.

- Patient develops neurological manifestations such as headache and paresthesia of extremities due to platelet-mediated ischemia and thrombi formation in microvasculature; and painful toes and fingers due to circulatory insufficiency related to thrombi formed in the microvasculature. Hemorrhagic episodes primarily affect skin and mucous membranes lining gastrointestinal tract, oral cavity, and urinary bladder.
- Slightly palpable spleen is observed in 50% of cases. Splenic atrophy or silent splenic infarction may occur. Platelet coagulation activity (i.e. platelet aggregation) may be increased due to loss of prostaglandin E_2 (PGE_2) receptor. Storage pool defects in platelets promote hemorrhagic manifestations.

LABORATORY DIAGNOSIS

Diagnosis of ET is established by examination of peripheral blood, bone marrow aspiration, tests for hemostasis (prothrombin time, activated partial thromboplastin time, platelet aggregation tests), molecular genetic analysis of JAK2 (V617F), CALR exon 9, MPL mutations, and other tests, i.e. elevated levels of serum cobalamin, unsaturated cobalamin binding capacity, serum uric acid, lactic dehydrogenase and acid phosphatase.

Laboratory Diagnosis of Essential Thrombocythemia

Biochemical Investigations

Biochemical laboratory tests demonstrate elevated levels of serum cobalamin, unsaturated cobalamin binding capacity, serum uric acid, lactic dehydrogenase and acid phosphatase.

Hemostasis Tests

- Laboratory tests alone are not reliable in predicting bleeding and thrombotic manifestations in essential thrombocythemia.
- Prothrombin time–INR (PT–INR) and activated partial thromboplastin time (APTT) are most often within normal range.
- Platelet aggregation studies are abnormal with defective platelet aggregation with ADP, epinephrine, and collagen.
- Other platelet abnormalities in essential thrombocythemia include decreased or mutate MPL receptors for thrombopoietin, shortened platelet survival, increased plasma β-thromboglobulin, acquired storage pool deficiency due to abnormal *in vivo* platelet activation and decreased ATP secretion.

Peripheral Blood Smear Examination

Red blood cells

- Development of anemia depends on severity of hemorrhagic episodes. Severe hemorrhagic episodes result in microcytic hypochromic picture.
- Nucleated red blood cells are demonstrated in 25% of patients. In some patients, erythrocytosis is demonstrated. It should be differentiated from polycythemia vera.
- Aggregated platelets can lead to an erroneous increase in the erythrocyte count on automated cell counters.

White blood cells

- Leukocytosis is almost always present. WBC count is often in the range of **22×10^9/L to 40×10^9/L.** Occasional myelocyte and metamyelocyte can be demonstrated.
- Mild basophilia and eosinophilia may be present.
- Neutrophilic alkaline phosphatase (NAP) score is variable.

Platelets

- Most striking finding in the peripheral blood smear is the presence of extreme and constant thrombocytosis.
- Platelet counts are >450×10^9/L and often in the range of 1000×10^9/L to 5000×10^9/L. Giant bizarre platelets and aggregates of platelets can be demonstrated.
- Megakaryocytes and megakaryocyte fragments can also be observed. However, platelet morphology may appear normal in many patients.
- Abnormalities in the platelet aggregation and adhesion defects suggest defects in the platelet function. Platelet abnormalities demonstrated in essential thrombocythemia are given in Table 9.100.
- Essential thrombocythemia in Giemsa-stained peripheral blood smear is shown in Fig. 9.89.

Bone Marrow Smear Examination

- Bone marrow smear examination demonstrates marked cellular hyperplasia with a striking increase in number of functional megakaryocytes either dispersed throughout smear or arranged in clusters along the sinusoidal borders.
  - The background of stained bone marrow smears demonstrates numerous platelets.
  - Megakaryocytes are large sized with abundant mature cytoplasm and frequently increased lobulation of nuclei. Mitotic figures are increased.
- Erythroid and myeloid hyperplasia are evident.
- Significant bone marrow fibrosis is generally absent.

Bone Marrow Trephine Biopsy Examination

- Essential thrombocythemia in hematoxylin and eosin-stained bone marrow trephine biopsy section examination demonstrates marked bone marrow hyperplasia with a striking increase in number of functional megakaryocytes either dispersed throughout smear or arranged in clusters along the sinusoidal borders.

- The background of stained sections demonstrates numerous platelets. Megakaryocytes are large sized with abundant mature cytoplasm and frequently increased lobulation of nuclei. Mitotic figures are increased.
- Essential thrombocythemia in hematoxylin and eosin-stained bone marrow trephine biopsy section is shown in Fig. 9.90.

Molecular Genetic Alterations Analysis

- About 65% of patients demonstrate JAK2 (V617F) mutation associated with increased risk of thrombosis.
- Approximately 20–30% of patients demonstrate CALR exon 9 mutation associated with increased rate of bone marrow fibrosis.
- About 3–5% of patients demonstrate MPL exon 10 mutation associated with short survival rate.
- About 5–10% of patients with triple negative mutations, i.e. JAK2 (V617F), CALR exon 9, MPL have longest survival rate.

MANAGEMENT

Essential thrombocythemia is treated by administration of hydroxyurea to achieve cytoreduction of platelets and leukocytes. Decreasing platelet and leukocyte count lower the risk of thrombosis in these patients.

- Although anagrelide, an inhibitor of megakaryocytic differentiation can be administered to reduce platelets, yet not tolerated by the patients due to side effects.
- Therapeutic trials of interferon-β (IFN-β) demonstrate improvement in both hematologic parameters and clinical manifestations on nearly all patients.

DIFFERENTIAL DIAGNOSIS

Essential thrombocythemia (ET) is diagnosed by exclusion of other myeloproliferative neoplasms and secondary or reactive thrombocytosis associated with many acute and chronic infections, inflammatory diseases, Hodgkin's disease and carcinoma.

- Platelet count in essential thrombocythemia often exceeds 1000×10^9/L, that remains persistent over a period of months or years.

Table 9.100 Platelet abnormalities demonstrated in essential thrombocythemia

Decreased or mutated MPL receptors on platelets for thrombopoietin (TPO)
Life span of platelets shortened
Increased plasma β-thromboglobulin (β-TG)
Acquired urinary thromboxane B_2 (vasoconstrictor and platelet aggregating agent)
Defective epinephrine, collagen, ADP-induced platelet aggregation
Decreased ATP secretion
Development of acquired von Willebrand disease and storage pool deficiency

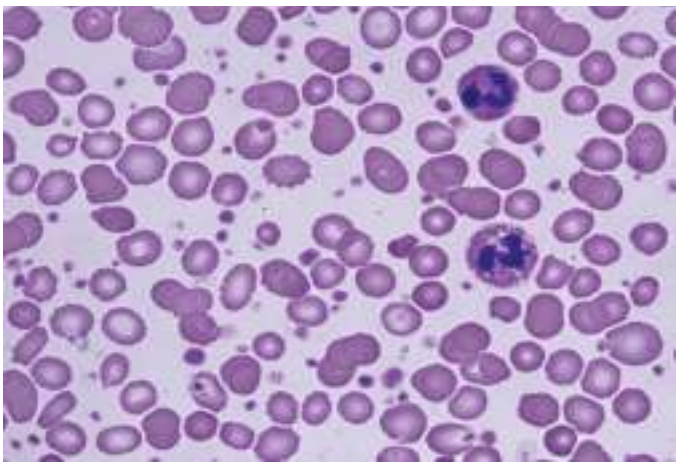

Fig. 9.89: Essential thrombocythemia in Giemsa-stained peripheral blood smear. Most striking finding in the peripheral blood is the presence of extreme and constant thrombocytosis. Platelet counts are $>450 \times 10^9$/L and often in the range of 1000×10^9/L to 5000×10^9/L. Giant bizarre platelets and aggregates of platelets can be demonstrated. Megakaryocytes and megakaryocyte fragments can also be observed. However, platelet morphology may appear normal in many patients. Abnormalities in the platelet aggregation and adhesion defects suggest defects in the platelet function (1000X).

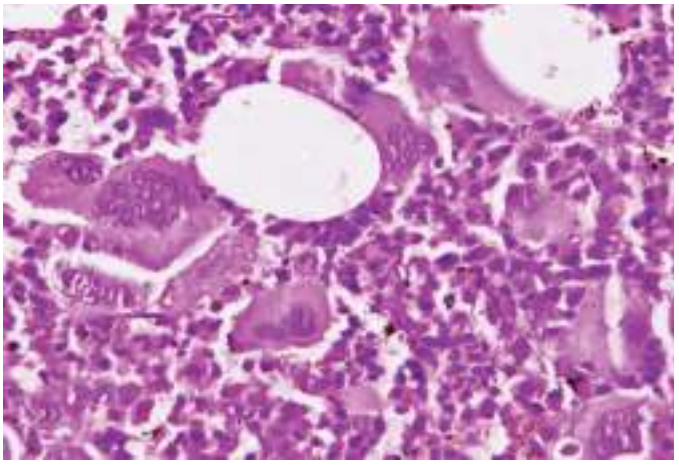

Fig. 9.90: Essential thrombocythemia in hematoxylin and eosin-stained bone marrow trephine biopsy section. It demonstrates marked hyperplasia with a striking increase in number of functional megakaryocytes either dispersed throughout smear or arranged in clusters along the sinusoidal borders. The background of stained smears demonstrates numerous platelets. Megakaryocytes are large sized with abundant mature cytoplasm and frequently increased lobulation of nuclei. Mitotic figures are increased (1000X).

- Platelet count in secondary or reactive thrombocytosis rarely reaches 1000×10^9/L, that is transitory. Platelet functions are normal in secondary or reactive thrombocytosis and absence of splenomegaly.
- Disorders associated with thrombocytosis are given in Table 9.101. Comparison of bone marrow morphologic findings in myelodysplastic/myeloproliferative neoplasm with ring sideroblasts and thrombocytosis

Table 9.101 Disorders associated with thrombocytosis

Essential thrombocythemia (ET)
Chronic myelogenous leukemia (CML)
Primary myelofibrosis (PML)
Secondary or reactive thrombocytosis ▪ Acute and chronic inflammatory conditions ▪ Hemolytic anemia ▪ Metastatic carcinoma ▪ Hodgkin disease ▪ Non-Hodgkin lymphoma ▪ Postsplenectomy ▪ Postoperative cases ▪ Iron deficiency anemia

(MDS/MPN with ring sideroblasts–thrombocytosis) and essential thrombocythemia is given in Table 9.102. Clinicomorphologic features in distinguishing essential thrombocythemia and secondary thrombocytosis are given in Table 9.103.

POLYCYTHEMIA VERA

Polycythemia vera (PV) is a myeloproliferative neoplasm characterized by unregulated proliferation of primarily, the erythroid lineage in the bone marrow and increased red blood cells in the peripheral blood. Blood that flows more slowly can reduce amount of oxygen to vital organs.

- Increased concentration of red blood cells can clump together and form clots inside the blood vessels and interrupt blood flow, that can cause cerebral stroke associated with fatal outcome.
- Polycythemia vera most often affects 40–60 years of age group. Males are more affected than females. Disease rarely affects children.
- Diagnostic criteria for polycythemia vera are given in Table 9.104. To clarify the pathogenesis of polycythemia vera, it is classified into three different groups: polycythemia vera, secondary thrombocytosis and relative thrombocytosis. Classification of polycythemia and associated conditions is given in Table 9.105. Comparison of polycythemia vera and other types of polycythemias is given in Table 9.106.

PATHOPHYSIOLOGY

Polycythemia vera (PV) is a clonal hematopoietic stem cell disorder characterized by increased

Table 9.102 Comparison of bone marrow morphologic findings in myelodysplastic/myeloproliferative neoplasm with ring sideroblasts and thrombocytosis (MDS/MPN with RS-T) and essential thrombocythemia

Bone Marrow Morphologic Findings	MDS/MPN with RS-T	Essential Thrombocythemia
Cellularity (age-matched)	Increased	Normal
Myeloid hyperplasia	Absent	Absent
Megakaryocyte proliferation	Present	Present
Megakaryocyte morphology	Hypolobated megakaryocyte	Staghorn hyperlobated nuclei
Megakaryocyte size	Small (micromegakaryocytes)	Large (macromegakaryocyte)
Megakaryocyte clusters	Absent	Present, arranged in loose clusters
Bone marrow fibrosis	MF-0 or MF-1	MF-0
Ring sideroblasts on iron stain	Present ≥15%	Absent

Table 9.103 Clinicomorphologic features in distinguishing essential thrombocythemia (ET) and secondary thrombocytosis

Parameters	Essential Thrombocythemia (ET)	Secondary Thrombocytosis
Platelet increase status	Persistent	Transient
History of thrombotic/bleeding episode/vasomotor symptoms	Present	Present (1–2%)
Hepatosplenomegaly	Present	Absent
History of infections/ inflammatory stimuli or nonmyeloid malignancy	Absent	Present
Increased phase reactants (e.g. CRP)	Absent	Present
Bone marrow megakaryocyte	Large megakaryocytes including staghorn appearance and showing clustering	Megakaryocytes with normal morphology or increased in size without clustering
Clonal molecular abnormality	Usually present [JAK2 (V617F), MPLW515K/L, or CALR mutations]	Absent

Table 9.104 Diagnostic criteria for polycythemia vera require two major criteria (1 and 2); and one minor criterion; or one major criterion and two minor criteria

Major Diagnostic Criteria
Absolute erythrocytosis in the range of 6×10^{12}/L to 10×10^{12}/L, hemoglobin >18.5 g/dl in males, 16.5 g/dl in females, or other evidence of increased red blood cells volume hematocrit >52% in males and >48% in females
Presence of JAK2 (V617F) or other functionally similar mutations, e.g. JAK2 exon 12 mutation
Minor Diagnostic Criteria
Bone marrow trephine biopsy shows panmyelosis with proliferation of myeloid elements (erythroid, myeloid and megakaryocytic cells)
Subnormal serum erythropoietin levels below the level of <4 mU/ml
Demonstration of endogenous erythroid colony formation *in vitro*

erythropoiesis and other cell lineages in bone marrow (erythropoietin level within normal range) and increased red blood cells in blood circulation. Polycythemia vera is an erythropoietin-independent unrestricted proliferation of erythroid lineage cells, which are hypersensitive to erythropoietin, insulin-like growth factor 1 and IL-3. Erythroid lineage cell escapes apoptosis. The maturation of erythroid lineage cells is morphologically normal, and the functions of red blood cells have normal life span.

JAK2 (V617F) Gene Mutation

JAK2 (V617F) is located on chromosome band 9p24, which encodes JAK2 protein. JAK2 protein is a

Table 9.105 Classification of polycythemia and associated conditions

Polycythemia Vera (Primary Polycythemia)—Erythropoietin-independent
Normal or increased erythropoietin levels
Autonomous proliferation of erythroid lineage
Secondary Polycythemia (Erythropoietin Driven)
High altitude
Chronic obstructive pulmonary disease
Congenital heart disease
Heavy tobacco smokers
Pickwickian syndrome (clinically known as obesity hypoventilation syndrome)
Familial erythrocytosis
Hemoglobin with high oxygen affinity
Congenital decrease in erythrocyte 2,3-bisphosphoglycerate (2,3-BPG)
Inappropriate increased erythropoietin production in various disorders: ▪ Renal cell carcinoma ▪ Hepatocellular carcinoma ▪ Cerebellar hemangioma ▪ Pheochromocytoma ▪ Adrenal adenoma with Cushing's syndrome ▪ Uterine leiomyoma ▪ Adult polycystic disease of kidney ▪ Administration of androgens ▪ Renal ischemia
Relative Polycythemia
Gaisbock's syndrome (stress polycythemia, spurious polycythemia, pseudopolycythemia)
Dehydration is present

Table 9.106 Comparison of polycythemia vera and other types of polycythemias

Parameters	Polycythemia Vera	Secondary and Relative Polycythemias
Total blood volume	Increased	Normal or increased
Total leukocyte count	Increased	Normal
Immature red blood cells	Occasional	None
Platelets	Increased	Normal
NAP score	Increased	Normal
Erythrocyte sedimentation rate (ESR)	Decreased	Normal
Serum iron	Decreased	Normal or increased
Erythropoietin	Decreased or absent	Normal or increased
Blood histamine	Increased	Normal
Unsaturated vitamin B_{12}-binding capacity	Increased	Normal
Basophil count	Increased	Normal
Hyperuricemia	Present or absent	Normal
Hyperuricosuria	Present or absent	Normal
Chromosome studies	Abnormal >90% JAK2 (V617F) positive	Negative

cytoplasmic protein, i.e. receptor tyrosine kinase closely associated with cytokine receptors and distributed near the cell membrane. When a cytokine receptor binds cytokine, JAK2 protein gets transphosphorylated and activated. In turn, JAK2 phosphorylates signal transducers and activators of transcription STAT5 proteins. JAK2 /STAT5 activation pathways are suppressed by negative regulators.

- Gain-of-function mutation in the JAK2 (V617F) receptor tyrosine kinase gene is demonstrated in 95–100% of polycythemia vera patients. JAK2 (V617F) mutation results in autonomous cell signal transduction leading to excessive proliferation of erythroid lineage cells.
- In addition, about 5% of patients carry other mutations in exon 12 of JAK2 that disrupts normal JAK2 function. It has been proposed that JAK2 (V617F) mutation triggers ET phenotype. Secondly, when a second JAK2 (V617F) mutation occurs, JAK2 protein triggers the erythropoietin (Epo) receptors converting the disease phenotype to polycythemia vera.
- JAK2 (V617F) mutation is demonstrated in polycythemia vera (95–100%), essential thrombocythemia (50%) and primary myelofibrosis (50%).

TET2 Gene Mutation

Ten-eleven translocation 2 (TET2) mutation is also demonstrated in some cases of polycythemia vera, that is not a disease initiating event, rather accelerating erythropoiesis and contributing to development of polycythemia vera.

MPL, LNK and BCL-X Gene Mutations

In the absence of mutations in JAK2 (V617F) gene, other mutations in genes coding for aberrant MPL, LNK (lymphocyte adaptor protein) and antiapoptotic protein members of the BCL-2 family (BCL-X) disrupt the normal JAK/STAT signaling pathway resulting in proliferation of clone in polycythemia vera. The defect in apoptosis creates accumulation of altered hypersensitive hematopoietic stem cell and erythroid lineage cells. Thrombopoietin receptor hyperresponsiveness and resistance to programmed cell death (apoptosis) are demonstrated in megakaryocytic lineage, resulting in thrombocytosis in polycythemia vera.

Epigenetic Alterations

Gene encodes isocitrate dehydrogenase 1 (IDH-1), that functions in citric acid cycle and converts isocitrate to α-ketoglycerate with the associated production of NADPH. Somatic mutation in the gene for the isocitrate dehydrogenase 1 manifests epigenetic modifications of citrate cycle, that contributes to development of polycythemia vera.

CLINICAL FEATURES

Polycythemia vera has been reported in the several members of the same family suggesting a familial predisposition can exist. It is gradual onset with history of mild symptoms for several years. Symptoms are related to increase in red blood cell mass and cardiovascular diseases due to hyperviscosity of blood.

- Patient presents with headache, weakness, pruritus, dizziness, diaphoresis, visual disturbances, weight loss, paresthesia, dyspnea, joint pain and epigastric discomfort.
- Clinical examination reveals splenomegaly due to expansion of red pulp and obliteration of white pulp, skin plethora (excess of blood and marked by turgescence and reddish complexion), conjunctival plethora (excess of blood and marked by turgescence and reddish complexion), retinal blood vessels engorged, hepatomegaly and hypertension.
- About 33% of the patients' experience hemorrhagic or thrombotic phenomenon linked to myocardial infarction, retinal vein thrombosis, thrombophlebitis, and cerebral stroke.
- After a span of 2–10 years, patient may develop bone marrow failure accompanied by moderate increase in spleen size, bleeding, and anemia.
- Acute myelogenous leukemia (AML) develops as an abrupt transition in 5–10% of patients due to administration of myelosuppressive drugs.
- Overall median survival of polycythemia vera exceeds 10–20 years. Clinical features and physical examination findings in polycythemia vera are given in Table 9.107.

Laboratory Diagnosis of Polycythemia Vera

Laboratory investigations of polycythemia vera (PV) include peripheral blood examination, bone marrow examination and bone marrow trephine biopsy.

Erythrocyte Sedimentation Rate

Erythrocyte sedimentation rate does not exceed 2–3 mm/hour.

Peripheral Blood Smear Examination

Peripheral blood smear examination in polycythemia vera shows following findings in RBCs, WBCs and platelets.

Red blood cells (RBCs)

- Most striking in the peripheral blood findings is an absolute erythrocytosis in the range of 6×10^{12}/L to 10×10^{12}/L, hemoglobin >18.5 g/dl in males, 16.5 g/dl in females, or other evidence of increased red blood cells volume, and hematocrit >52% in males and >48% in females.
- Absolute erythrocytosis is in the range of 6×10^{12}/L to 10×10^{12}/L, hemoglobin >18.5 g/dl in males and 16.5 g/dl in females, or other evidence of increased red blood cells volume, and hematocrit >49% in males and >48% in females.

- In early polycythemia vera disease, peripheral blood smear shows normocytic normochromic picture.
  - Repeated therapeutic phlebotomy, iron deficient erythropoiesis can result in iron deficiency anemia simulating a thalassemia.
  - Nucleated red blood cells may be demonstrated.
  - Red blood cells appear crowded even at the featured edge of peripheral blood smear.
- In advanced polycythemia vera disease, peripheral blood smear demonstrates thrombocytosis and large platelets, reactive lymphocytes and segmented neutrophils. Peripheral blood smear also shows leukoerythroblastic anemia, poikilocytosis, dacrocytes and thrombocytopenia resembling findings like myelofibrosis. In polycythemia vera, patients develop acute myelogenous leukemia. Peripheral blood smear examination shows numerous myeloblasts, marked anisopoikilocytosis of red blood cells and thrombocytopenia.

White blood cells

- Leukocytosis occurs in the range of 12×10^9/L to 20×10^9/L in 66% of patients.
- In the early polycythemia vera disease, there can be relative increase in granulocytes with normal white blood cell count.
- A shift to the left (presence of myelocytes and metamyelocytes) can be demonstrated. Demonstration of myeloblasts and promyelocytes is unusual.
- Relative and absolute basophilia is commonly demonstrated.

Platelets

- Megakaryocytic hyperplasia in the bone marrow is accompanied by increase in platelet count in peripheral blood in 50% of cases.
- Platelet count $>400 \times 10^9$/L is demonstrated in 20% of patients. In occasional case, platelet count occasionally exceeds 100×10^9/L. Giant platelets can be present.
- Qualitative abnormalities are reflected by abnormal platelet aggregation to epinephrine (most common), collagen, ADP or thrombin.
- Abnormal multimeric forms of von Willebrand factor (vWF) are demonstrated in 50% of patients, which acquire von Willebrand disease (vWD).

Reticulocyte Count

Reticulocyte count is normal or slightly elevated.

Neutrophil Alkaline Phosphatase (NAP) Score

Neutrophil alkaline phosphatase score is most often higher than 100.

Bone Marrow Smear Examination

- Bone marrow is moderate to marked hypercellular in majority of patients.
- Myeloid and erythroid hyperplasia are most often present.
- Myeloid to erythroid ratio is normal.
- Megakaryocytic hyperplasia is present.
- Megakaryocytes are large, but not bizarre arranged in clusters.
- Iron is absent in 95% of cases.
- Bone marrow fibrosis is absent in initial polycythemia vera disease.

Bone Marrow Trephine Biopsy Examination

Polycythemia vera, so-called masked/proliferation presentation stage

- In polycythemia vera, so-called masked/proliferation presentation stage, bone marrow trephine biopsy section shows mildly hypercellular bone marrow showing predominance of large and giant hypersegmented megakaryocytes.
- There is slight to marked increase in reticulin fibers directly proportion to the degree of bone marrow cellularity.
- Iron stores are depleted due to diversion of iron from storage sites to the numerous developing erythroblasts.

Postpolycythemic myelofibrosis overt stage

- In the postpolycythemic myelofibrosis overt stage, bone marrow trephine biopsy section shows reticulin and collagen fibrosis and shows prominent megakaryocytes arranged in clusters. There is decrease in erythropoiesis and granulopoiesis with shift to the left. Less than 10% blasts are present. Dysplasia is unusual.
- Megakaryocytes revealing different sizes are always prominent feature, which are more easily evaluated by using the periodic acid–Schiff (PAS) staining reaction.
- Immunostaining for CD61 demonstrates the atypia in the megakaryocytic population, including a population of small immature megakaryocytes. Overt reticulin fibrosis that is invariably present in postpolycythemic vera myelofibrosis with myeloid metaplasia in a span of 2–10 years.
- Trilineage proliferation is demonstrated by the naphthol-ASD-chloroacetate (CAE) stain, which is accurately identifying the granulocytic cells (red reaction product) assists in the assessment of the relative proportion of the major bone marrow lineages (erythropoietic and granulopoietic). At this stage megakaryocytes show increased pleomorphism, with significant differences in size but no relevant maturation defects such as cytoplasmic or nuclear differentiation.

PRIMARY MYELOFIBROSIS

Primary myelofibrosis (PMF) is a clonal hematopoietic stem cell (HSC) disorder characterized by proliferation of predominantly megakaryocytes and granulocytes in the bone marrow, which in fully developed disease is associated with gradual increase in reactive connective tissue (i.e. reticulin and collagen fibers) in bone marrow secondary to underlying disorder, and extensive extramedullary hematopoiesis in spleen (splenomegaly), liver and lymph nodes. PMF shows a stepwise evolution from an initial prefibrotic/early stage to overt fibrotic stage, which most often affects persons over 50 years of age with equal sex predilection and gradual onset disease.

- Primary myelofibrosis presents either as *de novo* or as an evolutionary consequence of essential thrombocythemia or polycythemia vera.

Table 9.107 Clinical presentation and physical examination findings and percentage in polycythemia vera (PV)

Clinical Features	
Headache	48%
Weakness	48%
Pruritus	43%
Dizziness	43%
Diaphoresis (sweating to an unusual degree)	33%
Visual disturbances	31%
Weight loss	29%
Paresthesia	29%
Dyspnea	26%
Joint symptoms	26%
Epigastric discomfort	24%
Physical Examination	
Splenomegaly	70%
Skin plethora (excess of blood and marked by turgescence and reddish complexion)	67%
Conjunctival plethora (excess of blood and marked by turgescence and reddish complexion)	60%
Retinal blood vessels engorged	46%
Hepatomegaly	40%
Systolic blood pressure >140 mm Hg	72%
Diastolic blood pressure >90 mm Hg	32%

- Extensive primary myelofibrosis inhibits normal hematopoiesis resulting in bone marrow hypoplasia and extensive extramedullary hematopoiesis in liver (hepatomegally), spleen (splenomegaly) and sometimes in lymph nodes (lymphadenopathy) as a result of islands of proliferating erythroid, myeloid and megakaryocytic lineage cells.
- Synonyms of primary myelofibrosis include agnogenic myeloid metaplasia, leukoerythroblastic anemia, myelofibrosis with myeloid metaplasia, chronic idiopathic myelofibrosis, aleukemic myelosis, myelosclerosis, and splenomegaly myelophthisic.

PATHOPHYSIOLOGY

Primary myelofibrosis (PMF) evolves from prefibrotic stage with minimal reticulin fibrosis to overt fibrotic stage with marked reticulin or collagen fibrosis of grades 2 and 3.

- Primary myelofibrosis is a reactive process secondary to clonal proliferation of hematopoietic stem cell (HSC) having chromosomal abnormalities. Fibroblasts do not demonstrate chromosomal abnormalities.
- Myelofibrotic component is composed of excessive collagen, fibroblasts, cytoadhesive molecules (fibronectin and vitronectin) and laminin (glycoprotein that supports adhesion and growth of cells).

Cytokines Role in Pathogenesis of Primary Myelofibrosis

Monoclonal megakaryocytes play an important role in the pathogenesis of primary myelofibrosis.

- Stromal reaction (fibroblasts proliferation, collagen deposition, necrosis) is demonstrated in the areas of megakaryocytes.
  - Stromal reaction is mediated by cytokines such as platelet-derived growth factor (**PDGF**), transforming growth factor-β (**TGF-β**) and epidermal growth factor (EGF) derived from platelets.
  - Reduced platelet concentration of PDGF and elevated serum PDGF are characteristics of primary myelofibrosis due to abnormal release. TGF-β stimulates increased expression of genes for collagen and fibronectin synthesis; and inhibits synthesis of collagenase enzymes. Thus, the net result is the accumulation of stromal elements in the bone marrow.
- Prominent angiogenesis in the bone marrow and spleen occurs due to increased serum levels of vascular endothelial growth factor (VEGF).
- Teardrop red blood cells and leukoerythroblastosis in peripheral blood are indicative of extramedullary hematopoiesis.

JAK2 (V617F) Gene Mutation

JAK2 (V617F) gene is located on chromosome band 9p24, that encodes JAK2 protein. JAK2 is a cytoplasmic protein, i.e. receptor tyrosine kinase closely associated with cytokine receptors and distributed near the cell membrane. When a receptor tyrosine kinase binds cytokine, the JAK2 protein gets transphosphorylated and activated. In turn, JAK2 phosphorylates signal transducers and activators of transcription STAT5 proteins. JAK2/STAT5 activation pathways are suppressed by negative regulators.

- Gain-of-function mutation in the JAK2 (V617F) receptor tyrosine kinase gene results in autonomous cell signal transduction leading to unrestricted proliferation of erythroid lineage cells. In addition, about 5% of patients carry other mutations in exon 12 of JAK2 that disrupts normal JAK2 function.
- Gain-of-function mutation in JAK2 (V617F) gene is also demonstrated in about 95–100% of polycythemia vera patients.
- JAK2 (V617F) allele burden has been associated with transformation and progression of primary myelofibrosis and increased cardiovascular symptoms.

Table 9.108 Clinical findings at diagnosis among patients with primary myelofibrosis (PMF)

Clinical Findings (>50% Cases)	Clinical Findings (10–50% Cases)	Clinical Findings (<10% Cases)
Splenomegaly (90%)	Weight loss	Jaundice
Hepatomegaly (50%)	Night sweats	Lymphadenopathy
Weakness	Bleeding manifestations	Peripheral edema
Anemia	Pain in the left hypochondrial region at splenic site	Gout
Leukocytosis	Leukocytopenia	
Thrombocytosis	Thrombocytosis or thrombocytopenia	

CLINICAL FEATURES

Patient with primary myelofibrosis presents with anemia, splenomegaly (90%) and hepatomegaly (50%), weakness, weight loss, anorexia, night sweats, low-grade fever, pruritus, bone pain and pain in extremities, Bleeding occasionally may be the presenting symptoms. Leukocytosis or marked thrombocytosis is common in primary myelofibrosis. Marked thrombocytosis may lead to thrombosis or hemorrhagic phenomenon.

- Clinical examination reveals splenomegaly (90%), hepatomegaly (50%), pallor and petechiae.
- Myeloid metaplasia occurs in spleen, liver, kidneys, adrenal glands, lymph nodes, peritoneal and extra-peritoneal surfaces and spinal cord. Clinical findings at diagnosis among patients with primary myelofibrosis (PMF) are given in Table 9.108.

Table 9.109 Revised 2024 WHO diagnostic criteria for prefibrotic/early primary myelofibrosis

Diagnostic criteria of primary myelofibrosis require all major criteria and at least one minor criterion
Major Diagnostic Criteria (must Fulfill all Four Criteria)
Bone marrow is hypercellular showing megakaryocyte proliferation and atypia, increased age-adjusted bone marrow cellularity, granulocytic proliferation
Bone marrow without evidence of reticulin fibrosis
Not meeting the criteria for other myeloproliferative neoplasms (MPNs), i.e. CML, polycythemia vera and essential thrombocythemia
Evidence of JAK2 (V617F), CALR, or MPL mutations; or in the absence of these mutations, presence of clonal marker or absence of minor reactive reticulin fibrosis
Minor Diagnostic Criteria (must Fulfill at least One of the Criteria)
Leukocytosis ≥11 × 10^9/L
Anemia
Palpable splenomegaly (infrequent)
Increased serum lactic dehydrogenase (LDH) above reference range

- Atypical acute form of primary myelofibrosis progresses rapidly within few months to one year is associated with development of anemia and leukopenia. Bone marrow trephine biopsy demonstrates proliferation of reticulin and collagen fibers.
- Patients with systemic lupus erythematosus (SLE) have cytopenia like primary myelofibrosis, who can develop autoimmune myelofibrosis but without splenomegaly. It is essential to perform antinuclear antibody (ANA) test to rule out systemic lupus erythematosus.
- Revised 2024 WHO diagnostic criteria for prefibrotic/early primary myelofibrosis and overt primary myelofibrosis are given in Tables 9.109 and 9.110.

Table 9.110 Revised 2024 WHO diagnostic criteria for overt primary myelofibrosis (PMF)

Diagnostic criteria of primary myelofibrosis require all major criteria and at least one minor criterion
Major Diagnostic Criteria (must Fulfill all Four Criteria)
Presence of megakaryocyte proliferation with abnormal morphology (atypia), reticulin and/or collagen bone marrow fibrosis >1 grade, accompanied by increased age adjusted bone marrow cellularity, granulocytic differentiation and often decreased erythropoiesis.
Bone Marrow Fibrosis Grade ≥MF2 (Grades 2 and 3)
Not meeting the criteria for other myeloproliferative neoplasms (MPNs), i.e. CML, polycythemia vera and essential thrombocythemia
Evidence of JAK2 (V617F), CALR, or MPL mutations; or in the absence of these mutations, presence of clonal marker or absence of minor reactive reticulin fibrosis
Minor Diagnostic Criteria (must Fulfill at least One of the Criteria)
Leukocytosis ≥11 × 10^9/L
Anemia
Palpable splenomegaly ≥5 cm
Increased serum lactic dehydrogenase (LDH) above reference range

Adapted from revised 2024 World Health Organization (WHO) classification of hematopoietic neoplasms.

Laboratory Diagnosis of Primary Myelofibrosis

Various laboratory tests performed in establishing diagnosis of primary myelofibrosis include peripheral blood smear, bone marrow, molecular genetics and elevated serum uric acid lactic dehydrogenase (LDH). Serum cobalamin level can be elevated or within normal range.

Peripheral Blood Smear Examination

- Peripheral blood smear findings in primary myelofibrosis demonstrate both qualitative and quantitative cellular abnormalities. Primary myelosclerosis in Giemsa-stained peripheral blood smear is shown in Fig. 9.91.
- Anemia, leukocytosis with shift to the left and thrombocytosis are demonstrated in the initial stage at diagnosis.
- At a later stage of disease, pancytopenia and leukoerythroblastosis with anisocytosis and poikilocytosis are seen. In 35–55% of patients, hemoglobin is <10 g/dl.

Red blood cells

- Peripheral blood smear shows normocytic normochromic. Utilization of folic acid by neoplastic clone results in macrocytic anemia.
- Anemia correlates directly with the extent of bone marrow fibrosis and the effectiveness of extramedullary hematopoiesis.
- Anemia becomes more severe with the progression of the disease due to sequestration of red blood cells and expanded blood volume.
- In primary myelofibrosis, most important abnormality in red blood cells is presence of teardrop cells (dacrocytes). However, ovalocytes (elliptocytes) may be demonstrated.
- Numerous or few normoblasts are seen. Basophilic stippling is commonly demonstrated.
- Reticulocyte count is increased to 2–15%.

White blood cells

- In the initial stage of disease, total leukocyte is usually elevated ranging from 15×10^9/L to 30×10^9/L. There is presence of immature granulocytes with <5% blasts.
- Other findings demonstrated in peripheral blood smear include basophilia, eosinophilia and pseudo-Pelger-Hüet anomaly. Philadelphia chromosome is not demonstrated.

Platelets

- In the initial stage of disease, platelet count may be high or normal or low. Thrombocytopenia occurs as a result of sequestration of platelets in enlarged spleen.
- The platelets demonstrate dysplastic change, giant and bizarre forms with hypogranularity.
- Circulating megakaryocyte fragments, naked megakaryocytes and mononuclear micromegakaryocytes are also demonstrated.
- Micromegakaryocytes should be differentiated from small lymphocytes by differentiating features such as demarcation in membranes, cytoplasmic blebbing with bull's eye granules in the cytoplasm.
- Qualitative platelet abnormalities include abnormal platelet aggregation, adhesion and defective procoagulant activity on exposure to collagen.

Bone Marrow Smear Examination

The bone marrow aspiration is usually difficult, hence 'dry tap' obtained. In case, bone marrow is successful, bone marrow smears do not demonstrate abnormality. Hence, bone marrow trephine biopsy is essential to demonstrate myelofibrosis and establish diagnosis.

Bone Marrow Trephine Biopsy Examination

- Bone marrow trephine biopsy section is hypercellular with varying degrees of diffuse fibrosis and focal aggregates of megakaryocytes.
- Three histologic patterns of bone marrow trephine biopsy have been described:
  - Bone marrow trephine biopsy demonstrates panhyperplasia with absence of myelofibrosis but a slight increase in connective tissue reticulin. It shows myeloid atrophy with fibrosis with prominent collagen and reticulin fibers and <30% cellularity.
  - Bone marrow demonstrates myelofibrosis and myelosclerosis with bony trabeculae occupying 30% of the bone marrow biopsy with extensive fibrosis.
- Primary myelofibrosis (PMF) in hematoxylin and eosin-stained bone marrow trephine biopsy is shown in Fig. 9.92. Primary myelofibrosis in reticulin stained bone marrow trephine biopsy section is shown in Fig. 9.93. Comparison of bone marrow morphologic findings in prefibrotic primary myelofibrosis and essential thrombocytosis/thrombocythemia is given in Table 9.111. World Health Organization grading of primary myelofibrosis is given in Table 9.112. Diagnostic findings in primary myelofibrosis are given in Table 9.113.

Molecular Genetic Alterations

- Molecular genetic analysis is essential to differentiate primary myelofibrosis from chronic myelogenous leukemia (positive Philadelphia chromosome), as both demonstrate some degree of fibrosis. Philadelphia chromosome is not demonstrated in myelofibrosis.
- JAK2 (V617F) mutation is demonstrated in 50% of patients.
- Trisomy or deletion of chromosome 6–12 abnormalities are associated with myelofibrosis. Complete or partial loss of chromosomes 5, 7 and 20 is associated with primary myelofibrosis treated with chemotherapy.

Clinical Course

- About 15% of patients can develop major intravascular hemolytic episodes during disease with hemosiderinuria and decreased haptoglobin.
- Hypersplenism, paroxysmal nocturnal hemoglobinuria-like defective red blood cells and anti-red blood cell antibodies contribute to intravascular hemolysis.
- Combination of thrombocytopenia and platelet abnormality result in bleeding diathesis ranging from petechiae and ecchymosis.
- Defective platelet aggregation is a common finding.Serum uric acid and lactic dehydrogenase are elevated in these patients.

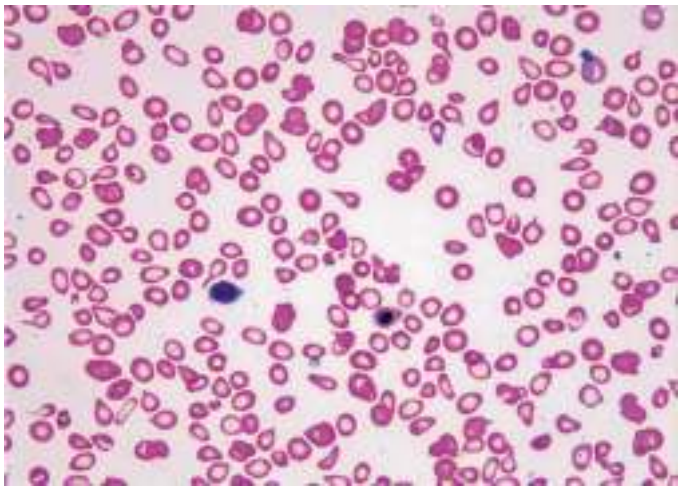

Fig. 9.91: Primary myelosclerosis in Giemsa-stained peripheral blood smear. It shows many teardrop cells (dacrocytes) and normoblasts. Basophilic stippling is commonly demonstrated. Reticulocyte count is increased to 2–15%. The majority of patients have absolute reticulocyte count >60 × 10^9/L. Combination of thrombocytopenia and platelet abnormality results in bleeding diathesis ranging from petechiae and ecchymosis. Defective platelet aggregation is a common finding. Anemia becomes more severe with the progression of the disease due to sequestration of red blood cells and expanded blood volume. Anemia correlates directly with the extent of bone marrow fibrosis and the effectiveness of extramedullary hematopoiesis (1000X).

PROGNOSIS AND TREATMENT

The average survival rate after the diagnosis of primary myelofibrosis is 4–5 years. The main causes of fatal outcome include recurrent infections, hemorrhage, thrombosis and cardiac failure. About 10–15% of patients with primary myelofibrosis can develop acute myelogenous leukemia (**AML**) in majority of patients and acute lymphoblastic leukemia (**ALL**) in some cases.

- Purpose of therapy in primary myelofibrosis is to improve cytopenia and reduce splenomegaly. Recombinant erythropoietin, androgens and corticosteroids are administered to stimulate hematopoiesis to treat anemia.

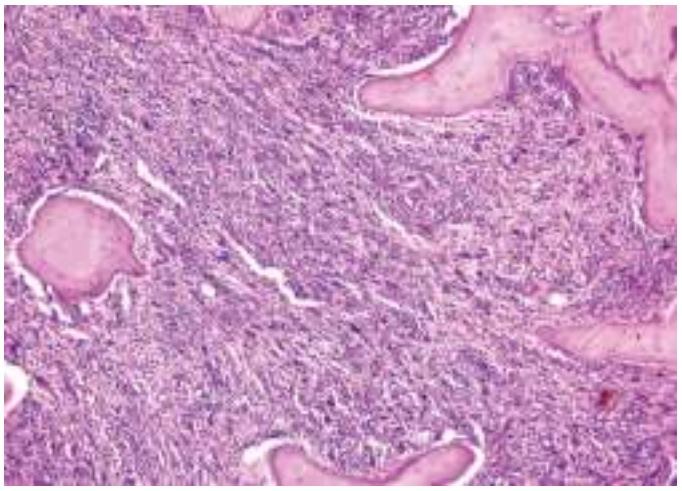

Fig. 9.92: Primary myelofibrosis (PMF) in hematoxylin and eosin-stained bone marrow trephine biopsy. Bone marrow trephine biopsy section is hypercellular with varying degrees of diffuse fibrosis and focal aggregates of megakaryocytes (400X).

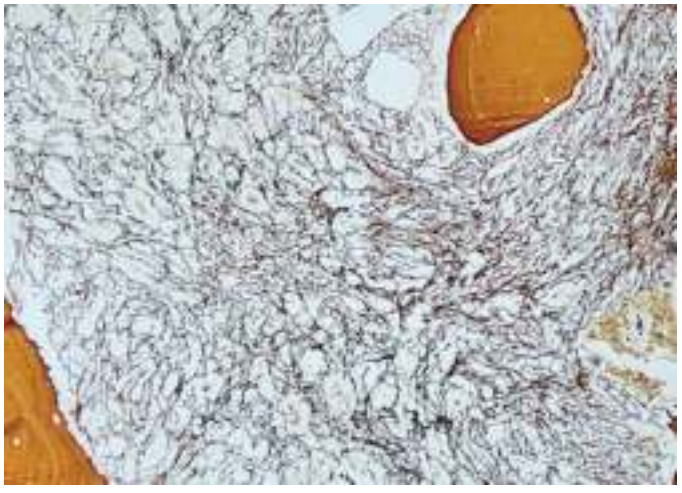

Fig. 9.93: Primary myelofibrosis (PMF) in reticulin stained bone marrow trephine biopsy section. The bone marrow aspiration is usually difficult, hence 'dry tap' obtained. In case, bone marrow is successful, bone marrow smears do not demonstrate abnormality. Hence, trephine bone marrow biopsy is essential to demonstrate myelofibrosis and establish diagnosis (1000X).

Table 9.111 Comparison of bone marrow morphologic findings in prefibrotic primary myelofibrosis and essential thrombocytosis/thrombocythemia (ET)

Bone Marrow Morphologic Features	Early/Prefibrotic Myelofibrosis	Essential Thrombocythemia
Bone marrow cellularity (age matched)	Increased	Normal
Myeloid hyperplasia	Present	Present
Megakaryocyte morphology	Present	Present
Megakaryocyte size	Bulbous, cloud-like, naked eye	Staghorn hyperlobated nuclei
Megakaryocyte clusters	Small and large	Large
Myelofibrosis (MF)	MF-0, MF-1	MF-0

Table 9.112 Diagnostic findings in primary myelofibrosis

Parameters	Clinical and Laboratory Findings
Primary myelofibrosis (PMF) prefibrotic stage	
Peripheral blood smear findings	▪ Anemia absent or mild ▪ Leukocytosis absent or slight ▪ Thrombocythemia invariable ▪ Absent or slight anisopoikilocytosis including teardrop red blood cells
Bone marrow	▪ Cellular bone marrow with mild increase in granulopoiesis, increased clustered dysmorphic megakaryocytes ▪ Slight increase in reticular fibers on silver stain
Cytogenetic and molecular alterations	▪ BCR-ABL1 fusion gene absent ▪ Presence of JAK2, CALR, or MPL mutations indicative of diagnosis MDS, one of these gene mutations is demonstrated in 90% of cases
Palpable splenomegaly	▪ Infrequent
Primary myelofibrosis (PMF) fully developed fibrotic stage	
Peripheral blood smear	▪ Anisopoikilocytosis with teardrop (dacrocytes) red blood cells in virtually every oil immersion field ▪ Nucleated red blood cells ▪ Increased CD34+ cells
Bone marrow	▪ Bone marrow reticulin fibrosis plus or minus collagen fibrosis present ▪ Bone marrow hypercellular but invariably has increased megakaryocytes, clusters of highly dysmorphic megakaryocytes, and megakaryocytes bare nuclei regardless of overall bone marrow cellularity
Cytogenetic and molecular alterations	▪ BCR-ABL1 fusion gene absent ▪ Presence of JAK2, CALR, or MPL mutations indicative of diagnosis MDS, one of these gene mutations is demonstrated in 90% of cases
Abdominal finding	Frequent palpable splenomegaly

Table 9.113 World Health Organization grading of myelofibrosis

WHO Grade of Myelofibrosis	Description
Myelofibrosis 0 (MF-0)	Scattered linear reticulum with no intersections (crossovers) corresponding to normal bone marrow
Myelofibrosis 1 (MF-1)	Loose network of reticulin with many interactions, especially in perivascular areas
Myelofibrosis 2 (MF-2)	Diffuse and dense increase in reticulin with extensive intersections, occasionally with focal bundles of collagen and /or focal osteosclerosis
Myelofibrosis 3 (MF-3)	Diffuse and dense reticulin with extensive interactions and collagen, often associated with osteosclerosis

Fiber density should be assessed in hematopoietic (cellular) areas.
In grades MF-2 and MF-3, an additional Masson trichrome stain is recommended.

- The patients may require frequent blood transfusion. Splenectomy is indicated in uncontrolled anemia.
- Irradiation helps in the reduction in the size of enlarged spleen and decrease red blood cells destruction.
- Chemotherapeutic agents such as hydroxyurea, thalidomide, lenalidomide and 2-chlorodeoxyadenosine (2-CdA or Leustatin) can be administered to reduce size of enlarged spleen.
- JAK protein receptor tyrosine kinase inhibitors can be administered in patients with advanced myelofibrosis, however, with variable results. Poor prognostic features in primary myelofibrosis are given in Table 9.114.

DIFFERENTIAL DIAGNOSIS

Differentiation of primary myelofibrosis from other conditions associated with myelofibrosis is most important to ensure appropriate therapeutic treatment. Disorders associated with bone marrow fibrosis are given in Table 9.115.

- Both primary myelofibrosis and chronic myelogenous leukemia (CML) demonstrate significant findings such as splenomegaly, anemia and leukoerythroblastic blood picture. Total leukocyte count in primary myelofibrosis is $<50\times10^9$/L and $>100\times10^9$/L (median of 170×10^9/L) in chronic myelogenous leukemia.

Table 9.114 Poor prognostic features in primary myelofibrosis

Hb <10 g/dl
WBC <4 or >30 × 10^9/L
Bone marrow chromosomal abnormalities
Advanced patient age
Raised number of CD34+ cells in the blood

Table 9.115 Disorders associated with bone marrow fibrosis

Primary myelofibrosis (PMF)
Atypical chronic myelogenous leukemia (CML)
Polycythemia vera (PV)
Essential thrombocythemia
Hairy cell leukemia
Acute megakaryocytic leukemia
Hodgkin disease
Non-Hodgkin lymphoma
Metastatic carcinoma
Miliary tuberculosis
Granulomatous diseases
Fungal infections
Radiation
Chemical agents

- Primary myelofibrosis demonstrates prominent poikilocytosis and less shift to the left in blood and bone marrow fibrosis and numerous megakaryocytes.
- Chronic myelogenous leukemia demonstrates some bone marrow fibrosis and prominent myeloid metaplasia. Differentiating features of primary myelofibrosis and chronic myelogenous leukemia (CML), BCR-ABL1 positive are given in Table 9.116.
- It is difficult to differentiate primary myelofibrosis from polycythemia vera. Bone marrow trephine biopsy aids in establishing diagnosis of primary myelofibrosis by demonstration of bone marrow fibrosis.

CLONAL HYPEREOSINOPHILIA

Eosinophils are derived from pluripotent hematopoietic stem cell (HSC) and lineage-specific committed hematopoietic progenitor cells in the bone marrow, which generate granulocytes, erythroblasts, megakaryocytes and macrophages.

- The production of eosinophils is tightly regulated by a network of transcription factors (GATA-1, PU.1, c/EBPs), growth factors and growth-inhibitory cytokines. These growth regulators are produced and secreted by activated T cells, mast cells and eosinophils.
- Major growth factors for eosinophils are GM-CSF, IL-3 and IL-5. IL-5 cytokine is relatively specific for eosinophils. The mobilization of eosinophils from the bone marrow into the blood is regulated by IL-5 and eotaxin.
- The eosinophils are released into the peripheral blood and rapidly migrate to tissues to perform physiologic functions.

Table 9.116 Differentiating features of primary myelofibrosis and chronic myelogenous leukemia (CML), BCR-ABL1 positive

Parameters	Primary Myelofibrosis	Chronic myelogenous leukemia (CML), BCR-ABL1 Positive
Splenomegaly	Present	Present
Anemia	Present	Present
Leukoerythroblastic picture	Present	Present
Total leukocyte count	<50 × 10^9/L	>100 × 10^9/L (median of 170 × 10^9/L)
Granulocyte left shift	Less pronounced	More pronounced
Poikilocytosis	More pronounced	Less pronounced
Bone marrow	Bone marrow fibrosis more pronounced with numerous megakaryocytes	Bone marrow fibrosis less pronounced with marked myeloid hyperplasia
Serum cobalamin level	Less elevated	More elevated
Neutrophil alkaline phosphatase (NAP)	Variable	More elevated
Philadelphia chromosome	Absent	Present

- In clonal hypereosinophilia, the eosinophils infiltrate and cause potential damage to the organs resulting in subsequent release of cytokines, enzymes, and other proteins. It is essential to diagnose the disorders associated with eosinophilia.
- The term 'hypereosinophilic syndrome' (**HES**) describes a group of disorders, that demonstrate an absolute eosinophil count $>1.5\times10^9$/L that persist for >4 weeks. Several mechanisms proposed in the pathogenesis of hypereosinophilic syndrome include overproduction of eosinophilopoietic cytokines or defects in the normal suppressive regulation of eosinophilopoiesis.
- Organ damage in hypereosinophilic syndrome occurs due to eosinophilic infiltration to the tissues such as myocardium, which may result in myocardial fibrosis, progressive heart failure and death.
- It is important to perform serological tests to rule out infection with *Strongyloides stercoralis*, because the patients treated with corticosteroids can experience dissemination of the disease associated with fatal outcome.
- Clonal hypereosinophilia pluripotent hematopoietic stem cell and lineage committed hematopoietic progenitor cells, which occurs in the settings of myeloid and lymphoid neoplasms with eosinophilia and abnormalities of platelet-derived growth factor receptor α (PDGFRA) and β (PDGFRB), or fibroblast growth factor receptor 1 (FGFR1) and chronic eosinophilic leukemia, not otherwise specified (CEL, NOS).
- Primary and secondary causes of eosinophilia are given in Table 9.117. Hypereosinophilic syndrome in Giemsa-stained peripheral blood smear is shown in Fig. 9.94. Hypereosinophilic syndrome in Giemsa-stained bone marrow aspirate smear is shown in Fig. 9.95.

MYELOID AND LYMPHOID NEOPLASMS ASSOCIATED WITH EOSINOPHILIA AND PDGFRA, PDGFRB, OR FGFR1

Myeloid and lymphoid neoplasms associated with eosinophilia are caused by gene mutations encoding the α or β chains of the protein kinases platelet-derived growth factor receptor α and β (PDGFRA, PDGFRB) or fibroblast growth factor receptor 1 (FGFR1). Mutations in these genes result in activation of receptor tyrosine kinase in chronic myeloproliferative disorders.

- Less frequently, these patients can present as acute myelogenous leukemia (AML) or precursor T cell lymphoblastic leukemia/lymphoma.

Table 9.117 Primary and secondary causes of eosinophilia

Primary (Clonal) Eosinophilia
Myeloid neoplasms
• Chronic myelogenous leukemia, BCR-ABL1 positive
• Acute myelogenous leukemia with inv(16)(p13.1;q22) or t(16;16)(p13.1;q22)
• Acute myelogenous leukemia with t(8;21) (p22;q22.1)
• Chronic myelomonocytic leukemia (CMML)
Myeloid and lymphoid neoplasms associated with PDGFRA, PDGFRB, or FGFR1 rearrangements or PCM1-JAK2, ETV6-JAK2, or BCR-JAK2 fusion genes
• Myeloid and lymphoid neoplasms associated with eosinophilia and abnormalities of PDGFRA, PDGFRB or FGFR1
• Myeloid and lymphoid neoplasms associated with PDGFRA rearrangement
• Myeloid and lymphoid neoplasms associated with PDGFRB rearrangement
• Myeloid and lymphoid neoplasms associated with FGFR1 abnormalities
• Acute myelogenous leukemia (AML)
Lymphoid neoplasms
• T cell non-Hodgkin lymphoma
• Hodgkin disease
• Acute lymphoblastic leukemia (ALL)
• Lymphocyte-variant hypereosinophilia caused by an aberrant population of lymphocytes
Mastocytosis
• Cutaneous mastocytosis
• Indolent systemic mastocytosis
• Systemic mastocytosis associated with other clonal, non-mast cell lineage disease
• Mast cell leukemia
• Mast cell sarcoma
• Extracutaneous mastocytoma
Secondary Eosinophilia
Infections: Parasites, specific fungal function
Collagen vascular diseases: Churg-Strauss disease, Wegener granulomatosis, systemic lupus erythematosus
Pulmonary diseases: Idiopathic acute or chronic eosinophilic pneumonia, tropical pulmonary eosinophilia, allergic bronchopulmonary aspergillosis
Gastroenteritis
Adrenal insufficiency
Immunologic conditions
Allergic state
Drug reactions

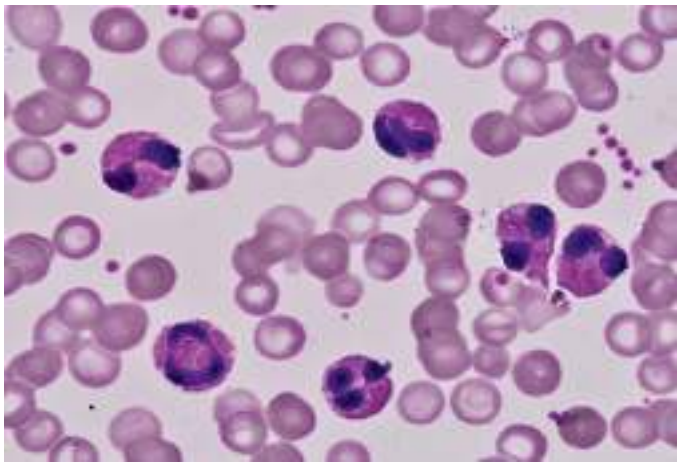

Fig. 9.94: Hypereosinophilic syndrome (HES) in Giemsa-stained peripheral blood smear. The term HES describes a group of disorders, that demonstrate an absolute eosinophil count >1.5×10⁹/L that persist for >4 weeks. Peripheral blood smear shows ring eosinophils (1000X).

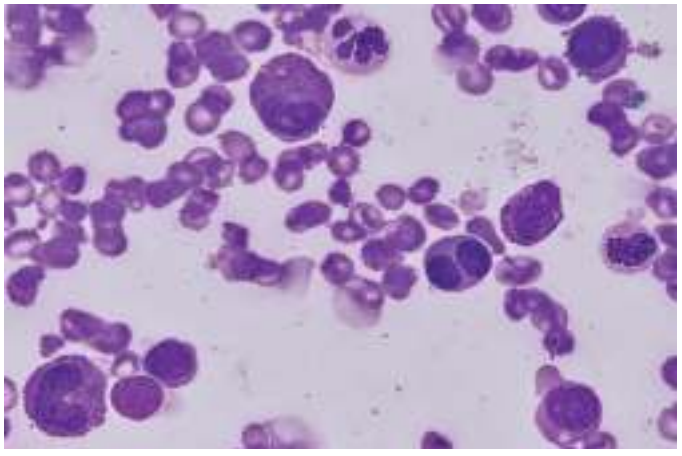

Fig. 9.95: Hypereosinophilic syndrome (HES) in Giemsa-stained bone marrow aspirate smear. The term HES describes a group of disorders, that demonstrate an absolute eosinophil count >1.5×10⁹/L that persist for >4 weeks (1000X).

- Eosinophilia is variable but present in majority of cases. These patients respond to treatment with receptor tyrosine kinase inhibitors (**RTKIs**) such as imatinib or other RTKIs.

Myeloid and Lymphoid Neoplasms with PDGFRA Rearrangement

A gain-of-function of receptor tyrosine kinase (RTK) fusion gene has been demonstrated in hypereosinophilic syndrome patients, who are unresponsive to cortico-steroid therapy, but responsive to receptor tyrosine kinase inhibitors (RTKIs).

- FIP1L1-PDGFRA fusion gene has been described in patients with eosinophilia-associated myeloid and lymphoid neoplasms.
- The mutation results from a small interstitial deletion in chromosome 4 (q12q12) leading to formation of FIP1L1/PDGFRA fusion gene and constitutively activation of receptor tyrosine kinase protein.
- Majority of the cases involving FIP1L1-PDGFRA fusion gene mutation affects 25–55 years of patient with male to female ratio (17:1), which develop eosinophil-induced tissue damage and tissue fibrosis associated with splenomegaly.
- Patients harboring FIP1L1-PDGFRA fusion gene mutation respond to imatinib first generation receptor tyrosine kinase inhibitor (RTKI) therapy.
- Patients developing resistance to imatinib first-line receptor tyrosine kinase inhibitors are treated by second-generation (nilotinib) and third-generation (ponatinib) receptor tyrosine kinase inhibitors (RTKIs) therapy.

Laboratory Diagnosis of Myeloid and Lymphoid Neoplasms with PDGFRA Rearrangement in Clonal Hypereosinophilia

Peripheral Blood Smear Examination

- **White blood cells:** Hypereosinophilia is the most important laboratory finding in myeloid and lymphoid neoplasms associated with FIP1L1-PDGFRA fusion gene mutation.
  - Mature eosinophils with few promyelocytes or myelocytes are present.
  - Eosinophils contain sparse granules, vacuoles and hyper-segmentation or hyposegmentation of nuclei.
  - Presence of <20% blasts in the peripheral blood and/or bone marrow can be demonstrated in few cases.
- **Red blood cells:** Peripheral blood smear shows anemic picture.
- **Platelets:** Platelet count is decreased (thrombocytopenia).

Bone Marrow Smear Examination

- Bone marrow is hypercellular with increased eosinophil promyelocytes and myelocytes.
- Charcot-Leyden crystals composed of eosinophil protein galectin 10 may be demonstrated.
- In majority of cases, bone marrow examination shows an increase in spindle-shaped atypical mast cells with a CD25+ immunophenotype. These findings are also demonstrated in systemic mastocytosis.
- Presence of <20% blasts in the peripheral blood and/or bone marrow can be demonstrated in few cases.

Molecular Genetic Alterations

FIP1L1-PDGFRA fusion gene mutation can be demonstrated by reverse transcriptase-polymerase chain reaction (RT-PCR) or fluorescence *in situ* hybridization (FISH) techniques.

Myeloid and Lymphoid Neoplasms with PDGFRB Rearrangement

Myeloid and lymphoid neoplasms with PDGFRB rearrangement are characterized by formation of ETV6-PDGFRB fusion gene as a result of t(5;12)(q33;p13) rearrangement (most common).

- Myeloid neoplasms originate from pluripotent hematopoietic stem cell (**HSC**), that is capable to differentiate into neutrophils, eosinophils, monocytes, and probably mast cells.
- Myeloid neoplasms with PDGFRB rearrangement can present as chronic myelomonocytic leukemia (CMML) with eosinophilia, atypical chronic myelogenous leukemia (aCML), or MPN with eosinophilia. These patients may develop blast phase.
- Myeloid neoplasms with PDGFRB affects in the age group of 8–72 years with male predilection. Patients are treated by imatinib receptor tyrosine kinase inhibitor (RTKI).

Laboratory Diagnosis of Myeloid and Lymphoid Neoplasms with PDGFRB Rearrangement in Clonal Hypereosinophilia

Peripheral Blood Smear Examination

- **White blood cells:** Total leukocyte count is increased. There is presence of variable increase in the neutrophils, eosinophils, monocytes and precursor cells. The peripheral blood and bone marrow smears demonstrate <20% blasts.
- **Red blood cells:** Peripheral blood smear examination shows anemic picture.
- **Platelets:** Platelet count is decreased (thrombocytopenia).

Bone Marrow Smear Examination

- **Cellularity:** Bone marrow is hypercellular with increase in spindle-shaped mast cells. Reticulin can be demonstrated.
- **Myeloid cells:** The bone marrow and peripheral blood demonstrate <20% blasts.

Molecular Genetic Alterations

- Myeloid neoplasms with PDGFRB rearrangement are diagnosed by molecular genetic analysis by using primers for all known breakpoints to confirm ETV6-PDGFRB.
- Cytogenetic analysis demonstrates the t(5;12).

Myeloid and Lymphoid Neoplasms with FGFR1 Abnormalities

Myeloid and lymphoid neoplasms with FGFR1 abnormalities belong to subgroup of eosinophilic neoplasms, which are characterized by 8p11 chromosome breakpoint resulting in a variety of fusion genes that incorporate part of the FGFR1 gene. All fusion gene products activate tyrosine kinase activity. These neoplasms probably originate from pluripotent hematopoietic stem cell (**HSC**) and affect 3–84 years with male predilection.

- Most of the cases are associated with genetic abnormalities: (a) t(8;13)(p11;q12)—the fusion gene being ZMYM2-FGFR1, (b) t(8;9)(p11;q33)—the fusion gene being CNTRL-FGFR1; and (c) t(6;8)(q27;p11-12)—the fusion gene being FGFR10P1-FGFR1.
- Myeloid and lymphoid neoplasms with FGFR1 abnormalities present with hypereosinophilia. These cases are transformed to acute myelogenous leukemia (AML) or T cell- or B cell-derived acute lymphoblastic leukemia/lymphoma or as mixed phenotype of acute leukemias. Progression of acute myelogenous leukemia to chronic myelogenous leukemia that demonstrates eosinophilia, neutrophilia and occasionally monocytosis.
- The patients do not respond to first-line imatinib receptor tyrosine kinase inhibitor (RTKI) therapy. However, these patients can respond to second-line or third-line RTKIs therapy. Bone marrow hematopoietic stem cell (HSC) transplant can be indicated in chronic phase of leukemia.

IDIOPATHIC HYPEREOSINOPHILIC SYNDROME

Idiopathic hypereosinophilic syndrome (I-HES) represents a heterogenous group of disorders with the common features of prolonged eosinophilia (eosinophil count 1.5×10^9/L for at least 6 months duration not meeting diagnostic criteria of chronic eosinophilic leukemia or familial eosinophilia) of an undetectable etiology and organ system dysfunction.

- There is no evidence of clonality or T cell abnormality. First-line therapy for most cases with idiopathic hypereosinophilic syndrome is the use of corticosteroids.
- Proper follow-up of these patients is essential to assess transformation to leukemia.

CHRONIC EOSINOPHILIC LEUKEMIA, NOS

Chronic eosinophilic leukemia, not otherwise specified (CEL, NOS) is a clonal chronic myeloproliferative disorder in which unregulated clonal proliferation of eosinophilic precursors results in persistently elevated number of eosinophils in the blood, bone marrow or peripheral tissues leading to organ damage and mortality. CEL, NOS most often affects middle-aged persons (male to female ratio 9:1).

- Chronic eosinophilic leukemia, not otherwise specified (CEL, NOS) excludes cases with BCR-ABL1 fusion gene and rearrangement of PDGFRA, PDGFRB or FGFR1, or PCM1-JAK2 or BCR-JAK2 fusion gene. In addition, it is essential to rule out causes of reactive eosinophilia, presence of aberrant T cells and disorders associated with abnormal release of cytokines (GM-CSF, IL-2, IL-3, IL-5).

- Chronic eosinophilic leukemia, not otherwise specified (CEL, NOS) may arise from hematopoietic stem cell (HSC), multipotent progenitor (MPP) cells, or a committed eosinophilic progenitor cell (CFU-E0).
  - In some cases, cytogenetic abnormality such as trisomy 8 can be demonstrated. It is important to distinguish CEL, NOS from idiopathic hypereosinophilic syndrome, that is characterized by eosinophil count 15×10^9/L persistent for 6 months without underlying cause.
  - Diagnostic criteria for chronic eosinophilic leukemia, not otherwise specified (CEL, NOS) are given in Table 9.118.

Clinical Features

Patient presents with fever, significant weight loss, hepatosplenomegaly, congestive heart failure, pulmonary fibrosis, central nervous system abnormalities and occasionally lymphadenopathy. Release of excessive eosinophilic granules into the blood circulation induces fibrosis of vascular endothelial cells resulting in peripheral vasculitis, gangrene of digits, organ damage such as heart and lungs.

Table 9.118 Diagnostic criteria for chronic eosinophilic leukemia, not otherwise specified (CEL, NOS)

Persistent peripheral blood eosinophilia $\geq 1.5 \times 10^9$/L
Presence of <20% blasts in the peripheral blood and bone marrow; and no inv(16) (p13.1q22), t(16;16) (p13.1;q22), t(8;21) (q22;q22.1) and other features of AML
There is presence of clonal cytogenetic or molecular genetic abnormality or blast cells are ≥2% in the peripheral blood or ≥5% in the bone marrow
Exclude eosinophilic disorders that bear PDGFRA, PDFGRB or FGFR1 mutations as well as PCM1-JAK2 or BCR-JAK2 fusion
No BCR-ABL1 fusion gene; and exclusion of polycythemia vera, essential thrombocythemia, primary myelofibrosis, chronic neutrophil leukemia, chronic myelomonocytic leukemia or atypical chronic myelogenous leukemia
Exclusion of all secondary causes of eosinophilia
Exclusion of neoplastic disorders with secondary eosinophilia
Exclusion of neoplastic disorders when eosinophils are a part of neoplastic clone such as AML
Exclude the presence of an aberrant phenotypic T cell population

(a) If the patient presents with persistent eosinophilia but does not meet these diagnostic criteria, the diagnosis can be reactive eosinophilia, idiopathic hypereosinophilia, or idiopathic hypereosinophilic syndrome. (b) Adapted from revised 2024 World Health Organization (WHO) classification of hematopoietic neoplasms.

Laboratory Diagnosis of Chronic Eosinophilic Leukemia, NOS (CEL, NOS)

- Chronic eosinophilic leukemia, not otherwise specified (CEL, NOS) is characterized by persistent eosinophilia $\geq 1.5 \times 10^9$/L.
- There is evidence of clonality and/or demonstration of >2% blasts in the peripheral blood or 5–19% blasts in the bone marrow.

Biochemical Investigations

Serum cobalamin, uric acid and muramidase levels are most often elevated.

Peripheral Blood Smear Examination

Presence of clonal eosinophil blasts ≥2% in the peripheral blood and 10–15% in the bone marrow supports the diagnosis of chronic eosinophilic leukemia, not otherwise specified (CEL, NOS). Anemia and thrombocytopenia may present. Chronic eosinophilic leukemia (CEL) in Giemsa-stained peripheral blood smear is shown in Fig. 9.96.

- **White blood cells:** Total leukocyte count is usually $>30 \times 10^9$/L with 30–70% eosinophils. CEL, NOS is characterized by persistent eosinophilia $\geq 1.5 \times 10^9$/L. There are presence mature eosinophils and some eosinophilic myelocytes. Eosinophil abnormalities are demonstrated such as sparse granularity, nuclear hypersegmentation and hyposegmentation. Clonal blasts >2% are demonstrated in the peripheral blood.
- **Red blood cells:** Peripheral blood smear examination shows anemia.
- **Platelets:** Platelet count is decreased.

Neutrophil Alkaline Phosphatase

Neutrophil alkaline phosphatase (NAP) score is within normal limit.

Bone Marrow Smear Examination

Presence of clonal eosinophil blasts ≥2% in the peripheral blood and 10–15% in the bone marrow supports the diagnosis.

- **Cellularity:** Bone marrow is hypercellular with increased myeloid to erythroid cells.
- **Myeloid lineage:** Bone marrow examination shows a shift to left with many mature eosinophils and eosinophilic myelocytes.
- **Erythroid lineage:** Bone marrow demonstrates normal erythropoiesis.
- **Megakaryocytic linegae:** Bone marrow shows normal megakaryopoiesis.
- **Charcot-Leyden crystals:** Charcot-Leyden crystals are demonstrated in the bone marrow.

Bone Marrow Trephine Biopsy Examination

- Bone marrow trephine biopsy examination shows evident bone marrow fibrosis.
- Charcot-Leyden crystals are most often present.

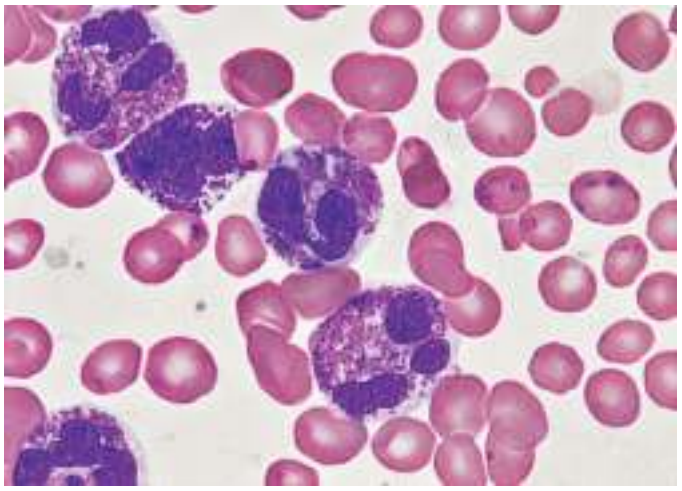

Fig. 9.96: Chronic eosinophilic leukemia (CEL) in Giemsa-stained peripheral blood smear. CEL is a chronic myeloproliferative neoplasm characterized by a clonal proliferation of eosinophil precursors that leads to increased eosinophilia in the peripheral blood, the bone marrow and possibly peripheral tissues. An eosinophil count in blood of 1.5×10^9/L or higher that lasts over time. There should not be parasitic infestation or allergic disorders or other causes of eosinophilia (1000X).

Treatment and Prognosis

In chronic eosinophilic leukemia, not otherwise specified (CEL, NOS), persistent eosinophilia invading heart causes severe cardiac injury resulting in congestive heart failure and fatal outcome within one year after diagnosis. Only a few patients survive beyond one year.

Differential Diagnosis

Chronic eosinophilic leukemia, not otherwise specified (CEL, NOS) should be differentiated from reactive eosinophilia and clonal eosinophilia found in hematologic disorders.

MASTOCYTOSIS (MAST CELL DISEASE)

Mastocytosis is a clonal disorder of bone marrow characterized by clonal proliferation of mast cells resulting in invasion of single organ (skin) or multiple organs.

- Cutaneous mastocytosis demonstrates mast cells in the skin associated with clinical signs without systemic involvement, which usually affects children.
- Systemic mastocytosis involves multiple organs and bone marrow. There can be anemia, leukocytosis or leukopenia, thrombocytopenia and marked eosinophilia. Mast cells share a common progenitor cell with myelomonocytic cells.
  - Other subgroup of systemic mastocytosis is mast cell leukemia (MCL). The diagnostic criteria for MCL must fulfill major and minor criteria for systemic mastocytosis; and bone marrow trephine biopsy demonstrates diffuse infiltration by atypical immature mast cells, bone marrow aspirate demonstrates 20% mast cells and peripheral blood shows 10% mast cells.
  - The aleukemic mast cell leukemia variant has <10% mast cells in the peripheral blood and bone marrow smears along with immature blast-like cells with bilobed or multilobated nuclei. The mast cells are tryptase positive with express c-KIT. Serum tryptase levels are elevated >20 ng/ml. In acute form of aleukemic mast cell leukemia, organ damage is present. Pancytopenia occurs in the later stage of disease, when bone marrow failure occurs in the patients.
- Molecular genetic analysis demonstrates that systemic mastocytosis is a clonal disorder characterized by a somatic point mutation of c-KIT proto-oncogene in mast cells.
  - Stem cell factor (SCF) and its receptor (SCFR), a member of the c-KIT gene critically regulates hematopoiesis and mast cell development.
  - When c-KIT gene is mutated, the SCFR receptor is activated resulting in unrestricted proliferation of clonal mast cells. Serum tryptase level persistently exceeds 20 ng/ml.
- Mast cell sarcoma is a rare, localized mast cell tumor, that demonstrates immature mast cells having sarcoma-like morphology. Mast cell sarcoma transforms to mast cell leukemia in a short span of time.
- Revised 2024 WHO classification of mastocytosis is given in Table 9.119. Diagnostic criteria for systemic mastocytosis and mast cell leukemia according to revised 2024 World Health Organization are given in Table 9.120.

CLINICAL FEATURES

Most patients of mastocytosis are adults with symptoms such as flushing, diarrhea, hypotension and headache related to release of chemical mediators and proteins from mast cells. Patients present with fever, weight

Table 9.119 Revised 2024 WHO classification of mastocytosis

Cutaneous mastocytosis
Indolent systemic mastocytosis
Systemic mastocytosis associated with other clonal, non-mast cell lineage disease
Mast cell leukemia
Mast cell sarcoma
Extracutaneous mastocytoma

Table 9.120 Diagnostic criteria for systemic mastocytosis and mast cell leukemia according to revised 2024 World Health Organization

Systemic Mastocytosis: Diagnostic Criteria
Major diagnostic criterion Bone marrow or other organs demonstrate multifocal, dense infiltrates of tryptase positive mast cells (>15 mast cells aggregate)
Minor diagnostic criteria ▪ Bone marrow trephine biopsy or other organs demonstrate spindle-shaped or atypical morphology in >25% of mast cells, or bone marrow shows >25% immature or atypical mast cells counting all bone marrow cells ▪ Presence of somatic point mutation at codon 816 of c-KIT proto-oncogene in the mast cells from bone marrow or other organs. ▪ Mast cells in peripheral blood, bone marrow, or other tissue coexpress CD2 and/or CD25, in addition to normal mast cell markers ▪ Serum tryptase level >20 ng/ml in the absence of associated clonal myeloid disorder
Mast Cell Leukemia: Diagnostic Criteria
▪ Diagnostic major and minor criteria for systemic mastocytosis must fulfill ▪ Bone marrow trephine biopsy demonstrates diffuse infiltration by atypical immature mast cells ▪ Bone marrow aspirate demonstrates ≥20% mast cells ▪ Peripheral blood shows ≥10% mast cells

Diagnosis of systemic mastocytosis can be made when the major criterion and one minor criterion is present; or when three minor criteria are present.

loss, sweats, cutaneous red brown macules or papules on shoulders or trunk, bone pain, organomegaly in the later stage of disease. Patients developing urticaria when scratched is known as Darier's sign.

Laboratory Diagnosis of Mastocytosis (Mast Cell Disease)

Diagnosis of mast cell disease is based on clinical manifestations, bone marrow examination, bone marrow trephine biopsy examination, histopathologic examination of skin and organs involved, molecular genetics, serum tryptase level, histochemical examination and immunohistochemistry.

Bone Marrow Smear Examination

- Bone marrow smear examination reveals scant cellularity due to marrow fibrosis.
- Aggregates of atypical mast cells admixed with eosinophils some hypogranular mast cells are demonstrated.

Histochemical Staining

- Mast cells are demonstrated by toluidine blue metachromatic stain.
- Mast cells also strongly react with naphthol-ASD-chloroacetate esterase (CAE).

Immunohistochemistry Technique

Mast cells show positivity for tryptase, CD2, CD25 and CD117.

Markers	Expression
▪ CD2	▪ Positive
▪ CD25	▪ Positive
▪ CD117	▪ Positive

PROGNOSIS AND TREATMENT

No standard therapy or long-term cure exists for mast cell disease. Patients are administered aspirin and antihistaminic drugs to relieve symptoms. Experience with chemotherapy and bone marrow hematopoietic stem cell transplantation (HSC) is lacking. Prognosis is worst in mast cell leukemia.

DIFFERENTIAL DIAGNOSIS

Immunophenotype plays important role in differentiating mastocytosis (CD2, CD25, CD117) from hairy cell leukemia (positive for CD25, CD103, CD123, Annexin A1) and Langerhans cell histiocytosis (positive for CD1, S-100 protein). Prognosis is worst in mast cell leukemia.

CHRONIC LYMPHOPROLIFERATIVE NEOPLASMS

Chronic lymphoproliferative disorders are morphologically, immunologically and clinically heterogenous, which include T cell, B cell or natural killer cell immunophenotypes and terminal deoxynucleotidyl transferase (TdT) negativity.

- B cell-derived chronic lymphoproliferative disorders include chronic lymphocytic leukemia (CLL), prolymphocytic leukemia, non-Hodgkin lymphoma (including mantle cell lymphoma) in leukemic phase, hairy cell leukemia and splenic lymphoma with villous lymphocytes.
- T cell-derived chronic lymphoproliferative disorders include T cell prolymphocytic leukemia, adult T cell leukemia/lymphoma, large granulated

lymphocytic leukemia and Sézary syndrome. Occasionally, lymphocytic proliferation is encountered that does not fulfill the morphologic and immunophenotyping criteria for any of the above-mentioned categories. These disorders are best left unclassified.

CHRONIC LYMPHOCYTIC LEUKEMIA

Chronic lymphocytic leukemia (CLL) is a monoclonal B cell disorder characterized by increased production of monomorphic, small, and mature but dysfunctional B cells in the blood (5×10^9/L) and bone marrow with or without nodal (i.e. lymph nodes) or extranodal manifestation (e.g. spleen).

- As CLL disease progresses the patient can present with lymphadenopathy, splenomegaly, and hepatomegaly. Due to widespread disease, clinical staging is used in CLL patients. Most cases are detected when a routine blood test is performed.
- CLL accounts for 25% of all leukemias, which is the most common leukemia in Western world. Incidence increases with age and peak is in age group of 60–80 years affecting both men and women.
- Anemia, thrombocytopenia, and neutropenia are related symptoms frequently occur in CLL patients.
- Autoimmune hemolytic anemia is common in CLL patients, which occurs due to autoimmune hemolysis and leukemic cells infiltration into bone marrow.
- Extramedullary involvement of CLL may occur in liver, skin, gastrointestinal tract mucosa and kidneys. Hypogammaglobulinemia and cellular dysfunction induce immunosuppression.
- Diagnosis of CLL is usually established by immunophenotypic analysis of peripheral blood, which reveals a clonal population of CD5+ and CD23+ B cells.
- Patients are treated by use of chemotherapy and an anti-CD20 monoclonal antibody to achieve remission without a complete cure. Best guide to prognosis is the stage of the disease.
- CLL disease, that has acquired somatic mutations in the immunoglobulin genes, is associated with relatively good prognosis as compared to unmutated immunoglobulin gene cases. Molecular genetic analysis also provides prognostic information.
- Approximately 50% of CLL patients demonstrate abnormal karyotype **trisomy chromosome 12**, chromosomal abnormalities of 13q, 14 and 16. Patients showing trisomy 12 have poor prognosis.
- Activation of BCL-2 proto-oncogene leads to decreased apoptosis resulting in increased accumulation of monoclonal B cells.

PATHOGENESIS

Chronic lymphocytic leukemia (CLL) is a disease of clonal B cells that have low proliferative rate and defect in the apoptosis of leukemic B cells. CLL leukemic B cells appear mature but are actually arrested during early development resulting in less capable of differentiating into antibody-synthesizing plasma cells.

- CLL leukemic B cells express B cell receptor (BCR) and antigenic stimulation of the B cell receptor appears to be major pathogenic driver. Recent advances highlight the importance of leukemic B cell proliferation that occurs primarily in the tissue environment of the bone marrow and lymph nodes.
- Key signaling pathways promoting proliferation of leukemic B cell in CLL and their survival in the bone marrow and lymph nodes include activation of B cell receptor (BCR) and NF-κB pathways.
- Positive family history of CLL increases 2–8 times risk for developing CLL. The role of environmental factors and viral infections in the pathogenesis of CLL remains ill-defined.

CLINICAL FEATURES

Patient with chronic lymphocytic leukemia is usually asymptomatic for many years. It is most often diagnosed following the incidental lymphocytosis on routine blood tests or asymptomatic lymphadenopathy.

- CLL patient presents with generalized lymphadenopathy (80%), abdominal fullness, hepatomegaly due to leukemic infiltration in 50–60%, splenomegaly (less marked), pallor, weakness, fatigue, and dyspnea.
- As the CLL disease advances, patient may have recurrent infections, weight loss, anemia and thromboytopenia (purpura and hemorrhagic manifestations). CLL patients can present with night sweats, fever and weight loss; similar to non-Hodgkin lymphoma (NHL) and Hodgkin disease.
- Leukemic B cells of CLL infiltrate lymph nodes, liver, and spleen leading to generalized nontender lymphadenopathy in cervical, axillary, inguinal and abdominal regions, not attached to skin, hepatomegaly, and splenomegaly respectively. Leukemic B cells infiltration may occur in skin, lungs, pleura, kidneys, and gastrointestinal tract. CNS involvement is unusual in CLL patients.

Clinical Pearls: Chronic Lymphocytic Leukemia—Clinical Features

Symptoms of CLL

- Asymptomatic cases detected on routine blood tests
- Susceptibility to infection (pneumonia, herpes simplex and herpes zoster)
- Generalized lymphadenopathy due to leukemic infiltration
- Abdominal discomfort from hepatosplenomegaly from leukemic infiltration
- Bleeding or petechiae in skin or mucous membranes from thrombocytopenia
- Tiredness and fatigue from anemia including autoimmune hemolytic anemia.

Signs of CLL

- Generalized or local lymphadenopathy
- Splenomegaly
- Hepatomegaly
- Petechiae
- Pallor
- Tonsillar enlargement
- Involvement of the lacrimal and salivary glands (Mikulicz's syndrome)
- Richter syndrome [CLL transformation to diffuse large B cell lymphoma (DLBCL)]

Recurrent Infections

Patient with CLL presents with recurrent infections in early course of the disease (respiratory tract, sinuses, ears, skin, and kidney) due to absence of immunoglobulin (IgG), neutropenia and corticosteroid therapy. Herpes zoster infection of skin results in pruritus, vesiculobullous and popular eruptions.

Autoimmune Hemolytic Anemia

Chronic lymphocytic leukemia (CLL) is a malignant neoplasm due to clonal expansion of CD5 expressing B cells. CD5 expressing B cells have been postulated to produce autoantibodies in 10–20% of CLL cases resulting in autoimmune hemolytic anemia. Therefore, direct Coombs test should be performed in CLL cases. Anemia may be accompanied by immune-mediated thrombocytopenic purpura.

Richter Syndrome

Richter syndrome is defined as the transformation of CLL into aggressive lymphoma especially diffuse large B cell lymphoma (**DLBCL**) in 3–5% of cases. Richter syndrome patient presents with rapid onset of fever, abdominal pain, and progressive lymphadenopathy and hepatosplenomegaly associated with aggressive clinical course. Patients are refractory to therapy and have a mean survival of 2 months.

Second Malignancies

The second malignancies that are observed most frequently in CLL patients may be due to specific risk factors, protumorigenic microenvironment and chemotherapy-related immunosuppression.

- Immunodeficiency in CLL may also predispose to the increased risk for developing other malignancies.
- Examples of second malignancies in CLL patients are Hodgkin's disease, B cell prolymphocytic leukemia, multiple myeloma, acute lymphoblastic leukemia, and cancers of breast, gastrointestinal tract, lung, skin, prostate, kidney, urinary bladder, and head and neck.

Gastrointestinal Tract Involvement

Gastrointestinal manifestations have very rarely been described in patients with chronic lymphocytic leukemia (CLL). Clonal B lymphocytic infiltration seems to depend on tumor burden and proliferative activity.

- Conventional staging according to Rai and Benet may not accurately reflect the whole extent of disease. It is not known whether CLL patients should undergo endoscopic evaluation.
- Normal mucosal appearance of GIT does not exclude infiltration of leukemic cells in CLL cases. Histologic examination establishes leukemic infiltration. Patient presents with anorexia and occasionally intestinal obstruction.

Mikulicz Syndrome

Patient with CLL may develop tonsillar enlargement along with Mikulicz syndrome characterized by chronic swelling of the lacrimal and salivary glands usually associated with significantly decreased or lack of lacrimation (dry eyes) and xerostomia (dry mouth), accompanied by lymphocytic infiltration.

LABORATORY DIAGNOSIS

Diagnosis of chronic CLL requires clonal lymphocytosis ($>5 \times 10^9$/L clonal B cells) in the peripheral blood sustained for three months with typical immunophenotype in the peripheral blood demonstrated by flow cytometry.

- Recently revised 2024 WHO classification of hematolymphoid neoplasms describes CLL being distinguishable from small lymphocytic lymphoma (SLL) by its leukemic appearance.
- Diagnostic criteria for SLL include lymphadenopathy and/or splenomegaly (defined by physical examination and CT scan), with $>5 \times 10^9$/L circulating clonal B cells.

- Lymph node biopsy is not generally required unless to establish diagnosis of Richter syndrome.
- **Lymph node biopsy** is the standard diagnostic test **for SLL**, however, presence of circulating clonal B cells with typical immunophenotype is sufficient in patients with an indolent presentation.
- Immunophenotyping is essential flow cytometry of peripheral blood or bone marrow or immunohistochemistry of biopsy material to diagnose chronic lymphocytic leukemia (CLL) cases.

Imaging Techniques

Computed tomography (CT) is not required for routine evaluation of CLL patients. But CT scan can capture the extent of lymph node involvement in CLL cases and response to treatment.

- Lymph node involvement in CLL has low metabolic activity on positron emission tomography (PET) scan.
- PET scan is not essential for routine evaluation of CLL patients, but it can add valuable information in advanced disease or relapsed disease especially when CLL transforms into high-grade lymphoma.

Laboratory Diagnosis of Chronic Lymphocytic Leukemia

Biochemical Investigations

- **Direct antiglobulin test (DAT):** Direct antiglobulin test should be performed before treatment in patient with anemia. Conversion of the DAT negative to DAT positive may herald the onset of autoimmune hemolytic anemia (AIHA).
- **Serum immunoglobulins:** Serum immunoglobulins decrease with the duration of disease. Immunoglobulin M (IgM) small spike is consistent in CLL cases.
- **Serum β_2-microglobulin:** Serum β_2-microglobulin may be elevated. Its level often increases with high tumor burden. High serum β_2-microglobulin more than 3 mg/L has been associated with poor response to treatment and survival.

Peripheral Blood Smear Examination

In chronic lymphocytic leukemia (CLL), monoclonal proliferation of B cells accumulates and replace bone marrow cells over a few years resulting in anemia and thrombocytopenia with advancing disease. Peripheral blood smear findings in CLL are shown in Fig. 9.97.

White blood cells

- About 50% of CLL cases demonstrate leukocytosis in the range of 20×10^9/L to 50×10^9/L. Some patients have total leukocyte count (TLC) >50 $\times 10^9$/L in the range of 100 $\times 10^9$/L even up to 500×10^9/L.
- The diagnosis of CLL requires the presence of $>5 \times 10^9$/L clonal B cells with typical immunophenotype in the peripheral blood, sustained for least three months.
- The clonality of B cells needs to be confirmed by demonstrating light chain restriction using flow cytometry.
- Clonal B cells are small- to medium-sized mature appearing lymphocytes with round nuclei, clumped fragile chromatin, and scanty cytoplasm exhibiting monotonous appearance. Clonal B cells in CLL appear to be more fragile than normal lymphocytes and are susceptible to mechanical disruption during preparing of blood smear producing smudge cells. Smudge cells, bare nuclei appear squashed, are classic features of CLL.
- However, smudge cells can be present in reactive lymphocytosis and other neoplasms. Therefore, presence of smudge cells should not be used to diagnose CLL. The number of smudge cells can be reduced by mixing drop of albumin with drop of blood prior to preparation of peripheral blood smear.
- Prolymphocytes number increase in proportion in rapidly progressive CLL disease. Prolymphocytes are medium- to large-sized cells with clumped chromatin and prominent vesicular nucleolus and abundant cytoplasm constituting <10% of the lymphocytes in typical CLL cases. Presence of >55% of prolymphocytes in the peripheral blood is recognized as a distinct known as 'prolymphocytic leukemia'.
- In advanced CLL disease, anemia and thrombocytopenia are common, most often as a result of replacement of bone marrow by clonal B cells, hypersplenism and immune-mediated hemolytic anemia and thrombocytopenia.

Red blood cells

- Hemoglobin is markedly reduced to <10 g/dl in the advanced disease.
- Peripheral blood smear examination shows normocytic normochromic picture due to bone marrow infiltration by neoplastic cells with a possible contribution to hypersplenism and autoimmune mechanism.

Platelets

In the early stage of disease, platelet count may be normal. But in the later stage, patient develops thrombocytopenia with platelet count $<100 \times 10^9$/L as a result of leukemic cells infiltration in bone marrow with possible hypersplenism and immune-mediated thrombocytopenia.

Bone Marrow Trephine Biopsy Examination

- Bone marrow is always involved in chronic lymphocytic leukemia and most cases of small lymphocytic lymphoma.
- Bone marrow trephine biopsy should be performed in those cases posing diagnostic difficulties or cases with low peripheral blood counts.
- Distinct patterns of bone marrow infiltration by clonal B cells, which have some prognostic value, are observed: nodular, interstitial, diffuse or mixed patterns.
- Advanced disease is most often associated diffuse pattern of bone marrow involvement.
- Reticulin stain demonstrates marked bone marrow fibrosis. There is moderate to marked decrease in hematopoiesis involving erythroid, myeloid and megakaryocytic series.

Bone Marrow Smear Examination

Bone marrow findings in chronic lymphocytic leukemia are shown in Fig. 9.98.

- **Cellularity:** Bone marrow is hypercellular due to monoclonal proliferation of lymphocytes in the bone marrow. Lymphocytes constitute >30% of nucleated cells in the marrow. There is gradual replacement of bone marrow erythroid, myeloid and megakaryocyte by clonal B lymphocytes over a few years. Therefore, the patient develops anemia, neutropenia and thrombocytopenia (Fig. 9.99).
- **Myeloid to erythroid cells ratio:** Myeloid to erythroid ratio is increased due to clonal proliferation of B cells and decreased erythroid cells.
- **Myeloid lineage:** Myeloid cells are normal in number and maturation in the initial stage of disorder.
- **Erythroid lineage:** Bone marrow shows normoblastic erythropoiesis. Patient developing autoimmune hemolytic anemia may show erythroid hyperplasia. Due to proliferation of neoplastic lymphocytes, erythroid precursors are suppressed.
- **Megakaryocytic lineage:** Megakaryopoiesis is normal in the initial stage of disorder. In the later stage, megakaryopoiesis is suppressed resulting in thrombocytopenia.

Immunophenotyping

Flow cytometry is the single most informative diagnostic analysis in CLL patients. Clonal B cells are positive for CD19, CD5 and CD23. These cells typically have weak expression of CD20, CD22 and surface immunoglobulin IgM and IgD. Clonal B cells are negative for FMC7, CD10 and CD103.

Markers	Expression
▪ CD19	▪ Positive
▪ CD5	▪ Positive
▪ CD23	▪ Positive
▪ Clonal Ig gene rearrangements	▪ Positive
▪ CD20	▪ Positive (weak expression)
▪ CD22	▪ Positive (weak expression)
▪ Surface immunoglobulin (IgM and IgD)	▪ Positive (weak expression)
▪ CD103	▪ Negative

CD200 is positive in atypical CLL. CD79a is pan B cell marker.

Surgical Pathology: Lymph Node Biopsy/Splenectomy in Chronic Lymphocytic Leukemia

Gross Morphology

Lymph nodes are enlarged. Cut surface if homogenous and fleshy. Spleen is enlarged and often showing military pattern of white pulp, homogenous infiltration.

Light Microscopy

- Lymph node biopsy is not generally required unless to establish diagnosis of Richter syndrome. Diagnosis of CLL is usually made by looking at peripheral blood smear, bone marrow aspirate and bone marrow trephine biopsy.
- Majority of clonal B cells in CLL are well-differentiated lymphocytes in the peripheral blood, bone marrow and lymph nodes. Many CLL patients develop swollen lymph nodes.
- Occasionally, a lymph node biopsy is performed to determine that a lymph node is swollen due to CLL and not some other condition.
- The architecture of lymph node in CLL is effaced by numerous small neoplastic lymphocytes with clumped chromatin. Mitotic activity is typically low.

Differential Diagnosis

Morphologic features, flow cytometry, immunohistochemistry and cytogenetic analysis are best diagnostic yield in differential diagnosis of chronic lymphocytic leukemia. Distinguishing features of CLL and closely resembling non-Hodgkin lymphomas are given in Table 9.121.

CLINICAL HISTORY AND STAGING SYSTEM

Clinical history of chronic lymphocytic leukemia (CLL) is quite variable, ranging from an indolent disease to incurable disease progressing from asymptomatic lymphocytosis to treatment-refractory disease within few years. Two staging systems have been used to

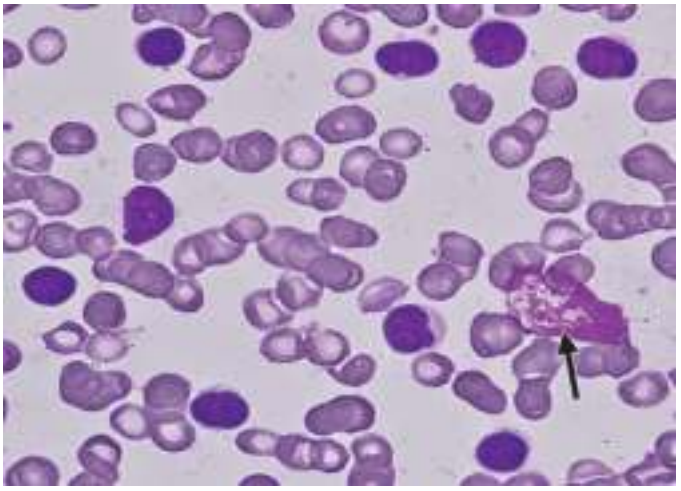

Fig. 9.97: Chronic lymphocytic leukemia (CLL) in Giemsa-stained peripheral blood smear. Peripheral blood smear examination shows round lymphocytes with clumped chromatin and numerous smudge cells (arrow). CLL and small lymphocytic lymphoma (SLL) seem to represent different clinical manifestations of single disease entity (CLL/SLL). Patient presents with peripheral blood lymphocytosis ($<5 \times 10^9$/L) but often develops lymphadenopathy (1000X).

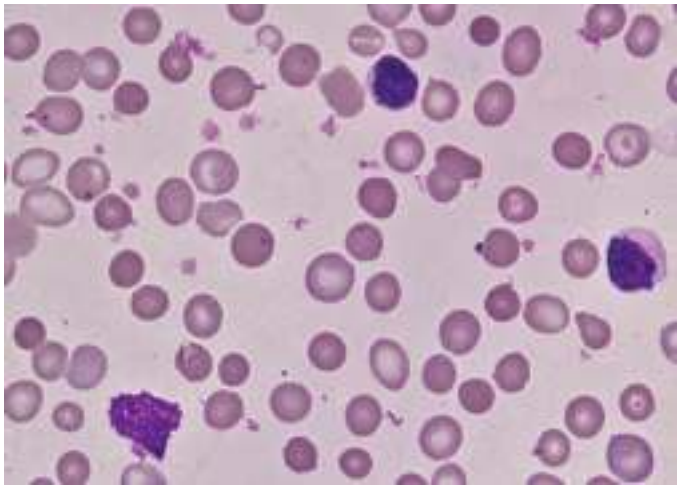

Fig. 9.98: Chronic lymphocytic leukemia (CLL) with autoimmune hemolytic anemia in Giemsa-stained peripheral blood smear. Anemia occurs because of autoimmune hemolysis and leukemic cells infiltration into bone marrow (1000X).

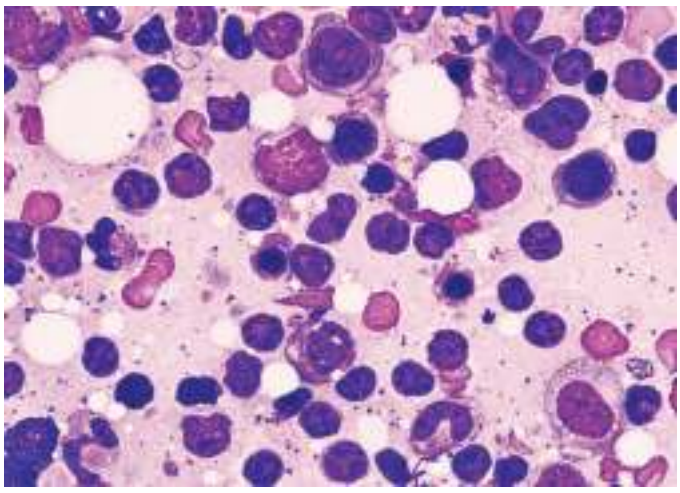

Fig. 9.99: Chronic lymphocytic leukemia (CLL) in Giemsa-stained bone marrow aspirate smear. It shows hypercellular bone marrow due to monoclonal proliferation of B lymphocytes gradually replacing erythroid, myeloid and megakaryocytic cell lines over a few years resulting in anemia, neutropenia and thrombocytopenia. Lymphocytes constitute >30% of nucleated cells in the marrow. Clonal B cells are small- to medium-sized mature appearing lymphocytes with round nuclei, clumped fragile chromatin, and scanty cytoplasm exhibiting monotonous appearance (1000X).

risk-stratify CLL. Rai clinical staging system in chronic lymphocytic leukemia (CLL) used in North America is given in Table 9.122. Binet staging system in chronic

Table 9.121 Morphologic features, flow cytometry, immunohistochemistry and cytogenetic analysis are best diagnostic yield. Distinguishing features of CLL and closely resembling non-Hodgkin lymphomas

Disease Entity	Surface Immunoglobulin (sIg)	CD5	CD10	CD19	CD20	CD23	Karyotype/ FISH
B chronic lymphocytic leukemia (B-CLL)	Weak expression	++	–	++	+	++	13q–, 11q–, 17p, trisomy 12
B cell prolymphocytic leukemia (B-PLL) with larger cells, eccentric nuclei and punched out nucleus	++	+/–	–	++	++	–	t(11;18) in occasional case
Follicular lymphoma (FL) leukemic phase	++	–	+	++	++	+/–	t(14;18), BCL-2a on chromosome 11
Mantle cell lymphoma (MCL)	++	++	–	++	++	–	t(11;14), cyclin D1b
Marginal zone lymphoma (MZL) leukemic phase	+	–	–	++	++	–	No consistent chromosomal abnormalities

BCL-2a on chromosome 11 is not expressed in normal B cells and detected by immunohistochemistry. FISH: Fluorescence in situ hybridization.

Table 9.122 Rai clinical staging system in chronic lymphocytic leukemia used in North America

Stage	Features	Risk Stratification and Median Survival	Median Survival
Stage 0	Blood and bone marrow lymphocytosis	Low risk	11.5 years
Stage I	Blood and bone marrow lymphocytosis + lymphadenopathy	Intermediate risk	11 years
Stage II	Blood and bone marrow lymphocytosis + splenomegaly or hepatomegaly with or without lymphadenopathy	Intermediate risk	7.8 years
Stage III	Anemia (Hb <11 g/dl)	High risk	5.3 years
Stage IV	Thrombocytopenia (platelet count <100,000/ μl)	High risk	7 years

Table 9.123 Binet clinical staging system in chronic lymphocytic leukemia used in Europe

Stage	Features	Lymph Nodes	Median Survival
Stage A	Hb and platelet count (normal range)	Lymphadenopathy <3 lymph nodes, hepatomegaly and splenomegaly	110 months
Stage B	Hb and platelet count (normal range)	Lymphadenopathy >3 lymph nodes, hepatomegaly and splenomegaly	80 months
Stage C	Hb <10 g/dl, platelet count <100,000/µl	Lymphadenopathy, hepatomegaly and splenomegaly	20 months

lymphocytic leukemia (CLL) in Europe is given in Table 9.123. Both the classifications are based on clinical and laboratory findings and prognosis.

PROGNOSIS

Biomarkers that are independent of clinical stage especially immunoglobulin heavy chain variable region gene (IgHV) mutation status and CD49a are valuable in assessing patients with early-stage CLL disease. Later, CLL progresses and requires treatment. CLL disease stage and several biomarkers correlate with prognostic information and overall median survival. Prognostic factors in chronic lymphocytic leukemia (CLL) are given in Table 9.124.

Immunoglobulin Heavy Chain Variable Region Mutation

The immunoglobulin expressed by B cells is composed of light and heavy chains encoded by different genes. CLL patients with somatic mutated IgVH genes (M-IgVH) are associated with good prognosis. These patients may not require treatment. CLL patients without somatic mutated IgVH genes are associated with poor prognosis. These patients require treatment within few years from diagnosis with median survival of 8–10 years.

Cytogenetic Alterations

Metaphase karyotyping has been used to risk-stratify chronic lymphocytic leukemia (CLL) patients into distinct subgroups. Complex chromosomal abnormalities in CLL patients are associated with poor prognosis.

- However, metaphase chromosomal analysis using G band technique has limited sensitivity due to the low mitotic rate in CLL patients.
- Therefore, fluorescence *in situ* hybridization (FISH) by using specific probe is currently used to demonstrate cytogenetic abnormalities.
  - Using a specific probe for chromosomal regions 13q, 11q, 17p and 12 alterations are detected in about 80% of CLL cases. Deletion 17q (TP53 locus) and 11q (ATM locus) are associated with poor prognosis.
  - Patient with isolated deletion 13q has longest survival in CLL patients. Deletion 17p is most often demonstrated in refractory CLL disease to treatment and associated with poor response to chemotherapy. Cytogenetic alterations restated to clinical course of chronic lymphocytic leukemia and other disorders are given in Table 9.125.

Table 9.124 Prognostic factors in chronic lymphocytic leukemia (CLL)

Parameters	Good Prognosis	Poor Prognosis
Stage of CLL	▪ Rai clinical staging system (0–1) ▪ Binet clinical staging system (A)	▪ Rai clinical staging system (III–IV) ▪ Binet clinical staging system (B, C)
Lymphocyte doubling time (LDT)	Slow doubling time <12 months	Rapid doubling time <6 months
Bone marrow trephine biopsy morphology	Nodular pattern	Diffuse pattern
Chromosomal abnormality	13q14 deletion	17p deletion (TP53 locus), 11q deletion (ATM locus), 6p deletion, 12q trisomy, t(11;14)
Molecular genetic mutations	Not applicable	NOTCH, TP53, SF3B1
IGVH genes	Hypermutated IgVH genes	Unmutated IgVH genes
ZAP expression	Low expression	High expression
CD38 expression	Negative	Positive
Lactic dehydrogenase (LDH) level	Normal level	Raised level

CD38 expression is surrogative marker of IgVH.

Table 9.125 Cytogenetic alterations restated to clinical course of chronic lymphocytic leukemia and other disorders

Cytogenetic Alterations	Associated Hematological Disorders	Features
11q deletion involving ATM	B-CLL	Marked lymphadenopathy associated with rapid progressive disease and poor prognosis
17p deletion involving TP53	B-CLL, prolymphocytic leukemia	Patients develop resistance to drugs associated with poor prognosis
12p Trisomy	Atypical CLL	Associated with aggressive clinical course and poor prognosis
13q14 deletion	B-CLL with IgVH gene mutation	Associated with favorable prognosis
6q deletion	B-CLL	CLL associated with progressive clinical course and poor prognosis

B-CLL: B cell chronic lymphocytic leukemia.

Molecular Genetic Alterations

Whole-exome sequencing has demonstrated more than 20 driver genes in CLL cases. Recurrent gene mutations have been found in noncoding genes. Somatic gene mutations of TP53, SF3B1, ATM or NOTCH1 are associated with short survival irrespective of IgVH mutation status in CLL cases.

- **ZAP-70 expression:** The receptor tyrosine kinase ZAP-70 is essential for T cell receptor signaling in response to antigen. CLL patients without mutated IgVH demonstrate higher expression of ZAP-70 by flow cytometry and have poor prognosis. ZAP-70 is a cytoplasmic protein expressed more in T cells than B cells. Such cases pose challenge in interpretation of results.
- **CD38 expression:** Increased CD38 expression on the cell surface of neoplastic lymphocytes in CLL patients is analyzed by flow cytometry, which correlates with poor prognosis. CD38 expression does not provide additional prognostic information derived from ZAP-70, CD49d expression and IgVH mutation status.
- **CD49d expression:** CD49d is an antigen subunit that regulates trafficking of B and T cells. Expression of CD49d analyzed by flow cytometry on CLL leukemic cells is associated with poor prognosis. CD49d analysis is superior to ZAP-70 and CD38. CD49d is independent prognostic marker for overall survival.
- **Lymphocyte doubling time:** Lymphocyte doubling time (LDT) of <12 months indicates progressive CLL disease. It is associated with decreased median survival independent of stage. Lymphocyte doubling time of <6 months reflects active CLL disease and requires treatment.

TREATMENT

Many different drugs and drug combinations can be used as the first-line treatment for chronic lymphocytic leukemia. Low-dose radiation therapy may be used if the patient with CLL disease has splenomegaly and lymphadenopathy in one part of the body. Leukapheresis and hematopoietic stem cell transplantation are also used for treating CLL patients. CLL active disease is defined by one of the above mentioned criteria in Table 9.126.

Assessing Response to Therapy

The international workshop on chronic lymphocytic leukemia published standardized criteria for analyzing response to therapy in CLL cases is determined clinical history, physical examination, peripheral blood and bone marrow examination. Minimal residual disease is analyzed by multicolor flow cytometry or polymerase chain reaction-based techniques.

Table 9.126 Chronic lymphocytic leukemia (CLL) active disease and associated clinical manifestations

Active CLL Disease Criteria	Clinical Manifestations of CLL
Constitutional symptoms	Fever, night sweats, weight loss
Symptomatic CLL patients with lymphadenopathy	Massive lymphadenopathy (>10 cm size in lymph node)
Symptomatic CLL patients with splenomegaly	Massive splenomegaly (>6 cm below costal margin)
Progressive bone marrow failure	Worsening anemia and/or thrombocytopenia
Rapidly progressive lymphocytosis	Lymphocyte doubling time <6 months
Autoimmune cytopenias	Autoimmune hemolytic anemia (AIHA), immune thrombocytopenia (ITP), pure red cell aplasia (PRCA), poorly responsive to corticosteroid treatment

HAIRY CELL LEUKEMIA

Hairy cell leukemia (HCL) is a rare indolent chronic lymphoproliferative neoplasm of mature B cells arising from post-germinal center mature memory B cell in marginal zone of lymph node. HCL is recognized as an entity according to revised 2024 classification of hematolymphoid neoplasms, which affects elderly persons during 40–85 years age group. It is four to five times more frequent in men than women. Disease most often involves bone marrow, peripheral blood and spleen; however, it may also involve liver, lymph nodes and skin.

- Hairy cell leukemia (HCL) has distinct clinical presentation that includes peripheral blood pancytopenias (anemia, leukemia and thrombocytopenia), bone marrow fibrosis (myelofibrosis), splenomegaly, hepatomegaly and small number of circulating monoclonal B cells with hair-like cytoplasmic projections. Leukemic infiltrates are demonstrated in the red pulp of spleen unlike other chronic lymphoproliferative disorders involving white pulp.
- Diagnosis of hairy cell leukemia (HCL) is based on morphologic evidence of monoclonal B cells with hair-like cytoplasmic projections (hairy cells), pancytopenia, monocytopenia, splenomegaly, BRAF V600 mutation and immunophenotype positive neoplastic hairy cells for CD11c, CD19, CD20 bright, CD22 bright, CD25, CD103 and CD305.
- Bone marrow trephine biopsy is essential to specify the degree of bone marrow involvement by monoclonal B cells with hair-like cytoplasmic projections (hair cells) and the presence of BRAF V600E somatic gene mutation (BRAF gene encoding threonine kinase) in hairy cell leukemia cases. Hairy cell leukemia patients are treated by BRAF inhibitors.
- Progression of hairy cell leukemia is based on a massive splenomegaly, leukocytosis, elevated numerous clonal B cells with hair-like cytoplasmic projections (hairy cells) in the peripheral blood and the immunoglobulin heavy chain variable region gene mutational status. IgG subclasses of VH4-34 encoded antibodies positive HCL cases are associated with poor prognosis. It is worth mentioning that IgG subclasses of VH4-34 encoded antibodies are demonstrated in systemic lupus erythematosus.

PATHOPHYSIOLOGY

BRAF V600E mutation is the causal genetic event in most patients with hairy cell leukemia. Gene mutation constitutively activates BRAF by autophosphorylation of the threonine kinase protein and downstream MEK-ERK signaling pathway leading to increased expression of genes involved in unrestricted proliferation and survival of monoclonal B cells leading to development of hairy cell leukemia.

CLINICAL FEATURES

Patient of hairy cell leukemia presents with moderate to massive splenomegaly due to pooling of blood and pancytopenia (anemia, leukopenia, and thrombocytopenia) as a result of bone marrow involvement.

- Patient may develop secondary hypersplenism due to increased splenic sequestration of peripheral blood cells in the spleen. Patient less often develops slight hepatomegaly, rarely lymphadenopathy.
- Constitutional symptoms are weakness, weight loss and fever. The patients are susceptible to bacterial infections especially mycobacterial organisms.
- Poor prognostic factors of hairy cell leukemia (HCL) include massive splenomegaly, leukocytosis ($>10\times10^9$/L), high number of neoplastic B cells with hair-like cytoplasmic projections (hairy cells) in the blood ($>5\times10^9$/L), high β_2-microglobulin, unmutated IgHV status, and IgHV4-34 positive immunoglobulin heavy chain variable gene rearrangement; and CD38 expression.

LABORATORY DIAGNOSIS

Laboratory investigations of HCL include peripheral blood smear, bone marrow, bone marrow trephine biopsy, histochemistry, immunohistochemistry, immunophenotyping, splenic histology and BRAF oncogene molecular analysis using DNA sequencing to detect somatic mutations.

Pathology Pearls: Hairy Cell Leukemia—Molecular Genetic Analysis of BRAF V600E Gene Mutation

- Using whole-exome sequencing, BRAF V600E somatic mutation has been demonstrated in 80–90% hairy cell leukemia cases. BRAF V600E somatic mutation in hairy cell leukemia is associated with poor prognosis.
- BRAF V600E gene is located on chromosome 7q34 and has 18 exons. BRAF V600E gene mutation occurs in exon 15 at position 1799, in which thymine and adenine are exchanged, leading to valine (V) being substituted by glutamate (E) at codon 600 (V600E) of the BRAF protein.
- The BRAF V600E mutation constitutively activates BRAF by autophosphorylation of the protein and downstream MEK-ERK signaling pathway, resulting in increased expression of genes involved in survival and proliferation.
- BRAF V600E gene mutation is also demonstrated in few cases of multiple myeloma, CLL and various solid malignant tumors such as cutaneous melanoma, cholangiocarcinoma, sarcoma, gastrointestinal stromal tumor (GIST), cancers of lung, ovary, urinary bladder, thyroid and prostate.

Laboratory Diagnosis of Hairy Cell Leukemia

Laboratory investigations of hairy cell leukemia (HCL) include peripheral blood smear examination, bone marrow examination, bone marrow trephine biopsy examination, histochemistry, immunophenotyping, splenic histology and BRAF oncogene analysis using DNA sequencing to detect somatic mutations.

Peripheral Blood Smear Examination

- Peripheral blood smear examination shows pancytopenia with a few monoclonal B cells (hairy cells) that are medium in size with moderately abundant pale blue cytoplasm, oval to reniform nuclei, open fine chromatin, absence of nucleoli and a characteristic circumferential cytoplasmic projection (hairs).
- White blood cell count is low due to both neutropenia and monocytopenia. Hairy cell leukemia (HCL), B cell derived in Giemsa-stained peripheral blood smear is shown in Figs 9.100 and 9.101.

Bone Marrow Smear Examination

Bone marrow aspirate smear is most often a dry tap in hairy cell leukemia due to extensive and diffuse bone marrow fibrosis as demonstrable by reticulin stain.

Bone Marrow Trephine Biopsy Examination

- Bone marrow trephine biopsy section shows a monotonous infiltrate of abnormal lymphocytes with abundant palestaining cytoplasm (fried egg appearance) and small nuclei.
- Monoclonal B cells (hairy cells) infiltration can vary and have a patchy and subtle and subtle interstitial or diffuse solid pattern.
- Presence of bone marrow fibrosis is common that can be markedly hypocellular and mimic of aplastic anemia.
- Hairy cell leukemia (HCL) in hematoxylin and eosin-stained bone marrow trephine biopsy section is shown in Fig. 9.102.

Histochemistry

Monoclonal B cells (hairy cells) show acid phosphatase staining after tartrate incubation (tartrate-resistant acid phosphatase).

Immunophenotyping

- Flow cytometric immunophenotyping is performed to establish a diagnosis of HCL.
- Monoclonal B cells (hairy cells) are positive for CD19 and CD20 (strong intensity), CD22, CD25, CD103 and CD11, which also demonstrate strong intensity for monoclonal surface immunoglobulins.

Markers	Expression
▪ CD19	▪ Positive (strong intensity)
▪ CD20	▪ Positive (strong intensity)
▪ CD200	▪ Positive (strong intensity)
▪ Monoclonal surface immunoglobulin-aS-HCL1	▪ Positive (strong intensity)
▪ CD22	▪ Positive
▪ CD25	▪ Positive
▪ CD103	▪ Positive
▪ CD11c	▪ Positive

Surgical Pathology: Splenectomy Specimen in Hairy Cell Leukemia (HCL)

Gross Morphology

Spleen is enlarged and weighing above 150 g. Cut surface of spleen shows diffuse and marked enlargement without nodules.

Light Microscopy

- Splenectomy specimen in hairy cell leukemia demonstrates marked expansion of red pulp because of an infiltrate of neoplastic hairy cells with fried egg appearance.
- Monoclonal B cells (hairy cells) are larger than lymphocytes with modest pale blue agranular cytoplasm, round or folded nuclei and without distinct nucleoli. There is an increase in volume, surface and length of red pulp vessels that can classically form lakes of blood lined by neoplastic hairy cells.

Immunohistochemistry Technique

Panel of immunohistochemical markers is performed in hairy cell leukemia mentioned below.

Markers	Expression
▪ CD19	▪ Positive
▪ CD20	▪ Positive
▪ Annexin A1	▪ Positive
▪ CD123	▪ Positive
▪ BRAF V600E mutation	▪ Positive

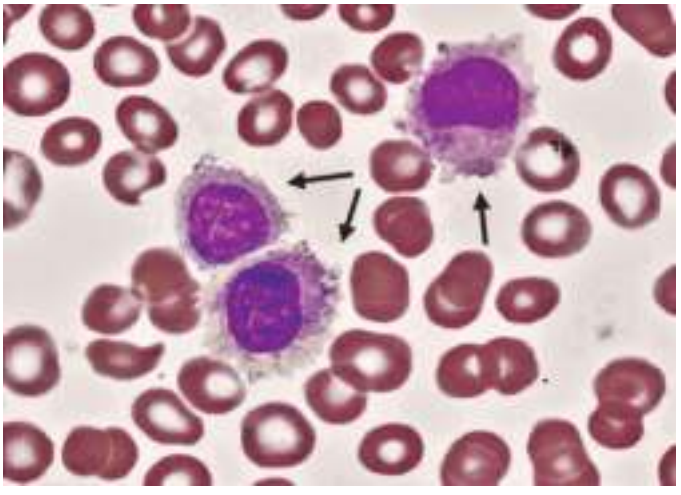

Fig. 9.100: Hairy cell leukemia (HCL), B cell derived in Giemsa-stained peripheral blood smear. It shows abnormal lymphocytes with oval or kidney cell nucleus, abundant pale-staining cytoplasm with hair-like circumferential cytoplasmic projections and relatively fine distributed chromatin (arrows). Flow cytometric analysis establishes HCL diagnosis with immunophenotype CD19, CD20 (strong intensity), CD22, CD25, CD103, and CD11C. In addition, HCL cells show acid phosphatase staining, after tartrate incubation (tartrate-resistant acid phosphatase—TRAP) (1000X).

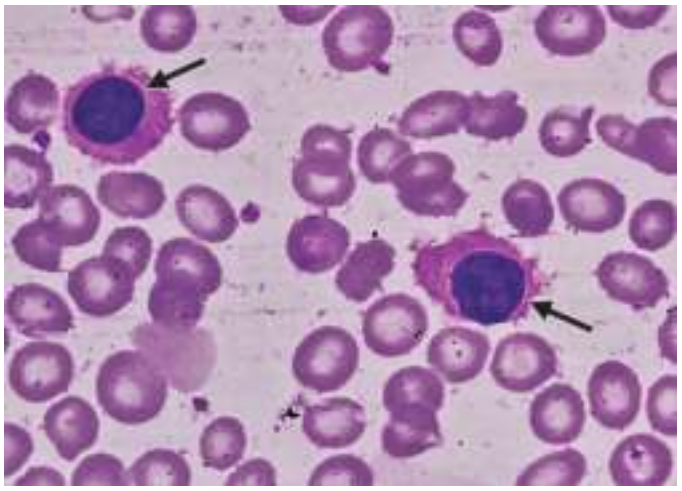

Fig. 9.101: Hairy cell leukemia (HCL), B cell derived in Giemsa-stained peripheral blood smear. It shows abnormal lymphocytes with oval or kidney cell nucleus, abundant pale-staining cytoplasm with hair-like circumferential cytoplasmic projections and relatively fine distributed chromatin (arrows) (1000X).

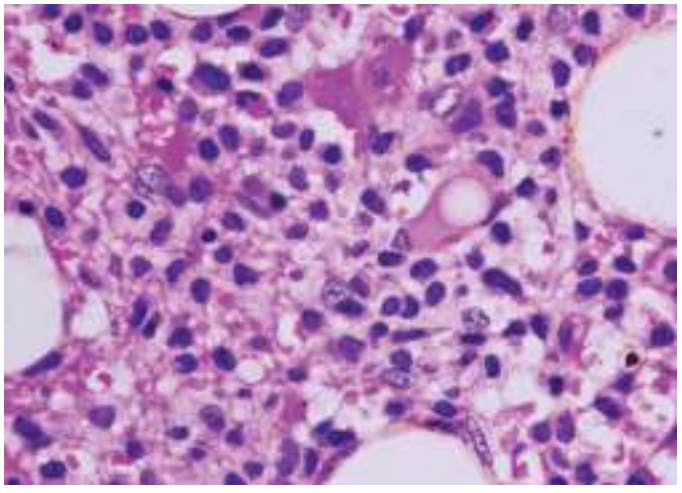

Fig. 9.102: Hairy cell leukemia (HCL) in hematoxylin and eosin-stained bone marrow trephine biopsy section. It shows a monotonous infiltrate of abnormal lymphocytes with abundant pale-staining cytoplasm (fried egg appearance) and small nuclei. Neoplastic hairy cells infiltration can vary and have a patchy and subtle and subtle interstitial or diffuse solid pattern. Presence of bone marrow fibrosis is common that can be markedly hypocellular and mimic of aplastic anemia (400X).

DIFFERENTIAL DIAGNOSIS

Hairy cell leukemia (HCL) should be differentiated from splenic lymphoma, with villous lymphocytes, prolymphocytic leukemia and large granular lymphocytic leukemia. Bone marrow aspirate is dry only in hairy cell leukemia. Hairy cells are positive with tartrate-resistant acid phosphatase (TRAP), but negative in other disorders.

TREATMENT

Hairy cell leukemia (HCL) often has an indolent course, and chemotherapy often produces long-lasting remission. Administration of chemotherapeutic agent 2-chlorodeoxyadenosine (2-CDA/cladribine) results in complete remissions for years.

B CELL PROLYMPHOCYTIC LEUKEMIA

B cell prolymphocytic leukemia (B-PLL) is an aggressive neoplasm defined by large prolymphocytes (55% of total circulating cells) in the peripheral blood. B-PLL is marked by absolute lymphocytosis **($>100\times10^9$/L).** Prolymphocytes contain abundant cytoplasm and nucleus with clumped chromatin and prominent vesicular nucleolus.

- B cell prolymphocytic leukemia involves peripheral blood, bone marrow and spleen. Although most cases of B-PLL originate *de novo* and can also be derived from chronic lymphocytic leukemia (CLL).
- Unlike CLL cases, patient with B-PLL presents with moderate to massive splenomegaly and minimal lymphadenopathy.
- Anemia and thrombocytopenia are demonstrated in 50% of cases. Bone marrow shows nodular or interstitial pattern of involvement.
- B cell prolymphocytic leukemia (B-PLL) demonstrates deletion of chromosome 17p resulting in inactivation of TP53 gene tumor suppressor gene.
- Poor prognostic factors of B cell prolymphocytic leukemia are aberrations in Myc and TP53 genes, lymphocytosis $>100\times10^9$/L and anemia. B-PLL does not respond to treatment and hence associated with worse prognosis.

Laboratory Diagnosis of B Cell Prolymphocytic Leukemia

Peripheral Blood Smear Examination

- Total leukocyte count is elevated. Differential leukocyte count shows marked lymphocytosis, most often $>100\times10^9$/L, anemia and thrombocytopenia.
- Size of prolymphocytes is larger than lymphocytes. The neoplastic B cells contain abundant pale basophilic cytoplasm, moderately condensed chromatin and prominent nucleolus.
- B cell prolymphocytic leukemia (B-PLL) demonstrates >55% prolymphocytes; and CLL cases show <10% prolymphocytes.
- In patients with B cell prolymphocytic leukemia (B-PLL), peripheral blood smear showing 11–55% prolymphocytes have an unpredictable clinical course.

Immunophenotyping	
Immunophenotyping of B cell prolymphocytic leukemia (B-PLL) most often differs from CLL demonstrating strong intensity expression of surface immunoglobulin and CD20, more variable expression of CD5, positivity with FMC7, and absence of CD23.	
Markers	**Expression**
▪ CD20 ▪ FMC-7 ▪ CD19 ▪ CD5 ▪ CD23	▪ Positive (strong intensity) ▪ Positive (strong intensity) ▪ Positive (strong intensity) ▪ Positive (variable intensity) ▪ Negative

ADULT T CELL LEUKEMIA

Adult T cell leukemia is an aggressive neoplasm associated with human T cell leukemia virus type 1 (HTLV-1) infection and prevalent in Japan and Central Africa affecting adults. It is classified into four different clinical variants that are acute, lymphomatous, chronic, and smoldering. In acute and chronic phase, condensed chromatin with a convoluted or polylobated nucleus, often called a "flower cell" or "cloverleaf".

- Patient presents with widespread lymphadenopathy, hepatosplenomegaly, skin rashes (50%) and elevated serum calcium levels due to increased osteoclastic activity.
- The number of circulatory leukemic cells does not correlate with the degree of bone marrow involvement, which suggests that circulating leukemic cells are recruited from other organs especially the skin involved in >50% of cases.
- The disease usually involves spleen, liver, skin, lungs, gastrointestinal tract and central nervous system.
- Skin lesions are classified as erythema, papules and nodules. In rare cases, tumor-like lesions on skin may be demonstrated.
- In adult T cell leukemia patients with hypercalcemia, imaging studies may reveal osteolytic lesions. FDG-PET/CT scan is most often positive in sites of disease activity.

Laboratory Diagnosis of Adult T Cell Leukemia
Total Leukocyte Count
Total leukocyte count is increased due to adult T cell leukemia spillover in blood.
Peripheral Blood Smear Examination
Leukemic cells medium- to large-sized lymphoid cells with prominent pleomorphic nuclei resembling clover leaf.

Bone Marrow Smear Examination	
Bone marrow smear examination shows patchy infiltration. Adult T cell leukemia has broad spectrum cytologic features such as pleomorphic small, medium and large cell types and rarely resembling angioblastic T cell lymphoma. Osteoclastic activity increases serum calcium levels.	
Immunophenotyping	
Leukemic cells are strongly positive with CD25.	
Marker	**Expression**
CD25	Positive

NON-HODGKIN'S LYMPHOMA: SPILLOVER IN BLOOD

Bone marrow is involved in stage IV of low-grade non-Hodgkin lymphoma in 60–80% cases and high-grade NHL in 30–40% cases. Neoplastic cells can spillover from bone marrow into peripheral blood, which can be identified in the peripheral blood of patients with non-Hodgkin's lymphoma (NHL) by several molecular genetic techniques and morphologic examination of peripheral blood smear in 8–20% of patients. It is essential to examine peripheral blood smear including blood counts and bone marrow trephine biopsy.

Laboratory Diagnosis of Non-Hodgkin's Lymphoma—Spillover in Blood
Peripheral Blood Smear Examination
Peripheral blood smears stained by Romanowsky stained demonstrate anemia (95%), thrombocytopenia (60%), neutropenia (35%) and atypical lymphoid cells in NHL patients.
Bone Marrow Examination
▪ Bone marrow shows deposits of NHL. Atypical lymphoma cells contain lobulated and notched nuclei. ▪ NHL deposits in bone marrow demonstrated in diffuse pattern is associated with poor prognosis. ▪ Deposits of follicular center cell lymphoma are demonstrated in paratrabecular pattern.
Immunophenotyping
Flow cytometry is a diagnostic tool to differentiate B and T cells origin in non-Hodgkin's lymphoma spillover in blood.

HODGKIN'S DISEASE

Hodgkin's disease is a malignant neoplasm of lymph node. It is important to determine whether the patient has only a single lymph node region involved, multiple node regions, or extranodal involvement.

- Diagnostic criteria of Hodgkin's disease include demonstration of neoplastic Reed-Sternberg cells

derived from B or T cells admixed with inflammatory cells in background due to cytokines produced by them. Hodgkin's disease has been discussed in detail under disorders of lymph node.

- Initially Hodgkin's disease involves adjacent lymph nodes then other nodes via lymphatic route in continuous and predictable fashion. Later it spreads via the blood and involves the spleen, liver and bone marrow. Spleen is practically always involved. Liver is involved if splenic hilum and retroperitoneal lymph nodes are involved. Bone marrow is involved in Hodgkin's disease depletion type. *Refer* to Hodgkin disease, details in Chapter 13.

MANTLE CELL LYMPHOMA: SPILLOVER IN BLOOD

Mantle cell lymphoma (MCL) occurs in the middle and elderly persons, which resembles small cell lymphoma except slightly different cellular details.

- Mantle cell lymphoma is disseminated, moderately aggressive incurable disease derived from the **naïve B cell** of lymphoid follicles in mantle zone of lymph node.
- Mantle cell lymphoma involves bone marrow in most cases. About 20% cases are associated with leukemia. MCL has tendency to involve gastrointestinal tract with submucosal polypoid nodules.
- Neoplastic cells in mantle cell lymphoma show t(11;14) with fusion of the cyclin D1 gene on chromosome 11 to the immunoglobulin heavy chain (IgH) promoter/enhancer region on chromosome 14. Fusion product leads to increased cyclins (CCND1/cyclin D1) expression with loss of cell cycle regulation.
- Median survival rate is 3–5 years in mantle cell lymphoma. Vast majority of patients do not respond to newer therapeutic modalities. A high proliferative rate (mitotic or Ki-67 indices) is associated with shorter overall survival. High Ki-67 proliferative index (>30%) is currently accepted cut off point.

Surgical Pathology: Lymph Node Biopsy in Mantle Cell Lymphoma (MCL)

Light Microscopy

- Mantle cell lymphoma comprises hyalinized blood vessels and scattered epithelioid histiocytes giving 'starry sky' appearance.
- Classic neoplastic cells are small with irregular indented nuclear contours. These neoplastic cells may have blastoid or pleomorphic, anaplastic morphology.
- Blastoid form of mantle cell lymphoma and sometimes classic cells may be accompanied by involvement of blood, bone marrow and spleen.

Immunophenotyping

- Neoplastic cells of mantle cell lymphoma express intense surface IgM /IgG/IgD with restriction of κ or λ.
- The lymphoma cells show positivity for BCL-2, CD5, FMC7 and CD43. These are sometimes positive for IRF4 and MUM1.
- Nuclear cyclin D1 is expressed in >95% of cases of mantle cell lymphoma.
- SOX11 positivity with monoclonal antibody is demonstrated in >90% of cases.
- Neoplastic cells are negative for CD10, CD25, CD23 and CD11C.

Markers	Expression
Surface IgM/IgG/IgD	Positive
BCL-2	Positive
CD5	Positive
CD43	Positive
FMC7	Positive (strong intensity)
Cyclin D1	Positive (strong intensity in nucleus)
IRF4	Positive (some cases)
MUM1	Positive (some cases)
CD10	Negative
CD25	Negative
CD23	Negative
CD11C	Negative

Translocation t(11; 14) creating cyclin D1–IgH fusion gene is demonstrated in mantle cell lymphoma.

Laboratory Diagnosis of Mantle Cell Lymphoma—Spillover in Blood

Mantle cell lymphoma, blastoid variant is diagnosed based on cytomorphology and flow cytometric immunophenotyping of the lymph node aspirate and peripheral blood smear examination.

Peripheral Blood Smear Examination

Peripheral blood smear examination shows a spectrum of cells ranging from small mature lymphocytes to medium- and large-sized lymphocytes with blast-like chromatin and prominent nucleoli.

Immunophenotyping

- The leukemic cells are monoclonal B cells with moderately intense surface IgM/IgG/IgD. These cells are CD5 positive, cyclin D1 positive and CD10 negative.
- The flow cytometric immunophenotyping and DNA ploidy analysis of the peripheral blood and material obtained by aspiration cytology support the diagnosis of mantle cell lymphoma, blastoid variant.

Markers	Expression
CD5	Positive
Cyclin D1	Positive
CD10	Negative

SPLENIC LYMPHOMA WITH VILLOUS LYMPHOCYTES

Splenic lymphoma with villous lymphocytes (SLVL) is a chronic B cell lymphoproliferative disorder characterized by a clonal expansion of atypical B cells with villous projections in the peripheral blood. The disease involves bone marrow and spleen resulting in anemia and splenomegaly. SLVL involves bone marrow in patchy manner and then spillover in blood. Neoplastic cells show a few short villi in one direction, which are negative for CD11 and CD103.

MULTIPLE MYELOMA AND OTHER MONOCLONAL GAMMOPATHIES

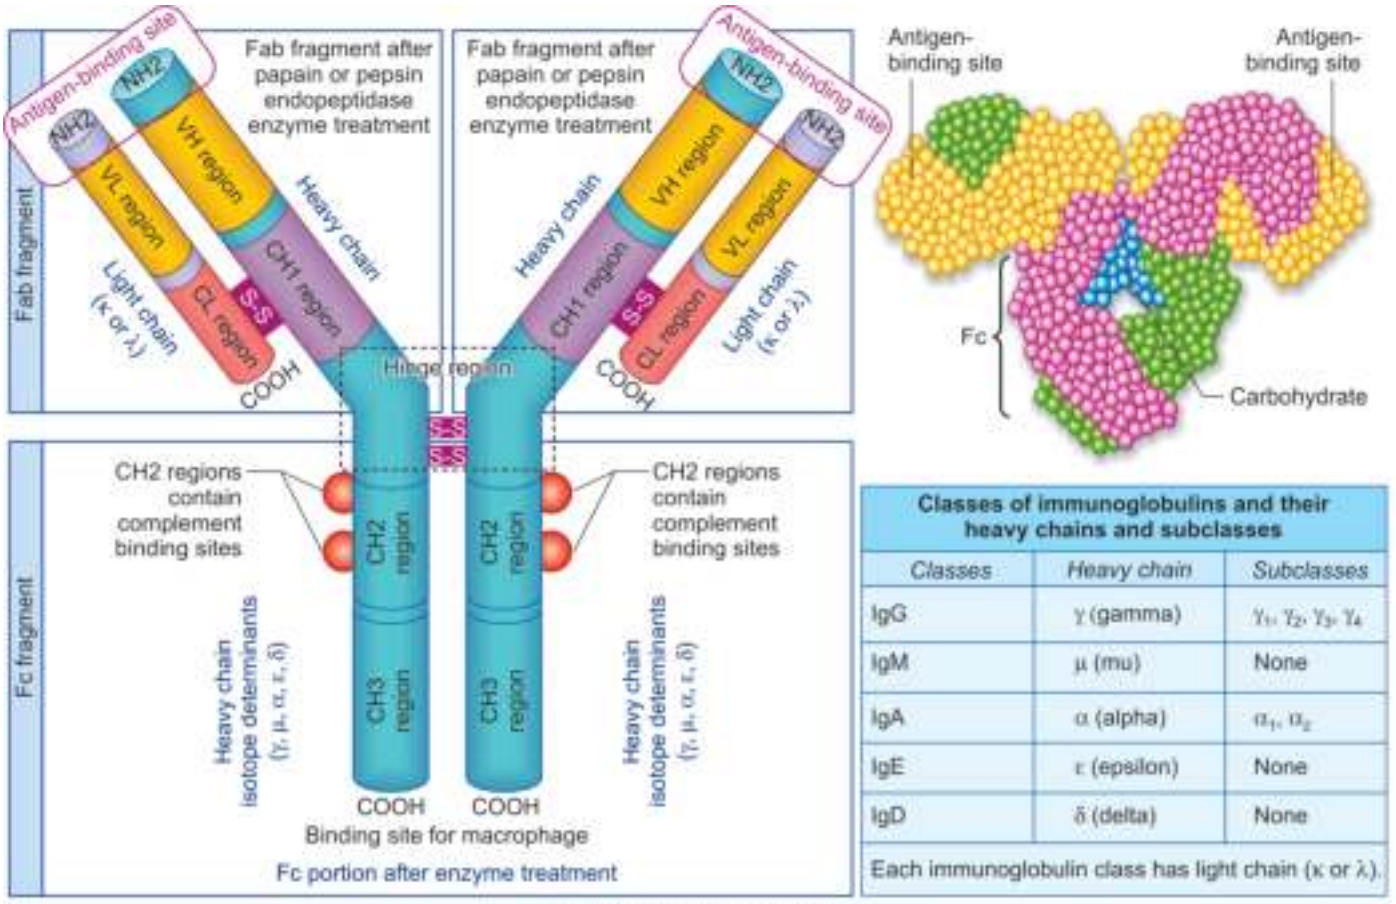
Healthy plasma cells synthesize immunoglobulins that fight infection. The immunoglobulins are made up of heavy and light chains. There are five types of immunoglobulins: IgG, IgA, IgM, IgD and IgE. Schematic representation of immunoglobulin structure is shown in Fig. 9.103.

- Clonal plasma cell proliferative disease usually produces monoclonal immunoglobulin (M protein) that may be used as a 'serologic tumor marker'. The exception to this rule is nonsecretory multiple myeloma, in which monoclonal proteins are not produced hence not detected in serum or urine. Because clonal plasma cells synthesize monoclonal immunoglobulin, clonal plasma cell disorders are also called monoclonal gammopathies or plasma cell dyscrasias.
- The secreted monoclonal immunoglobulins can be used as a diagnostic tool for the identification of the clone of plasma cells as well as quantitative serologic marker to follow-up the course of clonal plasma cell disorder and response to therapy.
- Unlike most serologic tumor markers, monoclonal immunoglobulins (M proteins) are extremely diverse. Each of the M proteins has unique variable region sequences and the molecules may range from pentameric IgM (~9,00,000 daltons) to monomeric free light chains (~24,000 daltons).
- In addition, although some plasma cell dyscrasias such as multiple myeloma, Waldenström macroglobulinemia, and benign monoclonal gammopathies of undetermined significance (MGUS) present with monoclonal immunoglobulin (M protein) concentrations expressed in grams per liter of serum, others have a little or virtually no circulating M-protein. It is the diversity of structure and concentration of M protein that make this clonal marker so interesting and challenging.
- The low-tumor burden in clonal plasma cell disorders represent a group of monoclonal gammopathies, in which there may not be increased proliferation of clonal plasma cells, but in which the cell products cause pathology. Some disorders associated with monoclonal immunoglobulins are given in Table 9.127.

MULTIPLE MYELOMA

Multiple myeloma (MM) is a clonal plasma cell proliferative disorder characterized by the excessive synthesis of monoclonal paraprotein (M protein) leading to evidence of specific end-organ damage, which constitutes 10–15% of hematopoietic stem cell neoplasms.

- Proliferation of monoclonal plasma cells in bone marrow results in extensive osteolytic skeletal lesions, hypercalcemia, anemia and/or soft tissue plasmacytomas. In addition, the excessive production of monoclonal proteins is nephrotoxic and can cause renal failure. Deficient production of functional immunoglobulin increased risk for developing life-threatening infections.
- Multiple myeloma occurs most commonly in people over 60 years of age. Median age is 65–70 years. Only 2% of cases in people under 40 years of age. Disease never affects children.
- Risk factors for development of multiple myeloma include over 60 years of age, exposure to ionizing radiation and chemical agents such as benzene, organic solvents, farmers exposed to insecticides and herbicides, and monoclonal gammopathy of undetermined significance (MGUS).
- Diagnosis of multiple myeloma is based on the combination of clinical, morphologic, radiologic and immunologic findings. Bone disease is the major cause of morbidity in patients with multiple myeloma, which can be detected on skeletal radiographs, magnetic resonance imaging (MRI), or computed tomography (CT) scans.
- Multiple myeloma is classified into four types: mature, immature, pleomorphic and plasmablastic.
- There are three patterns in which multiple myeloma infiltrates bone marrow: nodular, interstitial and diffuse. Dutcher bodies are highly specific to the clonal plasma cells. Immunophenotyping, CD138 marker is highly specific for plasma cells. Abnormal expression of CD56 is demonstrated in 70–80% of cases by flow cytometry analysis. CD56 expression definitely indicates multiple myeloma, suggesting its high diagnostic values.



Classes of immunoglobulins and their heavy chains and subclasses

Classes	*Heavy chain*	*Subclasses*
IgG	γ (gamma)	γ_1, γ_2, γ_3, γ_4
IgM	μ (mu)	None
IgA	α (alpha)	α_1, α_2
IgE	ε (epsilon)	None
IgD	δ (delta)	None

Each immunoglobulin class has light chain (κ or λ).

Immunoglobulin structure

1. Immunoglobulin consists of 2 heavy chains and 2 light chains joined together by disulfide bonds.
2. Each heavy chain consists of a variable region (VH) and constant region encompassing functional domains named CH1, CH2 and CH3. Each light chain has a variable region (VL) and a constant region (VC).
3. The carboxy (–COOH) end of both the heavy chains and light chains is highly conserved, the amino acid sequence is very similar for all immunoglobulins of the same class: IgG, IgM, IgA, IgE or IgD.
4. Both the heavy chains and light chains at the amino(–NH2) end of proteins are highly variable, which allows for the development of specific antigen-binding sites.
5. Enzyme will cleave the immunoglobulin molecule at several points in the hinge region, resulting in three fragments: one Fc fraction crystallizable and two Fab fragments (antigen-binding fraction). Hinge region is a flexible amino acid stretch in the central portion of the heavy chains of the IgG or IgA immunoglobulin classes, which link these two chains by disulfide bonds.
6. Papain cleaves the heavy chain CH2 domains above the disulfide bond that connect heavy chains and yields three different fragments. Pepsin endopeptidase enzyme cleaves IgG heavy chains at a point below the disulfide bond that links two heavy chains. The resulting fragment consists of two Fab fragments linked together by heavy chain disulfide bonds.

Fig. 9.103. Schematic representation of immunoglobulin structure. Immunoglobulins are composed of two heavy and two light chains. They can be separated functionally into variable (V) domains that bind antigens and constant (C) domains that specify effector functions such as activation of complement or binding to Fc receptors.

- Plasma cell neoplasms and their clinical variants are given in Table 9.128. Plasma cell neoplasms and their key features are given in Table 9.129. Differentiating features of multiple myeloma, smoldering myeloma and monoclonal gammopathy of undetermined significance (MGUS) are given in Table 9.130. Multiple myeloma-related organ or tissue impairment (end organ damage) due to the clonal plasma cell proliferative process is given in Table 9.131.

TERMINOLOGY

Multiple myeloma is not a single disease. There are wide variations of multiple myeloma subtypes: (a) inactive MGUS—monoclonal gammopathy of undetermined significance, (b) SMM—smoldering myeloma and (c) active multiple myeloma. Multiple myeloma can be determined by using specific tests like fluorescence *in situ* hybridization (FISH) analysis, cytogenetics testing and gene profiling through bone marrow aspirates.

Table 9.127 Some disorders associated with monoclonal immunoglobulins

Related to Clonal B Cell Proliferation
Multiple myeloma
Solitary plasmacytoma
Smoldering multiple myeloma (asymptomatic multiple myeloma)
Plasma cell leukemia
Amyloid light chain (primary) amyloidosis
Heavy chain deposition disease
Monoclonal gammopathy of undetermined significance
POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, skin changes)
Light chain deposition disease
Waldenström macroglobulinemia
Type 1 cryoglobulinemia
Non-Hodgkin lymphoma
Chronic lymphocytic leukemia
Castleman disease
Post-transplant monoclonal gammopathy
Autoimmune Disorders
Rheumatoid arthritis
Scleroderma
Systemic lupus erythematosus
Sjögren syndrome
Psoriatic arthritis
Immune complex vasculitis/type 2 cryoglobulinemia
Chronic inflammatory demyelinating polyneuropathy
Chronic Viral Infections
Human immunodeficiency virus
Hepatitis C virus (HCV)
Skin Disorders
Scleroderma
Schnitzler's syndrome
Pyoderma gangrenosum

Secretory Multiple Myeloma

Clonal proliferation of plasma cells synthesizing monoclonal immunoglobulins (paraproteins) are known as secretory multiple myeloma. Approximately 60–70% of secretory myeloma patients have IgG myeloma and about 20% have IgA myeloma. IgG or IgA monoclonal proteins are almost always found in multiple myeloma.

Table 9.128 Plasma cell neoplasms and their clinical variants

Plasma Cell Myeloma
▪ Smoldering multiple myeloma (asymptomatic multiple myeloma) ▪ Nonsecretory myeloma ▪ Plasma cell leukemia
Plasmacytoma
▪ Solitary plasmacytoma of bone ▪ Extraosseous (extramedullary) plasmacytoma in upper respiratory tract (nose, paranasal sinuses, nasopharynx and tonsils)
Monoclonal Gammopathy of Undetermined Significance (MGUS)
▪ MGUS IgM ▪ MGUS non-IgM ▪ MGUS light chain
Monoclonal Immunoglobulin Deposition Diseases
▪ Amyloid light chain (primary) amyloidosis ▪ Systemic light and heavy chain deposition
Plasma Cell Neoplasms with Associated Paraneoplastic Syndromes
▪ POEMS syndrome also known as osteosclerotic myeloma is characterized by polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, and skin changes ▪ TEMPI syndrome (provisional) is multisystem disease characterized by presence of telangiectasis, erythrocytosis with elevated erythropoietin levels, monoclonal gammopathy, perinephric fluid collections, and intrapulmonary shunting

- IgM multiple myeloma is very uncommon. Immunoglobulin D (IgD) multiple myeloma affects 1–2% of persons with multiple myeloma in elderly men under 60 years of age.
- Signs and symptoms are the same as other types. Immunoglobulin E (IgE) multiple myeloma rarest type of multiple myeloma.
- Secretory multiple myeloma tends to be aggressive and progresses to plasma cell leukemia, which spreads outside the bone marrow quickly. Multiple myeloma in Giemsa-stained bone marrow aspirate smear is shown in Fig. 9.104.

Light Chain Multiple Myeloma

Light chain multiple myeloma (LCMM) constitutes 15% of patients with multiple myeloma, which has a poor prognosis when compared to IgA or IgA variant. Patients with λ light chain multiple myeloma have a three times worse prognosis than κ light chain multiple myeloma.

- Renal failure, bone disease, and systemic light chain associated amyloidosis appear to be more frequent in patients with light chain multiple myeloma.
- Light chain multiple myeloma patients secrete either low molecular weight κ or λ chains when get filtered

Table 9.129 Plasma cell neoplasms and their key features

Key Features	Clinical Notes
Monoclonal gammopathy of undetermined significance (MGUS) non-IgM	
▪ Serum M protein (IgG or IgA;) <30 g/L ▪ Clonal bone marrow plasma cells <10% ▪ Absence of myeloma-defining events (MDE) end organ/tissue damage, e.g. hypercalcemia, renal insufficiency, anemia, and bone lesions (CRAB) and amyloidosis attributable to the plasma cell proliferative disorder	Progression risk to multiple myeloma, amyloidosis or plasmacytoma in 0.5–1.0% per year
Monoclonal gammopathy of undetermined significance (MGUS) IgM	
▪ Serum IgM protein <30 g/L ▪ Bone marrow demonstrates lymphoplasmacytic cells <10% ▪ Absence of end-organ damage (anemia, constitutional symptoms, hyperviscosity, lymphadenopathy), hepatosplenomegaly or myeloma-defining events (MDE) or amyloidosis	Progression of MGUS-IgM increases risk (1.5% per year) for Waldenström's macroglobulinemia or lymphoproliferative disorder
Monoclonal gammopathy of undetermined significance (MGUS) light chain	
▪ Abnormal free light chain ratio (<0.26 or >1.65) ▪ Increased level of the corresponding free light chain in serum ▪ No immunoglobulin heavy chains expression ▪ Urinary excretion of monoclonal protein <500 mg per 24 hours ▪ Clonal plasma cells <10% in bone marrow ▪ Absence of myeloma-defining events (MDE) end organ/tissue damage, e.g. hypercalcemia, renal insufficiency, anemia, and bone lesions (CRAB) and amyloidosis attributable to the plasma cell proliferative disorder	Progression of MGUS-light chain increases risk (0.3% per year) for multiple myeloma, amyloidosis or plasmacytoma
Plasma cell myeloma (multiple myeloma)	
▪ Bone marrow or bone marrow trephine biopsy proven plasmacytoma consisting of ≥10% clonal plasma cells ▪ M-spike in serum or urine on electrophoresis ▪ Related organ or tissue damage (CRAB), i.e. hypercalcemia, renal insufficiency, anemia, bone lesions ▪ Myeloma defining events (MDE): • Hypercalcemia (serum calcium >11 mg/dl) • Anemia (hemoglobin <10 g/dl) • Bone lesions ≥1 osteolytic lesion on conventional radiograph, CT scan, PET-CT scan • Bone marrow clonal plasma cells ≥60% • Involved/uninvolved serum free light chains ratio ≥100 with involved serum free light chains ≥100 mg/L • Presence of ≥1 focal lesion on MRI of spine	Must fulfill at least one myeloma defining events (MDE) should be related to plasma cell disorder
Asymptomatic (smoldering) myeloma	
▪ IgG or IgA; M protein spike in serum or urine >30 g/L ▪ Monoclonal plasma cells ≥10% in bone marrow ▪ Absence of myeloma-defining events (MDE) or amyloidosis	Progression risk to multiple myeloma, amyloidosis is 10% per year, then 3% per year, then 3% next 5 years per year; and then 1% per year thereafter
Nonsecretory myeloma	
▪ Monoclonal plasma cells ≥10% in bone marrow without monoclonal immunoglobulin (M proteins) synthesis hence absent in serum and urine ▪ Disorder is negative for serum protein electrophoresis (SPE)/serum immunofixation electrophoresis (IFE) ▪ There is lower incidence of renal insufficiency, hypercalcemia, and depression of normal IgG	Nonsecretory myeloma could be misdiagnosed if the workup does not include an accurate study of serum free light chain test only with small amounts monoclonal proteinuria
Osteosclerotic plasma cell myeloma	
▪ Plasma cells entrapped in areas of fibrosis in bone marrow ▪ Thickened trabecular bone present ▪ Usually, lambda light chain restricted	Excessive proliferation and improper functions of plasma cells in the bone marrow

Contd...

Table 9.129 Plasma cell neoplasms and their key features (*Contd...*)

Key Features	Clinical Notes
▪ Usually does not meet criteria for classical myeloma: • Bone marrow plasmacytosis usually <5–10%, if present • Serum M protein usually <3.5 g/dl, if present • Bence-Jones protein in urine usually <1 g/24 hours, if present	
Solitary plasmacytoma of bone	
▪ Biopsy proven solitary collection of clonal plasma cells in bone marrow (<10%) ▪ Can demonstrate M spike in serum or urine (<30 g/L) ▪ No clonal plasma cells elsewhere in bone marrow ▪ No related organ or tissue damage ▪ Absence of myeloma-defining events (MDE) or amyloidosis	Progression to multiple myeloma within 3 years in 60% of cases
Extraosseous (extramedullary) plasmacytoma	
▪ Localized tumor in soft tissues (oropharynx) other than bone ▪ M protein in serum or urine absent or lower than in myeloma	Progression to multiple myeloma within 3 years in 20% of cases
POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy and skin changes) syndrome	
▪ **Mandatory diagnostic criteria:** These include polyneuropathy, monoclonal plasma cell disorder (usually λ light chain) ▪ **Major diagnostic criteria:** These include osteosclerotic lesions, Castleman's disease, elevated VEGF (vascular endothelial growth factor) ▪ **Minor diagnostic criteria:** These must fulfill at least 1 criterion such as organomegaly, extravascular volume overload, endocrinopathy, skin changes, papilledema, thrombocytosis/polycythemia	POEMS syndrome occurs in the setting of plasma cell dyscrasia
Covert myeloma	
No tumor formation, but synthesis of abnormal paraprotein resulting in amyloidosis	Risk for amyloidosis
Primary amyloidosis	
▪ Amyloidosis occurs in the setting of plasma cell dyscrasia in which abnormal proteins build up in tissues and organs. Aggregation of abnormal proteins are called amyloid deposits ▪ Most common forms of system amyloidosis include light chain (AL amyloidosis) and reactive amyloid associated (AA amyloidosis) ▪ Monoclonal plasma cell disorder is diagnosed by demonstration of either by serum or urine electrophoresis, bone marrow, or abnormal serum free light chains ▪ Positive amyloid staining by Congo red stain in any tissue such as kidney, liver, heart or peripheral nerves	A biopsy from abdominal fat and affected organ is required to confirm amyloidosis
Light and heavy chain deposition disease	
Monoclonal immunoglobulins deposit usually light chain deposit disease (LCDD) or heavy chain deposit disease (HCDD) along basement membrane	Light and heavy chain deposition disease along basement membrane

Table 9.130 Multiple myeloma-related organ or tissue impairment (end-organ damage) due to the clonal plasma proliferative process

Hypercalcemia
Renal insufficiency
Anemia (hemoglobin 2 g/dl below the normal limit)
Bone lesions: osteolytic or osteoporosis with compression fractures possibly confirmed by MRI or CT scan
Others: amyloidosis, recurrent infections (more than two episodes in 12 years), extramedullary plasmacytomas and symptomatic hyperviscosity (rare)

at glomerulus, reabsorbed and catabolized in renal tubules.

- About 85% of patients with multiple myeloma, synthesize complete monoclonal immunoglobulins. When multiple myeloma progresses, monoclonal plasma cells start to synthesize more light chains than the heavy chains.
- In patients with light chain multiple myeloma, clonal plasma cells show rearrangements in immunoglobulin heavy chains (IgH) at the DNA level thereby leading to an inability to produce IgH.
- In most instances, one IgH allele has a germline configuration for the D, J and C domains, whereas

Table 9.131 Differentiating features of multiple myeloma, smoldering myeloma and monoclonal gammopathy of undetermined significance (MGUS)

Parameters	Multiple Myeloma	Smoldering Myeloma	Monoclonal Gammopathy of Undetermined Significance (MGUS)
Osteolytic lesions	Present	Absent	Absent
Myeloma related organs damage	Present	Absent	Absent
Clonal proliferation of plasma cells in the bone marrow	>30%	10–30%	<10%
Monoclonal protein (M protein)	>35 g/dl	>30 g/dl	<30 g/dl
Excretion of κ or λ light chains in urine	>3 g/24 hours	1–3 g/24 hours	>1 g/24 hours

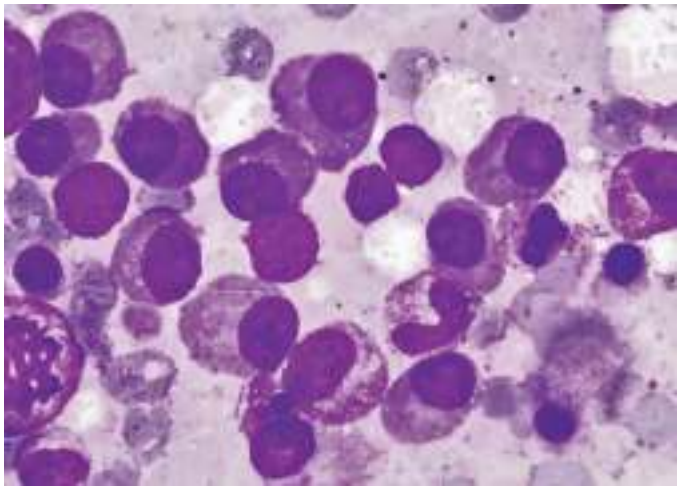


Fig. 9.104: Multiple myeloma in Giemsa-stained bone marrow aspirate smear. Replacement of bone marrow hematopoietic precursor cells by an infiltrate of malignant plasma cells is shown. Neoplastic plasma cells have eccentric nucleus and perinuclear halos. A few binuclear plasma cells are also present (1000X).

the second allele is involved in translocation. This molecular finding, in contrast with conventional multiple myeloma in which one allele has a functional rearrangement, whereas the second allele is usually involved in a translocation.

- Since light chain multiple myeloma is more aggressive disease, therefore serum-free light chain test is better predictor of clinical outcome than the amount of M protein in serum.

Nonsecretory Multiple Myeloma

Nonsecretory multiple myeloma is diagnosed by tissue infiltration by clonal plasma cells >10% without monoclonal immunoglobulin in serum or urine.

- Nonsecretory multiple myeloma is negative for serum protein electrophoresis (SPE)/serum immunofixation electrophoresis (IFE).
- About 85% cases of nonsecretory multiple myeloma demonstrate impaired secretion of immunoglobulin and have cytoplasmic immunoglobulin demonstrated by immunophenotyping and immunohistochemistry technique. There is lower incidence of renal insufficiency, hypercalcemia, and depression of normal IgG.

Hyperdiploid versus Hypodiploid Multiple Myeloma

Multiple myeloma can be categorized into hyperdiploid or hypodiploid myeloma based on the number of chromosomes found in the clonal plasma cells.

- Hyperdiploid multiple myeloma clonal plasma cells have more chromosomes than normal, which occurs in about 45% cases of multiple myeloma patients associated with less aggressive clinical course.
- Hypodiploid multiple myeloma clonal plasma cells have fewer chromosomes than normal, which occur in about 40% cases of multiple myeloma patients associated with more aggressive clinical course.

Osteosclerotic Multiple Myeloma

Osteosclerotic multiple myeloma occurs in young persons, which does not meet criteria of classical myeloma and shows (a) bone marrow plasmacytosis usually <5–10%, if present, (b) serum M protein usually <3.5 g/dl, if present, and (c) Bence-Jones protein in urine usually <1 g/24 hours, if present.

- There is excessive proliferation and improper functions of clonal plasma cells in the bone marrow. Clonal plasma cells are entrapped in areas of fibrosis in bone marrow.
- Trabecular bone shows thickening. λ light chain is usually restricted. **POEMS** (**P**: Polyneuropathies, **O**: Organomegaly, **E**: Endocrinopathy, **M**: Myeloma protein, **S**: Skin changes) is seen in rare cases of osteosclerotic multiple myeloma.

Smoldering Multiple Myeloma (Asymptomatic Multiple Myeloma)

Smoldering multiple myeloma is more likely to produce asymptomatic multiple myeloma than monoclonal gammopathy of undetermined significance (MGUS) without symptom. When compared to MGUS, smoldering multiple myeloma has a larger monoclonal protein (M protein) in the blood or presence of more monoclonal plasma cells in the bone marrow. The

levels of these markers are lower than those in active multiple myeloma.

- Smoldering multiple myeloma also progresses slowly, but in contrast to MGUS, after five years, about 50% of these patients progress to active multiple myeloma. PET-CT scan and MRI are essential to exclude bone disease.
- Diagnostic criteria of smoldering multiple myeloma are monoclonal immunoglobulins (IgG or IgA); M protein spike in serum or urine >30 g/L, and or bone marrow shows monoclonal plasma cells 10–30% and absence of myeloma-defining events (MDE) such as organ or tissue impairment including bone disease or amyloidosis.
- Risk of progression of smoldering multiple myeloma to active multiple myeloma is 10% per year in the first five years after diagnosis. Smoldering multiple myeloma in hematoxylin and eosin-stained bone marrow trephine biopsy section is shown in Fig. 9.105.

Plasmablastic Multiple Myeloma

Plasmablastic multiple myeloma is an aggressive neoplasm presenting with overlapping features of multiple myeloma and non-Hodgkin's lymphoma.

- The cytomorphologic features of plasma cell neoplasms range from mature, immature, pleomorphic and plasmablastic.
- Plasmablastic multiple myeloma is a morphologic subset of multiple myeloma, in which Giemsa-stained bone marrow aspirate smear shows 2% of plasmablasts.
  - Plasmablasts are characterized by fine reticular nuclear chromatin pattern, large nucleus (>10 µm in diameter), prominent large nucleolus and variable amount of cytoplasm.
  - Morphology of plasmablastic multiple myeloma is an independent predictor of poor survival after autologous hematopoietic stem cell transplantation for multiple myeloma.
  - There is no consensus on the management of plasmablastic multiple myeloma.
  - When combined with chemotherapy, anti-CD38 monoclonal antibody daratumumab may effectively target plasmablastic multiple myeloma clonal plasma cells.
- Plasmablastic multiple myeloma in Giemsa-stained bone marrow aspirate smear is shown in Fig. 9.106. Plasmablastic multiple myeloma in hematoxylin and eosin-stained bone marrow trephine biopsy is shown in Fig. 9.107.

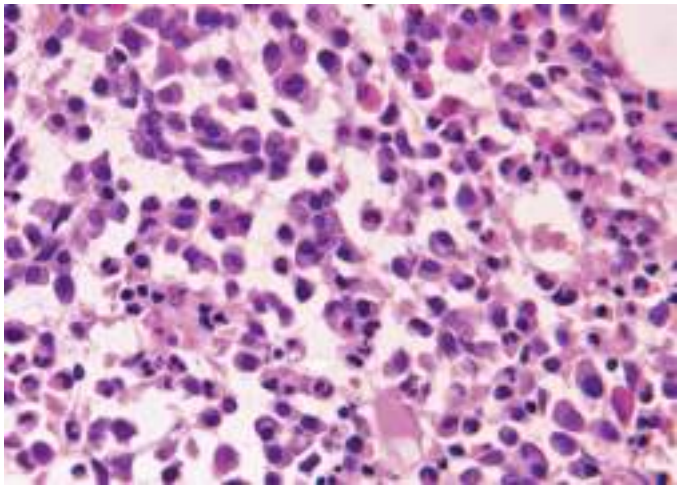

Fig. 9.105: Smoldering multiple myeloma in hematoxylin and eosin-stained bone marrow trephine biopsy section. It shows clusters of clonal plasma cells (400X).

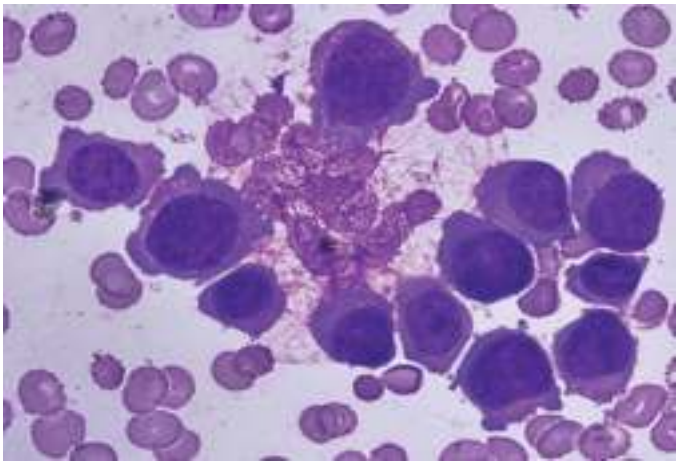

Fig. 9.106: Plasmablastic multiple myeloma in Giemsa-stained bone marrow aspirate smear. Plasmablastic clonal plasma cell contains centrally placed immature large nucleus with reticular chromatin and prominent nucleolus with high nucleocytoplasmic ratio and variable amount of cytoplasm (1000X).

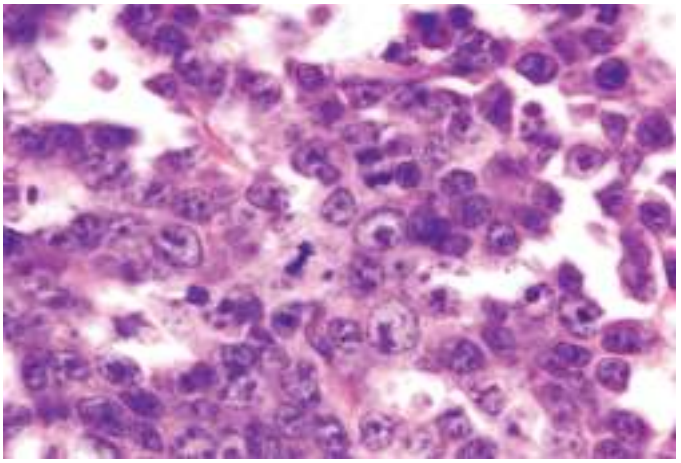

Fig. 9.107: Plasmablastic multiple myeloma in hematoxylin and eosin-stained bone marrow trephine biopsy section. It shows sheets of plasmablastic clonal plasma cells, which contain centrally placed immature large nucleus with reticular chromatin and prominent nucleolus with high nucleocytoplasmic ratio variable amount of cytoplasm (400X).

Plasma Cell Leukemia

Plasma cell leukemia (PCL) is diagnosed by absolute number of clonal plasma cells in peripheral blood $\geq 2 \times 10^9$/L or 20% of monoclonal plasma cells on differential white blood cell count. Disorder may be primary plasma cell leukemia or represent a late-stage transformation of multiple myeloma (secondary).

- Monoclonal plasma cells in plasma cell leukemia typically lack expression of CD56 and has more frequent abnormal karyotype. Genomic abnormalities analyzed by cytogenetic studies by fluorescence *in situ* hybridization (FISH) show predominance of monosomy and deletions of chromosome 13, t(11;14), del(17q), gain/amp(1q) and del(1p). Bone pain and osteolytic lesions are less common.
- Clonal plasma cells have ability to survive and grow outside of the bone marrow. Plasma cell leukemia is typically associated with extramedullary lesions (e.g. pleural effusion, lymphadenopathy, organomegaly and skin involvement).
- Plasma cell leukemia (PCL) in Giemsa-stained peripheral blood smear is shown in Fig. 9.108. Pleomorphic plasma cell leukemia in Giemsa-stained bone marrow aspirate smear is shown in Fig. 9.109.

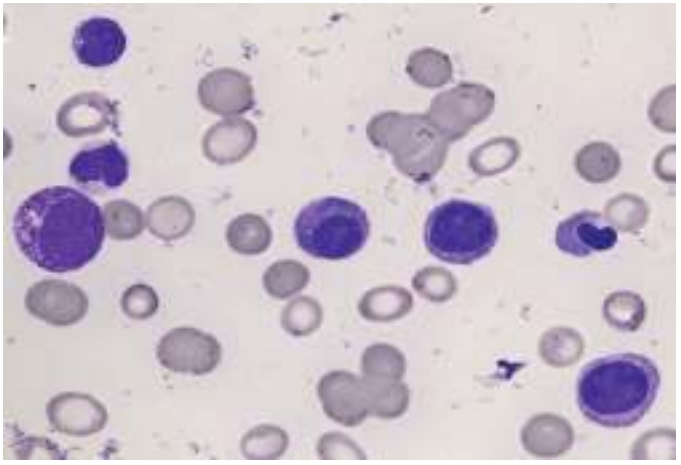

Fig. 9.108: Plasma cell leukemia (PCL) in Giemsa-stained peripheral blood smear. It shows spillover of myeloma cells in peripheral blood. Plasma cells constitute >20% of blood leukocytes in the peripheral blood (1000X).

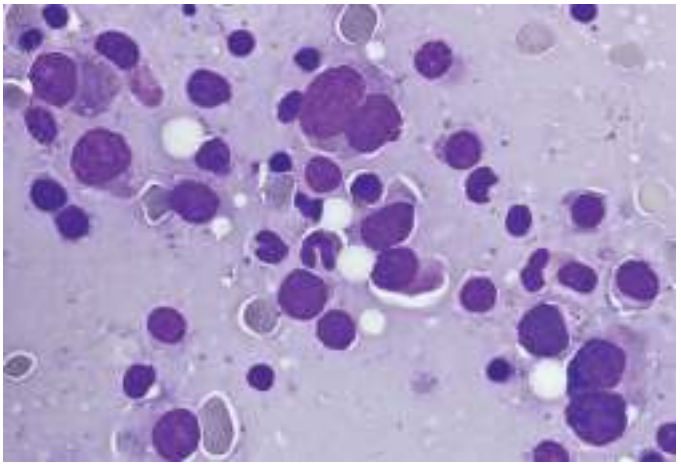

Fig. 9.109: Pleomorphic plasma cell leukemia in Giemsa-stained peripheral blood smear. It shows spillover of pleomorphic myeloma cells in peripheral blood. Plasma cells constitute >20% of blood leukocytes in the peripheral blood (1000X).

Solitary Osseous/Extraosseous Plasmacytoma

Unlike multiple myeloma, solitary osseous/extraosseous plasmacytoma occurs either in bone or soft tissues (oropharynx). Single area of bone destruction occurs due to clonal plasma cells.

- Bone marrow examination shows <10% clonal plasma cells, but findings are not consistent with multiple myeloma. There is no end-organ damage or amyloidosis other than solitary bone lesion. Most cases of solitary plasmacytoma involving bone evolve into multiple myeloma. Extraosseous plasmacytoma is commonly seen in IgD myeloma.
- Solitary plasmacytoma responds well to ionizing radiation, and/or surgery. Because patients with solitary plasmacytoma have a higher risk for multiple myeloma, these cases must be monitored closely with regular follow ups. It is essential to perform a baseline PET-CT scan and/or MRI to confirm solitary plasmacytoma. Skeletal surveys by regular X-rays are not sufficiently sensitive.

Monoclonal Gammopathy of Undetermined Significance

Monoclonal gammopathy of undetermined significance (MGUS) is the most common spectrum of diseases called plasma cell dyscrasias in elderly persons.

- The term MGUS refers to presence of a monoclonal immunoglobulin (Ig) also called M protein in the serum or urine in persons without evidence of multiple myeloma, Waldenström's macroglobulinemia, amyloidosis (AL), or lymphoproliferative disorders.
- Persons with MGUS generally remain asymptomatic, however, some persons may present with skin rash or numbness or tingling.
- Monoclonal gammopathy of undetermined significance (MGUS) patients may develop multiple myeloma, light chain amyloidosis, Waldenström's macroglobulinemia and lymphoma.

MOLECULAR CLASSIFICATION

Gene expression analysis of multiple myeloma has established the numerous genetic diversities of multiple myeloma neoplasm.

- Recently, multiple myeloma has been classified into seven different groups.

- **Favorable group** of multiple myeloma comprises low bone disease group, hyperploid (HY) group, CD1 group, and CD2 group.
- **Unfavorable group** of multiple myeloma comprises proliferation group, multiple myeloma SET domain group and MF group (MAF/MAFB).

- Each group demonstrates specific genetic structure and some of them have been associated with particular IgH translocation or ploidy status and characteristic clinical behavior. Molecular classification of multiple myeloma is given in Table 9.132.

MOLECULAR GENETIC ALTERATIONS

Multiple myeloma is B cell malignant disorder characterized by accumulation of terminally differentiated clonal plasma cells in the bone marrow, increased synthesis of monoclonal immunoglobulin detected in serum and/or urine and the presence of osteolytic lesions.

- In order to understand the pathogenesis of multiple myeloma, it is essential to review not only molecular changes involved in the development of clonal plasma cell, but also the interaction between clonal plasma cells and their microenvironment, since clonal plasma cells play relevant role in bone destruction, tumor growth, survival, migration and therapeutic drug response.

Cellular Origin of Multiple Myeloma

Normal differentiation of plasma cells from early B cells occurs by three B cell-specific DNA remodeling mechanisms that modify immunoglobulin genes: (a) VDJ rearrangement to form B cell receptor in the bone marrow; (b) somatic mutation; and (c) class switch recombination take place in the germinal center of lymph node.

- Sequencing analysis of IgVH genes supports that origin of clonal plasma cells occurs in the

Table 9.132 Molecular classification of multiple myeloma

Group	Chromosomal Translocation	Frequency	Cyclin D Expression	Genetic Signature	Prognosis
Low bone disease group	Nil	11%	CCND2	↑EDN1 ↑IL6R ↓DDK1 ↓FRZB	Favorable prognosis
Hyperploid (HY group)	Nil	26%	CCND1	↑TRAIL ↑DKK1 ↑FRZB ↓CKS1B	Favorable prognosis
CD1 group	t(11;14) CCND1 or t(6;14) CCND3	8%	CCND1 or CCND3	↑CEBPB ↑NID2 ↑SET7	Favorable prognosis
CD2 group	t(11;14) CCND1 or t(6;14) CCND3	17%	CCND1 or CCND3	↑MS4A1 (CD20) ↑PAX5 ↑CD27 ↑CXCR1	Favorable prognosis
Proliferation group	Nil	12%	CCND2	↑CCNB1 ↑CCNB2 ↑MCM2 ↑BUB1 ↑MAGEA6 ↑MAGEA3 ↑GAGE1	Unfavorable prognosis
Multiple myeloma SET domain	t(4;14) FGFR3/MMSET	18%	CCND2	↑FGR3 ↑MMSET ↑PBX1 ↑PAX5	Unfavorable prognosis
MF group (MAF/MAFB)	t(4;14) MAF or t(14;20) MAFB	8%	CCND2	↑ITGB7 ↓DKK1	Unfavorable prognosis

Prognosis of multiple myeloma: favorable prognosis (1, 2, 3, 4) and unfavorable prognosis (5, 6, 7).

postgerminal centers of the lymph node before migrating to the bone marrow.

- Multiple myeloma is B cell-derived neoplasm derived from terminally differentiating immunoglobulin producing long lived clonal plasma cells, which survive within the bone marrow over months to years.

Genomic Alterations in Multiple Myeloma

Genomic instability is the most important feature of multiple myeloma, that can contribute to therapeutic resistance and frequent relapses.

- Genomic instability occurs due to chromosomal translocations, mainly involving the IgH locus on chromosome 14q32, copy number abnormalities, mutations, methylation modifications and dysregulation of genes and microRNAs.
- A primary event in B cell neoplasm is dysregulation of an oncogene due to translocation to the IgG locus on chromosome 14q32 or somewhat less often IgL locus (κ on 2p11 or δ on 22q11) is juxtaposed near immunoglobulin enhancers.
- In multiple myeloma, IgH translocation can be classified into primary or secondary. Primary IgH chromosomal translocations occur as initiating events during pathogenesis of multiple myeloma, whereas secondary IgH translocations participate in the progression of disease.
- Most primary IgH chromosomal translocations occur due to errors in the B cell specific DNA modification process, mostly due to IgH switch recombination or, less often somatic hypermutation. The chromosomal breakpoints occur within or immediately adjacent to IgH switch regions or JH regions.
- On the other hand, secondary chromosomal translocations are mediated by the other kinds of combination, mechanism that do not specifically target B cell-specific DNA modification process. In multiple myeloma, there is a marked diversity of chromosomal loci involved in IgH translocations.
- Approximately 40% of multiple myeloma neoplasms have 14q32 IgH translocations with breakpoints involving five recurrent chromosomal patterns such as 11q13 (CCND1), 4p16 (FGFR/MMSET), 16q23 (MAF), 6p (CCND3) and 20q11 (MAFB).
- Whole genomic sequencing strategies revealed that there are about 35 nonsynonymous recurrent gene mutations per multiple myeloma sample, part from mutation in MAPK/ERK signaling pathway.
- Schematic representation of genomic instability in multiple myeloma is shown in Fig. 9.110. Multiple myeloma tumors having 14q32 IgH locus translocations involving five recurrent chromosomal patterns are given in Table 9.133.

Chromosomal Translocation t(11;14)

Chromosomal translocation t(11;14) involves and results in IgH/CCND1 fusion gene in 15–20% cases of multiple myeloma, which is detected by cytogenetic analysis and fluorescence *in situ* hybridization (FISH) technique. It is a standard risk prognostic marker in multiple myeloma based on studies conducted before the current therapies. As a result of chromosomal translocation t(11;14), CCND1 is juxtaposed to the powerful IgH 3'enhancer(s) on der(14q32) and its expression is dysregulated; as indicated by gene expression profiling and reverse transcriptase polymerase chain reaction (RT-PCR) in 100% cases of multiple myeloma.

Chromosomal Translocation t(4;14)

Chromosomal translocation t(4;14) results in overexpression of FGFR3 and MMSET domain in clonal plasma cells in 15–20% cases of multiple myeloma, which is detected by interphase fluorescence *in situ* hybridization or reverse transcriptase polymerase chain reaction (RT-PCR) and not by karyotyping techniques.

- The vast majority of patients whose tumor harbor chromosomal translocation t(4;14) also demonstrate deletion of chromosome 13.
- The chromosomal translocation t(4;14) is associated with upregulation of the fibroblast growth factor receptor 3 (FGFR3) on der(14) and multiple myeloma SET (MMSET) domain on der(14) in 15–20% cases of multiple myeloma.
- FGFR3 is one of the receptor tyrosine kinases for the FGF family of ligands. FGFR3 mutation is an adverse prognostic factor in patients with multiple myeloma. Gene expression profiling is done by reverse transcriptase polymerase chain reaction (RT-PCR) in 75% cases of multiple myeloma.
- MMSET gene plays critical transforming event in multiple myeloma. Normal plasma cells do not express both FGFR3 and multiple myeloma SET (MMSET domain) protein. In multiple myeloma patients with chromosomal translocation t(4;14) overexpress both FGFR3 and multiple myeloma SET (MMSET) domain protein, and associated with overall poor prognosis.

Chromosomal Translocation t(14;16)

Chromosomal translocation t(14;16) results in overexpression of c-MAF oncogenic transcription factor in 5–10% cases of multiple myeloma. The chromosomal

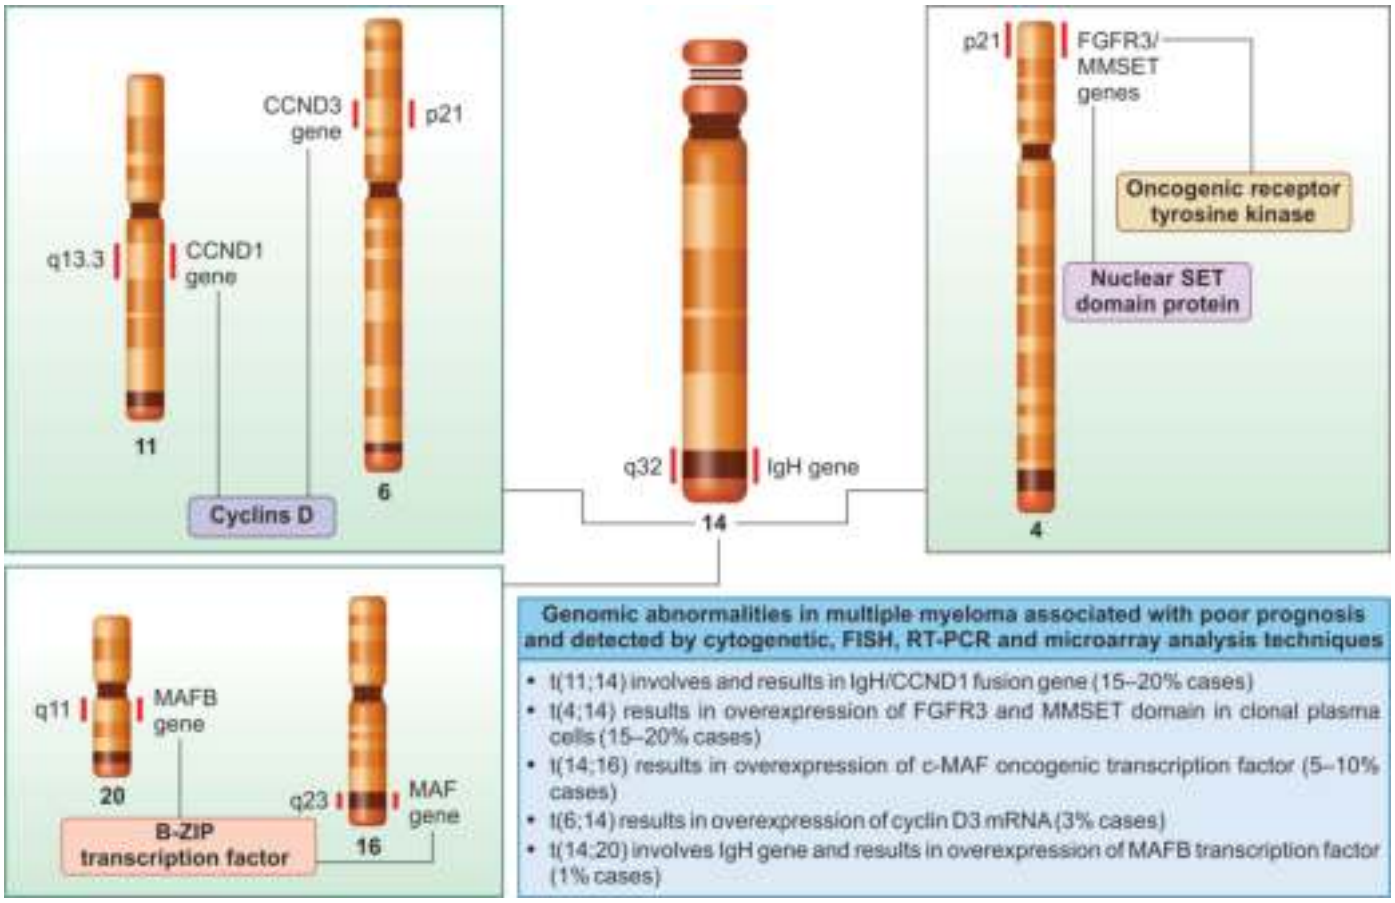

Fig. 9.110: Schematic representation of genomic instability in multiple myeloma. Genomic instability is a well-established driving force in natural history of multiple myeloma, which is difficult to treat and associated with fatal outcome. MAFB protein is a basic leucine zipper (B-ZIP) transcription factor that plays an important role in the regulation of lineage-specific hematopoiesis. MAFB gene mutation does not contain introns. The abnormal function of MAFB has been implicated in development of multiple myeloma, myeloid leukemia and multicentric carpotarsal osteolysis. Approximately 40% of multiple myeloma neoplasms have IgH translocations involving five recurrent chromosomal patterns: 11q13 (CCND1), 4p16(FGFR/MMSET), 16q23(MAF), 6p(CCND3) and 20q11(MAFB).

Table 9.133 Multiple myeloma tumors having 14q32 IgH locus translocations involving five recurrent chromosomal patterns

14q32 IGH Locus Translocations involving Recurrent Chromosomal Patterns	Frequency
Cyclins D	
▪ 11q13(CCND1) ▪ 6p21(CCND3)	20%
B-ZIP transcription factor	
▪ 20q11(MAFB) ▪ 16q23(MAF)	▪ 2% ▪ 5%
Oncogenic receptor tyrosine kinase (FGFR3) and nuclear SET domain protein	
4p16(FGFR3/MMSET)	15%

breakpoints on 16p23 occur over a region 550–1350 kb centromeric to MAF. Overexpression of c-MAF oncogenic transcription factor is demonstrated in 50% of multiple myeloma cases. Expression and stability of c-MAF transcription factor is finely tuned by several signaling pathways and the ubiquitin proteasome system. Inhibition of the signaling pathways and the ubiquitin proteasome system downregulate expression of c-MAF transcription factor.

Chromosomal Translocation t(6;14)

Chromosomal translocation t(6;14) results in overexpression of cyclin D3 mRNA in 3% cases of multiple myeloma. Using microarray analysis, elevated levels of cyclin D3 mRNA have been demonstrated in multiple myeloma cases by fluorescence *in situ* hybridization (FISH).

Chromosomal Translocation t(14;20)

Chromosomal translocation t(14;20) involves IgH gene and results in overexpression of MAFB transcription

factor in 1% cases of multiple myeloma, which like MAF encodes B-ZIP transcription factor. But in contrast to chromosomal translocation t(14;16), MAFB translocations have structural features that indicate these are secondary translocations.

Gain and Loss of Chromosomal DNA Content

Measurement of DNA content by flow cytometry and cytogenetic techniques have confirmed that all multiple myeloma cases are aneuploid.

- According to ploidy status, multiple myeloma cases have been categorized in two groups by cytogenetic analysis: (a) hyperdiploid group (>46/47 chromosomes) and (b) non-hyperdiploid group comprising hypodiploid (<44/45 chromosomes), pseudodiploid (44/45 to 46/47 chromosomes) and tetraploid (>74 chromosomes).
- Approximately 40% of multiple myeloma neoplasms have IgH translocations involving five recurrent chromosomal patterns: 11q13 (CCND1), 4p16 (FGFR/MMSET), 16q23 (MAF), 6p (CCND3) and 20q11 (MAFB).
- Monosomy/deletion 13 and gains on 1q occur predominantly in the non-hyperdiploid multiple myeloma cases. On the other hand, hyperdiploid group is associated with recurrent trisomies involving odd chromosomes (3, 5, 7, 9, 11, 15, and 19) and with a low frequency in structural chromosomal abnormalities.
- The deletion of chromosome 13 is the most common monosomy demonstrated in 40% of newly diagnosed multiple myeloma cases. This chromosomal 13 monosomy demonstrates strong association with t(4;14) and t(14;16), deletion of 17p and gains on 1q.
- Chromosomal 17p deletion includes loss of TP53 gene in 5–10% cases of multiple myeloma, which is also associated with extramedullary multiple myeloma.
- Chromosome 1 abnormality (1q gains as a result of tandem duplications and jumping duplications of the chromosome 1q band) is the most common in multiple myeloma cases demonstrated by conventional cytogenetics, fluorescence *in situ* hybridization (FISH) and comparative genomic hybridization. Recently, frequent 1p losses especially 1p22 and 1p32 deletions have been demonstrated in multiple myeloma cases.

Epigenetic Modifications

Little is known about the epigenetic changes involved in the pathogenesis of multiple myeloma. The most important epigenetic change demonstrated includes global DNA hypomethylation and gene-specific DNA hypermethylation in multiple myeloma as compared to monoclonal gammopathy of undetermined significance (MGUS).

Late Recurrent Genetic Mutations

Based on the key landmark analysis, a number of recurrent genetic mutations have been identified in multiple myeloma such as Myc, K-RAS, N-RAS, TP53, and BRAF genes involved in the progression of multiple myeloma.

- Dysregulation of Myc is a pattern for secondary chromosomal translocations in multiple myeloma, which corresponds to complex secondary nonreciprocal chromosomal translocations and insertions of different chromosomes.
- Activated RAS (K-RAS, N-RAS) gene mutations are considered molecular markers involved in the progression of multiple myeloma in >75% cases. TP53 inactivation results in progression of the disease.
- Methylation is an epigenetic change, that inactivates tumor suppressor genes such as CDKN2B and CDKN2A, which have been demonstrated in advanced extramedullary disease of multiple myeloma.

Dysregulation of Cyclin D Genes

Dysregulation of cyclin D genes is a potential unifying event in the pathogenesis of multiple myeloma. IgH translocations induce upregulation of different oncogenes resulting in increase unrestricted proliferation of clonal plasma cells in multiple myeloma.

- Gene profiling analysis has revealed that expression of CCND1, CCND2 and CCND3 is enhanced in all cases of multiple myeloma.
- About 25% cases of multiple myeloma demonstrate overexpression of one of the cyclins, which can be triggered by IgH translocation. IgH translocation t(11;14) dysregulates CCND1 and t(6;14) dysregulates CCND3. IgH translocation indirectly involves MAF and MAFB genes, which encode transcription factor that targets cyclin D2.
- Approximately 40% cases of multiple myeloma demonstrate increased cyclin D1 through biallelic CCND1 dysregulation without apparent t(11;14). Remaining multiple myeloma cases with t(4;14) demonstrate increased expression of cyclin D2.

Dysregulation of MicroRNAs

MicroRNAs (MiRNAs) are small noncoding RNAs that regulate gene expression at the post-transcription level involved in cellular growth and differentiation; Different studies have demonstrated that dysregulation of miRNAs is present in clonal plasma cells as compared to normal plasma cells. Several miRNAs participate in the pathogenesis of multiple myeloma. Recently

abnormal expression of miRNAs has been demonstrated in multiple myeloma, where miRNAs have been found deeply dysregulated and act as oncoproteins or tumor suppressors.

MOLECULAR PATHOGENESIS

Multiple myeloma develops through a multistep transformation of normal plasma cells to monoclonal gammopathy of undetermined significance (MGUS), which results in immortalization of plasma cells and subsequently transformation to smoldering multiple myeloma and active multiple myeloma, where clonal plasma cells cause end-organ damage.

- Cytogenetic study using fluorescence *in situ* hybridization and SNP-based mapping analysis and whole genome sequencing have demonstrated genetic abnormalities at MGUS stage.
- In monoclonal gammopathy of undetermined significance (MGUS) non-IgM (IgG or IgA; M protein <30 g/L), there is increased risk of progression to multiple myeloma, amyloidosis or plasmacytoma, i.e. 0.5–1.0% per year.
- In monoclonal gammopathy of undetermined significance (MGUS) light chain, there is increased risk for progression to multiple myeloma, amyloidosis or plasmacytoma, i.e. 0.3% per year.

Interaction between Clonal Plasma Cells and their Microenvironment

Interactions between clonal plasma cells (myeloma cells) and bone marrow stromal cells (BMSCs) in the bone marrow play an important role in the pathogenesis of multiple myeloma. Clonal plasma cells adhere to extracellular matrix (ECM) and bone marrow stromal cells through series of cell adhesion molecules.

Clonal Plasma Cells Adhere Through Adhesion Molecules

Bone marrow stromal cells express vascular cell adhesion molecule 1 (**VCAM-1**) and intercellular adhesion molecule 1 (**ICAM-1**). Clonal plasma cells express adhesion molecules of β1-integrin family such as VLA-4, VLA-5 and VLA-6 also called CD49d, CD49e and CD49f, respectively.

Chemotaxis and Homing of Clonal Plasma Cells

In addition, bone marrow stromal cells synthesize stromal derived factor 1 (SDF-1), that binds to CXCR4 on the surface of clonal plasma cells and induce both chemotaxis of myeloma cells and upregulation of cell adhesion molecules such as VLA-4, VLA-5 and VLA-6. Homing of clonal plasma cells in the bone marrow is further facilitated through other cell adhesion molecules (CD138, CD38, CD44 and CD106) expressed by clonal plasma cells.

Induction of Transcription Factors and Cytokines Synthesis

Binding of clonal plasma cells to the bone marrow microenvironment results in induction of transcription factors and synthesis of various cytokines such as IL-6, IL-21, TNF-α, insulin-like growth factor 1 (IGF-1), stromal derived factor 1 (SDF-1) and vascular endothelial growth factor 1 (VEGF-1) by clonal plasma cells and/or bone marrow stromal cells.

- The cytokines induce signaling pathways (e.g. RAF/MEK/MAPK, P13K/AKT, nuclear factor kappa B (NF-κB) and JAK/STAT), that induce unrestricted proliferation of clonal plasma cells and prevent apoptosis.
- RAF/MEK/MAPK signaling pathway activated by RAS protein results in unrestricted proliferation of clonal plasma cells.
- Simultaneously, RAS induced JAK/STAT signaling pathway and cytokines induced P13K/AKT signaling pathway prevent apoptosis of the clonal plasma cells. Signaling pathways involved in pathogenesis of multiple myeloma are shown in Fig. 9.111.

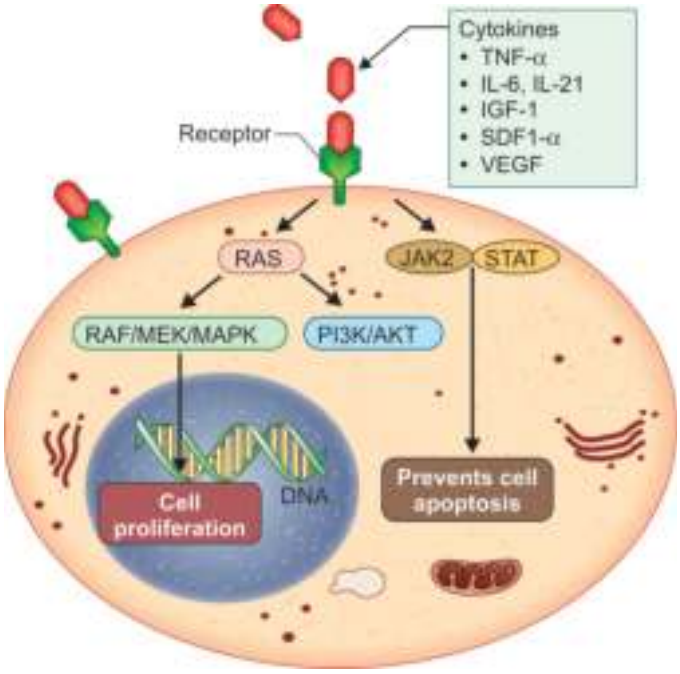

Fig. 9.111: Schematic representation of signaling pathways in the pathogenesis of multiple myeloma. Signaling pathways involved in pathogenesis of multiple myeloma. Binding of cytokines to the bone marrow microenvironment induces the transcription and synthesis of various cytokines by plasma cells and stromal cells; this trigger signaling pathways (REF/MEK/MAPK, PI13K/AKT, NF-κB and JAK2/STAT) that promote cell proliferation and prevent apoptosis. These signaling pathways are also potential targets for therapeutic intervention. In addition, cytokines modulate the synthesis of additional adhesion molecules, which, in a vicious circle further enhance cell adhesion.

Development of Drug Resistance Phenotype

Adhesion of clonal plasma cells to the bone marrow microenvironment induces a cell-mediated drug resistance phenomenon by three mechanisms: (a) cell cycle arrest at G1 by upregulation of p27, an inhibitor of cyclin-dependent kinases, (b) inhibition of apoptosis via overexpression of FLIP-L, an endogenous inhibitor of FAS (CD95) and (c) protection of clonal plasma cells from initial drug-induced DNA damage (double-stranded breaks) by reducing topoisomerase activity.

CLINICAL FEATURES

Patient with multiple myeloma presents with bone pain, pathological fractures, anemia, weakness, recurrent infections, hypercalcemia, spinal cord compression and renal failure.

- In 30% of cases, multiple myeloma is detected through routine blood screening when patients are evaluated for unrelated problems.
- In 30% of patients, multiple myeloma is diagnosed after a pathological fracture in the axial skeleton. Bone marrow involvement is multifocal and generalized in these cases. Osteolytic lesions and focal masses of clonal plasma cells are present in the sites of active hematopoiesis. Progression to advanced multiple myeloma disease involves extramedullary organs.
- Many patients with multiple myeloma present with complain of bone pain especially in the back region, long bones, skull and/or pelvis, nonspecific constitutional symptoms related to hyperviscosity and hypercalcemia.
- Diagnosis of multiple myeloma is based on the combination of clinical, morphologic features, radiological, and immunological findings by demonstration of clonal plasma cells in the bone marrow, osteolytic lesions by imaging techniques and increased M protein in serum and/or urine.
- Serum electrophoresis demonstrates M spike. Bence-Jones proteins are either κ or δ light chains excreted in the urine. These assays are used for monitoring therapeutic response and prognostic outcome.
- The interaction of clonal plasma cells (myeloma cells) and the bone marrow microenvironment favors multiple myeloma tumor growth and clinical manifestations. Clonal plasma cells synthesize excessive monoclonal protein, that is responsible for hyperviscosity, amyloidosis and renal failure.
- Clonal plasma cells fail to synthesize normal immunoglobulins responsible for life-threatening recurrent infections.
- Bone marrow infiltration by clonal plasma cells (myeloma cells) causes anemia and osteolytic lesions, i.e. bone destruction associated with hypercalcemia and bone pain. In addition to nephrotoxic effect of monoclonal protein (light chains), hypercalcemia and recurrent infections also contribute in the pathogenesis of renal failure.
- Clinical manifestations of multiple myeloma are given in Table 9.134. Schematic representation of clinical features of multiple myeloma and serum protein electrophoresis showing 'M-spike' in the gamma region are shown in Fig. 9.112. Schematic representation of clinical manifestations in a case of multiple myeloma is shown in Fig. 9.113.

Table 9.134 Clinical manifestations of multiple myeloma

Multiple Myeloma Characteristics	Clinical Manifestations	
Osteolytic bone lesions	▪ Bone pain ▪ Hypercalcemia	▪ Pathologic fractures
Bone marrow infiltration by myeloma cells	▪ Thrombocytopenia (bleeding tendencies) ▪ Paraprotein coating platelets (platelet function impaired)	▪ Anemia (fatigue and pallor) ▪ Neutropenia (decreased resistance to infection)
Failure to normal immunoglobulin synthesis	▪ Recurrent infections due to *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Escherichia coli* and *Haemophilus influenzae* ▪ Cellular immunity is relatively unaffected	
Plasma cell synthesis of paraprotein	▪ Hyperviscosity of body fluids	▪ Amyloid deposits in kidney and heart (AL)
Renal failure	▪ Deposition of light chains in the tubules known as myeloma kidney (most common cause of death) ▪ Hypercalcemia leads to nephrocalcinosis	▪ Hyperuricemia is directly toxic to renal tubules ▪ Bence-Jones protein clogs up glomeruli and directly toxic to renal tubules ▪ Amyloid deposit occurs in kidney
Proteinuria	Bence-Jones protein in urine	
Diagnostic testing	▪ Serum-free light chains ▪ Cytogenetic study	▪ Immunophenotype ▪ Immunohistochemistry

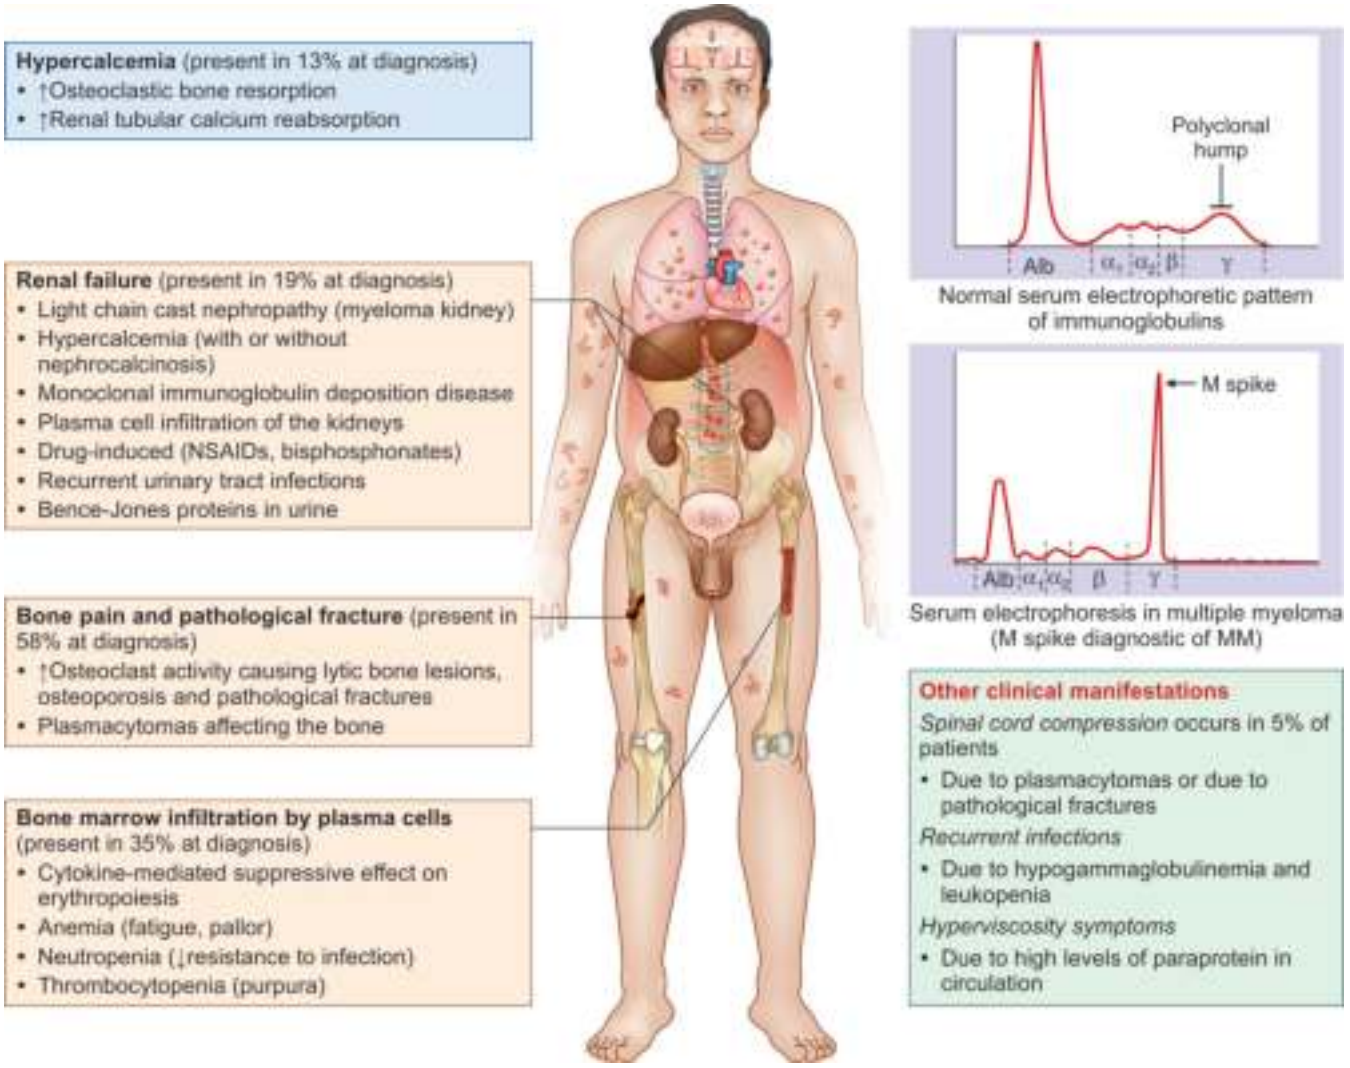

Fig. 9.112: Schematic representation of clinical features and serum electrophoresis in multiple myeloma. Diagnostic triad of multiple myeloma is characterized by presence of >10% clonal plasma cells in the bone marrow, osteolytic lesions, and presence of monoclonal protein (paraprotein) in the blood and urine. On serum electrophoresis, presence of monoclonal protein is characterized by a sharp, well-defined 'M spike' with a single heavy chain and a similar band with a κ- or λ-light chain. The absolute amount of monoclonal immunoglobulin, involved κ- or λ-light chain and κ-/λ-light chains ratio is followed by determine multiple myeloma response to therapy and progression of the disease. A broad diffuse band with one or more heavy chains and κ- or λ-light chains characterizes a polyclonal protein.

Skeletal Disease

Skeletal disease is one of the hallmarks of multiple myeloma. Osteolytic lesions begin in the medullary cavity, erode cancellous bone and progressively destroy the cortex. Bone lesions are associated with bone pain, pathologic fractures and hypercalcemia. Serum calcium is increased in multiple myeloma (IgG, IgA, IgD and Bence-Jones myelomas). Hypercalcemia results in confusion, lethargy, constipation, polyuria and renal failure.

Vertebral Column

Vertebral column is the most common site of osteolytic lesion especially in lumbar region of multiple myeloma cases. Osteolytic lesions affecting other bones in decreasing frequency include ribs, sternum, skull, pelvis, femur, clavicle and scapula. IgG and Bence-Jones myeloma produce osteolytic lesions. IgD produces extraosseous lesions. Bone pain is aggravated by movements in 65% of cases and sometimes associated with loss of vertebral height due to vertebral collapse.

Spinal Cord Compression

Spinal cord compression occurs in multiple myeloma patients due to compressed vertebral fracture and diffuse osteopenia. The symptoms that should alert clinicians to consider spinal cord compression are back pain, weakness, numbness, or dysesthesias in the extremities.

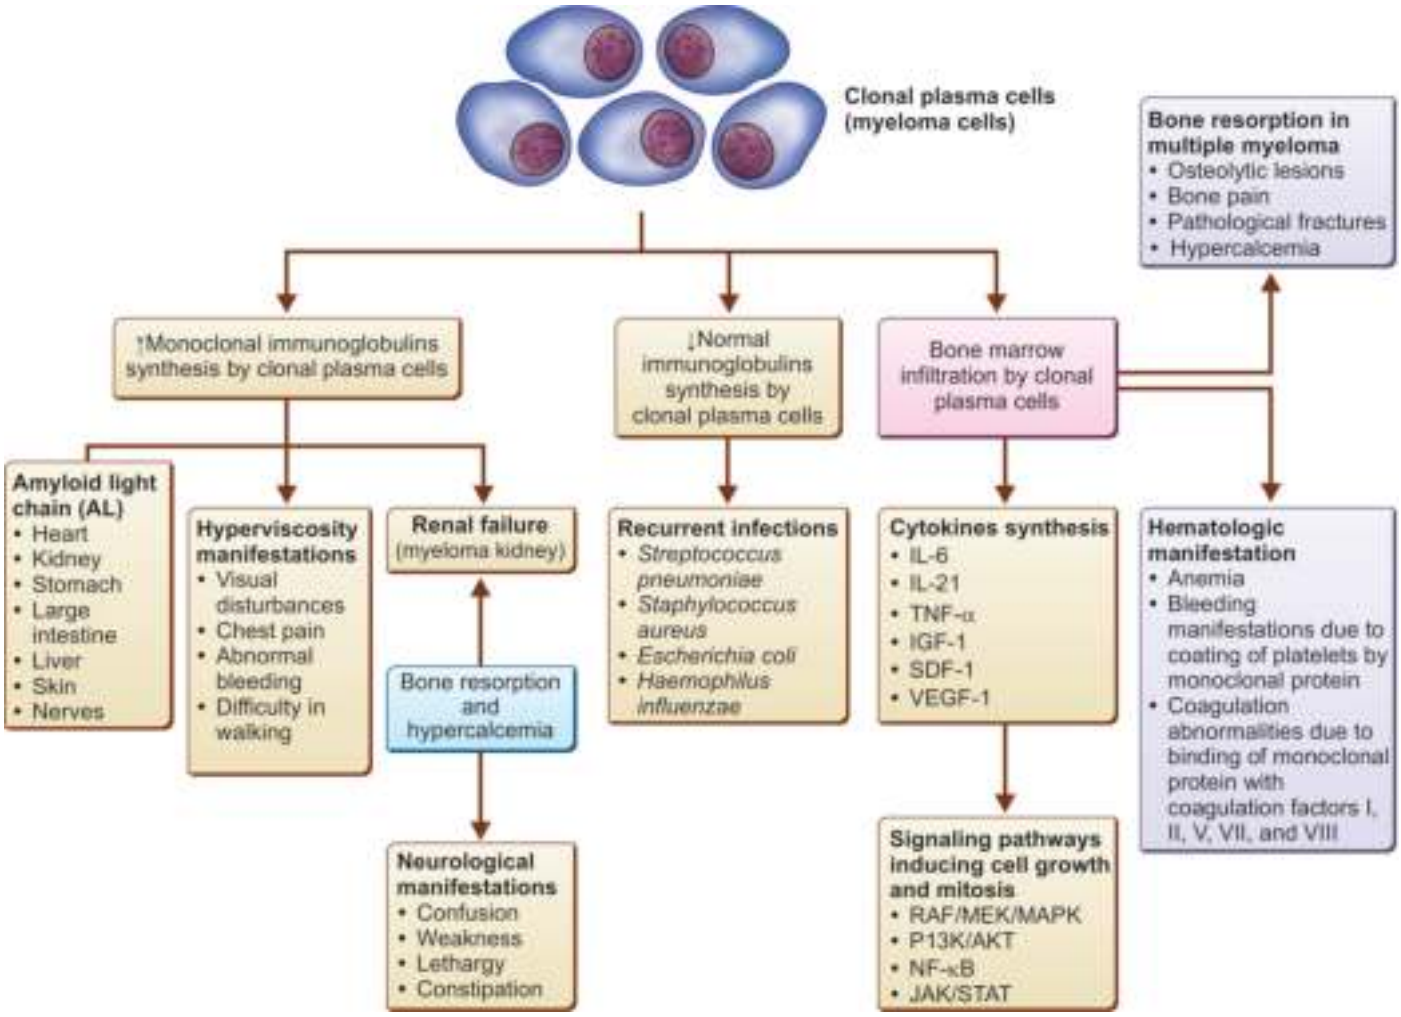

Fig. 9.113: Schematic representation of clinical manifestations in a case of multiple myeloma. Patient presents with bone pain commonly in lower back region, hypercalcemia, pathological fractures involving axial skeleton, anemia, bleeding manifestations, recurrent infection, spinal cord compression and renal failure.

Because spinal cord compression in multiple myeloma occurs at multiple levels, comprehensive evaluation of the spine is warranted. Patients who are ambulatory at the start of therapy have the best likelihood of preserving spinal cord function and avoiding paralysis.

Imaging Techniques to Detect Osteolytic Lesions in Multiple Myeloma

Osteolytic lesions are demonstrated by conventional radiography, MRI and PET-CT scan. Radiograph reveals rounded punched out osteolytic defects measuring 1–4 cm in diameter and diffuse osteopenia. Radiograph of skull demonstrates multiple punched out osteolytic lesions in a patient of multiple myeloma is shown in Fig. 9.114. Pathogenesis of bone disease in multiple myeloma because of increased synthesis of osteoclastic activating factors (OAFs) is shown in Fig. 9.115.

- Osteolytic lesions in multiple myeloma are mediated by an imbalance between osteoclastic activity of osteoblastic activity.
- Interaction of clonal plasma cells (myeloma cells) with bone marrow stromal cells and other cells in the bone marrow microenvironment induces the synthesis of numerous osteoclast-activating factors (OAFs). RANK-L, macrophage inflammatory protein-1α (MIP-1α) (also known as CCL3), vascular endothelial growth factor (VEGF), activin A, hepatocyte growth factor (HGF), interleukin 3 (IL-3), interleukin 7 (IL-7), interleukin 6 (IL-6), interleukin 1β (IL-1β), tumor necrosis factor α (TNF-α) and macrophage inflammatory protein-3α (MIP-3α).
- Two of the most important osteoclast-activating factors (OAFs) are **RANK-L** (receptor activator of NF-κB ligand) and macrophage inflammatory protein-1α **(MIP-1α)**.

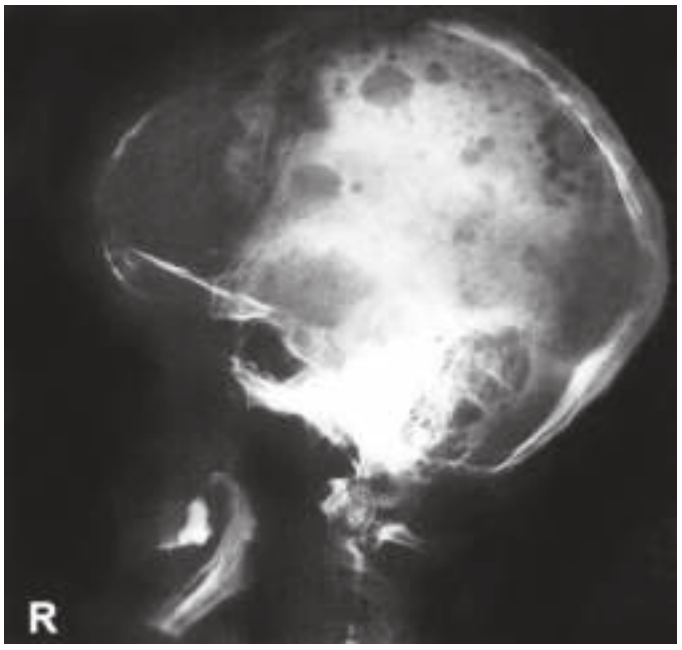

Fig. 9.114: Radiograph of skull shows osteolytic lesion in a case of multiple myeloma. It shows multiple punched-out osteolytic lesions giving 'motheaten appearance'. Skeletal disease is one of the hallmarks of multiple myeloma. Osteolytic lesions begin in the medullary cavity, erode cancellous bone and progressively destroy the cortex. Bone lesions are associated with bone pain, pathologic fractures and hypercalcemia. Vertebral column is the most common site especially in lumbar regions. Osteolytic lesions affecting other bones in decreasing frequency include ribs, sternum, skull, pelvis, femur, clavicle and scapula. IgG and Bence-Jones myeloma produce osteolytic lesions.

Pathology Pearls: Skeletal Disease in Multiple Myeloma—Pathophysiology

- Some cancers including multiple myeloma produce cytokines, which can cause resorption of bone (osteolytic activity) or cytokines that induce the proliferation of osteoblasts (osteoblastic activity), which are responsible for new bone formation.
- Cytokines are soluble proteins produced by a wide variety of hematopoietic and nonhematopoietic cells.
- Pathological fractures occur at sites of osteolytic bone lesions.
- Radionucleotide scans are very informative when osteoblastic lesions are being investigated.
- Osteolytic lesions are best detected by plain radiography or magnetic resonance imaging (MRI).

Increased Skeletal Osteoclastic Activity

In multiple myeloma, there is marked osteoclastic activity and bone resorption by following mechanisms:

Role of RANK-L (Receptor Activator of NF-κB Ligand)

- Receptor activator of NF-κB ligand (RANK-L) is a transmembrane molecule in bone marrow stromal cells/osteoprogenitors.
- RANK-L binds to functional receptor RANK on osteoclasts resulting in activation of osteoclasts and stimulation of resorption of bone. Osteoprotegerin (**OPG**) synthesized by bone marrow stromal cells blocks the RANK-L osteoclastic activity.
- Therefore, osteoclastic activity is regulated by a delicate imbalance between RANK-L present on bone marrow stromal cells and osteoprotegerin.
  - Under physiologic state, osteoprotegerin levels are higher than RANK-L.
  - RANK-L levels are higher than osteoprotegerin in multiple myeloma cases.

Role of Macrophage Inflammatory Protein-1α (MIP-1α)

- Macrophage inflammatory protein-1α (MIP-1α) is a potent stimulator of osteoclasts formation by two mechanisms: (a) MIP-1α increases the activity of RANK-L and (b) MIP-1α stimulates osteoclast precursors to differentiate into mature osteoclasts, whereas IL-3 inhibits formation of osteoclasts. Chemokines such as IL-7, TNF-α and IL-1β indirectly stimulate osteolytic activity by inducing RANK-L.
- Other osteoclast activating factors synthesized by clonal plasma cells such as IL-6, VEGF, HGF and activin A further augment osteoclastic activity and bone resorption.

Inhibition of Skeletal Osteoblastic Activity

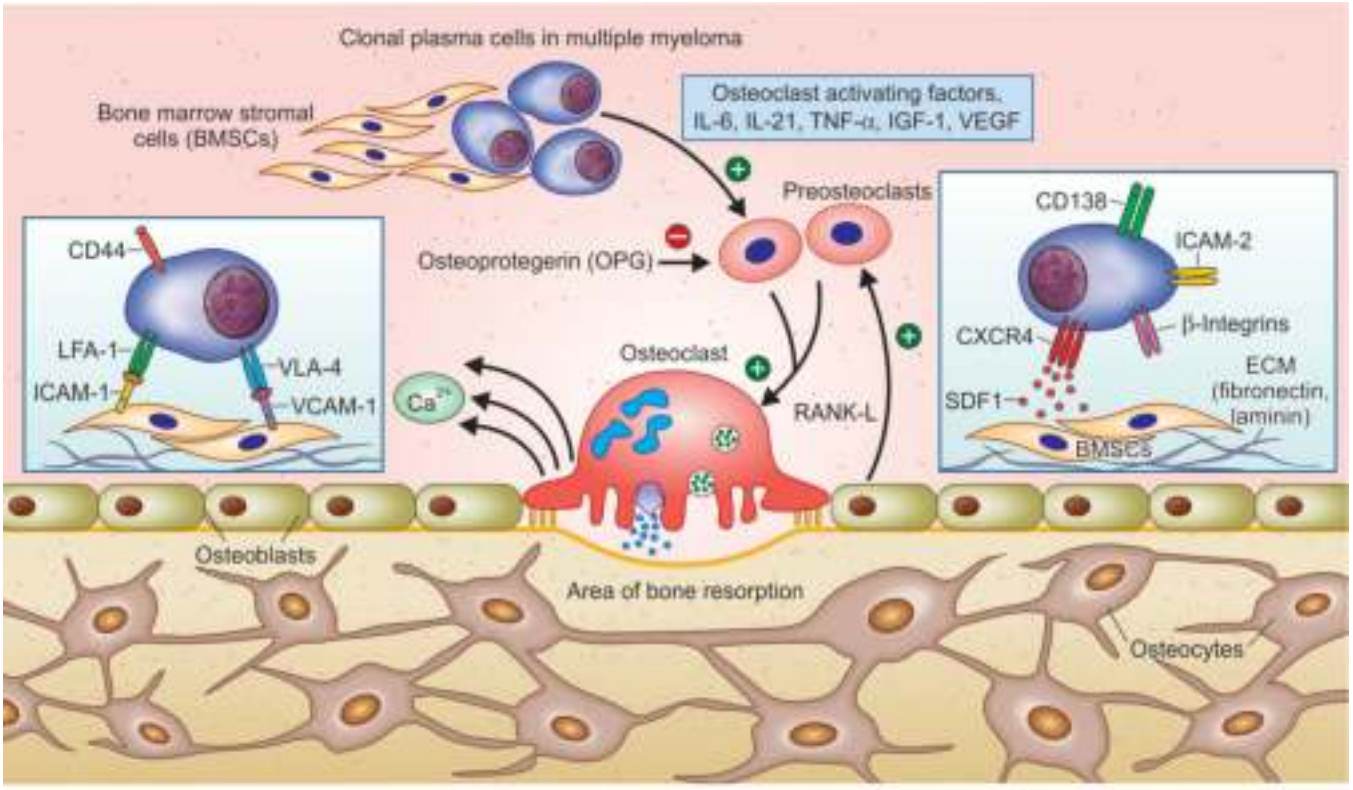
In multiple myeloma, in addition to increased osteoclast activation, there is inhibition of osteoblast formation mediated by soluble factors and direct cellular interactions between the clonal plasma cells and bone marrow stromal cells by following mechanisms.

Wnt/Bone Morphogenetic Protein Signaling Pathways

- The Wnt/bone morphogenetic protein (BMP) signaling pathways induce transcriptional factors, which participate in the osteogenic differentiation of mesenchymal stem cells to mature bone forming osteoblasts.
- RUNX2, transcriptional factor regulates osteoblastic differentiation. In multiple myeloma, osteolytic lesions demonstrate reduced RUNX2 activity.

Soluble Factors Synthesis by Clonal Plasma Cells

- Clonal plasma cells (myeloma cells) and bone marrow stromal cells synthesize numerous soluble factors that inhibit osteoblast differentiation and/or function of Wnt/bone morphogenetic protein signaling pathways.
- Various soluble factors inhibiting Wnt signaling pathways include DKK1, sclerostin and soluble frizzled related proteins 2/3 (sFRP-2/3).
  - Soluble factors inhibiting bone morphogenetic protein (BMP) include activin A, transforming growth factor-β (TGF-β) and hepatocyte growth factor (HGF).
  - Cytokines indirectly inhibiting osteoblastic differentiation include IL-7, IL-3 and TNF-α.



Skeletal lesions in multiple myeloma: pathogenesis, clinical manifestations and diagnosis

Osteoclastic activity in multiple myeloma

- RANK-L + RANK on osteoclasts → ↑Osteoclastic activity → Osteolytic lesions
- Chemokines (IL-7, TNF-α and IL-1β) stimulate RANK-L → ↑Osteoclastic activity → Osteolytic lesions
- MIP-1α stimulates RANK-L → ↑Osteoclastic activity → Osteolytic lesions
- MIP-1α stimulates RANK-L → ↑Differentiation of osteoclast precursors into mature osteoclasts → ↑Osteoclastic activity → Osteolytic lesions
- Osteoprotegerin/osteoclastogenesis inhibitory factor blocks RANK-L activity → ↓Osteoclastic activity

Skeletal lesions and manifestations

- Patients present with osteolytic bone lesions in decreasing frequency: Vertebral column in lumbar region, ribs, sternum, skull, pelvis, femur clavicle and scapula, bone pain, pathologic fracture and increased serum calcium levels (hypercalcemia)
- Presence of ≥1 osteolytic lesions on conventional radiograph, CT scan, PET-CT scan

Diagnosis of multiple myeloma

- Diagnosis of multiple myeloma is based on the combination of clinical, morphological, radiological and immunological findings by demonstration of clonal plasma cells in the bone marrow, osteolytic lesions by imaging techniques and increased M protein in serum and/or urine

Fig. 9.115: Pathogenesis of bone disease in multiple myeloma occurs as a result of synthesis of osteoclastic activating factors. Osteolytic lesions are mediated by an imbalance between osteoclastic activity of osteoblastic activity. Interaction of clonal plasma cells (myeloma cells) with bone marrow stromal cells and other cells in the bone marrow microenvironment induces the synthesis of numerous osteoclast-activating factors such as RANK-L, macrophage inflammatory protein-α (MIP-α) (also known as CCL3), vascular endothelial growth factor (VEGF), activin A, hepatocyte growth factor (HPG), interleukin 3 (IL-3), interleukin 7 (IL-7), interleukin 6 (IL-6), interleukin-1β, (IL-1β), tumor necrosis factor-α (TNF-α) and macrophage inflammatory protein-3α (MIP-3α). Two of the most important osteoclast-activating factors are RANK-L (receptor activator of NF-κB ligand) and macrophage inflammatory protein-1α (MIP-1α).

Hypercalcemia

Osteolytic skeletal lesions result in hypercalcemia in the advanced stage of multiple myeloma due to marked increase in osteoclastic bone resorption. Confusion, lethargy, bone pain, nausea, polydipsia, constipation, polyuria, and renal failure are the presenting symptoms of hypercalcemia in 30% of patients with multiple myeloma. In multiple myeloma, hypercalcemia does not adversely affect survival of multiple myeloma patients.

Recurrent Infections

Clonal plasma cells (myeloma cells) fail to synthesize normal immunoglobulins. Patients suffer from recurrent infections with *Streptococcus pneumoniae, Staphylococcus aureus, Escherichia coli* and *Haemophilus influenzae*. Cellular immunity is relatively unaffected. The absence of immunoglobulins (antibodies) directed against the bacterial capsule limits the ability of phagocytic cells to ingest and kill the bacteria.

Bleeding Diathesis, Severe Anemia and Easy Fatigue

Monoclonal protein synthesized by clonal plasma cells (myeloma cells) coats the platelets resulting in impairment of platelet functions and bleeding tendencies from gums, gastrointestinal tract and respiratory tract. Monoclonal protein binds with coagulation factors I, II, V, VII and VIII resulting in coagulation abnormalities. Patients present with easy fatigue and anemia as a result of proliferation of clonal plasma cells in the bone marrow, decreased hematopoiesis, and bleeding diathesis as a result of impaired platelet function.

Organs Damage

In multiple myeloma, excessive synthesis of light chains may lead to the amyloid light (AL) form of amyloid deposition in kidney, liver, spleen, lymph nodes and other organs. Renal amyloidosis occurs in Bence-Jones myeloma, IgG and IgD myeloma. IgD myeloma causes heavy proteinuria. Nephrotoxic effect of monoclonal protein leads to myeloma kidney. Monoclonal protein form casts in the renal tubules and induces giant cell reaction resulting in blockage of tubules and renal failure.

Cryoglobulinemia

In few multiple myeloma cases, monoclonal protein synthesized by clonal plasma cells behaves like cryoglobulins resulting in tingling sensation, numbness, and skin rashes.

Hyperviscosity Syndrome

Hyperviscosity syndrome may be associated with symptoms in multiple myeloma such as generalized malaise, infections, fever, paresthesia, sluggish motor functions and sensory losses.

- Patient presents with headache, somnolence, easy bruising and hazy vision.
- Occasionally, hyperviscosity can cause cerebral stroke or myocardial infarction. Epistaxis may be a presenting symptom of multiple myeloma with a high tumor burden.

Secondary Changes in the Bone Marrow

Due to infiltration of clonal plasma cells, secondary changes in the bone marrow are sometimes observed in cases of multiple myeloma. Interstitial acidophilic changes in bone marrow reflect hypoproteinemia, amyloid deposition and myelofibrosis. Myelofibrosis is observed in 10% of multiple myeloma cases. Genetic abnormality in FGFR3-IgH has been detected by fluorescence *in situ* hybridization (FISH).

LABORATORY DIAGNOSIS

Multiple myeloma accounts for approximately 10% of hematologic malignancies. The initial evaluation to confirm diagnosis of multiple myeloma includes clinical history, blood urine examination, bone marrow aspiration, bone marrow trephine biopsy, biochemical and immunological findings, conventional radiographs, MRI, CT scan, PET scan, and molecular genetic studies.

Clinical History

Patient presents with bone pain, backache, pathologic fractures of axial skeleton, weakness, anemia, recurrent infections (often pneumococcal), hypercalcemia, spinal cord compression and renal failure.

Physical Examination

Patient usually appear lethargic and fatigued. Physical examination reveals pallor, purpura, hepatosplenomegaly, bony tenderness, carpel tunnel syndrome, and signs of compression. Any of these physical findings may warrant further evaluation.

Skeletal Survey

- Conventional radiograph, computed tomography scan, or whole-body MRI or whole-body low-dose CT scan demonstrate osteolytic lesions in skull and axial skeleton and pathologic fracture.
- Fluorodeoxyglucose (FDG) positron emission tomography scan demonstrates areas of active multiple myeloma disease.

Molecular Genetic Alterations

Bone marrow aspirate and bone marrow trephine biopsy, cytogenetic study, or fluorescence *in situ* hybridization (FISH) and flow cytometry are performed to evaluate hyperploidy, chromosomal del 13, del 17p, t(4;14), t(14;16), t(11;14) and 1q21 amplification and aberrant plasma cell markers.

Pathology Pearls: Dutcher Bodies and Russell Bodies in Clonal Plasma Cells in Multiple Myeloma

- Dutcher bodies and Russell bodies are often found in clonal plasma cells.
- Dutcher body is an inclusion structure in the nucleus of clonal plasma cells in multiple myeloma.
- Russell body is an inclusion structure in the cytoplasm formed by immunoglobulin deposition. Cell with abundant grape-like cytoplasmic inclusions of immunoglobulin deposits is termed a Mott cell.
- Unlike Dutcher bodies, Russell bodies are sometimes found in reactive plasma cells; therefore, their presence is not definitive for neoplastic lesion.

Laboratory Diagnosis of Multiple Myeloma

- Diagnosis of multiple myeloma requires ≥10–30% clonal plasma cells in bone marrow or bone marrow trephine biopsy proven plasmacytoma plus evidence of one or more multiple defining events (MDE): CRAB (hypercalcemia, renal failure, anemia, or lytic bone lesions, features related to the plasma cell disorder, bone marrow clonal plasmacytosis ≥60%, serum involved/uninvolved free light chains (FLCs) ratio ≥100% or greater than focal lesion in bone on magnetic resonance imaging (MRI).

Blood Tests

- Hemoglobin is low in multiple myeloma patients such as <12 g/dl in women and <14 g/dl in men (i.e. <2 g/dl below normal range).
- Erythrocyte sedimentation rate (ESR) is increased often >100 mm/1st hr.
- Serum blood urea nitrogen (BUN), creatinine is elevated in renal failure in multiple myeloma.
- Serum calcium elevated due to osteolytic lesions.
- Serum β_2-microglobulin is a light chain gene of the class 1 histocompatibility antigen expressed on the surface of all nucleated cells. Increase in β_2-microglobulin in multiple myeloma reflects the tumor mass, which is excreted by the kidneys. It is most often raised in renal failure; and higher levels are associated with poor prognosis.
- Serum paraprotein levels are raised.
  - Serum paraprotein levels are increased with elevated globulins.
  - Serum paraprotein concentration is raised with suppression of normal immunoglobulin.
  - Paraprotein is IgG in 70% cases, IgA in 20%, IgM (uncommon); IgD and IgE rare.
  - Serum light chain (either κ or λ) is increased.
  - In immunofixation of serum, antibodies to IgG, IgD, IgE, κ and δ are used to show the paraprotein has a single light chain.
- Serum lactic acid dehydrogenase (LDH) is increased level not specific for diagnosis, but used as prognostic indicator.
- Serum quantitative immunoglobulins, protein electrophoresis, immunofixation, and free light chain assay are performed in multiple myeloma patients.
- Serum electrophoresis demonstrates monoclonal immunoglobulins (heavy chains and κ or δ light chains). M-spike is demonstrated in the γ-region in 80% of cases and occasionally in α or β regions). It demonstrates monoclonal IgG (50%), IgA (25%), IgD (10%) and rarely IgM or IgE.

Urine Analysis for Bence-Jones Proteins

- Urine electrophoresis is essential to demonstrate κ or λ light chains irrespective of serum electrophoresis study.
- Urine contains significant quantity of immunoglobulin κ or λ light chains, known as Bence-Jones proteins in 60–70% of cases. On heating urine specimen between 50 and 60°C, Bence-Jones proteins appear in the urine and disappear on temperature below 50°C and heating urine specimen above 60°C.
- Twenty-four hours urine analysis is done for total protein and protein electrophoresis with immunofixation.

Peripheral Blood Smear Examination

Red blood cells

- Peripheral blood smear shows '**rouleaux formation**' with a bluish background staining due to increased paraprotein concentration. Rouleaux formation of red blood cells in Giemsa-stained peripheral blood smear in multiple myeloma is shown in Fig. 9.116.
- Red blood cells are arranged in rolls and stacks (rouleaux formation), that happens with abnormal or increased plasma proteins particularly fibrinogen and globulins.
- Red blood cells can be dispersed by mixing red blood cells with saline. Rouleaux formation can be demonstrated in multiple myeloma, monoclonal gammopathy of undetermined significance (MGUS), amyloidosis, lymphomas, inflammation and infections. Leukoerythroblastic picture may be demonstrated.

White blood cells

- Clonal plasma cells (myeloma cells) fail to synthesize normal immunoglobulins resulting in recurrent infections.
- Leukocytosis is demonstrated because of recurrent infections.
- Patient with multiple myeloma may rarely develop plasma cell leukemia.
- The International Myeloma Working Group has defined the diagnostic criteria for plasma cell leukemia (PCL) by the presence of ≥20% circulating clonal plasma cells on peripheral blood and plasma cell count $>2 \times 10^9$/L may be too stringent. Organomegaly is common in plasma cell leukemia associated with unfavorable prognosis.
- **Peripheral blood plasmacytosis** is demonstrated in viral infections, bacterial endocarditis, streptococcal infections, serum sickness, sarcoidosis, Waldenström's macroglobulinemia, severe burns and kwashiorkor.

Platelets

Platelet count is decreased (thrombocytopenia) because of bone marrow infiltration by clonal plasma cells, which can lead to increased bleeding and bruising.

Bone Marrow Smear Examination

- Multiple myeloma cells are classified into four types: mature, immature, pleomorphic, and plasmablastic.
  - There are three patterns in which multiple myeloma infiltrates bone marrow: nodular, interstitial and diffuse.
  - Dutcher bodies are highly specific to the clonal plasma cells.
  - On histochemical staining, CD138 marker is highly specific for plasma cells.
  - Multiple myeloma in Giemsa-stained bone marrow aspirate smear is shown in Fig. 9.117. Grading system of clonal plasma cells in multiple myeloma is given in Table 9.135.
- **Cellularity:** Bone marrow is hypercellular because of clonal proliferation of plasma cells. Myeloid, erythroid and megakaryocytic series are relatively decreased. Bone marrow smear demonstrates ≥10% of mature clonal plasma cells, immature clonal plasma cells, plasmablastic clonal plasma cells and pleomorphic clonal plasma cells. Some clonal plasma cells are multinucleated with abnormal morphology.

- **Mature clonal plasma cells:** Mature clonal plasma cells measure 20–30 μm in diameter with abundant cytoplasm and eccentrically placed nuclei with dense clumped chromatin giving cartwheel appearance.
- **Immature clonal plasma cells:** Immature clonal plasma cells contain eccentrically placed nucleus with diffuse fine chromatin and prominent nucleus and clear cytoplasmic droplets due to aggregation of immunoglobulins known as Russell bodies. Morphology of immature clonal plasma cells is indistinguishable from normal plasma cells except that their number is increased in multiple myeloma. Presence of immature cells in the bone marrow is associated with poor prognosis.
- **Plasmablastic clonal plasma cells:** Plasmablastic clonal plasma cell contains centrally placed large immature nucleus with reticular chromatin and prominent nucleolus with high nucleocytoplasmic ratio (*refer to* plasmablastic myeloma, Figs 9.106 and 9.107).
- **Pleomorphic clonal plasma cells:** Bone marrow aspirate smear contains multilobulated pleomorphic clonal plasma cells with gray-blue basophilic cytoplasm and nuclear blebs. Some cells show monocytoid like resemblance. Pleomorphic multiple myeloma in Giemsa-stained bone marrow aspirate smear is shown in Fig. 9.118.

Methyl Green Pyronine Special Stain for Plasma Cells

- Plasma cells can be stained by methyl green pyronine stain. Plasma cells can also be demonstrated by toluidine blue and azures.
- Methyl green component stains nucleus of plasma cell as blue-green and pyronine component stains cytoplasm as red.
- Conditions associated with increase in number of plasma cells in bone marrow.
- Various disorders associated with increase in number of plasma cells (rarely >10%) in the bone marrow include metastatic bone disease, Hodgkin disease, sarcoidosis, systemic lupus erythematosus, rheumatoid arthritis, tuberculosis, syphilis, cirrhosis, and aplastic anemia.

Bone Marrow Trephine Biopsy Examination

- The single most specific test is the bone marrow trephine biopsy, which demonstrates high number of clonal plasma cells ≥10–60%. Bone marrow trephine biopsy of multiple myeloma reveals soft red tumor with gelatinous consistency typically filling bony trabeculae.
- Histologic examination of bone marrow trephine biopsy shows sheets of clonal plasma cells looking morphologically like normal plasma cells with eccentrically placed nuclei and abundant pale cytoplasm. In some cases, clonal plasma cells can be poorly differentiated.
- Immunophenotyping plays important role in quantification of clonal plasma cells in bone marrow trephine biopsy specimens. CD138 and CD38 markers are helpful for quantifying clonal plasma cells for κ and λ light chains.
- Mature multiple myeloma (MM) in hematoxylin and eosin-stained bone marrow trephine biopsy section is shown in Fig. 9.119. Dutcher body in multiple myeloma in hematoxylin and eosin-stained bone marrow trephine biopsy section is shown in Fig. 9.120. Pleomorphic myeloma with bone marrow fibrosis in hematoxylin and eosin-stained bone marrow trephine biopsy section is shown in Fig. 9.121.

Immunophenotyping

- Flow cytometry demonstrates that clonal plasma cells contain monotypic cytoplasmic immunoglobulin and lack surface immunoglobulin in multiple myeloma.
- Clonal plasma cells typically express CD38 and CD138. Normal plasma cells never demonstrate aberrant expression of antigens. Expression of CD38 positive (Syndecan 1) on plasma cell population in multiple myeloma is shown in Fig. 9.122.
- In contrast to normal plasma cells, clonal plasma cells demonstrate aberrant expression of antigens, e.g. CD56, CD200, CD28, CD117, CD20 and CD52.
- Abnormal expression of CD56 is demonstrated in 70–80% of cases by flow cytometry analysis. CD56 expression definitely indicates multiple myeloma, suggesting its high diagnostic values.

Markers	Expression
CD38	Positive (100%)
CD138	Positive (100%)
CD56	Positive (75–80%)
CD200	Positive (65–75%)
CD28	Positive (40%)
CD117	Positive (20–35%)
CD20	Positive (10–20%)
CD52	Positive (8–14%)

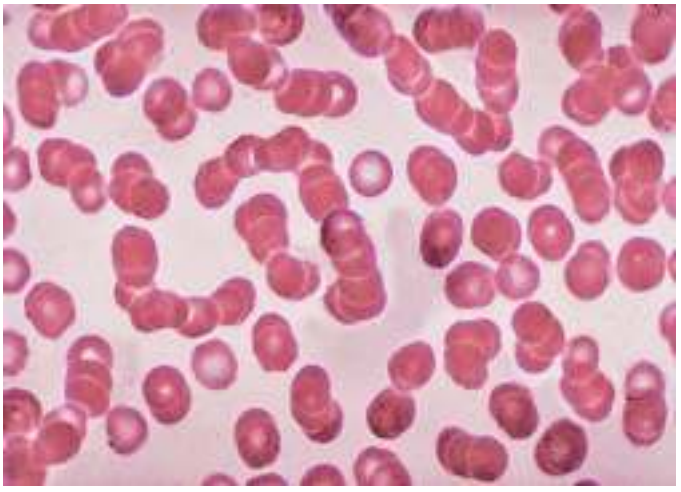


Fig. 9.116: Rouleaux formation of red blood cells in Giemsa-stained peripheral blood smear in multiple myeloma. It shows stacking of red blood cells as a result of coating of erythrocytes by increased immunoglobulin in multiple myeloma (1000X).

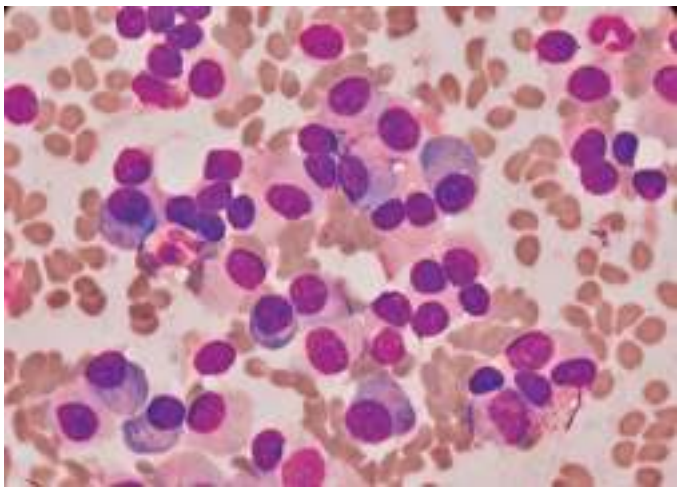

Fig. 9.117: Multiple myeloma in Giemsa-stained bone marrow aspirate smear. Replacement of bone marrow hematopoietic precursor cells by an infiltrate of malignant plasma cells is shown. Neoplastic plasma cells have eccentric nucleus and perinuclear halos. A few binuclear plasma cells are also present (1000X).

DIFFERENTIAL DIAGNOSIS

Multiple myeloma should be differentiated from reactive bone marrow changes due to infections or neoplastic process, lymphoplasmacytoid immunocytoma (Waldenström macroglobulinemia), monoclonal gammopathy of undetermined significance (MGUS), and concomitant paraproteinemia. Differential diagnosis in disorders associated with increase in number of plasma cells in the bone marrow is given in Table 9.136.

PROGNOSTIC FACTORS

On multivariable analysis of peripheral blood progenitor cell (PBPC), patient age, stage, bone marrow plasma cell leukemia 1 (PCL-1) and plasmablastic leukemia 1 (PBL1) are independent prognostic factors for survival. Circulating clonal plasma cells are also predictive for patients with smoldering multiple myeloma, who are likely to progress sooner to active multiple myeloma disease.

Table 9.135 Grading system of clonal plasma cells in multiple myeloma

Clonal Plasma Cell	Features
Mature multiple myeloma	Mature clonal plasma cell measures 20–30 µm in diameter with abundant cytoplasm and eccentrically placed nuclei with dense clumped chromatin giving cartwheel appearance
Immature multiple myeloma	▪ Immature clonal plasma cells contain eccentrically placed nucleus with diffuse fine chromatin and prominent nucleus and clear cytoplasmic droplets due to aggregation of immunoglobulins known as Russell bodies ▪ Morphology of immature plasma cells is indistinguishable from normal plasma cells except that their number is increased in multiple myeloma ▪ Presence of immature cells in the bone marrow is associated with poor prognosis
Plasmablastic multiple myeloma	Plasmablastic clonal plasma cell contains centrally placed large immature nucleus with reticular chromatin and prominent nucleolus with high nucleocytoplasmic ratio
Pleomorphic multiple myeloma	Bone marrow aspirate smear contains multilobulated pleomorphic clonal cells with gray-blue basophilic cytoplasm and nuclear blebs. Some cells show monocytoid like resemblance

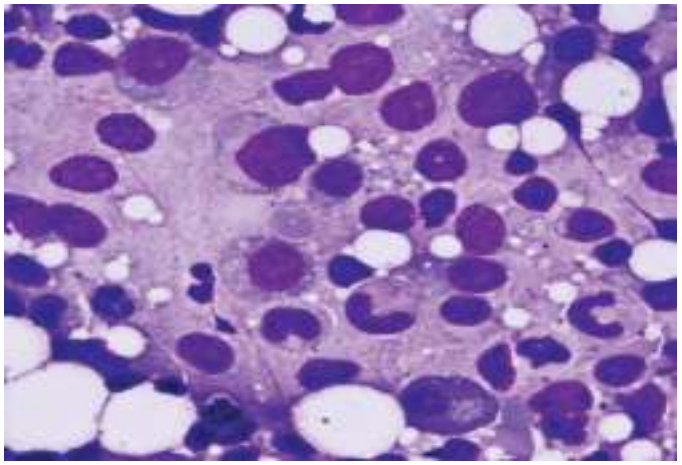

Fig. 9.118: Pleomorphic multiple myeloma in Giemsa-stained bone marrow aspirate smear. Multiple myeloma cells are classified into four types: mature, immature, plasmablastic and pleomorphic (1000X). Bone marrow aspirate smear shows pleomorphic myeloma cells, with nuclear pleomorphism, multinucleated polylobated nucleus, prominent nucleolus and abundant basophilic cytoplasm.

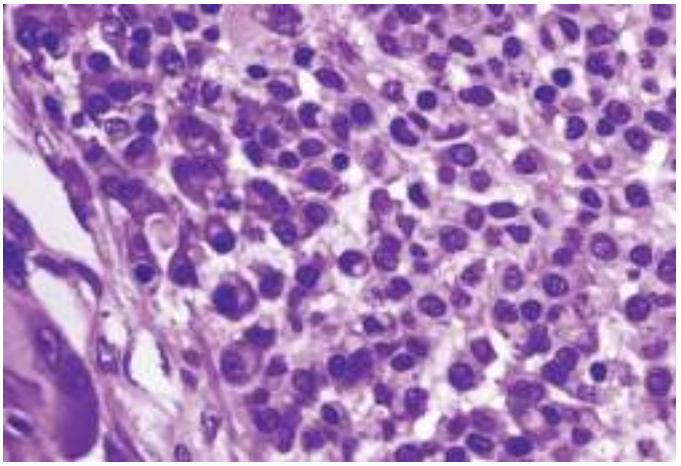

Fig. 9.119: Mature multiple myeloma in hematoxylin and eosin-stained bone marrow trephine biopsy section. Replacement of bone marrow hematopoietic precursor cells by an infiltrate of malignant mature plasma cells is shown. Neoplastic plasma cells have eccentric nucleus and perinuclear halos. A few binuclear plasma cells are also present (1000X).

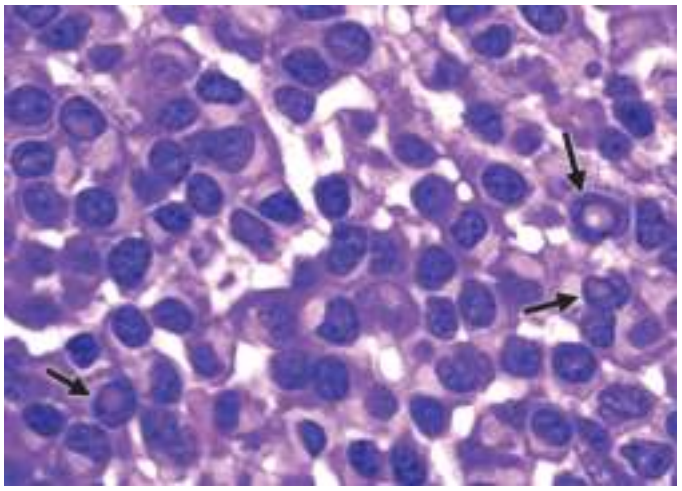

Fig. 9.120: Dutcher body in multiple myeloma in hematoxylin and eosin-stained bone marrow trephine biopsy section. A Dutcher body is an inclusion structure in the nucleus of clonal plasma cells in multiple myeloma (arrows) (1000X).

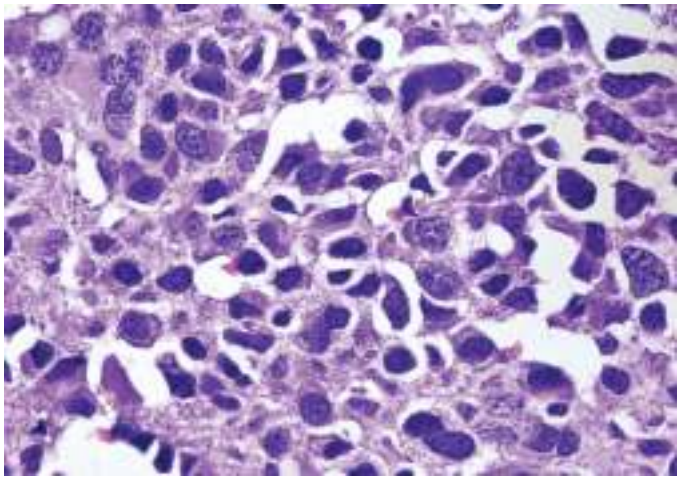

Fig. 9.121: Pleomorphic myeloma with bone marrow fibrosis in hematoxylin and eosin-stained bone marrow trephine biopsy section.

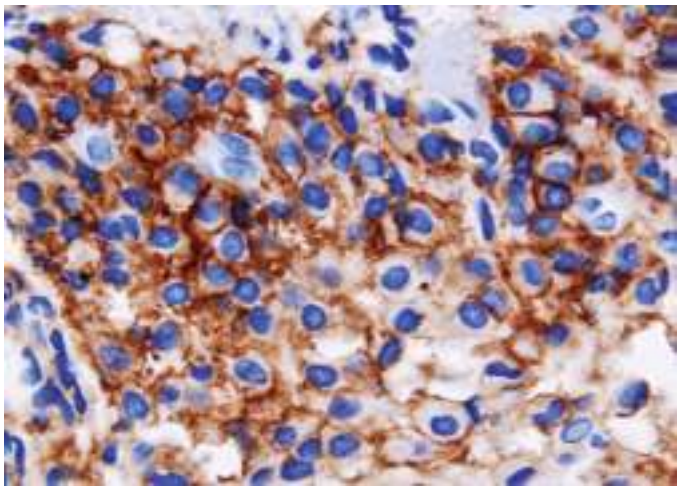

Fig. 9.122: Expression of CD38 positive (Syndecan 1) on clonal plasma cell population in multiple myeloma. CD38 expression is very high and uniform on multiple myeloma cells. CD38 is a good target for novel therapeutic strategies (400X).

Poor Prognostic Factors

Poor prognostic factors for multiple myeloma include advanced clinical stage, cytogenetic abnormalities t(4;14) (p16;q32), t(14,16), t(11;14) (q13;q32), 17p, Ip deletions, TP53 gene mutation, 1q gains, hypodiploidy tumors, diffuse involvement of bone marrow by monoclonal plasma cells, high plasma cell proliferative index, advanced osteolytic lesions, increased serum β_2-microglobulin, decreased plasma albumin, increased serum M proteins, Bence-Jones proteins in the urine, impaired renal functions, increased serum LDH, increased C-reactive protein, increased circulating clonotypic plasma cells in blood and immunophenotyping (e.g. positivity for CD28, CD19). Patients with λ light chain disease have a three-time worse prognosis than κ light chain disease.

Table 9.136 Differential diagnosis in disorders associated with increase in number of plasma cells in the bone marrow

Conditions	Number of Plasma Cells in Bone Marrow	Plasma Cell Morphology	Comments
Normal bone marrow	<5%	Small mature plasma cells	Polyclonal plasma cells
Reactive bone marrow changes due to infections or neoplastic process	5–10%	Small mature plasma cells	Plasma cells increased after HIV infection, chronic inflammatory processes
Multiple myeloma	>10–60%	Pleomorphic plasma cells (immature forms with atypical nucleoli)	Plasma cells are strongly positive for acid phosphatase
Lymphoplasmacytoid immunocytoma (Waldenström macroglobulinemia)	>10%	Plasma cells show marked pleomorphism	Marked lymphocytic infiltration and mast cells
Monoclonal gammopathy of undetermined significance (MGUS)	>10%	Plasma cells show slight pleomorphism	Transition to multiple myeloma is possible
Concomitant paraproteinemia	>10%	Plasma cells show slight pleomorphism	Occurs in systemic lymphoreticular disease and carcinoma

Favorable Prognostic Factors

Favorable prognostic factors for multiple myeloma include hyperdiploid tumors by (DNA cell content of tumor measured by flow cytometry) cytogenetic abnormalities (multiple trisomies involving chromosomes 3, 5, 7, 8, 11, 15, 19 and 21). Features of poor prognostic factors at diagnosis of multiple myeloma are given in Table 9.137.

TREATMENT

Smoldering multiple myeloma patients are asymptomatic and stable with normal blood counts and renal function, without skeletal disease and low level of paraprotein. High-risk patients with IgG paraprotein >30 g/dl may benefit from early treatment.

- Chemotherapy is indicated in multiple myeloma patients with CRAB (hypercalcemia, renal failure, anemia or bone lesion).
- In elderly multiple myeloma patients >65 years of age, induction therapy is started with melphalan, prednisolone and thalidomide. New protocol includes velcade, a proteasome inhibitor or lenalidomide instead of thalidomide.
- Multiple myeloma patients below 65 years of age benefit from intensive induction with cyclophosphamide, dexamethasone and thalidomide. Most patients will reach stable clinical stage, normal blood counts, <5% clonal plasma cells in the bone marrow, stable paraprotein levels after 4–6 cycles of treatment for a period of 1–3 years. Relapse occurs in most patients with median survival of 5–7 years.

Table 9.137 Features of poor prognostic factors at diagnosis of multiple myeloma

Features	Findings Related to Poor Prognosis
Durie and Salmon staging system	▪ Stage I (low tumor load) ▪ Stage II (intermediate tumor load) ▪ Stage III (high tumor load)
Multiple myeloma variant	Plasmablastic multiple myeloma
Cytogenetics/fluorescence *in situ* hybridization (FISH)	▪ t(4;14) (p16;q32) associated with shorter survival, and patient treated with autologous transplant ▪ t(14,16) ▪ t(11;14) (q13; q32) ▪ 17p, Ip deletions (with involvement of TP53 gene) ▪ 1q gains (independent major poor prognostic feature) ▪ Hypodiploidy of tumors ▪ TP53 gene mutation
Bone marrow	Diffuse involvement of bone marrow by monoclonal plasma cells
Clonal plasma cell proliferative index	High
Skeletal lesions	Advanced osteolytic lesions
Serum β_2-microglobulin concentration	Elevated (<6 mg/L) as a result of tumor burden and deteriorating renal functions; but not used to monitor the disease
Plasma albumin concentration	Low <30 g/L
Serum M proteins concentration	IgG >70 g/L; IgA >50 g/L
Bence-Jones protein in urine	>12 g/24 hours
Hemoglobin concentration	Low hemoglobin (<8.5 g/L)
Serum creatinine	Elevated (paraprotein blocks tubules resulting in impaired renal functions)
Serum calcium	Elevated
Serum CRP (C-reactive protein) surrogative marker for IL-6	Elevated
Serum lactic dehydrogenase (LDH) concentration	Elevated
Circulating clonotypic plasma cells in blood	High
Immunophenotyping for clonotypic plasma cells	▪ CD28 positive ▪ CD19 positive ▪ CD117 (KIT) negative ▪ CD56 negative
DNA copy number	Abnormalities detected by SNP arrays methodology

Favorable prognostic factors include hyperdiploid tumors by (DNA cell content of tumor measured by flow cytometry) cytogenetic abnormalities, i.e. with multiple trisomies involving chromosomes 3, 5, 7, 8, 11, 15, 19 and 21.

- Radiotherapy is administered to relieve pain from localized skeletal disease. Hemi body radiation may help to control systemic disease. Allogeneic hematopoietic stem cell transplantation may be curative in selected cases of <65 years. Surgery is indicated in patient developing pathologic feature and spinal cord compression.

WALDENSTRÖM MACROGLOBULINEMIA

Waldenström macroglobulinemia (WM) is a low-grade B cell lymphoproliferative disorder characterized by bone marrow infiltration with clonal post-germinal lymphoplasmacytic cells (immunophenotype: sIgM+, CD19+ and CD20+), together with immunoglobulin M (IgM) monoclonal gammopathy demonstrated on serum electrophoresis. The disorder affects elderly persons with median age 70 years and five-year survival from diagnosis.

- A point mutation in the MYD88 gene resulting in activation of NF-κB and other signaling pathways has been demonstrated in 90–100% of cases.
- Approximately 80% of patients present with monoclonal IgM spike on serum electrophoresis as a result of increased paraprotein level >3 g/dl.
- Serum IgM can be of κ or λ specificity. Bence-Jones proteinuria is demonstrated in 10% of cases. The osteolytic lesions are absent in these patients. These patients develop hyperviscosity of blood.

CLINICAL FEATURES

In Waldenström macroglobulinemia, high levels of IgM >50 g/L can cause hyperviscosity syndrome without osteolytic lesions.

- Patient presents with anemia, thrombocytopenia, fatigue, headache, blurred vision, mucosal bleeding (50% cases), retinal hemorrhages, reduced level of consciousness, hepatomegaly, splenomegaly and lymphadenopathy. Paraprotein coats the platelets and impairs their function leading to mucosal bleeding. Sometimes, plasmapheresis is performed to prevent blindness.
- Lymphoplasmacytic cells infiltrate in bone marrow, lymph nodes, liver and spleen resulting in lymphadenopathy, hepatomegaly and splenomegaly in one-third of patients.
- Other clinical manifestations include Raynaud phenomenon, hemostatic abnormalities, polyneuropathies related to anti-myelin-associated glycoprotein of antibodies, cryoglobulinemia, cold agglutinin disease and acquired von Willebrand disease and amyloidosis. Comparison of plasma cell myeloma and Waldenström disease is given in Table 9.138.

Laboratory Diagnosis of Waldenström Macroglobulinemia

- Laboratory investigations in Waldenström macroglobulinemia include assessment of serum IgM monoclonal protein, bone marrow infiltration in lymph node, liver and spleen.
- Assessment of bone marrow and serum IgM are essential taking into considerations on clinical findings.

Peripheral Blood Smear Examination

Peripheral blood smear examination demonstrates lymphocytosis and rouleaux formation of red blood cells.

Bone Marrow Smear Examination

Bone marrow aspirate smear demonstrates numerous lymphoplasmacytoid cells containing slightly eccentrically placed nucleoli and moderate amount of basophilic cytoplasm.

Immunophenotyping

Lymphoplasmacytoid cells show positivity for CD19, CD20, CD22 and light chains (κ and λ).

Markers	Expression
CD19	Positive
CD20	Positive
CD22	Positive
Kappa (κ) light chain	Positive
Lambda (λ) light chain	Positive

PREDICTIVE POOR PROGNOSTIC FACTORS

Predictive poor prognostic factors for Waldenström macroglobulinemia include hemoglobin <11 g/dl, age over 65 years, thrombocytopenia (platelet count $\leq 100 \times 10^9$/L), serum IgM monoclonal protein >70 g/L and elevated serum β_2-microglobulin (>3 g/L). Prognosis is poor in high-risk patients.

Table 9.138 Comparison of plasma cell myeloma and Waldenström disease

Feature	Multiple Myeloma	Waldenström Disease
Bone marrow lesions	Present	Absent
Serum viscosity	Present/absent	Markedly increased
Immunoglobulin	IgG (Bence-Jones proteins)	IgM (heavy chain)

MANAGEMENT

Patients with Waldenström macroglobulinemia are treated to relieve constitutional symptoms such as lymphadenopathy, hepatomegaly, splenomegaly, hyperviscosity syndrome, hematologic suppression due to bone marrow infiltration and IgM-related syndromes.

- Patients presenting with hyperviscosity syndrome should receive adjuvant plasmapheresis to prevent blindness.
- Symptomatic patients are administered alkylating agent such as chlorambucil with or without prednisolone producing remission in 50–70% of cases.
- Autologous hematopoietic stem cell (HSC) transplantation may be considered for patients with refractory or relapsing disease.

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Monoclonal gammopathy of undetermined significance (MGUS) is an asymptomatic condition in which there is a presence of an abnormal M protein <3 g/dl in the blood or urine in persons, minimal or absence of Bence-Jones proteins in urine, decreased normal immunoglobulins in blood; and <10% of plasma cells in bone marrow; without evidence of multiple myeloma, Waldenström macroglobulinemia, amyloidosis or other lymphoproliferative disorders. Clinical manifestations of variants of monoclonal gammopathy of undetermined significance (MGUS) are given in Table 9.139.

- MGUS most often affect about 4% of Caucasian persons over 50 years. The prevalence of MGUS is higher in African-Americans. Other risk factors are male sex, exposure to pesticide and family history of MGUS or multiple myeloma.
- MGUS is composed of two different kinds of neoplasms: (a) lymphoid MGUS (15%) and (b) plasma cell MGUS (85%).
  - The lymphoid MGUS secretes immunoglobulin M (IgM) and progresses to Waldenström macroglobulinemia, lymphoma or other malignant lymphoproliferative disorders.
  - The plasma cell MGUS does not secrete immunoglobulin M (IgM), but rather secretes IgG, IgD, IgE, or immunoglobulin light chain, which most commonly progresses to multiple myeloma IgG.

CLINICAL FEATURES

Monoclonal gammopathy of undetermined significance (MGUS) is usually asymptomatic without clinical consequences.

- There is no evidence of **CRAB** criteria: **C**: calcium elevation (high levels of calcium in the blood; also known as 'hypercalcemia'); **R**: renal insufficiency (poor function of the kidneys that may be due to a

Table 9.139 Clinical manifestations of variants of monoclonal gammopathy of undetermined significance (MGUS)

Key Features	Clinical Notes
Monoclonal gammopathy of undetermined significance (MGUS) non-IgM	
▪ IgG or IgA; M protein <30 g/L ▪ Bone marrow plasma cells <10% ▪ Absence of myeloma-defining events (MDE) such as organ/tissue damage or amyloidosis	Progression risk to multiple myeloma, amyloidosis or plasmacytoma is 0.5–1.0% per year
Monoclonal gammopathy of undetermined significance (MGUS) IgM	
▪ IgM (M protein) <30 g/L ▪ Bone marrow demonstrates lymphoplasmacytic cells <10% ▪ Absence of end-organ damage (anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, hepatosplenomegaly) or myeloma-defining events (MDE) or amyloidosis	Prognosis risk for Waldenström's or lymphoproliferative disorder is 1.5% per year
Monoclonal gammopathy of undetermined significance (MGUS) light chain	
▪ Abnormal free light chain ratio (<0.26 or >1.65) with an increased involved corresponding serum-free light chain ▪ No immunoglobulin heavy chains expression ▪ Urinary excretion of monoclonal protein <500 mg per 24 hours ▪ Bone marrow demonstrates plasma cells <10% ▪ Absence of myeloma-defining events (MDE) or amyloidosis	Progression risk for multiple myeloma, amyloidosis or plasmacytoma is 0.3% per year

reduction in blood flow to the kidneys); **A**: anemia (low RBC count); **B**: bone abnormalities (lesions).

- About 20–25% of MGUS patients can progress to multiple myeloma during their life-time. About risk of progression of MGUS to malignancy is about 20–25%.
- There are three spectrums of MGUS: (a) MGUS with an increased but **stable** number of tumor cells; (b) MGUS with **minimally progressive** multiple myeloma with end organ damage; and (c) **moderately progressive** multiple myeloma, but with end organ damage that is not yet detected.

MONONUCLEAR PHAGOCYTIC SYSTEM DISORDERS

In immunology, mononuclear phagocytic system is a part of immune system, that consists of monocytes and macrophages.

- Mononuclear phagocytes are derived from a common precursor in the bone marrow, which gives rise to monocytes. Blood monocytes migrate and differentiate into tissue macrophages known as reticuloendothelial cells diffusely distributed in the connective tissues in various organs. Reticuloendothelial cell distribution in various tissues is given in Table 9.140.
- Storage disorders of mononuclear phagocytic system are the consequence of inherited enzyme deficiencies that lead to accumulation of the substances that are incompletely catabolized and degraded in the cells of mononuclear phagocytic system in organs such as bone marrow, liver and spleen. Many of these metabolic products are derived from lipids of cell membrane.

Table 9.140 Reticuloendothelial cell distribution in various tissues

Tissue	Reticuloendothelial Cells
Blood	Monocytes
Connective tissue	Macrophages
Lung	Peritoneal macrophages
Peritoneum	Mesangial cells
Liver	Kupffer cells
Lymph node	Sinus histiocytes
Spleen	Littoral cells
Placenta	Hofbauer cells
Skin	Melanophages
Brain	Microglial cells
Synovium	Type 1 histiocytes
Bone	Osteoclasts
Adipose tissue	Lipophages
Specialized tissue macrophages (reticuloendothelial cells)	▪ Epithelioid cells ▪ Histiocytic giant cells ▪ Langerhans' giant cells ▪ Foreign body giant cells ▪ Touton giant cells

- Disorders of mononuclear phagocytic system include storage histiocytosis (e.g. Gaucher's disease, Niemann-Pick and Sea-blue histiocytosis) and Langerhans' cell histiocytosis [e.g. Letterer-Siwe disease (acute disseminated LCH), Hand-Schüller disease (multifocal LCH) and eosinophilic granuloma (unifocal LCH)].

LYSOSOMAL STORAGE DISORDERS

Lysosomal storage diseases are inherited metabolic disorders caused by gene mutations encoding lysosomal enzymes, which result in cell damage due to excessive accumulation of various toxic undegradable substrates in different organs of the body, including skeleton, skin, heart, liver, central nervous system. Lipid storage disorders include glucosylceramidase beta/GBA (Gaucher's disease), sphingomyelin phosphodiesterase 1/SMPD1(Niemann-Pick disease) and galactosidase alpha/GLA (Fabry disease).

GAUCHER'S DISEASE

Gaucher's disease is an autosomal recessive disorder most often seen in persons of European (Ashkenazi) Jewish lineage. A deficiency of β-glucocerebrosidase causes an accumulation of sphingolipid within mononuclear phagocytic cells in various organs such as bone marrow, liver, and spleen.

- Sphingolipid laden mononuclear phagocytic cells are known as Gaucher's cells. Mutations in the GBA1 gene can be demonstrated in these cases.
- Prenatal diagnosis through GBA1 gene mutation is feasible. Gaucher's disease can be confirmed by demonstration of deficiency of acid glucocerebrosidase activity in leukocytes.
- Bone marrow involvement and hypersplenism contribute to anemia and thrombocytopenia. Gaucher's cells accumulation in liver and spleen lead to hepatomegaly and splenomegaly.
- Hip fracture in a patient of any age with a palpable spleen—especially in a Jewish person of Eastern European origin—suggests the possibility of Gaucher's disease.

Diagnostic Hallmark

Diagnostic hallmark of Gaucher's disease is the presence of lipid-laden macrophages 'Gaucher's cells' with a distinctive fibrillary, wrinkled tissue paper-like cytoplasm and eccentric nuclei.

- Gaucher's cells are demonstrated in bone marrow, liver, spleen, central nervous system, tonsil, thymus, Peyer's patches, and lungs. Cytoplasm is fibrillary and crumpled (tissue paper-like).
- Definitive diagnosis requires the demonstration of deficient glucocerebrosidase activity in leukocytes.

Clinical Features

Clinical features are variable depending on three variants of type 1 (most common), type 2 (uncommon) and type 3 (uncommon) of Gaucher's disease. Comparison of three variants of Gaucher's disease types 1, 2, 3 is given in Table 9.141.

Gaucher's Disease Type 1

Gaucher's disease type 1 is an autosomal recessive lysosomal storage disorder and most common forms of Gaucher's disease affecting >90% persons in Europe and USA. It is caused by a mutation in GBA gene (1q21) that codes for the lysosomal enzyme glucocerebrosidase. The deficiency in glucocerebrosidase leads to the accumulation of glucocerebrosidase deposits in the cells of reticuloendothelial system of liver, spleen, and bone marrow (Gaucher's cells).

- **Clinical features:** Patient presents with cytopenias (anemia, leukopenia, and thrombocytopenia), splenomegaly, hepatomegaly, and bone disease. Symptoms range from mild to severe from childhood to adulthood. Gaucher disease type 1 does not involve the brain and spinal cord (central nervous system).
- **Diagnostic approach:** If Gaucher disease type 1 is suspected on the basis of clinical symptoms, diagnosis can be confirmed by molecular analysis of glucocerebrosidase (GBA) enzyme activity.
- **Treatment:** Most common complications of Gaucher's disease can be prevented by early administration of enzyme replacement therapy. The patients are treated by administration of glucocerebroside enzyme replacement therapy by intravenous route (imiglucerase, velaglucerase, or taliglucerase). Orally administered inhibitors of glucosylceramide biosynthesis can be used (miglustat of eliglustat), which reduce the total body stores of glycolipid and improve hematologic and orthopedic manifestations.
- **Prevention:** Carrier screening, especially among Ashkenazi Jews, detects those couple at high risk of having an affected infant. Prenatal diagnosis through GBA1 gene mutation analysis is feasible. Because of increased risk for developing multiple myeloma and other hematopoietic malignancies, regular screening of patients with Gaucher disease is warranted.

Gaucher's Disease Type 2

Gaucher's disease type 2 is an autosomal recessive lysosomal storage disorder caused by a mutation in GBA gene (1q21) that codes for the lysosomal enzyme glucocerebrosidase. The deficiency in glucocerebrosidase leads to the accumulation of glucocerebrosidase deposits in the cells of reticuloendothelial system of brain, liver, spleen and bone marrow (Gaucher's cells).

- **Clinical features:** Children develop symptoms by the age of three months of age, which include neurological impairment (seizures, abnormal eye movements), dysphagia, dystonia and hepatosplenomegaly.
- **Prognosis:** Many children have fatal outcome by two to four years of age. Heterozygotes for Gaucher's disease are at increased risk for developing Parkinson disease. Enzyme glucocerebrosidase replacement therapy is ineffective in these patients.

Gaucher's Disease Type 3

Gaucher's disease type 3 is an autosomal recessive lysosomal storage disorder caused by a mutation in GBA gene (1q21) that codes for the lysosomal enzyme glucocerebrosidase.

- **Pathogenesis:** The deficiency in glucocerebrosidase leads to the accumulation of glucocerebrosidase deposits in the cells of reticuloendothelial system of liver, spleen, and bone marrow (Gaucher's cells).

Table 9.141 Comparison of three variants of Gaucher's disease types 1, 2, 3

Parameters	Gaucher's Disease Type 1	Gaucher's Disease Type 2	Gaucher's Disease Type 3
Age group	Adults (>90% in Europe and USA)	Infants	Early childhood
Frequency	>90% most common	Uncommon	Uncommon
Organs involved	Liver, spleen, bone marrow, lymph nodes	Liver, spleen, bone marrow and central nervous system	Central nervous system and viscera
Clinical features	Splenomegaly, hepatomegaly, cytopenia, fracture of femoral head	Failure to thrive and neurological impairment	Myoclonic convulsions
Prognosis	Normal life span	Fatal by one year of age	Less severe disorder

It is the subacute neurological form of Gaucher's disease affecting children and adolescence age group. Neurological symptoms are variable in Gaucher's disease type 3.

- **Clinical features:** Children and adolescents can present with moderate systemic involvement and ophthalmoplegia, progressive myoclonic epilepsy, cerebellar ataxia, spasticity, and dementia.
  - Gaucher's disease type 3 can manifest as systemic disease with signs of asthenia, growth retardation, delayed puberty, and hepatosplenomegaly.
  - Skeleton anomalies may include deformities, osteopenia, pathological fractures, vertebral compression, bone infarctions or even aseptic osteonecrosis.
  - Pancytopenia is frequent leading to varying degrees of anemia, leukopenia, and thrombocytopenia.
  - Polyclonal hypergammaglobulinemia is often present and is sometimes complicated by monoclonal gammopathy.
- **Diagnostic approach:** Gaucher disease type 3 is diagnosed by ultrasonography and magnetic resonance imaging for initial; evaluation and subsequent monitoring of hepatomegaly, radiography, and bone scintigraphy to detect skeleton lesions, osteodensitometry for evaluation of osteopenia of the lumbar spine and femoral neck, and cardiac ultrasonography for the detection of pulmonary arterial hypertension.
- **Biochemical markers:** Certain biochemical markers such as chitotriosidase, an angiotensin converting enzyme, ferritin and tartrate-resistant acid phosphatases are analyzed for the initial; diagnosis and monitoring of Gaucher disease type 3.
  - Diagnosis can be confirmed by demonstrating a defect in the enzyme activity of glucocerebrosidase in circulating leukocytes.
  - Genotyping in a patient with homozygous L444P mutation in the GBA gene is at higher risk of developing neurological disease.
  - Heterozygotes for Gaucher disease are at high-risk for developing Parkinson disease.

Laboratory Diagnosis of Gaucher's Disease

Peripheral Blood Smear Examination

Peripheral blood smear shows cytopenia, i.e. anemia, leukopenia and thrombocytopenia due to involvement of bone marrow by Gaucher's disease.

Bone Marrow Examination

- Bone marrow aspiration reveals numerous lipid-laden macrophages 'Gaucher cells' with a distinctive fibrillary, wrinkled tissue paper-like cytoplasm and eccentric nuclei and PAS-positive inclusions.
- Gaucher cells are demonstrated in liver sinusoids (Kupffer cells) and bone marrow.
- Definitive diagnosis requires the demonstration of deficient glucocerebrosidase activity in leukocytes.
- Special enzymes such as chitotriosidase, an angiotensin converting enzyme, ferritin and tartrate-resistant acid phosphatases are used to demonstrate proliferation of macrophages. Gaucher's cells in bone marrow are shown in Fig. 9.123.

Histochemistry

PAS positive Gaucher cells in Gaucher disease in bone marrow trephine biopsy is shown in Fig. 9.124.

Bone Marrow Trephine Biopsy Examination

Bone marrow trephine biopsy section shows Gaucher's cells containing cigarette paper-like cytoplasmic appearance and eccentric nuclei, which are lipid-laden macrophages. Gaucher's cells in trephine bone marrow biopsy are shown in Fig. 9.125.

NIEMANN-PICK DISEASE

Niemann-Pick disease (NPD) is an inherited autosomal recessive pattern lysosomal storage disorder, which means both copies of the gene must have mutations for the manifestation of the disease.

- The three most recognized forms are Niemann-Pick disease type A and type B (NPA, NPB) also called acid sphingomyelinase enzyme deficiency, and Niemann-Pick type C (NPC).
- NPD types A and B occur due to missense mutations in the sphingomyelin phosphodiesterase 1 (SMPD1) gene. NPD type C is caused by mutations in NPC1 (located on chromosome 8) and NPC2 (located on chromosome 14) genes,

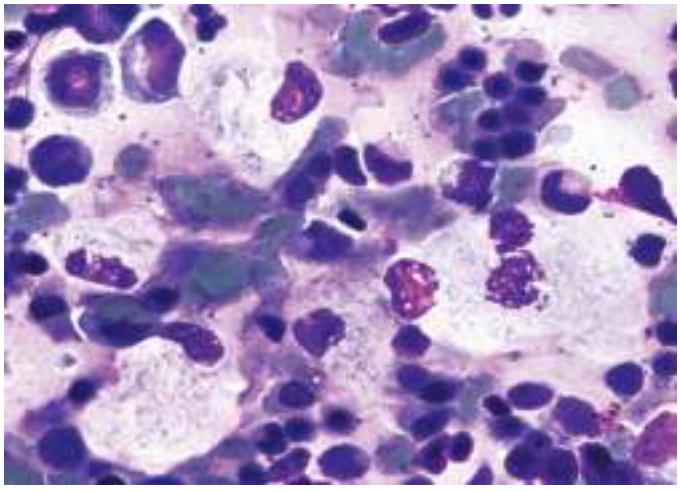

Fig. 9.123: Gaucher's disease in Giemsa-stained bone marrow aspirate smear. Bone marrow examination shows Gaucher's cells containing cigarette paper-like cytoplasmic appearance and eccentric nuclei, which are lipid-laden macrophages (400X).

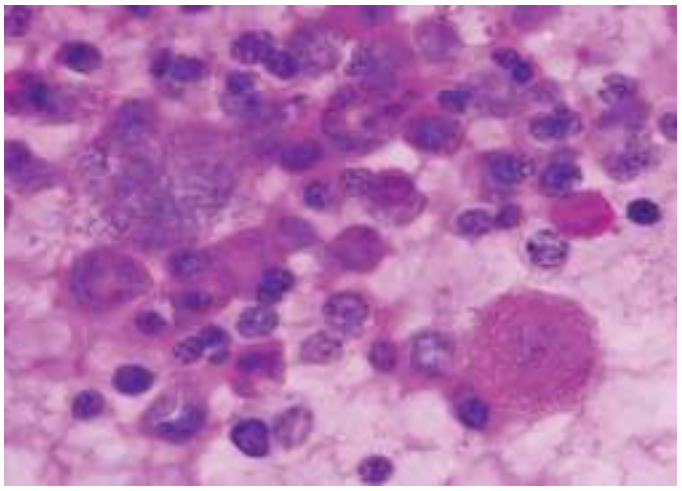

Fig. 9.124: PAS positive Gaucher cells in Gaucher disease in bone marrow trephine biopsy (400X)

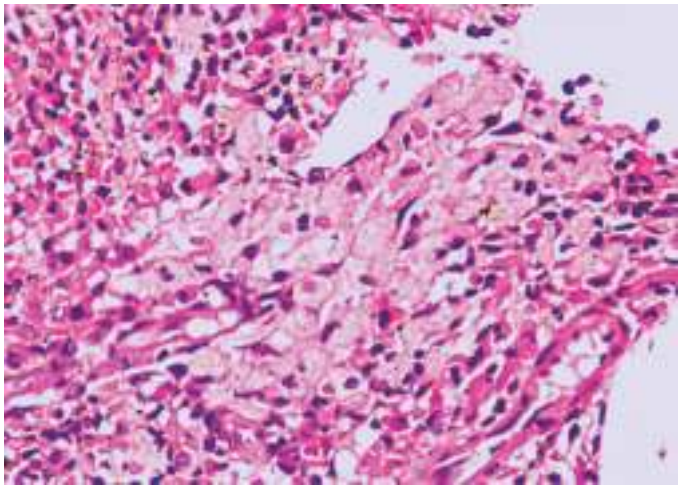

Fig. 9.125: Gaucher's disease in hematoxylin and eosin-stained bone marrow trephine biopsy section. Bone marrow trephine biopsy section shows Gaucher's cells containing cigarette paper-like cytoplasmic appearance and eccentric nuclei, which are lipid-laden macrophages (400X).

which result in synthesis of abnormal or defective proteins, which impair the movement of lipids out of the cells leading to their accumulation within macrophages.

Pathogenesis

Niemann-Pick disease type A and type B (NPA, NPB) are caused by the deficiency of lysosomal acid sphingomyelinase deficiency (ASMD). Lysosomal acid sphingomyelinase enzyme is required to metabolize lipid called sphingomyelin to ceramide and phosphocholine.

- If acid sphingomyelinase is deficient or not functioning properly, sphingomyelin cannot be metabolized properly and is accumulated within the lysosomes of macrophages. These lipid-laden macrophages deposit in the liver, spleen, bone marrow, lungs and brain, causing hepatosplenomegaly, cytopenias, lung disease and neurological symptoms.
- Diagnostic hallmark of Niemann-Pick disease is presence of foamy histiocytes containing sphingomyelin in liver, spleen, lymph nodes, skin, bone marrow, tonsil, gastrointestinal tract, and lungs.
- Niemann-Pick disease (type A and type B) is caused due to missense mutations in sphingomyelin phosphodiesterase 1 (SMPS1) gene.
  - Niemann-Pick disease type C is caused by mutations in NPC1 gene located on chromosome 18 and NPC2 gene located on chromosome 14.
  - The mutations in these genes (SMPS1, NPC1, NPC2) lead to production of abnormal of defective proteins, which impair the movement of lipids out of the mononuclear phagocytes leading to their accumulation within mononuclear phagocytes and cellular damage.
- Molecular testing is necessary to confirm the diagnosis in all persons with suspected Niemann-Pick disease.

Clinical Features

Niemann-Pick disease can affect all segments of population with cases reported in North America, South America, Europe, Africa, Australia and Asia. However, Niemann-Pick disease types A and B affect Ashkenazi Jewish population. Niemann-Pick disease type C affects French Canadian population of Nova Scotia. Comparison of three types (A, B, C) of Niemann-Pick disease is given in Table 9.142.

- **Niemann-Pick disease type A:** Niemann-Pick disease type A is also known as neurovisceral form with very low acid sphingomyelinase (ASM) activity and associated with fatal outcome before three years of age. It affects young children and results in hepatosplenomegaly, lymphadenopathy, cherry red spots inside the eyes, difficulty in feeding, neurological deficits and impaired growth.
- **Niemann-Pick disease type B:** Niemann-Pick disease type B is less severe and characterized by variable visceral symptoms and minimal neurological manifestations. The most common visceral symptoms in these phenotypes include hepatosplenomegaly, thrombocytopenia and interstitial pulmonary disease associated with relatively better prognosis.
- **Niemann-Pick dsease type C:** Niemann-Pick disease type C has heterogenous clinical manifestations as a result of systemic, neurologic and psychiatric involvement. It usually affects adults but can occur during any phase of life.

Table 9.142 Comparison of three types (A, B, C) of Niemann-Pick disease

Parameters	Type A Niemann-Pick Disease (Classic Infantile Type)	Type B Niemann-Pick Disease (Visceral Type)	Type C Niemann-Pick Disease (Visceral Type)
Age group	Infants (severe disease)	Adults (less severe)	10 and 25 years
Basic defect	SMPD1 gene mutation encoding acid sphingomyelinase (ASM) protein resulting in accumulation of sphingomyelin in the lysosomes of phagocytes	SMPD1 gene mutation encoding acid sphingomyelinase (ASM) protein resulting in accumulation of sphingomyelin in the lysosomes of phagocytes	NPC1 or NPC2 gene mutations resulting in accumulation of sphingomyelin in the lysosomes of phagocytes
Clinical features	Hepatomegaly, splenomegaly, anemia, fever, profound neurologic manifestations and cherry red spots inside eye, difficulty in feeding	Hepatomegaly, splenomegaly, pulmonary insufficiency and central nervous system manifestations	Hepatomegaly, splenomegaly, central nervous system manifestations
Prognosis	Fatal outcome by three years of age (rarely survival beyond three years of age)	Survival in adulthood	Sometimes fatal outcome

- The diagnosis of Niemann-Pick disease type C (visceral type) should be considered in persons presenting with clinical manifestations: (a) fetal ascites or neonatal liver disease accompanied by prolonged jaundice and pulmonary infiltrates, (b) infantile hypotonia without evidence of progression for months to years, (c) vertical supranuclear gaze palsy followed by progressive ataxia, dystonia, dysarthria and seizures, (d) psychiatric presentations mimicking depression or schizophrenia and (e) hepatomegaly or splenomegaly particularly in early childhood.

- Some patients can develop significant life-threatening complications including hepatocellular failure, hemorrhage, oxygen dependency, pulmonary infections, splenic rupture and coronary artery disease or valvular heart disease. There are no known treatments that effectively slow the progression of Niemann-Pick disease.

Laboratory Diagnosis of Niemann-Pick Disease (NPD)

Biochemical Analysis

- Niemann-Pick disease types A and B are diagnosed by analyzing the acid sphingomyelinase enzyme (ASM) activity in white blood cells. The test can be performed on blood sample from persons who are suspected of having Niemann-Pick disease.
- Niemann-Pick disease type C is diagnosed on skin biopsy to assess cholesterol in the mononuclear phagocytes.
- Periodic liver enzymes analysis, liver elastography and liver biopsy should be done in case of severe liver disease.
- Periodic spirometry and high-resolution computed tomography (HRCT) are performed for interstitial lung disease.
- Platelet counts and spleen volume should be analyzed. Fundoscopy is done to look for the cherry-red spot on the macula.
- Complete neurological examination should be performed at every visit. Lipid profile should be done to evaluate cardiovascular system.

Bone Marrow Smear Examination

- Bone marrow aspirate shows Niemann-Pick cells, which are large 25–100 μm in size with eccentric nuclei and foamy cytoplasm.
- Foam cells show positivity with oil red O and Sudan black B. Niemann-Pick disease in Giemsa-stained bone marrow aspirate smear is shown in Fig. 9.126.

Bone Marrow Trephine Biopsy Examination

- Niemann-Pick disease in bone marrow trephine biopsy section shows sheets of Niemann-Pick cells, which are large 25–100 μm in size with eccentric nuclei and foamy cytoplasm.
- Niemann-Pick disease in hematoxylin and eosin-stained bone marrow trephine biopsy section is shown in Fig. 9.127.

Electron Microscopy

Electron microscopy of skin, rectal neurons, liver, or brain tissues may demonstrate electron-opaque, concentrically laminated inclusions within macrophage cytoplasm.

Treatment

There is no known treatment for Niemann-Pick disease type A. Niemann-Pick disease type B can be treated by bone marrow hematopoietic stem cell transplantation, enzyme replacement therapy and gene therapy. Niemann-Pick disease type C is currently treated by miglustat, a glucosylceramide synthase inhibitor regularly for an average of two years.

SEA-BLUE HISTIOCYTOSIS

Sea-blue histiocytosis is a cutaneous condition, that may occur as familial inherited syndrome or as an acquired secondary or systemic infiltrative process.

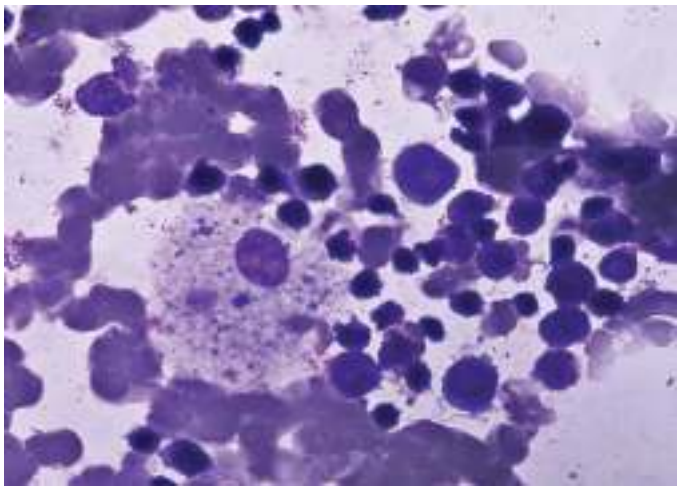

Fig. 9.126: Niemann-Pick disease in Giemsa-stained bone marrow aspirate smear (1000X).

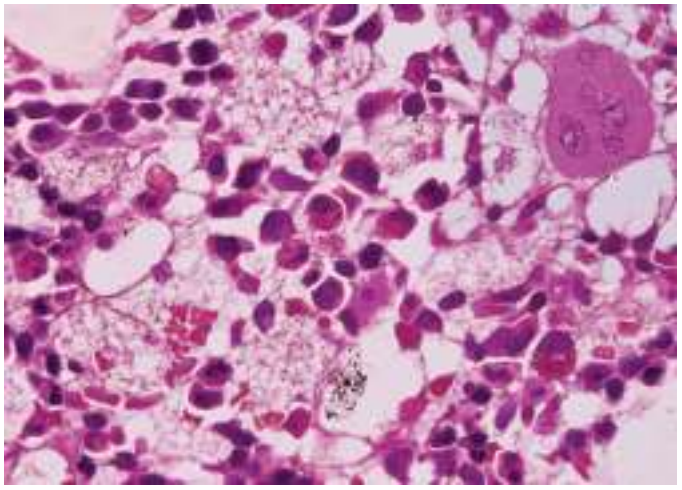

Fig. 9.127: Niemann-Pick disease in hematoxylin and eosin-stained bone marrow trephine biopsy section. Niemann-Pick cells are large 25–100 µm in size with eccentric nuclei and foamy cytoplasm. Foam cells show positivity with oil red O and Sudan black B (1000X).

- Sea-blue histiocytosis is characterized by splenomegaly, mild thrombocytopenia, bone marrow involvement, elevated blood triglyceride levels, impaired liver functions, heart disease, and numerous macrophages laden with incompletely degraded lipids and cytoplasmic granules in the bone marrow, which stain bright blue with the usual May-Grunwald Giemsa/PAS stains. Sea-blue histiocytes are ceroid-laden macrophages.
- Primary sea-blue histiocytosis is an autosomal dominant disorder caused by mutation in APOE gene.
- Secondary sea-blue histiocytosis may occur due to hematologic, lipid and ceroid metabolic and miscellaneous disorders. Causes of sea-blue histiocytosis are given in Table 9.143.

Table 9.143 Causes of sea-blue histiocytosis

Primary Sea-blue Histiocytosis
No known cause is after thorough investigation.
Secondary Sea-blue Histiocytosis
▪ **Hematological disorders** • Chronic myelogenous leukemia • Idiopathic thrombocytopenic purpura • Severe autoimmune neutropenia • Myeloproliferative dysplastic syndrome • Infectious diseases with bone marrow involvement
▪ **Lipid and ceroid metabolic disorders** • Gaucher disease • Niemann-Pick disease • Fabry disease • Hyperlipidemic disorders • Lecithin cholesterol acyltransferase deficiency
▪ **Miscellaneous disorders** • Batten's disease • Neuroaxonal dystrophy • Prolonged therapy with liposomal amphotericin B • Long-term parenteral nutrition with fat emulsion • Takayasu arteritis • Posterior column dysfunction

Laboratory Diagnosis of Sea-blue Histiocytosis

Bone Marrow Examination

Bone marrow aspirate shows numerous histiocytes with granules and sea-blue cytoplasm on May-Grunwald-Giemsa stain (Fig. 9.128).

Cytochemical Stains

Histiocytes contain granules, which are demonstrated by PAS stain and Sudan black.

Immunophenotyping

Marker	Expression
CD68	Positive

LANGERHANS' CELL HISTIOCYTOSIS

Langerhans' cells participate in immunity by presenting antigen to T cells. Langerhans' cell histiocytosis is a clonal disorder characterized by proliferation of epidermal antigen-presenting histiocytes that closely resemble the Langerhans' cells of the epidermis.

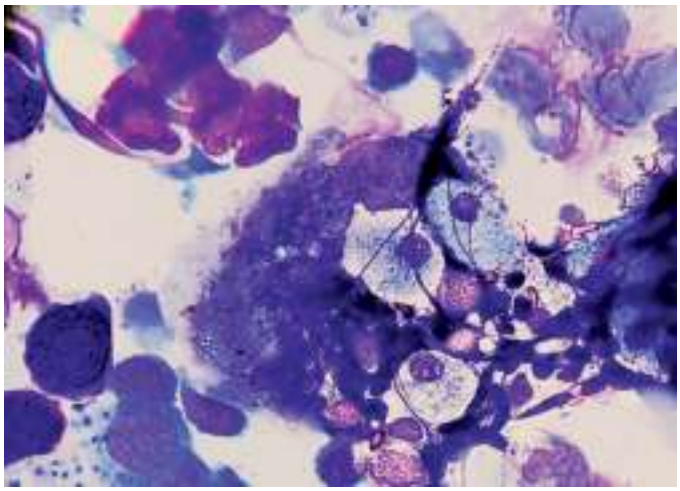

Fig. 9.128: Sea-blue histiocytosis in Giemsa-stained bone marrow aspirate smear. It shows histiocytes with sea-blue colored granules (400X).

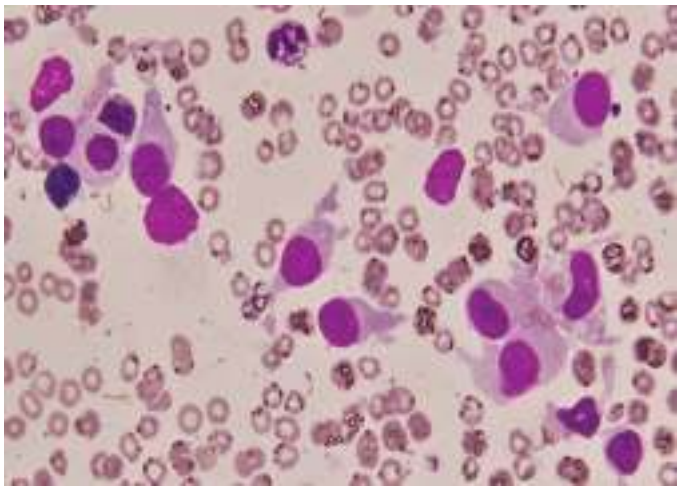

Fig. 9.129: Fine needle aspiration cytology in a case of Langerhans' cell histiocytosis. A two-year-old male child presented with fluctuant swellings measuring 2–3 cm on left frontal and occipital regions of the skull for the last one year. Fine needle aspiration from a swelling revealed hemorrhagic fluid. FNAC smear showed numerous cells and tennis racket-shaped cells consistent with Langerhans' cell histiocytosis (400X).

- Langerhans' cell histiocytosis (LCH) affects children, who can present as a solitary lesion requiring no treatment. A multiorgan life-threatening disorder requires aggressive therapy in 20% of cases.
- Langerhans' cells are tennis racket-shaped containing Birbeck granules demonstrated by electron microscopy, which contain various enzymes such as acid phosphatase, α-naphthyl acetate esterase and α-naphthyl butyrate esterase. Langerhans' cells express distinctive surface antigens, which cells show positivity with S-100, CD1a and langerin.
- BRAF gene mutation has been demonstrated in 50% cases especially in younger patients. High prevalence, recurrent BRAF mutations in LCH indicate that is a neoplastic disease, that may respond to RAF pathway inhibitors.
- Langerhans' cell histiocytosis includes Letterer-Siwe disease, Hand-Schüller-Christian disease and eosinophilic granuloma. Clinical manifestations range from involvement of single site (bone or lymph node) in 75% of cases to an aggressive systemic disorder involving multiple organs (25%).
- Fine needle aspiration cytology is helpful in achieving a rapid and accurate diagnosis of Langerhans' cell histiocytosis in an appropriate clinical and radiological setting. Fine needle aspiration cytology in a case of Langerhans cell histiocytosis is shown in Fig. 9.129.

LETTERER-SIWE DISEASE (ACUTE DISSEMINATED LCH)

Letterer-Siwe disease is **acute disseminated Langerhans' cell histiocytosis** affecting **infants** and **small children**. Disease has rapid aggressive course with fatal outcome.

Light microscopy reveals lack of lipids in histiocytes. Foci of necrosis are present.

- Langerhans' cells are normally present in the skin, which detect non-self antigens and present them to the T cells of immune system, thus allowing an appropriate immune response.
- But in Letterer-Siwe disease, Langerhans' cells disseminate to bone marrow, liver, spleen, lungs, lymph nodes, skin and brain. Granulomatous inflammatory lesions develop and may proliferate and become destructive lesions, which later become less cellular, necrotic and fibrotic.

Diagnostic Hallmarks

The hallmarks of Letterer-Siwe disease is the presence of pathologic Langerhans' cells involved tissues such as bone marrow, liver, spleen, lungs, lymph nodes, skin and brain. Specific histochemical, immunologic, immunohistochemical markers (Birbeck granules or positive S-100 protein and CD1a antigen) and multiorgan involvement.

Clinical Features

Patient presents with painless, yellow brown maculopapular skin lesions scattered over face, especially around eyes, mouth, trunk, perineum, axillae; and recurrent infection as a result of widespread histiocytic proliferation. Clinical examination reveals hepatosplenomegaly, lymphadenopathy, pulmonary involvement resulting in honeycomb appearance, spontaneous pneumothorax and pleural effusion.

Laboratory Diagnosis of Letterer-Siwe Disease	
Peripheral Blood Smear Examination	
Peripheral blood smear examination shows pancytopenia as a result of replacement of bone marrow elements due to accumulation of histiocytosis.	
Bone Marrow Smear Examination	
Bone marrow aspirate shows numerous histiocytes with abundant cytoplasm admixed with a few lymphocytes and eosinophils, which are laden with cholesterol.	
Electron Microscopy	
Birbeck granules in histiocytes may be demonstrated on electron microscopy.	
Immunophenotyping	
Panel of markers used to demonstrate Langerhans' cells includes S-100 protein, CD1a and langerin.	
Markers	**Expression**
▪ S-100 protein ▪ CD1a ▪ Langerin	▪ Positive ▪ Positive ▪ Positive

HAND-SCHÜLLER-CHRISTIAN DISEASE (MULTIFOCAL LCH)

Hand-Schüller-Christian disease is acute onset followed by chronic progressive histiocytosis affecting infants to elderly persons, which most often presents before 5 years of age and associated with better prognosis than Letterer-Siwe disease. Light microscopy shows numerous histiocytes admixed with eosinophil cells in bone, especially the skull, liver, spleen, and other tissues.

Clinical Features

Hand-Schüller-Christian disease has classic triad: (a) bone lesions, (b) diabetes insipidus and (c) exophthalmos.

- Bone lesions are demonstrated in the orbit, tooth-bearing area of mandible and mastoid bone. Diabetes insipidus occurs due to destruction of sella turcica. Exophthalmos is caused by involvement of the orbit.
- Other lesions may occur in femur, pelvis, ribs, humerus (end of shaft), spine, lung, skin and mucosa.
- Hepatosplenomegaly and lymphadenopathy may occur in 25–50% of cases.

EOSINOPHILIC GRANULOMA

Eosinophilic granuloma is the benign form of Langerhans' cell histiocytosis (LCH), which accounts for 60–80% cases and can affect children, adolescents and young adults. Disorder can cause bone lesions in solitary or multiple bones. When multiple bone lesions occur, new osseous lesions appear within a span of 1–2 years.

- Sites of bone lesion include thoracic spine, cervical spine, ramus of mandible, orbit, spine (especially vertebral bodies), ribs, clavicle, and long bones (diaphysis of femur and humerus). There may be involvement of lung and gastrointestinal tract.
- Exact pathogenesis is unknown. Epstein-Barr virus, human herpesvirus 6, bacteria and genetic factors have been implicated. An immunological dysfunction is reported with an increase in the cytokines such as IL-1 and IL-10 in the affected patients. Eosinophilic granuloma is extremely radiosensitive.

Clinical Features

Patient presents with localized bone pain, tenderness, swelling, restricted range of movements and fever. Lesions usually begin to regress within three months resulting in complete regression within two years.

- Patient with pulmonary eosinophilic granuloma presents with sudden onset, and has cough, weight loss, dyspnea and pneumothorax.
- Eosinophilic granuloma in gastrointestinal tract is solitary, which may simulate polyps, gastric carcinoma or duodenal ulcer.
- Laboratory findings in eosinophilic granuloma are usually nonspecific except for a moderate and inconsistent leukocytosis and rise in erythrocyte sedimentation rate.

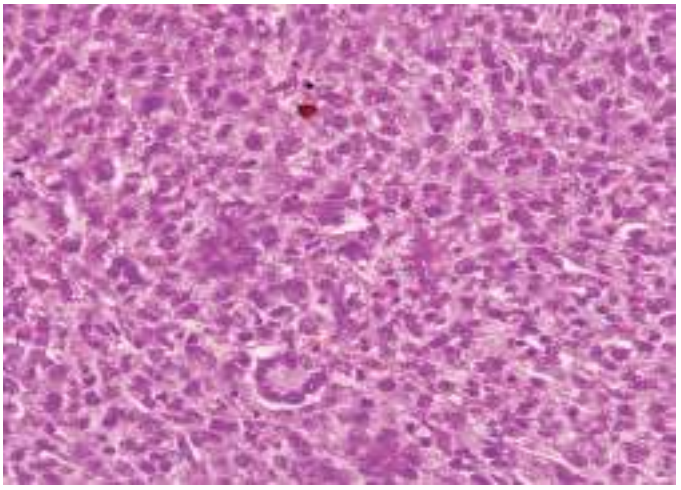

Fig. 9.130: Eosinophilic granuloma in hematoxylin and eosin-stained biopsy section. The lesion is composed of proliferation of histiocytes admixed with inflammatory cells, including ordinary macrophages, lymphocytes, and many eosinophils is characteristic (400X).

Radiologic Findings

The typical radiographic appearance of eosinophilic granuloma of the extremities is a punched-out osteolytic lesion without reactive sclerosis. In most cases, a hypervascularized soft tissue mass surrounds the affected bone.

- While reporting eosinophilic granuloma, differential diagnosis must be considered such as multiple myeloma, plasmacytoma, osteochondritis, tuberculosis, and chronic osteomyelitis.
- In the spine, imaging studies may demonstrate variable vertebral involvement ranging from isolated osteolytic lesion to a more significant vertebral collapse that involve the pedicles and posterior vertebral elements.

Laboratory Diagnosis of Eosinophilic Granuloma

Light Microscopy

Eosinophilic granuloma is composed of proliferation of histiocytes admixed with inflammatory cells, including ordinary macrophages, lymphocytes, and many eosinophils is characteristic (Fig. 9.130).

HEMATOPOIETIC STEM CELL TRANSPLANTATION

HEMATOPOIETIC STEM CELL TRANSPLANTATION: OVERVIEW

Hematopoietic stem cells (**HSCs**) develop during embryogenesis in a complex developmental process that involves multiple anatomical sites such as yolk sac, aorta-gonad-mesonephros region, placenta and fetal liver, after which hematopoietic stem cells colonize in the bone marrow at birth.

- Hematopoietic stem cells are defined as cells that are capable of self-renewal and their differentiation into myeloid and lymphoid lineages, which form the progenitor cells, which are committed to form and differentiate into mature functional cells (RBCs, WBCs and platelets) in the peripheral blood. Hematopoietic stem cells show positivity for CD34+ (most widely used, CD90, and CD123). Hematopoietic stem cells are negative for HLA-DR during postnatal life.
- Hematopoietic stem cell transplantation is the term now used in preference for bone marrow transplantation (BMT), in which a patient receives healthy hematopoietic stem cells to replace their own HSCs are destroyed by treatment with radiation or high doses of chemotherapy.
- The healthy HSCs may be derived from the blood or bone marrow of the patient or from a related or unrelated donor. HSC transplant may be autologous (using a patient's own hematopoietic stem cells that are obtained and preserved before treatment), allogeneic (using hematopoietic stem cells from a related or unrelated donor with different MHC/HLA alleles), syngeneic (using hematopoietic stem cells donated by identical twin) or umbilical cord blood (using umbilical cord blood donated after a baby is born).
- Generally, most common indications of autologous hematopoietic stem cell transplantation are multiple myeloma, non-Hodgkin lymphoma and acute myelogenous leukemia. Main indications for allogeneic hematopoietic stem cell transplantation is acute myelogenous leukemia (AML), acute lymphoblastic leukemia (ALL), myelodysplastic syndrome (MDS), CML refractory to receptor tyrosine kinase inhibitors, lymphoid malignancies and nonmalignant disorders such as bone marrow dysplasia, paroxysmal nocturnal hemoglobinuria and severe immunodeficiency disorders. Indications for hematopoietic stem cell transplantation are given in Table 9.144.
- In hematopoietic stem cell transplantation procedure, blood is obtained from a vein in the arm of the donor. The blood flows through a machine that removes HSCs. Blood is now returned to the donor through a vein in the other arm. The patient receives chemotherapy to eradicate hematopoietic stem cells. The patient may receive radiation therapy. The patient receives hematopoietic stem cells through a catheter placed into blood vessel in the chest. Hematopoietic stem cell transplantation is shown in Fig. 9.131 and overview of hematopoietic stem cell transplantation is shown in Fig. 9.132.

HEMATOPOIETIC STEM CELL HARVESTING

Hematopoietic stem cells (HSCs) for allogeneic transplants can be obtained from bone marrow, peripheral blood and umbilical cord blood. These sources differ in regard to collection procedures, cellular content and transplant outcomes.

- In the related setting, the use of peripheral blood hematopoietic stem cells, when compared to bone

Table 9.144 Indications of hematopoietic stem cell (HSC) transplantation

Hematolymphoid Malignant Disorders	Hematologic Nonmalignant Disorders	Nonhematologic Disorders
Multiple myeloma	Aplastic anemia	Solid organ malignancies (breast carcinoma, ovarian carcinoma, neuroblastoma, Wilms' tumor, germ cell tumors)
Non-Hodgkin lymphoma	Thalassemia	Inborn errors of metabolism (Hurler's syndrome)
Hodgkin disease	Sickle cell disease	Severe combined immunodeficiency
Acute myelogenous leukemia	Paroxysmal nocturnal hemoglobinuria	Wiskott-Aldrich syndrome
Acute lymphoblastic leukemia	Fanconi's anemia	Congenital leukocyte dysfunction syndromes
Chronic lymphocytic leukemia	Congenital pure red cell anemia	Malignant osteopetrosis
Chronic myelogenous leukemia refractory to tyrosine kinase inhibitors	Diamond-Blackfan anemia	
Myelodysplastic syndrome	Glanzmann thrombasthenia	
Primary myelofibrosis		

Hematopoietic stem cell transplantation is performed in patients, who are chemotherapy or radiotherapy resistant leukemias and multiple myeloma.

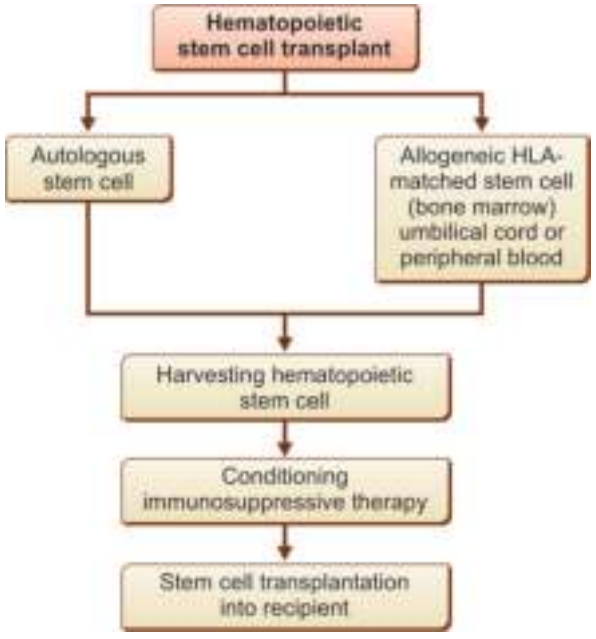

Fig. 9.131: Schematic representation of hematopoietic stem cell (HSC) transplantation.

marrow HSCs, leads to faster engraftment and may confer a survival benefit in advanced disease but also may lead to an increase chronic graft-versus-host disease. While umbilical hematopoietic stem cells are simplest to collect and permit the greater flexibility in HLA matching. Harvesting umbilical cord can save lives.

- Like bone marrow HSCs, umbilical cord blood contains HSCs capable of differentiating into mature functional blood cells (RBCs, WBCs and platelets).
  - Hematopoietic stem cells obtained from umbilical cord blood offers several advantages over those acquired from bone marrow including increased tolerance for human leukocyte antigen mismatches, decreased incidence of graft-versus-host disease, and easy availability.
  - Fetal bone marrow and liver are also rich in hematopoietic stem cells, but ethical issues limit their use. Comparison of hematopoietic stem cells obtained from umbilical cord and bone marrow is given in Table 9.145.

Bone Marrow HSCs Harvesting

Bone marrow hematopoietic stem cell is generally harvested by surgical procedure from posterior iliac crest, however bone marrow may be obtained from anterior iliac crest and sternum if required.

- The amount required to achieve hematopoiesis is 10–15 ml/kg of recipient body weight. Harvested bone marrow is filtered to remove debris. HLA typing is essential prior to bone marrow HSC transplantation.
- Bone marrow may be administered as fresh or preserved cryoprecipitate. There may be risk of infection. Patient may develop graft-versus-host disease.

Peripheral Blood HSCs Harvesting

Through a process of mobilization, hematopoietic stem cells are released from the bone marrow into the blood. Peripheral blood contains 0.1% of hematopoietic stem cells. Blood HSCs count is more than umbilical cord blood HSCs.

- Recombinant human granulocyte colony-stimulating factor (G-CSF) is used to mobilize hematopoietic

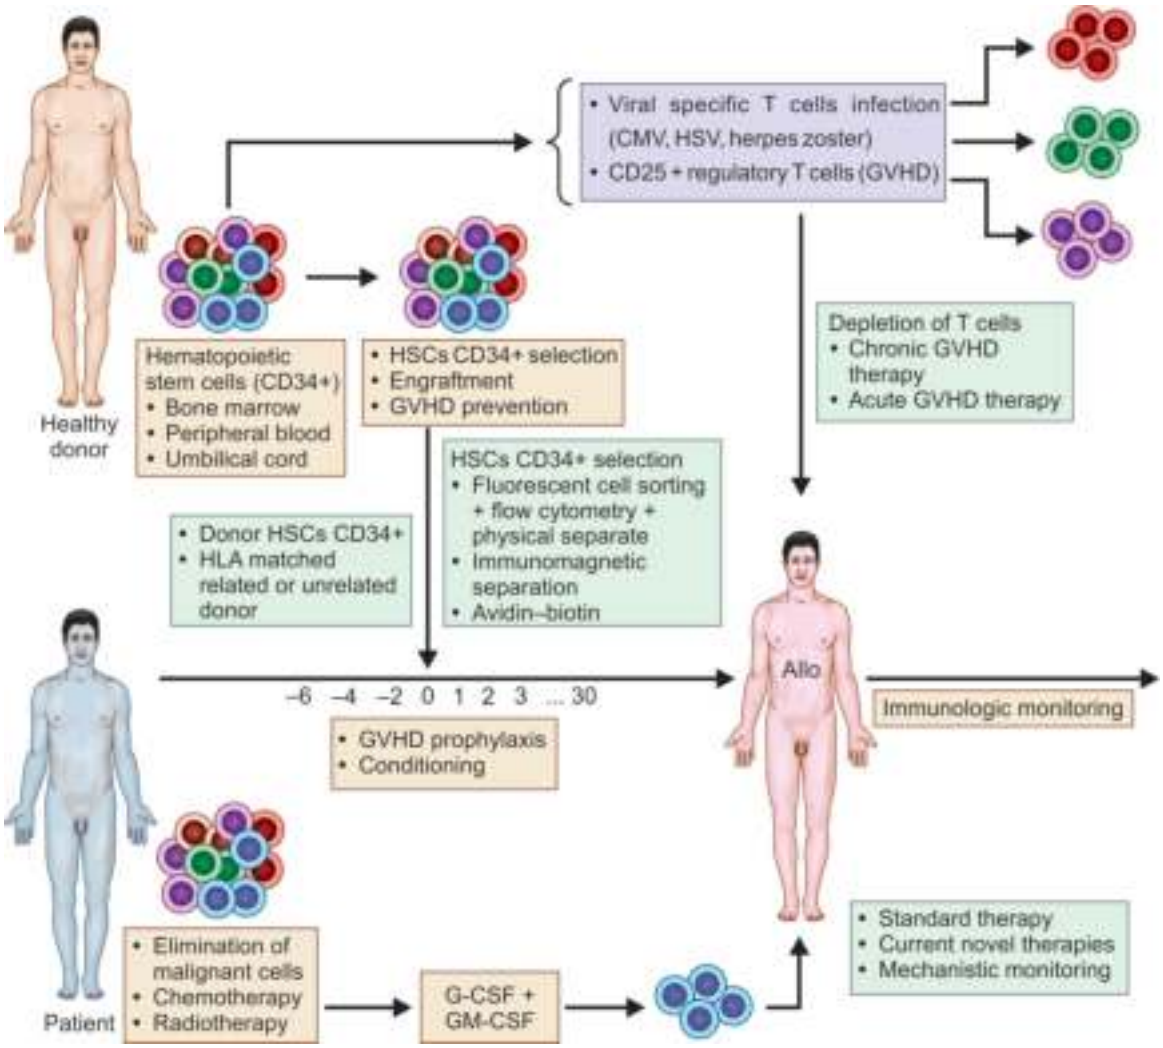

Fig. 9.132: Schematic representation of hematopoietic stem cell transplantation (HSCT) to treat malignant and nonmalignant diseases. It involves obtaining hematopoietic stem cell from the patient (autologous) or another person such as sibling or unrelated donor (allogeneic transplant) or an identical twin (synergetic transplant). Cell sources include bone marrow, umbilical cord or blood. Hematopoietic stem cells are infused by intravenous route into the recipients in order to re-establish hematopoiesis in patients whose bone marrow or immune system is damaged or defective.

Table 9.145 Comparison of hematopoietic stem cells obtained from umbilical cord blood and bone marrow

Characteristics	Hematopoietic Stem Cells (HSCs) Obtained from Umbilical Cord	Hematopoietic Stem Cells (HSCs) Obtained from Bone Marrow
Obtaining HSCs	Stored umbilical cord obtained from newborn baby	HSCs obtained from bone marrow by surgical procedure
Risk	No risk to the person as HSCs obtained from self-umbilical cord	Risk of infection to the donor; and risk to the recipient
Requirement of HLA typing	HLA typing required	HLA typing required
Time taken by engraftment of HSCs	Longer period	Shorter period
Graft-versus-host disease	Presence of immature T cells in the umbilical HSCs graft reduce risk for graft-versus-host disease	Graft-versus-host disease can occur

stem cells from the bone marrow into the blood for leukapheresis. Leukapheresis is usually performed after 4–5 days of G-CSF subcutaneous administration at as disease of 10 mg/kg of body weight.

- Through the process of apheresis, whole blood is separated into its components and hematopoietic stem cells can be collected and stored. Venous access via the antecubital vein may be used. A dual-lumen

central venous catheter may be required when venous access is inadequate. After processing, HSCs are cryopreserved in the vapor phase of liquid nitrogen for later infusion.

- Granulocytes do not survive during cryopreservation. To allow survival of granulocytes during cryopreservation, HSCs are placed in a medium containing 7.5–10% dimethyl sulfoxide. Engraftment of peripheral blood hematopoietic stem cells is more rapid than obtained from umbilical cord. There is increased in risk for developing acute/chronic graft-versus-host reactions.

Umbilical Cord Blood HSCs Harvesting

Umbilical cord blood is harvested via 16-gauze needle through the umbilical vein once the placenta has been delivered. Median volume harvested is 100 ml. Umbilical cord hematopoietic stem cells can be frozen and stored in blood bank and made readily available on demand.

- The risk of latent viral contamination due to cytomegalovirus and Epstein-Barr virus is low. Umbilical cord blood does not contain mature T cells and therefore likely to be less immunogenic and will reduce the incidence of graft-versus-host disease (GVHD).
- Umbilical cord blood HSC transplantation does not require HLA typing. Disadvantages of umbilical cord HSCs transplantation are inadequate in hematopoietic stem cells in stored umbilical cord and requirement of availability of only one unit for each transplant procedure.

Pathology Pearls: Hematopoietic Stem Cells Processing

- Prior to storage and/or administration, hematopoietic stem cells (HSCs) can be manipulated.
- Hematopoietic stem cells may be enriched with CD34+ or purged by removing T cells or malignant cells.
- Processing of HSCs include sterility testing, blood typing and a reduction of fluid volume, HSCs are cryopreserved until administration into recipients.
- Key principles of cryopreservation include: (a) reduction of the number of mature blood cells in the graft, (b) protection of HSCs from ice formation and dehydration during freezing using a cryoprotective agent such as dimethylsulfoxide or hydroxyethyl starch, (c) diluting cryoprotective agent with saline or tissue culture media, (d) reduction the risk of cell injury by adding plasma protein to the graft, and (e) cooling at controlled rate, storage at a temperature below 120°C in liquid nitrogen of mechanical freezers.
- Allogeneic hematopoietic stem cells are generally transfused into recipient within 24–72 hours of collection and do not require cryopreservation.

SELECTION OF DONOR FOR OBTAINING HSCs

Allogeneic hematopoietic stem cell transplantation (HSCT) is an established therapy for many malignancies of hematopoietic system and certain life-threatening nonmalignant disorders.

- The selection of the most suitable donor and hematopoietic stem cell (HSC) source is critical component of HSC transplantation. Donor evaluation is done for the safety of the HSCs for both donor and recipient.
- Hematopoietic stem cells (HSCs) may be collected from bone marrow, peripheral blood or umbilical cord blood. In order to minimize the risk for healthy HSC donors, thorough investigations are required before donation process.
- The donor work-up should include detailed medical history, history of previous blood transfusions, physical examination, ECG, chest radiograph, complete blood counts, coagulation screening studies, and testing for infectious disease (HIV, HBV, HCV and CMV) markers. Donors should be fully informed on the donation procedure and sign an informed consent for donation.
- Human leukocyte antigen (HLA) typing is most important contributing factor of donor selection, which is used to match patients and donors for bone marrow or umbilical cord blood transplants.
- The human leukocyte antigen system is a group of related proteins that are encoded by the major **histocompatibility complex (MHC)** gene located on the short arm of chromosome 6 in human genome. These **cell-surface proteins** are responsible for the regulation of the immune system.
- Major histocompatibility complex genes are inherited together and the most important determinants are HLA-A, HLA-B, HLA-C, HLA-DRB1, HLA-DQB1 and HLA-DPB1. Because a person inherits one HLA cluster (termed locus) from each parent. The siblings with the same parents have 25% chance to be a 'match' with the potential hemopoietic stem cell transplantation (HSCT) recipient.
- **HLA-matched identical sibling** is the **ideal donor**. Sibling in HLA-A, HLA-B, DRB1, DQB1 loci are considered identical. ABO compatibility is not essential for bone marrow transplantation.
- HLA matching promotes the growth and development of new healthy hematopoietic stem cells (called engraftment) and reduces the risk for a post-transplant complication called graft-versus-host disease (GVHD).

TECHNIQUES TO ISOLATE HSCs

Methods used to collect hematopoietic stem cells in their natural environment (bone marrow or umbilical cord blood) or the peripheral blood after stimulation by cytokines are well-defined to ensure the donor security and perform a quality hematopoietic stem cell transplantation. The hematopoietic stem cells in a graft and its characterization depend on the collection site of HSCs and on the technique used. HSCs (CD34+) selection is done by various methods.

Flow Cytometry Technique to Isolate HSCs

Hematopoietic stem cells can be identified by the use of flow cytometry technique, where combination of several different cell surface markers is used to isolate the rare HSCs from the surrounding blood cells.

- HSCs lack mature blood cell markers. Human HSCs express CD34+, EMCN+, CD59+, Thy1/CD90+, c-KIT/CD117 and lin+.
- Lack of expression of these lineage markers is used in combination with detection of several positive cell-surface markers to isolate HSCs.
- Flow cytometry is combined with fluorescent-activated cell sorting with physical separator segregates individual HSCs based on expression of molecules.
- HSCs are characterized by their small size and low staining with vital fluorescent dyes such as rhodamine.

Immunomagnetic Separation Technique of Isolate HSCs

Numerous techniques have been developed for immunomagnetic separation of human HSCs.

- A column immunoadsorption method on the high affinity between the protein avidin and the vitamin biotin has been used to obtain HSCs (CD34+) selection. Immunomagnetic separation is based on monoclonal antibodies coupled to magnetic beads.
- During incubation with cell suspension from bone marrow or peripheral blood or umbilical cord blood, the antibody/bead complex binds to cells expressing the corresponding epitope. When the cell suspension is placed into a magnetic field, magnetically labeled cells are retained, while unlabeled cells can be removed.
- To obtain the labeled cells, the sample is removed from the magnetic field. Positive selection enables the direct labeling and separation of human HSCs, whereas depletion strategies effectively remove non-HSCs to isolate untouched HSCs. Method of culture and selection of HSCs (CD34+) for transplantation is shown in Fig. 9.133.

TYPES OF HSC TRANSPLANTATION

There are two types of hematopoietic stem cell transplantation (HSCT): allogeneic and autologous. Allogeneic HSCT requires a donor to supply suitable hematopoietic stem cells. Clinicians performing allogeneic HSCT need to ensure that the donor is an appropriate match for a recipient. An autologous hematopoietic stem cell transplant uses healthy HSCs from own body to replace damaged bone marrow cells.

ALLOGENEIC HSC TRANSPLANTATION

Allogeneic HSC transplants are often indicated when the disease involves the patient's own hematopoietic stem cells in cases of acute leukemias, chronic leukemias, multiple myeloma, aplastic anemia, hemoglobinopathies, immunodeficiency disorders and metabolic inherited disorders.

- Essential criteria for successful HSC transplantation (HSCT) include: (a) infusing adequate HSCs into recipients help in engraftment in the bone marrow microenvironment, (b) recipient immune system can tolerate well the graft without rejection, and (c) patient does not develop severe graft-versus-host disease.
- Graft-versus-host disease (GVHD) occurs when immunocompetent donor T cells recognize HLA antigens on the host (recipient) cells as foreign and initiate cell injury.
  - HLA system is highly polymorphic (genetically variable). Genes present on the short arm of the chromosome 6 encode HLA antigens. Class I HLA antigens are encoded by three loci HLA-A, HLA-B, and HLA-C. On the other hand, class II HLA antigens are encoded by another three loci: HLA-DR, HLA-DP, and HLA-DQ. Serological and molecular genetic testing methods are available to analyze HLA type.
  - Graft-versus-host disease (GVHD) can occur even after compatibility testing, because serological and molecular testing do not recognize antigens that are incompatible or not encoded by major histocompatibility complex.
- **Syngeneic HSC transplantation** is performed by using HSCs derived from bone marrow or peripheral blood from identical twin to treat any disorder treated by allogeneic or autologous transplants except genetic disorders that affect both twins. Synergetic HSC transplantation has no risk of rejection or graft-versus-host disease; and not requiring special immunosuppressive drugs.

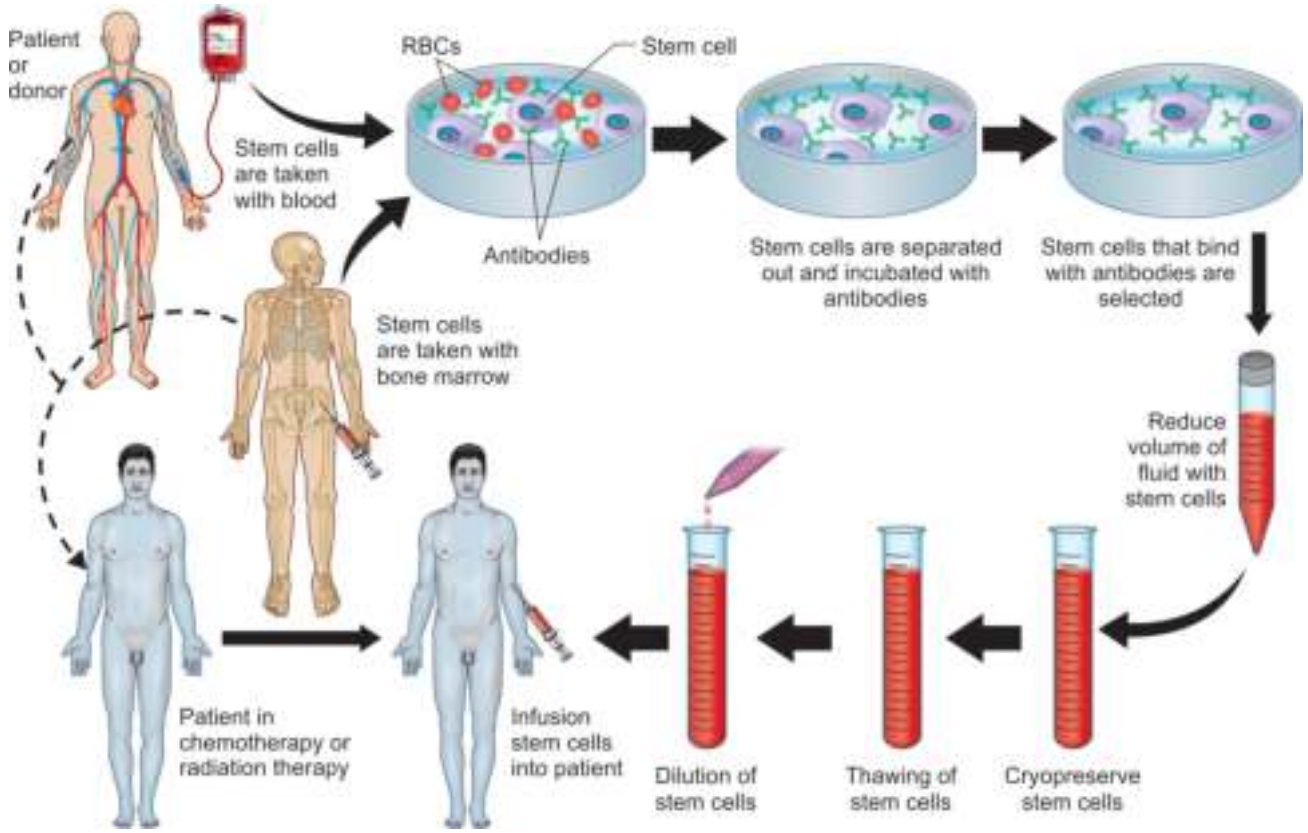

Fig. 9.133: Schematic representation of method of culture and selection of hematopoietic stem cells (HSCs) CD34+ for transplantation. HSCs and progenitor cells can be cultured under defined conditions designated to enhance self-renewal and increase the number of primitive cells or to promote lineage specific expansion and differentiation into mature blood cell types. HSCs are able to divide indefinitely, whereas progenitor cells are only able to divide defined number of times.

AUTOLOGOUS HSC TRANSPLANTATION

In autologous HSC transplantation, patient's own HSCs derived from bone marrow or peripheral blood are infused.

- Prior to collection of the hematopoietic stem cells, patient is administered intensive myeloablative chemotherapy and/or radiotherapy to eliminate the malignant cells.
- Autologous hematopoietic stem cell transplantation is usually indicated when the patient's hematopoietic stem cells are not affected by disease such as non-Hodgkin's lymphoma, Hodgkin's disease, breast carcinoma, ovarian carcinoma, neuroblastoma and Wilm's tumor.
- Autologous hematopoietic stem cell transplantation has certain advantages. Patient does not require HLA testing and secondly no graft-versus-host disease; and graft rejection does not take place.

UMBILICAL CORD HSC TRANSPLANTATION

Umbilical cord blood HSCs can be easily obtained immediately after baby birth without risk to the mother or infant, which can be frozen and stored in a blood bank and made readily available demand for HSC transplantation.

- The risk of latent viral contamination occurs due to cytomegalovirus and Epstein-Barr virus is low. Immature T cells in cord blood are less immunogenic hence reduction in graft-versus-host disease.
- Umbilical cord blood contains sufficient number of hematopoietic stem cells. Umbilical cord blood from siblings and unrelated donors can be used to reconstitute hematopoiesis in patients with malignant and nonmalignant disorders.

HEMATOPOIETIC STEM CELL TRANSPLANTATION IN THE RECIPIENTS

Hematopoietic stem cell (HSC) transplantation refers to the intravenous infusion of allogeneic or autologous HSCs, collected from bone marrow, peripheral blood, or umbilical cord blood, to replace aberrant HSCs in a patient.

CONDITIONING

In myeloablative regime, high dosage of chemotherapy and radiotherapy is given to achieve three goals: elimination of malignant cells, immunosuppression to allow engraftment and creation of physical space for adequate growth of donor HSCs. Alternative to myeloablative regimen, fludarabine based antiglobulin is administered in elderly patients to lower tumor burden in hematological malignancies.

INFUSION OF HSCs

Hematopoietic stem cells (HSCs) are obtained in a bag containing anticoagulant and infused through large-bore central catheter in recipient within a few hours of collection. Engrafting is considered as established, when peripheral blood neutrophil count reaches $>0.5 \times 10^9$/L on 3 successive days.

SUPPORTIVE MEASURES

High dosage of chemotherapy and radiotherapy induces pancytopenia in recipients may lead to infections. Therefore, antibiotics are administered to combat bacterial and fungal infections.

- Number of HSCs (CD34+) required for hematopoietic recovery is 2.5–5.0 × 10/kg.
- Blood components therapy is given in recipients. Hematopoietic growth factors such as G-CSF or GS-CSF are administered to stimulate myelopoiesis.

COMPLICATIONS OF HSC TRANSPLANTATION

Both infectious and noninfectious complications occur more frequently in allogeneic HSC transplantation.

- Complications of HSC transplantation include acute or chronic graft-versus-host disease (GVHD) and pulmonary infections.
- The goals of treatment for GVHD are to manage symptoms and to prevent further damage to the body's organs.
- Immunosuppression with corticosteroids forms the basis of therapy in both acute and chronic graft-versus-host diseases.
- Treatment decisions are determined by the severity of the patient's symptoms and concerns about complications.

Acute Graft-versus-host Disease

Acute graft-versus-host disease (GVHD) generally occurs within first 100 days after allogeneic hematopoietic stem cell transplantation, which is immunological reaction of donor's effector T cells against host tissues.

- The three main tissues that acute graft-versus-host disease (GVHD) affects the skin, gastrointestinal tract and liver.
- Recipient who develops acute GVHD presents with dermatitis (maculopapular skin rashes), cutaneous blisters, crampy pain abdomen with or without diarrhea, persistent nausea and vomiting and hepatitis with elevation of serum bilirubin and liver enzymes.

Chronic Graft-versus-host Disease

Chronic graft-versus-host disease occurs either *de novo* or progression of acute GVHD after 100 days of allogeneic HSCT.

- Chronic graft-versus-host disease is a serious, potentially life-threatening post-transplant complication. Progressive graft-versus-host disease evolving from acute graft-versus-host disease has worst prognosis.
- Pathophysiology of chronic graft-versus-host disease is different from acute GVHD and mainly characterized by impaired immune tolerance mechanisms affecting innate and adaptive immunity.
- Both alloreactive and autoreactive donor-derived T cells and B cells play a key role in pathogenesis of chronic GVHD.
- Other pathophysiologic factors for chronic GVHD include indirect presentation of alloantigens through antigen-presenting donor cells and mechanism of chronic inflammation and subsequent scar formation and fibrosis.
- There may be limited involvement of skin and liver in chronic graft-versus-host disease.
- Extensive chronic graft-versus-host disease causes oral infections, hepatic dysfunction, eye lesions and skin lesions.

Opportunistic Infections

Infections may occur 2–4 weeks prior to engraftment.

- During early post-engraftment, impaired cellular and humoral immunity leads to viral infections (cytomegalovirus, herpes simplex virus and herpes zoster) and fungal infections.
- During late post-engraftment, prolonged T cell dysfunction may cause infections with *Streptococcus pneumoniae, H. influenzae* and *N. meningitidis*.
- Patient may develop diffuse or interstitial pneumonias.

Failure of Engraftment

Failure of engraftment occurs due to inadequate HSC number, infections, GVHD and high-risk unrelated donor and HLA mismatch.

Annexure

Diagnostic workup of acute myelogenous/lymphoblastic leukemia

Comprehensive relevant data

Clinical history data

- Age, sex, and ethnicity
- History of hematologic disorder (MDS/MPN) linked to AML
- History of genetic disorders (Fanconi anemia, Bloom syndrome, ataxia-telangiectasia, Down syndrome, xeroderma pigmentosum, Li-Fraumeni linked to AML and ALL)
- History of prior malignancy and exposure to chemotherapeutic agents (alkylating agents, topoisomerases II inhibitors), immunotherapy, and radiotherapy linked to AML
- History of ionizing radiation or other cytotoxic agents
- Relevant physical examination findings: lymphadenopathy, hepatomegaly, and splenomegaly, pain and tenderness in bones and joints, skeletal muscle aches, shortness of breath, constitutional symptoms (fever, weight loss, recurrent infections, fatigue, anorexia, night sweats), anemia and skin lesions (purplish spots, easy bleeding, and bruising)
- Relevant imaging findings

Recording reporting data

- All laboratory testing performed for the initial workup and diagnosis of patient with acute leukemia and all related collection and evaluation of samples/specimens such as laboratory, morphologic, immunophenotypic and cytochemical data must be performed in the laboratory.

Collection and evaluation of samples/specimens

- Complete blood counts
- Peripheral blood smear examination
- Bone marrow aspiration and/or touch imprint
- Bone marrow trephine biopsy
- Tissue biopsy from extramedullary disease
- Cytogenetic analysis (karyotyping) to detect complex chromosomal alterations
- Flow cytometry panel to distinguish AML, B-ALL, T-ALL including early T cell precursor and AML of ambiguous lineage
- Flow cytometry to detect minimal residual disease
- Immunohistochemistry of tissue biopsy to establish diagnosis
- Immunophenotyping to establish acute leukemias
- Cerebrospinal fluid sample collection to enumerate leukemic blasts
- Cytochemical stains to diagnose and classify leukemias
- Flow cytometry of cerebrospinal fluid
- Molecular genetic analysis on cryopreserved cells, nucleic acid, formalin-fixed paraffin-embedded tissue, or unstained bone marrow aspirate or peripheral blood smear

- Acute myelogenous leukemia (AML-M0–AML-M7) based on ≥20% myeloblasts in bone marrow and peripheral blood
- Acute lymphoblastic leukemia (ALL-1, ALL-2, ALL-3) based on ≥20% lymphoblasts in bone marrow and peripheral blood

Diagnostic workup of chronic myelogenous leukemia (CML, BCR-ABL1 fusion gene) and chronic lymphocytic leukemia (CLL)

CML, BCR-ABL1 fusion gene (Philadelphia chromosome)

- CML originates in the pluripotent hematopoietic stem cells of myeloid lineage (erythroid, and granulocyte precursors and megakaryocytes) as well as in B cells but not in T cells.
- Complete blood counts and PBF show >200 × 10^9/L to 700 × 10^9/L, and unique shift to left circulating myeloblasts, myelocytes, metamyelocytes and stab forms. The hallmark is basophilia with basophil counts often >1 × 10^9/L.
- CML chronic phase: Bone marrow and peripheral blood show blasts <10% with myelocytic bulge, basophils <20%, no dysplasia in megakaryocytes and bone marrow fibrosis.
- CML accelerated phase: Bone marrow and peripheral blood show blasts 10–19% and basophils >20%, atypical megakaryocytes, bone marrow fibrosis.
- CML blast phase: Bone marrow and peripheral blood blasts >20% and basophils >20%, atypical megakaryocytes, bone marrow fibrosis.
- Philadelphia chromosome can be detected in blood and bone marrow samples by cytogenetic analysis, FISH and quantitative PCR techniques.

Chronic lymphocytic leukemia

- Complete blood counts and PBF: Absolute lymphocytosis with ≥5 × 10^9/L mature but nonfunctional clonal B cells sustained for at least 3 months. Smudge cells with bare nuclei appear squashed, damaged during the slide preparation.
- Immunophenotyping and flow cytometry: The clonality of B cells needs to be confirmed by demonstrating immunoglobulin light chain restriction using flow cytometry. A panel of CD5, CD19, CD23, and immunoglobulin light chains and an absence of FMC-7 staining are usually sufficient to establish the diagnosis of CLL.
- Bone marrow aspirate: CLL always involves bone marrow.
- Bone marrow trephine biopsy: It is only done in cases with depressed blood counts.
- Serum immunoglobulin and direct antiglobulin test (DAT) in CLL with autoimmune hemolytic anemia.
- Molecular cytogenetic alterations (FISH) for del(13q), del(11q), del(17), add(13) in peripheral blood sample.
- Molecular genetic testing reveals TP53, SF3B1, ATM, NOTCH and IGHV gene mutations.

CHAPTER 10

Platelet Disorders and Bleeding Diathesis

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

HEMOSTASIS

- Normal endothelial hemostasis
  - Vascular component endothelial
  - Platelet component
  - Coagulation system
  - Blood clot retraction
  - Blood clot dissolution (lysis)
  - Coagulation system inhibitors
  - Tissue factor pathway inhibitor

PLATELET DISORDERS

- Thrombopoiesis
- Bleeding diathesis

QUANTITATIVE PLATELET DISORDERS

- Immune thrombocytopenia purpura
- Neonatal alloimmune thrombocytopenia

QUALITATIVE INHERITED PLATELET DISORDERS

- Platelet phospholipid plasma membrane defects
  - Glanzmann disease (thrombasthenia)
  - Bernard-Soulier syndrome
  - Scot syndrome
- Platelet storage pool defects
  - Hermansky-Pudlak syndrome
  - Chédiak-Higashi syndrome
  - Wiskott-Aldrich syndrome
  - Platelet storage pool deficiency (platelet dense granules defect)
  - Gray platelet syndrome (platelet α-granules defect)
  - Paris-Trousseau syndrome (platelet α-granule defect)
  - Jacobsen syndrome (platelet α-granule defect)
  - Quebec platelet syndrome (platelet α-granule defect)
  - X-linked macrothrombocytopenia with dyserythropoiesis
  - Thrombocytopenia with absent radii bone (tar syndrome)
- Congenital amegakaryocytic thrombocytopenia
- Platelet disorders of receptors and signal transduction
  - Cyclooxygenase enzyme deficiency disorder
  - Thromboxane A_2 receptor defect disorder
  - ADP receptors of platelets and their inhibition disorder
  - Bleeding diathesis due to glycoprotein VI deficiency disorder
  - Platelet type von Willebrand disease

QUALITATIVE ACQUIRED PLATELET DISORDERS

- Post-transfusion purpura
- Drug-induced thrombocytopenia
- Heparin-induced thrombocytopenia
- Pooling of platelets in massive splenoinegaly
- Hypoplasia of megakaryocytes
- Disseminated intravascular coagulation
- Thrombotic thrombocytopenic purpura
- Hemolytic uremic syndrome
- Dengue hemorrhagic fever
- Paraproteinemia-induced platelet dysfunction
- Uremia-induced platelet dysfunction

DIAGNOSTIC APPROACH AND TREATMENT OF PLATELET DISORDERS

- Platelet disorders treatment

SECONDARY THROMBOCYTOSIS AND ESSENTIAL THROMBOCYTHEMIA

- Secondary thrombocytosis
- Essential thrombocythemia

BLEEDING ASSOCIATED WITH VASCULAR DISORDERS

- Scurvy purpura
- Henoch-Schönlein purpura
- Senile purpura
- Simple bruising
- Hereditary hemorrhagic telangiectasia
- Marfan's syndrome
- Ehlers-Danlos syndrome

HEMOSTASIS

NORMAL ENDOTHELIAL HEMOSTASIS

Normal laminar blood flow dilutes activated clotting factors, which increases the inflow of inhibitors of clotting factors resulting in inactivation of clotting factors.

- Hemostasis is the maintenance of blood flow within vascular system by inhibiting activation of platelets, coagulation system and fibrinolytic system.
- Hemostasis involves the interaction of the blood vessels, platelets, coagulation factors leading to formation of hemostatic plug at the site of injury. Bleeding and clotting are the result of the failure of hemostatic mechanisms: (a) antithrombotic properties of resting vascular endothelium, (b) prothrombotic properties of injured or activated vascular endothelium.
- Resting vascular endothelium secretes antithrombotic molecules that inhibit hemostasis by various mechanisms. Prostacyclin (PGI_2), nitric oxide (NO) and ADPase inhibit platelet activation. Heparan-like molecules (heparan sulfate/GAG cofactor for antithrombin III (AT-III), thrombomodulin (TM), endothelial protein C receptor (EPCR), tissue factor pathway inhibitor (TFPI), tissue plasminogen

activator (tPA) inhibit activation of pathways of coagulation system cascade. Tissue-type plasminogen activator (tPA) and urinary-type plasminogen activator (uPA) activate fibrinolytic system.

- When vascular endothelium is injured, it secretes prothrombotic molecules that activate coagulation system cascade. Thromboxane A_2 (TXA_2) and platelet activating factor (PAF) activate platelets. Tissue factor (TF) initiates extrinsic pathway of coagulation system cascade. Plasminogen activator inhibitor 1 (PAI-1) inhibits fibrinolytic system. von Willebrand factor promotes platelet aggregation and acts as carrier of factor VIII in plasma and facilitates platelet activation.
- Hemostatic (antithrombotic and prothrombotic) and nonhemostatic functions of vascular endothelium are depicted in Table 10.1 and Fig. 10.1A and B.

Table 10.1 Hemostatic (antithrombotic and prothrombotic) and nonhemostatic functions of vascular endothelium

Component Characteristics	Functions
Antithrombotic functions of vascular endothelium	
Negatively charged endothelial surface	Repulsion of platelets and hemostatic proteins
Nitric oxide (NO)	Vasodilators and inhibitors of platelet recruitment and aggregation
ADPase (CD39)	▪ Antiplatelet property ▪ Degrades platelet ADP to AMP and adenosine; hence prevents platelet aggregation
Prostacyclin (PGI_2)	▪ Potent vasodilator ▪ Antiplatelet property by inhibiting platelet activation, adhesion and aggregation
Heparan-like molecules (heparan sulphate)	▪ Inhibitor of coagulation system ▪ Inhibits fibrin formation (cofactor for antithrombin III) and inactivates thrombin, factor X and other clotting factors
Thrombomodulin (TM)	▪ Inhibitor of coagulation system ▪ Binds thrombin, enhances activation of protein C, that inhibits the activity of factor V and hence inhibits conversion of fibrinogen to fibrin
Endothelial protein C receptor (EPCR)	▪ Binds protein C; facilitates activation of protein C
Tissue factor pathway inhibitor (TFPI)	▪ Binds tissue factor/factor VIIa/factor Xa complex; inhibits extrinsic pathway of coagulation
Tissue plasminogen activator (tPA)	▪ Activates fibrinolytic system
Annexin A_2 (tPA receptor A_2)	▪ Binds tissue-type plasminogen activator (tPA) and plasminogen; activates fibrinolysis
Urinary-type plasminogen activator receptor (uPAR)	Binds urinary plasminogen activator and plasminogen; activates fibrinolysis
Prothrombotic functions of vascular endothelium	
Endothelin (ET)	Vasoconstriction of blood vessel
von Willebrand factor	▪ vWF acts as a bridging molecules at the sites of vascular injury ▪ vWF promotes platelet aggregation under high-shear conditions ▪ Carrier of factor VIII in plasma; facilitates platelet adhesion
Tissue factor (TF) induced by bacterial toxins, IL-1, TNF-α	▪ Procoagulant property ▪ Initiates fibrin formation, activates factor VII
Plasminogen activator inhibitor 1 (PAI-1)	▪ Procoagulant property ▪ Inhibits activation of fibrinolytic system
Nonhemostatic functions of vascular endothelium	
Selective blood/tissue barrier	Keep blood cells and macromolecules in blood vessels; allows nutrient and gas exchange
Processing of blood-borne antigens	Contributes to cellular immunity
Basement membrane collagen synthesis	Provides back up protection for endothelial cells
Collagen of the matrix synthesis	Promotes platelet adhesion
Elastin synthesis	Vasodilates and vasoconstricts
Fibronectin synthesis	Binds one cell to another cell
Laminin	Contributes to platelet adhesion after vascular injury
Vitronectin	Binds one cell to another, possibly promotes platelet adhesion
Thrombospondin (encoded by THBS1 gene)	Adhesive glycoprotein binds one cell to another, possibly promotes platelet adhesion

Normal blood flow dilutes clotting factors, inhibits activation of vascular endothelial cells and enhances inflow of inhibitors of coagulation.

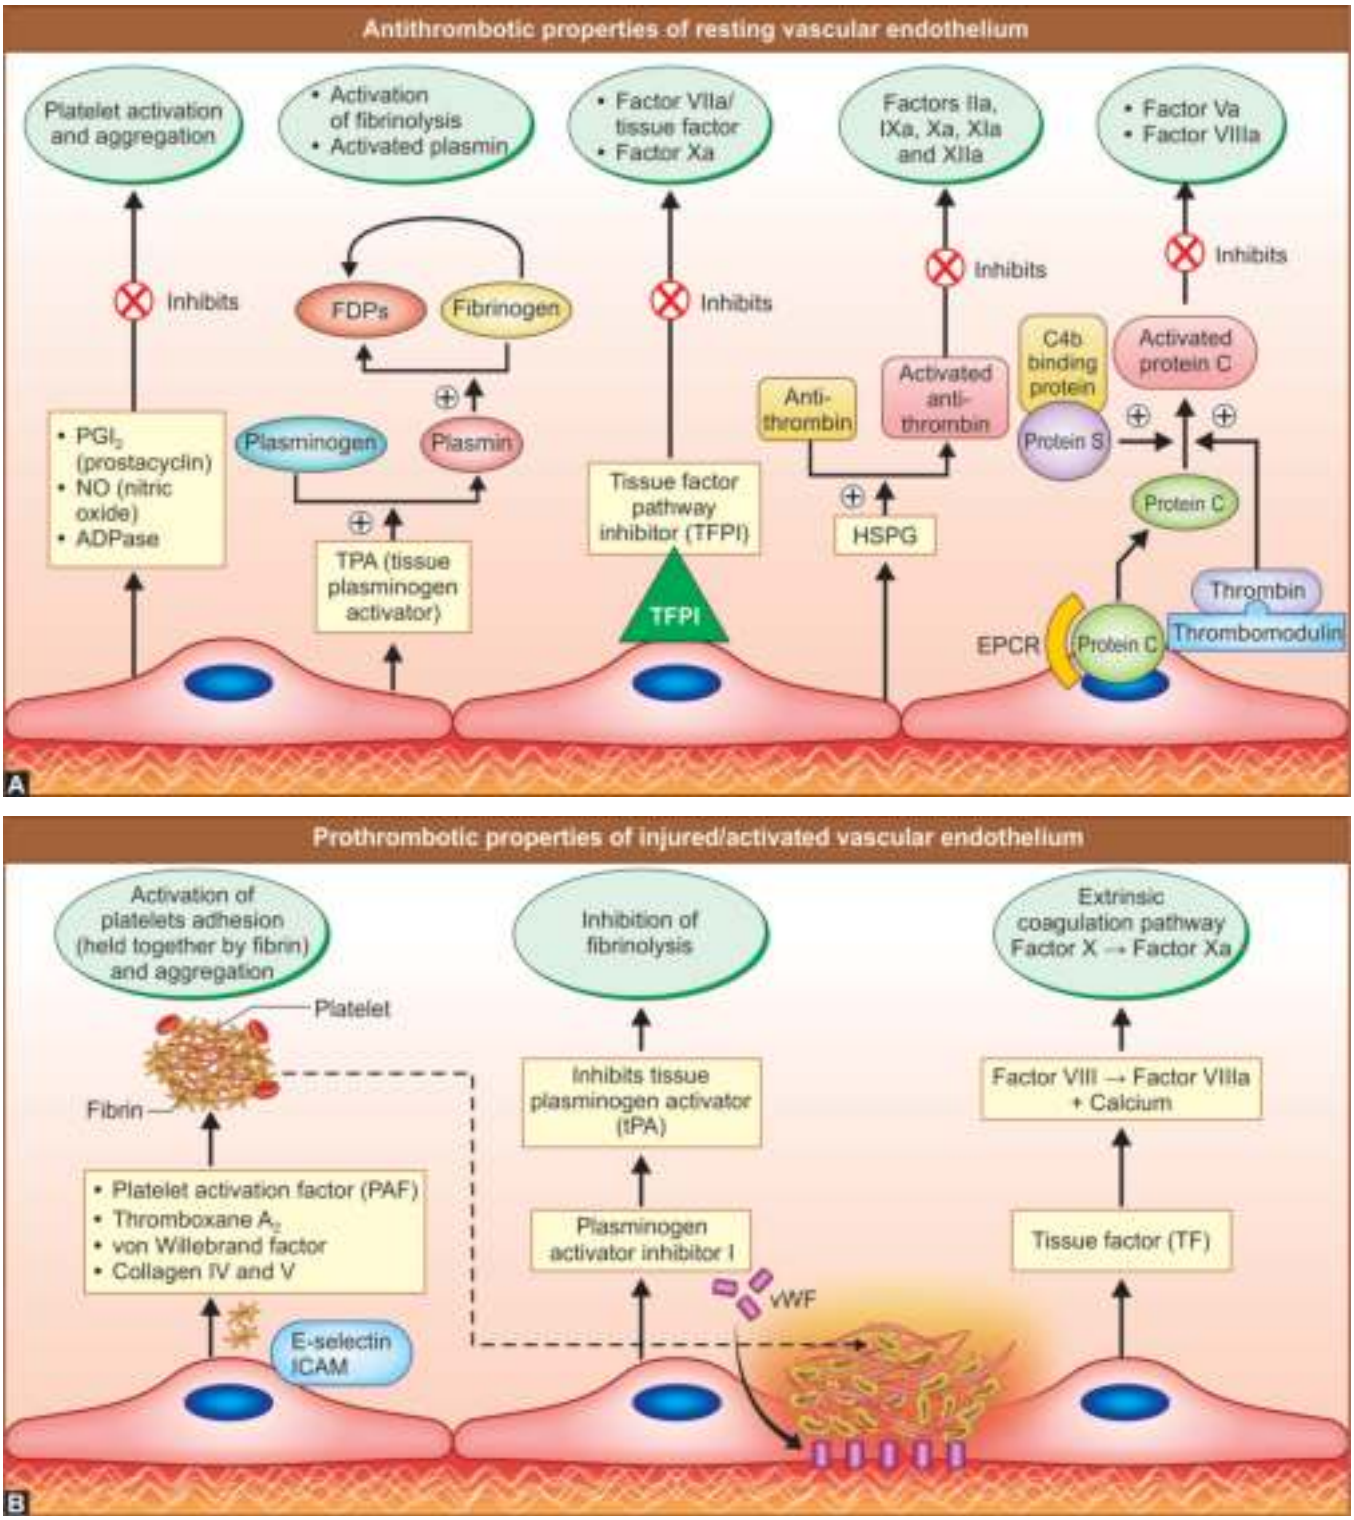

Fig. 10.1: Antithrombotic characteristics of resting vascular endothelium versus the prothrombotic effects of damaged or activated vascular endothelium. (A) Antithrombotic properties of resulting endothelium provide an environment that inhibit activation of hemostasis by secretion of substances that (1) inhibit platelet activation, e.g. PGI_2 (prostacyclin), NO (nitric oxide), ADPase; (2) inhibit coagulation (heparan sulfate/GAG as a cofactor for AT III (antithrombin III), TM (thrombomodulin) for activation of protein C, which inactivates activated FVa and FVIIIa, and TFPI 1, i.e. tissue factor pathway inhibitor 1); and (3) activate fibrinolysis (tPA, i.e. tissue-type plasminogen activator, uPA, i.e. urinary type plasminogen activator). (B) Prothrombotic properties of injured activated vascular endothelium secrete substances that (1) activate platelets (TXA_2, e.g. thromboxane, PAF, i.e. platelet activating factor) and bind them to the vessel wall (vWF, i.e. von Willebrand factor); (2) activate coagulation (TF, i.e. tissue factor which initiates formation of fibrin); and (3) inhibit fibrinolysis (PAI-1, i.e. plasminogen activator inhibitor 1). EPCR—endothelial protein C receptor. HSPG; heparin sulfate proteoglycans.

Hematology Pearls: Coagulation Factors

Coagulation factors	Synonyms	Site of synthesis
I	Fibrinogen	Liver
II	Prothrombin	Liver (vitamin K-dependent)
III	Tissue extract (thromboplastin)	Tissue
IV	Calcium	–
V	Labile factor	Liver
VI	Not assigned	NA
VII	Stable factor	Liver (vitamin K-dependent)
VIII	Antihemophilic globulin A	Liver, spleen, kidneys
IX	Christmas factor (anti-hemophilic factor B)	Liver (vitamin K-dependent)
X	Stuart-Prower factor	Liver (vitamin K-dependent)
XI	Plasma thromboplastin antecedent (antihemophilic factor C)	Unknown
XII	Hageman factor	Unknown
XIII	Fibrin stabilizing factor	Unknown
–	von Willebrand factor (factor vWF antigen assay)	Endothelial cells

Prekallikrein: Fletcher factor; Kininogen (high MW): Fitzerald factor; NA: Not applicable

Hematology Pearls: Stages of Primary Hemostasis

- Hemostasis is a stepwise process for stoppage of bleeding by sequentially transient vasoconstricting the blood vessel, forming a platelet plug and development of a blood clot.
- Blood clotting process requires the presence of platelets produced by bone marrow, von Willebrand factor generated by the vascular endothelium, and clotting factors synthesized in the liver by using vitamin K.
- Blood clot retraction and its dissolution also play significant role in hemostasis, which involves the interaction of substrates, enzymes, protein cofactors, and calcium ions in the blood or are released from platelets and cells in the blood vessel wall.

Injury to Vascular Endothelium and Vasoconstriction

- Injury ruptures the blood vessels. Injured vascular endothelium release chemical signals that cause transient vasoconstriction. It is mediated by reflex neural stimulation and endothelin release from vascular endothelial cells.
- Injury to the blood vessel causes contraction of vascular smooth muscle of the blood vessel wall and vasoconstriction, which reduces the blood flow.
- Both local nervous reflexes and local humoral factors such as thromboxane A_2 (TXA_2), which is released from platelets, contribute to the vasoconstriction.

Primary Hemostatic Plug Formation

On platelet activation, platelets synthesize their granule contents, which facilitates further activation of platelets. Platelet activation involves three overlapping machanisms.

- **Platelet adhesion:** Vascular endothelial injury causes platelets to adhere to subendothelial collagen. Shape change, secretion of granule contents, and aggregation follow. Within seconds of tissue injury, vWF (von Willebrand factor), released from the Weibel-Palade of vascular endothelium and α-granules of platelets, binds to the platelet using GpIa receptors resulting in adhesion of the platelets to the exposed collagen fibers of damaged blood vessels.
- **Platelet aggregation:** Platelets aggregate at the site of injury via GpIIb/3a using fibrinogen from the plasma as a linking molecule; results in formation of platelet primary hemostatic plug. Platelet primary hemostatic plug is weak; coagulation system cascade forms secondary hemostatic plug that stabilizes it.
- **Platelet secretion (degranulation):** The platelets become activated and release ADP and thromboxane A_2 (TXA_2), which attract additional platelets resulting in platelet aggregation and plug formation. Platelet shape change after stimulation by an agonist by ADP and thromboxane A_2 .
  - Agonist is a substance, which initiates a physiologic response when combined with a receptor. Pseudopodia develop on the surface of platelet, which contain a network of actin and myosin.
  - The microtubule circumferentially contracts resulting in activation of phospholipids and glycoprotein IIb/IIIa receptors.
  - Internal biochemical changes occur in the platelets resulting in granule secretion. Platelet-derived agonists and their receptors are given in Table 10.2.

Coagulation System

- Coagulation factors in intrinsic pathway, extrinsic pathway and common pathway are given in Table 10.3.
- Activators and inhibitors of clotting and fibrinolysis keep the coagulation system in balance.
  - Blood clotting occurs when vascular endothelium is injured and the activators of coagulation factors are exposed or released.
  - Blood clotting is controlled by fibrinolysis in response to activation of clotting factors. Inhibitors of both clotting and fibrinolysis serve to bring the coagulation system back to balance.
  - An imbalance in the activation or inhibition of either clotting and/or fibrinolysis causes thrombosis or bleeding manifestations. Activators and inhibitors of coagulation system and fibrinolytic system are given in Table 10.4.
- The terminal steps in both intrinsic and extrinsic pathways of coagulation system are same. Both coagulation system pathways lead to the activation of factor X.

- Intrinsic pathway of coagulation system is initiated by activation of circulating factor XII.
- Extrinsic pathway of coagulation system is activated by a cellular lipoprotein known as tissue factor that becomes exposed when tissues are injured.

- Calcium, factor X, factor V, platelet phospholipids combine to form prothrombin activator, which then converts prothrombin to thrombin. This interaction causes conversion of fibrinogen into fibrin strands stabilized by fibrin stabilizing factor that creates the insoluble blood clot, with platelets and red blood cells resulting in stoppage of bleeding.

Blood Clot Retraction

Within a few minutes after blood clot is formed, the actin and myosin in the platelets that are trapped in the blood clot, contract and pull fibrin strands (plasma without fibrinogen) from the blood clot resulting in shrinkage of blood clot.

Blood Clot Dissolution (Lysis)

- Blood clot dissolution begins shortly after blood clot is formed. Thrombin activates protein C. The protein C activates plasminogen activator, that gets trapped in the blood clot.
- The slow release of a very powerful plasminogen activator (tPA) from the injured tissues and vascular endothelium now converts plasminogen to plasmin, which digests the fibrin strands resulting in dissolution of the blood clot.
- Laboratory tests in defects of primary hemostasis in thrombocytopenia, platelet dysfunction and vascular purpura are given in Table 10.5.

Table 10.2 Platelet-derived agonists and their receptors

Platelet-derived Agonist	Agonist Receptors
ADP	▪ $P2Y_1$ ▪ $P2Y_2$
Serotonin	$5HT_2$
Platelet activating factor (PAF)	PAFR
Thromboxane A_2	TP

Agonist is a substance, which initiates a physiologic response when combined with a receptor.

Table 10.3 Coagulation factors in intrinsic, extrinsic and common pathways

Intrinsic Pathway of Coagulation System

- Prekallikrein
- High molecular weight kininogen
- Factor XII (Hageman factor)
- Factor XI (plasma thromboplastin antecedent)
- Factor IX (Christmas factor)
- Factor VIII (antihemophilic globulin A)

Extrinsic Pathway of Coagulation System

- Factor VII (stable factor)
- Tissue factor III (TF III)

Common Pathway of Coagulation System

- Factor X (Stuart-Prower factor)
- Factor V (labile factor)
- Factor II (prothrombin)
- Factor I (fibrinogen)

Table 10.4 Activators and inhibitors of coagulation system and fibrinolytic system

Activators	Inhibitors
Coagulation system	
▪ Coagulation factors ▪ Phospholipids ▪ Calcium ions	▪ Antithrombin ▪ Protein C ▪ Protein S, tissue factor pathway inhibitor (TFPI) ▪ α-Antitrypsin ▪ C_1-inhibitos, heparin cofactor II
Fibrinolytic system, also termed the plasminogen-plasmin system	
▪ Factor XIIa ▪ Factor XIa ▪ Kallikrein ▪ Tissue plasminogen activator (tPA) ▪ Urinary plasminogen activator (uPA)	▪ Plasminogen activator inhibitor I and II (PAI-I and PAI-II) ▪ α_2-Macroglobulin ▪ Thrombin activatable fibrinolysis inhibitor (TAFI)

Table 10.5 Laboratory tests in defects of primary hemostasis in thrombocytopenia, platelet dysfunction and vascular purpura

Screening Tests	Thrombocytopenia	Platelet Dysfunction	Vascular Purpura
Platelet count	Decreased	Usually normal	Normal
Prothrombin time (PT)	Normal	Normal	Normal
Activated partial thromboplastin time (APTT)	Normal	Normal	Normal
Template bleeding time	Abnormal	Normal or abnormal	Normal or abnormal

VASCULAR ENDOTHELIAL COMPONENT

Vascular system is composed of blood vessels, that carry blood and lymph throughout the body. Vascular endothelium is the first-line of defense for normal hemostasis, which is supported by subendothelial tissue, which maintains the integrity of structure, and lined by endothelium. Laminar blood flow dilutes clotting factors and inhibits endothelial cell activation, which increases the inflow of inhibitors of clotting factors.

- Normal (resting) vascular endothelium provides an environment that inhibits activation of hemostasis by synthesis of substances that (a) inhibit platelet activation, e.g. prostaglandin I_2 (PGI_2), nitric oxide (NO), ADPase; (b) inhibit coagulation, e.g. heparan sulfate/GAG as a cofactor for antithrombin (AT), thrombomodulin (TM) for activation of protein C, which inactivates activated factor Va, factor VIIIa; and TFPI; and (c) activates fibrinolysis, e.g. tissue-type plasminogen activator 1 (tPA-1) and urinary-type plasminogen activator (uPA). It is worth mentioning that protein C combines with endothelial protein C receptor (EPCR) and gets activated and then combine with protein C (PC) resulting in inhibition of factor V and factor VIIIa.
- Injured (activated) vascular endothelium synthesizes substances that (a) activate platelets, e.g. thromboxane A_2 (TXA_2) and platelet activating factor (PAF) and bind them to the vessel (vWF); (b) activate coagulation, e.g. tissue factor (TF), which initiates formation of fibrin; and (c) inhibit fibrinolysis.

PLATELET COMPONENT

Platelets play a central role in normal hemostasis by forming primary hemostatic plug. Platelets are membrane bound porous disc-like structures ranging from <5 to 12 femtoliter, which maintain the physical integrity of the vascular endothelium. Platelets synthesize platelet-derived growth factor (PDGF), which repairs injured vascular endothelium.

- Platelet contains α-granules and dense granules. In platelets, α-granules are the storage sites for certain proteins that are important for the hemostatic process, which contain platelet factor IV, thrombospondin, factor V, vWF, plasminogen and platelet-derived growth factor. Platelets dense granules contain ADP, ATP, calcium and serotonin, which play an important role in recruitment of additional platelets.
- β-Thromboglobulin is chemoattractant. PF4 (platelet factor 4) neutralizes chemoattractant property. Factors V and XI participate in fibrin formation. Fibrinogen is converted to fibrin.
- Fibrinogen also participates in platelet aggregation. Protein S regulates fibrin formation via protein C pathway. Tissue factor pathway inhibitor (TFPI) regulates fibrin formation by inhibiting factor VII/tissue factor complex.
- Fibronectin and von Willebrand factor (vWF) participate in adhesion of platelets to the collagen. Thrombospondin stabilizes platelets.
- Stages of thrombopoiesis are shown in Fig. 10.2. Normal megakaryocytes in bone marrow trephine biopsy are shown in Fig. 10.3. Structure of platelet is shown in Fig. 10.4. Structure and functions of platelet are given in Table 10.6. Formation of hemostatic plug by platelets adhesion, activation, aggregation and degranulation is shown in Fig. 10.5A to C.

Thrombopoiesis

Thrombopoietin, vitamin B_{12} and folic acid participate in platelets production in bone marrow. Platelets are formed by precursor cells called megakaryocytes that reside within bone marrow by a process called endomitosis where each megakaryocyte gives rise to approximately 3000 platelets. Two-thirds of platelets remain in circulation, while one-third of platelets is stored in spleen. Platelets express glycoprotein receptors of the integrin family on their surface. The survival of blood platelets is assured to be best criteria for their integrity, viability, and physiological activity. Recent studies have revealed life span of platelets is 3–7 days.

Primary Hemostatic Plug Formation

Formation of primary hemostatic plug involves platelet activation and subsequent generation of fibrin via coagulation system cascade. On platelet activation, platelets synthesize their granule contents, which facilitate further activation of platelets. Platelet activation involves three overlapping machanisms.

- **Platelet adhesion:** Exposure of subendothelial tissue activates platelets, which change their shape by producing pseudopodia. Platelets adhere to subendothelial tissue via receptor sites, which interact with von Willebrand factor (vWF) synthesized by vascular endothelial cells and megakaryocytes. The vWF binds with coagulation factor VIII in the plasma (Fig. 10.6).
- **Platelet aggregation:** Platelets interact with each other via receptor sites, which utilize fibrinogen as an intercellular bridge. Platelets contract and release α-granules and dense granules, which contain numerous substances participating in platelet aggregation. Cell membrane of platelets synthesizes

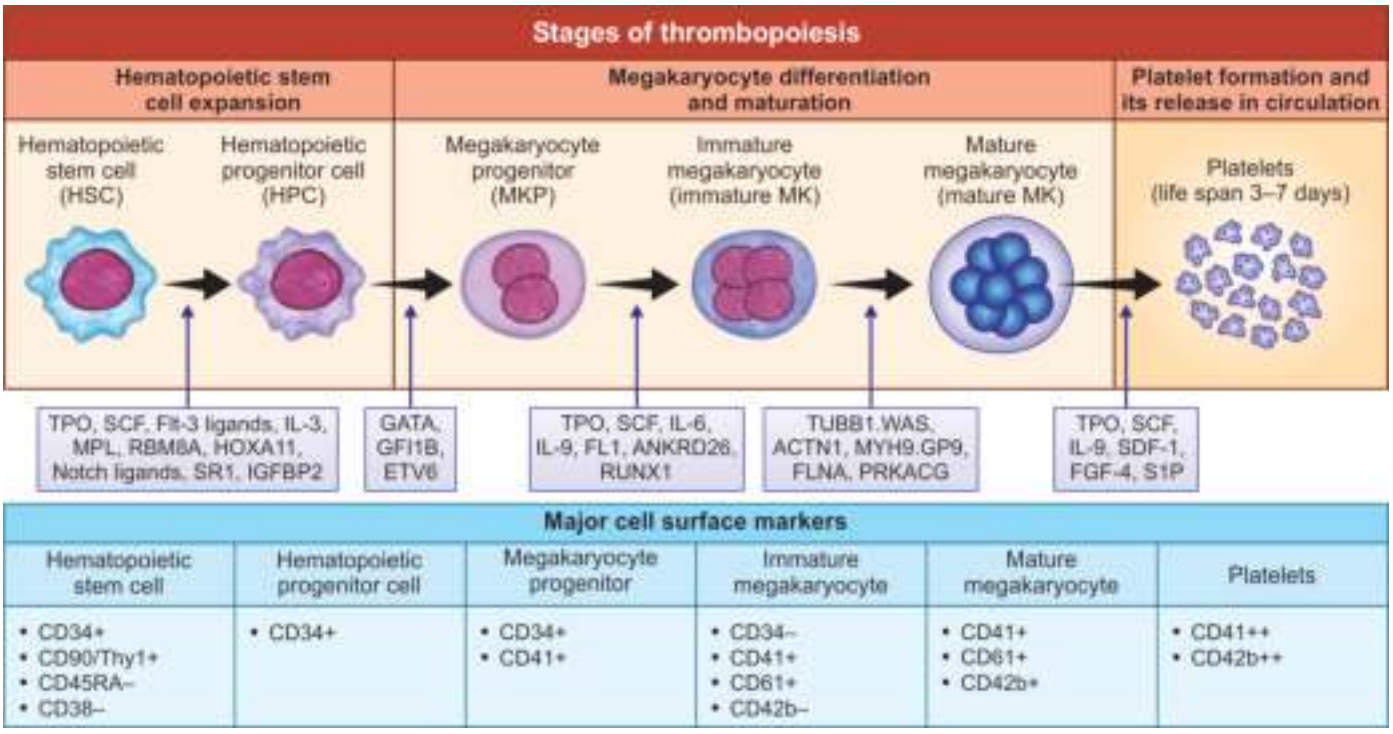

Fig. 10.2: Stages of thrombopoiesis. Thrombocytes are derived from hematopoietic stem cell (HSC) in the bone marrow. As megakaryocytes develop through stage of megakaryocyte differentiation and maturation under the influence of hematopoietic growth factors, mature megakaryocytes undergo a process of fragmentation that results in the release of approximately 3000 platelets per megakaryocyte.

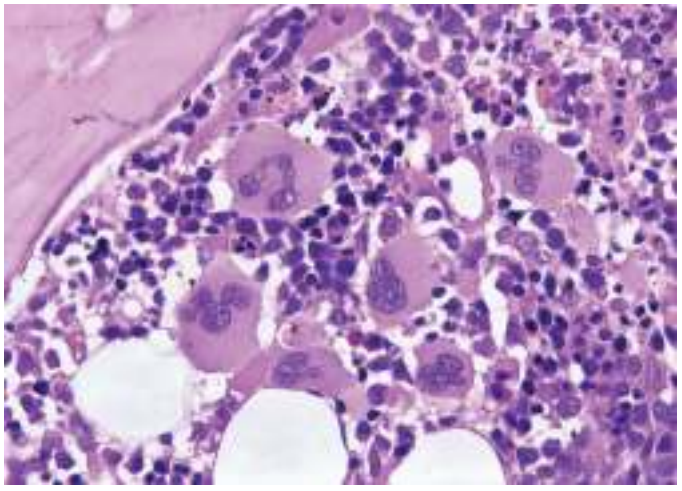

Fig. 10.3: Normal megakaryocytes in bone marrow trephine biopsy. Each megakaryocyte has a lobated nucleus responsible for the production of blood thrombocytes (platelets), which are essential for formation of primary hemostatic plug during bleeding.

metabolic arachidonic product such as thromboxane A_2, which also promotes platelet aggregation in addition to vasoconstriction (Fig. 10.7). Deficiency of GpIIb/IIIa results in Glanzmann's disease.

- **Platelet secretion (degranulation):** The platelets become activated and release ADP and thromboxane A_2 (TXA_2). The ADP and TXA_2 attract additional platelets resulting in platelet aggregation and primary hemostatic plug formation. Platelet changes its shape after stimulation by an agonist by ADP and thromboxane A_2 (TXA_2). Agonist is a substance, which initiates a physiologic response when combined with a receptor. Pseudopodia develop on the surface of platelet, which contain a network of actin and myosin. The microtubule circumferentially contracts resulting in activation of phospholipids and glycoprotein IIb/IIIa receptors. Internal biochemical changes occur in the platelets resulting in granule secretion. Formation of primary hemostatic plug occurs by platelet activation, adhesion, aggregation and degranulation.

COAGULATION SYSTEM

Exposure to tissue factor activates extrinsic pathway of coagulation system. Thrombin generation augments the platelet activation. The activated platelets provide phospholipid, which is an essential cofactor at several points in the coagulation.

- Formation of secondary hemostatic plug occurs by intrinsic and extrinsic pathways of coagulation system as a result of vascular endothelial injury, which lead to activation of factor X, conversion of prothrombin to thrombin. Thrombin converts fibrinogen to fibrin. Fibrin stabilizing factor stabilizes

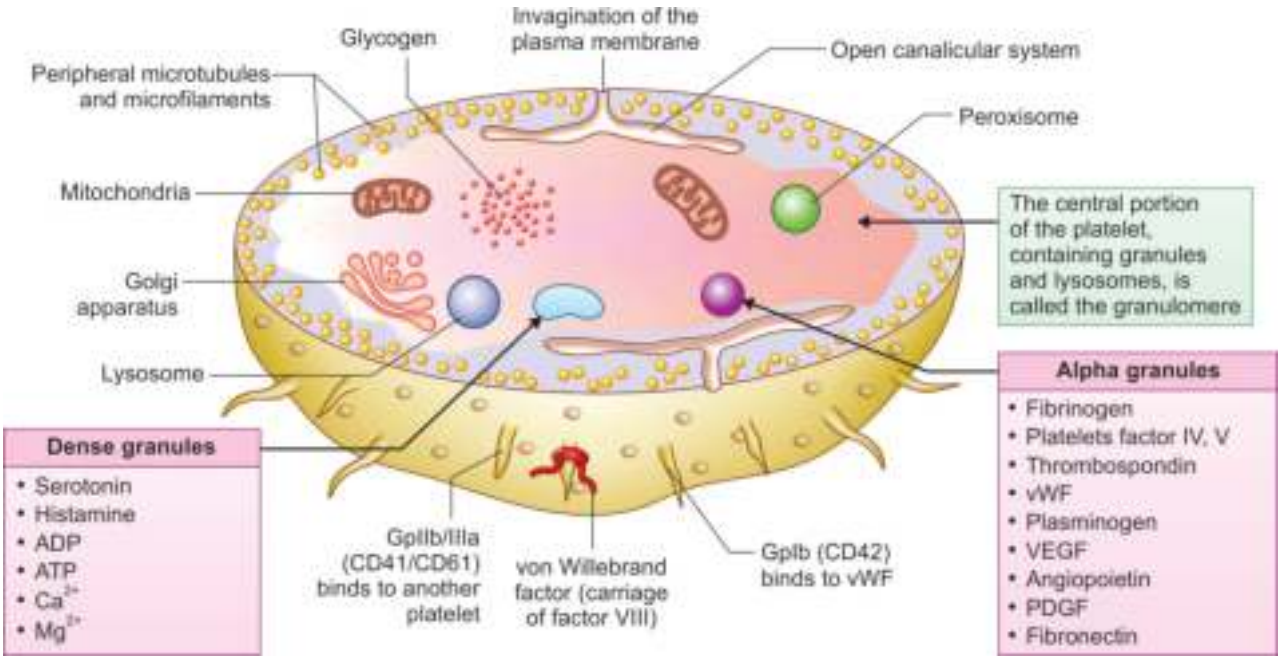

Fig. 10.4: Structure of platelets: Platelet contains α-granules and dense granules. In platelets, α-granules are the storage sites for certain proteins that are important for the hemostatic process. The α-granules contain platelet factor IV, thrombospondin, factor V, vWF, plasminogen and platelet-derived growth factor. The dense granules contain ADP, ATP, calcium and serotonin. Proteins of dense granules (ADP and serotonin) play an important role in recruitment of additional platelets. β-Thromboglobulin is chemoattractant. PF4 (platelet factor 4) neutralizes chemoattractant property. Factors V and XI participate in fibrin formation. Fibrinogen is converted to fibrin. Fibrinogen also participates in platelet aggregation. Protein S regulates fibrin formation via protein C pathway. TFPI (tissue factor pathway inhibitor) regulates fibrin formation by inhibiting factor VII/tissue factor complex. Fibronectin and vWF (von Willebrand factor) participate in adhesion of platelets to the collagen. Thrombospondin stabilizes platelets.

Table 10.6 Structure and functions of platelet

Features	Functions
Platelet membrane	
Glycocalyx	▪ Outermost coat comprising glycolipids, glycoproteins and mucopolysaccharide ▪ Negative charge due to sialic acid residue of proteins and lipids
Plasma membrane	▪ Composed of glycolipids, cholesterol and glycoproteins ▪ Lipoprotein layer containing platelet factor 3 involved in blood coagulation
Membrane glycoproteins (acting as receptors for cell-cell and ligand-cell interaction)	
Glycoprotein IIb/IIIa	▪ Cross-linking of GpIIb/3a to vWF and fibrinogen leading to platelets aggregation ▪ Deficiency of GpIIb/3a results in Glanzmann's disease
Glyoprotein Ib–IX	In Bernard-Soulier syndrome, deficiency of GpIb–IX results in bleeding diathesis
Cytoskeleton	
Short actin filament	Present under plasma membrane involved in maintaining discoid shape
Actin microfilament network	Present in cytoplasm
Microtubules	Present in peripheral part of cytoplasm involved in maintaining discoid shape
Dense granules	
ADP	Recruitment of platelets and activation of new platelets resulting in platelets aggregation
ATP	Agonist for platelets and other cells
Calcium	Extracellular source for hemostatic reactions
Serotonin	Vasoconstrictor

Contd...

Table 10.6 Structure and functions of platelet (*Contd...*)

Features	Functions
α-Granules	
Fibrinogen	▪ Aggregation of platelets ▪ Fibrinogen itself gets converted to fibrin
Platelet factor IV	Aggregation of platelets
Thrombospondin	Aggregation of platelets
Factor V	Adhesion of platelets
Hemostasis	vWF binds to factor VIII, platelets and connective tissue
Plasminogen	Plasminogen gets converted to plasmin. Plasmin participates in fibrinolysis
Platelet-derived growth factor (PDGF)	Promotes repair of injured blood vessel

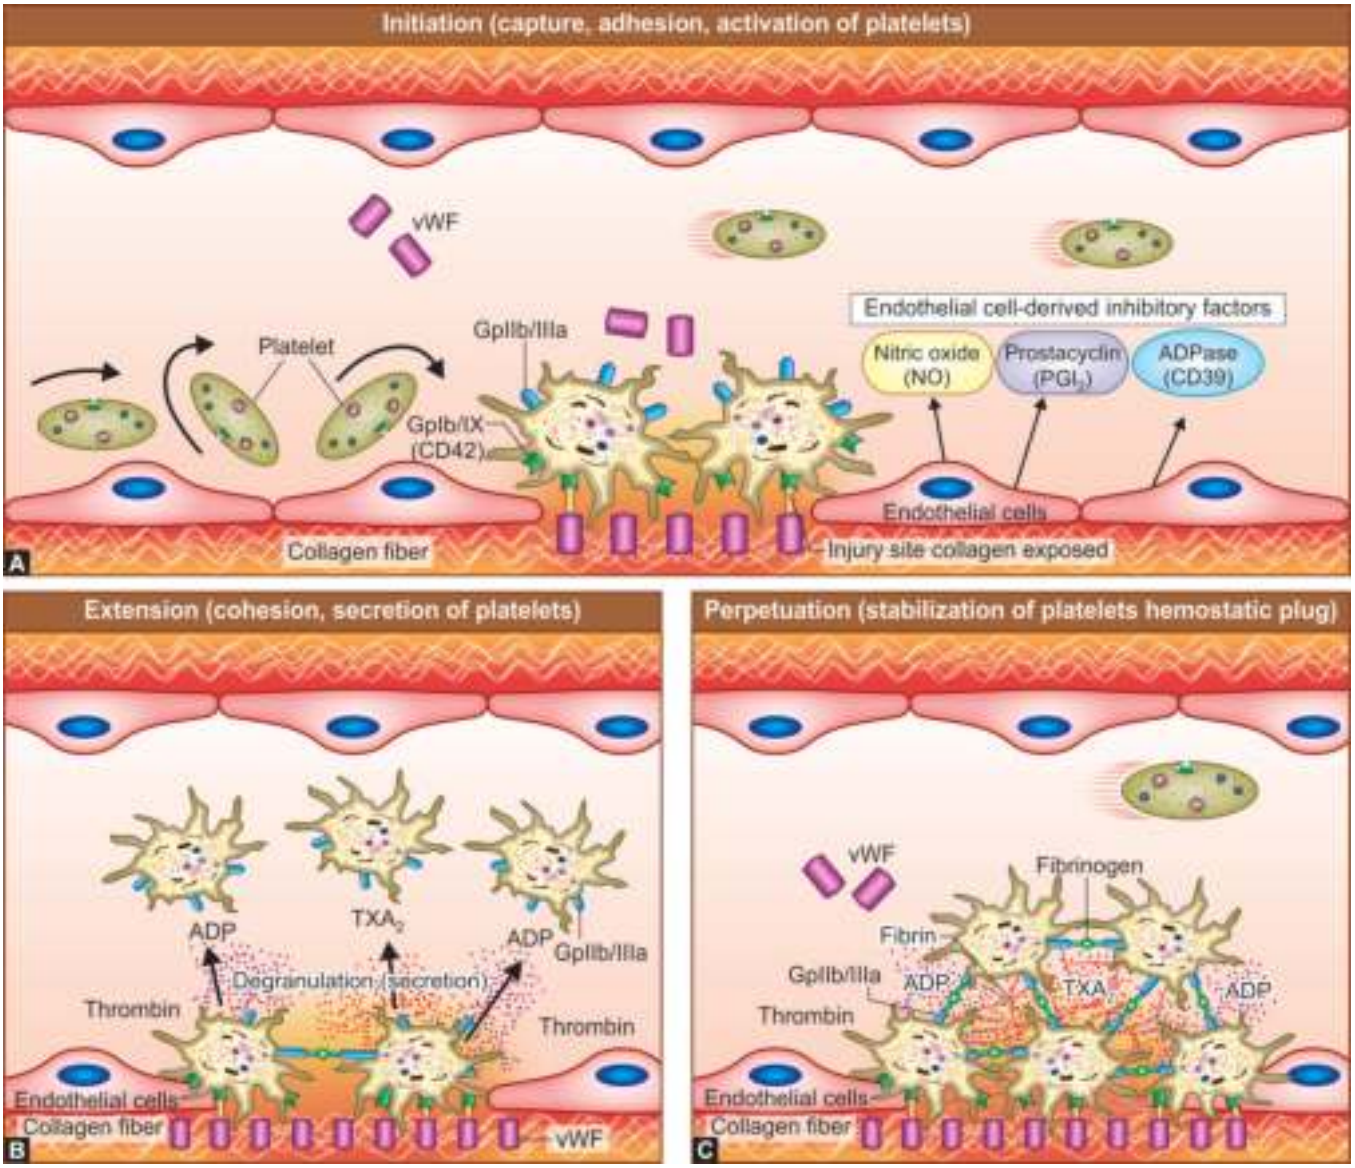

Fig. 10.5: Formation of primary hemostatic plug by platelets activation, adhesion, aggregation and degranulation. Platelet activation involves three overlapping mechanisms. (A) Adhesion of platelets to the exposed subendothelium is mediated by the binding of von Willebrand factor (vWF) to glycoprotein (Gp) Ib/IX (CD42) resulting in initiation of signal for activation of platelets. (B) Exposure of GpIIb/IIIa (CD41/61) to the fibrinogen receptor on the platelet surface permits for platelet aggregation. (C) At the same time, platelets synthesize their granule contents, which facilitate further platelets activation.

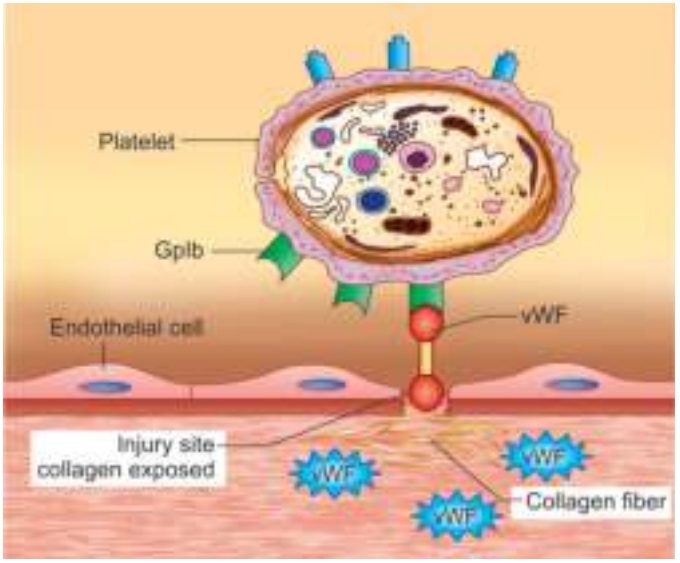

Fig. 10.6: Platelets adhesion participating in primary hemostatic plug.

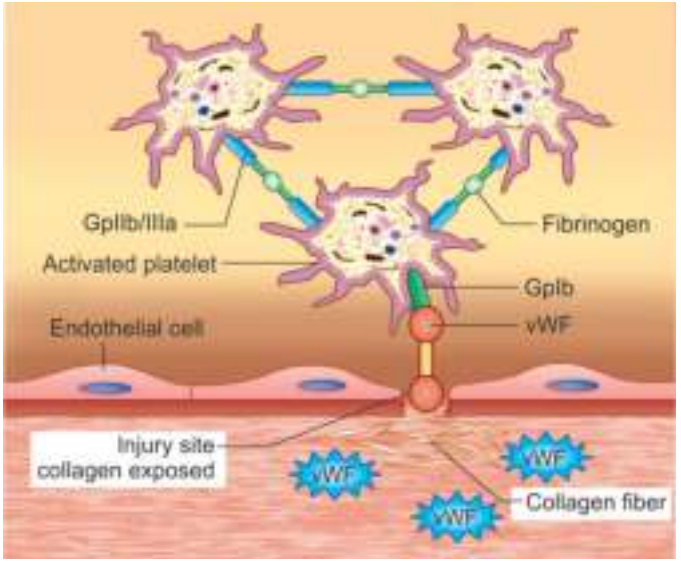

Fig. 10.7: Platelets aggregation participating in primary hemostatic plug.

fibrin resulting in holding of blood clot by insoluble fibrin strands.

- Coagulation system is composed of extrinsic and intrinsic pathways, which reflect how blood clotting occurs in the test tube during tests. Blood clotting in the body is initiated differently.
- Fibrinolysis is the controlled dissolution of the formed blood clot, that occurs when the injured blood vessel begins to heal, and initiated when formation of blood clot begins. In this way, fibrinolysis serves as regulatory mechanism to limit excess formation of blood clot. Plasminogen activator cleaves plasminogen to form plasmin. Plasmin binds to specific receptors on fibrin strands network and begins degrading the fibrin strands resulting in dissolution of blood clot. Plasmin also degrades fibrinogen, factor V, factor VIII, prothrombin, and factor XII.
- Dissolution of blood clot restores normal blood flow. Plasmin action is limited to the site of injury and formation of thrombus or clot. Systemic action of plasmin does not occur. Fibrinolytic system is shown in Figs 10.8 and 10.9.

BLOOD CLOT RETRACTION

Blood clot retraction occurs when platelets are trapped within the enlarging blood clot, which occurs within 20–60 minutes after a blood clot has formed, contributing to hemostasis. Actin and myosin of platelets pull the clot towards platelets. This phenomenon causes squeezing of serum from the blood clot resulting in shrinkage of blood clot. Blood clot retraction requires large number of platelets, and failure of clot retraction is indicative of a low platelet count. Thrombomodulin synthesized by vascular endothelium has antithrombotic activity.

BLOOD CLOT DISSOLUTION (LYSIS)

Blood clot dissolution begins shortly after a blood clot is formed.

- Thrombin activates protein C, which activates plasminogen activator, that gets trapped in the blood clot.
- The slow release of a very powerful plasminogen activator is called tissue plasminogen activator (tPA) from the injured tissues/vascular endothelium now converts plasminogen to plasmin. The plasmin digests the fibrin strands resulting in dissolution of the blood clot.

Clinical Pearls: Recombinant Tissue Plasminogen Activator (tPA)

- Tissue plasminogen activator functions by catalyzing the conversion of plasminogen to plasmin, the primary enzyme involved in dissolving blood clots.
- Recombinant biotechnology has allowed to manufacture tissue plasminogen activator (tPA) such as alteplase, reteplase and teneplase in the laboratories.
- Recombinant tissue plasminogen activators are administered in ischemic cerebral stroke within 3 hours of onset, myocardial infarction if there is delay of >1–2 hours before percutaneous transluminal coronary angioplasty, severe pulmonary thromboembolism causing severe instability due to pressure in heart, and deep vein thrombosis.

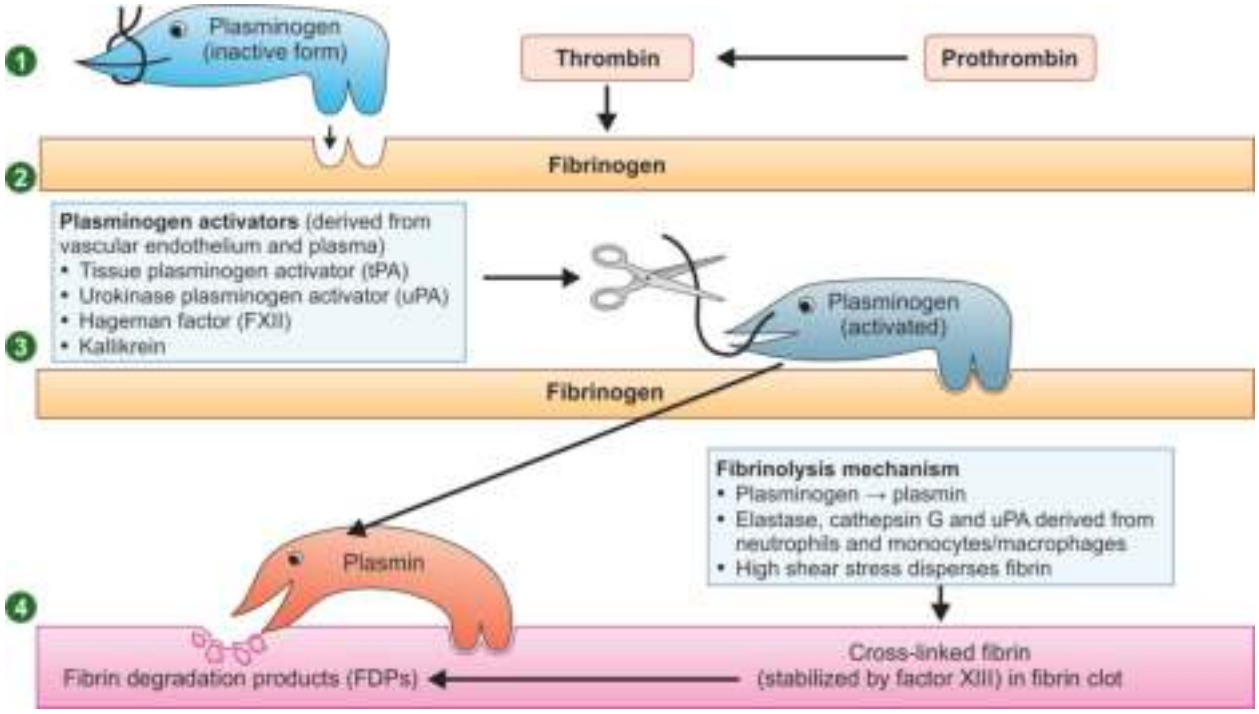

Fig. 10.8: Schematic representation of fibrinolysis. Thrombin converts plasminogen to plasmin, which breaks down the cross-linked fibrin into soluble fibrinogen degradation products (FDPs). Plasminogen activators such as tissue plasminogen activator or urokinase, activate plasminogen to form plasmin enzymatically cleaves insoluble fibrin polymers into soluble degradation products (FDPs), thereby affecting the removal of unnecessary fibrin clot. Fibrinolysis is inhibited by plasminogen activator inhibitors or plasmin inhibitors or thrombin-activable fibrinolysis inhibitors.

COAGULATION SYSTEM INHIBITORS

There are two major inhibitory pathways of coagulation system, that determine the role at which coagulation system cascade is amplified. Protein C and protein S inhibit pathways of coagulation system. An additional inhibitory mechanism is antithrombin III, that inhibits coagulation system cascade. Vitamin K-dependent clotting factors (II, VII, IX and X), protein C and protein S are synthesized by liver. Antithrombin III, protein C and protein S prevent thrombus formation. Deficiency of antithrombin III, protein C and protein S are associated with recurrent venous thrombosis and thromboembolism.

- **Antithrombin III:** Antithrombin III antagonizes thrombin activity and also inhibits factors XIIa, XIa, Xa, and IXa. Heparin-like molecules synthesized by vascular endothelium activates antithrombin III. Hence, in clinical practice, heparin is administered to minimize thrombosis.
- **Protein C:** Protein C is vitamin K-dependent natural anticoagulant presents in circulation, which inhibits factors V and VIII. Protein C is activated by modified thrombin protein. Thrombomodulin synthesized by vascular endothelium modifies thrombin molecule. The modified thrombin protein can no longer convert fibrinogen to fibrin. Protein C also enhances fibrinolysis. Protein C deficiency is the most common cause of inherited thrombophilia.
- **Protein S:** Protein S is vitamin K-dependent natural anticoagulant present in circulation. Protein C serves as a cofactor and enhances the activity of protein C resulting in inhibition of factors V and VIII. Protein S does not require activation.

TISSUE FACTOR PATHWAY INHIBITOR

Tissue factor pathway inhibitor (TFPI) is the main regulator of the tissue factor of coagulation system. TFPI encoded TFPI gene mapped on chromosome 2q32 is synthesized by vascular endothelium. Tissue factor plays a primary role in both normal hemostasis and thrombosis. With vascular injury, tissue factor binds plasma factor VIIa leading to hemostatic plug formation and vascular sealing. TFPI binds activated factor VII (VIIa) complex-activated factor X (Xa) and inactivates them rapidly in circulation, so limiting extrinsic pathway of coagulation system cascade. TFPI consists of three Kunitz domains. Kunitz domains (K1 and K2) bind with VIIa–Xa complex. The third Kunitz domain may interact with the plasma membrane.

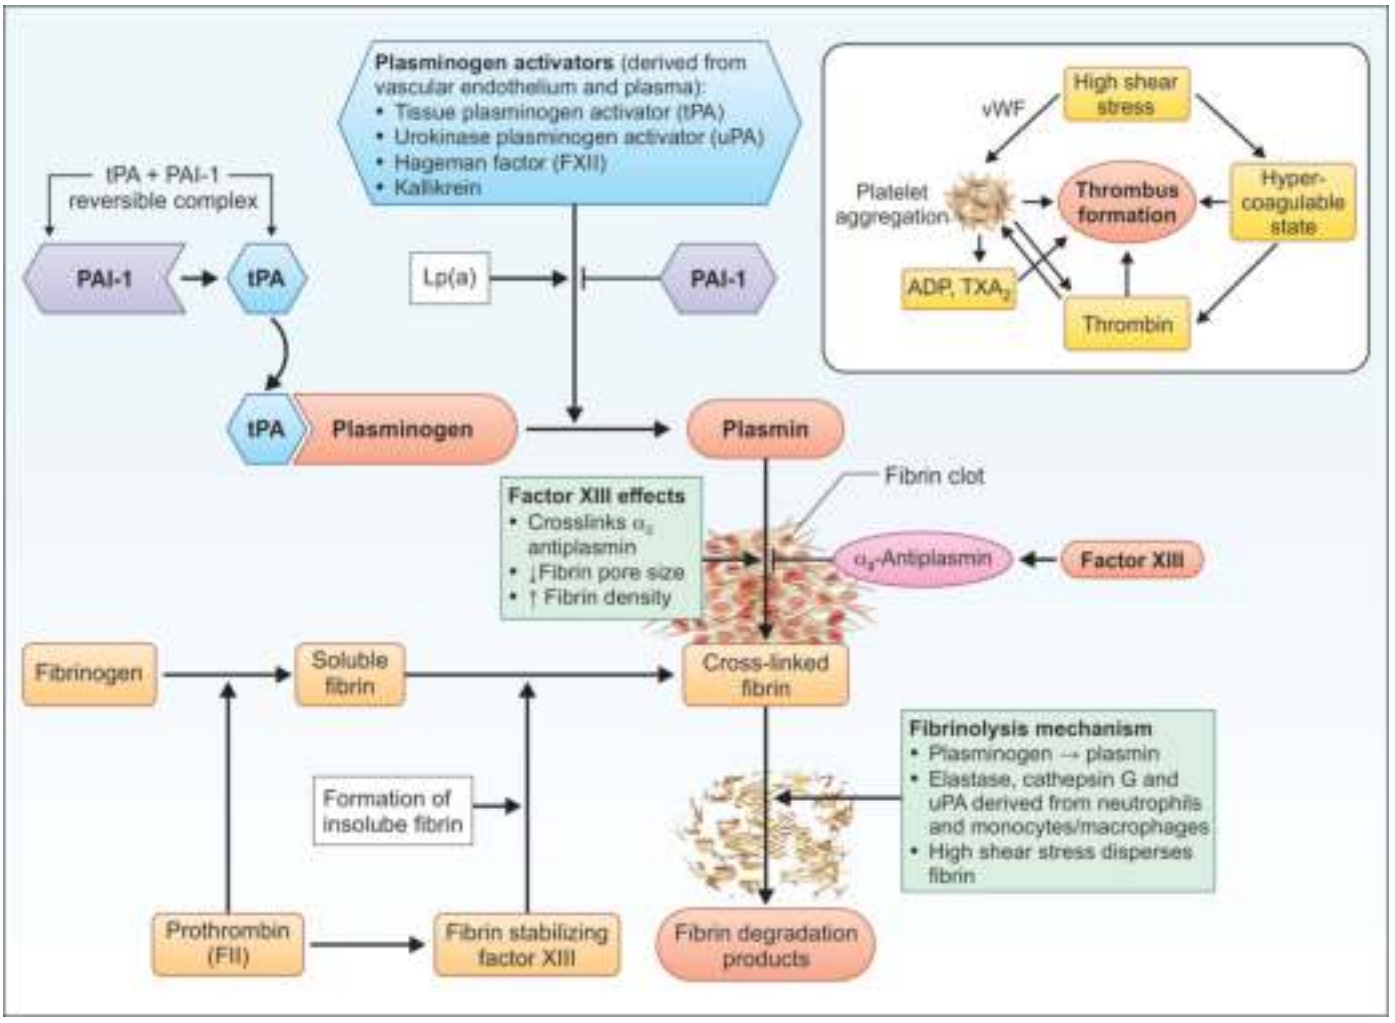

Fig. 10.9: Schematic representation of fibrinolysis. Thrombin converts plasminogen to plasmin, which breaks down the cross-linked fibrin into soluble fibrinogen degradation products (FDPs). Tissue plasminogen activator (tPA) is mainly responsible for the dissolution of fibrin formed in the circulation. Thrombolysis is inhibited by release of plasminogen activator inhibitor 1 (PAI-1) by platelets; and elastase and cathepsin G from white blood cells that become trapped in the thrombus, which directly breakdown fibrin; the plasminogen activators tPA and uPA (released from endothelial cells); and fibrin structural properties. The thickness and porosity of fibrin fibers also determines structural stability and susceptibility to thrombolysis. Lp(a), a homologue of plasminogen, can inhibit tPA-mediated plasminogen activation.

PLATELET DISORDERS

The hemostatic system consists of platelets, coagulation factors and the vascular endothelium. Platelets arise from the fragmentation of the cytoplasm of the megakaryocytes in the bone marrow and circulate in the circulation as disc-shaped anucleate particles for 3–7 days. Under physiologic state, the resistance of the vascular endothelium to interactions with platelets and coagulation factors prevent thrombosis. When vascular endothelium continuity is disrupted and the underlying subendothelial matrix is exposed, a coordinated series of events are set in motion to seal the defect. The process is known as primary hemostatic plug formation.

THROMBOPOIESIS

Developing megakaryocytes generally undergo nuclear maturation (ploidization) prior to cytoplasmic development. Megakaryocytes at any ploidy level 8N or higher can undergo cytoplasmic maturation and platelet production.

- Platelets are first released between the endothelial cells of the bone marrow sinuses as proplatelets, which break into mature platelets and released into the peripheral blood.
- Platelets are 3–4.5 μm in diameter with normal life span of 4–10 days. Normal platelet count is 150×10^9/L

to 450×10^9/L. Platelets are produced by pinching of cytoplasm of megakaryocytes situated close to sinusoids in the bone marrow. Thrombopoietin synthesized by liver regulates thrombopoiesis.

- Platelets participate in surveillance of vascular endothelium continuity, formation of primary and secondary hemostatic plugs; and healing of injured tissue. Platelets are also known to be involved in inflammation and, wound healing and cardiovascular disorders.

BLEEDING DIATHESIS

Patient presents with bleeding diathesis due to impaired blood vessel wall integrity, platelet deficiency or dysfunction; derangement in the coagulation system cascade; and combination of clotting factors. The most important cause of abnormal bleeding is a platelet disorder due to quantitative decreased production of platelets (thrombocytopenia) or defective qualitative platelet function.

- Quantitative platelet disorders (thrombocytopenias) occur when platelet count falls below $<100 \times 10^9$/L. Patient presents with bleeding into the skin and mucosa lining gastrointestinal tract and genitourinary tract.
- Qualitative platelet disorders are characterized by abnormal platelet function in the presence of normal platelet count due to various hereditary thrombocytopenias. Patient presents with spontaneous skin purpura, mucosal bleeding and prolonged bleeding after trauma; as a result of defective primary hemostatic plug.

Hematology Pearls: Type of Platelet Disorders

- Quantitative platelet disorders (thrombocytopenias) occur when platelet count falls below $<100 \times 10^9$/L. Patient presents with bleeding into the skin and mucosa lining gastrointestinal tract and genitourinary tract.
- Qualitative platelet disorders are characterized by abnormal platelet function in the presence of normal platelet count due to various hereditary thrombocytopenias.
- von Willebrand factor is a glycoprotein involved in primary and secondary hemostasis through platelet adhesion to damaged vascular subendothelium and subsequently platelet aggregation, and the intrinsic coagulation system cascade, through formation of vWF/factor VIII complex and stabilization.
- Bleeding diathesis associated with vascular disorders of blood vessel integrity result from structurally weak blood vessels or vascular damage due to inflammation and immune-mediated mechanisms.

Classification of inherited thrombocytopenias is given in Table 10.7. Classification of acquired thrombocytopenias is given in Table 10.8.

Table 10.7 Classification of inherited thrombocytopenias

Mechanism	Comments
Platelet phospholipid plasma membrane defects	
Glanzmann disease (thrombasthenia)	▪ Glycoprotein GpIIb-IIIa (GpIIB, GpIIIA) gene mutation ▪ Impaired binding of platelets to fibrinogen, hence impaired platelet aggregation ▪ Mild to severe bleeding epistaxis, petechiae **Diagnostic tests** Aggregometry (platelet aggregation impaired with platelet agonists, i.e. deficient ADP, collagen and arachidonic acid; but normal platelet aggregation with ristocetin)
Bernard-Soulier disease	▪ GpIBA; GpIBB; GpIX gene mutations ▪ Impaired binding of platelets to vWF resulting in impaired platelet aggregation ▪ Mild to severe bleeding ▪ Thrombocytopenia may be present **Diagnostic tests** ▪ Aggregometry (impaired agglutination only with ristocetin; but normal platelet aggregation normal with ADP, epinephrine, collagen and arachidonic acid) ▪ Defective clot retraction
Scot disease	▪ Autosomal recessive disorder ▪ Stem cell ANO6 gene mutation ▪ Defect in phosphatidylserine translocating to the platelet membrane resulting in impaired thrombin formation ▪ Episode of bleeding improved by platelet transfusion **Diagnostic tests** Coagulation studies

Contd...

Table 10.7 Classification of inherited thrombocytopenias (*Contd...*)

Mechanism	Comments
Storage pool defects	
Hermansky-Pudlak syndrome	▪ Autosomal recessive disorder ▪ HPSA1, AP3B1; HPS3; HPS4; HPS5; HPS6; DTNBP1 gene mutations ▪ Impaired platelet activation due to dense platelet granule defects ▪ Mucocutaneous bleeding, neutropenia, pulmonary fibrosis, and albinism (present or absent) **Diagnostic tests** ▪ Often on the basis of other abnormalities ▪ Absence of dense platelet granules on electron microscopy
Chédiak-Higashi disease	▪ Autosomal recessive disorder ▪ CHS1/LYST gene mutation ▪ Impaired activation of platelets due to dense platelet granule defects ▪ Mucocutaneous bleeding, neutropenia, recurrent pyogenic infections, peripheral neuropathy, and albinism **Diagnostic tests** ▪ Often on the basis of other abnormalities ▪ Absence of dense platelet granules on electron microscopy
Wiskott-Aldrich syndrome	▪ X-linked disorder ▪ WASp gene mutation located on chromosome Xp11, 23 ▪ Impaired activation of platelets due to dense platelet granule defects ▪ Mucocutaneous bleeding, neutropenia, immune deficiency, and bloody diarrhea **Diagnostic tests** ▪ Often on the basis of platelet count and genetic testing to defect gene mutation ▪ Absence of platelet dense granules on electron microscopy
Platelet storage pool deficiency due to defect of dense granules	▪ Autosomal dominant disorder ▪ Lack of granular nonmetabolic ADP ▪ Impaired platelet aggregation ▪ Prolonged bleeding after surgery and anemia **Diagnostic tests** ▪ Flow cytometry ▪ Bleeding time analysis ▪ Decrease in mean platelet volume
Gray platelet syndrome (platelet α-granule defect)	▪ Autosomal recessive disorder ▪ NBEAL2 gene mutation ▪ Impaired platelet activation due to α-granule defect ▪ Thrombocytopenia ▪ Large platelets ▪ Absence of α-platelet granule **Diagnostic tests** Absence of α-platelet granule on electron microscopy
Paris-Trousseau syndrome (platelet α-granule defect)	▪ Deletion of chromosome 11q23 involving FLI-1 gene ▪ Impaired platelet function due to α-granule defect ▪ Mild bleeding tendencies due to chronic thrombocytopenia **Diagnostic tests** Peripheral blood smear shows abnormal platelets with giant granules confirmed on electron microscopy
Jacobsen syndrome (platelet α-granule defect)	▪ Loss of genetic material of chromosome 11q ▪ Impaired platelet function due to α-granule defect ▪ Bleeding manifestations, distinctive facial features with delayed development of motor skills and speech; and cognitive impairment **Diagnostic tests** Genetic testing to demonstrate broken chromosome

Contd...

Table 10.7 Classification of inherited thrombocytopenias (*Contd…*)

Mechanism	Comments
Quebec platelet syndrome (platelet α-granule defect)	▪ Autosomal dominant disorder ▪ PLAU gene mutation leads to overexpression of urokinase plasminogen activator ▪ Impaired platelet function due to α-granule disorder with overexpression of urokinase plasminogen activator resulting in platelet dependence fibrinolysis ▪ Bleeding manifestations **Diagnostic tests** Genetic testing to demonstrate PLAU gene mutation
X-linked macrothrombocytopenia with dyserythropoiesis	▪ X-linked recessive disorder ▪ GATA1 gene mutation ▪ Bleeding manifestations **Diagnostic tests** Genetic testing to demonstrate GATA1 gene mutation
Thrombocytopenia with absent radius bone (TAR syndrome) (platelet dense granules defect)	▪ Deletion of genes on chromosome 1q21.1 ▪ Thrombocytopenia with absent radius bone **Diagnostic tests** ▪ Genetic testing to demonstrate chromosome breakage
Congenital amegakaryocytic thrombocytopenia	
Congenital amegakaryocytic thrombocytopenia	▪ cMPL gene mutation located on chromosome 3 ▪ Insensitivity to thrombopoietin ▪ Bleeding manifestations, severe thrombocytopenia from birth **Diagnostic tests** ▪ Bone marrow aspirate examination ▪ Elevated TPO (thrombopoietin) level ▪ Genetic testing to demonstrate cMPL gene mutation
Disorders of receptors and signal transduction	
Cyclooxygenase enzyme deficiency	▪ PTGS1 and PTGS2 gene mutations ▪ Quantitative deficiency of cyclooxygenase deficiency resulting in thromboxane A_2 synthesis ▪ Thrombotic and bleeding phenotype **Diagnostic tests** Bleeding and thrombosis work up
Thromboxane A_2 receptor defect	▪ Autosomal recessive disorder ▪ TBXA2R gene mutation ▪ TXA_2 functional activity impaired with loss of prothrombotic property ▪ Mucocutaneous gastrointestinal or surgical bleeding **Diagnostic tests** ▪ Platelet aggregometry ▪ Impaired platelet aggregation to low dose adenosine diphosphate (ADP), collagen and arachidonic acid) ▪ Normal platelet aggregation to thrombin
ADP (adenosine diphosphate) receptors of platelets and their inhibition	▪ Autosomal recessive disorder ▪ P2YC12 gene mutation (3q24–q25) ▪ Impairment of platelet aggregation ▪ Bleeding manifestations **Diagnostic tests** Selective impairment of platelet responses to ADP
Bleeding diathesis due to glycoprotein VI deficiency	▪ Autosomal recessive disorder ▪ GpVI gene mutation ▪ Bleeding manifestations **Diagnostic tests** Genetic testing to demonstrate GpVI gene mutation

Contd...

Table 10.7 Classification of inherited thrombocytopenias (*Contd...*)

Mechanism	Comments
Platelet-type von Willebrand disease	▪ Autosomal recessive disorder ▪ GpXA2R gene mutation ▪ Bleeding manifestations **Diagnostic tests** Genetic testing to demonstrate GpXA2R gene mutation

von Willebrand disease is also inherited autosomal dominant/recessive platelet function disorder; characterized by platelet aggregation with adenosine diphosphate (ADP), collagen and arachidonic acid; but impaired with ristocetin. Platelet aggregation abnormality is corrected by cryoprecipitate therapy.

Table 10.8 Classification of acquired thrombocytopenias

Mechanism	Causes
Failure of platelet production	
Generalized bone marrow failure	▪ Leukemias ▪ Myelodysplastic syndrome (MDS) ▪ Aplastic anemia ▪ Human immunodeficiency virus (HIV) infection ▪ Myelofibrosis ▪ Megaloblastic anemia ▪ Multiple myeloma ▪ Metastatic bone disease ▪ Lymphoma involving bone marrow ▪ Cytotoxic drugs
Selective megakaryocytic depression	▪ Drugs (aspirin, indomethacin, butazolidin, sulfinpyrazone, carbenicillin, phenothiazine, dipyridamole, tricyclic antidepressants) ▪ Viral agents ▪ Plasma expanders (dextran or hydroxyethyl starch coat platelets) ▪ Chemical agents ▪ Alcohol
Increased destruction of platelets	
Immune-mediated thrombocytopenia	▪ Alloantibodies (neonatal, post-transfusion) ▪ Autoantibodies causing primary or secondary thrombocytopenia (e.g. systemic lupus erythematosus, chronic lymphocytic leukemia, post-infection, HIV infection, post-stem cell transplantation)
Drug-induced thrombocytopenia either by immune mechanism or decreased platelet aggregation	▪ Aspirin inhibits prostaglandin synthesis ▪ Nonsteroidal anti-inflammatory drugs ▪ Platelet function inhibitors (e.g. carbenicillin, phenothiazines, dipyridamole)
Disseminated intravascular coagulation (DIC)	▪ Blood transfusion reactions ▪ Leukemia ▪ Pancreatitis ▪ Liver disease ▪ Retained placenta after delivery
Microangiopathic process	▪ Thrombotic thrombocytopenic purpura (TTP) ▪ Hemolytic uremic syndrome (HUS) ▪ Extracorporeal circulation ▪ Hemolysis, elevated liver enzymes and low platelet count in association with pre-eclampsia (HELLP) syndrome
Giant hemangioma (Kasabach-Merritt syndrome)	Giant hemangioma is associated with thrombocytopenia and bleeding manifestations
Pooling (abnormal distribution) of platelets	
Massive splenomegaly	Hyperfunctioning of phagocytic activity (e.g. chronic myelogenous leukemia, myelofibrosis, Gaucher disease, visceral leishmaniasis, β-thalassemia and malaria)
Malignant disorders	Pooling of platelets
Dilution loss of platelets	
Massive blood transfusions of stored blood	Dilutional thrombocytopenia
Pregnancy	Dilutional thrombocytopenia
Malignant disorders	Pooling of platelets
Platelet coated by paraproteins	
Paraproteinemias	▪ Multiple myeloma (coating of platelets by paraprotein) ▪ Waldenström's syndrome (coating of platelets by paraprotein)

QUANTITATIVE PLATELET DISORDERS

Quantitative platelet disorders (thrombocytopenias) occur when platelet count falls below $<100 \times 10^9$/L. Patient presents with bleeding into the skin and mucosa lining gastrointestinal tract and genitourinary tract. Failure to produce platelets by bone marrow and increased destruction in the peripheral blood are the causes of thrombocytopenia.

- Drug toxicity or viral infections lead to selective megakaryocyte depression. Aplastic anemia, leukemia, myelofibrosis, cytotoxic chemotherapy or bone marrow infiltration and decreased numbers of megakaryocytes can be part of a generalized bone marrow failure.
- Neonatal thrombocytopenia occurs in the newborn infants as a result of intrauterine rubella or other infections, platelet antibodies, disseminated intravascular coagulation, congenital absence of megakaryocytes, giant hemangiomas and inherited thrombocytopenias.

Hematology Pearls: Pathophysiology of Thrombocytopenia

- **Decreased platelet production by bone marrow:** Decreased platelet production by bone marrow occurs due to bone marrow hypoplasia, replacement of bone marrow by metastatic deposits, bone marrow failure syndrome, drug toxicity, viral infections and cytotoxic chemotherapeutic agents.
- **Ineffective maturation of platelets:** Ineffective maturation of platelets in the cytoplasm of megakaryocytes occurs due to megaloblastic anemia, myelodysplastic syndrome and myeloproliferative neoplasms.
- **Increased platelet destruction:** Increased platelet destruction due to immune-mediated mechanism, hypersplenism and heparin therapy.
- **Pooling of platelets:** Pooling of platelets in the spleen in cases of massive splenomegaly results in lowering of platelet counts in peripheral blood.

IMMUNE THROMBOCYTOPENIC PURPURA

Immune thrombocytopenic purpura (ITP), also known as autoimmune thrombocytopenic purpura, is an acquired autoimmune pathology characterized by isolated thrombocytopenia (peripheral blood platelet count $<100 \times 10^9$) due to pathogenic **a**ntiplatelet autoantibodies (IgG, IgA) directed against platelet membrane glycoproteins (GpIIb/ GpIIIa) or (GpIb–IX) or antibodies (IgG, IgA) directed against megakaryocyte antigen in the bone marrow leading to splenic sequestration of platelets coated by antiplatelet autoantibodies and their destruction by mononuclear macrophages in spleen and Kupffer cells in liver, and impaired bone marrow megakaryocyte function. In addition, impairment of T cells, cytokine imbalances (IL-6 and IL-11), and the contribution of the bone marrow niche have now been recognized to play role in pathogenesis of immune thrombocytopenic purpura, which manifests with hemorrhagic episodes. Normal platelet count is in the range of 150,000 to 450,000/L. With immune thrombocytopenic purpura, the platelet count is less than 100×10^9/L. By the time significant bleeding occurs, patient may have low-platelet count $<10 \times 10^9$/L. The lower the platelet count, the greater is the risk of bleeding episodes.

- **Predisposing factors:** Immune thrombocytopenic purpura (ITP) can occur following viral infection (chicken pox, HBV, HCV, HIV, EBV), bacterial infection (*Helicobacter pylori*), parasitic infection (malarial parasite) and in association with autoimmune disorders (rheumatoid arthritis, systemic lupus erythematosus), and hematological disorders (chronic lymphocytic leukemia, and low-grade non-Hodgkin lymphoma). In the infectious immune thrombocytopenic purpura (ITP) cases, viral antigen is recognized as being similar to platelet antigen, a process termed 'molecular mimicry', which then gives rise to cross-reactive anti-platelet autoantibodies and anti-megakaryocyte autoantibodies.
- **Clinical features:** Patient of immune thrombocytopenic purpura presents with petechiae (small red and purple dots), purpura, ecchymosis (larger red brown and purple dots), bleeding gums, hematuria, hematochezia, heavy menstrual bleeding and extreme tiredness. Serious and possible fatal complications occur due to very low-platelet count, which include subarachnoid hemorrhage or intracerebral hemorrhage, lower gastrointestinal bleeding or internal bleeding.

CLASSIFICATION OF IMMUNE THROMBOCYTOPENIC PURPURA

Immune thrombocytopenic purpura (ITP) can be observed in both children and adults, with both sexes being affected, however, the underlying mechanisms of pediatric immune thrombocytopenic purpura and adult immune thrombocytopenic purpura may be different. Immune thrombocytopenic purpura can be acute ITP (short-term following infection and resolves within two months) and/or chronic ITP (long-term persists longer than six months). Comparison between acute and chronic immune thrombocytopenic purpura is given in Table 10.9. Low-platelet count and clinical manifestations are given in Table 10.10.

Table 10.9 Comparison between acute and chronic autoimmune thrombocytopenic purpura

Features	Acute Immune Thrombocytopenic Purpura	Chronic Immune Thrombocytopenic Purpura
Age group	2–6 years of age	20–40 years of age
Sex predilection	Boys and girls equally affected	Males are more affected than females
Viral infection	Antecedent viral infection	Common 1–3 weeks of prior viral infection
Platelet destruction	Autoimmune mediated disorder	Autoimmune mediated disorder
Platelet count	$<20 \times 10^9$/L	$30–80 \times 10^9$/L
Onset of disorder	Abrupt onset	Gradual onset
Duration of disorder	2–8 weeks	Months to years (lifelong)
Spontaneous remission of disorder (% cases)	85–90% within six months	Uncommon more than six months
Nature of disorder	Self-limited	Not self-limited
Type of bleeding	Petechiae and superficial (e.g. epistaxis, bleeding gums, hematuria, subarachnoid hemorrhage and intracranial bleeding)	Petechiae and superficial (e.g. epistaxis, bleeding gums, hematuria, excessive menstrual flow, extensive soft tissue hemorrhages after minor surgery, melena, hematuria and excessive menstrual blood flow)
Splenomegaly	Uncommon	Common
Peripheral blood smear	▪ Platelet counts low ▪ Eosinophilia or basophilia present (common)	▪ Few giant platelets ▪ Eosinophilia or basophilia absent
Bone marrow aspirate	Compensatory hyperplasia of megakaryocytes (not indicated)	Compensatory hyperplasia of megakaryocytes (mature and immature megakaryocytes with smooth borders)
Prothrombin time	Normal	Normal
Activated partial thromboplastin time	Normal	Normal
Spontaneous remission	95% of cases	<15% of cases; course of disease fluctuates
Therapy	Corticosteroids, anti-D, immunoglobulin	Corticosteroids, splenectomy, rituximab

Table. 10.10 Low-platelet count and clinical manifestations

Platelet Count	Site of Bleeding
Platelet count $<10 \times 10^9$/L	▪ Genitourinary tract bleeding ▪ Gastrointestinal tract bleeding ▪ Intracranial bleeding
Platelet count $10–50 \times 10^9$/L	▪ Spontaneous bleeding in skin and mucosal surface ▪ Post-traumatic bleeding
Platelet count $>50 \times 10^9$/L	▪ No spontaneous bleeding

- **Acute immune thrombocytopenic purpura:** Acute immune thrombocytopenic purpura (acute ITP) is the most common disorder that usually affects 2–7 years old young children, which usually starts suddenly and the symptoms usually disappear spontaneously within 6 months, and often within few weeks.
  - The symptoms may follow a viral illness such as chicken pox, hepatitis C and human immunodeficiency virus during winter and spring season, which can prompt production of autoantibodies that can cross-react with platelets in blood and megakaryocyte in bone marrow leading to platelet destruction in macrophages in spleen and Kupffer cells in liver; and impaired function of bone marrow megakaryocytes. Patient presents with petechial hemorrhages, ecchymosis, epistaxis, bleeding gums, hematuria, subarachnoid hemorrhage, intracranial bleeding and easy bruising at joints of elbows and knees just from movement.
  - There is no significant splenomegaly. Minority of patients develop mucosal bleeding and should be treated with prednisolone or intravenous immunoglobulin.
- **Chronic immune thrombocytopenic purpura:** Onset of chronic immune thrombocytopenic purpura

(chronic ITP) can happen at any age and the symptoms usually can last for a minimum of six months, several years, or a life-time. Adults are more affected than children, but it does affect adolescents.

- Disorder is more common in females than males. Autoantibodies are demonstrated on the platelet surface and in free form in blood. Patient with chronic ITP is less likely to resolve without therapy, which can recur often and patient requires continual follow-up care with a clinical hematologist.
- Diagnosis of chronic ITP should be made only after exclusion of other causes of thrombocytopenia (e.g. chronic lymphocytic leukemia, non-Hodgkin lymphoma, HBC, HBV, HIV, Epstein-Barr virus infection, malarial parasite and systemic lupus erythematosus, rheumatoid arthritis, drug-induced thrombocytopenia). Evans syndrome is characterized by thrombocytopenia, autoimmune hemolytic anemia and positive Coombs' test.

PATHOPHYSIOLOGY

Cellular pathogenetic mechanisms in immune thrombocytopenic purpura involve dysregulation of B cells and autoreactive plasma cells, which produce autoantibodies (IgG, IgA), which bind to membrane glycoproteins (GpIIb/GpIIIa) or (GpIb–IX) on circulating platelets inducing their destruction in the spleen and liver or impaired functions of megakaryocytes.

- Immune response is also adversely affected, leading to decrease of CD4+ regulatory T cells (Treg) and B regulatory cells (Breg) which contributes to autoreactive plasma cell survival (supporting autoantibody production). Moreover CD8+ cytotoxic T cells are also activated, inducing platelets and megakaryocytes apoptosis as well as dysregulation of bone marrow niche homeostasis. Therefore, immune thrombocytopenic purpura (ITP) does not only result in platelet destruction by macrophages in spleen and Kupffer cells in liver, but also defects in the megakaryopoiesis and thrombopoiesis.
- The spleen plays a critical role in the pathogenesis of immune thrombocytopenic purpura due to destruction of platelets. Splenic macrophages expressing FcyR mediate the uptake of autoantibody-coated platelets with phagocytosis mediated through SYK signaling pathways.

LABORATORY DIAGNOSIS

Thrombocytopenia is common hematologic presentation with a variety of potential causes. Immune thrombocytopenic purpura (ITP) is diagnosed by identifying a low platelet count and based on the exclusion of other causes of low-platelet count (thrombocytopenia) such as exposure to drugs, infections (HBV, HCV, HIV, *Helicobacter pylori*) and other disorders, clinical history, physical examination (evidence of bleeding in the mucous membrane and skin, lymphadenopathy, splenomegaly or hepatomegaly) and addition investigation such as bone marrow trephinebiopsy.

- Peripheral blood smear from a patient with immune thrombocytopenic purpura shows low-platelet count ($<100 \times 10^9$/L) with typical normal morphology with varying numbers of large platelets, and normal morphology of red blood cells and leukocytes. An elevated reticulocyte count in immune thrombocytopenic anemia is an evidence of compensatory increased red blood cell production.
- Diagnostic value of bone marrow examination in immune thrombocytopenic purpura remains unresolved and data from a large perspective study would be helpful. A reasonable approach would be to limit the bone marrow aspirate examination to patients with typical clinical or hematologic feature (e.g. abnormal bleeding and clotting studies) or with a poor response to corticosteroids or those patients in whom septectomy is being considered.
- Bone marrow trephine biopsy is often performed in children with acute immune thrombocytopenic purpura (acute ITP) to rule out leukemia, particularly when treatment with corticosteroids is contemplated.
- Direct antiglobulin test (DAT, direct Coombs' test) is performed to detect autoantibodies attached to red blood cells. Quantitative platelet-bound immunoglobulin (IgG) sensitizing the circulating platelets and megakaryocytes in bone marrow are analyzed to diagnose immune thrombocytopenic purpura.

Laboratory Diagnosis of Immune Thrombocytopenic Purpura

Hemoglobin

Hemoglobin—low due to blood loss

Bleeding and Coagulation Studies

- Bleeding time—prolonged
- Clotting time—normal range
- Blood clot retraction—decreased
- Prothrombin time and international normalized ratio (PT–INR) within normal range
- Activated partial thromboplastin time (APTT) within normal range

Peripheral Blood Smear Examination

- Peripheral blood smear examination shows low-platelet count, few large platelets, normal morphology of red blood cells and leukocytes.
- Immune thrombocytopenic purpura is shown in Fig. 10.10.

Bone Marrow Trephine Biopsy Examination

- Bone marrow aspiration trephine biopsy shows normal number or increased number of mature and immature megakaryocytes. Borders of the megakaryocytes are smooth indicating nonfunctional megakaryocytes.
- Bone marrow trephine biopsy shows normoblastic or micro-normoblastic erythropoiesis and normal myelopoiesis.
- Iron stores are depleted due to bleeding. Iron is demonstrated by Perls Prussian blue stain.
- Immune thrombocytopenic purpura is shown in Fig.10.11.

Other Hematologic Tests

- Glycoprotein immobilization assays are performed to demonstrate antiplatelet antibodies.
- Plasma glycocalcin—high level
- Thrombopoietin—normal or slightly elevated

TREATMENT

Treatment strategies of immune thrombocytopenic purpura (ITP) are aimed at restoration of platelet counts compatible with adequate hemostasis rather than achieving platelet counts in physiologic range.

- First-line treatments consist of corticosteroids alone or in combination with intravenous immunoglobulin or anti-D, with an aim to inhibit anti-platelet autoantibody presentation by antigen-presenting cells (APCs) to restore normal immune response. These therapeutic agents also act on B cells and plasma cells, thus decreasing autoantibodies induced destruction of platelets in spleen and restoration of megakaryocytes function in bone marrow.
- Second-line treatments include immunosuppressive drugs (e.g. cyclophosphamide, azathioprine, ciclosporin, vincristine, rhesus anti-D, rituximab targeting B cells), and splenectomy. **Splenectomy** is indicated for non-responders with continuing symptoms, and/or very low-platelet count. Immunosuppressive drugs and splenectomy also modulate T cell compartment, notably increasing CD4+ regulatory T cell (Treg) function.
- Finally, third-line treatments aim at to stimulate production of megakaryocytes in the bone marrow by administration of thrombopoietin (TPO) receptor agonists (romiplostim and eltrombopag). Minority of patients develop mucosal bleeding and should be treated with prednisolone or intravenous immunoglobulin. Thrombopoietin (TPO) agonists present indirect immunoregulatory effects on regulatory B cells (Bregs) and CD4+ regulatory T cells (Tregs). Combining multiple therapeutic approaches are often required to ensure the restoration of a physiologic platelet count range. Treatment of immune thrombocytopenic purpura (ITP) is given in Table 10.11.

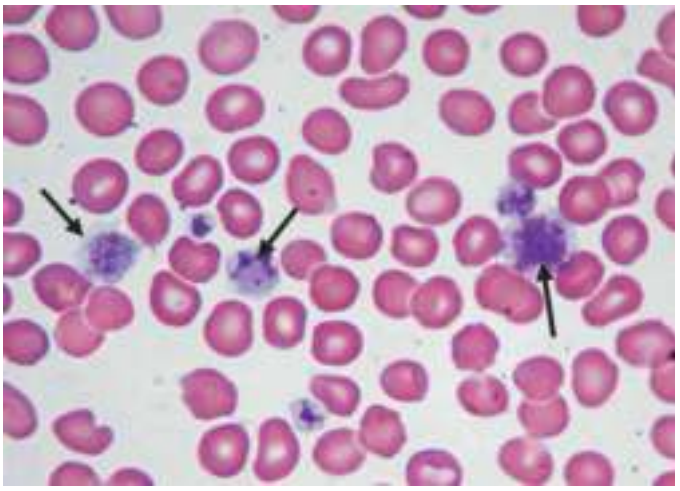

Fig. 10.10: Immune thrombocytopenic purpura. Peripheral blood smear shows lack of platelets and a few giant platelets (arrows).

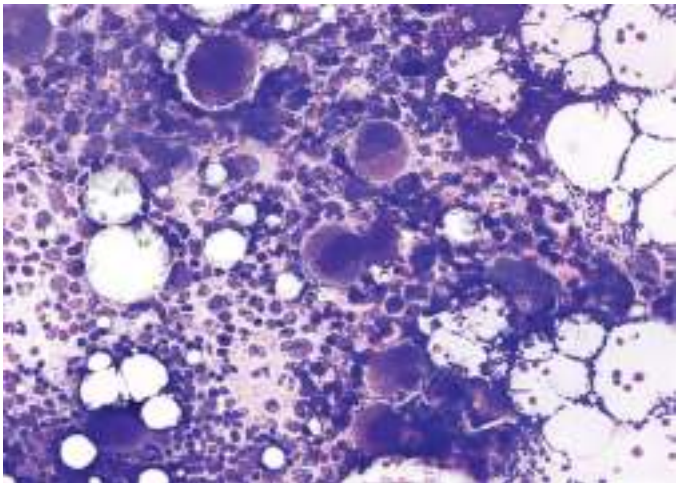

Fig. 10.11: Immune thrombocytopenic purpura. Bone marrow aspirate shows marked hyperplasia of megakaryocytes. Borders of megakaryocytes are smooth indicating nonfunctional megakaryocytes.

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

Neonatal alloimmune thrombocytopenia is similar to hemolytic disease of newborn except that antigenic stimulus comes from platelet specific antigens rather than red blood cell antigens.

- In about 80% of cases, the antigen is HPA-Ia (human platelet antigen Ia). The antibody is then directed against the HPA-Ia (human platelet antigen Ia) on platelets resulting in platelet destruction by reticuloendothelial cells.
- Transplacental passage of antibody from a mother with immune thrombocytopenia can lead to neonatal thrombocytopenia, which most often resolves spontaneously over a few weeks.

Table 10.11 Treatment of immune thrombocytopenic purpura

Findings	Treatment
Platelet count >50,000/mm^3	No treatment
Platelet count <50,000/mm^3 with minor bleeding	Prednisolone
Platelet count <10,000/mm^3 with severe bleeding	IVIg or RHo GAM (rho-D immune globulin)
Recurrent episodes of thrombocytopenia and bleeding	Splenectomy
No response to splenectomy	▪ Romiplostim (fusion protein equivalent to thrombopoietin) ▪ Eltrombopag (small molecule agonist of the c-mpl receptor, which is physiological target of thrombopoietin)

IVIg administration in patients with ITP has no direct activity against platelets. It is administered to prevent the action of macrophages against platelets. Drug stops up all the Fc receptors on the macrophages, IVIg leaves no room for the antibodies on the platelets. Thus, it prevents platelets destruction.

- Mothers who have been sensitized to platelet antigens by blood transfusion during previous pregnancy may develop antibodies, that cross the placenta and coat fetal and neonatal platelets resulting in platelet destruction by reticuloendothelial system.
- Neonates with platelet alloantibodies may also become thrombocytopenic following blood transfusion (post-transfusion thrombocytopenic purpura). Neonates present with unexplained bruising and purpura.

QUALITATIVE INHERITED PLATELET DISORDERS

Qualitative inherited platelet disorders are characterized by abnormal platelet function in the presence of normal platelet count due to various inherited thrombocytopenias. Defective platelet function disorders present with spontaneous skin purpura, mucosal bleeding and prolonged bleeding after trauma; as a result of defective hemostatic plug. Diseases of the platelet storage pool occur due to deficiencies in either the α-granules or dense granules resulting in poor secondary platelet aggregation. A neonate or small infant with bleeding manifestations must be evaluated for inherited bleeding disorders (inherited platelet disorders, hemophilia and von Willebrand disease).

PLATELET PHOSPHOLIPID PLASMA MEMBRANE DEFECTS

Plasma membrane of activated platelets provide a catalytic phospholipid surface on which factor IXa–factor VIIIa complex and the 'prothrombokinase' complex (factor Xa–factor–Va) can be assembled. The formation of a procoagulant platelet surface involves the exposure of anionic phospholipids, e.g. phosphatidylserine and is associated with shedding of microvesicles from the membranes of activated platelets. Moreover, tissue factor, which initiates extrinsic coagulation pathway, requires the presence of phospholipids for optional biological activity. Platelet phospholipid plasma membrane defects are linked to many platelet disorders.

GLANZMANN DISEASE (THROMBASTHENIA)

Glanzmann disease (thrombasthenia) is an autosomal recessive disorder due to inherited deficiency of glycoprotein GpIIb–IIIa (GpIIb, GpIIIa) resulting in impaired binding of platelets to fibrinogen, hence impaired platelet aggregation.

- Normally, GpIIb–IIIa act as receptor for fibrinogen bridging between adjacent platelets resulting in platelet aggregation.
- Patient presents with mild to severe bleeding (i.e. epistaxis, petechial hemorrhages, gum bleeding).
- Platelet count and morphology are normal.
- Diagnostic test includes aggregometry (platelet aggregation impaired with platelet agonists, i.e. deficient ADP, collagen and arachidonic acid; but normal platelet aggregation with ristocetin).

BERNARD-SOULIER SYNDROME

Bernard-Soulier syndrome is characterized by GpIBA; GpIBB; GpIX gene mutations, impaired binding of platelets to von Willebrand factor (vWF) resulting in impaired platelet aggregation and mild to severe bleeding.

Laboratory Diagnosis of Bernard-Soulier Syndrome

- Peripheral blood smear examination shows mild thrombocytopenia and giant platelets.
- Diagnostic tests include aggregometry (impaired agglutination only with ristocetin; but normal platelet aggregation with ADP, epinephrine, collagen and arachidonic acid) and defective blood clot retraction.

SCOT SYNDROME

Scot syndrome is an autosomal recessive disorder characterized by hematopoietic stem cell ANO6 gene mutation and defect in phosphatidylserine translocating to the platelet membrane resulting in impaired thrombin formation; and episode of bleeding improved by platelet transfusion. Coagulation studies are done.

PLATELET STORAGE POOL DEFECTS

Platelet storage pool defects are linked to coagulopathy resulting from defects in the granules in platelets particularly a lack of granular non-metabolic adenosine diphosphate.

HERMANSKY-PUDLAK SYNDROME

Hermansky-Pudlak syndrome is an autosomal recessive disorder due to mutations in HPSA1; AP3B1; HPS3; HPS4; HPS5; HPS6; DTNBP1 genes resulting in impaired platelet activation due to dense platelet granule defects.

Clinical Features

Patient presents with mucocutaneous bleeding, neutropenia, pulmonary fibrosis, and albinism. Electron microscopy demonstrates absence of dense platelet granules.

CHÉDIAK-HIGASHI SYNDROME

Chédiak-Higashi syndrome is an autosomal recessive disorder characterized by CHS1/LYST gene mutation, impaired activation of platelets due to platelet dense granule defects, mucocutaneous bleeding, neutropenia, recurrent pyogenic infections, peripheral neuropathy, and albinism. Electron microscopy demonstrates absence of platelet dense granules.

WISKOTT-ALDRICH SYNDROME

Wiskott-Aldrich syndrome is X-linked disorder with defects of both B and T cells, which occurs due to WASp gene mutation located on chromosome Xp11, 23 resulting in impaired activation of platelets due to platelet dense granule defects. WASp gene encodes WASp protein expressed on hematopoietic stem system. Platelets and T cells show deficient surface glycoproteins (CD43), which are ligand for intercellular adhesion molecule 1 (ICAM-1). Half-life of platelet is reduced. Electron microscopy demonstrates absence of dense platelet granules.

Clinical Features

Patient presents with mucocutaneous bleeding, neutropenia, recurrent infections, immune deficiency, and bloody diarrhea with fatal outcome due to bleeding tendencies, recurrent infections and development of lymphoma before attaining age of six years. Patient is treated by stem cell transplantation.

PLATELET STORAGE POOL DEFICIENCY (PLATELET DENSE GRANULES DEFECT)

Platelet storage pool deficiency dense granules defect is an autosomal dominant disorder due to lack of dense granular nonmetabolic ADP resulting in impaired platelet aggregation and prolonged bleeding after surgery and anemia. Diagnostic tests include flow cytometry, bleeding time analysis and decrease in mean platelet volume.

GRAY PLATELET SYNDROME (PLATELET α-GRANULES DEFECT)

Normal platelet contains α-granules and dense granules. The α-granules contain fibrinogen, platelet factors IV and V, thrombospondin. Dense granules contain ATP, ADP, calcium and serotonin.

- Gray platelet syndrome (platelet α-granule defect) is an autosomal recessive disorder due to NBEAL2 gene mutation. The term gray platelet syndrome is derived from gray appearance of platelets in the peripheral blood. Number of megakaryocytes is normal in bone marrow. But megakaryocytes are unable to produce mature platelets resulting in thrombocytopenia.
- Platelet survival is reduced due to deficient platelet α-granule mutation resulting in impaired platelet activation, thrombocytopenia and large platelets.
- Electron microscopy demonstrates absence of platelet α-granules.
- Patient meets all the criteria for idiopathic thrombocytopenic purpura (ITP). Peripheral blood smear examination shows large gray platelets demonstrated in gray platelet syndrome.
- Patient presents with epistaxis, bruising, ecchymosis, and splenomegaly resulting in fatal outcome.

PARIS-TROUSSEAU SYNDROME (PLATELET α-GRANULE DEFECT)

Paris-Trousseau syndrome (platelet α-granule defect) occurs due to deletion of chromosome 11q23 involving

FLI-1 gene resulting in impaired platelet function. Patient presents with mild bleeding tendencies due to chronic thrombocytopenia. Peripheral blood smear shows abnormal platelets with giant granules confirmed on electron microscopy.

JACOBSEN SYNDROME (PLATELET α-GRANULE DEFECT)

Jacobsen syndrome occurs due to loss of genetic material of chromosome 11q resulting in impaired platelet function due to platelet α-granule defect. Patient presents with bleeding manifestations, distinctive facial features with delayed development of motor skills and speech; and cognitive impairment. Cytogenetic testing is done to demonstrate broken chromosome.

QUEBEC PLATELET SYNDROME (PLATELET α-GRANULE DEFECT)

Quebec platelet syndrome (α-granule defect disorder) is an autosomal dominant disorder due to **PLAU gene** mutation leads to overexpression of urokinase plasminogen activator. Impaired platelet function due to α-granule defect disorder with overexpression of urokinase plasminogen activator resulting in platelet dependence fibrinolysis. Patient presents with bleeding manifestations. Genetic testing is done to demonstrate PLAU gene mutation.

X-LINKED MACROTHROMBOCYTOPENIA WITH DYSERYTHROPOIESIS

X-linked macrothrombocytopenia with dyserythropoiesis is X-linked recessive disorder due to GATA1 gene mutation. Patient presents with bleeding manifestations. Genetic testing is done to demonstrate GATA1 gene mutation.

THROMBOCYTOPENIA WITH ABSENT RADII BONE (TAR SYNDROME)

Thrombocytopenia with absent radii bone (TAR syndrome) is platelet dense granules disorder due to deletion of genes on chromosome 1q21.1. Patient presents with absence of radius bone bleeding manifestations due to thrombocytopenia. Cytogenetic testing is done to demonstrate chromosome breakage.

CONGENITAL AMEGAKARYOCYTIC THROMBOCYTOPENIA

Congenital amegakaryocytic thrombocytopenia occurs due to **cMPL gene mutation** located on chromosome 31b34 resulting in insensitivity to thrombopoietin. Patient presents with bleeding manifestations, and severe thrombocytopenia from birth. Diagnostic tests include bone marrow aspirate, elevated TPO (thrombopoietin) and genetic testing.

PLATELET DISORDERS OF RECEPTORS AND SIGNAL TRANSDUCTION

CYCLOOXYGENASE ENZYME DEFICIENCY DISORDER

Cyclooxygenase enzyme deficiency occurs due to PTGS1 or PTGS2 gene mutation. Quantitative deficiency of cyclooxygenase deficiency results in thromboxane A_2 synthesis. Thromboxane A_2 has prothrombotic properties, as it stimulates the activation of platelets and platelet aggregation. It also acts as vasoconstrictor in inflammation. Patient presents with thrombotic and bleeding phenotype. Bleeding and thrombosis work up should be done.

THROMBOXANE A_2 RECEPTOR DEFECT DISORDER

Thromboxane A_2 receptor defect is an autosomal recessive disorder due to **TBXA2R gene mutation**. TXA_2 functional activity is impaired with loss of prothrombotic property. Patient presents with mucocutaneous gastrointestinal tract or surgical bleeding. Diagnostic tests include platelet aggregometry, impaired platelet aggregation to low dose adenosine diphosphate (ADP), collagen and arachidonic acid) and normal platelet aggregation to thrombin.

ADP RECEPTORS OF PLATELETS AND THEIR INHIBITION DISORDER

Adenosine diphosphate (ADP) receptors of platelets and their inhibition is an autosomal recessive disorder due to P2YC12 gene mutation located on chromosome 3q24–q25 resulting in impairment of platelet aggregation. Patient presents with bleeding manifestations. Diagnostic test includes selective impairment of platelet aggregation responses to ADP.

BLEEDING DIATHESIS DUE TO GLYCOPROTEIN VI DEFICIENCY DISORDER

Bleeding diathesis due to glycoprotein VI deficiency is an autosomal recessive disorder due to GpVI gene mutation. Patient presents with bleeding manifestations. Genetic testing is done to demonstrate glycoprotein VI deficiency.

PLATELET-TYPE VON WILLEBRAND DISEASE

Platelet-type von Willebrand disease is an autosomal recessive disorder due to GpXA2R gene mutation. Patient presents with bleeding manifestations. Genetic testing is done to demonstrate GpXA2R gene mutation.

QUALITATIVE ACQUIRED PLATELET DISORDERS

Qualitative acquired platelet disorders are characterized by abnormal platelet function in the presence of normal platelet count in various acquired thrombocytopenias. Patient presents with spontaneous skin purpura, mucosal bleeding and prolonged bleeding after trauma; as a result of defective primary hemostatic plug.

POST-TRANSFUSION PURPURA

Post-transfusion purpura is a rare complication of blood transfusion presenting with severe thrombocytopenia 7–10 days after blood transfusion. Patients are usually multiparous women, who are negative for HPA1a (human platelet antigen Ia). Antibodies to HPA1a results in immune-mediated destruction of the patient's own platelets.

DRUG-INDUCED THROMBOCYTOPENIA

Drugs cause thrombocytopenia by either inhibiting bone marrow production or immune mechanism.

- The most common drug-induced immune mediated thrombocytopenia occurs when the drug (quinine, benzylpenicillin, heparin, chlorothiazide) or its metabolite combines with antibody (IgG) in plasma and forms antigen–antibody complex resulting in adsorption on the platelet surface.
- Antigen–antibody complex adsorbed on the platelet surface gives rise to highly immunogenic epitope resulting in platelet destruction by reticuloendothelial system.
- Administration of aspirin prevents platelet aggregation by inhibiting thromboxane A_2 and prostaglandin E_2 lasting for 3–4 days. Plasma expander dextran interferes with platelet function probably by coating of platelets.

HEPARIN-INDUCED THROMBOCYTOPENIA

Heparin-induced thrombocytopenia (HIT) is a complication of heparin therapy. There are two types of HIT. Features of heparin-induced thrombocytopenia are given in Table 10.12.

- Best initial diagnostic tests are analysis of platelet factor IV antibodies or heparin-induced antiplatelet antibodies in type 2 HIT.
- Best initial therapy is to stop heparin and use fondaparinux.

HEPARIN-INDUCED THROMBOCYTOPENIA TYPE 1

Heparin-induced thrombocytopenia (HIT) type 1 is nonimmune-mediated disorder. Patient presents within mild to moderate drop in platelets within first two days after exposure to heparin. The platelet count normalizes with the continued heparin therapy. It is not immune-mediated disorder, that results from the direct effect of heparin on platelet activation. It is treated by administration of low-molecular weight heparin preparations.

HEPARIN-INDUCED THROMBOCYTOPENIA TYPE 2

Heparin-induced thrombocytopenia (HIT) type 2 is immune-mediated disorder, that typically occurs 4–10 days after exposure to heparin. The most common drug-induced immune-mediated thrombocytopenia occurs when the drug (heparin) or its metabolite combines with antibody (IgG) in plasma and forms antigen–antibody complex resulting in adsorption on the platelet surface.

- Antigen–antibody adsorbed on the platelet surface gives rise to highly immunogenic epitope resulting in platelet destruction by reticuloendothelial system.
- Patient presents with thrombocytopenia and thrombosis in limbs coexisting. Once type 2 HIT is diagnosed, further administration of heparin is contraindicated.

POOLING OF PLATELETS IN MASSIVE SPLENOMEGALY

Spleen normally pools about one-third of the platelet mass, but in massive splenomegaly this can increase

Table 10.12 Features of heparin-induced thrombocytopenia (HIT)

Features of HIT	Comments
Platelet count in thrombocytopenia	▪ Fall of platelets >50% (20×10^9/L) ▪ Fall of platelets <30% ($<10 \times 10^9$/L) ▪ Fall of platelets 30–50% ($10–19 \times 10^9$/L)
Time of decrease in platelet count	Platelet count is decreased within 5–10 days after start of heparin administration
Type of heparin administered	Thrombocytopenia is more common with unfractioned heparin than low molecular weight heparin
Type of patient and sex predilection	Thrombocytopenia is more common in women than in men
Thrombosis frequency in blood vessels	Venous thrombosis is more common than arterial thrombosis in cases of HIT

up to 90% of platelet mass resulting in thrombocytopenia.

- Increased splenic platelet sequestration can occur in various disorders that cause splenomegaly. The platelet count is $>30 \times 10^9$/L unless the disorder causing splenomegaly also impairs platelet production (e.g. myelofibrosis with myeloid metaplasia).
- Sequestrated platelets are released from the spleen at the time of stress. Therefore, thrombocytopenia caused by splenic sequestration rarely causes bleeding manifestations.
- In patient with normal liver function, splenectomy corrects thrombocytopenia. Splenectomy is not indicated unless severe thrombocytopenia due to simultaneous bone marrow failure is present.

HYPOPLASIA OF MEGAKARYOCYTES

Hypoplasia of megakaryocytes refers to decrease in megakaryocytes in bone marrow due to drugs, chemical agents and following viral infection, thrombocytopenia with absent radii (TAR), May-Hegglin anomaly, Wiskott Aldrich syndrome and Bernard-Soulier syndrome. Bone marrow is deficient in megakaryocytes. However, bone marrow shows normal erythropoiesis and myelopoiesis.

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (**DIC**) is a reflection of an underlying systemic disorder, which affects the coagulation system simultaneously resulting in procoagulant activation, fibrinolytic activation, and consumption coagulopathy resulting deposition of fibrin clots in the small- and medium-sized blood vessels of organs dysfunction with fatal outcome. Widespread consumption of platelets results in thrombocytopenia. Though septicemia is the most common cause of DIC, yet several conditions (acute promyelocytic leukemia, prostatic carcinoma) may cause disseminated intravascular coagulation. Low molecular weight heparin is administered in these patients. Platelet count is low. Prothrombin time and international normalzed ratio (PT–INR) and activated partial thromboplastin time (APTT) are prolonged.

THROMBOTIC THROMBOCYTOPENIC PURPURA

Thrombotic thrombocytopenic purpura (TTP) is a rapidly fulminating blood disorder caused by deficiency of a plasma metalloprotease ADAMTS13, that cleaves von Willebrand factor when exposed to high shear stress in the microcirculation.

- The von Willebrand factor and platelets form widespread thrombi in the small blood vessels (arterioles and capillaries) throughout the body resulting in low platelet count and dysfunction of kidneys, heart and brain due to ischemia.
- Erythrocyte fragmentation and hemolysis are believed to result from mechanical injury induced by abnormally high shear stress in the microvasculature.
- Acquired thrombotic thrombocytopenic purpura is demonstrated in 90% of adults may be associated with systemic lupus erythematosus, pregnancy and infections.
- Patient presents with fever, bleeding manifestations (large bruises), pain abdomen, hematuria, weakness, shortness of breath, headache, seizures and confusion.

Laboratory Diagnosis of Thrombotic Thrombocytopenic Purpura (TTP)

- Peripheral blood smear shows schistocytes and low platelet count.
- Platelet count ranges between 5×10^9/L and 100×10^9/L.
- Reticulocyte count is increased.
- Coombs' test is negative
- Urine analysis shows hematuria and proteinuria due to flea bitten kidneys
- Blood urea and serum creatinine may be elevated.

- Treatment of TTP includes plasma exchange using fresh frozen plasma as the replacement fluid. Antiplatelet drugs (aspirin or dipyridamole), corticosteroids, splenectomy, rituximab and vincristine should be administered. Response to treatment may be monitored by analysis of hemoglobin level, reticulocyte count, platelet count, plasma bilirubin and presence of von Willebrand factor multimers in plasma.

HEMOLYTIC UREMIC SYNDROME

Hemolytic uremic syndrome is a clinical syndrome characterized by the triad of thrombotic microangiopathy, thrombocytopenia and acute renal injury. It is one of the most common causes of acute renal damage in children.

- Clinical findings in hemolytic uremic syndrome occurs as a result of thrombotic microangiopathy. Shiga toxin producing *Escherichia coli* is the most common cause of hemolytic uremic syndrome. Shiga toxin-induced vascular endothelial injury of arterioles and capillaries leads to thrombi formation in the microvasculature. The pathologic lesion is thickening of small blood vessels, vascular endothelial swelling

Table 10.13 Comparison between thrombotic thrombocytopenic purpura and hemolytic uremic syndrome

Features	Thrombotic Thrombocytopenic Purpura	Hemolytic Uremic Syndrome
Age group	20–40 years age group	Children <5 years of age
Etiology	Severe deficiency of ADAMTS13 protein due to gene mutation	Shiga toxin producing *Escherichia coli*
Thrombocytopenia	Present	Present
Microangiopathic hemolytic anemia	Present	Present
Renal injury induced manifestations	▪ Uncommon ▪ Mild renal dysfunction	▪ Common ▪ Rapidly progressive renal failure
Neurological manifestations	▪ Common manifestations ▪ Severe CNS symptoms	▪ Uncommon ▪ Mild CNS symptoms
Fever	Present	Absent
Bloody diarrhea	Absent	Present
Coagulation tests	Normal studies	Normal studies
Management	Plasma exchange	Suppurative

and detachment of arterioles and capillaries resulting in obstruction in the vascular lumen.

- Patient presents with diarrhea and rapidly progressive renal failure. In HUS, treatment for seizures, hypertension and renal failure is required. Comparison between thrombotic thrombocytopenic purpura and hemolytic uremic syndrome is given in Table 10.13.

DENGUE HEMORRHAGIC FEVER

Dengue hemorrhagic fever is caused by flavivirus transmitted by Aedes mosquito. Patient presents with fever, bleeding manifestations due to thrombocytopenia, hypotension and shock. There is impaired thrombopoiesis and increased platelet destruction.

Laboratory Diagnosis of Dengue Hemorrhagic Fever

- Peripheral blood smear examination shows many transformed lymphocytes and giant platelets.
- Platelet count ranges between 5×10^9/L and 80×10^9/L.
- Diagnosis is established by dengue hemagglutination inhibition antibody titer.

- Dengue hemorrhagic fever is treated by platelet transfusion, intravenous fluids and hydrotherapy. Immature platelet fraction (IPF), that contains RNA particles are analyzed by automatic counters.
- Immature platelet fraction is decreased in hypoplastic bone marrow. Immature platelet fraction (IPF) percentage can be used to evaluate the recovery of platelets in these patients. It can be used as a guide for platelet transfusion.

PARAPROTEINEMIA-INDUCED PLATELET DYSFUNCTION

Paraprotein synthesized in multiple myeloma and Waldenström's macroglobulinemia coat the platelets resulting in dysfunctional platelets.

UREMIA-INDUCED PLATELET DYSFUNCTION

Uremia by itself prevents platelets to perform normal functions. Platelets fail to degranulate.

DIAGNOSTIC APPROACH AND TREATMENT OF PLATELET DISORDERS

It is essential to evaluate patients with platelet disorders by taking clinical history, examination of patients, laboratory hematologic investigations and management.

- Abnormal bleeding associated with thrombocytopenia or abnormal platelet function is characterized by spontaneous skin petechiae and ecchymoses, bleeding from mucous membrane, menorrhagia, nose bleed in children. In thrombocytopenic patients, severe spontaneous bleeding is unusual with a platelet count of $\geq 20 \times 10^9$/L.
- Laboratory investigation of a suspected platelet disorder depends on the clinical presentation and history in each patient (e.g. complete blood count, peripheral blood smear examination, platelet function tests, coagulation studies and biochemical investigations).

PLATELET DISORDERS TREATMENT

All serious bleeding due to platelet disorders requires hematological assessment and treatment. Transient post-viral or aspirin-induced thrombocytopenia needs no active treatment.

INHERITED PLATELET DISORDERS TREATMENT

Newborn and small infants with bleeding should be evaluated for inherited bleeding disorders (inherited platelet disorders, hemophilia, von Willebrand disease). Congenital platelet disorders are treated by platelet transfusions (leukodepleted, HLA compatible and irradiated), DDAVP, tranexamic acid (antifibrinolytics), recombinant factor VII and bone marrow transplantation. It is worth mentioning that bone marrow transplantation can potentially cure many inherited platelet disorders.

ACQUIRED PLATELET DISORDERS TREATMENT

Bone marrow failure is treated by administration of platelet transfusions, if platelet count is $<10 \times 10^9$/L.

- Autoimmune thrombocytopenic purpura in adults is treated by prednisolone, intravenous immunoglobulin and splenectomy.
- Splenectomy is indicated in those patients not responding to therapy.
- Post-transfusion purpura is managed by administration of intravenous immunoglobulin and plasma exchange.
- In patient with heparin-induced thrombocytopenia type II, heparin should be discontinued, and another anticoagulant should be administered.
- Thrombotic thrombocytopenic purpura is treated by plasma exchange and aspirin when platelet count is $>30 \times 10^9$/L.
- Disseminated intravascular coagulation (DIC) is managed by treating underlying cause, fresh frozen plasma and platelet transfusion.
- Splenectomy is indicated in severe cases of hypersplenism causing thrombocytopenia. Platelet function disorders are treated by administration of platelet transfusion. Desmopressin acetate (DDAVP) is administered in patient with uremia.

SECONDARY THROMBOCYTOSIS AND ESSENTIAL THROMBOCYTHEMIA

In secondary thrombocytosis and essential thrombocythemia (ET), the platelet count is elevated above the upper limit of normal. The platelet count is $>450 \times 10^9$/L in secondary thrombocytosis.

- ET is blood clotting disorder in which bone marrow produces excess of platelet count is $>450 \times 10^9$/L.
- Patients with reactive thrombocytosis are normally asymptomatic. Patients with essential thrombocythemia present with excessive spontaneous bleeding.
- Antiplatelet drugs can be helpful to prevent thrombosis in high-risk patients in postoperative cases. Causes of increased platelet count are given in Table 10.14.

Table 10.14 Causes of increased platelet count

Primary/Clonal Thrombocytosis	
▪ Essential thrombocythemia	▪ POEMS syndrome
▪ Myeloproliferative disorders (e.g. chronic myelogenous leukemia, polycythemia vera, primary myelofibrosis)	▪ Familial thrombocytosis (thrombopoietin overproduction, MPL gene mutation)
▪ Myelodysplastic syndrome with isolated del 5q	▪ 5q– syndrome
Secondary/Reactive Thrombocytosis	
▪ Iron deficiency anemia	▪ Hyposplenism/splenectomy
▪ Acute hemorrhage or hemolytic anemia	▪ Drugs (gemcitabine, corticosteroids, adrenaline, thrombopoietin, following immunosuppressive therapy)
▪ Severe hemolysis	▪ 'Rebound' (correction of megaloblastic anemia, post-ethanol abuse, alcohol-induced thrombocytopenia, chemotherapeutic drugs)
▪ Traumatic injury, postoperative state	
▪ Infection, inflammation	
▪ Malignancy	
Spurious Thrombocytosis	
▪ Cryoglobulinemia	▪ Cytoplasmic fragments of malignant cells
▪ Schistocytes	▪ Bacterial infection
▪ Microspherocytes	
Transient Thrombocytosis	
▪ Vigorous exercise	▪ Epinephrine
▪ Childbirth	

SECONDARY THROMBOCYTOSIS

In secondary thrombocytosis, platelet count is elevated above the upper limit of normal. The platelet count is >450 × 10^9/L.

- Secondary thrombocytosis is caused by infection, malignant disorders, acute and chronic inflammatory diseases, pregnancy, post-splenectomy, hemorrhage and iron deficiency anemia. Patient is usually asymptomatic.
- Secondary thrombocytosis is the most common cause of thrombocytosis in adults (88–97%) and children (100%).
  - In adults, secondary thrombocytosis is attributed to chronic inflammation and malignancy in 75% of cases.
  - In children, secondary thrombocytosis is attributed to thalassemia. JAK2V617F, MPLW515L/L or CALR gene mutations are not demonstrated in secondary thrombocytosis.
- Platelets are produced by megakaryocytes in the bone marrow. Under physiologic state, about 2 × 10^9/L platelets are produced per day. Normal life span of platelets is 3–7 days.
- Thrombopoietin synthesized by liver regulates thrombopoiesis. Thrombopoietin binds to its receptor MPL on megakaryocytes and activates the signal transduction pathways that regulate megakaryocyte proliferation, maturation and platelet production.
  - Normally, thrombopoietin is mostly bound to MPL, with very low detectable free form in the serum.
  - Thrombopoietin levels are elevated in secondary thrombocytosis.
  - Besides thrombopoietin, cytokines (IL-1, IL-4, IL-6, IL-11, TNF) also participate in regulation of thrombopoiesis. C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) are usually elevated in reactive thrombocytosis.

Laboratory Diagnosis of Secondary Thrombocytosis

Peripheral Blood Smear Examination

- Peripheral blood smear shows increased platelets mainly of small granular mature forms.
- Microcytic hypochromic picture suggests iron deficiency anemia.
- Neutrophils containing toxic granules are suggestive of infectious or inflammatory etiology.

Bone Marrow Trephine Biopsy Examination

- Bone marrow trephine biopsy shows normal cellularity.
- Megakaryocytes show normal morphology. These can be increased and usually without clustering.
- Reticulin stain and trichrome stain are usually normal without significant fibrosis.

ESSENTIAL THROMBOCYTHEMIA

Essential thrombocythemia is a BCR-ALBL1 negative myeloproliferative neoplasm of bone marrow. It is characterized by abnormal morphology in the megakaryocytic lineage and sustained thrombocytosis over 450 × 10^9/L (Table 10.15).

- **Molecular genetics: JAK2V617F** (59–60%), **CALR** (calreticulin in 25–30%) and **MPLW515L/K** (3–5%) gene mutations are demonstrated in essential thrombocythemia.
- **Clinical features:** Patient presents with excessive spontaneous bleeding, headache, blurred vision, dizziness, erythromelalgia (red burning, pain of distal ends of toes and fingers). Thrombosis in small- and medium-sized arteries results in cerebral stroke, myocardial infarction, occlusion of deep vein and peripheral vessels. Bleeding is less common than thrombosis. Patient presents with bleeding tendencies, if platelet count is >1000 × 10^9/L. If there is palpable splenomegaly, a raised platelet count is much more likely to be due to primary thrombocythemia than to reactive thrombocytosis. The risk of occlusive vascular lesions is high in essential thrombocythemia but very small in reactive thrombocytosis.
- Bone marrow trephine biopsy examination: The bone marrow trephine biopsy from a patient with essential thrombocythemia shows clusters of megakaryocytes. Patient with advanced idiopathic myelofibrosis shows marked reticulin staining.

Comparison between secondary thrombocytosis and essential thrombocythemia is given in Table 10.16.

Table 10.15 2024 World Health Organization diagnostic criteria for essential thrombocythemia (diagnostic criteria include either all four major criteria or the first three major criteria and one minor criterion)

Major Diagnostic Criteria
▪ Platelet count ≥400 × 10^9/L
▪ Bone marrow: Normal cellularity, normal erythropoiesis and granulopoiesis; enlarged megakaryocytes including staghorn appearance and clustering or scattered focally; and minimal increase in reticulin fibrosis (up to grade I)
▪ Not meeting the WHO criteria for BCR-ABL1 positive for chronic myelogenous leukemia, polycythemia vera, primary myelofibrosis, myelodysplastic syndrome or other myelodysplastic neoplasms
▪ Presence of JAK2V617F (59–60%), CALR (25–30%) and MPLW515L/K (3–5%) gene mutations
Minor Diagnostic Criteria
Presence of a clonal marker or absence of evidence of reactive thrombocytosis

Table 10.16 Comparison between secondary thrombocytosis and essential thrombocythemia

Clinicopathologic Features	Secondary Thrombocytosis	Essential Thrombocythemia
Platelet count increase	Transient	Persistent
History of bleeding/thrombotic episode/ vasomotor symptoms	Present in 1–2%	Present
Hepatomegaly	Absent	Present
History of infections/inflammatory stimuli or nonmyelogenous malignancy	Present	Absent
Elevated acute phase reactants (C-reactive protein) and ESR	Present	Absent
Megakaryocyte morphology in the bone marrow	Megakaryocytes with normal morphology can be increased and usually without clustering	Enlarged megakaryocytes including staghorn appearance and clustering
Clonal molecular abnormality	Absent	Usually present (JAK2V617F, MPLW515L/L or CALR gene mutations)

Laboratory Diagnosis of Essential Thrombocythemia

Peripheral Blood Smear Examination

- Peripheral blood smear shows marked thrombocytosis with anisocytosis of platelets. Mean platelet volume is usually lower than normal. Leucocytes are within normal range.
- Red blood cells are normocytic normochromic except in patients with hemorrhage or iron deficiency anemia.
- Leukoerythroblastic picture raises the possibility of myelofibrosis.

Bone Marrow Trephine Biopsy Examination

- Bone marrow trephine biopsy is essential to differentiate essential thrombocythemia from polycythemia vera, primary myelofibrosis and myeloproliferative neoplasm.
- Bone marrow trephine biopsy in essential thrombocythemia shows normal cellularity, normal erythropoiesis and granulopoiesis; enlarged megakaryocytes including staghorn appearance and clustering or scattered focally.

BLEEDING ASSOCIATED WITH VASCULAR DISORDERS

Bleeding from vascular disorders is sometimes referred to as nonthrombocytopenic purpura.

- Vascular disorders may occur due to weakening of blood vessel wall by inherited or acquired disorders.
- Most of vascular disorders are characterized by easy bruising and spontaneous petechiae and purpura of the skin and mucous membranes.
- In patients with bleeding associated with vascular disorders, the platelet count, prothrombin time and international normalized ratio (PT–INR) and activated partial thromboplastin time (APTT) are normal.
- Inherited vascular disorders are characterized by thin-walled arterioles and capillaries.
- Scurvy caused due to vitamin C deficiency results in poor collagen synthesis and failure of the endothelial cells to be cemented together properly, which causes a fragile vascular wall.
- Senile purpura is caused by impaired collagen synthesis in the aging process resulting in bruising.
- Vascular defects also occur in the course of disseminated intravascular coagulation or as a result of microthrombi and corticosteroid therapy. It is triggered by tissue injury, endothelial cell injury, or combination of both of these processes. Due to failure of the normal mechanism controlling hemostasis, tissue factor expression, factor XII activation and platelet activation and thrombin generation; intravascular coagulation occurs.
- Characteristics of inherited connective disorders causing purpura are given in Table 10.17. Bleeding (purpura) associated with vascular disorders are given in Table 10.18.

SCURVY PURPURA

Vitamin C participates in the synthesis of collagen and reticulin fibrils from mucopolysaccharide ground substance in wound healing. Deficiency of vitamin C is known as scurvy, in which there is defective formation of mesenchymal tissue and osteoid matrix.

- Patient presents with hemorrhages in mucocutaneous and muscles along fascial planes due to capillary fragility. Insufficient production of osteoid matrix results in cartilaginous overgrowth, widening of epiphysis, bowing of the long bones and chest deformity.

Table 10.17 Characteristics of inherited connective disorders causing purpura

Disorder	Gene	Chromosome Locus	Pathological Effects
Hereditary hemorrhagic telangiectasia (Osler-Rendu disease)	▪ Endoglin/ENG-1 (HHT-1) ▪ ACVRL HHT-2	▪ 9q (HHT-1) ▪ 12q (HHT-2)	Arteriovenous malformations in skin, mucous membrane, lungs, liver, brain
Ehlers-Danlos syndrome	▪ COL1A1 ▪ COL1A2 ▪ COL3A1 ▪ COL5A1 ▪ COL5A2	Multiple chromosomes	Fragile blood vessels (bruises), flexible joints
Marfan's syndrome	Fibrillin 1 (FBN-1)	Chromosome 15	Decreased strength of blood vessels, overgrowth of long bones, arachnodactyly
Osteogenesis imperfecta	▪ COLA1 ▪ COLA2	Chromosome 2	Patchy defective bone matrix, brittle bones prone to fracture
Pseudoxanthoma elasticum	ABCC6	Chromosome 16	Degeneration and calcification of elastic fibers

Table 10.18 Bleeding (purpura) associated with vascular disorders

Purpura Associated with Vasculitis
▪ Henoch-Schönlein purpura ▪ Drug-induced purpura ▪ Infections (bacteria, viruses, rickettsia) ▪ Food allergen-induced purpura
Purpura Associated with Dysparaproteinemia
▪ Paraproteins (cryoglobulinemia, cryofibrinogenemia) ▪ Amyloidosis
Purpura Resulting from Decreased Connective Tissue
▪ Scurvy purpura (vitamin C deficiency) ▪ Senile purpura ▪ Cushing syndrome ▪ Glucocorticoid therapy
Miscellaneous Causes of Purpura
▪ Simple easy bruising syndrome ▪ Fat embolism ▪ Mechanical purpura ▪ Purpura fulminans ▪ Artificially induced purpura

- Osteoporosis is seen especially at the metaphyseal ends of bone. Other findings are gingival swelling and periodontal infection, impaired wound healing, impaired localization of focal infections and anemia.

HENOCH-SCHÖNLEIN PURPURA

Henoch-Schönlein purpura is the most common type of childhood immune complex-mediated vasculitis in the age group 4–11 years. The glomerular lesion is identical with that of IgA nephropathy. The disorder may be precipitated by exogenous antigens such as drugs, foods, or upper respiratory infections. IgA deposition occurs in blood vessel of skin often similar to IgA nephropathy in >50% cases.

- Patient presents with nephritic syndrome and skin rashes on extensor surfaces of the arms, legs, and buttocks, painful joints, gastrointestinal tract involvement (colicky abdominal pain with malena).
- Most patients do well, but a few progress to end stage renal disease. In adults, a rapidly progressive (crescentic) glomerulonephritis can occur.

SENILE PURPURA

Senile purpura occurs in elderly persons. There is atrophy of collagen fibers in the dermis with advancing age. Patient presents with purpura, ecchymosis on the back of neck, extensor aspect of forearms and legs.

SIMPLE BRUISING

Simple bruising is most often demonstrated in the women on arms and legs, which resolves rapidly. Hemostatic tests are within normal range.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

Hereditary hemorrhagic telangiectasia may form blood vessels without the capillaries (tiny blood vessels that pass blood from arteries to veins) that are usually between arteries and veins. The classic clinical

triad of hereditary hemorrhagic telangiectasia (HHT) disorder includes recurrent epistaxis, mucocutaneous telangiectasias, and one affected first-degree relative. Hereditary hemorrhagic telangiectasia type 1 is caused by mutations in the ENG gene. Type 2 is caused by mutations in the ACVRL1 gene. A person with diagnosis, HHT can be diagnosed by performing genetic testing.

- Patient presents with epistaxis, bright red spots on the face, lips, nose, flexor surface of forearms and conjunctiva.
- Bleeding from these malformed blood vessels in gastric mucosa may cause gastrointestinal hemorrhages resulting in iron deficiency anemia.

MARFAN'S SYNDROME

Marfan's syndrome is connective tissue disorder caused by missense mutations of the fibrillin gene 1 (FGN-1) mapped on chromosome 15, which encodes fibrillin protein essential for synthesis of elastic fibers in connective tissue. Fibrillin belongs to family of connective tissue proteins analogous to the collagen fibers. Fibrillin protein also affects another protein transforming growth factor β (TGF-β) in the body, which helps regulate how cells function throughout the body.

- **Molecular genetic alterations:** Missense mutations of fibrillin gene 1 (FGN-1) change the amount of fibrillin protein inadequate for normal cellular functions, which cause changes in the strength and performance of connective tissues of cardiovascular system (cardiac valve floppiness, aortic aneurysm, and aortic dissection), ligaments, tendons (hyperflexibility of joints), eyes (dislocation of the ocular lens in both eyes), lungs, and skin. Overgrowth of bones make them longer than usual.
- **Inheritance pattern:** In most cases, Marfan's syndrome is inherited as an autosomal dominant disorder meaning it occurs equally in men, women and children and can be inherited one normal copy of the FBN1 gene from one parent and one abnormal copy from another parent. Persons who have 50% chance of transmitting along the disorder to each of their children. Marfan's syndrome is also referred to as a 'variable expression' genetic disorder.
- **Physical appearance:** Physical features in Marfan's syndrome include: long narrow face, tall and thin body built, arms, legs, fingers, and toes seem too long for the rest of body, scoliosis, sternum caves in or sticks out, weak joints easily undergo dislocation, flat feet, highly arced roof of the mouth and crowding of teeth and loose joints.
- **Cardiovascular system manifestations:** About 90% of persons with Marfan's syndrome develop changes in their heart and blood vessels. Patient presents with life-threatening complications such as aortic aneurysm, aortic dissection, brain aneurysms, cardiac valve floppiness, mitral valve prolapse, cardiomyopathy, and cardiac arrhythmia. Tests to evaluate changes in the cardiovascular system may include: X-ray chest, magnetic resonance imaging, computed tomography scan, electrocardiogram, and echocardiogram.
- **Ocular manifestations:** More than 50% of persons with Marfan's syndrome develop nearsightedness, lens subluxation, cataracts, difference in the shape of eye, retinal detachment, and glaucoma.
- **Lung's manifestations:** The changes in the lung tissue that occur emphysema, chronic obstructive pulmonary disease, bronchitis, and pneumothorax.

EHLERS-DANLOS SYNDROME

Ehlers-Danlos syndrome (EDS) is a genetic disorder (autosomal dominant, autosomal recessive or sex-linked recessive inheritance) affecting generalized defect in collagen fibers synthesis, molecular structure, and function. Ehlers-Danlos syndrome affects virtually every organ system (skin, joint and blood vessels), which can result in significant morbidity and mortality. Complications of this disorder include arterial rupture, bleeding diathesis due to fragile skin, organ rupture, hypermobility of joints and dislocation, chronic pain, and fatigue.

- Ehlers-Danlos syndrome (EDS) is an autosomal dominant disorder of collagen and extracellular matrix with wide array of phenotypic expressions due to *de novo* gene mutations. Most clinically significant variants of EDS include classical EDS, classical-like EDS, cardiac valvular EDS, vascular EDS, and hypermobile EDS.
  - **Classical Ehlers-Danlos syndrome:** Classical EDS is an autosomal dominant disorder associated with COL5A and COL1A1 gene mutations encoding type V and type I collagen fibers respectively. Patient presents with atrophic scarring, skin hyperflexibility, and generalized joint hypermobility.
  - **Classical-like Ehlers-Danlos syndrome:** Classical EDS is an autosomal recessive disorder associated with TNXB gene mutation encoding tenascin XB. Patient presents with skin hyperextensibility without atrophic scarring, and easy bruising.
  - **Vascular Ehlers-Danlos syndrome:** EDS is an autosomal dominant disorder associated with

COL3A1 and/or COL1A1 gene mutations encoding type III and type I collagen fibers respectively. Patient presents with arterial rupture at young age, uterine rupture during third trimester, carotid cavernous sinus fistula formation without trauma, and family history established by genetic testing. Congenital hip dislocation and spontaneous pneumothorax are also observed.

- **Hypermobile Ehlers-Danlos syndrome:** Hypermobile EDS is an autosomal dominant disorder associated with unknown gene mutations.

- **Physical examination:** The skin becomes white in color, soft to the touch, easily hyperextensible, apparent blood vessels. Fragility of dermal skin with frequent bruises and lacerations is common. Smaller, deep, and movable subcutaneous nodules in the arms and over tibia are observed and demonstrated on radiograph. The joints are hyperextensible, but the degree of involvement varies. The digital joints are most often involved, but alterations can be present in all the joints.
- **Laboratory diagnosis:** The initiation workup of Ehlers-Danlos syndrome should focus on clinical history, extent of the involvement of body systems, imaging techniques (echocardiography, CT scan, MRI), coagulation studies, and genetic testing.

CHAPTER 11

Coagulation Disorders and Diagnostic Approach of Bleeding Diathesis

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

BLOOD COAGULATION SYSTEM
- Synthesis of coagulation factors
- Regulation of coagulation system
- Coagulation system disorders

INHERITED COAGULATION SYSTEM DISORDERS
- Hemophilia A
- Hemophilia B (Christmas disease)
- von Willebrand disease
- Factor I (fibrinogen) deficiency
- Factor II (prothrombin) deficiency
- Factor V (labile factor) deficiency
- Factor VII (stable factor) deficiency
- Factor X (Stuart-Prower factor) deficiency
- Factor XI (plasma thromboplastin antecedent) deficiency
- Factor XIII (fibrin stabilizing factor) deficiency

ACQUIRED COAGULATION SYSTEM DISORDERS
- Disseminated intravascular coagulation
- Hemorrhagic disease of newborn
- Coagulation system disorders in hepatic disease

THROMBOPHILIA (HYPERCOAGULABLE STATE)
- Hereditary thrombophilia (hypercoagulable state)
  - Antithrombin III deficiency
  - Protein C deficiency
  - Protein S deficiency
  - Factor V Leiden (rs6025)
  - Prothrombin G20210A gene mutation
  - Hyperhomocysteinemia
- Acquired thrombophilia (hypercoagulable state)
  - Antiphospholipid syndrome

BLEEDING DIATHESIS: DIAGNOSTIC APPROACH
- Clinical history
- Physical examination
- Hematologic investigations
  - Platelet count
  - Platelet function tests
  - Bleeding time
  - Coagulation profile
    - Activated partial thromboplastin time
    - Thrombin time
    - Blood clot retraction test
    - Euglobulin lysis time
    - Fibrinogen degradation products and D-dimer tests

BLOOD COAGULATION SYSTEM

Hemostasis is regulated by procoagulant and anticoagulation factors synthesized by vascular endothelium.

- The vascular endothelium forms a barrier between platelets and plasma coagulation factors and subendothelial connective tissues (basement membrane, collagen, microfibrils, mucopolysaccharides and fibronectin).
- Vascular endothelial cells synthesize procoagulant factor (e.g. tissue factor, prostacyclin, nitric oxide, von Willebrand factor) and anticoagulation factors (e.g. antithrombin III, tissue factor pathway inhibitor, protein S, protein C, tissue plasminogen activator).
- Hemostasis is initiated by vascular endothelial cell injury resulting in exposure of collagen and tissue thromboplastin.
- Coagulation factors and enzymes are activated and get assembled on the platelet surface resulting in formation of thrombin, that converts soluble fibrinogen to insoluble fibrin strands.
- The insoluble fibrin strands create a meshwork that cements platelets and other blood components to form the blood clot.
- Abnormalities of the coagulation system occur either due to deficiency of one or more coagulation factors or inappropriate activation of coagulation factors.

SYNTHESIS OF COAGULATION FACTORS

Majority of coagulation factors are proteins synthesized in the liver and present in inactive form. Vitamin K is essential for the synthesis of coagulation factors II, VII, IX, X, prothrombin and protein C.

- Liver enzyme reductase converts inactive coagulation factors to their active form. Liver reductase enzyme is inhibited by oral anticoagulants.

Table 11.1 Coagulation factors

Coagulation Factor	Synonyms	Site of Synthesis	Inheritance	Deficiency Affects	Therapy and Half-life of Infused Factor
I	Fibrinogen	Liver	Autosomal recessive (rare)	Both sexes	Cryoprecipitate, fresh frozen plasma, fibrinogen (96–144 hours)
II	Prothrombin	Liver (vitamin K dependent)	Autosomal recessive (rare)	Both sexes	Fresh frozen plasma, factors II, VII, IX, X concentrate (50–80 hours)
III	Tissue extract (thromboplastin)	Tissue	NA	NA	NA
IV	Calcium	–	–	–	–
V	Labile factor	Liver	Autosomal recessive	Both sexes	Fresh frozen plasma (24 hours)
VI	Not assigned	NA	NA	NA	NA
VII	Stable factor	Liver (vitamin K dependent)	Autosomal recessive	Both sexes	Factors II, VII, IX, X concentrate in plasma (4–6 hours)
VIII	Antihemophilic globulin A	Liver, spleen, kidneys	Sex-linked recessive	Male affected (1 in 3000) (female career)	Factor VIII concentrates, cryoprecipitate, fresh frozen plasma (12 hours)
IX	Christmas factor (anti-hemophilic factor B)	Liver (vitamin K dependent)	Sex-linked recessive (1 in 20,000)	Male affected (female career)	Factors II, VII, IX, X concentrate (20–30 hours)
X	Stuart-Prower factor	Liver (vitamin K dependent)	Autosomal recessive (rare)	Both sexes	Factors II, VII, IX, X concentrate in plasma
XI	Plasma thromboplastin antecedent (anti-hemophilic factor C)	Unknown	Autosomal dominant (rare)	Both sexes	Plasma (40–84 hours)
XII	Hageman factor	Unknown	Autosomal recessive (rare)	Both sexes	Treatment not required
XIII	Fibrin stabilizing factor	Unknown	Autosomal recessive (rare)	Both sexes	Plasma (150 hours)
–	von Willebrand factor (factor vWF antigen assay)	Endothelial cells	Autosomal dominant	Both sexes	DDAVP, cryoprecipitate, fresh frozen plasma, whole blood (24 hours)

Prekallikrein: Fletcher factor, Kininogen (high MW): Fitzerald factor, NA: Not applicable

- On the other hand, liver enzyme epoxide has opposite function by converting active coagulation factors into their inactive form. Vitamin K deficiency and hepatocellular failure lead to deficient synthesis of prothrombin resulting in bleeding manifestations.
- Each of the coagulation factors performs specific function in the coagulation system cascade. Majority of the inactive procoagulant factors are present in the blood at all times, the multistep process ensures inhibition of intravascular coagulation (Table 11.1).

REGULATION OF COAGULATION SYSTEM

Each step of coagulation system is regulated at two levels: (a) activation of the zymogen to an active enzyme; and (b) the presence of exquisite cofactor. Since some cofactors such as thromboplastin (tissue factor) and thrombomodulin are integral membrane proteins, so their functions are limited to the cells and tissues, that express these proteins.

- Presence of active enzyme and cofactor accelerate the activity of a coagulation factors as much as 1000-fold. In the absence of the cofactor, the enzyme has limited activity. Inactive precursor coagulation factor contains glutamyl residue. Inactive coagulation factor becomes active/functional coagulation factor by the addition of carboxyl from HCO_3 with the help of carboxylase enzyme. Calcium then binds to glutamyl residue.
- Binding of calcium to vitamin K-dependent coagulation factors is essential for normal coagulation system cascade at every step except first two steps. Calcium, factor X, factor V, platelet phospholipids combine to form **prothrombin activator**, which then converts prothrombin to thrombin. This interaction

causes conversion of fibrinogen into fibrin strands stabilized by fibrin stabilizing factor (factor XIII) that creates the insoluble blood clot, with platelets and red blood cells resulting in stoppage of bleeding. Without calcium, the coagulation factors fail to bind to platelet phospholipids resulting in reduction of rate of activation of coagulation system cascade.

- The extrinsic pathway of coagulation is initiated by a cellular lipoprotein known as tissue factor on the cell surface. Coagulation system is initiated by intrinsic pathway by activation of circulating factor XII.
- Both extrinisic and intrinsic pathways of coagulation system lead to the activation of factor X. When plasma comes in contact with tissue

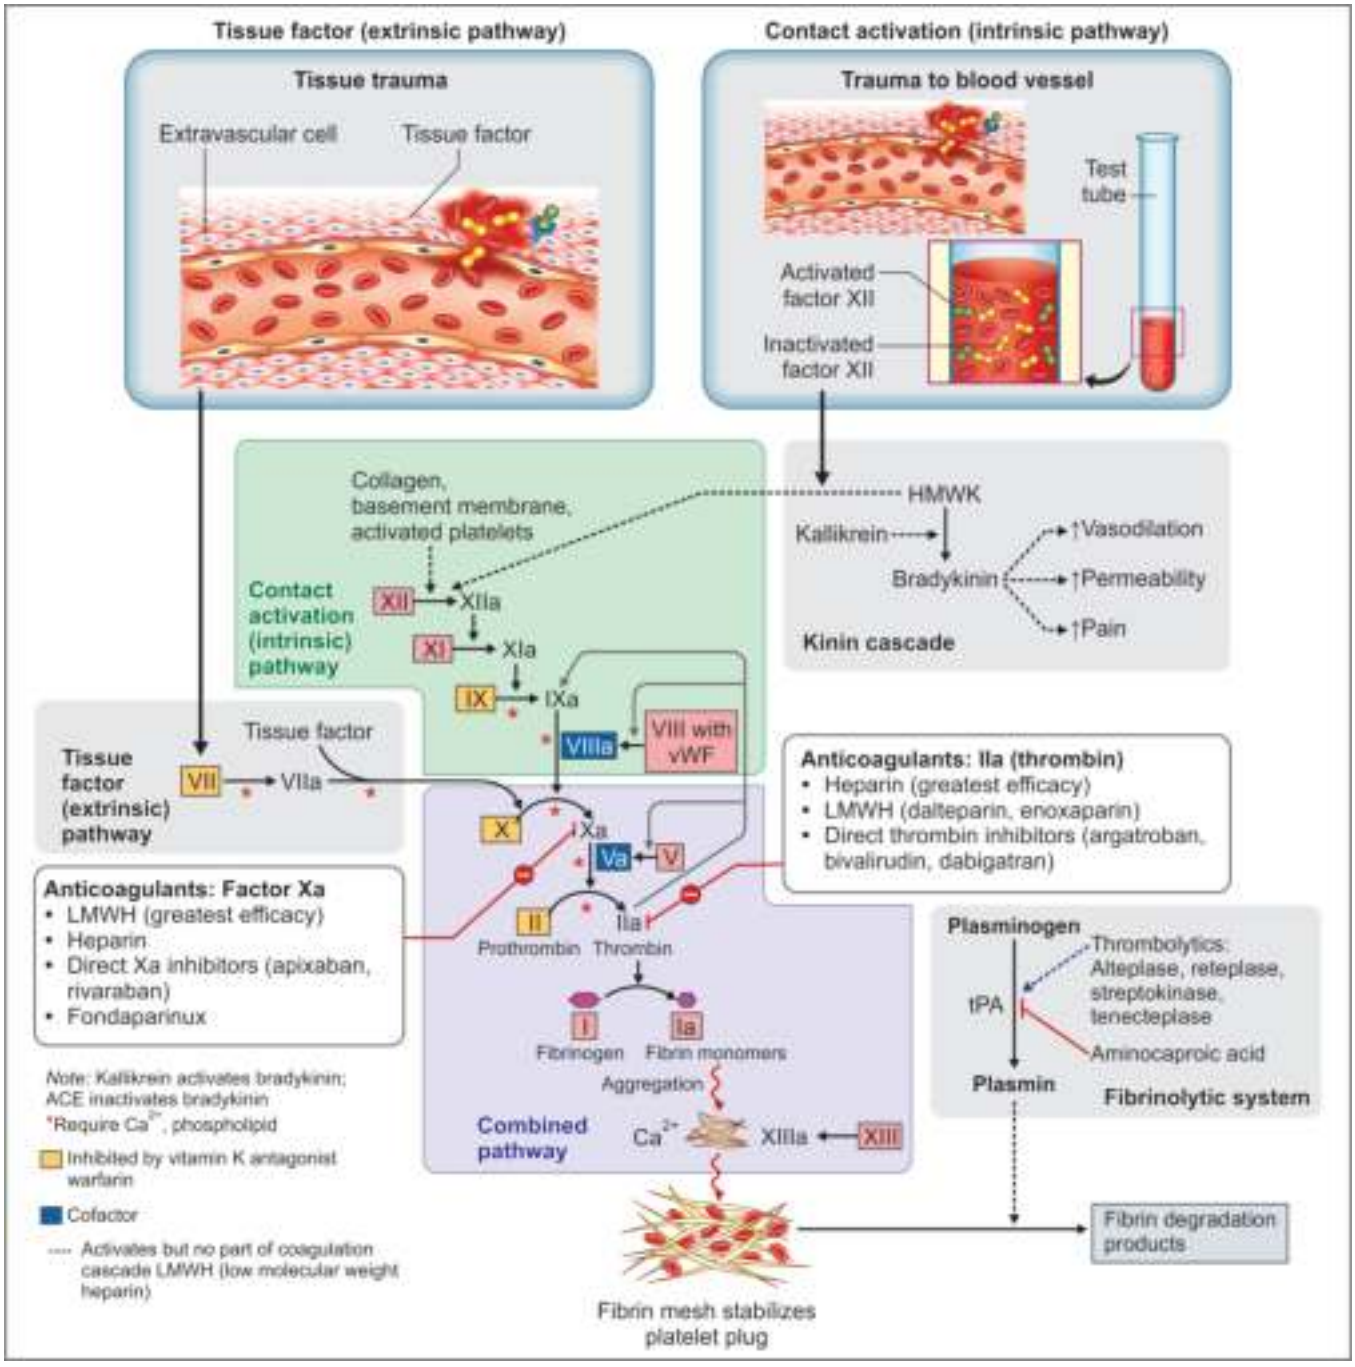

Fig. 11.1: Intrinsic, extrinsic and common pathways coagulation system; fibrinolysis and coagulation inhibition. Secondary hemostasis involves activation of the coagulation system and coagulation factors to produce cross-linked fibrinogen (fibrin) to stabilize the platelet plug. Fibrinolysis represents the process by which clot generated by coagulation system is degraded by plasmin to permit tissue repair. Anticoagulants are administered in clinical practice to prevent intravascular coagulation in various pathological disorders.

factor (TF), factor VII binds to the tissue factor resulting in formation of tissue factor/VIIa complex, which activates factors X and IX. Tissue factor pathway inhibitor (TFPI) is an important inhibitor of TF/VIIa complex. The VIIIa–IXa complex greatly amplifies Xa generated from factor X. The generation of thrombin from prothrombin by the action of Xa–Va complex leads to fibrin formation (Fig. 11.1).

- Thrombin is a central regulator of hemostasis and thrombosis, which has both procoagulant and anticoagulant properties. Thrombin promotes blood coagulation system by activation of factors V and X; conversion of fibrinogen into fibrin and platelet activation and platelet aggregation. Thrombin has anticoagulant properties, which activates protein C via thrombomodulin. Thrombin also induces thrombin activatable fibrinolysis inhibitor (TAFI), which protects the fibrin clot against lysis.
- Cell-based model of coagulation in which coagulation is regulated by properties of cell surfaces in three overlapping stages of initiation, amplification, and propagation, rather than the traditional cascade. Thrombin is important in each step. Cell-based model of coagulation system cascade is shown in Fig. 11.2A to C. Thrombin is a central regulator of hemostasis and thrombosis as shown in Fig. 11.3.

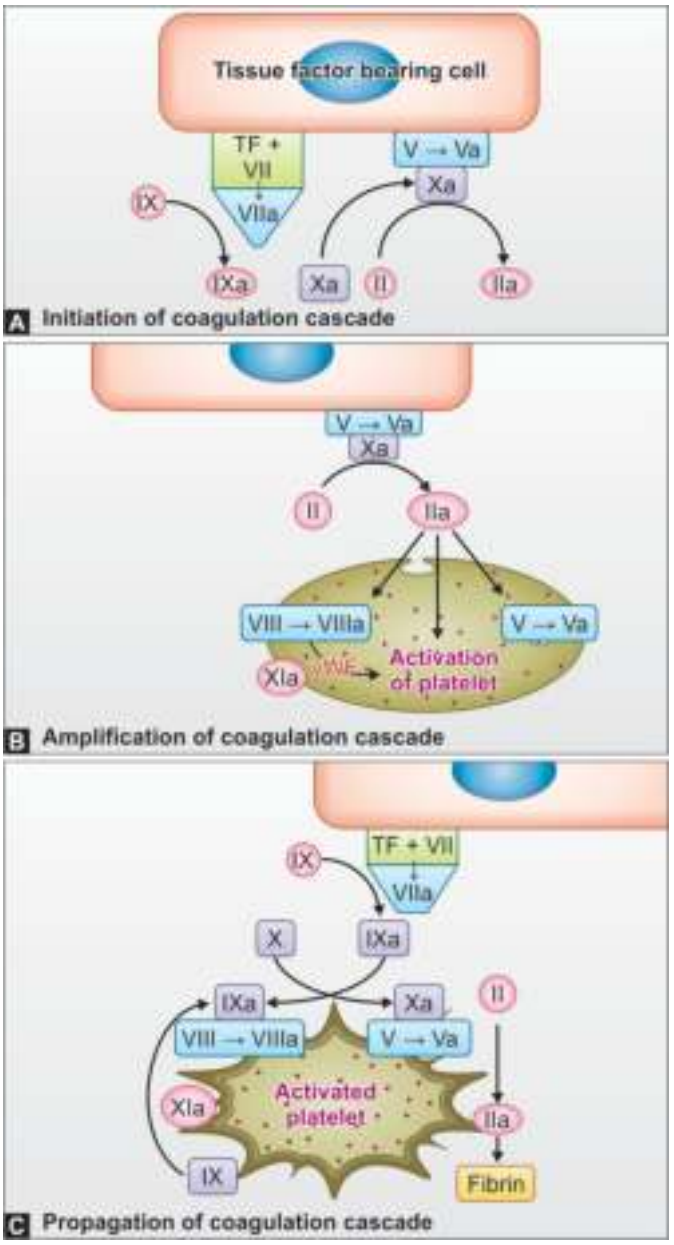

Fig. 11.2A to C: Cell-based model of coagulation system cascade is regulated by properties of cell surfaces in three overlapping stages of initiation, amplification and propagation rather than the traditional coagulation cascade. Thrombin is important in each step.

COAGULATION SYSTEM DISORDERS

INHERITED COAGULATION SYSTEM DISORDERS

Inherited coagulation system disorders occur due to deficient or reduced level of coagulation factors. Clinical manifestations vary according to the type of clotting factors. Common inherited coagulation disorders include von Willebrand disease (most common), hemophilia A (factor VIII deficiency), Christmas disease (factor IX deficiency). Rare inherited coagulation disorders include deficiency of clotting factors I, II, V, VII, X, XI and XIII.

ACQUIRED COAGULATION SYSTEM DISORDERS

Major causes of acquired coagulation system disorders include vitamin K deficiency, liver disease, disseminated intravascular coagulation and development of circulating anticoagulants. Severe liver diseases (cirrhosis, fulminant hepatitis, acute fatty liver of pregnancy) may disturb hemostasis by impaired synthesis of coagulation factors.

- Because, all the coagulation factors are synthesized by liver and vascular endothelium; thus, both prothrombin time and international normalized ratio (PT–INR) and activated partial thromboplastin time (APTT) are prolonged.
- Occasionally, decompensated liver disease also causes excessive fibrinolysis and bleeding manifestations due to decreased hepatic synthesis of antiplasmin.
- Disseminated intravascular coagulation (DIC) and hemorrhagic disease of newborn are acquired important causes of bleeding diathesis.
- Causes of inherited and acquired abnormalities of hemostasis are given in Table 11.2A to C.

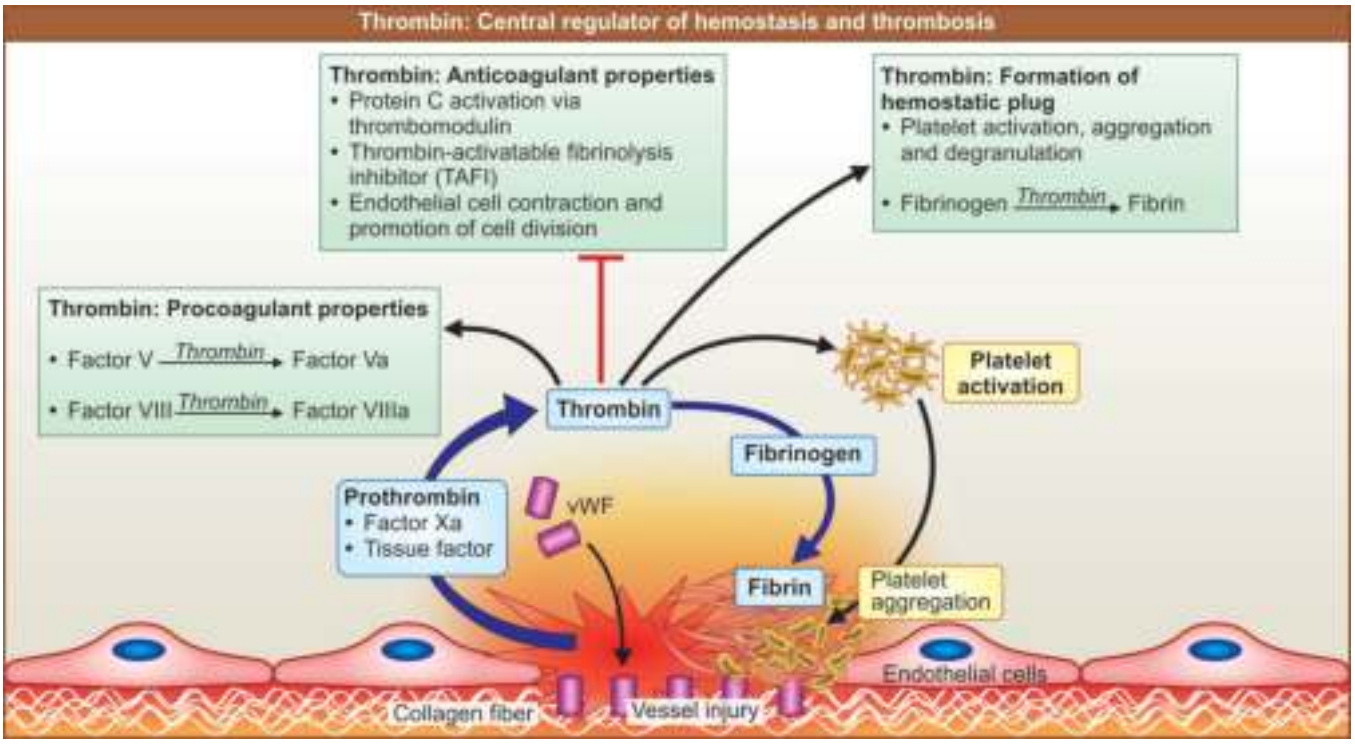

Fig. 11.3: Thrombin is a central regulator of hemostasis and thrombosis. Thrombin has both procoagulant and anticoagulant properties. Procoagulant properties include activation of factors V and VIII, conversion of fibrinogen to fibrin and activation and aggregation of platelets. Anticoagulant properties include activation of protein C via thrombomodulin and activation of TAFI. Endothelial effects of thrombin also include contraction of endothelial cells and acquisition of prothrombotic properties and promotion of cell division.

Table 11.2 Causes of inherited and acquired abnormalities of hemostasis

Inherited Abnormalities of Hemostasis	
Hemophilia A	▪ X-linked disorder ▪ Decreased or depletion of coagulation factor VIII deficiency ▪ Activated partial thromboplastin time (APTT) prolonged ▪ Severity and risk of bleeding depend on severity of deficiency of coagulation factor VIII ▪ About 5–20% of patients develop inhibitors to coagulation factor VIII due to treatment
Hemophilia B	▪ X-linked recessive disorder ▪ Decreased or depletion of coagulation factor IX deficiency ▪ Activated partial thromboplastin time (APTT) prolonged ▪ About 1–3% of patients develop inhibitors to coagulation factor IX due to treatment
Hemophilia C	▪ Decreased or depletion of coagulation factor XI deficiency ▪ Autosomal recessive disorder (heterozygotes, homozygotes) ▪ Common in Ashkenazi Jews
Afibrinogenemia/hypofibrinogenemia	▪ Patient has fibrinogen level 50% of normal level—heterozygous gene mutation with mild bleeding ▪ Prothrombin time and international normalized ratio (PT–INR) prolonged ▪ Activated partial thromboplastin time (APTT) prolonged ▪ Thrombin time prolonged
Dysfibrinogenemia—structural abnormality	▪ Structural abnormality of fibrinogen—usually heterozygous ▪ About 50% of patients have no clinical bleeding, 25% of cases with clinical bleeding; and 25% of cases develop thrombosis ▪ Prothrombin time and international normalized ratio (PT–INR) prolonged ▪ Activated partial thromboplastin time (APTT) prolonged ▪ Thrombin time (TT) prolonged ▪ Fibrinogen levels variable
von Willebrand disease (some cases)	Decreased vWF leads to decreased stability and function of factor VIII

Contd...

Table 11.2 Causes of inherited and acquired abnormalities of hemostasis (*Contd...*)

Acquired Abnormalities of Hemostasis	
Vitamin K deficiency	Impaired synthesis of coagulation factors II, VII, IX and X; and natural anticoagulant protein C and protein S
Liver disease	Impaired synthesis of coagulation factors I, II, V, VIII, IX, X, XI; and natural anticoagulant protein C, protein S and antithrombin III
Disseminated intravascular coagulation (DIC)	Multiple coagulation factor deficiencies especially fibrinogen depletion; as well as thrombocytopenia
Nephrotic syndrome	Loss of antithrombin III and antiplasmin in urine along with massive proteinuria
Multiple myeloma and amyloidosis	Consumption of coagulation factor X
Direct oral administration of anticoagulants for therapeutic purpose	Oral anticoagulants antagonize thrombin

INHERITED COAGULATION SYSTEM DISORDERS

Inherited coagulation system disorders occur due to deficient or reduced level of coagulation factors. Clinical manifestations vary according to the type of clotting factors. Common inherited coagulation system disorders include von Willebrand disease (most common), hemophilia A (factor VIII deficiency), Christmas disease (factor IX deficiency). Rare inherited coagulation disorders include deficiency or reduced levels of clotting factors I, II, V, VII, X, X1 and XIII.

HEMOPHILIA A

Normal factor VIII is essential for blood clotting. Gene encoding factor VIII is located on tip of the long arm of the X chromosome. Hemophilia A is an X-linked recessive disorder of blood clotting, which results from mutation in the gene encoding factor VIII. Patient presents with spontaneous bleeding into joints, muscles, and internal organs.

MODE OF INHERITANCE

As males have only one X chromosome, hence, defective VIII gene leads to decreased synthesis of factor VIII resulting in hemophilia.

- Heterozygous females are carriers, which transmit hemophilia A disease to the male progeny, which is clinically indistinguishable from hemophilia B (factor IX deficiency). The family pedigree of Queen Victoria shows a number of hemophilic descendents as she has been carrier of the disease. In females, the other normal X chromosome corrects the abnormality, but females can be asymptomatic carriers of hemophilia A.
- In males, hemophilia A disease is expressed because there is no normal X chromosome to correct the abnormality. Family trees in a case of hemophilia A are shown in Figs 11.4 and 11.5.

FACTOR VIII (ANTIHEMOPHILIC GLOBULIN)

Factor VIII gene encoding factor VIII glycoprotein is located on X chromosome, which comprises A1, A2, B, A3, C1 and C2 domains. First 19 amino acids of protein sequence comprise secretory leader peptide of precursor factor VIII. Factor B domain of factor VIII is cleaved off during its activation. Most of the 23 cysteine residues of mature factor VIII are located in A and C domains.

POSSIBLE SYNTHESIS SITES OF FACTOR VIII

Possible sites of synthesis of factor VIII are liver, spleen, bone marrow and kidney. Factor VIII concentration in plasma is 0.1 mg/dl with half-life of 5–12 hours.

- On starch electrophoresis, factor VIII migrates as α-globulin. Factor VIII solvents of high ionic strength such as NaCl and $CaCl_2$ form high MW fractions (VIIIAg and vWF) and low MW (VIIIc).
- Normal plasma adsorbed with barium salts removes factor IX and not VIII, which will correct activated partial thromboplastin time (APTT). Serum contains factor IX but not VIII.
- Comparison of subunits of factor VIII (VIIIc and vWF) is given in Table 11.3.

SEVERITY OF HEMOPHILIA A

Depending on the concentration of factor VIII in comparison to its normal activity. Hemophilia A cases are categorized as severe deficiency of factor VIII

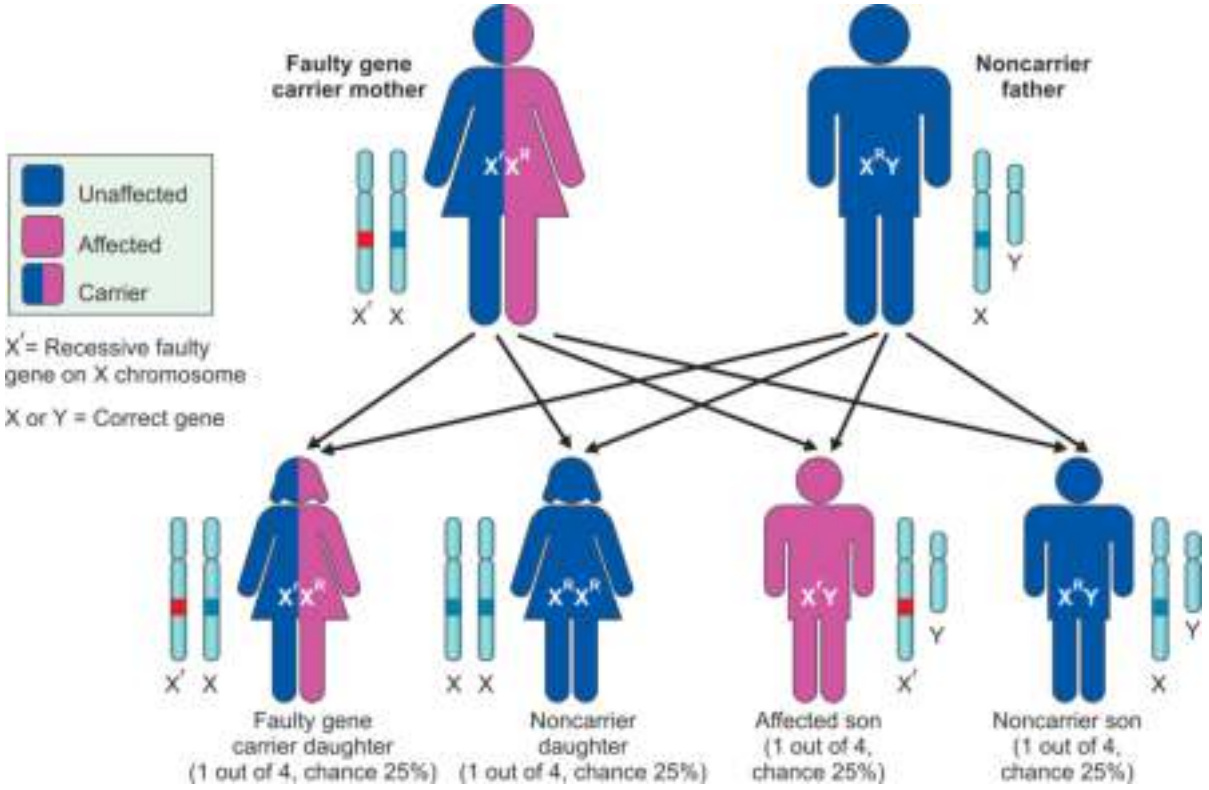

Fig. 11.4: Family tree in a case of hemophilia A, where mother is faulty gene carrier and noncarrier father. Chances of hemophilia in their children are shown.

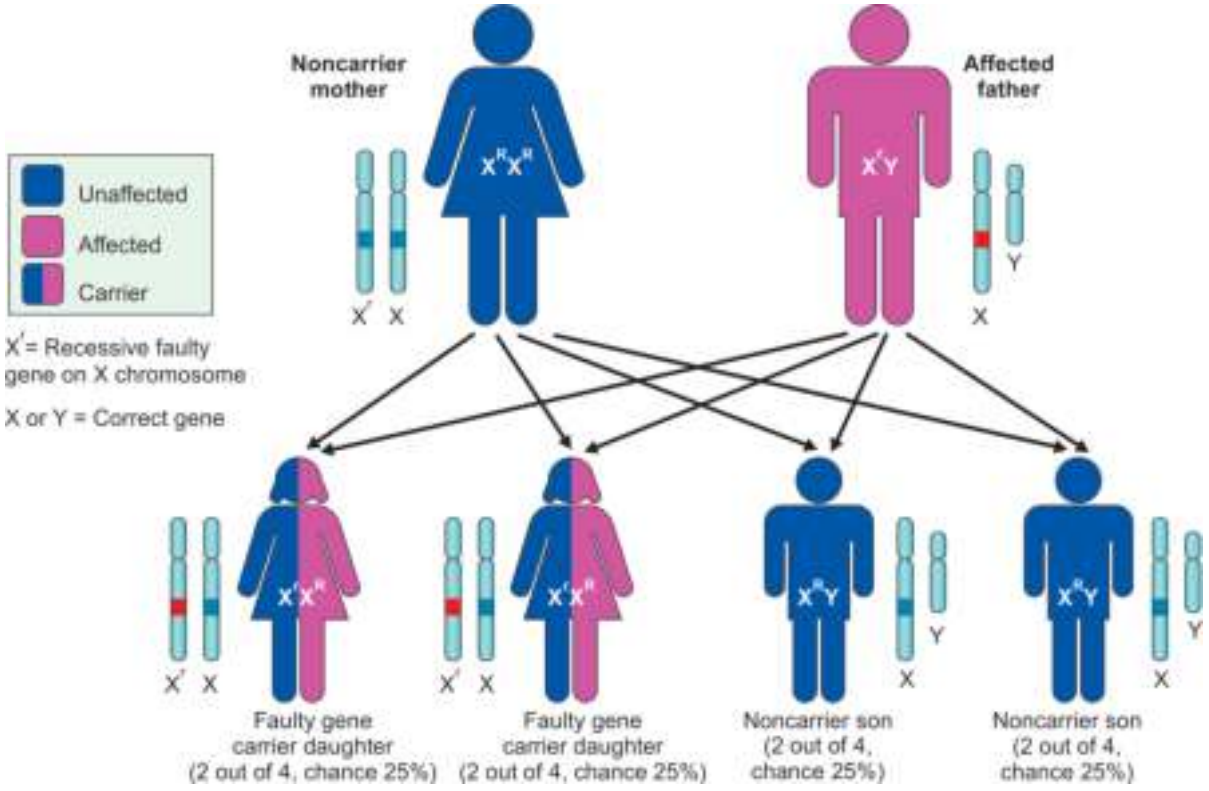

Fig. 11.5: Family tree in a case of hemophilia A, where mother is noncarrier and father with faulty gene carrier. Chances of hemophilia in their children are shown.

Table 11.3 Comparison of subunits of factor VIII (VIIIc and vWF)

Parameters	Factor VIIIc	von Willebrand Factor (vWF)
Possible sites of synthesis	Liver (most common site), spleen, bone marrow and kidney	Endothelial cells and megakaryocytes
Gene control	X-linked gene	Chromosome 12
Function	Participates in intrinsic coagulation pathway resulting in formation of hemostatic plug	Platelet adhesion (aggregation by ristocetin *in vitro*)
Deficiency	Hemophilia	von Willebrand disease

Table 11.4 Clinical manifestations in deficiency of factor VIII (hemophilia) and factor IX (Christmas disease)

Features	Severe Deficiency of Factors VIII and IX	Moderate Deficiency of Factors VIII and IX	Mild Deficiency of Factors VIII and IX
Factor VIII or IX level, units/dl	▪ <1 unit/dl	▪ 1–5 unit/dl	▪ 6–30 unit/dl
Frequency	▪ 15%	▪ 15%	▪ 70%
Detection of disorder	▪ Newborn	▪ Children	▪ Adults
Clinical features	▪ Frequent spontaneous hemarthrosis with crippling disease ▪ Frequent severe, spontaneous hemorrhage in the intracranial and intramuscular regions	▪ Severe bleeding from major/minor surgery or trauma ▪ Bleeding after circumcision site ▪ Infrequent spontaneous joint and tissue bleeding	▪ Rare spontaneous bleeding ▪ Excessive bleeding after surgery or trauma ▪ Disorder might not be discovered until bleeding episode occurs

level (<1%), moderate deficiency of factor VIII level (1–5%) and mild deficiency of factor VIII level (6–25%). Clinical manifestations in deficiency of factor VIII (hemophilia) and factor IX (Christmas disease) are given in Table 11.4.

CLINICAL FEATURES

Patient presents with hemorrhage from minor wounds and trauma, bleeding from oral mucosa, hematuria, and bleeding into joints. Recurrent hemarthroses can lead to progressive crippling deformities. Clinical manifestations of hemophilia A are shown in Fig. 11.6.

Hemarthrosis

Hemarthrosis is the most common event, which can be spontaneous or with trauma. Joints involved in hemophilia include knee, elbow, ankle, wrist, shoulder, hip and temporomandibular joints.

- Repeated bouts of bleeding lead to the joint destruction resulting in deformities in weight-bearing joints.
- Joints are swollen, tender and painful. Approximately 400 units of factor VIII are administered by intravenous route.

Soft Tissue Bleeding

Soft tissue bleeding is the second most bleeding manifestation occurring between fascial planes such as retropharyngeal region, oral cavity and between two heads of gastrocnemius muscles. To avoid pain, the patient hyperextends the ankle to shorten the gastrocnemius muscles.

- If these hemophilia A patients are not treated, gastrocnemius muscle deformities become chronic and the patient walks on the toes of the affected legs.
- The classic equine gait is often the first orthopedics event due to bleeding into gastrocnemius muscle. Approximately 300–400 units of factor VIII are administered by intravenous route.

Genitourinary System Bleeding

Nontraumatic spontaneous genitourinary bleeding without a structural lesion is encountered in hemophilics. Epsilon aminocaproic acid (**EACA**) is usually administered in hemophilia A patients to prevent lysis of blood clots. But this drug is contraindicated in patients with genitourinary bleeding for the fear of causing obstructive uropathy from blood clots.

Retroperitoneal Hemorrhage

Retroperitoneal hemorrhage should always be considered in hemophilia A patients, who presents with hypotension, tachycardia and mild abdominal pain. Surgical exploration is not indicated.

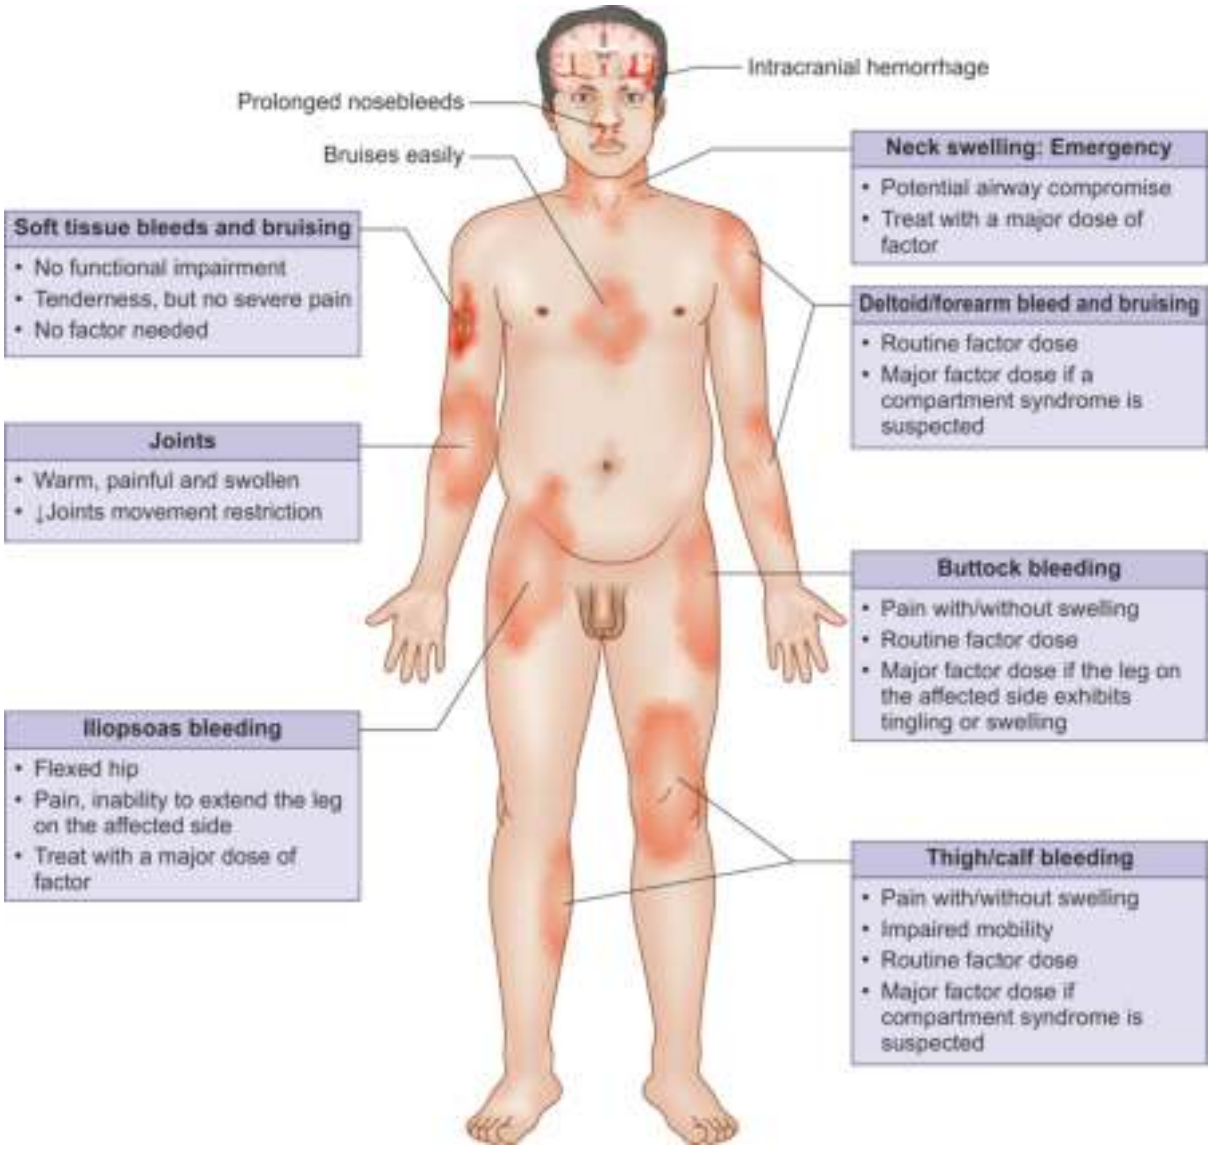

Fig. 11.6: Clinical manifestations of hemophilia A.

Gastrointestinal Tract Bleeding

Gastrointestinal tract bleeding in hemophilia A patients is associated with a structural lesion in contrast to genitourinary bleeding. Traumatic bleeding occurs following tonsillectomy and tooth extraction. Approximately 300–400 units of factor VIII are administered by intravenous route to stop bleeding in these patients.

Delayed Wound Healing

Delayed wound healing occurs due to intermittent bleeding and infection in hemophilia A patients.

Bleeding-related to Dental Procedures

In normal persons, bleeding may persist for 12 hours after dental procedures. But bleeding persists for 3 days in hemophilic patients. Factor VIII should be administered to control bleeding.

Laboratory Diagnosis of Hemophilia A
Bleeding Time and Prothrombin Time
▪ Bleeding time and prothrombin time and international normalized ratio (**PT–INR**) are within normal range. ▪ Platelet count and functions are normal.
Clotting Time
Clotting time is prolonged.
Activated Partial Thromboplastin Time
▪ Activated partial thromboplastin time (**APTT**) is prolonged. Mixing of a patient's blood with that of a normal donor normalizes the APTT. Normal APTT is 30–35 seconds.

- APTT measures intrinsic pathway of coagulation system cascade, coagulation factors XI, IX, VIII, X, V, prothrombin and fibrinogen. Phospholipid is added to plasma and clotting is observed. Phospholipid is a part of thromboplastin. Therefore, test is known as activated partial thromboplastin time.

Factor VIII Assay

Factor VIII assay is analyzed to assess severity of hemophilia A disease.

DIFFERENTIAL DIAGNOSIS

Hemophilia A should be differentiated from hemophilia B (factor IX deficiency) and severe von Willebrand disease. Comparison between hemophilia A and von Willebrand disease is given in Table 11.5.

DETECTION OF CARRIER

Most of the carrier women of hemophilia A are asymptomatic. Only a few females with very low factor VIII levels may present with menorrhagia. Accurate family tree study is carried out in hemophilia A patients.

- Coagulation profile should be estimated on three occasions by analyzing factors VIII, IX and VWAg to diagnose hemophilia in 75% of cases.
- Exact detection of hemophilia carriers is carried out by DNA analysis. Heterozygous women carriers are diagnosed by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) or Southern blotting to detect intron 12 inversion.

TREATMENT

Approximately 6–12% hemophilia A patients develop antibodies against exogenous administered fresh frozen plasma (factor VIII).

- Factor VIII inhibitors develop in patients with no detectable factor in their plasma. Therefore, recombinant factor VIII is being administered in hemophilia A patients by intravenous route, which has a half-life of 8–12 hours.
- Fresh frozen plasma is prepared from fresh blood <12 hours old. It is stored at –20°C for one year. It is administered in the dose of 7–15 ml/kg body weight for 30–60 minutes.
- Plasma products/recombinant factor VIII concentrates used in hemophilia are given in Table 11.6.

DDAVP Therapy

DDAVP (D-amino-delta-D-arginine vasopressin) hormone preparation is administered to enhance activity of factor VIII in mild hemophilia A patients.

Epsilon Aminocaproic Acid (EACA)

Epsilon aminocaproic acid is usually administered in hemophilia A patients to prevent lysis of blood clots in patients undergoing dental procedures.

Table 11.5 Comparison between hemophilia A and von Willebrand disease

Features	Hemophilia A	von Willebrand Disease
Sex predilection	Males	Females > males
Skin and mucous membrane bleeding	Rare bleeding	Common, persistent and profuse bleeding
Superficial ecchymoses	Common; large and solitary	Small and multiple
Deep hematoma	Common	Rare
Hemarthroses	Common	Rare
Delayed bleeding	Common	Rare
Gastrointestinal bleeding	Present with GIT lesions	Present
Hematuria	Present	Present
Epistaxis	Present	Present
Gingival bleeding	Present	Present
Excessive bleeding after tooth extraction	Present	Present
Intracranial bleeding	Present	Present
Bleeding time	Normal	Increased
Clotting time	Increased	Increased
Prothrombin time	Normal	Normal
APTT	Increased	Increased
Factor VIII assay	Decreased	Normal or decreased
vWF ristocetin cofactor assay	Normal	Decreased

Table 11.6 Plasma products/recombinant factor VIII concentrates used in hemophilia

Plasma Products/Recombinant Factor VIII Concentrates	Indications for Use
Human factor VIII	Hemophilia A, von Willebrand disease
Human factor VIII (high purity)	Hemophilia A especially with HIV infection
Recombinant factor VIII	Hemophilia A
Porcine factor VIII	Factor VIII inhibitors
Activated prothrombin complex concentrates	Factor VIII inhibitors

HEMOPHILIA B (CHRISTMAS DISEASE)

Hemophilia B is also known as Christmas disease. Hemophilia B is an X-linked recessive disorder caused by mutations in the F9 gene encoding factor IX, which affects 1 in 40,000 males and accounts for 15% of hemophilia cases. One-third of all cases represents new gene mutations. Hemophilia B (factor IX deficiency) is clinically indistinguishable from hemophilia A (factor VIII deficiency).

CLINICAL FEATURES

Patient presents with mild clinical manifestations such as hemarthrosis during 5–15 years of age.

Laboratory Diagnosis of Hemophilia B

- In both forms of hemophilia A and B, the activated partial thromboplastin time (APTT) is prolonged. Mixing of a patient's blood with that of a normal donor normalizes the APTT.
- Prothrombin time and international normalized ratio (PT–INR) is within normal range.
- Activated plasma thromboplastin time (APTT) is increased (normal 30–40 seconds).
- Thromboplastin generation time is performed to differentiate factor VIII deficiency (hemophilia A) from factor IX deficiency (Christmas disease).

TREATMENT

Patients with factor IX deficiency (Christmas disease) are treated with recombinant factor IX (Benefix), prothrombin complex concentrates (e.g. Konya, Proplex), factor IX concentrates (ergonovine) and gene therapy (under research phase). Differentiating features of hemophilia A, hemophilia B and hemophilia C are given in Table 11.7.

VON WILLEBRAND DISEASE

The von Willebrand disease is a common bleeding disorder. Most cases present with mild mucocutaneous bleeding. It occurs due to a reduction or structural

Table 11.7 Differentiating features of hemophilia A, hemophilia B and hemophilia C

Features	Hemophilia A (Factor VIII Deficiency)	Hemophilia B (Factor IX Deficiency)	Hemophilia C (Factor XI Deficiency)
Mode of inheritance	X-linked disorder	X-linked disorder	Autosomal recessive
Frequency	1:5000	1:30.000	▪ Common in Ashkenazi Jews ▪ 1:8 Heterozygotes ▪ 1:90 Homozygotes
Classification of hemophilia according to factor concentration	▪ Severe deficiency of factor VIII <1% of normal ▪ Moderate deficiency of factor VIII ≥1% and <5% of normal ▪ Mild deficiency of factor VIII >5% of normal	▪ Severe deficiency of factor IX <1% of normal ▪ Moderate deficiency (factor IX ≥1% and <5% of normal) ▪ Mild deficiency of factor IX >5% of normal	▪ Severe deficiency of factor XI <20 IU/L ▪ Not application ▪ Mild deficiency of factor XI ≥20 IU/L
Clinical features	▪ Hemarthrosis ▪ Intramuscular hematoma ▪ Genitourinary bleeding ▪ Retroperitoneal hemorrhage ▪ Equine gait ▪ Delayed wound healing	▪ Hemarthrosis ▪ Intramuscular hematoma	Mucocutaneous bleeding in mouth, nose and genitourinary regions (areas of fibrinolysis)

Contd...

Features	Hemophilia A (Factor VIII Deficiency)	Hemophilia B (Factor IX Deficiency)	Hemophilia C (Factor XI Deficiency)
Laboratory findings	▪ Prothrombin time: Normal ▪ APTT: Increased ▪ Platelet aggregation with ristocetin: Normal	▪ Prothrombin time: Normal ▪ APTT: Increased ▪ Platelet aggregation with ristocetin: Normal	▪ Prothrombin time: Normal ▪ APTT: Increased ▪ Platelet aggregation with ristocetin: Normal
Treatment	▪ Plasma derived factor VIII concentrates ▪ Recombinant factor VIII concentrates ▪ Gene therapy under clinical trials	▪ Plasma derived factor IX concentrates ▪ Recombinant factor IX concentrates ▪ Gene therapy under clinical trials	▪ Plasma derived factor XI concentrates ▪ Recombinant factor XI concentrates ▪ Antifibrinolytic agents
Incidence of development of inhibitors against coagulation factor	33% of patients with severe deficiency of factor VIII	3% of patients with severe deficiency of factor IX	33% of patients with null gene mutations (Glu117 stop gene mutation)

abnormality of large multimeric glycoprotein von Willebrand factor.

- Monomers of von Willebrand factor (vWF) glycoprotein undergo N-glycosylation to form dimers, which get arranged to give multimers. Binding of von Willebrand factor with factor VIII is the main function of von Willebrand factor.
- The von Willebrand disease occurs inherited and acquired forms.
- Inherited von Willebrand disease is of three types: type 1 (most common about 70%), type 2 (2A, 2B, 2M, 2N), and type 3 (most severe disease). Type 2 has similar symptoms of hemophilia A and B.
- The pathophysiology of each type of inherited of von Willebrand disease depends on the qualitative or quantitative defects in vWF antigen, vWF activity and factor VIII coagulant activity. The von Willebrand disease, subtypes and characteristics are given in Table 11.8.

Table 11.8 von Willebrand disease, subtypes and characteristics

VON WILLEBRAND FACTOR AND FACTOR VIII SYNTHESIS

The von Willebrand factor (vWF) is stored in Weibel-Palade bodies of vascular endothelial cells. The vWF is secreted from activated vascular endothelial cells into the subendothelial space. vWF is also synthesized by α-granules of platelets. von Willebrand factor (vWF) is involved in hemostasis.

- After vascular endothelial injury, vWF binds to platelet glycoprotein (Gp) receptors, GpIb-α and promotes platelet adherence and protects factor VIII. Released vWF stabilizes plate adhesion to the damaged blood vessel wall and promotes platelet–fibrin interactions. The vWF also binds GpIIb/IIa on the activated platelet surface to promote platelet aggregation. ADAMTS13 is the protease that cleaves ultra-large multimers of vWF.
- Factor VIII is an essential blood coagulation protein, also known as antihemophilic factor (AHF), synthesized in liver sinusoidal cells and vascular endothelial cells outside liver throughout the body. Factor VIII protein circulates in the blood in an inactive form bound to another molecule called von Willebrand factor.
- Human, factor VIII is encoded by **FB gene.** Defects in FB gene result in hemophilia A, recessive X-linked coagulation disorder.

vWF and Factor VIII Complex

Both factor VIII (10%) and vWF (90%) form complex and circulate in the plasma to promote blood clotting and the interaction with vascular endothelium and platelets resulting in primary hemostatic plug. vWF serves as a carrier for factor VIII. vWF stabilizes half-life of factor VIII in the circulation for 12 hours. If patient has deficient vWF, half-life of factor VIII is reduced to 2–4 hours (Fig. 11.7).

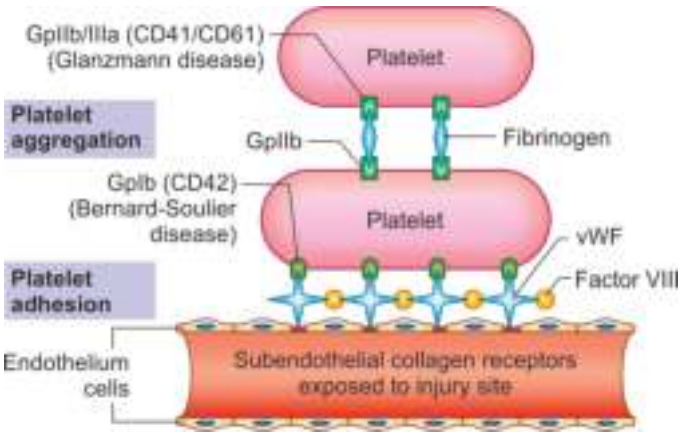

Fig. 11.7: vWF and factor VIII complex shows platelet aggregation on exposed subendothelial tissue.

CLINICAL FEATURES

Patient with von Willebrand disease presents with mild to severe spontaneous bleeding from mucous membranes, excessive bleeding from wounds and menorrhagia. It is worth mentioning that hemarthroses are rare in contrast to hemophilia A. Unlike other forms of hemophilia, von Willebrand disease is not X-linked disorder, so men and women are equally affected. Clinical manifestations of von Willebrand disease worsen following intake of aspirin and NSAID.

LABORATORY DIAGNOSIS

Factor VIII and vWF levels are decreased in von Willebrand disease. Tourniquet test (Hess test) is positive. Platelet aggregation test is normal with ADP, collagen and epinephrine (absent with ristocetin). Activated partial thromboplastin time (APTT) is normal or decreased. Template bleeding time, platelets count, Prothrombin time and international normalized ratio (PT–INR), thrombin time (TT) and fibrinogen lysis tests are within normal range (Table 11.9).

Table 11.9 Laboratory findings in von Willebrand disease

Parameters	Results
Tourniquet test (Hess test)	Positive
Template bleeding time	Normal
Platelet count	Normal
Platelet aggregation test	Normal with ADP, collagen and epinephrine (absent with ristocetin)
Factor VIII assay	Decreased
vWF assay	Decreased
Prothrombin time and international normalized ratio (PT–INR)	Normal
Thrombin time (TT)	Normal
Activated partial thromboplastin time (APTT)	Normal or increased
Fibrinolysis test	Normal

TREATMENT

The von Willebrand disease is treated by administration of desmopressin or DDAVP to stop bleeding. This therapeutic agent will release subendothelial stores of vWF and factor VIII. If DDAVP is not effective, patient is treated by factor VIII replacement. If DDAVP and factor VIII administration are not effective, and recombinant of von Willebrand factor (vWF) is administered.

FACTOR I (FIBRINOGEN) DEFICIENCY

Fibrinogen is synthesized in the liver, which plays an important role in primary hemostasis due to normal platelet aggregation. Due to proteolytic cleavage of fibrinogen by thrombin, fibrin is produced. Inherited abnormality of fibrinogen results in abnormal hemostasis (Table 11.10).

Table 11.10 Inherited abnormalities of fibrinogen associated with abnormal hemostasis

Parameters	Afibrinogenemia	Hypofibrinogenemia	Dysfibrinogenemia
Definition	Total absence of fibrinogen measured by antigenic assay	Decreased level of fibrinogen	Structural abnormality of fibrinogen molecule with altered functional properties
Clinical manifestations	▪ Umbilical stump bleeding ▪ Mucosal bleeding ▪ Central nervous system bleeding ▪ Musculoskeletal bleeding ▪ Intra-abdominal bleeding ▪ Recurrent miscarriage ▪ Antepartum and postpartum bleeding	▪ Umbilical stump bleeding ▪ Mucosal bleeding ▪ Central nervous system bleeding ▪ Musculoskeletal bleeding ▪ Intra-abdominal bleeding ▪ Recurrent miscarriage ▪ Antepartum and postpartum bleeding	▪ Umbilical stump bleeding ▪ Central nervous system bleeding ▪ Soft tissues bleeding ▪ Bleeding in pregnant women following vaginal delivery, cesarean section ▪ Postpartum bleeding ▪ Bleeding following dental extraction and surgical procedures ▪ Delayed wound healing
Clinical course	Clinical course variable in severity	Clinical course variable in mild	Clinical course variable in severity
Laboratory diagnosis	▪ ↑Prothrombin time ▪ ↑Activated partial thromboplastin time ▪ ↑Thrombin time ▪ ↑Bleeding time ▪ Fibrinogen levels undetectable by antigen assay ▪ Coagulation tests are markedly prolonged	▪ ↑Prothrombin time ▪ ↑Activated partial thromboplastin time ▪ ↑Thrombin time ▪ ↑Bleeding time ▪ Fibrinogen level and function reduced ▪ Coagulation tests abnormal depending on fibrinogen level	▪ ↑Thrombin time (most sensitive) ▪ ↑Prothrombin time (may be prolonged) ▪ ↑Activated partial thromboplastin time (may be prolonged) ▪ Reptilase time variable (increased or normal) ▪ Diagnosed by demonstration of fibrinogen molecule defect

- Afibrinogenemia is total absence of fibrinogen analyzed by an antigenic assay.
- Hypofibrinogenemia refers to decreased level of fibrinogen.
- Dysfibrinogenemia refers to structural abnormality of fibrinogen molecule leading to altered functional properties.

CLINICAL FEATURES

Clinical manifestations depend on concentration of factor I (fibrinogen) in the blood.

- Patient with afibrinogenemia presents with life-threatening bleeding diathesis, e.g. mucosal bleeding, umbilical stump bleeding, muscle hematoma, hemarthrosis, intracranial bleeding, recurrent miscarriage with antepartum and postpartum hemorrhages.
- Patient suffering from dysfibrinogenemia presents with delayed wound healing, umbilical stump bleeding, intracranial bleeding, muscle hematoma, and bleeding after tooth extraction.

MOLECULAR GENETIC ALTERATIONS

Three subunits of fibrinogen (Aα, Bβ and γ) are encoded by three different genes located on chromosome 4. Subunit Aα represents 99% of RNA. Synthesis of Bβ chain is the rare-limiting step in the production of mature molecule of fibrinogen. The γ-chain is produced by alternative splicing. Fibrinogen constitutes 15% and contains binding site for thrombin and factor XII.

LABORATORY DIAGNOSIS

Fibrinogen antigen assay is done to measure fibrinogen protein concentration in blood.

- **Afibrinogenemia:** In afibrinogenemia, there is marked prolongation of prothrombin time and international normalized ratio (**PT–INR**), activated partial thromboplastin time (**APTT**), thrombin time (**TT**) and bleeding time (**BT**). Fibrinogen is undetectable by analyzing functional and antigenic assays.
- **Hypofibrinogenemia:** In hypofibrinogenemia, there is prolongation of PT–INR, APTT and TT. Thrombin time is most sensitive test. Fibrinogen level is detected by analysis of functional and antigen assays.
- **Dysfibrinogenemia:** In dysfibrinogenemia, there is prolongation of TT. Prothrombin time and international normalized ratio (PT–INR), APTT may be prolonged.

FACTOR II (PROTHROMBIN) DEFICIENCY

Prothrombin (factor II) is synthesized by liver. It is one of the vitamin K-dependent coagulation factors that functions in the blood coagulation cascade. Prothrombin is encoded by a gene located on chromosome 11.

- Prothrombin requires post-translational carboxylation to become functionally active. In the presence of factor V and calcium, factor Xa activates prothrombin.
- Prothrombin deficiency is an autosomal recessive disorder characterized by hypoprothrombinemia (type I prothrombin deficiency with reduced antigen and activity) and dysprothrombinemia (type II prothrombin deficiency with normal activity but normal antigen level).

CLINICAL FEATURES

Patient may present with hemarthrosis, muscle hematomas, and intracranial bleeding.

Laboratory Diagnosis of Factor II (Prothrombin) Deficiency

- Prothrombin time and international normalized ratio (PT–INR) is prolonged.
- Activated partial thromboplastin time (APTT) is also prolonged.
- Bleeding time (BT) is within normal reference range.
- Diagnosis of mild prothrombin deficiency may be difficult in premature neonates.

TREATMENT

Prothrombin deficiency is treated by administration of prothrombin concentrate. Factor III concentrate contains factors II, IX and X. Prophylactic administration of prothrombin concentrate prevents development of chronic arthropathy in children.

FACTOR V (LABILE FACTOR) DEFICIENCY

Coagulation factor V (labile factor) is a large glycoprotein encoded by a gene located on chromosome 1. Factor V is synthesized by liver and megakaryocytes.

- Platelets contain 20% of total circulating factor V.
- Thrombin activates factor V resulting in formation of factor Va, which acts as a cofactor for factor Xa involved in the conversion of prothrombin to thrombin.
- Factor V deficiency is an inherited autosomal recessive disorder, also known as **Owren's disease** or parahemophilia that results in poor coagulation after an injury or surgical procedures.
- Factor V deficiency should not be confused with factor V Leiden mutation that causes excessive blood coagulation.

CLINICAL FEATURES

Homozygous deficiency of factor V results in moderate to severe bleeding tendencies, e.g. epistaxis and oral

mucosal bleeding. Hematuria and gastrointestinal bleeding are rare.

Laboratory Diagnosis of Factor V (Labile Factor) Deficiency

- Factor V deficiency is associated with prolongation of prothrombin time and international normalized ratio (PT–INR) as well as activated partial thromboplastin time (APTT).
- Thrombin time (TT) is within normal range.
- Immunological assay of factor V is essential in establishing its deficiency.
- Factor VIII immunological assay should also be performed to exclude combined deficiency of factors V and VIII deficiency.

TREATMENT

Fresh frozen plasma (FFP) containing factor V should be administered to achieve hemostasis. Close monitoring of factor V deficiency is essential in pregnant women.

FACTOR VII (STABLE FACTOR) DEFICIENCY

Factor VII (stable factor) is a vitamin K-dependent glycoprotein encoded by factor VII gene located on chromosome 13. Factor VII deficiency is rare inherited autosomal recessive coagulation disorder.

CLINICAL FEATURES

Patient presents with epistaxis, mucosal bleeding in gums, menorrhagia, chronic iron deficiency anemia and bleeding into central nervous system.

LABORATORY DIAGNOSIS

Factor VII deficiency results in prolonged prothrombin time and international normalized ratio (PT–INR). It is essential to exclude vitamin K deficiency and other acquired clotting factor disorders. Immunological analysis of factor VII and factor VII antigen (VIIa) is performed by using enzyme-linked immunosorbent assay and immunoradiometric assay.

TREATMENT

Therapeutic agents, e.g. fibrinolytic inhibitors, factor VII concentrates are administered to control bleeding during surgical procedures and postoperative period. Prophylactic administration of factor VII is essential to prevent intracranial bleeding in neonates.

FACTOR X (STUART-PROWER FACTOR) DEFICIENCY

Factor X (Stuart-Prower factor) is a vitamin K-dependent protein encoded by gene located on chromosome 13. Factor X is synthesized by liver and activated by tissue factor, factor VIIa, calcium ions and phospholipid membrane. Severe deficiency of factor X is an autosomal recessive disorder.

CLINICAL FEATURES

Patient with severe deficiency of factor X presents with mucosal bleeding, umbilical stump bleeding, recurrent hemarthrosis, menorrhagia and postoperative bleeding. Moderate deficiency of factor X results in bleeding due to trauma or surgical procedures.

LABORATORY DIAGNOSIS

Factor X deficiency results in prolonged prothrombin time and international normalized ratio (PT–INR) and activated partial thromboplastin time (APTT). Diagnosis is confirmed by analyzing plasma factor X levels using PT–INR and APTT-based assays or Russell viper venom assay or chromogenic assay. It is essential to exclude vitamin K deficiency or other acquired causes of coagulation disorder.

TREATMENT

Patient suffering from factor X deficiency is treated by therapeutic administration of fibrinolytic inhibitors and plasma to control or prevent bleeding in neonates and during surgical procedures.

FACTOR XI (PLASMA THROMBOPLASTIN ANTECEDENT) DEFICIENCY

Factor XI is a serine protease encoded by factor XI gene. Factor XI is activated by thrombin resulting in initiation of intrinsic pathway of coagulation. Factor XI deficiency is an autosomal recessive disorder that may be associated with bleeding provoked by injury or surgery. Other terms used for factor XI deficiency disorder include plasma thromboplastin deficiency, hemophilia C and Rosenthal syndrome.

CLINICAL FEATURES

Patient presents with bleeding provoked by injury or surgery from nose, mouth and genitourinary tract. Women are at risk of bleeding during childbirth and menorrhagia.

LABORATORY DIAGNOSIS

Factor XI deficiency results in prolongation of activated partial thromboplastin time (APTT).

TREATMENT

Patient with factor XI deficiency is administered oral tranexamic acid with or without a virtually inactivated fresh frozen plasma (**FFP**). Factor XI concentrate is

administered during major surgical procedures and labor. Neonatal intracranial bleeding does not occur due to deficiency of factor XI.

FACTOR XIII (FIBRIN STABILIZING FACTOR) DEFICIENCY

Factor XIII (fibrin stabilizing factor) is involved in stabilizing of blood clot, which also participates in wound repair and healing. Factor XIII deficiency is an autosomal recessive disorder characterized by potentially life-threatening hemorrhagic diathesis. Paradoxically, alterations in factor XIII may predispose to thrombosis. Congenital deficiency of factor XIII occurs due to defects in the catalytic A subunits of factor XIII. Approximately >100 mutations in the factor XIII gene have been demonstrated.

CLINICAL FEATURES

Clinical features of factor XIII deficiency depend on concentration of factor XIII in blood. Patient with severe deficiency of factor XIII presents with severe bruising, muscle hematomas, hemarthrosis, delay in wound healing, intracranial bleeding, miscarriages and bleeding following trauma and postoperative surgical procedures.

Laboratory Diagnosis of Factor XIII Deficiency

- All routine coagulation tests, e.g. bleeding time, prothrombin time (PT–INR) and activated partial thromboplastin time (APTT) are normal in factor XIII deficiency, which complicates the diagnosis of this disorder.
- Factor XIII activity, antigen assays and molecular studies confirm factor XIII deficiency.
- Clot solubility test is a qualitative screening test.

ACQUIRED COAGULATION SYSTEM DISORDERS

Major causes of acquired coagulation system disorders are vitamin K deficiency, liver disease, disseminated intravascular coagulation (DIC) and development of circulating anticoagulants.

- Severe liver diseases (cirrhosis, fulminant hepatitis, acute fatty liver of pregnancy) may disturb hemostasis by impaired synthesis of coagulation factors by diseased liver.
- Because all the coagulation factors are synthesized by liver and vascular endothelium; thus, both prothrombin time and international normalized ratio (PT–INR) and activated partial thromboplastin time (APTT) are prolonged.
- Occasionally, decompensated liver disease also causes excessive fibrinolysis and bleeding manifestations due to decreased hepatic synthesis of antiplasmin.
- Disseminated intravascular coagulation and hemorrhagic disease of newborn are important acquired causes of bleeding diathesis.

DISSEMINATED INTRAVASCULAR COAGULATION

Disseminated intravascular coagulation (DIC) is characterized by widespread coagulation due to consumption of platelets and coagulation factors, especially factors II, V, and VIII, and fibrinogen. DIC occurs as a result of release of tissue thromboplastin (tissue factor) or activation of the intrinsic pathway of coagulation system, and fibrinolytic system. The history of DIC is typical of amniotic fluid embolism, one of the major obstetric causes of disseminated intravascular coagulation, also known as consumptive coagulopathy.

PATHOGENESIS

Neoplastic causes of disseminated intravascular coagulation (DIC) include malignancies of the lung, pancreas, prostate, and stomach, and FAB-AML-3 acute myelogenous (promyelocytic hypergranular) leukemia.

- Tissue damage can result from lung surgery, hemolysis or hemolytic transfusion reactions, gram-negative sepsis and immune complex disease. Pathophysiology of disseminated intravascular coagulation is shown in Fig. 11.8.
- Activation of both intrinsic and extrinsic pathways of coagulation system lead to wide systemic thrombi formation in small vessels. Entrapment of platelets in the thrombi causes thrombocytopenia, in addition due to marked reduction of coagulation factors in consumptive coagulopathy.
- Tissue factor inhibitor mechanism having anticoagulant property is disabled in DIC. Proteins C and S having anticoagulant properties are reduced due to consumption of coagulation factors in DIC. Causes of disseminated intravascular coagulation are given in Table 11.11.

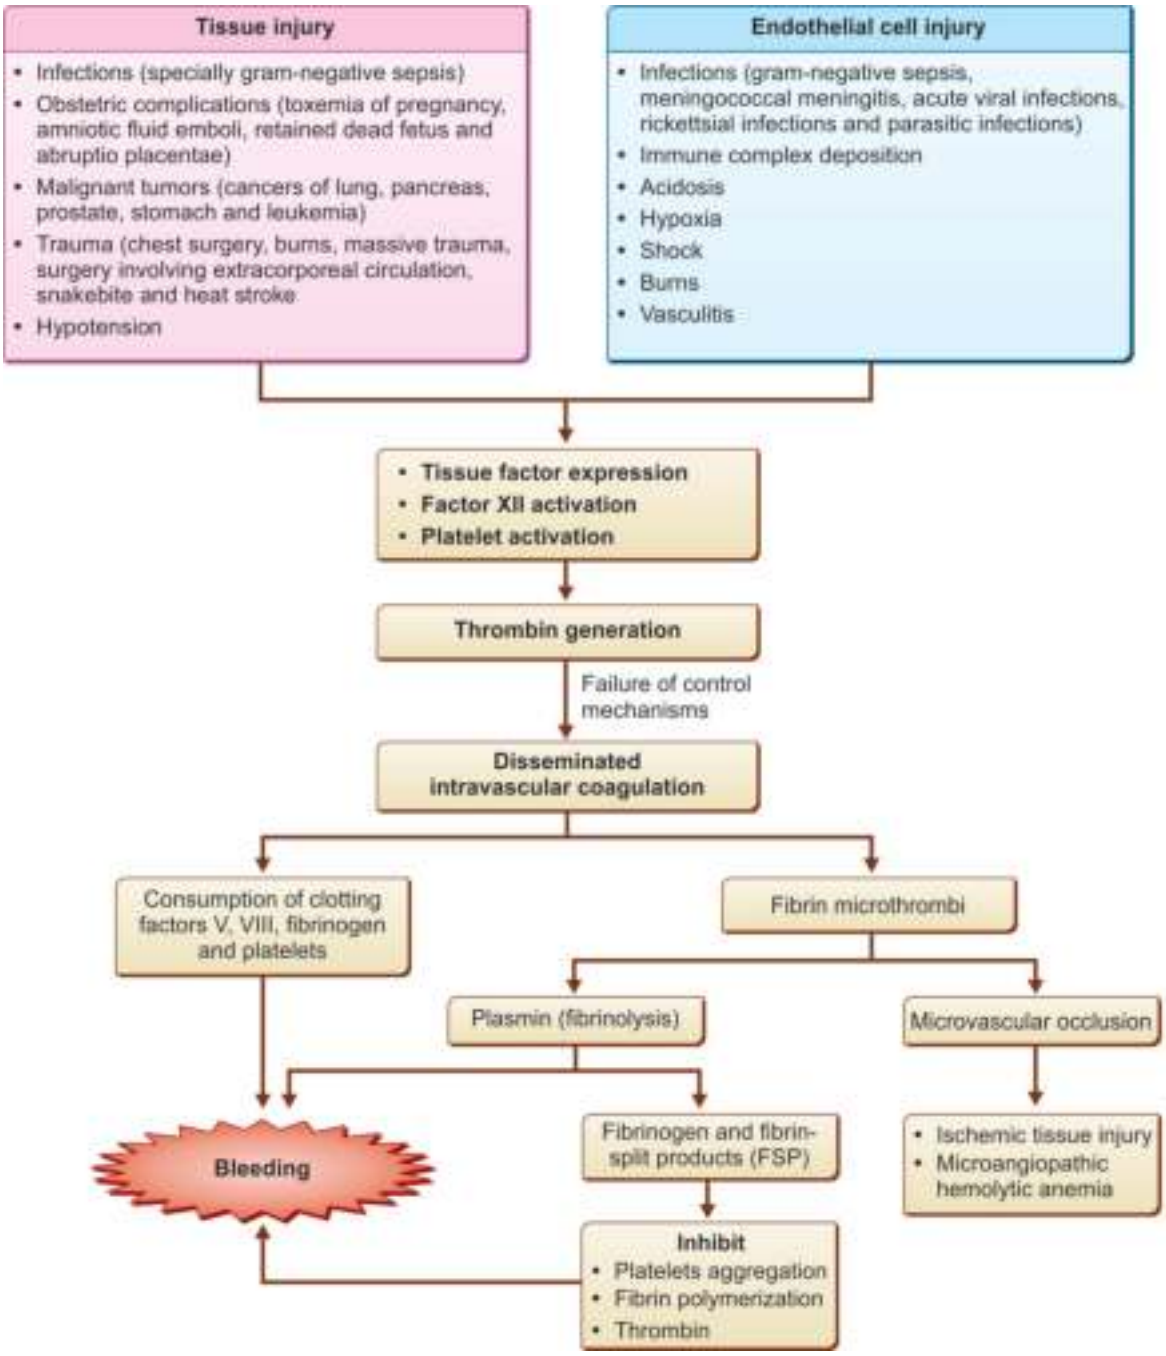

Fig. 11.8: Pathophysiology of disseminated intravascular coagulation. It is triggered by tissue injury, vascular endothelium injury or combination of both these processes. Intravascular coagulation occurs as a result of normal mechanisms controlling hemostasis.

CLINICAL FEATURES

Clinical manifestations of disseminated intravascular coagulation are thrombotic phenomena in small blood vessels of multiple organs and hemorrhages. Patient presents with abrupt onset of bleeding in the form of petechiae or ecchymosis. There may be bleeding from gums. Patient develops hypotensive shock, intracranial bleeding and pulmonary hemorrhages.

Clinical features of disseminated intravascular coagulation are given in Table 11.12.

Laboratory Diagnosis of Disseminated Intravascular Coagulation

- Peripheral blood smear examination shows microangiopathic hemolytic anemia with fragmented red blood cells (schistocytes) and low platelet count.
- Fibrin and fibrinogen degradation products (FDPs) are increased. FDP-dimer test is specific diagnostic test for disseminated intravascular coagulation.
- Bleeding time (BT) is prolonged.

- Prothrombin time and international normalized ratio (PT–INR) is increased.
- Activated partial thromboplastin time (APTT) is increased.
- Thrombin time (TT) is increased.
- Euglin lysis time measures fibrinolytic activity in disseminated intravascular coagulation.
- D-dimer assay can be measured by commercially available latex agglutination. It can be analyzed by ELISA or immunodilution-based D-dimer assay kits.
- Hematologic findings in disseminated intravascular coagulation are given in Table 11.13.

TREATMENT

Patient with disseminated intravascular coagulation (DIC) manifestations is treated by heparin therapy, platelets transfusion, replacement therapy with coagulation factors and fresh frozen plasma (FFP).

Table 11.11 Causes of disseminated intravascular coagulation

Infections	
▪ Gram-negative infections	▪ Endotoxic shock
Obstetric Causes	
▪ Placental abruption ▪ Amniotic fluid embolism ▪ Intrauterine death	▪ Severe pre-eclampsia or eclampsia
Malignant Tumors	
▪ Prostatic carcinoma ▪ Lung carcinoma ▪ Pancreatic carcinoma ▪ Ovarian carcinoma	▪ Gastric carcinoma ▪ Colon carcinoma ▪ Acute promyelocytic leukemia (FAB-AML-3)
Trauma	
▪ Head injury	▪ Burns
Vascular Causes	
▪ Aortic aneurysms	▪ Giant hemangioma

Table 11.12 Clinical features of disseminated intravascular coagulation

Coagulation Manifestations
Venous thromboembolism, acute renal failure due to renal cortical ischemia, skin necrosis or skin gangrene, coma due to cerebral infarction, hepatocellular failure due to hypotension and infection.
Hypotensive Shock
Hypotensive shock occurs due to underlying disease together with disseminated intravascular coagulation
Central Nervous System Manifestations
▪ Transient neurological symptoms ▪ Signs of coma and delirium
Respiratory System Manifestations
Transient hypoxemia due to impairment of lung functions, pulmonary hemorrhage, adult respiratory distress syndrome (ARDS).

Table 11.13 Hematologic findings in disseminated intravascular coagulation (DIC)

Laboratory Investigations	Results
Peripheral blood smear	Anemia and thrombocytopenia
Platelet count	Low
Fibrinogen	Low
Prothrombin time and international normalized ratio (PT–INR)	Increased
Activated partial thromboplastin time (APTT)	Increased
Thrombin time (TT)	Increased
Fibrin and fibrinogen degradation products (FDPs)	Increased
Antithrombin III, protein C and protein S levels	Low
Prothrombin time and INR	Increased

Euglin lysis time measures fibrinolytic activity in DIC. FDP-dimer test is specific diagnostic test for DIC. Other laboratory investigations in patient with suspected DIC include blood urea, serum creatinine, liver function tests, blood culture and pulse oximetry (oxygen saturation). INR: International normalized ratio.

HEMORRHAGIC DISEASE OF NEWBORN

Vitamin K is needed for production of vitamin K-dependent coagulation factors in the liver. Vitamin K is a cofactor for hepatic carboxylation of prothrombin, factors VII, IX, and X, protein C and protein S. Vitamin K deficiency leads to serious life-threatening hemorrhagic disease of the newborn.

PATHOGENESIS

Vitamin K deficiency is exclusively in breastfed and premature babies, because human milk is low in vitamin K, and their gut is not yet colonized with bacteria. Vitamin K deficiency is uncommon in adults, except in those with severe liver disease and an oral anticoagulant. There is excessive bleeding from umbilical stump or gastrointestinal tract (malena) in the newborn. Intracranial bleeding is life-threatening in the newborns. Hemorrhagic disease of newborn is given in Table 11.14.

LABORATORY DIAGNOSIS

Prothrombin time and international normalized ratio (PT–INR) and activated partial thromboplastin time (APTT) are prolonged.

Table 11.14 Hemorrhagic disease of newborn

Type	Clinical Signs	Causes
Early hemorrhagic disease of newborn	Severe bleeding often internal within early 24 hours	Mother receiving drugs affecting vitamin K, e.g. anticonvulsant (phenytoin), warfarin, antitubercular drugs (isoniazid, rifampicin)
Classic hemorrhagic disease of newborn	Classic bruising or bleeding from gastrointestinal tract or after circumcision within 2–5 days	Breastfeeding full term
Delayed hemorrhagic disease of newborn	Intracranial hemorrhage common up to one month	Prolonged breastfeeding without prophylaxis; chronic diarrhea, malabsorption syndrome or oral antibiotics

TREATMENT

Liver of the newborn is not mature to synthesize vitamin K-dependent coagulation factors. Routine vitamin K is administered prophylactically. Coagulation factors are required to activate both intrinsic and extrinsic pathways of coagulation.

COAGULATION SYSTEM DISORDERS IN HEPATIC DISEASE

Vitamin K is needed for synthesis of vitamin K-dependent coagulation factors (II, VII, IX and X) and protein C and protein S in the liver. Hepatic disease is unable to synthesis of vitamin-K dependent coagulation factors (II,VII, IX, X).

CLINICAL FEATURES

Patient with hepatic disease presents with bleeding from gastrointestinal tract; a few patients develop spontaneous superficial hemorrhage.

LABORATORY DIAGNOSIS

Prothrombin time and international normalized ratio (PT–INR) and activated partial thromboplastin time (APTT) are prolonged. PT–INR is increased, which test measures for the blood to clot. PT–INR estimation helps to monitor anticoagulant therapeutic response. It can also be used to check blood coagulation system disorder. Laboratory findings in various coagulation system disorders and anticoagulant therapy are given in Table 11.15. Drugs affecting coagulation system are given in Table 11.16.

Table 11.15 Laboratory findings in various coagulation disorders and anticoagulant therapy

Disorder	Platelet Count	Prothrombin Time and INR (PT–INR)	Activated Partial Thromboplastin Time (APTT)	Thrombin Time (TT)	Fibrinogen Assay	Other Findings
Hemophilia A	Normal	Normal	Increased	Normal	Normal	Decreased factor VIII assay
Hemophilia B	Normal	Normal	Increased	Normal	Normal	Decreased factor IX assay
von Willebrand disease	Normal	Normal	Increased	Normal	Normal	▪ Decreased factor VIII and vWF ▪ Increased bleeding time
Liver disease	Normal	Increased	Increased	Normal	Normal	Decreased synthesis of coagulation factors II, VII, IX and X
Massive blood transfusions	Decreased	Increased	Increased	Normal	Normal or decreased	Normal FDP (fibrinogen degradation products)
Warfarin drug	Normal	Increased	Increased	Normal	Normal	Decreased synthesis of factors II, VII, IX and X
Heparin drug	Normal	Normal	Increased	Increased	Normal	Increased anti-Xa

Table 11.16 Drugs affecting coagulation system

Hemostatic Process Affected	Class of Therapeutic Drug	Specific Therapeutic Drug
Platelet plug formation	Antiplatelet plug drug	Nonsteroidal anti-inflammatory drugs (NSAIDs)
Coagulation cascade	Intravenous and oral anticoagulant drugs	Heparin and warfarin
Fibrinolysis	Fibrinolytic agents	Streptokinase and urokinase

THROMBOPHILIA (HYPERCOAGULABLE STATE)

Hereditary thrombophilia is a prothrombotic familial syndrome caused by deficiency of a number of anti-thrombotic proteins, including antithrombin III, protein C, and protein S.

- Hereditary hemophilia is characterized by recurrent venous thrombosis and thromboembolism, which most often occurs in adolescents or young women. Patient has history of thrombosis at young age, unexplained recurrent episodes of thromboembolic phenomenon. Strong family history of thrombosis in the first degree relatives, recurrent abortions and pregnancy associated thrombi in women should be investigated.
- Secondary (acquired) hypercoagulable thrombophilia is due to underlying systemic diseases or clinical conditions and cannot be identified until thrombosis occurs.
- Most common causes of hereditary and acquired thrombophilia are given in Table 11.17. Laboratory diagnosis of thrombophilia is given in Table 11.18.

Table 11.17 Most common causes of hereditary and acquired thrombophilia

Inherited Thrombophilia	Acquired Thrombophilia
Risk of clinical thromboembolic disease	
Excessive risk patients ▪ Homozygous or double heterozygous antithrombin III deficiency ▪ Homozygous or double heterozygous protein C (PC) deficiency ▪ Homozygous or double heterozygous protein S (PS) deficiency	**Excessive risk patients** Mucin secreting adenocarcinoma
High risk patients ▪ Double heterozygotes activated protein C resistance (APCR) ▪ Homozygous prothrombin gene G20210 A mutation ▪ Homozygous factor V Leiden mutation	**High risk patients** ▪ Hip fracture ▪ Total hip or knee replacement ▪ Acute promyelocytic leukemia
Moderate risk patients ▪ Heterozygous antithrombin III deficiency ▪ Heterozygous protein C deficiency ▪ Heterozygous protein S deficiency	**Moderate risk patients** ▪ Sepsis ▪ Malignancy ▪ Antiphospholipid syndrome (lupus anticoagulant causing pregnancy loss) ▪ Prolonged immobilization and post-surgical state ▪ Paroxysmal nocturnal hemoglobinuria ▪ Major surgery/major trauma
Low risk patients ▪ Heterozygous activated protein C resistance (APCR) ▪ Heterozygous heparin cofactor II (HC II) ▪ Tissue factor pathway inhibitor variant ▪ Dysfibrinogenemia/hyperfibrinogenemia ▪ Methylene tetrahydrofolate reductase gene mutation (MTHFRC677T) ▪ Elevated factor VIII ▪ Factor XII deficiency ▪ Plasminogen activator deficiency ▪ Elevated plasminogen activator inhibitor 1 (PAI-1) ▪ Sickle cell anemia	**Low risk patients** ▪ General surgery ▪ Oral contraceptives use ▪ Pregnancy ▪ Elevated factor VIII ▪ Elevated lipoprotein A, i.e. Lp(a) ▪ Heparin-induced thrombocytopenia ▪ Nephrotic syndrome (loss of antithrombin III and antiplasmin in urine) ▪ Congestive heart failure ▪ Complicated atheromatous plaque
Family history of thrombophilia	
Present of family member with known thrombophilia	Absence of family member with known thrombophilia
Venous thromboembolism	
Unprovoked venous thromboembolism or with minor risk factor	Unprovoked venous thromboembolism
Site of thrombosis	
Recurrent venous thromboembolism in <50 years	Thrombosis at unusual sites especially in patient >50 years (e.g. splanchnic region)
Clinical manifestations	
Skin necrosis associated with vitamin K antagonists	Late or recurrent pregnancy loss

Patient with history of deep vein thrombosis or pulmonary embolism should receive prophylactic LMW heparin.

Table 11.18 Laboratory diagnosis of thrombophilia

Laboratory Test	First Diagnostic Step	Comments
Factor V Leiden (FVL)	Deficient factor V Leiden (FVL) coagulation-based functional assay	DNA analysis for factor V Leiden
Prothrombin G20210A mutation (FII G20210A)	DNA analysis	Measurement of prothrombin (F-II) activity in plasma should not be used to screen thrombophilic patients for this mutation due to its inability to clearly distinguish carriers from non-carriers of the mutation
Antithrombin (AT) deficiency	Functional coagulation-based antigenic chromogenic assay	Measurement of antithrombin antigen by an immunoassay in order to classify the type of deficiency as type I or II
Protein C (PC) deficiency	Functional coagulation-based chromogenic assay	Measurement of protein C antigen by an immunoassay in order to classify the type of deficiency as type I or II or III
Protein S (PS) deficiency	Functional coagulation-based antigenic assay	Measurement of protein S antigen by an immunoassay in order to classify the type of deficiency as type I or II or III
Activated protein C resistance (APCR)	APTT (activated partial thromboplastin time) or RVVT (Russell's viper venom time)-based assays	Work up for congenital or acquired thrombophilia, e.g. APCR (activated protein C resistance) and FVL (factor V Leiden)
Antiphospholipid antibodies (aPLAs): LA, ACL and anti-β_2-GP1	▪ LA: A panel of screening two or more assays and at least one confirmatory assay ▪ ACL and anti-β_2-GP1: Enzyme immunosorbent assays for both IgM and IgG isotopes	Repeat testing for a positive test result with at least 12 weeks apart in order to confirm a positive test result
Increased factor VIII level (F VIII >159%)	Coagulation or chromogenic functional assay	Repeat testing 3–6 months after initial testing
Hyperhomocysteinemia (HHC)	Plasma level of homocysteine	Repeat testing in case of questionable or borderline test result or to confirm a positive test result
Dysfibrinogenemia	Screening assays: Thrombin time (TT) and reptilase time (RT), functional (Clauss) fibrinogen level	Parallel analysis of functional and immunoreactive fibrinogen as confirmatory assays

HEREDITARY THROMBOPHILIA (HYPERCOAGULABLE STATE)

Hereditary thrombophilia has autosomal dominant, autosomal recessive or X-linked inheritance, which has tendency to form blood clots in arteries and veins. Hereditary thrombophilia and its characteristics of most common defects are given in Table 11.19.

ANTITHROMBIN III DEFICIENCY

Antithrombin III is synthesized by liver, which prevents thrombus formation by inhibiting the activity of thrombin, Xa, IXa and XIa.

- Gene coding for antithrombin III is located on chromosome 1, band q23.1–23.9. Hereditary deficiency of antithrombin III is an autosomal dominant disorder.
- Approximately 50% reduction in the plasma concentration of antithrombin III results in venous thrombosis and recurrent thromboembolic pulmonary phenomenon in adolescents or early life.

Clinical Aspects

In clinical practice, heparin is most often administered to prevent thrombus formation. Heparin combines with antithrombin III.

- Patient with hereditary deficiency of antithrombin III, antithrombotic action of heparin is markedly reduced.
- Acquired deficiency of antithrombin III occurs in nephrotic syndrome due to its loss in urine along with massive proteinuria.

Assessment of Antithrombin III

Assessment of antithrombin III is performed by chromogenic assay and coagulation assay.

PROTEIN C DEFICIENCY

Vitamin K is required to synthesize protein C, which prevents thrombus formation. Thrombin, factor Xa and protein C activating enzyme convert protein C into activated form. Normally, activated protein C along with protein S degrade factors Va and VIIIa. Protein C enhances clot lysis.

Clinical Features

Hereditary deficiency of protein C is an autosomal dominant disorder.

- Approximately, 50% reduction in the plasma concentration of protein C results in venous thrombosis and recurrent thromboembolic pulmonary phenomenon in adolescents or early life.

Table 11.19 Inherited thrombophilia and its characteristics of most common defects

Features	Factor V Leiden Deficiency	Prothrombin Deficiency	Protein C Deficiency	Protein S Deficiency	Antithrombin Deficiency
Frequency and physiologic effects					
General population frequency	4–10%	2–4%	0.2–0.4%	0.07–2.3%	0.02%
First deep vein thrombosis	20%	7%	3%	2–3%	1–2%
Thrombophilic families	40%	18%	6%	4%	4%
Physiologic effects	Factor Va is resistant to cleavage by activated protein C	Increased formation of prothrombin and thrombin	Decreased inactivation of factor Va, factor VIIIa and upregulation of coagulation	Decreased cofactor for activated protein C and upregulation of coagulation	Inhibition of factor Xa, thrombin and upregulation of coagulation
Clinical manifestations					
Homozygous state	Increased risk of venous thromboembolism (80 times)	Increased risk of venous thromboembolism and possible arterial thromboembolism	Purpura fulminans	Purpura fulminans	Lethal *in utero*
Heterozygous state	Increased risk of venous thromboembolism (4–7 times)	Increased risk of venous thromboembolism (3–4 times)	Increased risk of deep vein thrombosis (4–8 times)	Increased risk of deep vein thrombosis (4–8 times)	Increased risk of venous thromboembolism (10 times)

Family history of pulmonary embolism is most important cause of death due to inherited defect. Patient with history of deep vein thrombosis or pulmonary embolism should receive prophylactic LMW heparin.

- A total lack of protein C is usually associated with death *in utero*.
- Repeated infusions of prothrombin complex help in keeping these children alive. Deficiency of protein C may also occur in liver disease.

PROTEIN S DEFICIENCY

Vitamin K is required to synthesize protein S, which prevents thrombus formation. Normally, activated protein C along with protein S degrade coagulation factors Va and VIIIa.

- Hereditary deficiency of protein S is an autosomal dominant disorder due to mutation of PROS1 gene. Hereditary deficiency of protein S is associated with arterial and venous thrombi.
- Protein C activity is measured by enzyme-linked immunosorbent assay (ELISA), functional and antigenic assays.

Laboratory classification of protein S deficiency is given in Table 11.20.

Table 11.20 Laboratory classification of protein S deficiency

Features	Type I Protein S Deficiency	Type II Protein S Deficiency	Type III Protein S Deficiency
Total protein S	Decreased	Normal	Normal
Free protein S	Decreased	Normal	Decreased
Protein S activity	Decreased	Decreased	Decreased

FACTOR V LEIDEN (rs6025)

Factor V Leiden is a mutation of one of the coagulation factors in blood and has been named after the city in Netherlands. It is the most common cause of hereditary thrombophilia. Pregnancy and oral contraceptive intake increases risk of hypercoagulable state.

Molecular Genetic Alterations

Factor V Leiden protein is formed due to specific mutation by substitution of glutamine for arginine at position 506. It alters the cleavage site targeted by APC.

This abnormal factor V Leiden protein becomes resistant to cleavage by protein C. As a result, an important antithrombotic counter-regulatory mechanism is lost. There is increased generation of prothrombokinase–thrombin complex.

Clinical Features

Patient presents with cerebral and recurrent deep venous thrombosis in legs. Arterial thrombi are rare. There is increased risk of abortions during second trimester of pregnancy.

Laboratory Diagnosis

Laboratory tests for factor V Leiden mutation include activated protein C resistance assay and genetic analysis by polymerase chain reaction (PCR).

PROTHROMBIN G20210A GENE MUTATION

Prothrombin G20210A gene mutation is the second most common cause of hereditary thrombophilia. Mutation of prothrombin gene occurs due to a single nucleotide change (G to A) in the 3′-untranslated region at position 20210, which is associated with elevated plasma prothrombin levels. Patient has almost three times increased risk of arterial and venous thrombosis.

HYPERHOMOCYSTEINEMIA

Methylenetetrahydrofolate reductase gene mutation (MTHFRC677T) results in mild elevation of homocysteine levels in 5–15% of White and East Asia population.

- Elevated levels of homocysteine in blood inhibit antithrombin III and thrombomodulin leading to increased risk for thrombosis.
- The increased homocysteine in blood can be reduced by dietary supplementation with folic acid and vitamins B_6 (pyridoxine) and B_{12} (cobalamin).
- Hyperhomocysteinemia is also associated with an increased risk for neural tube defects and possibly a number of diverse neoplasms.

ACQUIRED THROMBOPHILIA (HYPERCOAGULABLE STATE)

ANTIPHOSPHOLIPID SYNDROME

Antiphospholipid antibody syndrome has underlying etiology of systemic lupus erythematosus, which is associated with high titers of circulating antibodies (IgG) directed against anionic phospholipids (cardiolipin) such as plasma protein epitopes prothrombin.

Pathogenesis

Lupus anticoagulant is an IgG or IgM, which binds to phospholipid used in activated partial thromboplastin time (APTT) resulting in prolonged activated partial thromboplastin time (normal 30–40 seconds). *In vivo*, these antibodies induce a hypercoagulable state by activating platelets, interfering in protein C activity and inhibiting synthesis of PGI_2 by vascular endothelial cells.

Clinical Features

Lupus anticoagulant is associated with recurrent venous thrombosis in deep veins of legs or arterial thrombi. But renal, hepatic, and retinal veins are also susceptible.

- There is history of repeated miscarriages due to inhibition of tissue plasminogen activator (tPA), which is required for trophoblastic invasion of uterus.
- There is increased risk of cardiac valvular vegetations or thrombocytopenia in systemic lupus erythematosus patients. Anticardiolipin antibodies are associated with arterial thrombi.

Laboratory Diagnosis

In vitro, these antibodies interfere with the assembly of phospholipid complexes and thus inhibit coagulation. Activated partial thromboplastin time (APTT) is prolonged. Prothrombin time and international normalized ratio (PT–INR), thrombin time and fibrinogen level are within normal range. Confirmatory tests include kaolin clotting time, platelet neutralizing test and Russell viper venom time test.

BLEEDING DIATHESIS: DIAGNOSTIC APPROACH

Bleeding diathesis occurs due to abnormalities in coagulation factors; platelet quantitative and qualitative disorders; disorders associated with thrombosis and miscellaneous acquired causes of bleeding diathesis, e.g. vitamin K deficiency, liver disease, disseminated intravascular coagulation (DIC) and heparin-induced thrombocytopenia (HIT) (Fig. 11.9).

- Investigations of hemostatic function are essential if patient has clinical history of excessive bleeding following injury or dental extractions, menorrhagia, hematuria, poor healing of superficial lacerations, easy bruising, hemarthrosis, incidental abnormal hemostatic test; and past or family history of excessive bleeding or bruising.

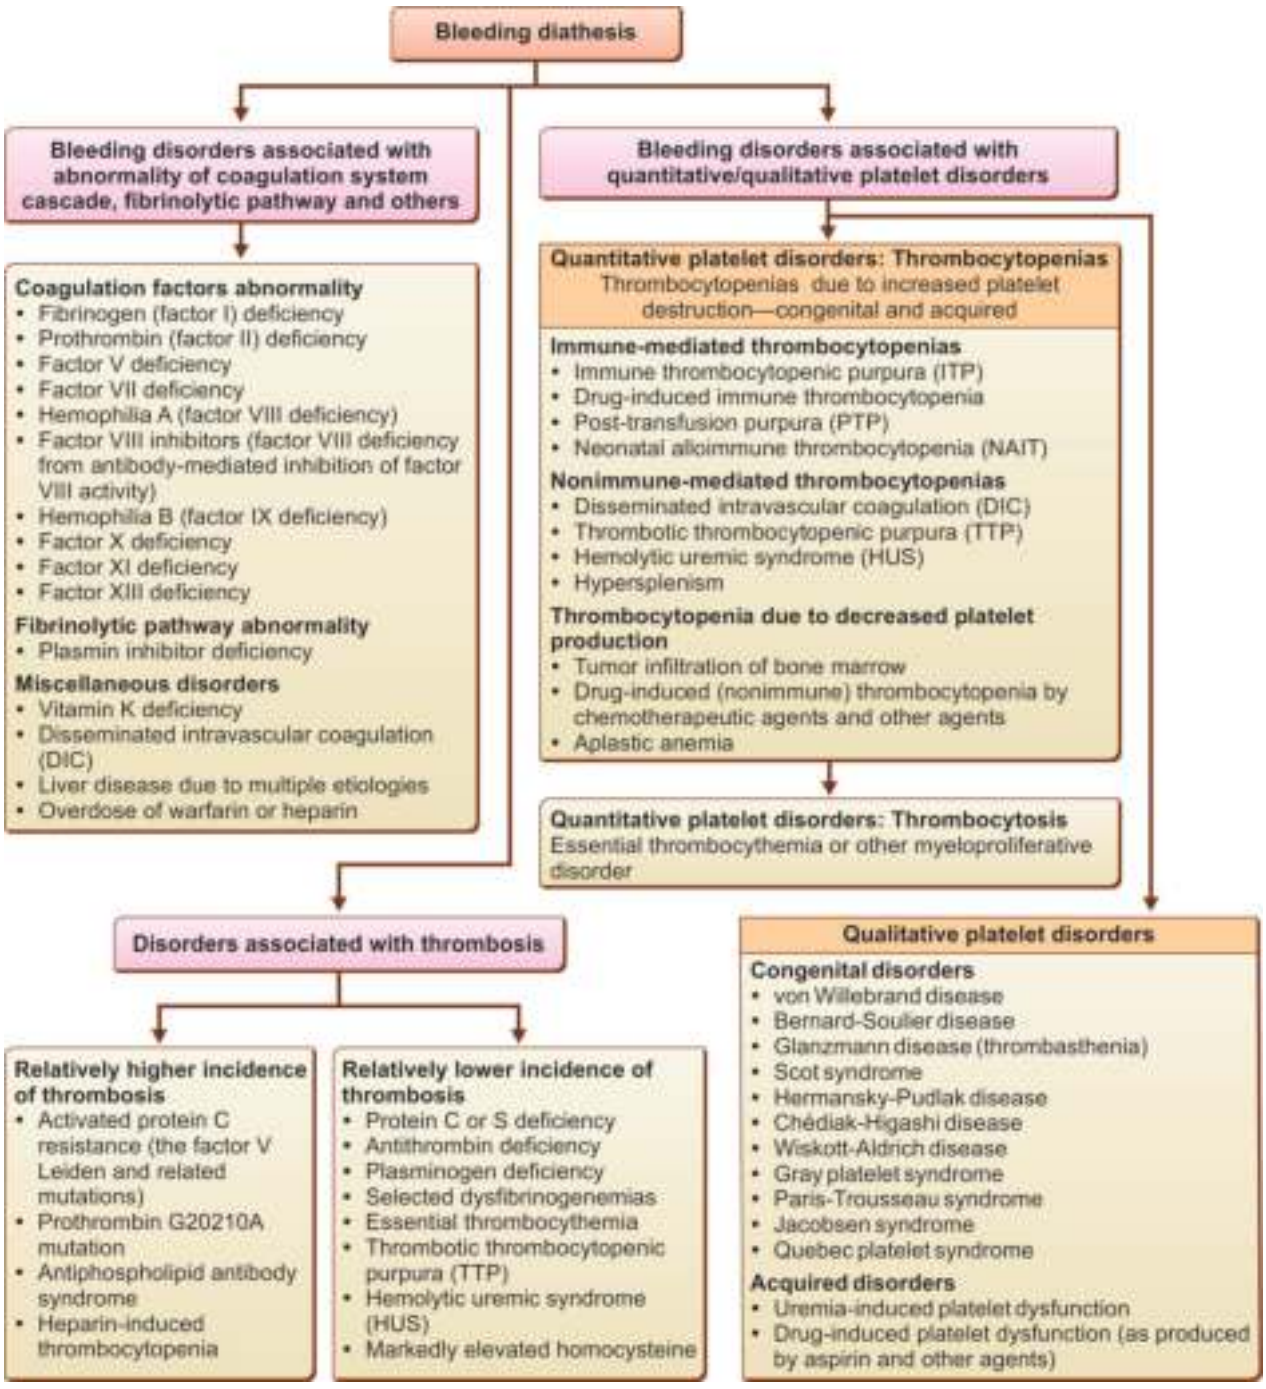

Fig. 11.9: Bleeding diathesis occurs due to abnormalities in coagulation factors; platelet quantitative and qualitative disorders; disorders associated with thrombosis; and miscellaneous acquired causes.

- Four steps of investigating hemostatic function include: complete history, physical examination, screening tests of hemostasis and special hematological tests such as PT–INR and APTT to assess the bleeding risk.
- Clinical manifestations in vascular, platelet and coagulation disorders are given in Table 11.21. Laboratory tests for primary and secondary hemostasis are given in Table 11.22.

CLINICAL HISTORY

Patient suffering from bleeding diathesis may present with easy bruising, purpura, epistaxis, heavy menstruation with passage of blood clots, excessive bleeding following dental procedures, passage of red-colored urine, painful joints or muscles and delayed wound healing and tissue repair. Exposure to drugs or toxins and family history of bleeding should be enquired.

Table 11.21 Clinical manifestations in vascular, platelet and coagulation disorders

Clinical Manifestations	Vascular Disorders	Platelet Disorders	Coagulation Disorders
Petechial hemorrhages	Common	Common	Rare
Bleeding superficial cuts and scratches	Persistent; often profuse bleeding	Persistent; often profuse bleeding	Minimal bleeding
Superficial ecchymosis	Small and multiple	Small and multiple	Common; large and solitary
Deep hematoma	Rare	Rare	Common
Hemarthrosis	Rare	Rare	Common
Delayed bleeding	Rare	Rare	Common
Gastrointestinal bleeding	Absent	Present	Present with GIT lesions
Hematuria	Absent	Present	Present
Epistaxis	Absent	Present	Present
Gingival bleeding	Absent	Present	Present
Excessive bleeding after tooth extraction	Absent	Present	Present
Intracranial bleeding	Absent	Present	Present
Sex predilection	More common in females	More common in females	80–90% of inherited forms occur only in male patients
Family history	Rare (except vWD and HHT)	Rare (except vWD and HHT)	Common

Table 11.22 Laboratory tests for primary and secondary hemostasis

Laboratory Test	Normal Range	Type of Assay	Application
Assessment of primary hemostasis			
Bleeding time (BT)	1–9 minutes	Small incision on forearm and time recorded for the platelets to stop bleeding	Bleeding time is affected by depth of the incision, platelet count; and pressure on the arm
Platelet function analyzer 100 (PFA-100)		Platelet function analyzed by passing whole blood through cartridge containing agonists (collagen/epinephrine and collagen/ADP) and time needed for platelets to occlude aperture is analyzed	Platelet function defect or thrombocytopenia
Assessment of secondary hemostasis			
Prothrombin time (PT)	10–14 seconds	Tissue factor and phospholipids are added to plasma and clotting time is recorded	▪ Measures extrinsic pathway of coagulation (tissue factor VII), or common pathway of coagulation (factors X, V, II, I), presence of inhibitor, or circulating anticoagulant. ▪ Prothrombin time is also prolonged in the presence of deficiency of vitamin K-dependent factors ▪ Most common causes (liver disease, warfarin therapy, disseminated intravascular coagulation)
Prothrombin time and international normalized ratio (PT–INR)	2.0 to 3.0	INR = PT/mean prothrombin time	Monitoring oral anticoagulant therapy

Contd...

Table 11.22 Laboratory tests for primary and secondary hemostasis (*Contd...*)

Laboratory Test	Normal Range	Type of Assay	Application
Activated partial thromboplastin time (APTT)	30–40 seconds	Activators such as micronized silica, phospholipids and calcium are added to plasma and clotting time recorded	▪ Measures intrinsic pathway (contact factors VIII, IX, XI, XII) or common pathway (factors X, V, II, I), presence of inhibitor or circulating anticoagulant ▪ Prolonged APTT is associated with abnormality of the above mentioned. ▪ Measuring unfractioned heparin ▪ Most common causes (liver disease, unfractioned heparin therapy, hemophilia A and hemophilia B; disseminated intravascular coagulation)
Fibrinogen assay (factor)	150–400 mg/dl	Functional fibrinogen assay or derived from another assay, e.g. prothrombin time	▪ Decreased fibrinogen occurs in disseminated intravascular coagulation (DIC), primary or secondary fibrinolysis, afibrinogenemia or dysfibrinogenemia and liver disease ▪ Increased fibrinogen occurs in acute phase reactants, pregnancy, hormone therapy ▪ Inverse relationship (longer clotting time = lower fibrinogen)
Thrombin time (TT)	15–19 seconds	Excess of thrombin is added and fibrinogen to fibrin conversion is measured	▪ Evaluates formation of fibrin ▪ Measurement of thrombin time is affected in afibrinogenemia, dysfibrinogenemia, presence of fibrin/fibrinogen degradation products and circulating heparin ▪ Most common causes (disseminated intravascular coagulation, heparin therapy, fibrinolysis)
Specific factor assays	5–150%	Assessed by PT or depending on factor suspected	Tests are functional-based assays
Factor XIII assay: Urea solubility test	Not applicable	Clot solubility is measured in the presence of urea or monochloroacetic acid in 24 hours	▪ Clot dissolution corresponds to factor XIII level of 1–2% ▪ Symptoms of deficiency are delayed bleeding or increased bruising
von Willebrand factor (vWF)	Not applicable	vWF measured by platelet aggregation test and using antibody against vWF by enzyme immunoassay, ELISA, immunoturbidometric	▪ Results assessed in conjunction with APTT, vWF multimers, ADAMS-13 ▪ Essential to assess functional and antigenic levels to accurately diagnose and treat disease
Assessment of fibrinolysis			
Fibrin/fibrinogen degradation products (FDPs)	<10 mg/dl	Patient blood sample is collected into special test tube containing thrombin and a fibrinolytic inhibitor (prevents *in vitro* fibrinolysis). Now it mixed with latex beads coated with antibodies for FDPs	Agglutination is positive result in liver disease, deep vein thrombosis, disseminated intravascular coagulation and kidney disease
D-dimers (DD)	<0.5 µg/ml	Automated immunological assay or semiquantitative latex assay	Breakdown products of fibrin, and monitoring clot dissolution in deep vein thrombosis (DVT), pulmonary embolism and disseminated intravascular coagulation (DIC)

Contd...

Table 11.22 Laboratory tests for primary and secondary hemostasis (*Contd...*)

Laboratory Test	Normal Range	Type of Assay	Application
Assessment of inhibitors			
Bethesda titer (factor inhibitors)	Not applicable	Mix patient plasma with normal plasma and incubate at 37°C for two hours and measure factor level	▪ Presence of inhibitor inactivates patient factor resulting in decreased activity ▪ Factor VIII administration is ineffective in hemophiliac patient in the presence of factor inhibitor
Lupus-like anticoagulant (LA)	Not applicable	Diagnosis is based on several tests, e.g. APTT, dilute Russell viper venom test	Criteria for lupus-like anticoagulant are prolongation of phospholipid-dependent coagulation reaction, demonstration that is an inhibitor against and not a factor deficiency, and demonstration of inhibitor against phospholipid inhibitor

When a blood sample is obtained for prothrombin time, activated partial thromboplastin time and thrombin time, sodium citrate is as the anticoagulant in the sampling tubes.

PHYSICAL EXAMINATION

Patient may have evidence of bleeding such as petechial hemorrhages, purpura and ecchymosis, bleeding from mucous membranes, hemarthroses, muscle hematoma, gastrointestinal bleeding, renal hematuria or epistaxis. One must look for hepatosplenomegaly, jaundice, fever and joint abnormalities.

Clinical summary of bleeding disorders is given in Table 11.23. Clinical findings and diagnostic possibilities in thrombotic disease in various age groups are given in Table 11.24.

Table 11.23 Clinical summary of bleeding disorders

Observations	Diagnostic Possibilities
History observations	
▪ History of bleeding/bruising since childhood ▪ Recent history of bleeding/bruising since childhood ▪ Sudden onset of bleeding/bruising, poorly healing cuts	▪ Congenital defect of platelet/coagulation factor ▪ Acquired defect of platelet/coagulation factor ▪ Acquired defect, probably drug induced
Physical examination	
▪ Small hemorrhages from skin, mucous membrane especially in females ▪ Persistent bleeding from superficial lesions ▪ Delayed bleeding, hemarthrosis, hematomas, joint deformities, bleeding following trauma, bleeding from GIT and renal hematuria, epistaxis in males with positive family history ▪ Bleeding from only one organ	▪ Abnormalities of the blood vessels or low platelet count or impaired platelet function ▪ Defects in coagulation factor ▪ Probably not caused by hemostatic defect

Table 11.24 Clinical findings and diagnostic possibilities in thrombotic disease in various age groups

Age Group	Clinical Findings	Possible Causes
Birth to 45 years	▪ Family history with migratory or recurrent thrombi ▪ Smoking and hormones (estrogen, progesterone and oral contraceptives)	▪ Hereditary hypercoagulable state (deficiency of antithrombin III, protein C and protein S) and homocystinuria ▪ Aggravate thrombotic disease
10–45 years	▪ Migratory or recurrent thrombi ▪ Multiple organs failure, massive purpura (severely ill patients)	▪ Acquired hypercoagulable state (lupus inhibitor) ▪ Disseminated intravascular coagulation and hemolytic uremic syndrome

Contd...

Table 11.24 Clinical findings and diagnostic possibilities in thrombotic disease in various age groups (*Contd...*)

Age Group	Clinical Findings	Possible Causes
>45 years	▪ Localized sudden onset thrombi without recurrence ▪ Arterial occlusion ▪ Weight loss, anorexia, weakness ▪ Fever, infection (localized or systemic) ▪ Severe or massive trauma ▪ Deep vein thrombosis or thrombophlebitis, emboli	▪ Acquired thrombosis associated with infection/inflammation, trauma, venous stasis and drug reaction ▪ Atherosclerosis, hyperlipidemia, diabetes mellitus and protein S deficiency ▪ Underlying malignancy (lung, pancreas, prostate, stomach and AML—acute myelomonocytic leukemia) ▪ AML (M3) is commonly associated with DIC due to release of thromboplastin-like substance ▪ Underlying infection or inflammation ▪ Disseminated intravascular coagulation ▪ Any thrombotic disease

HEMATOLOGIC INVESTIGATIONS

Complete blood counts, hemoglobin or packed cells volume, WBC count, platelet count, erythrocyte sedimentation rate and peripheral blood smear examination to rule out macrocytic anemia, aplastic anemia and acute leukemia for underlying cause of thrombocytopenia. Interpretation of routine blood tests in bleeding disorders is shown in Fig. 11.10. Comparison between platelets and coagulation system defects is given in Table 11.25.

PLATELET COUNT

A normal platelet count in adults ranges from 150,000 to 450,000 platelets per microliter of blood. Platelets normally clump in groups of 2–5. Normal value is 4–8 platelets per 100 RBCs. A reasonable estimate of platelet number can be obtained by counting platelets present in relation to 500 RBCs. If platelet count is low, one should rule out secondary causes of thrombocytopenia before establishing acute or chronic ITP. Giant platelets are demonstrated in Bernard-Soulier syndrome, myeloproliferative disorders and May-Hegglin anomaly.

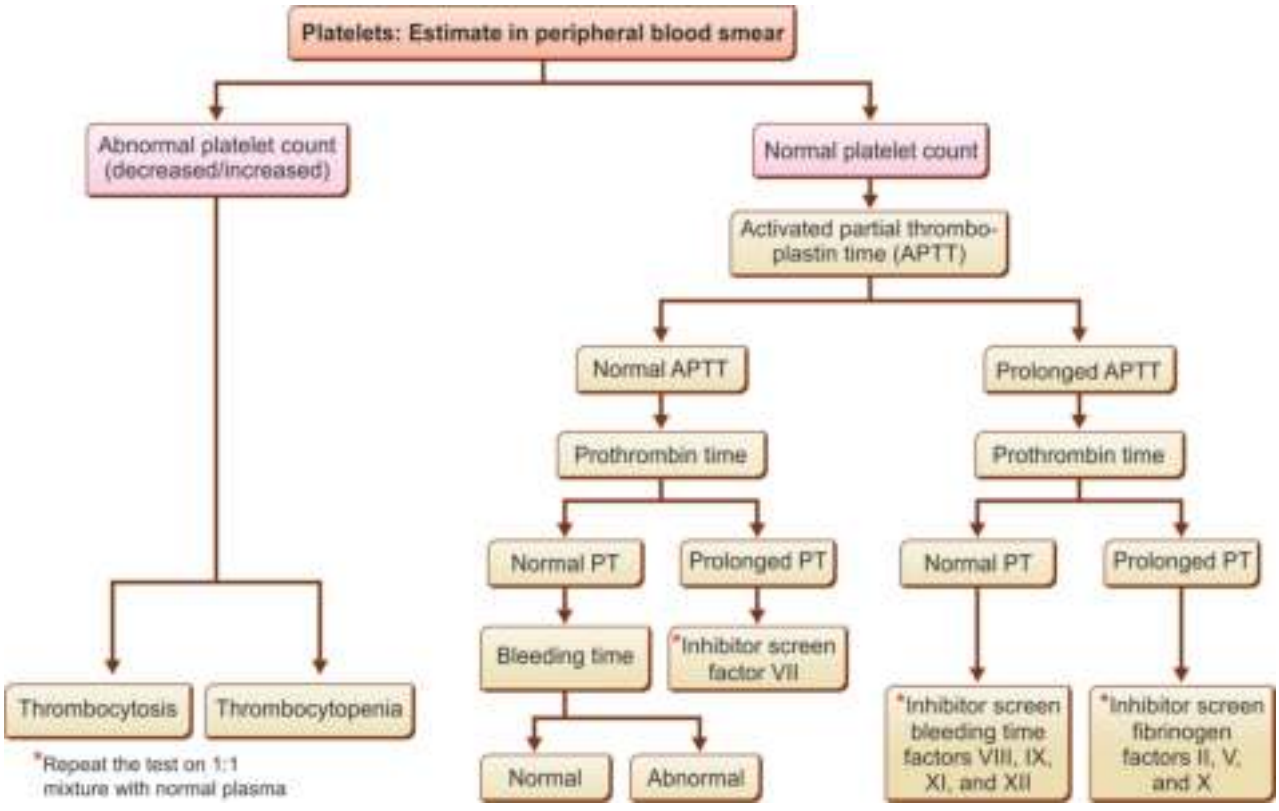

Fig. 11.10: Interpretation of routine blood tests in bleeding disorders.

Table 11.25 Comparison between platelet and coagulation system defects

Feature	Platelet Defects	Severe Coagulation System Defects
Purpura (petechiae)	Very common	Absent
Spontaneous bleeding	Common	Uncommon
Application of local pressure	Bleeding does not stop quickly	Bleeding stops quickly
Bleeding from superficial cut	Present	Absent
Family history	Absent	Possible
Mucosal bleeding from mouth and gut	Usually present	Relatively uncommon except urinary tract
Hemarthroses (bleeding in joints)	Absent	Very common in severe coagulation defect
Muscle hematomas	Present in response to trauma	Spontaneous even without trauma
Bleeding after trauma or surgery	Immediate for short time	Often delayed, after several more than 48 hours

PLATELET FUNCTION TESTS

Platelet aggregation test with ADP, collagen, epinephrine and ristocetin should be performed to rule out various platelet function disorders.

- In Bernard-Soulier syndrome, platelet aggregation is deficient with ADP, epinephrine, and collagen, but normal with ristocetin.
- In Glanzmann disease and von Willebrand disease, platelet aggregation is normal with ADP, epinephrine, and collagen, but deficient with ristocetin. Laboratory tests in bleeding diathesis are given in Table 11.26.

BLEEDING TIME

The bleeding time measures vascular and platelet integrity, which is estimated by Ivy method and template method. In general, 95% of all values are <4 minutes. If the bleeding time is >4 minutes, abnormality of platelets should be considered.

COAGULATION PROFILE

Prothrombin Time and International Normalized Ratio

Prothrombin time and international normalized ratio (PT–INR) is the time required for plasma to clot after tissue thromboplastin and optimum amount of calcium chloride is added. Incubate plasma at 37°C in a water bath for five minutes. Add 0.2 ml thromboplastin and 0.1 ml of calcium chloride to the test tube. Record the time for formation of blood clot every second. End point is identified by formation of fibrin strand attached to the wire hook.

Prothrombin time is measured to diagnose bleeding diathesis, monitoring patients on anticoagulant therapy and prior to liver biopsy. Normal range of prothrombin time is between 11 and 16 seconds. Procedure of one stage prothrombin time is shown in Fig. 11.11.

Prothrombin Time and International Normalized Ratio

- Prothrombin time measures extrinsic pathway of coagulation system.
- Prothrombin time is prolonged in disseminated intravascular coagulation, vitamin K deficiency, deficiency of one or more of clotting factors (fibrinogen, prothrombin, V, VII or X), liver disease and oral coagulant therapy.

Activated Partial Thromboplastin Time

Activated partial thromboplastin time (APTT) measures the intrinsic procoagulant activity of plasma. Partial thromboplastin is a substitute for platelet factor III. Contact activation is standardized by adding an activator (kaolin) to the reagent.

- Activated partial thromboplastin time test does not measure activities of factors VII and IX. APTT is prolonged in hemophilia A, hemophilia B, disseminated intravascular coagulation (DIC) and von Willebrand disease. Normal range of APTT is between 30 and 40 seconds.

Table 11.26 Laboratory tests in bleeding diathesis

Laboratory Test	Component Measured	Normal Values
Bleeding time (BT)	Platelet function vascular integrity	2–9 minutes
Prothrombin time (PT)	I, II, V, VII, IX and X	11–16 seconds
Activated partial thromboplastin time (APTT)	I, II, V, VIII, IX, X, XI and XII except VII and XIII	30–40 seconds
Thrombin time (TT)	I and II	15–19 seconds

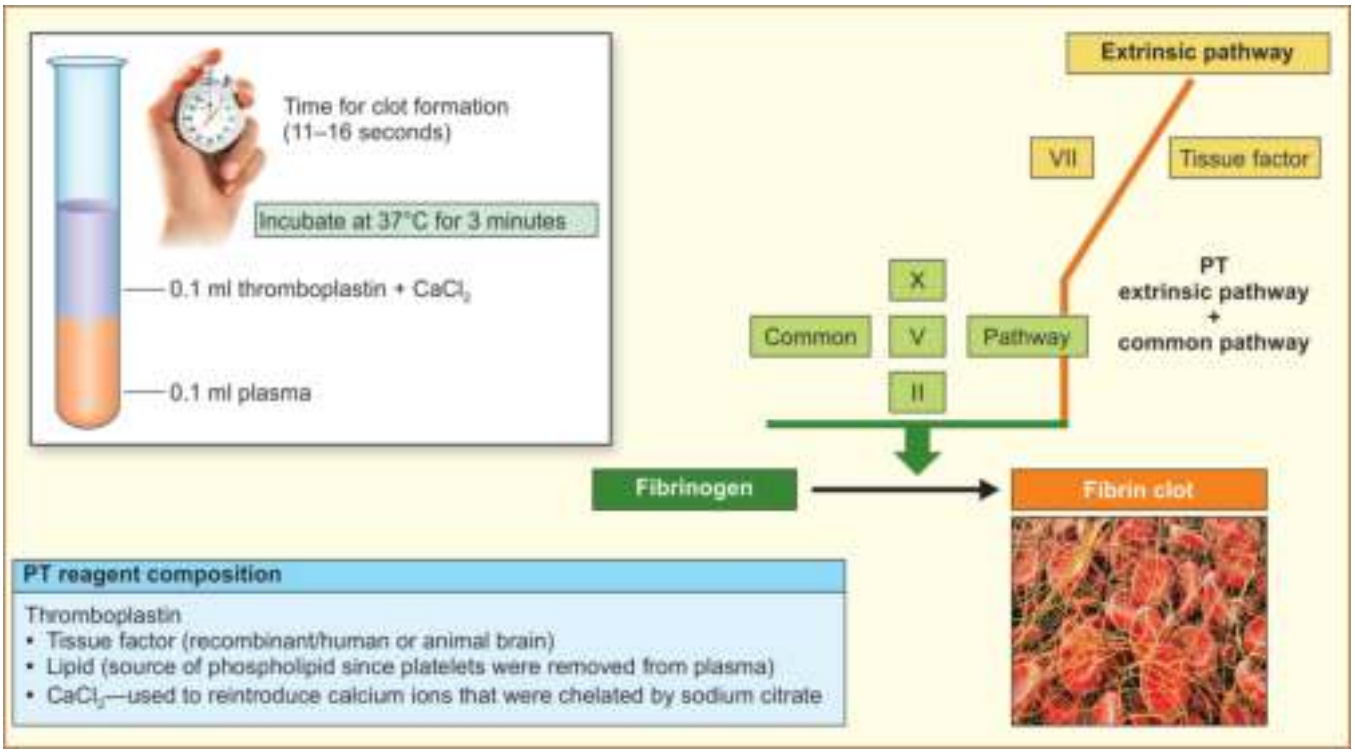

Fig. 11.11: Procedure of one stage prothrombin time.

- Procedure of activated partial thromboplastin time is shown in Fig. 11.12. Interpretation of tests of hemostasis function in normal and abnormal patients is given in Table 11.27.

Thrombin Time

Thrombin time (TT) measures fibrinogen concentration. Normal thrombin time is between 15 and 19 seconds.

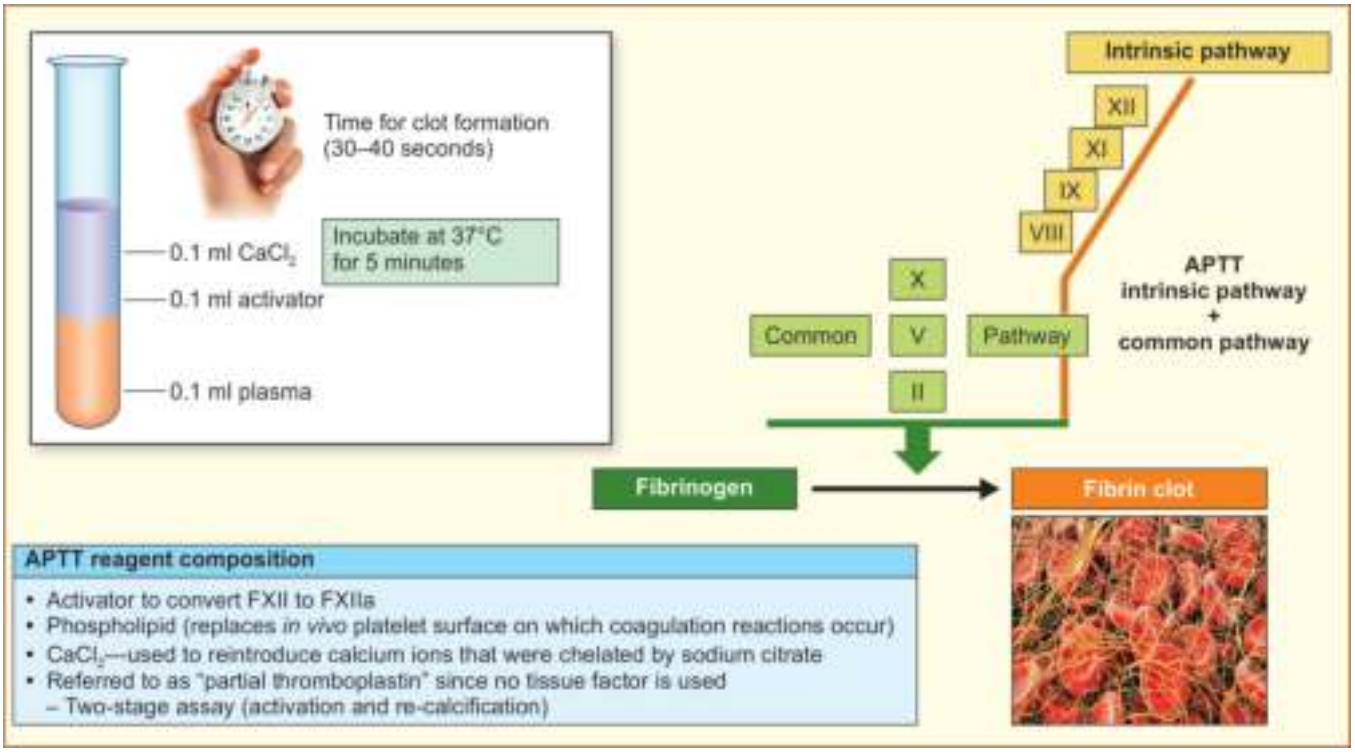

Fig. 11.12: Procedure of activated partial thromboplastin time (APTT).

Table 11.27 Interpretation of tests of hemostasis function in normal and abnormal patients

Tests and Results		Conclusion
Platelet count	Bleeding time	Interpretation
Normal platelet count	Normal	Normal result (platelets are related to bleeding disorders, so suspect coagulation defect in case of bleeding diathesis)
Low platelet count	Prolonged	Low platelet count (thrombocytopenia)
Normal platelet count	Prolonged	Abnormal platelet function
Prothrombin time (PT)	Activated partial thromboplastin time (APTT)	Interpretation
Normal PT	Normal APTT	Normal function of coagulation system (suspect platelet or vascular defect)
Abnormal PT	Abnormal APTT	Defects in common pathway of coagulation system
Normal PT	Abnormal APTT	Defects in the intrinsic pathway of coagulation system
Abnormal PT	Normal APTT	Defects in the extrinsic pathway of coagulation system

Thrombin time is prolonged in disseminated intravascular coagulation (DIC) and fibrinogen deficiency.

- Thrombin time is also prolonged in patient on anticoagulant therapeutic drugs, e.g. heparin, warfarin, hirudin, argatroban and hirulog.
- A prolonged thrombin time can be caused by the presence of paraproteins in a case of multiple myeloma.

Blood Clot Retraction Test

Blood clot retraction depends on the release of coagulation factors and platelets trapped in the fibrin mesh of the clot. Examination of blood clot found in a test tube provides information regarding concentration of fibrinogen, number and function of platelets; and activity of the fibrinolytic system. Test tube containing anticoagulant free blood is placed in water bath at 37°C for three hours. In normal persons, 30% of the total volume in the test tube should be blood clot.

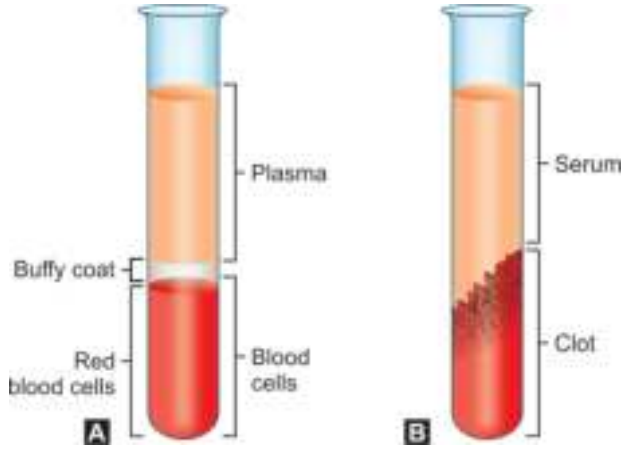

Fig. 11.13: (A) Unclotted whole blood with anticoagulant showing blood cells, plasma and buffy coat after centrifuge, (B) clotted whole blood without adding anticoagulant showing blood clot and serum.

Interpretation of blood clot retraction in various hematological disorders is shown in Figs 11.13, 11.14 and Table 11.28.

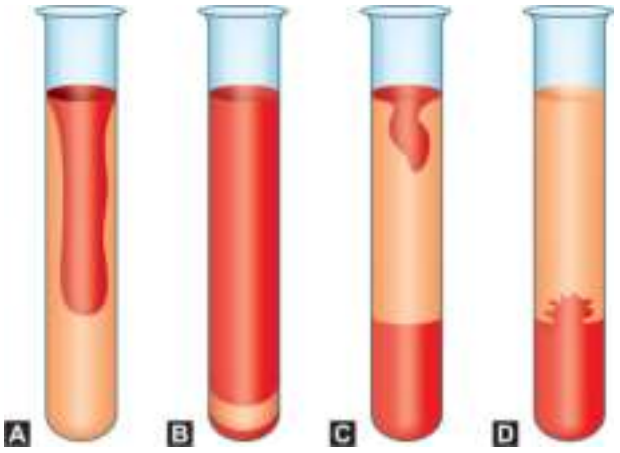

Fig. 11.14: Blood clots observed in normal persons and patients with coagulation disorders. (A) Blood clot in normal person, (B) blood clot in thrombocytopenia and thrombasthenia, (C) blood clot formed due to low fibrinogen concentration, (D) blood clot formed due to enhanced fibrinolysis in disseminated intravascular coagulation.

Table 11.28 Blood clots observed in various hematologic disorders

Blood Clot Structure	Disorders
Large blood clot with weak structure	▪ Thrombocytopenia ▪ Thrombasthenia
Severely affected blood clot retraction due to dysproteinemias	▪ Multiple myeloma ▪ Waldenström syndrome
Small clot with regular shape	Low fibrinogen concentration
Small irregular blood clot digested by enhanced fibrinolysis	▪ Afibrinogenemia ▪ Disseminated intravascular coagulation

Table 11.29 Interpretation of euglobulin lysis time

Time	Interpretation of Results
<2 minutes	Severe fibrinolysis, explaining severe bleeding
2–10 minutes	Moderate fibrinolysis, explaining postoperative or post-traumatic bleeding
10–30 minutes	Mild fibrinolysis, but not explaining bleeding
30 minutes to 2 hours	Physiological enhanced fibrinolysis
2–4 hours	Normal
>4 hours	Possibly defective fibrinolysis

Euglobulin Lysis Time

Euglobulin lysis time (ELT) is a blood test that measures how fast blood clots break down in the blood, which reflects the overall fibrinolytic activity of plasma. Euglobulins are proteins that precipitate when citrated platelet poor plasma is diluted in water. Precipitate contains plasmin, plasminogen and fibrinogen. Euglobulins are redissolved on fibrin gets clotted with thrombin.

- Activated thrombin activates plasminogen to plasmin.
- Time required for the plasmin to lyse fibrin is the euglobulin lysis time. Interpretation of euglobulin lysis time is given in Table 11.29.

Fibrinogen Degradation Products (FDPs) and D-Dimer Tests

Fibrinogen degradation products (FDPs) are formed as a result of breakdown of fibrinogen and fibrin.

- Increased fibrinogen degradation products are demonstrated in disseminated intravascular coagulation (DIC), severe liver disease, cirrhosis, eclampsia of pregnancy, thrombotic episodes, following fibrinolytic therapy, trauma and surgery.
- D-dimer is a protein fragment that is made when a blood clot dissolves in the body. Plasmin-mediated degradation of fibrinogen to fibrin degradation products is given in Fig. 11.15.

Fibrinogen Degradation Products (FDPs) and D-Dimer Tests: Interpretation

The fibrin degradation products (FDPs) test is a specific test that determines the amount of FDPs in blood.

- The tests, i.e. FDPs and D-dimer tests together are performed to evaluate suspected cases of primary fibrinogenolysis. In this, FDP test will be positive but D-dimer test remains normal.
- In disseminated intravascular coagulation (DIC), FDPs as well as D-dimer tests are positive. Fibrinogen degradation products are normally and rapidly cleared from blood circulation.
- Presence of large quantities of FDPs can interfere with the hemostatic process through several mechanisms.
- Forming soluble complexes with fibrin monomer from polymerizing antithrombin activity and by binding to platelets surface resulting in interference with platelet function.

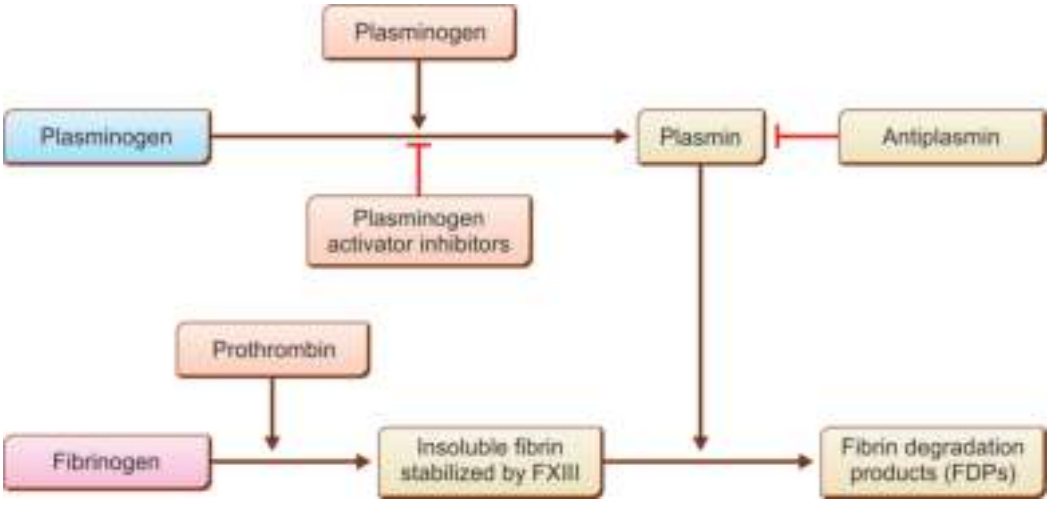

Fig. 11.15: Plasmin-mediated degradation of fibrinogen to fibrin degradation products. Fibrinolysis is the regulated dissolution of formed blood clot. Plasmin enzyme derived from plasminogen is involved in fibrinolysis. Plasmin degrades fibrin polymers and generate fibrin degradation products (FDPs) detected in plasma.

Annexure

Diagnostic workup of hemophilia A

Comprehensive relevant data

Hemophilia A is hereditary X-linked recessive disorder characterized by the deficiency of factor VIII resulting in bleeding and abnormal activated partial thromboplastin time (APTT). It is the most common hereditary bleeding disorder encountered in clinical practice affecting males, whereas females are usually carriers.

Clinical history data

- Clinical history is elicited with special emphasis on the following parameters: age, sex, ethnicity, demographic features, duration of bleeding diathesis, symptoms following injury or surgery, symptom profile, family history, number of previous blood transfusions and history of male relatives with hemophilia A such as maternal uncles, grandfathers, and cousins. The severity of hemophilia A depends on the amount of coagulation factor VIII and its activity in the blood.
- Patient with mild hemophilia A most often has bleeding only with major surgeries or tooth extractions. The patient may not be diagnosed until bleeding complications occur from surgical procedure. Patient with severe hemophilia A can experience bleeding with minimal activities of daily life or without known injury.
- Patient with severe hemophilia A may experience bruising under the skin causing hematoma, tendency to bleed from nose, mouth and gums with minor injury, bleeding while brushing teeth or dental extraction, and bleeding into the skeletal muscles induces swelling, pain, and redness.
  - Swelling from excessive blood in these areas can increase pressure on tissues and nerves. This can cause permanent damage and deformity.
  - The hallmark of hemophilia A is bleeding in the joints in ankles and elbows. Repeated bleeding in these joints can lead to chronic painful arthritis, deformity and crippling, and equine gait.
  - This bleeding is painful and leads to long-term inflammation and deterioration of the joint.
  - Bleeding in the brain from injury or spontaneously is the most common cause of death in children. Blood found in the urine or stool may also signal hemophilia A.

Recording reporting data

- All laboratory testing performed for the initial workup and diagnosis of patient with hemophilia and all related collection and evaluation of samples/specimens.

Collection and evaluation of samples/specimens

- Complete blood counts are normal in hemophilia A, however, if person with hemophilia A has unusually heavy bleeding for a long time, hemoglobin and red blood cell count can be low. Platelet number and functions are normal in hemophilia A.
- Activated partial thromboplastin time (APTT) test measures how long it takes for blood to clot.
  - APTT test evaluates the coagulation factors (XII, XI, IX and VIII) in the intrinsic pathway of coagulation system.
  - APTT test is prolonged among persons with hemophilia A.
- Prothrombin time and international normalized ratio (PT–INR) test also measures the time it takes for blood to clot. PT–INR evaluates primarily the clotting ability coagulation factors (I, II, V, VII and X) in the extrinsic pathway of coagulation system. If any of these coagulation factors are too low, it takes longer than normal time for the blood to clot. PT–INR also evaluates coagulation factors (X, V, II and I) in the common pathway of coagulation system.
  - The results of PT–INR test will be normal among persons with hemophilia A.
  - International normalized ratio (INR) is used to standardized prothrombin test results to adjust for the difference in thromboplastin reagents made by different manufacturers and used by different institutions.
- Fibrinogen (factor I) test also helps in assessment of patient's ability to form blood clot. Fibrinogen test is done either along with other blood coagulation tests or when patient has an abnormal PT–INR or APTT test result or both.
- Coagulation factor assays are required to diagnose bleeding diathesis such as hemophilia A.
  - Coagulation factor is a protein in the blood that helps stop bleeding.
  - Coagulation factor assays show the type of hemophilia A and the severity.
  - It is important to know severity of disease to create the best treatment plan.

- Babies should be tested for hemophilia A soon after birth: babies born to families with history of hemophilia A and whose mothers are carriers of hemophilia A and who have bleeding after symptoms at birth. Blood sample can be drawn from the umbilical cord immediately after birth and testing to determine the level of the factor VIII. Mild hemophilia A patient has FVIII level 6–40% of normal. Moderate hemophilia A patient has FVIII level 1–5% of normal. Severe hemophilia A patient has FVIII level <1% of normal.
- Acquired hemophilia A is characterized by the presence of autoantibodies against coagulation factor VIII, which can trigger bleeding diathesis. It has high morbidity and mortality, hence the importunate of establishing an early diagnosis and treatment.

CHAPTER 12

Blood Banking and Transfusion Practices

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

ABO AND Hh BLOOD GROUP SYSTEMS

- ABO blood group genetics
  - Chromosomes and alleles
  - Amorphic 'O' gene
  - ABO gene products
  - Hh genes and ABO phenotypes
  - ABO and Hh blood group antigens
  - ABO and Hh blood group antibodies

Rh BLOOD GROUP SYSTEM

- Antigens of Rh blood group system
  - CDE (Fisher-Race) nomenclature system
  - Dr Alexander Wiener nomenclature system
  - Current genetic analysis nomenclature system
- Rh factor incompatibility during pregnancy
- Anti-D antibody (RgoGAM) administration

BOMBAY PHENOTYPE AND PARA-BOMBAY PHENOTYPE

- Bombay phenotype
- Para-Bombay phenotype

OTHER BLOOD GROUP SYSTEMS

BLOOD COLLECTION, PROCESSING AND STORAGE

- Donor selection criteria
- Blood donation process
- Anticoagulant preservatives used in blood bank
  - Acid-citrate-dextrose
  - Citrate-phosphate-dextrose
  - Citrate-phosphate-dextrose-adenine 1
- Preparation of blood components from whole blood
  - Whole blood composition
  - Red blood cell component
  - Plasma component
  - Platelet component
  - Granulocyte component
- Removal of blood components by apheresis
  - Collection of red blood cells by apheresis
  - Collection of plasma by apheresis
  - Collection of platelets by apheresis
  - Collection of granulocytes by apheresis
- Therapeutic apheresis
  - Therapeutic plasma exchange
  - Therapeutic leukapheresis
  - Therapeutic erythrocytapheresis
  - Therapeutic fluid replacement
  - Hematopoietic progenitor cells collection
  - Immunoadsorption/selective adsorption
  - Photopheresis
- Blood component labeling
- Changes in stored blood components
  - Red blood cell changes in stored blood
  - Platelet changes in stored blood
  - White blood cell changes in stored blood
  - Plasma protein component changes in stored blood
  - Bacterial contamination in stored blood
- Transportation of blood components
- Modification of blood components
  - Leukoreduction before blood storage
  - Inactivation of pathogens in stored blood
  - Aliquoting of blood components
  - Pooling of blood components
  - Volume reduction from blood components
  - Irradiation of blood components
  - Washing of blood components
  - Freezing, thawing and deglycerolizing red blood cells
  - Rejuvenation of red blood cells
- Blood plasma fractionation
- Recombinant plasma protein production

BLOOD TRANSFUSION AND BLOOD COMPONENT THERAPY

- Blood transfusion: goals
- Blood transfusion: indications
- Blood components transfusion
  - Whole blood transfusion
  - Red blood cell component transfusion
  - White blood cell component transfusion
  - Hematopoietic stem cells used for transplantation
  - Modification of cellular components
  - Transfusable plasma components
  - Platelet component transfusion
  - Fibrin glue and platelet gel
  - Plasma fractionation products
  - Pharmaceutical drugs used to reduce/prevent bleeding in hematologic disorders
  - Massive blood transfusion

ADVERSE BLOOD TRANSFUSION REACTIONS

- Blood transfusion-related immune hemolytic reactions
  - Blood transfusion-related acute hemolytic reactions
  - Blood transfusion-related delayed hemolytic reactions
- Blood transfusion-related febrile nonhemolytic reactions
  - Pathophysiology
  - Clinical features
- Blood transfusion-related allergic reactions
  - Clinical features
- Blood transfusion-related anaphylactic/anaphylactoid reactions
  - Pathophysiology
  - Clinical features
- Blood transfusion-related acute lung injury
  - Clinical features
- Blood transfusion-related circulatory overload
- Blood transfusion-related dyspnea
- Blood transfusion-related hypotension
  - Pathophysiology
  - Clinical features
- Blood transfusion-related graft-versus-host disease
  - Pathophysiology
  - Clinical features
- Blood transfusion-related sepsis
  - Pathophysiology
  - Prevention
- Blood transfusion-related hemosiderosis
  - Clinical features
- Blood transfusion-related purpura
  - Pathophysiology

- Rapid massive blood transfusion-related reactions
  - Citrate toxicity
  - Hypothermia
  - Dilutional coagulopathy
- Blood transfusion-related nonimmune hemolysis
- Blood transfusion-related hyperkalemia
- Blood transfusion-related hypokalemia
- Blood transfusion-related air embolism
- Blood transfusion-related thrombophlebitis

BLOOD GROUPING

- ABO blood grouping
  - Methods of ABO blood grouping
  - Methodology
- Rh blood grouping

BLOOD CROSS-MATCHING (COMPATIBILITY) TEST

- Immediate spin blood cross-matching
- Electronic based blood cross-matching
  - Electronic based major blood cross-match
  - Electronic based minor blood cross-match

ABO AND Hh BLOOD GROUP SYSTEMS

The ABO blood group system was first described by Karl Landsteiner in an article published in 1901. Landsteiner's rule states that normal, healthy persons possess ABO antibodies to ABO blood group antigens absent from their red blood cells. He obtained blood from his coworkers and then mixed with serum and red blood cells obtained from different persons. He observed three patterns of agglutination of red blood cells that he named A, B, and C. The 'C' pattern is now known as 'O'. Decastello and Sturli later describe AB blood group. Agglutination of red blood cells is still one of the standard detection methods being followed today in blood transfusion medicine.

- ABO and Rh blood group systems are most important in the blood transfusion in clinical practice. Red blood cell antigens (A, B and RhD) elicit strong humoral immune response. Alloantibodies formed can cause destruction of transfused red blood cells. ABO antigens are also significant in organ transplantation.
- A blood group may be defined as an inherited character of the red blood cell surface antigens detected by specific antibody. However, cell surface antigens on platelets and leukocytes might also be considered blood groups.
- Most blood groups are organized into blood group systems. Each blood group represents a single gene or cluster of two or more closely linked genes. Of the 347 red blood surface antigens classified by the International Society of Blood Transfusion, 303 red blood cell surface antigens belong to one of 36 blood group systems. Major red blood cell group systems containing 303 gene specificities are given in Table 12.1.

Table 12.1 Major red blood group system containing 303 gene specificities

Number	Name of RBC Blood Group System	Symbol	Gene Symbol(s)	Chromosome	RBC Membrane Associated with Antigen Expression
001	ABO blood group system	ABO	ABO	Chromosome 9	4
002	MNSs blood group system	MNS	GYPA, GYPB, GYPE	Chromosome 4	48
003	PIPK blood group system	PIPK	A3GALT	Chromosome 4	3

036	Augustine blood group system	AUG	SLC29A1	Chromosome 6	2

- Most blood group antigens are proteins or glycoproteins, with the blood group specificity determined primarily by the amino acid sequence. Most of the blood group polymorphisms result from substitution of single amino acid with some exceptions. Some of these proteins cross the red blood cell membrane several times and attached by a glycosylphosphatidylinositol anchor.
- Some blood group antigens including the ABO, PIPK, Lewis, H and I blood group systems are carbohydrate structures on glycoproteins and glycolipids. These blood group antigens are not synthesized directly by the genes controlling their polymorphisms; rather by genes encoding transferase enzymes that catalyze the final biosynthetic stage of an oligosaccharide chain.

ABO BLOOD GROUP GENETICS

ABO blood group system follows Mendelian law. DNA constitutes for building blocks of life. Sequence of flow of genetic information includes DNA → RNA → synthesis of structural proteins and enzymes → cells → organs → human body.

CHROMOSOMES AND ALLELES

The gene for the ABO blood group system resides on chromosome 9. There are three alleles for A, B and O genes. Every individual has two copies of chromosome 9, hence every person has two ABO genes: one ABO gene inherited from father and one ABO gene inherited from mother. The particular alleles at a specific gene locus in a person constitute genotype, and their outward expression is known as phenotype. ABO blood group system consists of four major blood groups: A, B, AB and O identified based on presence or absence of A and/or B antigens on red blood cells.

- According to Landsteiner's law, anti-A and/or anti-B antibodies are always present in the plasma of persons, who lack corresponding antigen(s). ABO antibodies are mainly IgM type; however, there may be IgG, which have thermal activity at 37°C. IgM and IgG activate complement system and cause intravascular destruction of red blood cells, which can give rise to severe fatal hemolytic blood transfusion reactions. ABO antibodies seldom cause less severe hemolytic disease of the fetus and newborn. There are possible six combinations of ABO genotypes and corresponding phenotypes are given in Table 12.2.

Table 12.2 ABO genotypes and corresponding phenotypes

Genotype	Phenotype
▪ AA ▪ AO	A
▪ BB ▪ BO	B
O	O
AB	AB

- Most of the ABO genes are expressed in co-dominant manner, like most blood group system genes. It means that if the gene is present, its gene product is an enzyme or a protein. No gene or allele is dominant over another gene or allele. Hence, one gene does not suppress the other gene in co-dominant system. The particular alleles at specific gene locus in person constitute genotype, and their outward expression is known as phenotype.
- In ABO blood group system, person lacking an antigen on red blood cells has corresponding anti-A or anti-B antibodies. Both A and B red blood group genes are dominant; while O blood group gene is recessive. ABO blood group system, genotype, quantity of H antigen on red blood cells, antigens on ABO, corresponding antibodies in plasma, reaction of antigen with antiserum and Indian frequency are given in Table 12.3.

AMORPHIC 'O' GENE

Amorphic gene describes that does not express a detectable functional gene product. The O gene is amorph, meaning no functional gene product (a protein or an enzyme) is produced from the sequence of DNA. As ABO genes are co-dominant, the phenotype of person with blood group A can result from one of two allelic combinations: AA or AO. Similarly, the phenotype of person with blood group B can result from one of two allelic combinations: BB or BO. Person with blood group AB has AB genotype.

ABO GENE PRODUCTS

Genes usually code only for proteins. ABO antigens are not proteins, rather carbohydrates. A gene codes for the production of an enzyme that makes the A antigen. Likewise, the B antigen codes for the synthesis of an enzyme that makes the B antigen. The flow of genetic information in the ABO blood group system is in the following sequence: DNA → RNA → synthesis of enzymes → A or B antigen (sugar) on the red blood cell membrane.

Hh GENES AND ABO PHENOTYPES

H antigen is the precursor substance for both A and B antigens. Hh system is different from the ABO system. ABO and Hh genes are inherited independently. ABO genes are located on chromosome 9. On the other hand, Hh genes are found on chromosome 19. 'H' gene encodes α1, 2-L-fucosyltransferase 1 (FUT-1) enzyme essential for A and B antigens. Like the O gene, the H gene is also amorph. Only one copy of the H gene is essential to make the H antigen. In person having two copies of the H gene (Hh), neither the enzyme nor the H antigen is produced.

Table 12.3 ABO blood group system, genotype, quantity of H antigen on red blood cells, antigens on ABO, corresponding antibodies in plasma, reaction of antigen with antiserum and Indian frequency

Blood Group Phenotype	Genotype	Quantity of H Antigen on RBCs	Antigens on RBCs	Corresponding Antibodies in Plasma	RBC Antigen Reacts with Antiserum Antibodies	Indian Frequency
A	▪ AA (homozygous) ▪ AO (heterozygous)	++	A	Anti-B antibody (IgM)	Anti-A antibodies	27%
B	▪ BB (homozygous) ▪ BO (heterozygous)	++	B	Anti-A antibody (IgM)	Anti-B antibodies	30%
AB	AB (heterozygous)	+	AB	None	Anti-A and anti-B antibodies	8%
O	OO	++++	None	Anti-A, anti-B (IgG), hence crosses placenta resulting in hemolytic disease of newborn	None	34%

Large amount of H antigen is present on O blood group red blood cells, while AB blood group has least amount of H antigen on their red blood cells. Immunohematology is study of blood group antigens and antibodies. Antigens are foreign molecules that bind specifically to an antibody or a T cell receptor. Antigens that exhibit great degree of foreignness from the host elicit the strongest immune response.

Immunodominant Sugars

Immunodominant sugar molecules are responsible for ABO blood group specificity, which are attached at the end of the carbohydrate precursor substance, which is H antigen. Immunodominant sugars of the ABO and Hh blood group systems are given in Table 12.4. Interaction of the Hh and ABO genes is shown in Fig. 12.1. Diagrammatic representation of the oligosaccharides representing H, A, B, Le^a and Le^b and the biosynthetic precursor of H and Le is shown in Fig. 12.2. Molecular basis of A and B antigens on the red blood cells are shown in Fig. 12.3.

- 'H' gene encodes the α1,2-L-fucosyltransferase enzyme, which adds L-fucose immunodominant sugar to precursor carbohydrate chain to form the H antigen.
- 'A' gene encodes the α1,3-N-acetyl-galactosaminyl-transferase enzyme, which adds N-acetyl-D-galactosamine immunodominant sugar to H antigen and not the precursor substance of H antigen.
- 'B' gene encodes the α-1,3-D-galactosyltransferase enzyme, which adds D-galactose immunodominant sugar to H antigen and not the precursor substance of H antigen.
- 'O' gene synthesizes an inactive transferase resulting in unchanged H antigen, individuals with blood group O has large amount of H antigen.

Type 1 and Type 2 Carbohydrate Chains

ABH precursor substance is of two types: type 1 (abundant) and type 2. Type 1 ABH precursor substance is present in the plasma, gut lining and secretions such as saliva, milk and urine. Type 2 ABH precursor substance is found on red blood cells and some in plasma. The difference between type 1 and type 2 ABH precursor substance is the attachment of the last galactose sugar molecule on the precursor substance. ABO and Hh blood group system carbohydrate chains are composed of hexoses which are sugar molecules with six carbon atoms.

ABO AND Hh BLOOD GROUP ANTIGENS

The red blood cell membrane is bilipid bilayer. ABO red blood antigens are carbohydrate structures expressed predominantly oligosaccharide molecules, which are attached to glycoproteins, glycolipids and glycosphingolipids in the red blood cell membrane.

ABO Antigens Expression

The red blood cell membranes contain over two million ABO antigens. ABO gene locus has been mapped on chromosome 9q34 and encodes the A and B glycosyltransferases. ABO gene contains seven exons, which encodes 354-amino acid transferase activity. Gene mutation may result in loss of glycosyltransferase activity, thus resulting in blood group '**O**' red blood cells.

Table 12.4 Immunodominant sugars of the ABO and Hh blood group systems

Red Blood Cell Antigen	Immunodominant Sugar	Enzymes that Add Sugar
H	L-fucose	α1, 2-L-fucosyltransferase
A	N-acetyl-D-galactosamine	α1, 3-N-acetylgalactosaminyltransferase
B	D-galactose	α1, 3-D-galactosyltransferase

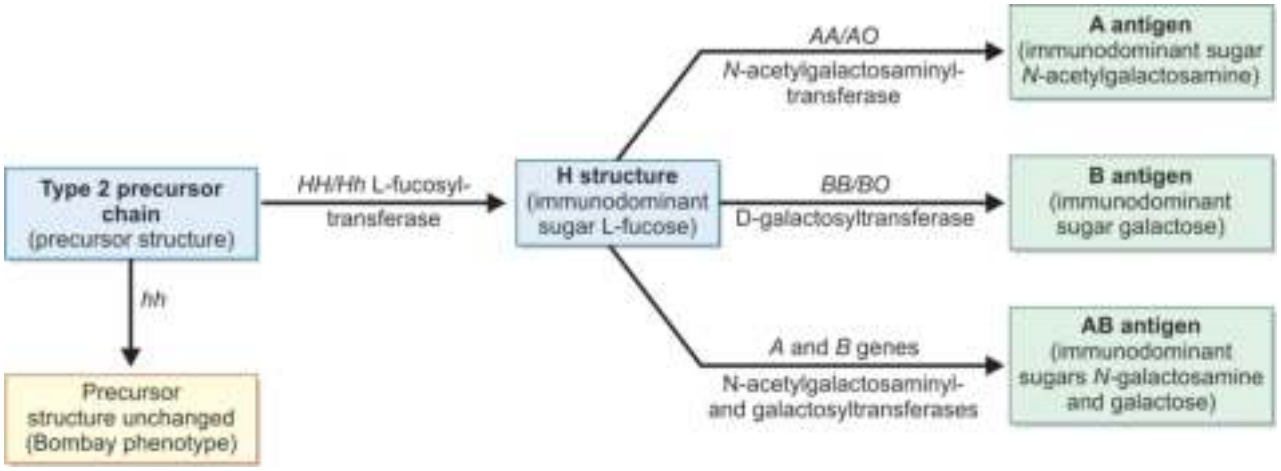

Fig. 12.1: Interaction of the Hh and ABO genes.

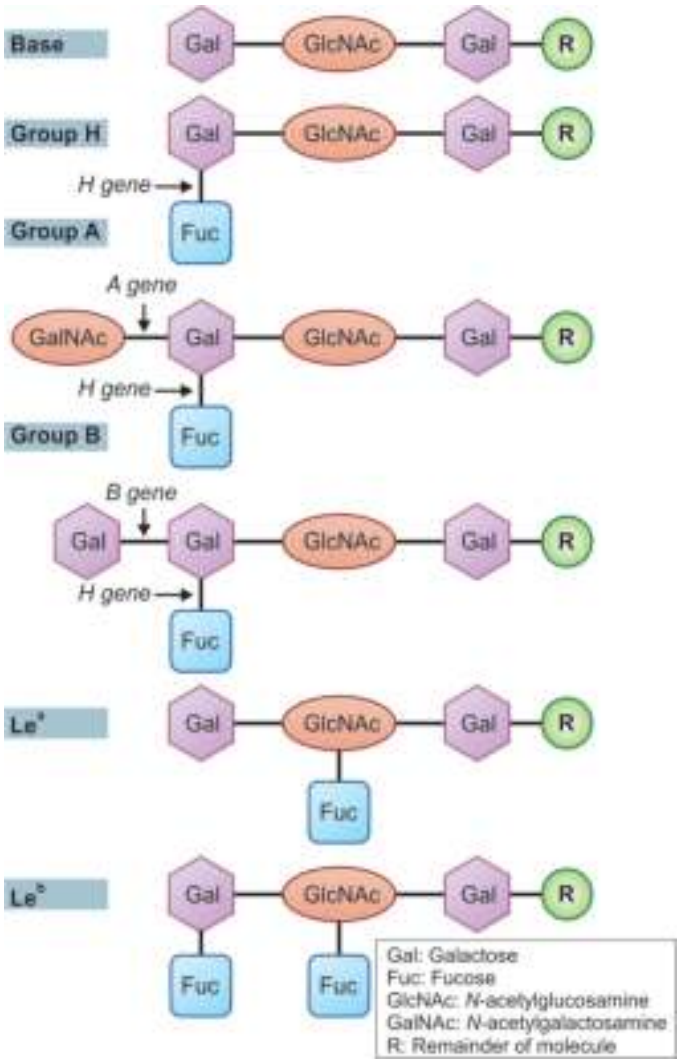

Fig. 12.2. Diagrammatic representation of the oligosaccharides representing H, A, B, Le^a and Le^b and the biosynthetic precursor of H and Le^a.

Many other mutations of these transferase genes result in decreased expression of antigens leading to weak/absent reactivity with standard anti-A and anti-B sera.

- ABO antigens are also expressed on vascular endothelial cells and epithelial cells of the lung, gastrointestinal tract and genitourinary tract in their secretions. Hence, these ABO antigens are very important in solid organs transplant. ABO matching is considered to be more important than human leukocyte antigen matching. ABO antibodies in the recipient are capable of binding antigens in the transplanted organ, resulting in activation of complement system and acute rejection of transplant.
- ABO antigens are also present in saliva, milk and urine in persons who carry the Se (FUT2) gene in 80% of population. Se (FUT2) gene encodes fucosyltransferase 1 (FUT1) enzyme similar to the H gene product and permits the formation of the H antigen on type 1 glycoproteins versus type 2 glycoproteins present in the secretions synthesized by the epithelial cells. Subsequently, persons who have the appropriate genes coding for A and B glycosyltransferases can synthesize ABO antigens and are called secretors.

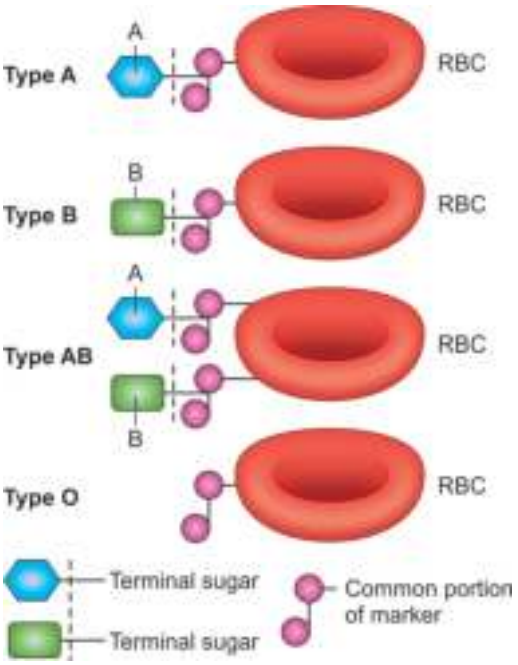

Fig. 12.3. Molecular basis of A and B antigens on the red blood cells. In general persons with blood group A, B and AB inherit a gene for the transferase enzyme that adds a certain terminal sugar to the basic red blood cell membrane. Blood group O persons do not have such an enzyme and lacks terminal sugar.

- Blood group O persons lack A and B glycosyltransferases and therefore only have H antigen present on the surface of the red blood cells. Rare persons lacking H antigen are designated as the 'Bombay phenotype'. These persons lacking 'H' antigen have potent anti-H antibody in addition to anti-A and anti-B antibodies, which must be transfused blood only from other persons with the 'Bombay phenotype'.
- ABO antigens are synthesized by glycosyltransferase enzymes, which participate in addition of terminal monosaccharide to sugars of the backbone carbohydrate chain, which is termed the H antigen. The A glycosyltransferase adds N-acetylgalactosamine in α_1, 3-linkage to the H antigen. The glycosylation may be (a) N-glycosylation, large, branched sugars attached to asparagine residues of the amino acid backbone or (b) O-glycosylation, smaller glycans (usually tetrasaccharides) attached to serine or threonine residues.

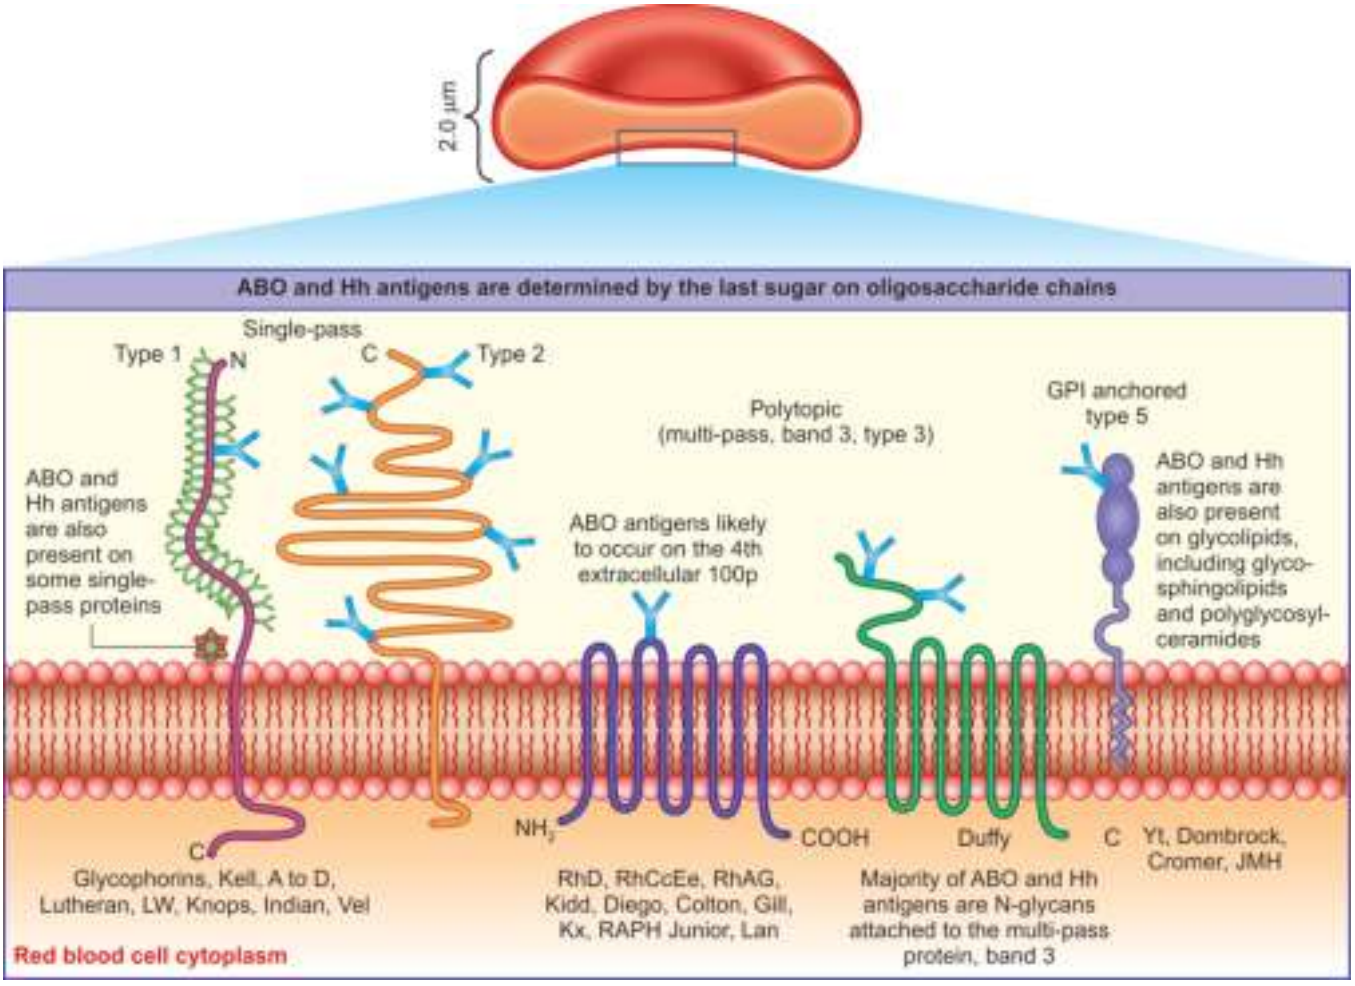

Fig. 12.4: Simplified schematic of different types of blood group active proteins and glycoproteins based on their integration into the red blood cell surface membrane. These are examples of blood group antigens for each type. Type 4 proteins are cytoplasmic and not present in the red blood cells. Single-pass type 1 and type 2 blood group antigens, multi-pass (polytopic) type 3 blood group antigens crossing the red blood cell membrane several times, and GPI anchored 5 blood group antigens are demonstrated.

- The majority of ABO and Hh antigens are N-glycans attached to the multi-pass proteins and band 3. Other multi-pass proteins that carry ABO and Hh antigens include RHAG and band 4.5. ABO and Hh antigens can be less frequently attached as O-glycans.
- ABO and Hh antigens are also present on some single-pass proteins. ABO and Hh antigens are also found on glycolipids, including glycosphingolipids and polyglycosylceramides. Red blood cell (RBC) antigens on RBC membrane include single-pass type 1 and type 2, multi-pass (polytopic) type 3 and GPI anchored type 5 blood group antigens are shown in Fig. 12.4.

Hematology Pearls: Red Blood Cell (RBC) Antigens on RBC Membrane

Red blood cell antigens on RBC membrane include single-pass type 1 and type 2, multi-pass (polytopic) type 3 and GPI anchored type 5 blood group antigens.

Single-pass Type 1 and Type 2 Blood Group Antigens

- Some blood group proteins pass through the RBC membrane, which have an external N-terminal domain and cytoplasmic C-terminal domain.
- Examples of single-pass type 1 and type 2 blood group antigens are Kell proteins A to D, Lutheran, LW, Knops, Indian, Vel.

Multi-pass (Polytopic) Type 3 Blood Group Antigens

- Multi-pass (polytopic) type 3 blood group antigens cross the red blood cell membrane several times.
- Usually both termini are cytoplasmic, but the Duffy glycoprotein has an odd number of membrane-spinning domains and an extracellular domain and an extracellular N-terminal domain.
- The multi-pass proteins that carry ABO and Hh antigens include RHAG and band 4.5.
- Examples of multi-pass (polytopic) type 3 proteins are RhAG, RhD, RhCcEe, Kidd, Diego, Colton, Gill, Kx, RAPH Junior and Lan.

GPI Anchored Type 5 Blood Group Antigens

- Finally, some red blood cell antigens lack membrane spinning domain, but are anchored to the RBC membrane by lipid tail (called glycosylphosphatidylinositol or GPI anchor), which is attached to the C-terminus of the protein through carbohydrate (type 5).
- There is deficient type 4 glycoprotein, which has no external domain in the red blood cell membrane.

Hematology Pearls: ABO Subgroups

- Most common ABO blood group is group O. Genetic variations in the ABO gene can produce subgroups of A, B and AB.
- Individuals have most often variations in A gene than B gene. A_1 and A_2 are the common subgroups of blood group A.
- Antigen frequency is approximately 45% for blood group O, 40% for blood group A, 10% for blood group B, and 5% for blood group AB. ABO subgroups are blood group A, blood group B, blood group AB and blood group O.
- Genes, antigens of the ABH and ABO type of donor RBCs suitable for patients are given in Table 12.5. Major blood group system, their genes and locus on chromosome are given in Table 12.6.

Blood Group A

- Genotype of individuals with blood group A is AA (homozygous) or AO (heterozygous). These individuals have both B and H antigens on red blood cells. Their plasma contains anti-B antibodies of IgM in nature.
- There are two subgroups of blood group A: A_1 (80%) and A_2 (20%). Both A_1 and A_2 antigens have same immunodominant sugar, i.e. N-acetyl-D-galactosamine. Both subgroups A_1 and A_2 antigens encode transferase, α-1,3-N-acetylgalactosaminyltransferase. However, the enzyme encoded by A_1 gene is better at converting H substance to A antigen. Both A_1 and A_2 phenotypes demonstrate 3+ to 4+ reactions with commercial anti-A reagents.
- Anti-A_1 lectin agglutinates only A_1 RBCs. This lectin is used to distinguish the A_1 and A_2 phenotypes in resolving ABO typing problems when A_2 phenotypes develop anti-A_1.
- It is important to identify donors as a weak subgroup of A. Donors with a very weak A antigen expression may be mistyped as blood group O.
- The presence of the antigen can be demonstrated by adsorption (a process by which unwanted antigen is removed from the RBCs) and elution.
- Other methods to resolve the discrepancy include molecular analysis, family studies and saliva analysis.

Blood Group B

Genotype of individuals with blood group B is BB (homozygous) or BO (heterozygous). These individuals have both B and H antigens on red blood cells. Their plasma contains anti-A antibodies of IgM in nature.

Blood Group AB

Genotype of individuals with blood group AB has both A and B antigens on RBCs. Their plasma lacks anti-A and anti-B antibodies. Subgroups of B are extremely rare: B3, Bx, Bel and Bm. Sometimes patients/donors with a very weak subgroup of B will produce a weak anti-B.

Blood Group O

- Genotype of individuals with blood group O contains large amount of H antigen on RBCs.
- 'O' gene synthesizes an inactive transferase resulting in unchanged H antigen. Individuals with blood group O have large amount of H antigen.
- Their plasma contains both anti-A and anti-B antibodies of IgG in nature. IgG can cross the placenta and induce hemolytic disease of fetus and newborn.

Hematology Pearls: Secretors and Nonsecretors

Nonsecretor is the individual who inherits the genotype sese and does not express soluble H substance in secretions. Comparison of secretors and nonsecretors is given in Table 12.7.

Secretors

- Secretor is the individual, who inherits Se allele (amorph Se gene also called FUT2 located on chromosome 19, close to H gene) and expresses soluble forms of H antigens in secretions.
- A, B, and/or H antigens can be present in various fluids in 80% of general population. ABO antigens are present in large quantity in their plasma (except those with Bombay phenotype), saliva, gastric juice, tears, semen, milk and urine.

Nonsecretors

- The Se gene encodes an α2-L-fucosyltransferase that is similar to the enzyme encoded by the H gene. Secretor studies may be useful in identifying a subgroup A or B antigens.
- The people who are 'sese' do not produce any A, B, or H antigen in their secretions are called nonsecretors. These individuals do not produce a functional fucosyltransferase.
- The type 1 precursor substance is not converted to H substance in their secretions, therefore cannot be converted to A or B antigens, regardless of their ABP genotype.
- ABH antigens found in secretions are primarily glycoproteins except ABH antigens found in milk and urine. ABH antigens found in milk and urine are oligosaccharides. ABH antigens found are either glycoproteins or glycosphingo lipids.
- ABH antigens in plasma can adsorb onto the cell membrane of platelets and lymphocytes, these ABH antigens are expressed on cell membrane of the platelets. But granulocytes and monocytes do not possess A, B or H antigens.

Table 12.5 Genes, antigens of the ABH and ABO type of donor red blood cells suitable for patients

Gene	Glycosyltransferase	Antigen Determining Sugar	ABH Antigen	ABO Type	Antibody Present	Preferable Donor	Other Acceptable Donors*
A	α1, 3-N-acetyl-galactosaminyltransferase	N-acetylgalactosamine	A	A	B	A	O
B	α1, 3-D-galactosyltransferase	D-galactose	B	B	A	B	O
H	α1, 2-L-fucosyltransferase	L-fucose	H	O	A and B	O	None
A and B	All of the above	All of the above	A and B	AB	None	AB	A or B or O**

**If blood is used as red blood cells. **Blood group A is preferable.*

Table 12.6 Major blood group system, their genes and locus on chromosome

Blood Group System	Chromosome of Gene Locus	RBC Membrane Associated with Antigen Expression	Antigen Composition
AB blood group system	Chromosome 9	Anionic transport protein (band 3)	Glycoprotein
H blood group system	Chromosome 19	CD173	Glycoprotein
Lewis blood group system	Chromosome 19	Not applicable	Carbohydrate
P blood group system	Chromosome 22	Globoside I	Carbohydrate
Rh blood group system	Chromosome 1	Polypeptides	Lipoprotein
LW blood group system	Chromosome 19	CD242, ICAM; 1qSF	Lipoprotein
MNSs blood group system	Chromosome 4	Glycophorin A, glycophorin B	Glycoprotein
Kell blood group system	Chromosome 7	CD239 endopeptidase	Glycoprotein
Kx blood group system	X chromosome	Unknown	Protein
Duffy blood group system	Chromosome 1	CD234 receptor	Glycoprotein
Lutheran blood group system	Chromosome 19	CD 239 IgSF	Glycoprotein
Gerbich blood group system	Chromosome 2	Glycophorin C, glycophorin D	Glycoprotein
Kidd blood group system	Chromosome 18	Urea transporter	Glycoprotein
Xg blood group system	X chromosome	CD99	Glycoprotein
Colton blood group system	Chromosome 7	Aquaporin	Glycoprotein
Chido/Rogers blood group system	Chromosome 6	C4A; C4B	Glycoprotein
John Multon Hagen blood group system	Chromosome 15	CDW108 semiphorin	Glycoprotein
Raph blood group system	Chromosome 11	Unknown	Glycoprotein
Ok blood group system	Chromosome 19	CD147	Glycoprotein
Diego blood group system	Chromosome 17	Band 3	Glycoprotein
Yt blood group system	Chromosome 7	Acetylcholinesterase	Glycoprotein
Cromer blood group system	Chromosome 1	Decay accelerating factor (DAF)	Glycoprotein
Dombròck blood group system	Chromosome 12	Ribosyltransferase	Glycoprotein
Scianna blood group system	Chromosome 1	Unknown	Glycoprotein
Knops blood group system	Chromosome 1	CD35; CR1	Glycoprotein
Indian blood group system	Chromosome 11	CD44	Glycoprotein
Ii blood group system	Unknown	Glucose transport protein (band 4.5), poly-N-acetyl-lactosaminyl glycolipids	Glycoprotein; glycolipid

Table 12.7 Comparison of secretors and nonsecretors

Features	Secretors (Fluids Containing A, B and H Antigens)	Nonsecretors (Fluids with Absence of A, B and H Antigens)
Genotype	Sese/Sese	Not applicable
Frequency	80%	20%
Plasma	Present in all individuals except Bombay phenotype	Traces/absent
Amniotic fluid, saliva, bile, digestive juices, milk, tears and urine	Present	Absent

ABO AND Hh BLOOD GROUP ANTIBODIES

Immunohematology is study of blood group antigens and antibodies. Most ABO antibodies are IgM. Red blood cell antibodies must be detected and identified to avoid serious blood transfusion reactions.

- Red blood cells of an individual contain antigens on their cell surfaces that correspond to their blood group. Antibodies in the serum that identify such antigens present on surface of red blood cells of another blood group.
- Blood group A has A antigen on their red blood cells and anti-B antibodies in the plasma. **Blood group B** has B antigen on their red blood cells and anti-A antibodies in plasma. **Blood group O** has neither A nor B antigens on red blood cells and anti-A, anti-B, and anti-A, B antibodies in plasma. Blood group AB has both A and B antigens on their red blood cells and neither anti-A nor anti-B in the plasma.
- Blood group antibodies are usually IgM or IgG. Naturally occurring antibodies are usually predominantly IgM, whereas immune antibodies are predominantly IgG.
- IgM antibodies cause directly agglutinate antigen present red blood cells in the saline medium. On the other hand, most IgG antibodies require potentiators or anti-human globulin to affect agglutination. Currently three methods are routinely used to detect antibodies: tube, gel and solid phase testing. Antigens and antibodies in common ABO blood groups are given in Table 12.8. ABO blood group reactions are given in Table 12.9.

Table 12.8 Antigens and antibodies in common ABO blood groups

ABO Blood Group	Antigens Present on Red Blood Cell	Antibodies Present in Plasma
A	A antigen	Anti-B antibody
B	B antigen	Anti-A antibody
AB	Neither A nor B antigens	Anti-A, anti-B, and anti-A, B antibodies
O	Both A and B antigens	Neither anti-A nor anti-B antibodies

Table 12.9 ABO blood group reactions

Phenotype	Reactions with Red Blood Cells with		Reactions with Plasma Tested with		Interpretation
	Anti-A Serum	Anti-B Serum	A1 Red Blood Cells	B Red Blood Cells	ABO Blood Group
Group A	+	0	0	+	0
Group B	0	+	+	0	A
Group O	0	0	+	+	B
Group AB	+	+	0	0	AB

+: Agglutination; O: No agglutination; Blood group O lacks both A and B antigens. Blood group AB lacks circulating ABO antibodies in their plasma.

Rh BLOOD GROUP SYSTEM

Landsteiner and Wiener in 1941, injected rhesus monkey red blood cells into the rabbits and guinea pigs and observed increase in antibodies titer. Red blood cells of rhesus monkey and human (white residents of New York city) have similar antigens. Antigen involved was called Rh factor. In 1939, Levin and Steven later discovered anti-D antibody that is responsible for hemolytic disease of newborn.

ANTIGENS OF Rh BLOOD GROUP SYSTEM

Rh blood group system has about 40 antigens. Most antigens are **C, D, E, c, d** and **e**. The genes encoding Rh proteins determine the phenotype of person. A related protein, the Rh glycoprotein is essential for assembly of Rh complex in the red blood cell membrane and expression of Rh antigens. CDE (Fisher-Race) and Dr Alexander Wiener nomenclature systems are employed for Rh blood group inheritance.

CDE (FISHER-RACE) NOMENCLATURE SYSTEM

According to Fisher-Race nomenclature of Rh blood group system, three closely linked loci located on chromosome 1 are inherited from each parent. The alleles occupying these loci are known as C, D, E, c, d and e. Out of these, **D gene is dominant over d gene**. On the other hand, loci such as C, c, E and e are codominant. Each gene (except d gene) encodes a specific antigen on RBCs. Each person inherits one haplotype from each parent making 8 possible genotypes (Fig. 12.5).

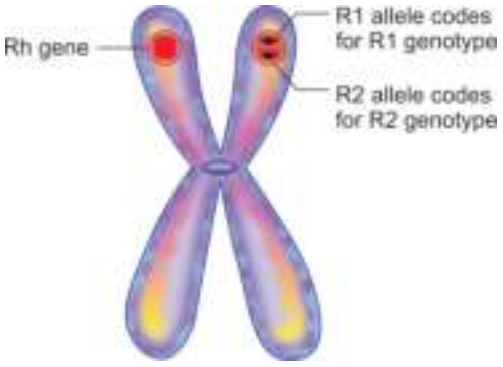

Fig. 12.6: Dr Alexander Wiener nomenclature of Rh blood group system.

Dr ALEXANDER WIENER NOMENCLATURE SYSTEM

According to Dr Alexander Wiener nomenclature of Rh blood group system, single Rh gene having multiple alleles is inherited from each parent. R_1 gene encodes Rh1 antigen comprising three factors, which correspond with C, D, and e of Fisher-Race nomenclature system. Similarly, R_2 gene encodes one Rh_2 antigen comprising factors, which correspond with Fisher-Race nomenclature system (Fig. 12.6).

CURRENT GENETIC ANALYSIS NOMENCLATURE SYSTEM

According to current genetic analysis nomenclature system, RHCE and RHD genes are located on chromosome 1. Presence of D gene makes the person Rh positive, while Rh negative lacks D antigen. RHCE gene can synthesize C or c, CE and ce (Fig. 12.7).

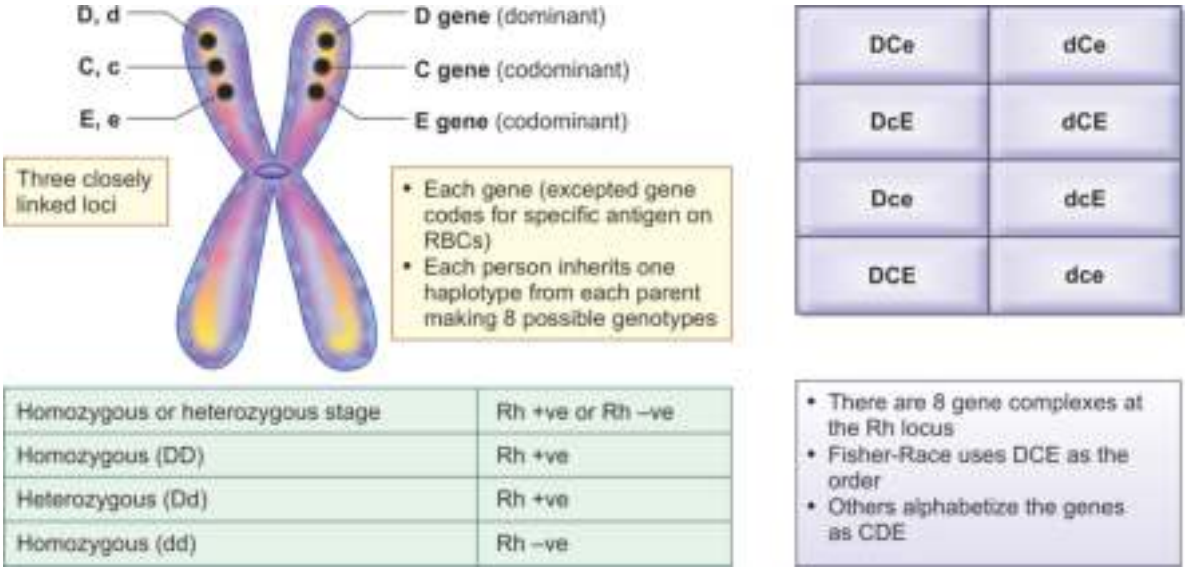

Fig. 12.5: Fisher-Race nomenclature system of Rh blood group inheritance.

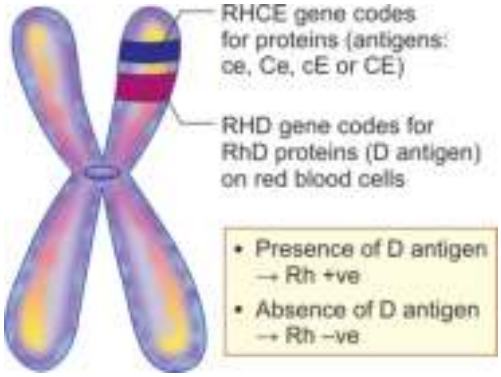

Fig. 12.7: Current genetic analysis nomenclature system of RHCE and RHD genes.

Rh FACTOR INCOMPATIBILITY DURING PREGNANCY

Rh factor incompatibility can cause lysis of red blood cells known as hemolytic disease of newborn. Naturally occurring red blood cell incompatibility results when Rh positive (+ve) fetus develops within Rh negative (–ve) mother. Initial sensitization of the immune system occurs when fetal red blood cells pass the placental barrier. In most cases, the fetus develops normally. However, subsequent pregnancy with Rh +ve fetus results in severe fetal red blood cell hemolysis and causes hemolytic disease of newborn. Pathogenesis of hemolytic disease of newborn and its prevention is shown in Fig. 12.8A to C.

ANTI-D ANTIBODY (RhoGAM) ADMINISTRATION

Routine antenatal prophylaxis is to infuse 500 IU anti-D antibody (RhoGAM) to Rh –ve mothers at 28 weeks and 34 weeks of pregnancy to inactivate and remove any Rh factor that may be transferred from the fetus in maternal circulation. Post-delivery anti-D immunoglobulin must be administered to Rh –ve mother, if an infant is Rh +ve.

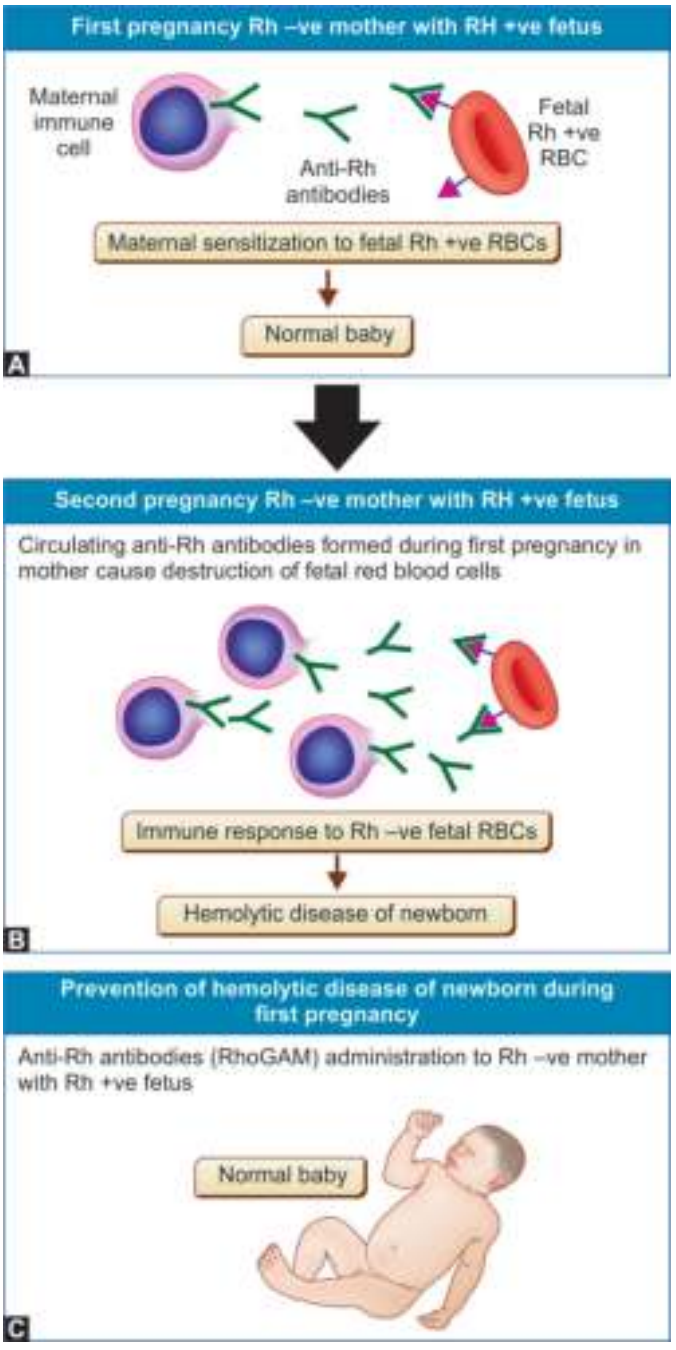

Fig. 12.8A to C: Pathogenesis of hemolytic disease of newborn and its prevention.

BOMBAY PHENOTYPE AND PARA-BOMBAY PHENOTYPE

Bombay phenotype persons lack H substance on the surface of RBCs and anti-H in their secretions. There are some individuals, who appear to be Bombay phenotype, but have very small amounts of A and/or B antigen on the surface of RBCs.

BOMBAY PHENOTYPE

Bombay blood group is a rare blood group reported by Dr YM Bhende in 1952 in India. **Bombay phenotype results from hh and sese genotypes**.

These individuals lack H substance on the surface of RBCs and anti-H in their secretions. Their RBCs and secretions also lack A and/or B antigens, because there is no H substance to be converted to A and/or B antigens.

- Red blood cells of Bombay phenotype appear to be group O in ABO blood grouping analysis.
- Bombay phenotype has autosomal recessive pattern of inheritance due to mutation of H gene on chromosome 19 that leads to synthesis of non-functional H-glycosyltransferase. Their serum contains anti-A and anti-H antibodies, which react with all with O blood group. These persons are nonsecretors and not demonstrated in body fluids.

PARA-BOMBAY PHENOTYPE

There are some individuals who appear to be Bombay phenotype, but have very small amounts of A and/or B antigens on their red blood cells. It was discovered that their genotype is hh but they possess at least one Se gene. The Se gene synthesizes a fucosyltransferase that acts on type 1 precursor substance in fluids and secretions.

- The H substance type 1 formed by the Se gene can be converted into A and/or B antigens depending on which ABO genes are inherited.
- Red blood cell membrane of para-Bombay individuals lacks intrinsic A, B, or H antigens, because the type 2 precursor substance on their RBCs remains unconverted due to lack of H gene.

OTHER BLOOD GROUP SYSTEMS

Blood group systems other than ABO Rh are Lewis, Kell, MNS, Duffy, P, Kidd, Lutheran, Yt, Dombròck, Diego, Colton, Indian, XG, Landsteiner-Wiener and John-Milton Hagen systems. Lewis, Kell, MNS, Duffy, P, Kidd blood group systems are given in Table 12.10.

Table 12.10 Lewis, Kell, MNS, Duffy, P, Kidd blood group systems

Blood Group System	Gene Locus	Antigens	Antibodies	Comments
Lewis blood group system	Lewis (Le) gene on chromosome 19 codes for fucosyltransferase	Present on glycosphingolipids (integral part of RBC)	IgM (not crossing placenta, hence does not cause hemolytic disease of newborn)	Lewis antigens present in plasma are passively adsorbed on RBCs
Kell blood group system	Kell locus on chromosome 7p23	Present on surface of RBC	IgG (crossing placenta, hence causing hemolytic disease of newborn)	▪ Acute hemolytic blood transfusion reaction (10%) ▪ Anemia but no hemolysis in hemolytic disease of newborn ▪ Some persons express weak Kell antigens resulting in McLeod syndrome characterized by acanthocytes, progressive cardiomyopathy, muscle wasting and neurological disorders
MNS blood group system	MNS genes created by swapping of DNA between GYPA and GYPB genes lying close together on chromosome 4	MN antigens present on glycophorin A, while S antigen on glycophorin B on surface of RBC	IgM	▪ Hemolytic blood transfusion reaction in rare case ▪ Hemolytic disease of newborn is rare case ▪ Anti-M and anti-N antibodies are rarely associated with transfusion reactions ▪ Anti-S antibody is formed following sensitization to transfusion and determined by indirect Coombs' test
Duffy blood (Fy) group system	Duffy antigens are resistant to *Plasmodium vivax*	Fya and Fyb present in glycoprotein of RBCs	IgG (crossing placenta, hence causing hemolytic disease of newborn)	▪ Anti-Fya more common ▪ Hemolytic blood transfusion reaction in occasional case

Contd...

Table 12.10 Lewis, Kell, MNS, Duffy, P, Kidd blood group systems (*Contd...*)

Blood Group System	Gene Locus	Antigens	Antibodies	Comments
				▪ Hemolytic disease of newborn in occasional case ▪ *Plasmodium vivax* is commonly seen in Duffy negative antigen
P blood group system	P blood group system represented by two chromosome loci	P1 and P2 antigens on surface of RBC most important (other antigens P+, P–, Pk)	IgG	▪ P negative persons are resistant to Parvovirus B19 infection ▪ Auto-anti-P persons are demonstrated in paroxysmal nocturnal hemoglobinuria
Kidd blood group system	Kidd/urea transporter gene	Jks on RBC	IgG	▪ Dangerous fatal ('killer Kidd') ▪ Hemolytic blood transfusion reaction in occasional case ▪ Hemolytic disease of newborn in occasional case ▪ IgG causes delayed hypersensitivity reaction and mild hemolytic disease of newborn

BLOOD COLLECTION, PROCESSING AND STORAGE

DONOR SELECTION CRITERIA

Donor selection criteria must meet safety criteria to protect both donor and recipient. Blood donor must have age 17–60 years, hemoglobin ≥13 g/dl for men and 12 g/dl for women, minimal donation interval of 12 weeks (16 weeks advised) and three donations per year maximum, afebrile, normal pulse and blood pressure. There should not be evidence of skin infections in antecubital fossa of both arms. Donor exclusion criteria include intravenous drug abuse, positivity for HBV, HCV, HIV, syphilis and malaria; pregnant and lactating woman due to increased iron requirement, insulin-dependent diabetes mellitus, chronic diseases related to urinary system, cardiovascular system, respiratory system and central nervous system. Donor selection and exclusion criteria are given in Table 12.11.

BLOOD DONATION PROCESS

Under aseptic conditions, large 16 gauze needle is used to puncture antecubital vein and ensure uninterrupted continuous blood flow in a span of 8 minutes. Approximately 30% of donors during donation process may develop local or systemic complications.

- Local adverse effects include pain, hematoma, accidental arterial puncture, thrombophlebitis, allergic rash and infection.

Table 12.11 Donor selection and exclusion criteria

Donor Selection Criteria
▪ Age 17–60 years ▪ Weight >50 kg ▪ Hemoglobin ≥13 g/dl for men and ≥12 g/dl for women ▪ Hematocrit ≥38% ▪ Temperature ≤37.50°C (afebrile) ▪ Minimal donation interval of 12 weeks (16 weeks advised) and three donations per year maximum ▪ Pulse rate 50–100 beats/minute without pathological abnormalities or <50 beats/minute in athletes ▪ Normal blood pressure
Donor Exclusion Criteria
▪ Donor showing positivity for HBV, HCV, HIV, syphilis and malaria ▪ Intravenous drug abuse ▪ Pregnant and lactating woman due to increased iron requirement ▪ Donation deferred for nine months post-pregnancy ▪ Insulin-dependent diabetes mellitus ▪ Cardiovascular diseases including hypertension ▪ Significant respiratory disorders ▪ Epilepsy and another CNS disorders ▪ Chronic renal disease ▪ Defer blood donation for six months after body piercing or tattoo, after acupuncture ▪ Defer blood donation for two months after vaccinations, e.g. measles, mumps ▪ Exclusion of any donor returning to driving bus, plane or heavy machine or crane operator, mining because delayed faint would be dangerous

- Systemic complications include vasovagal shock, syncope, nausea, vomiting, fatigue, cerebral stroke and myocardial infarction.
- Each blood donation removes 200–250 g of iron. Blood collected in >8 minutes is unsuitable for preparation of blood components such as platelet concentrate, fresh frozen plasma and cryoprecipitate. Blood bag should be stored at 20–25°C within 6–8 hours of collection for harvesting platelets.
- Double pack system is used to prepare red blood cells and plasma under sterile closed system conditions.
- Triple pack system is used to prepare red blood cells, platelet concentrate and fresh frozen plasma.
- In quad pack system, the blood collection center prepares a unit of red blood cells and divides it into four bags with equal volume under sterile closed system conditions used for pediatric and neonatal multiple blood transfusions in these patients.

ANTICOAGULANT PRESERVATIVES USED IN BLOOD BANK

In India, blood collection, processing, storage and preparations of blood components are regulated by Food and Drug Administration (FDA).

- Anticoagulants are used to prevent the activation of coagulation factors and to maintain blood in the liquid state for blood transfusion. Blood bags also contain preservatives that extend the shelf-life of the blood components.
- The anticoagulant preservative solutions approved in the blood bank include citrate-phosphate-dextrose (CPD), citrate-phosphate-dextrose-dextrose (CP2D), acid-citrate-dextrose (ACD), and citrate-phosphate-dextrose-adenine solution 1 (CPDA-1).
- Constituents of approved blood bank anticoagulant preservative solutions are given in Table 12.12. Contents of anticoagulant preservative solutions are given in Table 12.13.

ACID-CITRATE-DEXTROSE

Acid-citrate-dextrose (ACD) contains trisodium citrate (22 g), citric acid (8 g), and dextrose (24.5 g) dissolved in 1000 ml of distilled water with initial pH 5.6. Each blood bag of 450 ml contains 67.5 ml of ACD preservative. Initial pH of preservative is 5.6. Initial pH of blood bag on first day is 7. Storage time of blood bag is 21 days at 2–6°C.

CITRATE-PHOSPHATE-DEXTROSE

Citrate-phosphate-dextrose (CPD) contains trisodium citrate (26.30 g), citric acid (3.27 g), dextrose (25.5. g), and monobasic sodium phosphate (2.22 g) dissolved in 1000 ml of distilled water with initial pH 5.6. Each blood bag of 450 ml contains 63 ml of preservative. Initial pH of preservative is 5.6. Initial pH of blood bag on first day is 5.6. Storage time of blood bag is 21 days at 2–6°C.

CITRATE-PHOSPHATE-DEXTROSE-ADENINE 1

Citrate-phosphate-dextrose-adenine 1 (CPDA-1) contains trisodium citrate (26.35 g), citric acid (3.27 g),

Table 12.12 Constituents of approved blood bank anticoagulant preservative solutions

Constituents of Anticoagulant Preservative Solutions	Purpose	Blood Bank Preservative
Sodium citrate	Sodium citrate binds calcium and prevents coagulation cascade	▪ Citrate-phosphate-dextrose (CPD) ▪ Citrate-phosphate-dextrose-dextrose (CP2D) ▪ Acid-citrate-dextrose (ACD) ▪ Citrate-phosphate-dextrose-adenine 1 (CPDA-1)
Citric acid	Citric acid slows down glycolysis that occurs through cell metabolism	▪ Citrate-phosphate-dextrose (CPD) ▪ Citrate-phosphate-dextrose-dextrose (CP2D) ▪ Acid-citrate-dextrose (ACD) ▪ Citrate-phosphate-dextrose-adenine 1 (CPDA-1)
Dextrose	Dextrose supports generation of adenosine triphosphate (ATP) by glycolytic pathways for cell metabolism	▪ Citrate-phosphate-dextrose (CPD) ▪ Citrate-phosphate-dextrose-dextrose (CP2D) ▪ Acid-citrate-dextrose (ACD) ▪ Citrate-phosphate-dextrose-adenine 1 (CPDA-1)
Monobasic sodium phosphate	Monobasic sodium phosphate (buffer) maintains pH of blood bags	▪ Citrate-phosphate-dextrose (CPD) ▪ Citrate-phosphate-dextrose-dextrose (CP2D) ▪ Citrate-phosphate-dextrose-adenine 1 (CPDA-1)
Adenine	Adenine maintains ATP levels during cell metabolism, thus extending shell-life of red blood cells to 42 days	Citrate-phosphate-dextrose-adenine 1 (CPDA-1)

Table 12.13 Contents of anticoagulant preservative solutions

Contents of Preservative Solutions	Anticoagulant Preservatives used in Blood Bank			
	Anticoagulant-Citrate-Dextrose (ACD)	Anticoagulant-Citrate-Phosphate-Dextrose (CPD)	Anticoagulant-Citrate-Phosphate-Dextrose-Dextrose (CP2D)	Anticoagulant-Citrate-Phosphate-Dextrose-Adenine 1 (CPDA-1)
Trisodium citrate	22.0 g/L	26.3 g/L	26.3 g/L	26.3 g/L
Citric acid	8.0 g/L	3.7 g/L	3.7 g/L	3.7 g/L
Monobasic sodium phosphate	Nil	2.22 g/L	2.22 g/L	2.22 g/L
Dextrose	24.5 g/L	24.5 g/L	51.1 g/L	31.9 g/L
Adenine	Nil	Nil	Nil	0.275 g/L
Distilled water	1000 ml	1000 ml	1000 ml	1000 ml

Initial pH of prepared anticoagulant preservative	5.6	5.6	5.6	5.6
Initial pH of anticoagulant preservative in blood bag on first day	7.0	7.2	7.2	7.3
Shelf life	21 days	21 days	21 days	35 days

dextrose (31.9 g) and monobasic sodium phosphate (2.22), and adenine (0.27 g) dissolved in 1000 ml of distilled water with initial pH 5.6. Initial pH of preservative is 5.6. Each blood bag of 450 ml contains 63 ml of CPDA-1 preservative. Initial pH of blood bag on first day is 7. Storage time of blood bag is 42 days at 6°C.

PREPARATION OF BLOOD COMPONENTS FROM WHOLE BLOOD

Whole blood is collected from a donor into a plastic bag containing anticoagulant preservative. The volume of the anticoagulant preservative in the collection bag varies based on the target amount for whole blood collection volume in order to maintain appropriate ratio of the anticoagulant preservative to the whole blood.

- Generally, 63 ml of anticoagulant preservative is used to collect a target volume of 450 ml of whole blood. The blood collection set also includes a number of satellite containers also known as satellite collection bags that are integrally attached to the main collection bag with hollow tubing.
  - Satellite collection bags become storage sites for the blood components prepared from whole blood.
  - The entire closed system prevents bacterial contamination of blood from outside environment. Blood component preparation and donor blood processing may occur simultaneously. Processing of whole blood units from collection to labeling is shown in Fig. 12.9.
- Separation of whole blood into blood components is also moderately expansive. Due to different specific gravity of blood components, these are separated by

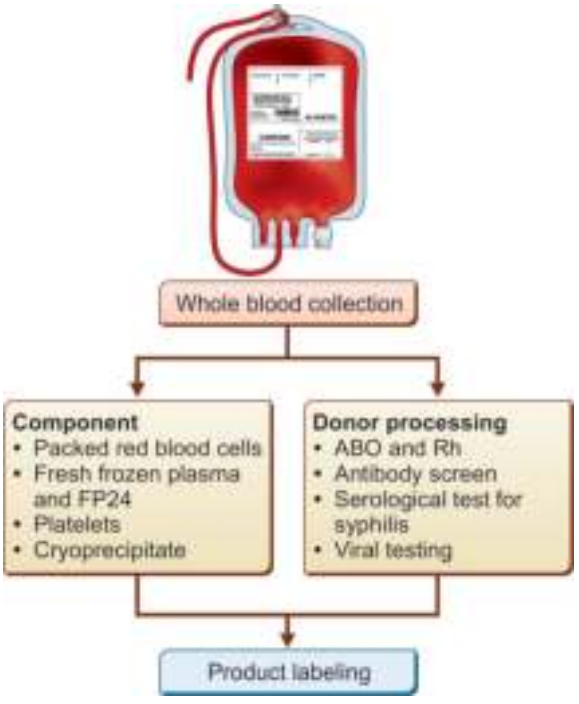

Fig. 12.9: Processing of whole blood units from collection to labeling.

centrifuging blood bag at different centrifugal force for different time. Packed red blood cells are obtained and stored at 1–6°C. Plasma containing platelets are obtained and centrifuged.

- Separated plasma is stored at <18°C. Separated platelet concentrate is stored at 20–40°C. Fresh frozen plasma is prepared within twenty-four hours and used to prepare cryoprecipitate, immunoglobulin, albumin and coagulation factor concentrate. Preparation of plasma products from whole blood is shown in Fig. 12.10.
- Each unit of blood (450 ml) contains 65 g of hemoglobin, 225 mg of iron, platelets and coagulation factors. Coagulation factors V and VIII begin to deteriorate within an hour of blood collection. Refrigerated red blood cells are viable up to six weeks.
- Production of red blood cell component, plasma, buffy coat pool and pooled platelet component is shown in Fig. 12.11.
- Preparing blood components from whole blood allow multiple patients to benefit from a single blood donation unit. Production of red blood cell component, platelet-rich plasma, fresh frozen plasma, plasma cryoprecipitate reduced and cryoprecipitate antihemophilic factor from whole blood is shown in Fig. 12.12.

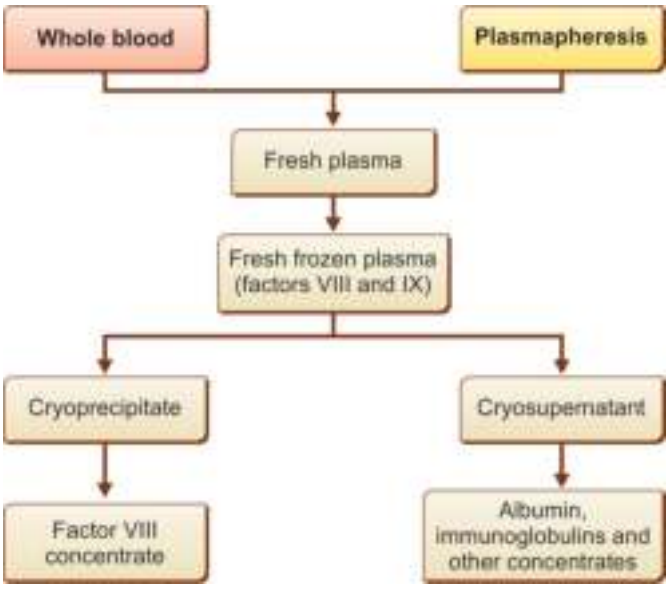

Fig. 12.10: Preparation of plasma products from whole blood.

WHOLE BLOOD COMPOSITION

Whole blood contains plasma and cellular component, which is not commonly used anymore because most patients do not require all the elements in the whole blood. Fresh whole blood is sometimes used by defense

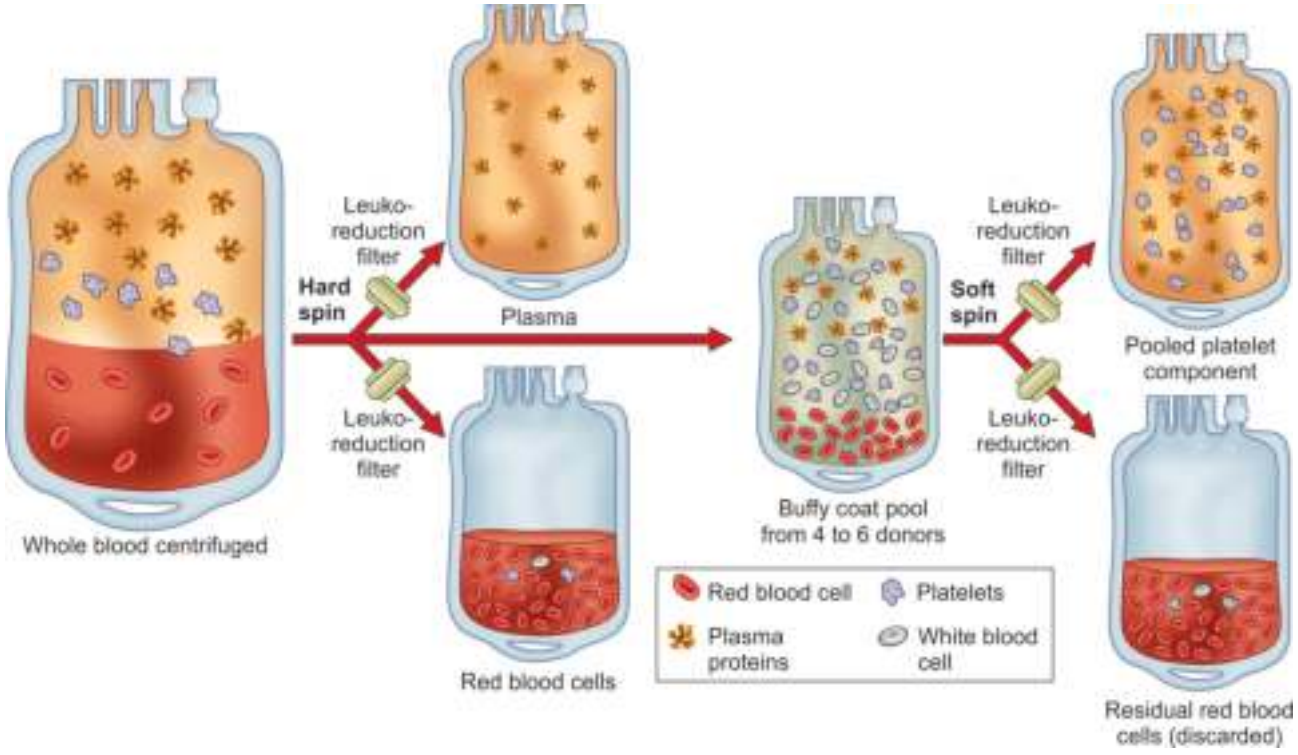

Fig. 12.11: Production of RBC component, plasma and buffy coat is done by hard spin and using leukoreduction filter. Buffy coat pool from 4 to 6 donors is centrifuged with soft spin by using leukoreduction filter to prepare pooled platelet component.

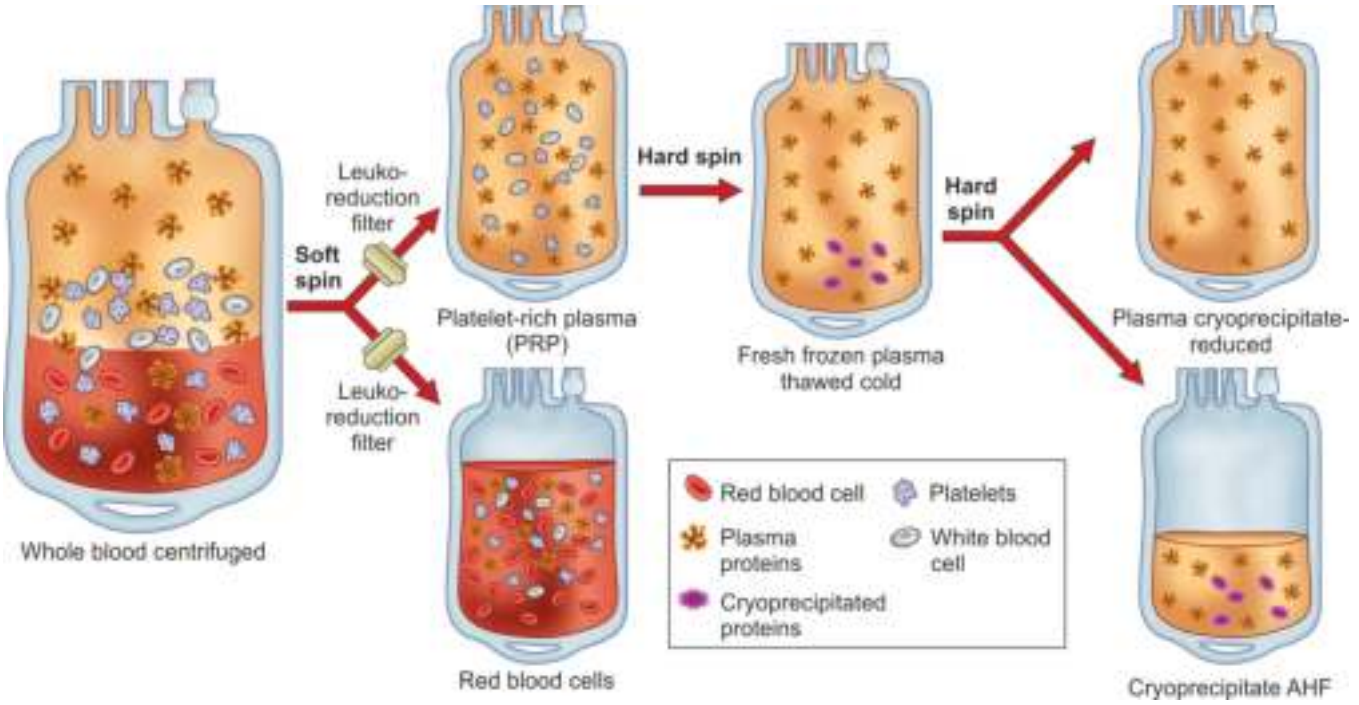

Fig. 12.12: Production of RBC component and platelet-rich plasma is prepared by centrifuging whole blood with soft spin and using leukoreduction filter. Platelet-rich plasma is centrifuged with hard spin to prepare fresh frozen plasma, plasma cryoprecipitate-reduced and cryoprecipitate antihemophilic factor.

forces in cases of requiring massive blood transfusion support.

RED BLOOD CELL COMPONENT

Red blood cell component is prepared by centrifuging whole blood in large centrifuge. Centrifugation results in settling of heaviest cellular components at the bottom of the collection bag and lighter components at the top. In general, RBCs tend to settle at the bottom of the container followed by white blood cells and platelets, which settle at top of the RBC layer.

- After centrifugation, the blood unit is placed into a device known as a 'plasma press' also known an expressor. Once the plasma has been pressed, the resultant RBCs and plasma bags are separated by using a tubing sealer. Tube sealers ensure the closure of the system for maintenance of sterility.
- RBC component in blood bag has volume of 225–350 ml and hematocrit of 65–80%. Transfusion of one unit of RBC component increases 1 g/dl in recipient, who is not actively bleeding.
- Typical RBC component unit prepared from whole blood contains 50–80 g of hemoglobin.

PLASMA COMPONENT

Plasma separated from whole blood can be used depending on the collection, processing and storage conditions.

- Plasma is frozen to preserve the activity of labile coagulation factors such as factor V and factor VIII. Stored frozen plasma must be thawed prior to transfusion.
- Fresh frozen plasma can be further processed to produce cryoprecipitate containing antihemophilic factor (factor VIII).
- On a large scale, plasma from 2500 donors are pooled and treated with solvent/detergent solution, which inactivates lipid-enveloped viruses such as hepatitis B virus (HBV), human immunodeficiency virus (HIV) and cytomegalovirus (CMV). Viruses without envelops are not inactivated by solvent/detergent and hence treated with second process to inactivate them.
- The pooled plasma is stored frozen into 200 ml bags. The process leads to slight reduction in all coagulation system proteins. But its use is similar to fresh frozen plasma. Plasma can be separated into individual proteins such as immunoglobulin, albumin and specific coagulation factors. Preparation of plasma cryoprecipitate-reduced and cryoprecipitate containing antihemophilic factor is shown in Fig. 12.13. Plasma fractionation process is used to prepare immunoglobulin, albumin and coagulation factor concentrate from plasma pool as shown in Fig. 12.14.

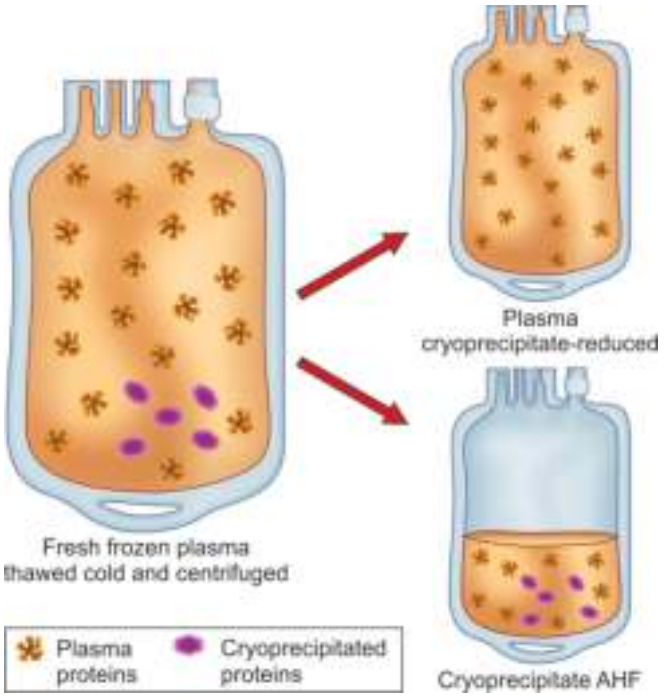

Fig. 12.13: Preparation of plasma cryoprecipitate-reduced and cryoprecipitate containing antihemophilic factor by thawing and centrifuging fresh frozen plasma.

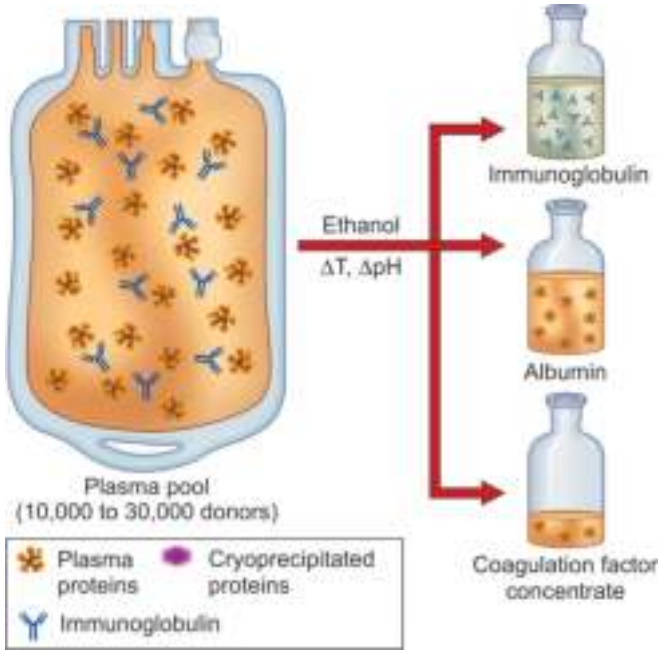

Fig. 12.14: Plasma fractionation process is used to prepare immunoglobulin, albumin and coagulation factor concentrate from plasma pool of 10,000 to 30,000 donors.

PLATELET COMPONENT

Platelet function is impaired following storage at colder temperature. Therefore, donated blood bags must be maintained at room temperature during all stages of collection, storage and production of platelet component. Platelet components are prepared by platelet-rich plasma (**PRP**) and buffy coat methods.

Platelet-rich Plasma Method to Prepare Platelet Component

Platelet-rich plasma method produces single platelet component from single whole blood donated bag. It is achieved by centrifuging the whole blood at low relative centrifugal force. Soft centrifugal spin produces platelet-rich plasma. Hard spin leads to platelets concentrate. Platelet-rich plasma is obtained by resuspension of aggregated platelets into supernatant plasma. Production of platelet-rich plasma component by centrifuging whole blood by soft centrifuge spin is shown in Fig. 12.15. Production of platelet component and plasma by centrifuging platelet-rich plasma with hard centrifuge spin is shown in Fig. 12.16.

- **Advantages of platelet-rich plasma method:** Platelet-rich plasma is used in pediatric age group. RBCs are not lost during the processing.
- **Disadvantages of platelet-rich plasma method**: Concentrated platelets into pellet causes platelet activation and platelet aggregation. Soft centrifugal force of whole blood traps a significant amount of plasma and platelets into the red blood cell layer.

Buffy Coat Method to Prepare Platelet Component

Buffy coat method produces a pool of platelets from four to six whole blood donated bags. Hard centrifugal spin

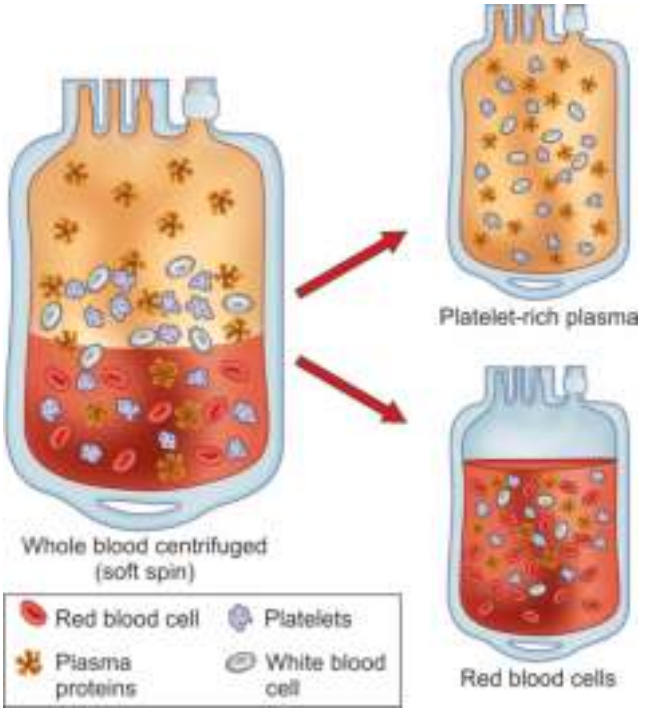

Fig. 12.15: Production of platelet-rich plasma component from whole blood by soft centrifuge spin.

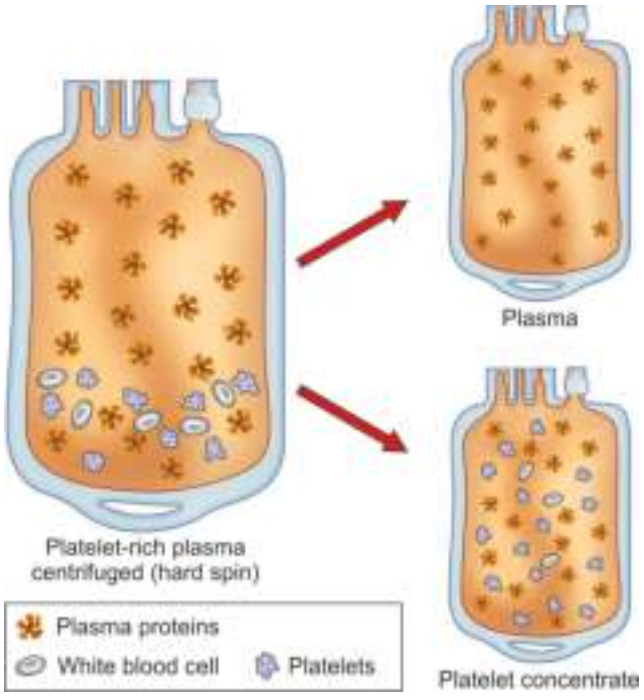

Fig. 12.16: Production of platelet component and plasma by centrifuging platelet-rich plasma with hard centrifuge spin.

is used to concentrate platelets in the buffy coat layer. Pooling and soft centrifugal spin is used to remove RBC contamination. Production of RBC component, plasma and buffy coat pool of platelets by centrifuging with hard spin of whole blood obtained from 4 to 6 donors is shown in Fig. 12.17. Production of pooled platelet component by centrifuging buffy coat pool with soft centrifuge spin of the buffy coat pool obtained from 5 to 6 donors is shown in Fig. 12.18.

- **Advantages of buffy coat method:** Concentrating platelets in the buffy coat layer reduce platelet activation resulting in better platelet quality. Hard centrifugal spin of whole blood minimizes the amount of plasma and platelets trapped in the red blood cell layer.
- **Disadvantages of buffy coat method:** Pooled product is not ideal for pediatric age group. Some RBCs are lost in the buffy coat. Buffy coat method requires the use of specialized equipment such as semi-automated plasma press and sterile docking device.

GRANULOCYTE COMPONENT

Granulocyte component is usually not prepared from whole blood. Apheresis technique is used to achieve higher number of granulocytes. Granulocytes component can be prepared from whole blood by isolating the buffy coat. Hydroxyethyl starch (**HES**), is a precipitating agent added to the whole blood and then the blood bag is left to settle by gravity. The plasma and buffy layer are then extracted into satellite container using manual or semiautomatic press. The satellite container is then centrifuged using hard spin to concentrate the granulocytes. Granulocyte component prepared from the whole blood contains 1.25×10^9 granulocytes.

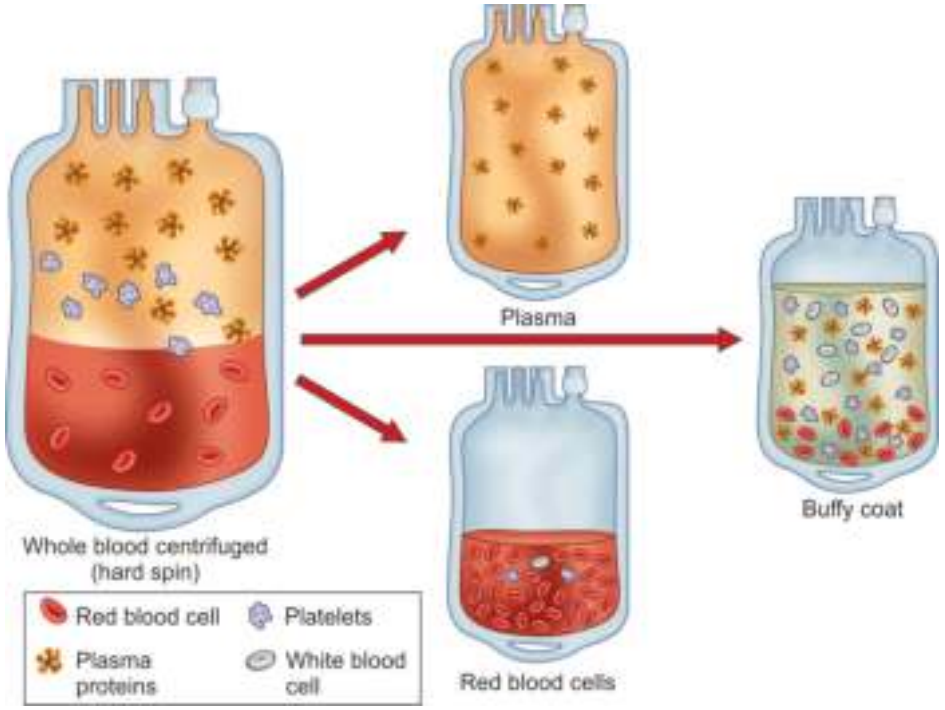

Fig. 12.17: Production of RBC component, plasma and buffy coat pool of platelets by hard centrifuge spin of whole blood obtained from 4 to 6 donors.

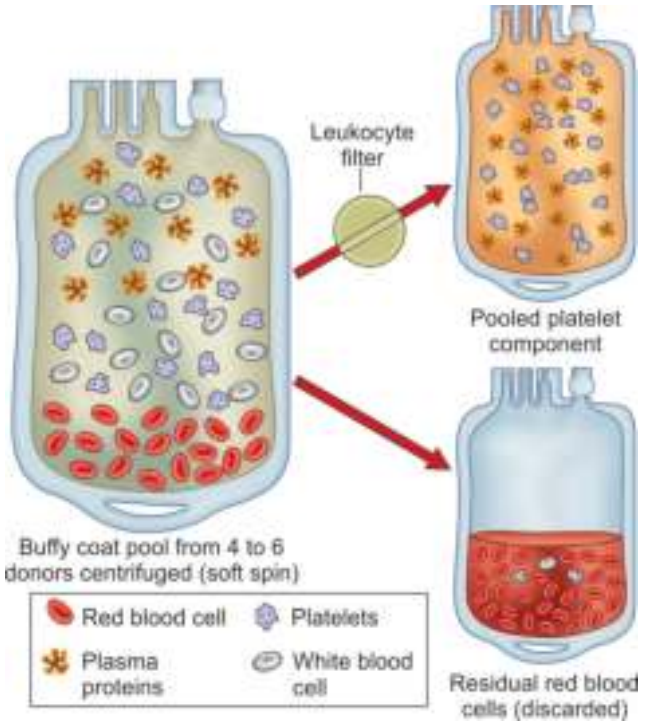

Fig. 12.18: Production of pooled platelet component by centrifuging buffy coat pool with soft centrifuge spin of the buffy coat pool obtained from 5 to 6 donors.

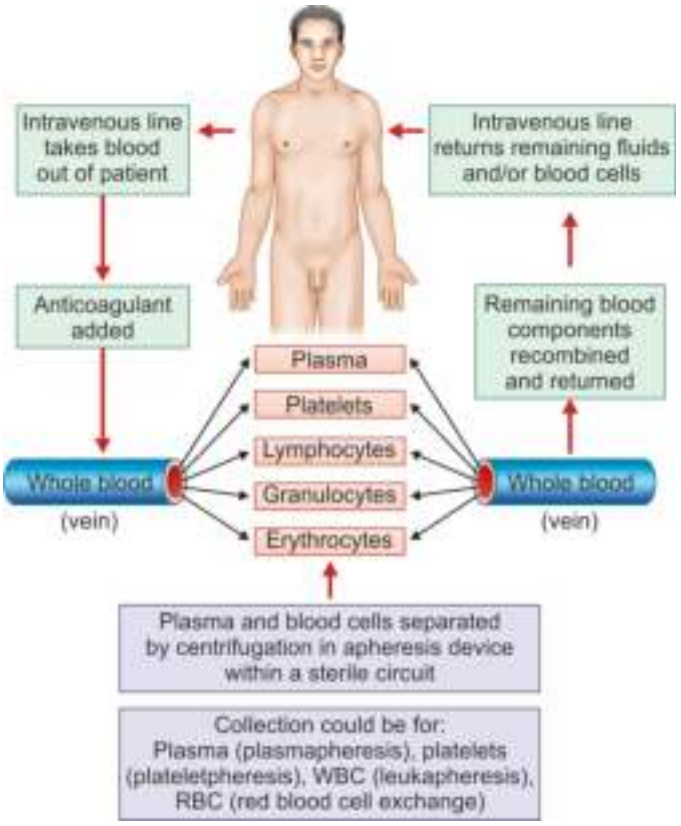

Fig. 12.19: Principle of apheresis: Apheresis is a technique by which a particular blood component is removed from the whole blood by using machine, and the main volume is returned back to the donor through the same collection line.

REMOVAL OF BLOOD COMPONENTS BY APHERESIS

Apheresis is a technique by which particular blood component is removed from the whole blood by using machine, and the main volume is returned back to the donor through the same collection line. The separation of the blood components is based on the specific gravity of each individual blood constituent. The entire process occurs in a closed system. Principle of apheresis is shown in Fig. 12.19. Intravenous line takes blood out of patient.

- Anticoagulant is added to prevent coagulation in the machine used for apheresis. The anticoagulated blood is centrifuged, distinct layers develop with the heavier red blood cells at the bottom and the lighter plasma portion at the top. Between these two layers, a small layer is known as buffy coat composed of white blood cells and platelets. Sedimented blood sample shows various blood constituents is shown in Fig. 12.20.
- Most apheresis machines use centrifugation to separate the various whole blood components. Collection set consisting of centrifuge bowl is loaded into a machine.
  - The donor is attached to the collection set through phlebotomy. As the machine rotates the centrifuge bowl, whole blood is drawn into the bowl and then mixed with acid-citrate-dextrose (ACD) anticoagulant preservative.
  - When the centrifuge bowl reaches capacity, the machine increases rate of rotation to optimal centrifugation speed resulting in separation of the whole blood into components.
  - The selected component is collected into container. The remainder of the donation is returned back to the donor through same collection tube.
- Membrane filtration technology can also be used to separate blood components. Membrane separators have specific size of pores, which separate specific blood component. Remaining blood constituents are returned back to the donor.
- Apheresis is used to collect plasma, platelet, RBCs and granulocytes. Fresh frozen plasma and cryoprecipitate are prepared whole blood. Procedures of apheresis are given in Table 12.14.

COLLECTION OF RED BLOOD CELLS BY APHERESIS

Collection of RBCs by apheresis is termed **erythropheresis**. RBCs are collected as a double unit.

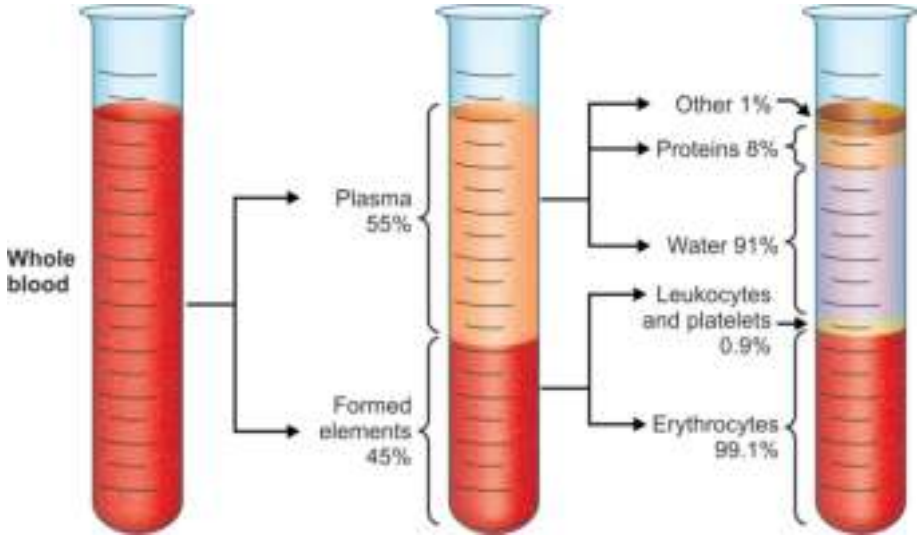

Fig. 12.20: Sedimented blood sample shows various blood constituents.

Table 12.14 Procedures of apheresis

Procedure	Blood Component Removed
Plasmapheresis (plasma exchange)	Removal of plasma
Plateletpheresis	Removal of platelets
Leukapheresis	Removal of white blood cells (e.g. granulocytes and lymphocytes)
Erythrocytapheresis	Removal of red blood cells
Hematopoietic progenitor cells (HPCs) apheresis	Hematopoietic progenitor cells (HPCs) also known as peripheral blood stem cells

- Double RBC apheresis components can be collected from one donor if the donor meets eligibility requirements and no other apheresis components are collected during the same donation. Depending on the instrument used, plasma and platelets are returned back to the donor. The period between two units of red blood cells obtained by erythropheresis from the donor is 16 weeks.
- The red blood cells are transfused back to the donor in near future for clinical management. It reduces exposure to other donor red blood cells. Each unit contains about 60 g of hemoglobin per component.

COLLECTION OF PLASMA BY APHERESIS

Collection of plasma by apheresis is termed **plasmapheresis**. Maximum volume of plasma obtained by plasmapheresis is 600 ml. In plasmapheresis, whole blood from the donor is centrifuged. The plasma is diverted into a collection bag. The cellular components (red blood cells, platelets, white blood cells) are returned back to the donor.

- The plasmapheresis process allows to collect large volume of plasma. The plasma can be used as fresh frozen plasma (FFP). Plasma can be collected from donors with high titers of antibodies against infections as hepatitis B virus, cytomegalovirus and herpes zoster to prepare immunoglobulin. These immunoglobulins are administered to provide prophylaxis against these infectious agents.
- Plasmapheresis is used to collect plasma for further manufacturing of various products such as intravenous immunoglobulin (**IVIg**), hepatitis immunoglobulin and Rh immunoglobulin. Donors undergoing frequent plasmapheresis must be evaluated periodically to analyze total proteins, serum electrophoresis and measurement of immunoglobulin levels.

COLLECTION OF PLATELETS BY APHERESIS

In plateletpheresis procedure, platelets along with a portion of plasma (100–500 ml) are removed and remaining red blood cells, white blood cells and major portion of plasma are returned back to the donor. Platelets are suspended in the donor plasma in the collection bag designed for platelet storage. A routine plateletpheresis takes 45–90 minutes.

- Prior to plateletpheresis, it is essential to analyze donor's platelet count. Donor should have at least 1,50,000/µl.

- Minimal acceptable platelet count in platelet component is 3,00,000/μl. Plateletpheresis should not be performed on donors taking medicines that interfere with the functioning of the platelets. Plateletpheresis should be performed after every seven days.

COLLECTION OF GRANULOCYTES BY APHERESIS

Granulocyte transfusion is beneficial in patients with **neutropenia** induced by chemotherapeutic agents. Patient with neutropenia unresponsive to antibiotics and antifungal drugs need granulocyte transfusion. Granulocyte transfusion has favorable results in the treatment of neutropenic neonates with sepsis.

- Collection of granulocytes by leukapheresis provides a high yield. A minimum of therapeutic dose of granulocyte component is 1×10^{10} per day. During centrifugation of whole blood, granulocytes are present in the buffy coat between red blood cells and plasma. Leukocyte depletion filter should not be used. A standard blood administration filter is sufficient for leukapheresis.
- Adding the red blood cell sedimenting agent, e.g. hydroxyethyl starch (**HES**) allows demarcation of layers resulting in improved granulocyte yield. During leukapheresis, some quantity of hydroxyethyl starch may enter donor blood circulation, which is cleared by reticuloendothelial system. Side effects of hydroxyethyl starch include expansion of circulatory volume, headache and peripheral edema.
- Granulocytes collected by leukapheresis contain large number of viable lymphocytes. Transfusion of lymphocytes in severely immunocompromised patient, there is significant risk for graft-versus-host disease (**GVHD**). Therefore, it is essential to irradiate leukocyte product prior to transfusion.
- Donor may be administered hematopoietic growth factors (**G-CSF**) or corticosteroids or hydroxyethyl starch (**HES**) to increase the number of granulocytes. The granulocytes can be collected. The minimum number of granulocytes is 1×10^{10} per granulocyte component. Drugs used in leukapheresis are given in Table 12.15.

Table 12.15 Drugs used in leukapheresis

Drugs	Actions
Hydroxyl starch	Hydroxyl starch that permits enhanced granulocyte harvest
Corticosteroids (i.e. prednisone, dexamethasone)	Corticosteroids mobilize granulocytes from the marginal pool, thus increasing harvest
Growth factors (i.e. colony stimulating factors)	Colony stimulating factor increases granulocyte yields

THERAPEUTIC APHERESIS

Therapeutic apheresis is based on existence of pathogenic substance in the blood that contributes to a disease process and its symptoms; and removal of the substance by apheresis.

- Pathogenetic substance is removed from the body by apheresis and remaining blood constituents are returned back.
- Therapeutic apheresis has become a standard therapy for many hematologic, renal, metabolic, autoimmune and other disorders.
- Therapeutic apheresis is accepted as a relatively safe procedure. But adverse effects may be observed in therapeutic procedures.
- Adverse effects of therapeutic apheresis include citrate toxicity, hematoma, sepsis, phlebitis, neuropathy, vasovagal reactions, hypovolemia, allergic reactions, hemolysis, depletion of coagulation factors, cardiopulmonary distress, transfusion-transmitted diseases, loss of lymphocytes and depletion of proteins and immunoglobulins.

THERAPEUTIC PLASMA EXCHANGE

Therapeutic plasma exchange (**TPE**) is the removal of undesirable harmful substances in blood circulation and retention of the plasma, with return of all the cellular components to the patient.

- Purpose of plasmapheresis is to remove the undesirable harmful agents present in the plasma such as immune complexes, alloantibodies, autoantibodies, immunoglobulins causing hyperviscosity, protein bound toxins or drugs, lipoproteins and phytanic acid. Indications of therapeutic apheresis are given in Table 12.16.

Hematology Pearls: Factors Removed by Therapeutic Plasmapheresis

- Immune complexes (e.g. systemic lupus erythematosus)
- Alloantibodies (e.g. antibody-mediated transplant rejection)
- Autoantibodies (e.g. Guillain-Barré syndrome, Goodpasture's syndrome)
- Immunoglobulins causing hyperviscosity (e.g. Waldenström's macroglobulinemia)
- Protein bound toxins and drugs (e.g. Amanita mushroom)
- Lipoproteins (e.g. familial hypercholesterolemia)
- Phytanic acid (e.g. Refsum disease involving peripheral neuropathy).

- Therapeutic plasmapheresis is performed in clinical practice in patients suffering from glomerular basement membrane disease, renal focal glomerulosclerosis, renal transplant antibody-mediated rejection, renal transplantation, HLA desensitization,

recurrent focal glomerulosclerosis, hemolytic uremic syndrome (HUS), familial hypercholesterolemia, cryoglobulinemia, thrombotic thrombocytopenic purpura, hyperviscosity associated with monoclonal gammopathy, acute inflammatory demyelinating polyneuropathy (Guillain-Barré syndrome), chronic inflammatory demyelinating polyneuropathy, Lambert-Eaton myasthenic syndrome, myasthenia gravis and paraproteinemic polyneuropathy due to IgG, IgA or IgM.

Table 12.16 Indications of therapeutic apheresis

Disorders	Procedure	Indication Category	Comments
Renal disorders			
Antiglomerular basement membrane disease	Plasma exchange	Category I	Standard and curative
Renal focal glomerulosclerosis	Plasma exchange	Category I	Standard and curative
Renal transplant antibody rejection	Plasma exchange	Category I	Standard and curative
Renal transplantation	Plasma exchange	Category I	Standard and curative
HLA desensitization	Plasma exchange	Category I	Standard and curative
Recurrent focal glomerulosclerosis	Plasma exchange	Category I	Standard and curative
Hemolytic uremic syndrome (HUS)	Plasma exchange	Category I	Standard and curative
Rapidly progressive glomerulonephritis (RPGN)	Plasma exchange	Category III	Conflicting results
Metabolic disorders			
Familial hypercholesterolemia	▪ Selection absorption ▪ Plasma exchange	▪ Category I ▪ Category II	▪ Standard and curative ▪ Supportive
Overdose or poisoning	Plasma exchange	Category II	Supportive
Acute hepatocellular failure	Plasma exchange	Category III	Conflicting results
Sepsis and multiorgan failure	Plasma exchange	Category III	Supportive
Thyrotoxicosis	Plasma exchange	Category III	Supportive
Autoimmune disorders			
Cryoglobulinemia	Plasma exchange	Category I	Standard and curative
Rheumatoid arthritis (refractory)	Immunoadsorption	Category II	Supportive
Systemic lupus erythematosus (SLE) severe	Plasma exchange	Category II	Supportive
Autoimmune hemolytic anemia (warm antibody mediated)	Plasma exchange	Category III	Conflicting results
Scleroderma (progressive systemic sclerosis)	▪ Plasma exchange ▪ Photopheresis	▪ Category III ▪ Category IV	▪ Conflicting results ▪ May be harmful
Hematologic disorders			
Thrombotic thrombocytopenic purpura	Plasma exchange	Category I	Standard and curative
Hyperviscosity associated with monoclonal gammopathy	Plasma exchange	Category I	Standard and curative
Sickle cell disease	Red blood cell apheresis	Category I	Standard and curative
Malaria or babesiosis	Red blood cell exchange	Category I	Standard and curative
Leukocytosis and thrombocytosis (symptomatic)	Cytapheresis	Category I	Standard and curative
ABO-incompatible hematopoietic stem cell transplant	Plasma exchange	Category II	Supportive
Cutaneous T cell lymphoma	Photopheresis	Category II	Supportive
Red blood cell alloimmunization in pregnancy (if intrauterine transfusion in not available)	Plasma exchange	Category II	Supportive
Aplastic anemia	Plasma exchange	Category III	Supportive
Post-transfusion purpura	▪ Plasma exchange ▪ Immunoadsorption ▪ Plasma exchange	▪ Category III ▪ Category III ▪ Category IV	▪ Supportive ▪ Supportive ▪ May be harmful

Contd...

Table 12.16 Indications of therapeutic apheresis (*Contd...*)

Disorders	Procedure	Indication Category	Comments
Neurological disorders			
Acute inflammatory demyelinating polyneuropathy (Guillain-Barré syndrome)	Plasma exchange	Category I	Standard and curative
Chronic inflammatory demyelinating polyneuropathy	Plasma exchange	Category I	Standard and curative
Lambert-Eaton myasthenic syndrome	Plasma exchange	Category I	Standard and curative
Myasthenia gravis	Plasma exchange	Category I	Standard and curative
Paraproteinemic polyneuropathy due to IgG, IgA or IgM	Plasma exchange	Category I	Standard and curative
Pediatric autoimmune neuropsychiatric disorder associated with streptococci (PANDAS)	Plasma exchange	Category I	Standard and curative
Paraproteinemic polyneuropathy due to multiple myeloma	Plasma exchange	Category II	Supportive
Rasmussen's encephalitis	Plasma exchange	Category III	Supportive

- IgM is distributed in the intravascular compartment, and IgG in intravascular and extravascular compartments. Therefore, therapeutic plasmapheresis performed to remove IgG antibodies is most effective when combined with immunosuppressive drugs. A large volume of plasma (maximum 600 ml) must be removed during therapeutic plasmapheresis and replaced with sufficient physiologic fluid to maintain the intravascular compartment.

THERAPEUTIC LEUKAPHERESIS

Therapeutic leukapheresis has been widely used to treat patients with very high leukocyte count of >100,000/µl. High leukocyte count causes organ dysfunction due to formation of microthrombi in cerebral and pulmonary circulation.

- Leukocytosis is more common in acute myelogenous leukemia (AML) than acute lymphoblastic leukemia (ALL). Single procedure of therapeutic leukapheresis should reduce the leukocyte count by 30–60%.
- However, more than one procedure is essential to mobilize leukocytes from the extracellular compartment. About one liter of fluid is lost in the therapeutic leukapheresis, hence these patients require fluid replacement.

THERAPEUTIC ERYTHROCYTAPHERESIS

Therapeutic erythrocytapheresis (red blood cell exchange) procedure removes a large number of red blood cells from the patients and returns to the patient's plasma and platelets along with compatible allogeneic donor red blood cells.

- Indication of red blood cell exchange (therapeutic erythrocytapheresis) includes sickle cell disease in order to decrease the number of hemoglobin S containing red blood cells, to prevent complications of sickle cell disease such as acute chest syndrome, painful crises and cerebral stroke. Basic aim of red blood cell exchange is to reduce the number of hemoglobin S containing red blood cells below 30%. Patient may require more than one red blood cell exchange procedure.
- The donor red blood cells selected for transfusion should be ABO and Rh compatible with the patient. Fresh red blood cells donated in last days should be preferred to transfuse the patient with sickle cell disease. Some of these patients need regular red blood cell exchange to reduce the complications of sickle cell disease. Finally, red blood cell exchange can be done to remove incompatible red blood cells from patient's blood circulation, e.g. ABO and Rh incompatibility.

THERAPEUTIC FLUID REPLACEMENT

In therapeutic fluid replacement procedures, the extracorporeal circuit (tubing, collection chamber, blood warmer) is normally primed with normal saline with an initial bonus of crystalloid. It is important to maintain intravascular volume and oncotic pressure. Human serum albumin may be administered as 5% solution. The use of fresh frozen plasma may be reserved for treatment of thrombotic thrombocytopenic purpura (TTP) and preexistent coagulopathy.

HEMATOPOIETIC PROGENITOR CELLS COLLECTION

Hematopoietic progenitor cells (**HPCs**) are also known as peripheral blood stem cells (**PBSCs**), which can be collected by apheresis from an autologous or allogeneic donor. After centrifuging blood, HPCs are found in the upper portion of the **buffy coat**. Large volumes of blood are processed to obtain the required yield.

- Donor may be administered hematopoietic growth factors (G-CSF) or corticosteroids or hydroxyethyl starch (HES) to increase the number of PBSCs.
- Hematopoietic progenitor cells express the cell surface glycoprotein CD34+, and measurement of CD34+ in the peripheral blood prior to collection is performed to ensure adequate mobilization of HPCs has taken place.
- Hematopoietic growth factors (G-CSF) should be administered four to five times to mobilize sufficient HPCs. Collection of PBSCs is done in outdoor department without the help of anesthetist.
- Peripheral blood stem cells (PBSCs) are also used for bone marrow transplantation.

IMMUNOADSORPTION/SELECTIVE ADSORPTION

Immunoadsorption/selective adsorption is alternative blood purification technique used to eliminate pathogenic antibodies.

- Plasma is removed by apheresis and then passed through an adsorption medium to remove harmful antibodies by column immunoadsorption.
- Indications for immunoadsorption include removal of high-titer ABO antibodies before ABO-incompatible renal transplantation.
- Immunoadsorption technique is also used to treat patients with either refractory idiopathic thrombocytopenic purpura, rheumatoid arthritis and familial hypercholesterolemia.
- Other uses of immunoadsorption include removal of endotoxin, bile acids, granulocytes and monocytes.

PHOTOPHERESIS

Photopheresis utilizes leukapheresis to obtain the buffy coat from the whole blood. The remaining cells are treated with 8-methoxypsoralen (8-MOP), exposed to ultraviolet A light and then reinfused into the patient. The combination of 8-methoxypsoralen and ultraviolet irradiation leads to cross-linking of leukocyte DNA resulting in apoptosis. Photopheresis is used to treat cutaneous T cell lymphoma, acute and chronic graft-versus-host disease, solid organ transplant rejection and selected immunomediated disorders.

BLOOD COMPONENT LABELING

Blood component labeling is the stage where all donation, production, and testing records available in blood banks. The label on a blood component gives all the information essential to handle the blood component appropriately, which also provides a link through the blood donation identification number, back to the original donor of blood product.

- According to International Society for Blood Transfusion (ISBT), a barcode containing the same information may be available. **Barcode scanners** are used to electronically transfer the data to the information systems. At minimum, the following information may be present. Unique identification number assigned at the time of blood donation provides back to the original donor of blood product. The blood group must consist of details of ABO group and Rh type of blood component.
- The product code provides information about type and volume of blood component, anticoagulant used; and/or the target whole blood collection volume. It is mandatory to mention expiry date of the blood component. Special tests are performed on donor cells. Tests performed on donor cells are given in Table 12.17. Sequence of testing of donated blood and confirmatory test are given in Table 12.18.

Table 12.17 Tests performed on donor cells

Tests on Donor Cells	Comments
ABO blood grouping	Resolution of ABO blood group discrepancies
Rh blood grouping	Resolution of Rh blood grouping
Antibody screening	Fresh frozen plasma cannot be prepared from donor plasma containing antibody
Serologic tests for transmission disease	Rapid plasma regain (RPR) for syphilis and antibody to *Trypanosoma cruzi*
Screening of viral diseases for transmission disease	▪ HbsAg (hepatitis B surface antigen) ▪ Hepatitis B nucleic acids ▪ Hepatitis B core antigen (anti-hepatitis B core antigen) ▪ Hepatitis C antibody (anti-HCV antibody) ▪ Hepatitis C nucleic acids ▪ HTLV-I/II antibody (human T cell lymphotrophic virus (HTLV) causes leukemia and lymphoma) ▪ Cytomegalovirus in immunodeficient patients ▪ NAT (nucleic acid testing) for HIV-RNA, HCV-RNA, West Nile RNA and HBV-DNA

Table 12.18 Sequence of testing of donated blood and confirmatory test

Pathogen	Sequence of Testing	Confirmatory Test
HIV 1, HIV 2	▪ HIV 1/2 EIA* ▪ HIV-NAT (HIV—nucleic acid testing)	▪ HIV 1 Western blot or immunofluorescence assay ▪ HIV 2 Western blot or immunofluorescence assay ▪ HIV 2 EIA
HCV	▪ EIA/ChLIA ▪ HCV-NAT (HCV—nucleic acid amplification testing)	▪ RIBA or RNA test ▪ Confirmatory NAT, demonstration of seroconversion on follow-up
HBV	▪ HBsAg EIA/ChLIA ▪ Anti-HBc EIA/ChLIA	▪ Neutralization test ▪ No license test

**Enzyme-linked immunosorbent assay also called ELISA.*

CHANGES IN STORED BLOOD COMPONENTS

Storage of blood components is essential for safe blood transfusion. As soon as blood is obtained from the donor, it starts to undergo changes that influence how its component function, e.g. red blood cells, platelets, white blood cells, plasma proteins and bacterial contamination. Some changes in stored blood components are reversible. Shelf-life of blood components to 42 days may be achieved by additive solutions containing AS-1 (Adsol), AS-3 (Nutricel) and A-5 (Optisol) admixed with dextrose, adenine, monobasic sodium phosphate, mannitol, sodium chloride, sodium citrate and citric acid in different proportions. Recently, it has been discovered that addition of potassium, magnesium and L-carnitine significantly improve platelet viability during storage. Storage conditions for blood components are given in Table 12.19.

Table 12.19 Storage conditions for blood components

Blood Component	Storage Temperature	Expiry Time from Collection
Whole blood and red blood cells, granulocytes and platelets storage		
Whole blood (ACD/CPD/CP2D anticoagulant preservative)	1–6°C	21 days
Whole blood (CPDA-1 anticoagulant preservative)	1–6°C	35 days
Red blood cells (ACD/CPD/CP2D anticoagulant preservative)	1–6°C	21 days
Red blood cells (CPDA-1 anticoagulant preservative)	1–6°C	35 days
Red blood cells (additive solution)	1–6°C	42 days
Platelets	20–24°C (continuous gentle agitation)	24 hours to 5 days
Granulocytes	20–24°C (continuous gentle agitation)	24 hours
Plasma products storage		
Fresh frozen plasma or plasma frozen within 24 hours of phlebotomy	≤–18°C	12 hours
Fresh frozen plasma or plasma frozen within 24 hours of phlebotomy after thawing	1–6°C	24 hours
Thawed plasma	1–6°C	5 days after thawing
Liquid plasma	1–6°C	5 days after expiration of whole blood
Cryoprecipitate containing antihemophilic factor	≤–18°C	12 months
Cryoprecipitate containing antihemophilic factor thawed	20–24°C	6 hours
Plasma cryoprecipitate reduced	≤–18°C	12 months
Plasma cryoprecipitate reduced and thawed	1–6°C	5 days after thawing

RED BLOOD CELL CHANGES IN STORED BLOOD

The aim of blood preservative is to provide functional and viable blood components for patients requiring blood transfusion.

- Blood stored at 2–6°C maintains optimal viability of RBCs. Normally, RBCs contain abundant 2,3-diphosphoglycerate (2,3-DPG) level, which increases delivery of oxygen to the tissues.
- Various biochemical changes affecting viability of RBCs include decrease in pH, production of lactic acid, decrease in consumption of glucose and low levels of 2,3-diphosphoglycerate (2,3-DPG).
- Many of biochemical changes in red blood cells are reversible after blood transfusion, with intracellular potassium levels returning to normal within a few hours RBC component of transfusion. Levels of ATP and 2,3-DPG are slower to return to normal; 2,3-DPG levels usually recover within 12–24 hours.
- Red blood cell membrane changes due to reduced levels of ATP may be irreversible depending on blood storage conditions. RBC storage changes are given in Table 12.20.

Hemolysis of Red Blood Cells in Stored Blood

When whole blood is collected from donor, it contains red blood cells (RBCs) of various life span. Over the time, older RBCs undergo apoptosis. When RBCs undergo apoptosis, their cell membrane ruptures resulting in release of free hemoglobin into the stored blood. The stored RBCs maintain their metabolic activity. Basic approach to improve the quality and efficacy of stored RBCs has been focussed on reducing oxidative damage to RBCs by removing oxygen at the beginning of storage and maintaining the anaerobic state throughout the storage period.

Table 12.20 Red blood cell storage changes

Features	Changes in Red Blood Cells Observed
Percentage of viable red blood cells	Decreased
Glucose	Decreased
Adenosine triphosphate (ATP)	Decreased
Lactic acid	Decreased
pH	Decreased
2,3-diphosphoglycerate (2,3-DPG)	Decreased
Oxygen dissociation curve	Shift to the left (increase in hemoglobin and oxygen affinity; less oxygen delivered to the tissues)
Plasma K^+	Increased
Plasma hemoglobin	Increased

Reduction of ATP and 2,3 Diphosphoglycerate (2,3-DPG) in Stored Blood

Normally, adenine participates in synthesis of adenosine triphosphate (ATP) resulting in increase in ATP level and shelf life of red blood cells to 42 days. Sufficient ATP is associated with the viability of red blood cells. Metabolic activity and release of oxygen cause reduction of adenosine triphosphate (ATP) and 2,3-diphosphoglycerate (2,3-DPG) in stored blood. Reduction in ATP levels leads to changes in red blood cell membrane such as reduction in RBC flexibility and their removal from circulation by reticuloendothelial system when transfused. Reduction in 2,3-DPG leads to impaired oxygen release by the red blood cells following blood trans fusion. Red blood cell membrane changes also cause intracellular potassium to leak into extracellular storage fluid. Blood stored in citrate-phosphate-dextrose with adenine 1 (CPDA-1) maintains high levels of 2,3-DPG for 10–14 days in stored blood.

Decreased pH in Stored Blood

There is increased glycolysis resulting in production of lactic acid and decline in pH in stored blood. Storage of blood at low temperature keeps the rate of glycolysis at lower limit so pH is maintained. Preservative solutions used in blood bag provide a buffering capability to minimize changes in pH and optimize the storage period. Fall in pH in stored blood leads to decrease in level of 2, 3-DPG in the RBCs resulting in impaired capacity to deliver oxygen to the tissues.

Maintenance of Stored Blood at Lower Temperature

Lower temperature at 2–6°C minimizes the growth of bacteria that might have entered the blood bag during venepuncture. Labile coagulation factors in plasma are best maintained at low temperature. Low temperature storage of blood bags slows glycolytic activity and allows the shelf life of the red blood cells component to be extended. At higher temperature, red blood cell membrane changes cause intracellular potassium to leak into extracellular storage fluid.

PLATELET CHANGES IN STORED BLOOD

Platelets are very fragile cells and adversely affected by temperature and forces applied during centrifugation resulting in changes in platelet cytoskeleton and impaired ability to aggregate in stored blood. These platelet changes are reversible in the early stage of storage of platelet component. But storage of platelet

Table 12.21 Platelet storage changes

Features	Changes in Platelets Observed
Lactate	Increased
pH	Decreased
Adenosine triphosphate (ATP)	Decreased
Morphology scores change from discoid to spherical (loss of swirling effect)	Decreased
Degranulation (β-thromboglobulin, platelet factor 4)	Increased
Platelet activating markers, e.g. P-selectin (CD62P) or CD63	Increased
Platelet aggregation	Drop in responses to some agonists

component over several days results in platelet degranulation and irreversible platelet membrane changes. Platelet storage changes are given in Table 12.21.

- Platelets have increased metabolic activity during storage. Lactic acid is produced through glucose metabolism and carbon dioxide through fatty acid metabolism. Oxygen is consumed during these activities, while pH falls and carbon dioxide levels rise. Prolonged storage of platelet component in this environment eventually leads to apoptosis.
- Preservation of viable and functional platelets depend on temperature, pH and use of plastic bag. Platelets should be stored at 20–24°C. Temperature of the platelet component plastic bag should be controlled with continuous gentle agitation in platelet incubator and agitator.
- Maintenance of pH above 6 and function of platelets are dependent on the permeability of the storage bag. New plastic blood bags made of polyolefin without plasticizer maintain pH and functions of platelets up to 7 days. It is recommended that platelets must be stored in blood bag for 5 days from the date of blood collection. The pooled platelets may be stored for 4 hours at 22–24°C before used for platelet transfusion.

WHITE BLOOD CELL CHANGES IN STORED BLOOD

Granulocytes and other white blood cells (WBCs) are fragile, which deteriorate very quickly after obtaining through blood donation.

- Rapid deterioration of WBCs can have serious consequences for preparation of other blood components from whole blood.
- When WBCs disintegrate, these release cytokines and intracellular enzymes resulting in acceleration of apoptosis of RBCs and platelets.
- The cytokines and enzymes released by white blood cells may cause serious reactions in patients when the blood components are transfused.
- Shelf life of granulocytes is 24 hours at 22–24°C, which do not require agitation. WBCs should be transfused within 3 hours of blood storage to reach to the site of inflammation.

PLASMA PROTEIN COMPONENT CHANGES IN STORED BLOOD

Most of the plasma proteins of interest in transfusion medicine are very stable in a wide range of storage conditions. However, coagulation factors V and VIII undergo degradation rapidly when plasma components are stored at temperatures above freezing.

Fresh Frozen Plasma Preparation

Shelf life of fresh frozen plasma (FFP) storage below –18°C is 12 months. After thawing, FFP may be stored at 2–6°C for 12 hours before use for transfusion. Fresh frozen plasma (FFP) contains factors VIII and IX, which is administered in patients with hemophilia A (factor VIII deficiency) and Christmas disease (factor IX deficiency). Fresh frozen plasma (FFP) contains coagulation factors I, II, VII, VIII, IX, X, XI; and vWF in the same concentration present in plasma.

Cryoprecipitate Preparation

Cryoprecipitate is a cold insoluble fraction of plasma proteins obtained from FFP, which contains coagulation factors such as fibrinogen, factor VIII, factor XIII, von Willebrand factor (vWF) and fibronectin. Cryoprecipitate can be stored at –18°C or lower temperature for 12 months. Thawed cryoprecipitate can be stored for 6 hours at 2–6°C. One unit of cryoprecipitate is 15–20 ml in volume.

BACTERIAL CONTAMINATION IN STORED BLOOD

At every step of blood collection and production of blood components are done in closed system to reduce bacterial contamination. But there is a little chance for bacterial contamination of the blood. Bacteria may

flourish in blood components under ideal conditions. Bacterial contamination accelerates the destruction of RBCs, WBCs and platelets. Transfusion of contaminated blood components with bacteria can also cause severe blood components transfusion reactions in the patients.

TRANSPORTATION OF BLOOD COMPONENTS

Transportation of blood is a critical step in preparation of blood components. Blood collected from the donors is transported to laboratory for preparation of blood components to be used in hospitals.

- It is essential to maintain appropriate temperature range for the blood components being transported. In general, blood products should be transported at temperature of 1–10°C.
- Granulocyte and platelet components transportation should be carried out at temperature of 20–24°C. Frozen blood components should be transported in dry ice.

MODIFICATION OF BLOOD COMPONENTS

Blood components may be modified to increase the safety of the blood product. Some modifications affect blood storage conditions by increasing expiry time.

LEUKOREDUCTION BEFORE BLOOD STORAGE

Pre-storage leukoreduction is preformed while preparing blood components. Leukoreduction is a process that removes WBCs from the whole blood or blood components.

- Leukoreduction is performed to reduce the undesirable effects that WBCs have on stored blood components and to reduce the risk of adverse febrile reactions; and organ transplant rejection due to alloimmunization to HLA antigens in patients receiving blood components.
- Whole blood is centrifuged by using hard spin to remove granulocytes from buffy coat layer. Leukoreduction may also be achieved through the use of a specialized filter that trap WBCs in a matrix. Both these methods remove majority of granulocytes and monocytes sparing lymphocytes in final leukoreduction process.
- The acceptable number of WBCs in the final leukoreduction process has 5×10^9 leukocytes per blood component.
- After leukoreduction, there is decreased risk for graft-versus-host disease, immunosuppression, transmission of cytomegalovirus, Epstein-Barr virus, T cell lymphotropic virus and bacteria.

INACTIVATION OF PATHOGENS IN STORED BLOOD

Inactivation of bacteria and viruses is essential in prepared blood components. Few manufactures of blood components have developed processes and equipment to achieve pathogen inactivation.

- Plasma is treated by adding methylene blue, psoralen, or riboflavin to the component in a closed system, then exposing the blood component to light at specific wavelengths. The methods cause some reduction in plasma coagulation factors after treatment.
- A similar process has been developed for platelets using psoralen or riboflavin, but both methods have adverse effects on functioning of platelets. No manufactures have successfully developed commercial methods for treating RBCs.

ALIQUOTING OF BLOOD COMPONENTS

Aliquoting is most often performed to prepare a product for low-volume transfusion to neonates or pediatric patients. It is performed in an open system or closed system. Blood components may be aliquoted into syringes or transfer satellite containers. Blood components prepared in an open system must be transfused within short time after modification. There is always risk for bacterial contamination in open system. To maintain a closed system, aliquot containers must be attached to the original blood component bag with sterile docking device.

POOLING OF BLOOD COMPONENTS

Pooling of blood components may be performed to reduce the number of blood product bags that have to be accessed at the time of transfusion, which can be done in an open. Pooling of blood components is usually performed with platelet-rich plasma or cryoprecipitate containing antihemophilic factor (factor VIII) to create a single treatment dose. RBCs can also be pooled with thawed plasma to recreate most of the constituents of whole blood for transfusion.

VOLUME REDUCTION FROM BLOOD COMPONENTS

Volume reduction is performed to remove plasma or additive solution from blood components. It is done by centrifuging cellular components and removing supernatant fluid usually with plasma press either by open or closed system. Both methods affect survival of the RBCs or platelets. Volume reduction reduces risk for circulatory overload. Removal of excess plasma reduces the risk for adverse reactions related to transfusion of certain plasma proteins.

IRRADIATION OF BLOOD COMPONENTS

Cellular blood components containing active T cells can cause transfusion-associated graft-versus-host disease (GVHD) in susceptible persons.

- T cells are inactivated by exposure to gamma rays or X-rays radiation without affecting function of RBCs and platelets.
- Radiation dose may be minimum of 25 Gy or maximum 50 Gy. Radiation does not adversely affect function of platelets.
- But radiation has some impact on the cell membrane of red blood cells with increased potassium level in the storage fluid.

WASHING OF BLOOD COMPONENTS

Washing of RBC or platelet components is performed to remove plasma proteins that can cause severe reactions in certain persons. Washing of these blood components is done with normal saline either manually or in automated cell washer. Washing of blood components is performed in an open system or closed system resulting in shortened expiry date.

FREEZING, THAWING AND DEGLYCEROLIZING RED BLOOD CELLS

Red blood cells may be stored for a long time by way of freezing. Red blood cells normally undergo cell lysis when frozen and then thawed. It is essential to reduce red blood cell damage during frozen storage by using cryoprotective agent such as glycerol.

- Glycerol limits the formation of ice crystals within Red blood cells (RBCs) resulting in reduction of damage to the RBC membrane. Frozen RBCs are thawed at 37°C. It is essential to remove glycerol prior to transfusion.
- Deglycerolization is performed by washing the thawed red blood cell component with successive concentration changes of sterile saline solution, starting with hypertonic saline, which can also be done in an automated closed system, if red blood cell component has been originally frozen in closed system.

REJUVENATION OF RED BLOOD CELLS

Rejuvenation is a method used to reverse adverse effects of stored RBCs. Rejuvenating solutions contain adenine, pyruvate, inosine and phosphate, which are capable to return ATP and 2,3-DPG levels to normal levels in stored RBC component. It is essential to wash rejuvenating RBC component prior to transfusion. Rejuvenation may also be done to improve the condition of red blood cells prior to freezing in glycerol.

BLOOD PLASMA FRACTIONATION

Blood plasma fractionation refers to the general processes of separating the various components of blood, which in turn is a component of blood obtained through blood fractionation.

- Separation of blood plasma components is achieved by pooling plasma from up to 10,000 donors. Ethanol is added to the blood plasma and then manipulated the pH and temperature of the solution. Blood plasma fractional process causes individual plasma proteins to precipitate of the solution at specific pH and temperature.
- Three major categories of plasma proteins that are fractioned from pooled plasma include albumin, immunoglobulins and coagulation proteins (e.g. factor VIII, factor IX, fibrinogen, anti-thrombin III), and protein C. Albumin is usually packaged and distributed as a liquid in 5% or 25% concentration.
- Specific immunoglobulin contains IgG antibody to specific antigen, which include Rh(D) immunoglobulin and hepatitis B immunoglobulin.
- Nonspecific immunoglobulin is available as an intravenous solution and referred as intravenous immunoglobulin (**IVIg**). Fractionation of 1000 kg of plasma yields about 4 kg of IVIg.
- Commercially available coagulation proteins include von Willebrand factor combined with factor VIII and prothrombin complexes that contain factor II, factor VII, factor IX and factor X, with or without protein C. Many plasma products, plasma pool undergoes solvent/detergent treatment is to inactivate lipid-enveloped viruses. Plasma may also be filtered through small pore nanofilter to trap bacteria and viruses to prepare safe plasma products.

Plasma Fractionation Products

- Albumin
- Immunoglobulins
- Coagulation factor concentrates factor VIII, factor IX, fibrinogen, anti-thrombin III and protein C
- Rh(D) immunoglobulin
- Hepatitis B immunoglobulin
- Intravenous immunoglobulin (IVIg)

RECOMBINANT PLASMA PROTEIN PRODUCTION

Genetic engineering has developed recombinant plasma protein products. Recombinant plasma protein products are prepared by inserting the genetic information that codes for a specific plasma protein into the DNA of plant or animal cells. Currently, recombinant factor VIII and factor IX are available for clinical use.

BLOOD TRANSFUSION AND BLOOD COMPONENT THERAPY

BLOOD TRANSFUSION: GOALS

Blood transfusion is indicated in the abnormalities in the hematologic or coagulation systems, whether congenital or acquired. Basic aim of blood transfusion is to increase tissue oxygenation and/or restore hemostasis. Common investigations performed prior to transfusion include complete blood count, hemoglobin, hematocrit values, platelet count, prothrombin time and international normalized ratio (PT–INR), activated partial thromboplastin time (APTT).

BLOOD TRANSFUSION: INDICATIONS

Patient with hemoglobin levels or hematocrit <20%, 10 g/dl or hematocrit <30%, while those with hemoglobin level <7 g/dl frequently require blood transfusion.

- Fresh frozen plasma (**FFP**) is transfused in the treatment of the bleeding patient with disseminated intravascular coagulation (**DIC**) and massive blood transfusion cases.
- Cryoprecipitate is a rich source of fibrinogen and factor XIII. Blood components are classified in four categories given in Table 12.22. Indications of blood component transfusion are given in Table 12.23. Plasma-derived products obtained by blood plasma fractionation and their indications are given in Table 12.24.

Table 12.22 Categories of blood components

Categories	Blood Components
Cellular components	▪ Whole blood ▪ Red blood cell component ▪ Granulocytes
Plasma components	▪ Platelet products ▪ Fresh frozen plasma ▪ Cryoprecipitate ▪ Other transfusion products
Hematopoietic stem cell (HSC) products	▪ Bone marrow stem cells ▪ Peripheral blood stem cells ▪ Cord blood preparations
Plasma fractionation products	▪ Albumin ▪ Immunoglobulins ▪ Coagulation factor concentrates (factor VIII, factor IX, fibrinogen, anti-thrombin III) and protein C ▪ Rh(D) immunoglobulin ▪ Hepatitis B immunoglobulin ▪ Intravenous immunoglobulin (IVIg) ▪ Commercially available coagulation proteins (von Willebrand factor combined with factor VIII and prothrombin complexes that contain factor II, factor VII, factor IX and factor X, with or without protein C)

Table 12.23 Indications of blood component transfusion

Blood Component	Indications	Comments
Red blood cell component	▪ Hemoglobin 7 g/dl or hematocrit <21% in a patient with uncompromised cardiovascular function ▪ Hemoglobin 10 g/dl or hematocrit <30% with cardiovascular disease, sepsis or hemo globinopathy	▪ Red blood cell concentrate obtained by additive solution saline-adenine-glucose mannitol (OAS), e.g. SAGM; and stored at 4°C ▪ Common adult dose one unit
Platelet component	▪ Prophylactic platelet transfusion in patient with $<10 \times 10^9$/L (adults) or 50×10^9/L (neonates) ▪ Platelet count $<30 \times 10^9$/L in patient with bleeding or minor bedside procedure ▪ Platelet count $<50 \times 10^9$/L in a patient with intraoperative or postoperative bleeding ▪ Platelet count $<100 \times 10^9$/L in a patient with bleeding post-cardiopulmonary bypass	▪ Buffy coat pooled plasma is obtained from four donors. Buffy coat residue is discarded ▪ Platelets are stored at room temperature ▪ Do not transfuse platelets in the setting of thrombotic thrombocytopenic purpura, heparin-induced thrombocytopenia. Platelet transfusions are unlikely to be useful in idiopathic thrombocytopenic purpura or post-transfusion thrombocytopenic purpura
Fresh frozen plasma	▪ Activated partial thromboplastin time (APTT) and/or prothrombin time (PT) increased ▪ Bleeding in patient with international normalized ratio (INR) ≥2 ▪ Bedside procedure and international normalized ratio (INR) ≥2	Fresh frozen plasma (FFP) replaces coagulation factors in those patients with an elevated prothrombin time (PT), activated partial thromboplastin time (APTT) or INR and bleeding. It is used as replacement with plasmapheresis. It is not the choice for patients with hemophilia A, hemophilia B or von Willebrand disease

Contd...

Table 12.23 Indications of blood component transfusion *(Contd...)*

Blood Component	Indications	Comments
	▪ Prophylactic (bleeding) with international normalized ratio (INR) ≥10 ▪ Fresh frozen plasma (FFP) is not indicated for patients with international normalized ratio (INR) <1.5 and thrombotic thrombocytopenic purpura ▪ Fresh frozen plasma (FFP) is indicated in the treatment of bleeding in a patient with disseminated intravascular coagulation (DIC)	▪ Fresh frozen plasma (FFP) for fractionation (e.g. albumin, γ-globulin, specific antiviral immunoglobulin, anti-D and coagulation factors)
Cryoprecipitate	Cryoprecipitate transfusion is done in the setting of dysfibrinogenemia, fibrinogen concentration <100 mg/dl and von Willebrand disease	Cryoprecipitate is rich in fibrinogen, factor VIII, factor XIII, von Willebrand factor and fibronectin
Granulocytes	Documented sepsis unresponsive to antimicrobial therapy	Normally, granulocytes phagocytose microbes

Table 12.24 Plasma-derived products obtained by blood plasma fractionation and their indications

Plasma Products	Indications in Clinical Practice
Hemophilia A (factor VIII deficiency)	
Factor VIII (antihemophilic factor)	Treatment or prevention of bleeding in patients with hemophilia A
Factor VIII (high purity)	Hemophilia A with HIV infection
Recombinant factor VIII	Hemophilia A
Porcine factor VIII	Treatment of bleeding episodes in hemophilia A in the presence of complex factor VIII inhibitor
Activated prothrombin complex concentrates	Treatment of bleeding episodes in hemophilia A in the presence of complex factor VIII inhibitor
Hemophilia B (Christmas disease) (factor IX deficiency)	
Factor IX complex	Prophylaxis and treatment of hemophilia B bleeding episodes and other bleeding disorders
Factor IX (high purity)	Hemophilia B
Recombinant factor IX	Hemophilia B
von Willebrand disease	
von Willebrand factor/factor VIII concentrate	Treatment or prevention of bleeding in von Willebrand disease
Hemophilia C (factor XI deficiency)	
Fresh frozen plasma (FFP)	Treatment or prevention of bleeding in hemophilia C associated with cardiovascular disorders
Factor I (fibrinogen) deficiency	
Fibrinogen	Treatment of hemorrhagic diathesis in hypofibrinogenemia, dysfibrinogenemia and afibrinogenemia
Factor VII (stable factor) deficiency	
Factor VII	Treatment of factor VII deficiency, anticoagulant overdose, severe liver disease
Recombinant factor VII	Treatment of factor VII deficiency with factor VII inhibitor
Fibrin stabilizing factor (factor XIII deficiency)	
Factor XIII	Treatment of bleeding disorders of wound healing due to factor XIII deficiency
Multiple factors deficiency and other diseases	
Prothrombin complex concentrate	Treatment of factors I and X deficiency; factor VIII inhibitors, oral coagulants overdose and severe liver disease

Contd...

Table 12.24 Plasma-derived products obtained by blood plasma fractionation and their indications (*Contd...*)

Plasma Products	Indications in Clinical Practice
Antithrombin III plasma product	
Antithrombin III	Treatment of bleeding associated with liver disease, antithrombin III deficiency and thromboembolism
Hemolytic disease of fetus and newborn	
RhO(D) immunoglobulin	Treatment and prevention of hemolytic disease of fetus and newborn resulting from Rh incompatibility and incompatible blood transfusions
Restoration of plasma volume	
Albumin	Restoration of plasma volume subsequent to shock, trauma, surgery and burns
Plasma protein fraction	Restoration of plasma volume subsequent to shock, trauma, surgery and burns
Immunoglobulin deficiency	
Immunoglobulin (intravenous and intramuscular)	Treatment and agammaglobulinemia, chronic lymphocytic leukemia, immune-mediated thrombocytopenic purpura; and passive immunization for hepatitis A and measles
Dissolution of intravascular clots	
Fibrinolysin	Dissolution of intravascular clots
Alpha-1 proteinase inhibitor for emphysema and cirrhosis	
Alpha-1 proteinase inhibitor	Treatment of emphysema and cirrhosis due to genetic alpha-1 antitrypsin deficiency
Hereditary angioedema	
C1 esterase inhibitor	Treatment of angioedema
Apnea after administration of succinylcholine chloride	
Serum cholinesterase	Treatment of prolonged apnea after administration of succinylcholine chloride
Bacterial diseases	
IgM-enriched immunoglobulin	Treatment and prevention of septicemia and septic shock due to toxin liberation in the course of antibiotic treatment
Tetanus immunoglobulin	Passive immunization subsequent to exposure to tetanus
Viral diseases	
Haptoglobin	Supportive therapy in viral hepatitis and pernicious anemia
Hepatitis B immunoglobulin	Passive immunization to hepatitis B
Immunoglobulin (intravenous and intramuscular)	Passive immunization to hepatitis A
Rabies immunoglobulin	Passive immunization subsequent exposure to rabies
Rubella immunoglobulin	Passive immunization subsequent to exposure to German measles
Varicella-zoster immunoglobulin	Passive immunization subsequent to exposure to smallpox
Varicella-zoster immune	Passive immunization subsequent to exposure to globulin chickenpox
Cytomegalovirus immune	Passive immunization subsequent to exposure to globulin cytomegalovirus

BLOOD COMPONENTS TRANSFUSION

Transfusion of blood components except fractionation products in <4 hours ensures the product would deliver the most therapeutic response with minimal bacterial contamination. Refrigerated storage of blood products inhibits bacterial growth. Basic transfusion set has flexible plastic tubing and standard inline blood filter with very small pore.

- Microaggregate filters may be used for transfusion of RBC component. These microaggregate filters also reduce the degenerated platelets, wWBC fragments and small strands of fibrin. While transfusion of RBC component or platelet component, leukocyte

reduction filters may be used to reduce the number of leukocytes. Leukocyte reduction may be performed in prestorage blood, while the blood components are prepared; or just before transfusion at bedside.

- Using too small needle for transfusion may cause RBC hemolysis especially rapid administration of the RBC component. Typically, 18 gauge or large needles are used for blood transfusion especially RBCs.
- Massive blood transfusion may cause hypothermia resulting in cardiac arrhythmia with fatal out. Therefore, body warmer should be used to treat hypothermia. Normal saline 0.9% sodium chloride may be added to most blood components. Ringer's lactate solution should not be added to the blood components, because high level of calcium content inactivates the anticoagulant resulting in formation of blood clots. When transfusing fractionation blood plasma products, instructions of manufacture should be checked.

WHOLE BLOOD TRANSFUSION

Whole blood consists of red blood cells, white blood cells, platelets and plasma. The platelets in stored whole blood in refrigerator become nonfunctional. Whole blood is transfused in medical and surgical emergencies in patients with excessive bleeding. Whole blood replacement is performed to treat hemolytic disease of newborn. Each unit of whole blood increases hemoglobin concentration by 1 g/dl and hematocrit by three points in adults.

- Autologous blood transfusion refers to collection of blood from the patient prior to surgery 1–3 weeks before surgery for whom the blood transfusion is used later. Benefits of autologous transfusion are to avoid transfusion transmitted infectious diseases and immunological adverse reactions.
- Autologous blood transfusion is safe and useful in patients with rare blood group and with multiple alloantibodies. Another form of autologous blood collection is intraoperative blood salvage. Blood is collected from the surgical site during surgery or postoperative period. Blood lost during surgery is collected by suction mixed with anticoagulant, and washed in a machine designed for this purpose. The salvage blood cells are reinfused. Contraindications for intraoperative salvage include the presence of infection or cancer cells at the site of surgery.

RED BLOOD CELL COMPONENT TRANSFUSION

Red blood cell component is most often called packed RBCs and obtained by removal of plasma, which are most often used to treat anemia. Transfusion of RBCs permits restoration of oxygen carrying capacity with less risk of volume overload. The hematocrit of packed RBCs is about 70–80%. Removal of plasma from whole blood, hematocrit is double of the normal range. Each unit of packed RBCs should raise the hematocrit by about 3 points per unit or 1 g/dl of hemoglobin.

- Patients with anemia fall into two categories: (a) patient developing anemia over time is hemodynamically stable and treated for anemia and (b) patient develops anemia as a result of an acute blood loss due to trauma, surgery or severe bleeding due to underlying medical illnesses. These patients most often require treatment for both anemia and volume depletion.
- The clinician should assess overall clinical picture of patient especially symptoms related to decreased oxygen carrying or not. Donation from first degree family member should be irradiated prior to infusion in order to prevent transfusion associated graft-versus-host disease (TA-GVHD). These blood units are screened for infectious diseases.

WHITE BLOOD CELL COMPONENT TRANSFUSION

Granulocyte units are collected by apheresis. Granulocytes are removed from whole blood, and remainder of the blood is transfused back to the donor.

- Granulocytes may be used to treat neutropenic patients suffering from bacterial and/or fungal sepsis, who have been resistant to antimicrobial therapy. Granulocyte transfusion may benefit patients with abnormality of neutrophil function.
- Continued neutropenia is treated with granulocyte colony-stimulating factor (G-CSF) to stimulate granulopoiesis. If the patient does not respond to G-CSF, donor granulocytes should be transfused. Recombinant growth stimulating hormones, usually **G-CSF** may be administered to mobilize the donor's bone marrow to release larger numbers of granulocytes to produce high yield of granulocytes.
- Granulocyte units should be administered within 24 hours of collection from donor, which are always irradiated prior to transfusion to prevent transfusion associated graft-versus-host disease (**TA-GVHD**).
- Granulocytes should not be infused through leukoreduction filters. The donor and recipient should be both human leukocyte antigen (HLA) and Rh compatible.

HEMATOPOIETIC STEM CELLS USED FOR TRANSPLANTATION

Hematopoietic stem cells (HSCs) are primitive stem cells that have the capacity for self-renewal and maturation into different lineages such as RBCs, WBCs and

platelets. Transplantation of HSCs is combined with high-dose chemotherapy or radiation to treat leukemia, lymphoma, multiple myeloma, severe aplastic anemia, myelodysplastic syndrome, myelodysplastic neoplasms, severe combined immunodeficiency (SCID) syndrome, some hemoglobinopathies, some solid tumors and metabolic disorders.

- Hematopoietic stem cells (HSCs) are obtained from bone marrow, peripheral blood or umbilical cord. By using recombinant colony-stimulating factor, HSCs are mobilized from bone marrow and usually collected from peripheral blood. Peripheral blood HSCs collection requires a catheter, that may carry pathogens. HSCs take short time to engraft, but there is increased risk for development of graft-versus-host disease (GVHD).
- Conversely, hematopoietic stem cells (HSCs) collection directly from bone marrow carries higher risk for the donor from surgical procedure and anesthesia. HSCs take longer time to engraft, but development of graft-versus-host disease is less severe.
- An alternative source of HSCs is umbilical cord blood. HSCs are collected from the umbilical cord and placenta immediately after birth of newborn. Umbilical cord has high number of hematopoietic stem cells, which are cryopreserved using 10% diethyl sulfoxide and stored frozen in public cord banks for further use. Hematopoietic stem cell transplants can be either autologous or allogeneic depending on the disease being treated. Autologous HSCs refer to cells or tissue obtained from self. Allogeneic HSCs refer to cells or tissue obtained from a genetically different individual.

Hematology Pearls: Autologous and Allogeneic Hematopoietic Stem Cells

Autologous Hematopoietic Stem Cells used for Transplant

- Hematopoietic stem cells (HSCs) are collected from patient's peripheral blood or bone marrow after lower doses of chemotherapy and cryopreserved using 10% diethyl sulfoxide in frozen state.
- Hematopoietic stem cells (HSCs) are further treated by high doses of chemotherapy and radiation to eradicate remaining cancer cells. These cryopreserved HSCs are now thawed and infused to restore hematopoietic function.
- Hematopoietic stem cells (HSCs) are currently used for disorders such as Hodgkin's disease, non-Hodgkin's lymphoma, multiple myeloma, neuroblastoma and testicular cancer, which are more often resistant to first-line chemotherapy and irradiation.

Allogeneic Hematopoietic Stem Cells used for Transplant

- Allogeneic hematopoietic stem cell transplant is used in certain patients after failure of an autologous transplant.
- Hematopoietic stem cells (HSCs) are obtained from HLA-matched related healthy donor.
- Allogeneic HSCs are used in patients suffering from acute myelogenous leukemia, high risk cytogenetic acute lymphoblastic leukemia, aplastic anemia, high-risk cytogenetic myelodysplastic syndrome and late stage imatinib-resistant chronic myelogenous leukemia. Prior to infusion of HSCs, the patient is administered immunosuppressive therapy to prevent graft-versus-host disease.
- Allogeneic HSCs may be incompatible for ABO/Rh antigens for both donor and recipient.
- After an HLA-match allogeneic HSC transplant, some patients experience a relapse of their original disease. Donor lymphocytic infusion (CD3 positive) is done to induce destruction of malignant cells in the recipient.

MODIFICATION OF CELLULAR COMPONENTS

Modification of cellular components is performed by leukoreduction, irradiation of cells, washing and freezing and deglycerolization of RBCs in blood bags.

Pre-Transfusion Modifications of Blood Cellular Components

Leukoreduction

- Febrile reactions are common in sensitized patients, who receive components >5×10^9 leukocytes per blood component and alloimmunization to the HLA antigens of residual lymphocytes.
- Leukoreduction helps to prevent the formation of antibodies to HLA antigens expressed on lymphocytes. Leukocytes are removed by use of leukocyte reduction filters because of their large size compared with RBCs.
- Leukoreduction reduces risk of febrile nonhemolytic blood transfusion reactions, graft-versus-host disease (GVHD), transplant rejection, reactivation of cytomegalovirus, human T cell lymphotropic virus 1 (HTLV-1) and Epstein-Barr virus.

Irradiation of RBCs and Granulocytes

- Irradiation of granulocytes is performed to prevent transfusion associated graft-versus-host disease (TA-GVHD). Gamma-radiation disrupts the DNA in WBCs.
- Blood bags are given γ-irradiation dose of 25 Gy. Irradiated RBCs result in increased potassium leakage.
- Fresh frozen does not need to be irradiated because it seldom contains viable WBCs.
- In immunocompromised persons, cytomegalovirus can cause significant morbidity and mortality, which include premature and low birth neonates. Testing of blood component of donor for cytomegalovirus is essential prior to transfusion.
- cytomegalovirus seronegative blood component is transfused to the recipients.

Washing of RBCs

Washing of RBC units eliminates 85% of WBCs, 15% of RBCs and 99% of plasma; that can be transfused to IgA deficient patients having antibodies to IgA. Washing is also indicated in patients, who have severe allergic reactions to blood products.

Freezing and Deglycerolization of RBCs

- Blood from donors with rare RBC phenotypes may be frozen for a period of 10 years and used for autologous of allogeneic transfusion.
- Each blood unit is frozen with cryoprotective agent such as 20–40% of glycerol. Prior to blood transfusion, blood unit should be washed, a process known as deglycerolization.
- The blood product should be used within 24 hours for open system or two weeks for closed systems. Frozen platelet products can be stored for two years.

TRANSFUSABLE PLASMA COMPONENTS

Several blood components are used to treat deficiencies and abnormalities of coagulation proteins. Administration of fresh frozen plasma (**FFP**) provides many coagulation factors and improves hemostasis in patients with multiple deficient coagulation factors and massive transfusions. Cryoprecipitate provides factors VIII, XIII, von Willebrand factor, fibrinogen and fibronectin. Cryoprecipitate can be used prior to surgical procedures in patient with dysfibrinogenemia.

Fresh Frozen Plasma

Fresh frozen plasma (FFP) is obtained by separation of plasma and frozen at –18°C within 8 hours of whole blood collection. Plasma is frozen rapidly either in a dry ice-ethanol or in a dry ice-antifreeze bath or in a mechanical freezer kept at –65°C or lower. It can be stored at –65°C for 7 years.

- **Indications:** Fresh frozen plasma is administered by intravenous route in a dose 7–15 ml/kg body weight in patients suffering from hemophilia A and Christmas disease. It is also valuable in treatment of thrombotic thrombocytopenic purpura. It can also be used in the reversal of adverse effects of oral coagulant therapy associated with bleeding occurring due to depletion of coagulation factors.
- **Adverse effects:** Approximately 6–12% cases of hemophilia A patients develop antibodies against factor VIII after transfusion of fresh frozen plasma (FFP). Therefore, recombinant factor VIII is being transfused in hemophilia A patients.

Cryoprecipitate

Cryoprecipitate is a cold insoluble fraction of plasma proteins obtained from fresh frozen plasma (FFP) and prepared by process of centrifugation of fresh frozen plasma after thawing at 4°C. Cryoprecipitate is stored at –18°C within one hour of separation from fresh frozen plasma, which can be used within one year from the date of blood collection.

- **Constituents:** Important constituents of cryoprecipitate are fibrinogen, factor VIII, factor XIII, von Willebrand factor (vWF) and fibronectin. Cryoprecipitate cannot serve as a therapeutic source of the coagulation factors II, V, VII, IX, X, XI and XII. The coagulation factors should be obtained from fresh frozen plasma (FFP) in specific concentration.
- **Indications:** Currently, the major use of cryoprecipitate is a source of fibrinogen. Deficiency of fibrinogen is seen in massive blood transfusion and disorders involving activation of the coagulation system. Cryoprecipitate is administered by intravenous route to promote hemostasis in various coagulation disorders, e.g. fibrinogen deficiency, hemophilia A, factor XIII deficiency and von Willebrand disease. Advantage of administration of cryoprecipitate is exposure of the recipients to a few donors. Blood products are costly and limited worldwide. Excessive administration of cryoprecipitate is not beneficial to the patients suffering from hemophilia A, von Willebrand disease, fibrinogen deficiency and factor XIII deficiency.

Cryosupernatant Plasma

Cryosupernatant refers to plasma from which the cryoprecipitate has been removed. Thawing of fresh frozen plasma (FFP) between 1°C and 6°C, cold insoluble cryoprecipitate is separated. The remaining thawed plasma is known as cryosupernatant, which is stored at –18°C. It should be administered to the patients within one year from the date of whole blood collection.

- **Constituents:** Since cryoprecipitate contains fibrinogen, factor VIII, von Willebrand factor (vWF) and fibronectin, and these components are reduced in cryosupernatant. Levels of factor VIII and fibrinogen are greatly reduced.
- **Indications:** Cryosupernatant plasma can be used when replacement of factor VIII is not required. It may be used in refractory thrombotic thrombocytopenic purpura (**TTP**) and hemolytic uremic syndrome (**HUS**).

Factor VIII Concentrate

Factor VIII concentrate is the product of choice for patients with hemophilia A, which has a short half-life about 12 hours *in vivo*. High purity factor VIII concentrate is administered continuously during surgery.

Factor IX Concentrate

High purity factor IX concentrate is used for patients with hemophilia B also known as Christmas disease.

Prothrombin Complex Concentrate

Prothrombin complex concentrate contains coagulation factors IX, X, II and sometimes factor VII, which are more effective than fresh frozen plasma (FFP). Prothrombin complex concentrate is used to treat hemophilia A patients, who have circulating antibody (inhibitor) to factor VIII.

Specific Immunoglobulins

Specific immunoglobulins are obtained from donors, who have high concentration of IgG and administered in patients for passive prophylaxis against infectious agents. Anti-D is administered to the Rh –ve mother having Rh +ve fetus in the prevention of hemolytic disease of newborn.

PLATELET COMPONENT TRANSFUSION

Platelet component transfusion usually controls bleeding in thrombocytopenic patients or dysfunctional platelet disorders, either due to suppressed platelets production in leukemias, chemotherapy, radiotherapy; or dilutional thrombocytopenia after massive transfusions. Platelets circulate for a week in stable non-immunized thrombocytopenic patients.

- Prophylactic platelet component transfusion in a patient with $<10\times10^9$/L is administered to prevent intracranial hemorrhage.
- Platelet-rich plasma (PRP) is an autologous concentrate of platelets in a small volume of plasma used to stimulate acceleration of healing of bone fracture and soft tissue injury.
- Random donor platelet components are prepared from donor's whole blood within 4–5 hours of collection by process of centrifugation in platelet apheresis machine.
- Platelet components obtained from single donor are administered to treat acute hemorrhage secondary to thrombocytopenia.
- One unit of plateletpheresis can be divided into four equal packs for creating pediatric sized platelets component to minimize platelet wastage. An adult dose of pooled platelets is obtained from 4 donors.

FIBRIN GLUE AND PLATELET GEL

Commercial preparations of fibrin glue are used as sealant during surgery in order to produce tight closure of the wound. Platelet gel is composed of autologous platelet and WBC-rich plasma, calcium chloride and thrombin, that are used to stimulate coagulation system and healing of surgical wound.

PLASMA FRACTIONATION PRODUCTS

Plasma fractionation products include albumin, Rh immunoglobulin, intravenous immunoglobulin (IVIg), hyperimmunoglobulin and coagulation factor concentrates.

Hematology Pearls: Plasma Fractionation Products

Albumin

Albumin is most commonly used as a volume replacement in trauma, shock, burns and therapeutic plasma exchange.

Rh Immunoglobulin

Rh immunoglobulin is administered to prevent immunization to the D antigen. Rh immunoglobulin is administered to Rh negative mother with Rh positive fetus in the 28th week of pregnancy.

Intravenous Immunoglobulin

Intravenous immunoglobulin (IVIg) is administered in hypogammaglobulinemia/agammaglobulinemia, severe combined immunodeficiency syndrome, Wiskott-Aldrich syndrome, pediatric HIV with recurrent bacterial infections, post-allogeneic transplant, chronic lymphocytic leukemia, immune thrombocytopenic purpura, pure red cell aplasia, neonatal alloimmune thrombocytopenic purpura, hemolytic disease of the fetus and newborn, post-transfusion purpura, myasthenia gravis, Guillain-Barré syndrome, dermatomyositis/polymyositis and staphylococcal toxic shock syndrome.

Hyperimmunoglobulin

Hyperimmunoglobulin is administered to provide passive immunity in patients suffering from rabies, rubella, cytomegalovirus, tetanus, varicella zoster and hepatitis. Coagulation factor concentrates are administered to prevent or treat bleeding episodes in patients with coagulation factors deficiency. Hemophilia patients most often develop inhibitors to antihemophilic factor.

PHARMACEUTICAL DRUGS USED TO REDUCE/ PREVENT BLEEDING IN HEMATOLOGIC DISORDERS

There are several drugs administered to reduce or prevent bleeding in hematologic disorders. Recombinant products are available in modern age.

Hematology Pearls: Pharmaceutical Drugs used to Reduce/Prevent Bleeding in Hematologic Disorders

Desmopressin Acetate

Desmopressin acetate is a synthetic peptide, 1-deamino-8-D-arginine vasopressin (DDAVP). It is prophylactically administered prior to surgery to reduce bleeding or prevent bleeding in patients with mild hemophilia A or type 1 von Willebrand disease. DDAVP releases factor VIII and von Willebrand factor from the vascular endothelial cells.

Vitamin K Preparations

Vitamin K can be administered to reverse the effect of oral anticoagulants and prepare patients for surgery. Vitamin K-dependent coagulation proteins include: factors II, VII, IX and X.

Erythropoietin

Erythropoietin is synthesized by kidney to stimulate erythropoiesis. Recombinant erythropoietin is administered to stimulate erythropoiesis in patient with chronic renal failure.

Thrombopoietin

- Thrombopoietin is synthesized by liver and kidneys and to a lesser extent by bone marrow, spleen, testes, brain and muscle that stimulate megakaryopoiesis.
- Recombinant thrombopoietin can be administered to stimulate megakaryopoiesis in patients with suffering from bone marrow suppression that has caused thrombocytopenia.
- Biological agents such as romiplostim and eltrombopag are thrombopoietin receptor agonists stimulate platelet production in patient suffering from idiopathic thrombocytopenic purpura (ITP).

Colony Stimulating Factors

- Recombinant preparations of colony stimulating factors such as G-CSF and GM-CSF are administered in patients with neutropenia after chemotherapy in cancer patients.
- Plerixafor preparation is administered to patients, who are unable to produce sufficient amounts of autologous hematopoietic stem cells.

Antifibrinolytic Preparations

Antifibrinolytic preparations inhibit fibrinolysis. Fibrinolysis normally increases during cardiopulmonary bypass. These agents are administered during cardiac surgery to reduce bleeding due to increased fibrinolysis.

Recombinant Factor VIIa Product

Recombinant factor VIIa is administered to patients suffering from hemophilia A and hemophilia B having inhibitors, which initiates deposition of fibrin on platelets and induces platelet aggregation at the site of injury.

MASSIVE BLOOD TRANSFUSION

Massive blood transfusion is defined as replacement of recipient patient's total blood volume with donor components within 24 hours in cases of trauma, obstetrics related conditions, surgery, gastrointestinal tract bleeding, aneurysm and plasma exchange in thrombotic thrombocytopenic purpura or hemolytic uremic syndrome (HUS). Patients receiving multiple blood transfusions are at increased risk for febrile reactions, allergic reactions, volume overload, sepsis, viral infections, transfusion-related acute lung injury (TRALI), hemolytic reactions, alloimmunization, anticoagulant toxicity, hyperkalemia and hypothermia.

ADVERSE BLOOD TRANSFUSION REACTIONS

Blood transfusion reactions are defined as adverse events associated with the transfusion of whole blood or its components. Acute adverse blood transfusion reactions may occur within 24 hours of transfusion. Delayed blood transfusion reactions occur after one day to many weeks. Acute and delayed adverse blood transfusion reactions are given in Table 12.25. One important aspect of blood transfusion safety is the reporting and surveillance of adverse blood transfusion events. Hemolytic blood transfusion reactions and cytokines are given in Table 12.26. Clinical pearls of blood transfusion-related manifestations are given as follows.

Table 12.25 Acute and delayed adverse blood transfusion reactions

Adverse Blood Transfusion Reactions	Comments
Acute adverse blood transfusion reactions	
Acute hemolytic transfusion reactions	Donor red blood cells are destroyed by recipient's blood containing IgM. Intravascular hemolysis results in hemoglobinuria, acute renal failure and oliguria
Air embolism	Air embolism occurs due to entry of excess air >100 cc at infusion site and obstructing blood flow
Allergic transfusion reactions	Skin rashes, urticaria (hives), pruritus (itching), generalized flushing, edema of lips, tongue and/or uvula, erythema (redness of skin), edema in the periorbital area and conjunctival edema
Anaphylactic transfusion reactions	Bronchospasm and rarely anaphylactic shock
Citrate toxicity	Citrate binds with calcium and magnesium resulting in hypocalcemia and hypomagnesemia
Febrile nonhemolytic transfusion reactions	Fever, rigors and chills due to sensitization of donor WBCs within an hour of transfusion

Contd...

Table 12.25 Acute and delayed adverse blood transfusion reactions *(Contd...)*

Adverse Blood Transfusion Reactions	Comments
Hypotensive transfusion reactions	Hypotension occurs due to platelet component transfusion related to bradykinin production
Hypothermia	Rapid transfusion of cold-temperature blood products
Transfusion-associated circulatory overload (TACO)	Acute pulmonary edema with impaired cardiac functions
Transfusion-associated dyspnea (TAD)	Transfusion-associated dyspnea term is used when the patient develops respiratory distress; and exclusion of transfusion-associated acute lung injury and transfusion-associated circulatory overload
Transfusion-related acute lung injury (TRALI)	Acute respiratory distress syndrome occurs within six hours of transfusion due to formation of antibodies against RBC antigens and phagocytes
Delayed adverse blood transfusion reactions	
Delayed hemolytic transfusion reactions	Delayed hemolytic reactions occur four days to two weeks after blood transfusion due to extravascular destruction of RBCs
Transfusion related hemosiderosis	Occurs due to multiple blood transfusions. Chelating agents should be administered to prevent hemosiderosis
Post-transfusion purpura (PTP)	Pre-existing alloantibodies in recipient's plasma against donor's platelet antigens result in platelet destruction by reticuloendothelial cells
Transfusion associated graft-versus-host disease (TA-GVHD)	Occurs when immunocompetent T cells from the donor are transfused to immunodeficient recipients recognize HLA as foreign

Table 12.26 Hemolytic blood transfusion reactions associated with cytokines

Cytokines Terminology	Biological Activity	
Pro-inflammatory cytokines		
IL-1, TNF-α	▪ Hypotensive shock, death ▪ Mobilization of leukocytes from bone marrow ▪ Activation of T and B cells	▪ Induction of IL-1, TNF-α, IL-6, chemokines (CXCL-8 and CCL-2) ▪ Induction of adhesion of molecules
IL-6	▪ Fever ▪ Synthesis of acute phase reactants	▪ Activation of B and T cells
Chemokines		
CXCL-8 (C-X-C)	▪ Chemotaxis of neutrophils and their activation ▪ Chemotaxis of lymphocytes ▪ Induction of histamine release by basophils	
CCL-2 (C-C)	▪ Induction of IL-1, adhesion molecules and respiratory burst ▪ Chemotaxis of monocytes	
Anti-inflammatory cytokines		
IL-1Ra	Competitive inhibition of receptors of IL-1	

Clinical Pearls: Blood Transfusion-related Clinical Manifestations

Blood Transfusion-related ABO Incompatibility

- During blood transfusion, patient presents with hypotensive shock, tachycardia, chest pain, backache and passage of dark urine. Serum bilirubin and lactic acid dehydrogenase levels are elevated. Serum haptoglobin level is low.
- ABO incompatibility presents with acute symptoms of hemolysis while the blood transfusion is continuing.

Blood Transfusion-related Acute Hemolytic Reaction

Acute hemolytic reaction is a complication of transfusion-related blood to intravascular hemolysis, characterized by rapid onset with symptoms of fever, chills, hemoglobinemia and hypotension, major complications such as irreversible shock, renal failure and disseminated intravascular coagulation.

Blood Transfusion-related Acute Lung Injury (TRALI)

- Thirty minutes after a patient receives blood transfusion, patient presents with shortness of breath.

- Transfusion-related acute lung injury (TRALI) presents with acute shortness of breath from antibodies in the donor blood against recipient WBCs.
- Chest radiograph shows transient infiltrates in lungs. Symptom resolves spontaneously with any treatment.

Blood Transfusion-related IgA Deficiency

- As soon as patient receives blood transfusion, patient presents with hypotensive shock, shortness of breath and tachycardia. Serum bilirubin and lactic acid dehydrogenase levels are within normal range.
- IgA deficiency presents with anaphylaxis. Clinician should use blood donations from IgA deficient donor or washed red blood cells.

Minor Blood Group Incompatibility

- A few days after blood transfusion, patient develops jaundice. The hematocrit does not rise with blood transfusion.
- Minor blood group incompatibility to Kell, Duffy, Lewis or Kidd antigens or Rh incompatibility presents with delayed jaundice. There is no specific therapy for these patients.

Febrile Nonhemolytic Reactions

- A few hours after blood transfusion, patient presents with fever above 1°C. There is no evidence of hemolysis.
- Febrile nonhemolytic reactions result in a small rise in temperature. These reactions are against donor WBC antigens. These reactions are prevented by using filtered blood transfusions in the future to remove the WBC antigens.

BLOOD TRANSFUSION-RELATED IMMUNE HEMOLYTIC REACTIONS

Immune-mediated hemolytic blood transfusion reactions are most commonly associated with patient antibodies that are directed against antigens present on the transfused RBCs, which reactions can be divided into two categories.

- Blood transfusion-related acute hemolytic reactions occur immediately after exposure to the transfusion component, that is associated with complement-mediated intravascular hemolysis.
- Blood transfusion-related delayed hemolytic reactions may occur days to week after transfusion, that is associated with extravascular hemolysis by antibody and/or complement-coated RBCs are cleared through phagocytosis by macrophages in spleen, liver and bone marrow.
  - Proper pretransfusion testing can prevent immune-mediated hemolytic reactions.
  - Delayed hemolytic reactions usually occur due to the presence of patient antibodies to non-ABO red blood cell (RBC) antigens.
- Immediate and delayed blood transfusion-associated hemolytic reactions are given in Table 12.27.

BLOOD TRANSFUSION-RELATED ACUTE HEMOLYTIC REACTIONS

Blood transfusion-related acute hemolytic reactions occur when antibodies (IgM) react with antigens on RBCs. Antigen–antibody reactions activate complement system resulting in intravascular hemolysis.

Pathophysiology

Activated potent anaphylatoxins such as C3a and C5a stimulate the release of histamine and serotonin from mast cells resulting in vasodilation and smooth muscle contraction.

- Antigen–antibody complexes can activate factor XIII and trigger the intrinsic pathway of coagulation system.
- While activated complement system increases expression of tissue factor expressed on endothelial cells and leukocytes resulting in triggering extrinsic pathway of coagulation system.
- Both intrinsic and extrinsic pathways of coagulation lead to development of disseminated intravascular coagulation (**DIC**) resulting in formation of microthrombi in the capillaries associated with uncontrolled bleeding due to consumption of coagulation factors and platelets.

Table 12.27 Immediate and delayed blood transfusion associated hemolytic reactions

Parameters	Immediate Blood Transfusion Associated Hemolytic Reactions	Delayed Blood Transfusion Associated Hemolytic Reactions
Time of onset	Within one hour of blood transfusion	Within 7–10 days of blood transfusion
Antibody responsible for hemolysis	IgM (e.g. anti-A, anti-B) natural occurring antibody	IgG (e.g. anti-RhD) formed due to immune response
Site of hemolysis	Intravascular hemolysis	Extravascular hemolysis
Clinical features	Headache, backache, hypotension, renal failure	Asymptomatic or mild fever or jaundice
Laboratory findings	▪ Hemoglobinemia ▪ Methemalbuminemia	▪ Serum bilirubin raised ▪ Anemia positive/negative
Mortality	5–10%	0–1%

- Renal damage is most important complication of blood transfusion-related acute hemolytic process, which may be partially due to free hemoglobin in the tubules and reduced renal blood flow.

Clinical Features

Patient most often presents with fever with or without chills and hemoglobinuria. Other signs and symptoms are variable, which include hemoglobinemia (free hemoglobin in the plasma), positive direct antiglobulin test (DAT), pain at the intravenous site, pain in abdomen, chest, flank or back, nausea and vomiting, hypotension progressing to shock, dyspnea, disseminated intravascular coagulation (DIC) and renal failure. In anesthetized patients, hypotension and bleeding are the only findings.

BLOOD TRANSFUSION-RELATED DELAYED HEMOLYTIC REACTIONS

Blood transfusion-related delayed hemolytic reactions may occur days to weeks after blood transfusion, that is associated with extravascular hemolysis by antibody and/or complement system protein coated RBCs are cleared through phagocytosis by macrophages in spleen, liver and bone marrow. Delayed hemolytic reactions are less severe than acute hemolytic reactions.

Pathophysiology

Antibodies directed against the RBC antigens bind to the RBC membrane. There is absence or minimal activation of complement system. Hence, antigen–antibody-coated RBCs remain in the circulation, where these RBCs are cleared by reticuloendothelial cells in the spleen, liver and bone marrow resulting in extravascular hemolysis.

Clinical Features

Patient presents with fever, anemia, jaundice, hemoglobinuria and leukocytosis days to weeks after blood transfusion. Some patients progress to hyperhemolysis due to formation of autoantibodies in patients receiving multiple blood transfusions in cases of sickle cell anemia and thalassemia. Hyperhemolysis involves both intravascular and extravascular hemolysis resulting in fatal outcome.

BLOOD TRANSFUSION-RELATED FEBRILE NONHEMOLYTIC REACTIONS

Blood transfusion-related febrile nonhemolytic reactions involve increase in body temperature of at least 10°C either during blood transfusion or shortly after the blood transfusion especially patients receiving multiple blood transfusions or previously pregnant women.

PATHOPHYSIOLOGY

Blood transfusion-related febrile nonhemolytic reaction is a leukocyte-mediated reaction occurring by two mechanisms: (a) the recipient has been alloimmunized to human leukocyte antigens (HLA) as a result of exposure to foreign WBCs during a prior blood transfusion, organ transplant or pregnancy. The recipient's HLA antibody attacks the transfused WBCs that possess the concurrent antigen; (b) during blood storage, cytokines released by WBCs, which are passively transfused to the recipient resulting in initiation of inflammatory response.

- Both these mechanisms result in the release of pyrogens responsible for fever. The cytokine-mediated reactions are most often associated with the transfusion of platelet products.
- Leukoreduction of blood products reduces risk of febrile nonhemolytic reaction. Febrile blood transfusion reactions are also observed in acute hemolytic blood transfusion reaction, bacterial contamination of donor unit, blood transfusion-related lung injury and delayed blood transfusion reactions.

CLINICAL FEATURES

Patient presents with fever 39°C, rigors and chills, wheezing, coughing, dyspnea, hypertension or hypotension, headache or vomiting.

BLOOD TRANSFUSION-RELATED ALLERGIC REACTIONS

Blood transfusion-related allergic reactions occur due to protein-based allergens that react with preformed plasma IgG or IgE antibodies. The antibody binds to the allergen resulting in activation and degranulation of mast cells and releasing cell products, i.e. histamine and heparin, which stimulate vasodilation and influx of fluids to the tissues with subsequent edema.

CLINICAL FEATURES

Patient presents with at least two of the following signs and symptoms occur during or within two hours of blood transfusion, which include skin rash, urticaria (hives), pruritus (itching), generalized flushing, edema of lips, tongue and/or uvula, erythema (redness of skin), edema in the periorbital area and conjunctival edema.

BLOOD TRANSFUSION-RELATED ANAPHYLACTIC/ANAPHYLACTOID REACTIONS

Blood transfusion-related anaphylactic/anaphylactoid reactions are rare but severe life-threatening nonhemolytic type 1 hypersensitivity reactions.

PATHOPHYSIOLOGY

Blood transfusion-related anaphylactic reactions occur due to allergic responses to plasma-containing blood products. There is a reaction between a protein allergen in the transfused blood product and its corresponding antibody, which is either in the donated blood component or in the recipient's plasma.

- Antigen–antibody complexes activate mast cells, which release histamine and other chemical mediators resulting in anaphylactic reactions.
- Anaphylactoid blood transfusion reactions occur in IgA-deficient persons, they have made antibody to IgA after exposure to IgA through pregnancy or prior transfusion. When these persons are subsequently transfused with plasma-containing blood products, IgA in the blood-containing plasma blood product initiates the anaphylactoid response. Clinical presentation of anaphylactic and anaphylactoid blood transfusion reactions is indistinguishable.

CLINICAL FEATURES

Patient presents with immediate severe respiratory symptoms such as laryngeal edema, tightness in throat, dysphagia, dysphonia, hoarseness of voice, stridor, dyspnea, coughing, wheezing and bronchospasm. Anaphylactic and anaphylactoid transfusion reactions can be prevented by using washed RBCs or platelet units, autologous donation of blood and/or plasma and deglycerolized rejuvenated RBC units.

BLOOD TRANSFUSION-RELATED ACUTE LUNG INJURY

Blood transfusion-related acute lung injury is an acute adverse reaction, that occurs within 6 hours of blood transfusion.

- Patient develops inadequate oxygenation of blood (hypoxemia) in the absence of cardiac involvement. Hypoxemia is defined by oxygen saturation <90% on room air or PaO_2.
- Chest radiograph shows bilateral pulmonary infiltrates. It is presumed that neutrophils play an important role in causing damage to pulmonary capillaries resulting in pulmonary edema.
- Acute lung injury occurs by both immune and nonimmune mechanisms. Immune response is antibody-mediated reaction, in which antibody is directed against HLA class I, HLA class II or human neutrophil antigens. Antibody-coated neutrophils accumulate in the pulmonary microvasculature and activate complement system resulting in destruction of pulmonary capillaries.

CLINICAL FEATURES

Patient presents with chills, cough, fever, cyanosis, tachycardia and hypotension, pulmonary edema without cardiac involvement. Most cases recover within hours to days with supportive therapy. Blood transfusion-related acute lung injury has been identified as a leading cause of blood transfusion-related death. Diagnostic criteria for blood transfusion-related acute lung injury are given in Table 12.28.

BLOOD TRANSFUSION-RELATED CIRCULATORY OVERLOAD

Rapid rate of transfusion of blood products is the most important cause of transfusion-related circulatory overload. Excess fluid volume in the circulation can result in pulmonary edema and/or congestive heart failure. Blood transfusion-related circulatory overload is diagnosed by presence of at least three symptoms, e.g. acute respiratory distress (dyspnea, orthopnea, cough), evidence positive fluid balance, elevated brain natriuretic peptide, radiograph evidence of pulmonary edema, evidence of left heart failure and elevated central venous pressure. Infusion of red blood cell concentrate is helpful in the management of these cases.

BLOOD TRANSFUSION-RELATED DYSPNEA

Blood transfusion-related dyspnea term is used when the patient develops respiratory distress; and exclusion

Table 12.28 Diagnostic criteria for blood transfusion-related acute lung injury

Features	Comments
Onset of acute lung injury	Within 6 hours of transfusion
Oxygenation	▪ Partial pressure of arterial oxygen (PaO_2)/fraction of inspired oxygen in mm Hg (FiO_2) ▪ Oxygenation saturation of ≤90 and on room temperature
Chest radiograph	Bilateral pulmonary infiltrates
Blood pressure	▪ Pulmonary artery occlusion pressure ≤18 mm Hg when measures ▪ No evidence of left atrial hypertension

of transfusion-related acute lung injury and transfusion-related circulatory overload.

BLOOD TRANSFUSION-RELATED HYPOTENSION

Blood transfusion-related hypotension occurs during or within 1 hour of transfusion, which is characterized by sudden drop of blood pressure (systolic or diastolic) to >30 mm Hg.

PATHOPHYSIOLOGY

Platelet component infusion is usually implicated in hypotensive blood transfusion reactions. Whole blood and packed RBC component administration may cause blood transfusion reactions but to a lesser extent. Hypotensive blood transfusion reactions are related to **bradykinin** produced by kinin-kallikrein system of blood proteins. Activated factor XIII releases kallikrein from high molecular kininogen resulting in generation of bradykinin. Normally, angiotensin-converting enzyme (ACE) degrades bradykinin.

CLINICAL FEATURES

Patient receiving inhibitors of angiotensin-converting enzyme (ACE) is more prone to develop hypotensive transfusion reactions.

- Angiotensin-converting enzyme (ACE) inhibitor-related hypotensive reaction has been observed in liver transplantation in recipients. Patient receiving ACE inhibitors should not be transfused blood component. Leukoreduction of blood products should be preferred.
- Hypotensive blood transfusion reactions should be treated with vasopressor agents resulting in quick increase in blood pressure.
- Immunodeficient recipients fail to eliminate donor T cells resulting in blood transfusion-related graft-versus-host disease.

BLOOD TRANSFUSION-RELATED GRAFT-VERSUS-HOST DISEASE

Blood transfusion-related graft-versus-host disease is a rare complication, but fatal in 90% of cases within 1–3 weeks of onset of graft-versus-host disease.

PATHOPHYSIOLOGY

The blood transfusion-related graft-versus-host disease is caused by donor T cells of transfused blood products. Donor T cells carrying different human leukocyte antigen (HLA) attack the recipient host tissues.

- Immunocompetent recipients may be at risk of developing transfusion-related graft-versus-host disease.
- Recipient patient with fully functional immune system, patient's lymphocytes may not recognize donor's lymphocytes because both share the HLA A_1 antigen. However, donor's lymphocytes may recognize recipient's HLA A_2 as non-self and can attack the recipient's tissues.
- Patient develops blood transfusion-related graft-versus-host disease within a few days to six weeks after transfusion of blood products.

CLINICAL FEATURES

Patient presents with fever, skin rashes, hepatomegaly, diarrhea, anorexia, nausea and vomiting. Pancytopenia develops within 3–4 weeks after blood transfusion resulting in recurrent infections. Definite diagnosis of graft-versus-host disease includes evidence of liver dysfunction (elevated serum enzymes and serum bilirubin), pancytopenia, bone marrow suppression (bone marrow aspirate and bone marrow trephine biopsy show hypoplasia or aplasia) and characteristic histology of skin (blister and bullae formation) and liver pathology (bile duct damage with lymphocytic infiltration of the portal tracts).

BLOOD TRANSFUSION-RELATED SEPSIS

Blood transfusion-related sepsis is nonimmune transfusion reaction resulting in immediate fever (rise of temperature above 2°C of normal), rigor and hypotension shortly after blood transfusion.

PATHOPHYSIOLOGY

Blood transfusion-related sepsis occurs when bacteria-contaminated blood is transfused to the recipient. Bacterial endotoxins generated during blood storage may lead to transfusion associated sepsis. Sources of bacterial contamination of blood components may occur during blood collection and storage of blood products.

PREVENTION

Storage of red blood cell component in refrigerator reduces risk for blood transfusion-related sepsis.

- The blood component should be inspected for lysis of RBCs or platelet clumping, analysis of biochemical markers, light microscopy of gram stained smears and immunoassays prior to blood transfusion.
- Blood transfusion-related sepsis can be prevented by donor clinical history, proper phlebotomy technique,

Table 12.29 Blood transfusion-related sepsis

Gram Stain	Bacterial Contamination	Blood Transfusion-related Sepsis	Source
Gram-positive bacteria	▪ *Staphylococcus* species ▪ *Streptococcus* species ▪ *Bacillus* species	▪ Red blood cell component ▪ Platelet component	▪ Skin flora ▪ Natural environment
Gram-negative bacteria	▪ *Pseudomonas* species ▪ *Escherichia* species ▪ *Yersinia* species ▪ *Serratia* species	▪ Red blood cell component ▪ Platelets component	▪ Blood stream ▪ Natural environment

single arm collection technique, using diversion pouch, prestorage leukoreduction, pathogen inactivation, performing automated culture of bacteria, visual inspection of blood component, biochemical markers, microscopy of gram stained smear and immunoassays. Blood transfusion-related sepsis is given in Table 12.29.

BLOOD TRANSFUSION-RELATED HEMOSIDEROSIS

Blood transfusion-related hemosiderosis is an adverse response to multiple (usually >100) RBC component transfusion in patients suffering from thalassemia major, sickle cell disease and other hereditary hemolytic anemias. One RBC component unit contains approximately 250 mg of iron. Following multiple blood transfusions, iron begins to accumulate and deposit in tissues of the body. Iron deposits interfere with normal functions of major organs.

CLINICAL FEATURES

Patient presents with anemia, weakness and fatigue. Serum ferritin and total iron binding capacity should be assessed to confirm the diagnosis. Perls Prussian blue stain is applied to tissue section or bone marrow aspirate smear to demonstrate iron. Prevention of hemosiderosis is achieved by limiting blood transfusion of RBC products, administration of young RBCs and chelating agents.

BLOOD TRANSFUSION-RELATED PURPURA

Blood transfusion-related purpura presents as severe life-threatening thrombocytopenia within 5–12 days especially in females over the age of 60 years. Platelet level is <20% of pretransfusion level. Cerebral hemorrhage is the main cause of death.

PATHOPHYSIOLOGY

Transfusion of leukocyte-reduced blood products has decreased the incidence of blood transfusion-related thrombocytopenia over years.

- Pre-existing alloantibodies in recipient's plasma against donor's platelet antigens result in platelet destruction by reticuloendothelial cells in spleen.
- Majority of cases develop alloantibodies after exposure to platelet antigens during pregnancy and prior blood transfusion. Blood transfusion-related purpura occurs as a result of transfusion of whole blood, RBC component and any cellular blood product. Leukoreduction decreases the incidence of blood transfusion-related thrombocytopenia.
- Anti-HPA-1a is the most commonly identified antibody in blood transfusion thrombocytopenia accounting for more than 75% of cases. Patient presents with fever, chills and thrombocytopenia.

RAPID MASSIVE BLOOD TRANSFUSION-RELATED REACTIONS

Rapid massive blood transfusion-related reactions occur due to citrate toxicity (hypocalcemia and/or metabolic acidosis and/or hypomagnesemia), hypothermia and dilution coagulopathy.

CITRATE TOXICITY

Following rapid massive blood transfusion, there is transient increase in the plasma citrate level, because normal liver has capacity to metabolize the citrate.

- Citrate toxicity occurs in patients undergoing exchange blood transfusion in newborns and massive blood transfusion in adults, who have liver dysfunction.
- Elevated plasma citrate binds to calcium and magnesium resulting in hypocalcemia and hypomagnesemia.

- Hypocalcemia results in tingling sensations, muscle spasm, skeletal muscle tremors and electrocardiogram changes. Citrate toxicity can cause metabolic acidosis.

HYPOTHERMIA

Rapid massive blood transfusion of cold-temperature blood products especially requiring thawing prior to transfusion results in hypothermia. Patient presents with body temperature less than 35°C, lactic acidosis, ventricular arrhythmia and impaired immune system. Hypothermia can be prevented by the use of blood warming devices, when large amounts of blood products are being transfused.

DILUTIONAL COAGULOPATHY

Rapid massive transfusion of red blood cell component, fluids, colloids and crystalloids can cause dilution of platelets and coagulation factors resulting in coagulopathy.

BLOOD TRANSFUSION-RELATED NONIMMUNE HEMOLYSIS

Several conditions, both physical and chemical in origin such as improper storage of blood at higher or freezing temperature, use of small-bore needles during rapid transfusion, osmotic hemolysis using hypotonic/hypertonic solutions and drugs causing nonimmune hemolysis. Nonimmune hemolysis can be prevented through adherence to written protocols and standards. Equipment function must be regularly analyzed.

BLOOD TRANSFUSION-RELATED HYPERKALEMIA

Blood transfusion-related hyperkalemia in the blood is serious adverse blood transfusion reaction. If not immediately treated, patient can develop respiratory failure and death. Red blood cells release potassium during storage of old blood products resulting in hyperkalemia. Irradiation of red blood cell component also leads to hyperkalemia. Plasma exchange in neonates is performed if serum potassium level reaches 8 mEq/L.

BLOOD TRANSFUSION-RELATED HYPOKALEMIA

Hypokalemia in the blood occurs due to blood transfusion of washed RBCs and deglycerolized RBCs. Hypokalemia causes cardiac disturbances. Premature infants and patients suffering from renal disease are at high risk for developing hypokalemia.

BLOOD TRANSFUSION-RELATED AIR EMBOLISM

Air embolism is a rare adverse reaction of blood transfusion. Excess of air (>100 cc) is introduced into the infusion site as a result of leak or crack in the infusion set. Air embolism may also occur due to improper monitoring of intravenous blood transfusion.

- The consequence of an air bubble in the blood vessels leads to obstruction to circulatory blood flow.
- Patient presents with cough, chest pain and dyspnea. Use of plastic infusion sets has reduced incidence of air embolism.
- Air embolism can be prevented by expelling air from blood infusion set and changing of cracked infusion set before starting blood transfusion.

BLOOD TRANSFUSION-RELATED THROMBOPHLEBITIS

Blood transfusion-related thrombophlebitis occurs in patients with indwelling catheters on infusion site of blood transfusion, which is painful but not a serious complication. Cellulitis may extend from wrist to the elbow.

BLOOD GROUPING

ABO BLOOD GROUPING

ABO blood grouping is performed by two methods in blood bank: cell grouping (forward grouping) and serum grouping (reverse grouping). Both cell and serum groupings should be performed since each test acts as a check on the other.

- Cell grouping (forward grouping) identifies the ABO antigen on the recipient/donor red blood cells employing known (commercial) anti-A and anti-B sera (sometimes anti-A/anti-B sera).
- Serum grouping (reverse grouping) identifies antibodies in the recipient/donor plasma using (commercial) A_1 and B RBCs. ABO-incompatible blood transfusion results in immediate hemolytic blood transfusion reactions, which may have fatal outcome.
- ABO blood group system compatibility is critical in many transplant procedures. ABO discrepancy occurs

Table 12.30 Pretransfusion common blood bank tests

Blood Bank Tests	Blood Bank Test Reactants
ABO forward blood grouping	Recipient RBCs (unknown blood sample) are tested with known commercial antisera anti-A and anti-B
ABO reverse blood grouping	Recipient serum (plasma) is tested with known antigenic make up A1 and B RBCs
Rh testing	Recipient RBCs are tested with anti-D and Rh control, if needed
Antibody screening	Recipient serum (plasma) is tested with donor RBCs
Cross-matching	Recipient serum is tested with donor RBCs

when the cell grouping (forward grouping) and serum grouping (reverse grouping) results do not correlate. Further investigations must be performed before ABO blood group is interpreted.

- ABO discrepancies fall into four categories: (a) weak or missing reaction is observed in the forward grouping, (b) weak or missing reaction is observed in the reverse grouping, (c) unexpected positive reaction is demonstrated in the forward grouping, and (d) unexpected positive reaction is demonstrated in the reverse grouping. Pretransfusion common blood bank tests are given in Table 12.30.

METHODS OF ABO BLOOD GROUPING

There are two methods of ABO blood grouping: cell grouping (forward grouping) and serum grouping (reverse grouping). ABO blood grouping performed by two methods in blood bank: Cell grouping (forward grouping) and serum grouping (reverse grouping) are shown in Fig. 12.21.

Cell Grouping (Forward Grouping)

Cell grouping (forward grouping) identifies the ABO antigen on the recipient/donor RBCs employing known (commercial) anti-A (blue-colored vial), anti-B (yellow-colored vial) sera and anti-A/anti-B (colorless vial) sera. Now add antibodies to A, B and Rh antigens in three test tubes (1 for A, 1 for B, 1 for Rh) containing patient's RBCs.

- Clumping of the RBCs indicates presence of antigen on the patient's RBCs.
- Failure to clump RBCs indicates absence of antigen on the patient's RBCs. Sodium azide is added to antiserum and stored at 4–6°C to prevent bacterial growth.

Serum Grouping (Reverse Grouping)

Serum grouping (reverse grouping) identifies antibodies in the recipient/donor plasma using (commercial) A_1 and B RBCs. These antibodies bind to the RBC antigens.

- Now add patient's serum, which can bind to red blood cells in two test tubes (A cells in 1 test tube and B cells in 2 test tubes).
- Clumping of the RBCs indicates absence of antibody to RBC antigens.
- ABO antisera used for blood group typing include anti-A (blue-colored vial), anti-B (yellow-colored vial) and anti-A/anti-B (colorless vial).

METHODOLOGY

ABO blood grouping is performed by three methods: (a) slide test, (b) test tube, and (c) microplate. Tube and microplate tests are better than slide test; and employed in blood banking.

Blood Grouping by Slide Test

Red blood cells (RBCs) from blood sample are reacted with anti-A and anti-B sera. Demonstration of agglutination of RBCs indicates presence of corresponding antigen on the RBCs (Fig. 12.22).

- One drop of anti-A and one drop of anti-B are placed on different areas on the slide ensuring that these are not mixed. Now add one drop of blood sample containing RBCs to be tested to the anti-A and anti-B sera and then mixed by using a stick.
- Presence of RBCs agglutination is observed in both the areas of the slide. Results of the slide test are always confirmed by cell grouping (forward grouping) and serum grouping (reverse grouping) by test tube method.

Blood Grouping by Test Tube Method

Blood grouping by test tube method is more reliable than slide test. Red blood cells (RBCs) of blood sample are washed with saline and then mixed with known antiserum in the test tube.

- Mixture is incubated at room temperature and centrifuged. Following centrifugation, cell button formed is dislodged gently by tapping the base of the test tube and examined for agglutination of RBCs.
- Agglutination of RBCs is graded from 1+ to 4+ with naked eye. Blood grouping using test tube is shown in Fig. 12.23.

	Forward grouping reaction with serum		Reverse grouping reaction with RBCs	
Blood group	**Anti-A**	**Anti-B**	**A cells**	**B cells**
A	+	0	0	+
B	0	+	+	0
O	0	0	+	+
AB	+	+	0	0

Fig. 12.21: ABO blood grouping is performed by two methods in blood bank: Cell grouping (forward grouping) and serum grouping (reverse grouping).

Blood Grouping by Microplate Method

Microplate technique uses automated platforms in blood banking laboratory for testing blood specimens to detect weaker serum antigen–antibody reactions, i.e. RBC surface antigens and serum antibodies. The reactants are centrifuged and incubated in microplates, and the ABO/Rh(D) blood group is read through an automated system. Microplate composed of polystyrene consists of automated 96 microwells of either U or V shape. The U-shaped microplate can detect multiple blood specimens simultaneously.

Rh BLOOD GROUPING

Both ABO and Rh antigens are immunogenic. Therefore, RBCs for D antigen is routinely performed in blood banking by mixing RBCs with anti-RhD antibodies. Depending on the presence or absence of D antigen, persons are called Rh positive or Rh negative. Importance of Rh blood grouping in clinical practice is that Rh negative mother with Rh positive fetus develops anti-RhD antibodies against fetus Rh positive cells. Antibodies from mother's cross placenta result in hemolytic disease of newborn.

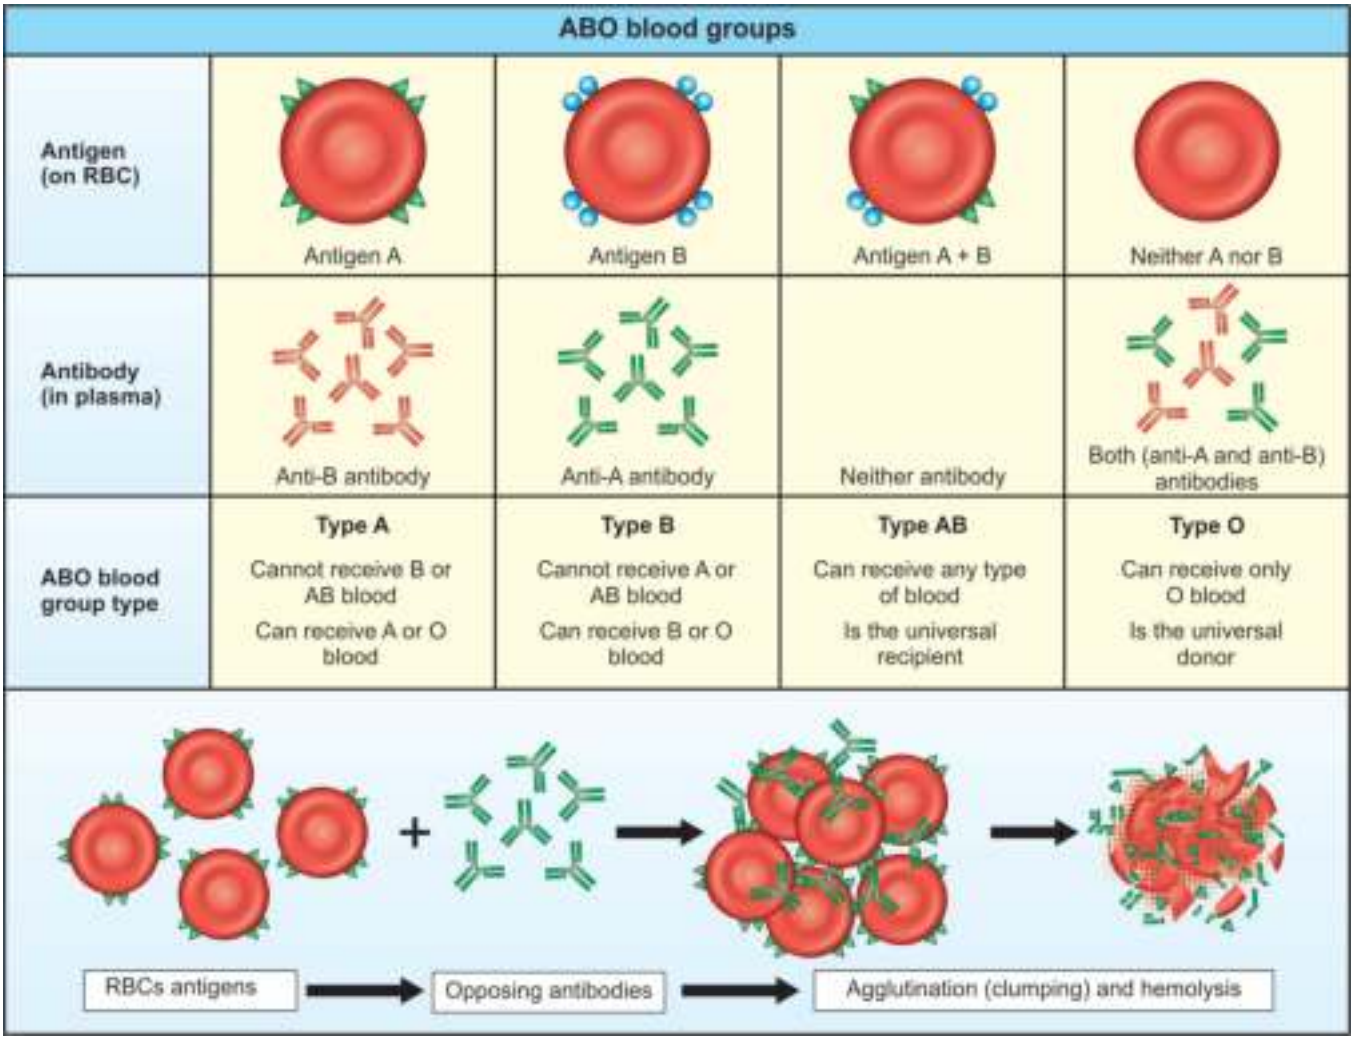

Fig. 12.22: Blood grouping performed by using slide test.

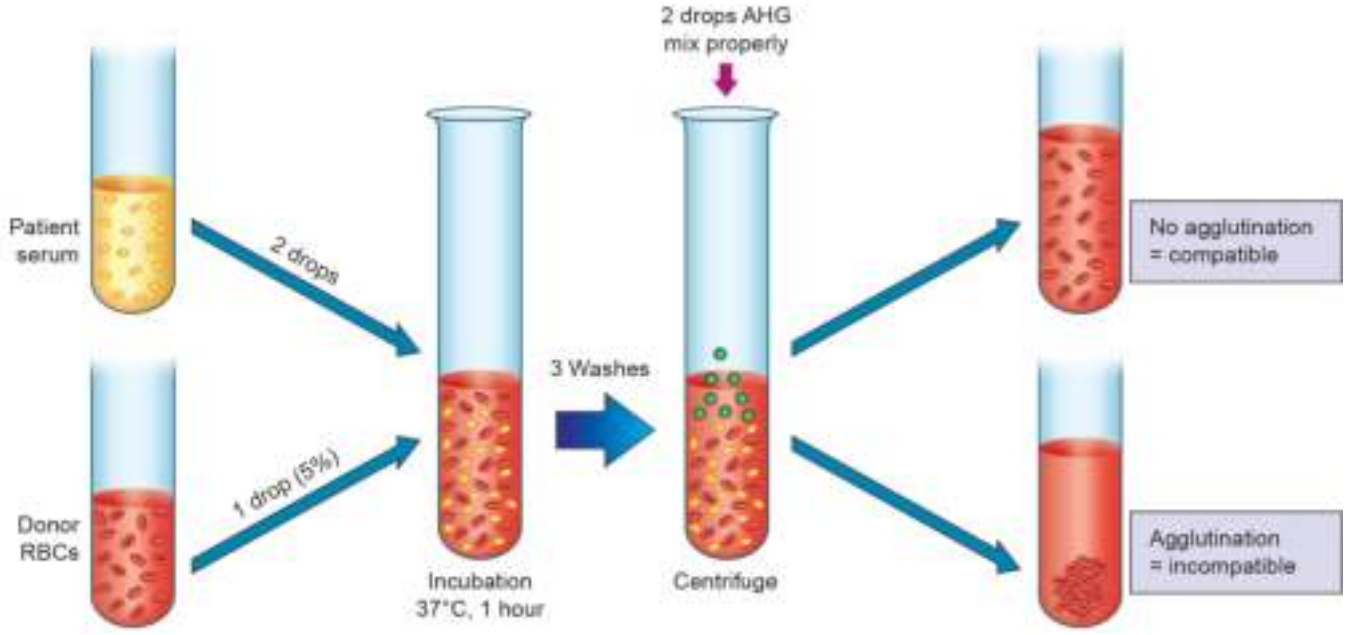

Fig. 12.23: Blood grouping performed by test tube method.

BLOOD CROSS-MATCHING (COMPATIBILITY) TEST

In blood transfusion medicine, cross-matching (part of series of steps in compatibility tests) is done before blood transfusion to determine if the donor's blood is compatible with the blood of an intended recipient. Blood cross-matching is also performed to determine compatibility between a donor and recipient in organ transplantation. Compatibility is determined through matching of different blood group systems. The most important is the ABO and Rh blood group system and/or by directly testing for the presence of antibodies against the RBC antigens in a sample of donor blood or the tissue. Blood cross-matching can be performed by electronic method with a database, if the recipient has previously been tested. Recipient blood sample should be tested to screen antibodies by indirect Coombs' test. Red blood cell antigens and antibodies and their significance are given in Table 12.31. Blood cross-matching is shown in Fig. 12.24.

Table 12.31 Red blood cell (RBC) antigens and antibodies and their significance

Red Blood Cell Antigens	Natural Occurring Antibodies (Usually IgG)	Antibodies Only Occurring After Sensitization or Immune (Usually IgG)	Significance
ABO blood group			
A antigen	Anti-B antibody	Nil	Hemolytic blood transfusion reaction common
B antigen	Anti-A antibody	Nil	Hemolytic blood transfusion reaction common
AB antigen	Nil	Nil	Hemolytic blood transfusion reaction common
O antigen	Anti-A and anti-B antibody	Nil	Hemolytic blood transfusion reaction common
Rh blood group			
D antigen	Nil	Anti-D antibody	▪ Extremely common (90%) ▪ Hemolytic disease of newborn (most common)
Kell (KEL) blood group			
Kell antigen	Nil	Anti-Kell antibody	Acute hemolytic blood transfusion reaction (10%)
Duffy (Fy) blood group			
Duffy antigen	Nil	▪ Anti-Fya antibody ▪ Anti-Fyb antibody	▪ Anti-Fya more common ▪ Hemolytic blood transfusion reaction in occasional case ▪ Hemolytic disease of newborn in occasional case
Kidd (Jk) blood group			
Kidd antigen	Nil	▪ Anti-Jka antibody ▪ Anti-Jkb antibody	▪ Dangerous fatal ('killer Kidd') ▪ Hemolytic blood transfusion reaction in occasional case ▪ Hemolytic disease of newborn in occasional case
Lutheran (LU) blood group			
Lutheran antigen	Nil	Anti-Lutheran antibody	▪ Hemolytic blood transfusion reaction in rare case ▪ Hemolytic disease of newborn absent

Table 12.31 Red blood cell (RBC) antigens and antibodies and their significance *(Contd...)*

Red Blood Cell Antigens	Natural Occurring Antibodies (Usually IgG)	Antibodies Only Occurring After Sensitization or Immune (Usually IgG)	Significance
Lewis (LE) blood group			
Lewis antigen	Nil	Anti-Lewis antibody	▪ Hemolytic blood transfusion reaction in rare case ▪ Hemolytic disease of newborn absent
P (PI) blood group			
P antigen	Nil	Anti-P antibody	▪ Hemolytic blood transfusion reaction in rare case ▪ Hemolytic disease of newborn in rare case
MNS (MNS) blood group			
MNS antigen	Nil	Anti-MNS antibody	▪ Hemolytic blood transfusion reaction in rare case ▪ Hemolytic disease of newborn in rare case

	Compatible with		
Patient's ABO group	**Whole blood**	**Red blood cells (RBCs)**	**Plasma**
O	O	O	O, A, B, AB
A	A	A, O	A, AB
B	B	B, O	B, AB
AB	AB	AB, A, B, O	AB

Fig. 12.24: Blood cross-matching.

IMMEDIATE SPIN BLOOD CROSS-MATCHING

Immediate spin blood cross-matching is faster, less expensive but less sensitive. It is an immediate test that combines recipient's serum and the donor's red blood cells (RBCs) at room temperature. No agglutination of RBCs indicates a negative test reaction, and thus compatible blood cross-matching.

ELECTRONIC BASED BLOOD CROSS-MATCHING

Electronic based blood cross-matching is a computer-assisted analysis using data from the donor unit, where a donor's blood is tested prior to donation. Recipient blood sample is also tested, which includes ABO/Rh typing of the blood unit and the recipient for the presence of antibodies. Electronic based blood cross-matching can only be performed if the recipient has a negative antibody screen below the detectable level of current test methods. Blood cross-matching falls into two groups: major cross-match and minor cross-match.

ELECTRONIC BASED MAJOR BLOOD CROSS-MATCH

In electronic based major blood cross-match, recipient serum is tested against donor packed red blood cells to determine if the recipient has preformed antibodies against any antigens on the donor's red blood cells. This is essential cross-match prior to release of a blood unit of packed cells.

ELECTRONIC BASED MINOR BLOOD CROSS-MATCH

In electronic based minor blood cross-match, recipient RBCs are tested against donor serum to detect donor antibodies directed against recipient's RBC antigens. This technique is no longer required. It is assumed that the small amount of donor serum antibodies left in the blood unit of packed RBCs would have been diluted in the recipient.

CHAPTER

13

Lymph Node, Spleen and Thymus Gland Disorders

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

DISORDERS OF LYMPH NODE

- Lymph node organization
  - Lymph node compartments
  - Arterial supply and venous drainage of lymph node
- Developmental stages of hematopoietic stem cells
  - T cell development
  - B cell development
- Lymph node non-neoplastic disorders
  - Suppurative lymphadenitis
  - Granulomatous lymphadenitis
  - Reactive lymphoid hyperplasia
  - Sinus histiocytosis
  - Infectious mononucleosis
  - Kikuchi disease
  - Kumura's disease
  - Castleman disease
- Cervical lymphadenopathy
- Lymphoid neoplasms
  - 2024 WHO classification of lymphoid neoplasms
  - Predisposing factors
  - Molecular diagnostics
  - Staging of lymphoid neoplasms

HODGKIN'S DISEASE

- Hodgkin diseases: overview
  - Diagnostic criteria of Hodgkin's disease
    - Reed-Sternberg cells (growth and survival of Reed-Sternberg cells and role of EB virus in pathogenesis of Hodgkin's disease)
  - Clinical features
  - Chest radiographs
  - Mode of spread
  - Clinical staging
    - Ann Arbor staging system
  - Laboratory diagnosis
  - Differential diagnosis
- Hodgkin's disease: morphologic subtypes
  - Lymphocyte-rich classic variant of Hodgkin's disease
  - Lymphocyte-depletion classic variant of Hodgkin's disease
  - Nodular sclerosis classic variant of Hodgkin's disease
  - Mixed cellularity classic variant of Hodgkin's disease
  - Nodular lymphocytic–histiocytic predominant variant of Hodgkin's disease

NON-HODGKIN'S LYMPHOMAS

- Non-Hodgkin's lymphomas: overview
  - Non-Hodgkin's lymphomas: grades
  - Approach to NHL work up
  - Immunophenotyping
- Precursor B cell and T cell NHLs
  - Precursor B cell lymphoblastic leukemia/lymphoma
  - Precursor T cell lymphoblastic leukemia/lymphoma
  - Myeloid and lymphoid neoplasms with FGFR1 abnormalities
- Mature B cell non-Hodgkin's lymphoma
  - Burkitt's lymphoma
  - Diffuse large B cell lymphoma
  - Chronic lymphocytic leukemia/small lymphocytic lymphoma
  - Follicular lymphoma
  - Mantle cell lymphoma
  - Marginal zone lymphoma (nodal marginal zone lymphoma, extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue, splenic marginal zone lymphoma)
  - Plasmablastic lymphoma
  - Hairy cell leukemia
  - B cell prolymphocytic leukemia
  - Multiple myeloma
- Mature T cell and NK cell lymphomas
  - Angioimmunoblastic T cell lymphoma
  - Adult T cell leukemia/lymphoma
  - Anaplastic lymphoma kinase (ALK) positive anaplastic large T cell lymphoma
  - Extranodal NK cell/T cell lymphoma
  - Mycosis fungoides
  - Sézary syndrome

DISORDERS OF SPLEEN

- Spleen: structure
  - White pulp of spleen
  - Red pulp of spleen
- Functional disorders of spleen
  - Therapeutic splenectomy
  - Splenomegaly
  - Fibrocongestive splenomegaly
  - Hypersplenism
  - Autosplenectomy
  - Hyposplenism
  - Splenosis
  - Splenic rupture
  - Hemosiderosis of spleen
- Reactive splenic disorders
  - Granulomatous inflammation of spleen
  - Splenic infarct
- Non-neoplastic infiltrative disorders of spleen
  - Gaucher's disease involving spleen
  - Spleen involvement in amyloidosis
- Neoplastic disorders of spleen
  - Splenic marginal zone lymphoma
  - Metastases in spleen
  - Angiosarcoma of spleen

DISORDERS OF THYMUS GLAND

- Anatomy and histology of thymus gland
  - Anatomy
  - Histology
- Thymus hyperplasia
- Immunodeficiency disorders of thymus gland
  - DiGeorge syndrome
  - Wiskott-Aldrich syndrome (X-linked disorder)
- Thymic neoplasms
  - Thymoma
- Thymic carcinoma

DISORDERS OF LYMPH NODE

LYMPH NODE ORGANIZATION

Lymph nodes are collections of lymphoid tissue widely distributed within the lymphoreticular system. Beneath the collagenous capsule of lymph node is the subareolar sinus, which is lined by phagocytic cells. Lymphocytes and antigens from surrounding tissue spaces or adjacent lymph nodes pass into the sinus via the afferent lymphatic system.

LYMPH NODE COMPARTMENTS

On histologic examination, lymph nodes show four compartments: cortex showing primary and secondary lymphoid follicles containing B cells found near capsule, paracortex containing T cells surrounding follicles, medullary region and sinuses. T cells in the cortex are associated with the interdigitating antigen-presenting cells (APCs).

ARTERIAL SUPPLY AND VENOUS DRAINAGE OF LYMPH NODE

Each lymph node has its own arterial supply and venous drainage. Lymphocytes enter the lymph node from the circulation through the specialized high endothelial venules in the paracortex. The medulla contains both T and B cells as well as plasma cells, organized into cords of lymphoid tissue. Lymphocytes can leave the lymph node through the efferent lymphatic vessel.

DEVELOPMENTAL STAGES OF HEMATOPOIETIC STEM CELLS

During intrauterine life, hematopoiesis initially occurs in the yolk sac, later takes place in the liver and spleen. After birth, hematopoiesis function is taken over by the red bone marrow. All the blood cells derived from a pluripotent hematopoietic stem cell differentiate into various lineages forming erythrocytes, megakaryocytes, neutrophils, eosinophils, basophils, lymphocytes and monocytes. The precursor cells of these lineages are known as colony-forming units (CFUs).

T CELL DEVELOPMENT

Precursor T cells reach the thymus for development through several stages of thymocytes, i.e. stage I: prothymocyte, stage II: common thymocyte, stage III: mature thymocyte and finally stage IV: post-thymic mature T cells. T cells express terminal deoxynucleotidyl transferase (TdT) in the nucleus, CD3 in the cytoplasm, CD38, and CD71 on surface of T cells. Earliest T cell surface marker is CD7. Immunophenotyping of different developmental stages of T cells is given in Table 13.1.

B CELL DEVELOPMENT

Development of B cells is confined to the bone marrow through various stages, i.e. progenitor B cell, pre-pre-B cell, pre-B cell, immature B cell, mature B cell,

Table 13.1 Immunophenotyping of different developmental stages of T cells. Adapted from flow cytometry, immunohistochemistry and molecular genetics for hematologic neoplasms

Immunophenotyping	Stage I: Prothymocyte	Stage II: Common Thymocyte	Stage III: Mature Thymocyte	Stage IV: Post-thymic Mature T Cells
TdT*	Positive	Positive	Positive	Negative
CD7	Positive	Positive	Positive	Positive
cCD3*	Positive	Positive	Positive	Positive
CD2	Positive	Positive	Positive	Positive
CD5	Negative	Positive	Positive	Positive
CD34	Positive	Negative	Negative	Negative
HLA-DR	Positive	Negative	Negative	Negative
TCR*	Negative	Negative	Positive	Positive
CD1	Negative	Positive	Negative	Negative
CD71	Positive	Negative	Negative	Negative
CD4	Negative	Positive	Positive	Positive
CD8	Negative	Positive	Positive	Positive
CD3	Negative	Negative	Positive	Negative

**TdT (terminal deoxynucleotidyl transferase); *TCR—T cell receptor (TCR ab 95%, TCR gd 5%); *cCD3 (cytoplasmic CD3)*

activated B cell and plasma cell. As the heavy chain of immunoglobulin switching takes place on B cell activation, the activated B cells express surface IgA, IgM or IgG. CD21 disappears at this stage. Plasma cells synthesize cytoplasmic immunoglobulin and express CD38, CD138, PCA-1 and PC-1 (Table 13.2).

- Lymph node consists of four compartments: (a) cortex, (b) paracortex, (c) medullary cords, and (d) sinuses.

Table 13.2 Immunophenotyping of different stages of B-lymphocytes (adapted from 2024 WHO classification of tumors of the hematopoietic and lymphoid tissues)

Progenitor B cell	TdT, HLA-DR, CD34, cCD79
↓	
Pre-pre-B cell	TdT, HLA-DR, CD34, CD19, CD10, cCD22, cCD79
↓	
Pre-B cell	TdT, HLA-DR, CD19, CD10, CD20, CD79, cCD22
↓	
Immature B cell	HLA-DR, CD19, CD20, CD79, CD21, cCD72, sIgM
↓	
Mature B cell	HLA-DR, CD19, CD20, CD21, CD22, CD79, sIgM, sIgD
↓	
Activated B cell	HLA-DR, CD19, CD20, CD22, CD79, sIgM, IgG
↓	
Plasma cell	Immunoglobulins, CD38, CD138, PCA-1, PC1

c (cytoplasmic), s (surface), TdT (terminal deoxynucleotidyl transferase), Ig (immunoglobulin)

- Cortex of a lymph node is composed of primary lymphoid follicles containing resting B cells. Antigenic stimulation of resting B cells leads to proliferation and lymphoblastic transformation, and formation of germinal center, now termed secondary lymphoid follicle.
- In the germinal center of secondary lymphoid follicles, B cells are activated by antigens resulting in proliferation. Generation of plasma cells and memory cells as well as switching of heavy chain class takes place in the germinal center of secondary lymphoid follicles. A germinal center is surrounded by a mantle zone. In the mantle zone, small lymphocytes develop into mantle cells and finally into blastoid cells. Tissue sampling and preparation of histologic slides are given in Table 13.3.

LYMPH NODE NON-NEOPLASTIC DISORDERS

Lymph node non-neoplastic disorders include acute and chronic nonspecific lymphadenitis occurring in response to a number of infectious agents or immune stimuli.

SUPPURATIVE LYMPHADENITIS

Suppurative lymphadenitis occurs in the draining lymph nodes following acute bacterial infection. The lymph nodes rapidly become enlarged due to edema and hyperemia and are tender due to distension of the capsule. Histologic examination of lymph node shows polymorphonuclear leukocytic infiltration in lymph node sinuses and stroma associated with prominent follicular hyperplasia. Infective and granulomatous lymphadenopathy are given in Table 13.4.

Table 13.3 Tissue sampling and histologic slide preparation of lymph node

Sampling of Lymph Node	Utility
Wet touch preparation	▪ Hematoxylin and eosin (fixed in formalin) ▪ Papanicolaou staining (fixed in 95% alcohol)
Air-dried touch smears	▪ Myeloperoxidase stain ▪ Nonspecific esterase ▪ FISH (fluorescence *in situ* hybridization) for cytogenetics
Rapid frozen tissue	▪ Immunohistochemistry ▪ Cytochemistry ▪ Genetic analysis
Fresh tissue in RPMI 1640 medium or saline	Flow cytometry
Sterile fresh tissue	Microbial culture
Formalin fixed paraffin-embedded sections	▪ Hematoxylin and eosin ▪ Giemsa stain ▪ Periodic acid–Schiff (PAS) stain ▪ Masson's trichrome
Thin shaved tissue	Electron microscopy (fixed in glutaraldehyde)

Table 13.4 Infective and granulomatous lymphadenopathy

Suppurative Granulomatous Lesions
▪ Cat-scratch fever (*Bartonella hensalae*)
▪ Lymphogranuloma venereum (*Chlamydia trachomatis*)
▪ Tularemia
▪ *Yersinia enterocolitica*
▪ *Listeria monocytogenes*
▪ *Corynebacterium bovis*
Necrotizing Granulomatous Lesions
▪ Mycobacterium tubercle bacilli
▪ Atypical mycobacterium tubercle bacilli
▪ Mycobacterium lepra bacilli
▪ Systemic fungal infections (e.g. *Cryptococcus neoformans, Histoplasma capsulatum, Coccidioides immitis, Blastomycosis dermatitidis*)
Non-necrotizing Granulomatous Lesions
▪ Sarcoidosis
▪ Berylliosis
▪ Crohn's disease
▪ Protozoal infection
▪ Lymph node draining carcinoma
▪ Reaction to foreign material

GRANULOMATOUS LYMPHADENITIS

Granulomatous lymphadenitis is characterized by formation of epithelioid granulomas in the lymph nodes.

- Caseating granulomas with central necrosis and caseation are demonstrated in *Mycobacterium tuberculosis*. Acid-fast bacilli are stained by Ziehl-Neelsen stain appearing as bright red, slender and beaded rods. *Mycobacterium leprae* and histoplasmosis are other examples of caseating lymphadenitis.
- Noncaseating granulomas are seen in sarcoidosis composed of epithelioid histiocytes with scattered multinucleated giant cells. Noncaseating epithelioid granulomas can be demonstrated in draining lymph nodes in Crohn's disease. Granulomatous lymphadenitis is shown in Fig. 13.1.

REACTIVE LYMPHOID HYPERPLASIA

Reactive lymphoid hyperplasia refers to enlargement of lymphoid follicles (principally in the cortex of the lymph node), which consist of B cells. Reactive follicular lymphoid hyperplasia of lymph nodes represents a response to infections, inflammation, or malignant tumors. Reactive hyperplasia of the secondary follicles, germinal centers, and increased plasma cells in medullary cords indicates B cell immune response. Reactive hyperplasia of the deep cortex or paracortex (diffuse hyperplasia in interfollicular region) is characteristic of T cell immune response. Patterns of reactive follicular hyperplasia of lymph node are given in Table 13.5.

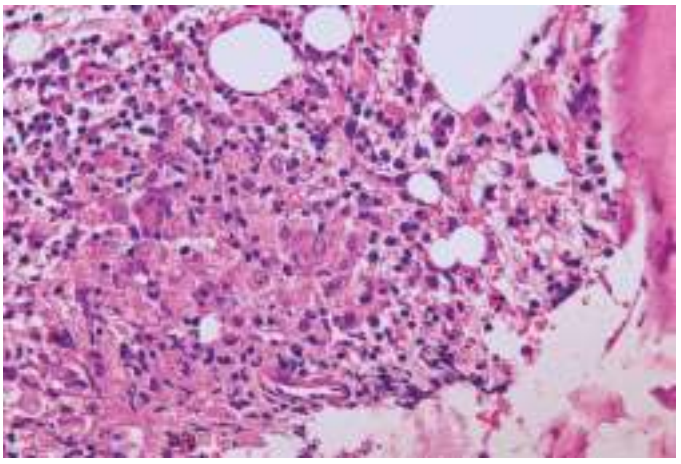

Fig. 13.1: Lymph node shows granulomatous lymphadenitis (400X).

Table 13.5 Patterns of reactive hyperplasia of lymph node

Reactive Follicular Hyperplasia of Lymph Node
▪ Nonspecific follicular hyperplasia
▪ Castleman disease
▪ Kimura disease—syphilis
▪ Cytomegalovirus lymphadenitis
▪ Toxoplasmosis
▪ Human immunodeficiency virus lymphadenitis
▪ Rheumatoid lymphadenopathy
Paracortical Expansion of Lymph Node
▪ Dermatopathic lymphadenopathy
▪ Systemic lupus erythematosus
▪ Drug-induced lymphadenopathy
▪ Viral lymphadenitis (Epstein-Barr virus, cytomegalovirus (CMV), HSV-6, varicella, adenovirus)
▪ Inflammatory pseudotumor of lymph node
▪ Autoimmune lymphoproliferative syndrome
Sinus Expansion of Lymph Node
▪ Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy)
▪ Langerhans' cell histiocytosis
▪ Lipogranulomatous reaction (exogenous lipid during lymphangiogram, endogenous lipid in diabetes mellitus and hyperlipidemia)
▪ Silicone lymphadenopathy
▪ Storage disorders

SINUS HISTIOCYTOSIS

Necrotic products of the malignant tumor antigens often evoke reactive changes in the lymph nodes such as enlargement and hyperplasia of the lymphoid follicles, proliferation of macrophages in the subcapsular sinuses known as sinus histiocytosis.

INFECTIOUS MONONUCLEOSIS

Infectious mononucleosis is a benign self-limited disorder caused by Epstein-Barr virus (EBV), which has an affinity for B cells. It occurs frequently in young adults.

- Circulating atypical reactive CD8+ cytotoxic T cells are characteristic of infectious mononucleosis. The disorder is marked by a number of serum anti-EBV antibodies and heterophil antibodies (heterophil agglutinins) directed against sheep erythrocytes.
- Patient presents with history of sore throat, fever, generalized lymphadenopathy, and hepatosplenomegaly. The spleen is especially susceptible to traumatic rupture. Heterophil agglutinins (antibodies) negative infectious mononucleosis is most often associated with cytomegalovirus infection.

KIKUCHI DISEASE

Kikuchi disease is a benign disorder characterized by generalized necrotizing lymphadenopathy, which affects more often young women than men. Patient presents with recurrent necrotizing lymphadenitis often associated with other systemic inflammatory disorders such as systemic lupus erythematosus, tuberculosis, HIV and parvovirus B19.

Surgical Pathology: Kikuchi Disease
Light Microscopy
Histopathologic examination of lymph node shows paracortical expansion, admixture of lymphocytes, histiocytes, widespread apoptosis of cellular infiltrate and necrosis. Neutrophils are absent (Fig. 13.2).

KIMURA'S DISEASE

Kimura's disease is characterized by angiolymphoid proliferation of lymph nodes predominantly in the head and neck region forming eosinophilic abscess involving of subcutaneous tissue and eosinophilia. Salivary gland involvement, glomerulonephritis, nephrotic syndrome, eosinophilia and increased IgE are more common in Kimura's disease than Kikuchi disease.

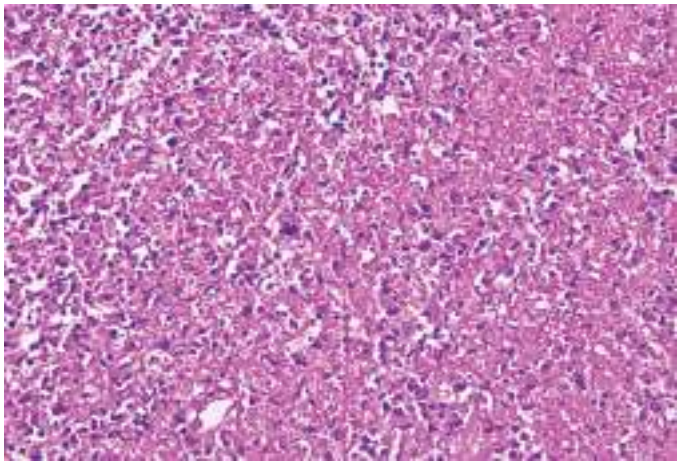

Fig. 13.2: Kikuchi disease shows necrotizing lymph node with paracortical expansion, admixture of lymphocytes, histiocytes and widespread apoptosis. However, neutrophils are absent (100X).

CASTLEMAN DISEASE

Castleman disease is also known as angiofollicular hyperplasia of lymph node or giant lymph node hyperplasia or angiomatous lymphoid hamartoma. Disorder may be localized (hyaline vascular variant and multicentric cell variant) or multicentric lymph nodes involvement in mediastinum, which most often affects adults but less prevalent in children. Castleman disease variants are given in Table 13.6.

Clinical Features

Patient presents with dyspnea and radiograph reveals widening of mediastinum due to solitary or multicentric lymph node enlargement. It may be associated with

Table 13.6 Castleman disease variants

Hyaline Vascular Variant of Castleman Disease	Multicentric Plasma Cell Variant of Castleman Disease	Multicentric Variant of Castleman Disease (IL-6 Lymphadenopathy)
Age group		
Young adults	Wide range age group	Older age group
Clinical features		
Mediastinal lymph nodes involved	▪ Abdominal lymph nodes involved ▪ Anemia, raised ESR, raised serum globulins and increased plasma cells in bone marrow	▪ Multicentric lymph nodes involved due to dysregulation of IL-6 ▪ Association with HIV/AIDS; and POEMS syndrome
Histologic features		
▪ Hyaline follicles are composed of endothelial cells and dendritic reticulum cells ▪ Mantle zone shows onion-skin appearance ▪ Interfollicular areas are vascular	▪ Follicular hyperplasia with narrow mantle zones ▪ Numerous plasma cells in interfollicular regions with obscuring lymph node architecture ▪ One-third of cases exhibit light-chain restriction	▪ Follicular hyperplasia with narrow mantle zones ▪ Numerous plasma cells in interfollicular regions with obscuring lymph node architecture ▪ About 33% of cases exhibit light-chain restriction

POEMS (polyneuropathy, organomegaly, endocrine abnormalities, monoclonal gammopathy, skin rashes) syndrome.

Kaposi sarcoma, mantle cell lymphoma, and diffuse large B cell lymphoma (DLBCL).

Castleman Disease: Histologic Variants

- Hyaline-vascular variant of Castleman disease is unicentric and asymptomatic disease. Patient presents with anemia, night sweats, weight loss, elevated sedimentation rate and hypergammaglobulinemia. Histologic examination shows increased lymphoid follicles in cortex and medulla. Follicles contain hyalinized and sclerosed blood vessels resembling white pulp of spleen.
- Plasma cell variant of Castleman disease is multicentric disease. Patient presents with generalized lymphadenopathy. Histologic examination exhibits proliferation of blood vessels surrounded by mature plasma cells. There is distension of lymph node sinuses. Children have good prognosis with corticosteroid therapy. It is associated with HHV8+ infection, with an accumulation of HHV8+ lymphocytes in mantle zone leading to dissolution of the germinal center.
- Multicentric variant of Castleman disease is an atypical lymphoproliferative disorder characterized by systemic lymphadenopathy and constitutional inflammatory symptoms. Dysregulated overproduction of interleukin-6 (IL-6) is responsible for clinical manifestations.

CERVICAL LYMPHADENOPATHY

The most common swellings in cervical region are enlarged lymph nodes caused by bacterial or viral infections, lymphomas and metastatic deposits. Inflammatory lymphadenopathy is most often painful, firm and mobile located in the midline or lateral side of neck. Delphin lymph nodes located along thyrohyoid membrane are enlarged in thyroid carcinoma. Malignant lymph nodes are painless and hard in consistency. *Leishmania donovani* (*LD*) bodies in the fine needle aspirate of lymph node are shown in Fig. 13.3. Metastatic deposits in lymph nodes are shown in Figs 13.4A to C and 13.5. Lymphadenopathy may be generalized or

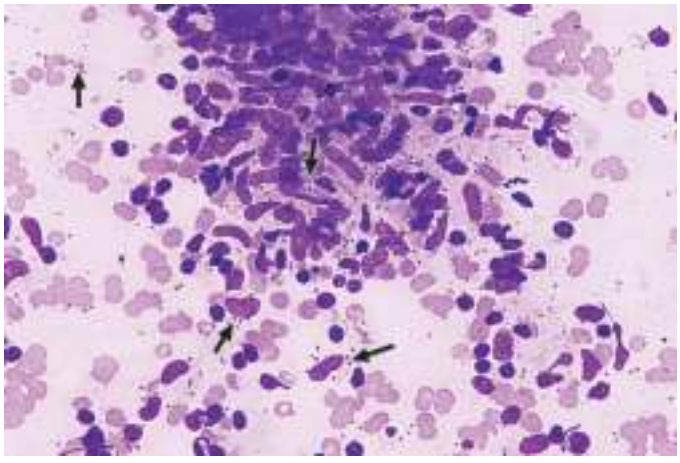

Fig. 13.3: *Leishmania donovani* bodies are demonstrated in the fine needle aspirate of lymph node. Epithelioid granuloma is also seen (arrows) (400X).

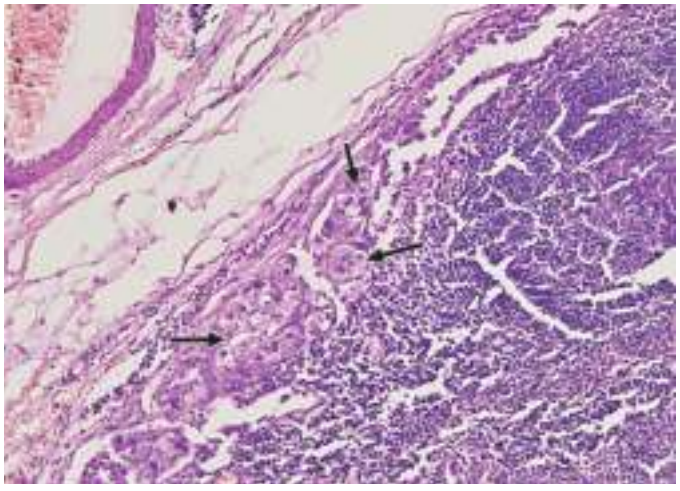

Fig. 13.4A: Metastatic deposits from carcinoma are seen in subcapsular area of lymph node (arrows) (400X).

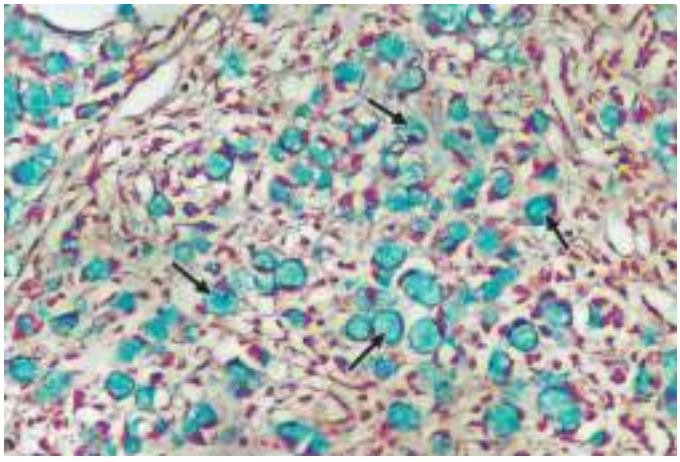

Fig. 13.4B: Metastatic deposits from adenocarcinoma to lymph node show positivity with Alcian blue (arrows) (400X).

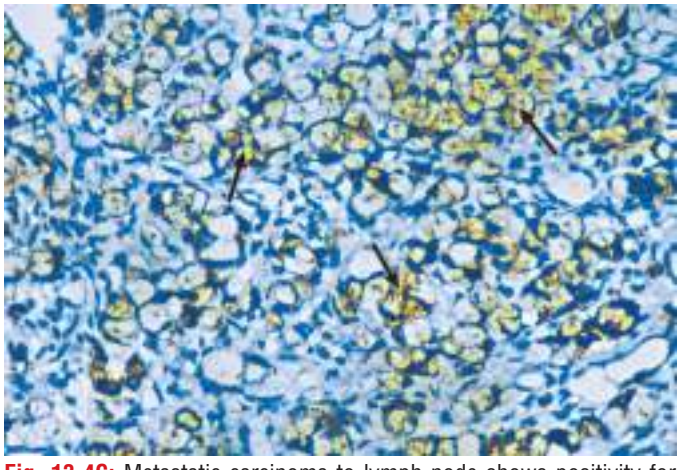

Fig. 13.4C: Metastatic carcinoma to lymph node shows positivity for cytokeratin (arrows) (400X).

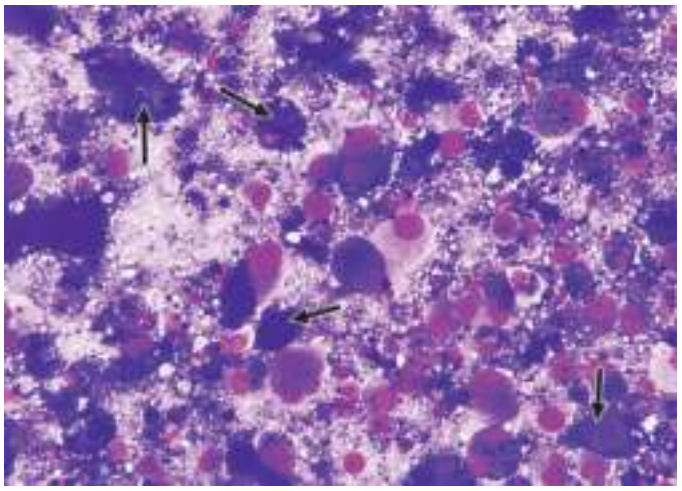

Fig. 13.5: Fine needle aspirate from lymph node shows metastatic deposits from melanoma (arrows) (400X).

localized (Table 13.7). Differential diagnosis of cervical lymphadenopathy is given in Table 13.8.

LYMPHOID NEOPLASMS

Lymphoid neoplasms arise from T or B cells and their precursor cells. Patient presents with localized lymphadenopathy characterized by formation of gross malignant tumor nodules.

- Conversely, neoplastic proliferation of lymphocytes with diffuse and systemic involvement from their inception are categorized as leukemias. Malignant lymphoid neoplasms can be divided into two major categories—Hodgkin's disease and non-Hodgkin's lymphoma.

Table 13.7 Causes of lymphadenopathy

Categories	Causes
Generalized lymphadenopathy	
Lymphomas	▪ Hodgkin's disease ▪ Non-Hodgkin's lymphoma
Leukemias	▪ Acute lymphoblastic leukemia ▪ Chronic lymphocytic leukemia
Infections	▪ Tuberculosis ▪ Brucellosis ▪ Syphilis ▪ *Toxoplasma gondii* ▪ Sarcoidosis
Autoimmune disorders	▪ Systemic lupus erythematosus ▪ Rheumatoid arthritis
Hypersensitivity reaction	Serum sickness
Lipid storage diseases	▪ Gaucher's disease ▪ Niemann-Pick disease
Drug	Phenytoin
Miscellaneous	▪ Sarcoidosis ▪ Pseudolymphoma
Localized lymphadenopathy	
Infections	Acute or chronic infections
Metastatic cancers	▪ Breast carcinoma ▪ Lung carcinoma ▪ Kidney carcinoma ▪ Head and neck carcinoma

- Non-Hodgkin's lymphoma may develop at each stage of differentiation in lymph nodes, e.g. mantle cell

Table 13.8 Differential diagnosis of cervical lymphadenopathy

Lymph Node Groups	Areas Drained by Lymph Node Group	Categories of Etiology	Differential Diagnosis
Preauricular or posterior cervical lymph nodes	Scalp and skin	▪ Infections ▪ Cancers	▪ Tubercular lymphadenitis ▪ Squamous cell carcinoma skin (head and neck regions) ▪ Hodgkin's disease ▪ Non-Hodgkin's lymphoma
Supraclavicular nodes	Gastrointestinal tract, pulmonary and genitourinary systems	▪ Infections ▪ Cancers	▪ Tubercular lymphadenitis ▪ Fungal infections ▪ Cancers of thorax, abdomen, thyroid and larynx
Submandibular or anterior lymph nodes	Oral cavity	▪ Infections ▪ Cancers	▪ Tubercular lymphadenitis ▪ Dental or upper respiratory tract infections ▪ Infectious mononucleosis ▪ *Toxoplasma gondii* ▪ Cytomegalovirus ▪ Rubella ▪ Squamous cell carcinoma of head and neck ▪ Leukemia ▪ Hodgkin's and non-Hodgkin's lymphomas

lymphoma, follicular lymphoma, nodal marginal zone lymphoma, plasma cell myeloma and lymphoplasmacytic lymphoma.

- Pre-germinal center lymphoma comprises B cell lineage CLL/small lymphocytic lymphoma and mantle cell lymphoma.
- Germinal center lymphoma is represented by follicular lymphoma, Burkitt's lymphoma and diffuse large B cell lymphoma. Lymphomas that express immunoglobulin VH (IgVH) gene mutation and intraclonal diversity are derived from germinal center.
- Post-germinal center lymphoma is represented by nodal zone B cell lymphoma, plasma cell myeloma and lymphoplasmacytic lymphoma. Lymphomas that express VH gene mutation but not intraclonal diversity is derived from post-germinal center B cell.

- Diagnostic criteria of Hodgkin's disease are demonstration of Reed-Sternberg cells in the lymph nodes. World Health Organization (WHO) classification identifies a number of Hodgkin's disease variants: classic variants (lymphocyte rich, lymphocytic depletion, nodular sclerosis and mixed cellularity) and nodular lymphocytic–histiocytic predominant. Epstein-Barr virus has been demonstrated in Reed-Sternberg cells in Hodgkin's disease.

2024 WHO CLASSIFICATION OF LYMPHOID NEOPLASMS

Revised 2024 WHO classification of hematolymphoid B cell and T cell/NK cell tumors (adapted from 5th edition, WHO classification of hematolymphoid tumors) is given in Tables 13.9A and B.

Table 13.9A Revised 2024 WHO classification of hematolymphoid B cell tumors (adapted from 5th edition, WHO classification of hematolymphoid tumors)

Tumor-like Lesions with B Cell Predominance

- Reactive B cell-rich lymphoid proliferations that can mimic lymphoma
- IgG4-related disease
- Unicentric Castleman disease
- Idiopathic multicentric Castleman disease
- KSHV/HHV8-associated multicentric Castleman disease

Precursor B Cell Lymphoblastic Leukemia/Lymphoma

- B-lymphoblastic leukemia/lymphoma, NOS
- B-lymphoblastic leukemia/lymphoma with hyperdiploidy
- B-lymphoblastic leukemia/lymphoma with hypodiploidy (hypodiploid ALL)
- B-lymphoblastic leukemia/lymphoma with iAMP21
- B-lymphoblastic leukemia/lymphoma with BCR-ABL1 fusion
- B-lymphoblastic leukemia/lymphoma with BCR-ABL1-like
- B-lymphoblastic leukemia/lymphoma with KMT2A rearrangement
- B-lymphoblastic leukemia/lymphoma with ETV6-RUNX1 fusion
- B-lymphoblastic leukemia/lymphoma with TCF3-PBX1 fusion
- B-lymphoblastic leukemia/lymphoma with IGH/IL3 fusion
- B-lymphoblastic leukemia/lymphoma with other genetic abnormalities

Mature B Cell Neoplasms

- Pre-neoplastic and neoplastic small lymphocytic proliferations
  - Monoclonal B cell lymphocytosis, CLL type
  - Monoclonal B cell lymphocytosis, non-CLL type
  - Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL)
- Splenic B cell leukemia/lymphoma
  - Hairy cell leukemia-defining mutation in BRAF V600E
  - Hairy cell leukemia-defining MAP2K1 mutations in 50% of cases
  - Splenic marginal zone lymphoma
  - Splenic diffuse red pulp small B cell lymphoma
  - Splenic B cell leukemia/lymphoma with prominent nucleoli
- Lymphoplasmacytic lymphoma
- Marginal zone lymphoma
  - Extranodal cutaneous marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT)
  - Extranodal cutaneous marginal zone lymphoma
  - Nodal marginal zone lymphoma
  - Pediatric nodal marginal zone lymphoma
- Follicular lymphoma
  - *In situ* follicular B cell neoplasia
  - Follicular lymphoma—molecular landscape, CREBBP, EZH20 and KMT20 (MML2) possibly early mutations
  - Pediatric-type follicular lymphoma
  - Duodenal-type follicular lymphoma
  - Testicular follicular lymphoma
- Cutaneous follicle center lymphoma
- Primary cutaneous follicle center lymphoma
- Mantle cell lymphoma
  - *In situ* mantle cell lymphoma
  - Leukemic non-nodal mantle cell lymphoma
- Transformation of indolent B cell lymphoma
- Large B cell Lymphoma
  - Diffuse large B cell lymphoma, NOS
  - T cell/histiocyte-rich large B cell lymphoma
  - Diffuse large B cell lymphoma/high-grade B cell lymphoma with Myc and BCL-2 rearrangements
  - ALK-positive diffuse large B cell lymphoma
  - Large B cell lymphoma with IRF4 rearrangement
  - High-grade B cell lymphoma with 11q aberrations

Contd...

Table 13.9A Revised 2024 WHO classification of hematolymphoid B cell tumors (adapted from 5th edition, WHO classification of hematolymphoid tumors) (*Contd...*)

- Lymphomatoid granulomatosis
- EBV-positive diffuse large B cell lymphoma
- Diffuse large B cell lymphoma associated with chronic inflammation
- Fibrin-associated large B cell lymphoma
- Fluid overload-associated large B cell lymphoma
- Plasmablastic lymphoma
- Primary large B cell lymphoma of immune-privileged sites
- Primary cutaneous diffuse large B cell lymphoma
- Primary cutaneous diffuse large B cell lymphoma, leg type
- Intravascular large B cell lymphoma
- Primary mediastinal (thymic) large B cell lymphoma
- High-grade B cell lymphoma, NOS
- High-grade B cell lymphoma with Myc and BCL-2 and/or BCL-6 rearrangements

- Burkitt lymphoma

- KSHV/HHV8-associated B cell lymphoid proliferations and lymphomas
  - Primary effusion lymphoma
  - KSHV/HHV8-positive diffuse large B cell lymphoma
  - KSHV/HHV8-positive geminotropic lymphoproliferative disorder

- Lymphoid proliferations and lymphomas associated with immune deficiency and dysregulation
  - Hyperplasia arising in immune deficiency/dysregulation
  - Polymorphic lymphoproliferative disorders arising in immune deficiency/dysregulation
  - EBV-positive mucocutaneous ulcer
  - Lymphomas arising in immune deficiency/dysregulation
  - Inborn error of immunity-associated lymphoid proliferations and lymphomas

Contd...

- Hodgkin's lymphoma
  - Nodular sclerosis classic variant of Hodgkin's lymphoma
  - Lymphocyte-rich classic variant of Hodgkin's lymphoma
  - Mixed cellularity classic variant of Hodgkin's lymphoma
  - Lymphocytic-depletion classic variant of Hodgkin's lymphoma

- Plasma cell neoplasms and other diseases with paraproteins
  - Monoclonal gammopathies
    - Cold agglutin disease
    - IgM monoclonal gammopathy of undermined significance (Waldenström macroglobulinemia)
    - Non-IgM monoclonal gammopathy of undermined significance
    - Monoclonal gammopathy of renal significance
  - Diseases with monoclonal immunoglobulin deposition
    - Immunoglobulin-related AL amyloidosis
    - Monoclonal immunoglobulin deposition disease
  - Heavy chain diseases
    - μ (Mu) heavy chain disease
    - γ (Gamma) heavy chain disease
    - α (Alpha) heavy chain disease
  - Plasma cell neoplasms
    - Solitary osseous/extraosseous plasmacytoma
    - Plasma cell myeloma
    - Plasma cell neoplasm with associated paraneoplastic syndrome
      - POEM syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal plasma cell disorder)
      - TEMPI syndrome (telangiectasia, elevated erythropoietin and erythrocytosis monoclonal gammopathy, perinephric fluid collection, intrapulmonary shunting)
      - AESOP syndrome (adenopathy and an extensive skin scratch overlying plasmacytoma)

Table 13.9B Revised 2024 WHO classification of tumors of hematolymphoid T cell/NK cell tumors tumors (adapted from 5th edition, WHO classification of hematolymphoid tumors)

Tumor-like Lesions with B Cell Predominance

- Indolent T-lymphoblastic proliferation
- Autoimmune lymphoproliferative syndrom

Precursor T Cell Neoplasm

- T-lymphoblastic leukemia/lymphoma, NOS
- Early T cell precursor lymphoblastic leukemia/lymphoma

Mature T Cell and NK Cell Neoplasm

- T-lymphocytic leukemia
- T large granular lymphocytic leukemia
- NK large granular lymphocytic leukemia
- Adult T cell leukemia/lymphoma
- Sézary syndrome
- Aggressive NK cell leukemia

Contd...

Primary Cutaneous T Cell Lymphoma

- Primary cutaneous CD4+ small or medium T cell lymphoproliferative disorder
- Primary cutaneous CD8+ lymphoproliferative disorder
- Mycosis fungoides
- Primary cutaneous CD30+ T cell lymphoproliferative disorder: lymphomatoid papulosis
- Primary cutaneous CD30+ T cell lymphoproliferative disorder: primary cutaneous anaplastic large cell lymphoma
- Subcutaneous panniculitis-like T cell lymphoma
- Primary cutaneous γ/δ T cell lymphoma
- Primary cutaneous CD8+ aggressive epidermotropic cytotoxic T cell lymphoma
- Primary cutaneous peripheral T cell lymphoma, NOS

Table 13.9B Revised 2024 WHO classification of tumors of hematopoietic and lymphoid tissues (*Contd...*)

Intestinal T Cell and NK Cell Lymphoid Proliferations
▪ Indolent T cell lymphoma of the gastrointestinal tract (GIT)
▪ Indolent NK cell lymphoproliferative disorder of the GIT
▪ Enteropathy-associated T cell lymphoma
▪ Monomorphic epitheliotropic intestinal T cell lymphoma
▪ Intestinal T cell lymphoma, NOS
Hepatosplenic T Cell Lymphoma
Hepatosplenic T cell lymphoma
Anaplastic Large Cell Lymphoma
▪ ALK-positive anaplastic large cell lymphoma
▪ ALK-negative anaplastic large cell lymphoma
▪ Breast implant-associated anaplastic large cell lymphoma
Nodal T-Follicular Helper (TFH) Cell Lymphoma
▪ Nodal TFH cell lymphoma, angioimmunoblastic-type
▪ Nodal TFH cell lymphoma, follicular-type
▪ Nodal TFH cell lymphoma, NOS
Other Peripheral T Cell Lymphoma
▪ Peripheral T cell lymphoma, NOS
EBV-positive NK Cell/T Cell Lymphoma
▪ EBV-positive nodal T cell and NK cell lymphoma
▪ Extranodal NK cell/T cell lymphoma
EBV-positive NK Cell/T Cell Lymphoid Proliferations and Lymphomas of Childhood
▪ Severe mosquito bite allergy
▪ Hydroa vacciniforme lymphoproliferative disorder
▪ Systemic chronic active EBV disease
▪ Systemic EBV-positive T cell lymphoma of childhood

Contd...

CLL: Chronic lymphocytic leukemia, SLL: Small lymphocytic lymphoma, DLBCL: Diffuse large B cell lymphoma; MALT: Mucosa-associated lymphoid tissue; NK cell: Natural killer cell; PTLD: Post-transplant lymphoproliferative disorders. Adapted from WHO classification of tumors of hematopoietic and lymphoid tissues.

WHO Classification of Lymphoid Neoplasms

2024 WHO Classification of non-Hodgkin's Lymphomas

- High-grade non-Hodgkin's lymphoma (NHL) may involve a single lymph node, a localized group of lymph nodes, or an extranodal site.
- Low-grade NHL tends to involve multiple lymph nodes at multiple sites, whereas high-grade NHL tends to be more localized. B cell NHLs are more common than T cells. WHO classification of non-Hodgkin's lymphoid neoplasms is based on origin of NHL derived from B or T cells—precursor cells or mature cells.
- Development of lymphoid malignancies is shown in Fig. 13.6. Pathway of B cells differentiation within and without follicle center is shown in Fig. 13.7. Normal and abnormal counterparts of B cell progeny are shown in Fig. 13.8. Normal T cell progeny is shown in Fig. 13.9.

2024 WHO Classification of Hodgkin's Disease

- **Diagnostic criteria** of Hodgkin's disease are demonstration of Reed-Sternberg cells in the lymph nodes.
- World Health Organization (WHO) classification identifies a number of disease variants: classic variants (lymphocyte rich, lymphocytic depletion, nodular sclerosis and mixed cellularity) and nodular lymphocytic–histiocytic predominant.
- Differences between Hodgkin's disease and non-Hodgkin's lymphoma are given in Table 13.10.

PREDISPOSING FACTORS

Most mature B cell, T cell and NK cell non-Hodgkin's lymphoid neoplasms demonstrate recurrent genetic alterations including non-random chromosomal translocations, somatic mutations, DNA gains, or losses.

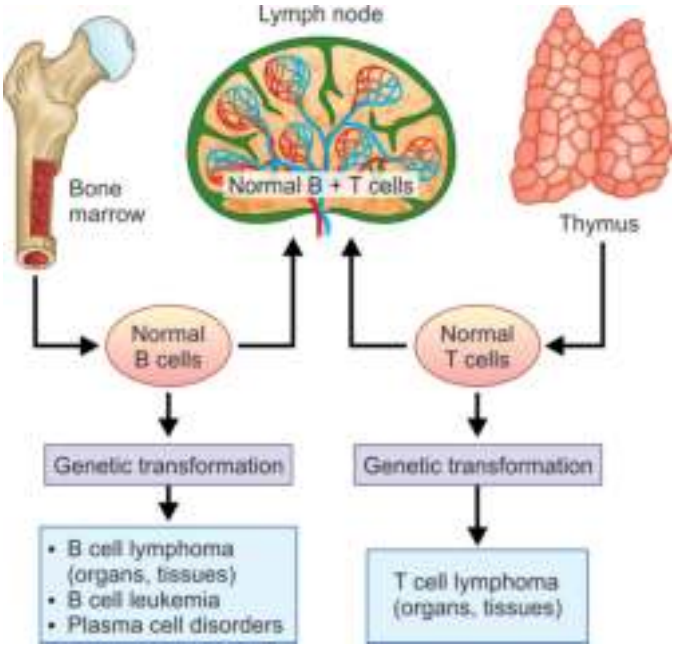

Fig. 13.6: Development of lymphoid malignancies.

Some of these genetic alterations can be preferentially involved in individual lymphoma entities. But the vast majority of genetic alterations are shared by different lymphoma subtypes.

- At the molecular level, genetic alterations can result in activation of oncogenes due to chromosomal translocations, as well as inactivation of tumor suppressor genes by chromosomal deletion or mutation.
- It is now known that the genome of certain lymphoid neoplasms can be altered by introduction of

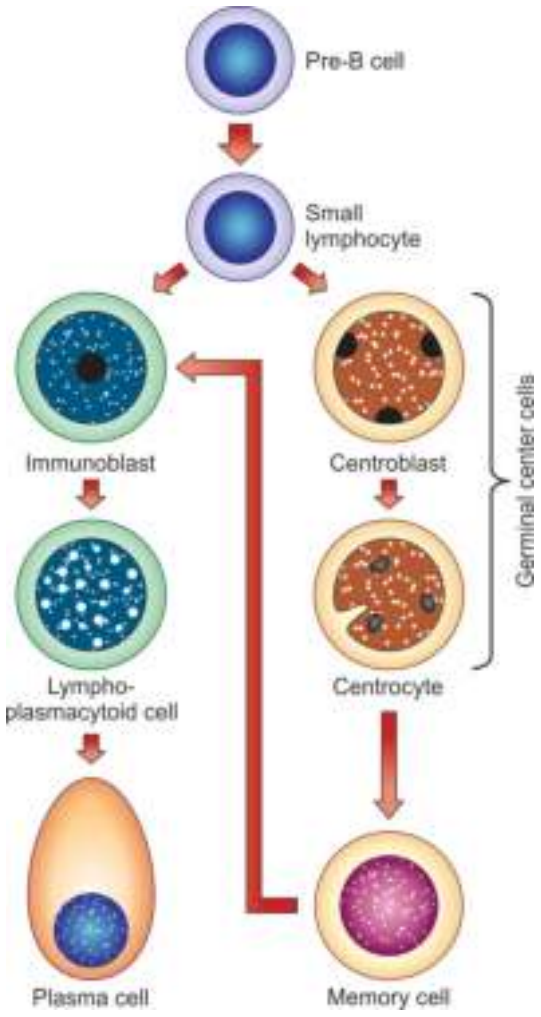

Fig. 13.7: Pathway of B cells differentiation within and without follicle center. Clones of malignant cells may arise any stage differentiation.

exogenous genes by oncogenic viruses such as Epstein-Barr virus, HHV8 and DTLV-1.

- Molecular genetic alterations are detected by cytogenetics or fluorescence *in situ* hybridization (FISH), together with histologic examination and clinical features of the disease.
- In contrast to some subtypes of NHL, no recurrent specific chromosomal translocations have been demonstrated in Hodgkin's disease.
  - Comparative genomic hybridization demonstrates recurrent gains of the chromosomal subregions on chromosomal arms 2p, 9p, and 12q and high level of amplifications on 4p16, 4q23.24 and 9p23-p24.
  - Amplification on 9p24.1 represents a recurrent genetic abnormality in nodular sclerosis variant of Hodgkin's disease.
  - Reed-Sternberg cells have been infected by Epstein-Barr virus in 40% cases of Hodgkin's disease. Human immunodeficiency virus has been associated with 100% cases of Hodgkin's disease.

Chemical Carcinogen-induced Lymphoid Neoplasms

There is increased risk for development of Hodgkin's disease and non-Hodgkin's lymphoma in patients receiving alkylating agents are such as nitrogen mustard, cyclophosphamide and chlorambucil administered to treat various cancers. Prolonged exposure to aromatic hydrocarbons such as benzene increases the risk for development of Hodgkin's disease. Chemical carcinogens associated cancers are given in Table 13.11.

Bacterial and Viruses-induced Lymphoid Neoplasms

The cause of lymphoid neoplasms is not completely understood, but there have been some associations with the development of lymphoma. Both bacterial and viral infections have been associated with lymphomas.

- For example, MALT lymphoma derived from mucosa-associated lymphoid tissue in gastric region has been associated with ***Helicobacter pylori*** infection. Antibiotic therapy can lead to regression of MALT lymphoma.
- Hepatitis C has been associated with an increased risk of marginal zone lymphomas.
- Epstein-Barr virus (EBV) is associated with Burkitt's lymphoma, primary effusion lymphoma and high-grade B cell lymphoma in 60–90 years elderly persons, Hodgkin's disease and lymphoproliferative disorders in post-organ transplant patients.
- Human immunodeficiency virus (HIV) infection has been associated with several types of aggressive B cell NHL.
- Human T cell lymphotropic virus (HTLV-1) has been associated with T cell lymphoma especially in Japan, South America, Central and West Africa. Infectious agents associated lymphomas are given in Table 13.12.

Autoimmune Disorders Associated Lymphoid Neoplasms

Patients suffering from autoimmune disorders such as systemic lupus erythematosus, rheumatoid arthritis, celiac disease and Sjögren's syndrome are at great risk of development of lymphoid neoplasms. Tumor necrosis factor (TNF) inhibitors administered in autoimmune disorders increase the risk for development of lymphoid neoplasms. Immunosuppressive drugs administered in persons undergoing organ transplantation increase the risk for development of lymphoid neoplasms.

MOLECULAR DIAGNOSTICS

In lymphoid neoplasms, clonality is determined by the presence of a dominant clone with identical gene arrangement involving the immunoglobulin heavy chain (IgH) in B cell-, or T cell-derived lymphomas.

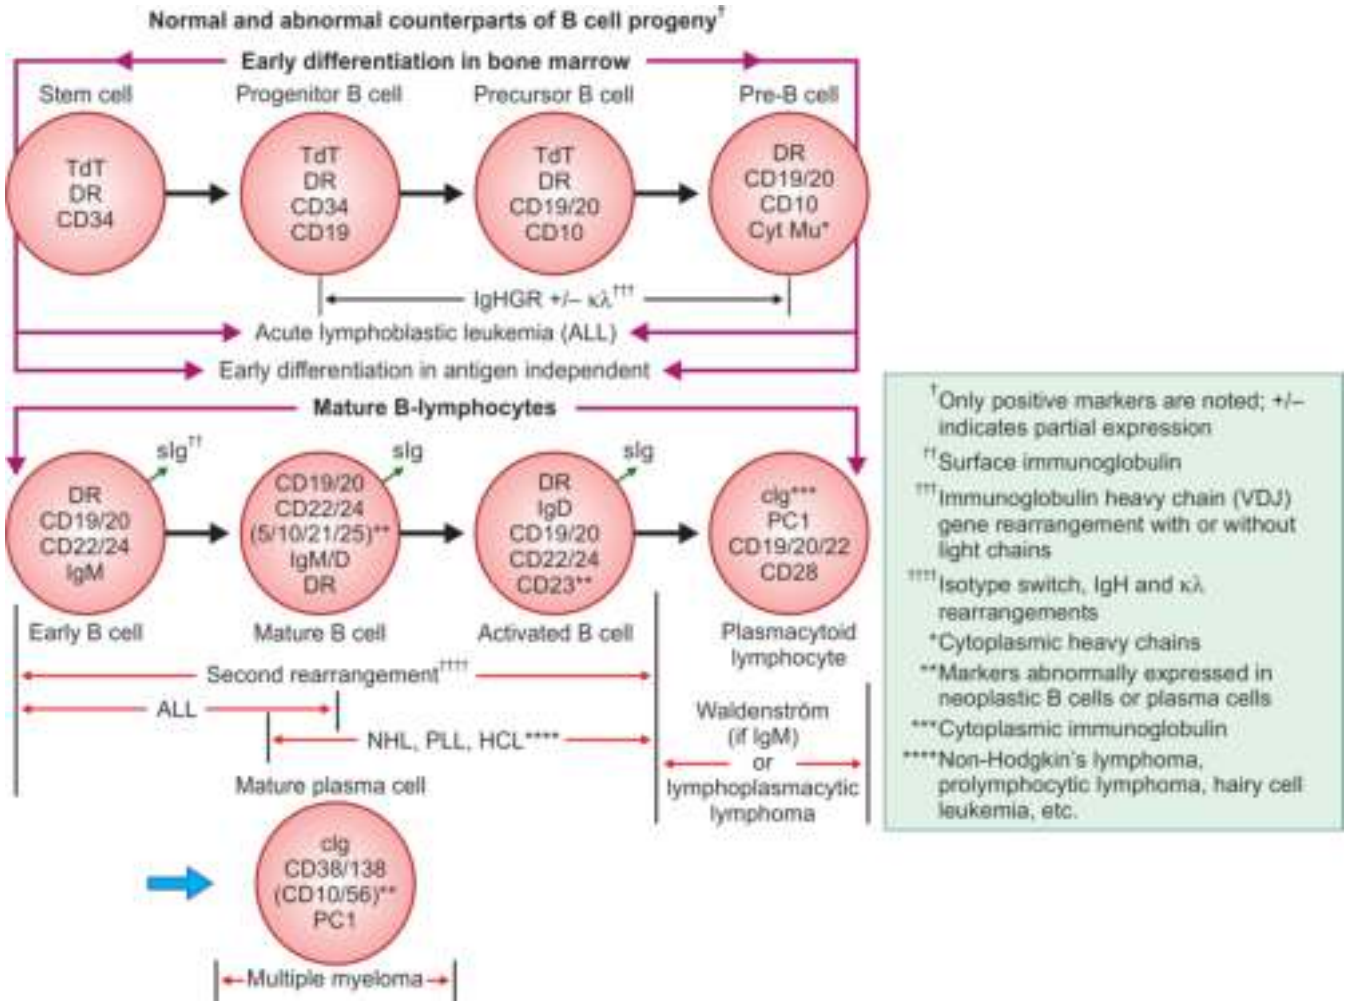

Fig. 13.8: Normal and abnormal counterparts of B cell progeny.

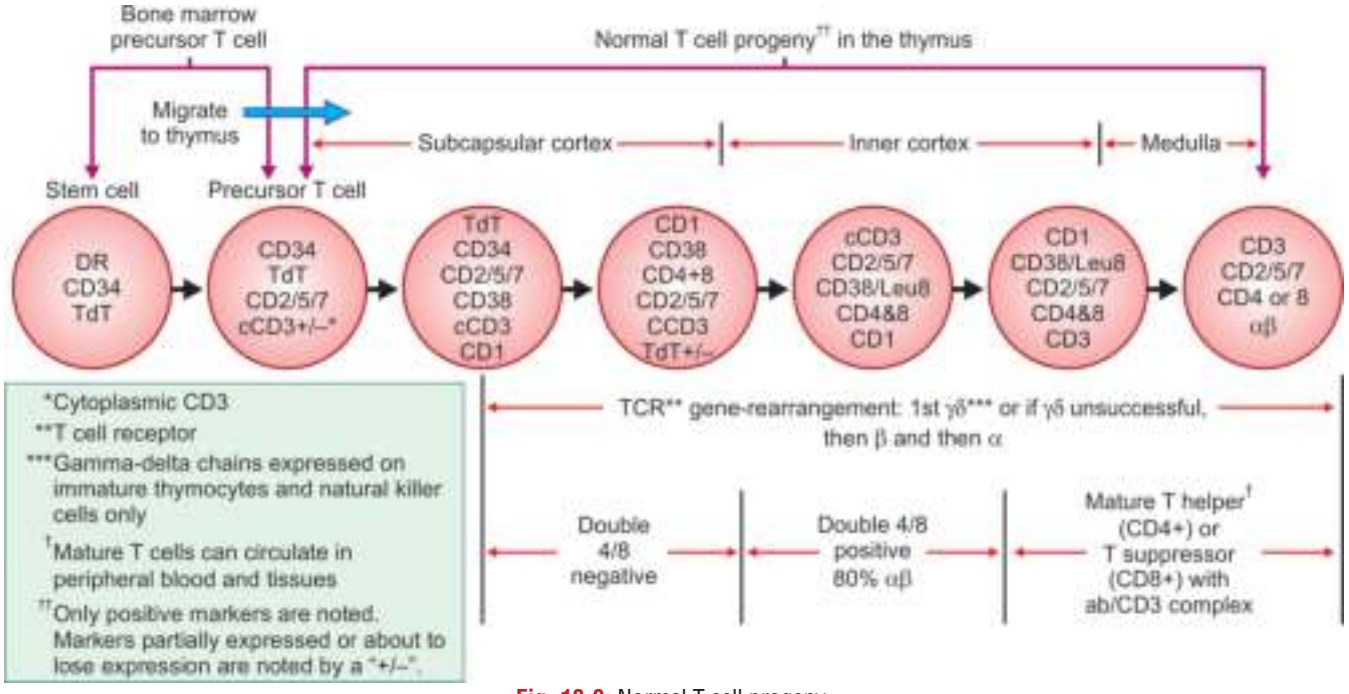

Fig. 13.9: Normal T cell progeny.

Table 13.10 Differences between Hodgkin's disease and non-Hodgkin's lymphoma

Parameters	Hodgkin's Disease	Non-Hodgkin's Lymphoma
Cell derivation	Mostly B cells	B cells (90%), T cells (10%)
Stage/grade	Begins in one lymph node then spread to other lymph nodes. In some cases, grade may be significant, but it is mostly unremarked	Systemic disease and grade influences prognosis and therapy more than stage
Source of mass	Neoplastic Reed-Sternberg cells are usually <1% of the total population of other benign inflammatory cells	Majority of the lymphoid cells are malignant
Lymph nodes involvement	Localized to single axial group of nodes (cervical, mediastinal, para-aortic lymph nodes)	Frequent involvement of multiple peripheral nodes
Gastrointestinal tract mesenteric/ Waldeyer's involvement	Rare involvement	Common involvement
Extranodal involvement	Uncommon (10% cases)	Common (40% cases)
Immune deficiency	Cell-mediated immunity impaired in all classic variants except nodular sclerosis Mycobacterial, fungal, viral and protozoal infections	▪ Humoral immunity impaired ▪ Recurrent bacterial infections
Bone marrow involvement	Common (significant)	Uncommon (bone marrow involvement occurs in some cases)
Architecture of lymph node	Effaced	Effaced
Other autoimmune disease	Uncommon	Common
Constitutional symptoms	Common	Uncommon
Chromosomal defects	Aneuploidy	Translocation and deletion
Mode of spread	Ordinarily contiguous spread	Noncontiguous spread
Treatment	Radiotherapy (mild localized lesion)	Chemotherapy and radiotherapy (systemic disorder)
Prognosis	Good	Poor

Table 13.11 Chemical carcinogens associated cancers

Chemical Carcinogens	Examples	Associated Cancers
Direct-acting chemical carcinogens associated cancers		
Alkylating agents	Nitrogen mustard, cyclophosphamide, chlorambucil, nitrosoureas, β-propiolactone, dimethyl sulphate and diepoxibutane are chemo-therapeutic agents	▪ Hodgkin's disease ▪ Non-Hodgkin's lymphoma ▪ Leukemias ▪ Ovarian carcinoma
Indirect-acting chemical carcinogens associated cancers		
Aromatic hydrocarbons	Benzene presens in crude oil (petrochemical), benz(a)anthracene and benz(a)pyrene	▪ Hodgkin's disease ▪ Acute leukemia ▪ Urinary bladder carcinoma

- The tests can be performed by polymerase chain reaction (PCR) assay and DNA sequences. Characteristics of chromosomal translocations can be detected by fluorescence *in situ* hybridization (FISH). For examples, chromosomal rearrangement t(14;18)involving B cell lymphoma 2 (BCL-2) gene is frequently demonstrated in follicular lymphoma and diffuse large B cell lymphoma (DLBCL). BCL-1 gene involvement is demonstrated in mantle cell lymphoma.

Table 13.12 Infectious agents associated lymphomas

Infectious Agent	Lymphoid Malignancy	
Viruses-associated lymphoid malignancies		
Epstein-Barr virus (EB virus)	▪ Hodgkin's disease ▪ Burkitt's lymphoma ▪ Primary diffuse large B cell lymphoma (DLBCL) of CNS	▪ Post-organ transplant lymphoma ▪ Extranodal NK/T cell lymphoma, nasal type ▪ Primary effusion lymphoma
Human T cell lymphotropic virus 1 (HTLV-1)	Adult T cell leukemia/lymphoma	
Human herpesvirus 8	▪ Primary effusion lymphoma	▪ Castle's disease
Human immunodeficiency virus (HIV)	▪ Diffuse large B cell lymphoma (DLBCL)	▪ Burkitt's lymphoma
Hepatitis C virus (HCV)	▪ Lymphoplasmacytic lymphoma	▪ Marginal zone lymphoma
Bacteria-associated lymphoid malignancies		
Helicobacter pylori	Gastric mucosa-associated lymphoid tissue (MALT) lymphoma	
Chlamydia psittaci	Orbital adnexal lymphoma	
Campylobacter jejuni	Immunoproliferative small bowel disease	
Borrelia burgdorferi	Cutaneous mucosa-associated lymphoid tissue (MALT) lymphoma	

NK cell: Natural killer cell

- **Myc rearrangement** is observed in Burkitt's lymphoma and in rare case of diffuse large B cell lymphoma (DLBCL). Finally, gene arrangement t(2;17) involving ALK is observed in ALK gene positive anaplastic large cell lymphoma.
- DNA and RNA sequencing assays are increasingly performed in the clinical settings of lymphoid neoplasms to detect clonal genetic alterations, including mutations, and copy number changes.
- Chromosomal translocations in non-Hodgkin's lymphoma (NHL) are given in Table 13.13. Correlation between protein expression status and prognosis in different non-Hodgkin's lymphoma subtypes is given in Table 13.14.

Table 13.13 Chromosomal translocations in non-Hodgkin's lymphoma (NHL)

Lymphoid Neoplasm	Chromosomal Abnormalities	Fusion Transcript, Involved Genes
B cell non-Hodgkin lymphomas (high fraction lymphomas)		
Diffuse large B cell lymphoma (DLBCL)	▪ t(14;18)(q27;q11-13) ▪ t(3;14)(q27;q32) ▪ t(2;17)(p23;q23)	▪ BCL-2; IgH (30%) ▪ BCL-6; IgH (30%) ▪ ALK; clathrin
Burkitt's lymphoma	▪ t(8;14),(q24;q32) ▪ t(2;8)(p11;q24) ▪ t(8;22)(q24;q11)	▪ c-Myc; IgH (80%) ▪ Igκ; c-Myc (10%) ▪ c-Myc; IgH-λ (10%)
Burkitt-like lymphoma	t(8;14),(32q2;q21)	c-Myc; IgH
B cell non-Hodgkin lymphomas (low fraction lymphomas)		
Follicular lymphoma	t(14;18)(q32;q21)	BCL-2; IgH
Small cell lymphocytic lymphoma/CLL	▪ t(14;19)(q32;q13) ▪ Trisomy 12,13q	BCL-3; IgH
Lymphoplasmacytic lymphoma	t(9;14)(p13;q32)	PAX5 (BSAP); IgH
Mantle cell lymphoma	t(11;14)(q13;q32)	BCL-1 (cyclin D1); IgH
Marginal zone/MALT lymphoma	▪ t(11;18)(q21;q11) ▪ t(11;14)(q22;q32)	▪ API2; MLT ▪ BCL-10; IgH

Contd...

Table 13.13 Chromosomal translocations in non-Hodgkin's lymphoma (NHL) (*Contd...*)

Lymphoid Neoplasm	Chromosomal Abnormalities	Fusion Transcript, Involved Genes
Plasma cell myeloma	▪ t(4;14)(p16;q32) ▪ t(14;16)(q32;q23) ▪ t(16;22)(q23;q11)	▪ FGFR3; IgH ▪ c-MAF; IgH ▪ c-MAF; IgH-λ
T cell lymphomas		
T-chronic lymphocytic leukemia/T-prolymphocytic leukemia	▪ Inv14(q11;q32) ▪ Trisomy 8q	▪ BCL-3 ▪ TCR gene rearrangement
Mycosis fungoides	Not applicable	TCR gene rearrangement
Angioimmunoblastic T cell lymphoma	Trisomy 3 or 5	▪ TCR gene rearrangement ▪ Epstein-Barr virus
Adult T cell leukemia/lymphoma	Not applicable	▪ TCR gene rearrangement ▪ HTLV1 integration

MALT: Mucosa associated lymphoid tissue; CLL: Chronic lymphocytic leukemia.

Table 13.14 Correlation between protein expression status and prognosis in different non-Hodgkin's lymphoma subtypes

Biomarker	Non-Hodgkin's Lymphoma	Prognosis
SOX1	Mantle cell lymphoma	Poor prognosis
Myc and BCL-2 expression	Diffuse large B cell lymphoma	Poor prognosis
CD10	Diffuse large B cell lymphoma	Good prognosis
ALK	Anaplastic large cell lymphoma	Good prognosis

STAGING OF LYMPHOID NEOPLASMS

Once the diagnosis of lymphoid neoplasm is established, the next step is to determine the extent of the disease and assigning the stage, i.e. stages I, II, III and IV. Staging is determined by computed tomography (CT), magnetic resonance imaging (MRI) and positron emission tomography (PET) scan. Bone marrow trephine biopsy is frequently required to evaluate the extent of the disease, complete staging of the disease and response at the end of therapy especially in non-Hodgkin's lymphoma. Bone marrow trephine biopsy is not required in patients with early stage I classical Hodgkin's disease, who are adequately staged with CT scan, MRI scan and PET scan; as the bone marrow is not involved in early stage I.

- Stage I lymphoid neoplasm is the least advanced early stage with involvement of one lymph node region or one extranodal site, and stage IV being the most advanced stage with involvement of nodal and extranodal sites (bone, bone marrow, liver, lungs).
- Stage II lymphoid neoplasm is established when more than one nodal involvement regardless of the number and size; on one side of the diaphragm.
- Stage III lymphoid neoplasm is established when lymph node involvement regardless of the number and size; on both sides of the diaphragm.
- Stage IV lymphoid neoplasm is the most advanced stage of the disease that has started in the lymph nodes and spread to at least one body organ outside the lymphatic system (lungs, liver, bone marrow or solid bones).

Lumbar Puncture

Lumbar puncture is indicated to determine whether the lymphoid neoplasms have spread to spinal cord in patients with Burkitt's lymphoma, testicular lymphoma and aggressive B cell lymphoma involving the paranasal lymphoma. Patients with advanced stage diffuse large B cell lymphoma (DLBCL) with multiple extranodal involvement, higher level of lactic dehydrogenase (LDH) and poor performance status are at higher risk for involvement of central nervous system, who require prophylactic intrathecal chemotherapy.

Additional Tests

Before initiating chemotherapeutic agents, it is essential to analyze patient's cardiac function including the left ventricular ejection fraction. Patients with evidence of hepatitis B and C are adequately treated by administration of antiviral therapy. Patients with human immunodeficiency virus (HIV) infection

should be treated to decrease their viral load and to restore CD4+ helper T cell counts before initiation of chemotherapy.

TREATMENT

A definite cure is the goal for patients with Hodgkin's disease, Burkitt's lymphoma, diffuse large B cell lymphoma (DLBCL), anaplastic large T cell lymphoma, in addition to several common lymphoid neoplasms presented in localized stage. It is essential to improve survival and/or the quality of life in advanced stage of follicular lymphoma (FL) and mantle cell lymphoma (MCL).

Pretreatment Evaluation

Pretreatment evaluation is essential to know the extent of disease before initiating treatment. Pretreatment evaluations must include complete medical history with presence or absence of B symptoms such as fever, night sweats, weight loss; complete physical examination with particular attention to superficial lymph nodes, Waldeyer's ring, size of liver and spleen.

- The extension of the disease is established by CT scan, MRI scan and PET scan and bone marrow trephine biopsy. Head region CT scan or brain MRI and lumbar puncture are performed to evaluate spinal cord involvement by Burkitt's lymphoma, testicular lymphoma and aggressive B cell lymphoma.
- Various laboratory tests must include complete blood counts, erythrocyte sedimentation rate, serum lactic dehydrogenase, hepatitis B, hepatitis C, HIV testing and β_2-microglobulin.
- Multigated acquisition (MUGA) scan or echocardiogram is essential prior to initiation of anthracyclines containing regimes.

Cytotoxic Drugs and Radiotherapy

Combined chemotherapy and radiotherapy represent backbone of treatment for most lymphoid neoplasms. The addition to chemotherapy of the anti-20 monoclonal antibody rituximab has significantly improved the outcome of patients suffering from B cell non-Hodgkin's lymphoma. Splenectomy may represent a treatment option in some cases of lymphoid neoplasms as with spleen involvement.

- Alkylating agents such as chlorambucil, cyclophosphamide, melphalan, dacarbazines and bendamustine are administered to treat the patients with lymphoid neoplasms.
- Other cytotoxic drugs can be used to treat these patients, which include anthracyclines (doxorubicin), glycopeptides (bleomycin), antimetabolites (methotrexate), vinca alkaloids (vincristine, vinblastine), purine analogues (fludarabine) and topoisomerase inhibitors (etoposide).
- Administration of combined corticosteroids and chemotherapeutic drug produce both lympholytic and antiemetic effects.
- Chemotherapeutic agents may produce bone marrow failure, infertility, myelodysplasia, cardiomyopathy, pulmonary fibrosis, peripheral neuropathy, renal failure and peripheral neuropathy.
- Lymphoid neoplasms are highly radiosensitive. Radiation therapy is used in patients with follicular lymphoma.

Hematopoietic Stem Cell Transplantation

High-dose chemotherapy followed by allogenic or autologous hematopoietic stem cell transplantation can be curative in some forms of chemotherapy-sensitive relapsed lymphomas. Hematopoietic stem cells (HSCs) obtained from peripheral blood are infused after administration of high doses chemotherapy-induced bone marrow aplasia.

HODGKIN'S DISEASE

HODGKIN'S DISEASE: OVERVIEW

Hodgkin's disease (HD) is a malignant neoplasm of lymph node. It is important to determine whether the patient has only a single lymph node region or multiple lymph node regions involved, or extranodal involvement. After therapy, about 5% of patients develop myelodysplastic syndromes, acute myelogenous leukemia, or carcinomas, particularly of the lung. Hodgkin's disease has bimodal age distribution with a peak at 15–40 years and second small peak during seventh decade. Classification of Hodgkin's disease according to revised 2024 WHO classification of tumors of hematopoietic and lymphoid tissues is given in Table 13.15.

DIAGNOSTIC CRITERIA OF HODGKIN'S DISEASE

Diagnostic criteria of Hodgkin's disease include demonstration of neoplastic Reed-Sternberg cells in the lymph nodes, which are derived from B cells admixed with inflammatory cells in background as a result of cytokines synthesis such as IL-1, IL-4, IL-5, IL-6, TNF-α, GM-CSF,

Table 13.15 Classification of Hodgkin's disease according to revised 2024 WHO classification of tumors of hematopoietic and lymphoid tissues

Hodgkin's Disease: Histologic Subtypes
▪ Nodular lymphocyte predominant Hodgkin disease
▪ Classic variants of Hodgkin's disease • Nodular sclerosis classic variant of Hodgkin's disease • Lymphocyte-rich classic variant of Hodgkin's disease • Mixed cellularity classic variant of Hodgkin's disease • Lymphocyte-depletion classic variant of Hodgkin's disease

Adapted from 2024 WHO classification of tumors of hematopoietic and lymphoid tissues.

and TGF-β. Reed-Sternberg cells develop as a result of genetic rearrangement and constitute 1–5% of cell population. Background lymphocytes are usually T cells in Hodgkin's disease.

Reed-Sternberg Cells

Mystery of the origin of Reed-Sternberg cells in Hodgkin's disease was solved by molecular studies that relied on single cell of Reed-Sternberg cells, coupled with amplification of RNA and genomic DNA by polymerase chain reaction (PCR) technique, which established that Reed-Sternberg cell arises from germinal center or post-germinal center B cells. Reed-Sternberg cells usually have clonal somatically mutated IgG rearrangements indicative of B cell origin. Some reports suggest that classic Reed-Sternberg cells can be of T cell origin, where T cell markers are expressed on neoplastic Reed-Sternberg cells.

Growth and Survival of Reed-Sternberg Cells

Growth and survival of classic Reed-Sternberg cells are closely related to the activation of the nuclear factor kappa B (NF-κB) transcription factor-signaling pathway. The consecutive nuclear activity of NF-κB can prevent both apoptosis and promote cell proliferation. Epstein-Barr (EB) virus, which is found in the Reed-Sternberg cells expresses viral proteins such as latent membrane protein 1 (LMP1) leading to NF-κB activation.

Role of Epstein-Barr Virus in Pathogenesis of Hodgkin's Disease

Approximately 40% cases of Hodgkin's disease (classic or lymphocytic depletion) are associated by Epstein-Barr virus detected in Reed-Sternberg cells, which plays an important role in the pathogenesis of Hodgkin's disease and protects Reed-Sternberg cells from apoptosis and CD8+ cytotoxic T cells, which would ordinarily destroy the neoplastic Reed-Sternberg cells. It may cause mutation in the TP53 tumor suppressor gene. Epstein-Barr virus is demonstrated by EBV-LMP1 immunohistochemistry or EBV encoded early RNA (EBER) by fluorescence *in situ* hybridization.

Pathogenesis of Hodgkin's disease is shown in Fig. 13.10. Cellular interactions in the Hodgkin's disease and Reed-Sternberg cells microenvironment are shown in Fig. 13.11.

Pathology Pearls: Reed-Sternberg Cell Variants

- **Classical Reed-Sternberg Cells:** Classical Reed-Sternberg cells (RS cells) are large and binucleated or bilobed, with two halves often appearing as mirror images of each other resembling owl eyes from prominent nucleoli. Classical Reed-Sternberg cells measure 20–50 μm in diameter with amphophilic cytoplasm. Nuclear membrane is thick and sharply defined. These RS cells are seen in mixed cellularity variant of Hodgkin's disease (Fig. 13.12A and B).
- **Mononuclear Reed-Sternberg Cells:** Mononuclear Reed-Sternberg cells may be seen in any type of Hodgkin's disease but are encountered in mixed cellularity Hodgkin's disease (Fig. 13.13A and B).
- **Pleomorphic Reed-Sternberg Cells:** Pleomorphic Reed-Sternberg cells are larger than other type of Reed-Sternberg cells, which contain hyperchromatic large nuclei. Reed-Sternberg cells are seen in lymphocytic depletion variant of Hodgkin's lymphoma (Fig. 13.14A and B).
- **Lacunar Reed-Sternberg Cells:** Lacunar Reed-Sternberg cells are predominantly seen in the nodular sclerosis variant of Hodgkin's disease. Lacunar RS cells have more delicate folded or solitary nuclei surrounded by abundant pale cytoplasm in histological sections that can retract during processing (Fig. 13.15A and B).
- **Lymphocytic–Histiocytic Reed-Sternberg Cells:** Lymphocytic–histiocytic (L&H) Reed-Sternberg cells are sometimes called popcorn cells seen in nodular lymphocyte predominant Hodgkin's disease. Popcorn cells have bubbly outline of nucleus (Fig. 13.16A and B).

Reed-Sternberg Cells versus Reed-Sternberg-like Cells

Reed-Sternberg cells should be differentiated from Reed-Sternberg-like multinucleated cells in lymph node. Megakaryocyte can simulate closely in hematoxylin and eosin stained sections. Megakaryocytes are strongly positive for factor VIII related antigen and CD61.

- Immunoblasts in infectious mononucleosis are morphologically similar to Reed-Sternberg cells.
- Reed-Sternberg-like cells are demonstrated in peripheral T cell lymphoma, anaplastic large cell lymphoma, infectious mononucleosis and reactive viral lymphadenitis.

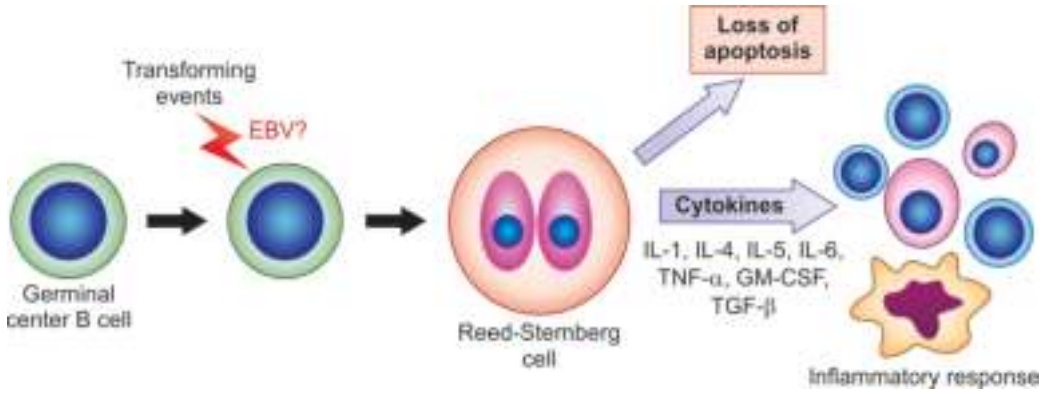

Fig. 13.10: Pathogenesis of Hodgkin's disease.

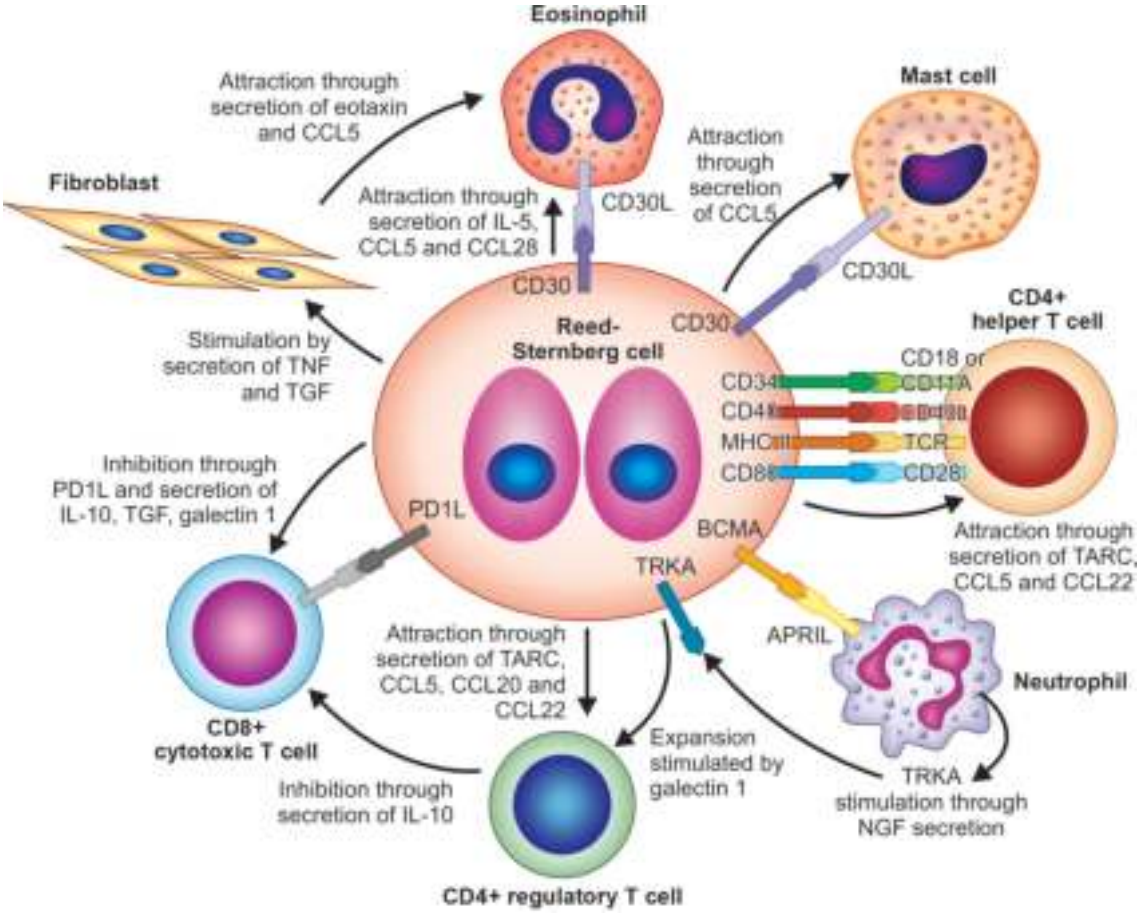

Fig. 13.11: Cellular interactions in the Hodgkin's disease and Reed-Sternberg cells microenvironment.

- Differences between Reed-Sternberg cells and Reed-Sternberg-like cells are given in Table 13.16.

CLINICAL FEATURES

Patient with Hodgkin's disease presents with painless lymphadenopathy most often in upper half of body in cervical or mediastinal regions, but occasionally in the axilla or inguinal-femoral region.

- **Constitutional symptoms** such as fever, night sweats, and weight loss are observed in 40–50% of cases. Pruritus is present in some cases. Ingestion of alcohol may cause pain at involved sites.
- Patients with Hodgkin's disease are categorized into two grades: grade B with one or more of these symptoms and grade A lacking these symptoms.
- On clinical examination, the lymph nodes are enlarged discrete, rubbery, painless and mobile.

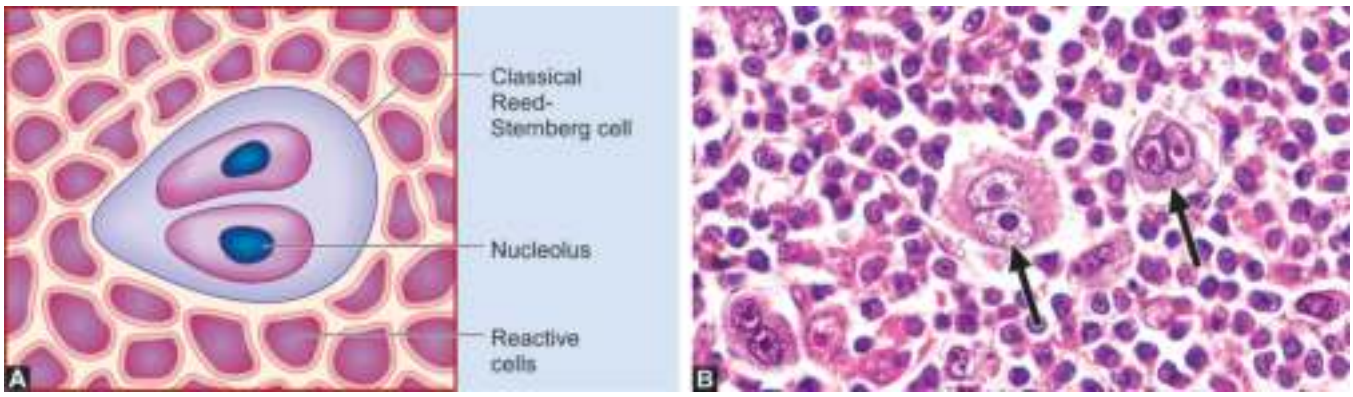

Fig. 13.12A and B: Classical Reed-Sternberg cells (arrows).

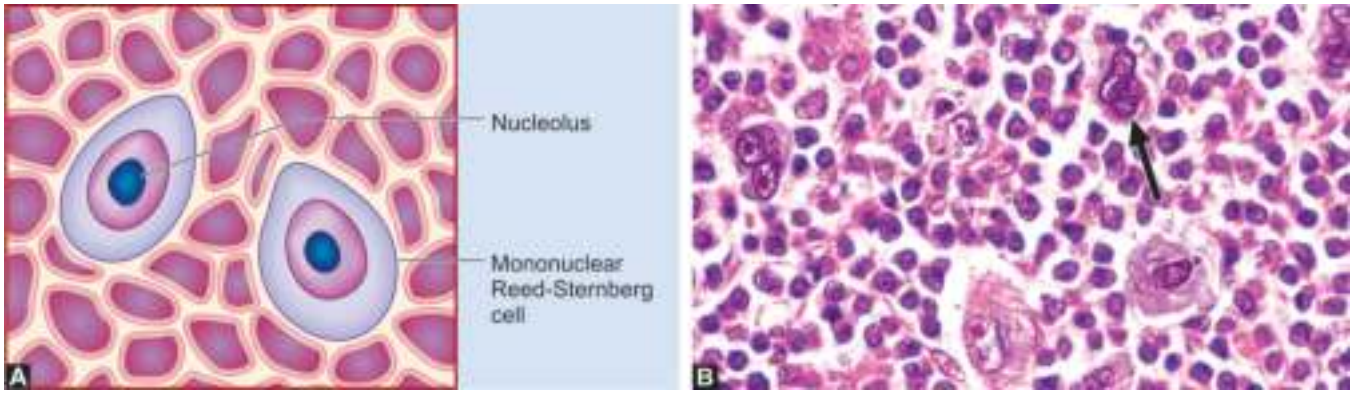

Fig. 13.13A and B: Mononuclear Reed-Sternberg cells (arrow).

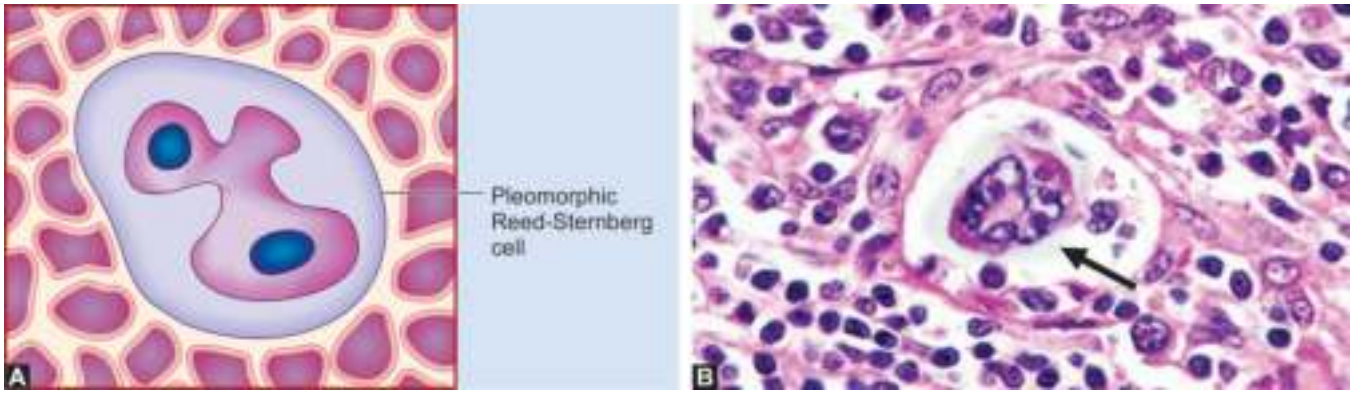

Fig. 13.14A and B: Pleomorphic Reed-Sternberg cells (arrow).

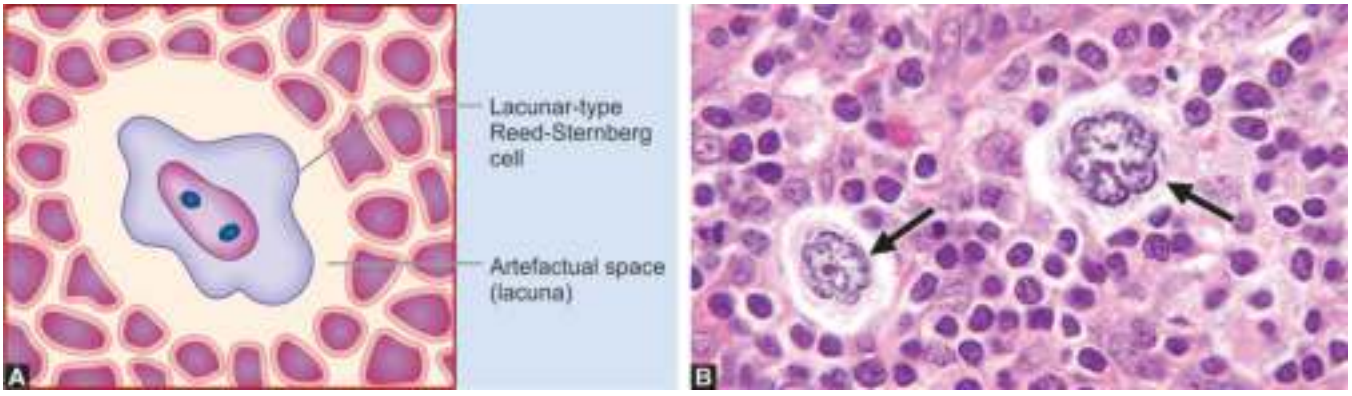

Fig. 13.15A and B: Lacunar-type Reed-Sternberg cells (arrows).

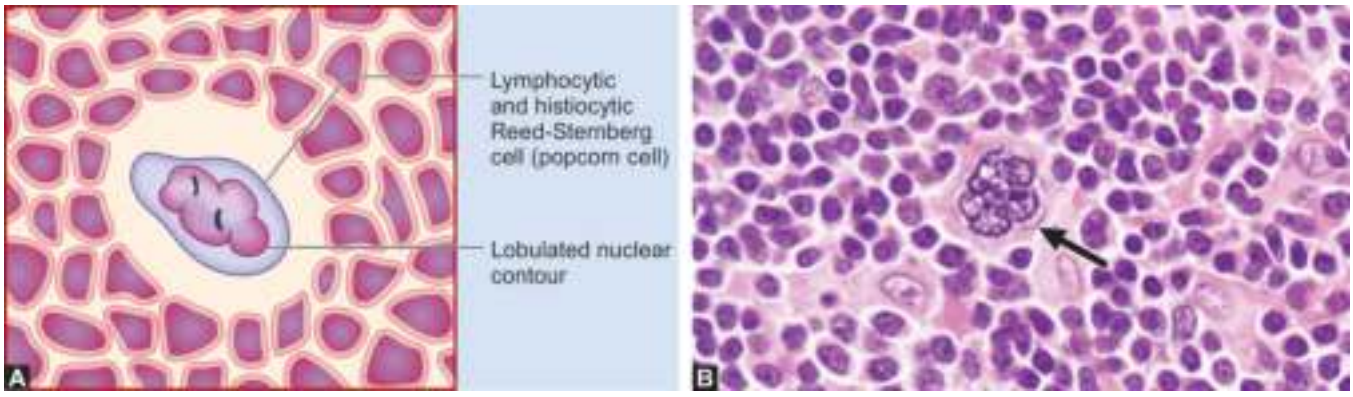

Fig. 13.16A and B: Lymphocytic–histiocytic Reed-Sternberg cells (arrow).

Table 13.16 Differences between Reed-Sternberg cells and Reed-Sternberg-like cells

Parameters	Reed-Sternberg Cells	Reed-Sternberg-like Cells
Cell morphology	Reed-Sternberg cells are present in Hodgkin's disease	Reed-Sternberg-like cells are present in infectious mononucleosis, peripheral T cell lymphoma and anaplastic large cell lymphoma
Nucleolus	Acidophilic, regular with clear halo and more centrally placed	Basophilic, irregular and adjacent to nuclear membrane
Cytoplasm	Usually acidophilic and variable	Amphophilic with usual strong pyroninophilic
Surrounding cells	Lymphocytes and histiocytes	Mononuclear immunoblasts and plasmacytoid cells

CHEST RADIOGRAPHS

Chest radiographs demonstrate mediastinal lymphadenopathy in 40% of cases, with associated lower cervical lymphadenopathy in Hodgkin's disease.

MODE OF SPREAD

Hodgkin's disease spreads via direct extension, lymphatic and hematogenous routes.

- **Direct extension:** Direct extension of Hodgkin's disease involves adjacent lymph nodes, skin, skeletal muscle, while mediastinal lymph nodes invade large vessels, lung and chest wall in nodular sclerosis variant of Hodgkin's disease.
- **Lymphatic route:** Initially Hodgkin's disease involves other lymph nodes via lymphatic route in continuous and predictable fashion.
- **Hematogenous route:** Later, Hodgkin's disease spreads via the blood and involves the spleen, liver and bone marrow. Spleen is practically always involved. Liver is involved if splenic hilum and retroperitoneal lymph nodes are involved. Other organs like lung, GIT, skin and CNS may also be involved. Bone marrow is involved in lymphocytic depletion variant of Hodgkin's disease. Bone marrow involvement is often asymptomatic but may produce pain with vertebral osteoblastic lesions (ivory vertebrae) and, rarely, osteolytic lesions and compression fracture.

CLINICAL STAGING

Clinical staging of Hodgkin's disease is most important in determining extent of disease, therapeutic modalities and prognosis. It is done by radiological techniques.

- Chest radiograph is low cost method for diagnosis and surveillance of Hodgkin's disease. It is useful in detection of mediastinal mass.
- Ultrasonography determines the size of the lymph nodes, in chest and abdomen and involvement of liver and spleen. CT scan is standard imaging technique for thoracic examination in Hodgkin's disease patients. It is useful for determination of sites on initial involvement as well as extent of Hodgkin's disease. It helps in classification of early stage patients.
- Whole body FDG-PET scan using fluorodeoxyglucose-18 is a sensitive indicator of Hodgkin's disease. It is recommended when other diagnostic modalities are inconclusive.
  - FDG-PET scan most accurately demonstrates the correct pretreatment stage in Hodgkin's disease compared with high-dose contrast-enhanced computed tomography (CECT), which tends to understage or over-stage of Hodgkin's disease.
  - FDG-PET scan is able to distinguish viable/active tumor cells from fibrosis or necrosis in a residual mass after treatment.

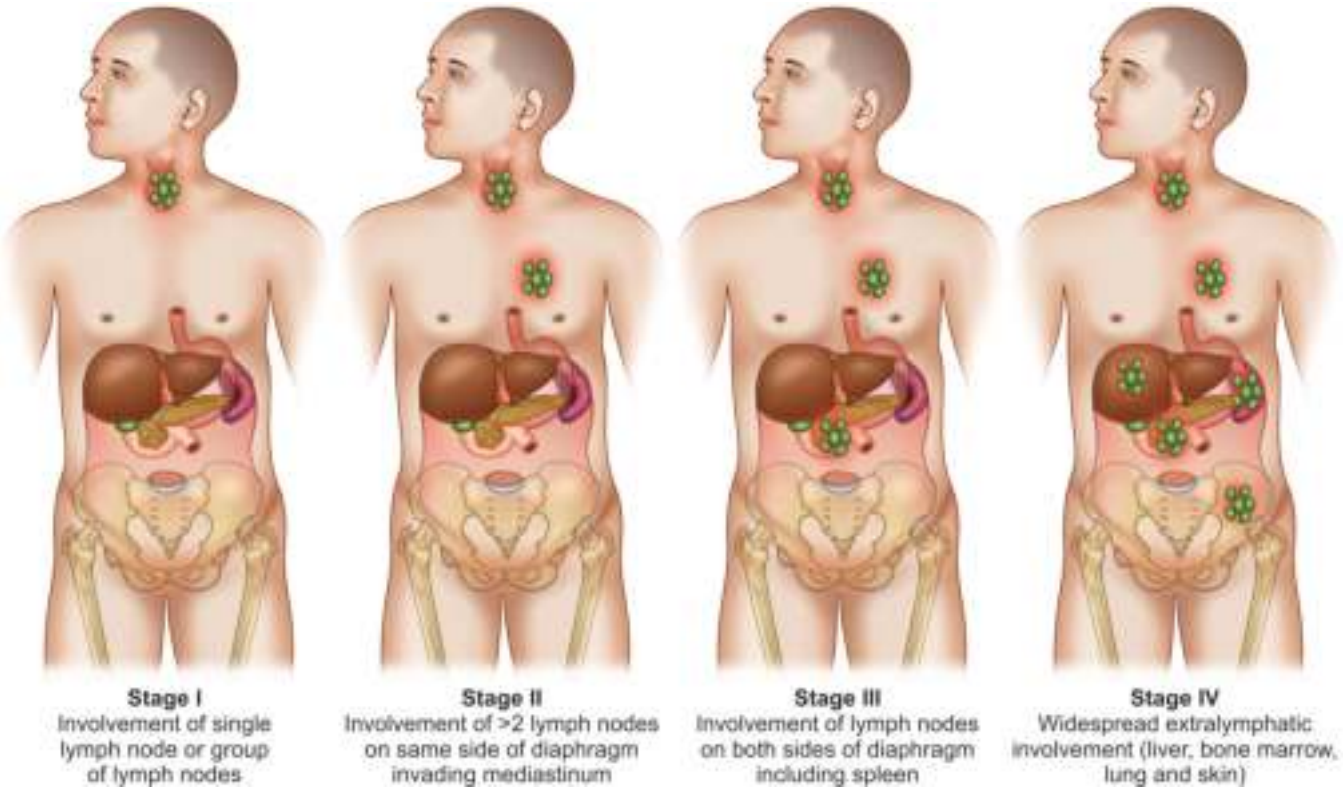

Fig. 13.17: Staging of Hodgkin's diseases.

Table 13.17 Modified Ann Arbor staging system of Hodgkin's disease by Costwold

Stage	Organs Involved
Stage I	Single lymph node or lymphoid structures (spleen, thymus, Waldeyer's ring)
Stage II	Two or more lymph nodes on the same sides of the diaphragm
Stage III	▪ Lymph nodes involved on both sides of the diaphragm ▪ Stage III_1 (with or without splenic, hilar, celiac or portal nodes) ▪ Stage III_2 (with para-aortic, iliac or mesenteric nodes)
Stage IV	Involvement of extranodal site(s) beyond those designated E

The stages can also have a designation of 'A' for asymptomatic or 'B' for constitutional symptoms (weight loss >10%, drenching sweats, fever).

Ann Arbor Staging System

Ann Arbor staging system is the basis for most Hodgkin's disease staging based on the degree of dissemination, involvement of extralymphatic sites, and presence or absence of systemic signs such as fever. It is an essential part of the diagnostic evaluation of patients with Hodgkin's disease. Although grading of histopathologic variants of Hodgkin's disease roughly correlates with clinical behavior, prognosis is better predicted by staging. Modified Ann Arbor staging system of Hodgkin's disease by Costwold is shown in Fig. 13.17 and Table 13.17.

LABORATORY DIAGNOSIS

Hematologic abnormalities may be caused by extensive bone marrow involvement by Hodgkin's disease. Hypersplenism may appear, but mainly in patients with marked splenomegaly. Elevated serum alkaline phosphatase levels usually indicate bone marrow or liver involvement or both.

Laboratory Diagnosis of Hodgkin's Disease
Indicators of Active Disease
Increase in leukocyte alkaline phosphatase, serum haptoglobin, ESR, serum copper, and other acute phase reactants usually reflect active Hodgkin's disease.
Anemia and Iron Parameters
Patient most often develops microcytic-hypochromic anemia in advanced Hodgkin's disease. Defective iron reutilization is characterized by low serum iron, low iron-binding capacity, and increased bone marrow iron.

Total and Differential WBCs

Slight-to-moderate polymorphonuclear leukocytosis may be present in Hodgkin's disease. Lymphocytopenia may occur early and become pronounced with advanced Hodgkin's disease. Eosinophilia is present in about 20% of patients, and thrombocytosis may be observed.

Erythrocyte Sedimentation Rate

The erythrocyte sedimentation rate is commonly elevated in patients with active Hodgkin's disease and sometimes may be the only evidence that the disease has been inadequately treated or that clinical recurrence is imminent.

Bone Marrow Smear Examination

- Bone marrow involvement by Hodgkin's disease can be demonstrated by the usual bone marrow aspirate technique and examination of marrow smears.
- Bone marrow involvement is focal, often associated with fibrosis. It may be found with increasing frequency as the Hodgkin's disease becomes more widespread with systemic symptoms and often associated with an elevated serum alkaline phosphatase, radiologic evidences of bone involvement and unexplained pancytopenia.

Preferred Lymph Node Biopsy Sites in Hodgkin's Disease

- Hodgkin's disease is very rare in the absence of lymphadenopathy.
- Lymph node biopsy must be taken from cervical region, axillary region, splenic hilum and retroperitoneal region.
- Biopsy specimens then can be obtained from bone marrow, liver, or other parenchymal tissue.
- Mesenteric and inguinal lymph nodes are usually spared, hence should not be biopsied for histological diagnosis. Excised lymph node should be fixed in 10% buffered formalin or Zenker's fixative.

Gross Morphology

Cut surface of involved lymph node is uniform. Capsule is rarely involved, hence not invading surrounding adipose tissue.

Light Microscopy

- Sections stained with hematoxylin and eosin are examined by light microscopy. Hodgkin's disease can be definitively diagnosed by lymph node biopsy that reveals characteristic Reed-Sternberg cells in a characteristic histologic setting.
- On histologic examination, one finds difficulty in differentiating Hodgkin's disease from granulocytic leukemia and large cell lymphoma, hence imprint smears are helpful in differentiating these entities.

Immunophenotyping

- Reed-Sternberg cells in classic variants of Hodgkin's disease express B cell markers such as CD15 (Leu M-1), CD30 (Ki-1) and PAX5.
- On the other hand, nodular lymphocytic–histiocytic variant of Hodgkin's disease shows negativity for CD15 (Leu M-1), CD30 (Ki-1) and PAX5, CD20, CD45 and epithelial membrane antigen (EMA).
- CD30 is expressed on Reed-Sternberg cells of Hodgkin's disease, immunoblasts in infectious mononucleosis, peripheral T cell NHL, embryonal carcinoma and pancreatic carcinoma. Reed-Sternberg cells in Hodgkin's disease show positivity for CD15 (Leu M-1) as shown in Fig. 13.18A.
- Reed-Sternberg cells in Hodgkin's disease show positivity for CD30 (Ki-1) as shown in Fig. 13.18B.

DIFFERENTIAL DIAGNOSIS

Hodgkin's disease may be difficult to differentiate from lymphadenopathy caused by infectious mononucleosis, toxoplasmosis, cytomegalovirus, NHL, or leukemia. The clinical picture can also be simulated by lung carcinoma, sarcoidosis, tuberculosis, and various diseases in which splenomegaly is the predominant feature.

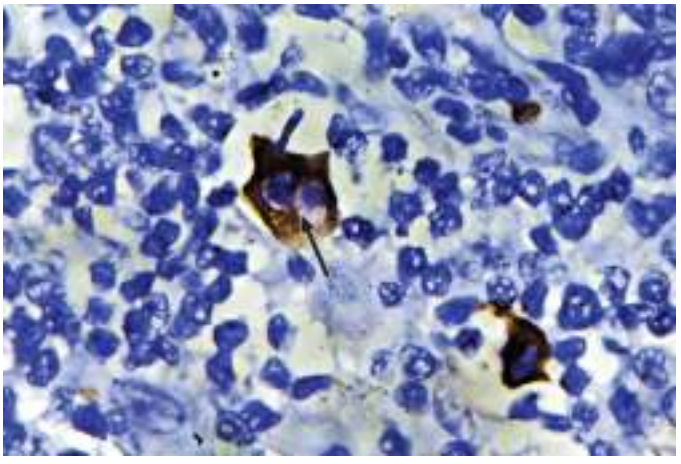

Fig. 13.18A: Reed-Sternberg cells in Hodgkin's disease show positivity for CD15 (Leu M-1) (arrow).

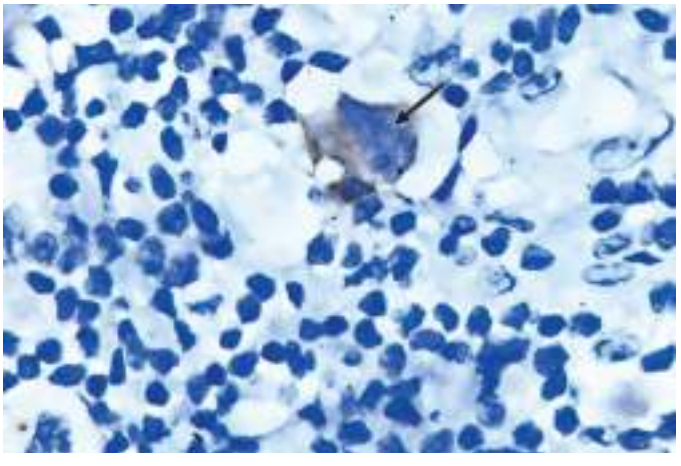

Fig. 13.18B: Reed-Sternberg cells in Hodgkin's disease show positivity for CD30 (Ki-1) positive (arrow).

HODGKIN'S DISEASE: MORPHOLOGIC SUBTYPES

There are two morphologic subtypes of Hodgkin's disease: classical Hodgkin's disease (lymphocyte-rich, lymphocyte depletion, nodular sclerosis and mixed cellularity) and nodular lymphocytic–histiocytic-predominant variant with or without histiocytes and Hodgkin's disease. Nodular sclerosis, mix cellularity and nodular lymphocyte predominant variants of Hodgkin's disease arise from B cells. Rest Hodgkin disease variants originate from T cell. Morphologic subtypes of Hodgkin's disease are given in Table 13.18. Immunophenotyping features of classic variant of Hodgkin's disease are given in Table 13.19. Histologic

Table 13.18 Morphologic subtypes of Hodgkin's disease

Hodgkin's Disease Variant	Immunophenotyping	Reed-Sternberg Cells	Prognosis
Classic variants of Hodgkin's disease			
Lymphocyte-rich classic variant of Hodgkin's disease (B cell markers)	▪ CD30+ (Ki-1) specific marker ▪ CD15+ (Leu M-1)	Popcorn Reed-Sternbeg cells (lymphocytic–histiocytic cells)	Good prognosis
Lymphocyte-depletion classic variant of Hodgkin's disease (B cell markers)	▪ CD30+ (Ki-1) specific marker ▪ CD15+ (Leu M-1)	Many Reed-Sternbeg cells with diffuse fibrosis	Worst prognosis
Nodular sclerosis classic variant of Hodgkin's disease (B cell markers)	▪ CD30+ (Ki-1) specific marker ▪ CD15+ (Leu M-1) ▪ CD20+ ▪ CD79a+ ▪ CD5+ ▪ CD3+ ▪ IgM+ ▪ IgD+	Lacunar Reed-Sternbeg cells with bands of collagen fibers	Best prognosis
Mixed cellularity classic variant of Hodgkin's disease (B cell markers)	▪ CD30+ (Ki-1) specific marker ▪ CD15+ (Leu M-1)	Classic Reed-Sternbeg cells with heterogeneous population of reactive cells	Commonest variant in India with fair prognosis
Nodular lymphocytic–histiocytic predominant variant of Hodgkin's disease with or without benign histiocytes (L&H cells)			
Nodular lymphocytic–histiocytic predominant with L&H cells (pan-B markers)	▪ CD19+ ▪ CD20+ ▪ CD22+ ▪ CD45RA+ ▪ CD45RB (LCA)+ ▪ CD74+ ▪ CDw75+ ▪ EMA+	Lymphocytic–histiocytic cells (L&H cells)	Good prognosis

All are classic variants of Hodgkin's lymphoma except nodular lymphocytic–histiocytic predominant variant.

Table 13.19 Immunophenotyping features of classic variant of Hodgkin's disease

Cell Type	Immunophenotyping	Expression
Reed-Sternberg cells		
Reed-Sternberg cells immunophenotyping	▪ CD15 (Lu M-1) ▪ CD30 (Ki-1)	▪ Positive ▪ Positive
Cellular environment		
T cells (Th2)	CD3, CD4	Positive
Eosinophils	CD16	Positive
Histiocytes	CD68	Positive
Plasma cells (variable)	CD138	Positive
Neutrophils (variable)	CD15	Positive

Table 13.20 Histologic variants of classic Hodgkin's disease (HD)

Characteristics	Nodular Sclerosis HD	Mixed Cellularity HD	Lymphocyte-rich HD	Lymphocyte-depletion HD
Origin	B cells	B cells	B cells	B cells
Frequency	Most frequent type (75%)	Overall second most frequent (25%)	Uncommon (6%)	Uncommon (4%)
Age group	Young age group	Young adults and older persons (more than 55 years), bimodal peak	Young age group	Older age group
Sex predilection	Female predominance	Males predominance	Males predominance	Males predominance
EB virus association	No association	Associated with EB virus	No association	Associated with EB virus
Clinical features	Mediastinal mass, lower cervical, supraclavicular lymphadenopathy	Lower cervical and supraclavicular lymph nodes	Axillary lymphadenopathy (mediastinal uncommon)	Patient is associated with HIV infection having dis-seminated disease
Light microscopy	Lacunar Reed-Sternberg cells with bands of collagen fibers divide the lymph node in multiple nodules	Classic and mononuclear Reed-Sternberg cells admixed with many reactive cells	A few popcorn Reed-Sternberg cells	Many Reed-Sternberg cells with diffuse fibrosis
Immunophenotyping	**Reed-Sternberg cells:** CD30 (Leu M-1) and CD15 (Ki-1)	**Reed-Sternberg cells:** CD30 (Leu M-1) and CD15 (Ki-1)	**Reed-Sternberg cells:** CD30 (Leu M-1), CD15 (Ki-1) and CD20	**Reed-Sternberg cells:** CD30 (Leu M-1) and CD15 (Ki-1)
Stage	Most cases are in stage I or II	Most cases are in stage III or IV (>50%)	Most cases are in stage I or II	Most cases are in stage III or IV
Prognosis	Best prognosis	Fair prognosis	Good prognosis	Worst prognosis

variants of classic Hodgkin's disease are given in Table 13.20.

LYMPHOCYTE-RICH CLASSIC VARIANT OF HODGKIN'S DISEASE

Lymphocyte-rich classic variant of Hodgkin's disease constitutes about 5–10% of patients, which is a slow-growing disease associated with excellent prognosis. It is more common in men than women under 35 years of age. There is an association of Epstein-Barr virus (EBV) infection in 40% of cases.

Clinical Features

Patient usually presents with solitary enlarged painless lymph node usually in cervical or inguinal regions, persistent fatigue, fever, night sweats, weight loss, severe itching and painful lymph node after drinking alcohol. Lymphocyte-rich classic variant of Hodgkin's disease never involves liver, spleen and bone marrow except when it changes to more aggressive histologic pattern. The clinical course is moderately aggressive.

Surgical Pathology: Lymphocyte-rich Classic Variant of Hodgkin's Disease

Light Microscopy

Lymphocyte-rich classic variant of Hodgkin's disease is composed of mature lymphocytes admixed with Reed-Sternberg cells, i.e. popcorn or elephant's foot cells which have excessively lobulated nuclei.

Immunophenotyping

- Reed-Sternberg cells have same immunophenotyping as in other subtypes of classic Hodgkin's lymphoma.
- These show positivity for T cell markers such as CD30 (Leu M-1) and CD15 (Ki-1).
- Reed-Sternberg B cells are constantly negative for pan-B markers such as CD19, CD20, CD22, 45RA, 45RB (LCA), CD74, CDw75, CD20 or CD45.
- Immunophenotyping of lymphocyte-rich classic variant of Hodgkin's disease is given as follows:

Markers	Expression
▪ CD30 (Leu M-1)	▪ Positive
▪ CD15 (Ki-1)	▪ Positive

Prognosis

Lymphocyte-rich classic variant of Hodgkin's disease is slow growing and associated with best prognosis.

LYMPHOCYTE-DEPLETION CLASSIC VARIANT OF HODGKIN'S DISEASE

Lymphocyte-depletion classic variant of Hodgkin's disease is least common constituting 4% of Hodgkin's disease with worst prognosis. It is most often associated with Epstein-Barr virus. It usually affects elderly persons associated with HIV infection.

Clinical Features

The lymphocyte-depletion classic variant of Hodgkin's disease is usually not diagnosed until the disease is widespread and involving liver (60%), bone marrow (40%), spleen and retroperitoneal lymph nodes. Advanced stage and systemic symptoms are frequent. Pancytopenia is occasionally caused by bone marrow involvement in these cases.

Surgical Pathology: Lymphocyte-depletion Classic Variant of Hodgkin's Disease

Light Microscopy

Lymphocyte-depletion classic variant of Hodgkin's disease can easily be confused with non-Hodgkin's lymphoma. It should only be diagnosed when anaplastic large cell lymphoma has been excluded. On histologic examination, it may show any of two patterns: diffuse fibrosis and reticular pattern.

- **Diffuse fibrosis pattern:** Lymph node shows diffuse fibrosis, few lymphocytes and polypoid Reed-Sternberg cells. Diffuse fibrosis is demonstrated by nonbirefringent collagen fibers in polarizing microscopy.
- **Reticular pattern:** Lymph node shows reticular pattern with sheets of bizarre Reed-Sternberg cells and areas of necrosis. Reticular pattern needs to be differentiated from large cell NHL.

Immunophenotyping

Immunophenotyping of lymphocyte-depletion variant of Hodgkin's disease is mentioned below:

Markers	Expression
▪ CD30 (LeuM-1)	▪ Positive
▪ CD15 (Ki-1)	▪ Positive

Prognosis

Lymphocyte-depletion classic variant of Hodgkin's disease has the worst prognosis among all the variants of Hodgkin's disease.

NODULAR SCLEROSIS CLASSIC VARIANT OF HODGKIN'S DISEASE

Nodular sclerosis classic variant of Hodgkin's disease constitutes 60–75% of all cases, which involves B cells (all other types of Hodgkin's disease involve T cells). Presence of large bundles of collagenous connective tissue separates the lymph node into nodules. Most cases in the stage I or II.

Age and Sex Predilection

Nodular sclerosis classic variant of Hodgkin's disease usually affects adolescents and young adults between 20 and 30 years of age. Females are more affected than males.

Clinical Features

Patient presents with lymphadenopathy in upper mediastinum (50%), supraclavicular or lower cervical regions. There is rarely an association with Epstein-Barr virus (EBV) infection. Patient may have recurrent laryngeal paralysis due to compression of recurrent laryngeal nerves. Neurologic pain follows nerve root compression. Lymphadenopathy in thorax compresses respiratory tract (trachea and bronchi) resulting in cough, chest pain and severe dyspnea.

Laboratory Diagnosis

Hematologic findings are anemia, leukocytosis, and an elevated erythrocyte sedimentation rate.

Surgical Pathology: Nodular Sclerosis Classic Variant of Hodgkin's Disease

Gross Morphology

- Lymph node is enlarged, firm, fleshy with formation of irregular nodules separated by bands of firmer fibrotic tissue.
- Fibrosis in lymph node is caused by cytokines synthesized by neoplastic lacunar cells, i.e. IL-5 (attracting eosinophils), IL-4, TNF-α and GM-CSF.

Light Microscopy

- Lymph node from nodular sclerosis classic variant of Hodgkin's disease shows broad bands of pink-staining birefringent collagen fibrous tissue on polarizing microscopy (Fig. 13.19).
- There is presence of numerous lacunar Reed-Sternberg cells and reactive cells. Lacunar RS cells contain more delicate folded or solitary nuclei surrounded by abundant clear or pale eosinophilic cytoplasm in histologic sections that can retract during processing. It is an artifact of formalin fixation.

- Cytokines synthesized by Reed-Sternberg cells are currently believed to cause progressive attraction of T cells, histiocytes, plasma cells and eosinophils.
- Nodular sclerosis of Hodgkin's disease has cellular phase and syncytial phase. Nodular sclerosis classic variant of Hodgkin disease in syncytial phase is more aggressive in clinical behavior.

Immunophenotyping

- Reed-Sternberg cells have same immunophenotyping as in other subtypes of classic Hodgkin's disease. Reactive component consists of small lymphocytes bearing phenotype of mantle B cells.
- B cells show positivity for CD30 (Leu M-1), CD15 (Ki-1), CD20, CD79a, CD5, CD3, IgM and IgD.
- Immunophenotyping of nodular sclerosis classic variant of Hodgkin's disease is mentioned as under:

Markers	Expression
CD30 (Leu M-1)	Positive
CD15 (Ki-1)	Positive
CD20	Positive
CD79a	Positive
CD5	Positive
CD3	Positive
IgM	Positive
IgD	Positive

Prognosis

The prognosis of nodular sclerosis classic variant of Hodgkin disease is relatively good. Patients respond to locoregional treatment with radiation and have an excellent prognosis. Cell-mediated immunity is often reduced, as evidenced by anergy (absence of normal immune response to a particular antigen) by skin testing.

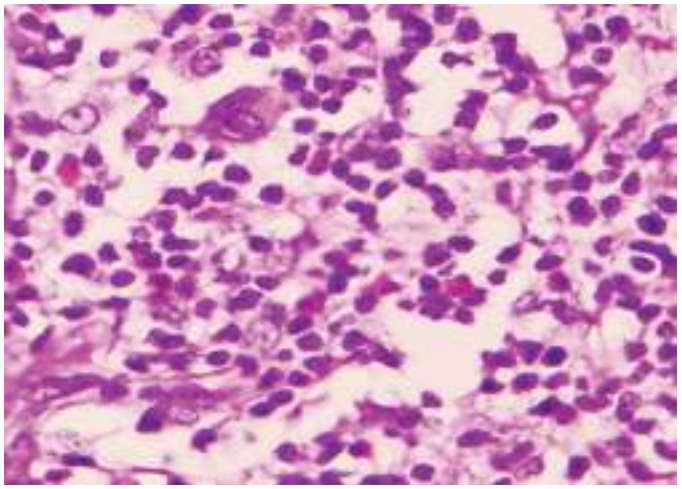

Fig. 13.19: Nodular sclerosis classic variant of Hodgkin's disease (400X).

MIXED CELLULARITY CLASSIC VARIANT OF HODGKIN'S DISEASE

Mixed cellularity classic variant of Hodgkin's disease constitutes 5–25% of all cases, which is most common in India. It is associated with EBV infection in 70% of cases. Although >50% of cases progress to stage III or IV, yet prognosis is still good.

Age and Sex Predilection

Mixed cellularity classic variant of Hodgkin's disease most often affects elderly men and women. It may also affect immunocompromised children.

Clinical Features

Patient presents with multiple painless, rubbery discrete lymph node groups. Spleen, liver and bone marrow may be involved. Reed-Sternberg cells synthesize powerful cytokines such as IL-1, IL-6 and TNF-α, which cause local pain, fever, night sweats and weight loss exceeding 10% of body weight. Pruritus indicates progression of the disease. Mixed cellularity classic variant of Hodgkin's disease—patients have moderately aggressive clinical course but disease is curable.

Surgical Pathology: Mixed Cellularity Classic Variant of Hodgkin's Disease

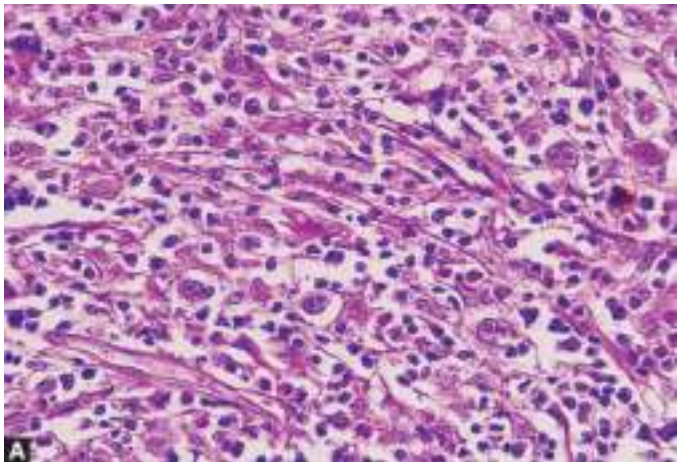
Gross Morphology

- Lymph nodes are enlarged with diffuse involvement.
- Cut surface is fleshy, gray tan without well-defined nodules or fibrosis.

Light Microscopy

- Histologic examination of lymph node in mixed cellularity classic variant of Hodgkin's disease shows classic Reed-Sternberg cells admixed with reactive inflammatory cells such as eosinophils, plasma cells, and small lymphocytes, histiocytes in the background. Cytokine IL-5 synthesized by Reed-Sternberg cells and exotoxin released by fibroblasts participate in chemotaxis of eosinophils.
- Patches of necrosis and fibrosis may be present.
- Presence of noncaseating epithelioid granulomas in Hodgkin's disease indicates good prognosis is shown in Fig. 13.20A and B.
- Classic Reed-Sternberg cells constitute 1–10% of total population of cells, which are large and binucleated or bilobed, with two halves often appearing as mirror images of each other resembling owl eyes. Reed-Sternberg cells measure 20–50 μm in diameter with amphophilic cytoplasm.
- Nuclear membrane is thick and sharply defined. Mononuclear Reed-Sternberg cells are also encountered in mixed cellularity disease, which synthesize IL-5, IL-4, TNF-α and GM-CSF.

Immunophenotyping	
▪ Reed-Sternberg cells have same immunophenotyping as in other subtypes of classic Hodgkin's disease. ▪ Reed-Sternberg cells show positivity for B cell markers such as CD30 (Leu M-1) and CD15 (Ki-1), which are constantly negative for pan-B markers such as CD19, CD20, CD22, 45RA, 45RB (LCA), CD74, CDw75 or CD45. ▪ Immunophenotyping of mixed cellularity classic variant of Hodgkin's disease is shown as under.	
Markers	**Expression**
▪ CD30 (Leu M-1) ▪ CD15 (Ki-1)	▪ Positive (100%) ▪ Positive (75–80%)



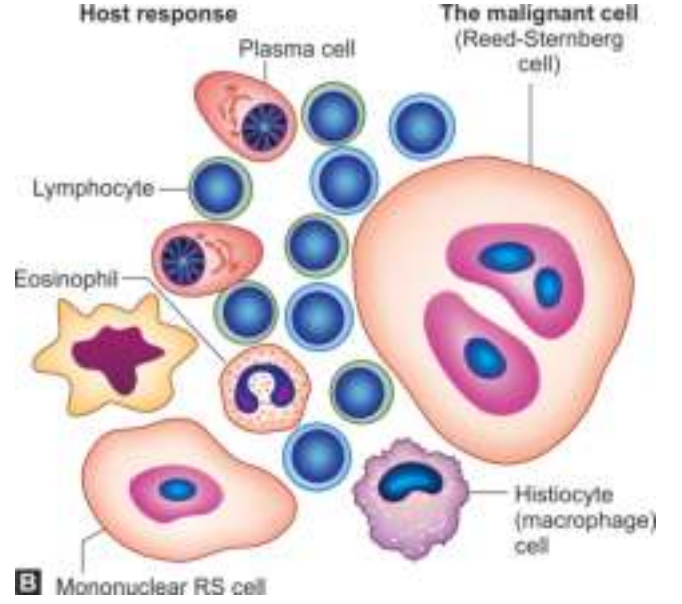


Fig. 13.20: Mixed cellularity classic variant of Hodgkin's disease. (A) Histologic examination of lymph node shows numerous classic Reed-Sternberg (RS) cells admixed with reactive inflammatory cells such as eosinophils, plasma cells, lymphocytes and histiocytes including epithelioid cell granulomas (400X), (B) mononuclear RS cells.

NODULAR LYMPHOCYTIC–HISTIOCYTIC PREDOMINANT VARIANT OF HODGKIN'S DISEASE

Nodular lymphocytic–histiocytic predominant variant is distinct entity from classic Hodgkin's disease. It constitutes 5% of all Hodgkin's disease cases. It most often affects young males involving cervical or axillary adenopathy with long history. Rarely, mediastinal or bone marrow may be involved. It has indolent behavior, but higher recurrence rate than classic Hodgkin's disease.

Clinical Features

Patients with stage I/II have excellent prognosis with 10-year survival of 80–90% cases. Recurrence is frequent and associated with progressive transformation of germinal centers with infiltration by small lymphocytes. Approximately 3–5% transform to diffuse large B cell lymphoma. Bone marrow involvement is associated with aggressive disease.

Surgical Pathology: Nodular Lymphocytic–Histiocytic Predominant Variant of Hodgkin's Disease	
Gross Morphology	
Lymph node architecture is completely effaced with formation of vague nodules of small lymphocytes.	
Light Microscopy	
▪ Nodular lymphocytic–histiocytic-predominant variant of Hodgkin's disease is composed of small B cells with or without accompanying population of benign appearing histiocytes. ▪ Eosinophils, plasma cells and foci of fibrosis are scanty or absent. Endothelium of postcapillary venules may be prominent.	
Immunophenotyping	
Reed-Sternberg cells of nodular lymphocytic–histiocytic variant of Hodgkin's disease show positivity for pan-B markers such as CD19, CD20, CD22, 45RA, 45RB (LCA), CD74, CDw75 and EMA. These RS cells are constantly negative for B cell markers such as CD15 (Ki-1) and CD30 (Leu M-1).	
Markers	**Expression**
▪ CD19 ▪ CD20 ▪ CD22 ▪ 45RA ▪ 45RB (LCA) ▪ CD74 ▪ CDw75 ▪ EMA	▪ Positive ▪ Positive ▪ Positive ▪ Positive ▪ Positive ▪ Positive ▪ Positive ▪ Positive

NON-HODGKIN'S LYMPHOMAS

NON-HODGKIN'S LYMPHOMAS: OVERVIEW

Non-Hodgkin's lymphomas (NHLs) arise from lymphoid cells or other cells native to lymphoid tissue. They originate most frequently within lymph nodes or in other lymphoid areas. Tumor involvement of the para-aortic lymph nodes is frequent. The seriousness of non-Hodgkin's lymphoma depends on which type of cell has undergone mutation, and how quickly it replicates. Revised 2024 WHO classification of non-Hodgkin's lymphoid neoplasms is based on origin from B or T cells: precursor lymphoid neoplasms and mature B cell neoplasms (*refer* to Table 13.17). Origin of non-Hodgkin's lymphoid neoplasms derived from B and T cells is shown in Fig. 13.21A and B.

NON-HODGKIN'S LYMPHOMAS: GRADES

The disease is sometimes described by the behavior of its cells: low-grade, intermediate grade and high-grade non-Hodgkin's lymphoma (Table 13.21).

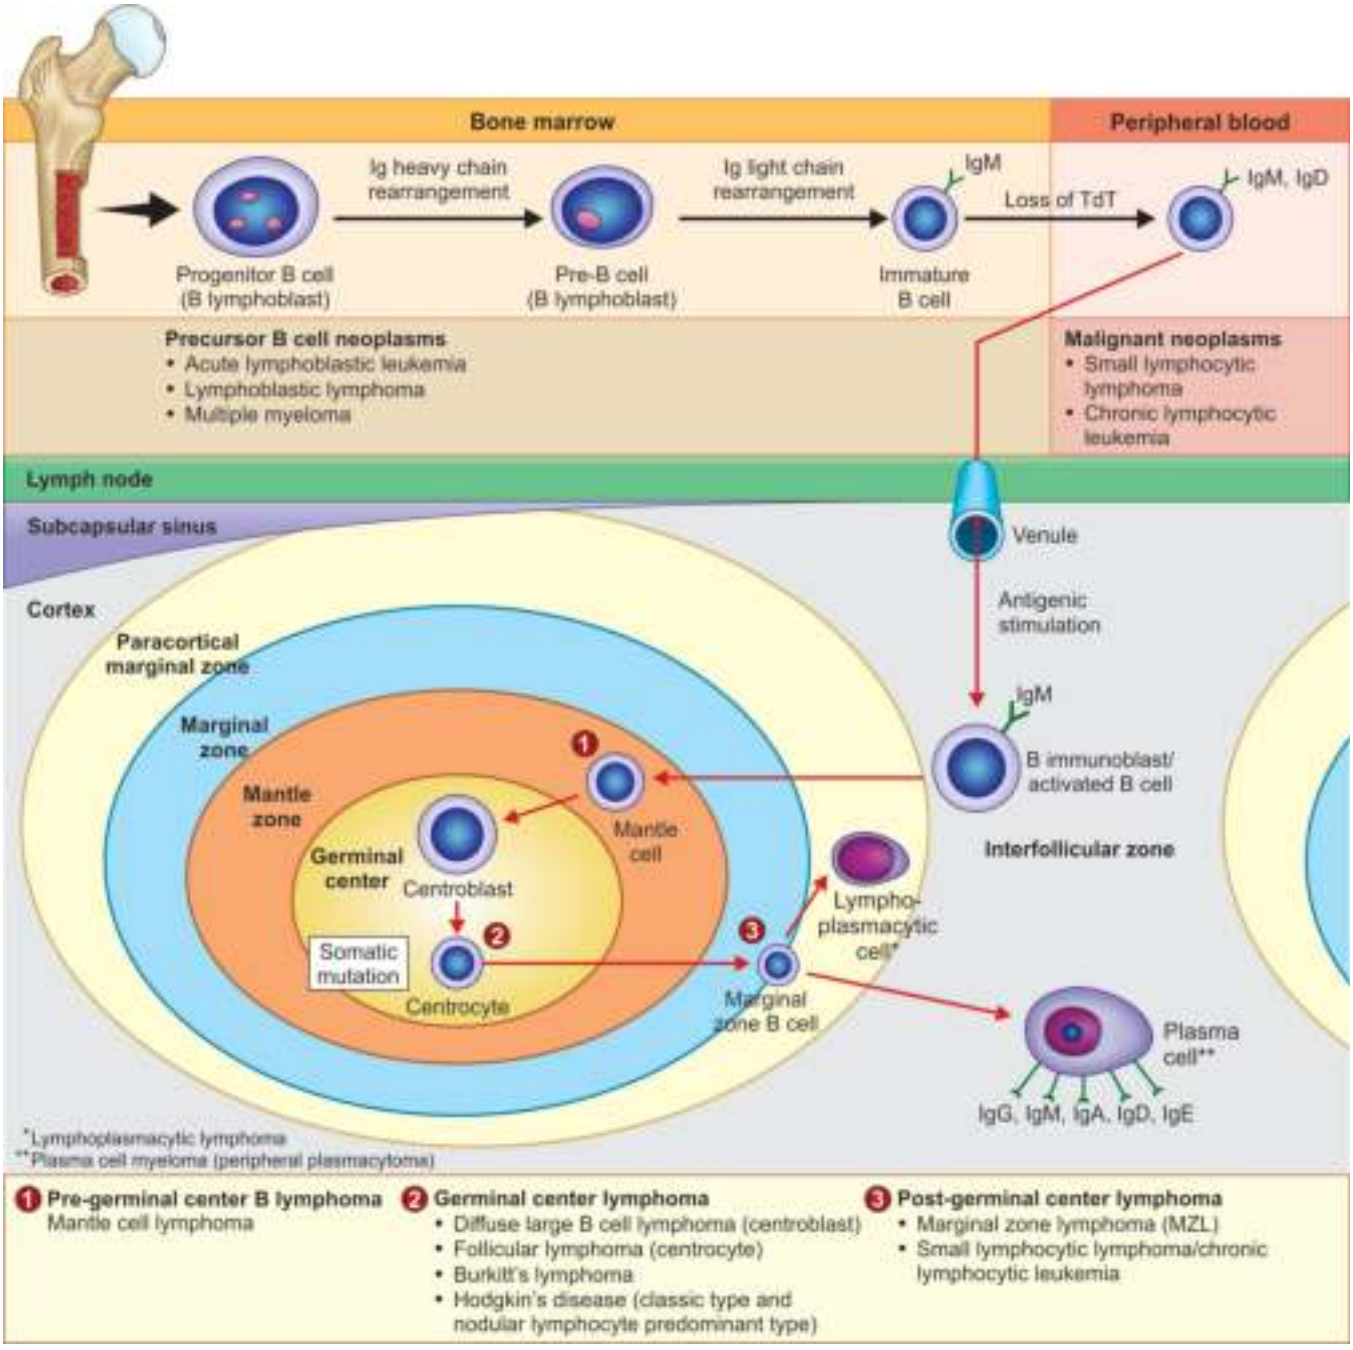

Fig. 13.21A: Origin of B cell derived non-Hodgkin's lymphoid neoplasms.

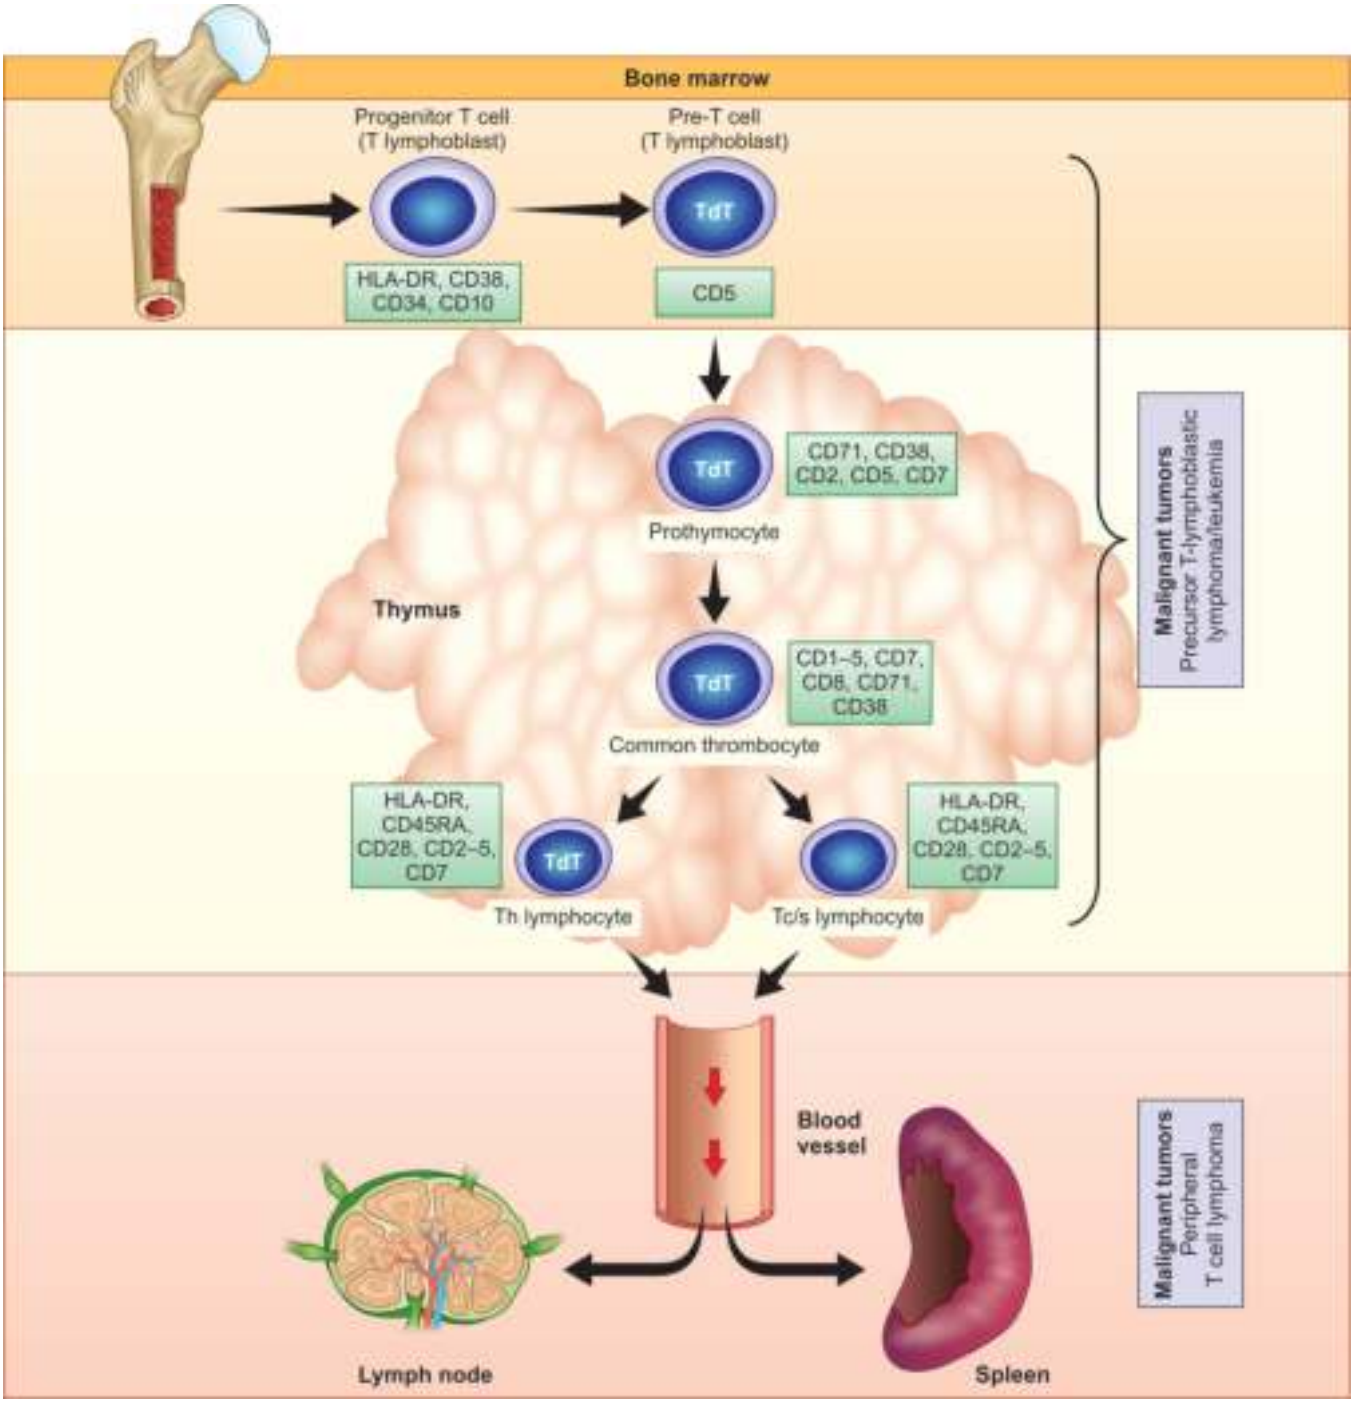

Fig. 13.21B: Origin of T cell-derived non-Hodgkin's lymphoid neoplasms.

- Low-grade NHLs tend to involve multiple lymph nodes at multiple sites, whereas high-grade NHLs tend to be more localized. Low-grade NHLs are slow growing and responsive to treatment.
- Intermediate-grade NHLs are rapidly growing, aggressive but responsive to treatment.
- High-grade NHLs are rapidly growing, aggressive and more localized but may be resistant to treatment.

APPROACH TO NHL WORK UP

Antigen markers useful in delineating and sub-classifying non-Hodgkin's lymphoid malignancies are given in Table 13.22. The work up of NHLs is done by evaluation of disease-specific markers such as cyclin D1 and anaplastic large lymphoma kinase 1 (ALK-1), which can only be evaluated by immunophenotyping on tissue sections.

Table 13.21 Updated Kiel classification of non-Hodgkin's lymphoma (adapted from flow cytometry, immunohistochemistry and molecular genetics of hematologic neoplasms)

Grades of NHL	Histologic Subtypes (B Cell Origin)	Histologic Subtypes (T Cell Origin)	Clinical Course
Low-grade NHL*	**Lymphocytic NHLs** ▪ Chronic lymphocytic leukemia ▪ Prolymphocytic leukemia ▪ Hairy cell leukemia **Lymphoplasmacytic/plasmacytoid (immunocytoma)** ▪ Plasmacytic NHL ▪ Centroblastic-centrocytic (follicular ± diffuse or diffuse) NHL ▪ Mantle cell (centrocytic) NHL ▪ Monocytoid NHL ▪ Marginal zone cell NHL	**Lymphocytic NHLs** ▪ Chronic lymphocytic leukemia ▪ Prolymphocytic leukemia ▪ Small cell NHL ▪ Cerebriform NHL **Mycosis fungoides/Sézary syndrome** ▪ Lymphoepithelioid (Lennet NHL) ▪ Angioimmunoblastic NHL ▪ T-zone NHL ▪ Pleomorphic, small cell (HTLV-1 ±) NHL	▪ Low-grade NHLs are slow growing neoplasms and responsive to therapy. ▪ Low-grade NHL may transform to high-grade NHL
High-grade NHL	▪ Centroblastic NHL ▪ Immunoblastic NHL ▪ Burkitt's lymphoma ▪ Large cell anaplastic NHL (Ki-1 ±)	▪ Pleomorphic, medium sized and large cell NHL (HLTV-1 ±) ▪ Immunoblastic NHL (HTLV-1 ±) ▪ Large cell anaplastic NHL (Ki-1 ±)	High-grade NHLs are rapidly growing neoplasms, which may be resistant to therapy. Intermediate grade NHLs are rapidly growing neoplasms, but responsive to therapy

**Low-grade or indolent NHL may change to a more aggressive form later. Intermediate NHLs are rapidly growing, aggressive but responsive to treatment.*

Table 13.22 Antigen markers used in subclassification of non-Hodgkin's lymphoma

Examples of Markers	Cellular Distribution
Leukocyte marker	
CD45 (known as common leukocyte antigen)	All leukocytes
Markers of immaturity	
TdT (terminal deoxynucleotidyl transferase, a specialized DNA polymerase)	Nuclear expression in pre-B and pre-T lymphoblasts
CD34	Pluripotent hematopoietic stem cells (HSCs) and progenitor cells of many lineages
CD10 (CALLA—common acute lymphoblastic leukemia antigen)	Bone marrow pre-B cells and mature follicular center B cells (ALL, B cell lymphoma)
CD22	Pre-B cells (B cell lymphoma)
Cytoplasmic μ heavy chains	B cells in bone marrow
Primary B cell associated markers	
CD19	Bone marrow pre-B cells, mature B cells (not on plasma cells) (B-ALL, B cell lymphoma, CLL)
CD20	Bone marrow pre-B cells, mature B cells (not on plasma cells) (B-ALL, B cell lymphoma, CLL)
CD79a	Bone marrow pre-B cells, mature B cells and plasma cells (B cell lymphoma)
CD22 (transmembrane molecule)	Bone marrow pre-B cells (cCD22) and mature B cells (B cell lymphoma)
Markers helpful in sub-classifying mature B cell lymphomas	
CD5	T cells, small subsets of B cells, neoplastic CLL and mantle cell lymphoma cells (T-ALL, CLL, T and B cell lymphoma)
CD10	Immature B cells in germinal centers and mature granulocytes (ALL, B cell lymphoma)

Contd...

Table 13.22 Antigen markers used in subclassification of non-Hodgkin's lymphoma (*Contd...*)

Examples of Markers	Cellular Distribution
CD11c	Monocytes/macrophages, natural killer cells, granulocytes, subsets of B and T cells (AML)
CD23	Activated mature B cells (B cell lymphoma, chronic lymphocytic leukemia)
CD38	Mature B cells and plasma cells (multiple myeloma)
CD43	All leukocytes except resting B cells, also demonstrated in B cell lymphoma, T cell lymphoma
BCL-6	Germinal center lymphocytes in normal lymph node
BCL-2	T cells and normal mantle B cells, also expressed in aberrantly B cell lymphomas
Cyclin D1 (cell regulatory protein)	Rearranged through t(11;14) in mantle cell lymphoma, weakly expressed in hairy cell leukemia and plasma cell dyscrasias
CD138 (Syndecan 1)	Multiple myeloma, but also present in carcinomas
Markers of clonality	
κ or λ immunoglobulins	Multiple myeloma
Primarily T cell and NK cell associated markers	
CD1a	Thymocytes and Langerhans' cell histiocytosis (T cell lymphoma, T-ALL)
CD2	T cells in thymus and peripheral blood and NK cells (T-ALL, T cell lymphoma)
CD3	Lineage specific marker for T cells and cytoplasmic form expressed in NK cells
CD5	All T cells and subsets of B cells (T-ALL, B cell lymphoma, CLL)
CD7	All T cells and subsets of myeloid precursor cells (T-ALL, T cell lymphoma)
CD8	Cytotoxic T cells, subset of peripheral T cells, thymocytes and NK cells
CD16	NK cells and granulocytes (NK cell disorders)
CD56	NK cells, subset of T cells and multiple myeloma (NK cell disorders)
TIA is a cytoplasmic granule-associated RNA binding protein	NK cells and cytotoxic T cells
Flow cytometry	
κ or λ immunoglobulins	B cell lymphoid neoplasms, clonality of T cell neoplasms can be demonstrated by molecular or genetic analysis
Southern blot analysis	
Clonal immunoglobulin heavy chain (IgH) or TCR rearrangements	Southern blot targets TCRb detects additional band in B cell and T cell malignancies (normal T cells rearrange TCR genes such as α, β, γ and δ)
PCR (polymerase chain reaction)	
TCRg gene	T cell lymphoid neoplasms
Cytogenetic analysis	
Conventional karyotyping	Acute leukemias
FISH (fluorescence *in situ* hybridization)	B cell, T cell and NK cell lymphoid neoplasms

IMMUNOPHENOTYPING

Immunophenotying in NHLs plays important role in those cases, who lack diagnostic cytologic and histomorphologic features.

- Immunophenotying can distinguish a benign lesion from malignant one; and thus achieve definite diagnosis. It plays important role in differential diagnosis, subclassification and prediction of prognosis in various non-Hodgkin's lymphomas, e.g. low-grade lymphomas such as small lymphocytic lymphoma, chronic lymphocytic leukemia, mantle cell lymphoma, follicular lymphoma, hairy cell leukemia and various types of marginal zone B cell lymphoma.

- Availability of **CD23** monoclonal antibody facilitates the distinction between small lymphocytic lymphoma and mantle cell lymphoma.
  - Mantle cell lymphoma and chronic lymphocytic leukemia/small lymphocytic lymphoma (SLL/CLL) share many histomorphologic and immunophenotyping features.
  - Typically, SLL/CLL is CD23+, whereas mantle cell lymphoma is CD23–.
- Prognosis of certain non-Hodgkin's lymphomas is analyzed by assessing quantitative proliferation-associated antigens, such as Ki-67 and proliferating cell nuclear antigen (PCNA). Presence of high percentages of activated antigens, e.g. CD25, CD38, CD71 and human leukocyte antigen (HLA) has poor prognosis.
- Diagnostic criteria of hematolymphoid neoplasms by flow cytometry include restrictive of Ig light chain, loss of surface Ig in B cells, coexistence of two different cell lineage markers on the same cell population, expression of numerous cell markers in large number of cells, selective loss of one or more cell lineage antigens and analysis of T cell receptor Vb repertoire.

PRECURSOR B CELL AND T CELL NHLs

Precursor B and T cell leukemias/lymphomas include precursor B cell lymphoblastic leukemia/lymphoblastic lymphoma, precursor T cell lymphoblastic leukemia/lymphoblastic lymphoma; and myeloid and lymphoid neoplasms with FGFR1 abnormalities.

PRECURSOR B CELL LYMPHOBLASTIC LEUKEMIA/LYMPHOMA

Precursor B cell lymphoblastic leukemia and B cell lymphoblastic lymphoma are essentially one disease process. Patient with involvement of blood and bone marrow is designated precursor B cell lymphoblastic leukemia, if the bone marrow contains >25% lymphoblasts. On the other hand, patient with nodal or extranodal disease especially bone marrow is designated as precursor B cell lymphoblastic lymphoma. Disease predominantly affects children below the age of six years and occasional adult patient. Common sites of involvement are skin, bone and lymph nodes. Central nervous system and testes are common sites of relapse.

Clinical Features

Patient presents with multiple skin nodules, bone mass or soft tissue mass and lymphadenopathy. Recurrent infections, anemia, bleeding are related to pancytopenia.

Molecular Genetic Alterations

- Majority of cases of precursor B cell lymphoblastic leukemia/lymphoma demonstrate clonal, but not mutated, rearrangements of the immunoglobulin genes.
- About 66% of cases demonstrate clonal immunoglobulin heavy chain (IgH) rearrangements; and remaining cases show clonally rearranged IgH and light chain genes.
- About 50% of cases demonstrate t(12;21) and hyperploidy, usually with trisomy of chromosomes 4 and 8. These patients have a favorable prognosis. Philadelphia chromosomal abnormality is demonstrated in a small number of cases.

Surgical Pathology: Precursor B Cell Lymphoblastic Leukemia/Lymphoma

Light Microscopy

- Morphologically percursor B cell lymphoblastic leukemia/lymphoma and percursor T cell lymphoblastic leukemia/lymphoma are indistinguishable.
- In precursor B cell lymphoblastic leukemia/lymphoma, lymph node involved is composed of medium-sized blast cells with round or convoluted nuclei and small or inconspicuous nucleoli. Neoplastic cells may either uniform or varying degrees of anisocytosis. Mitotic figures are usually demonstrated.
- Tumor cells infiltrate lymph nodes in the manner of a leukemia, leaving reticulin architecture partially intact. Residual reactive germinal centers may be present.
- Tumor cells infiltrate in the capsule and around blood vessels often show 'Indian file pattern'.

Immunophenotyping

Most reliable B cell markers expressed on precursor B cell lymphoblastic lymphoma are CD19, cytoplasmic CD22, and cytoplasmic CD79a. It also shows positivity for CD10, CD34, PAX2, CD43 and TdT.

Markers	Expression
CD19	Positive
CD22	Positive
CD79a	Positive
CD10	Positive
CD34	Positive (50%)
PAX2	Positive (sensitive marker)
CD43	Positive (sometimes)
TdT	Positive (nuclear staining)
CD45	Negative
CD20	Negative
CD3	Negative

Table 13.23 Distinction of precursor B cell lymphoblastic leukemia/lymphoma from precursor T cell lymphoblastic leukemia/lymphoma

Features	Precursor B Cell Lymphoblastic Leukemia/Lymphoma	Precursor T Cell Lymphoblastic Leukemia/Lymphoma
Frequency	More common	Less common
Age group	Children below 6 years	Adolescents
Organs involved	▪ Skin, bone and lymph nodes ▪ Central nervous system and testes are commonly involved in the course of disease during relapse	▪ Anterior mediastinum, lymph nodes liver, spleen and skin ▪ Central nervous system and testes are commonly involved in the course of disease during relapse
Clinical features	▪ Multiple skin nodules, bone or soft tissue tumors and lymphadenopathy ▪ Recurrent infections, anemia, bleeding related to pancytopenia	Symptoms related to mediastinal obstruction and pleural effusion, involvement of lymph nodes, liver, spleen and skin. Central nervous system and testes are commonly involved in the course of disease during relapse. Patient with involvement of blood and bone marrow is designated T cell lymphoblastic leukemia, if the bone marrow contains more than 25% lymphoblasts
Molecular genetics	▪ Rearrangements of the immunoglobulin genes involving heavy and light chains ▪ Chromosomal translocation t(12;21) and hyperploidy, usually with trisomy of chromosomes 4 and 8 in 50% of cases with favorable prognosis	▪ Clonal rearrangement of one or more of the T cell receptor gene ▪ Loss of chromosome 9p results in loss of tumor suppressor gene CDCK2A. About 25% of cases show dysregulation of hematopoiesis due to involvement of TAL-1 gene
Light microscopy	▪ Morphologically B cell lymphoblastic lymphoma and T cell lymphoblastic lymphoma are indistinguishable ▪ Lymph node involved is composed of medium-sized blast cells with round or convoluted nuclei and small or inconspicuous nucleoli. Neoplastic cells are either uniform or varying degrees of anisocytosis. Mitotic figures are usually demonstrated	▪ Morphologically B cell lymphoblastic lymphoma and T cell lymphoblastic lymphoma are indistinguishable ▪ Lymph node involved is composed of medium-sized blast cells with round or convoluted nuclei and small or inconspicuous nucleoli. Neoplastic cells are either uniform or varying degrees of anisocytosis. Mitotic figures are usually demonstrated
Immunophenotyping	Positivity for CD19, CD22, CD79a, CD10, CD34, PAX2, CD43, TdT	Positive for CD3 and CD99 (most reliable), CD1a, CD2, CD4, CD5, CD7, CD8, CD34

PRECURSOR T CELL LYMPHOBLASTIC LEUKEMIA/ LYMPHOMA

Precursor T cell lymphoblastic leukemia/lymphoma is less common than precursor B cell lymphoblastic leukemia/lymphoma. Majority of patients of precursor T cell lymphoblastic leukemia/lymphoma present with solid tumor without evidence of leukemia. It occurs in children and young adults with male predominance. Distinction of precursor B cell lymphoblastic leukemia/lymphoma from precursor T cell lymphoblastic leukemia/lymphoma is given in Table 13.23.

Clinical Features

Precursor T cell lymphoblastic leukemia/lymphoma involves anterior mediastinum resulting in mediastinal obstruction and pleural effusion. It may also involve lymph nodes, liver, spleen and skin. Central nervous system and testes are commonly involved in the course of disease during relapse. Patient with involvement of blood and bone marrow is designated precursor T cell lymphoblastic leukemia, if the bone marrow contains >25% lymphoblasts.

Surgical Pathology: Precursor T Cell Lymphoblastic Leukemia/Lymphoma

Light Microscopy

- Morphologically precursor B cell lymphoblastic leukemia/lymphoma and T cell lymphoblastic leukemia/lymphoma are indistinguishable.
- In precursor T cell lymphoblastic leukemia/lymphoma, lymph node involved is composed of medium-sized lymphoblasts with round or convoluted nuclei and small or inconspicuous nucleoli. Lymphoblasts are either uniform or having variable sizes. Mitotic figures are usually demonstrated.
- Lymphoblasts infiltrate lymph nodes in the manner of leukemia, leaving reticulin architecture partially intact. Residual reactive germinal centers may be present.
- Lymphoblasts infiltrate in the capsule and around blood vessels often show 'Indian file pattern'.

Immunophenotyping

Precursor T cell lymphoblastic leukemia/lymphoma shows variable expression of CD1a, CD2, CD4, CD5, CD7, CD8 and CD34. CD3 and CD99 are the most reliable lineage markers, which indicate the precursor nature of the tumor cells.

Markers	Expression
▪ CD1a	▪ Positive
▪ CD2	▪ Positive
▪ CD4	▪ Positive
▪ CD5	▪ Positive
▪ CD7	▪ Positive
▪ CD8	▪ Positive
▪ CD34	▪ Positive
▪ CD3 and CD99	▪ Positive (most reliable marker)

Molecular Genetic Alterations

Precursor T cell lymphoblastic leukemia/lymphoma most often demonstrate clonal rearrangement of one or more of the T cell receptor gene. About 33% of cases demonstrate translocation between the TCR genes and a number of the oncogenes. Loss of chromosome 9p results in loss of tumor suppressor gene CDCK2A. About 25% of cases show dysregulation of hematopoiesis due to involvement of TAL-1 gene.

MYELOID AND LYMPHOID NEOPLASMS WITH FGFR1 ABNORMALITIES

Myeloid and lymphoid neoplasms with FGFR1 abnormalities are pluripotent hematopoietic stem cell neoplasms and also known as 8p11 myeloproliferative syndrome. Patient presents initially with T cell lymphoblastic lymphoma of lymph node and most often accompanied by eosinophilia and myeloproliferative neoplasm. Involved lymph node shows nemerous eosinophils. Disorder may affect 3–85 years of age and is characterized by translocation or insertion of fibroblast growth factor receptor 1 (FGFR1) gene at chromosome 8p11.

MATURE B CELL NON-HODGKIN'S LYMPHOMA

Mature B cells are characterized by the synthesis, expression and sometimes secretion of immunoglobulin molecules.

- Diversity of immunoglobulin molecules is achieved by rearrangement of immunoglobulin genes by somatic mutations.
- Analysis of the immunoglobulin genes provides a valuable means for the detection and subdivision of mature B cell lymphomas.
- Classification of B cell lymphoid neoplasms based on clinical presentation according to 2024 World Health Organization is given in Table 13.24. Lymphoid neoplasms derived from B cell and T cell are given in Table 13.25. Chromosomal abnormalities in B cell derived non-Hodgkin's lymphoma (NHL) are given in Table 13.26. Characteristic features of various B cell leukemias/lymphomas are given in Table 13.27.

Table 13.24 Classification of B cell lymphoid neoplasms based on clinical presentation according to revised 2024 WHO criteria. Adapted from flow cytometry, immunohistochemistry, and molecular genetics for hematologic neoplasms

Categories	Organs Involved	Histologic Type of B Cell Lymphoid Neoplasms
Predominantly disseminated lymphoma/leukemia	▪ Bone marrow with or without peripheral blood ▪ Lymph nodes ▪ Spleen	▪ Chronic lymphocytic leukemia ▪ Hairy cell leukemia ▪ Splenic marginal zone lymphoma ▪ Plasma cell myeloma
Primary extranodal lymphomas	▪ Stomach ▪ Eye and ocular adnexa ▪ Skin ▪ Lung ▪ Salivary glands ▪ Breasts ▪ Thyroid gland	▪ Extranodal marginal zone B cell lymphoma of mucosa-associated lymphoid tissue (MALT)
Predominantly nodal lymphomas	▪ Lymph nodes ▪ Bone marrow ▪ Liver ▪ Spleen ▪ Peripheral blood	▪ Follicular lymphoma ▪ Mantle cell lymphoma ▪ Nodal marginal zone B cell lymphoma

Table 13.25 Lymphoid neoplasms of precursor B and T cells

Disorder	Origin	Age Group	Clinical Features	Genotype	Immunophenotyping
B cell acute lymphoblastic leukemia or lymphoma	Precursor B cells in bone marrow	Children	Recurrent infections, anemia and bleeding related to pancytopenia	Diverse chromosomal translocation t(12;21) involving RUNX1 and ET16	CD19, CD79a, CD22, CD10, CD22, CD24 and PAX5
T cell acute lymphoblastic leukemia or lymphoma	Precursor T cells in thymus	Adolescents	Mass in thymus, variable bone marrow involvement with aggressive clinical course	Diverse chromosomal translocation, NOTCH mutations in 50–70% of cases	TdT, CD1a, CD2, CD3 (specific), CD4, CD5 and CD8

Table 13.26 Chromosomal abnormalities in B cell derived non-Hodgkin's lymphomas

Histologic Variant of Lymphoma	Cytogenetic Abnormality	Oncogene	Juxtaposed Gene
Burkitt's lymphoma* (tropical and nontropical)	▪ t(8;14) ▪ t(8;22) ▪ t(2;8)	▪ c-Myc ▪ c-Myc ▪ c-Myc	▪ Ig heavy chain ▪ Ig κ chains ▪ Ig λ chains
Centroblastic/centrocytic lymphoma	t(14;18)	BCL-2	Ig heavy chain
Centrocytic (intermediate cell) mainly lymphoma in mantle zone	t(11;14)	BCL-2 (PRAD 1)	Ig heavy chain
Small lymphocytic B cell lymphoma	Trisomy 12	–	–
B cell chronic lymphocytic leukemia	t(14;19)	BCL-3	Ig heavy chain
Centroblastic/centrocytic large cell type lymphoma	t(3;22)	–	Ig λ chains

**In Burkitt's lymphoma, t(8q24) is always involved.*

Table 13.27 Characteristic features of various B cell leukemias/lymphomas

Disease	Origin	Clinical Presentation	Morphology	Immunophenotyping	Genetics
Chronic lymphocytic leukemia/small lymphocytic leukemia	Naïve B cell or memory B cells	Weakness, autoimmune hemolytic anemia, enlargement of lymph nodes, liver and spleen	Small mature appearing lymphocyte cells involving bone marrow	Bright staining (CD5, CD19), weak staining (CD20, CD22, CD23, CD19, IgD, CD79a, CD43)	▪ Favorable prognosis t(13q14) ▪ Poor prognosis (deletion of 17p and TP53), trisomy 12, deletions (11q22–23) and rearrangement of IgH (50–60%)
Prolymphocytic leukemia	B cells in marginal zone of lymph node	Marked splenomegaly without lymphadenopathy, rapidly rising lymphocyte count (>100 × 10^9/L)	**Peripheral blood smear:** Medium-sized cells with round nucleus, moderately condensed chromatin, and prominent central nucleolus	CD20 (bright), CD19, IgM, CD22, CD79a, FMC7, CD23 typically absent, CD5 present in 30% of cases	Complex karyotypes are common, abnormalities of TP53 in ~50%, IgH clonally rearranged
Hairy cell leukemia	Memory B cell	Predominantly middle-aged men, splenomegaly, pancytopenia with monocytopenia	Hairy cells in peripheral blood, bone marrow virtually always involved, and spleen infiltration (red pulp)	CD19, CD20, CD22 (bright), CD79a, CD11c (bright), CD25 (bright), CD103, TRAP, DBA in tissue sections	Activating FRAF mutations, rearrangement of IgH
Splenic marginal zone B cell lymphoma	B cell in spleen	Splenomegaly, sometime associated with autoimmune thrombocytopenia or anemia, peripheral lymphadenopathy uncommon	**Peripheral blood smear:** Small- to medium-sized cells with polar villi (villous lymphocytes) **Spleen:** Both white pulp and red pulp infiltration	CD19, CD20, CD79a, IgM and IgD, no expression of CD10, CD5, CD23, and CD43	Allelic loss of chromosome 7q21–32 in 40% of cases, trisomy 3 in rare cases, IgH clonally rearranged
Extranodal marginal zone B cell lymphoma (MALT lymphoma)	Naïve B cell	GI tract most common site of involvement	Small lymphocytes with ample cytoplasm	CD19, CD20, CD79a, IgM, no expression of CD5, CD23, CD10	t(11;18), t(14;18), t(14;18) creating API2-MALT1, BCL10-IgH fusion genes, respectively

Contd...

Table 13.27 Characteristic features of various B cell leukemias/lymphomas (*Contd...*)

Disease	Origin	Clinical Presentation	Morphology	Immunophenotyping	Genetics
Nodal marginal zone B cell lymphoma	B cell	Localized or generalized lymphadenopathy	Marginal zone and interfollicular areas infiltrated by centrocyte-like B cells, monocytoid B cells, or small lymphocytes; plasma cell differentiation may be present	CD19, CD20, CD79a, IgM (no expression of CD5, CD23, CD10)	The translocations associated with extranodal MZL are not detected; IgH clonally rearranged
Follicular lymphoma	Germinal center B cell	Widespread peripheral and central lymphadenopathy, infiltration in liver (portal tract), spleen (white pulp) and bone marrow (85%)	Neoplastic cells with variable morphology forming closely packed neoplastic follicles	CD19, CD20, CD22, CD79a, BCL-6, BCL-2, CD10	t(14;18) (q23;q21) → rearrangement of BCL-2 gene leading to overexpression of the BCL-2 protein and survival advantage of malignant cells; IgH clonally rearranged
Mantle cell lymphoma	Naïve B cell	Lymphadenopathy, most common extranodal site is the GI tract (multiple lymphomatous polyposis)	Small neoplastic lymphocytes with nuclei showing clefts	CD19, CD20, CD5, FMC-7, CD43, cyclin-D1 (lack of expression of CD23, CD10, BCL-6)	t(11;14) creating cyclin D1-IgH fusion gene
Diffuse large B cell lymphoma (DLBCL)	Germinal center or post-germinal center B cell	Rapidly enlarging, often symptomatic mass, often disseminated disease	Variable morphology (centroblastic, immunoblastic, anaplastic cells with round to oval nucleus, prominent nucleoli and frequent mitosis	CD19, CD20, CD22, CD79a, CD10, BCL-6	Diverse chromosomal rearrangement, BCL-6 (30%), BCL-2 (10%) and Myc (5%)
Mediastinal (thymic) large B cell lymphoma	B cell in thymus	Mostly women in their third to fifth decade, large anterior mediastinal mass, sometimes with impending superior vena cava syndrome	Large cells with associated delicate interstitial fibrosis causing compartmentalization, possible thymic remnants, biopsy samples often small and obscured by profuse sclerosis and crush artifact	CD19, CD20, CD30 (weak), IgH, and HLA class I and II expression is often absent	IgH clonally rearranged; hyperdiploid karyotype gains in chromosome 9p
Burkitt's lymphoma	Germinal center B cell	African variant (EB virus-related tumor in maxilla, mandible), Western variant (abdominal lymph nodes around ileocecal region in children), and lymphoma in HIV patients	Medium-sized cells with basophilic vacuolated cytoplasm and regular nuclei with several small nucleoli, tangible-body macrophages imparting "**starry-sky**" appearance	CD19, CD20, CD22, CD38, CD10, CD79a, BCL-6, Ki-67 index (100%)	IgH clonally rearranged; t(8;14) in most cases, t(2;8) and t(8;22) rare

- Mature B cell non-Hodgkin's lymphomas may be categorized into those with low growth fraction (e.g. B-CLL/SLL, lymphoplasmacytic lymphoma, mantle cell lymphoma, marginal zone lymphoma and follicular lymphoma) and high-grade fraction (e.g. diffuse large B cell lymphoma and Burkitt's lymphoma). A proportion of low-fraction mature B cell non-Hodgkin's lymphomas may transform into high-fraction mature B cell non-Hodgkin's lymphoma. Low-fraction mature B cell

non-Hodgkin's lymphomas demonstrate alterations in genes controlling apoptosis. On the other hand, high-fraction mature B cell non-Hodgkin's lymphomas show abnormalities of genes involving proliferation control.

- Immunophenotyping plays important role in analysis of lineage markers for the identification of B cells (e.g. CD20, CD79a) on paraffin-embedded tissues. CD79a is the most reliable marker, expressed on B cells from pre-B cell stage of maturation through to plasma cells. CD5 is expressed on B-CLL/SLL and primary mediastinal large B cell lymphoma. Transcription factor BCL-6 is expressed in the nuclei of follicle center cell-derived lymphomas.

BURKITT'S LYMPHOMA

Burkitt's lymphoma is a highly aggressive neoplasm derived from germinal B cell. It most often involves maxilla, mandible and abdominal organs. Patient responds to aggressive chemotherapy. Upon initiation of chemotherapy, patient may develop 'tumor lysis syndrome' due to rapid tumor cell death.

- Burkitt's lymphoma is divided into three subtypes: (a) African endemic Burkitt's lymphoma, (b) Western sporadic Burkitt's lymphoma, and (c) immunodeficiency-associated Burkitt's lymphoma, with identical cytomorphologic and histopathologic features but different clinical and gross anatomical characteristics. Burkitt's lymphoma is composed of monomorphic small to medium blast cells with basophilic cytoplasm containing lipid droplets/vacuoles, numerous apoptotic bodies, starry-sky macrophages and proliferative index 100%.
- The characteristic c-Myc gene translocation t(8,14) in Burkitt's lymphoma to Ig locus (usually IgH on chromosome 14) and BCL rearrangements are commonly demonstrated. Combination of morphology, genetic analysis or immunophenotyping can be used as the gold standard for diagnosis.

Clinical Features

Patient most often presents with bulky disease and high tumor burden due to the short doubling time of the neoplasm. Upon initiation of chemotherapy, patient may develop tumor lysis syndrome due to rapid tumor cell death. In the course of disease, few patients may present with Burkitt's cell leukemia with involvement of peripheral blood, bone marrow and central nervous system.

Clinical Pearls: Burkitt's Lymphoma: Variants

African Endemic Burkitt's Lymphoma

- African endemic Burkitt's lymphoma affects children with median age seven years with male predominance. It is strongly associated with Epstein-Barr virus in Central African children.
- Patient presents with bulky disease and high tumor burden due to the short doubling time of Burkitt's lymphoma in the maxilla or mandible. Gastrointestinal tract, kidneys, liver, pancreas, retroperitoneum, gonads, breast, endocrine glands and brain may be involved. Leukemic manifestations are rare. Burkitt's cell leukemia most often involves central nervous system in the early course of disease.
- Epstein-Barr virus activates oncogene (c-Myc). It stimulates proliferation of B cells. It increases opportunity for translocation t(8;14) of N-RAS gene.

Western Sporadic Burkitt's Lymphoma

- Western sporadic Burkitt's lymphoma affects children and young adults with male predominance. It is not strongly associated with Epstein-Barr virus.
- Sites of involvement are ileocecal region, omentum, gonads, kidneys, thyroid gland, salivary glands, female breasts, Waldeyer's ring and peripheral lymph nodes. Leukemic manifestations are uncommon.
- Patient presents with intra-abdominal tumor in ileocecal region.

Immunodeficiency-associated Burkitt's Lymphoma

- Immunodeficiency-associated Burkitt's lymphoma mainly occurs in the early stages of HIV-infected persons before CD4+ helper T cells count fall.
- Patient may present with nodal or extranodal disease. Lymph nodes are frequently involved in immunodeficiency associated Burkitt's lymphoma.
- Adjacent organs and tissues may be compressed and/or infiltrated by tumor cells.

Molecular Genetic Alterations

Burkitt's lymphoma is associated with t(8;14) in 75% of cases, t(2;8) in 5% of cases and t(8;22) in 10% of cases. Epstein-Barr virus promotes polyclonal B cell proliferation, which increases risk translocation (8;14). Epstein-Barr virus activates c-Myc proto-oncogene located on chromosome 8, which is transposed to the site adjacent to the immunoglobulin heavy chain (IgH) locus on chromosome 14. Pathogenesis of Burkitt's lymphoma is shown in Fig. 13.22.

- Proximity of regulatory sequences of the immunoglobulin heavy chain gene results in increased expression of the c-Myc gene. This chromosomal rearrangement is the basis of malignant transformation of lymphocyte in Burkitt's lymphoma.

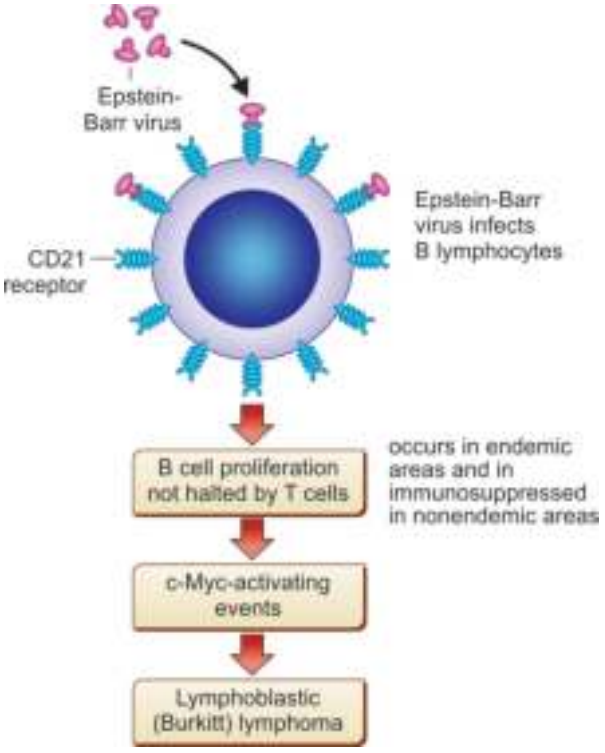

Fig. 13.22: Pathogenesis of Burkitt's lymphoma.

- In endemic areas, chromosomal translocation t(8;14) occurs in the pre-B cell, but in nonendemic areas at later stage of B cell development. Burkitt lymphoma associated with t(8;14) is shown in Fig. 13.23.

Surgical Pathology: Burkitt's Lymphoma

Gross Morphology

- Organs involved in Burkitt's lymphoma are replaced by masses with a fish-flesh appearance.
- Cut surface of tumor mass usually shows areas of hemorrhage and necrosis.
- Adjacent organs or tissues are compressed and/or infiltrated by tumor mass.
- Lymph node involvement is rare in endemic and sporadic variants of Burkitt's lymphoma.
- Lymph nodes are most frequently involved in immunodeficiency-associated Burkitt's lymphoma.
- Uninvolved lymph nodes are surrounded by tumor mass.

Light Microscopy

- Lymph node in Burkitt's lymphoma is composed of medium-sized tumor cells showing a diffuse monotonous pattern of growth.
- Tumor cells appear to be cohesive but often show squarred-off borders of retracted cytoplasm in formalin embedded tissue sections. Nuclei of tumor cells are round with finely clumped chromatin containing multiple basophilic and usually containing lipid vacuoles, better demonstrated in imprint preparations or fine needle aspiration cytology.
- Tumor has extremely high-proliferative rate with many mitotic figures. High rate of spontaneous tumor cell death by apoptosis. Cellular debris of tumor cells is cleared by numerous non-neoplastic macrophages, whose scattered appearance termed "Starry-sky appearance".
- It is worth mentioning the "Starry-sky appearance" can be seen in any lymphoid tumor with high proliferative rate (Fig. 13.24).

Immunophenotyping

- Tumor cells in Burkitt's lymphoma express moderate to strong membrane IgM with light chain restriction, B cell antigens such as CD19, CD22, CD79a and PAX5 and germinal centre markers (e.g. CD10 and BCL-6). CD43 and CD77 are also frequently positive.
- Most cases of Burkitt's lymphoma have strong expression of Myc protein.
- Proliferate rate of tumor is very high showing strong positivity for Ki-67 in all cases. Immunophenotyping of Burkitt's lymphoma is mentioned below.

Markers	Expression
Surface membrane IgM with light chain restriction	Positive
CD19 (B cell antigen)	Positive
CD22 (B cell antigen)	Positive
CD79a (B cell antigen)	Positive
PAX5 (B cell antigen)	Positive
CD10 (germinal center marker)	Positive
BCL-6 (germinal center marker)	Positive
CD10	Positive
CD77	Positive
Myc protein	Positive
Ki-67	Positive

Prognosis

Burkitt's lymphoma is highly-aggressive but potentially curable. Even patients with advanced stage disease with bone marrow and central nervous system involvement can be cured with high intensity chemotherapy.

DIFFUSE LARGE B CELL LYMPHOMA

Diffuse large B cell lymphoma (DLBCL) is a high-grade neoplasm with diffuse growth pattern derived from germinal center or post-germinal center B cell.

- Tumor cells are more than twice the size of small lymphocytes. BCL-2 gene rearrangements are often demonstrated, suggesting a potential germinal center origin.
- Disease may arise in *de novo*, or may represent transformation of pre-existing low-grade B cell lymphoma, and occur at all ages; with median age in seventh decade.

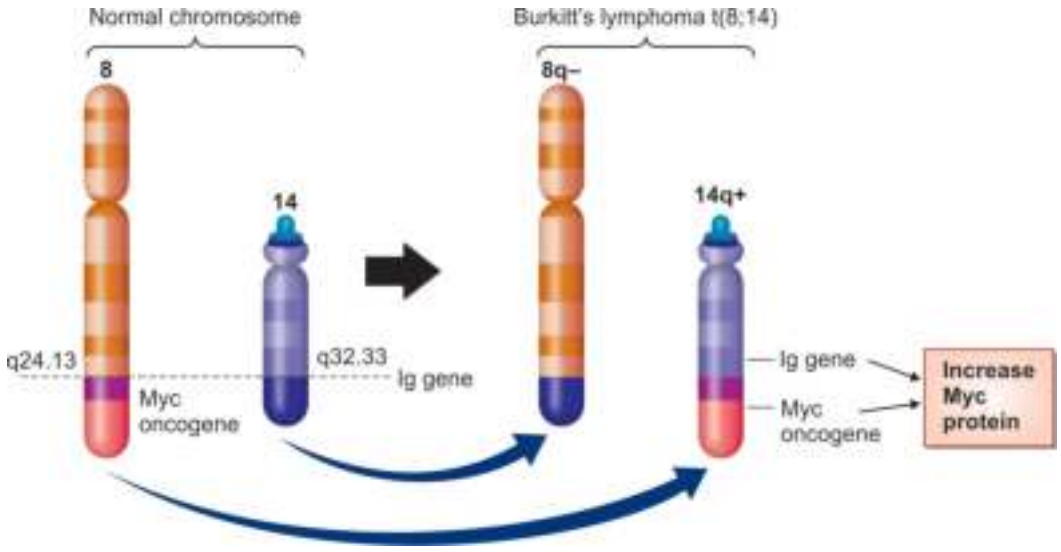

Fig. 13.23: Burkitt's lymphoma showing t(8;14) in which c-Myc proto-oncogene located on chromosome 8 is transposed to a site adjacent to the immunoglobulin heavy chain locus on chromosome 14.

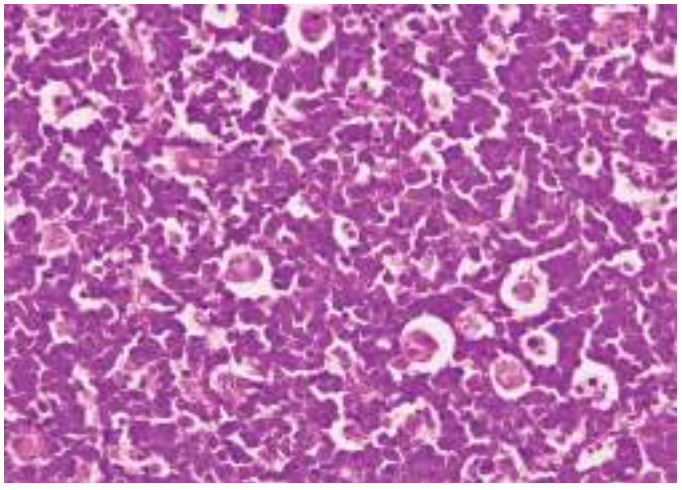

Fig. 13.24: Burkitt's lymphoma. Tumor is composed of medium-sized cells with round nuclei with fine clumped chromating and cellular debris showing starry-sky appearance (400X).

- Involvement of lymph nodes occurs in 60% of cases and extranodal sites occur in 40% of cases. Diffuse large B cell lymphoma has three histologic variants, i.e. centroblastic, immunoblastic and anaplastic subtypes. Three histologic variants of diffuse large B cell lymphoma (DLBCL) are given in Table 13.28.

Age Group Predilection

Diffuse large B cell lymphoma, not otherwise specified constitutes 25–35% of adult non-Hodgkin's lymphoma. It most often affects elderly persons in seventh decade of life. However, it may also occur in children and young adults.

Pathogenesis

Pathogenesis of DLBCL, not otherwise specified remains unknown, which usually arises *de novo* referred to as primary, but can also represent transformation of a less aggressive non-Hodgkin's lymphoma referrd to as secondary DLBCL.

- Diffuse large B cell lymphoma (DLBCL) may arise by transforming low-grade B cell large cell lymphoma (Richter syndrome).

Table 13.28 Three histologic variants of diffuse large B cell lymphoma (DLBCL)

Parameters	Centroblastic Variant of DLBCL	Immunoblastic Variant of DLBCL	Anaplastic Variant of DLBCL
Architecture	Diffuse	Diffuse	Diffuse in some cases
Sinus involvement	Obliteration	Obliteration	Distension
Cell population	▪ Centroblasts (10–100%) admixed with centrocytes ▪ Cytoplasm scanty ▪ Nucleus vesicular with several nucleoli near nuclear membrane	▪ Centroblasts (10%) admixed with plasmablasts with plasmacytoid features ▪ Cytoplasm moderate to abundant with deep staining ▪ Nucleus solitary centrally placed with prominent nucleus	▪ Anaplastic cells ▪ Cytoplasm to abundant with deep staining ▪ Nucleus large with prominent nucleus
Mitotic activity	Low-proliferative index	High-proliferative index	High-proliferative index

- Richter syndrome is characterized by rapid onset of fever, abdominal pain, and progressive lymphadenopathy and hepatosplenomegaly. Richter syndrome is aggressive and refractory to therapy, with a mean survival of 2 months.
- Follicular lymphoma, marginal zone lymphoma or nodular lymphocyte predominant Hodgkin's lymphoma (NLPHL) can transform to DLBCL.

Molecular Genetic Alterations

Diverse chromosomal aberrations are seen in 30% of cases of DLBCL. These tumors show activation of BCL-2 gene, amplification of cREL, t(14;18), point mutations and DNA breakage of BCL-6 regulatory regions.

Localization of DLBCL Disease

Patients may present with lymph nodal disease in 60% of cases. In 40% of cases, disease is confined to extranodal sites such as gastric region and ileocaecal region, bone, spleen, testes, liver, Waldeyer's ring, thyroid gland, salivary glands, kidneys and adrenal glands.

- DLBCL involving the kidneys and adrenal glands is associated with an increased risk for metastasizing to central nervous system. Bone marrow involvement occurs late in 10–25% of cases.
- Recent studies suggest that fluorodeoxyglucose (FDG) positron emission tomography (PET), i.e. **(FDG-PET)** is a sensitive diagnostic imaging technique for detecting bone marrow involvement. If FDG-PET is negative, routine staging by bone marrow trephine biopsy is not required.

Surgical Pathology: Diffuse Large B Cell Lymphoma

Light Microscopy

Three common histologic variants of DLBCL have been recognized: centroblastic, immunoblastic, anaplastic variants.

- The tumor cells in DLBCL are large 4–5 times diameter of small lymphocytes. These have round to oval nucleus, with either 2–3 nucleoli located adjacent to the nuclear membrane or a single nucleolus centrally placed and moderate pale or basophilic cytoplasm. Mitoses are frequent.
- These are arranged in diffuse pattern. More anaplastic tumors may contain multinucleated Reed-Sternberg-like cells with large, inclusion-like nucleoli, and these may be termed immunoblastic lymphoma. Light microscopy of DLBCL is shown in Fig. 13.25A and B.

DLBCL: Subtypes

DLBCL subtypes include histiocyte-rich large B cell lymphoma, primary DLBCL of the CNS, primary cutaneous DLBCL of leg, and EBV positive DLBCL of the elderly.

Differential Diagnosis

DLBCL should be differentiated from metastatic carcinomas. The presence of cell surface monoclonal immunoglobulin by immunohistochemistry would help to confirm this lesion as a malignant lymphoma.

Immunophenotyping

- Tumor cells of DLBCL typically express pan-B cell markers such as CD19, CD20, CD22, CD79a and PAX-5. But tumor cells may lack one or more of these markers. DLBCL shows positivity for CD20 (Fig. 13.26A and B).
- Surface as well as cytoplasmic immunoglobulin most often IgM followed by IgG and IgA can be demonstrated in 50–75% of cases.
- Expression of CD10, BCL-2, BCL-6, IRF-4/MUM-1 varies in tumor cells.
- Tumor cells are negative for TdT.
- The tumor cells often express CD19, CD20, CD22 and CD79a.
- Most express surface immunoglobulin. Expression of CD10, BCL-6, and IRF4/MUM1 varies in tumor cells.
- DLBCL shows positivity for BCL-2 (Fig. 13.27).

Markers	Expression
CD19	Positive
CD20	Positive
CD22	Positive
CD79a	Positive
PAX-5	Positive
Surface and cytoplasmic immunoglobulin (IgM followed by IgG and IgA)	Positive

Clinical Features

Patient with DLBCL most often presents with a rapidly tumor mass involving single lymph node or multiple lymph nodes or extranodal organs/tissues.

- Almost 50% of cases have stage I or II disease. In the initial stage of the disease PET/CT imaging technique helps in reducing the percentage of cases to advanced stage.
- Patients may have localized symptoms depending on the site of extranodal involvement. Patient presents with rapidly growing single large nodal mass confined to local region. It has greater propensity to be extranodal disseminating to various organs than the low-grade NHL.
- DLBCL can be associated with immunocompromised state and another with Kaposi sarcoma herpesvirus.

Immunodeficiency Associated Diffuse Large B Cell Lymphoma

Immunodeficiency associated diffuse large B cell lymphoma occurs in end stage of HIV infection, severe

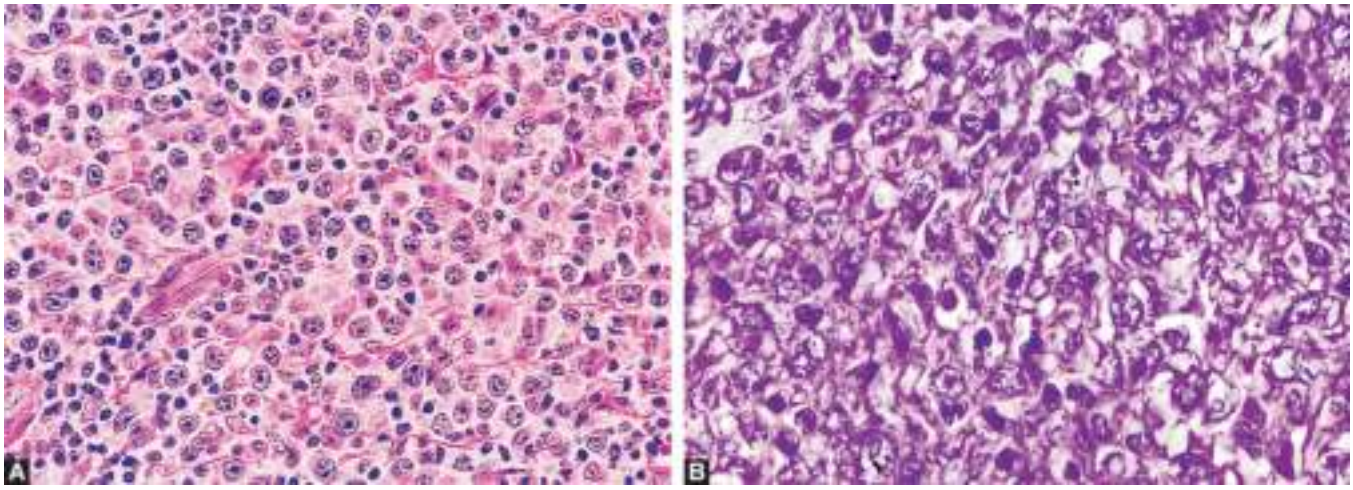

Fig. 13.25A and B: Diffuse large B cell lymphoma (DLBCL) shows large lymphoid cells with round to oval nuclei and 2–3 nucleoli arranged in diffuse pattern (400X).

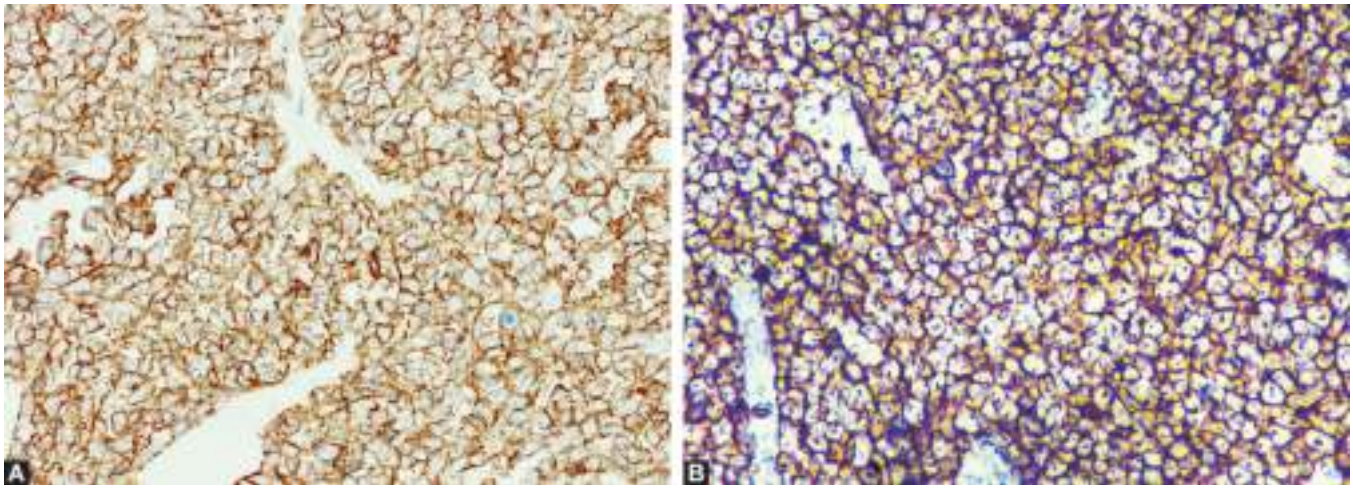

Fig. 13.26A and B: Diffuse large B cell lymphoma (DLBCL) shows positivity for CD20 (400X).

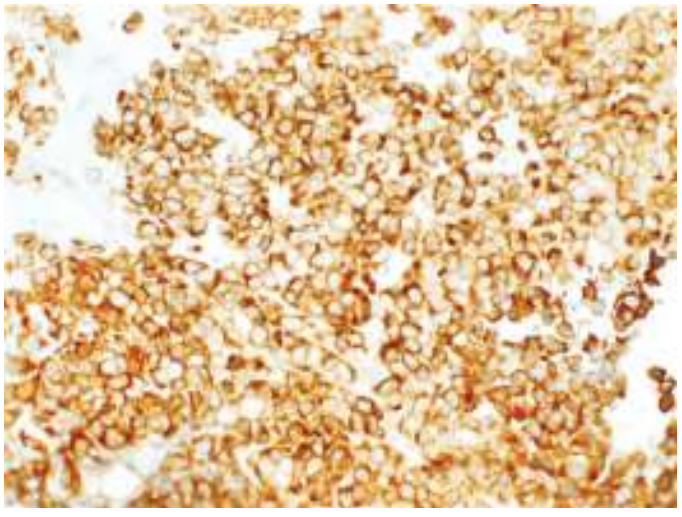

Fig. 13.27: Diffuse large B cell lymphoma (DLBCL) shows positivity for BCL-2 (400X).

combined deficiency and organ transplantation (bone marrow or solid organs). Tumor B cells are infected with Epstein-Barr virus, which may play critical role in its pathogenesis.

Body Cavity Diffuse Large B Cell Lymphoma

Patient with body cavity diffuse large B cell lymphoma develops malignant pleural or ascitic effusions especially in advanced HIV infection. The tumor cells are infected with KSHV (most often) or HHV8 in cases, which may play role in its pathogenesis.

CHRONIC LYMPHOCYTIC LEUKEMIA/SMALL LYMPHOCYTIC LYMPHOMA

Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) arises from naïve B cell or post-

germinal center memory B cell. About 10% of cases transform to a diffuse large B cell lymphoma. An autoimmune hemolytic anemia appears in about one-sixth of CLL/SLL cases.

- **Chronic lymphocytic leukemia:** A diagnosis of CLL is made if bone marrow and peripheral blood are primarily involved. Peripheral blood smear examination shows atypical small lymphocytes (smudge cells due to fragile chromatin), autoimmune hemolysis and thrombocytopenia in a minority.
- **Small lymphocytic lymphoma:** If the tumor cells give rise to lymphadenopathy or solid tumor masses, the term small lymphocytic lymphoma is used. Both disorders most often affect elderly persons.
- **Molecular genetics:** Chromosomal translocations are rare in CLL/SLL. Chromosomal aberrations occur such as trisomy 12, deletions of 11q, 13q, and 17p. In some cases, immunoglobulin genes are somatically hypermutated, and there may be a small immunoglobulin 'spike' in the serum.
- **Organs involved:** Tumor cells of CLL/SLL infiltrate many organs. Liver (portal tracts), spleen (white and red pulp), and lymph nodes may become enlarged, although organ function is often not markedly impaired.

Surgical Pathology: Chronic Lymphocytic Leukemia/ Small Lymphocytic Lymphoma

Light Microscopy

- Architecture of lymph node is diffusely obliterated.
- Tumor cells completely surround benign germinal center and form inverse follicular pattern.
- Tumor cells may completely surround benign follicles as third layer and form marginal zone pattern.
- Tumor cells are mature appearing lymphocytes measuring 6–12 μm in diameter replacing the lymph node and extending through the capsule of the lymph node and into the surrounding adipose tissue.
- Tumor cells are small round containing irregular nuclei with condensed chromatin and scanty cytoplasm. There is scant mitotic activity.
- Tumor cells are admixed with prolymphocytes with prominent mitotic activity. Presence of prolymphocytes is pathognomonic for CLL/SLL (Fig. 13.28).

Immunophenotyping

The tumor cells of chronic lymphocytic leukemia/small lymphocytic lymphoma express surface immunoglobulin and pan-B cell markers such as CD19, CD20, CD22, CD5, CD79a, CD23 and CD43. Chronic lymphocytic leukemia/small lymphocytic lymphoma shows positivity for CD5 (Fig. 13.29) and positivity for CD23 (Fig. 13.30).

Markers	Expression
IgM (either κ or λ light chain)	Positive
IgG (either κ or λ light chain)	Positive
CD19	Positive
CD20	Positive
CD22	Positive
CD5	Positive
CD79a	Positive
CD23	Positive
CD43	Positive

Neoplastic cells are negative for CD11c, CD10, FMC7 and CD79b.

Prognosis

Mean survival rate of chronic lymphocytic leukemia/small lymphocytic lymphoma is 4–6 years. The presence of deletions of 11q and 17p correlates with higher stage disease and worse prognosis.

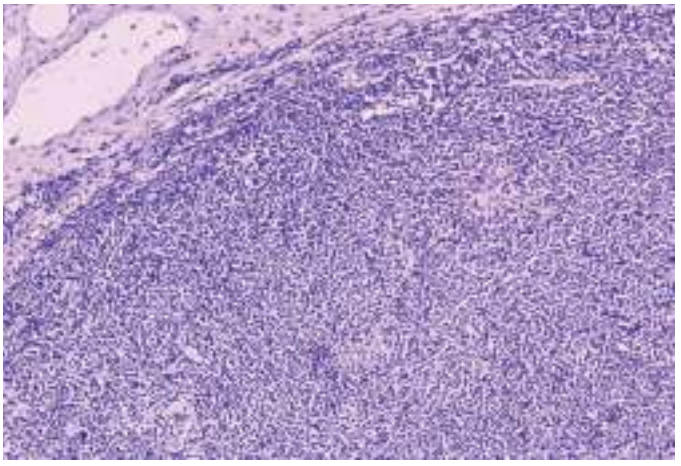

Fig. 13.28: Chronic lymphocytic leukemia/small lymphocytic lymphoma. Lymph node architecture is obscured. It is composed of mature appearing lymphocytes surrounding benign germinal center. Tumor cells contain irregular nuclei with condensed chromatin (100X).

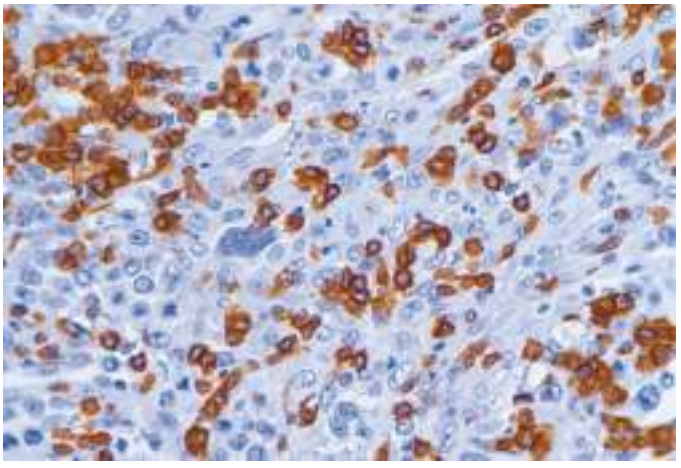

Fig. 13.29: Chronic lymphocytic leukemia/small lymphocytic lymphoma shows positivity for CD5.

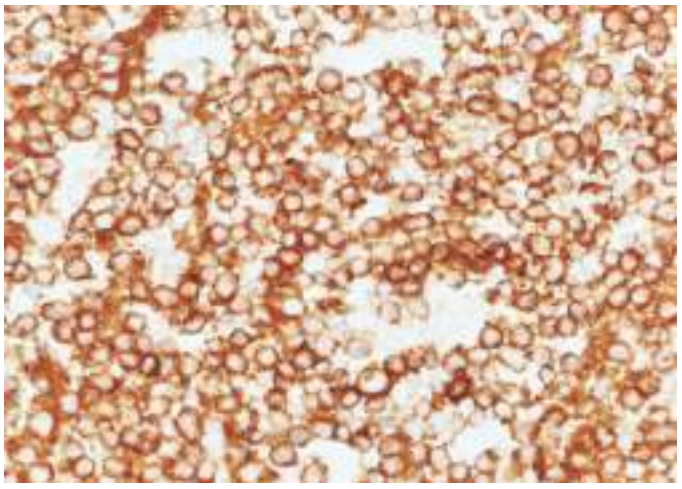

Fig. 13.30: Chronic lymphocytic leukemia/small lymphocytic lymphoma shows positivity for CD23.

FOLLICULAR LYMPHOMA

Follicular lymphoma (FL) is the commonest subtype of the low-grade non-Hodgkin's lymphoma derived from follicle center B cells, which is slow-growing tumor with fatal outcome. Tumor is composed of variable mixture of centroblasts and centrocytes randomly distributed and forming partially follicular pattern. It is most prevalent in Western world especially USA and less common in Africa and Asia.

- Follicular lymphoma involves lymph nodes, bone marrow, peripheral blood, spleen and Waldeyer's tonsillar lymphatic ring. It most often affects in sixth and seventh decades of life and usually presents with stage III or stage IV disease.
- Approximately 30–50% cases of follicular lymphoma may transform to diffuse large B cell lymphoma (DLBCL). Primary follicular lymphomas of the gastrointestinal tract and skin are clinically different from nodal non-Hodgkin lymphomas.
- Four histologic variants of follicular lymphoma include: *in situ* follicular neoplasia, duodenal type of follicular lymphoma, testicular follicular lymphoma and diffuse pattern of follicular lymphoma. Chemotherapy may be administered to control the disease, but it is rarely curative.

Molecular Genetic Alterations

Mutations affecting histone-modifying genes are crucial in pathogenesis of follicular lymphoma.

- **Physiologic state:** Normally '**cytochrome c**' leaving mitochondria and entering into the cytosol activates caspases initiating apoptosis. Protein products of antiapoptotic genes prevent **cytochrome c** from leaving mitochondria. BCL-2 gene family produces gene products that prevent mitochondrial leakage of 'cytochrome c' (signal for apoptosis).
- **Pathologic state:** Chromosomal translocation t(14;18) causes overexpression of BCL-2 protein product, which prevents apoptosis of B cells leading to B cell follicular lymphoma and chronic lymphocytic leukemia. Lymphoma cells do not die but accumulate in the lymph nodes, bone marrow, and the blood circulation. All follicular lymphomas also express BCL-6, a transcriptional repressor that regulates development of germinal center B cell.

Localization of Disease

Follicular lymphoma predominantly involves lymph nodes in the peripheral, thoracic and abdominal regions, bone marrow (tumor cells present in paratrabecular pattern), peripheral blood, spleen and Waldeyer's tonsillar lymphatic ring. Tumor cells may infiltrate portal tracts of liver, splenic white pulp, soft tissue, gastrointestinal tract, breast and ocular adnexa.

Clinical Features

Majority of patients with follicular lymphoma have widespread disease at diagnosis including peripheral and central lymphadenopathy in thoracic and abdominal region, and splenomegaly. Bone marrow involvement is demonstrated in 40–70% of cases. Involvement of central nervous system, testes and gastrointestinal tract is uncommon. Approximately 15–25% of cases are in stage I at the time of diagnosis. Despite widespread disease, patients most often remain asymptomatic. The disease follows chronic relapsing clinical course. Overall median survival of patients is 3–5 years. However, majority of the patients cannot be cured.

Imaging Techniques

CT and MRI tecniques are used to assess degree of lymphadenopathy and extent of disease. Fluro-deoxyglucose (FDG)-positron emission tomography (PET), i.e. FDG-PET imaging is done only in more aggressive metabolically active lymphomas and in identifying patients with higher risk of progression of the disease.

Staging of Disease

Stage of follicular lymphoma is now determined by Cotswold's classification, modification of the Ann Arbor staging system. Bone marrow trephine biopsy is essential to assess involvement of bone marrow. Bone marrow aspiration has lower yield due to dificulty in aspiration from the paratrabecular lymphoid aggregates.

Surgical Pathology: Follicular Lymphoma

Gross Morphology

- Cut surface of lymph node involved shows a vaguely nodular pattern.
- The neoplastic follicles most often have a bulging appearance. However, reactive follicular hyperplasia can exhibit the same pattern.
- Spleen involved in follicular lymphoma displays uniform expansion of white pulp, usually with no evidence of involvement of red pulp.

Light Microscopy

- Lymph node architecture is effaced in follicular lymphoma. It shows numerous irregularly shaped lymphoid follicles in cortex and medulla with loss of corticomedullary distinction and giving nodular appearance. Tumor cells invade the lymph node capsule and extend into the surrounding adipose tissue.
- Tumor is composed of varying degrees of centrocytes and centroblasts. Centrocytes have clefted nuclei with clumped chromatin and no nucleoli. Centroblasts have open nuclei with nucleoli located against the nuclear membrane.
- Growth patterns of (a) follicular >75% follicles, (b) mixture of diffuse and follicles 25–75%, and (c) minimally follicular with <25% follicular pattern. Histology of follicular lymphoma is shown in Figs 13.31 and 13.32.
- According to revised 2024 World Health Organization, grading of follicular lymphoma is based on the fact that prognosis worsens with increase in number of centroblasts.
  - Grade I: Centroblasts 0–5/high power field.
  - Grade II: Centroblasts 6–15/high power field.
  - Grade IIIa: Centroblasts admixed with centrocytes >15/high power field.
  - Grade IIIb: Centroblasts admixed with centrocytes >15/high power field (high-grade with worst prognosis).

Histochemistry

- There is considerable variation in histologic appearances within follicular lymphoma. Follicles may be highlighted by reticulin stain and immunohistochemistry.
- Sclerosis is a common feature of follicular lymphoma especially in retroperitoneal lymph node. Eosinophilic PAS positive extracellular amorphous material may be demonstrated in reactive and neoplastic follicles obscuring the neoplastic cells.
- Signet ring follicular lymphoma is composed of PAS negative clear cytoplasmic inclusions.
- Follicular lymphoma with plasmacytic differentiation shows plasma cell differentiation within follicles and interfollicular compartments.
- Marginal zone differentiation in follicular lymphoma is most often demonstrated in the spleen.
- Infarction of the lymph nodes may occur in follicular lymphoma.
- Composite follicular lymphoma may show areas of higher grade or diffuse growth pattern.

Immunophenotyping

- Tumor cells of follicular lymphoma are usually positive for surface IgM with or without IgG, IgA or IgD.
- Tumor cells express B cell-associated antigens such as CD19, CD20, CD22 and CD79a.
- Tumor cells are most often positive for BCL-2, BCL-6 and CD10. These are negative for CD5 and CD43.
- CD10 expression is stronger in the follicles rather than in the interfollicular tumor cells.
- BCL-2 overexpression is the hallmark of follicular lymphoma in 85–90% of grade I and II of follicular lymphoma.
- Other germinal center markers such as LMO2, GOET1 and HGAL also known as GCET2 are positive. But these are not required for routine diagnosis.

Markers	Expression
Surface IgM	Positive
CD10 (CALLA)	Positive
CD19	Positive
CD20	Positive
CD22	Positive
CD79a	Positive
BCL-2	Positive
BCL-6	Positive
LMO2	Positive
GOET1	Positive
HGAL (also known as GCET2)	Positive

Translocation t(14; 18) is demonstrate in follicular lymphoma.

Mann and Berard Grading of Follicular Lymphoma

Follicular lymphomas are graded as I, II and III based on number of centroblasts (Table 13.29). Comparison between follicular reactive hyperplasia and follicular lymphoma is given in Table 13.30.

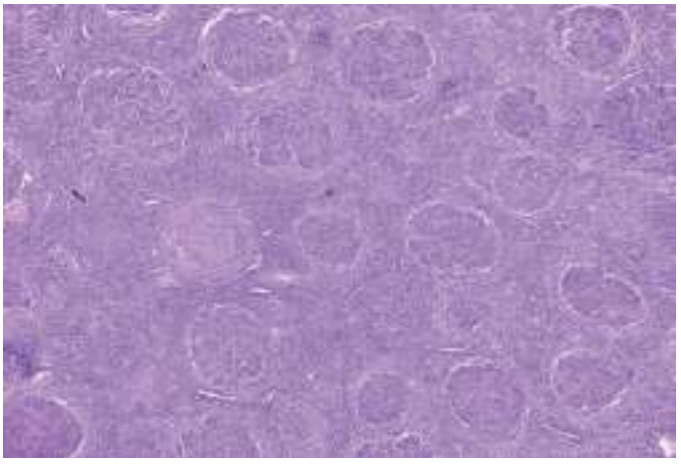

Fig. 13.31: Follicular lymphoma shows numerous irregularly shaped lymphoid follicles in cortex and medulla with loss of corticomedullary distinction (100X).

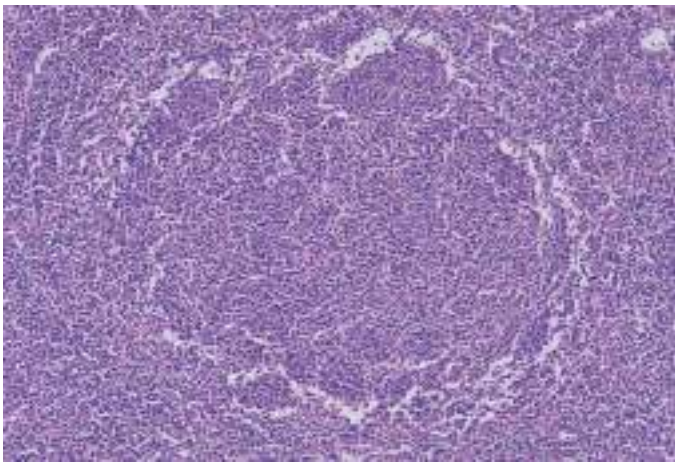

Fig. 13.32: Follicular lymphoma shows lymphoid follicle comprises small cleaved cells with scanty cytoplasm (200X).

Table 13.29 Mann and Berard grading of follicular lymphoma based on number of centroblasts/histopathological findings

Grade	Histologic Findings
Grade I	Centroblasts (0–5/high power fields)
Grade II	Centroblasts (6–15/high power fields)
Grade III	Centroblasts (>15/high power fields)

Prognosis

- Prognosis of follicular lymphoma is closely related to the disease at diagnosis. Follicular lymphoma prognostic index (FLPI) is useful predictive outcome.
- FLPI uses hemoglobin concentration, survival age >60 years, increased serum lactate dehydrogenase, Ann Arbor stage III/IV disseminated disease, and >4 involved lymph nodes.
- Genetic profile may provide additional information.
- Transformation of follicular lymphoma to diffuse large B cell lymphoma is demonstrated in 25–35% of cases.

Table 13.30 Comparison between follicular reactive hyperplasia and follicular lymphoma

Feature	Follicular Reactive Hyperplasia	Follicular Lymphoma
Epidemiology		
Age group	Younger persons	Elderly persons
Histological features		
Lymph node architecture	Maintained	Effaced
Follicle density	Normal	Increased back to back follicles
Location of follicles	Cortex	Cortex and medulla
Follicles size and shape	Pleomorphic follicles	Monomorphic follicles
Follicles demarcation	Sharply demarcated	Poorly demarcated
Follicle confinement	Within lymph node	May be seen in perinodal tissue
Mantle zone of lymphocytes around follicles	Well defined	Thin or absent
Subcapsular sinus obliteration	Absent	Present
Distribution of centroblasts and centrocytes	Zonal distribution	Random distribution
Centroblasts forming component of follicle	Forms large component of the follicle	Forms minority of follicles
Morphology of centroblasts and centrocytes	Typical morphology	Serpiginous, multinucleated and multilobated centroblasts may be present in the follicles and in interfollicular zones
Cellular polarization	Present	Absent
Tingible body macrophages containing apoptotic debris	Usually prominent	Usually absent
Mitosis	Frequent	Few
Atypical cells between follicles	Absent	May be present
Immunohistochemistry and molecular techniques		
Immunohistochemical marker BCL-2 in follicle center cells	Negative	Positive
Ig light chain restriction in follicle center cell	Ig light chain restriction absent	Ig light chain restriction present
Rearrangement of Ig/BCL-2 genes	Absent	Present and demonstrated by Southern blot or polymerase chain reaction

MANTLE CELL LYMPHOMA

Mantle cell lymphoma (MCL) is derived from B cell, which gives rise to a characteristic mantle zone expansion resulting in nodular pattern. MCL is most often composed of monomorphic small- to medium-sized lymphoid cells with oval or angulated nuclei frequently exhibit small clefts in >95% of patients. MCL is very aggressive, but incurable in majority of cases.

- MCL constitutes 3–10% of non-Hodgkin's lymphomas. Middle-aged to elderly persons with a median age of 60 years are affected. It occurs more in males than in females.
- MCL is an aggressive malignancy that manifests in middle-aged to elderly male patients as stage III or IV disease involving lymph nodes, bone marrow, peripheral blood, spleen, Waldeyer's ring and gastrointestinal tract (lymphomatous polyposis). Central nervous system involvement is commonly demonstrated at the time of diagnosis.
- MCL is characterized by chromosomal translocation of t(11;14) (q13;q32), which brings cyclin D1 gene on chromosome 11 under promoter influence of the immunoglobulin heavy chain gene on chromosome 14. Cyclin D1 gene, together with cyclin-dependent kinase-4 (CDK4) phosphorylates retinoblastoma protein (pRB), releasing transcription factors that permit transition from the G1 to the S phase of the cell cycle.
- Lymph nodes are most often involved in mantle cell lymphoma. Spleen and bone marrow involvement with or without blood are also important sites. Extranodal sites involved include gastrointestinal tract, Waldeyer's ring, lungs and pleura.
- Central nervous system involvement is commonly demonstrated at the time of diagnosis.
- Majority of mantle cell lymphoma (MCL) patients present with lymphadenopathy in stage III or stage IV disease, hepatomegaly, splenomegaly and bone marrow involvement. Extranodal involvement is common in the presence of extensive lymphadenopathy. Peripheral blood involvement is common and demonstrated by **flow cytometry** in almost all cases.

Surgical Pathology: Mantle Cell Lymphoma

Light Microscopy

- Mantle cell lymphoma is composed of small cells with irregular and intended nuclear contours.
- There are two histologic variants of mantle cell lymphoma—blastoid (classic form) and anaplastic (pleomorphic form).
  - Blastoid form may be accompanied by involvement of blood, bone marrow and spleen, hence termed mantle cell leukemia.
  - Anaplastic mantle cell lymphoma is characterized by a higher mitotic index and proliferative rare and poor survival.
- There is presence of hyalinized blood vessels and scattered epithelioid histiocytes sometimes resembling starry-sky appearance (Figs 13.33 and 13.34).

Immunophenotyping

- Tumor cells of mantle cell lymphoma express intense surface IgG/IgD with restriction of κ or λ.
- Tumor cells show positivity for BCL-2, CD5, FMC7 and CD43. These are sometimes positive for IRF4 and MUM1.
- Nuclear cyclin D1 is expressed in >95% of cases of mantle cell lymphoma.
- SOX11 positivity with monoclonal antibody is demonstrated in >90% of cases.
- Tumor cells are negative for CD10, CD25, CD23 and CD11c.

Markers	Expression
Surface IgG/IgD	Positive
BCL-2	Positive
CD5	Positive
FMC7	Positive
CD43	Positive
IRF4	Positive (some cases)
MUM1	Positive (some cases)
Nuclear cyclin D1	Positive (>95% of cases)
CD10	Negative
CD25	Negative
CD23	Negative
CD11c	Negative

Translocation t(11; 14) creating cyclin D1–IgH fusion gene is demonstrated in mantle cell lymphoma.

- **Prognosis of disease:** Median survival rate is 3–5 years in mantle cell lymphoma. Vast majority of patients do not respond to newer therapeutic modalities.

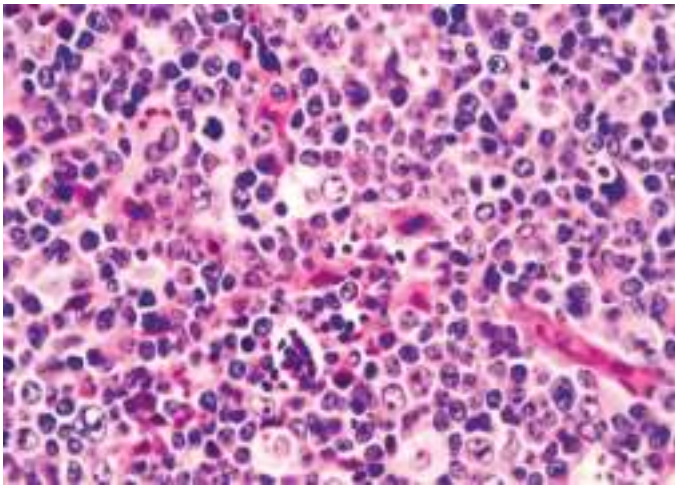

Fig. 13.33: Mantle cell lymphoma (MCL). Tumor is composed of small cells with irregular and indented nuclear contours (400X).

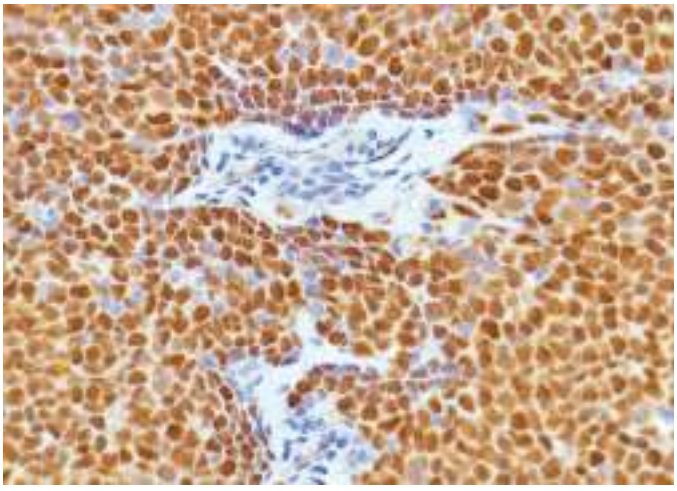

Fig. 13.34: Mantle cell lymphoma shows positivity for cyclin D1.

A high proliferative rate (mitotic or Ki-67 indices) is associated with shorter overall survival. High Ki-67 proliferative index (>30%) is currently accepted cut off point.

MARGINAL ZONE LYMPHOMA

There are three histologic variants of marginal zone lymphoma: nodal type, extranodal mucosa-associated lymphoid tissue (MALT) type and splenic type.

Nodal Marginal Zone Lymphoma

Nodal marginal zone lymphoma (NMZL) is a primary nodal B cell neoplasm without evidence of extranodal or splenic disease, which arises from mature B cells in marginal zone of lymph node.

- **Epidemiology:** Nodal marginal zone lymphoma (NMZL) accounts for <2% of all lymphoid neoplasms, which most often occurs in adults. Males and females are equally affected. Recently, NMZL has been detected in hepatitis C virus infection and autoimmune disorders.
- **Localization of disease:** NMZL most often involves peripheral lymph nodes. But it can involve bone marrow and occasionally the peripheral blood.
- **Clinical features:** Majority of patients present with asymptomatic localized or generalized lymphadenopathy especially in cervical region. About 10–25% of cases are symptomatic. Bone marrow involvement occurs in 33% of cases.

Surgical Pathology: Nodal Marginal Zone Lymphoma

Light Microscopy

- Lymph nodes demonstrate proliferation of lymphoid cells, that surround reactive follicles and expand into the interfollicular areas.
- Tumor cells are composed of variable numbers in marginal zone (centrocyte-like and monocytoid cells), B cells, plasma cells and transformed B cell.
- Bone marrow involvement is most often interstitial or nodular, with an intertrabecular or paratrabecular distribution.

Immunophenotyping

- Most cases of NMZLs express pan-B cell markers. CD43 is expressed in 20–75% of cases. CD5 may be expressed in 30% of cases. CD5 expression is observed in 17% of cases with disseminated cases.
- BCL-2 overexpression is demonstrated in most of the cases.
- Expression of MNDA and IRTA1 are observed in 75% of cases.
- CD23 may be expressed in 29% of cases.

Markers	Expression
CD43	Positive (20–75% of cases)
CD23	Positive (30% of cases)
CD5	Positive (30% of cases)
BCL-2	Positive (almost all cases)
MNDA	Positive (75% of cases)
TRTA1	Positive (75% of cases)
Cyclin D1	Negative

Extranodal Marginal Zone Lymphoma of Mucosa-associated Lymphoid Tissue

Extranodal marginal zone lymphoma of MALT most often involves gastric mucosa, which arises from mature B cells in marginal zone of lymph node. Patient develops extranodal marginal zone lymphoma of MALT often arises in *Helicobacter pylori* associated chronic gastritis, Hashimoto's thyroiditis and sialadenitis with Sjögren's syndrome.

- **Epidemiology:** Extranodal marginal zone lymphoma of MALT accounts for about 10% of all B cell lymphomas. It most often occurs in adults with median age in seventh decade. Both men and women are equally affected.
- **Localization of disease:** Extranodal marginal zone lymphoma of MALT occurs in gastric region in 50% of cases. Other common sites include the eyes, ocular adnexa, skin, salivary glands, breast and thyroid gland.
- **Molecular genetic alterations:** Trisomy 18, t(11;18), t(1;14), latter create MALT1-IAP2 and BCL-10 IgH fusion genes, respectively.
- **Clinical features:** Majority of patients present with stage I or II disease. Extranodal involvement occurs in 25–40% of cases. Bone marrow involvement is higher in non-gastric extranodal marginal zone lymphoma of MALT than extranodal marginal zone lymphoma of gastric MALT.

Surgical Pathology: Extranodal Marginal Zone Lymphoma of MALT

Light Microscopy

- Extranodal marginal zone lymphoma of MALT shows small- to medium-sized round to irregular lymphocytes admixed with plasma cells present in the marginal zone of lymphoid follicles. Some of tumor cells show plasmacytoid appearance.
- Tumor cells tend to invade gastric epithelium as small nests producing lymphoepithelial lesions.

Immunophenotyping

Tumor cells of extranodal marginal zone lymphoma are positive for CD20, CD79a, CD21 and CD35. Tumor cells are negative for CD10, CD23, and CD11c.

Markers	Expression
CD20	Positive
CD79a	Positive
CD21	Positive
CD35	Positive

- **Prognosis of disease:** Extranodal marginal zone lymphoma of MALT has **indolent course** and is slow to disseminate. Antibiotic therapy induces remission in *Helicobacter pylori* associated gastric MALT lymphoma, whereas cases with t(11;18) are resistant to antibiotic therapy. Tumor may be surgically excised.

Splenic Marginal Zone Lymphoma

Splenic marginal zone lymphoma (SMZL) is a specific low-grade small B cell lymphoma. It is characterized by splenomegaly, moderate lymphocytosis with villous morphology involving various organs, especially bone marrow. It has relatively indolent course in most of the cases except blastic form with aggressive behavior.

- Therapeutic options include treatment abstention, splenectomy, splenic irradiation, and chemotherapy.
- Mild neutropenia ($<1 \times 10^9$/L) occurs due to a combination of splenic sequestration and bone marrow infiltration in 5% of cases.

PLASMABLASTIC LYMPHOMA

Plasmablastic lymphoma is a very aggressive neoplasm, which arises from B cell that corresponds to the differentiation stage between B immunoblasts and plasma cell. It was initially described in the oral cavity in association with HIV infection. It may also occur in lymph nodes and extranodal sites.

- **Epidemiology:** Plasmablastic lymphoma most often occurs in adults with immunodeficiency state due to HIV infection. It may also occur in the settings of iatrogenic immuosuppresion in autoimmune diseases and organ transplantation.
- **Localization of disease:** Plasmablastic lymphoma most often presents as a mass in the extranodal regions of head and neck, especially in the oral cavity. The gastrointestinal tract is the most common next site after oral cavity.
  - Other extranodal sites of involvement occurs in skin, bone, genitourinary tract, nasal cavity, central nervous system, paranasal sites, liver, lungs and orbits.
  - Nodal involvement is demonstrated in <10% of cases, especially in post-transplantation cases.
- **Clinical features:** Patient presents with disseminated disease in stage III and stage IV with bone marrow involvement in 75% of HIV positive patients. About 25% of patients develop plasmablastic lymphoma with apparent immunodeficiency state.

Surgical Pathology: Plasmablastic Lymphoma

Light Microscopy

- Plasmablastic lymphoma is composed of diffuse and cohesive proliferation of neoplastic cells resembling immunoblasts and cells with more obvious plasmacytic differentiation, which resemble plasma cell myeloma.
- Tumor cells are large with vesicular nuclei, centrally located nucleoli, abundant cytoplasm and perinuclear halo.
- Mitotic figures are abundant. Apoptic cells and tingible body macrophages may be present.
- In monomorphic plasmablastic lymphoma, morphology of tumor cells is most often seen in the setting of HIV infection and located in the oral cavity, nasal region and paranasal sinuses.
- Cases with plasmablastic lymphoma most often occur in the nodal as well as extranodal sites.

Immunophenotyping

- Tumor cells express plasma cell phenotype, Which show positivity with CD138, CD38, VS38c, IRF4/MUM1, FRDM1 (also known as BLIMP1) and XBP1.
- CD20, CD45 and PAX5 are either negative or weakly positive.
- **CD79a positivity** is demonstrated in 40% of cases.
- **CD10 positivity** is demonstrated in 20% of cases.
- Cytoplasmic IgG is either κ or λ light chain, and CD56 is expressed by tumor cells in 25% of cases. EMA and CD30 are frequently expressed.
- Ki-67 proliferation rate is most often high, i.e. >90% of cases.
- BCL-2, BCL-6 and cyclin D1 expression are negative.

Markers	Expression
CD138	Positive (100%)
CD38	Positive (100%)
VS38c	Positive (100%)
IRF4/MUM1	Positive (100%)
FRDM1	Positive (100%)
XBP1	Positive (100%)
CD79a	Positive (40%)

▪ CD10	▪ Positive (20%)
▪ Cytoplasmic IgG is either κ or λ light chain	▪ Positive (25%)
▪ CD56	▪ Positive (25%)
▪ EMA	▪ Positive (frequently)
▪ CD30	▪ Positive (frequently)
▪ Ki-67	▪ Positive (>90%)
▪ BCL-2	▪ Negative
▪ BCL-6	▪ Negative
▪ Cyclin D1	▪ Negative

- **Prognosis:** Prognosis of plasmablastic lymphoma is generally poor with median survival of 6–12 months. Myc translocation has been associated with worse prognosis.

HAIRY CELL LEUKEMIA

Hairy cell leukemia (HCL) arises from activated small mature B memory cells and most often affects middle and elderly persons. Hairy cell leukemia most often involves peripheral blood, bone marrow and splenic red pulp.

- **Clinical features:** Most patients present with splenomegaly, pancytopenia, weakness, fatigue, pain in left upper quadrant, fever and bleeding. Bone marrow is virtually always involved. Hairy cells are demonstrated in the peripheral **blood** by the presence of cytoplasmic projections, hence named hairy cell leukemia. Hairy cell leukemia is resistant to conventional chemotherapy. Sometimes hairy cells may invade spleen.

Laboratory Diagnosis: Hairy Cell Leukemia

Light Microscopy

- Hairy cells are small- to medium-sized lymphoid cells with bean-shaped nucleus with ground glass chromatin, absent or inconspicuous nucleoli and abundant pale blue cytoplasm with circumferential hairy projections.
- The abundant cytoplasm and prominent cell borders produce '**fried egg appearance**' in bone marrow biopsies.

Cytochemistry

Hairy cells are tartrate-resistant acid phosphatase (TRAP) positive.

Immunophenotyping

Hairy cells express CD20, CD22, CD11c, CD103, CD25, CD123, T-bet, Annexin A1 and DBA 44.

Markers	Expression
▪ CD20	▪ Positive
▪ CD22	▪ Positive
▪ CD11c	▪ Positive
▪ CD103	▪ Positive
▪ CD25	▪ Positive
▪ CD123	▪ Positive
▪ T-bet	▪ Positive
▪ Annexin A1	▪ Positive
▪ DBA 44	▪ Positive

Flow Cytometry

Hairy cells show positivity with pan-B antigens: CD19 and CD20. In addition, these neoplastic cells coexpress CD11c, CD25, CD103 and FMC7.

- **Prognosis of disease:** Complete remissions are achieved in hairy cell leukemia with purine analogs or α-interferon. Overall 10-year survival exceeds 90%. There is an increased risk for secondary cancers such as Hodgkin's disease, NHL and thyroid cancer.

B CELL PROLYMPHOCYTIC LEUKEMIA

B cell prolymphocytic leukemia (B-PLL) arises from B cell prolymphocytes in marginal zone of lymph node, which involves peripheral blood, bone marrow and spleen. Prolymphocytes must constitute >55% of lymphoid cells in peripheral blood. It is difficult to distinguish B cell prolymphocytic leukemia from chronic lymphocytic leukemia and mantle cell lymphoma with leukemic expression.

- **Age group:** B cell prolymphocytic leukemia (B-PLL) accounts for 1% of lymphocytic leukemias. It affects elderly persons of >60 years with a median age of 65–69 years. Men and women are equally affected.
- **Localization of disease:** Leukemic cells of B-PLL are demonstrated in peripheral blood, bone marrow trephine biopsy, spleen and lymph node.
- **Clinical features:** Majority of patients present with massive splenomegaly, rapidly increasing lymphocyte count $>100 \times 10^9/L$ and absent or minimal lymphadenopathy. Anemia and thrombocytopenia are demonstrated in >50% of patients.

Laboratory Diagnosis: B Cell Prolymphocytic Leukemia

Peripheral Blood

B cell prolymphocytic leukemia cells in peripheral blood and bone marrow show >55% and most often >90% of lymphoid cells. These are medium-sized cells with round nucleus, condensed chromatin, a prominent central nucleus and scant basophilic cytoplasm.

Bone Marrow Trephine Biopsy Examination

Bone marrow trephine biopsy examination reveals an interstitial or nodular intertrabecular infiltration of prolymphocytes similar to those demonstrated in peripheral blood.

Light Microscopy (Spleen and Lymph Node)

- Spleen demonstrates expansion of white and red pulp due to infiltration of intermediate to large lymphoid cells with irregular to round nucleus, a central eosinophilic nucleus with abundant cytoplasm.
- Lymph nodes show deposits of similar lymphoid cells in diffuse or vague nodules.

Differential Diagnosis

- B cell prolymphocytic leukemia poses diagnostic difficulty in differentiating from pleomorphic mantle cell lymphoma, marginal zone lymphoma, and chronic lymphocytic leukemia. Diagnosis is established by immunophenotyping and genetic studies.
- Mantle cell lymphoma shows overexpression of cyclin D1 and t(11,14) (q13q32).
- Evaluation of SOX11 amd cyclin D1 expression in pure leukemia cases may require mRNA analysis by quantitative polymerase chain reaction (PCR).

Immunophenotyping

- B cell prolymphocytic leukemia cells express surface IgM/IgD as well as B cell antigens positivity with CD19, CD20, CD22, CD79a, CD79b and FMC7.
- **CD5 positivity** is seen in 20–30% of cases. CD23 positivity is demonstrated in 10–20% of cases.
- **ZAP70** and **CD38** are expressed in 50% of cases. ZAP70 expression does not correlate with IGHV gene mutation status.

Markers	Expression
Surface IgM/IgD	Positive (100%)
CD19	Positive (100%)
CD20	Positive (100%)
CD22	Positive (100%)
CD79a	Positive (100%)
CD79b	Positive (100%)
CD5	Positive (20–30%)
CD23	Positive (10–20%)
ZAP70	Positive (50%)
CD38	Positive (50%)

- **Prognosis of disease:** B cell prolymphocytic leukemia has a poor prognosis with a median survival of 30–50 months. Splenectomy may help in improvement of symptoms. Various chemotherapeutic drugs such as fludarabine and cladribine are administered. A combination of chemotherapy with rituximab may be effective treatment approach. Allogeneic bone marrow transplantation is also considered in these cases.

MULTIPLE MYELOMA

Multiple myeloma is malignant tumor of plasma cells resulting in synthesis of monoclonal light chain and heavy chain immunoglobulins.

- Multiple myeloma or solitary plasmacytoma arises from post-germinal center B cell. There is diverge rearrangements involving IgH, which most often affects elderly adults.
- Proliferation and survival of clonal plasma cells depend on elaboration of IL-6 by plasma cells and marrow stromal cells.
- Patient presents with osteolytic bone lesions, pathologic fractures, hypercalcemia, renal failure, and primary amyloidosis. In decreasing frequency, bones involved in multiple myeloma include vertebral column 66% (especially lumbar regions); ribs 44%; skull 41%; pelvis 28%; femur 24%; clavicle 10%; and scapula 10%.
  - The lesions begin in the medullary cavity, erode cancellous bone and progressively destroy the bony cortex (osteolytic lesions).
  - Patient is prone to pathologic fractures and compressed vertebral fractures.
  - Radiograph study reveals rounded punched-out defects, of 1–4 cm in diameter in an older adult. Such lesions can produce bone pain.
- Hypercalcemia and an elevated serum alkaline phosphatase are common laboratory findings. Most cases of solitary plasmacytoma involving bone evolve into multiple myeloma.
- Molecular genetic alterations include t(4;14), which juxtapose the IgH locus on 14q32 with the fibroblast growth factor receptor 3 (FGFR3) gene on chromosome 4p16. Clonal plasma cells synthesize cytokines such as MIP1a and the receptor activator of NF-κB ligand (RANKL), which serves as an osteoclast-activating factor (OAF).

Laboratory Diagnosis of Multiple Myeloma

Serum Electrophoresis

Serum protein electrophoresis shows monoclonal immunoglobulin (light chain class or single heavy chain) spike of M protein indicates increased level of IgG (50%) or IgM (25%). There is no increase in circulating immunoglobulin is <1% of cases.

Urinary Findings

In 60–70% of cases, increased light chains (either κ or λ), known as Bence Jones protein, are synthesized and excreted in the urine termed Bence Jones proteinuria. The light chains are toxic to renal tubules, and can lead to tubular injury with renal failure.

Bone Marrow Examination

- Bone marrow examination shows >30% of clonal plasma cells, which are well-differentiated with eccentric nuclei and perinuclear halo (clear cytoplasm representing the Golgi apparatus). Clear cytoplasmic droplets contain immunoglobulin.

- Morphology of clonal plasma cells is indistinguishable from normal plasma cells except by their increased numbers. Patient rarely develops plasma cell leukemia.

Bone Marrow Trephine Biopsy Examination

Tumor is composed of sheets of clonal plasma cells that are very similar to normal plasma cells, with eccentric nuclei and abundant pale purple cytoplasm. In some cases, clonal plasma cells may also be poorly differentiated (Fig. 13.35).

- The diminished amount of normal circulating immunoglobulin increases the risk for infections, particularly with bacterial organisms such as *Streptococcus pneumoniae, Haemophilus influenzae, Staphylococcus aureus,* and *Escherichia coli.*
- The excessive light chain production may lead to the AL form of amyloidosis, with deposition of amyloid in many organs. Renal failure due to amyloid deposition is most common cause of death. Plasma cell neoplasms and their key features are given in Table 13.31.

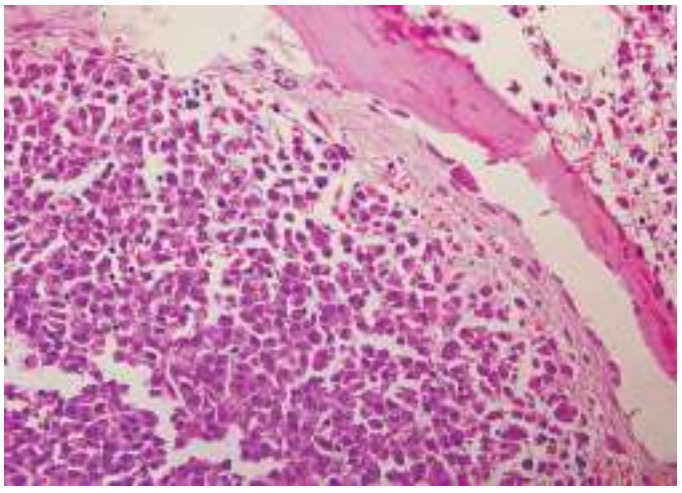

Fig. 13.35: Trephine bone marrow biopsy shows sheets of plasma cells with eccentric nuclei and abundant pale purple cytoplasm (400X).

MATURE T CELL AND NK CELL LYMPHOMAS

T cell and NK cell lymphomas are more common in Asia. Features of non-Hodgkin lymphomas derived from mature T cells and NK cells are given in Table 13.32.

ANGIOIMMUNOBLASTIC T CELL LYMPHOMA

Angioimmunoblastic T cell lymphoma accounts for 15–20% of T cell lymphomas and 1–2% of all non-Hodgkin's lymphoma, which affects 50–70 years of age group with equal sex incidence.

- The eye-catching feature of angioimmunoblastic T cell lymphoma is the presence of a rich small blood vessel meshwork with PAS positive on histologic examination. The tumor cells express CD4, CD10 and other markers of follicular CD4+ helper T cells.
- T cell receptor gene arrangement has been found in 75% of cases and appears to be limited to CD10+ cells.
- Follicular dendritic cells are abundant around the vessels and can be identified by CD21 immunophenotyping. Despite intensive therapy, prognosis is poor.

Clinical Features

Patient presents with generalized lymphadenopathy, hepatosplenomegaly, skin rash with pruritus, ascites, pleural effusion and arthritis. Laboratory investigations demonstrate frequent polyclonal hypergammaglobulinemia, elevated erythrocyte sedimentation rate, and lactic dehydrogenase (LDH), and autoimmune hemolytic anemia (Coombs' positive). Other autoantibodies are demonstrated such as rheumatoid factor, thyroid autoantibodies and anti-smooth muscle antibodies in these cases.

Molecular Genetic Alterations

Southern blotting technique and polymerase chain reaction (PCR) demonstrate the presence of rearrangement of T cell receptor gene in angioimmunoblastic

Table 13.31 Plasma cell neoplasms and their key features

Form	Characteristics
Plasma cell myeloma (multiple myeloma)	▪ Bone marrow or bone marrow trephine biopsy proven plasmacytoma consisting of ≥10% clonal plasma cells ▪ M-spike in serum or urine on electrophoresis ▪ Related organ or tissue damage (CRAB), i.e. hypercalcemia, renal insufficiency, anemia, bone lesions ▪ Myeloma defining events (MDE) must fulfill at least one MDE defining events: (a) serum calcium >11 mg/dl), (b) anemia, (c) bone lesions ≥1 osteolytic lesion on imaging techniques, (d) bone marrow clonal plasma cells ≥60%, (e) involved/uninvolved serum-free light chains ratio ≥100, and (f) presence of ≥1 focal lesion on MRI of spine
Osseous plasmacytoma	Single bone plasmacytoma, which does not produce M protein

Contd...

Table 13.31 Plasma cell neoplasms and their key features (*Contd...*)

Form	Characteristics
Extraosseous plasmacytoma	Nose, paranasal sinuses, nasopharynx, and tonsils
Osteosclerotic myeloma (POEMS syndrome)	▪ Polyneuropathy (chronic inflammatory polyneuropathy) ▪ Organomegaly (hepatomegaly, splenomegaly, or lymphadenopathy) ▪ Endocrinopathy (e.g. gynecomastia, testicular atrophy, M protein)
Nonsecretory myeloma	▪ Monoclonal plasma cells ≥10% in bone marrow ▪ Absence of M protein and serum-free light chain in serum and urine
Asymptomatic (smoldering) myeloma	▪ Monoclonal plasma cells ≥10% in bone marrow ▪ M protein spike in serum or urine >30 g/L ▪ Absence of myeloma-defining events (MDE) or amyloidosis
Covert myeloma	Synthesis of abnormal paraprotein and amyloidosis but without tumor formation

Table 13.32 Features of NHLs derived from mature T cells and NK cells

Disorder	Origin	Age Group	Clinical Features	Genotype
Angioimmunoblastic T cell lymphoma	T cell	Elderly adults	Generalized lymphadenopathy, hepatomegaly, skin rashes, pruritus, autoimmune hemolytic anemia	Rearrangement of T cell receptor gene and immunoglobulin gene
Adult T cell leukemia/lymphoma	Helper T cell	Adults	Cutaneous lesions, bone marrow involvement and hypercalcemia	HTLV-1 provirus demonstrated in neoplastic cells
Peripheral T cell lymphoma	Helper or cytotoxic T cell	Elderly persons	Lymphadenopathy with aggressive behavior	No specific chromosomal abnormalities
Anaplastic large cell lymphoma, ALK positive	Cytotoxic T cell	Children and young adults	Lymphadenopathy and soft tissue involvement with aggressive behavior	Rearrangement of ALK (anaplastic large cell kinase) in a subset
Extranodal NK cell/T cell lymphoma	NK cell (common) or cytotoxic T cell (rare)	Adults	Destructive extranodal masses (most common in sinonasal region) with aggressive course	EBV-associated without specific chromosomal abnormality
Mycosis fungoides	Helper T cell	Adults	Cutaneous lesions, and generalized erythema	No specific chromosomal abnormality
Sézary syndrome	Helper T cell	Adults	Cutaneous lesions, and generalized erythema	No specific chromosomal abnormality
Large granular lymphocytic leukemia	Cytotoxic T cell or NK cell	Adults	Anemia, splenomegaly, neutropenia, anemia accompanied by autoimmune disorder	

lymphoma. However, immunoglobulin gene rearrangement may also be demonstrated in these cases.

Surgical Pathology: Angioimmunoblastic T Cell Lymphoma

Light Microscopy

- Lymph node in angioimmunoblastic T cell lymphoma shows complete or partial effacement, which is composed of polymorphous population of reactive and tumors cells including scattered blasts often Epstein-Barr virus positive. Tumor cells extend into perinodal tissues, often leaving subcapsular sinus patent.
- There is presence of prominent branching of endothelial venules surrounded by PAS positive basement membrane.
- Lymph node also shows expanded follicular cell network and clusters of medium-sized T cells with clear cytoplasm.

Immunophenotyping

- Clonal T cells show positivity for CD3, CD5, CD4, CD10 and PD-1. Residual B cell areas pushed to periphery of lymph node are positive for CD20, CD79a, CD20 and CD79a.
- Clonal T cells may express EBV-encoded RNAs (EBERs) and EBV-latent antigens. Expanded network of dendritic cells shows positivity for CD21, CD23 and CD35.

Cell Type	Markers	Expression
▪ T cells	▪ CD3, CD5, CD4, CD10, PD-1	▪ Positive
▪ Residual B cell areas pushed to periphery of lymph node	▪ CD20, CD79a	▪ Positive
▪ Blast cells	▪ EBV-encoded RNAs (EBERs) and EBV-latent antigens	▪ Positive
▪ Expanded network of dendritic cells	▪ CD21, CD23, CD35	▪ Positive

ADULT T CELL LEUKEMIA/LYMPHOMA

Adult T cell leukemia/lymphoma is derived from a mature CD4+ helper T cell. It is composed of highly pleomorphic lymphoid cells.

- Patient develops widespread disseminated disease, which is caused by human retrovirus T cell leukemia virus 1 (HTLV-1).
- Tumor cells most often show multilobed appearance. Neoplastic T cells express T cell-associated antigens such as CD2, CD3 and CD9 but lack CD7.
- The disease most often occurs in endemic regions for HTLV-1. Males are more affected than females. Adult T cell leukemia/lymphoma is a systemic disease associated with poor prognosis.
- **Localization of disease:** Majority of patients present with widespread involvement of lymph nodes as well as peripheral blood. Circulating tumor cells are recruited from skin, the most commonly extralymphatic site involvement is >50% of cases.
- **Clinical features:** Patient presents with widespread lymphadenopathy. Skin is the most common extra-lymphatic site involved. Several clinical variants of adult T cell leukemia/lymphoma have been described: acute, lymphomatous, chronic and smouldering. Progression from chronic or smouldering variant to the acute variant occurs in 25% of patients most often after a long duration. On clinical examination, lesions of skin have been classified as erythema, papules and nodules. Tumor-like lesion is demonstrated in rare cases.
  - **Acute adult T cell leukemia/lymphoma:** It is most common and characterized by leukemic phase.
  - **Chronic adult T cell leukemia/lymphoma:** It is characterized by exfoliative skin rash.
  - **Lymphomatous adult T cell leukemia/lymphoma:** It is characterized by lymphadenopathy.
  - **Smouldering adult T cell leukemia/lymphoma:** It is characterized by skin or pulmonary lesions with normal TLC and >5% circulating tumor cells.
- **Imaging technique:** In patients with hypercalcemia, imaging studies may reveal osteolytic lesions. Fluorodeoxyglucose (FDG)-positron emission tomography (PET), i.e. FDG-PET is most often positive in 25% of cases after long clinical course in adult T cell leukemia/lymphoma.

Surgical Pathology: Adult T Cell Leukemia/Lymphoma

Light Microscopy

- Lymph node in adult T cell leukemia/lymphoma is characterized by a broad spectrum cytologic features of tumor cells (pleomorphic small, medium and large tubes).
- Rarely, tumor cells may be demonstrated resembling angioimmunoblastic T cell lymphoma. Nuclear chromatin of tumor cells is coarsely clumped with sometimes distinct nucleoli. Multiple indentations of clefts in nuclei are evident. Multinucleated giant cells may be present simulating Reed-Sternberg cells. Mitotic activity is high in the tumor cells.
- In the peripheral blood, tumor cells are multilobed termed flower cells. Giemsa stained blood smear examination reveals multilobed tumor cells with deeply basophilic cytoplasm.
- Tumor cell infiltrating in the bone marrow are most often patchy ranging from sparse to moderate.
- Tumor cells in the skin can produce skin lesions in >50% of patients. Tumor cells in filtratijng into the epidermis form microabscesses. Tumor cells in dermis are present around the blood vessels. Extension of tumor infiltrate may form subcutaneous nodules.
- Histopathology of adult T cell leukemia/lymphoma is shown in Fig. 13.36.

Immunophenotyping

- Tumor cells express E cell associated antigens such as CD2, CD3 and CD5.
- Tumor cells are CD4 positive and CD8 negative but reverse may be seen in most cases.
- CD25 is strongly expressed in nearly all cases.
- CD30 may be positive in transformed cells.
- CCR4 chemokine is expressed by neoplastic cells.

Markers	Expression
▪ CD2	▪ Positive (100%)
▪ CD3	▪ Positive (100%)
▪ CD5	▪ Positive (100%)
▪ CD25	▪ Positive (100%)
▪ CCR4	▪ Positive

- **Prognosis of disease:** The acute and lymphomatous variants of adult T cell leukemia/lymphoma have shorter survival. Death occurs due to infectious agents such as *Pneumocystis pneumoniae*, Cryptococcus and herpes zoster.

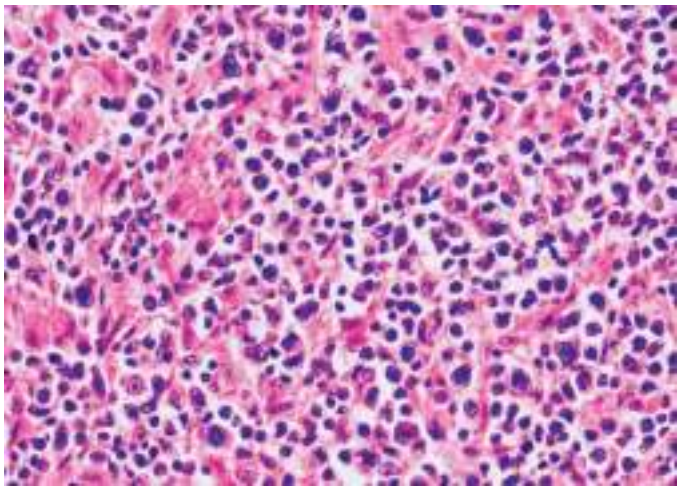

Fig. 13.36: Adult T cell leukemia/lymphoma shows pleomorphic population of neoplastic cells composed of small, medium and large types. Nuclear chromatin is coarsely clumped (400X).

ANAPLASTIC LYMPHOMA KINASE (ALK) POSITIVE ANAPLASTIC LARGE T CELL LYMPHOMA

Anaplastic lymphoma kinase (ALK) positive anaplastic large T cell lymphoma is derived from CD8+ cytotoxic T cells and also known as Ki-1 lymphoma. Primary anaplastic large T cell lymphoma originates *de novo* in lymph node or skin. Secondary anaplastic large T cell lymphoma represents transformation of another lymphomas.

- Tumor is composed of large lymphoid cells of variable size containing horseshoe-shaped nuclei and abundant cytoplasm involving ALK gene and expression of ALK protein and CD30.
- ALK positive anaplastic large T cell lymphoma should be differentiated from primary cutaneous adult anaplastic large cell lymphoma and T cell or B cell lymphoma with anaplastic features and/or CD30 expression.
  - **Epidemiology:** ALK positive anaplastic large T cell lymphoma has bimodal age distribution with one peak in children and another in older patients. It is more frequent in the first three decades of life. Males are more affected than females.
  - **Localization of disease:** ALK positive anaplastic large T cell lymphoma most often involves both lymph nodes and extranodal sites such as soft tissue, skin, bone, liver and lungs. Involvement of central nervous system and gastrointestinal tract is rare. Bone marrow involvement is demonstrated in <30% of cases by using immunohistochemical stains.
  - **Clinical features:** Approximately 70% of patients present with advanced stage III or IV disease with lymphadenopathy in peripheral and/or abdominal regions and often associated with extranodal involvement of bone marrow. About 75% of patients have high fever.
  - **Molecular genetic alterations: Anaplastic lymphoma kinase (ALK)** gene is located on chromosome 2. As a result of chromosomal translocation t(2;5), ALK gene is fused with the NPM (nucleophosmin) gene, resulting in the production of a hybrid NPM–ALK protein. It is demonstrated by ALK-1 (p80) monoclonal a ntibody. Chromosomal translocation and formation of hybrid NPM–ALK gene is seen in majority of children and young adults. These patients have a relatively good prognosis. Anaplastic large T cell lymphoma shows chromosomal translocations involving ALK gene, ALK staining pattern and frequency (Table 13.33).

Surgical Pathology: Anaplastic Large T Cell Lymphoma (ALK Positive)

Light Microscopy

- In ALK positive anaplastic large T cell lymphoma, lymph node exhibits a broad morphologic spectrum and composed of large pleomorphic cells with eccentric horseshoe or doughnut-shaped nuclei with eosinophilic cytoplasm. Morphology of tumor cells may mimic poorly differentiated carcinoma.
- Morphologic of ALK positive anaplastic large T cell lymphoma is shown in Fig. 13.37.

Immunophenotyping

- ALK expression is absent in all normal postnatal human tissues except in rare case in brain.
- Immunophenotyping with specific anti-ALK monoclonal antibodies plays significant role in diagnosing the neoplasm.
- Tumor cells show positivity for epithelial membrane antigen (EMA), CD30 (Ki-1), CD2, CD5, CD4, IL-2 receptor, clustrin, cadherin and galectin in most of the cases. Immunophenotyping in common histologic types of T cell lymphomas is given in Table 13.34.

Markers	Expression
EMA	Positive
CD30 (Ki-1)	Positive
CD2	Positive
CD5	Positive
CD4	Positive
IL-2 receptor	Positive
Clustrin	Positive
Cadherin	Positive
Galectin	Positive

- **Prognosis of disease:** Anaplastic large B cell lymphoma (ALK positive) has good prognosis with 75% cure rate treated with chemotherapy. Relapses most often remain sensitive to chemotherapy. Allogeneic bone marrow transplantation may be

Table 13.33 Categories of anaplastic large T cell lymphoma

Parameters	ALK Positive	ALK Negative
Age group	Children and young persons	Elderly persons
Prognosis with treatment	Good	Poor outcome

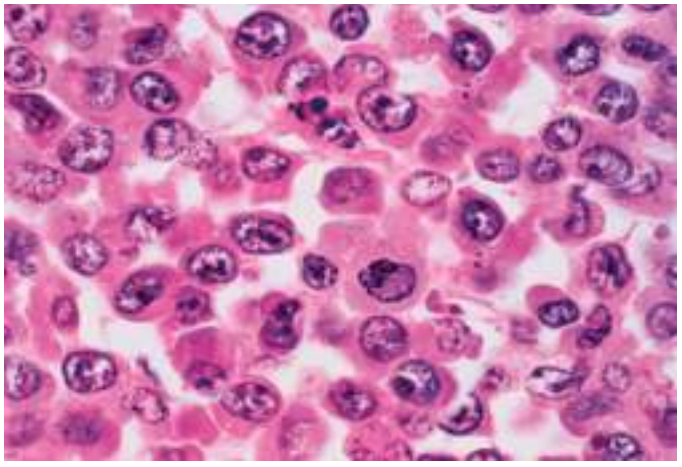

Fig. 13.37: ALK positive anaplastic large T cell lymphoma shows large pleomorphic cells with eccentric horseshoe-shaped nuclei with eosinophilic cytoplasm (400X).

effective in refractory cases. Small molecule inhibitors of ALK kinase and CD-targeting with antibody drug may be administered in relapse cases.

EXTRANODAL NK CELL/T CELL LYMPHOMA

Extranodal NK/T cell lymphoma derived from NK/T cell lineage is characterized by vascular destruction, necrosis and cytotoxic phenotype associated with Epstein-Barr virus.

- **Epidemiology:** Extranodal NK/T cell lymphoma is more prevalent in **Asians** and populations in **Mexico**, **central** and **South America**. It most often affects adults between 44 and 54 years of age. Males are more affected than females.
- **Localization of disease:** Extranodal NK/T cell lymphoma most often involves nasal cavity, nasopharynx, paranasal sinuses and palate. Nasal cavity is most often involved. Other organs may be involved such as skin, soft tissue, gastrointestinal tract. Some cases may be accompanied by involvement of lymph node.
- **Clinical features:** Patient presents with nasopharyngeal mass with obstruction and epistaxis. There are extensive destructive midfacial lesions.
  - Neoplasm may extend to surrounding structures such as nasopharynx, paranasal sinuses, oral cavity, orbit, palate and oropharynx. Bone marrow involvement is uncommon.
  - Disease may disseminate to skin, gastrointestinal tract, central nervous system, tests and cervical lymph nodes during clinical course. Some patients may develop hemophagocytic syndrome.

Surgical Pathology: Extranodal NK Cell/T Cell Lymphoma

Light Microscopy

- Histologic features of extranodal NK cell/T cell lymphoma are similar irrespective of the site of involvement.
- Mucosal sites most often show extensive ulceration.
- Tumor cells infiltrate is diffuse and permeative. There is loss of mucosal glands.
- An angiocentric and angiodestructive growth patterns are most often present. Coagulative necrosis and apoptotic bodies are commonly demonstrated.
- Tumor is composed of small- and medium-sized, large or anaplastic cells with irregularly folded nuclei.
  - Chromatin in granular in small- and medium-sized neoplastic cells.
  - Cytoplasm is moderate in amount either pale or clear in the cells.
  - Mitotic figures are most often demonstrated.

Immunophenotyping

- Most typical immunophenotyping of extranodal NK cell/T cell lymphoma is CD2 positive, CD56 positive, cCD3 epsilon positive, CD3 negative and CD5 negative. CD56 is a specific marker for NK cells but not specific for extranodal NK cell/T cell lymphoma.
- CD43 and CD45RO are most often positive. CD7 is invariably expressed in tumor cells.
- Subset of cases of cytotoxic T cell lineage may express CD5, CD8 and T cell receptor (gamma–delta or alpha–beta). Cytotoxic molecules such as granzyme B, perforin and TIA1 are positive.
- Tumor cells show positivity for HLA-DR, CD25, FAS (CD95) and FASL. CD30 is positive in 30% of cases.
- Nuclear expression of megakaryocyte-associated tyrosine kinase (MATK) is common in these cases.
- EBV encoded RNA (ERER) *in situ* hybridization demonstrates EB virus in neoplastic cells.

Markers	Expression
CD2	Positive (most often)
CD56	Positive (most often)
cCD3 epsilon	Positive
CD56	Positive (not specific marker)
CD43	Positive
CD45RO	Positive
HLA-DR	Positive
CD25	Positive
FAS (CD95)	Positive
FASL	Positive
CD30	Positive (30% of cases)
MATK	Positive (most often)

Table 13.34 Immunophenotyping in common histologic types of T cell lymphomas

Markers	Anaplastic Large T Cell Lymphoma	Peripheral T Cell Lymphomas	T Lymphoblastic Lymphoma
CD3	Positive/negative	Positive	Positive/negative
CD30	Positive (sheets of cells)	Positive (focal cells)	Negative
EMA	Positive	Negative	Negative
ALK1	Positive	Negative	Negative
CD99	Positive/negative	Negative	Positive
TdT	Negative	Negative	Positive

MYCOSIS FUNGOIDES

Mycosis fungoides is an epidermotropic primary T cell lymphoma derived from CD4+ helper T cells composed of small- and medium-sized T cells with cerebriform nuclei. Term mycosis fungoides may be used for classic cases characterized by the presence of cutaneous erythematous patches, plaques, and tumors.

- **Epidemiology:** Mycosis fungoides is the most common type of T cell lymphoma. It constitutes 50% of all cutaneous lymphomas, which most often occurs in adults/elderly. However, it may affect children and adolescents. Males are more affected than females. Disease is more prevalent in crop and vegetable farmers, painters, carpenters and wood workers suggesting environmental etiology of the disease.
- **Localization of disease:** Mycosis fungoides is most often limited to the skin. Extracutaneous dissemination may be demonstrated in advanced stage of disease involving lymph nodes, liver, spleen, blood and lungs. Bone marrow involvement is very rare.
- **Clinical features:** Patient presents with cutaneous patches ranging from plaques or nodules, or generalized erythematous plaques in the early stage. Patient with tumor stage mycosis fungides shows combination of skin lesions with ulceration. Later neoplastic cells may disseminate to lymph nodes, liver, spleen, lungs and blood. Clinical stage of the disease is the most important prognostic factor.

Surgical Pathology: Mycosis Fungoides

Light Microscopy

The histology of the skin lesions varies with the stage of the disease (Fig. 13.38).

- **Early patch stage:** Band-like or lichenoid infiltrates of lymphocytes and histiocytes are demonstrated. Atypical cells are small- and medium-sized with cerebriform nuclei present mainly in the basal layer of epidermis.
- **Plaque stage:** Epidermotropism is prominent with intraepidermal atypical cell collections called Pautrier microabscesses.
- **Tumor stage:** Dermal infiltrates of neoplastic cells are more diffuse with prominent nuclei. Intradermal atypical cell collection is less.

Immunophenotyping

Tumor cells of mycosis fungoides express CD2, CD3, TCR-β, CD5, and CD4 T cell. Cutaneous lymphocyte antigen (CLA) is expressed in most of the cases. Mycosis fungoides; cutaneous plaque shows CD3 positivity (Fig. 13.39).

Markers	Expression
CD2	Positive
CD3	Positive
TCR-β	Positive
CD5	Positive
CD4	Positive
CLA	Positive (in most of the cases)

- **Prognosis of disease:** Most important prognostic factors for mycosis fungoides is the extent of cutaneous and extracutaneous disease as reflected by the clinical stage. Prognosis is poor in advanced

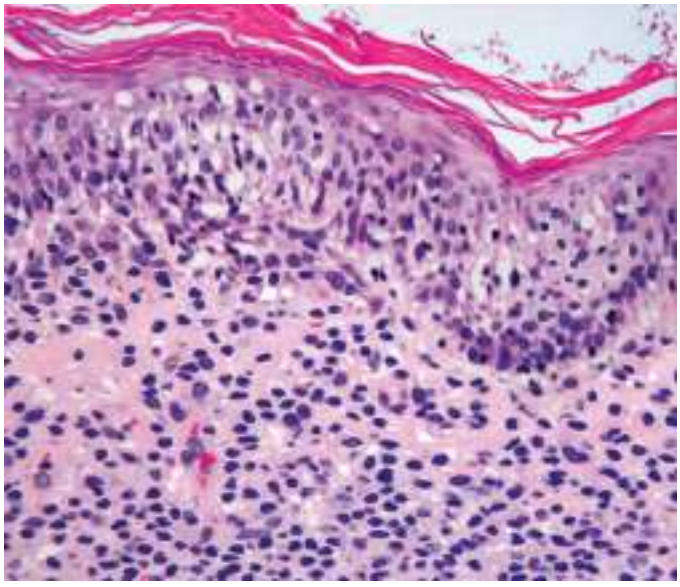

Fig. 13.38: Mycosis fungoides shows dermal infiltrates of neoplastic cells arranged in diffuse pattern with prominent nuclei (400X).

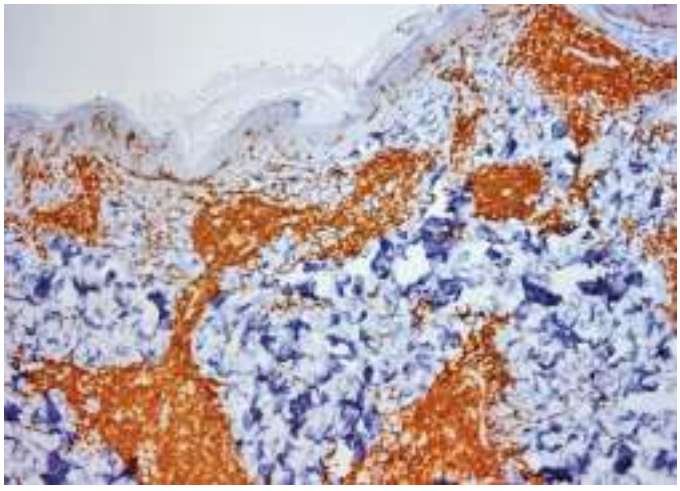

Fig. 13.39: Mycosis fungoides shows positivity for CD3.

disease. Advese prognostic factors for mycosis fungoiders include extracutaneous dissemination, patient age >60 years, elevated lactate dehydrogenase and histologic transformation to blast stage with >25% blast cells.

SÉZARY SYNDROME

Sézary syndrome is defined by the triad of erythroderma, generalized lymphadenopathy and presence of clonal neoplastic T cells with cerebriform nuclei (Sézary-Lutzner cells). Leukemic cells from skin lesion in mycosis fungoides most often involve bone marrow and lymph nodes.

- **Epidemiology:** Sézary syndrome accounts for <5% of all cutaneous T cell lymphoma, which occurs in adults of >60 years of age.
- **Localization of disease:** Sézary syndrome is generalized disease, which can involve any visceral organ in advanced disease especially in oropharynx, lungs and central nervous system. Bone marrow involvement is variable.
- **Clinical features:** Patient presents with erythroderma (intense and widespread reddening of skin), generalized lymphadenopathy, pruritus, plantar or palmar hyperkeratosis, alopecia, ectropion and alteration of nail morphology, i.e. onychodystrophy. Patient with Sézary syndrome develops generalized exfoliative erythroderma associated with cutaneous T cell lymphoma.

Surgical Pathology: Sézary Syndrome

Light Microscopy

- Histologic features in Sézary syndrome may be similar to mycosis fungoides.
- Histologic examination of lymph node shows a dense, monotonous infiltrate of Sézary cells with effacement of normal architecture of lymph node.
- Bone marrow involvement is variable and showing neoplastic T cells (leukemic T cells) which are arranged mainly in interstitial pattern.
- Peripheral blood shows **Sézary-Lutzner cells** with deep-clefted, cerebriform nuclei.

Immunophenotyping

- Neoplastic T cells express CD3, CD4, CD279 (also known as PD1), CD2 and TCR-β in almost all cases.
- Sézary-Lutzner cells express cutaneous lymphocyte antigen (CLS) and skin homing receptor (CR7).
- Flow cytometry analysis of peripheral blood lymphocytes exhibits CD4+ helper T cells in >30% of cases.

Markers	Expression
CD3	Positive
CD4	Positive
CD279 (PD1)	Positive
CD2	Positive
TCR-β	Positive

- **Prognosis of disease:** Sézary syndrome is an aggressive disease with a 5-year survival rate of 10–30%, depending on stage of the disease.
  - Majority of patients die of opportunistic infections involvement of lymph node, and viscera indicates poor prognosis. Degree of peripheral blood involvement at diagnosis affects prognosis.
  - Chromosomal translocations in non-Hodgkin's lymphoma are given in Table 13.35. Interpretation of verious non-Hodgkin's lymphomas is shown in Fig. 13.40.

Table 13.35 Chromosomal translocations in non-Hodgkin's lymphoma (NHL). Adapted from flow cytometry, immunohistochemistry and molecular genetics for hematologic and lymphoid neoplasms

Non-Hodgkin's Lymphoma (Histologic Variants)	Chromosomal Translocations	Genes Involved
Anaplastic large cell lymphoma	t(2;5) (p23;q35)	2ALK; 5NPM
Burkitt's lymphoma	▪ t(8;14) (q24;q32) ▪ t(2;8) (q12;q24) ▪ t(8;22) (q24;q11)	▪ 8-c-Myc, 14 IgH ▪ 2-kappa, 8-c-Myc ▪ 8-c-Myc, 22 lambda IgH

Contd...

Table 13.35 Chromosomal translocations in non-Hodgkin's lymphoma (NHL). Adapted from flow cytometry, immunohistochemistry and molecular genetics for hematologic and lymphoid neoplasms (*Contd...*)

Non-Hodgkin's Lymphoma (Histologic Variants)	Chromosomal Translocations	Genes Involved
Diffuse large B cell lymphoma (DLBCL)	▪ t(3;14) (q27;q32) ▪ t(14;18)	▪ IgH; BCL-6 (30% of cases) ▪ IgH BCL-2 (10–20% of cases)
Cutaneous T cell lymphoma	t(10;14) (q24;q32)	NFK, δ_2 (LYT-10); IgH
Burkitt-like lymphoma	t(14;18) (q32;q21)	IgH; BCL-2
Follicular lymphoma	t(14;18) (q32;q21)	14-IgH; BCL-2
Mantle cell lymphoma	t(11;14) (q13;q32)	BCL-1 (CCND-1); IgH, 11-cyclin D1
Lymphoplasmacytic lymphoma	t(19;14) (p13;q32)	PAX5 (BSAP); IgH
Marginal zone lymphoma (MALT lymphoma)	▪ t(11;18) (q21;q21) ▪ t(1;14) (p22;q32)	▪ AP12-MALT-1 ▪ BCL-10; IgG
Small cell lymphocytic lymphoma/chronic lymphocytic leukemia (CLL)	t(14;19) (q32;q13)	BCL-3, IgH
Plasma cell myeloma	▪ t(4;14) (p16;q32) ▪ t(14;16) (q32;q23) ▪ t(16;32) (q23;q11)	▪ FGFR3; IgH ▪ IgH; c-MAF ▪ c-MAF, Igδ

MALT: Mucosa-associated lymphoid tissue; CLL: Chronic lymphocytic leukemia.

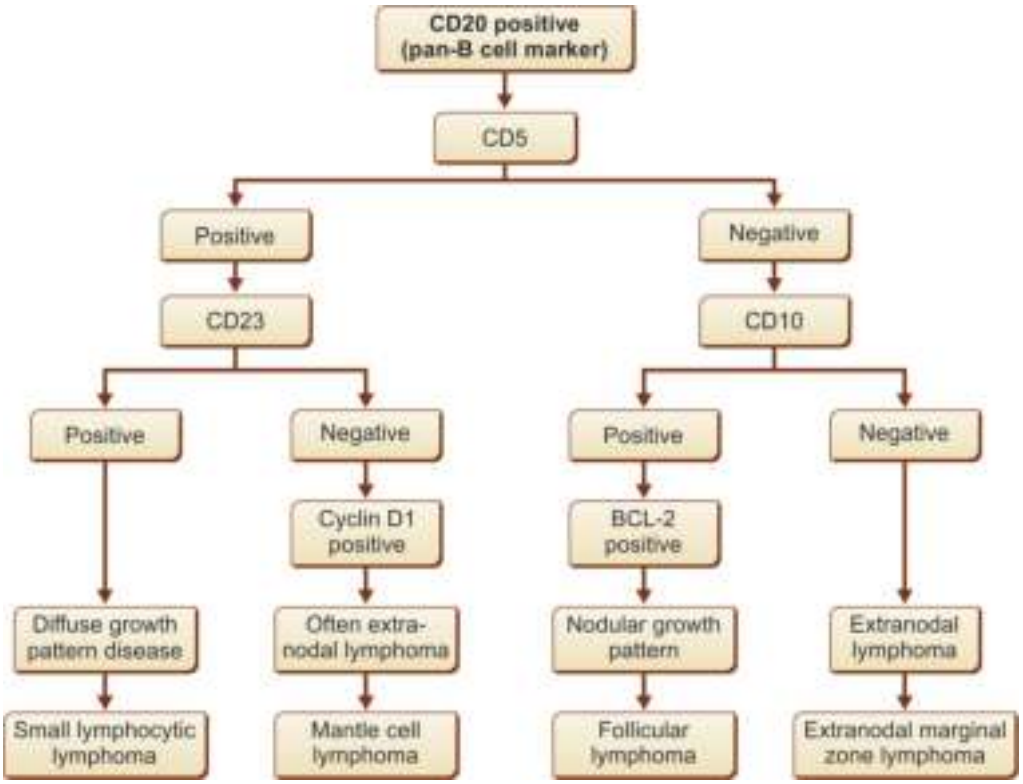

Fig. 13.40: Interpretation of various non-Hodgkin's lymphomas.

DISORDERS OF SPLEEN

SPLEEN: STRUCTURE

Spleen is the largest lymphoid organ. In normal adults, spleen weighs 50–200 g, which contributes in the maturation of red blood cells by pitting function. It has ability to remove solid particles from the cytoplasm of red blood cells without causing injury to the cell membrane.

- Normal red blood cells squeeze through slit pores in the sinusoids, but red blood cells with membrane defect (spherocytosis or elliptocytes) and sickle cells cannot squeeze resulting in red blood cells destruction in spleen termed extravascular hemolysis.
- Spleen is divided into white pulp and red pulp regions, separated by an ill-defined interface known as marginal zone. Organization of lymphoid tissue in the spleen is shown in Fig. 13.41.

WHITE PULP OF SPLEEN

The white pulp of spleen contains periarteriolar lymphoid sheath (PALS), germinal lymphoid follicles, which are surrounded by marginal zone. Marginal zone of spleen contains numerous macrophages, antigen-presenting cells (APCs), slowly recirculating B cells and natural killer cells. Periarteriolar lymph sheath contains T cells. B cells are distributed in the lymphoid follicles. In routine hematoxylin and eosin stained sections, white pulp appears basophilic due to dense heterochromatin in lymphocytes nuclei.

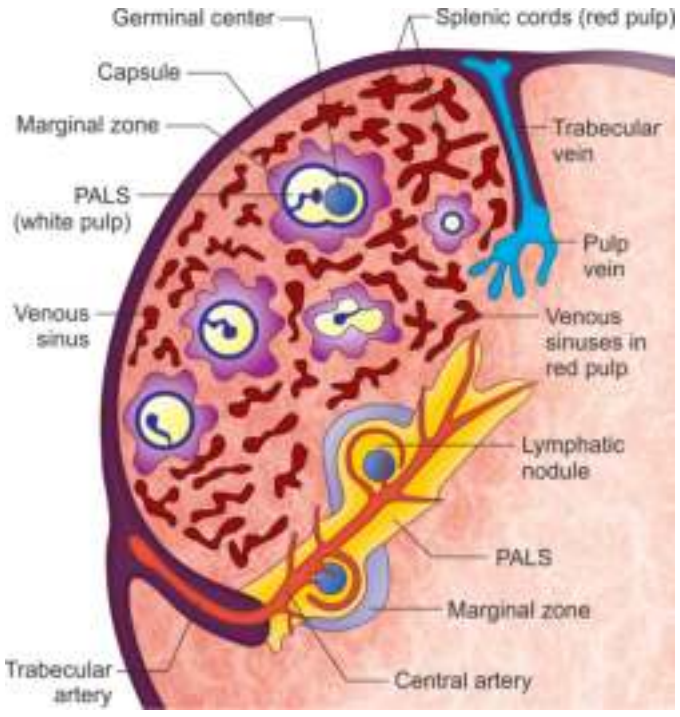

Fig. 13.41: Organization of lymphoid tissue in the spleen. Blood enters the tissue via the trabecular arteries, which give rise to the many-branched central arteries. Some of these end in the white pulp, supplying the germinal centers and mantle zones, but most empty into or near the marginal zones (PALS—periarteriolar lymphoid sheath).

RED PULP OF SPLEEN

The red pulp of spleen contains venous sinuses separated by splenic cords, which participates in the storage of red blood cells, white blood cells and platelets.

- When splenomegaly occurs, excessive pooling of red blood cells may cause fall in the peripheral blood count. Special endothelial cells in red pulp of spleen that express both reticular cells and histiocytic markers are known as **Littoral cells**.
- Blood enters into the spleen via the trabecular artery, which divides into many-branched central arteries. Some of these arteries end in the white pulp, supplying the germinal centers and mantle zones, but most empty into or near the marginal zones. The splenic venous outflow is drained into the portal vein, adding as rich supply of antibodies to the portal vein entering the liver.

FUNCTIONAL DISORDERS OF SPLEEN

THERAPEUTIC SPLENECTOMY

Therapeutic splenectomy is performed in idiopathic thrombocytopenic purpura, chronic myeloproliferative disorders, Hodgkin's disease and non-Hodgkin's lymphoma. Following splenectomy, children under the age of three years are susceptible to infection by pneumococci, streptococci group A, enteric group and *Haemophilus influenzae*, therefore, resulting in septicemia, meningitis and disseminated intravascular coagulation (DIC).

SPLENOMEGALY

Spleen is most often enlarged due to infections and congestive state. Red pulp congestion is most common finding. Massive splenomegaly occurs due to chronic myelogenous leukemia, myelofibrosis, kala-azar, malaria, Gaucher's disease and hepatosplenic T cell lymphoma. Conditions associated with splenomegaly are given in Table 13.36.

FIBROCONGESTIVE SPLENOMEGALY

Fibrocongestive splenomegaly most often occurs in portal hypertension due to cirrhosis and right-sided cardiac failure with cor pulmonale. Decreased portal venous drainage in these disorders leads to fibro-congestive splenomegaly.

Table 13.36 Conditions associated with splenomegaly

Categories	Conditions
Bacterial infections	Infectious endocarditis, tuberculosis, syphilis
Viral infections	Infectious mononucleosis, cytomegalovirus
Parasitic infection	Malaria
Fungal infection	Histoplasmosis
Congestive states	▪ Cirrhosis ▪ Congestive heart failure ▪ Splenic vein thrombosis
Hematologic malignancies	▪ Myeloproliferative disorders ▪ Hodgkin's disease, non-Hodgkin's lymphoma, hepatosplenic T cell lymphoma, splenic marginal B cell lymphoma, mantle cell lymphoma, hairy cell leukemia, multiple myeloma
Immune-related conditions	Systemic lupus erythematosus, rheumatoid arthritis, Gaucher's disease

- The increased portal venous pressure causes dilatation of sinusoids, with slowing of blood flow from the cords to the sinusoids that prolongs the exposure of the blood cells to the cordal macrophages, resulting in excessive trapping and destruction (hypersplenism).
- Perivascular hemorrhages result in organization and formation of Gamna-Gandy bodies (dystrophic calcification).

Surgical Pathology: Fibrocongestive Splenomegaly

Gross Morphology

- Spleen shows irregular tan-white fibrous plaques over the purple capsular surface.
- Cut surface of fibrocongestive splenomegaly shows firm and brown fibrotic nodules termed Gamna-Gandy bodies.

Light Microscopy

Gamna-Gandy body is an organized hemorrhage forming nodule with dystrophic calcification and hemosiderin pigment in spleen (Fig. 13.42).

HYPERSPLENISM

Hypersplenism refers to destruction of one or more blood cell lines by the spleen, which is characterized by splenomegaly, anemia, leukopenia, thrombocytopenia, bone marrow hyperplasia.

- Cytopenias occur due to sequestration of blood elements in the spleen, which can be corrected by splenectomy.
- Diagnostic criteria for hypersplenism include cytopenia of one or more cell lines, bone marrow hyperplasia, splenomegaly and correction of cytopenias following splenectomy. Disorders associated with hypersplenism are given in Table 13.37.

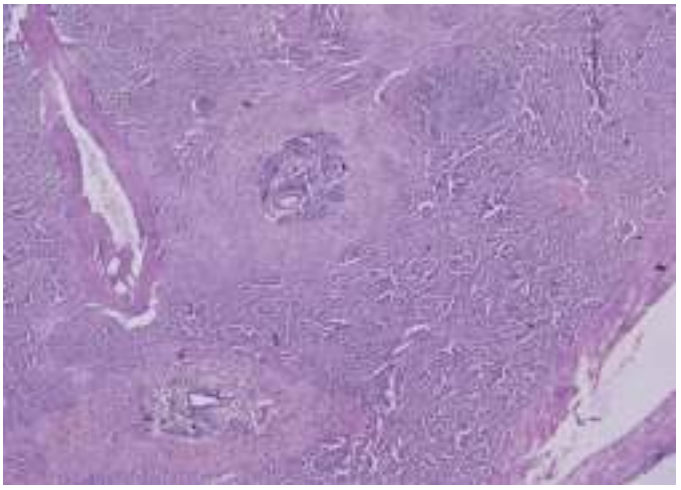

Fig. 13.42: Chronic venous congestion of spleen shows formation of Gamna-Gandy bodies as a result of organization of hemorrhage with dystrophic calcification and hemosiderin pigment in spleen (400X).

AUTOSPLENECTOMY

Sickle cell disease is important cause of autosplenectomy, which leads to susceptibility to disseminated infection with encapsulated bacteria such as pneumococci, meningococci, and *Haemophilus influenzae*.

HYPOSPLENISM

Hyposplenism refers to absence of functioning of spleen following splenectomy. Hematologic findings suggestive of hyposplenism are presence of Howell-Jolly bodies, poikilocytosis, target cells, acanthocytes, and nucleated red blood cells in the peripheral blood smear. Other causes of hyposplenism are Fanconi anemia and sickle cell disease, infiltrative disorders involving spleen and old age.

Table 13.37 Disorders associated with hypersplenism

Mechanism	Disorders
Abnormal sequestration of blood cells with intrinsic defects in normal spleen	Inherited disorders (hereditary spherocytosis and elliptocytosis), malaria, autoimmune hemolytic anemia, autoimmune thrombocytopenia and/or neutropenia
Sequestration of normal blood cells in abnormal spleen	▪ Gaucher's disease ▪ Niemann-Pick disease ▪ Langerhans' cell histiocytosis ▪ Chronic congestive splenomegaly ▪ Malignant infiltrative disorders (CML, AML, splenic marginal B cell lymphoma, mantle cell lymphoma, hairy cell leukemia, hepatosplenic T cell lymphoma, Hodgkin's disease, plasma cell dyscrasias, metastatic carcinoma) ▪ Extramedullary hematopoiesis (severe hemolytic states, chronic idiopathic myelofibrosis) ▪ Chronic infections (tuberculosis and brucellosis) ▪ Vascular tumors ▪ Splenic cysts ▪ Hamartomas
Miscellaneous conditions	▪ Hypogammaglobulinemia ▪ Hypothyroidism ▪ Progressive multifocal leukoencephalopathy

SPLENOSIS

Splenosis refers to splenic implants of splenic tissue over the peritoneal surface, pleural surface, and lung parenchyma following trauma or surgical procedure for splenectomy.

SPLENIC RUPTURE

Splenic rupture most often results from blunt injury to abdominal organs. The hemorrhage can extend into the peritoneal cavity to produce hemoperitoneum. Spontaneous rupture of spleen following minor trauma may occur due to malaria, infectious mononucleosis, subacute bacterial endocarditis, lymphoid neoplasms and typhoid fever.

HEMOSIDEROSIS OF SPLEEN

Thalassemia major is important cause of hemosiderin deposition in spleen, liver, pancreas, myocardium, adrenal glands and pituitary gland. The hemosiderin is deposited as refractile granular golden brown pigment in macrophages lining sinusoids in spleen. Hemosiderin is demonstrated by Pearl's Prussian stain.

REACTIVE SPLENIC DISORDERS

GRANULOMATOUS INFLAMMATION OF SPLEEN

Granuloma in spleen is focal benign process ranging from lipogranulomatous inflammation to caseating and noncaseating inflammation. Caseating granulomas occur due to Mycobacterium tubercle bacilli, fungal infection and X-linked chronic granulomatous disease. Noncaseating granulomas are most often demonstrated in sarcoidosis.

SPLENIC INFARCT

Splenic infarct occurs as a consequence of systemic arterial embolization in a patient with an infective endocarditis involving either aortic or mitral valve.

Wedge-shaped Splenic Infarct

Most splenic infarcts are due to emboli that arise from thrombi in the heart, either cardiac vegetations on valves or mural thrombi.

- Emboli from infective endocarditis lead to septic infarct in spleen, which reach the spleen via splenic artery and obstruct splenic branches resulting in ischemic wedge-shaped infarct with base towards capsule.
- The remaining splenic parenchyma appears dark red. This wedge-shaped infarct gets replaced by granulation tissue resulting into fibrous scar. Patient presents with left upper quadrant pain and splenic enlargement.

Nonwedge-shaped Splenic Infarcts

Nonwedge-shaped splenic infarcts are most often occur in essential thrombocythemia and myelofibrosis. Less common causes are paroxysmal nocturnal hemoglobinuria, sickle cell anemia, aplastic anemia, polyarteritis nodosa and splenic artery aneurysm.

NON-NEOPLASTIC INFILTRATIVE DISORDERS OF SPLEEN

Non-neoplastic disorders involving the spleen are given in Table 13.38.

GAUCHER'S DISEASE INVOLVING SPLEEN

The enlarged Gaucher's spleen is pale and has a firm feel. It is an autosomal recessive disorder error of metabolism due to lack of the enzyme glucocerebrosidase, resulting in accumulation of storage product in cells of the mononuclear phagocyte system.

Table 13.38 Non-neoplastic disorders involving the spleen

Pattern of Involvement of Spleen	Non-neoplastic Disorders
White pulp involvement (reactive lymphoid hyperplasia with or without germinal centers)	▪ Castleman disease ▪ Common variable immunodeficiency state ▪ Autoimmune lymphoproliferative syndrome
Red pulp involvement	▪ Gaucher's disease ▪ Niemann-Pick disease ▪ Extramedullary hematopoiesis
Cystic lesions	▪ *Echinococcus granulosus* ▪ *Histoplasma capsulatum* ▪ Coccidioidomycosis ▪ Miliary tuberculosis ▪ Lipogranuloma
Granulomatous disorders	▪ Infectious mononucleosis (EB virus) ▪ Malarial parasite ▪ *Mycobacterium avium intracellulare* ▪ Cytomegalovirus ▪ Pyogenic bacterial infections

- **Hallmark of Gaucher's disease:** The hallmark of Gaucher's disease is the presence of Gaucher's cells with a distinctive cigarette paper-like cytoplasmic appearance and eccentric nuclei.
  - Gaucher's cells are lipid-laden macrophages present in the red pulp of the spleen, liver sinusoids (Kupffer cells), lymph nodes, lungs (alveolar macrophages), and bone marrow.
  - Gaucher's cells contain specific enzymes such as chitotriosidase and angiotensin-converting enzyme. These Gaucher's disease enzyme markers of macrophage proliferation assay are required to confirm the diagnosis.
- **Clinical variants of Gaucher's disease:** Gaucher's disease has three variants: adult type (normal life span), infantile type (fatal disease) and juvenile type (less severe).

SPLEEN INVOLVEMENT IN AMYLOIDOSIS

Deposition of amyloid in spleen results in splenomegaly. Gross examination shows diffuse lardaceous pattern or the nodular sago pattern due to amyloid deposition (AL or AA) in **white pulp**.

NEOPLASTIC DISORDERS OF SPLEEN

Considering spleen's size and blood flow, the spleen is uncommon site for either primary hematologic malignant disorders (leukemias) or metastatic malignancies (extranodal Hodgkin's disease and NHL) due to immunological role of spleen.

- Spleen involved due to Hodgkin's and non-Hodgkin lymphoma (NHL) shows multiple nodular pale deposits.
- Splenic masses are more likely due to hematologic diseases (leukemias) rather than metastases. Neoplastic disorders of spleen according to recent 2024 World Health Organization are given in Table 13.39.

Table 13.39 Neoplastic disorders of spleen according to recent 2024 World Health Organization

Disorder	Origin	Spleen Morphology	Other Characteristics
Primary splenic lymphoma			
Primary splenic lymphoma	B or T cells	Diffuse large B cell lymphomas (origin germinal center or post-germinal center B cell) with single or multiple nodules of varying size	Diverse chromosomal rearrangement, BCL-6 (30%), BCL-2 (10%) and Myc (5%)
Secondary splenic lymphomas			
Hodgkin's disease (classic variant)	B cells Reed-Sternberg cells are CD30+ (Ki-1) specific marker, CD15+ (Leu M1)	Splenomegaly	Prognosis varies depending on variants and staging

Contd...

Table 13.39 Neoplastic disorders of spleen according to recent 2024 World Health Organization (*Contd...*)

Disorder	Origin	Spleen Morphology	Other Characteristics
Low grade non-Hodgkin's lymphoma	B or T cells	Splenomegaly (single or multiple nodules)	50% of cases show splenomegaly and splenic lymph nodes involvement
Lymphomas presenting with prominent lymphadenopathy			
Splenic marginal B cell lymphoma	B cells	Massive splenomegaly (infiltration in both red and white pulp)	Allelic loss of chromosome 7q31–32 in 40% of cases, trisomy 3 in rare cases, IgH clonally rearranged Peripheral cytopenias
Mantle cell lymphoma	Naïve B cell	Prominent splenomegaly	t(11;14) creating cyclin D1-IgH fusion gene
Hairy cell leukemia	Memory B cell	Prominent splenomegaly	Activating FRAF mutations, rearrangement of IgH
Hepatosplenic T cell lymphoma	T cell	Triad of peripheral cytopenias, sinusoidal tropism and massive splenomegaly (>3000 gm)	Isochrome 7q10 and trisomy 8 strong genetic abnormality
Myeloid neoplasms involving spleen			
Chronic myeloid leukemia with blast crisis	Pluripotent stem cell	▪ Leukemic cells are confined to bone marrow and spleen. Bone marrow and blood contain <10% myeloblasts ▪ Anemia, massive splenomegaly and hepatomegaly. Splenomegaly correlates with magnitude of leukocytosis	Philadelphia chromosome t(9;22)
Acute myeloid leukemia	Myeloid cell	Anemia, neutropenia (recurrent upper respiratory tract infections) and thrombocytopenia (bleeding tendencies), bone tenderness, mild to moderate hepatomegaly and splenomegaly	AML with recurrent genetic alterations
Mast cell disease with systemic mastocytosis	Mast cell	Spleen frequently involved (both red and white pulp involved)	Flow cytometry helpful in establishing diagnosis

SPLENIC MARGINAL ZONE LYMPHOMA

Splenic marginal zone lymphoma (SMZL) is derived from B cell and composed of small lymphocytes replacing splenic white pulp germinal centers and effacing follicle mantle zone. There is presence of transformed blasts, both small and large cells in the red pulp of spleen. SMZL most often involves spleen, splenic hilar lymph nodes, bone marrow and peripheral blood. SMZL cells are frequently demonstrated in the peripheral blood as villous lymphocytes.

- **Epidemiology:** Splenic marginal zone lymphoma constitutes 2% of lymphoid neoplasms, which most often involves adults >50 years of age. Both men and women are equally affected.
- **Localization of disease:** Splenic marginal zone B cell lymphoma involves spleen, splenic hilar lymph nodes, bone marrow and peripheral blood.
- **Clinical features:** Patient most often presents with splenomegaly and sometimes, autoimmune thrombocytopenia and peripheral blood villous lymphocytes. Bone marrow is involved in almost all cases. Peripheral lymphadenopathy is extremely uncommon.

Surgical Pathology: Splenic Marginal Zone Lymphoma

Gross Morphology

Gross examination of the splenic marginal zone lymphoma shows marked expansion of white pulp and infiltration of red pulp by tumor cells.

Light Microscopy

- Normal architecture of spleen is affected by neoplastic cells present in white pulp's mantle zone.
- Tumor cells are small- and medium-sized with dispersed chromatin and pale cytoplasm admixed with transformed cells.

Immunophenotyping

- Tumor cells express surface IgM and IgD. These tumors are positive for CD20 and CD79a.
- Ki-67 staining shows targetoid pattern due to increased growth fraction in both the germinal center as well as marginal zone.
- Tumor cells are negative for CD5, CD10, CD 23, CD43 and annexin-A1.
- SMZL is distinguished by the presence of lymphocytosis and diffuse infiltration of bone marrow by tumor cells.

Markers	Expression
Surface IgM and IgD	Positive
CD20	Positive
CD79a	Positive
Ki-67	Positive
CD5	Negative
CD10	Negative
CD23	Negative
CD43	Negative
Annexin-A1	Negative

- **Molecular genetic alterations:** Antigen receptor genes, e.g. immunoglobulin heavy and light chains, show clonal rearrangements in 50% of splenic marginal zone lymphoma (SMZL) cases. Somatic hypermutation of antigen receptor gene is demonstrated in half of the patients.
  - SMZL lacks recurrent chromosomal translocations.
  - NOTCH2 gene mutation is demonstrated in 10–25% of cases.
  - Few cases of SMZL show recurrent t(2;7) (p12; q21) translocations.
- **Prognosis of disease:** Clinical course of splenic marginal zone lymphoma is indolent with a 10-year survival in >70% of cases. Approximately 10–15% of cases undergo transformation to diffuse large B cell lymphoma (DLBCL) associated with poor prognosis.
- Prognosis is poor in cases with poor general health and large tumor mass.
- NOTCH2, TP53 and KLF2 gene mutations are adverse prognostic factors.

METASTASES IN SPLEEN

Despite its size, the spleen is a rare site for metastases from nonhematological malignancies. Melanomas are aggressive neoplasms that can often be widely metastatic. Most of these masses are tan, but some have brown-black pigmentation from the melanin elaborated by the neoplastic cells.

The most common epithelial malignancies metastasizing to spleen are carcinomas of breast and lung origin. Sarcomas involving the spleen tend to be of dendritic/histiocytic or vascular lineage. Carcinoma metastasizing to spleen is shown in Fig. 13.43.

ANGIOSARCOMA OF SPLEEN

Angiosarcoma is malignant proliferation of primitive mesenchymal cells with vascular differentiation.

Fig. 13.43: Carcinoma metastasizing to spleen (arrows).

DISORDERS OF THYMUS GLAND

ANATOMY AND HISTOLOGY OF THYMUS GLAND

ANATOMY

Thymus gland situated in the anterior mediastinum of the chest is prominent during third trimester (late fetal life), infancy and childhood. It is populated with T cells. During late fetal life, progenitor cells of bone marrow origin migrate to the thymus and give rise to mature T cells that are exported to the peripheral lymphoid organs. Thymus undergoes atrophy during adulthood. Anterior compartment is most common site for mediastinal masses in >50%. Primary tumors of the mediastinum include thymoma, neurogenic tumors, germ cell tumors and lymphoma. Primary lung cancer can invade mediastinum. Summary of mediastinal masses is given in Table 13.40.

HISTOLOGY

On histologic examination, thymus gland consists of cortex and medulla. Cortex consists of large cells with prominent nucleoli in the superficial zone. In the

Table 13.40 Summary of mediastinal masses

Mediastinum Compartment	Pathological Disorders
Anterior mediastinum	Thymic tumors, retrosternal thyroid mass, germ cell tumors, lymph nodes (lymphomas), cystic hygroma, aortic aneurysm, hernia (Morgagni), pericardial cysts, sternal masses
Middle mediastinum	Lymph nodes (sarcoidosis, tuberculosis, lymphomas, metastases), aortic aneurysm, mediastinal paraganglioma, carcinoma bronchus, fatty mediastinal tumors, mediastinal lipomatosis, hiatal hernia
Posterior mediastinum	Myeloma, metastases, aortic aneurysm, sympathetic ganglion cell tumors, lateral thoracic meningocele, paravertebral abscess, extramedullary hematopoiesis, pancreatic pseudocyst

deeper zone, the cells are small with less prominent nucleoli. Medulla consists of spindle cells with densely stained nuclei and inconspicuous nucleoli. Hassall corpuscles composed of epithelial cells are present in the center of the medullary regions. These become keratinized on enlargement. Thymus also consists of macrophages, dendritic cells, a few B cells; rare neutrophils and eosinophils.

THYMUS HYPERPLASIA

Normally, adult thymus is composed mostly of adipose tissue, with a few clusters of lymphocytes and residual Hassall corpuscles. Approximately 75% of patients diagnosed with myasthenia gravis demonstrate thymic hyperplasia composed of lymphoid cells associated with autoantibody production. These autoantibodies bind to acetylcholine receptor and diminish the receptor function in the skeletal muscle motor end plates, resulting in onset of muscular weakness, particularly with repetitive muscular contraction (Fig. 13.44).

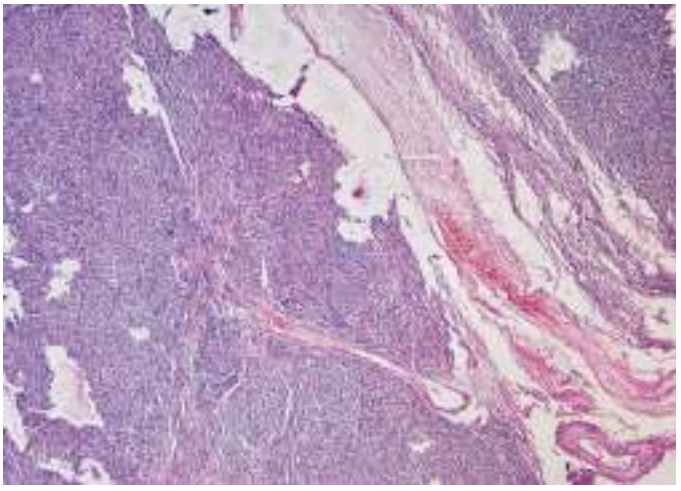

Fig. 13.44: Thymic hyperplasia is composed of lymphoid cells (100X).

Clinical Features

Affected children develop recurrent infections (bacterial, fungal and viral) and tetany from hypoparathyroidism with hypocalcemia.

IMMUNODEFICIENCY DISORDERS OF THYMUS GLAND

DiGEORGE SYNDROME

In DiGeorge syndrome, there is failure of maturation of T cells, but B cells remain unaffected. Thymus gland shows hypoplasia.

- In DiGeorge syndrome, aberrant embryonic development of third and fourth branchial arches, results in hypoplasia of thymus and parathyroid glands as well as anomalies of aortic arch, mandible and ear.
- It can be summed up by **CATH22**, which denotes cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia and microdeletion of chromosome **22q11**.
- In about 30% of cases, this syndrome is also associated with behavior disorders and psychosis (bipolar disorder and schizophrenia) that develop during adolescence.

WISKOTT-ALDRICH SYNDROME (X-LINKED DISORDER)

Wiskott-Aldrich syndrome is X-linked disorder associated with defects of both B cell and T cell functions (humoral and cellular immunity). It is associated with thymic hypoplasia, eczema, thrombocytopenia, bloody diarrhea, recurrent infections and poor antibody response to polysaccharide antigens. Patient has fatal outcome before six years of age due to bleeding, infection or malignancy (most often lymphoma).

Surgical Pathology: Wiskott-Aldrich Syndrome

Light Microscopy

Thymus gland shows hypoplasia characterized by absence of thymocytes. A few Hassall corpuscles, and only epithelial components may be present.

THYMIC NEOPLASMS

Neoplasms of the thymus gland are thymoma, thymic carcinoma and neuroendocrine tumors including thymic carcinoid. Revised 2024 WHO classification of tumors of thymus gland is given in Table 13.41.

Table 13.41 Revised 2024 WHO classification of tumors of thymus gland

Thymoma	
▪ Thymoma type A	▪ Micronodular thymoma
▪ Thymoma type AB	▪ Microscopic thymoma (rare)
▪ Thymoma type B1	▪ Sclerosing thymoma (rare)
▪ Thymoma type B2	▪ Lipofibroadenoma (rare)
▪ Thymoma type B3	▪ Thymoma C
▪ Metaplastic thymoma	
Thymic Carcinoma	
▪ Squamous cell carcinoma	▪ Lymphoepithelioma-like carcinoma
▪ Basaloid carcinoma	▪ NUT carcinoma
▪ Mucoepidermoid carcinoma	▪ Undifferentiated carcinoma
▪ Sarcomatoid carcinoma	▪ Adenosquamous carcinoma (rare)
▪ Clear cell carcinoma	▪ Hepatoid carcinoma (rare)
▪ Adenocarcinoma (papillary, mucinous, not otherwise specified and adenoid cystic subtypes)	▪ Thymic carcinoma, not otherwise specified
Thymic Neuroendocrine Tumors	
▪ Carcinoid tumor (typical and atypical)	
▪ Large cell neuroendocrine carcinoma (combined large cell neuroendocrine carcinoma)	
▪ Small cell neuroendocrine carcinoma (combined small cell neuroendocrine carcinoma)	
Ectopic Tumors of Thymoma	
▪ Ectopic thyroid tumor	▪ Other rare ectopic tumors
▪ Ectopic parathyroid tumor	

Adapted from 2024 WHO classification of tumors of thymus gland.

THYMOMA

Thymoma is most common primary anterior mediastinal tumor. It is most often located in anterosuperior mediastinum.

- All thymomas, regardless of histology, are associated with invasion and metastases. Reliable indicator of thymoma malignancy is capsular invasion by tumor cells.
- In recent years, histologic classification of thymoma and clinical staging are considered important prognostic factors.
- Poor prognostic factors for thymoma include high stage, B3 or C classification, invasion of capsule and positive tumor margins. Weakly overexpression of podoplanin may predict lymph node metastasis and poor clinical course.
- Thymoma may develop in newborns to elderly persons of >90 years of age.
- There is some correlation between WHO classification of histologic variants of thymoma having aggressive behavior with invasive features. Revised 2024 WHO classification of thymomas (A, B1, B2, B3, AB and C system) is given in Table 13.42.

Clinical Features

Patient presents with clinical manifestations associated with myasthenia gravis such as muscular weakness of the arms and legs, facial drooping of upper eyelid, difficulty in speaking swallowing, double vision and

Table 13.42 WHO classification of thymomas (A, AB, B1, B2, B3 and C system)

WHO Type Categories	Histologic Type	Morphologic Features	Frequency (%)	Invasiveness (%)
A	Medullary type thymoma	▪ Predominantly spindle cells arranged in diffuse or hemangiocytic-like pattern ▪ Lymphocytes absent	8	10
AB	Mixed thymoma	Mixed spindle and epithelial cells	30	40
B1	Predominantly cortical thymoma	▪ Lymphocytes rich without atypical epithelial cells with or without Hassall's corpuscles ▪ Morphology of lymphocytes similar to normal thymus glands	15	45
B2	Cortical thymoma	▪ Higher epithelial cell/lymphocyte ratio with presence of more atypical neoplastic cells ▪ Epithelial cells are polygonal forming lobules and separated by immature T cell	28	70

Contd...

Table 13.42 WHO classification of thymomas (A, AB, B1, B2, B3 and C system) (*Contd...*)

WHO Type Categories	Histologic Type	Morphologic Features	Frequency (%)	Invasiveness (%)
B3	Well differentiated thymic carcinoma	▪ Atypical epithelial cells, polygonal in shape ▪ Atypical epithelial cells are arranged in sheets with minimal lymphocyte components	11	85
C	Nonorganized thymic carcinoma	Nonorganized thymic carcinoma with squamous, lymphoepithelial, clear cell, mucoepidermoid, basaloid, papillary, mucinous or sarcomatoid differentiation	5	5

Adapted from 2024 WHO classification.

fatigue, symptoms related to tumor mass such as chest pain, cough, hoarseness of voice, and pneumonia; and nonmyasthenic paraneoplastic syndrome.

- Thymomas may be associated with pure red cell aplasia, hypogammaglobulinemia, lymphopenia, rheumatoid arthritis, scleroderma, Sjögren's syndrome and systemic lupus erythematosus.
- Significant number of thymoma cases may be asymptomatic, and are diagnosed during routine X-ray chest, CT scan, cardiothoracic surgery and autopsy findings.
- Approximately 65–75% patients are often associated with myasthenia gravis due to autoantibodies against acetylcholine receptors in the motor end plates of skeletal muscles (type II hypersensitivity reaction).
  - The antibodies bind to postsynaptic receptors and block neurotransmission resulting in progressive skeletal muscle weakness involving particularly the external ocular, eyelids and proximal limb muscles. It may cause death due to respiratory muscles paralysis.
  - Thymectomy may reduce the plasma concentrations of autoantibodies and improve clinical picture.

Surgical Pathology: Thymoma

Gross Morphology

- Tumor is well circumscribed, encapsulated and firm.
- Invasive thymoma has poorly-defined edges and tend to ensheath blood vessels and neighboring organs within the mediastinum.
- Average weight of tumor is 150 g. It may weigh up to several kilograms.

Light Microscopy

- Thymoma is composed of neoplastic epithelial cells admixed with non-neoplastic thymic lymphocytes (Fig. 13.45).
- Histologic features of thymoma depend on morphology of cells based on categories defined by revised 2024 WHO classification (A, B1, B2, B3, AB and C). Histologic variant A of thymoma has indolent variant. Other B2 and B3 types are more invasive. Thymic carcinoma or type C is regarded as separate distinctive category of thymoma. Neoplastic epithelial cells may be either spindle on nonspindle shape. Clinicopathological staging of thymoma according to Masaoka is given in Table 13.43.
  - Spindle neoplastic epithelial cells of thymoma are demonstrated in A and AB subtypes. This variant has indolent behavior. It may be associated with hematological malignancies.
  - Nonspindle neoplastic epithelial cell variant of thymoma is also known as cortical thymoma. Epithelioid neoplastic cells are demonstrated in B1, B2 and B3.
- Further subdivision of thymoma depends on the content of neoplastic epithelial cells and non-neoplastic immature T cells.
  - Type A thymoma is composed of densely packed spindle cells admixed with immature T cells.
  - Type B3 thymoma shows sheets of polygonal neoplastic epithelial cells.
  - Types AB, B1 and B2 thymomas show variable and reciprocal content of immature T cells.
- Confirmation of immature T cells is confirmed by CD1a, TdT and CD99.

Immunophenotyping

Neoplastic cells of thymoma show positivity for CK7, CD15 and BCL-2.

Markers	Thymoma According to WHO (ABC System)	Expression
▪ CK7 ▪ CD15 ▪ BCL-2	▪ Type A ▪ Type A ▪ Types A and C	▪ Positive ▪ Positive ▪ Positive

- CK5, CK6 and CK7 are positive in both thymoma and thymic carcinoma.
- CK18, CD5, CD117, MUC1 and GLUT-1 are positive in thymic carcinoma.

- **Laboratory diagnosis:** Most thymomas can be detected by imaging techniques, and confirmed on histologic examination of biopsy from thymoma. Features for laboratory diagnosis of thymoma are given in Table 13.44. Thymoma on imaging technique is shown in Fig. 13.46.

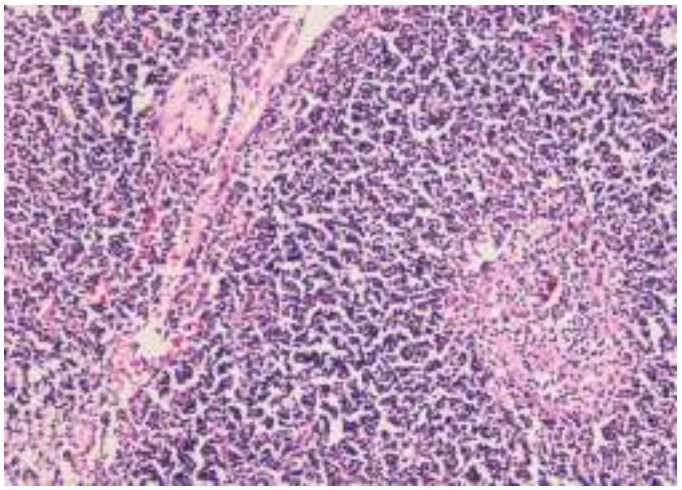

Fig. 13.45: Thymoma is a neoplasm of thymic epithelial cells. Cytologically, bland epithelial cells are admixed with non-neoplastic thymic lymphocytes (100X).

Fig. 13.46: Thymoma on imaging technique. Thymoma presents as sharply demarcated round to oval soft tissue mass in the anterior mediastinum compartment.

Table 13.43 Clinicopathological staging of thymoma according to Masaoka

Stages	Qualifying Features	5-year Survival (%)
I	Completely encapsulated tumor without invasion of capsule	95–100
II	Gross invasion of tumor into surrounding soft tissues or mediastinal pleura and/or microscopic invasion into capsule	80–85
III	Gross invasion of tumor into pericardium, lung and great vessels (intraoperative biopsy obtained for confirmation)	60–70
IVa	Dissemination of tumor to pericardium and/or pleura without contiguous spread as in stage III	40–50
IVb	Distant metastases of tumor to lung, liver, bone and skin	25–30

Table 13.44 Features for laboratory diagnosis of thymoma

Parameters	Diagnostic Features
Terminal deoxynucleotidyl transferase (TdT)	Positive in all stages
T cell markers	Positive for CD1, CD2, CD3, CD4, CD5, CD7, CD8 depend on the stage of thymoma
Common thymocyte stage, positivity for	CD1, CD4, CD8 (most common)
CD117 (KIT)	▪ Positive for thymic carcinoma ▪ Negative for thymoma
Immunophenotyping	▪ Positive for thymic carcinoma ▪ Negative for leukocyte common antigen (LCA)
Electron microscopy	Presence of desmosomes and tonofilaments
TCR gene rearrangement	Germline or deletion

- **Treatment:** Diagnosis and treatment of thymoma are best achieved by complete excision of thymus gland along with tumor.

THYMIC CARCINOMA

Thymic carcinoma is a rare but highly aggressive and easily metastasizing neoplasm derived from thymic epithelial cells. It constitutes 5% of all primary neoplasms of thymus gland. It occurs most frequently in adults between 30 and 60 years of age. It arises *de novo* in the thymus gland.

- Thymic carcinoma presents as multilocular cyst. Unlike thymoma, thymic carcinoma is associated with paraneoplastic syndrome.
- Thymic carcinoma is almost always found at an advanced stage because patients often have atypical symptoms. Gross morphology of thymic carcinoma is shown in Fig. 13.47.

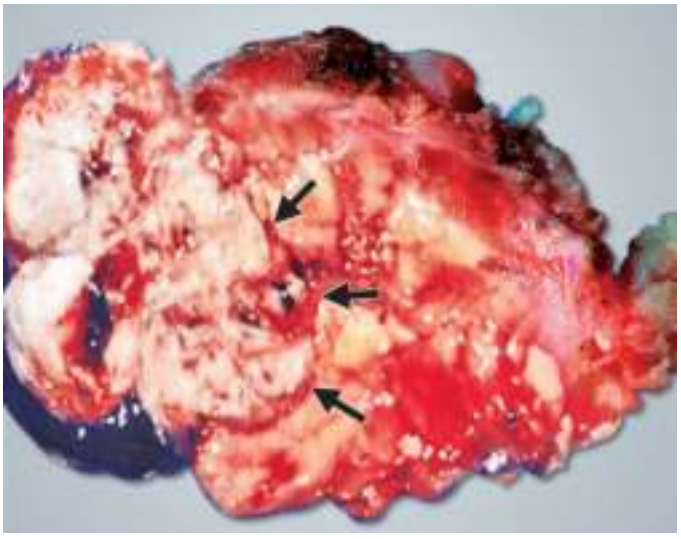

Fig. 13.47: Gross morphology of thymic carcinoma. Cut surface of thymic carcinoma reveals gray-white, firm to hard, gritty with areas of hemorrhage and necrosis (arrows).

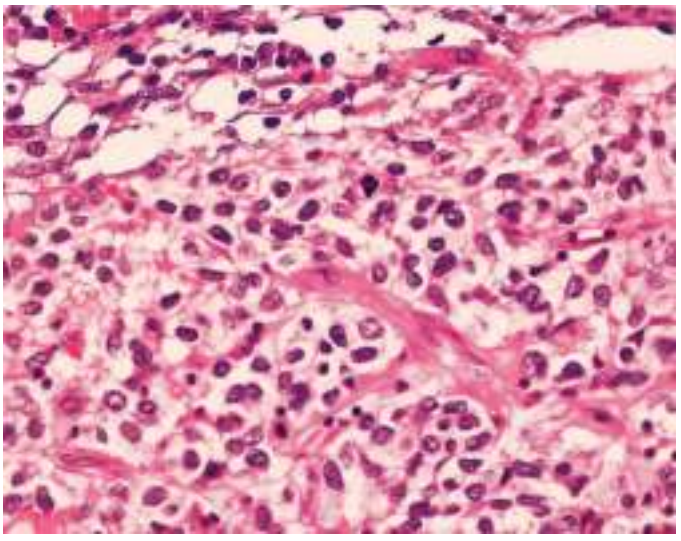

Fig. 13.48: Thymic carcinoma is composed of undifferentiated neoplastic cells (400X).

Surgical Pathology: Thymic Carcinoma

Gross Morphology

Thymic carcinoma is uncapsulated tumor without internal fibrous separation. Cut surface is gray-white, firm to hard, and gritty with areas of hemorrhage and necrosis.

Light Microscopy

- Most common histologic variant of thymic carcinoma is composed of undifferentiated neoplastic cells with or without squamous differentiation.
- There may diverse histopathologic features such as basaloid, adenoid cystic, papillary, clear cell, lymphoepithelial-like or adenocarcinoma type (Fig. 13.48).

Immunophenotyping

Immunophenotyping of thymic carcinoma is shown below. Differential diagnosis of atypical thymoma, thymic carcinoma and lung carcinoma is given in Table 13.45.

Markers	Expression
▪ BCL-2	▪ Positive
▪ CK5	▪ Positive
▪ CK6	▪ Positive
▪ CK7	▪ Positive
▪ CK18	▪ Positive
▪ CD5	▪ Positive
▪ CD117	▪ Positive
▪ MUC1	▪ Positive
▪ GLUT-1	▪ Positive

CK5, CK6 and CK7 are positive in both thymoma and thymic carcinoma.

- Complete resection of the thymic carcinoma is the mainstay of treatment and leads to the best survival rate for patients. However, the complete resection rate is only approximately 50% and the recurrence rate after complete resection is high, up to 40%.

Table 13.45 Differential diagnosis of atypical thymoma, thymic carcinoma and lung carcinoma

Immunophenotyping	Atypical Thymoma	Thymic Carcinoma	Lung Carcinoma
CK7	Positive	Positive	Positive/negative
CD5	Negative	Positive	Negative
CD117	Negative	Positive	Negative
CD1a	Positive in immature thymocytes	Negative	Negative
TTF-1	Negative	Negative	Positive
CD205	Positive	Positive	Positive/negative
FOXN1	Positive (nuclear staining)	Positive (nuclear staining) or negative	Negative

Annexure

Diagnostic workup of Hodgkin disease

- **Clinical history:** Patient (young or >55 years) presents with painless, discrete, and swollen multiple lymph nodes in cervical region, chest pain, cough, shortness of breath and constitutional B symptoms such as intermittent fever >38°C, night sweats, unexplained weight loss (>10% within 6 months), fatigue, recurrent infections, and pruritus. There is family history of development of nodular sclerosis classic variant Hodgkin disease.
- **Physical examination:** Physical examination revealed multiple, painless, and palpable lymph nodes in cervical, axillary, and inguinal regions. Chest tenderness, wheezing and superior vena cava syndrome indicate compression by thoracic mass. Abdominal examination reveals abdominal tenderness, splenomegaly, and hepatomegaly.
- **Imaging techniques:** Ultrasonography and thorax and abdominal computed tomography scan of revealed multiple lymph nodes in the neck, supraclavicular region, and mediastinum. Fluorodeoxyglucose positron emission tomography (FDG-PET) scan revealed marked hypermetabolic lymph nodes, multiple scattered consolidation involving the bones.
- **Laboratory investigations:** The laboratory results showed increased sedimentation rate and C-reactive proteins and neutrophilic leukocytosis.

1. **What is the most likely diagnosis?**

   Answer: Hodgkin disease. Hodgkin disease is follicular center B cell lymphoid malignancy and has two distinct entities: (a) **classic variants of Hodgkin disease** with positive CD30 and CD15 markers (e.g. nodular sclerosis, mixed cellularity, lymphocyte depletion, and lymphocyte-rich); and (b) **nodular lymphocytic-histiocytic predominant variant of Hodgkin disease** with negative CD30 and CD15 markers. Fluorodeoxyglucose positron emission tomography (FDG-PET) radiographic diagnostic tool has emerged in staging. PD-L1 expression and MHC class II positivity on Reed-Sternberg cells are indicative of favorable prognosis after PD-1 blockade. As a rule, patients with early-stage classic variant of Hodgkin disease (stages I–IIa) are treated with combined chemotherapy followed by involved-field radiation therapy (IFRT) in most cases.

2. **What is pathogenesis of Hodgkin disease?**

   Answer: Epstein-Barr virus plays important role in the pathogenesis of Hodgkin disease, which protects Reed-Sternberg cells from apoptosis and CD8+ cytotoxic T cells, which would ordinarily destroy these cells. EBV may cause mutation in the TP53 tumor suppressor gene. Human immunodeficiency virus positive patients are associated with advanced-stage disease at unusual sites and associated with poor outcome after therapy.

3. **What is diagnostic hallmark of Hodgkin disease?**

   Answer: The initial diagnosis of Hodgkin disease can only be confirmed by histologic examination of lymph node biopsy and bone marrow trephine biopsy. The architecture of lymph node is extremely important for an accurate diagnosis. Presence of Reed-Sternberg cells (classic or lacunar, or mononuclear) is the pathologic hallmark of Hodgkin disease.

Textbook of Pathology

General Pathology & Hematology

2nd Edition

Volume I

Second Edition of ***Textbook of Pathology*** has been designed for undergraduate and postgraduate medical students, and aspirants for postgraduate courses and related health sciences.

Textbook of Pathology has three sections: (a) general pathology, (b) hematology, (c) systemic pathology and molecular diagnostics. It provides comprehensive coverage of etiology, molecular pathogenesis of the disorders, clinical manifestations, clinicopathological correlation and diagnostic approach.

The chapters of this textbook have been rewritten and shared with the eminent teachers, and young promising postgraduate residents across nation. After taking their valuable suggestions, chapters have been finalized to meet the need of young generation of pathologists.

An unrivaled collection of high-resolution lavishly colored illustrations/photographs of surgical pathology and hematolymphoid disorders have complemented the clear concise text.

Salient Features

- Textbook has unrivaled collection of high-resolution lavishly 1901 colored figures and 1719 tables complementing the clear concise text.
- Textbook has clinical photographs, schematic illustrations, flow diagrams, gross morphologic and microscopic photographs of surgical specimens, and photographs of peripheral blood smear, bone marrow aspirate smear and bone marrow trephine biopsy section to understand clinicopathologic correlation of human disorders and diagnostic approach.
- Textbook has reader-friendly large font-size of the text for quick revision of chapters.
- Revised WHO classification of solid neoplasms and hematolymphoid malignancies is given in this textbook.
- Chapters on 'Cellular–Molecular Diagnostic Techniques in Clinical Practice' and 'Blood Banking and Transfusion Practices'.
- Recent concepts in cellular biology with key points of the disorders are given in boxes in the chapters.
- Immunohistochemistry of surgical specimens and immunophenotyping of hematolymphoid neoplasms have been given in tabulated forms.

Vinay Kamal has more than three-decade of teaching experience at India's premier institution, while serving as Director Professor, Department of Pathology, Maulana Azad Medical College, New Delhi. An alumnus of Post Graduate Institute of Medical Sciences (PGIMS), Rohtak, Haryana, he has also served in the premier institute. He has published articles in national and international journals. Budding medical professionals Dr Anubhav and Dr Vigyat have put sincere efforts in the completion of *Textbook of Pathology*.
