Dedication

Dedication of this small work on Second Edition of Textbook of Pathology to the great scientists Juan Rosai (Rosai and Ackerman's Surgical Pathology), and Christopher DM Fletcher (Diagnostic Histopathology of Tumors), whose profound contribution to the field of Pathology has touched countless lives. Their legacy will continue to inspire and educate the generation of pathologists.

Dedication to our worthy teachers for teaching basics of pathology and excellence in medicine, Esteemed Faculty Members, and promising undergraduate and postgraduate Medical Students for enduring inspiration and encouragement, while working on Second Edition of Textbook of Pathology.

Dr Vinay Kamal
Dr Anubhav
Dr Vigyat

Dedication

Second Edition of Textbook of Pathology is dedicated to our family, who inspired, supported, encouraged, and patiently endured long hours of inattention and hearing from me during the creation of this final project to achieve an academic career. But for their understanding, it would be difficult to get away with the disproportionate amount of time that such projects consume.

Dr Mrs Manita Kamal

Siya Kamal

Dr Anubhav

Dr Vigyat

Dr Spriha Arun

Dr Mansi Siddharth Dhende

Contents

Section I: General Pathology

Section II: Hematology

Section III: Systemic Pathology and Molecular Diagnostics

Preface to the Second Edition

Rudolph Virchow (1821–1902) is the father of 'Cellular Pathology' in terms of the dysfunction of cells. Many pathologic observations are being published in the Textbooks and Journals by great authors across world. Their outstanding contribution in the field of medical practice and education has been a great source of inspiration.

Second Edition of *Textbook of Pathology*, extensively revised, updated with recent developments as needed and amended as per the 'Competency-Based Medical Education Curriculum' is intended to provide undergraduate and postgraduate medical students with clear, and concise presentation of the pathologic basis of the human disorders.

The field of pathology emerged from the application of the scientific method to study of nature, etiology, molecular mechanism, and interrelated anatomical, functional, clinical manifestations and consequences of human diseases through examination of blood and tissue specimens.

The description of the human disorders evolved over time from gross morphology observation to the histologic examination of the diseased tissues based on the specific immunohistochemical stains, immunofluorescence microscopy, immunophenotyping, fluorescence *in situ* hybridization, molecular diagnostics and more recently to ultrastructural analysis of the disease with the advent of electron microscope. Thus, molecular pathology as a discipline represents the complementary intersection of medicine and basic science discoveries and the basis for the development of new strategies for disease prevention.

Textbook of Pathology has three sections: (i) General Pathology, (ii) Hematology including chapter on 'Blood Banking and Transfusion Practices', and (iii) Systemic Pathology and Molecular Diagnostics. This textbook contains approximately 1901 high-resolution colored figures and 1719 tables, which would complement quick revision of the chapters. It provides comprehensive coverage of etiology, molecular pathogenesis of human disorders, clinical manifestations, clinicopathological correlation and diagnostic approach.

Pathology is the fundamental bridging discipline linking the basic biomedical sciences to clinical medicine. Therefore, our basic aim is for our undergraduate as well as postgraduate medical students to use their knowledge of pathology to become scientifically grounded effective clinicians and healthcare professionals.

We hope that *Textbook of Pathology* will accomplish its purpose of providing medical students and researchers with in-depth coverage of molecular basis of a wide spectrum of human disorders in the context of understanding the molecular mechanisms of the disease and advancing the theory and practice of molecular medicine.

Preface to the First Edition

The study of pathology is essential for safe clinical practice. In modern era, tremendous growth is in progress in diagnostic pathology with recent advances in molecular methods, cytogenetics and immunohistochemistry. Rapidly changing hematology needs integration of guidelines and diagnostic criteria of hematological disorders.

I joined India's premier institution in Department of Pathology, Maulana Azad Medical College, New Delhi. I puzzled over the fact that students admitted of very high caliber still had problems in grasping the teaching material. I interacted with students and eminent faculty members across country. I discussed problems faced by the students in reproducing text. I analyzed their inputs and then started working on Textbook of Pathology in 2007. The primary aim of this book is to discuss complex topics in a 'straightforward', clear and organized manner.

All the chapters have been shared with the eminent teachers and young budding students across country. Their valuable opinion on various aspects has been taken positively during drafting of the chapters to meet the need of the young generation of pathologists. Each chapter focuses on the essentials necessary to build a broad fundamentals backed up with numerous colored figures, gross morphology, and light microscopy photographs, tables and flow diagrams.

I trust, you will enjoy reading this book. I have a great deal of time and energy ensuring easy grasp and retaining the topics. I am inviting your comments, valuable suggestions and criticism.

Foreword

It gives me great pleasure to write the Foreword for this wonderful Second Edition of *Textbook of Pathology* written by Dr Vinay Kamal, Ex-Director Professor of Pathology, Maulana Azad Medical College, New Delhi. His vast teaching experience for undergraduate and postgraduate medical students is well-known in the corridors in the premier institution, where medical students have interacted to seek the advice.

I have gone through many chapters of this *Textbook of Pathology* and find his unique teaching experience that has been successfully transformed into wonderful method of writing and communication. Textbook abounds with revised WHO classification of neoplasms, approximately 1901 high-resolution colored figures and 1719 tables, and molecular diagnostics that explain everything in simple language—always the best way to teach.

I have no doubt that this *Textbook of Pathology* will help undergraduate and postgraduate medical students to achieve a better understanding and create strong foundation for medical education.

Dr Venkateswaran K Iyer
Senior Professor and Head
Department of Pathology
All India Institute of Medical Sciences
New Delhi

Foreword

It is with great enthusiasm, I look forward to Second Edition of *Textbook of Pathology* written by Dr Vinay Kamal, Ex-Director Professor, Maulana Azad Medical College, New Delhi. The first edition of Textbook by him received a brilliant response from the undergraduate as well as postgraduate medical students throughout the country.

Bringing out the Second Edition of *Textbook of Pathology* within a short span of time, speaks volumes about the passion of the author to constantly update the information and share it in a presentable format to his medical students.

All the chapters of textbook have been updated with incorporation of revised WHO classification of neoplasms, new information on immunohistochemistry and molecular alterations. *Textbook of Pathology* contains around 1901 high-resolution colored figures and 1719 tables.

Enormous effort has been put in recreating the tables with additional content, making the flowcharts and illustrations as well as adding new and clear microphotographs. All these are the unique feature of this textbook to enable the medical students to learn pathology in context of etiology and pathogenesis making it a valuable source for gaining knowledge to build a solid foundation in pathology for the future doctors.

I hope the undergraduate and postgraduate medical students and teachers will benefit from the Second Edition of *Textbook of Pathology*.

Dr Nita Khurana
Director Professor and Head
Department of Pathology
Maulana Azad Medical College
New Delhi

Foreword

It is my privilege to write the Foreword to Second Edition of *Textbook of Pathology* written by Dr Vinay Kamal, Ex-Director Professor of Pathology, Maulana Azad Medical College, New Delhi, releasing in 2025. The author of this *Textbook of Pathology* has more than three-decade long teaching experience at one of the country's finest and reputed medical institutes.

I had an opportunity to read the preprint of few topics, and I am immensely pleased to express that the latest Second Edition of *Textbook of Pathology* is in accordance with the 'Competency Based Medical Education Curriculum' recommended by the National Medical Commission.

Textbook of Pathology contains around 1901 high-resolution colored figures and 1719 tables, which makes the understanding of concepts very lucid for the undergraduate and postgraduate medical students.

Textbook of Pathology includes important topics like tissue fixatives, microscopy, frozen/cryostat section techniques, and histochemical stains which covers the much-needed practical aspects of the subject. Topics like recent updates, molecular pathogenesis, revised WHO classification of neoplasms, immunohistochemistry, hematology, flow cytometry, cytogenetic study, fluorescence *in situ* hybridization (FISH), enzyme-linked immunosorbent assay (ELISA), DNA sequencing, tissue microarray (TMA), high-performance liquid chromatography (HPLC), and electrophoresis have been presented in such a way that it would help the postgraduate medical students, teaching faculty and fellow practitioners also. Updated content on 'Blood Transfusion' being included, makes the *Textbook of Pathology* a very comprehensive read.

I wish Dr Vinay Kamal for all the success and hope that this latest Second Edition of *Textbook of Pathology* will receive wide acceptance by the undergraduate and postgraduate medical students and faculty members.

Dr Srivani N
Senior Professor and Head
Department of Pathology
Government Medical College
Nalgonda, Telangana

Foreword

I have known Dr Vinay Kamal, Ex-Director Professor, Department of Pathology, Maulana Azad Medical College, New Delhi for more than two decades, and have been interacting with him on various issues of pathology. The importance of pathology can be summarized in a quote by Great Sir Boyd "*As good is your pathology, so good will be your clinical practice*."

The undaunted association with teaching undergraduate and postgraduate medical students for more than three decades as faculty at Maulana Azad Medical College, New Delhi, distinguishes him from many other academicians by way of his integrated innovative approach to make the subject of pathology simple, and easy with clinico-pathological correlation of various diseases for medical students.

It is my proud privilege to write the Foreword to Second Edition of *Textbook of Pathology* written by Dr Vinay Kamal, which consists of the essence of his teaching experience in academics. This textbook contains revised WHO classification of neoplasms, molecular pathogenesis, and chapters on Blood Banking and Transfusion Practices and Cellular–Molecular Diagnostic Techniques in Clinical Practice. This textbook contains numerous high-resolution colored figures, tabulated data analysis, and methodology for diagnosis of various diseases accurately.

I am confident that this *Textbook of Pathology* by Dr Vinay Kamal will open a whole new avenue for all students in world of pathology, which will go long away in making undergraduate as well as postgraduate medical students to understand pathology and its relevance, and significance in medicine. I wish great success of new release Second Edition of *Textbook of Pathology*.

Dr Hansa Goswami
Senior Professor and Head
Department of Pathology
BJ Medical College
Ahmedabad, Gujarat

Foreword

I joined MAMC as a postgraduate student. He connects with the students and takes keen interest in their learning and tries to help them out in all their personal and academic problems. A similar helpful attitude towards staff with all help extended to them has been his nature at all times.

It is my distinct pleasure and honour to endorse the Second Edition of *Textbook of Pathology* written by Dr Vinay Kamal, Ex-Director Professor, Department of Pathology, Maulana Azad Medical College, New Delhi, whom I have known for some years and interacted on various issues of pathology.

Second Edition of *Textbook of Pathology* written by Dr Vinay Kamal covers various aspects of the subject in a systematic manner. The content in this textbook is in simple language, which makes it reader-friendly and is well illustrated by numerous gross and microscopic pictures.

The beauty of the *Textbook of Pathology* is that it highlights the clinicopathological correlation, diagnostic approach and includes revised WHO classification of neoplasms. Various illustrations in the form of figures, tables, flow diagrams and incorporation of basics of immunohistochemistry and molecular biology in this textbook provide a comprehensive understanding to medical students in pathology. The key highlights in every section of textbook also helps in quick revision of the topics.

I congratulate Dr Vinay Kamal for his dedication and immense passion of teaching medical students, who will enjoy reading this textbook and understand the basic concepts along with updated knowledge in the subject.

Dr Ranjana Solanki
Senior Professor
Department of Pathology
SMS Medical College
Jaipur, Rajasthan

Foreword

A seasonal writer—is the most appropriate word for Dr Vinay Kamal, Ex-Director Professor, Department of Pathology, Maulana Azad Medical College, New Delhi, which has more than three decades of teaching experience in the premier institution.

It gives me an immense pleasure to write the Foreword to Second Edition of *Textbook of Pathology* with recent updates. I have gone through many chapters penned down by him in this textbook. Nothing can be more informative and more simplified for undergraduate as well as postgraduate medical students than this version.

Beautifully integrating numerous high-resolution colored illustrations, images, flowcharts, tables and providing relevant knowledge in a well-structured and designed text is an art and his textbook is a perfect example of these qualities. The contents not only include the knowledge of basic *Textbook of Pathology* for undergraduate students but also integrates trivial topics of recent diagnostic techniques and advancements, and molecular and genetic pathology for postgraduate students as well.

I congratulate Dr Vinay Kamal for having the insight to produce a novel *Textbook of Pathology* that allows the undergraduate as well as postgraduate medical students of all levels to understand pathology with clinicopathological correlation and relish it while reading it cover to cover.

I wish and hope that this splendid contribution of Dr Vinay Kamal gets the well-deserved acclamation and applause.

Dr Reeni Malik
Senior Professor and Head
Department of Pathology
Gandhi Medical College
Bhopal, Madhya Pradesh

Foreword

I have this proud privilege to write the Foreword to Second Edition of *Textbook of Pathology* written by Dr Vinay Kamal, Ex-Director Professor, Department of Pathology, Maulana Azad Medical College, New Delhi. He is a renowned Pathologist, who enjoys teaching undergraduate and postgraduate medical students and has put in dedicated efforts to facilitate teaching–learning methods.

Textbook of Pathology is in two volumes. The first volume deals with General Pathology and Hematology including chapter on Blood Banking and Transfusion Practices. The second volume deals with Systemic Pathology including a chapter on Cellular–Molecular Diagnostic Techniques in Clinical Practice.

This Second Edition of *Textbook of Pathology* is an integration of molecular pathology and routine histopathology and thorough in all aspects. The upcoming scientific discipline of molecular basis of disease development has been described in a simplified yet extensively detailed manner in this textbook. Numerous high-resolution colored illustrations are eye-catching and self-explanatory. All topics are covered comprehensively making it extremely student friendly for undergraduate and postgraduate medical students.

I congratulate Dr Vinay Kamal for his dedication and immense passion of teaching undergraduate and postgraduate medical students, I am confident that this splendid contribution of the author gets the well-deserved acclamation and applause.

Dr Roma Issacs
Senior Professor
Department of Pathology
Christian Medical College and Hospital
Ludhiana, Punjab

Foreword

It gives me an immense pleasure to write the Foreword to Second Edition of *Textbook of Pathology* written by Dr Vinay Kamal, Ex-Director Professor, Department of Pathology, Maulana Azad Medical College, New Delhi, who brings out new concepts defining various learning domains for the undergraduate as well as postgraduate medical students of pathology.

As all of us know that pathology is a very vast subject but it forms the basis for understanding the disease process. This textbook covers all the aspects of pathology in a systemic manner. Every effort has been made to make the subject interesting and easy to understand by using numerous well illustrated diagrams, flowcharts, tables as well as key points placed separately in the boxes for quick revision.

An attempt has also been made to include revised WHO classification of neoplasms, recent advances in pathology, molecular and immunohistochemical correlations in various aspects of tumor diagnosis, which are aimed at individualized treatment.

I congratulate Dr Vinay Kamal for this new venture and wish him all the success in his future endeavors.

Dr Sunita Singh
Senior Professor and Head
Department of Pathology
Pandit Bhagwat Dayal Sharma Post Graduate
Institute of Medical Sciences
Rohtak, Haryana

Foreword

The first edition of *Textbook of Pathology* authored by Dr Vinay Kamal released in the year 2017, was well appreciated by undergraduate as well as postgraduate medical scholars, and eminent faculty all over India. Textbook of Pathology was the result of years of hard work and commitment by a professional teacher and experienced pathologist.

I congratulate Dr Vinay Kamal, Ex-Director Professor, Department of Pathology, Maulana Azad Medical College, New Delhi for bringing out the Second Edition of *Textbook of Pathology*. Keeping in line with the recent advances in the field of pathology, the focus in this new venture is on the molecular pathogenesis of various disorders and clinicopathological correlation. The revised WHO classification of neoplasms has been incorporated in the discussions on various entities. Updated information on immunohistochemical markers has also been provided.

I am sure that Second Edition of *Textbook of Pathology* will be of immense help to the budding undergraduate as well as postgraduate medical students, and pathologists in reproducing their knowledge.

I wish great success to the latest endeavor by Dr Vinay Kamal.

Dr Syed Besina Yasin
Senior Professor and Head
Department of Pathology
Sher-I-Kashmir Institute of Medical Sciences
Srinagar, Jammu and Kashmir

Foreword

Dr Vinay Kamal, Ex-Director Professor, Department of Pathology, Maulana Azad Medical College, New Delhi, is well known name in the field of pathology, who needs no introduction. He has more than three decades of teaching experience in nation's most prestigious institution at Maulana Azad Medical College, New Delhi. I am delighted to know about the new release of his Second Edition of *Textbook of Pathology* with recent updates.

This is a very well written textbook with numerous high-resolution figures and tables which make it a handy tool to understand the fine nuances of the subject. This textbook would make the subject interesting for both the undergraduate as well as postgraduate medical students. Seldom we come across a thorough professional who is also a person with a kind heart, always keen to go extra mile to help others.

I congratulate Dr Vinay Kamal all the best for new release of *Textbook of Pathology*. I am sure this textbook is going to be a milestone for all the medical fraternity in the times to come.

Dr Geeta Pachori
Senior Professor and Head
Department of Pathology
Jawahar Lal Nehru Medical College
Ajmer, Rajasthan

Foreword

Second Edition of *Textbook of Pathology* written by Dr Vinay Kamal, Ex-Director Professor, Department of Pathology, Maulana Azad Medical College, New Delhi, is in your hands.

Dr Vinay Kamal has worked very hard and has rewritten all the chapters of textbook incorporating most of the contemporary knowledge and developments in the field as relevant within the scope of the book.

Many new tables, flow diagrams and illustrations have been added for easy remembrance. He has been constantly updating the content and has made tremendous efforts to present the content in a comprehensive yet concise style.

Revised WHO classification of neoplasms, concepts in the molecular pathogenesis, current Cellular–Molecular Diagnostic Techniques in Clinicale Practice of pathology and diagnostic approach have been incorporated.

I am sure the textbook is going to be useful not only to undergraduate but also to postgraduate medical students, and teachers of pathology.

Dr Rajeev Sen
Senior Professor and Head
Department of Pathology
Faculty of Medicine and Health Sciences
SGT University
Gurugram, Haryana

Foreword

Ever since the first edition of *Textbook of Pathology* by Dr Vinay Kamal was released in the year 2017, the author started working on its new edition as the book became so popular in just a couple of months that most of the undergraduate and postgraduate medical students, as well as faculty in pathology across the country procured this book for personal use and for the library of their institutions. This was due to numerous qualities of the textbook such as unique presentation, topics discussed in a simple, clear, and well-organized manner backed up with numerous colored figures, photographs of gross and microscopic lesions, tables, and diagrams along with the recent updates.

Second Edition of *Textbook of Pathology* by Dr Vinay Kamal, Ex-Director Professor, Department of Pathology, Maulana Azad Medical College, New Delhi, is releasing in 2025. In this textbook, all the chapters have been updated with incorporation of revised WHO classification of neoplasms, etiopathogenesis of the disease, clinical manifestations, clinicopathological correlation, and molecular diagnostics.

Textbook of Pathology contains around 1901 high-resolution colored figures, 1719 tables, chapters on Blood Banking and Transfusion Practices and Cellular–Molecular Diagnostic Techniques in Clinical Practice. All the chapters have been shared with eminent teachers and young budding residents across the country and their opinions have been given due weightage during drafting of the chapters.

While going through the chapters, the Author's honest, hard, and intelligent work is clearly felt by the reader. The book is designed to provide accurate, authoritative, and most current information and thus meets the need of the young generation of pathologists.

Dr Vinay Kamal's heart always beats for every medical student. I congratulate Dr Vinay Kamal on the Second Edition of *Textbook of Pathology* and wish good luck in his future endeavors.

Dr Kuldeep Kumar Kaul
Medical Advisor
J and K Thalassaemia Welfare Society
Former Professor and Head
Department of Pathology
Government Medical College
Jammu, Jammu and Kashmir

Foreword

It is indeed a pleasure and honour to write the Foreword to Second Edition of *Textbook of Pathology* written by Dr Vinay Kamal, Ex-Director Professor, Department of Pathology, Maulana Azad Medical College, New Delhi. The book is an excellent compilation of knowledge of pathology in a very organized manner.

I have been associated with Dr Vinay Kamal for the last fifteen years and had the opportunity to review many of the chapters in this textbook. All the chapters in this new release *Textbook of Pathology*, have been updated with recent advances with strong emphasis on molecular pathogenesis, immunohistochemistry, flow cytometry and other molecular techniques. The book is easy to read and comprehend and shall prove student-friendly for undergraduate as well as postgraduate medical students.

I wish all the best to Dr Vinay Kamal for success of Second Edition of *Textbook of Pathology* and sincerely hope that he will keep on contributing more to the knowledge of medical students.

Dr Subhash Chander Bhardwaj
Senior Professor and Head
Department of Pathology
Government Medical College
Jammu, Jammu and Kashmir

Foreword

Books are the best to windows of the world as they are best source to gain knowledge and discipline. Pathology is the scientific study of the diseases. I have known Dr Vinay Kamal, Ex-Director Professor, Department of Pathology, Maulana Azad Medical College, New Delhi for many years by reading an excellent *Textbook of Pathology* authored by him in the year 2017.

It is my pleasure, and an honour to write the Foreword for the Second Edition of *Textbook of Pathology* by Dr Vinay Kamal releasing in 2025. The only thing that surpasses his knowledge is his humility about capabilities.

Textbook of Pathology contains around 1901 high-resolution colored figures and 1719 tables with recent updates including revised WHO classifications of neoplasms, molecular pathogenesis, immunohistochemistry, flow cytometry and molecular diagnostic techniques. This textbook contains two chapters on Cellular–Molecular Diagnostic Techniques in Clinical Practice and Blood Banking and Transfusion Practices.

Undergraduate and postgraduate medical students seeking a resource should consider Second Edition of *Textbook of Pathology* written by Dr Vinay Kamal. I congratulate Dr Vinay Kamal for grand success of the textbook releasing in 2025.

Dr Soumitra Biswas
Senior Professor and Head
Department of Pathology
Calcutta National Medical College
Kolkata, West Bengal

Foreword

The influence of a good teacher can never be erased. Dr Vinay Kamal, Ex-Director Professor, Department of Pathology, Maulana Azad Medical College, New Delhi, besides being a dedicated teacher and pathologist par excellence, is an awakener.

It is my proud privilege and I feel honored to be given an opportunity to write the Foreword to Second Edition of *Textbook of Pathology*. All the chapters of the book have recent updates including molecular pathogenesis. Many features such as revised WHO classification of neoplasms, immunohistochemistry, microscopy, histochemical stains, flow cytometric analysis, cytogenetic study, fluorescence *in situ* hybridization, enzyme-linked immunosorbent assay, DNA sequencing and tissue microarray.

This textbook contains around 1901 high-resolution colored figures and 1719 tables that will help undergraduate and postgraduate medical students to understand pathology of diseases and their clinicopathological correlation.

I convey my heartfelt appreciation for the untiring efforts and the hard work done by Dr Vinay Kamal for conceptualizing and executing his work. This new release Textbook of Pathology is a great boon to the undergraduate and postgraduate medical students, and will enjoy reading this book.

I wish Dr Vinay Kamal a grand success in his endeavor and happy to release this Second Edition of *Textbook of Pathology*.

Dr Pranita Medhi
Senior Professor and Head
Department of Pathology
Assam Medical College and Hospital
Dibrugarh, Assam

Foreword

I am privileged to write the Foreword to Second Edition of *Textbook of Pathology* written by a well experienced and excellent talented teacher Dr Vinay Kamal, Ex-Director Professor, Maulana Azad Medical College, New Delhi.

Textbook of Pathology contains 1901 high-resolution colored images, 1719 tables, chapters on 'Cellular–Molecular Diagnostic Techniques in Clinical Practice' which makes the understanding of concepts very lucid for the undergraduate and postgraduate medical students, which make the book unique.

The author has meticulously considered valuable suggestions and criticism after thorough discussions with many subject experts in upgradation of this Second Edition of *Textbook of Pathology*. Inclusion of recent advances in diagnostic pathology, cytogenetics, molecular pathology, and immunohistochemistry are the added advantages of the textbook. Recently revised WHO classification of neoplasms has also been included in the book. All the chapters of textbook are written, and edited with recent updates.

I am sure this Textbook of Pathology will prove to be an asset for undergraduate and postgraduate medical students in view of the 'Competency Based Medical Education' implemented by National Medical Commission. Salient features given in the boxes will help the medical students in quick revision of the course prior to their formative and summative assessments.

I wish Dr Vinay Kamal all the best in his endeavor.

Dr Naval Kishore Bajaj
Senior Professor and Head
Department of Pathology
Osmania Medical College
Hyderabad, Telangana

Acknowledgments

Our motivation in writing Second Edition of *Textbook of Pathology* continues to share recent scientific concepts, clinical applications, and molecular diagnostics with colleagues and undergraduate and postgraduate medical students. We have strived to provide explanatory text, 1901 photographs and 1719 tables to enhance pictorial insights into human diseases.

We acknowledge the support and encouragement of colleagues and undergraduate and postgraduate medical students, who have critically revied the draft chapters and provided photographs related to surgical pathology and hematology section. Their constructive invaluable suggestions have served to significantly improve the work.

We gratefully recognize the continual invaluable support of Dr Naval Kishore Bajaj (Senior Professor and Head, Department of Pathology, Osmania Medical College Hyderabad, Telangana), Dr Nita Khurana (Director Professor and Head, Department of Pathology, Maulana Azad Medical College, New Delhi), Dr Jyoti Priyadarshini (Professor, Department of Pathology, GR Medical College Gwalior, Madhya Pradesh), Dr Tushar Kalonia (Assistant Professor, Department of Pathology), Dr Neha Kumari (Assistant Professor, Department of Pathology), Rajiv Aggarwal, Sh PL Jayant, Smt Shanti Devi, Dr Satya Pal Jayant, Dr Vijaya Jayant, Mr Arjun Jayant, Dr Rohan Jayant, Dr Vimal Singh, Dinesh Kumar, and Dr Divyark Singh.

Words are less to express our gratitude to eminent faculty colleagues for showering their blessings by endorsing Second Edition of *Textbook of Pathology*. Comments from eminent faculty and undergraduate and postgraduate medical students are always welcome.

CBS PUBLISHERS AND DISTRIBUTORS PRIVATE LIMITED, NEW DELHI

We express our gratitude to Mr Satish Kumar Jain CHAIRMAN AND MANAGING DIRECTOR, Mr Varun Jain MANAGING DIRECTOR and Mr Sunil Dutt MANAGER PROMOTION AND DEVELOPMENT of CBS Publishers and Distributors Private Limited for extending their whole hearted support at every step in completion of this book.

A special thanks to Ram Murti SENIOR GRAPHIC ARTIST, Ananda Mohanty SENIOR PROOF READER and Mrs Sunita Rautela SENIOR DTP OPERATOR for their invaluable support in the completion of the book.

Associate Professor and Head of Pathology
• Dr Seema Mondal

Deben Mahata Government Medical College Purulia, West Bengal
Senior Professor and Head of Pathology
• Dr Debashis Chakraborty

Section I

GENERAL PATHOLOGY

CHAPTER 1

Cellular Pathology and Biology of Aging

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

CELL UNIT OF LIFE AND INTRODUCTION TO PATHOLOGY

- Cell unit of life
- Introduction to pathology

CELLULAR RESPONSE TO STRESS AND HARMFUL STIMULI

- Cellular adaptations
- Cell injury
  - Reversible cell injury
  - Irreversible cell injury

CELLULAR ADAPTATIONS

- Hyperplasia
- Hypertrophy
- Atrophy
- Metaplasia
- Dysplasia
- Reduction in size of organs in other pathologic processes

CELL INJURY AND CELL DEATH: OVERVIEW

- Causes of cell injury and cell death
  - Oxidative stress/hypoxia-induced cell injury
  - Ischemia-reperfusion-induced cell injury
  - Pathogen-induced cell injury
  - Physical agents induced cell injury
  - Chemical agents induced cell injury
  - Drug-induced cell injury

PATHOPHYSIOLOGY OF CELL INJURY, MORPHOLOGIC PATTERNS AND OUTCOME OF NECROSIS

- Reversible cell injury
  - Decreased ATP production in mitochondria
  - Plasma membrane Na^+/K^+ pump failure
  - Plasma membrane calcium pump failure
  - Plasma membrane bleb formation
  - Myelin figures
- Irreversible cell injury (cell death)
  - ATP depletion in mitochondria
  - Mitochondrial damage
  - Calcium influx and impaired calcium homeostasis
  - Reactive oxygen species production induced by cell stressors
  - Defects in permeability of plasma membrane and cell organelles
  - Rough endoplasmic reticulum disruption
  - Cytoskeleton disruption
  - Genetic apparatus disruption
- Morphologic patterns of necrosis
  - Coagulative necrosis
  - Liquefactive necrosis
  - Caseous necrosis
  - Fat necrosis
  - Gangrene
  - Fibrinoid necrosis
  - Gummatous necrosis
  - Subcutaneous necrosis in newborn
  - Zenker's necrosis in skeletal muscle
  - Postmortem autolysis
- Outcome of necrosis
  - Complete resolution
  - Injured tissue repair by fibrosis
  - Dystrophic calcification
  - Resorption of necrotic tissue

REGULATED CELL DEATH (RCD)

- Mitochondrial permeability transition pore driven necrosis
- Apoptosis
- Necroptosis
- Pyroptosis
- Ferroptosis
- Autophagy
- Lysosomal-dependent cell death

APOPTOSIS

- Three pathways of apoptosis
  - Extrinsic death receptor pathway of apoptosis
  - Intrinsic mitochondrial pathway of apoptosis
  - CD8+ cytotoxic T cells/NK cells (granzyme B/perforin) mediated pathway of apoptosis
- Family of cysteine proteins 'caspases'
  - Initiator/inducer caspases
  - Executioner/effector caspases
- Morphologic and biochemical changes in apoptotic cells
  - Histologic changes
  - Ultrastructural changes
  - Biochemical changes
- Apoptosis in health
  - Apoptosis during embryogenesis
  - Apoptosis during adult life
- Apoptosis in diseases
  - Apoptosis induced by viruses
  - Neuronal apoptosis and formation of red neurons in brain
  - Keratinocyte apoptosis in epidermis
  - Apoptosis of neutrophils in acute inflammation
  - Apoptosis of parenchymal organ's cells due to obstruction in ducts
  - Apoptosis of cells with damaged DNA
  - Apoptosis of cells with accumulated misfolded proteins
  - Apoptosis of cancer stem cells
- Laboratory diagnosis
  - Light microscopy
  - Electron microscopy
  - Electrophoresis
  - Flow cytometry
  - TUNEL assay
  - Immunohistochemistry

INTRACELLULAR ACCUMULATION OF SUBSTANCES

- Lipid accumulation
  - Triglyceride accumulation inducing fatty change in liver
  - Cholesterol and its esters accumulation inducing atherosclerosis, xanthomas and gallbladder cholesterolosis
- Glycogen accumulation
  - Glycogen storage diseases: types 1 to 10
- Protein accumulation
  - Increased protein droplets reabsorption in the proximal renal tubule in renal disease with proteinuria
  - Increased protein production by plasma cells forming Russell bodies
  - Accumulation of cytoskeleton proteins
  - α_1-Antitrypsin protein accumulation

- Pigment accumulation
  - Endogenous pigments
    - Lipofuscin pigment
    - Melanin pigment
    - Bilirubin pigment
    - Hemosiderin pigment
    - Hematin pigment
    - Homogentisic acid pigment
    - Hamazaki-Wesenberg bodies
  - Exogenous pigments
    - Coal pigment
    - Tattoo ink pigment

EXTRACELLULAR ACCUMULATION OF SUBSTANCES

- Intracellular and extracellular hyaline change
- Aggregation of misfolded proteins (amyloidosis)
- Fibrinoid necrosis of arterioles
- Hyalinization of glomenular basement membrane
- Dysgenetic hyalinization in seminiferous tubules

PATHOLOGIC CALCIFICATION

- Dystrophic calcification
- Metastatic calcification
- Pulmonary alveolar microlithiasis (PAM)

CELLULAR BIOLOGY OF AGING

CELL UNIT OF LIFE AND INTRODUCTION TO PATHOLOGY

Cell is defined as the most basic structural and functional unit of life. Normal cells handle physiological demands and maintains a steady state called homeostasis. More severe physiologic stresses stimuli may bring about a number of physiologic and morphologic cellular adaptations, during which new but altered steady states are achieved, preserving the viability of the cell. The adaptive response may consist of an increase in the size of the individual cell called hypertrophy and increase in the number of cells called hyperplasia. Conversely, **atrophy** is an adaptive response in which there is decrease in the size and function of cells.

CELL UNIT OF LIFE

Cell consists of cell membrane (plasma membrane), the nucleus and cytoplasm. The cell membrane is a phospholipid bilayer containing many different molecular components, including proteins and cholesterol, some with carbohydrate groups attached. A phospholipid molecule consists of a polar phosphate "head," which is hydrophilic and a nonpolar lipid "tail," which is hydrophobic. Unsaturated fatty acids result in links in the hydrophobic tails.

- The lipid bilayer provides the basic structure and serves as a relatively impermeable barrier to most water-soluble substances. Transmembrane proteins that span the phospholipid bilayer of cell membranes serve a variety of structural, transport, signaling and enzymatic functions.
- Cytoplasm is internal material between the cell membrane and nucleus of a cell. It consists of a clear, semi-fluid, water-based fluid called cytosol, within which are all specialized membrane-bound cell organelles (mitochondria and lysosomes) in the cell and cellular solute and suspended materials. Each organelle has its specific function, that is essential for cell survival.
- The cytoskeleton in cell is formed by rod-like proteins that support the cell's shape and provide other functions, locomotive abilities. Cytoskeleton consists of microtubules, microfilaments, and intermediate filaments, which plays an important role in maintaining cell shape and structure, in promoting cellular movement, and aiding cell division.
- Mitochondria are the energy-conversion factories of the cell. Mitochondrion, one of the cellular organelles, is bound by a double lipid bilayer membrane that functions primarily in the production of cellular energy (ATP).
- The endoplasmic reticulum (ER) is a winding network of thin interconnected membranous sacs found in close association with the cell nucleus.
- The smooth and rough endoplasmic reticula are very different in appearance and function.
  - Rough ER is studded with numerous ribosomes, which are sites of protein synthesis. Smooth endoplasmic reticulum is formed by a series of flattened, membrane-bound sacs that functions in protein modification, tagging, packaging, and transport within the other areas of cytoplasm. Some of these products are exported from the cell through exocytosis.
  - Enzymatic proteins are packaged and sent for fusion with existing lysosomes. Lysosomes and membrane-bound cellular organelles are originating from the Golgi apparatus and containing digestive enzymes.
  - Smooth ER synthesizes phospholipids, steroid hormones, regulates the concentration of cellular Ca^{++}, metabolizes some carbohydrates, and breaks down certain toxins.
- Peroxisome is a small membrane-bound organelle in the cytoplasm of many cells, which contains the reducing enzyme catalase and some oxidase for detoxifying harmful substances and lipid synthesis.

- The centrosome contains the small replicating organelle 'centriole' that provides the origin for microtubule growth and moves DNA during cell division.
- The nuclear envelope, a double membrane, surrounding the nucleus contains nuclear pores that control the movement of substances into and out of the nucleoplasm.
- Human DNA is described as a double helix that resembles a molecular spiral staircase. DNA has an antiparallel configuration with one strand arranged 5′ to 3′ in one direction and the other strand in the opposite direction. A purine is bound to pyrimidine by the hydrogen bonds: adenine:thymine and guanine:cytosine. The double helix of DNA is the result of bonds in the sugar-phosphate backbone. DNA is organized around histone proteins into nucleosomes, which are compacted and progressively coiled and finally supercoiled into 46 chromosomes. DNA is inactive in the coiled form and must be uncoiled for biological processes such as transcription and translation into proteins. The dense nucleolus is the site of ribosome production. The nucleus of a eukaryotic cell directs the cell's activities and stores DNA.

Pathology Pearls: Conditions Associated with Alteration in Cell Organelles

- Certain conditions are associated with alterations in cell organelles (lysosomes, smooth endoplasmic reticulum, and mitochondria) or the cytoskeleton.
- Lysosomal catabolism occurs by heterophagy or autophagy
- Smooth endoplasmic reticulum hypertrophy occurs due to induction of drug tolerance to barbiturates and alcohol
- Mitochondrial defects (number, size and shape)
- Cytoskeleton defects (phagocytosis and locomotion)
- Nucleus (pyknosis, karyorrhexis and karyolysis)
- Membranes (plasma membrane and subcellular membrane such as endoplasmic reticulum)

CELL ADHESION MOLECULES (CAMs)

Cell adhesion molecules are transmembrane-linked glycoproteins that mediate connections between cells or the attachment of cells to basement membrane. There are at least six groups of cell adhesion molecules: selectins, integrins, cadherins, members of immunoglobulin superfamily, mucins and lymphocyte homing receptors (CD44). Cell adhesion receptors enable cells to recognize and bind cell adhesion molecules on other cells or in the extracellular matrix. Cell adhesion receptors form homophilic adhesions (cadherin-cadherin) or heterophilic adhesions between different types of molecules (selectin-mucin). Major family of cell adhesion molecules (CAMs) is given in Table 1.1.

Table 1.1 Major family of cell adhesion molecules (CAMs)

Selectins (calcium-dependent)
Integrins (calcium-dependent)
Cadherins (calcium-dependent)
Members of immunoglobulin superfamily (calcium-dependent)
Lymphocyte homing receptor (CD44) (calcium-dependent)

Selectins

The selectins are a family of carbohydrate-binding transmembrane molecules found on the surface of endothelial cells, leukocytes and platelets. Members of selectin family include endothelial selectin (E-selectin), leukocyte selectin (L-selectin) and platelet selectin (P-selectin). E-selectin adheres to integrins, P-selectin interacts with platelets, and L-selectin interacts with leukocytes. Selectins mediate the adhesion of white blood cells and platelets to endothelial cells. In collaboration with other CAM families, selectins play important roles in leukocyte trafficking to the sites of inflammation.

Integrins

Integrins are the principal cell surface receptors that function mechanically by binding the cell microfilament (actin) of cytoskeleton to the extracellular matrix (ECM). The integrin family of proteins consists of α and β subtypes, which form transmembrane heterodimers. Integrins are responsible for transduction of external signals to the cytoskeleton.

Cadherins

Cadherins are calcium-dependent transmembrane proteins that constitute the major intercellular link at adherens junctions and bind to catenin and other proteins inside cell to link to the microfilament (actin) of the cytoskeleton. Different members of cadherin family are found in different locations: E-cadherin (epithelial cells), N-cadherin (neurons) and P-cadherin (placenta). Cadherins form homophilic adhesions (cadherin-cadherin). Failure of cadherin mediated cell-to-cell adhesion cascade is observed in breast lobular carcinoma.

Members of Immunoglobulin Superfamily CAMs

The immunoglobulin superfamily CAMs are calcium-independent transmembrane. Members of immunoglobulin superfamily include intercellular adhesion molecule (ICAM), vascular adhesion molecule 1 (VCAM-1), neural cell adhesion molecule (NCAM), and platelet endothelial cell adhesion molecule 1 (PECAM 1 or CD31). Nectins have been recently identified as new calcium-independent CAMs consisting of four members.

- Each immunoglobulin superfamily CAM has an extracellular domain, which contains several Ig-like intra-chain disulphide-bonded loops with conserved cysteine residues, a transmembrane domain, and an intracellular domain that interacts with the cytoskeleton.
- Immunoglobulin superfamily CAMs function by both homophilic and heterophilic binding. These are involved in recognition, binding or adhesion processes of cells.

Lymphocyte Homing Receptors

Lymphocyte homing receptor (CD44) is involved in lymphocyte adhesion to endothelial cells of venules and lymphocyte exit from the blood circulation. It may also be involved in hematogenous dissemination of malignant lymphoma.

CELL JUNCTIONS

At molecular level, intercellular junctions consist of three multiprotein components which differ depending on the type of junctions: transmembrane adhesion protein, cytoplasmic adapter protein and cytoskeleton proteins.

- Five types of cellular junctions are present between the epithelial cells: tight junctions (zona occludens), adherent junctions (zona adherens), desmosomes (macula adherens), gap junctions and hemidesmosomes.
- Cell junctions provide contact between neighboring cells or between a cell and the extracellular matrix. They also build up the paracellular barrier of epithelia and control the paracellular transport. Functional classification of cell junctions is given in Table 1.2.

Table 1.2 Functional classification of cell junctions

Occluding Junctions
Tight junctions (zona occludens)
Anchoring Junctions

▪ Intermediate filament attachment sites
  • Desmosomes (cell-to-cell junction)
  • Hemidesmosomes (cell-extracellular matrix junction)
▪ Actin filament attachment sites
  • Zonula adherens (cell-to-cell junctions)
  • Focal adhesions (cell-extracellular matrix junction)

Communicating Junctions
Gap junctions
Signal Relaying Junctions
▪ Chemical synapses in the nervous system ▪ Immunological synapses in the immune system ▪ Transmembrane ligand-receptor cell-to-cell signaling contacts

Zona Occludens (Tight Junctions)

Zona occludens is a membrane protein complex composed of occludens and claudins, which are attached to three proteins called ZO1, ZO2 and ZO3, which help in holding occludens and claudins properly in their positions. Occludens and claudins exit cell membrane and interact with each other and seal the surface of two adjacent cells. Zona occludens is present in the lateral surfaces of epithelial cells, which prevents floating of protein channels from apical surface to basal surface. Zona occludens regulates fluid movement through paracellular route.

Zonula Adherens (Cell-to-Cell Junctions)

Zonula adherens is a cell-to-cell adherens junction that forms a belt in the apical most region of the lateral cell surface of many epithelia.

Desmosomes

Desmosomes are specialized adhesive proteins that localize intercellular junctions of epithelia and cardiac muscle. Desmosomes resist mechanical stress and maintain the mechanical integrity of tissues.

Hemidesmosomes

Hemidesmosomes are the only cellular junctions present on the basal surface of the epithelium, which link the cell to the basal lamina and through integrin attaches to extracellular matrix. Intermediate filaments are present inside hemidesmosomes.

Gap Junction Channels

Gap junction channels are formed by docking of two connexons, that are present at cell-to-cell appositions. Gap junction channels are responsible for direct intercellular transfer of ions and small molecules including propagation of inositol triphosphate-dependent calcium waves.

Signal Relaying Junctions

Chemical synapses are specialized junctions through which neurons signal to each other and to non-neuronal cells such as those in the glands and muscles. Chemical synapses allow neurons to form circuits within the central nervous system. Their key feature is the presence of synaptic vesicles at presynaptic terminals, which are filled with one or more neurotransmitters, which act as messengers between the communicating neurons.

CYTOSKELETON

Cytoskeleton of a cell represents network of protein filaments in the cytosol that maintains cell shape, cell movement, cell division, intracellular organization and intracellular transport of organelles and molecules.

- There are three main components of the cytoskeleton: microtubules, microfilaments and intermediate filaments, along with other proteins that support these components. All three components of cytoskeleton interact with each other noncovalently.
- Cytoskeleton helps cells in maintaining their shape and internal organization, and also provides mechanical support that enables cells to perform essential functions like cell division and cell movement. Hypoxic injury may cause damage to cytoskeleton.
- Blebs are observed on cell surface, most likely caused by disorderly function of the cellular cytoskeleton. Components of cytoskeleton, their arrangement, functions and disorders are given in Table 1.3.

Pathology Pearls: Disorders of Cytoskeleton

Disorders of Microfilaments

The membrane skeleton composed of spectrin, actin, and protein provides structural integrity to the cell membrane of red blood cells. Congenital spherocytosis, an autosomal dominant disease, is an example of a defect in spectrin resulting in a hemolytic anemia.

Disorders of Microtubules

- **Male sterility:** Defects in microtubules inhibit sperm motility results in sterility.
- **Kartagener's syndrome (immotile cilia syndrome):** It refers to immobilization of cilia of respiratory epithelium causes interference of clearance of pathogens resulting in bronchiectasis.
- **Dysfunctional leukocytes:** Colchicine drug used in acute attacks of gout binds to tubulin and prevents the assembly of microtubules, thus prevents migration and phagocytosis of leukocytes in response to urate crystals.
- **Chédiak-Higashi syndrome:** It is autosomal recessive disorder due to defect in the assembly (polymerization) of microtubules in the cytoplasm. It is characterized by defective degranulation of neutrophils, impaired microbial killing, and recurrent *Staphylococcus aureus* bacterial infections forming soft tissue abscess. This disorder results from a mutation in the '**LYST gene**' on chromosome 1q42 that encodes a protein for microtubules involved in intracellular trafficking of proteins.

Disorders of Intermediate Filaments

- **Mallory hyaline:** In chronic alcoholic persons, Mallory hyaline demonstrated in hepatocytes. It is an example of intermediate filaments (cytokeratins) abnormality.
- **α_1-Antitrypsin deficiency:** Structurally abnormal α_1-antitrypsin molecules accumulate in the liver.
- **Parkinson disease:** α-Synuclein accumulates in neurons in the substantia nigra of patients with Parkinson disease.

Microfilaments

Microfilaments or actin filaments (6–8 nm) are the thinnest, linear and strong filaments of the cytoskeleton; predominantly of a contractile protein called actin subunits. These are protein filaments primarily composed of polymers of actin and found in the cytoplasm of eukaryotic cells, which interact with numerous other proteins in the cell.

- Microfilaments are intimately involved in many plasma and internal membrane functions. Functions of microfilaments include cytokinesis, cell motility, amoeboid movement leukocytes, changes in cell shape, endocytosis (phagocytosis) and exocytosis, cell contractility, transmembrane signaling and mechanical stability.

Table 1.3 Components of cytoskeleton, their arrangement, functions and disorders

Cytoskeleton Component Size	Arrangement	Functions	Disorders
Microfilaments			
8 nm	Microfilaments thin, twisted strands of protein molecules	Movement of pigment granules	Impairment of leukocytes
Microtubules			
25 nm	Microtubules hollow, tough and durable fibers have spiral arrangement of protein subunits	▪ Maintenance of shape of cells, intracellular transport, movement of organelles and chromosomes ▪ Colchicine drug disrupts microtubules hence impairs movement of chromosomes	▪ Male sterility ▪ Kartagener's syndrome ▪ Dysfunctional leukocytes ▪ Chédiak-Higashi syndrome
8–10 nm	Intermediate filaments are thick hollow tubes, twisted protein strands (e.g. keratin, glial filaments, desmin and vimentin)	In most of the cells, intermediate filaments are forming a basket around the nucleus and present in cell-to-cell junction	▪ Mallory's hyaline ▪ α_1-Antitrypsin deficiency ▪ Parkinson disease

- Microfilaments in leukocytes participate in leukocytic movement and phagocytosis. Phalloidin toxin (*Amanita phalloides*) inhibit actin filaments resulting in disruption of phagocytic activity of the cells.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome protein (WASp) regulates remodeling of actin filaments of cytoskeleton to regulate cell movement, cell signaling and cell division.

- Abnormality of microfilaments is linked to Wiskott-Aldrich syndrome, a X-linked recessive immunodeficiency disorder characterized by recurrent bacterial sinopulmonary infections, eczema (atopic-like), platelet dysfunction (thrombocytopenia), bloody diarrhea (secondary to low platelet count) and T cell defect.
- Wiskott-Aldrich syndrome is treated with stem cell transplant by using bone marrow, peripheral blood or umbilical cord blood from a healthy suitably tissue matched donor.

Microtubules

Microtubules are the major components of the cytoskeleton and formed by the polymerization of a dimer of two globular proteins, tubulin α and β subunits, assembled into linear protofilaments that can then associate laterally to form hollow tubes, the microtubules with a diameter of 20–25 nm.

- Microtubules are capable of undergoing rapid assembly and disassembly in the cytosol. Microtubules function in maintenance of cell shape, intracellular organelle motility, structural support, keeping cell organelles in place and chromosome segregation during cell division (mitosis and meiosis, i.e. movement of chromosomes and creation of the mitotic spindle).
- Microtubules are essential for leukocytic migration and phagocytosis. Cytochalasin B drug prevents the assembly of microtubules also results in disruption of phagocytic activity of the cells.
- Microtubule abnormalities are linked to male sterility, Kartagener's syndrome (immotile cilia syndrome), dysfunctional leukocytes and Chédiak-Higashi syndrome (defective degranulation of neutrophils, impaired microbial killing).
- Male infertility can be caused by low sperm production, abnormal sperm function or blockages that prevent the delivery of the sperm. A sperm (spermatozoon) has three parts: head, neck, midpiece and tail (exoneme).

Clinical Pearls: Structure of Spermatozoon

- **Head of spermatozoon:** The head of the sperm contains nucleus with haploid number of chromosomes, that holds DNA of the cell. The head also contains numerous enzymes such as hyaluronidase, corona penetrating enzyme and zona lysine (acrosin) collectively called 'spermatolysins', which help the sperm breakthrough the cell membrane of ovarian ovum.
- **Neck of spermatozoon:** Neck of the sperm contains proximal and distal centrioles that form the cilium of the sperm. And after fertilization form the major microtubule-organizing center of the zygote.
- **Midpiece of spermatozoon:** Midpiece of the sperm contains mitochondria.
- **Tail of spermatozoon:** The structure of tail (exoneme) of sperm consists of 9+2 microtubules, molecular motors (flagellar dyneins), and their regulatory linker proteins. Microtubules are the prime component of the cytoskeleton, which are vital for organelle transport and cellular division during spermatogenesis, sperm motility and functional capacity of sperm. Tail (exoneme) of the sperm is well preserved. Defects in the microtubules in axonemal structure cause defects in sperm abnormality (teratozoospermia, oligospermia, oligozoospermia, asthenozoospermia or even azoospermia), sperm motility and often leads to male infertility.

Kartagener's Syndrome (Immotile Cilia Syndrome)

Kartagener's syndrome, also called immotile cilia syndrome, is an autosomal recessive ciliary microtubule associated disorder and characterized by triad of situs inversus, chronic sinusitis and bronchiectasis. The basic defect lies in the defective movement of cilia lining nose, paranasal sinuses, and bronchus. Eustachian tube and fallopian tube that cause interference of clearance of pathogens leading to recurrent infections of upper respiratory tract, otitis media and infertility. These patients are treated with colchicine drug.

Dysfunctional Leukocytes

Gout is caused by excessive uric acid in blood resulting from breakdown of purine. Defective metabolism of uric acid causes arthritis especially of smaller bones of the feet, due to deposition of uric acid crystals. Gout is characterized by sudden, severe episodes of acute pain, swelling and tenderness in the small joints, often at the base of the big toe resulting from dysfunctional leukocytes due to microtubule defects.

- Colchicine drug works by decreasing swelling and lessening the buildup of uric acid crystals that cause severe acute pain in the affected joints. Colchicine is a classical antimitotic drug which blocks mitotic cells in metaphase.

- Colchicine binds to tightly to ends of unpolymerized tubulin and forms a colchicine-tubulin complex resulting in inhibition of microtubule polymerization essential for cell mitosis.
- Colchicine may enhance activation, migration and phagocytic activity of neutrophils to the site of inflammation in response urate crystals.

Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome is an autosomal recessive disorder caused by mutation in the 'LYST gene' on chromosome 1q42 that encodes a protein essential for assembly of microtubules in neutrophils.

- Defect in assembly of microtubules in neutrophils results in impaired chemotaxis, defective degranulation of neutrophils, impaired microbial killing, and recurrent *Staphylococcus aureus* bacterial infections forming soft tissue abscess with fatal outcome.
- Neutrophils contain giant granules due to aberrant organelles. Accelerated phase of the syndrome results in fatal outcome due to multiorgan failure in 85% of cases.

Intermediate Filaments

Intermediate filaments are composed of a variety of proteins. These are 8–10 nm diamtere filaments highly stable cytoskeletal component expressed in different types of cells. Examples of intermediate filaments are keratin, microfilaments, glial filaments, desmin and vimentin. Immunochemical stains utilizing monoclonal antibodies against individual intermediate filaments (e.g. desmin to identify muscle) are useful in identifying the origin of neoplasms.

- The most important function of intermediate filaments is to provide mechanical support for the plasma membrane where it comes in contact with other cells and extracellular matrix for maintenance of cell shape.
- Unlike microtubules and microfilaments, intermediate filaments do not participate in cell motility.
- Abnormalities of intermediate filaments are linked to Mallory hyaline formation in liver diseases, accumulation of α-synuclein in neurons in the substantia nigra in Parkinson disease, and other diseases like epidermolysis bullosa simplex (EBS) and desmin myopathy.

Mallory Hyaline (Mallory-Denk Body)

In histopathology, Mallory hyaline also known as Mallory-Denk body or Mallory body, is an irregular eosinophilic intracytoplasmic inclusion, that represents aggregates of intermediate filaments (cytokeratins 8 and 18). The cytokeratins form a filamentous support within the hepatocytes. Liver disorders associated with Mallory-Denk bodies in hepatocytes are given in Table 1.4.

Table 1.4 Liver disorders associated with Mallory-Denk bodies

Alcoholic liver disease
Biliary atresia
Extrahepatic bile duct obstruction
Primary biliary cirrhosis
Primary sclerosing cholangitis
α_1-Antitrypsin deficiency
Abetalipoproteinemia
Hepatic adenomatosis in glycogen storage disease type 1a (von Gierke disease)
Wilson disease
Ethanol-induced hepatocellular injury
Amiodarone-induced hepatocellular injury
Indian childhood cirrhosis
Nonalcoholic steatohepatitis
Hepatic adenoma
Hepatocellular carcinoma
Focal nodular hyperplasia of liver

Neuronal Intermediate Filaments Related Neurodegenerative Diseases

Neuronal intermediate filaments (NIFs) are most abundant cytoskeleton component in mature neurons. These are composed of different protein units encoded by separate genes such as neurofilament light chain (NFL), neurofilament medium chain (NFM), neurofilament heavy chain (NFH), α-internexin and peripherin.

- Neuronal intermediate filament proteins give cells shape, determine axonal caliber, which control signal conduction, and regulate the transport of synaptic vesicles and modulate synaptic plasticity by binding to neurotransmitter receptors.
- Mutations in genes encoding neuronal intermediate filaments result in their aggregation in neurons responsible for neurodegenerative diseases such as Parkinson's disease, Alzheimer's disease, amyotrophic lateral sclerosis, Charcot-Marie-Tooth disease, dementia with Lewy bodies and giant axonal neuropathy.
  - **Parkinson disease:** α-Synuclein is normally wavy-like presynaptic neuronal protein. In Parkinson disease, α-synuclein protein misfolds and forms toxic aggregates, which damage neurons in the part of the brain called the substantia nigra. Normally,

neurons in this part of brain are responsible for production of a chemical called dopamine. Neuronal damage in this part of brain results in reduction of dopamine production. An antibody that binds the misfolded α-synuclein can be used to intercept the protein as it passes between neurons.

- **Alzheimer's disease:** It is a neurodegenerative disorder characterized by brain pathology of intracellular neurofibrillary tangles made of hyperphosphorylated R-protein and extracellular amyloid plaques present in cortical and limbic areas of human brain. It is characterized by memory loss and progressive neurocognitive dysfunction.
- **Amyotrophic lateral sclerosis (ALS):** It is also known as motor neuron disease or Lou Gehrig's disease affecting 50–60 years elderly persons. Peripherin is an intermediate filament protein detected in spheroids, a hallmark of amyotrophic lateral sclerosis. Increased levels of peripherin mRNA have been observed in some cases of amyotrophic lateral sclerosis. Disorder is characterized by death of neurons controlling voluntary muscles. Patient presents with muscle stiffness, muscle twitching and gradually worsening muscle weakness. Life expectancy is 2–4 years.
- **Charcot-Marie-Tooth disease type 2:** Neurofilaments (NFs) are the major intermediate filaments of mature neurons. Charcot-Marie-Tooth disease type 2 is a hereditary disorder involving motor and sensory neuropathies of the peripheral nervous system characterized by progressive skeletal muscle weakness and decreased touch sensation across various parts of the body. Recently, two mutations in the neurofilament light subunit have been detected in families affected by Charcot-Marie-Tooth disease type 2.
- **Dementia with Lewy bodies:** In dementia, Lewy bodies are intracytoplasmic inclusion bodies composed of the neurofilament (intermediate filament) protein, ubiquitin, α-synuclein and α-crystallin. Lewy bodies may occasionally be surrounded by neurofibrillary tangles.
- **Giant axonal neuropathy:** Giant axonal neuropathy (GAN) is an autosomal recessive slowly progressive neurodegenerative disorder caused by mutation in GAN gene that encodes gigaxonin, a member of the BTH/Kelch family of E3 ligase adaptor proteins. The disease is characterized by the aggregation of intermediate filaments of cytoskeleton. Patient presents with progressive motor and sensory peripheral neuropathy, central nervous system involvement (including cerebellar and pyramidal signs), and kinky hair in most cases.

Epidermolysis Bullosa Simplex

Epidermolysis bullosa simplex (EBS) is an inherited skin disorder caused by mutation in the keratin 5 (KRT5) and keratin 14 (KRT14). Genes with fragility of basal keratinocytes resulting in epidermal cytolysis and blistering produced with even a slight mechanical stress. Cells with severe mutations in KRT5 and KRT14 are more sensitive to osmotic stress and take longer time to recover from it.

Desmin Myopathy

Desmin myopathy is an autosomal dominant or autosomal recessive disorder caused by mutation in desmin or α-crystallin B. Patient presents with lower limb muscle weakness slowly spreading to involve truncal, neck-flexor, facial, bulbar and respiratory muscles. Histologic examination of tissue section shows abnormal fiber area containing amorphous eosinophilic deposits seen as granular or granulofilamentous material. Immunohistochemical examination demonstrates positive staining for desmin in each region containing abnormal structures.

MITOCHONDRIA

Mitochondria are cylindrical-shaped double membrane-bound organelle with inner part being folded inwards to form cristae and found in the cytoplasm of eukaryotic cells. Numerous mitochondria are found in human liver cells, with 1000–2000 mitochondria per cell, making up one fifth of the cell volume.

- Mitochondria utilize cytoplasmic proteins to degrade sugars and produce cellular energy in the form of ATP (i.e. phosphorylation of ADP) through cellular respiration for regulation of cellular metabolism. The set of reaction involved in ATP production are collectively known as the citric acid cycle, or the Krebs cycle.
- The Krebs cycle occurs in the mitochondrial matrix and generates chemical energy (ATP, NADH, and $FADH_2$) from the oxidation of pyruvate, the end product of glycolysis. When acetyl-CoA is oxidized to carbon dioxide in the Krebs cycle, chemical energy is released and captured in the form of ATP, NADH, and $FADH_2$.
- $FADH_2$ is high energy electron carrier used to transport electrons generation in glycolysis and Krebs cycle to the electron transport chain.

Mitochondrial Dysfunction

Mitochondrial dysfunction results in cell injury and apoptosis. Mitochondrial dysfunction has been indicated as a potential player of development of cardiac hypertrophy. Mitochondrial number is increased in hypertrophy and decreased in atrophy.

Mitochondrial Hypertrophy

Hypertrophy of mitochondria termed megamitochondria can be induced by a variety of processes. By electron microscopy, megamitochondria demonstrate normal cristae and matrix density; and associated with normal oxidative phosphorylation. It should be differentiated from swollen mitochondria, which have swollen cristae and irregular densities in the matrix; and associated with uncoupling of oxidative phosphorylation and reduction in ATP production induced by NSAIDs and tolcapone.

- Mild to severe hypertrophy of mitochondria is seen with disruption of mitochondrial β-oxidation of drug-induced hepatocellular injury. By electron microscopy, the amount of mitochondrial matrix increases and becomes electron lucent. By light microscopy, these changes may be observed as cytoplasmic vacuolation.
- Microvesicular steatosis, inflammation and necrosis occur in human beings as a feature of severe interference with mitochondrial β-oxidation of free fatty acid.
- Hypertrophy of mitochondria (megamitochondria) may be seen in alcohol liver disease, mitochondrial myopathies, certain nutritional diseases and benign tumors arising from oncocytes of salivary glands, thyroid, parathyroid and kidneys (known as oncocytes).

Mitochondrial Gene Mutations Associated Disorders

Mitochondrial disorders may be caused by inherited or acquired mutations in mitochondrial DNA or nuclear genes that code for mitochondrial components. Acquired mitochondrial dysfunction can be caused by drugs, infections and environmental factors. Mitochondrial gene mutations and associated disorders are given in Table 1.5.

- Mitochondrial diseases caused by mutations in mitochondrial genes include mitochondrial myopathies, cardiomyopathy, exercise intolerance, diabetes mellitus and deafness (DAD), Kearns-Sayre syndrome (KSS), Leigh syndrome, mitochondrial depletion syndrome (MDS), mitochondrial encephalopathy, subacute sclerosing encephalopathy, Leber's hereditary optic neuropathy (LHON); and neuropathy, ataxia, retinitis pigmentosa and ptosis (NARP).
- Even autoimmune diseases such as systemic lupus erythematosus, rheumatoid arthritis and Sjögren syndrome appear to have a mitochondrial basis. Mitochondrial diseases can occur at any age.
- Mitochondrial diseases can be diagnosed by biochemical tests on blood, urine and cerebrospinal fluid, skeletal muscle biopsy to examine the mitochondria and test enzyme levels, magnetic resonance imaging of the brain and spinal cord.
- Prognosis is variable in mitochondrial diseases. Minimally affected individuals live a normal life. Severely affected persons manifest with mitochondrial disease. The progression of mitochondrial disease is unpredictable and different for each individual.

Table 1.5 Mitochondrial gene mutations and associated disorders

Mitochondrial myopathies
Cardiomyopathy
Exercise intolerance, diabetes mellitus and deafness (DAD)
Kearns-Sayre syndrome (KSS)
Leigh syndrome
Mitochondrial depletion syndrome (MDS)
Mitochondrial encephalopathy
Subacute sclerosing encephalopathy
Leber's hereditary optic neuropathy (LHON)
Neuropathy, ataxia, retinitis pigmentosa and ptosis (ANRP)

LYSOSOMES

Lysosomes are sphere-shaped important membrane-enclosed cytoplasmic organelles, that contain numerous acid hydrolases (acid phosphatase, glucuronidase, sulfatase, ribonuclease, and collagenase). The pH in lysosomal lumen ranges between 4.5 and 5.0. Lysosomes degrade macromolecules (proteins, carbohydrates, some lipids) taken up into the cells by endocytosis (heterophagy). Major proteins present in lysosomes are given in Table 1.6. Lysosomal disorders are given in Table 1.7.

- Lysosomal proteases make up a great contribution to the overall process of intracellular degradation of most of proteins and carbohydrates. However, some lipids remain undigested. When examined under electron microscope, newly formed 'primary lysosomes' are more uniform in size, with an amorphous electron-opaque content. After fusion of lysosomes with phagocytic vesicles or other cell contents, these form 'secondary lysosomes', whose size and internal density is more variable. Lysosomes

Table 1.6 Major proteins present in lysosomes

Lysosomal Luminal Proteins
Acid hydrolases (enzymes) or their activators
Lysosomal Integral Proteins
▪ Structural proteins (amino acids and lipid transporters) ▪ Ion channels like calcium channels ▪ Trafficking and fusion machinery ▪ Vesicular ATPase which functions both as a proton pump and nutrient sensor
Lysosomal Associated Proteins

Table 1.7 Lysosomal disorders

Categories	Diseases
Sphingolipidosis	Niemann-Pick disease: types A, B and C, Gaucher's disease: types 1, 2 and 3, Fabry disease (classic and late-onset types), metachromatic leukodystrophy, globoid leukodystrophy, multiple sulfatase deficiency, GM1 gangliosidosis: types 1, 2, GM2 gangliosidosis: Tay-Sachs disease, and Sandhoff disease and GM2 activator deficiency
Mucopolysaccharidosis	Hurler syndrome, Scheie syndrome, Hunter syndrome, Sly syndrome, Morquio syndrome: types A, B, Sanfilippo syndrome: types A, B, C and D, and Maroteaux-Lamy syndrome
Oligosaccharidosis	Schindler disease, fucosidosis, α-mannosidosis and aspartylglucosaminuria
Neuronal ceroid lipofuscinosis	Neuronal ceroid lipofuscinosis 1 through neuronal ceroid lipofuscinosis 14 (lipofuscin pigment)
Sialic acid disorders	Galactosialidosis, infantile sialic acid storage disease, salla disease and sialuria
Mucolipidosis	Mucolipidosis I (sialidosis I and II), mucolipidosis II (I cell disease), mucolipidosis III (pseudo-Hurler polydystrophy), and mucolipidosis IV
Miscellaneous disease	Pompe disease (glycogen storage disease type 2), Dannon disease (glycogen storage disease), cystinosis and lysosomal acid lipase deficiency (infantile and childhood/adult types—accumulation of cholesterol esters, triglycerides)

containing indigestible material often remain in the cytoplasm as residual bodies (e.g. lipofuscin pigment in elderly persons).

- Lysosomes participate in removal of damaged cell organelles during cell injury and the cellular remodeling of differentiation, and atrophic cells due to nutrient deprivation. Chloroquine antimalarial drug raises the intracellular pH of the lysosomes, thus inactivating its enzymes reduces tissue damage in inflammatory reactions.
- Certain substances are not metabolized by cells resulting in abnormal accumulation of glycogen and phospholipids in lysosomes and impairment of functions. Deficiency of enzyme results in accumulation of endogenous substances and causes lysosomal storage diseases. Insoluble endogenous pigments such as lipofuscin and melanin accumulate in the cells. Exogenous particulate particles accumulate such as silica, carbon and asbestos in the lungs.

Pathology Pearls: Autophagy and Heterophagy

Autophagy

- Autophagy usually inhibits apoptosis; however, if uncontrolled, it can cause lysosomal digestion of the cell's own components. Autophagy participates in removal of damaged cell organelles during cell injury and the cellular remodeling of differentiation, and atrophic cells due to nutrient deprivation.
- Chloroquine antimalarial drug raises the intracellular pH of the lysosomes, thus inactivating cell enzymes reduces tissue damage in inflammatory reactions.
- Autophagy is categorized as macroautophagy, microautophagy (direct pinocytosis by the lysosomes) and chaperone-assisted autophagy.
- In macroautophagy, portions of cytosol and cell organelles are enveloped in a double-membrane autophagosome, which subsequently fuses with a lysosome to form a single-membrane bound autophagolysosome resulting in degradation of the cell's own cytoplasmic organelles by releasing proteolytic enzymes.

Heterophagy

- Heterophagy is the process of lysosomal degradation of materials ingested from the extracellular environment by the general process of endocytosis.
- Ingestion of particulate particles by the cells is known as phagocytosis, and uptake of soluble smaller macromolecules is called pinocytosis.
- Extracellular materials are endocytosed into phagosomes, which eventually fuse with lysosomes to form phagolysosomes, where the engulfed extracellular material is degraded.
- Heterophagy is the most common in the professional phagocytes, such as neutrophils and macrophages. Examples of heterophagy include the uptake and degradation of bacteria by neutrophils and the removal of apoptotic cells by macrophages.

ENDOPLASMIC RETICULUM

The smooth endoplasmic reticulum is a multifunctional membranous organelle found in most eukaryotic cells, which lacks ribosomes. It participates in lipid biosynthesis, steroid hormones synthesis and detoxification of harmful metabolic byproducts, protein folding and processing; and storage of calcium ions in the cell.

- Smooth endoplasmic reticulum is especially abundant in mammalian liver and gonad cells. When cells exposed to chemical agents, the endoplasmic reticulum shows hypertrophy as an adaptive response.
- Proper functioning of endoplasmic reticulum is disturbed by a number of physiologic, pathologic conditions and pharmacologic agents resulting in impairment of protein folding and risk of proteotoxicity.

- Smooth endoplasmic reticulum stress is triggered by intracellular alterations (e.g. calcium or redox imbalances), microenvironmental conditions (e.g. hypoxia, hypoglycemia, and acidosis), high sugar-diet, high-fat diet, natural compounds (e.g. tunicamycin and geldanamycin), and several drugs (e.g. bortezomib (Velcade®), Celebrex and nelfinavir). The cell reacts to smooth endoplasmic reticulum stress by initiating a defensive cellular mechanism, known as the unfolded protein response (UPR) aimed at cellular adaptations and safeguarding cellular survival.
- A malfunction of the endoplasmic reticulum stress response induced by aging, genetic mutations, or environmental factors can result in various diseases such as diabetes mellitus type 2, obesity, inflammation, Alzheimer's disease, Parkinson's disease, amyotrophic lateral sclerosis, atherosclerosis and nonalcoholic fatty liver. Obesity also induces endoplasmic reticulum stress. Hyperglycemia and free fatty acids disrupt endoplasmic reticulum homeostasis and induce pancreatic β cell death through C/EBP homologous protein, which has a central role in apoptotic execution pathways triggered by endoplasmic reticulum stress.
- Endoplasmic stress triggers a protective cellular mechanism, which includes the unfolded protein response (UPR). When activation of the UPR is severe and prolonged, the final cellular outcome is pathologic apoptotic cell death. Stress that impairs endoplasmic reticulum homeostasis leads to accumulation of unfolded or misfolded proteins such as amyloid β (Aβ) peptide, the major component of amyloid plaques in Alzheimer's disease.
- Endoplasmic reticulum stress has been implicated in the pathogenesis of Parkinson's disease. Accumulation of a substrate of Parkin in the endoplasmic reticulum activates endoplasmic reticulum stress. Human ubiquitin ligase HRD1 is associated with protection against endoplasmic reticulum stress. Human ubiquitin ligase HRD1 also prevents apoptosis of neurons.
- Dysfunction in protein handling in endoplasmic reticulum has been implicated in the pathogenesis of amyotrophic lateral sclerosis. Mutation in Cu/Zn-superoxide (SOD1) induces endoplasmic reticulum and motor neuron death resulting in amyotrophic lateral sclerosis (ALS). Exact mechanism of SOD1 induced death is unknown.
- Prolonged endoplasmic reticulum stress has been implicated in the pathogenesis and progression of atherosclerosis. Oxidized phospholipids, homocysteinemia and cholesterol loading induce death of macrophages, vascular smooth muscle cells and endothelial cells via CHOP.
- Disruption of endoplasmic reticulum homeostasis, often termed endoplasmic reticulum has been observed in liver and adipose tissue with nonalcoholic fatty liver disease and/or obesity. Endoplasmic reticulum contributes to hepatic SREBP-Ic activation and lipid accumulation in fructose-evoked nonalcoholic fatty liver disease (NAFLD).

INTRODUCTION TO PATHOLOGY

A disease is an alteration from the normal function/structure of an organ or system, which manifests as a characteristic of signs and symptoms. Disease can be congenital (genetic or nongenetic) or acquired. Pathology emphasized three aspects of disease process: (a) mechanism of development of disease (pathogenesis), (b) the alterations of structure and forms (morphology), and (c) functional alterations (pathophysiology).

- Etiopathogenesis refers to study the causes such as genetic defects, environmental including iatrogenic or idiopathic.
- Pathogenesis is defined as the mechanism that leads to a diseased state by progression of processes of cellular lineage, maturation, migration, and eventual morphogenesis of both individual cells and their architecture in formation of a tissue or organ.
- Pathophysiology refers to the study of functional changes in body functions that are the causes, consequences or concomitants of disease processes.
- Most important aspects in clinical practice of medicine and surgery are diagnosis, prognosis, treatment and prophylaxis.

PATHOLOGY

Pathology is the scientific study of disease, that identifies etiology, mechanism and functional changes in cells, tissues and organs that underlie disease. Pathology lays a strong foundation of every aspect of patient care from diagnostic testing and treatment. Alterations at the molecular level and cellular level correlate with the clinical manifestations of the disease. Understanding the processes of the disease helps in the accurate recognition, diagnosis (biochemical investigations, hematologic tests, surgical pathology and immunohistochemistry) and treatment of diseases.

Pathology Divisions

Pathology is divided into following clinical discipline: general pathology, systemic pathology, chemical pathology and forensic pathology. There are three main subtypes of pathology: anatomic pathology, clinical pathology, and molecular pathology.

General Pathology

General pathology is the study of the reactions of cells or tissues to injury with a focus on the mechanisms of that response, which involves all aspects of pathology. It deals with clinical history, examination of patient, diagnosis and management of the disease by use of laboratory medicine and diagnostic techniques.

Systemic Pathology

Systemic pathology is the pathology of systems in the human body. Anatomic pathology is the study of tissues, organs and tumors. Systemic pathology is not a separate discipline from general pathology, but a different approach at the level of the tissue or organ or even the entire body. Pathologists are specialists in the disciple of pathology. Although general pathology and systemic pathology are educationally useful divisions of pathology discipline. Pathologists can be specialists in a particular organ system.

Histopathology

Histopathology is the study of histologic abnormalities of diseased cells and tissues under a microscope, which enables pathologists to look for changes in cells or tissues that explain the actual cause of the patient's illness. Pathologists are able to reach a diagnosis by examining a biopsy (punch, wedge, excision) from various organs. Histopathology is essential as it broadens and progresses treatment options.

Cytopathology

Cytopathology is the study of cellular changes related to cells and mainly used to diagnose or screen for cancer. Cell samples can be obtained during routine diagnostic procedures, such as bronchoscopy and cystoscopy or fine needle aspiration from specific body's sites for diagnosis. Cytopathology is also used to screen for fetal abnormalities and Papanicolaou smears are prepared from cells taken from the cervix to diagnose cervical cancer and infectious organisms. Two methods can be used in a Papanicolaou test: conventional and automated liquid tests.

Immunopathology

Immunopathology is a branch and manifestation of conditions concerned with immune responses associated with the production of diseases through the analysis of humoral and cellular immune function. There is a great deal of synergy between the adaptive immune system and its innate immune system, and defects in either of immune system can provoke disease such as inappropriate inflammation, autoimmune diseases, immunodeficiency diseases and hypersensitivity reactions.

Molecular Pathology

Molecular pathology is the study of disease at the molecular level by testing deoxyribose nucleic acid (DNA), ribonucleic acid (RNA) and proteins found in tissues, organs, and even body fluids within a clinical context. The applications of molecular diagnostics span a range of human disorders including hereditary, neoplastic and infectious diseases. Molecular-based *in vitro* biological assays such as polymerase chain reaction enzyme-linked immunosorbent assay (PCR-ELISA) or fluorescence *in situ* hybridization (FISH) are used to detect a molecule, often in low concentrations, that is a marker of disease or risk in a sample from a patient.

Hematology

Hematology is a branch of internal medicine in relation to health and disease, that deals with the pathophysiology, diagnosis, treatment, prognosis and prevention of blood-related disorders such as anemias, leukemias, lymphoma, bleeding and coagulation disorders. Hematology tests are performed on the blood, blood proteins and hematopoietic organs. Full blood count is a routine test that evaluates three major components found in the blood: red blood cells, white blood cells and platelets.

Chemical Pathology

Chemical pathology is the study of biochemical abnormalities associated with disease, which involves biochemical investigations of body fluids such as blood, urine and cerebrospinal fluid.

Forensic Pathology

Forensic pathology refers to perform autopsies and legal pathology tests. Autopsy room sessions can provide students with an excellent opportunity to correlate the gross and histopathologic features with the natural history of the disease.

Basis of Pathology Study

Understanding the processes of the disease help in the accurate recognition, diagnosis (biochemical investigations, hematological tests, surgical pathology and immunohistochemistry) and treatment of diseases.

Etiology

The word etiology refers to the scientific study of disease process, which generally falls into three main categories: intrinsic, extrinsic and idiopathic (unknown cause).

- Pathologic change that has occurred from inside the body as a result of intrinsic factors such as inherited, metabolic, neoplastic and immune system disorders. Hemophilia is an example of inherited disorder that

leads to excessive bleeding. Diabetes mellitus is a metabolic and endocrine disorder that causes high blood sugar.

- Pathologic change that has occurred from outside as a result of extrinsic factors include: (a) infectious agents such as bacteria, viruses, fungi and parasites, (b) animal bites or stings, (c) physical trauma, chemical agents, electricity burns and radiation; and (d) iatrogenic causes resulting from medical professional's actions or within a medical setting, and (e) idiopathic of unknown cause.
- Reactive oxygen species (ROS) is a group of extremely reactive peroxides and oxygen-containing radicals that may contribute to cellular damage.
- Autophagy refers lysosomal breakdown of a cell's own components. Autolysis refers to breakdown of cells by their own enzymatic action.

Risk Factors

A risk factor confers an increased risk of developing a disease. For example, tobacco smoking is a risk factor for lung cancer and obesity is a risk factor for heart disease.

- Types of risk factors include tobacco smoking, alcoholism, nutritional, physical inactivity, prolonged exposure to sunlight, not having certain vaccination and unprotected sexual activity leading to sexual transmitted diseases.
- The risk factors of chronic diseases are modifiable for men and women such as unhealthy diet, physical inactivity and tobacco use. These risk factors are expressed through the intermediate risk factors of raised blood pressure, raised blood glucose levels, abnormal lipids, overweight and obesity.
- Chronic diseases are the major causes of mortality and disability worldwide, which include heart disease (coronary artery disease, ischemic heart disease), cerebral stroke, chronic respiratory diseases (chronic obstructive pulmonary disease, bronchial asthma), bone and joint disorders, genetic orders and neoplastic disorders.

Predisposition

Predisposition is a term applied for patients having an increased susceptibility to develop a disease. A genetic predisposition is an increased likelihood of developing a genetic disorder. For example, familial adenomatous polyposis (FAP) patients have a mutated APC gene associated risk of developing colorectal carcinoma resulting from succession of mutations in one or more polyps. Other examples of genetic disorders include Down syndrome, thalassemia, cystic fibrosis and sickle cell disease.

Pathogenesis

Pathogenesis is the pathologic mechanism which results in clinically evident disease. For example, the way in which the interaction between *Mycobacterium tuberculosis* and the host immune system produces the caseating epithelioid granulomatous lesion in tuberculosis.

- Atherosclerosis is a chronic inflammatory disease, which begins with fatty streak due to accumulation of lipid laden foam cells in the intimal layer of large elastic and medium-sized arteries and then progresses to formation of atheromatous plaque.
- The atheromatous plaque has cellular component (e.g. smooth muscle cells and inflammatory cell), a fibrous component composed of connective tissue, and central core fat component of lipids. Major risk factors of atheromatous plaque are hypertension, diabetes mellitus, dyslipidemia, tobacco smoking, obesity, sedentary lifestyle and family history.

Morphologic Changes in Cells and Tissues

Morphologic changes are characterized by structural alterations in the cells and tissues and altered cellular functions such as cell–pathogen interaction, tumor formation and stem cell differentiation.

- Cellular adaptation is the ability of cells to respond to various types of stimuli and adverse environmental changes. If cells are unable to sustain to the adverse injurious insults, cell undergoes apoptosis or cell death in the form of necrosis.
- Morphology is a branch of life science dealing with the study of gross structure of diseased tissue and microscopic examination of tissue.

Functional Derangements and Clinical Manifestations

External and internal factors adversely affecting cell, tissue, organ or person cause structural and functional changes and cellular adaptation and response from cellular to whole person level resulting in symptoms and signs.

- For example, *Streptococcus pneumoniae* causes acute inflammatory response (consolidation is structural change in lung parenchyma that becomes solid, reduced exchange of gases in alveoli is functional change) resulting in symptoms (cough, breathlessness, hemoptysis) and signs such as reduced chest movements, dull percussion notes and radiologic changes.
- Injury to the cells and extracellular matrix results in tissue and organ injury, which determines the morphologic and clinical patterns of the disease.

Diagnosis

Understanding the processes of the disease help in the accurate recognition, diagnosis (biochemical investigations, hematological tests, surgical pathology and immunohistochemistry) and treatment of diseases.

CELLULAR RESPONSE TO STRESS AND HARMFUL STIMULI

Normal cells are the structural and functional units of tissues, which remain in a state of homeostasis with the extracellular fluid and respond to changes in their environment. The cells are capable of adjusting their structure and functions in response to various physiologic and pathologic mild to severe stimuli throughout life. Genetic or acquired metabolic defects and chronic cell injury cause intracellular accumulation of glycogen, proteins and pigments; and pathologic dystrophic and metastatic calcification. Cellular response to injurious stimuli is given in Table 1.8. Cellular response to injurious stimuli is shown in Fig. 1.1.

- Altered physiologic stimuli and some nonlethal stimuli produce cellular adaptations: atrophy, hypertrophy, hyperplasia and metaplasia. Intracellular accumulations occur due to altered metabolism.
- Cellular stress beyond the level of adaptive response results in cell injury. Cellular injury occurs when a stress exceeds the cells ability to adapt due to altered physiologic stimuli, reduced oxygen supply, extremes of temperature, electrical injury, radiation, biologic agents, and nutritional deficiency, metabolic alteration and cumulative aging.
- Cell injury depends on injurious stimuli: (a) type, duration and severity of injury, (b) ability of the tissues to regenerate (e.g. labile or dividing cells/stable cells/permanent cells), (c) metabolic needs of cell, (d) adaptability of cell, and (e) genetic constitution. Neurons are highly susceptible to ischemic injury; whereas skeletal muscle is relatively more resistant to ischemic injury.
- Depending on severity of cell injury, various cellular changes occur: (a) subcellular alterations (intracellular accumulation of biomolecules and calcium), (b) reversible cell injury, (c) irreversible cell injury

Table 1.8 Cellular response to injurious stimuli

Cellular Adaptations
▪ Hyperplasia ▪ Atrophy ▪ Hypertrophy ▪ Metaplasia
Cell Injury
▪ Reversible cell injury ▪ Irreversible cell injury (necrosis and apoptosis)
Intracellular Accumulations
▪ Normal endogenous substances (e.g. fatty liver and protein droplets in renal tubules) ▪ Normal endogenous substances due to enzyme defects (e.g. glycogen storage diseases and lipid storage disorders) ▪ Mutated gene products (misfolded proteins) ▪ Abnormal exogenous products (e.g. silicosis and anthracosis)
Subcellular Changes
▪ Lysosomal catabolism (heterophagy or autophagy) ▪ endoplasmic reticulum hypertrophy (induction of drug tolerance to barbiturates and alcohol) ▪ Mitochondrial defects (number, size and shape) ▪ Cytoskeleton defects (phagocytosis and locomotion) ▪ Membranes (plasma membrane and subcellular membrane such as endoplasmic reticulum) ▪ Nucleus (pyknosis, karyorrhexis and karyolysis)

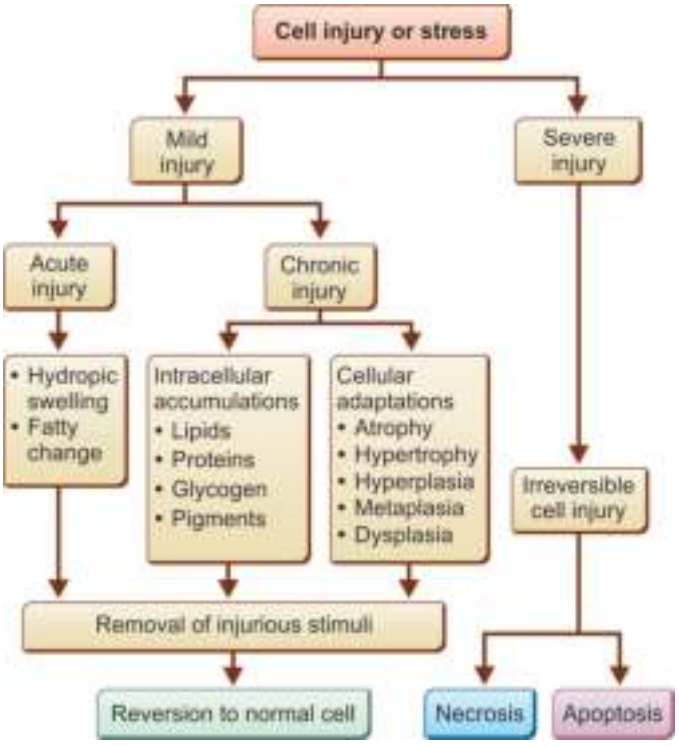

Fig. 1.1: Cellular response to injurious stimuli. Cellular adaptations, reversible injury and cell death may be stages of progressive impairment following different types of insults depending on type and duration of injurious stimuli. Acute cell mild injury can cause hydropic change and fatty change. Chronic cell injury can cause intracellular accumulation of biomolecules and cellular adaptations. Severe cell injury can cause necrosis and apoptosis.

and (d) ischemic/reperfusion injury. Initially, cellular injury may be reversible, but prolonged or severe stress leads to irreversible cell injury (necrosis or apoptosis). Reversible cell injury is the ability to heal without permanent damage.

- Ultrastructural signs in both reversible and irreversible cell injury include: (a) cellular swelling occurs due to diminished activity of the sodium/potassium pump in the cell membrane causing influx of sodium along with water and efflux of potassium, (b) mitochondrial swelling results in reduced adenosine triphosphate (ATP), aerobic respiration (oxidative phosphorylation), (c) dilatation and degranulation of rough endoplasmic reticulum results in cessation of protein synthesis, and (d) autophagocytosis occurs due to ingestion of damaged cell organelles by the lysosomes.

CELLULAR ADAPTATIONS

Cellular adaptations are usually reversible changes that result in increased, decreased, or altered functions of cells, tissues and organs, which can be physiologic or pathologic and have many causes. Cellular adaptations encompass several processes: (a) hyperplasia, (b) hypertrophy, (c) atrophy, (d) metaplasia, and (e) dysplasia. Cellular adaptations are shown in Fig. 1.2.

- **Hyperplasia:** Hyperplasia is the enlargement of the tissue/organ caused by an increase in the reproduction rate of its cells. Physiologic hyperplasia occurs in normal cells: (a) hormones-driven increase in the thickness of endometrium during menstrual cycle, lactating breast and uterus during pregnancy, (b) tissue damage-driven proliferation of connective tissue cells in wound healing, and (c) hepatocellular regeneration after partial resection. Pathologic hyperplasia is linked to cancer in endometrium and breast.
- **Hypertrophy:** Hypertrophy is defined as an increase in the size of the cell due to the synthesis of structural components and expression of embryonic genes triggered by mechanical and trophic factors (growth factors and stretch receptors). Physiologic hypertrophy occurs due to increased functional demands placed on the cell (e.g. skeletal muscle hypertrophy from weight lifting). Pathologic hypertrophy occurs when the limit of cardiac hypertrophy is exceeded and the cells can longer compensate for the increased burden (e.g. congestive heart failure and systemic hypertension).
- **Atrophy:** Atrophy refers to reduction in size of cell and tissues. Physiologic atrophy of skeletal muscles occurs in bed-ridden persons. Pathologic atrophy occurs due to loss of stimulus to a specific region due to diminished blood supply, loss of hormone stimulation, and neurogenic diseases (poliomyelitis, Guillain-Barré syndrome, Charcot-Marie-Tooth disease, amyotrophic lateral sclerosis).
- **Metaplasia:** Metaplasia is the conversion of one adult tissue type into another in same tissue. It is an adaptive response to a hostile environment that increase risk of development lung carcinoma in tobacco smokers (glandular to squamous epithelium conversion in respiratory mucosa) and esophageal adenocarcinoma in 'Barrett's esophagus' (squamous to glandular epithelium conversion).
- **Dysplasia:** Dysplasia is used to describe acquired disorderly growth and maturation of cells that are abnormal but not obviously malignant under a light microscope. This type of preneoplastic condition is

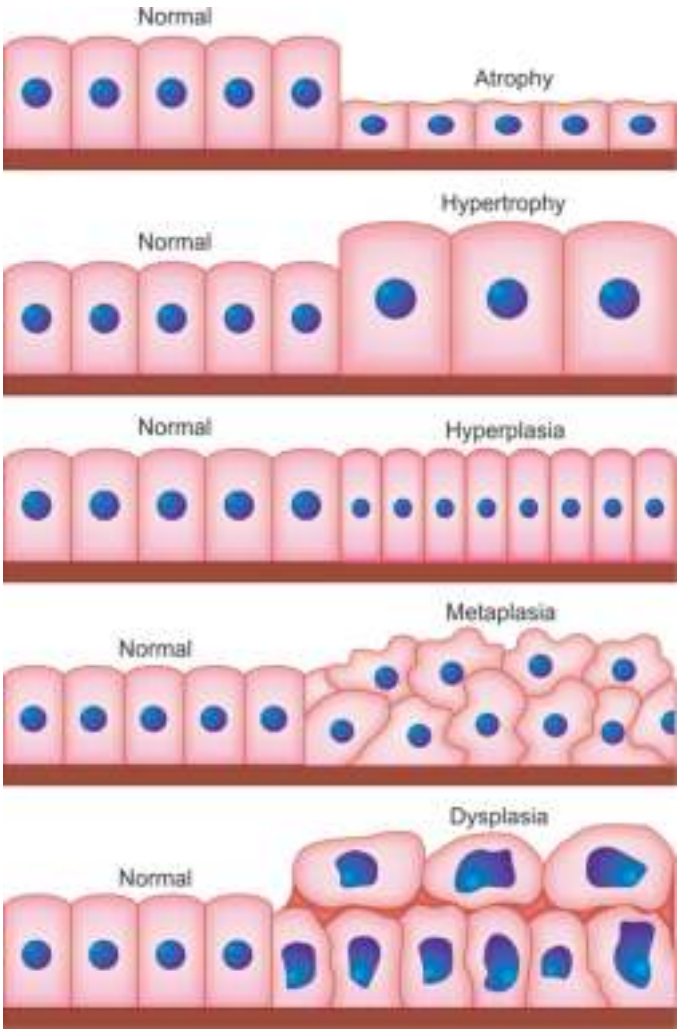

Fig. 1.2: Cellular adaptations. In cell biology and pathophysiology, cellular adaptation refers to alteration made by a cell in response to adverse or varying environmental changes. Cellular adaptations may be physiologic or pathologic (atrophy, hypertrophy, hyperplasia, metaplasia and dysplasia).

a precursor of invasive neoplasia. High-risk human papillomavirus (HPV 16, 18) is linked to cervical intraepithelial neoplasia (CIN) that may progress to invasive cervical carcinoma.

CELL INJURY

Cell can be injured by a variety of injurious stimuli such as hypoxia (oxygen deficiency), ischemia (lack of blood flow), physical or mechanical injury, chemical injury, radiation, biological injury (viruses, pathogens), and nutritional injury. Depending on the type of injurious agent and severity, cell injury may be reversible and irreversible process.

- **Mild and transient sublethal cell injury:** Mild and transient sublethal cell injury results in reversible injury, which can be repaired and cell returns to normal function by removal of damaged cell components by autophagy. In sublethal injury, cell shows swelling of endoplasmic reticulum and some mitochondria; and loss of ribosomes.
- **Severe progressive lethal cell injury:** Severe progressive lethal cell injury is irreversible, that results in cell death by necrosis or apoptosis. In lethal cell necrosis, initial cellular changes are loss of nucleolus, loss of ribosomes, swelling of all mitochondria and swelling of endoplasmic reticulum. Later cellular changes are nuclear condensation, plasma membrane blebs and holes, lysosomal rupture and fragmentation of all inner membranes of cell organelles and degradation of nucleus (pyknosis, karyorrhexis and karyolysis).

REVERSIBLE CELL INJURY

Reversible cell injury is acute sublethal injury with a hallmark of morphologic changes in cytoplasmic organelles sparing nucleus. These morphologic changes in reversible cell injury can be reversed if injurious noxious stimulus is removed.

- One global response in reversible cell injury is cellular swelling, that is a result of misfunctioning ion channels ($Na^+/K^+/Cl^-/Ca^{++}$ pumps) in the plasma membrane. Another global response in reversible cell injury is fatty change (large lipid vacuoles in cytoplasm) in the organs. Reversible cell injury occurs in the metabolically active cells of liver, heart and kidneys. Examples of reversible cell injury are hydropic change and fatty change in organs.
- In reversible cell injury, cell swelling occurs as a result of misfunctioning ion channels ($Na^+/K^+/Cl^-/Ca^{++}$ pumps) in the plasma membrane. Subcellular changes in the reversible injured cells include endoplasmic reticulum cisternae swelling, mitochondrial swelling, plasma membrane blebbing due to disordered cytoskeleton, segregation of fibrillary and granular components of nucleolus in the nucleus and intracellular myelin figures. Mitochondrial swelling results in reduced oxidative phosphorylation, downregulation of adenosine triphosphate (ATP), and decreased glycogen.
- Plasma membrane blebbing occurs due to disordered cytoskeleton. Myelin figures are derived from damaged membranes of mitochondria, or rough endoplasmic reticulum and the plasma membrane; demonstrated in cytoplasm on electron microscopy.

IRREVERSIBLE CELL INJURY

Severe and progressive cell injury results in irreversible cell injury (necrosis) induced by prolonged ischemia, viral infection, chemical agents and immunologic response. Following severe cell injury, cell and its organelles start to disintegrate resulting in rupture of the cells and inducing acute inflammatory response. On the other hand, apoptosis is a process of programmed cell death that occurs in multicellular organisms. Apoptosis can be triggered through either intrinsic pathway or extrinsic pathway.

Necrosis

Necrosis is fundamentally a cytoplasmic driven uncontrolled process in response to prolonged or severe injurious stimuli resulting in damage to plasma membrane and membrane of organelles resulting in depletion of ATP, increased acidosis, leakage of lysosomal hydrolytic enzymes in the cellular environment, protein digestion, loss of basophilia, increased cytoplasmic eosinophilia and nuclear changes (pyknosis, karyorrhexis, karyolysis due to endonucleases), calcification, release of cellular breakdown products and cytokines incites an inflammatory reaction.

- Morphologic patterns of necrosis are coagulative necrosis, liquefactive necrosis, gangrenous necrosis, caseous necrosis, fat necrosis and fibrinoid necrosis.
- The tissue in coagulative necrosis has firm texture, maintenance of general tissue architecture, ghost outlines of necrotic cells lacking nuclei for weeks before undergoing phagocytosis.
- In liquefactive necrosis, normal tissue architecture is rapidly transformed into a liquid mass due to autolysis and heterolysis leading to liquefactive necrosis in brain and pyogenic lung abscess with suppurative (neutrophil-rich) inflammation.
- In fat necrosis, fat degradation with possible saponification occurs most commonly due to release of enzymes from pancreas.

- Fat necrosis occurs due to physical trauma to the female breasts, radiation to a particular area of tissue, history of surgery to a particular area and history of removal of breast implants.
- Caseous necrosis occurs in tuberculosis and certain fungal infections.

Apoptosis

Apoptosis is a process of programmed cell death mediated by caspases. Apoptosis features nuclear shrinkage, DNA fragmentation by endonucleases, cytoskeleton breakdown by proteases, membrane blebbing; and membrane-bound apoptotic bodies, which are phagocytosed by macrophages and adjacent cells without generating inflammatory response.

- Apoptosis is an essential physiologic mechanism triggered by normal healthy processes in the body to regulate embryonic development, cell differentiation and tissue turnover. Apoptosis of embryonic cells in the limb beds results in formation of fingers and toes. Hormone-induced apoptosis of endometrial cells occurs at the end of menstrual cycle. In pathologic state, apoptosis can be triggered by radiation, chemotherapeutic agents and cell deprived of growth factors. Hepatitis virus-induced hepatocellular injury results in formation of acidophilic Mallory bodies.
- Primary pathways of apoptosis include: extrinsic (death receptor) pathway, intrinsic (mitochondrial) pathway and CD8+ cytotoxic T cell/NK cell's granzyme B/perforin-mediated pathway.
  - **Intrinsic (mitochondrial) pathway:** Intrinsic pathway of apoptosis is induced by chemotherapy and/or radiotherapy. Intrinsic pathway works by increasing mitochondrial permeability and releasing cytochrome c into cytoplasm, which combines with APAF-1 (apoptosis activating factor 1) to activate caspases, which cleave DNA into fragments, if analyzed on a gel electrophoresis will form a **'ladder pattern'**. In contrast, in necrosis, DNA breakdown will form smear pattern.
  - **Extrinsic (death receptor) pathway:** Extrinsic pathway of apoptosis is initiated through the stimulation of the transmembrane death receptors, such as the Fas receptors located on the cell membrane. In Fas-Fas ligand binding, the Fas ligand binds to a member of tumor necrosis factor family known as the Fas receptor. The activated Fas receptor in turn activates FADD (Fas-associated death domain), which in turn activates caspases.
  - **CD8+ cytotoxic T cell/NK cell's granzyme B/perforin-mediated pathway:** CD8+ cytotoxic T cell/NK cell's granzyme B/perforin-mediated pathway induces apoptosis releasing two types of preformed cytotoxic proteins such as granzyme B and perforin. Granzyme B induces apoptosis of target cell, and the pore forming perforin protein, which punches holes in the target cell membrane through which the granzyme B can enter the target cell to induce apoptosis.
- Apoptosis has two phases: (a) initiation phase (activation of caspases) and (b) execution phase (caspases induced cell death). Apoptosis can be triggered through either intracellular (mitochondrial) pathway or extracellular pathway. Both pathways share similar endpoints, culminating with the use of caspases and prevention of inflammatory reaction.
- Steps of apoptosis are cell shrinkage, chromatin condensation and DNA fragmentation by endonuclease, formation of apoptotic bodies and phagocytosis by macrophages and surrounding epithelial cells.
  - Examples of physiologic apoptosis include: (a) programmed death of cells in the limb buds with formation of fingers and toes, (b) predetermined death of cells on the surface of the intestinal mucosa and (c) hormone-induced death of endometrial cells at the endo of menstrual cycle.
  - Examples of pathologic apoptosis include: (a) hepatitis virus-induced death of hepatocytes (acidophilic bodies), (b) corticosteroid-induced atrophy of the neonatal thymus, (c) immune-mediated injury-related skin keratinocytes (Civatte bodies).

Pathology Pearls: Necrotic Cell versus Apoptotic Cell

- Necrotic cells release danger-associated molecular patterns (DAMPs), whereas apoptotic cells lack release of DAMPs.
- Injurious stimuli that induce necrosis (severe cellular damage), which results in rapid cell rupture with consequent release of intracellular DAMPs. DAMPs then cells of the immune system and can promote inflammation.
- On the other hand, injurious stimuli that initiate apoptosis are typically physiologic and relatively mild in nature, apoptotic cells do not rupture and their removal is coordinated by macrophage and other cells the innate immune system, before release of DAMPs can occur. For this reason, apoptosis process is not typically associated with activation of the immune system.

METABOLIC DERANGEMENTS

Stresses of different may induce changes in cells and tissues other than cellular adaptations, cell injury and cell death. Metabolic derangements in cells and sublethal chronic injury may be associated with intracellular accumulation of biochemical molecules such as carbohydrates, lipids and proteins as a result of derangements in cell metabolism because of defect in enzymatic mechanism and transport of biomolecules.

INTRACELLULAR ACCUMULATIONS

Intracellular accumulation occurs by two mechanisms: (a) it occurs due to overproduction of normal endogenous substance at increased rate and inadequate metabolism (fatty changes in liver), and (b) it occurs due to accumulation of normal endogenous substance and inadequate metabolism as a result of lack of enzyme that blocks metabolic pathway. Three categories of intracellular accumulations are given in Table 1.9.

Lipid Accumulation

Lipid accumulates in the liver in alcoholic patients and obese persons. Excessive fat accumulation in various organs such as liver, heart or the kidneys can occur due to toxins, malnutrition, diabetes mellitus, obesity, anorexia and alcohol consumption. Cholesterol accumulates within atheromatous plaque.

Table 1.9 Three categories of intracellular accumulations

Accumulation of Constituents of Normal Cell Metabolism
▪ Lipids ▪ Proteins ▪ Carbohydrates
Accumulation of Abnormal Substance of Cell Metabolism
▪ Storage disease ▪ Inborn error of metabolism
Accumulation of Pigments
▪ Endogenous pigments ▪ Exogenous pigments

- Gross examination of fatty liver reveals enlarged, bright yellow and soft greasy. Calcium is often deposited at the sites of cell death. Calcification is buildup of calcium in the injured tissues such as soft issues, arteries and other regions.
- Light microscopy shows lipid vacuoles in the cytoplasm displacing the nucleus to the periphery of the cell. Rarely, lipid laden cell rupture and enclosed lipid globules coalesce and form fatty cyst.

Glycogen Accumulation

Glycogen accumulates in the renal tubular cells in diabetic patients, liver and skeletal muscles in inborn errors of metabolism caused by enzymatic defect in synthesis and breakdown of glycogen.

Protein Accumulation

Protein accumulates as protein droplets in the proximal renal tubules in renal disease with heavy protein leakage across the glomerular basement membrane.

Pigments

Pigment that can accumulate in various cells include lipofuscin (wear and tear pigment, a product of lipid peroxidation and deposited in lysosomes of organs in elderly persons), anthracotic pigment in alveolar macrophages, melanin (found in melanocytes and melanomas), hemosiderin (iron-rich brown pigment derived from hemolyzed red blood cells). Abnormal endogenous substances accumulate due to alteration in protein folding and transport.

CELLULAR ADAPTATIONS

Cells are the structural and functional units of tissues. **Hemostasis** is the state of internal equilibrium at which normal physiologic demands of a cell are met. Pathologic state results when injurious stimuli sufficiently disrupt homeostasis. Cellular response to injury depends on the type, duration and severity of injury.

- Some diseases represent spontaneous alterations in the ability of a cell to proliferate and function normally, and in other cases, disease occurs when an external injurious stimulus induces alterations in the cell's environment that make it impossible for the cell to maintain new steady state 'homeostasis'. In such situations, cells must adapt and become compatible with their viability in the new environment.
- Cellular adaptations include hyperplasia (increased number of cells in an organ or tissue), hypertrophy (increased number of cells in an organ or tissue), atrophy (shrinkage of cells in an organ or tissue), and metaplasia (transformation or replacement of one adult cell type with another), which can be physiologic or pathologic, depending on whether the stimulus is normal or abnormal.
- A cell can adapt to certain point, but the stimulus continues beyond this point resulting in failure of the cell and hence the organ. If the cells are unable to adapt to the pathologic injurious stimulus, the cells can die. This chapter will discuss cellular adaptation, cell injury, cellular accumulations and cellular aging.
- Mild and transient cell injury results in reversible injury. Severe and progressive cell injury leads to irreversible injury (e.g. necrosis or apoptosis). Genetic or acquired metabolic defects and chronic injury cause intracellular accumulation of glycogen,

proteins and pigments; and pathological calcification (e.g. dystrophic and metastatic types). Cumulative sublethal injury causes cellular aging.

- In cellular biology, labile cells multiply constantly throughout life. Labile cells are alive for only a short period of time. Due to this, labile cells can end up reproducing new stem cells and replace functional cells.
  - Labile cells include bone marrow epidermis, epithelial lining of gastrointestinal tract, bronchi and vagina; and epithelial lining of excretory ducts (salivary glands, pancreas, and biliary tract).
  - Stable cells multiply only when needed. These cells spend most of the time in the quiescent G0 phase of the cell cycle, but can be stimulated to enter the cell cycle when needed. Stable cells include hepatocytes, proximal tubules of kidney, endocrine glands, fibroblasts, vascular endothelium, cartilage and bone.
  - Permanent cells are incapable of regeneration and considered to be terminally differentiated and nonproliferative in postnatal life. Examples of permanent cells are brain cells, neurons, cardiac myocytes, skeletal muscle, renal glomeruli and red blood cells. Cells based on proliferative activity in the context of the cell cycle are given in Table 1.10.

HYPERPLASIA

Hyperplasia is defined as an increase in number of cells as an adaptive response to stress, usually resulting in increased volume of an organ or tissue. Cells must be capable of mitotic division. Hyperplasia involves the production of new cells from stem cells. Hyperplasia can only occur in tissues containing labile or stable cells. Common cause of hyperplasia is growth factor-driven proliferation of mature cells in tissues having lot of stem cells. Only cells that can divide will undergo hyperplasia. It is worth mentioning that hyperplasia of the terminal differentiated cells such as myocytes in the heart and neurons in the brain does not occur. Schematic representation of hyperplasia is shown in Fig. 1.3. Physiologic, pathologic and compensatory hyperplasias are shown in Table 1.11.

Table 1.10 Cells based on proliferative activity in the context of the cell cycle

Labile Cells	
▪ Bone marrow	
▪ Epidermis	
▪ Epithelium lining (gastrointestinal tract, bronchi and vagina)	
▪ Epithelium lining excretory ducts (salivary glands, pancreas, and biliary tract)	
Stable Cells	
▪ Hepatocytes	▪ Vascular endothelium
▪ Proximal tubules of kidney	▪ Cartilage
▪ Endocrine glands	▪ Bone
▪ Fibroblasts	
Permanent Cells	
▪ Central nervous system	▪ Skeletal muscle
▪ Sensory organs	▪ Renal glomeruli
▪ Cardiac muscle	▪ Red blood cells

PHYSIOLOGIC HYPERPLASIA

Physiologic hyperplasia occurs due to a normal sensor. Examples of physiologic hyperplasia include increase in the size of breasts during pregnancy (as a result of increased circulating hormones), increase in the thickness of endometrium during menstrual cycle (as a result of increased circulating hormones), bone marrow hyperplasia at high altitude, thyroid hyperplasia during puberty and pregnancy, proliferation of epidermis in wound healing by primary intention, and liver hyperplasia after partial resection.

Endometrial Hyperplasia during Menstrual Cycle

The normal thickness of the endometrium changes throughout a person's life from childhood, through to sexual maturity, fertile years and after menopause. Estrogen and progesterone participate in the regulation of menstrual cycle.

- The endometrium is at its thinnest during menstrual phase, when it usually measures between 2 and 4 mm in thickness.
- At end of the menstrual cycle, estrogen plays important role in proliferation of endometrial cells; during proliferative phase endometrium begins to thicken and measures 5–7 mm in thickness.
- As the menstrual cycle progresses and moves towards ovulation, the endometrium in early secretory phase grows thicker, up to about 11 mm. About 14 days into a woman menstrual cycle, hormones trigger the release of an ovum.
- During the secretory phase, endometrial thickness is at its greatest and can reach 16 mm. In case fertilization does not take place, progesterone signals shedding of endometrium.

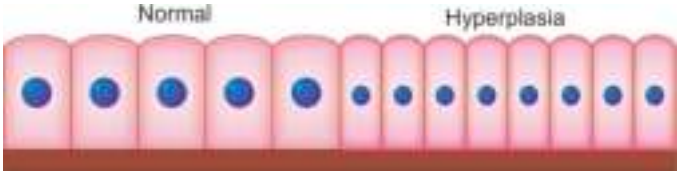

Fig. 1.3: Schematic representation of hyperplasia. Hyperplasia refers to an increase in the number of cells in the tissue.

Table 1.11 Physiologic, pathologic and compensatory hyperplasias

Hyperplasia of Organs	Mechanism
Physiologic hyperplasia	
Uterine endometrial hyperplasia	Estrogen hormone
Uterine muscle hypertrophy and hyperplasia	Estrogen hormone during pregnancy
Breast glandular epithelial hyperplasia	Hormones synthesis during pregnancy
Bone marrow hyperplasia	Higher altitude
Islet β-cells hyperplasia of fetus	Diabetic mother
Pathologic hyperplasia	
Ductal hyperplasia of breast in fibrocystic disease	Hormonal imbalance
Cystoglandular or adenomatous or atypical hyperplasia of endometrium	Hormonal imbalance
Thyroid follicular hyperplasia	Increased TSH level
Hyperplasia of surface epithelium of skin	Wound-healing by primary intention
Skin epidermal cell hyperplasia	Psoriasis
Compensatory hyperplasia	
Hyperplasia of hepatocytes	TGF-α, TGF-β, HGF synthesis following partial resection of liver

Breast Hyperplasia during Pregnancy

Female breasts show structural and functional variations during puberty, pregnancy, lactation, the normal menstrual cycle, and at the menopause. Pregnancy affects levels of estrogen and progesterone hormones.

- Estrogen stimulates growth of breast ductal and lobular cells and synthesis of prolactin.
- Progesterone supports the formation and growth of milk-producing cells within the glands of the breasts.
- Prolactin stimulates breast enlargement and milk production. Breast histology from a woman of 30 weeks pregnancy shows the lobular acini lined by cells containing secretory vacuoles and with pink secretions in their lumens.

Thyroid Gland Hyperplasia

During puberty, changes in thyroid functions and an increase in thyroid volume occur as an adaptation to body and sexual development. Benign physiologic changes of the thyroid are known to occur during pregnancy due to increased demand of thyroid hormones. TSH stimulates thyroid follicular cells and produce benign hyperplasia (adenomatous change) with diffuse enlargement of thyroid glands.

Bone Marrow Hyperplasia at High Altitude

Hypoxia at high altitudes can lead to increased production of red blood cells in bone marrow through the hormone erythropoietin (EPO).

- Erythropoietin is synthesized by kidney (89–90%), and liver (<15%). Normal plasma concentration is 2–25 IU/L.
- Erythropoietin stimulates BFU-E and CFU-E to divide and mature, increases rate of mRNA and protein (hemoglobin) synthesis, decreases normoblasts maturation time, increases rate of extrusion of nucleus from normoblasts and stimulates early release of bone marrow reticulocytes.
- It is well known that the body's hemoglobin concentration increases due to the hypoxic environment of high altitude.

Beta Cells of Islets of Langerhans Hyperplasia in Fetus in Severe Maternal Diabetes Mellitus

Severe maternal diabetes mellitus poses short- and long-term consequences for the infant. Maternal hyperglycemia increases transport of glucose, amino acids, and fatty acids via placenta to fetus resulting in β cell hyperplasia mainly due to formation of numerous small islets of Langerhans during intrauterine period followed by synthesis of excess of insulin (hyperinsulinemia) and thus hypoglycemia at birth in newborn. Hypoglycemic can cause shakiness, blue tint to the skin, breathing and feeding problems.

PATHOLOGIC HYPERPLASIA

Pathologic hyperplasia occurs due to an abnormal stressor either excessive hormonal stimulation or abnormal production of hormonal growth factors.

- Proto-oncogenes code for growth factors, growth factor receptors, signal transducers (e.g. mitogen-induced protein kinases), and DNA transcription factors to initiate cell mitosis. It may be associated with increased risk for cancer.

- Examples of pathologic hyperplasia include growth of adrenal glands due to production of adrenocorticotropic hormone (ACTH) by pituitary adenoma, proliferation of endometrium and breast due to prolonged estrogen stimulation, proliferation of thyroid follicles due to increased TSH, proliferation of epidermis in psoriasis. Women with pathologic endometrial hyperplasia can progress to dysplasia and eventually endometrial carcinoma.

Endometrial Hyperplasia

Endometrial hyperplasia refers to abnormal proliferation of endometrial glands caused by estrogenic stimulation. It occurs in anovulatory cycles as a result of estrogenic effect not opposed by progesterone.

- Excess of estrogens also occurs in women with polycystic ovary syndrome, estrogen-secreting ovarian tumors, i.e. granulosa cell tumor, estrogen replacement therapy and ovarian cortical stromal hyperplasia.
- Hormonal imbalance may lead to cystoglandular, adenomatous and atypical hyperplasia of endometrium, that may progress to endometrial carcinoma and manifest with postmenopausal bleeding. Young women manifest with menorrhagia and anovulation.

Benign Nodular Hyperplasia of Prostate Gland

Benign nodular hyperplasia of prostate gland is also known as benign prostatic hypertrophy (BPH), which primarily affects periurethral and transitional zones of men after 40 years of age. It is the most common cause of urinary tract obstruction.

- Digital rectal examination reveals a firm, enlarged, nodular prostate. It is an androgen-dependent disorder. Dihydrotestosterone (DHT) is a major growth factor for prostate gland derived from testosterone by the action of 5-reductase enzyme, that stimulates prostate glandular acini leading to prostatic hyperplasia.
- Patient presents with frequency of micturition, difficulty in starting urination, nocturia, dribbling, incomplete emptying of urinary bladder and dysuria. Persistent obstruction to urine outflow may result in urinary bladder distension, muscular hypertrophy, diverticulum formation and trabeculae formation.
- Histologically, benign nodular hyperplasia of prostate gland is diagnosed on samples like transurethral resection of prostate (TURP chips), simple or radical prostatic specimens. Benign nodular hyperplasia of prostate gland is composed of hyperplasia of glands and stroma in variable proportions forming papillary buds, infoldings and cysts. The lining epithelium ranges from flat to columnar, sometimes facing each other in the same gland. Basal layer is demonstrated immediately above a well-developed epithelium. The glands are dilated or even cystic and containing an inspissated secretion of glycoprotein nature (corpora amylacea), which is sometimes calcified. Histology of benign nodular hyperplasia of prostate gland is shown in Fig. 1.4.

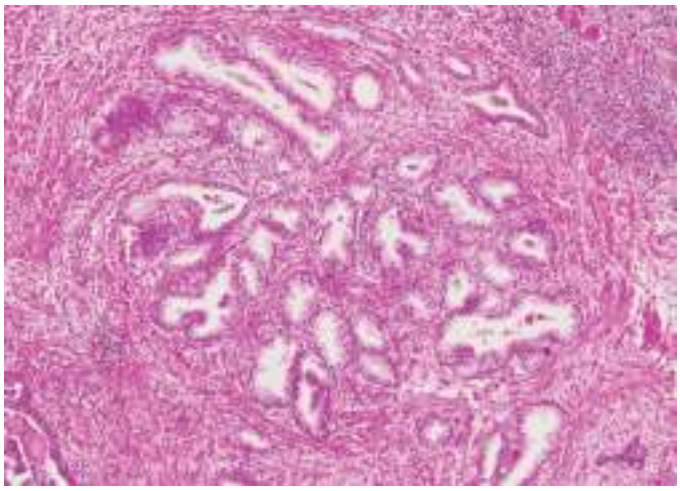

Fig. 1.4: Histology of benign nodular hyperplasia of prostate gland. It is benign nodular lesion with proliferation of glandular and stromal components predominantly located in the transition zone of the prostate gland. The acini are relatively uniform and evenly spaced are lined by columnar secretory cells. The basal cell layers may be inconspicuous, but may be highlighted by high molecular weight cytokeratin immunohistochemical stain (400X).

Thyroid Gland Hyperplasia in Graves' Disease

Graves' disease is an autoimmune disorder which primarily affects thyroid gland. It is most common cause of hyperthyroidism accounting for 60–80% of hyperthyroidism cases, which may affect eye and skin.

- Graves' disease is caused by thyroid stimulating immunoglobulin, that binds with thyroid-stimulating hormone receptor on the thyroid follicular cell membrane and stimulates the action of the thyroid stimulating hormone resulting in both thyroid hormone synthesis, hyperthyroidism and thyroid follicular epithelial hyperplasia causing thyromegaly.
- Graves' oculopathy occurs due to inflammation, cellular proliferation and increased growth of extraocular muscles and retro-orbital connective tissue and adipose tissue by the action of thyroid stimulating antibodies and cytokines synthesized by cytotoxic T cells.
- Thyroid stimulating autoantibodies and cytokines activate periorbital fibroblasts and preadipocytes causing excessive growth of retro-orbital adipose tissue and hydrophilic glycosaminoglycans leading to extraocular muscle swelling by trapping water.

- Changes in ocular and extraocular muscles give rise to proptosis, diplopia, congestion and periorbital edema.
- Graves' disease is diagnosed by thorough clinical history, physical examination, thyroid function tests, thyroid autoantibodies such as thyroid stimulating immunoglobulin (TSI) and thyrotropin-binding inhibiting (TBI) immunoglobulin or thyrotropin-binding inhibitory immunoglobulin (TBII)) and radioactive iodine uptake scan with ^{123}I or ^{131}I.

Defect in Primary Intention of Wound Healing

The epidermis is a stratified epithelium composed of several layers of keratinocytes. It provides a physical barrier between the environment and the microorganisms, thereby protecting it from external injurious agents and pathogens and limiting the loss of fluids.

- Keratinocytes of epidermis are responsible for restoring the epidermis after injury through a process of epithelialization. Epithelialization is defined as a process of covering denuded epithelial surface.
- The cellular and molecular processes involved in the initiation, maintenance and completion of epithelialization are essential for successful closure of skin wound.
- There are three distinct epidermal stem cell (ESC) niches identified to date: (a) bulge of the hair follicle (HF), (b) the base of the sebaceous gland, and (c) the basal layer of the interfollicular epidermis (IFE). In response to epidermal injury, both the HF and HFE niches participate in the re-epithelialization of the skin wound defect.
- A wound cannot be considered healed in the absence of re-epithelialization. The epithelialization process is impaired in all types of chronic skin wounds.

Psoriasis

Psoriasis is a chronic nonpruritic disease of the dermis and epidermis and characterized by persistent epidermal hyperplasia resulting in sharply demarcated erythematous plaques covered with a silvery scale commonly on the elbows, knees, scalp, umbilicus and lumbar region.

- Psoriasis may be caused by defective epidermal cell surface receptors and altered intracellular signaling. Cw6 gene mutation has the strongest association with psoriasis.
- Scratching of scaly lesion causes rupture of small blood vessels in suprapapillary thinned area resulting in pinpoint hemorrhages known as 'Auspitz sign'. Histology in a case of psoriasis is shown in Fig. 1.5.

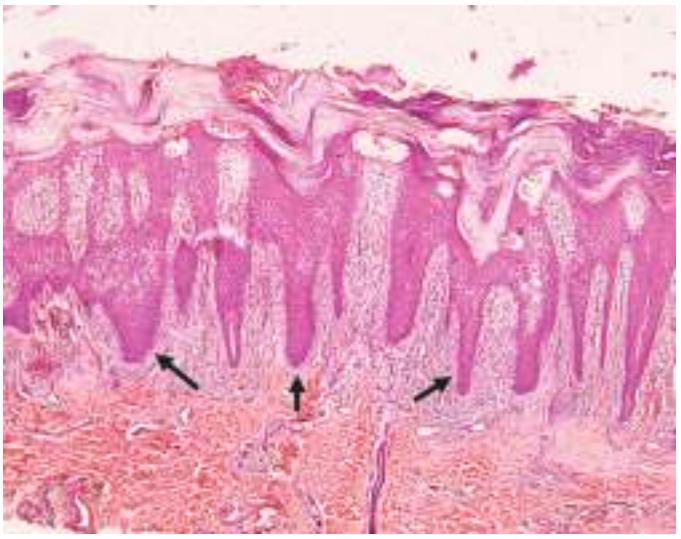

Fig. 1.5: Histology in a case of psoriasis. Hematoxylin and eosin-stained section shows downward elongation of the rete ridges (arrows) with thinning of overlying stratum granulosum, with parakeratosis above this. Small aggregates of neutrophils with surrounding spongiform change are seen in the superficial epidermis. Capillaries within dermal papillae are brought close to the surface (400X).

COMPENSATORY HYPERPLASIA OF HEPATOCYTES FOLLOWING PARTIAL RESECTION

The liver has a remarkable capability to regenerate after injury. Within a week after partial hepatectomy of two-thirds of the liver, the hepatocytes regenerate and also transdifferentiate into biliary epithelial cells and endothelial cells; and the liver retains back essentially to what it was during normal health prior to surgery.

- DNA synthesis is initiated in these cells within 10–12 hours after surgery and essentially ceases in about 3 days. Cellular proliferation begins in the portal triads (i.e. periportal region) and proceeds toward the centers of the hepatic lobules.
- Proliferative hepatocytes initially form clumps, which get transformed into classical plates. Similarly, proliferative endothelial cells develop into the type of fenestrated cells of those observed in hepatic sinusoids.
- Proliferating hepatocytes appear to at least partially revert to a fetal phenotype and express markers such as α-fetoprotein. Transforming growth factor-β is the main cytokine involved in this process. Other cytokines such as transforming growth factor-α and human growth hormone (HGH) also participate in the regeneration of hepatocytes.

HYPERTROPHY

Hypertrophy is defined as an increase in cell size of an organ or tissue due to synthesis of cellular structural

components in response to various stimuli (hormones and growth factors), without an increase in the number of cells.

- It is worth mentioning that both hyperplasia and hypertrophy result in an increase in organ size, therefore both cannot always be distinguished on gross examination, hence histologic examination is required to distinguish the two entities.
- Both hypertrophy and hyperplasia can occur due to upregulation or downregulation of receptors and induction of new proteins synthesis, which include transcription factors (e.g. c-Jun, c-Fos), contractile proteins (e.g. myosin light chain), and embryonic proteins (e.g. β-myosin heavy chain).
- Hypertrophy may be physiologic, pathologic, compensatory and subcellular. Schematic representation of hypertrophy is shown in Fig. 1.6. Physiologic, pathologic, compensatory and subcellular hypertrophies are given in Table 1.12. Differences between hypertrophy and hyperplasia are shown in Table 1.13.

PHYSIOLOGIC HYPERTROPHY

Physiologic hypertrophy occurs due to normal stressor. It is usually adaptive response that improves cell function. For example, hypertrophy of skeletal muscle occurs due to exercise and physical labor. Uterine smooth muscle hypertrophy occurs during pregnancy.

Physiologic Skeletal Muscle Hypertrophy

Exercise, hard physical labor or weight lifting stimulate skeletal muscle fibers to increase in diameter as a result of increased synthesis of more structural contractile proteins. **Phosphoinositide-3 kinase pathway** is postulated to play role in exercise-induced skeletal muscle hypertrophy. Skeletal muscle shows increased number of myofilaments and mitochondria; abundant endoplasmic reticulum, mild nuclear enlargement, which leads to synthesis of more membranes, enzymes, ATP and higher levels of aerobic respiration.

Physiologic Uterine Hypertrophy during Pregnancy

The adaptive uterine hypertrophy is a critical event that involves changes in cellular phenotypes throughout pregnancy. In early pregnancy, uterine hypertrophy involves the endometrial glandular epithelial cells and/or the myometrial muscle cells during pregnancy induced by circulating estrogens. The glandular epithelial cells become tall columnar with increase in cytoplasm to nucleus ratio, basophilic cellular cytoplasm and mitotic figures. Mechanical stress by growing fetus and placenta regulates hypertrophic phenotype of the myometrium during pregnancy; however, major component of myometrial hypertrophy occurs after mid-gestation.

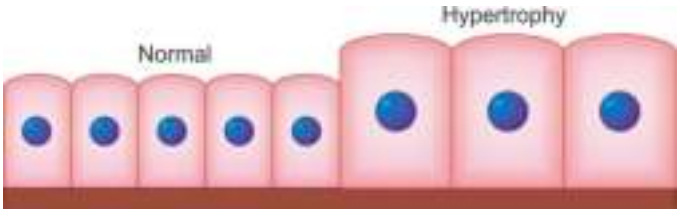

Fig. 1.6: Schematic representation of hypertrophy. Hypertrophy refers to enlargement of cells without cell division.

Table 1.12 Physiologic, pathologic, compensatory and subcellular hypertrophies

Hypertrophy of Organs	Mechanism
Physiologic hypertrophy	
Skeletal muscle hypertrophy	Physical labor and weight training
Uterus hypertrophy in pregnancy	Hormonal response
Pathologic hypertrophy	
Cardiac hypertrophy	Systemic hypertension and valvular disease
Adrenal gland hypertrophy (zona glomerulosa)	Increased ACTH synthesis
Focal hypertrophy of retinal pigment epithelium	Following retinal detachment
Compensatory hypertrophy	
Hypertrophy of residual cardiac myocytes	Following myocardial infarction
Renal hypertrophy	Following nephrectomy of opposite kidney, congenital absence of one kidney or nonfunctional kidney
Subcellular hypertrophy of cell organelles	
Subcellular hypertrophy of liver organelles such as endoplasmic reticulum	Hepatotoxic agents such as phenobarbital, alcohol and other anticonvulsant drugs

Table 1.13 Differences between hypertrophy and hyperplasia

Hypertrophy	Hyperplasia
Increase in cell size and cytoplasm without cell division results in increase in size of organ that does not induce neoplastic transformation	Cell size usually remains normal, cytoplasm may be reduced with cell division that may not induce neoplastic transformation
Physiologic state	
A demand for additional work met by skeletal muscle hypertrophy	▪ Hormone-induced hyperplasia in female breast ▪ Uterus during pregnancy ▪ Erythroid bone marrow hyperplasia at altitude ▪ Compensatory hyperplasia after partial hepatectomy and nephrectomy
Pathologic state	
▪ Cardiac hypertrophy (hypertension, valvular disease) ▪ Urinary bladder hyperplasia during obstruction to urine outflow due to prostate enlargement	▪ Uterus hypertrophy during pregnancy ▪ Cystic glandular and adenomatous hyperplasia of endometrium ▪ Atypical hyperplasia of the endometrium and endometrial carcinoma ▪ Prostatic hyperplasia (prostatic glands and stromal smooth muscle cells) ▪ Thyroid gland hyperplasia (toxic or nontoxic goiter), hyperplasia of epidermis in wound healing

Physiologic Myocardial Hypertrophy

Physiologic myocardial hypertrophy is characterized by normal organization of cardiac structure and normal or increased cardiac function. It can ensue as a result of exercise or pregnancy, and is deemed mild and/or reversible.

PATHOLOGIC HYPERTROPHY

Pathologic hypertrophy occurs due to abnormal stressor and is commonly associated with upregulation of fetal genes, fibrosis, organ dysfunction and increased mortality. Cardiac hypertrophy is caused in the presence of chronic stressful conditions such as systemic hypertension, valvular disease, hypertrophic cardiomyopathy and congenital heart disease.

- Cardiac hypertrophy is usually associated with upregulation of fetal genes, excessive increase in ventricular dimensions, accompanied by fibrosis, myocardial dysfunction and increased mortality.
- Ventricular hypertrophy is considered as a predictor of cardiovascular morbidity such as cardiac arrhythmias, myocardial infarction, cerebrovascular events, and sudden death. The most common symptoms of left ventricular hypertrophy are shortness of breath, chest pain after activity, dizziness and rapid heartbeats.
- Since the cardiac muscle is composed of terminally differentiated myocytes that cannot divide. Increased demand for action can be met only by increased size of the cardiac myocytes.
- Three stages of myocardial hypertrophy are recognizable: (a) initiation of myocardial hypertrophy, (b) stable function of the hypertrophied heart, and (c) deterioration of cardiac function associated with degeneration of hypertrophied cardiac myocytes. Histologic examination of myocardial hypertrophy shows enlarged myocytes with large nuclei.

Pathology Pearls: Molecular Basis of Cardiac Hypertrophy

- The molecular basis of cardiac hypertrophy reflects increased expression of growth-promoting genes (proto-oncogenes) such as c-Jun, c-Fos, c-Myc and RAS (nuclear transcription factors). It leads to increase synthesis of cellular proteins and number of intracellular organelles (e.g. mitochondria, Golgi apparatus). Only labile and stable cells are able to undergo hypertrophy as well as hyperplasia.
- Mechanical stretch induces production of growth factors such as TGF-β, FGF, insulin-like growth factor 1 and vasoactive agents (angiotensin II and endothelin), which bind to G protein-coupled receptors, induce signal to synthesize increased synthesis of contractile proteins, embryonic genes (e.g. cardiac α-actin and ANF) and growth factors.
- Cardiac hypertrophy resulting from transcriptional regulation leads to increased synthesis of mRNA, rRNA, and protein, which increase the strength and work capacity of heart.
- Cardiac hypertrophic muscles show increased cytosol, number of organelles and DNA content. Gross morphology of left ventricular hypertrophy is shown in Fig. 1.7.

Pathologic Adrenal Gland Hypertrophy

Pathologic adrenal gland hypertrophy may be bilateral and diffuse and focal. Bilateral diffuse cortical hypertrophy is usually caused by increased synthesis of ACTH; when associated with increase in thickness

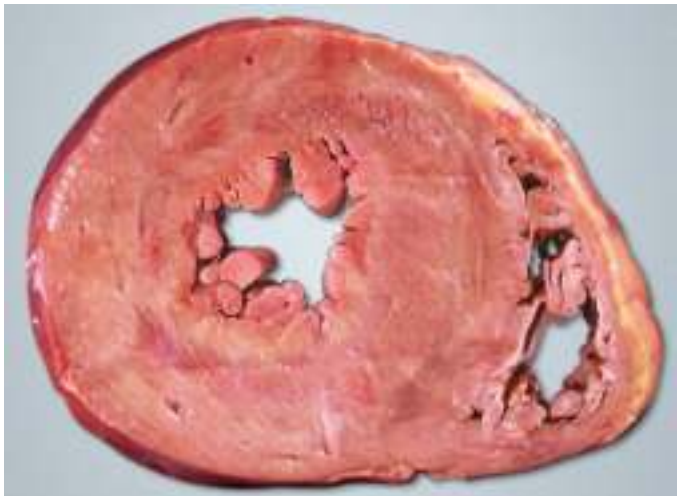

Fig. 1.7: Gross morphology of left ventricular hypertrophy. It is the enlargement and hypertrophy (increase in thickness of the wall) of left ventricle. This thickening may result in elevation of pressure within the heart and sometimes poor pumping action. The most common cause is severe hypertension. Normal thickness of wall of left ventricle is 1.2–1.5 cm.

of cortex and weight of adrenal gland. Zona fasciculata is usually increased in thickness, whereas the zona reticularis increases to a lesser extent. The cytoplasm of the affected cells is usually eosinophilic and finely granular with or without clear lipid vacuoles.

COMPENSATORY HYPERTROPHY IN RESIDUAL CARDIAC MYOCYTES

Compensatory hypertrophy in residual cardiac myocytes can take place only if some portion of the original structure is left to react to the loss. The growth can be a result of increased cell size or increase in cell division or both. Compensatory hypertrophy occurs in residual cardiac myocytes following myocardial infarction and renal hypertrophy of opposite side following nephrectomy.

- For instance, if one kidney is surgically removed, the cells of the other kidney divide at an increased rate. Compensatory renal hypertrophy can also occur on opposite side due to congenital absence of one kidney or nonfunctional kidney.
- Hypertrophy can occur as a compensatory response to injury when parenchymal cardiac myocyte cells are irreversibly damaged following myocardial infarction, in which residual cardiac myocytes increase in size.

SUBCELLULAR ENDOPLASMIC RETICULUM HYPERTROPHY IN LIVER

Subcellular endoplasmic reticulum hypertrophy occurs in liver in response to hepatotoxic agents.

Endoplasmic Reticulum Hypertrophy in Liver by Phenobarbital

Ingestion of administration of lipid soluble drugs, e.g. phenobarbital and other anticonvulsant drugs induces the hepatocytes to increase synthesis of cytochrome P450 oxidase enzyme available to detoxify the drugs. The process of synthesis of drug metabolizing enzyme takes place in the endoplasmic reticulum is a sequential event and can be divided into three stages as demonstrated on electron micrographs: (a) increased production of rough endoplasmic reticulum and its hypertrophy in the cytoplasm, (b) increased synthesis of cytochrome P450 oxidase enzyme available to detoxify the drugs, and (c) shedding of attached ribosomes of rough endoplasmic reticulum converting into smooth endoplasmic reticulum with the same attached enzymes and accumulation in the cytoplasm.

Endoplasmic Reticulum Hypertrophy in Liver by Excessive Alcohol Consumption

Excessive alcohol consumption induces numerous pathologic stress responses, part of which is endoplasmic reticulum. Alcohol crosses the biological membrane and disturbs numerous biological pathways and causing damage to liver, brain, pancreas, heart and immune system.

- In addition to conversion of alcohol into acetaldehyde in the circulation by aldehyde dehydrogenase, cytochrome P450 activities, mainly CYP2E1 in the endoplasmic reticulum of hepatocytes also oxidize alcohol to acetaldehyde and hydrogen peroxide (H_2O_2).
- There is excessive accumulation of unfolded proteins in the endoplasmic reticulum of hepatocytes.

ATROPHY

Atrophy is reduction in size of the cell (organ or tissue) due to loss of structural components of the cells, that has at one time been of normal size. The number of cells remain same as before the atrophy occurred, but the size of some fibers is reduced.

- Atrophy occurs as a result of insufficient blood flow, disuse of organs, denervation, or reduced endocrine stimulation. Cell attempts to reduce demand to match reduced energy supply. The entire tissue/organ diminishes in size when enough cells are involved.
- Decrease in cell size occurs via ubiquitin-proteosome degradation of the cytoskeleton and autophagy of the cellular components. In ubiquitin-proteosome degradation, intermediate filaments of the cytoskeleton are 'tagged' with ubiquitin and degraded by proteosomes. Autophagy of cellular components involves generation of autophagic vacuoles. These vacuoles

fuse with lysosomes whose hydrolytic enzymes breakdown the cellular components.

- Uterus returns to nongravid state after parturition is an example of physiologic atrophy. Hypoxia, loss of innervation, disuse of organ and aging are examples of pathologic atrophy.
- Schematic representation of atrophy is shown in Fig. 1.8. Physiologic and pathologic (systemic or local) atrophies are given in Table 1.14.

PHYSIOLOGIC ATROPHY

Physiologic atrophy is associated with the natural aging process. Examples of physiologic atrophy include thymus atrophy during puberty, embryonic structures atrophy (notochord, thyroglossal duct and patent ductus arteriosus), atrophy of female breasts, uterus and vagina during menopause, brown atrophy of organs (heart, liver, adrenal gland and ganglion cells) and brain atrophy during advancing age.

Embryonic Structures Atrophy

During eighth weeks of fetal development, embryonic folding converts a flat sheet of cells into a hollow, tube-like embryonic structures such as notochord, thyroglossal duct, and patent ductus arteriosus derived from the ectoderm, mesoderm and endoderm, undergo atrophy.

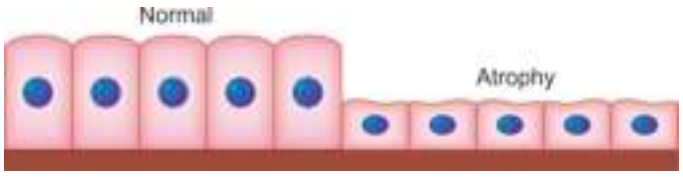

Fig. 1.8: Schematic representation of atrophy. Atrophy refers to reversible reduction in the size of the cells.

Female Breasts, Uterus and Vaginal Atrophy

During reproductive period, estrogen hormone plays key role in normal metabolism and function of breast and reproductive organs. After menopause, the ovaries, uterus, vagina and breasts normally undergo a degree of atrophic changes. In postmenopausal women, the walls of the vagina become thinner (atrophic vaginitis). After menopause the body have no further functional biological need to maintain the reproductive system.

Brain Atrophy in Advancing Age

Brain atrophy in advancing age is defined as the loss of neurons, which destroys the connections that help the cells to communicate. Focal brain atrophy affects cells in certain areas of the brain and results in loss of function in those specific areas. Generalized brain atrophy affects cells all over the brain. In old age, frontal cortex undergoes marked atrophy revealing thinning of the gyri and widening of the sulci.

Brown Atrophy of Organs in Advancing Age

Lipofuscin is the name given to fine yellow-brown pigment electron dense granules composed of lipid-containing residues of lysosomal digestion. Lipofuscin pigment is considered to be one of the aging or 'wear-and-tear' pigments, that accumulates progressively over time in lysosomes of postmitotic cells, such as cardiac myocytes, liver, kidney, adrenal glands, nerve cells and ganglion cells. The intracellular accumulation of lipofuscin-like material may be the result of an imbalance between formation and disposal mechanisms.

Table 1.14 Physiologic and pathologic (systemic or local) atrophies

Atrophy of Organs	Mechanism
Physiologic atrophy	
Atrophy of thymus gland	Physiologic phenomenon
Atrophy of embryonic structures (notochord, thyroglossal duct and patent ductus arteriosus)	Physiologic phenomenon
Female breasts, uterus and vagina during menopause	Decreased estrogens in menopausal women
Brown atrophy of heart, liver, adrenal gland and ganglion cells	Lipofuscin pigment (wear and tear pigment), important indicator of free radical induced injury
Brain atrophy	Aging process
Pathologic generalized atrophy	
Atrophy of thyroid gland and adrenal gland	Hypopituitarism
Pathologic local atrophy	
Skeletal muscle atrophy	Denervation
Renal cortex atrophy	Nephrolithiasis
Brain atrophy	Alzheimer disease
Exocrine gland atrophy	Cystic fibrosis

The lipofuscin pigment is found at the periphery of the lobule in hepatocytes and some bile ductular cells. The adrenal cortex accumulates lipofuscin granules with advancing age.

PATHOLOGIC ATROPHY

Pathologic atrophy occurs due to an abnormal stressor. In general, pathologic atrophy occurs due to the loss of stimulus to the organ such as insufficient blood flow and nutrients, disuse of organs, denervation, or reduced endocrine stimulation. The organ is smaller than usual. Atrophy occurs in a once normally developed organ. If the organ was never of normal size and does not develop normally, the condition is called hypoplasia.

- **Systemic pathologic atrophy:** Systemic pathologic atrophy occurs in cases of insufficient nutrition, chronic infection, disorders of endocrine glands, and disorders of central nervous system.
- **Local pathologic atrophy:** Local pathologic atrophy can occur in the settings of: (a) trophic nerves involvement results in atrophy of skeletal muscles in poliomyelitis, (b) atherosclerotic plaques in carotid arteries cause insufficient blood supply to brain leading to brain atrophy, (c) dysfunctional atrophy of optic nerve occurs after removal of diseased eye, (d) prolonged immobilization of extremities due to fracture results in atrophy of skeletal muscles, and (e) application of iodine preparation causes thyroid gland atrophy.

Brown Atrophy of Organs in Disorders

Lipofuscin pigment accumulation is also demonstrated in adrenocortical tumors associated with Cushing syndrome, particularly those with **PRKAR1A gene** mutations, such as in primary pigmented nodular adrenocortical disease (PPNAD).

- Lipofuscin accumulation in the eye can cause macular degeneration and inherited juvenile form of macular degeneration in Stargardt disease, an inherited disorder. Abnormal accumulation of lipofuscin in the peripheral nervous system can cause lipofuscinosis.
- Batten disease is a familial neurodegenerative disorder showing neuronal ceroid lipofuscinosis. Pathologic accumulation of lipofuscin has been implicated in Alzheimer's disease, Parkinson's disease, amyotrophic lateral sclerosis, melanosis coli and lipid myopathy. Calorie reduction, vitamin E and increased glutathione appear to reduce production of lipofuscin pigment.

Brain Atrophy in Disorders

Diseases that cause cerebral atrophy in adults include cerebral stroke due to interruption of blood supply, traumatic brain injury, Alzheimer's disease, Pick disease, frontotemporal dementia, cerebral palsy (abnormal development of brain during gestation period), multiple sclerosis, Huntington's disease and AIDS. Alzheimer disease is secondary to extensive cell death resulting in marked atrophy of the frontal lobe, thinning of gyri and widening of sulci. Patient with multiple sclerosis can have close to a normal life span if treated effectively.

Skeletal Muscle Atrophy in Disorders

Normally, skeletal muscle is maintained by multiple pathways regulating turnover of cell and proteins. There are three types of skeletal muscle atrophy: physiologic, pathologic and neurogenic. Physiologic atrophy of skeletal muscle is caused by not using the muscles for long time.

- Pathologic atrophy of skeletal muscle occurs due to reduced workload, loss of innervation, reduced blood supply, protein calories malnutrition, osteoporosis, immobilization of skeletal fracture in a plaster cast for prolonged period, loss of endocrine stimulation and aging.
- Activation of proteolytic system leads to removal of contractile proteins, cytoplasm and cell organelles resulting in shrinkage of skeletal muscle fibers and thus skeletal muscle atrophy.
- Excessive removal of skeletal muscle mass is associated with poor prognosis in myopathies and muscular dystrophies as well as diabetes mellitus, cancer cachexia, sepsis, AIDS, heart failure, chronic renal failure and aging.
- The cells exhibit autophagic granules, which are intracytoplasmic vacuoles containing debris from degraded organelles.
- In skeletal muscle, the ubiquitin-proteasome system is required to remove sarcomere proteins upon changes in muscle activity.
- Atrophy of skeletal muscle mass is associated with (a) increased conjugation of ubiquitin to muscle proteins; (b) increased proteasomal ATP-dependent activity; (c) increased breakdown of proteins; and (d) upregulation of transcripts encoding ubiquitin; some ubiquitin-conjugating enzymes (E2), a few ubiquitin-protein ligases (E3) and several proteasome subunits.

Endocrine Glands Atrophy in Disorders

A destructive or atrophic lesion affecting the pituitary gland with loss of its hormones (hypopituitarism) leads to atrophy of the thyroid gland, adrenal glands and gonads and in turn brings atrophic changes to their target. The decrease in size of the endocrine glands may be extreme.

Cachexia (Irreversible Wasting Syndrome)

Cachexia is a multiorgan and multifactorial and irreversible wasting syndrome associated with cancer and other chronic illnesses such as chronic heart failure, chronic renal failure, chronic obstructive pulmonary disease and chronic inflammatory diseases.

- Cancer cachexia is characterized by systemic inflammation, negative protein and energy balance and involuntary marked muscle wasting and anorexia.
- Multiple mechanisms are reported in the development of cachexia, with a number of cytokines including TNF-α postulated to play important role in the etiology of the persistent catabolic state.
- Cachexia is treated with dietary supplements and/or exercise and therapeutic agents, such as megestrol acetate, medroxyprogesterone, ghrelin, omega-3-fatty acids and erythropoietin.

Renal Atrophy in Disorders

Renal atrophy may be associated with antiphospholipid syndrome, tuberculosis, metabolic syndrome, renal artery stenosis, atheromatous plaques in renal artery, sickle cell disease, obstruction of the urinary tract due to urolithiasis and cancer. Atrophic kidney has impaired renal functions. Patient presents with changes in urination, drowsiness, nausea, vomiting, anorexia, muscle cramps, increased serum creatinine and electrolytes imbalance.

Exocrine Glands Atrophy in Cystic Fibrosis

Normally, cystic fibrosis transmembrane conductance regulator (CFTR) gene located on long arm of chromosome 7 codes for a membrane protein that regulates chloride channel in epithelial cells and thus participates in the movement of chloride and other ions across membranes.

- Cystic fibrosis is autosomal recessive disorder, that occurs due to mutation of cystic fibrosis transmembrane conductance regulator/CFTR gene resulting in thick secretions in the respiratory tract and exocrine glands and causes pressure atrophy on the ducts.
- Patient develops recurrent respiratory infections, meconium ileus and sterility in males. Sweat chloride test is an important diagnostic tool.

METAPLASIA

The epithelium normally presents at a site cannot handle the new microenvironment induced by persistent stimuli (chronic inflammation or irritation), so one adult cell type is transformed to another adult cell type, in response to persistent injury (chronic inflammation or irritation).

- Metaplasia is a reversible phenomenon. New metaplastic cells are better able to handle the new stressor.
- Examples of pathologic metaplasia include Barrett esophagus, squamous metaplasia in the tracheobronchial mucosa, metaplasia in ocular and exocrine gland ducts in vitamin A deficiency, myositis ossificans, apocrine metaplasia in breast.
- Schematic representation of metaplasia is shown in Fig. 1.9. Schematic representation of squamous metaplasia is shown in Fig. 1.10. Differences between

Fig. 1.9: Schematic representation of metaplasia. Metaplasia refers to replacement of an adult cell with another adult cell as a response to chronic inflammation or irritation.

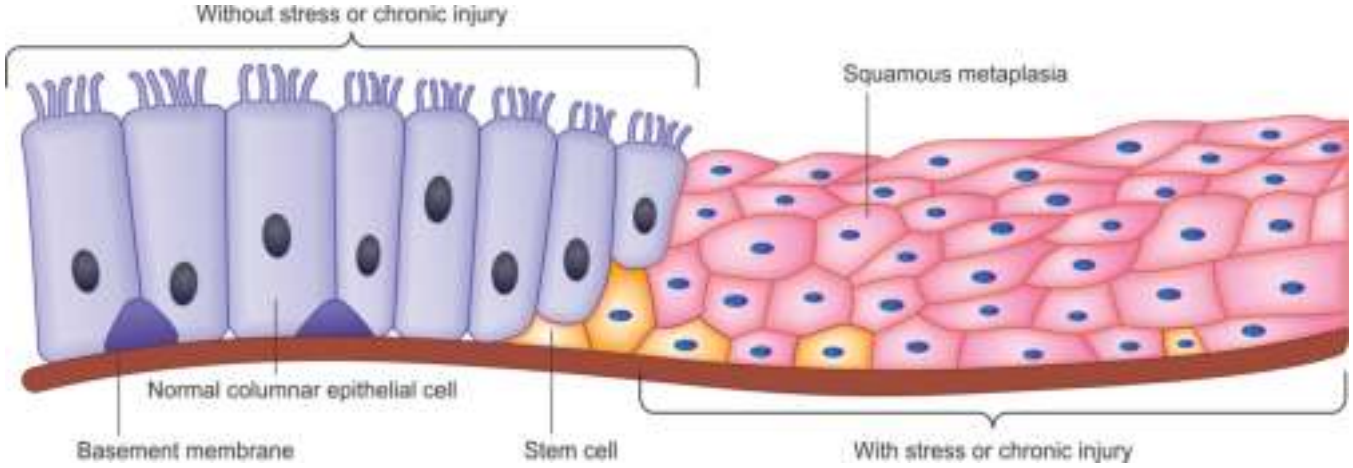

Fig. 1.10: Schematic representation of squamous metaplasia. Squamous metaplasia is used to designate the focal or extensive replacement of mucus-secreting glandular epithelium by stratified squamous epithelium in response to chronic irritation.

Table 1.15 Differences between physiologic metaplasia and pathologic metaplasia

Original Tissue	Stimulus	Replaced by Metaplastic Lining/Tissue
Physiologic metaplasia		
Monocytes in blood circulation	Physiologic state	Tissue macrophages
Pathologic metaplasia		
Ciliated columnar epithelium in bronchial tree	Tobacco smoking	Squamous metaplasia
Columnar glandular epithelium lining ducts pancreas	Vitamin A deficiency	Squamous metaplasia
Transitional epithelium in urinary bladder	Renal stones	Squamous metaplasia
Squamous epithelium in Barrett's esophagus	Gastric acid (gastroesophageal reflux disease)	Columnar metaplasia
Transitional epithelium in urinary bladder	Chronic inflammation prostatitis	Glandular epithelium (cystitis glandularis)
Fibrocollagenous tissue	Traumatic injury	Osseous metaplasia
Myeloid metaplasia and agnogenic myeloid metaplasia (myelofibrosis, polycythemia vera)	Agnogenic myeloid metaplasia, myelofibrosis, polycythemia vera	Extramedullary hematopoiesis in liver and spleen
Metaplasia in benign neoplasm	Benign neoplastic process	Cartilaginous and bony tissue in pleomorphic adenoma
Squamous or osseous metaplasia in malignant neoplasm	Malignant neoplastic process	Breast carcinoma

physiologic metaplasia and pathologic metaplasia are given in Table 1.15.

PHYSIOLOGIC METAPLASIA

Physiologic metaplasia is generally a normal transient response to changing conditions. For example, in the body's normal response to inflammation, monocytes migrate to inflamed tissues and transform into macrophages.

PATHOLOGIC METAPLASIA

Pathologic metaplasia is usually a response to chronic irritation (e.g. tobacco smoking or chronic inflammation). This process is usually reversible. Examples of pathologic hyperplasia are described as under.

Squamous Metaplasia in Tissues/Organs

Squamous metaplasia is a benign non-neoplastic change of surface lining epithelial cells to a squamous morphology. Common sites of squamous metaplasia include urinary bladder, bronchi, cervix, and ducts of exocrine gland.

Squamous Metaplasia in Cervix

The uterine cervix measures 3–4 cm in length and 2.5 cm in diameter. However, it varies in size and shape depending on age, menstrual status and parity of the women.

- Ectocervix is most often readily visible portion of cervix and lined by stratified squamous epithelium consisting of multiple layers of cells.
- Endocervix is invisible and lies proximal to the external os and lined by columnar epithelium consisting of single layer of cells.
- The location of squamocolumnar junction in relation to the external os varies depending on age, menstrual status, parity and contraceptive use.
- Squamous metaplasia in cervix occurs in the transformation zone, in which the endocervical epithelium is replaced by subcolumnar reserve cells, which differentiate into immature and then mature squamous epithelium. Squamous epithelium overlies endocervical glands, may replace glands.

Squamous Metaplasia in Urothelium Lining Urinary Bladder

Squamous metaplasia is defined as the transformation of the normal urothelium into nonkeratinized or keratinized stratified squamous epithelium due to urolithiasis in trigone region.

Squamous Metaplasia in Bronchi Lined by Columnar Epithelium

Although metaplasia is considered to be a protective mechanism, yet it may be harmful. Columnar epithelium of tracheobronchial mucosa undergoes epithelial squamous metaplasia in response to chronic tobacco smoke exposure. Squamous metaplasia also impairs the production of mucus and ciliary clearance of debris. It is widely acknowledged that continuous exposure to tobacco smoke is linked to the development of chronic obstructive pulmonary disease (COPD). A history of cigarette smoking is independent risk factor for lung

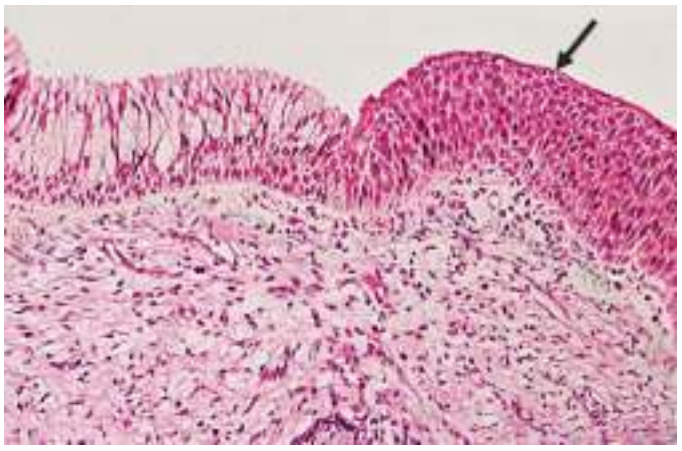

Fig. 1.11: Histology of squamous metaplasia. Squamous metaplasia is preneoplastic change of the bronchial columnar epithelium. It is observed in the bronchi in response to toxic injury induced by tobacco smoke. It is a multistage process, which may eventually lead to full neoplastic transformation, i.e. bronchogenic carcinoma (arrow) (100X).

cancers. Squamous metaplasia is a preneoplastic change of the bronchial columnar epithelium is shown in Fig. 1.11.

Squamous Epithelium Metaplasia in Conjunctiva

Vitamin A deficiency can also result in squmous metaplasia. Vitamin A is essential for differentiation of specialized epithelial surfaces such as the conjunctiva covering eye. In vitamin A deficiency, the thin squamous epithelium lining the conjunctiva undergoes metaplasia into stratified keratinizing squamous epithelium. The different ocular signs of vitamin A deficiency in children, as graded by the WHO, are: night blindness, conjunctival xerosis and Bitot's spots.

Squamous Epithelium Metaplasia in Pancreatic Ducts

Vitamin A deficiency can cause squamous metaplasia of epithelium lining pancreatic duct, since vitamin A maintains orderly differentiation of epithelia.

Squamous Epithelium Metaplasia to become Columnar Epithelium in Barrett's Esophagus

Barrett esophagus is classic example of metaplasia. Esophagus is normally lined by nonkeratinizing squamous epithelium, that is suited to handle friction of a food bolus.

- Barrett esophagus occurs due to gastroesophageal reflux of gastric contents into the esophagus, which causes the epithelium type to convert from squamous to intestinal type columnar epithelium, which can handle the stress of gastric acid. Metaplasia is thought to arise from reprogramming of stem cells present in adult tissue. Metaplasia is reversible with removal of the driving stressor.
- Treatment of gastroesophageal reflux may reverse Barrett disease. Under persistent stress, metaplasia can progress to dysplasia and eventually lead to cancer. Barrett esophagus may progress to adenocarcinoma. A notable exception is apocrine metaplasia of breast, which carries no increased risk for cancer.

Transitional Epithelium Metaplasia to Glandular Epithelium

Metaplasia of transitional epithelium to glandular epithelium is seen in patients with chronic inflammation of the bladder (cystitis glandularis).

Osseous Metaplasia in Myositis Ossificans

Mesenchymal tissues can also undergo metaplastic change. Osseous metaplasia is the formation of bony trabeculae within striated muscle at the site of repetitive traumatic injury.

- Fibrocollagenous tissue transforming to osseous tissue is known as myositis ossificans. It is worth mentioning that dystrophic calcification occurring at injury site does not lead to the formation of bone trabeculae.
- Most of the times, myositis ossificans occurs in the large skeletal muscles of the arms or the legs in young adults and athletes. Regardless of the cause, myositis ossificans happens when the body makes an error in the healing process. Patient may notice that pain worsens with time instead of getting better.

Myeloid Metaplasia

Myeloid metaplasia occurs due to proliferation of hematopoietic cells at the site other than bone marrow, such as liver and spleen. It is known as extramedullary hemopoiesis. Various causes of myeloid metaplasia are agnogenic myeloid metaplasia, myelofibrosis and polycythemia vera.

Metaplasia in Neoplasms

Metaplasia is seen in pleomorphic adenoma of salivary gland. Tumor shows areas of cartilage and bone. Breast carcinoma may show squamous or osseous metaplasia in some cases. Prognosis of metaplastic breast carcinoma is poor.

DYSPLASIA

Dysplasia means loss of regular appearance of cells in epithelium. It is characterized by variations in size and shape of dividing cells with mitotic activity arranged in disordered fashion with loss of cell maturation as cells progress to the surface, as a result of chronic irritation or inflammation. It may revert to normal, if stimulus is removed. If stimulus persists, it can precede malignant change. Differences between metaplasia and dysplasia are given in Table 1.16.

Table 1.16 Differences between metaplasia and dysplasia

Metaplasia	Dysplasia
Definition	
Transformation of one type of cell (epithelial or mesenchymal) into another adult cell type	Disordered cell growth, that may progress to development of cancer
Type of change	
Adaptive change and reversible if injurious stimuli removed	Nonadaptive change and irreversible even injurious stimulus removed
Cellular changes	
▪ Pleomorphism in cells absent ▪ Normal nuclei ▪ Few mitotic figures ▪ Normal architecture of cells in tissue maintained	▪ Pleomorphism in cells present ▪ Hyperchromatic nuclei ▪ Numerous mitotic figures ▪ Architecture of cells in tissue lost
Examples	
▪ Ciliated columnar to squamous metaplasia in trachea and bronchi (tobacco smoking) ▪ Columnar to squamous metaplasia due to stones in the ducts of salivary gland, pancreas and biliary system; and vitamin A deficiency ▪ Squamous to columnar metaplasia in Barrett's esophagus caused by chronic irritation by gastric juices in gastroesophageal reflux ▪ Transitional to squamous metaplasia of urinary bladder due to trauma ▪ Fibrocollagenous tissue to osseous metaplasia in myositis ossificans ▪ Tumor metaplasia (adenosquamous cell carcinoma, stromal mucinous metaplasia in pleomorphic adenoma, and squamous or osseous metaplasia in breast carcinoma)	▪ Cervical dysplasia due to human papillomavirus 16 ▪ Dysplasia of the bronchus due to cigarette smoking causing squamous metaplasia progressing to squamous dysplasia ▪ Skin dysplasia due to exposure to sun ultraviolet light causing skin dysplasia

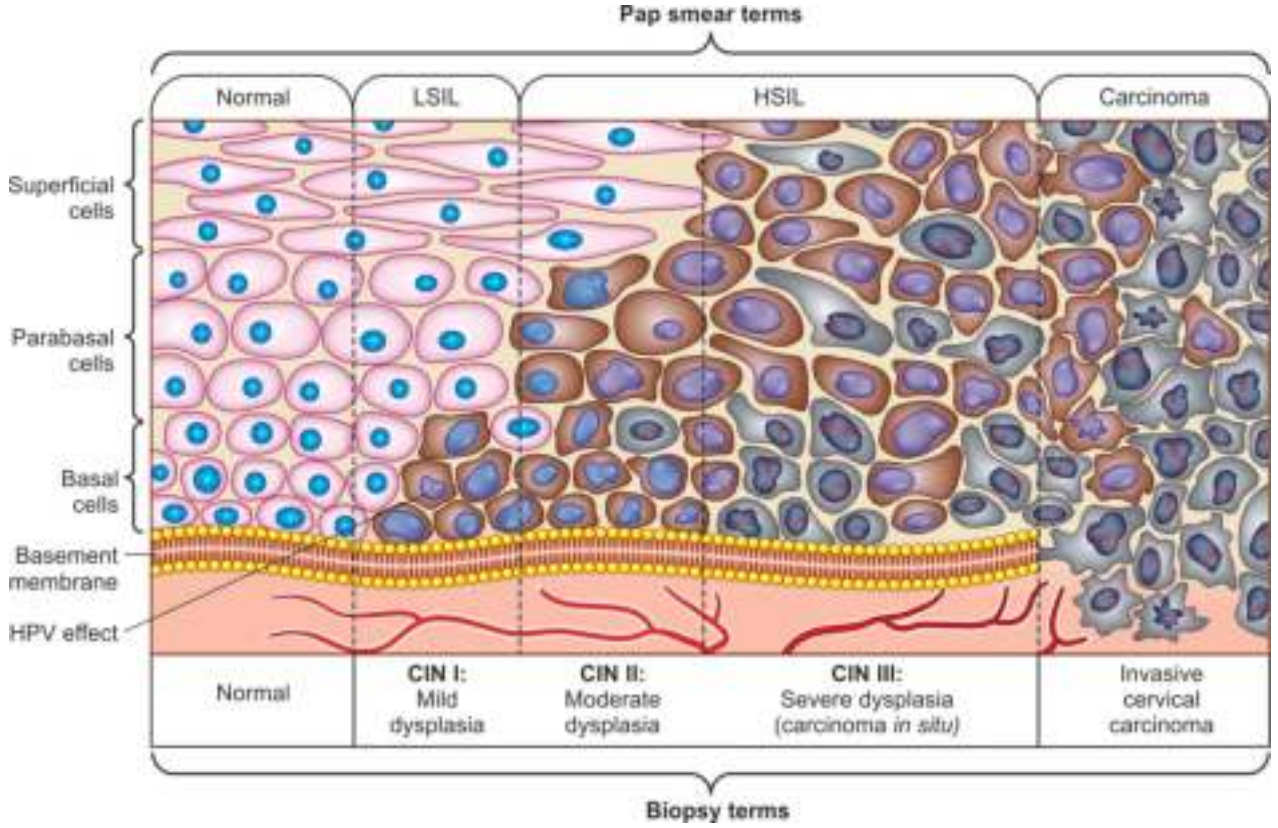

Fig. 1.12: Schematic representation of development of cervical intraepithelial neoplasia (CIN I, CIN II, CIN III) and invasive cervical carcinoma.

- **Cervical intraepithelial dysplasia:** Human papillomavirus 16, 18, 31, 33, 35, 39, 45 and 51 causes cervical intraepithelial dysplasia. The distinction between severe dysplasia and early cancer of the cervix is a common diagnostic problem for the pathologist. Schematic representation of development of cervical intraepithelial neoplasia (CIN I, CIN II, CIN III) and invasive cervical carcinoma is shown in Fig. 1.12. CIN III (cervical intraepithelial neoplasia) is shown in Fig. 1.13.
- **Dysplasia in bronchial epithelium:** Tobacco smoking produces dysplasia in respiratory epithelium. It is potentially reversible if the patient stops tobacco smoking. It may progress to bronchogenic carcinoma in heavy tobacco smokers.

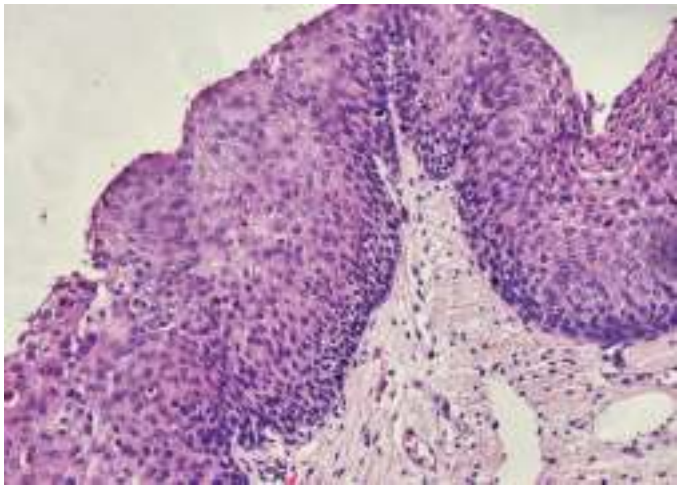

Fig. 1.13: Histology of CIN III. This is cervical squamous dysplasia at high magnification extending from the center to the right. The epithelium is normal at the left. Note how the dysplastic cell nuclei are larger and darker, and the dysplastic cells have a disorderly arrangement (400X).

- **Skin dysplasia:** Exposure to sun ultraviolet light causes skin dysplasia, which may lead to squamous cell carcinoma.
- **Actinic keratosis:** It is a form of dysplasia in sun-exposed skin. Histologic examination reveals atypical cells, varying in size and shape without, signs of regular maturation as the cells move from the basal layer of the epidermis to the surface.

REDUCTION IN SIZE OF ORGANS IN OTHER PATHOLOGIC PROCESSES

Pathologic processes other than atrophy associated with reduced organ size include agenesis, aplasia and hypoplasia.

- **Agenesis:** Agenesis refers to absence of organ resulting from failure to develop during embryonic development (e.g. renal agenesis). Renal agenesis differs from atrophy, in which a decrease in the size of an organ results from a decrease in preexisting cells. Bilateral renal agenesis is incompatible with life. Unilateral renal agenesis causes compensatory hypertrophy of opposite kidney.
- **Aplasia:** Aplasia is failure of cell production during embryogenesis. During fetal development, there is no development of adrenal cortex. During postnatal period, aplasia may occur due to permanent loss of bone marrow precursor cells as seen in aplastic anemia.
- **Hypoplasia**: Hypoplasia refers to incomplete development of an organ due to decrease in cell production. It may also occur due to partial lack of growth and maturation of gonadal structures in Klinefelter's syndrome and Turner syndrome.

CELL INJURY AND CELL DEATH: OVERVIEW

Homeostasis refers to the ability of an organism to maintain the vital internal environment within limits that allow it to survive. The fundamental pathogenesis of cell injury is a perturbation of homeostasis.

- Cell injury is defined as a change in cell structure, metabolism, physiochemical properties, and function which leads to impairment of its vital activity.
- Cell injury occurs due to defects in membrane permeability, mitochondrial damage with ATP depletion, accumulation of oxygen-derived free radicals (oxidative stress) and influx of intracellular calcium and loss of calcium homeostasis.
- Cell injury is initiated at the molecular level. Cell injury may be reversible or irreversible process depending on the type, severity and duration of cell injury. In reversible cell injury, cells can recover to their normal function. If the stress remains severe, cell injury becomes irreversible and leads to cell death.
- Cell injury can be caused by several intrinsic or extrinsic stresses. The basic mechanisms of cell injury can be categorized: (a) adenosine triphosphate (ATP) depletion, (b) permeabilization of plasma membrane and organelles with membranes, (c) disruption of biochemical pathways (impaired synthesis of structural protein and enzymes), and (d) DNA damage (pyknosis, karyorrhexis, karyolysis). Injury to the components of the cell can lead to disease as the cells lose their ability to adapt.

- Cell injury occurs when a stress exceeds the cells ability to adapt. Cell continues to function by adaptation despite mild to severe stress through its life. Cellular stress beyond the level of adaptive response results in cell injury, which may progress through a reversible cell injury stage and culminate in cell death.
- Basic principles of cell injury depend on nature of injurious stimuli, duration and severity of injury, type, ability of the tissues to regenerate (labile cells/stable cells/permanent cells), metabolic needs of cell, adaptability of the injured cells, genetic constitution and biochemical mechanisms acting on the several essential cellular components.
- In reversible cell injury, initially mitochondrial oxidative phosphorylation is disrupted that leads to decreased ATP production. Increase in cellular glycolysis to increase ATP stores leads to decreased in glycogen store and lactic acid accumulation resulting in decrease in intracellular pH. Decrease in ATP stores impairs membrane Na^+/K^+/calcium pumps that lead to accumulation of sodium and calcium; and diffusion of potassium leading to cellular swelling. Continued oxygen depletion leads to cytoskeleton disruption, mitochondrial changes, dilatation of the endoplasmic reticulum, distortion of microvilli, loosening of intercellular junctions, and blebbing of plasma membrane. Acute cell swelling is an example of reversible cell injury.
- Oncotic necrosis is the term currently used for nonapoptotic, accidental cell death. It is generally regarded as a severe injury to cell membrane integrity. The term 'oncotic necrosis' is defined as cell death with swelling (oncosis), that can be caused by ischemia, and toxic agents that interfere with ATP generation by mitochondria and plasma membrane pumps failure ($Na^+/K^+/Cl^-/Ca^{++}$).
  - Oncotic necrosis is characterized by cell swelling (oncosis), organelles swelling, plasma cell blebbing, loss of plasma membrane integrity, increased membrane permeability, dispersion of ribosomes, chromatin fragmentation (pyknosis, karyorrhexis, karyolysis), release of lysosomal enzymes into extracellular spaces, eosinophilic cytoplasm, leakage of proteins (creatine kinase, troponins, myoglobin, cellular enzymes) into blood, inflammation, vascularization and tissue repair. Necrosis is always pathologic as a result of irreversible cell injury.
- Irreversible cell injury results in a loss of cell functions. Myocardial cell injury results in loss of heart contraction. Motor neuron injury leads to skeletal muscle paralysis. Irreversible injury to islets of Langerhans results in diabetes mellitus. Pathophysiology of oxidative stress-induced cell death is shown in Fig. 1.14.
  - Neurons are highly susceptible to ischemic injury, that begins to die within three to five minutes after the oxygen supply has been cut off. Myocardial infarct develops within 20–30 minutes of interruption of blood supply to myocardium.
  - Watershed areas in brain and bowel are susceptible to oncotic necrosis. Skeletal muscles are relatively more resistant to ischemic injury. Fibroblasts are resistant to ischemia.

Pathology Pearls: Reversible and Irreversible Cell Injury

Reversible Cell Injury

The initial phase of cell injury is reversible. The hallmark of reversible cell injury is cellular swelling: (a) cytosol swelling results in loss of microvilli and membrane blebbing; and (b) swelling of the rough endoplasmic reticulum results in dissociation of ribosomes and decreased protein synthesis.

Irreversible Cell Injury

- Eventually, prolonged cell injury results in irreversible cell injury. The hallmark of irreversible cell injury (cell death) is membrane damage.
- Plasma membrane damage results in leakage of cytosolic enzymes and proteins into the blood (cardiac troponins in myocardial infarction, leakage of liver enzymes in hepatocellular injury); and influx of additional calcium occurs into the cell.
- Mitochondrial membrane damage results in loss of the electron transport system located in inner mitochondrial membrane; and leakage of cytochrome c into the cytosol; that activates apoptosis.
- Lysosomal membrane damage results in leakage of hydrolytic enzymes into the cytoplasm, which in turn, are activated by the high cytosolic calcium. The end result of irreversible injury is cell death.
- The morphological hallmark of cell death is degradation of the nucleus, which occurs via nuclear condensation (pyknosis), fragmentation (karyorrhexis), and dissolution (karyolysis). The death of large group of cells is followed by acute inflammation.

CAUSES OF CELL INJURY AND CELL DEATH

Cell injury can be caused by several intrinsic or extrinsic stresses. Causes of cell injury are given in Table 1.17.

- Intrinsic stressors of cell injury include genetically determined metabolic imbalances, genetic abnormalities, gross malformations, hypersensitivity reactions, oxidative stress (hypoxia), and ischemia-perfusion injury, hypoxia is the most important cause of cell injury.

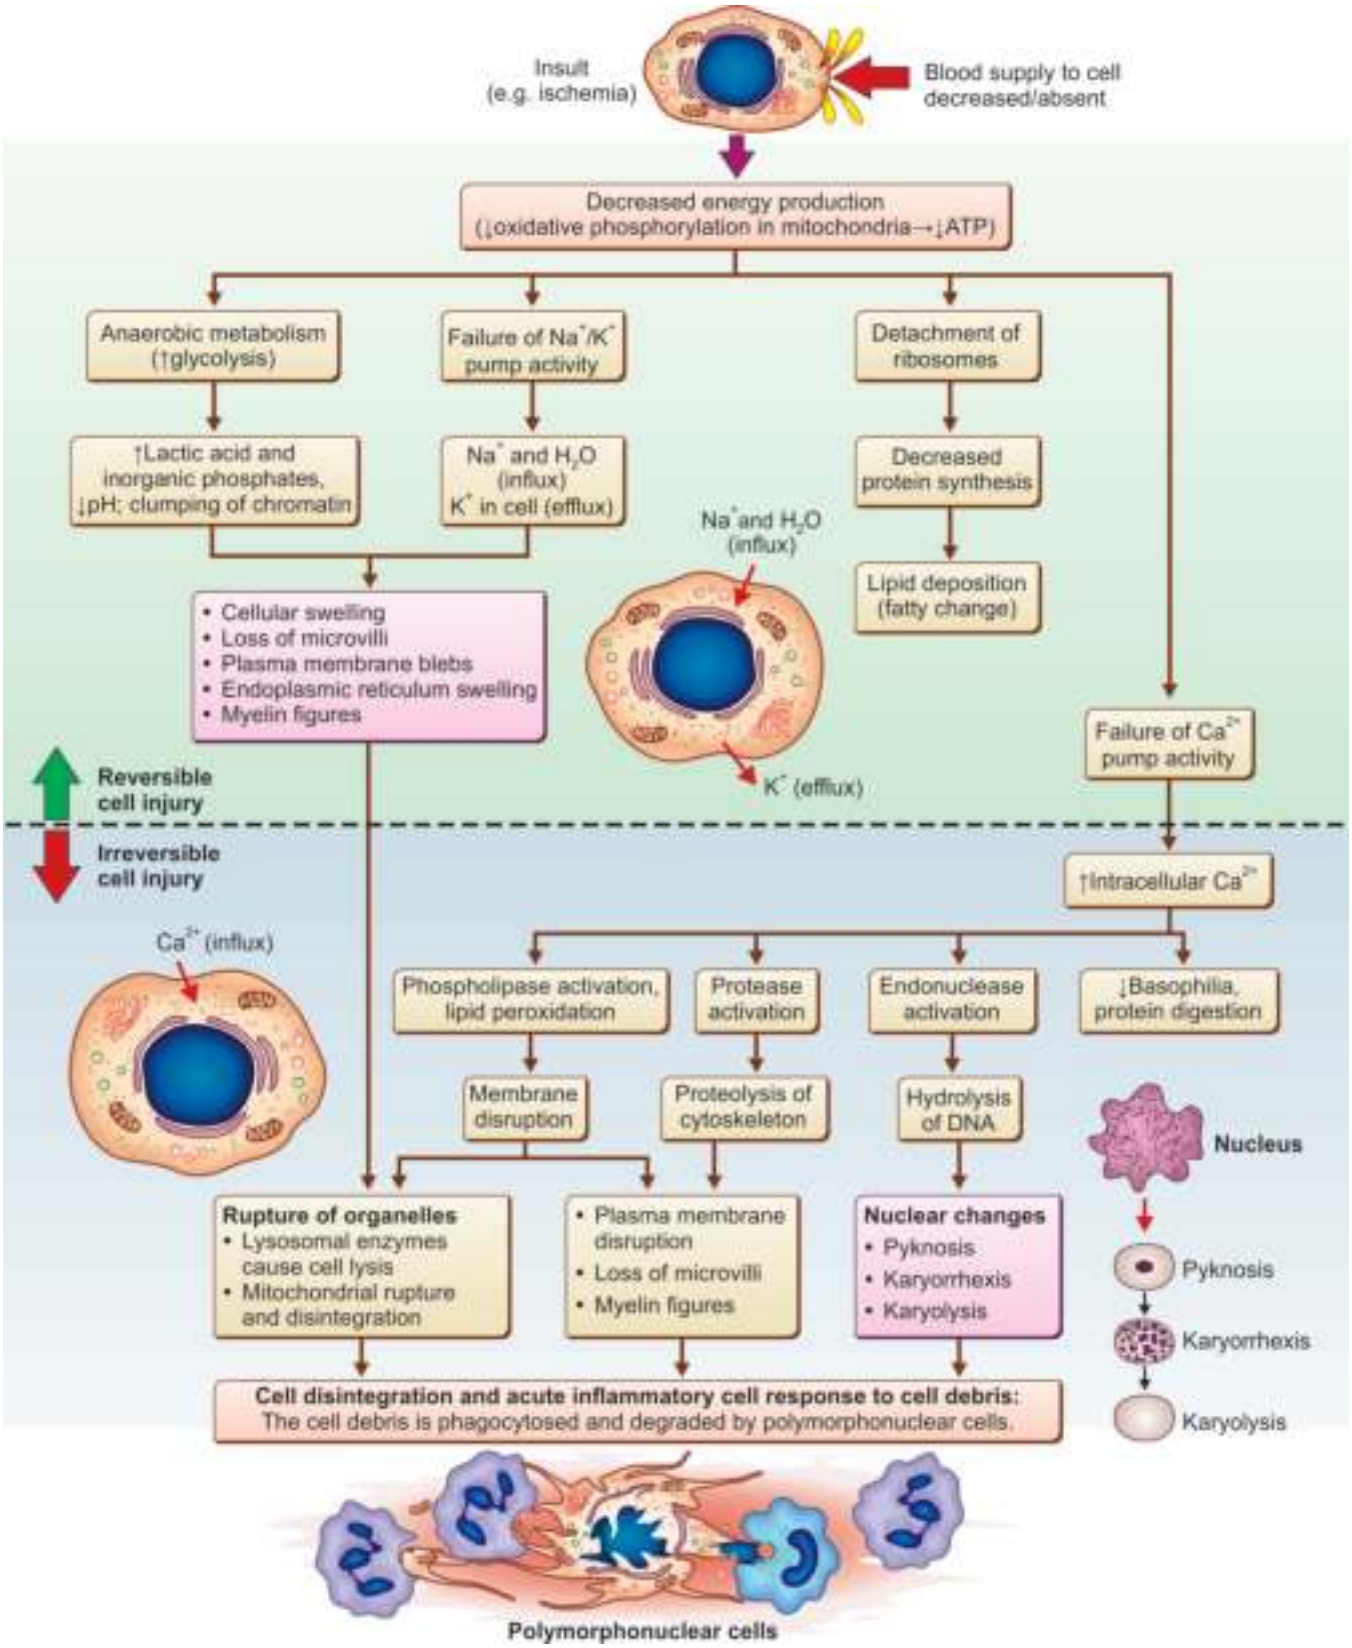

Fig. 1.14: Pathophysiology of oxidative stress-induced cell death. Oxidative stress-induced cell injury that occurs when there is an imbalance between the generation of reactive oxygen species (ROS) and the antioxidant defense systems in the body. The reactive oxygen species comprises many molecules that have divergent effects on cellular function leading to disintegration of cell membranes and nucleus and inflammatory response.

Table 1.17 Causes of cell injury

Mechanism	Cell Injury
Oxidative stress (oxygen deprivation → hypoxia/ischemia)	Pneumonia, cardiopulmonary failure (hypotensive shock), anemia, carbon monoxide (CO) poisoning, relative ischemia-induced cell injury (poor blood supply to organs), complete cessation of blood supply induced cell injury causing organs infarcts (heart, kidney, spleen, lung, intestine)
Ischemia-reperfusion injury in various organs	Myocardial infarction, cerebral stroke, peripheral vascular disease
Infectious agents	Bacteria, viruses, parasites, fungi
Physical injury	Mechanical trauma, extreme of temperature (burns and severe cold), electric shock, radiation, sudden changes in atmospheric pressure
Chemical agents	Mercury, cyanide, arsenic, carbon monoxide, strong acids, strong alkali
Drugs	Alcohol, narcotic drugs, therapeutic drugs
Immunological reactions	Anaphylaxis, autoimmune diseases
Genetic defects (DNA alterations)	Congenital malformations, inborn errors of metabolism
Nutritional imbalance	Starvation, protein energy malnutrition disorder (marasmus and kwashiorkor), obesity, vitamins deficiency
Cellular aging	Cellular degeneration, cellular senescence

- Extrinsic stressors of cell injury include physical agents (mechanical trauma, extremes of temperature—burns and deep cold), electrical injury, radiation, sudden fluctuations of the barometric pressure, chemical agents, alcohol consumption, carbon monoxide, lead, drugs, chemotherapeutic agents, immunosuppressive drugs, infectious agents (bacteria, viruses, fungi and protozoa interfere in maintaining cell integrity and its function), venoms, poisons, insecticides, carbon monoxide, asbestos, nutritional deficiency, and immunological reactions.

OXIDATIVE STRESS/HYPOXIA-INDUCED CELL INJURY

The ability to maintain oxygen homeostasis is essential to the survival of cells in each organism. Normally, O_2 diffuses down a gradient from the atmosphere to the alveoli, to plasma, and into the red blood cells (RBCs), where O_2 attaches to heme groups. Oxygen is essential for aerobic respiration.

- Hypoxia literally means 'low-oxygen' but is defined as a deficiency in the amount of oxygen that reaches the tissues/organs of the body.
- Hypoxia prevents normal oxidative phosphorylation process, and thus reducing the capacity of mitochondria to generate adenosine triphosphate (ATP). Without ATP, the cell is unable to maintain its vital functions.

Causes of Hypoxia

Hypoxia can result from inadequate blood supply of oxygen (atherosclerosis, hypotensive shock), obstruction of airways, inadequate oxygenation of blood in the lungs (lung diseases), inadequate oxygen transport (e.g. anemia), inadequate perfusion of blood in the tissues (e.g. heart failure) and inhibition of cellular respiration (e.g. inhibition of oxygen utilization by cyanide poisoning of respiratory enzymes).

- Hypoxemia refers to a low partial pressure of oxygen in the blood due to high altitude, hypoventilation or diffusion defect. Decreased venous drainage can also impair adequate oxygen to the tissues.
- Hypoxia can be classified as acute or chronic, with acute meaning a rapid onset, and chronic meaning that hypoxia has been ongoing for some time.
- Decreased oxygen carrying capacity occurs due to hemoglobin loss or dysfunction in the settings of anemia and carbon monoxide poisoning.
- Carbon monoxide (CO) is a harmful gas produced from firewood smoke and motor vehicles exhaust. When carbon monoxide is breathed, it binds hemoglobin more avidly than oxygen and forms carboxyhemoglobin leading to deprivation of oxygen to heart, brain and other vital organs. Early signs and symptoms in carbon monoxide poisoning are headache, and cherry-red appearance of skin. Significant exposure to carbon monoxide results in loss of consciousness and death.
- Methemoglobinemia is a condition of elevated methemoglobin (normal range 1%) in the circulating red blood cells. It can occur due to inherited disorder or acquired causes such as benzocaine, dapsone or nitrates. The underlying mechanism involves some of the iron in hemoglobin being converted from ferrous (Fe^{++}) to the ferric (Fe^{+++}) form, that

cannot bind oxygen that leads to decreased oxygen supply to the tissues/organs. **Cyanosis** occurs, when methemoglobin level in the red blood cells reaches around 15%. Symptoms may include headache, dizziness, shortness of breath, nausea, poor muscle coordination and blue-colored skin (cyanosis). Complications of methemoglobinemia may include seizures and cardiac arrhythmias. Methylene blue is an effective treatment for reducing methemoglobin, however, it is associated with adverse reactions in glucose-6-phosphate dehydrogenase (G6PD)-deficient individuals. Abnormal hemoglobins inducing hypoxia are given in Table 1.18.

Mechanism of Hypoxia-induced Cell Injury

Hypoxia implies damage to the cells/tissues resulting from reduced oxygen availability due to poor hemoglobin saturation, inadequate ventilation and hemolysis. Causes of hypoxia are ischemia, hypoxemia, and decreased oxygen carrying capacity of blood.

- Ischemia is a state of significantly reduced blood flow due to thrombotic occlusion and trauma which leads to tissue damage if not reversed.
- Oxygen deprivation is the most common cause of cell injury. Oxygen is the final electron acceptor in the electron transport chain of oxidative phosphorylation in mitochondria.
  - Early consequences of ischemia injury include transient shift of anaerobic glycolysis, disturbed ionic and fluid balance and inhibited β-oxidation of fatty acids.
  - Late consequences of ischemic injury include lysosomal activation and leakage of proteins such as creatine kinase, troponins, myoglobin, cellular enzymes into blood.
- Reduced oxygen availability impairs oxidative phosphorylation in mitochondria resulting in decreased ATP (essential source of energy) production. Adenosine triphosphate (ATP) depletion results in failure to energizes several important homeostatic processes leading to ischemia-induced necrotic cell death.
- During ischemia, the affected cells become dependent on anaerobic glycolysis for their ATP supply, which leads to an accumulation of lactate and NAD^+, and therefore causes a drop in cytosolic pH.
- Calcium and reactive oxygen species (ROS) are common players in necrotic cell death irrespective of the stimulus. ATP depletion results in additional cell damage by causing failure of energy-dependent enzymes, especially the cell membrane ATP ion pumps ($Na^+/K^+/Cl^-/Ca^{++}$) that control cell volume and electrolyte balance, which results in rapid intracellular increase of calcium, sodium and chloride leading to cell swelling.
- Increased cytosolic calcium results in the activation of signaling kinases such as mitogen-activated protein kinase (MAPK or MAP kinase) and calmodulin kinase, which act as transcription factors. Elevated cytosolic calcium levels result in modification of cytoskeleton, plasma cell membrane blebbing, activation of phospholipases, proteases and endonucleases, which seem to trigger cell membrane damage through phospholipase, proteins degradation through protease and DNA degradation through endonuclease.
- Mitochondria are the major site of ATP production and also one of the most vulnerable organelles of the cell. Mitochondrial injury leads to ATP depletion and increased permeability of mitochondrial membranes with resultant loss of calcium homeostasis and activation of cellular enzymes such as phospholipases, proteases and endonucleases. Activated cellular enzymes inflict damage to membranes (plasma membrane, mitochondrial membrane and other organelles membranes), structural molecules (lipids, proteins) and enzymatic proteins, and nucleic acids.
- The excessive reactive oxygen species (ROS) such as superoxide, hydroxyl radical, hydrogen peroxide formed in the mitochondria cause damage to the lipids, proteins, DNA, membrane integrity (plasma membrane and organelles) consequently results in $Na^+/K^+/Cl^-/Ca^{++}$ pump failure, ionic balance deregulation, mitochondrial dysfunction and cell swelling.

Table 1.18 Abnormal hemoglobins inducing hypoxia

Hemoglobin	Acquired Alteration	Abnormal Function	Spectroscopy Hemoglobin Maximum Absorption Band
Methemoglobin	Hemoglobin iron in ferric form	Methemoglobin cannot with oxygen	630 nm (chocolate color)
Sulfhemoglobin	Sulphur combines with hemoglobin	Sulfhemoglobin has 1/100 oxygen affinity of HbA	620 nm
Carboxyhemoglobin	Carbon monoxide combined with hemoglobin	Affinity of carboxyhemoglobin is 200 times higher than oxygen	541 nm

Table 1.19 Vulnerability of cells (organs) to ischemic irreversible cell injury

Cells/Tissues Vulnerable to Ischemia	Duration of Irreversible Injury
Neurons (cerebellum's Purkinje cells and hippocampus area most susceptible to injury)	3–5 minutes
Myocardium	20–30 minutes
Hepatocytes	1–2 hours
Intestine	8–16 hours
Skeletal muscle	24–72 hours
Fibroblasts	Resistant to ischemic injury

Watershed areas are present mesenteric arteries and cerebral arteries.

- Reactive oxygen species (ROS) can react with the nucleic acids attacking the nitrogen bases and the sugar phosphate backbone and evoke single-stranded or double-stranded DNA breaks. The change of nuclear morphology upon induction of necrosis includes pyknosis, karyorrhexis and karyolysis.
- Furthermore, necrotic cells release immunomodulatory factors that result in recognition and engulfment of necrosed cells by phagocytes and the subsequent immunologic response.
- Hypoxia adversely affects function of brain, heart and liver. Hypoxic cell injury depends on type of tissues undergoing necrosis. Vulnerability of cells (organs) to ischemic irreversible cell injury are given in Table 1.19.
- Ischemia-reperfusion injury occurs when blood flow is restored, cells that survived the initial ischemia may now be irreversibly injured by process initiated by oxygen-derived free radicals, inflammatory cells, or activation of the complement cascade.

Hypoxia-induced Brain Injury

Border zone or watershed infarcts are ischemic lesions that occur in characteristic locations at the junction between two main arterial territories.

- Progressive hypoxia of brain in the setting of hypotension and hypovolemia progresses and eventually becomes irreversible within 3–5 minutes of ischemia except if oxygenation is restored.
- The most vulnerable regions to oxygen deprivation (hypoxia) seem to be the brainstem especially cerebellum's Purkinje cells, hippocampus and cerebral cortex.
- Prolonged brain hypoxia can cause coma, seizures and even brain death. Histologically, these can be wedges of cortical and subcortical infarction.
- Extracellular brain adenosine levels are low under normal conditions, but increase substantially in response to hypoxia.
- Adenosine acts as an inhibitory neurotransmitter in the brain through the activation of four specific G protein-coupled receptors (A1, A2B and A3 receptors), that facilitates sleep and dilates the blood vessels probably to ensure good oxygen supply to brain during sleep.
- In contrast, a robust and prolonged activation of the G protein-coupled receptor A3 adenosine receptor has been observed to trigger cell death by either necrosis or apoptosis.
- During brain hypoxia, low oxygen quickly results in a fall of ATP production and consequent increase in adenosine. Both these alterations prevent the hypoxia-induced membrane depolarization resulting in reduction of Ca^{++} influx and K^{+} efflux. Adenosine acts as a neuroprotective agent in cerebral hypoxia or ischemia by suppressing neurotransmitter through synaptic receptors.
- The regulation and generation of extracellular adenosine in response to oxidative stress are critical in tissue protection.

Hypoxia-induced Myocardial Infarction

Myocardial infarction develops within 20–30 minutes of complete cessation of blood flow to a portion of the myocardium. It is closely associated with coronary artery disease induced by modifiable risk factors (tobacco smoking, hypertension, hyperlipidemia, diabetes mellitus, abdominal obesity, lack of physical activity) or non-modifiable risk factors (advanced age, male gender, genetics).

- When the coronary artery is occluded due to atheromatous plaques, the myocardium is deprived of the oxygen.
- Prolonged deprivation of oxygen supply to heart leads to the myocardial cell death and necrosis. Myocardial infarction may be associated with ECG changes and elevated biochemical markers such as cardiac troponins and enzymes (CK-MB, LDH and SGOT).
- Patient presents with crushing chest pain lasting for more than 20 minutes that can radiate to the neck, jaw, shoulder or arm, breathlessness, nausea, palpitations or silent without symptoms. As myocardial infarction is associated with several serious complications. These patients are best managed in intensive coronary care unit.

Hypoxia-induced Hepatocellular Injury

A diverse set of ischemic, metabolic, toxic and hepatotropic viruses, inflammatory insults result in hepatocellular injury. Interruption of blood supply to liver

leads to irreversible hepatocellular injury after 1–2 hours of hypoxia.

- Necrosis and apoptosis are the most widely recognized forms of hepatocyte cell death.
- Necrosis occurs due to ATP depletion during ischemia or hypoxic cell injury, excessive formation of reactive oxygen species (ROS) during reperfusion of ischemic tissue, acetaminophen toxicity, xenobiotics toxicity, and sustained increase in intracellular calcium.
- Oncotic necrosis is characterized by cell swelling, organelle swelling, formation of blebs in plasma membrane, cell rupture, release of lysosomal enzymes into extracellular environment, and inflammatory response.

Bowel Ischemia

Bowel ischemia can affect small intestine or large intestine as a result of reduction in arterial blood flow to these regions within 8–16 hours.

- Intestinal tract receives dual blood supply from two most distal branches of superior mesenteric artery and inferior mesenteric artery. The celiac artery has also collateral branches to supply intestine.
  - Superior mesenteric artery supplies the bowel from lower part of the duodenum to proximal two-thirds of the transverse colon.
  - Inferior mesenteric artery supplies the bowel from the distal one-third of the transverse colon to the rectum.
- Watershed area is the region in intestine where blood supply does not overlap and thus is susceptible to hypoxia injury.
  - Two main watershed regions between two major arteries that supplying colon include splenic flexure (Griffiths point) and rectosigmoid junction (Sudek's point), which are prone to ischemia.
  - Splenic flexure is the watershed area between superior mesenteric and inferior mesenteric artery, and the rectosigmoid junction is the watershed region between inferior mesenteric artery and superior rectal artery.
- Patients may develop small intestine (mesenteric) ischemia or colon ischemia. Clinical manifestations in a case of colon ischemia are abdominal pain, tenderness, rectal bleeding or bloody diarrhea. An abdominal computed tomography (CT) scan is done in hemodynamically stable patients who present with acute abdominal pain. CT angiography and MRI scan are performed to diagnose highly suspicious intestinal ischemia.

Hypoxia-induced Rhabdomyolysis in Skeletal Muscle

Skeletal muscle ischemia, damage and eventual necrosis lead to rhabdomyolysis within 24–72 hours. The classic presentation in a case of rhabdomyolysis includes myalgia, weakness and dark urine. Physical examination demonstrates skeletal muscle tenderness. Creatine phosphokinase activity is the most sensitive indicator of skeletal muscle damage; it may continue to increase for several days.

- Calcium may be deposited in damaged skeletal muscle. Lactic acidosis and anion gap metabolic acidosis can result from release of other organic acids from cells.
- Rhabdomyolysis is particularly common in people with diabetes mellitus or sickle cell anemia.
  - Complete interruption of blood supply to skeletal muscle causes irreversible cell death within many hours. In uncontrolled diabetes mellitus patients, skeletal muscle ischemia occurs from thrombosis of medium or small arterioles in the setting of atherosclerosis.
  - Skeletal muscle ischemia leads to severe pain with a palpable mass with or without swelling of especially vastus thigh skeletal muscle and calf skeletal muscle. The ischemia may start in the calf skeletal muscle and progress to the vastus skeletal muscles.
  - Bilateral lower limbs involvement is observed in more than one-third of cases. More than 50% of cases have coexistent diabetic nephropathy, neuropathy and retinopathy.

Cardiac Fibroblasts Resistant to Hypoxia

Fibroblasts are mesenchymal cells, abundantly distributed in connective tissues of most organs, which synthesize the extracellular matrix and collagen types 1, 3 and 4, including proteoglycans, glycosaminoglycans, fibronectin, laminins, metalloproteinases. Fibroblasts produce the structural framework for tissues (skin, lung, heart, kidney, liver, eye and other organs). These also play a critical role in wound healing.

- Cardiac fibroblasts represent the largest population of interstitial cells in myocardium surrounding cardiomyocytes.
  - Cardiac fibroblasts are resistant to hypoxia, which rather protect cardiomyocytes against lethal ischemia-reperfusion injury and so play important roles in the cascade of events after ischemic injury.
  - Cardiac fibroblasts transform into myofibroblast produce α-smooth muscle actin.

- Myofibroblasts play critical role in cardiac remodeling by forming collagen-rich scar that allows the infarcted region to maintain structural integrity after cardiomyocyte death.

ISCHEMIA-REPERFUSION-INDUCED CELL INJURY

In the clinical settings of myocardial infarction, cerebral stroke, organ transplantation and peripheral vascular disease, restoration of blood flow to the diseased organs triggers further ischemic cellular damage, this paradoxical effect is known as reperfusion injury. It is a challenge for the clinicians to control further cell damage and restore organ functions.

- The role of nitric oxide (an endothelial-derived relaxing factor) as a cardioprotective agent against reperfusion injury, has been demonstrated as nitric oxide works to inactivate reactive oxygen species, thereby, ameliorating the process of reperfusion injury.
- The extent of cell/tissue injury is directly related to the extent of reduction in blood flow and duration of ischemic period, which influence the exchange of ions across cell membrane (sodium, potassium, hydrogen, chloride and calcium), oxidative phosphorylation in mitochondria and drop in intracellular pH (tissue acidosis occurs).
- By impairing ATPase-dependent ion transport across cell membrane, ischemia causes increased calcium levels (calcium overload) in the cellular cytoplasm and mitochondria. Cell volume regulatory mechanisms are also disrupted due to lack of ATP production, which induce lysis of cell organelles and plasma membranes.
- It is essential to restore the blood flow to hypoxia-induced tissue/organ injury. For example, percutaneous coronary angioplasty and fibrinolytic therapy are performed to restore blood flow to limit myocardial infarct size. The restoration of blood flow to ischemic tissues/organs causes additional myocardial damage, which is termed reperfusion injury. All tissues are susceptible to reperfusion injury, but susceptibility varies between tissues/organs.
- Ischemia-reperfusion injury influences the outcome of patients after myocardial infarction, cerebral stroke, organ transplantation and cardiovascular surgery. Reperfusion of the tissues produces paradoxical tissues/organs response that fuel to the production of reactive oxygen species (ROS) through the xanthine oxidase pathway released from activated neutrophils, sequestration of proinflammatory cells (neutrophils, macrophages and T cells) in ischemic tissue, endoplasmic reticulum stress and development of post-ischemic capillary absence of reflow as a result of decreased nitric oxide (vasodilator) production resulting in amplification of tissue injury.
- These pathologic events culminate in opening mitochondrial permeability transition pores in the inner mitochondrial membrane as a common end-effector of ischemia-reperfusion-induced ionic loss homeostasis, matrix swelling, outer membrane rupture, cell lysis and death.
- It is evident that therapeutic approaches will be effective only when multiple pathologic processes are targeted in the management of perfusion injury to tissues/organs. Pathophysiologic mechanisms of ischemia-reperfusion-induced myocardial injury are given in Table 1.20.

Table 1.20 Pathophysiologic mechanisms of ischemia-reperfusion-induced myocardial injury

Mechanism of Ischemia-reperfusion-induced Myocardial Injury	Biochemical Alterations	
Accumulation of ions	▪ Intracellular calcium workload ▪ Increased intracellular sodium	▪ Drop in intracellular pH with rapid normalization with upon reperfusion
Dissipation of mitochondrial membrane potential essential component in the process of energy storage during oxidative phosphorylation	Dysfunctional mitochondrial transition pore potential may result in sustained transport of ions and proteins essential for normal functioning of mitochondria	
Reactive oxygen species (ROS)	▪ Xanthine oxidase pathway ▪ Release of mitochondrial intermediates	▪ Neutrophil infiltration
Dysregulated nitric oxide (NO) metabolism	▪ Loss of nitric oxide (an endothelial-derived relaxing factor)	▪ Accumulation of reactive peroxynitrite
Endothelial dysfunction	▪ Cytokine and chemokine signaling ▪ Expression of cellular adhesion markers	▪ Impaired vasodilation
Platelets aggregation and microembolization	▪ Platelets aggregation	▪ Microembolization
Immune system activation	▪ Innate immunity (e.g. complement activation and expression of toll-like receptors) ▪ Neutrophil accumulation	▪ Cell-mediated damage (macrophages and T cells)

PATHOGEN-INDUCED CELL INJURY

Induction of host cell death either directly or indirectly has been demonstrated in several cases by invading pathogens such as bacterial, viral, parasitic and fungal infections, which induce diverse responses in the host that include activation of innate immune response, inflammation and cell death.

- The death of an infected cell can promote efficient pathogen clearance. Destruction of infected tissues may also eliminate a pathogenic niche thereby inhibiting pathogen replication and dissemination.
- *Mycobacterium tuberculosis* thrive within immature phagosome of the infected cells by inhibiting phagosome-lysosome fusion. Phagocytosis of the apoptotic bodies sequestering pathogens permits more efficient fusion of phagosome with lysosome resulting in the degradation of the pathogen.
- Apoptosis of alveolar macrophages in *Streptococcus pneumoniae* infection results in pathogen elimination rather than evasion of the immune system.
- *Chlamydia* species are a group of obligatory bacteria that replicate inside of cytoplasm and protect infected cells from death during invasive stages of disease, presumably by blocking cytochrome c release from mitochondria.
- Rickettsia continues to replicate within cells through stimulating NF-κB signaling that prevents cell death.
- Pathogen-induced cell death is manifested by various distinct morphologic and biochemical characteristics indicative of oncotic necrosis, apoptosis, pyroptosis or autophagic cell death. Oncotic necrosis is highly inflammatory process that favors pathogen dissemination.Apoptosis and autophagy do not induce inflammation that are beneficial to the host.

Oncotic Necrosis

Necrosis is the term currently used for nonapoptotic, accidental cell death. It is generally regarded as a severe form of injury to cell membrane integrity. Oncotic necrosis can be induced by pathogens. The term 'oncotic necrosis' is defined as cell death with swelling (oncosis), that can be caused by ischemia, and toxic agents that interfere with ATP generation by mitochondria and plasma membrane ($Na^+/K^+/Cl^-/Ca^{++}$) pumps failure. Oncotic necrosis is characterized by cell swelling (oncosis), cell organelles swelling, plasma cell blebbing, loss of plasma membrane integrity, increased membrane permeability, chromatin fragmentation (pyknosis, karyorrhexis, karyolysis), release of lysosomal enzymes into extracellular spaces, eosinophilic cytoplasm, inflammation, vascularization and tissue repair.

Apoptosis

Several pathogens have been reported to trigger **apoptosis** through several mechanisms including bacterial toxins and virulence factors that interact with cell machinery.

- Apoptosis is a programed cell death mediated by initiator caspase enzymes (2, 8, 9, 10)/executioner caspases (3, 6, 7), which are cysteinyl aspartate-specific proteases.
- During apoptosis, pathogens are contained within apoptotic bodies and digested in the lysosomes of macrophages and surrounding cells, that phagocytose apoptotic bodies. It is worth mentioning, infected epithelial cells and lymphocytes undergo apoptosis.

Heterophagy

Heterophagy is the process by lysosomes digest material from the extracellular environment. Extracellular pathogens are taken up by the cells through the general process of endocytosis, which eventually fuse with lysosomes to form phagolysosomes, where engulfed material is digested in neutrophils and macrophages. Examples of heterophagocytosis include uptake and degradation of bacteria by neutrophils and removal of apoptotic cells by macrophages.

Pyroptosis

Pyroptosis is a process of cell death mediated by the activation of caspase 1, a protease that detects pathogen in the cytosol and also activates the inflammatory cytokines, IL-1β and IL-18. Pyroptosis also features cell lysis and release of cellular contents. It is worth mentioning that macrophages and dendritic cells die primarily by pyroptosis.

PHYSICAL AGENTS INDUCED CELL INJURY

Physical agents capable of causing cell injury include mechanical trauma, extremes of temperature (burns and severe cold), electric shock, radiation and sudden changes in atmospheric pressure.

Physical Trauma

The type of tissue injury is incurred with the type and severity of trauma (blunt injury, crush injury and gunshot wound) and the type of structures involved. Several broad categories of tissue injury are recognized: abrasion, contusion (bruise) and laceration.

- **Skin abrasion:** Skin abrasion is minor form of injury of superficial layers of epidermis. Healing of skin abrasion is rapidly achieved by regeneration of epidermal cells from the remaining deeper basal epidermal layers, and there is no scarring.

- **Contusion (bruise):** Contusion (bruise) in skin, myocardium and brain usually results from blunt trauma. Blunt trauma injures blood vessels leading to extravasation of blood into the tissue. The bleeding is usually rapidly controlled by hemostatic mechanisms.
  - The red blood cells present in the injured tissue slowly undergo degradation. The various pigments derived from the breakdown of hemoglobin are responsible for the change in the color from red through purple, black, green and brown in contusion site.
  - Histologic examination of such contusion in tissue demonstrates hemosiderin-laden macrophages that signify evidence of hemorrhage. In more severe injuries, collection of sufficient blood in the tissues produces a distinct swelling called hematoma.
  - Contusions are dangerous in patients with hemophilia as a result of massive bleeding in the soft tissues, skeletal muscles and joints.
  - Myocardial contusion may cause cardiac arrhythmias and acute cardiac failure.
  - In head injuries, contusions are usually formed in the inferior frontal lobe due to movement of the brain against the irregular bony surface of base of the skull in the anterior cranial fossa. Cerebral lesions represent foci for possible development of epileptic seizures.
- **Gunshot wound (GSW):** A gunshot wound is an example of physical trauma caused by a bullet from a firearm. A gunshot wound can produce penetrating wound, in which the bullet enters the body but does not exit. In re-entry wounds, the bullet passes through a body segment, exits and re-enters the body. Such physical trauma can cause bleeding, bone fracture, organ damage, infection of the wound or loss of the movements of the affected body part.

Extremes of Temperature

Extreme of temperature can adversely affect cellular functions. Temperatures between 46° and 60°C induce irreversible cellular injury proportional to the exposure time. Between 60° and 100°C, protein coagulation occurs instantly with irreversible cell injury of key cytosolic and mitochondrial enzymes and nucleic acid–histone complexes. Frostbite and extreme hypothermia can also cause impairment of cellular functions.

- **Frostbite:** Frostbite is a dire condition in which skin and tissues freeze after being exposed to extreme cold for a prolonged time. Frostbite most commonly occurs on the fingers, toes, nose and ears, that can lead to severe and permanent damage to blood vessels and tissues.
- **Extreme hypothermia:** Extreme hypothermia can cause heart, nervous system and other organs to enter a state of shock that may increase risk of myocardial infarction, respiratory failure and possibly fatal outcome. Symptoms of hypothermia include shivering, slow breathing, lack of coordination and confusion, cold air can cause wheezing and shortness of breath.
- **Heat stress:** Heat stress (higher than 50°C) is a physical stressor that stimulates excessive production of reactive oxygen species (ROS) in the mitochondria, triggering protein and DNA oxidative damage as well as lipid peroxidation of membranes and cell death. Excessive production of ROS has been associated with the number of pathologic disorders, including infertility, ischemic-perfusion injury, bone disorders, neurological disorders and aging by means of lipid peroxidation.

CHEMICAL AGENTS INDUCED CELL INJURY

Exposure to chemical agents or drugs do not result in overt tissue injury, but may adversely affect cellular functions in a more subtle way, thereby increasing the susceptibility to other forms of cell damage.

Acute Cellular Toxicity

Some inert gases and chemical agents cause oxygen deprivation and induce cellular toxicity in central nervous system.

- **Carbon monoxide (CO):** Carbon monoxide competes with oxygen for binding to hemoglobin and therefore causes oxygen deprivation to tissues for cellular metabolism resulting in cell death.
- **Cyanide poisoning:** Cyanide poison damages to mitochondrial cytochrome oxidase and thus inhibits oxidative phosphorylation resulting in impairment of cellular metabolism and utilization for energy. Methemoglobin has strong affinity to cyanide ion and keeps cyanide ions away from the target cells, hence it forms the basis for antidotal therapy.
- **Solvents used for sedation/anesthesia:** Some solvents used for sedation/anesthesia interact with the membranes of cells in the nervous system, which impair transmission of electrical and chemical signals. Strong acids and alkaline chemical agents can cause irritation, chemical burns and possible scarring.
- **Skin sensitization with 2,4-dinitrochlorobenzene:** Skin sensitization occurs, when 2,4-dinitrochlorobenzene binds with natural proteins in the skin resulting in formation of altered protein-bound complex. Subsequent exposure to 2,4-dinitrochlorobenzene triggers immune system response, which recognizes

and eliminates the altered protein-bound complex by releasing cytokines resulting in dermatitis.

- **Lung injury with toluene diisocyanate (TDI):** Toluene diisocyanate is easily absorbed by lungs. Lung sensitization occurs in workers on exposure to toluene diisocyanate. Subsequent prolonged exposure to toluene diisocyanate causes acute lung injury characterized by pulmonary edema, bronchial constriction and impaired breathing. Patient presents with progressive breathlessness, dry cough, arthralgia and headache.

Long-term Chronic Cellular Toxicity

On frequent exposures or acute exposure, chronic toxicity can produce irreversible cellular adverse effects. An example of chronic toxicity related to cigarette smoking and lung cancer. The majority of toxic effects are due to specific biochemical interactions without causing recognizable damage to a cell or its organelles.

- Toxic effects to cell and its organelles include: (a) interference with a chemical agent that transmits a message across a neural synapse such as the inhibition of the enzyme cholinesterase by organophosphorus pesticides, and (b) when one toxic chemical agent inhibits or replaces another essential chemical agent such as the replacement of oxygen on the hemoglobin molecule with carbon monoxide.
- Toxic damage to cells and tissues can be transient and nonlethal or lethal. There are four main endpoints to the cellular or biochemical toxicity.
  - Cells and tissues may be completely repaired and return to normal.
  - Cells and tissues may be incompletely repaired but are capable of sustaining its function and reduced capacity.
  - Complete loss of tissue organ can cause death of organism. In certain instances, the organism can continue to survive with the aid of medical treatment or organ transplantation.
  - Toxic agents can induce malignant transformation associated with fatal outcome. Some patients can be treated by medical and/or surgical treatment.

Acetylcholinesterase Enzyme Inhibitors

Acetylcholinesterase enzyme is involved in the termination of impulse transmission by rapid hydrolysis of the neurotransmitter acetylcholine in many cholinergic pathways in the central and peripheral nervous systems.

- Any pesticide such as organophosphates (OPs) and the carbamates (CMs) bind and inhibit acetylcholinesterase enzyme, making it unable to induce hydrolysis of acetylcholine, that leads to accumulation of acetylcholine, hyperstimulation of nicotine and muscarinic receptors and disruption of neurotransmission resulting in various symptoms, including respiratory arrest and death.
- The primary treatment of pesticide is the administration of atropine, which blocks the adverse effects of acetylcholine, and the administration of pralidoxime chloride, which reactivates acetylcholinesterase enzyme.

Metabolic Activation of Chemical Agents

Many chemical agents such as carbon tetrachloride (CCl_4), chloroform, 2-acetylaminofluorene, nitrosamines and paraquat are metabolically activated to form oxygen-derived free radicals or reactive intermediates, which inhibit and interfere with normal cellular function.

- Carbon tetrachloride (CCl_4) can induce hepatocellular injury through its metabolic products, that are generated by a cytochrome P450 enzyme dependent step. Immediately within minutes of exposure to carbon tetrachloride, it leads to modest accumulation of malondialdehyde formation, a fall in cellular glutathione and substantial injury in isolated hepatocytes.
- Subsequent exposure to carbon tetrachloride leads to increased malondialdehyde formation, oxygen-derived free radicals induced lipid peroxidation, a fall in cellular glutathione and substantial hepatocellular damage.

Malignant Transformation in Injured Cells

The fundamental abnormality resulting in development of cancer is the continued and unregulated proliferation of injured cells. Cancer can involve in any tissue of the body and have many different forms in each body area. The vast majority of cancer cases are due to environmental risk factors. Alterations in DNA involving critical genes can cause increased susceptibility to malignant lesions. DNA damage can be induced by exposure to natural and synthetic chemical agents and physical agents (ultraviolet radiation, radon from the soil, γ-radiation from medical procedures). Genetic syndromes predispose to development of cancer.

DRUG-INDUCED CELL INJURY

The mitochondria are a frequent subcellular target that is involved in the toxicity of therapeutic drugs. Following drug administration, inhibition of mitochondrial complex 1 activates pathway of cell death.

- The mitochondrial complex 1 inhibition causes ATP depletion, reactive oxygen species (ROS) production, reactive nitrogen species (RNS) production from the metabolism of L-arginine amino acid, and sirtuin 3 inhibition.

- Peroxynitrite production is a major mechanism of mitochondrial-mediated cell injury. The antiviral drug efavirenz (EVF) induces mitochondrial complex 1 inhibition. Iron porphyrins provide protection to hepatocytes against antiviral EVF-induced lethal injury.

PATHOPHYSIOLOGY OF CELL INJURY, MORPHOLOGIC PATTERNS AND OUTCOME OF NECROSIS

Depending on severity of cell injury, various cellular changes occur: (a) reversible cell injury, in which cells remain in hemodynamic equilibrium, (b) irreversible cell injury results in cell death (necrosis) and tissue damage, (c) ischemic/reperfusion injury.

- **Reversible cell injury** is usually the result of the initial stages of lack of oxygen supply (hypoxia) or lack of blood flow to the cells. Inadequate ATP supply impaired membrane $Na^+/K^+/Ca^{++}$ pumps resulting in cellular swelling, lipid accumulation, and cellular 'blebbing' on the plasma membrane.
  - Decreased pH causes swelling of endoplasmic reticulum, detachment of ribosomes from the endoplasmic reticulum leading to decreased protein synthesis. Low ATP production or ATP depletion disrupts key cellular functions.
  - Bleb formation in plasma membrane results from outpouching from the cell membrane to accommodate more water.
  - Myelin figures are aggregates of damaged cellular membranes in cell injury, which are demonstrated as intracellular whorls of laminated phospholipid material resembling myelin sheath of nerves. Presence of membrane bound structures containing lysosomal enzymes are known as myelin or myelinoid bodies.
- In irreversible cell injury, sustained hypoxia results in ATP depletion that impairs membrane calcium pump leading to increased cytosolic calcium.
  - Cells switch from aerobic glycolysis to anaerobic respiration to produce ATP, which results in accumulation of lactic acid, which decreases the cellular pH leading to dispersion of ribosomes. Mitochondrial permeabilization results in increased cytosolic calcium that activates phospholipases, proteases, endonucleases and DNAases, which damage the cell.
  - Nuclear fragmentation occurs via pyknosis, karyorrhexis, and karyolysis. Membrane permeabilization leads to release of lysosomal enzymes into extracellular spaces, leakage of proteins (creatine kinase, troponins, myoglobin, cellular enzymes) into blood, inflammation, vascularization and tissue repair. Schematic representation of pathophysiology of reversible and irreversible cell injury is shown in Fig. 1.15. Ultrastructural differences between reversible cell injury and irreversible cell injury are given in Table 1.21.

Pathology Pearls: Reversible Cell Injury versus Irreversible Cell Injury

- The hallmark of reversible injury is cellular swelling, swelling of endoplasmic reticulum and loss of microvilli.
- The hallmark of irreversible injury (cell death) is damage to membranes and genetic apparatus via nuclear condensation (pyknosis), fragmentation (karyorrhexis), and dissolution (karyolysis). The death of large group of cells is followed by acute inflammation.
- Reversible cell injury can usually be reversed by withdrawal of the noxious stimuli; while irreversible cell injury has progressed past a point of 'no return' to normal state.
  - Reversible cell injury is usually the result of the initial stages of lack of oxygen supply or lack of blood flow to the cells; while irreversible cell injury involves more injurious agents such as viruses, immunological responses, or genetic damage.
  - Reversible injury results in cellular swelling, lipid accumulation, and cellular 'blebbing' on the plasma membrane.
- Irreversible cell injury results in acidosis of the cellular microenvironment, damage to plasma membrane and organelles membranes (mitochondria, and lysosomes).
  - Mitochondrial membrane damage results in loss of the electron transport system located in inner mitochondrial membrane; and leakage of 'cytochrome c' into the cytosol; that activates apoptosis.
  - Lysosomal membrane damage results in leakage of hydrolytic enzymes into the cytoplasm, which in turn, are activated by the high cytosolic calcium. The end result of irreversible injury is cell death.
- Reversible cell injury is pharmacologically treatable leading to recovery; while irreversible cell injury results in permanent cell loss and death.

REVERSIBLE CELL INJURY

Hypoxia is most important cause of cell injury, which can result from inadequate blood supply of oxygen, obstruction of airways, inadequate oxygenation of

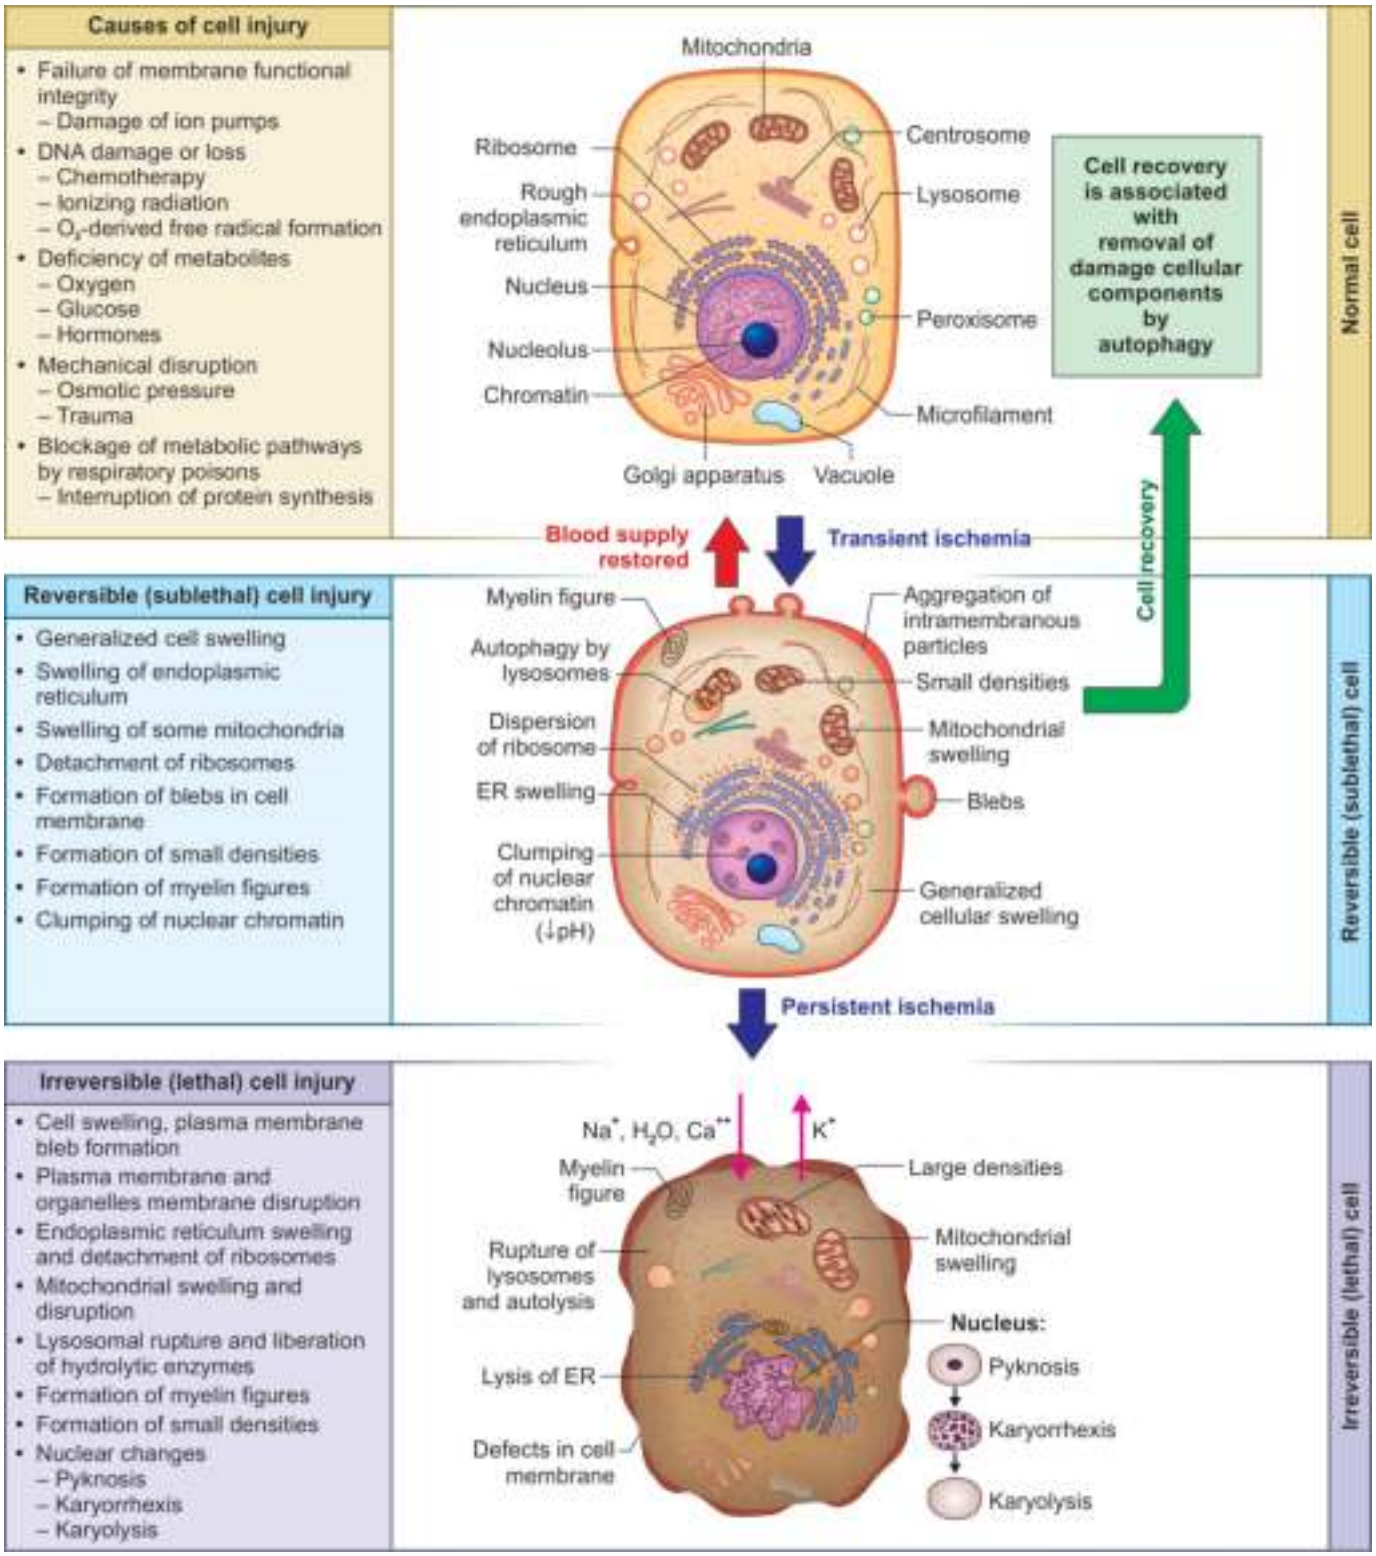

Fig. 1.15: Schematic representation of pathophysiology of reversible and irreversible cell injury. The main difference between reversible and irreversible cell injury is that the reversible cell injury can return to the normal state by altering homeostasis of the cells, whereas the irreversible cell injury cannot return to the viable state as the cell has passed the point of no return.

blood in the lungs, inadequate oxygen transport, inadequate perfusion of blood in the tissues and inhibition of cellular respiration. One global response of hypoxia in reversible cell injury is cellular swelling, that is a result of misfunctioning ion channels (Na^+/K^+ pump and calcium pump) in the plasma membrane.

Table 1.21 Ultrastructural differences between reversible cell injury and irreversible cell injury

Cellular Changes	Reversible Cell Injury	Irreversible Cell Injury
Adaptative response from cell	Adaptative response from cell is intact and in balance or better than cell injuries	Adaptative response from cell has been exceeded by cell injury
Cell membrane function	Sodium/potassium pump malfunction resulting in loss of homeostasis of fluids and ions; blebbing and loss of villi	Degradation of plasma membrane and organelle membrane occurs with lease of lysosomal enzymes
Global cellular response	Moderate cell swelling, increased lipid accumulation (fat storage)	Marked cell swelling, loss of cellular permeability, chemical absorption and toxin formation
Mitochondrial changes	Moderate mitochondrial swelling, rarefaction and accumulation of amorphous densities (precipitated calcium)	Marked mitochondrial swelling, leakage of cytochrome c into cell cytoplasm and accumulation of large amorphous densities (precipitated calcium) and aggregates of fluffy material (denatured proteins)
Endoplasmic reticulum	Swelling of endoplasmic reticulum with detachment of ribosomes	Swelling of endoplasmic reticulum with dissolution
Myelin figures	Myelin fibers (laminated structures derived from damaged plasma membrane and organelles) less prominent	Myelin fibers (laminated structures derived from damaged plasma membrane and organelles) more prominent
Lysosomal changes	Autophagy by lysosomes	Autolysis by rupture of lysosomes
Nucleus/chromatin changes	Aggregation of fibrillar elements in the nucleus	Dissolution of chromatin (pyknosis, karyorrhexis and karyolysis of nuclei)
Examples of type of cell injury	Hydropic change, fatty change in liver	Myocardial and cerebral infarction

DECREASED ATP PRODUCTION IN THE MITOCHONDRIA

Hypoxia impairs oxidative phosphorylation resulting in decreased adenosine triphosphate (ATP) production in mitochondria. Normally, ATP is required for the activity of Na^+/K^+/calcium pumps. Cell injury is induced, when ATP production in mitochondria reduces to 5–10% of normal levels.

- Decreased ATP supply causes impaired activity of Na^+/K^+/calcium pumps. It leads to influx of sodium and water in cells and efflux of potassium resulting in cell swelling, bleb formation on plasma membrane caused by disorderly function of the cellular cytoskeleton, and formation of myelin figures derived from damaged membranes of mitochondria, or rough endoplasmic reticulum and the plasma membrane. These cellular changes are demonstrated in cytoplasm on electron microscopy.
- Mild and transient injury results in reversible cell injury, in which cells can recover to their normal function. These cellular changes can be reversed if injurious noxious stimulus is removed.
- Reversible cell injury is acute sublethal injury to cytoplasmic organelles sparing nucleus in metabolically active cells of liver, heart and kidneys. In coronary artery disease, impaired myocardial contractility is reversed to normal on quick restoration of blood circulation in coronary arteries.
- Examples of reversible cell injury are hyaline change, hydropic change, and fatty change in the metabolically active cells of liver, heart and kidneys.

PLASMA MEMBRANE NA^+/K^+ PUMP FAILURE

Normally, adequate supply of ATP plays important role in regulating membrane. Ouabain sensitive Na^+/K^+-ATPase ion pump plays key role in maintenance of relatively high potassium and low levels of sodium concentration within cells.

- Cell membrane permeability is increased due to decreased ATP production. Decreased availability of ATP results in failure of the Na^+/K^+-ATPase pump, which causes influx of sodium ions along with water into cell. Potassium diffuses out of cell.
- These cellular changes cause swelling of endoplasmic reticulum as well as hydropic change in cytoplasm of cells. When intracellular acidosis threatens due to anaerobic glycolysis, hydrogen ions (H^+) are pumped out of the cell in exchange of Na^+ ion to maintain proper intracellular pH.

PLASMA MEMBRANE CALCIUM PUMP FAILURE

Under physiologic state, excess intracellular Ca^{++} is extruded by a calcium pump that is ATP-dependent. Increased Na^+ ion inhibits efflux of calcium due to activation of sodium/calcium exchanger. It leads to excessive accumulation of calcium in the cell resulting

in mitochondrial dysfunction and decreased oxidative phosphorylation.

PLASMA MEMBRANE BLEB FORMATION

Plasma membrane bleb formation on the surface of cell has been well observed in liver, brain, heart and kidney tissue during cell injury.

- Plasma membrane blebs are most likely caused by disorderly function of the cellular cytoskeleton. The formation of plasma membrane blebs may have unique injurious consequences specific for the organ in which they develop.
- For example, plasma membrane bleb formation during ischemic injury to proximal renal tubule cells may be shed into the tubules, promoting formation of tubular casts and obstruction of tubules. By phase contrast microscopy, plasma membrane blebs appear as bubble-like projections extending from the cell surface.

MYELIN FIGURES

Myelin figures are long, thin cylindrical structures derived from damaged membranes of mitochondria, rough endoplasmic reticulum and the plasma membrane; demonstrated in the cytoplasm on electron microscopy. Myelin figures are long, thin cylindrical structures.

Pathology Pearls: Examples of Reversible Cell Injury

Another global response in reversible cell injury is hyaline change, hydropic change, and fatty change (large lipid vacuoles in cytoplasm) in the metabolically active cells of liver, heart and kidneys.

Hyaline Change

This term hyaline change denotes a characteristic glassy, homogeneous, and eosinophilic staining of tissues demonstrated in hematoxylin and eosin-stained sections. Intracellular hyaline material is demonstrated as Russell bodies in plasma cells, reabsorption plasma protein droplets in proximal tubules, tumoral hyaline globules and Mallory alcoholic hyaline in liver.

Hydropic Change in Organs

- Hydropic change is acute sublethal reversible cell injury characterized by accumulation of fluid in cytoplasm resulting in pale and swollen cytoplasm.
- Hypoxia, chemical agents and pathogen toxins cause hydropic change by three mechanisms: (a) increasing the permeability of the plasma membrane to sodium, (b) damaging the membrane sodium potassium ATPase (pump), and (c) interfering with the synthesis of ATP, thereby depriving the pump of its fuel.
- Accumulation of sodium in the cell leads to an increase in water content to maintain isosmotic conditions, and the cell then swells.

Fatty Change in Organs

- Fatty change in organs is also known as fatty metamorphosis or steatosis. It is acute sublethal reversible cell injury characterized by accumulation of lipid droplets as a result of disturbance of ribosomal function and uncoupling of lipid from protein metabolism.
- Moderate degree of fatty change is in organs reversible, but severe fatty change may not be reversible. Fatty change is observed most frequently in the liver, heart, and kidney.
- Fatty change may be secondary to alcoholism, diabetes mellitus, protein malnutrition, obesity, acute fatty liver of pregnancy, congestive cardiac failure, methotrexate, steroid carbon and tetrachloride poisoning. It results from an imbalance between the uptake, utilization, and mobilization of fat from liver cells.
- Fatty change in liver can result from any of the mechanisms: (a) increased transport of triglycerides in hepatocytes, (b) decreased mobilization of fat from liver due to decreased synthesis of transporting apolipoproteins, (c) decreased utilization of fat by the cells, and (d) increased concentration of lipoproteins in cells.
- Fatty change is thus linked to the disaggregation of ribosomes and consequent decreased protein synthesis caused by failure of ATP production in CCl_4 induced injured cells.
- Fat accumulation in hepatocytes may disrupt the normal blood flow in the hepatic sinusoids. Fat accumulation may cause hepatocytes to become resistant to insulin. Oxidation of excessive fat stores in hepatocytes may generate free radical, that induces fibrosis resulting in liver damage. Mechanism of fatty change liver is shown in Fig. 1.16.

IRREVERSIBLE CELL INJURY (CELL DEATH)

Persistent severe cell injury transforms reversible into irreversible cell injury. **Necrosis** is defined as the cell death in living tissue, which results in the unregulated digestion of cell components. Lipid peroxidation and nuclear changes such as pyknosis, karyorrhexis, and karyolysis are signs of irreversible cell injury.

- **Causes of irreversible cell injury:** Irreversible cell injury is caused by environmental factors such as infections, toxins, mechanical trauma, ischemia, thermal damage from high or low temperature. Hypoxia is one of the severe cellular stressors, that can cause cell injury and even cell death. Cell injury results from functional and biochemical abnormalities in one or more of several essential cellular components such as mitochondria, plasma membranes, $Na^+/K^+/Ca^{++}$ ionic channels in cell membranes, rough endoplasmic reticulum, cytoskeleton and genetic appratus.
- **Pathophysiology of irreversible cell injury (cell necrosis):** Cell necrosis features membrane disruption, plasma membrane blebbing due to disorderly function of the cellular cytoskeleton, mitochondrial

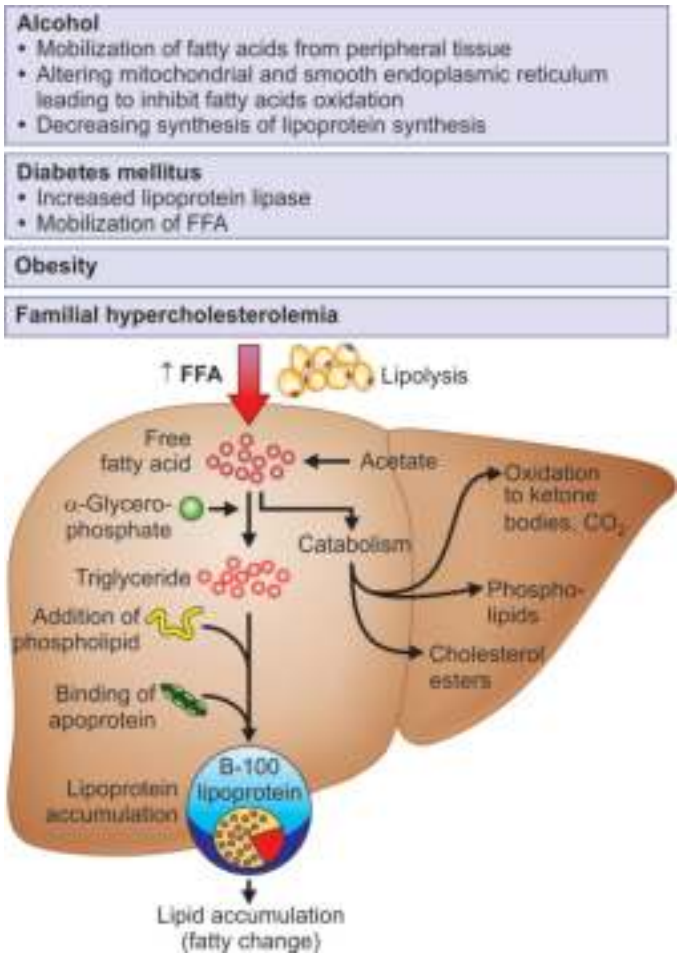

Fig. 1.16: Schematic representation of mechanism of fatty change in liver. Potential pathophysiologic mechanisms of fatty change in liver include the following: decreased mitochondrial fatty acid β-oxidation, increased endogenous fatty acid synthesis or enhanced delivery of fatty acids to liver, and deficient incorporation or export of triglycerides as very low-density lipoprotein (VLDL).

swelling, and cytoplasmic swelling, adenosine triphosphate (ATP) depletion, generation of reactive oxygen species, influx of calcium, random nuclear DNA fragmentation by different nucleases (pyknosis, karyorrhexis followed by karyolysis), formation of myelin figures derived from damaged membranes of mitochondria, or rough endoplasmic reticulum and the plasma membrane; demonstrated in cytoplasm on electron microscopy, uncontrolled release of cellular contents into the extracellular space resulting in initiation of inflammatory response attracting leukocytes.

- The leukocytes along with nearby phagocytic cells eliminate the necrotic cells and necrotic debris by phagocytosis. Initially, the tissue is infiltrated by neutrophils followed by accumulation of monocytes/macrophages. The sequence of events helps in establishing the date and time of tissue injury.
- On light microscopy, cellular outlines in irreversible cell injury are maintained with loss of structural details. Hematoxylin and eosin-stained section shows intense cytoplasmic eosinophilia of dead cell due to loss of cytoplasmic RNA and denaturation (coagulation) of proteins. Loss of basophilia is a sign of irreversible cell injury, indicating a cessation of protein synthesis.
- In irreversible cell injury (cell death), intracellular enzymes and proteins released from the dead cells into the blood circulation are used as diagnostic parameters. Creatine kinase-MB fraction enzyme and cardiac troponins are estimated in patients with myocardial infarction. Liver cell necrosis releases transaminases, alkaline phosphatase, glutamyltransferase and their levels are increased in blood circulation. Creatine kinase levels are increased in cardiac and skeletal muscle injury.

Pathology Pearls: Mechanism of Cell Injury

- Depletion of ATP
- Mitochondrial damage
- Influx of calcium and loss of calcium homeostasis
- Accumulation of oxygen-derived free radicals
- Defects in plasma membrane permeability
- Damage to endoplasmic reticulum
- Damage to genomic proteins

ATP DEPLETION IN MITOCHONDRIA

Mitochondria are surrounded by double-membrane system, consisting of inner and outer mitochondrial membranes separated by an intermembrane space. Inner membrane forms numerous folds which extend into the interior (matrix) of the organelle.

- In normal cells, adenosine triphosphate (ATP) synthesized by mitochondria oxidative phosphorylation is required for synthetic and degradation processes. Nutrients, such as glucose and fatty acids, as well as oxygen, enter the cell across the cell membrane.
  - Mitochondria play a critical role in the generation of metabolic energy derived from the breakdown of carbohydrates and fatty acids, which are converted to ATP by the process of oxidative phosphorylation in the interior folds.
  - The mitochondrial permeability transition pore (MPTP) opens and closes sporadically. Prolonged mitochondrial injury leads to sustained opening of MPTP and release of mitochondrial 'cytochrome c' from electron transport chain into cytosol. This process further diminishes ATP production. Under certain circumstances, it may also trigger apoptotic pathway resulting in cell death.

- Mitochondria are the earliest organelles affected in cell injury. Persistent hypoxia and cyanide poisoning cause injury to mitochondria leading to decreased oxidative phosphorylation and reduction in ATP production to 5–10% of normal levels.
- Depletion of ATP production in irreversible cell injury causes: (a) failure of oxidative phosphorylation in mitochondria decreases the delivery of O_2 and glucose to the cells, (b) failure of Na^+/K^+ pump results in influx of sodium, water and calcium, efflux of potassium ions, swelling of endoplasmic reticulum and loss of microvilli resulting in bleb formation, (c) failure of calcium pump results in excessive accumulation of calcium in the cell and thus mitochondrial dysfunction; because increased intracellular concentration of sodium inhibits calcium efflux, (d) increased anaerobic glycolysis results in overproduction of lactic acid by increased activities of phosphofructokinase and phosphorylase; hence mitochondria fail to oxidize lactic acid to pyruvate. Instead, pyruvate is reduced to lactate in cytosol, and its accumulation in the cytosol lowers the intracellular pH resulting in clumping of nuclear chromatin (pyknosis), karyorrhexis and karyolysis, (e) detachment of ribosomes results in decreased protein synthesis, and (f) lipid peroxidation is the oxidative degradation of lipids in the cell membrane resulting in defects in cell membrane.

Biochemical Alterations

In the initial stage, glucose metabolism (glycolysis) occurs in the cytosol, where glucose is converted to pyruvate. Pyruvate is then transported into mitochondria and oxidized to CoA, where its complete oxidation to CO_2 occurs via the citric acid cycle, yields bulk of usable energy ATP obtained from glucose metabolism. The oxidation of fatty acids also yields acetyl-CoA, which is similarly metabolized by the citric acid cycle in the mitochondria. The enzymes of the citric acid cycle are located in the matrix of mitochondria, which participate in the oxidative breakdown of both carbohydrates and fatty acids. Nutrients such as glucose and fatty acids, as well as oxygen, enter the cell across the cell membrane.

- Hypoxic injury results in an inadequate flow of glucose, fatty acids and oxygen to the cell. Persistent hypoxia and inadequate tissue perfusion lead to decreased anaerobic metabolic pathways for energy production. Consequences of mitochondrial damage are depletion of ATP production, formation of reactive oxygen species (ROS), formation of mitochondrial permeability pore and release of '**cytochrome c**'. Release of cytochrome c activates apoptotic pathway of cell death.
- Cellular ATP stores are rapidly used up. ATP production in mitochondria reduces to 5–10% of normal levels. In hypoxia, fall in cellular oxygen level results in rapid shift from aerobic to anerobic glycogen metabolism. Anaerobic glycolysis leads to the accumulation of lactic acid, that further causes reduction in ATP production in mitochondria for cellular function. Accumulation of excess of lactic acid in cell and blood results in lowering the intracellular pH, which interferes with cellular enzymes.
- Lactic acidosis reduces myocardial contractility, arteriolar responsiveness to further adrenaline and noradrenaline release, potentiating vasomotor collapse and stimulating the disseminated intravascular coagulation. However, low pH (acidemia due to accumulation of lactic acid) is beneficial in facilitating the release of oxygen from hemoglobin.
- Eventually, a large number of vasoactive, vasodilator and cytotoxic substances are released from injured cell into the blood circulation, resulting in progressive vasodilation, increased capillary permeability, myocardial contractility and eventually disseminated intravascular coagulation.

MITOCHONDRIAL DAMAGE

Damage to mitochondria is one of the hallmarks of irreversible cell injury. It is usually a common feature of all injurious pathways that follow cell injury.

- Two features that characterize irreversible cell injury (cell death) from reversible cell injury: (a) irreversible mitochondrial damage occurs that results in ATP depletion and lack of oxidative phosphorylation despite removal of the injurious stimulus; and (b) profound disturbances in cell membrane function occurs, that affect internal ionic concentrations and lysosomal enzyme activity.
- Mitochondria are damaged by increase in cytosolic calcium coupled with inorganic phosphate and fatty acids, reactive oxygen species, oxygen deprivation by ischemia/hypoxia; and defective turnover of mitochondrial proteins.
- It is worth mentioning that high inorganic phosphate and fatty acids alone cannot cause mitochondrial damage, but when coupled with high calcium are extremely damaging to a cell. High cytosolic calcium alone can still cause mitochondrial damage. If mitochondria are indeed damaged, then there are three major consequences discussed as under.

Mitochondrial Permeability Transition

Mitochondrial permeability transition (MPT) is defined as an increase in the permeability of the mitochondrial membranes to freely permit entry of molecules <1500 daltons molecular weight (MW).

- Outer membrane of the mitochondria contains proteins, that permit movement of molecules into the mitochondria. Because all molecules below 1500 daltons MW cannot be regulated due to presence of mitochondrial permeability transition brought about by a high conductance channel, the mitochondrial permeability transition pore (MPTP). All solutes <1500 daltons MW rush into and out of the cell.
- The mitochondria slowly swell as the MPTP channel opens. The opening of MPTP channel is triggered by increase in cytosolic calcium concentration. Thus, calcium interacts with calcium receptors on the matrix side of the MPTP.
- MPTP channel opening is triggered by abundance of reactive oxygen species. MPTP channel is closed, if there is high concentration of NADH, ATP, ADP and magnesium ions in the cell. MPTP contains cyclophilin D, that is crucial for the proper opening of MPTP.
- In clinical practice, it is essential to limit cellular injury to target cyclophilin D protein present in MPTP by an immunosuppressive drug, cyclosporine. In cases of ischemia/hypoxia, cyclosporine can act on cyclophilin D to reduce cellular damage.

Increase in Mitochondrial Oxidative Stress

Normally, antioxidant molecules such as glutathione are stored in the mitochondria to combat reactive oxygen species. As a result of opening of the MPTP channel, stored antioxidant molecules such as glutathione are removed leading to accumulation of reactive oxygen species within the cell. Further, improper oxidative phosphorylation by the compromised electron chain generates oxygen-derived free radicals resulting in cell necrosis.

Induction of Apoptosis

Apoptosis is a process of genetically programmed cell death that occurs in multicellular organisms. It is characterized by nuclear shrinkage, DNA fragmentation by endonucleases, cytoskeleton breakdown by proteases, membrane blebbing; and membrane-bound apoptotic bodies, which are phagocytosed by macrophages and adjacent cells. The mitochondrial damage results in sequestration of proapoptotic proteins such as 'cytochrome c' and caspases between the inner and outer membrane of mitochondria. As the cell permeability increases, these proteins and proapoptotic proteins leak into the cytosol and trigger cell death by apoptosis.

CALCIUM INFLUX AND IMPAIRED CALCIUM HOMEOSTASIS

Calcium pump ion transporter is present in the plasma cell membrane. It is responsible for the active transport of calcium out of cell for the maintenance of the steep calcium electrochemical gradient across the cell membrane.

- Normally, cytosolic calcium is maintained at extremely low levels. Excess intracellular Ca^{++} is extruded by a ATP-dependent calcium pump. Decreased ATP production causes failure of calcium pump across the plasma membrane. Increased cytosolic sodium inhibits efflux of calcium due to activation of sodium/calcium exchanger. Influx of calcium to the cytosol comes from the extracellular fluid and stores in mitochondria and smooth endoplasmic reticulum.
- Failure of the calcium pump leads to influx of Ca^{++} into the cell, activation of various enzymes such as phospholipase, protease, ATPase and endonuclease causing cell death. Influx of excess calcium in cytosol and activation of cellular enzymes is given in Table 1.22. Schematic representation of role of influx of excess calcium in cytosol and activation of cellular enzymes inducing irreversible cell injury is shown in Fig. 1.17.
- Activation of phospholipase degrades the membrane phospholipids releasing free fatty acids, which are potent mediators of inflammation. These free fatty acids also act as detergent that solubilize cell membrane. Hence, phospholipase results in decreased synthesis of phospholipids of all cellular membranes including cell organelles.
- Activated proteases attack the cytoskeleton and its attachments to the cell membrane resulting in disruption of interactions between cytoskeleton proteins and the plasma membrane; and formation of membrane plasma blebs, and alteration of shape of the cell. High cytosolic calcium activates ATPase, resulting in degradation of ATP.

Table 1.22 Influx of excess calcium in cytosol and activation of cellular enzymes

Phospholipase Cellular Enzyme
Membrane phospholipids degradation
Potent mediators of inflammation
Decreased synthesis of phospholipids in plasma cell membrane including mitochondrial membrane
Protease Cellular Enzyme
Disruption in interaction of cytoskeleton proteins to plasma cell membrane resulting in formation of membrane blebs and alterations of shape
ATPase Cellular Enzyme
ATP degradation
Endonuclease Cellular Enzyme
DNA fragmentation and dissolution

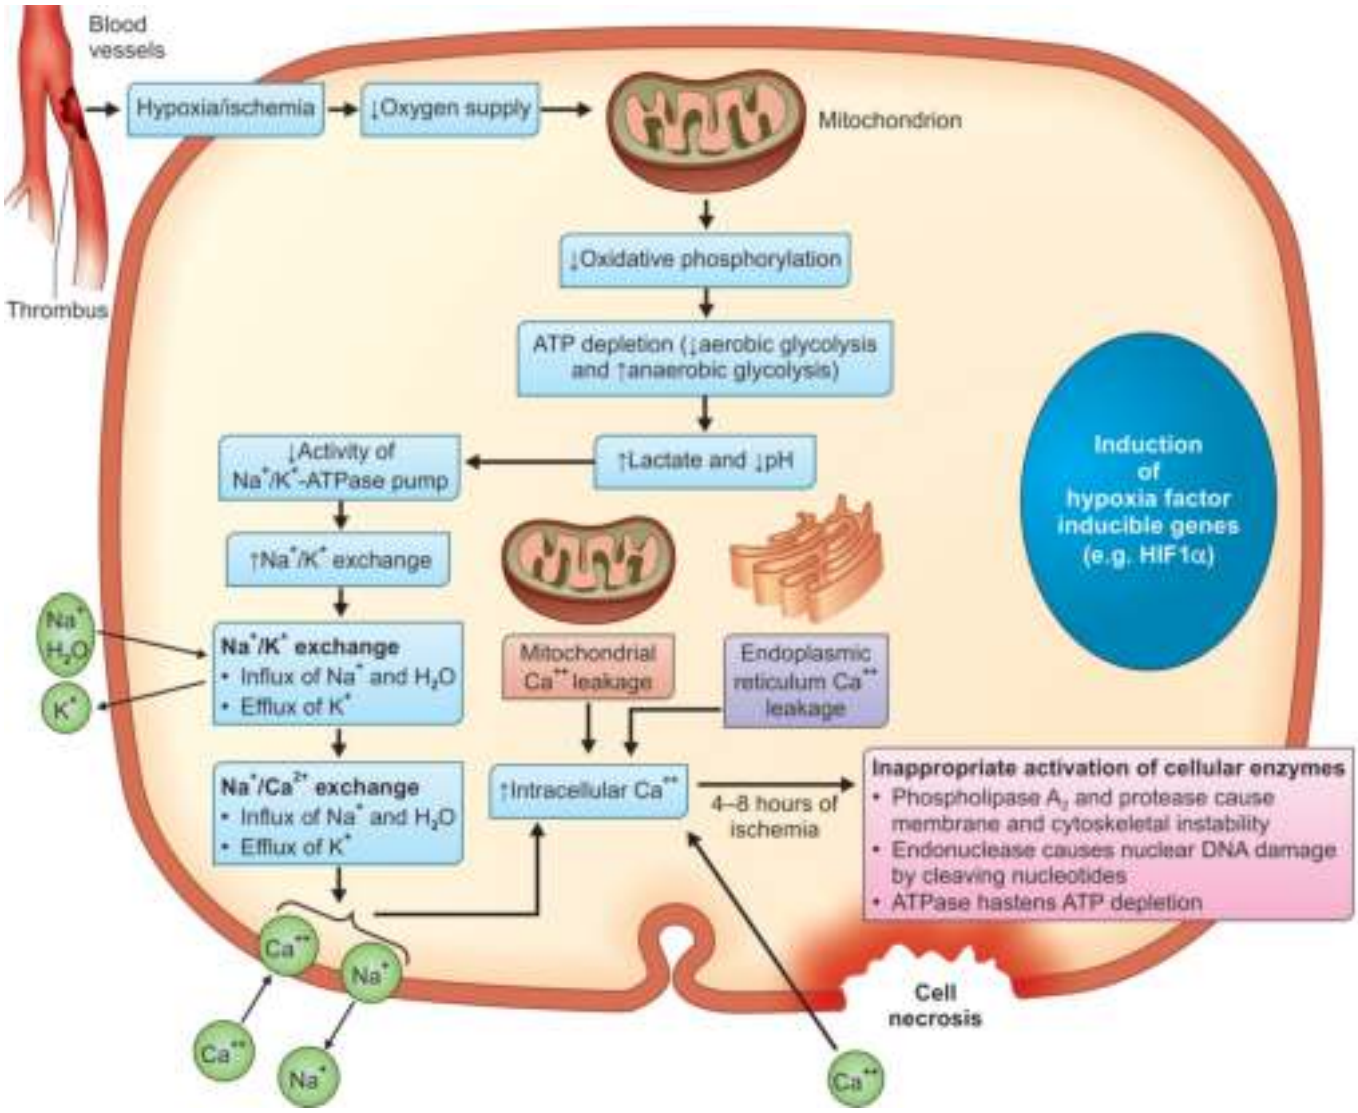

Fig. 1.17: Schematic representation of role of influx of excess calcium in cytosol and activation of cellular enzymes inducing irreversible cell injury. Increased cytosolic calcium concentration is responsible for cytoskeleton modification which alter cell shape, activation of cellular enzymes (phospholipases, endonucleases and ATPase) which results in perpetuation of membrane damage and finally mitochondrial calcification.

- Activation of endonuclease causes fragmentation and lysis of DNA. Myelin figures are derived from damaged membranes of mitochondria, or rough endoplasmic reticulum and plasma membrane.

REACTIVE OXYGEN SPECIES PRODUCTION INDUCED BY CELL STRESSORS

Under normal conditions, O_2 has emerged as an important signaling molecule, which regulates specific biochemical reactions and metabolic processes. A free radical is a molecule with an unpaired electron in its outer orbit. Another term for oxygen-derived free radicals is reactive oxygen species (ROS).

- Physiologic generation of reactive oxygen species occurs during oxidative phosphorylation in the mitochondria, when oxygen is reduced along the electron transport chain.
- Reactive oxygen species occur in the pathologic settings of hypoxia (oxidative stress), ischemia-reperfusion injury, inflammation, ultraviolet light, X-rays, ionizing radiation, inflammation, transitive metals (copper and iron), drugs and chemical agents (e.g. carbon tetrachloride). The excessive generation of highly reactive oxygen-derived free radicals induce oxidative stress in human beings and cause damage to cellular DNA, proteins and lipids and thus cell death. Most reactive oxygen species are generated as chemical intermediates in a variety of enzymatic reactions.
- Reactive oxygen species are formed in number of ways. During normal cellular respiration, about 3% of oxygen enters the mitochondrial electron transport chain. The sequential reduction of oxygen through the addition of electrons results in the formation of a

number of oxygen-derived free radicals collectively called as reactive oxygen species such as superoxide anionic radical (O_2^-), hydroxyl radical (–OH), hydrogen peroxide (H_2O_2), nitric oxide, peroxynitrite ($ONOO^-$), lipid peroxide radical (RCOO), and hypochlorous acid (HClO). Normally, nitric oxide is a potent vasodilator and regulator of blood flow.

- O_2-derived free radicals interact with DNA, biomolecules (proteins, lipids, carbohydrates, nucleic acids) and cause oxidative damage by lipid peroxidation of cell membranes, DNA fragmentation, and protein cross-linking (e.g. sulfhydryl groups) leading to increased degradation of biomolecules and decreased cell activity. Schematic representation of role of reactive oxygen species in cell injury is shown in Fig. 1.18.
- Nitric oxide can accumulate in high concentrations and can react with other oxygen-derived free radicals thereby setting up two mechanisms of cell death: oxidative stress injury and ATP depletion. The mitochondria can lose their membrane potential in high concentrations of nitric oxide and halt ATP production all together. This process can cause endothelial damage resulting in stimulation of the inflammatory response.
- Oxygen-derived free radicals can be prevented by various mechanisms: (a) catalase degrades hydrogen peroxide, (b) superoxide dismutase converts superoxide to hydrogen peroxide, (c) glutathione catalyzes breakdown of hydroxyl radicals, and (d) vitamins A, C and E have an antioxidant property.

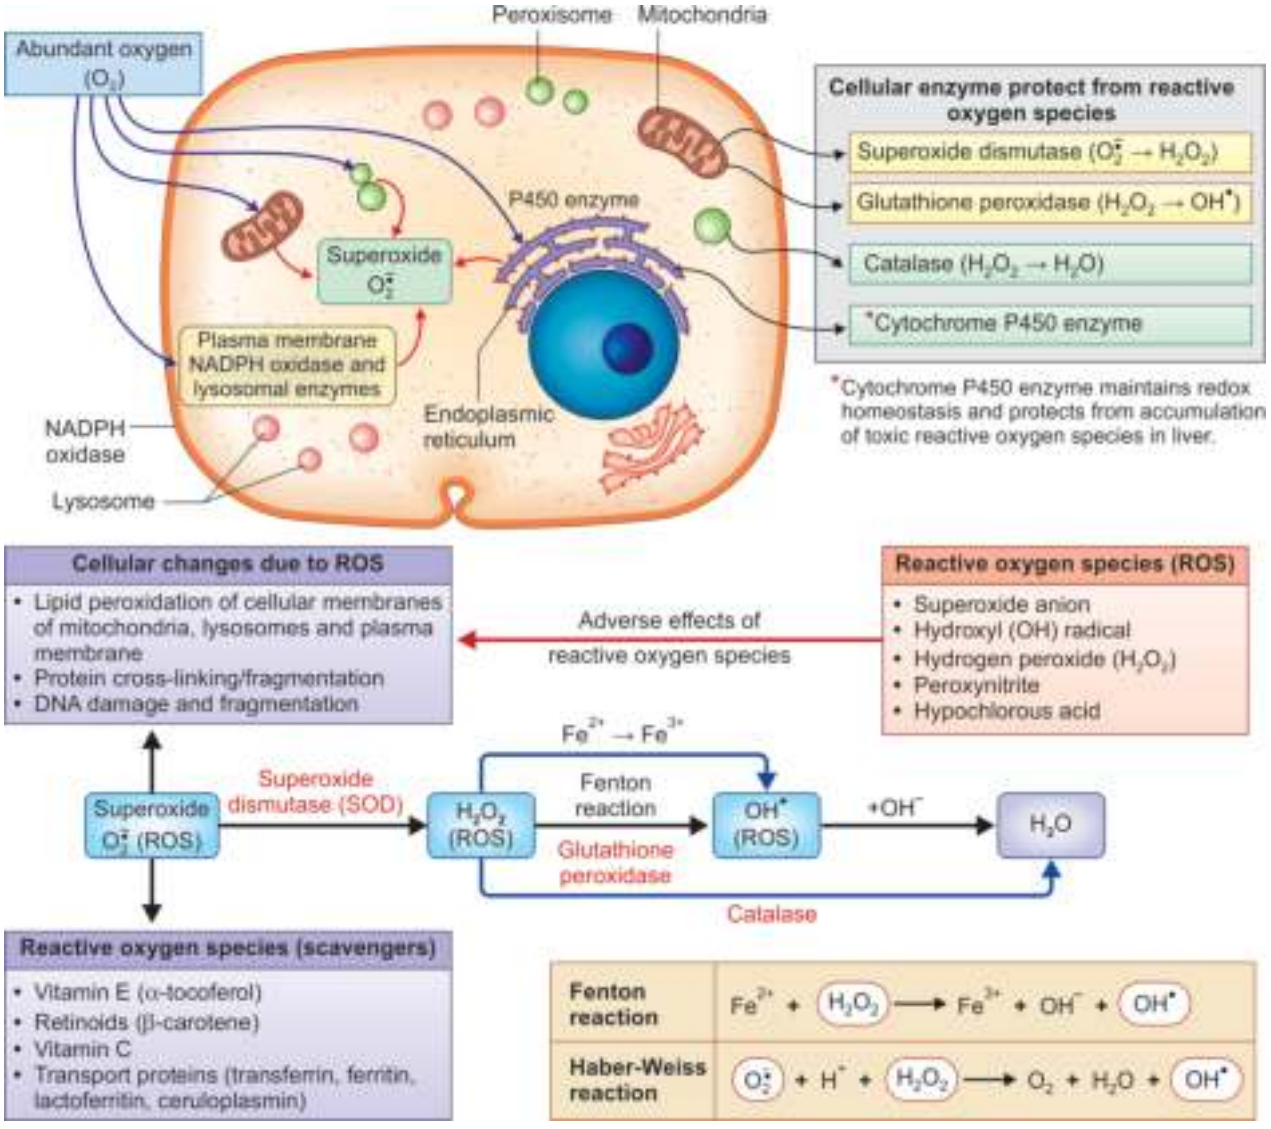

Fig. 1.18: Schematic representation of role of reactive oxygen species (ROS) in cell injury. Oxidative enzymes generating reactive oxygen species are located in mitochondria (sodium dismutase, glutathione peroxidase), peroxisome (catalase) and endoplasmic reticulum (cytochrome P450 enzyme). Reactive oxygen species (hydroxyl ions, hydrogen peroxide and superoxide, peroxynitrite, hypochlorous acid) react with cellular fatty acids, proteins and DNA leading to irreversible cell injury.

Table 1.23 Conditions generating reactive oxygen species

Reduction–oxidation reactions during normal metabolism
Transit metals (copper and iron)
Radiation (ionizing radiation hydrolyzes H_2O, which generate reactive oxygen species
Rapid burst in polymorphonuclear cells and macrophages during inflammation
Polymorphonuclear cells xanthine oxidase (reperfusion injury after ischemia)
Carbon tetrachloride (CCl_4) and barbiturates toxicity (inducing P450 oxidase system of smooth endoplasmic reticulum of hepatocytes)
Mutagens (chemical carcinogens)
Mitochondrial metabolism (biological aging)

- Protective molecules against accumulated toxic oxygen-derived free radicals in cells include superoxide dismutase, glutathione peroxidase, vitamin E, vitamin C and catalase.

Generation of Reactive Oxygen Species

Oxygen-derived free radicals also known as ractive oxygen species are derived from both endogenous sources (mitochondria, peroxisomes, endoplasmic reticulum, phagocytic cells) and exogenous sources (pollutants, tobacco smoke, transition metals such as copper and iron, industrial solvents, peptides, radiation, drugs). Conditions generating reactive oxygen species are given in Table 1.23.

Reactive Oxygen Species (ROS) Generation during Reduction–Oxidation Reaction during Normal Metabolic Process

Reactive oxygen species are formed during reduction-oxidation reaction during normal metabolism within the cell and within organelles such as mitochondria, peroxisomes, and endoplasmic reticulum. The reduction of molecular oxygen (O_2) produces superoxide, which is the precursor of most other reactive oxygen species. Dismutation of superoxide by superoxide dismutase produces hydrogen peroxide. The product hydrogen peroxide in turn may be partially reduced to form hydroxyl radical or fully reduced to water. Reactive oxygen species play important role in cell signaling and homeostasis. Generation of reactive oxygen species increases dramatically during environmental stress such as ultraviolet B or heat.

Reactive Oxygen Species (ROS) Generation during Absorption of Ionizing Radiation

The absorption of ionizing radiation by living cells/tissues can directly disrupt atomic structures, which produce biochemical changes in the cells/tissues. Ionizing radiation can act indirectly through radiolysis of water, thereby generating toxic reactive oxygen species such as superoxide, hydroxyl radical and hydrogen peroxide. These toxic chemical species interact with DNA, proteins and lipids and cause oxidative damage and cell death.

Reactive Oxygen Species (ROS) Generation by Transit Metals (Copper and Iron)

Transit metals, such as copper and iron ions, are common catalysts of lipid oxidation. Copper and iron promote the generation of oxygen-derived free radicals such as hydroxyl radicals, which cause damage to DNA, proteins, lipids and carbohydrates.

- Copper is more efficient catalyst. In the presence of both hydrogen peroxide and ascorbate, copper is reduced to Cu^+, that then reacts with hydrogen peroxide (H_2O_2) to generate hydroxyl radical (–OH) in the Fenton reaction.
- In healthy normal cells, iron is tightly controlled to promote the growth of the cell as well as to protect of the cell against toxicity.
- Accumulation of iron within tissues can generate toxic reactive oxygen species via Fenton reaction and Haber-Weiss reaction: (a) **Fenton reaction** results in the formation of hydroxyl radical from hydrogen peroxide (H_2O_2), a mitochondrial oxidative respiration and an iron catalyst. Highly toxic hydroxyl ions react with DNA, proteins; and lipids of cell membranes resulting in irreversible cell injury. (b) **Haber-Weiss reaction** generates hydroxyl radical (OH) from hydrogen peroxide (H_2O_2) and superoxide catalyzed by iron ions.

Respiratory or Oxidative Burst of Reactive Oxygen Species (ROS) in Activated Phagocytes during Inflammation

Phagocytic cells such as neutrophils, eosinophils, monocytes and macrophages phagocytose and kill internalized pathogens by respiratory or oxidative burst.

- During respiratory burst, phagocytes require energy and oxygen for the generation of a variety of cytotoxic reactive oxygen species. These phagocytes contain NADPH-dependent oxidase enzyme, which transfers one electron to an oxygen molecule to generate superoxide anion.
- The superoxide ion dismutases spontaneously in the presence of superoxide dismutase to hydrogen peroxide. The product hydrogen peroxide then serves as the parent product for a variety of other highly reactive metabolites such as hydroxyl radical and hypochlorous acid; which enter phagosome and together with enzymes participate in the killing of phagocytosed pathogens.

Reactive Oxygen Species (ROS) Generation due to Carbon Tetrachloride-induced Hepatocellular Injury

The liver plays an essential role in various metabolic processes. Carbon tetrachloride (CCl_4) belongs to the class of hepatotoxins, which acts after metabolic activation. CCl_4 is metabolized in the endoplasmic reticulum by cytochrome P450 enzymes (mostly CYP2E1) to the highly reactive trichloromethyl radical (CCl_3).

- CCl_3 rapidly reacts with oxygen to form the highly reactive trichloromethylperoxyl radical (CCl_3OO), that rapidly reacts with DNA, proteins; and lipids of all cell membranes resulting in formation of lipid peroxidation products.
- Polyunsaturated fatty acids of the endoplasmic reticulum are more susceptible to oxidation by the O_2-derived free radicals. The free radical mediated lipid peroxidation of cell membranes is one of the main mechanisms of hepatocellular injury by CCl_4.

Reactive Oxygen Species (ROS) and their Actions

In living organisms, there are two major reactive oxygen species, superoxide radical and hydroxyl radical that are being continuously formed in a process of reduction of oxygen to water.

- In the Haber-Weiss reaction hydroxyl radicals are generated in the presence of hydrogen peroxide and iron ions.
  - The first step involves reduction of ferric into ferrous ion: $Fe^{3} + {}^{\bullet}O_2^- \rightarrow Fe^{2++} + O_2$.
  - The second step is the Fenton reaction $Fe^{2+} + H_2O_2^- \rightarrow Fe^{3+} + OH^- + {}^{\bullet}OH$.
- Reactions involving reactive oxygen species and their actions are given in Table 1.24.

Superoxide Anion Radical (O_2^-)

Superoxide anion (O_2^-) is a highly reactive radical generated when oxygen is reduced by a single electron, and may be generated during the normal catalytic function of a number of enzymes. It is then converted to H_2O_2 eventually to other reactive oxgen species (ROS).

- Normally, cells are able to maintain low levels of superoxide radical with the help of superoxide dismutase (SOD) enzyme. It does not readily diffuse far from its origin.
- Superoxide radical becomes toxic due to its capability to inactivate iron-sulfur cluster containing enzymes critical in various metabolic pathways, thereby releasing highly reactive free iron radical in the cell via Fenton reaction.

Hydroxyl Radical

The hydroxyl radical, the three-electron reduction product of molecular oxygen, is the most reactive oxygen-derived free radical also called reactive oxygen species.

- Normally, hydroxyl radicals are formed by the hydrolysis of water, the reaction of H_2O_2 with ferrous ions (Fenton reaction), and the reaction of O_2^- with H_2O_2 (Haber-Weiss reaction).
- Excessive intracellular accumulation of hydroxyl radical can damage virtually all types of macromolecules: carbohydrates, lipids (lipid peroxidation). DNA nucleic acids (single DNA strand breaks, modification of bases, and cross-links between strands) and cross-linking of amino acids (sulfur-containing amino acids—cysteine and methionine, as well as arginine, histidine, and proline).

Table 1.24 Reactions involving reactive oxygen species (ROS) and their actions

Reactive Oxygen Species	ROS Generation by Reactions	Actions
Superoxide anion (O_2^-)	Reduction of molecular oxygen by leaks in the electron transport chain	Not diffusing far from its origin
Hydroxyl radical (OH)	During physiologic state, hydroxyl radicals are formed by the hydrolysis of water, the reaction of H_2O_2 with ferrous ions (Fenton reaction), and the reaction of O_2^- with H_2O_2 (Haber-Weiss reaction)	Hydroxyl radical attacking cellular macromolecules
Hydrogen peroxide (H_2O_2)	Superoxide dismutase by Fenton reaction	Diffusing within cell
Peroxynitrite (ONOO)	NO + O_2^- (ONOO.)	Damaging macromolecules
Lipid peroxide radical (RCOO.)	Generated during lipid peroxidation	Initiating chain breakage, destroying unsaturated fatty acids resulting in a loss of membrane integrity
Hypochlorous acid (HOCl)	Generated by neutrophils (myeloperoxidase) and macrophages during respiratory burst that accompanies phagocytosis	Dissociating to yield hypochlorite radical

- During lipid peroxidation, hydroxyl radicals remove a hydrogen atom from bonds of unsaturated fatty acids of membrane phospholipids resulting in loss of membrane integrity.

Hydrogen Peroxide (H_2O_2)

Normally, superoxide dismutases (SOD1 in cytoplasm, SOD2 in mitochondria and SOD3 in extracellular region) are group of enzymes that catalyzes the dismutation of superoxide radicals to molecular oxygen (O_2) and hydrogen peroxide (H_2O_2) in small concentration.

- Hydrogen peroxide is a product of metabolism, that can do some nasty things. It can break apart to yield highly reactive hydroxyl radical in Fe^{++} catalyzed Fenton reaction, that can attack all variety of macromolecules such as lipid, carbohydrate, proteins and DNA resulting in cell damage.
- To protect itself from cell damage by hydrogen peroxide, the cells make catalase (within peroxisomes) and glutathione peroxidase (within cytosol and the mitochondria), that decompose hydrogen peroxide to oxygen and water before it can form hydroxyl radicals. In neutrophils, myeloperoxidase transforms hydrogen peroxide (H_2O_2) to the potent radical hypochlorite, which is lethal for microorganisms and cells.

Peroxynitrite ($ONOO^-$)

Peroxynitrite is an oxidant and nitrating agent formed by the interaction of superoxide with nitric oxide (NO). Peroxynitrite is a powerful oxidant, that exhibits a wide array of tissue damaging effects, including lipid peroxidation, inactivation of enzymes and dysfunctional ion channels via protein oxidation and nitration, and inhibition of mitochondrial respiration.

Hypochlorous Acid

Hypochlorous acid (HClO) is a weak acid that forms when chlorine dissolves in water, which partially dissociates to form hypochlorite (ClO^-). Hypochlorous acid and hypochlorite are oxidizers and primary disinfectant agents of chlorine solution. In biology, hypochlorous acid is generated in activated neutrophils by myeloperoxidase-mediated peroxidation of chloride ions, and contributes to the destruction of bacteria during respiratory burst that accompanies phagocytosis.

Nitric Oxide

Nitric oxide (NO) is a highly reactive gas that is involved in many biological processes. It is potent oxidant, that takes part in termination of lipid peroxidation reactions. Nitric oxide is synthesized by the NO synthase in vascular endothelium, that acts as vasodilator. Nitric oxide can also act as an oxidant in indirect reactions with oxygen molecules and superoxide ion.

Lipid Peroxides

Lipid peroxides are oxidative degradation products of lipids, generated by a free radical chain reaction. Ferrous iron can react with a lipid peroxide to generate the corresponding alkoxy radical that can propagate new peroxidation reactions, i.e. extensive peroxidation of polyunsaturated fatty acids of cell membrane, which compromise the integrity and function of cell membrane.

- The aldehyde degradation products of lipid peroxides exert toxic effects on cells by cross-linking of DNA and proteins.
- Lipid peroxides are divided into two classes: lipid hydroperoxide and lipid endoperoxide.
  - Lipid hydroperoxide is a key mediator of cell injury and cell death.
  - Lipid endoperoxide is a key intermediate in the synthesis of prostaglandins, that has importance in inflammation and disease.
- Additionally, ferroptosis is a form of regulated non-apoptotic cell death involving overwhelming iron-dependent peroxidation.

Reactive Oxygen Species and their Pathologic Effects

Reactive oxygen species (ROS) react with fatty acids, proteins and DNA resulting in peroxidation of cell membranes, oxidation of amino acids, abnormal folding of proteins (protein-protein cross linkages) and DNA mutations. Proteosomes act on altered proteins leading to further cell damage. Role of cellular enzymes in generation and removal of reactive oxygen species are given in Table 1.25.

- **Disruption of cell membrane:** Reactive oxygen species react with fatty acids present in plasma membrane and membranes of organelles resulting in disruption of membranes. During peroxidation, hydroxyl radicals remove a hydrogen atom from bonds of unsaturated fatty acids of membrane phospholipids leading to loss of membrane integrity.
- **Abnormal folding of proteins:** Reactive oxygen species adversely affect rough endoplasmic reticulum leading to decreased synthesis of proteins. Protein fragmentation occurs as a result of oxidation of amino acids residue side chain by reactive oxygen species. Oxidation of proteins leads to loss of enzymatic activity and abnormal folding of proteins.
- **DNA damage:** Reactive oxygen species react and cause oxidation of DNA leading to mutations and DNA breaks.

Reactive Oxygen Species Degradation

Fortunately, reactive oxygen species are inherently unstable and generally decay spontaneously. Antioxidants either block the initiation of oxygen-derived

Table 1.25 Role of cellular enzymes in generation and removal of reactive oxygen species

Generation Reactive Oxygen Species by Oxidative Enzymes	Removal of Reactive Oxygen Species by Antioxidant Mechanism
Mitochondria cell organelle	
Respiratory oxidase enzymes generate reactive oxygen species	▪ Superoxide dismutase (SOD) in mitochondria converts oxygen to hydrogen peroxide ▪ Glutathione converts hydroxyl ion to hydrogen peroxide
Cytoplasm	
Peroxisome oxidase enzymes generate reactive oxygen species	Catalase in peroxisome converts hydrogen peroxide (H_2O_2) to water and oxygen
Endoplasmic reticulum cytochrome P450 generates reactive oxygen species	Not applicable

Table 1.26 Mechanism of inactivation of oxygen-derived free radicals

Categories	Mechanism of Action
Intracellular oxidative enzymes	
Superoxide dismutase (SOD)	▪ First-line of defense against O_2^-, converting it to H_2O_2 and O_2 in cytosol and mitochondria ▪ Endoplasmic reticulum also contains P450 oxidase
Catalase	▪ Catalase located in peroxisomes ▪ Catalase eliminating H_2O_2 to O_2 ▪ Completing the dissolution of O_2^- by eliminating H_2O_2 and, therefore, its potential conversion to OH^-
Glutathione peroxidase (GPX)	Catalyzing the reduction of H_2O_2 and lipid peroxides in mitochondria and the cytosol
Exogenous antioxidants (either inhibit synthesis or scavenge free radicals)	
Vitamin E (α-tocopherol)	Fat-soluble vitamin protecting cell membranes against peroxidation by blocking free radical chain reaction
Retinoids	▪ Precursor of fat-soluble vitamin A ▪ Retinoids function as chain breaking antioxidants
Vitamin C (ascorbate)	Water-soluble and reacting directly with O_2, hydroxyl (OH^-) and some products of lipid peroxidation serving to regenerate the reduced form of vitamin E
Transport proteins	
Transferrin, ferritin, lactoferritin, ceruloplasmin	Endogenous antioxidants minimizing the generation of reactive forms by transition metals

free radical formation or scavenge oxygen-derived free radicals. In addition, several systems, i.e. detoxifying enzymes, antioxidants and transporting proteins contribute to free radical inactivation. Mechanism of inactivation of reactive oxygen species is shown in Table 1.26.

DEFECTS IN PERMEABILITY OF PLASMA MEMBRANE AND CELL ORGANELLES

Ionic and osmotic homeostasis of the cellular plasma membrane and its organelles membrane depend on cell membranes. Cell injury induced by hypoxia, mechanical trauma, chemical agents, radiation and pathogens adversely affects plasma membrane, cytoskeleton and membranes of mitochondria, lysosomes.

- Oxygen deprivation is accompanied by cellular plasma membrane disruption resulting in electrolyte disturbance. Without sufficient ATP supply to cell, the plasma membrane can no longer maintain normal ionic gradient across the cell membranes; and ATP-dependent Na^+/K^+ pump and calcium pump can no longer function, which leads to change in ionic concentration of sodium and potassium concentration. Potassium ions leak out of cell to the extracellular space and influx of sodium ions followed by water move into the cell resulting in cellular edema and an increased intracellular osmotic pressure.
- Oxidative stress leads to accumulation of oxygen-derived free radicals. DNA damage caused by ionizing radiation, chemotherapy and oxygen-derived free radicals adversely affect endoplasmic reticulum to synthesize proteins. Failure of the calcium pump leads to influx of Ca^{++} into the cell, activate various enzymes such as phospholipase, protease, ATPase and endonuclease causing cell death. The cells may eventually burst.

- Normally, adequate supply of ATP is essential to maintain high potassium and low sodium levels in the cellular cytosol with functional membrane Na^+/K^+ ATP-dependent pump.
- Reduced Na^+/K^+ ATP-dependent pump results in influx of sodium and water; and efflux of potassium. Cellular swelling may interfere with organelle function. The cytoplasmic membrane of the cells becomes more permeable to high molecular weight proteins due to the systemic intracellular energy debt. NADPH oxidase (phagocytic oxidase) is present in the plasma membrane and the membranes of the phagosomes of leukocytes. NADPH oxidase generates superoxide radical.

Lipid Peroxidation of Cell Membranes

Lipids, the main component of cellular membranes, maintain the structural integrity of the cells. Excessive oxidation of lipids alters the physical properties of cell membranes and can cause selective alterations in cell signaling, covalent modification of proteins and nucleic acids, and cytotoxicity.

- Reactive oxygen species (ROS) are common oxidants in the cells. Reactive oxygen species are formed by the partial reduction molecular oxygen to superoxide ($O_2^{\bullet}$), hydrogen peroxide (H_2O_2), lipid oxides (ROOH) or the corresponding hydroxyl ($OH^{\bullet}$) and peroxyl radicals ($ROO^{\bullet}$).
- Lipid peroxidation degrades cell membrane phospholipids results in loss of cell membrane integrity due to accumulation of unesterified free fatty acids, acylcarnitine, and lysophospholipids, catabolic products in the lipid bilayer of cell membrane and inside cell.

Pathology Pearls: Lipid Breakdown Products and Membrane Damage

Lipid Peroxidation Products

- During lipid peroxidation, hydroxyl radicals remove a hydrogen atom from the unsaturated fatty acids of membrane phospholipids. The lipid radicals so formed react with molecular oxygen and form a lipid peroxide radical.
- A chain reaction is initiated. Lipid peroxides are unstable and break down into smaller molecules. The destruction of the unsaturated fatty acids of phospholipids results in a loss of membrane integrity.
- Unesterified free fatty acids, acylcarnitine, and lysophospholipids, catabolic products accumulate in the injured cells as a result of phospholipid degradation. They have a detergent effect on membranes. They also either insert into the lipid bilayer of the membrane or exchange with membrane phospholipids, potentially causing changes in permeability and electrophysiological alterations. The important sites of membrane damage are as follows.

Lipid Peroxidation-induced Membrane Damage

- Plasma membrane damage leads to loss of osmotic balance and influx of fluids and ions, as well as loss of cellular contents. The cells may also leak metabolites that are vital for the reconstitution of ATP, thus further depleting energy stores.
- Damage to mitochondrial membrane results in decreased ATP production, culminating in necrosis, and release of proteins that trigger apoptotic death.
- Injury to lysosomal membrane results in leakage of their enzymes into the cytoplasm and activation of the acid hydrolases in the acidic intracellular pH the injured (e.g. ischemic) cell. Lysosomes contain RNases, DNases, proteases, glucosidases, and other enzymes. Activation of these enzymes leads to enzymatic digestion of cell components, and the cells die by necrosis.

ROUGH ENDOPLASMIC RETICULUM DISRUPTION

Rough endoplasmic reticulum (ER) plays a pivotal role in the folding and processing of newly synthesized proteins, which are calcium-dependent.

- Endoplasmic reticulum calcium homeostasis plays an important role in maintaining the physiologic state in cells. Irreversible cell injury to rough endoplasmic reticulum leads to decreased synthesis of protein due to detachment of ribosomes. Increased intracellular calcium and reactive oxygen species adversely affect rough endoplasmic reticulum leading to decreased protein synthesis.
- Misfolded proteins lead to the unfolded protein response which may further injure the cell. Intense eosinophilia of dead cell occurs due to loss of RNA and coagulation of proteins.

CYTOSKELETON DISRUPTION

Cytoskeleton filaments serve as anchors connecting the plasma membrane to the cell interior. It is a network of protein fibers and composed of three main structural components: (a) microtubules formed by tubulins, (b) microfilaments formed by actins; and (c) intermediate filaments (keratin filaments, neurofilaments, desmin filaments, vimentin filaments and glial filaments).

- All three components of cytoskeleton interact with each other noncovalently. Cytoskeleton helps cells in maintaining their shape and internal organization, and also provides mechanical support that enables cells to perform essential functions like cell division and movement.
- Hypoxia-induced cell injury leads to decreased ATP production resulting in increased cytosolic calcium, that activates series of proteases.
- Activated proteases attack the cytoskeleton and its attachments to the cell membrane. As the interactions between cytoskeleton proteins and the

plasma membrane are disrupted, it leads to formation of membrane blebs, and alteration of shape of the cell.

GENETIC APPARATUS DISRUPTION

The cell nucleus is a membrane-bound structure that contains a cell's hereditary information and controls its growth and reproduction. The nucleus involves regulating expression of gene, initiating cellular material essential for all these tasks. The cell nucleus regulates the synthesis of proteins through the messenger RNA (mRNA) resulting in protein synthesis and then travelling to cytoplasm through nuclear pores of the nuclear envelope. Once in the cytoplasm, ribosomes and another RNA molecule called transfer RNA work together to regulate mRNA in order to synthesize proteins.

- Hypoxic injury may cause damage to DNA resulting from increased intracellular calcium and reactive oxygen species.
- When the cell can no longer maintain itself as a metabolic unit, necrotic cell death occurs. Disruption of electron transport system and sustained opening of mitochondrial permeability transition pore (MPTP) indicate irreversible cell injury.
- Nuclear changes include condensation of chromatin (pyknosis), fragmentation of the chromatin (karyorrhexis) and lysis of chromatin due to the action of endonuclease (karyolysis) leaving a shrunken cell devoid of nucleus.
- Hematoxylin and eosin-stained section shows intense cytoplasmic eosinophilia of dead cell due to loss of cytoplasmic RNA and denaturation (coagulation) of proteins. Loss of basophilia is a sign of irreversible cell injury, indicating a cessation of protein synthesis.

MORPHOLOGIC PATTERNS OF NECROSIS

Necrosis is a morphologic sign of cell death in a living tissue. It is the result of denaturation of intracellular proteins and enzymatic digestion of the lethally injured cell.

- Necrotic cells are unable to maintain cell membrane integrity. Necrotic cells may ultimately become calcified in the settings of coagulative necrosis, liquefactive necrosis, caseous necrosis, fat necrosis, gangrenous necrosis and fibrinoid necrosis.
- An infarct is a localized area of coagulative necrosis in an organ. Coagulative necrosis involves multiple tissue planes in gangrene.
- Liquefactive necrosis occurs due to enzymatic dissolution of necrotic cells that results in transformation of the tissue into a liquid viscous mass. It most often seen in cerebrum and in abscesses.
- Fat necrosis in mesentery results from release of activated pancreatic lipases that cause fat destruction in a localized area.
- Caseous necrosis in tuberculosis is a collection of lysed cells and amorphous granular debris enclosed within a distinctive inflammatory border.

COAGULATIVE NECROSIS

Coagulative necrosis is the type of necrosis in which protein denaturation is more prominent than enzymatic breakdown. It most often occurs when sudden interruption in blood supply to an organ supplied by end arteries with limited collateral circulation (e.g. heart, kidney, spleen, adrenal gland except brain) results in cell ischemia and cell death. Widespread tissue necrosis, is called as an infarction. In brain with a high fat content, coagulative necrosis is rapidly followed by liquefactive necrosis.

- Coagulative necrosis occurs in myocardial tissue following a myocardial infarction, which takes several hours to develop coagulative necrosis. However, the loss of integrity of plasma membrane in coagulative necrosis allows the leaking of cardiac enzymes and troponins into the blood stream, making them useful as biochemical markers to aid in the diagnosis of myocardial infarction.
- Microscopically, cellular outlines of the affected tissue are maintained but structural details are lost. The necrotic tissue appears homogenous, glassy eosinophilic cells due to loss of cytoplasmic RNA (basophilic) and glycogen (granular) within preserved tissue architecture. Nucleus may show pyknosis, karyorrhexis or karyolysis. Brain with high lipid content does not contain protein content, hence shows liquefactive necrosis due to ischemia.
- Exposure of cells to heavy metals (e.g. lead and mercury) and ionizing radiation lead to intracellular accumulation of lactate anions (intracellular acidosis); which cause denaturation of structural proteins. Renal cortical coagulative necrosis is seen in mercurial poisoning.

Pathogenesis

Normally, calcium concentration in interstitial fluids is 10,000 times higher than that inside the cell. Lack of O_2 impairs mitochondrial electron transport results in depletion of ATP, which facilitates the generation of oxygen-derived free radicals.

- Following damage to plasma membrane, massive influx of calcium ion into the cell. Ischemia inhibits activity of lysosomal hydrolytic enzymes in the cells, so there is no dissolution of dead cells.
- Mitochondrial damage promotes the release of '**cytochrome c**' into the cytosol, and the cell dies.

Hydrolytic enzymes released by lysosomes start to dissolve cellular components, and trigger an acute inflammatory reaction in which white blood cells migrate to the necrotic area and begin to digest the dead cells.

Pathology Pearls: Pale and Hemorrhagic Infarcts

Pale (Ischemic) Infarct in Solid Organs

- Pale/white infarct is secondary to the sudden occlusion of a vessel. It is commonly seen in solid organs such as heart, kidney, and spleen. Gross morphology of pale/white infarct in spleen is shown in Fig. 1.19.
- Increased density of solid tissue prevents RBCs from diffusing through necrotic tissue. It produces wedge-shaped infarct with apex pointing to the source of obstruction, and the base of infarct at the periphery of the organ.
- Myocardial infarct is most often caused by ischemia related to coronary artery occlusion by atheromatous plaque.

Hemorrhagic (Red) Infarct in Loose-textured Organs

- Hemorrhagic infarct is present in loose-textured tissue such as that found in the organs (e.g. lung and small intestine, ovaries, testis) allowing RBCs to diffuse through necrotic tissue.
- Hemorrhagic infarct is wedge-shaped area of hemorrhage extending to the pleural surface due to embolus in one of the pulmonary artery tributaries.
- Venous occlusion also causes hemorrhagic infarcts (e.g. splenic vein thrombosis).
- Arterial infarcts typically appear as wedge-shaped lesions that are white in appearance (blood poor).
- Venous infarcts typically appear as irregularly shaped lesions that are red in appearance (blood-rich). Infarction is gross manifestation of coagulative necrosis.

Fig. 1.19: Gross morphology of pale/white infarct in spleen. Infarct is a localized area of tissue necrosis caused by arterial occlusion and is usually seen in the spleen, kidney and heart. Pale/white infarct lacks hemorrhage and limited red blood cells accumulation, when compared to hemorrhagic infarct. (*Courtesy*: Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru).

Surgical Pathology: Coagulative Necrosis

Gross Morphology

Infarction is gross manifestation of coagulative necrosis. Infarcts are of two types, i.e. pale infarct and hemorrhagic infarct depending on the consistency of the tissue.

- Pale infarct appears as wedge-shaped, pale/white and firm (blood poor) and retains its normal shape due to lack of enzymatic lysis as cellular proteins including enzymes have undergone coagulation.
- Hemorrhagic infarct appears as irregularly-shaped lesions that are red in appearance (blood-rich). Gross morphology of renal infarct due to occlusion of arterial segment is given in Table 1.27.

Light Microscopy

- Hematoxylin and eosin-stained section shows intense cytoplasmic eosinophilia with dead cell is due to loss of cytoplasmic RNA and denaturation (coagulation) of proteins.
- Loss of basophilia is a sign of cell injury, indicating a cessation of protein synthesis.
- Nuclei undergo phases of condensation of chromatin along the nuclear membrane (pyknosis), fragmentation of the chromatin (karyorrhexis) and lysis of chromatin due to the action of endonuclease (karyolysis) leaving a shrunken cell devoid of nucleus.

LIQUEFACTIVE NECROSIS

Liquefactive necrosis, also known as colliquative necrosis, occurs in situations in which enzymatic breakdown is more prominent than protein denaturation in organs that lack a substantial protein-rich matrix (e.g. lipid-rich organs such as brain).

- Liquefactive is typically found in brain due to prolonged ischemia or in suppurative bacterial or fungal infections in lung (lung abscess). Examples of liquefactive necrosis include brain infarct, abscess and wet gangrene.
- The necrotic tissue is transformed into soft, circumscribed and creamy liquid viscous through the action of hydrolytic enzymes liberated from brain cells or in the case of an abscess from neutrophils and macrophages.

Liquefactive Necrosis in Brain

Hypoxia causes liquefactive necrosis by digestive enzymes (hydrolases) in brain. The necrotic area of brain becomes soft (encephalomalacia) with liquefied center containing necrotic debris by digestive enzymes.

- Necrotic tissue is phagocytosed by macrophages. Later, a cyst is formed in the necrotic tissue of brain, which is filled by diffusion of fluid from the surrounding interstitial spaces of the brain.

Table 1.27 Gross morphology of renal infarct due to occlusion of arterial segment

Branch of Renal Artery	Size of Renal Infarct	Relationship to the Renal Lobes
Segmental artery	4–5 cm	Entire lobe and portion of adjacent lobe
Interlobar artery	2–3 cm	Columns of Bertin and portion of adjacent lobe
Arcuate artery	0.5–1.0 cm	One sixth to one eighth of a lobe extending to the middle of the lobe
Intralobular artery	0.1–0.2 cm	Small portion of a lobe

- Microscopically, the cystic space contains necrotic cell debris, macrophages filled with phagocytosed material. The cyst wall is formed by proliferating capillaries, inflammatory cells, and gliosis (proliferating glial cells) in brain.
- It is worth mentioning that hypoxia causes liquefactive necrosis in central nervous system, that lacks proteins. On the other hand, hypoxia causes coagulative necrosis in solid organs rich in proteins (e.g. kidney, spleen and heart).
- Gross morphology of liquefactive necrosis in the frontal lobe of brain with formation of cystic spaces is shown in Fig. 1.20. Gross morphologic and histologic features of cerebral infarct are given in Table 1.28.

Fig. 1.20: Gross morphology of liquefactive necrosis in the frontal lobe of brain with formation of cystic spaces (arrow). Liquefactive necrosis is type of necrosis which results in a transformation of the tissue into liquid viscous mass as a result of lysosomal release of digestive enzymes.

Liquefactive Necrosis in Organ's Abscess

An abscess is a collection of pus that has built up within the tissue of the body due to bacterial infections. Typically, it presents as a cavity filled with pus—that is, liquefied tissue of the affected organ permeated with dead or dying bacteria and neutrophils.

- Abscess can form throughout the body, both in locations that are visible and internally, where it may go unnoticed and cause serious problems including organ damage.
- The most common sites of abscesses are skin and dental region. Less common sites of abscess are abdomen, liver (amoebic or pyogenic), brain, epidural region, Bartholin gland, anorectal region, peritonsillar region, spinal cord.

Partial Liquefactive Necrosis in Wet Gangrene of Extremities

Wet gangrene is a clinical term for ischemic necrosis accompanied by superadded bacterial decomposition, which results in partial liquefaction of the tissues. It occurs due to lytic activity of bacteria and inflammatory cells in the affected tissue. Swelling, blistering and wet appearance are common features of wet gangrene. It may develop after severe burns, frostbite and diabetes mellitus in foot or toes. Wet gangrene needs to treated immediately, because it spreads quickly and can be fatal.

Table 1.28 Gross morphologic and histologic features of cerebral infarct

Feature	Duration	Gross Features	Histologic Features
Acute cerebral infarct	Hours to few days	Poorly defined soft and edematous infarct	Liquefactive necrosis of neurons, mild neutrophilic infiltrate and rarefaction of white matter
Subacute cerebral infarct	Hours to weeks	Partially liquefied infarct	Liquefactive necrosis of neurons and glial components drop out, marked macrophage infiltrate, reactive capillaries and gliosis at periphery
Chronic cerebral infarct	Months to years	Cystic cavity with collapse of surrounding tissue	Cystic spaces lined by 'gliotic scar' at periphery without collagen, loss of parenchyma, sparing of subpial region as opposed to old contusion; with or without hemosiderin and macrophages

CASEOUS NECROSIS

Caseous necrosis is hallmark of tuberculosis, which appears as amorphous, coarsely granular, eosinophilic debris. Certain fungal infections can also exhibit caseous necrosis. Caseous necrosis is a combination of coagulative and liquefactive necrosis seen in tuberculosis, in which cellular outlines as well as structural details are lost.

- Mycobacterium tubercle bacillus is a nonmotile acid-fast, 2–4 μm in length with very slow generation time between 15 and 20 hours. The cell envelope of Mycobacterium tubercle bacillus is composed of peptidoglycan (40%) and of lipids (60%). The lipid fraction of mycobacterial tubercle bacillus cell wall is composed of three major components, mycolic acids, cord factor and wax-D. It is partially resistant to digestion and phagocytosis by tissue macrophages.
- Exposure to Mycobacterium tubercle bacillus leads to activation and recruitment of macrophages to form epithelioid cell granulomas and Langhans type of giant cells. Caseous necrosis is derived from mycolic and other lipid constituent of the lipid-rich envelope of Mycobacterium tubercle bacillus, hence the descriptive term 'caseous necrosis'. Differences between coagulative and caseous necroses are shown in Table 1.29.

Pathogenesis

Lungs are the most common site of tuberculosis in children and adults. Most common organs involved in children include lungs, lymph nodes, spleen and meninges. Lungs, adrenal glands, kidneys, liver, spleen, bone, meninges, serous membranes, fallopian tubes, epididymis and lymph nodes are involved in adults. Tissues rarely involved include cardiac muscle, skeletal muscle, stomach, thyroid gland, and pancreas.

Pathogenesis of Tuberculosis in <3 Weeks Duration

Mycobacterium tubercle bacilli's mannose capped glycolipid (lipoarabinomannan) binds to mannose receptors expressed on alveolar macrophages leading to engulfment of AFB within three weeks of infection. Cord factor synthesized by AFB prevent fusion of phagosomes with lysosomes. Hence, unchecked proliferation of tubercle bacilli continues inside alveolar macrophages.

Pathogenesis of Tuberculosis in >3 Weeks Duration

Macrophages are antigen presenting cells, which present Mycobacterium tubercle bacilli antigen to CD4+ helper T cells. Macrophages synthesize IL-12, which takes part in differentiation of T-helper cells in lungs and lymph nodes in >3 weeks duration of infection.

- Bactericidal activity of immune system occurs due to synthesis of interferon-γ by T cells. Interferon-γ stimulates nitrogen synthase enzyme, which causes synthesis of nitrogen intermediates (NO, NO_2 and HNO_3) and O_2-derived free radicals resulting in oxidative destruction of AFB.
- Macrophages synthesize tumor necrosis factor and chemokines, which participate in recruitment of monocytes and sensitization of CD4+ helper T cells.
- This process of recruitment of monocytes and sensitization of T cells leads to formation of epithelioid granulomas composed of macrophages and surrounded by lymphocytes. Epithelioid cell granulomas prevent spread of infection by confining bacteria within a compact collection of activated macrophages and T cells.

Table 1.29 Differences between coagulative and caseous necroses

Coagulative Necrosis	Caseous Necrosis
Etiopathogenesis	
Hypoxic injury to heart, kidney and spleen	Mycobacterium tubercle bacillus
Due to intracellular acidosis (due to hypoxia) structural as well as enzymatic denaturation of proteins occurs. Dead cells are removed by fragmentation and phagocytosis	Reaction between Mycobacterium tubercle bacillus antigens and inflammatory cells. Cellular outlines are completely obscured
Gross morphology	
Firm texture of organs	Cheesy white appearance
Light microscopy	
Cellular outlines are maintained and structural details are lost. Cells are acidophilic, coagulated with loss of nuclear details due to blockage of cytoplasmic hydrolytic enzymes. There is no dissolution of tissue.	Cellular outline as well as structural details are lost. It is amorphous granular debris (fragmented, coagulated cells and granular debris) surrounded by chronic inflammatory cells. Epithelioid granulomas and Langhans giant cells are present

Surgical Pathology: Caseous Necrosis

Gross Morphology

- Caseous material resembles clumpy cheese-like consistency, hence the name caseous necrosis. It is formed by the release of lipid from the cell walls of Mycobacterium tubercle bacilli after destruction by macrophages.
- This type of caseous necrosis appearance also occurs in systemic fungal infection by *Histoplasma capsulatum*. Gross morphology of tubercular lymphadenitis is shown in Fig. 1.21.

Light Microscopy

- The tubercular lesion is composed of epithelioid granulomas (activated macrophages, CD4+ helper T cells), caseous necrosis and Langhans' type giant cells.
- Tissue architecture is distorted. Caseous necrotic tissue lack cellular outlines as well as cellular details, which appears amorphous, finely granular, eosinophilic appearance with increased affinity for acidophilic dye. Histology of tuberculous lymphadenitis is shown in Fig. 1.22.

Histochemical Stain

- Ziehl-Neelsen staining is a type of acid-fast bacteriological stain used to identify Mycobacteria tuberculosis.
- Ziehl-Neelsen stain contains carbol fuchsin, acid alcohol and methylene blue.
- Mycobacterium tubercle bacilli appear as slightly curved or straight under oil immersion. Ziehl-Neelsen staining for demonstration of acid-fast bacilli is shown in Fig. 1.23.

FAT NECROSIS

Fat necrosis refers to the destruction and death of fat cells causing scar to form in breast, pancreas and other tissues. It often occurs in breast tissue and anywhere in the body that contains fat tissue.

Fig. 1.21: Gross morphology of tubercular lymphadenitis. Cut surface of tubercular lymphadenitis shows cheesy appearance on cut surface. (*Courtesy*: Department of Pathology, Dr. DY Patil Medical College, Pune, Maharashtra.)

- Fat necrosis occurring in acute pancreatitis is mediated by pancreatic enzymes.
- Traumatic fat necrosis, unlike enzymatic fat necrosis, is not enzyme-mediated but is secondary to direct severe trauma to organs rich in fat, i.e. female breast, surgical trauma to organs rich in adipose tissue such as abdominal wall and omentum. Fat necrosis in breasts occurs due to severe traumatic injury or breast augmentation surgery.

Fat Necrosis in Female Breast

Damage to the adipose tissue can occur following severe traumatic injury, breast biopsy, radiotherapy to the breast, breast surgery including breast reconstruction or augmentation or breast reduction or lipomodelling (fat taken from another region and injected into the breast).

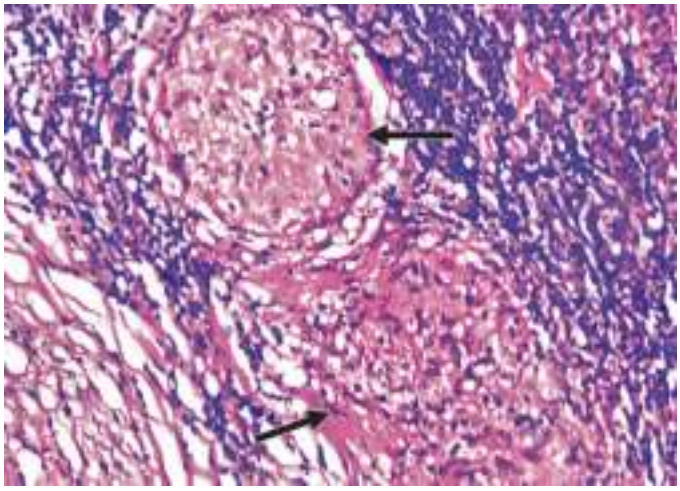

Fig. 1.22: Histology of tuberculous lymphadenitis. It shows epithelioid granulomas (arrows) caseous necrosis and Langhans' giant cells (400X).

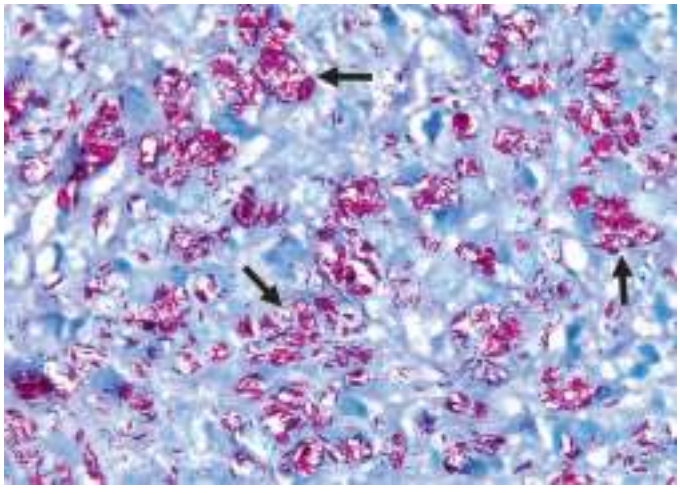

Fig. 1.23: Ziehl-Neelsen staining for demonstration of acid-fast bacilli. Microscopic examination of clinical samples for acid-fast bacilli using Ziehl-Neelsen stain has been a standard diagnostic tool and is used globally for rapid tuberculosis diagnosis (arrows) (400X).

- Lipase enzyme liberated from traumatized adipose tissue breaks down intracellular triglycerides into free fatty acids. Free fatty acids released, via hydrolysis react with calcium, sodium, magnesium to form chalky white areas known as 'saponification'.
- The tissue becomes opaque and chalky white demonstrated as calcified lesion on radiograph.
- Patient presents with unilateral painful localized superficial irregular breast mass in acute stage.
- On clinical examination, affected breast shows firm, erythema of the overlying skin, dimpling and nipple retraction mimicking breast cancer. If the mammogram or ultrasound scan clearly shows fat necrosis, fine needle aspiration cytology, core biopsy or vacuum assisted biopsy may not be needed.
- Fat necrosis in breast is harmless, that may resolve in few months. It does not increase risk for breast cancer. Patients do not require any surgical or medical treatment.

Surgical Pathology: Fat Necrosis in Breast

Gross Morphology

- Fat necrosis of breast shows chalky white areas of fat saponification.
- Variegated color and areas of hemorrhage are demonstrated on the cut surface of this lump.
- The lesion is gritty to cut because of the presence of spotty calcification.

Light Microscopy

- Initially, acute inflammatory reaction consists of necrosis of adipocytes and hemorrhage.
- Chronic inflammatory lesion is composed of plasma cells, macrophages, multinucleated giant cells, foam cells termed as lipophages.
- There is presence of foreign body giant cells and dystrophic calcification demonstrated by imaging techniques.
- Fibroblastic proliferation leads to fibrosis. As a result, an irregular, fixed, hard mass may ensue and clinically resemble breast cancer. Thus, the lesions often require biopsy to establish their benign character.

Fat Necrosis in Pancreas

Enzymatic fat necrosis in pancreas represents autodigestion by pancreatic enzymes such as lipases and proteases released from pancreatic cells.

- The lipase and protease enzymes damage peripancreatic fat cells laden with triglycerides leading to liberation of free fatty acids, which combine calcium ions, sodium, or magnesium to form calcium soaps (saponification). Hemorrhage occurs as a result of vessel erosion.
- Predisposing factors of acute pancreatitis include alcoholism, hypercalcemia, hyperlipemia and autoimmune etiology. Serum calcium level is decreased in patients, who had a recent bout of acute pancreatitis.
- Patient experiences sudden-onset abdominal pain, distention, and vomiting. The precipitated calcium in the soaps can be visualized by radiological imaging.

Surgical Pathology: Fat Necrosis in Pancreas

Gross Morphology

Macroscopically, fat necrosis looks like opaque chalky-white nodules composed of calcium soaps in the fat surrounding the pancreas or in the abdominal cavity.

Light Microscopy

- Microscopic examination reveals irregular islands of necrotic fat cells, which lose their outlines and become indistinct.
- There is presence of inflammatory cells, macrophages filled with fat and calcium deposits.
- Deposition of calcium around the periphery of necrotic fat cells gives a basophilic tinge.
- Giant cell reaction around these foam cells may occur. Histology of fat necrosis in pancreas is shown in Fig. 1.24.

GANGRENE

The terms 'gangrene' and 'necrosis' are often confusing. Necrosis refers to irreversible cell injury and cell death without superadded bacterial infection in a living organism. Gangrene involves the cellular and morphological changes that can lead to scarring and permanent tissue/organ loss of function. Gangrenous necrosis is most often seen on extremities usually due to trauma.

- Gangrene refers to the death of body tissue/organ due to either a lack of blood flow or a serious superadded bacterial infection or traumatic wounds (gunshot or crush injuries) affecting extremities including toes/fingers, muscles and internal organs in living organism.

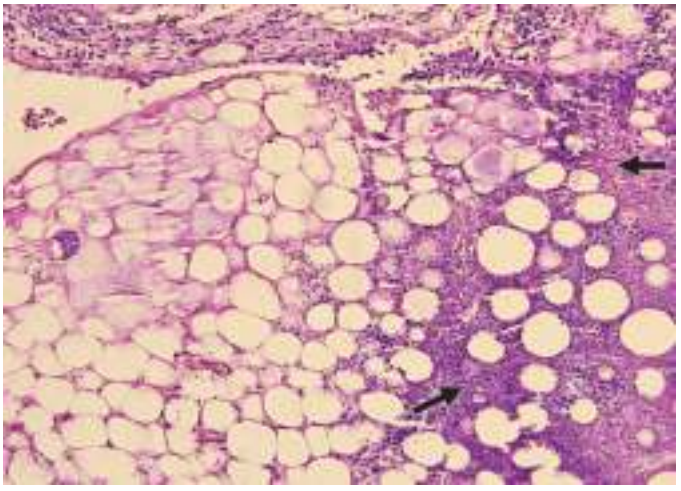

Fig. 1.24: Histology of fat necrosis in pancreas. It shows irregular islands of necrotic fat cells, which have lost their outlines. There is presence of chronic inflammatory cells. Macrophages are filled with fat and calcium (arrows) (100X).

Table 1.30 Differences between dry gangrene and wet gangrene

Dry Gangrene	Wet Gangrene
Etiopathogenesis	
Slow occlusion of arteries	Sudden interruption of blood flow in both artery and vein
Atheromatous plaques in medium-sized arteries	Emboli, ligation, crush injury
Organs involved	
Limbs (small area involved due to presence of collaterals)	Bowel (large area involved due to absence of collaterals)
Odor absent	Odor present
Line of demarcation of dry gangrene presents at the junction of healthy and gangrenous part	Line of demarcation of wet gangrene absent
Superadded infection absent	Superadded infection present
Gross morphology	
Dry, decreased in size with black discoloration	Wet, swollen, edematous and soft in consistency
Prognosis	
Prognosis is most often better due to little septicemia	Prognosis is most often poor due to profound toxemia
Treatment	
Conservative amputation	Major surgical resection essential

- There are two main categories of gangrene, i.e. dry and wet. Dry gangrene refers to death of tissue/organ without superadded bacterial infection. Wet gangrene refers to death of tissue/organ with superadded bacterial infection, multiplication and release of toxins and pus.
- Several risk factors for gangrene include diabetes mellitus, atherosclerosis (tibial and popliteal arteries), severe traumatic injury, tobacco smoking and obesity. Differences between dry gangrene and wet gangrene are given in Table 1.30.

Dry Gangrene

Dry gangrene refers to ischemic necrosis without superadded bacterial infection accompanied by drying of the organs/tissues. It occurs most commonly in persons, who have arterial blood vessel disease of extremities (atherosclerosis) or diabetes mellitus. Dry gangrene is characterized by dry, brown to purplish blue or black skin due to the deposition of iron sulphide from degraded hemoglobin.

Wet Gangrene

Wet gangrene is a clinical term for ischemic necrosis accompanied by superadded bacterial infection, which results in partial liquefaction of the tissues due to lytic activity of bacteria and inflammatory cells in the affected tissue. Swelling, blistering and wet appearance are common features of wet gangrene. It may develop after severe burns, frostbite and diabetes mellitus in foot or toes. Wet gangrene needs to be treated immediately, because it spreads quickly and can be fatal. Gross morphology of ischemic bowel disease (gangrene intestine) is shown in Fig.1.25.

Fig. 1.25: Gross morphology of ischemic bowel disease (gangrene intestine). Gangrene of the bowel occurs due to sudden occlusion of arterial blood supply by a thrombus leading to ischemia involving short or long segments of bowel. External surface shows dusky blackish discoloration. Gangrene bowel represents an irreversible cell injury.

Clinical Pearls: Gas Gangrene

- Gas gangrene is synonymous with myonecrosis, which occurs in an injured deep muscle tissue or surgical wound with infection by *Clostridium* species, that is depleted of blood supply.

- Gas gangrene is highly lethal infection of deep soft tissue caused by *Clostridium perfringens* (80–90%), *Clostridium novyi* (40%), *Clostridium septicum* (20%), *Clostridium bifermentans* (10%), and *Clostridium fallax* (10%). These organisms are present in soil and organic wastes especially contaminated with fecal matter.
- Bacterial infection releases toxin produces toxin, that releases gas bubbles in the injured deep tissues. Like wet gangrene, gas gangrene can be life-threatening. Lecithinase released by *Clostridium perfringens* breaks down cell membrane resulting in cell death and tissue necrosis. Lecithinase causes hemolysis and adverse effect on heart.

FIBRINOID NECROSIS

Fibrinoid necrosis is a descriptive term for irreversible cell necrosis of arterioles and muscular arteries. Deposition of antigen–antibody complex leads to activation of complement cascade and subsequent chemotactic influx of neutrophils and monocytes associated with type 3 hypersensitivity reaction.

- Deposits of these immune-complex, together with fibrin that has leaked out of blood vessel, results in a bright eosinophilic (pink) amorphous necrotic debris that appears brightly eosinophilic (i.e. fibrin-like) in hematoxylin and eosin-stained tissue sections, called 'fibrinoid necrosis' (fibrin-like) by histopathologist.
- If necrotic cells and cellular necrotic debris are not promptly destroyed and reabsorbed, they tend to attract calcium salts and often minerals and to become calcified. In small blood vessel vasculitis, fibrin plugs frequently occur into the blood vessel lumen, but the term 'fibrinoid necrosis' usually refers to material outside the lumen of a blood vessel.
- Fibrinoid necrosis also occurs in the walls of arterioles in malignant hypertension (blood pressure more than 200/130 mm Hg), immune-mediated vasculitis (e.g. eclampsia, immune-mediated vasculitis (Henoch-Schönlein purpura, lupus erythematosus and polyarteritis nodosa), infection and hyperacute organ transplant rejection.
- Fibrinoid necrosis has no distinct grow morphologic features. Histologic examination shows glassy, eosinophilic fibrin-like material deposit within vascular walls.
- Symptoms related to fibrinoid necrosis involves bleeding gums, muscle bruises, hematuria, blood in stool and hemorrhage of spleen.
- Treatment of fibrinoid necrosis involves treating the underlying cause.

GUMMATOUS NECROSIS

Gummatous necrosis is a granulomatous destructive rubbery soft lesion seen in the tertiary syphilis, which most often occurs in the liver (gumma hepatitis). It may also be demonstrated in brain, heart, testes and bone leading to numerous potential problems such as neurological and cardiac valve disorders.

- A gumma has a soft, necrotic center surrounded by inflamed tissue. On gross examination, gumma has firm necrotic amorphous proteinaceous mass that may be partly hyalinized.
- Histologic examination of gumma shows central area of necrosis with partly retaining structural details of previously normal tissue. There is presence of epithelioid cell granulomas, multinucleated giant cells in the central region of gumma. Peripheral zone of gumma shows fibroblasts, capillaries, lymphocytes and plasma cells.

SUBCUTANEOUS NECROSIS IN NEWBORN

Subcutaneous necrosis in newborn is self-limited disease affecting term neonates and young infants. It is characterized by circumscribed, indurated, nodular areas of fat necrosis. It is related to trauma on bony prominences during delivery or maternal diabetes mellitus, which resolves spontaneously by 2–4 weeks without fibrosis. Subcutaneous necrosis in newborn is also called adiponecrosis neonatorum.

ZENKER'S NECROSIS IN SKELETAL MUSCLE

Zenker's necrosis refers to glassy waxy necrosis of the striated muscle such as rectus abdominis and diaphragm in acute severe infectious diseases such as typhoid fever and burns. It has been named by Friedrich Albert von Zenker. Zenker's necrosis in skeletal muscle appears pale and friable. Histologic examination shows pale and friable swollen skeletal muscles with loss of striations.

POSTMORTEM AUTOLYSIS

Postmortem autolysis occurs secondary to the release of endogenously derived intracellular enzymes moments after death. There is no inflammatory infiltrate, since an inflammatory response occurs only in living tissue.

OUTCOME OF NECROSIS

Cell injury can be reversible or irreversible. Depending on the extent of injury, cellular response may be adaptative and where possible, homeostasis is restored. Cell death occurs when the severity of the injury exceeds the cell's ability to repair itself. It is essential to remove necrotic tissue and cell debris at or near the site of the cell death surgically in a case of gangrene, a procedure known as debridement.

COMPLETE RESOLUTION

Macrophages phagocytose necrotic cellular debris and apoptotic neutrophils leading to removal from injured site. Edema fluid and proteins are finally drained into the lymphatics. Injured cells with intact supporting stroma undergo regeneration of labile and stable cells by mitosis with restoration of normal structure and function.

- Labile cells multiply constantly throughout life. These are present in bone marrow epidermis, epithelial lining gastrointestinal tract, bronchi and vagina; and epithelial lining excretory ducts (salivary glands, pancreas, and biliary tract).
- Stable cells spend most of the time in the quiescent G0 phase of the cell cycle, but can be stimulated to enter the cell cycle when needed. These cells are present in proximal tubules of kidney, liver, endocrine glands, fibroblasts, vascular endothelium, cartilage and bone. Liver is composed of stable cells, which have limited proliferative capacity. Following partial hepatectomy or chemical induced liver injury, liver is able to regenerate by proliferation of remaining hepatocytes. It is well known that as little as 25% of the original liver tissue can regenerate back to its full-size organ.
- Permanent cells are terminally differentiated and incapable of regeneration. Examples are brain cells, neurons, cardiac myocytes, skeletal muscle, renal glomeruli and red blood cells.

INJURED TISSUE REPAIR BY FIBROSIS

Injured tissue repair by fibrosis involves removal of injured tissue by inflammation, angiogenesis, migration and proliferation of fibroblasts, scar formation and remodeling of connective tissue.

- Organization is defined as the replacement of necrosed tissue (infarct), thrombi, fibrinous exudates, hematoma (wound, bone fracture) by granulation tissue.
- Myofibroblasts, which are hybrids of fibroblasts and smooth muscle cells, contain both myofilaments and rough endoplasmic reticulum and thus have purple-staining cytoplasm. These cells play central role in wound healing and fibrosis in various organs (liver, lung, kidney) by synthesizing extracellular matrix (ECM), which consists of structural fibrous glycoproteins (collagen fibers, fibronectin, laminin, and elastin) and amorphous ground substance (gel-like material that absorbs water).
- Myofibroblasts are derived from epithelial cells of epithelial–mesenchymal transition (EMT), activation of stellate cells (e.g. hepatic Ito cells or pancreatic stellate cells), direct myofibroblastic differentiation of a progenitor cell resident in a stromal tissue.

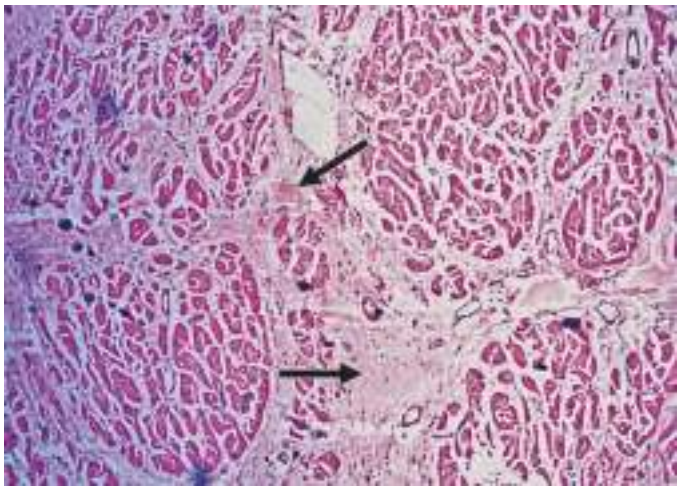

Fig. 1.26: Histology of healed myocardium after infarction. Myocardial infarct shows healing by fibrosis (arrows) (100X).

Healing in Myocardial Infarct

In myocardial infarction, the dead myocardial cells are removed by inflammatory cells and replaced by a fibrous scar. Healing starts with granulation tissue formation by first week. By second week, granulation tissue is replaced by yellow necrotic myocardium. By third week, yellow necrotic myocardium is replaced by fibrous scar. Phagocytosis of necrotic debris by macrophages is complete. By sixth week, infarct tissue is replaced by white, patchy and noncontractile scar tissue. Histology of healed myocardium after infarction is shown in Fig. 1.26.

DYSTROPHIC CALCIFICATION

Dystrophic calcification is deposition of calcium salt in the injured tissues in the presence of normal calcium and phosphorous metabolism. It is different from systemic mineral imbalance causing metastatic calcification, in which calcium deposition occurs in normal tissues. Calcium is demonstrated by alizarin stain and von Kossa stain. Dystrophic calcification occurs by two processes: initiation and propagation. Calcium has strong affinity for cellular phospholipids.

- Membrane bound vesicles containing calcium are formed inside cell. Now tiny crystals of calcium are released from membrane bound vesicles into the extracellular compartment. Phosphatase participates in deposition of phosphates.
- Further deposition of calcium is known as propagation, that depends on the presence of calcium and phosphate in the extracellular compartment; and presence of collagen fibers and other proteins.

Dystrophic calcification occurs in caseous necrosis, liquefactive necrosis, fat necrosis (acute pancreatitis, traumatic fat necrosis in breasts) and hematomas in the vicinity of the bone fracture.

RESORPTION OF NECROTIC TISSUE

Liquefactive necrosis (or colliquative necrosis) results in transformation of the tissue into a liquid viscous mass. It most often occurs in the lungs, especially in lung abscess and certain infections.

- After removal of cell debris by hydrolytic enzymes of neutrophils and macrophages, a fluid-filled soft circumscribed pseudocyst consisting of remains of necrosed tissue and pus is left. Dead leukocytes will remain as a creamy yellow pus. The pseudocyst wall is formed by proliferating capillaries, inflammatory cells and proliferating fibroblasts in abscess cavities.
- Hypoxia causes liquefactive necrosis of central nervous system by brain digestive enzymes (hydrolases). The affected area of brain becomes soft with liquefied center containing necrotic debris by brain digestive enzymes. Later, a cyst is formed in the affected area of brain. Microscopically, the cystic space contains necrotic cell debris, macrophages filled with phagocytosed material. The cyst wall is formed by proliferating capillaries, inflammatory cells, and gliosis (proliferating glial cells) in brain.

REGULATED CELL DEATH (RCD)

Nomenclature Committee on Cell Death (NCCD) 2018 has formulated guidelines for highlighted nomenclature of cell death on morphologic, molecular, pharmacologic, and functional basis; and identification of dead cells with irreversible plasma membrane disruption and complete cellular fragmentation.

- Cell death manifests with macroscopic and morphologic alterations. Dead cells and their fragments are disposed by three mechanisms: necrosis, apoptosis, and autophagy. Necrosis occurs when cells are irreversibly damaged by an external stimulus. In contrast, apoptosis is considered to be physiologic form of programmed cell death, a cell provokes its own demise in response to a stimulus. Autophagy manifests with extensive cytoplasmic vacuolization and similarly culminating with phagocytic uptake and consequent degradation.
- Oncotic necrosis is the term currently used for nonapoptotic, accidental cell death. It is generally regarded as a severe lethal injury to cell membrane integrity. The term 'oncotic necrosis' is defined as cell death with swelling (oncosis), that can be caused by ischemia, and toxic agents that interfere with ATP generation by mitochondria and plasma membrane ($Na^+/K^+/Cl^-/Ca^{++}$) pumps failure. Oncotic necrosis is characterized by cell swelling (oncosis), organelles swelling, plasma cell blebbing, loss of plasma membrane integrity, increased membrane permeability, chromatin fragmentation (pyknosis, karyorrhexis, karyolysis), release of lysosomal enzymes into extracellular spaces, eosinophilic cytoplasm, inflammation, vascularization and tissue repair.
- Morphologically, necrosis occurs in several forms such as coagulative necrosis, liquefactive necrosis, caseous necrosis, fibrinoid necrosis, gummatous necrosis, subcutaneous necrosis and autolysis in newborn.
- Biochemically, necrosis of cell has been demonstrated to represent a number of genetically determined signaling pathways. Novel ancillary tests are performed to detect abnormal signaling pathways in cell necrosis.

- Regulated cell death functions to eliminate potentially harmful cells to maintain tissue homeostasis. Multiple cell death pathways have been defined according to the morphologic, biochemical and functional aspects.
  - Examples of regulated cell death include apoptosis (type 1 cell death), autophagic cell death (type 2 cell death), necroptosis, pyroptosis, ferroptosis, entotic cell death, NETotic cell death, lysosomal dependent cell death, antibody-dependent cell death, and immunogenic cell death. The morphologic alteration is focused on cell size, membrane integrity, chromatin density, organelle arrangement and presence of vacuoles. Features of regulated cell death (RCD) are given in Table 1.31.
  - The clinical implications of necroptosis, pyroptosis, ferroptosis and many other emerging forms of programmed necrosis extend across a range of pathologists and disease models, but play an obvious and prominent role in cancer, the ultimate imbalance between cellular life and mortality.

Table 1.31 Features of regulated cell death (RCD)

Apoptosis
▪ Apoptosis is mediated by extrinsic death receptor/intrinsic mitochondrial/granzyme and perforin pathways ▪ Apoptosis features cell shrinkage, plasma membrane blebbing, DNA chromatin condensation and karyorrhexis, cell breaks apart into several apoptotic bodies and phagocytosed by macrophages and surrounding epithelial cells and lack of inflammation
Autophagy-dependent Cell Death
▪ Starvation induced cell death ▪ Massive cytoplasmic vacuolization and loss of organelles ▪ Fusion of autophagosome and lysosome and forming phagolysosome ▪ Cell degradation
Pyroptosis
▪ Pyroptosis is cytokines-induced cell death ▪ PAMP/DAMP → CASP1/cytosolic lipopolysaccharide (LPS) → caspase 11 → proteolytic maturation of the pore-forming protein gasdermin D (GSDMD) → N-terminal fragments → plasma membrane pores and rupture ▪ DNA condensation and karyorrhexis
Necroptosis
Necroptosis is triggered by perturbations of extracellular or intracellular homeostasis that is critically depends on MLKL, RIPK3 or RIPK1. It leads to membrane rupture and random DNA degradation
NETosis
▪ Infection → NADPH oxidase activation → reactive oxygen species (ROS) → histone citrullination → NETotic cell death → release of neutrophil chromatin traps containing antimicrobial products ▪ Membrane rupture and DNA decondensation
Ferroptosis
▪ Ferroptosis is initiated by oxidative perturbances of the intracellular microenvironment, generation of reactive oxygen species causing lipid peroxidation that is under control of GPX4 and can be inhibited by iron chelators and lipophilic antioxidants ▪ Can be inhibited by iron chelators and lipophilic antioxidants
Entotic Cell Death
Entotic cell death originates from actomyosin-dependent cell-in-cell internalization (entosis) and is executed by lysosomes
Parthanatos (PARP-1-dependent cell death)
Parthanatos is initiated by PARP1 hyperactivation and precipitated by the consequent bioenergetic catastrophic coupled to AIF-dependent and MIF-dependent DNA degradation
Anoikis
Specific variant of intrinsic apoptosis initiated by loss of integrin-dependent anchorage
Immunologic Cell Death
Adaptive immune response in immunocompetent hosts induces immunologic cell death occurs
Autosis
A specific instance of autophagy-dependent cell death that critically relies on the plasma membrane Na/K- ATPase

MITOCHONDRIAL PERMEABILITY TRANSITION PORE DRIVEN NECROSIS

Mitochondria are surrounded by double-membrane system, consisting of inner and outer mitochondrial membranes separated by an intermembrane space. Inner membrane forms numerous folds which extend into the interior (matrix) of the organelle.

- Mitochondrial permeability transition pore (MPTP) is a transmembrane protein residing in the mitochondrial inner membrane.
- Normally, MPTP is closed. Mitochondria are key players in cell survival by providing ATP energy for vital cellular processes.
- Mitochondria participate in programmed cell death (apoptosis) *via* activation of caspase cascade, which

requires preserved ATP levels. When mitochondria cannot maintain adequate ATP levels, cell death occurs via necrosis.

MOLECULAR PATHOGENESIS

During ischemia (MPT priming phase), cytosolic Ca^{++} overload, long chain fatty acid accumulation, increased phosphate concentration, and severe oxidative stress (reactive oxygen species) and ATP depletion progressively increase mitochondrial susceptibility to mitochondrial permeability transition (MPT), increasing the likelihood that MPT will occur on reperfusion (MPT triggering phase) leading to matrix swelling, osmotic breakdown of both mitochondrial membrane, release of apoptotic signaling molecules such as 'cytochrome c' from the intermembrane space, and irreversible injury. Minimal mitochondrial permeability transition leads to full recovery. Localized mitochondrial permeability transition can result in recovery or apoptosis in 50% of cases. Generalized mitochondrial permeability transition leads to cell necrosis in 50–90% of cases.

APOPTOSIS

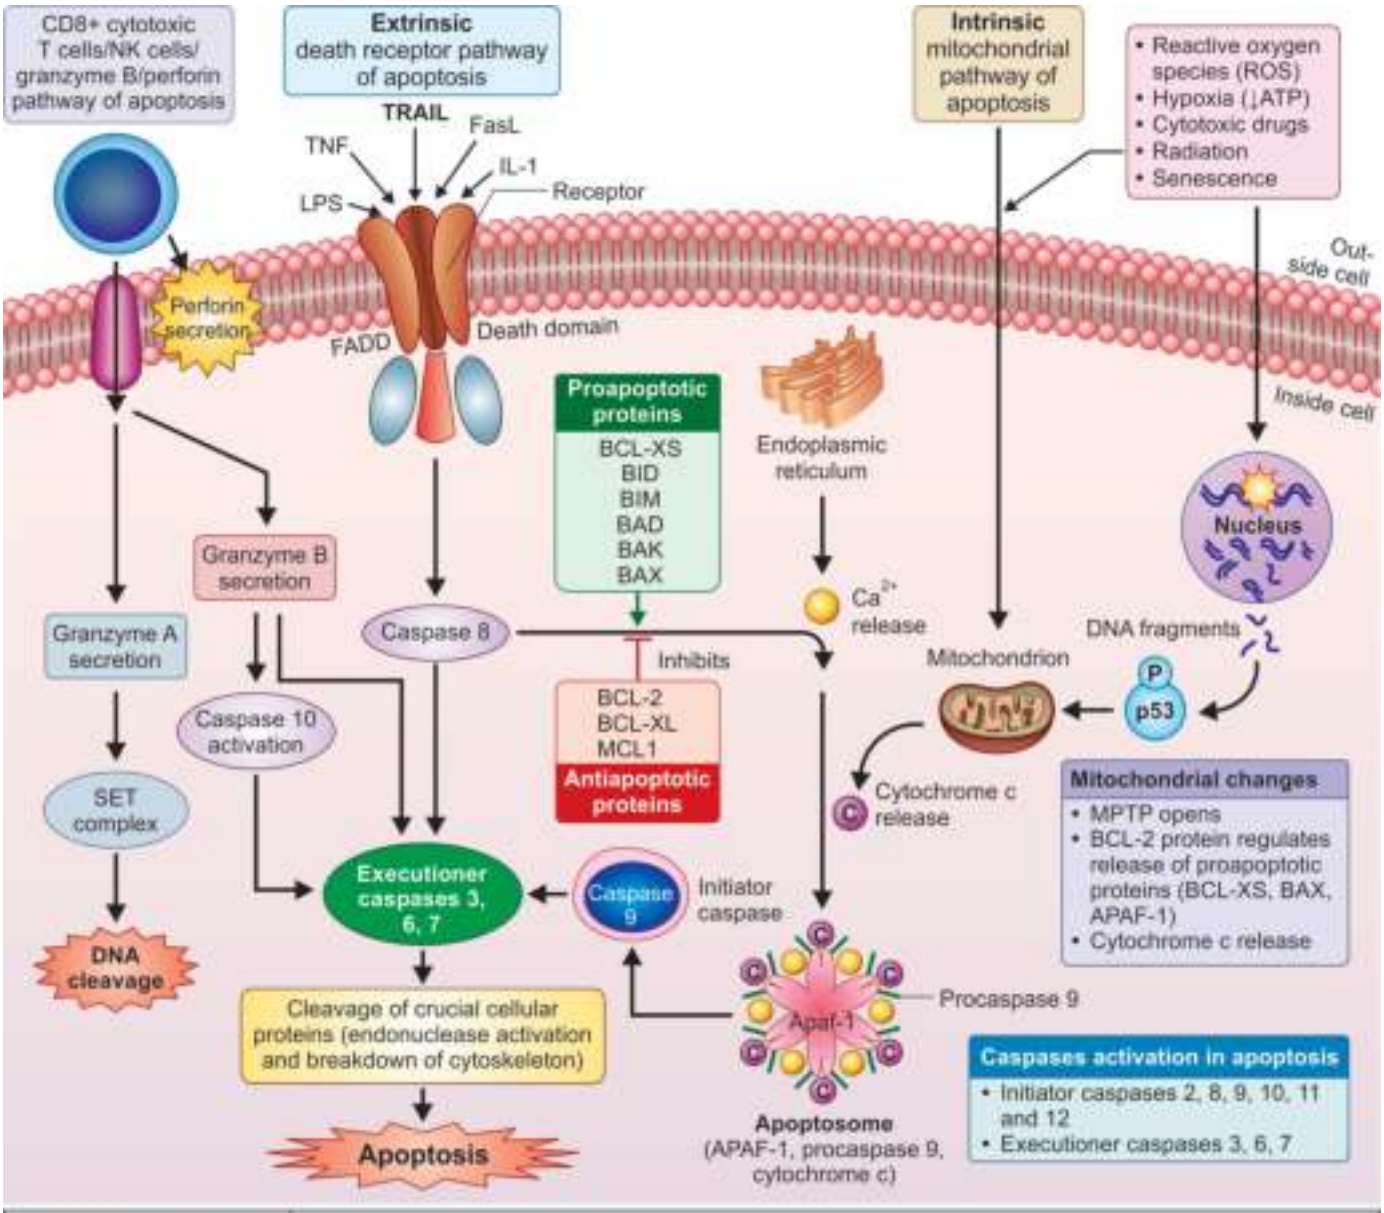
Apoptosis is an 'ATP-dependent' death receptor/mitochondrial pathway mediated programmed cell death that enables the removal of potentially harmful single or group of DNA damaged cancerous cells, virus infected cells, or otherwise unwanted cells in a controlled manner without releasing harmful contents into surrounding environment. Hence, apoptotic signaling pathways help to safeguard the 'genomic stability'. Kindly refer to apoptosis in details in this chapter.

- Apoptosis is characterized by cell shrinkage, plasma membrane blebbing, DNA chromatin condensation and karyorrhexis, cell breaks apart into several apoptotic bodies and phagocytosed by macrophages and surrounding epithelial cells and without inducing inflammation.
- Apoptosis is mediated by molecular pathways that culminate in the activation of family of cysteine proteases, known as the caspases in order to maintain tissue homeostasis during embryogenesis and postnatal life, which orchestrate the dismantling and clearance of the apoptotic cell.
- Apoptosis is initiated via three molecular pathways: (a) extrinsic (signal through cell membrane death receptors such as Fas or tumor necrosis factor) pathway, (b) intrinsic (release of 'cytochrome c' from mitochondria through an extracellular domain) pathway, and (c) CD8+ cytotoxic T cells/NK cells (granzyme B/perforin) mediated pathway. Schematic representation of extrinsic (death receptor) and intrinsic (mitochondrial) pathways of apoptosis is shown in Fig. 1.27.
- Apoptosis exhibits cytoplasmic shrinkage, condensation of nuclear chromatin (pyknosis), nuclear DNA fragmentation (karyorrhexis), plasma membrane blebbing, mitochondrial dysfunction, culminating with the formation of apparently intact small vesicles (known as apoptotic bodies), that are efficiently phagocytosed by macrophages and neighboring healthy cells and degraded within lysosomes. There is no inflammatory response in apoptosis, because harmful cellular contents of apoptotic cells are not released into the surrounding tissue.
- Techniques for detection of apoptotic cells include: cytomorphologic changes (light and electron microscopy), DNA discontinuous fragmentation ladder assay (conventional agarose gel electrophoresis), terminal deoxynucleotidyl transferase (TdT) dUTP nick-end labeling (TUNEL) assay, annexin V (immunohistochemistry), p53 (immunohistochemistry and RT-PCR, Western blot, enzyme-linked immunosorbent assay, flow cytometry), executioner 3 activation (immunohistochemistry, Western blot, enzyme-linked immunosorbent assay), Fas, TNF-α (tumor necrosis factor α), TRAIL: tumor necrosis-related apoptosis-inducing ligand (RT-PCR, Western blot, immunohistochemistry) and cytochrome c release (ELISA: enzyme-linked immunosorbent assay).

NECROPTOSIS

Necroptosis is an alternative mode of regulated caspase independent and receptor interacting protein (RIP1, RIP3) kinase mediated cell death mimicking features of apoptosis and necrosis. Formation of the necrosome is key event in the induction of necroptosis by inducing cell swelling, cell membrane disruption, inflammation and vascularization. Necroptosis is a strong trigger of innate and adaptive immune response. Apoptosis and necroptosis differ in several aspects.

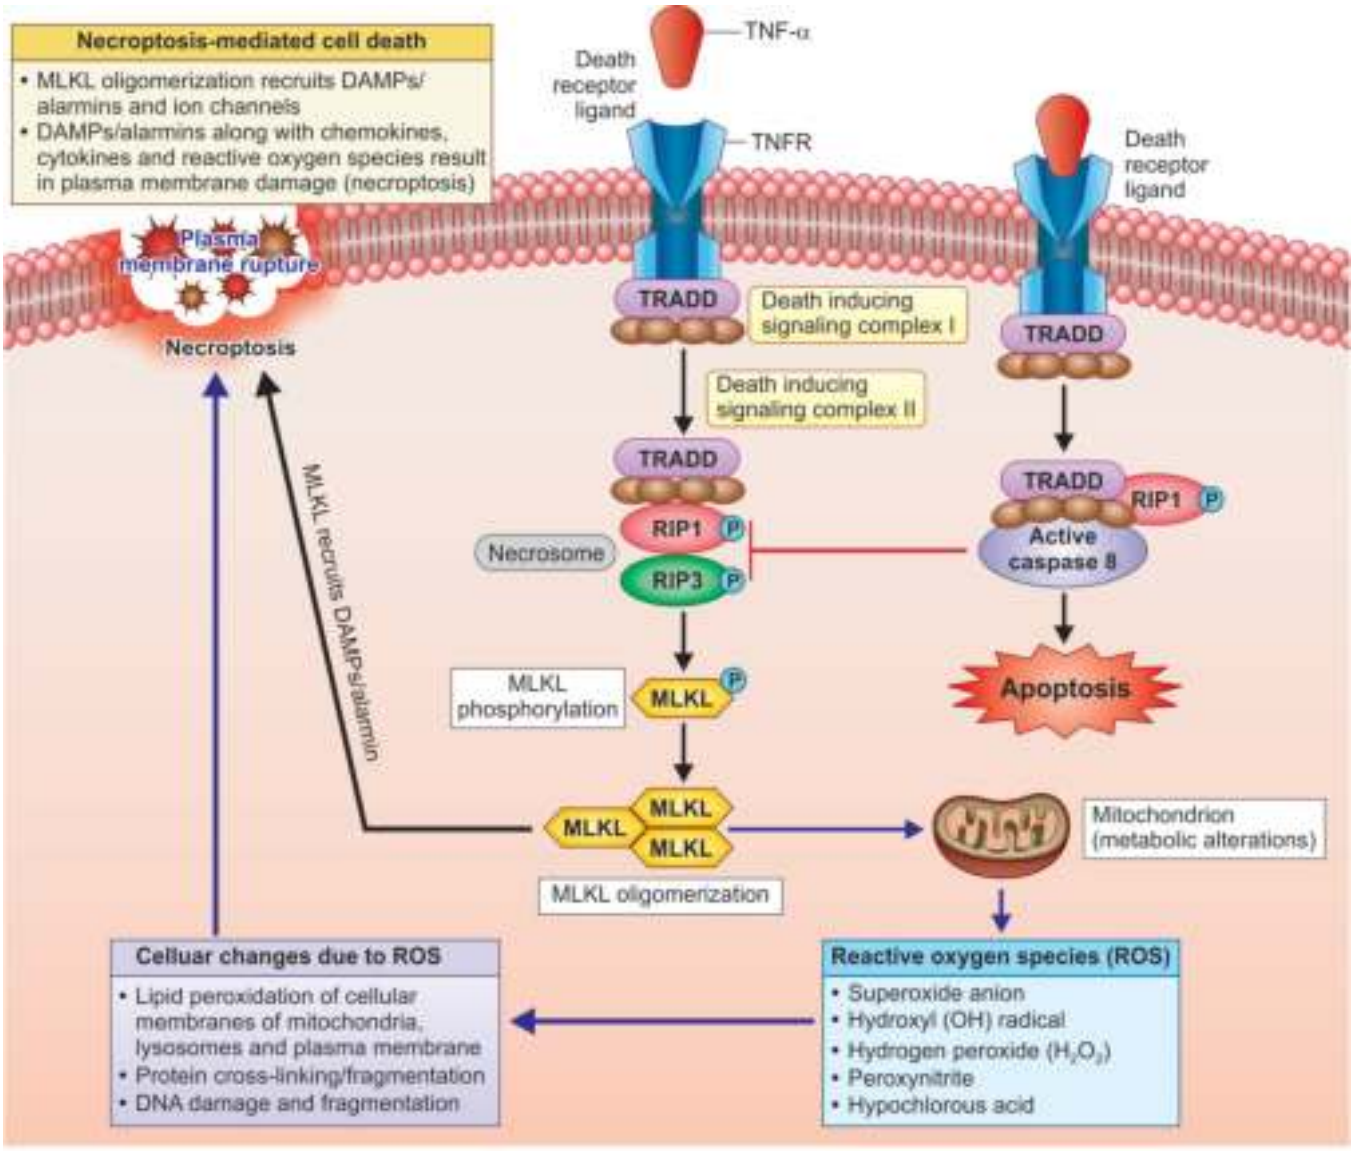
- Apoptosis mainly occurs during embryogenesis, while necrosis is more common during disease states. Apoptosis is mediated by caspases. Generally, in apoptosis, cells undergoing apoptosis maintain the integrity of their cell membranes and avoiding the exposure of intracellular contents to surrounding environment and there is no inflammatory response.
- Necroptosis may directly activate and modulate inflammatory responses by releasing intracellular contents through the disrupted plasma membrane



Morphologic changes	Apoptosis is characterized by cell shrinkage, chromatin condensation, nuclear fragmentation, plasma membrane blebbing without loss of cell integrity, organelles in the plasma membrane blebs, generation of apoptotic bodies.
Clearance	Degradation of apoptotic bodies by phagocytes (macrophages and surrounding cells).
Laboratory diagnosis	Techniques for detection of apoptotic cells include: (a) cytomorphologic changes, (b) DNA discontinuous fragmentation ladder assay on agarose gel electrophoresis, (c) TUNEL assay, executioner caspase 3 and annexin V (IHC), (d) p53, executioner caspase 3 activation, FasR, TNF-α, and TRAIL (IHC, RT-PCR, Western blot, ELISA), and (e) cytochrome c release (ELISA).

Fig. 1.27: Schematic representation of extrinsic (death receptor) pathway, intrinsic (mitochondrial) pathways of apoptosis. The extrinsic pathway is activated by signal such as Fas ligand (FasL), that on binding to the Fas receptor, forming a death-inducing complex by joining the Fas-associated death domain (FADD) to the death domain of the Fas receptor. Intrinsic pathway is activated by injurious stimuli such as reactive oxygen species and DNA damage that induce the release of mitochondrial cytochrome c into the cytoplasm. Both pathways of apoptosis differ in their induction and regulation. Both pathways culminate in the activation of 'executioner' caspases and activation of caspases by cytotoxic T cells.

into the surrounding environment. However, cells undergoing necroptosis are indistinguishable from that undergoing necrosis, using standard histologic techniques. Necroptosis requires that the function of caspase 8 either be disrupted or inhibited. Schematic representation of necroptosis is shown in Fig. 1.28.



Death receptor-dependent pathway of necroptosis	
• **Necroptosis** is an alternative mode of regulated kinase mediated cell death mimicking features of apoptosis and necrosis. It emerges as a backup mechanism, when apoptosis remains nonfunctional. It involves the release of intracellular 'danger signals' which results in considerable inflammation. • Necroptosis depends on receptor interacting protein kinase 3 (RIP3)-mediated phosphorylation of the pseudokinase mixed-lineage kinase domain-like (MLKL). • Necroptosis is demonstrated by immunohistochemistry and immunofluorescence employing antibodies to phosphorylated MLKL. Patients are treated with inhibitors of necroptosis such as necrostatins.	
Process	Mostly passive process, always pathological
Induction stimuli	Viruses, chemical exposure, radiation, endogenous or pathological factors
Morphologic changes	Swelling of cells and organelles, loss of plasma membrane integrity, receptor shedding, lysosomal exocytosis
Molecular changes	Acidosis, random degradation, release of cellular proteins
Clearance of necrotic cells	Necrotic cells phagocytosed by macrophages associated with significant inflammation

Fig. 1.28: Schematic representation of necroptosis. Necroptosis mimics features of necrosis and apoptosis. It involves the release of intracellular danger that results in considerable inflammation. Necroptosis requires protein RIPK3, a regulator of inflammation, cell survival and disease. Necroptosis is regulated by receptor-interacting protein kinase 1 and 3 (RIPK1, RIPK3) mediated phosphorylation of mixed-lineage kinase domain-like (MLKL). Necroptosis is demonstrated by immunohistochemistry and immunofluorescence microscopy by applying monoclonal antibody to phosphorylated MLKL.

MOLECULAR PATHOGENESIS

Necroptosis can be triggered by multiple stimuli such as toll-like receptors superfamily (TLR3, TLR4), death receptors (Fas/CD95, TNFR1), TNF-α, reactive oxygen species (ROS), interferon and some other mediators; but without activation of caspases (especially caspase 8); and regulated by receptor-interacting protein kinase 1 and 3 (RIPK1, RIPK3) mediated phosphorylation of mixed-lineage kinase domain-like (MLKL). Receptor-interacting protein kinase 1 and 3 (RIPK1, RIPK3) have been well recognized regulator of inflammation, cell survival and diseases. Key proteins involved in the necroptosis pathway are given in Table 1.32.

- Based on the driving forces, necroptosis is classified into three categories: (a) TNF-α mediated extrinsic necroptosis, (b) reactive oxygen species mediated intrinsic necroptosis, and (c) ischemia mediated necroptosis.
- All signaling components converge on RIP3 for the execution of necroptosis. TNF-α mediated extrinsic necroptosis occurs by activation of TNFR1 by engagement of TNF-α, which can trigger the formation of a prosurvival complex I containing receptor-interacting protein kinase 1 (RIPK1). When complex I undergoes ubiquitination, it leads to NF-κB mediated survival.
- Alternately, deubiquitination of RIPK1 due to ubiquitin carboxyl-terminal hydrolase or cellular targeted pharmacological inhibitors of apoptosis can activate complex IIa containing tumor necrosis factor receptor type 1 (TNFR1) associated death domain protein (TRADD), Fas-associated protein with death domain (FADD) and RIP1. In the process of caspase 8, complex II preferentially drives toward complex IIa resulting in apoptosis.
- However, in the presence of caspase 8 and presence of RIP3, complex II switches to pro-necroptotic complex IIb. The complex IIb induces necroptosis via the phosphorylation of mixed-lineage kinase domain-like (MLKL) by RIPK3 or complex IIb association of phosphoglycerate mutase family member 5 (PGAM-5), that results in opening of the mitochondrial permeability transition pore (MPTP) complexes.
- Necroptosis plays a role in the pathogenesis of biological processes involving central nervous system, cardiovascular system, respiratory system, urinary system, gastrointestinal system including liver and pancreas. Necroptosis may induce autoimmune disorders, organ transplant rejection and infections.

Table 1.32 Key proteins involved in the necroptosis pathway

Protein	Protein Role in Necroptosis
RIPK1	Protein kinase that recruits RIPK3 to necrosome, resulting in mutual phosphorylation of RIPK1 and RIPK3
RIPK3	Protein kinase that phosphorylates MLKL. RIPK3 is activated by phosphorylation by RIPK1 and subsequent oligomerization
MLKL	MLKL is kinase domain-like protein. Once phosphorylated by RIPK3, MLKL translocate to the cell membrane to mediate cell death.
Caspase 8	Caspase 8 inhibits necroptosis

Necroptosis disrupts caspase 8.

CLINICAL SIGNIFICANCE

Necroptosis can be both beneficial and deleterious during viral infections. HIV-1 can induce necroptosis of T cells. Hence, it is most important to block necroptosis in HIV infection. Hence, blockage of necroptosis is a primary concern for controlling certain viral diseases.

- **Necroptosis beneficial effects:** Necroptosis can be beneficial during certain viral infection. Cell death by the process of necroptosis occurs before completion of viral replication cycle, that can limit disease progression. For example, murine cytomegalovirus replication can be prevented by necroptosis.
  - Cancer is treated by radiotherapy and chemotherapy to induce apoptosis and kill malignant cells.
  - Resistance to these therapeutic modalities (i.e. radiotherapy and chemotherapy) occur due to the malignant cells resisting apoptotic death. In such cases, alternate mechanisms of cell death can be successfully induced by necroptosis.
- **Necroptosis harmful effects:** Necroptosis can induce various human disorders involving multiorgans. Patients are treated with inhibitors of necroptosis such as necrostatins. Necroptosis induced various human disorders are given in Table 1.33.

DIAGNOSTIC TECHNIQUES

Necroptosis is demonstrated by immunohistochemistry and immunofluorescence employing antibodies to phosphorylated mixed-lineage kinase domain-like (MLKL).

- Four types of immunohistochemical techniques include enzyme-linked immunosorbent assay, flow cytometry, immunoelectron microscopy and Western blotting.
- Necroptosis is diagnosed by detection of RIPK1, RIPK3; receptor interacting serine/threonine-protein kinase (immunofluorescent staining), MLKL (quantitative RT-PCR), RIPK1/RIPK3 complex, RIPK3, MLKL (Western blot), RIPK1, RIPK3, mixed-

Table 1.33 Necroptosis induced various human disorders

Organs/Systems	Disorders
Central nervous system	Neurodegenerative disorders (Alzheimer's disease, Huntington's disease, Parkinson's disease), cerebral stroke
Cardiovascular system	Coronary atherosclerosis, myocardial infarction, abdominal aortic aneurysm
Respiratory system	Chronic obstructive pulmonary disease (COPD), acute respiratory distress syndrome (ARDS)
Gastrointestinal tract	Inflammatory bowel disease
Liver	Hepatocellular injury
Pancreas	Pancreatitis
Urinary system	Acute renal injury
Autoimmune disorders	Psoriasis, rheumatoid arthritis
Organ transplantation	Organ transplant rejection
Infections	Influenza, West Nile

lineage kinase domain-like (MLKL) pseudokinase, enzyme-linked immunosorbent assay (ELISA), annexin V/propidium iodide + or annexin V +/propidium iodide + (flow cytometry), RIPK1/RIPK3 complex (immunoprecipitation and electron microscopy), RIP1 (immunoblotting), membrane translocation (immunofluorescence microscopy) and TRF (microscopy).

PYROPTOSIS

Pyroptosis is a highly inflammatory form of programmed cell death that occurs most frequently upon infection with intracellular pathogens. Caspase 1 is the most important enzyme that mediates pyroptosis, which controls intracellular pathogens by immune system. Schematic representation of pyroptosis is shown in Fig. 1.29.

MOLECULAR PATHOGENESIS

The immune cells recognize foreign danger signals within themselves by toll-like receptors (TLRs) and nod-like receptors (NLRs).

- Toll-like receptors recognize pathogen-associated molecular patterns (PAMPs), which are located either on cell surface or within endosomes. The resulting recognition by TLRs initiate signaling pathway including activation of transcription factors NF-kB and MAPKs signaling pathway. This in turn will be responsible for synthesis of inflammatory cytokines (IFN-α/-β, TNF-α and IL-12); and proinflammatory cytokines (IL-1β, IL-6, IL-8, IL-18) processed by cysteine mediated caspase 1.
- Nod-like receptors are similar to toll-like receptors, which also perform similar functions. The released inflammatory cytokines attract other immune cells to fight infection and contribute to inflammation in the tissues leading to rapid clearance of intracellular pathogens by host defense system.
- Pyroptosis requires three key molecules: (a) inflammasome formed in the macrophage within minutes of infection, (b) caspase 1 activation by inflammasome, and (c) membrane-pore forming effective gasdermin-D protein activation by inflammasome.
- Pyroptosis features cell membrane pore formation, cytoplasmic swelling, rupture of plasma membrane and the release of cytosolic contents such as damage-associated molecular pattern (DAMP) molecules, IL-1β and IL-18 into the extracellular environment, amplifying the local or systemic inflammatory effects. At the same time, the nucleus is damaged and important intracellular substrates are cleaved including cytoskeleton, chaperones, glycolytic proteins and caspase 7, which contribute to pyroptotic cell death.

CLINICAL SIGNIFICANCE

Pyroptosis acts as a defense mechanism to control intracellular pathogens (Salmonella, Shigella). The formation of inflammasome and the activity of caspase 1 determine the balance between pathogen resolution (clearance of infectious agents) and disease.

- In contrast, persistent inflammation will attract excessive immune cells, which may cause metabolic disorders (obesity, type 2 diabetes mellitus), autoimmune disorders and hepatocellular injury associated inflammation. Subsequent excessive production of IL-1β and IL-18 cause destruction of β-cells of islets of Langerhans' of pancreas and impaired secretion of insulin resulting in type 2 diabetes mellitus.
- Mutation in the gene NRPR3 encoding inflammasome leads to gain of function of inflammasome

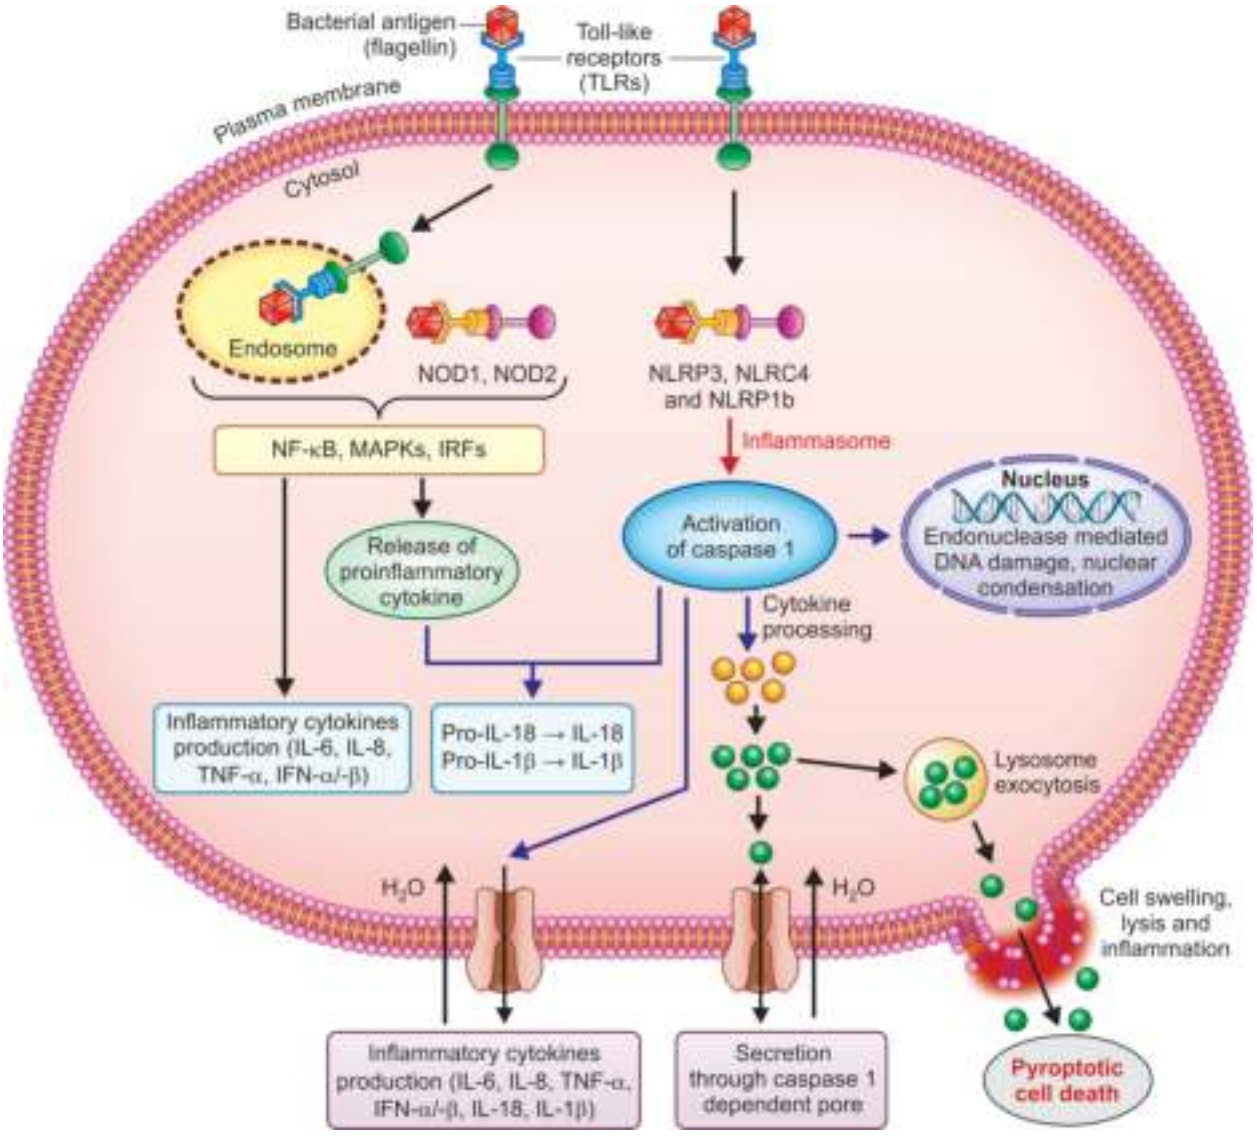


Fig. 1.29: Schematic representation of pyroptosis. Pyroptosis is recently identified caspase 1, interleukins (IL-6, IL-8, TNF-α, IFN-α/-β, IL-18, IL-1β) and inflammasome-dependent pathway of host cell death associated with inflammation. It is triggered by proinflammatory signals and a range of microbial infections. Necroptosis is seen primarily in inflammatory cells such as macrophages. Pyroptosis is stimulated by a range of microbial infections. Pyroptosis is characterized by cell swelling, plasma membrane lysis and endonuclease-mediated DNA damage, nuclear condensation.

resulting in autoinflammatory disorders called cryopyrinopathies such as Muckle-Wells syndrome, cold autoinflammatory syndrome and chronic infantile neurologic cutaneous and articular syndrome. All these autoinflammatory disorders present with sudden onset of fever and localized inflammation.

- Recent studies revealed that caspase 1 mediated pyroptosis drives CD4+ helper T cell depletion and inflammation by HIV. In pathogenic inflammation elicited by HIV infection leads to destruction of CD4+ helper T cells resulting in progression to AIDS. Caspase 1 inhibitors ('anti-AIDS') are safe therapeutic agents used to treat AIDS patients in clinical practice.
- Atherosclerotic plaques are formed by number of events: endothelial dysfunction, accumulation and oxidation of low-density lipoproteins (LDLs), recruitment monocytes and lymphocytes, migration and proliferation of smooth muscle cells; activation of proinflammatory cytokines; adherence of platelets.
  - Recent studies showed that risk factors of atherosclerosis could activate NLRP3 inflammasome in both endothelial cells and macrophages.
  - In addition, NLRP3 inflammasome-mediated pyroptosis plays an important role in the progression of atherosclerotic plaque.
  - Cholesterol crystals have been demonstrated in atherosclerotic plaque. Various studies revealed that

cholesterol crystals activate NLRP3 inflammasome that induces lysosomal damage resulting in release of IL-1β.

- Caspase 1 activation induced by NLRP3 inflammasome is a major mediator for pyroptosis, that takes part in the progression of atherosclerosis.
- NLRP3 inflammasome activation and related pyroptosis are potential novel therapeutic targets for myocardial ischemia–reperfusion injury (MIRI). Patients are treated with inhibitors of inflammasome.

DIAGNOSTIC TECHNIQUES

Pyroptosis can be analyzed by looking at caspase 1 activation by employed antibody, gasdermin-D cleavage, or by inhibiting key components of the pyroptotic pathway by immunohistochemistry and immunofluorescence employing specific antibodies against epitopes in gasdermin protein family members. Pyroptosis can be diagnosed by detection of bicinchoninic acid (BCA), caspase 1 (Western blot; RT-PCR), caspase 1, CD31 (TUNEL staining, terminal deoxynucleotidyl transferase and immunostaining), IL-1β, IL-18, pro-IL-1β, IL-1α, ELISA (enzyme-linked immunosorbent assay), FAM-FLICA-caspase 1 and Pl (flow cytometry), NLRP3 (NOD-like receptor protein 3), caspase 1, IL-1β, IL-18 (immunofluorescence microscopy), calcium (immunofluorescence microscopy), IL-1β, caspase 1, caspase 8 (immunostaining), determination of LDH (lactate dehydrogenase), phospholipid fatty acid (PLFA) (isotope labeling), DAB (3,3′-diaminobenzidine) staining and AEC chromogranic staining.

FERROPTOSIS

Ferroptosis is a regulated cell death dependent on iron that involves the depletion of intracellular antioxidants including reduced glutathione (GSH) and consequent accumulation of lethal lipid peroxides and reactive oxygen species (ROS) in cells, ultimately leading to oxidative cell death. Ferroptosis is inhibited by glutathione peroxidase 4 (GPX4), a major gatekeeper of intracellular redox homeostasis.

MOLECULAR PATHOGENESIS

Normally, glutathione (GSH) is an antioxidant capable of preventing damage to important cellular components caused by reactive oxygen species (ROS) such as oxygen-derived free radicals, lipid peroxides, and heavy metals. **Erastin** is a small molecule capable of initiating ferroptotic cell death.

- Glutathione peroxidase 4 (GPX4) converts glutathione into oxidized glutathione (GSSG) and reduces the cytosolic lipid peroxides to the corresponding alcohols. Inhibition of **glutathione peroxidase 4** activity can lead to the accumulation of lethal lipid peroxides, which is marker of ferroptosis.
- Lipid peroxides and iron are two major participants of ferroptosis. Thus, iron chelators (e.g. deferoxamine) and several lipophilic antioxidants (e.g. α-tocopherol) can rescue ferroptosis. Additionally, reactive oxygen species (ROS) produced through Fenton reaction catabolized by iron contributes to the initiation of ferroptosis.
- Ferroptosis diagnosed by detection of ATP5G3, PTGS2, IREB2 (iron responsive element binding protein 2), CS, RPLS (quantitative RT-PCR), JNK, ERK1/ERK2 (extracellular signal-regulated kinase 1), p38, LC3-I/LC3-II, NRF2, p62, Slc7a11 (Western blot), Fe^{++} release assay (flow cytometry), GPX4; glutathione peroxidase 4, ELISA (enzyme-linked immunosorbent assay), NADP/NADPH, LC3 (immunofluorescence microscopy).
- Recent studies revealed that ferroptosis is closely related to the pathophysiologic processes of many disorders, such as tumors, nervous system disorders, heart diseases, liver diseases, gastrointestinal diseases, pancreatic diseases, lung diseases and kidney diseases. Ferroptosis induced disorders are given in Table 1.34.

Table 1.34 Ferroptosis induced disorders

Organ/System	System-related Disorders
Nervous system	Neurodegenerative diseases, cerebral stroke, traumatic brain injury
Cardiovascular system	Ischemia-perfusion injury
Liver	Hepatocellular carcinoma, liver fibrosis, ischemia-related injury
Gastrointestinal tract	Gastric carcinoma, colorectal carcinoma
Lungs	Lung carcinoma
Kidney	Acute renal injury, ischemia-related injury, clear cell variant of renal cell carcinoma

AUTOPHAGY

Term autophagy, nonapoptotic cell death is derived from Greek words '*auto*' meaning self and '*phagy*' meaning eating, that maintains homeostasis.

- Autophagy is the process that delivers cytoplasmic material of endogenous (cell's own contents such as mitochondria, endoplasmic reticulum and peroxisomes) or exogenous material (misfolded proteins) to the lysosomes for degradation and recycle nutrients for new cell formation and survival.

- Cell features in autophagy include vacuolization, degradation of cytoplasmic contents, slight condensation of chromatin.

MOLECULAR PATHOGENESIS

Autophagy is initiated in response to extracellular or intracellular stress signals such as starvation, hypoxia, deprivation of nutrients and growth factors, accumulation of misfolded proteins, endoplasmic reticulum stress, pathogens, irradiation, chemotherapy and change in cell volume. Autophagy handles damaged cellular organelles and protein aggregates.

- Damage to mitochondria causes disruption of electron transport and dissipates the electrochemical gradient across the mitochondrial membrane.
  - Increased reactive oxygen species (ROS) result in oxidative damage to mitochondria leading to recruitment of cytosolic proteins, parkin and a ubiquitin-like (UBL) protein.
  - The complex of fragmented mitochondria-parkin-ubiquitin-like protein binds to p62. Proteins that have sustained oxidative damage are conjugated to UBL protein and form aggregates, which are then bound by p62.
  - The p62-bound complexes with damaged mitochondria and aggregated proteins are recognized by a specific receptor in the phagophore, thereby resulting in autophagy.
- Defective autophagy plays important role in the pathogenesis of cancer, infectious diseases and neurodegeneration.

TYPES OF AUTOPHAGY

Autophagic degradation is generally divided into three categories: microautophagy, macroautophagy, and chaperone-mediated autophagy. Schematic representation of macroautophagy is shown in Fig. 1.30. Schematic representation of chaperone-mediated autophagy is shown in Fig. 1.31. Comparison of macroautophagy, microautophagy and chaperone-mediated autophagy is given in Table 1.35.

Microautophagy

In microautophagy, cytosolic cargoes are phagocytosed by inward invagination of lysosomal membrane for delivery. The contents are then degraded by lysosomal enzymes. Insulin suppresses autophagy in the liver, while glucagon encourages it.

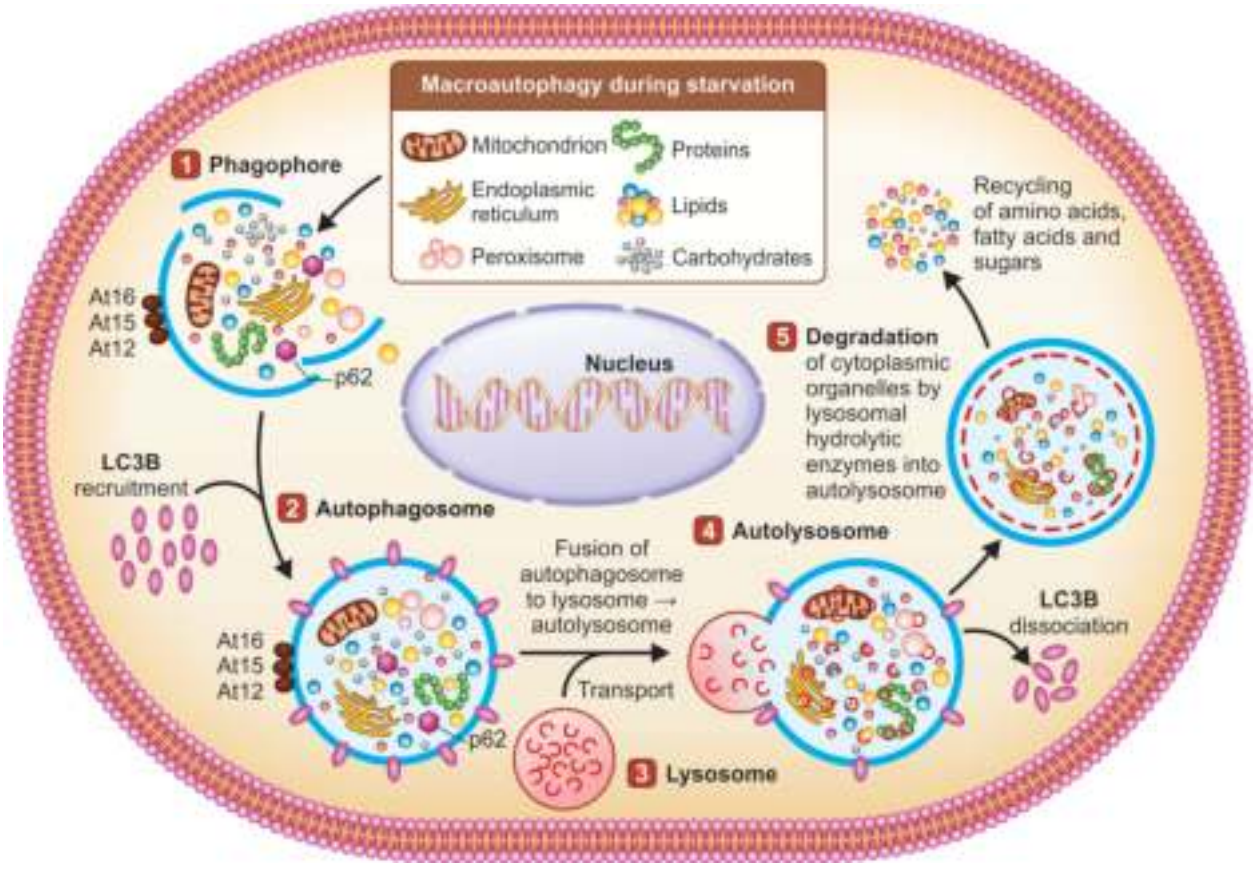

Fig. 1.30: Schematic representation of macroautophagy. Macroautophagy is a form of autophagy process substrates are sequestrated within cytosolic double-membrane vesicles termed autophagosomes before it fuses with the lysosomes. The substrates of macroautophagy include superfluous and damaged organelles, cytosolic proteins and invasive microbes.

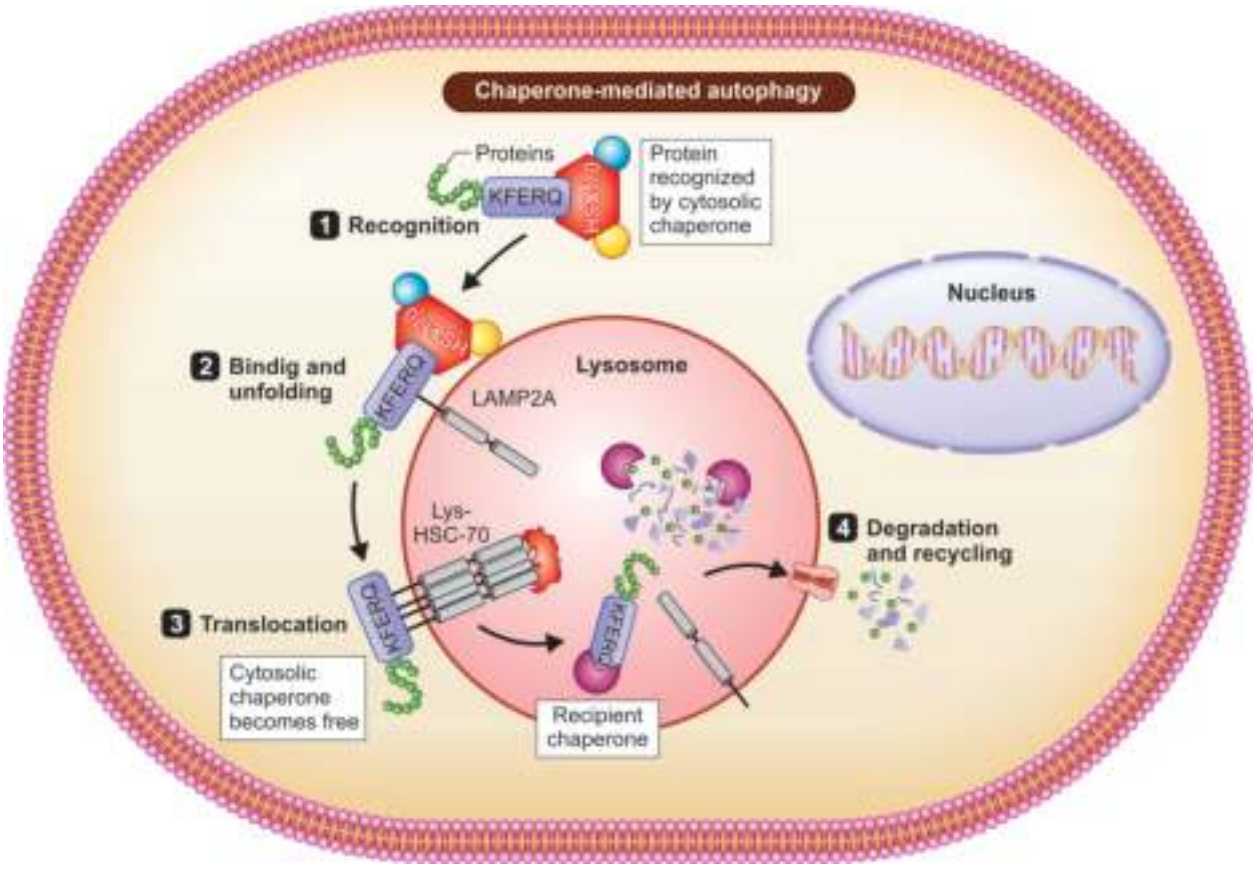

Fig. 1.31: Schematic representation of chaperone-mediated autophagy. It is a lysosomal pathway of proteolysis that degrades 30% of cytosolic proteins under conditions of prolonged nutrient deprivation. Molecular chaperones in the cytosol and in the lysosomes stimulate this proteolytic pathway.

Table 1.35 Comparison of microautophagy, macroautophagy and chaperone-mediated autophagy

Definition	Morphological Features	Laboratory Diagnosis
Microphagy (normal physiologic process digesting soluble cytosolic proteins)		
Transport of cytoplasmic contents within lysosomal membrane invagination or deformation and phagocytosis of organelles	Lysosomal membrane invagination or deformation	Transmission electron microscopy
Macrophagy (stress-related process digesting soluble cytosolic proteins)		
Cargo is transported to the lysosome by *de novo* formation of autophagosomes and phagocytosis of organelles	Membrane expansion and bend; phagophore nucleation and elongation and formation of autophagosome	▪ Electron microscopy ▪ Immune colloidal gold technique ▪ Immunofluorescence microscopy (GFP-LC3 or mRFP-GFP-LC3) ▪ Western blot (LC3-II/LC1, Beclin, ATG5, ATG7, p62 and phosphorylation status of ULK) ▪ Radiolabeling (LDH sequestration) ▪ MDC staining
Chaperone-mediated autophagy (stress-related and receptor-mediated process digesting only one letter code for amino acid sequence)		
KFERQ tagged, the one letter code for amino acid sequence Lys-Glu-Phe-Arg-Gln		
Unfolded proteins containing the KFERQ motif are transported directly across the lysosomal membrane through the action of cytosolic chaperones without phagocytosis of organelles	Multimerization of LMP2A binding to the luminal side of the lysosomal membrane by HSP90	▪ Immunofluorescence microscopy (Hsc with lysosomal markers) ▪ Western blot (LAMP2A) ▪ Radiolabeling (LAMP2A)

Macroautophagy

Macroautophagy is the major form of autophagy involving the sequestration and transportation of cytoplasmic organelles in the cytosol in a double membrane bound autophagic vacuoles. In macroautophagy, cytoplasmic organelles (mitochondria, endoplasmic reticulum, Golgi appratus, soluble protein, aggregated protein) are directly sequestrated by the lysosomes by an open membrane, called 'phagophore'.

- Upon closure by fusion, phagophore becomes autophagosome, which then delivers its content to a lysosome. Lysosomal enzymes degrade the contents to small molecules for reutilization.
- Macroautophagy is regulated by the mammalian target of rapamycin (mTOR) and AMP-activated kinase (AMPK) pathways. Macroautophagy inhibits mTOR and stimulates unc-51-like autophagy-activating kinase (ULK) and class III phosphatidylinositol-3 kinase complex.
- Further, the phagophore formation is concluded by light chain 3 (LC3) and autophagy-related gene 12 systems. Then the autophagosome can fuse with the lysosome to form an autolysosome for substrate degradation in the lysosome through autophagosomes.
- In selective macroautophagy, there are receptors like p62 that recognize the cargo proteins and target them to the autophagosome.

Chaperone-mediated Autophagy

Chaperone-mediated autophagy is a lysosomal pathway of proteolysis, in which target proteins with a KFERQ sequence are recognized by a cytosolic chaperone heat stroke cognate 70 (HSC-70) and form a chaperone complex.

- Subsequently, these chaperone-mediated autophagy substrates are recognized by lysosomal-receptor proteins (LAMPs) and translocated to the lysosomal interior through the action of LAMP-2A, where they are received by a second chaperone.
- Targeted intracellular proteins are degraded in the lysosome. The original, extralysosomal chaperone survives to work further.

LABORATORY DIAGNOSIS

Autophagy is diagnosed by detection of immune colloidal gold technique, GFP-LC3 (green fluorescent protein-light chain 3) or mRFP-GFP-LC3 (immunofluorescence microscopy), LC3-II/LC3-1, beclin, ATG5, ATG7 (autophagy-related protein 5/7), p62 and phosphorylation status of ULK (unc-51-like kinase) (Western blot), LDH (lactate dehydrogenase) sequestration, MDC staining, HSC-70 with lysosomal markers (immunofluorescence microscopy) and LMP2A assay (Western blot).

LYSOSOMAL-DEPENDENT CELL DEATH

Lysosomes contain numerous hydrolases that can degrade most cellular macromolecules. Lysosomal membrane permeabilization (LMP) and consequent leakage of the lysosomal hydrolases into the cytosol results in lysosomal-dependent cell death.

- **Reactive oxygen species (ROS):** Reactive oxygen species (ROS) and ischemia-reperfusion injury contribute to lysosomal membrane permeabilization. Various oxidative stimuli include drugs, metals, ionizing radiation, ischemia-perfusion injury, inflammation and neurodegenerative disorders.
  - Upon oxidative stress, excess H_2O_2 diffuses into lysosomes where it reacts with redox active iron, resulting in the production of hydroxyl radicals in Fenton-type reaction.
  - Hydroxyl radicals are highly reactive, that can destabilize the lysosomal membrane by causing lipid peroxidation and damaging lysosomal membrane proteins.
  - Additionally, reactive oxygen species (ROS) contribute lysosomal membrane permeabilization by activating Ca^{++} channels or altering the activity of lysosomal phospholipase A2 enzyme. Various antioxidants and redox regulators as well as iron-binding proteins confer protection against oxidative stress-induced lysosomal membrane permeabilization.
- **Viral proteins:** Virus infection requires the transmission of viral proteins into the cell, which mostly occurs by penetrating the endolysosomal membranes with viral entry proteins that become active in the acidic environment. Nonenveloped viruses (adenovirus, rhinovirus HRV14, poliovirus) contribute to lysosomal membrane permeabilization resulting in release of lysosomal contents into the cytosol.

Pathology Pearls: Cellular Senescence and Mitotic Catastrophe

The term 'cellular senescence' refers a pathophysiologic process by which the cells permanently lose their proliferative capacity (i.e. permanent state of cell cycle arrest) subjected to different stresses, while remaining viable and metabolically active. Senescence is therefore a cellular defense mechanism that prevents cells to acquire an unnecessary damage.

- Senescence takes place in several tissues during physiologic and pathologic processes such as tissue remodeling, embryogenesis, cell injury, cellular aging and cancer. In tissue remodeling and embryogenesis, senescent cells are required for tissue repair and proper development of the embryo.
- In cancer, senescent cells act as potent barrier to prevent tumorigenesis. Research is going on to induce senescence in cancer cells by pharmacological interventions in the light of the development of novel therapeutic targets.

- Mitotic catastrophe is a mechanism of delayed mitotic-linked cell death resulting from aberrant mitosis during the metaphase/anaphase transition, which occurs due to combination of deficient cell-cycle checkpoints (DNA structure checkpoints and the spindle assembly checkpoint) and cellular damage.
- In aberrant mitosis, cells fail to execute apoptotic program divide asymmetrically in the next round of cell division with subsequent degeneration of aneuploid cells.

APOPTOSIS

Apoptosis word is derived from Greek in 1972, that means dropping of the leaves and petals from flowers. Apoptosis is an 'ATP-dependent' programmed cell death ('cell suicide') that enables the removal of potentially harmful single or group of DNA damaged cancerous cells, virus infected cells, or otherwise unwanted cells in a regulated manner. Hence, apoptotic signaling pathways, help to safeguard the 'genomic stability'.

- Apoptosis can be induced by a broad range of injurious stimuli such as deprivation of growth factors, loss of hormone stimulation, DNA damage, ionizing radiation, chemotherapeutic drugs, accumulation of misfolded proteins (endoplasmic reticulum stress), reactive oxygen species (ROS), replication stress, increased cytosolic calcium, microtubular alterations or mitotic defects.
- Apoptosis is mediated by molecular pathways that culminate in the activation of a family of cysteine proteases, known as the caspases in order to maintain tissue homeostasis during embryogenesis and postnatal life, which orchestrate the dismantling and clearance of the apoptotic cell.
- Inducers of apoptosis are growth factor withdrawal, TNF family, calcium, nutrient deprivation, toxins, ultraviolet radiation, γ-radiation and oncogenes. A cell that has been treated with an apoptotic inducer can also initiate apoptosis that does not rely on caspase activation.
- Apoptosis does not induce inflammatory response. In contrast to apoptosis, necrosis is an energy-independent process that can cause inflammation.
- Apoptotic cells can be detected by hematoxylin and eosin-stained section examination by light microscopy, electronic microscopy, gel electrophoresis (showing typical DNA ladder pattern) or quantification using fluorescent dyes, flow cytometry, *in situ* end labeling (ISEL) method, terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL), and caspase 3 by immunohistochemistry.
- Dysregulation of apoptotic signaling pathways can cause cancerous growth or autoimmune disorders, while accelerated apoptosis is evident in degenerative disorders, immunodeficiency disorders and infertility. Comparison of necrosis and apoptosis is given in Table 1.36.

Table 1.36 Comparison of necrosis and apoptosis

Characteristics	Necrosis	Apoptosis
Major pathways involved		
Definition	Accidental cell death by injurious agents	Controlled (programmed cell death) results in nuclear fragmentation
Provoking stimuli	Usually associated with a pathologic process such as severe hypoxia, toxins, massive insult, conditions of ATP depletion, metabolic stress, absence of nutrients, changes in pH	Physiologic (embryology, thymus involution), and pathologic (removal of misfolded proteins, removal of neutrophils in acute inflammation) conditions without ATP depletion
Enzyme(s) activation	Phospholipase, protease and endonuclease activation	Initiator caspases (2, 8, 9, 10, 11, 12), executioner caspases (3, 6, 7) activation by intrinsic and extrinsic pathways
ATP level	ATP depletion and metabolic disruption	ATP and protein synthesis sustained

Contd...

Table 1.36 Comparison of necrosis and apoptosis (*Contd...*)

Characteristics	Necrosis	Apoptosis
Protein synthesis	Cessation of protein synthesis	Requires protein synthesis
Energy requirement	Energy independent	Energy dependent
Gross morphological changes		
Gross findings	Disruption of normal tissue architecture, i.e. infarct and later scarring	Minimal changes or atrophy without scarring
Histologic changes		
Extent of cell death	Contiguous regions of cell death in whole fields	Death of single cells separating from neighbor cells scattered throughout the affected tissue
Inflammatory response	Present	Absent
Cell size	Cell swelling	Cell shrinkage
Cell borders	▪ Plasmalemmal blebs without organelles (loss of cell borders with irregular fragmentation) ▪ Cell lysis with release of intracellular contents	▪ Zeiotic blebs containing large organelles (formation of round bodies, often within a clear halo) ▪ Cell fragmentation into apoptotic bodies
Nuclear changes	▪ Nuclear swelling and karyolysis ▪ Random DNA degradation (irregular chromatin clumping, pyknosis, karyorrhexis, karyolysis; rupture of nuclear envelope)	▪ Chromatin condensation and fragmentation (apoptotic bodies) ▪ Intranucleosomal DNA degradation (chromatin condensation into caps or crescents, within round nuclear bodies; preservation of nuclear envelope)
Ultrastructural changes		
Cell membrane	Swelling and loss of surface structures with blebbing and loss of apical portions of cytoplasm	Cell condensation with formation of membrane blebs or buds in degenerating cells
Cytoplasm	Rarefaction of cytoplasm followed by condensation after death	Condensation of cytoplasm followed by rarefaction after ingestion by phagocytes
Cell organelles	Swelling and loss of morphology organelles	Organelles preserved
Mitochondria	Mitochondrial swelling and dysfunction	Mitochondrial permeabilization
Lysosomes	Lysosomes abnormal, rupture with release of enzymes	Lysosomes unaffected and remain intact
Internal and external cell membranes	Rupture of cell membranes, bursting of cell and leakage of cell contents	Preservation of cell membranes and nuclear envelope
Intracellular calcification	Present	Absent
Molecular changes		
Gene involved	Gene activity none	BCL-2 (antiapoptotic), BAX (proapoptotic) and BAK (proapoptotic) genes involved
Chromosomal DNA	Random cleavage of chromosomal DNA	Cleaved at specific sites
Ion pump function	Ion pumps lost	Ion pumps continue to function
Intracellular calcium	Unaffected	Increased
Sequelae		
Lysosomal enzymes	Release of intracellular enzymes into extracellular compartment	Retention of intracellular enzymes within the apoptotic bodies
Neutrophils and macrophages	Tissue infiltrated by neutrophils followed by macrophages, which phagocytose dead cells	Ingestion of apoptotic cells by tissue macrophages or surrounding healthy parenchymal cells
Inflammation and scarring	Active inflammation with scarring of tissue	Atrophy with stromal collapse without scarring

THREE PATHWAYS OF APOPTOSIS

Apoptosis is initiated via three molecular pathways: (a) extrinsic (signal through cell membrane death receptors such as Fas or tumor necrosis factor) pathway, (b) intrinsic mitochondrial (release of cytochrome c from mitochondria through an extracellular domain) pathway, and (c) CD8+ cytotoxic T cells/NK cells (granzyme B/perforin) mediated pathway. Schematic representation of apoptosis mediated by extrinsic (death receptor), intrinsic (mitochondrial) and perforin/granzyme (CD8+ cytotoxic T cells and natural killer cells) pathways is shown in Fig. 1.32. Schematic representation of apoptosis mediated by extrinsic (death receptor) and intrinsic (mitochondrial) pathways is shown in Fig. 1.33. Schematic representation of intrinsic (mitochondrial) and extrinsic (death receptor) pathways of apoptosis is shown in Fig. 1.34.

- Apoptosis cascade can be categorized into three phases: (a) signal activation-induction of apoptosis, (b) regulation and execution, and (c) cellular structural alterations.
- The caspases trigger apoptosis by cleaving specific proteins present in cytoplasm and nucleus of all cells in the inactive precursors or procaspases, which are usually activated by cleavage by other caspases.
- Extrinsic death receptor pathway of apoptosis begins with a pro-death signal originating from outside the cell, most often by CD8+ cytotoxic T cells/natural killer cells, granzyme B/perforin-mediated pathway, when conditions in the extracellular environment determine that a cell must die.
- Intrinsic mitochondrial pathway of apoptosis begins when an injury occurs within the cells and depends on the release of cytochrome c and proapoptotic proteins from the intermembrane space of mitochondria.
- During intersection of the extrinsic and intrinsic pathways of apoptosis, a receptor-ligand interaction activate caspase 8, which may in turn cleave cytosolic BID to yield truncated derivative, BID. In turn, tBID translocates to mitochondria, thereby activating the intrinsic pathway of apoptosis. Sequence of events includes: caspase 8 → activates BID → cleavage to truncated derivative BID → activates intrinsic (mitochondrial) pathway.
- CD8+ cytotoxic T cell/NK cell (granzyme B/perforin) mediated pathway induces apoptosis releasing two types of preformed cytotoxic proteins such as granzyme B and perforin. Granzyme B induces apoptosis of target cell, and the pore forming perforin protein, which punches holes in the target cell membrane through which the granzyme B can enter the target cell to induce apoptosis.
- All three pathways of apoptosis can flow independently and converge until the last step of DNA degradation by executioner caspases (3, 6, 7). The executioner caspases disrupt cytoskeletal components or cell replication machinery, changes to cell surface molecules, which facilitate phagocytosis. Apoptotic cells are removed by macrophages and surrounding epithelial cells.
- Apoptosis inducible factor (AIF) is a caspase-independent pathway of apoptosis, which regulates intrinsic or mitochondrial pathway. AIF migrates to the nucleus, passes through the membrane, binds to DNA and triggers the characteristic condensation of chromatin, which is the hallmark of apoptosis. Role of caspases and mitochondrial proteins in apoptosis is given in Table 1.37.

Pathology Pearls: Regulation of Apoptosis by Gene Products

- Mitochondria play a pivotal role in apoptosis, which contain genes regulating proapoptotic and antiapoptotic proteins.
- Apoptosis is regulated by caspases and gene regulating proteins and p53 tumor suppressor proteins. Glucocorticoids induce apoptosis. Sex steroids inhibit apoptosis.
- Proapoptotic proteins facilitate apoptosis. When cells are deprived of survival signals or subjected to stress, BCL-2 and/or BCL-X are lost from the mitochondrial membrane and replaced by proapoptotic members of the family, such as BAX, BAK, and BIM.
- Antiapoptotic proteins normally reside in mitochondrial membranes and the cytoplasm. Growth factors and other survival signals stimulate the production of antiapoptotic members of the BCL-2 family of protein.
- Mitochondrial proteins, i.e. BAD, BID and PUMA that regulate balance between proapoptotic and antiapoptotic proteins.
- DNA is protected by p53 tumor suppressor gene. The p53 protein induces apoptosis by several mechanisms: (a) it downregulates transcription of the antiapoptotic protein: BCL-2, (b) it upregulates transcription of the proapoptotic genes: BAX, BAK and BIM, (c) it activates proteins that arrest the cell in G1 phase of cell cycle, permitting time for DNA repair to go ahead. If the DNA damage is irreparable, p53 tumor suppressor gene activates mechanisms that terminate in apoptosis.

EXTRINSIC DEATH RECEPTOR PATHWAY OF APOPTOSIS

In extrinsic death receptor pathway of apoptosis, ligand–receptor interactions lead to caspase activation. A number of ligands bind their corresponding death receptors, which include FasL/FasR, TNF-α/TNFR1, Apo3L/DR3, Apo2L/DR4 and Apo2L/DR5. The sequence of events that define the extrinsic pathway of apoptosis are best characterized with TNF-α/TNFR1 and FasL/FasR models.

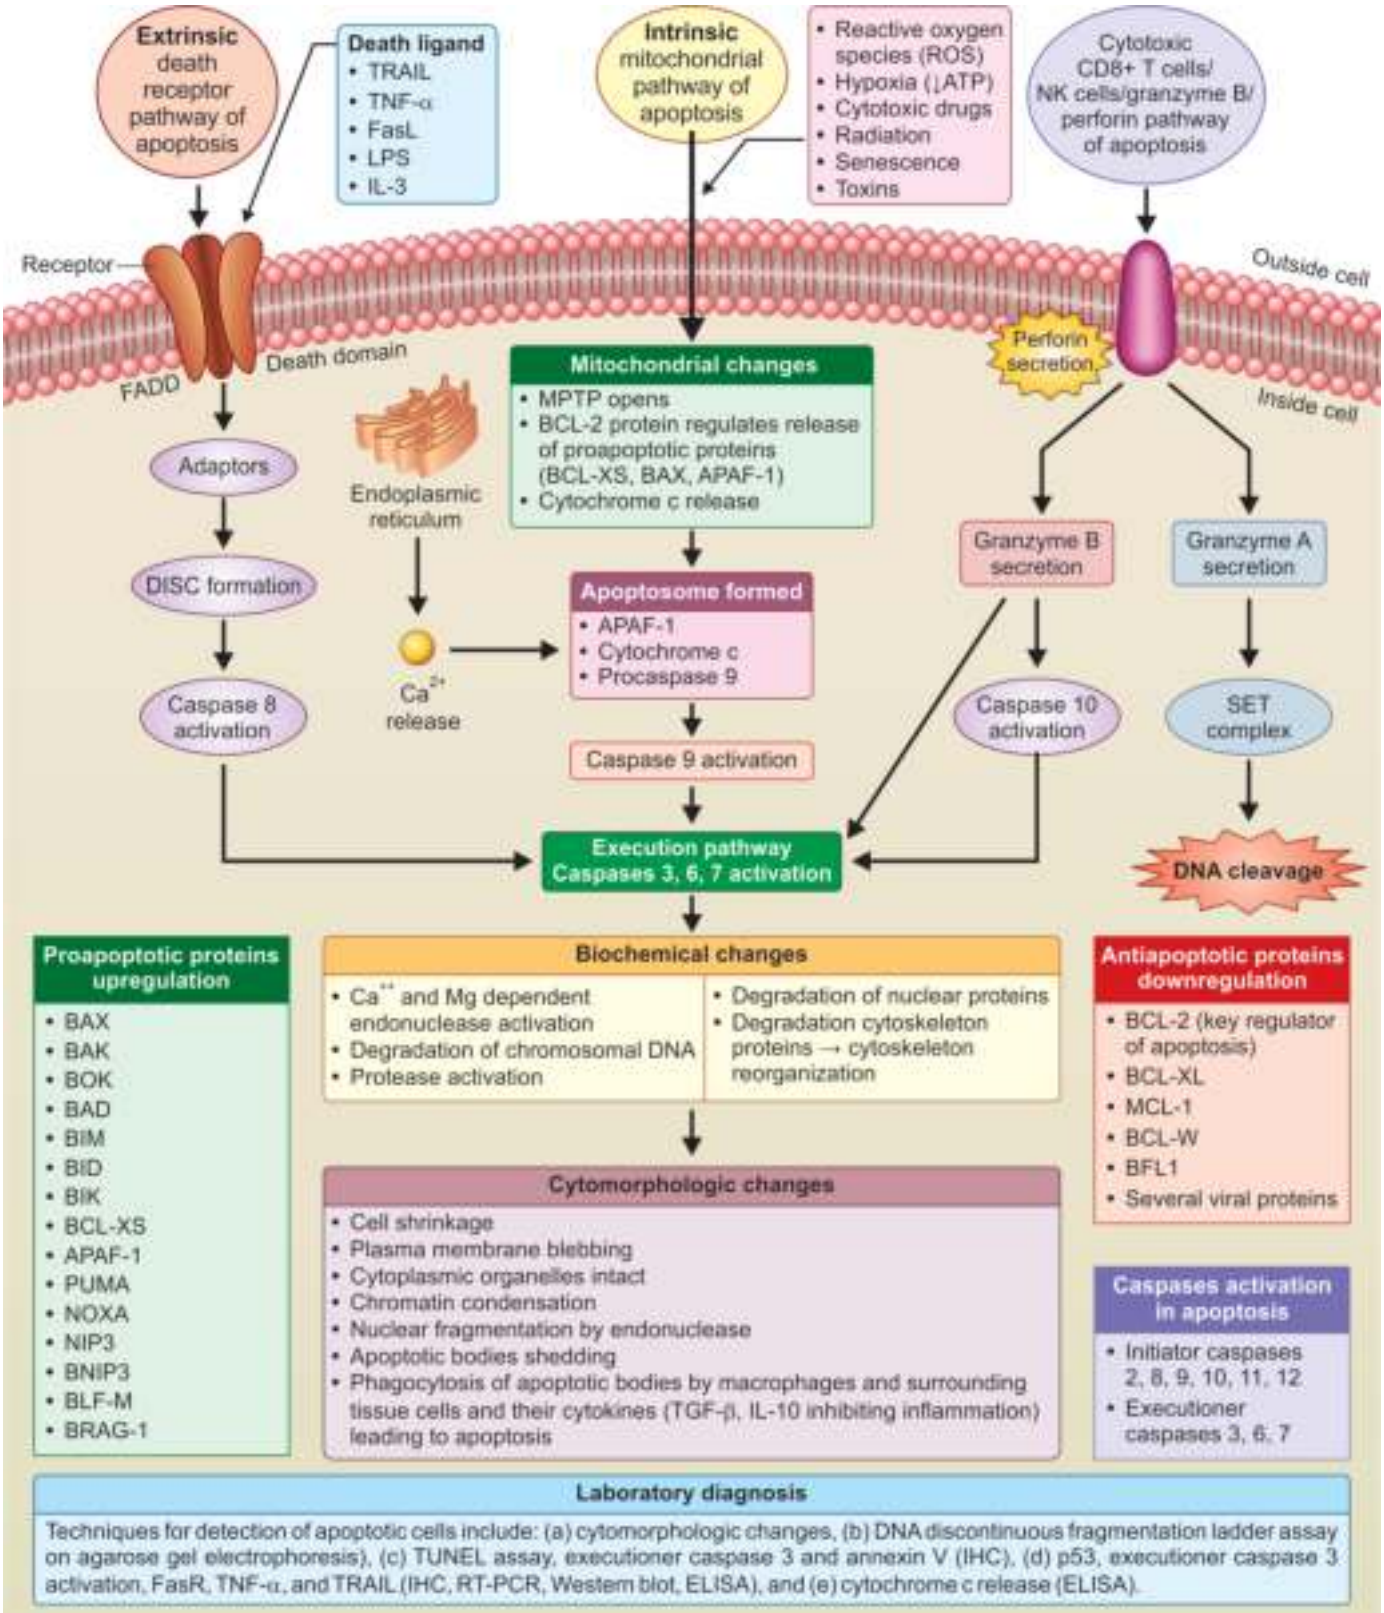

Fig. 1.32: Schematic representation of apoptosis mediated by extrinsic (death receptor), intrinsic (mitochondrial) and perforin/granzyme (cytotoxic T cells and natural killer cells) pathways. Apoptosis is characterized by cell shrinkage, plasma membrane blebbing, intact cytoplasmic organelles, chromatic condensation, nuclear fragmentation by endonuclease, apoptotic cell bodies shedding and phagocytosis of apoptotic bodies by macrophages and surrounding epithelial cells and lack of inflammation.

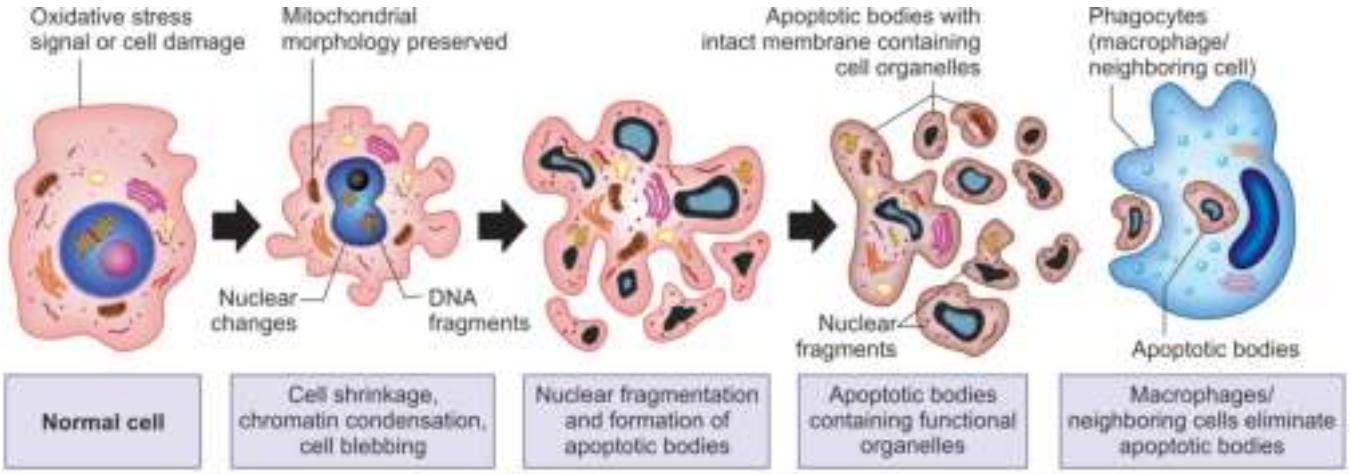

Apoptosis (programmed cell death)	
Induction stimuli	Oxidative stress, death receptor ligands and chemotherapy
Process	Active process executed by caspases (physiologic or pathologic processes)
Sequence of events to induce apoptosis in normal cell	***Role of TP53 (p53 protein) pathway to induce apoptosis in normal cell:*** Phosphorylated p53 protein → Activation of **BAX, PUMA** and **NOXA** → **Apoptosome** (APAF, cytochrome c, procaspase) → Activated **caspases 9 and 3** → **Apoptosis**
Sequence of events to induce apoptosis under pathologic state	***Extrinsic death receptor pathway of apoptosis:*** **FasL** → **Fas** → **FADD** (Fas activated death domain) → Activation of **caspase 8** → Activation of **caspases 3, 6, 7** → **Apoptosis** ***Intrinsic mitochondrial pathway of apoptosis:*** **BCL-2** protein → **BAX** proapoptotic protein → **Mitochondrial cytochrome c leakage/APAF-1** (apoptotic protease activating factor) → **Apoptosome** (cytochrome c + APAF-1 + caspase 9) → Activation of **caspase 9** → Activation of **caspases 3, 6, 7** → **Apoptosis** • Both extrinsic and intrinsic pathways can flow independently until the last step of DNA degradation by executioner caspases. The caspases cause proteolysis of specific substrates resulting in various morphological and biochemical characteristics in cells. • **Initiator caspases or upstream caspases like 2, 8, 9, 10, 11 and 12** • **Effector caspases or downstream caspases like 3, 6 and 7**
Cytomorphologic changes	Cell shrinkage, chromatin condensation, nucleus undergo fragmentation, plasma membrane blebbing without loss of cell integrity, organelles located in the plasma membrane blebs, and generation of apoptotic bodies.
Molecular changes	Cleavage of caspases, poly (ADP-ribose) polymerase (PARP involved in DNA repair) and nuclear fragmentation by endonucleases.
Clearance	Apoptotic bodies containing functional organelles are phagocytosed by neighboring cells and macrophages.
Laboratory diagnosis	Techniques for detection of apoptotic cells include: (a) cytomorphologic changes, (b) DNA discontinuous fragmentation ladder assay on agarose gel electrophoresis, (c) TUNEL assay, executioner caspase 3 and annexin V (IHC), (d) p53, executioner caspase 3 activation, FasR, TNF-α, and TRAIL (IHC, RT-PCR, Western blot, ELISA), and (e) cytochrome c release (ELISA).

Fig. 1.33: Schematic representation of apoptosis mediated by extrinsic (death receptor), intrinsic (mitochondrial) pathways. Both pathways can flow independently until the last step of DNA degradation by executioner caspase. Apoptosis is characterized by cell shrinkage, chromatin condensation, nuclear fragmentation by endonuclease, plasma membrane blebbing, generation and phagocytosis of apoptotic bodies by macrophages and surrounding epithelial cells and lack of inflammation.

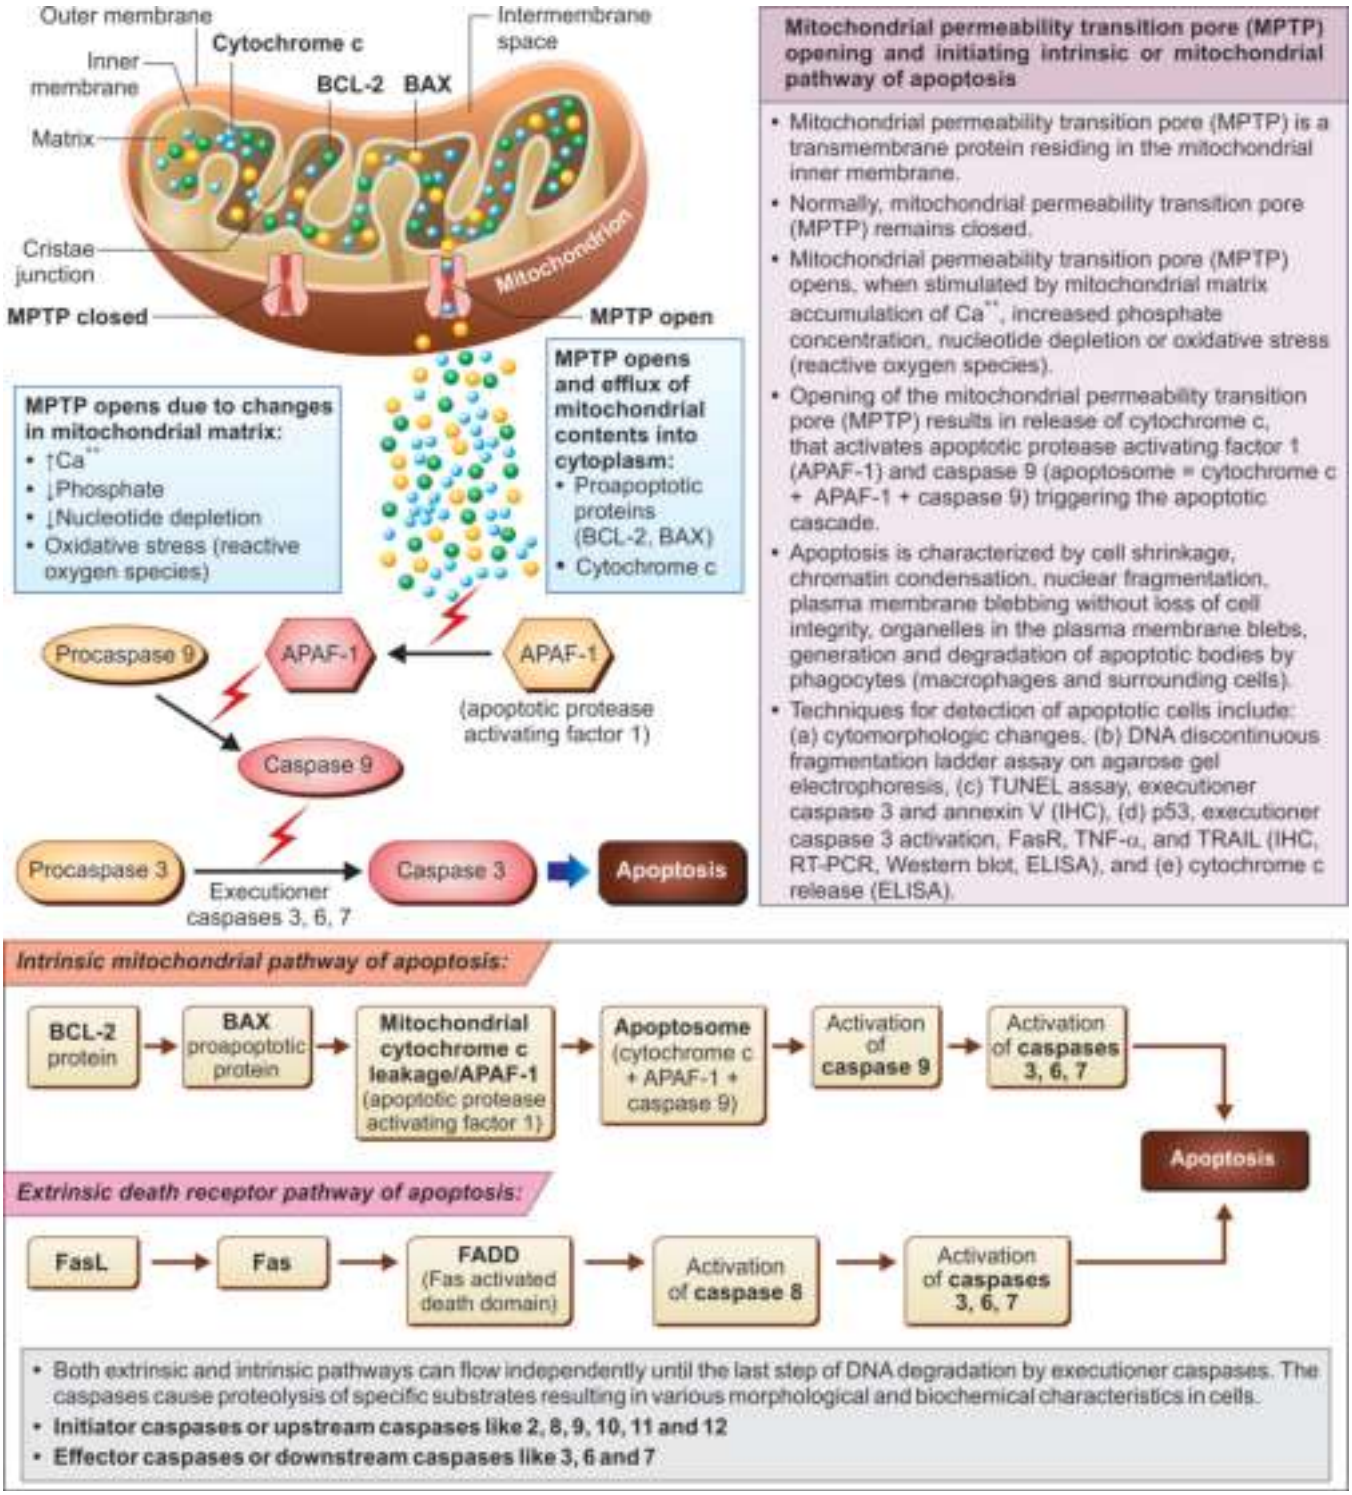

Fig. 1.34: Schematic representation of intrinsic (mitochondrial) and extrinsic (death receptor) pathways of apoptosis. Both pathways can flow independently until the last step of DNA degradation by executioner caspases, which cause proteolysis of specific substrates resulting in various cytomorphological and biochemical characteristics in cells.

- The intracellular portion of all these receptors contains a cytoplasmic region of about 80 amino acids called 'death domain', of docking proteins, to form a **death-inducing signaling complex (DISC)**. The death domain plays a critical role in transmitting the death signal from the cell surface to the intracellular signaling pathways.
- Death domains possess the capacity to oligomerize with each other thereby promoting interactions between proteins such as the TNF-receptor-associated

Table 1.37 Role of caspases and mitochondrial proteins in apoptosis

Caspases Role in Apoptosis and Inflammation	
Initiator or inducer caspases	2, 8, 9, 10.
Executioner or effector caspases	3, 6, 7
Other caspases	11, 12, 13, 14
Inflammatory caspases	1, 4, 5
Mitochondrial Proteins Role in Apoptosis	
Proapoptotic proteins	BAX, BAK, BIM, BCLXs, APAF-1, BAD, BID, PUMA, NOXA, BOK (BCL-2 related protein), BIK (BCL-2 interacting killer), APAF-1 (apoptotic protease activating factor 1), NIP3, BNIP3, BLF-M, BRAG-1
Anti-apoptotic proteins	BCL-2 (key gene regulator of apoptosis) located on chromosome 18), BCL-XL, MCL-1, BFL1, BCL-W,

Mitochondrial proteins, i.e. BAD, BID and PUMA that regulate balance between proapoptotic and antiapoptotic proteins.

death domain (TRADD) or Fas-associated death domain (FADD) adaptor proteins, that are not present in unliganded receptor molecules.

- Binding of ligand to corresponding death domains lead to recruitment of cytoplasmic adaptor proteins. The binding of Fas ligand to Fas receptor results in the binding of the Fas-associated death domain adaptor protein and the binding of TNF ligand to TNF receptor results in the binding of TRADD with recruitment of FADD and receptor interacting protein (RIP).
- Fas-associated death domain adaptor protein then associates with procaspase 8 via dimerization of the death effector domain. At this point DISC is produced leading to autocatalytic activation of procaspase 8.
- Caspase 8 is the most upstream protease participating in the activation of cascade responsible for death receptor-induced cell death.
- The conversion of procaspase 8 to activated caspase 8 then converts precursor procaspases (3, 6, 7) to their active form. Caspases 3, 6 and 7, especially caspase 3, are executioners and cleave target proteins, which lead to apoptosis.
- Caspase 8 cleaves BID into tBID, which initiates the intrinsic mitochondrial pathway of apoptosis leading to release of cytochrome c and proapoptotic proteins, which induce apoptosis.
- Extrinsic death receptor pathway of apoptosis can be inhibited by a protein called cellular FLICE inhibitory protein (c-FLIP) which will bind to FADD adaptor protein and caspase 8 rendering them ineffective. Another point of potential apoptosis regulation involves a protein called 'Toso', also known as Fas apoptosis inhibitory molecule 3 (FAIM3), which has been shown to block Fas-induced apoptosis in T cells via inhibition of caspase 8 processing.
- The sequence of events in extrinsic death receptor pathway of apoptosis include: FasL-FasR → FADD (Fas-associated death domain) and TNF ligand-TNFR → TRADD (TNF-receptor-associated death domain) → activation of caspase 8 → activation of executioner caspases (3, 6, 7) → FADD and RIP recruitment → cleavage of cellular proteins → apoptosis.

INTRINSIC MITOCHONDRIAL PATHWAY OF APOPTOSIS

Intrinsic mitochondrial pathway of apoptosis plays a pivotal role in apoptosis. Mitochondria are central regulatory organelle involved in apoptosis, where antiapoptotic and proapoptotic proteins interact and determine the fate of the cell.

- Sequence of events in intrinsic mitochondrial pathway of apoptosis include: inhibition of antiapoptotic BCL-2 proteins → activation of proapoptotic proteins (e.g. BAK, BAX, BOK, BIM, BID, BAD) → mitochondrial cytochrome c leakage/APAF-1 (apoptotic protease activating factor 1) → apoptosome (cytochrome c + APAF-1 + caspase 9) → activation of caspase 9 → activation of caspases (3, 6, 7) → cleavage of cellular proteins → apoptosis. Due to DNA damage, activating p53 raises the level of BAX, which enhances cytochrome c release.
- In a healthy cell, the outer membrane of the mitochondria displays BCL-2 family of apoptosis-related proteins regulated by BCL-2 (B cell lymphoma/leukemia 2) gene mapped on chromosome 18. BCL-2 family of apoptosis related-proteins are given in Table 1.38.
- BCL-2 family of apoptosis-related proteins are key players of both antiapoptotic and proapoptotic processes.
- BCL-2 family can be divided into three groups, differentiated by structure and function. This division reflects the numbers of BCL-2 homology (BH) domains on the protein.
  - The presence of the BH4 domain characterizes the antiapoptotic family members.

Table 1.38 BCL-2 family of apoptosis-related proteins

Numbers of BCL-2 homology (BH) Domains	BH4 Domain	Examples
Multi-BH antiapoptotic proteins	BH4 domain present	BCL-2, BCL-XL, MCL-1 and other proteins
BH-to-BH3 proapoptotic proteins	BH4 domain absent	BAK, BAX, BOK
BH3 only proapoptotic proteins	BH4 domain absent	BIM, BID, BAD, BIK, BMF, NOXA, PUMA and HRK

- Multi-BH antiapoptotic proteins include BCL-2. BCL-XL, MCL-1 and others. Multi-BH antiapoptotic BCL-2 proteins prevent mitochondrial leakage of cytochrome c. On the other hand, proapoptotic BCL-2 family members lack the BH4 domain and may have BH1-to-BH3 or only BH3.
- BH1-to-BH3 proapoptotic proteins which lack BH4 domain, and include BAK, BAX and BOK. BH3 proapoptotic proteins lack BH4 domain, and include BIM, BID, BAD, BIK, BMF, NOXA, PUMA and HRK.

Pathology Pearls: BCL-2 (B Cell Lymphoma 2) Gene

- BCL-2 is human proto-oncogene located on chromosome 18. Its gene product is an integral outer mitochondrial membrane protein (called BCL-2), that works to prevent apoptosis by intrinsic apoptotic pathway.
- Overexpression of BCL-2 can contribute to metastasis in certain human cancers. In hematologic malignancies (follicular lymphoma, Burkitt's lymphoma, diffuse large cell lymphoma), reciprocal chromosomal translocation t(8;14) (q24;q32) involves the c-Myc gene (8q24) and the immunoglobulin heavy chain (IgH) locus (14q32) results in fusion of BCL-2 gene located near to IgH locus (14q32) resulting in overexpression of BCL-2 antiapoptotic protein.
- BCL-2 inhibitors are being developed to downregulate BCL-2. BCL-2 consists of four conserved domains (BH4, BH3, BH1 and BH2), which differentiate it from other BCL-2 family of members (e.g. BIM, BID, PUMA, NOVA, BAD, HRK, BMF and BIK). Among these homologies, motifs, BH3, BH1 and BH2 are the most commonly targeted therapy in clinical practice.

Intrinsic Mitochondrial Pathway of Apoptosis Activation

Intrinsic mitochondrial pathway of apoptosis is activated by numerous stimuli, including growth factor deprivation, oxidants, calcium overload, oncogene activation, DNA-damaging agents and microtubule targeting drugs.

- Mitochondrial permeability transition pore (MPTP) is a transmembrane protein residing in the mitochondrial inner membrane. Normally, MPTP remains closed.
- At equilibrium, '**cytochrome c**', DIABLO protein encoded by DIABLO gene mapped on chromosome 12 also referred to as second mitochondrial-derived activator of caspases (SMAC), and apoptosis inducing factor (AIF) either are attached to the mitochondrial inner membrane or float in the intramembranous space. The complex of oligomeric BAK/BAX with antiapoptotic BCL-2 family of proteins resides at the outer membrane of mitochondria. SMAC/DIABLO protein binds inhibitor of apoptosis proteins, thus freeing caspases to achieve apoptosis.
- When BH3-only members of BCL-2 family members are activated, they interpose themselves between their prosurvival relatives and BAK/BAX, thereby freeing BAK/BAK proteins.
- Later BAK protein forms mitochondrial permeability transition pore in the outer mitochondrial membrane.
- MPTP opens when stimulated by mitochondrial matrix accumulation of Ca^{++}, increased phosphate concentration, nucleotide depletion or oxidative stress by reactive oxygen species.
- Opening of the mitochondrial permeability transition pore results in release of proapoptotic proteins, SMAC/DIABLO, apoptosis inducing factor, 'cytochrome c', that activate apoptotic protease activating factor 1 (APAF-1) and caspase 9 (apoptosome = cytochrome c + APAF-1 + caspase 9) triggering the apoptotic cascade.
- Apoptosis is characterized by cell shrinkage, chromatin condensation, nuclear fragmentation, plasma membrane blebbing without loss of cell integrity, organelles in the plasma membrane blebs, generation and degradation of apoptotic bodies by macrophages and surrounding healthy cells.

CD8+ CYTOTOXIC T CELLS/NK CELLS (GRANZYME B/PERFORIN) MEDIATED PATHWAY OF APOPTOSIS

CD8+ cytotoxic T cells and natural killer cells carry out their killing function of virus-infected and/or transformed cells by releasing two types of preformed proteins: granzymes and pore-forming perforins. Synaptotagmin VII, Rab-27A and unc-13 homolog D (Munc12-4) regulate cytotoxic granules maturation and fusion with the plasma membrane leading to exocytosis. Schematic representation of perforin-granzyme pathway of apoptosis is shown in Fig. 1.35.

- **Perforin:** Perforin is a pore-forming protein that punches holes in the target cell-membrane through which the granzyme can enter into the cytosol, mitochondria and nucleus.

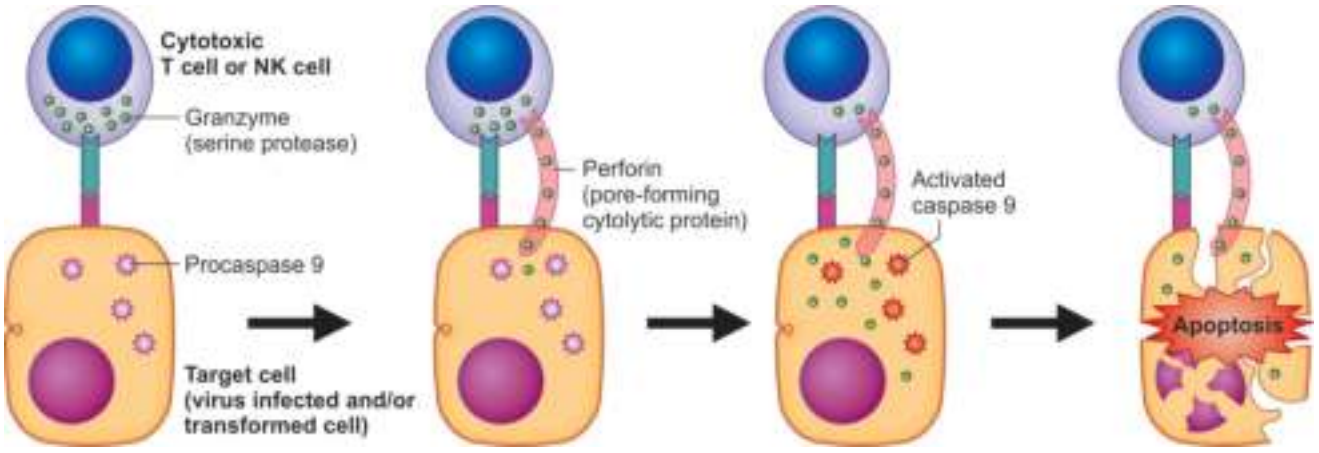

Fig. 1.35: Schematic representation of perforin-granzyme pathway of apoptosis. Perforin-granzyme induced is the main pathway used by cytotoxic T cells and natural killer cells (NK cells) to eliminate virus-infected or transformed cells. Perforin delivers granzyme to induce target cell apoptosis. At higher concentrations, perforin multimerizes in the plasma membrane to form pores. Granzyme is serine protease released by cytoplasmic granules within cytotoxic T cells and NK cells, that induces apoptosis by activating caspase 3, that cleaves many substrates, inducing caspase-activated DNase to execute apoptosis.

- **Granzyme B:** Granzyme B directly cause a rapid increase in superoxide, which is a key molecule of nuclear translocation of another granzyme A substrate, known as endoplasmic reticulum-associated SET complex.
  - Cleavage of SET complex liberates granzyme A activated DNase and NDPK-A that causes DNA damage. NDPK-A activates p53 tumor suppressor protein that can induce p53-dependent apoptosis.
  - Granzyme B cleaves cytoplasmic BID to its active forms, tBID, which translocates into mitochondria and triggers the intrinsic mitochondrial pathway of apoptosis. Granzyme B also activates procaspases 3, 6, 7 to executioner caspases 3, 6, 7, which leads to apoptosis. Granzyme B may also disrupt the complex between caspase activated DNase (CAD) and caspase activated DNase inhibitor (ICAD).
  - Disruption of CAD-ICAD releases the caspase-activated DNase, which elicits a caspase-independent form of apoptosis. The CAD-ICAD complex may also be cleaved by caspase 3.

Clinical Pearls: Role of Granzymes and Perforin in Acute Rejection of Solid Organ Allografts

- Granzymes/perforin act together to directly induce cell death of allograft parenchymal cells, thereby leading to organ failure.
- In heart allografts, the formation of plasma membrane pores by perforin alone may cause cardiac myocyte contractile dysfunction through the dysregulation of cytoplasmic ion concentrations.
- Granzyme B (GrB) and perforin act together to induce endothelial cell death within solid organ allografts. The destruction of the graft microvasculature in this manner leads to hemorrhage and thrombosis, thereby contributing to acute rejection by causing ischemic organ failure.

FAMILY OF CYSTEINE PROTEINS 'CASPASES'

Caspases are a family of endoproteases important for maintaining homeostasis through regulating apoptosis and inflammation. The caspases exist in all cells as inactive precursors or procaspases, which are usually activated by cleavage by other caspases, producing a proteolytic caspase cascade.

- Caspases cut off contact with surrounding cells, reorganize cytoskeleton, shut down DNA replication and repair, interrupt splicing, degrade DNA, disrupt nuclear structure, induce cell to display signals marking it for phagocytosis and disintegrate cells into apoptotic bodies.
- Within these proteolytic cascades, caspases can be positioned as either upstream 'initiators' (caspases 2, 8, 9, 10, 11 and 12) or downstream 'effectors (executioner caspases 3, 6 and 7)' of apoptosis. Initiator caspases activate executioner caspases that frequently coordinate their activities to demolish key structural proteins and activate other enzymes.
- The caspases cleave key cellular components that are required for normal cellular function including cytoskeleton proteins and nuclear proteins such as DNA repair enzymes. The caspases can also activate other degradative enzymes such as DNases, which begin to cleave the DNA in the nucleus.

INITIATOR/INDUCER CASPASES

Initiator/inducer caspases (2, 8, 9, 10, 11, 12) are initially produced as inactive procaspase monomers that are activated by dimerization and often cleave for activation. Dimerization also facilitates autocatalytic cleavage of caspase monomers into one large and one small subunit, which results in stabilization of the dimer.

EXECUTIONER/EFFECTOR CASPASES

Executioner/effectors caspases (3, 6, 7) activate cellular enzymes such as proteases and endonucleases. Activation of cellular enzymes degrade the cells own nuclear DNA and cytoplasmic proteins.

- Proteases degrade cytoskeleton and endonucleases break down DNA of targeted cell resulting in impairment of transcription, DNA replication and DNA repair.
- Caspase 3 converts a cytoplasmic DNAase into an active form, which induces internucleosomal cleavage of DNA. Caspase 3 also degrades cytoskeleton proteins.
- Caspase 3 antibodies serve as excellent biomarkers to monitor induction of apoptosis by analyzing the levels of procaspase 5 and its active form by Western blotting technique.
- Cleavage and activation of caspase 3 is catalyzed by caspase 8, caspase 9 and granzyme B to generate the active heterodimer of caspase 3 subunits.

MORPHOLOGIC AND BIOCHEMICAL CHANGES IN APOPTOTIC CELLS

Apoptosis exhibits characteristic morphologic features, such as highly condensed chromatin within nucleus, breakdown of nucleus, plasma membrane blebs, fragmentation of cells forming membrane-bound apoptotic bodies containing intact cytoplasmic organelles sometimes chromatin. Apoptotic bodies are phagocytosed by macrophages and surrounding cells within an hour, rendering their appearance very transient. Morphologic and biochemical alterations associated with apoptosis and their consequences are given in Table 1.39.

HISTOLOGIC CHANGES

On histologic examination, apoptotic cell exhibits various morphologic changes that occur during apoptosis. During early phase of apoptosis, cell shrinkage and pyknosis are visible by routinely hematoxylin and eosin-stained by light microscopy. The apoptotic cell appears as a round or oval mass with dark eosinophilic cytoplasm and dense chromatin fragments.

ULTRASTRUCTURAL CHANGES

Apoptotic cell demonstrates following ultrastructural changes in plasma membrane, cell shrinkage, nuclear changes, fragmentation of cell forming apoptotic bodies and clearance of apoptotic bodies by macrophages and surrounding epithelial cells.

Plasma Membrane Blebbing

Plasma membrane blebbing is the well-defined feature of apoptosis. During apoptosis, the cell's cytoskeleton breaks up and causes the membrane to bulge outward. These bulges may separate from the cell taking as portion of cytoplasm with them, to become known as apoptotic blebs.

Table 1.39 Morphologic and biochemical alterations associated with apoptosis and their consequences

Biochemical Alterations	Consequences
Activation of endonuclease	
Nonidentifies enzyme(s): internucleosomal DNA cleavage	'Ladder' aspect of DNA migrating in agar gel electrophoresis
Cytoskeleton changes	
Transglutamase and protease activation that results in the formation of an insoluble protein network	Prevent lysosomal and membrane rupture and the appearance of an inflammatory reaction 'cage effect'
Plasma membrane changes	
▪ Increased isoprenoid synthesis and loss plasma membrane dissymmetry ▪ Alterations in plasma membrane surface receptors especially their sugar composition ▪ Probable activation of ATP-dependent pumps, allowing influx of water against a concentration gradient	▪ Differentiate apoptotic cells from phagocytic cells ▪ Reduction in size of apoptotic cells being useful in isolation of these cells on Percoll gradient (low density gradient medium for preparation of cells)
Inconsistent changes	
Increased intracellular calcium	Transduction of a membrane signal or transcription of a specific gene (e.g. calmodulin)
▪ Increased synthesis of 3-galactoside, a link protein ▪ Increase in TRPM-2 gene transcription ▪ Activation of collagenases and metalloproteinases, TGF 31 synthesis	Inhibition of cell proliferation, increased intracellular calcium, separation of cells from neighboring cells and regulation of apoptosis/proliferation balance of cells and epithelia

Shrinking of Cytoplasm

Cell shrinkage or decrease in cell volume, is a ubiquitous characteristic of programmed cell death that is observed in all examples of apoptosis.

Nuclear Changes

Condensation of chromatin (**pyknosis**) occurs at the nuclear membrane followed by DNA fragmentation (**karyorrhexis**) by endonucleases.

Fragmentation of Cell into Apoptotic Bodies

During execution phase, cell's cytoskeleton breaks up and causes the plasma membrane to bulge outward and separate from the cell, taking a portion of cytoplasm with them, to become membrane-bound apoptotic bodies, which are tightly packed and contain intact mitochondria, lysosomes and ribosomes and other cell organelles, with or without nuclear fragments.

Clearance of Apoptotic Bodies

Apoptotic bodies are phagocytosed by macrophages and surrounding healthy cells without inducing inflammatory reaction. Macrophages and surrounding healthy cells prevent spillage of cellular lysosomal enzymes into surrounding tissue, thus protecting tissue from harmful exposure to the inflammatory and immunogenic contents of the dying cells. Glucocorticoids induce apoptosis; and sex steroid hormones inhibit apoptosis.

- Several receptors are implicated in the uptake of apoptotic bodies by macrophages and surrounding healthy cells. These receptors interact with their ligands on the apoptotic cells either directly or via bridging proteins. C1q serves as a bridging molecule for apoptotic cell clearance by binding to the apoptotic cell and the phagocyte and stimulating phagocytosis, independent of the classical complement pathway.
- Several studies revealed that alterations in cell surface receptors of phagocytes induced by apoptotic cells, externalization of phosphatidylserine and qualitative changes in the intercellular adhesion molecule 3 (ICAM-3) play an important role in the clearance of apoptotic bodies.
- Phosphatidylserine is normally present on the cytosolic surface of the plasma membrane. During apoptosis, scramblase causes redistribution of phosphatidylserine to the extracellular surface. These molecules mark the cell for phagocytosis by phagocytic cells possessing appropriate receptors. Upon recognition, the phagocyte recognizes its cytoskeleton for engulfment of the cell. The removal of dying cells by phagocytes occurs in an orderly manner without eliciting an inflammatory response.
- Apoptotic cells release various anti-inflammatory molecules such as transforming growth factor β (TGF-β), IL-10, annexin I, thrombospondin 1 (TSP-1), fractalkine, which inhibit proinflammatory cytokines synthesis of the phagocytes such as tumor necrosis factor α (TNF-α), IL-12, IL-1β, IL-18. Defining the ligands on apoptotic cells and corresponding receptors on phagocytes (macrophages and surrounding cells) with which they engage, is likely to lead to the development of novel anti-inflammatory protherapeutic agents.

BIOCHEMICAL CHANGES

Apoptosis is ATP-dependent programmed cell death mediated by caspases and characterized by nucleus fragmentation (karyorrhexis) resulting from the cleavage of double-stranded nuclear DNA via activation of calcium-magnesium-dependent endonuclease enzyme.

- Cleavage of DNA into high molecular weight structures may be detected with histochemical techniques or agarose gel electrophoresis (nonrandom mono- and oligonucleosomal length fragmentation of DNA giving 'ladder pattern').
- Another biochemical alteration is the translocation of phosphatidylserine to the outer surface of the plasma membrane. This translocation constitutes one of the principal targets of phagocytic recognition of apoptotic body.
- Mitochondria release '**cytochrome c**' and apoptosis-inducing factor (AIF) and other factors into cytoplasm.

APOPTOSIS IN HEALTH

Apoptosis is a programmed cell death by which a single cell or group of cells in a tissue is eliminated from the living tissue, which plays an important role for tissue modeling during embryogenesis and cellular/tissue hemostasis during adult life. Apoptosis during embryogenesis and adult life is given in Table 1.40.

APOPTOSIS DURING EMBRYOGENESIS

Apoptosis plays an important role in the processes of gamete maturation as well as in embryo development by removing cells, contributing to the appropriate formation of various organs and structures.

Involution of Embryonic Wolffian or Müllerian Structures

Apoptosis begins in the early blastocyst and plays an important role in the processes of embryonal and fetal development, contributing to the appropriate formation of various organs and structures.

Table 1.40 Apoptosis during embryogenesis and adult life

Apoptosis during Embryogenesis
▪ Involution of embryonic Wolffian or Müllerian structures
▪ Digits formation in fetus
▪ Lumen formation in hollow organs
▪ Development of nervous system
Apoptosis during Adult Life
▪ Apoptosis of self-reactive B and T cells in immune system
▪ Apoptosis of endometrial cells during menstrual cycle
▪ Atrophy of thymus
▪ Apoptosis of hepatocytes in viral hepatitis and formation of Councilman bodies
▪ Apoptosis of neuron and formation of red neurons
▪ Keratinocyte apoptosis in epidermis
▪ Apoptosis of neutrophils in acute inflammation

- Hormonal effect on apoptosis is also important in the maturation of the human reproductive system. The reproductive system has an early indifferent phase when it is neither male or female.
- Wolffian duct forms epididymis and vas deferens in males. Müllerian duct differentiates into uterus and fallopian tubes in female. It is well known that administration of estrogens will feminize the male, while administration of testosterone in females will musculinize the female. In order for that to happen, there has to be regression of the primitive Wolffian or Müllerian structures via apoptosis.

Digits Formation in Fetus

Interdigital cells are eliminated by apoptosis without affecting the living cells forming the digits, thus contributing to digit individualization by restricting interdigital tissue growth.

Lumen Formation in Hollow Organs

Lumen formation in hollow organs occur *de novo* by three processes: apoptosis of centrally located cells, autophagy of centrally located cells, and membrane separation by epithelial remodeling. The lumens present in the ductal structures are required for transport of fluids and air.

Development of Nervous System

The development of the nervous system is also dependent on apoptosis. Neural cell death has a pivotal role in the development and pathophysiology of the nervous system. About 50% of neurons are eliminated by programed cell death (apoptosis). Remaining 50% of neurons are produced with correct synaptic connections in target cells.

APOPTOSIS DURING ADULT LIFE

Apoptosis is programmed cell death that has been damaged beyond repair. Apoptosis also plays a role in preventing cancer. If apoptosis does not occur in DNA damaged cell, it can lead to uncontrolled cell division and subsequent development of cancer.

Apoptosis of Self-reactive B and T Cells in Immune System

Apoptosis is required for the development and maintenance of a healthy immune system.

- Self-reactive B and T cell antigen receptors are eliminated by apoptosis during their development in the thymus, a process known as negative selection.
- If self-reactive B and T cell antigens are not eliminated by apoptosis during their development, then these B and T cells may be released into the body, which can attack tissues resulting in autoimmune disorders [rheumatoid arthritis, systemic lupus erythematosus (SLE), autoimmune lymphoproliferative syndrome, and others].

Apoptosis of Endometrial Cells during Menstrual Cycle

The endometrium is a hormone-dependent tissue that undergoes cyclic changes during reproductive period as well as involutionary changes after menopause. The endometrial cycle in regularly menstruating women consists of three distinct phases: proliferative, secretory and menstrual.

- Apoptosis helps to maintain cellular homeostasis during the menstrual cycle by eliminating senescent endometrial cells from the functional layer of the uterine endometrium during the late secretory and menstrual phase of the cycle. Fas death receptor (CD95) and Fas ligand (FasL) are expressed in endometrium throughout the menstrual cycle.
- During late proliferative phase, Fas and FasL proteins are retained within cell's Golgi apparatus and cytoplasm, hence these are unable to interact and thus apoptotic signal is turned off. During secretory phase, Fas and Fas proteins are extruded as a part of cellular membranes, where Fas can bind FasL and 'turn on' apoptotic signal.
- Fas immunostaining on endometrial glandular cells is stronger during secretory phase than during proliferative phase of endometrium.

Thymus Gland Atrophy

The thymus is large in the fetus and infant, that undergoes atrophy before adulthood. This involution of thymus occurs via apoptosis, which is thought to be steroid sensitive.

- The steroid hormones are synthesized in the adrenal gland so that, in this case, one organ is responsible for the involution of another via its secreted product. This observation is useful in perinatal autopsies to study whether the baby *in utero* has been under stress or not.
- Adrenal steroid hormones in stressed baby *in utero* results in premature involution of thymus. If the baby has been normal *in utero*, but has suffered birth asphyxia, the thymus gland will be of normal size.

APOPTOSIS IN DISEASES

Apoptosis eliminates potentially harmful DNA-damaged cells that are injured beyond repair by activating DNA damage checkpoint pathways without eliciting a host reaction, thus limiting collateral tissue damage. Hence, apoptotic signaling pathways, help to safeguard the 'genomic stability'. Evidence indicates that dysregulation of apoptotic signaling pathways can cause cancerous growth or autoimmune disorders, while accelerated apoptosis is evident in degenerative disorders, immunodeficiency disorders and infertility. Dysregulation of apoptosis-associated disorders is given in Table 1.41.

APOPTOSIS INDUCED BY VIRUSES

Apoptosis can be induced by viruses either by stimulating the immune response or by introducing viral suicidal genes that kill the host cells.

- Immune response is mediated by CD8+ cytotoxic T cells/natural killer cells (perforin/granzyme) associated pathway of apoptosis. Many cells undergo apoptosis in response to viral infection, with a consequent reduction in the release of progeny virus.

Table 1.41 Dysregulation of apoptosis-associated disorders

Categories	Disorders
Human cancers	Breast carcinoma, lung carcinoma, renal cell carcinoma, ovarian carcinoma, endometrial carcinoma, head and neck carcinoma, melanoma, follicular lymphoma and leukemia
Viruses	Herpesvirus, adenovirus and poxvirus
Neurological disorders	Alzheimer disease, Parkinson disease, Huntington disease, amyotrophic lateral sclerosis, cerebral stroke, cerebellar degeneration
Cardiovascular disorders	Ischemic heart disease, heart failure, infectious diseases, bacteria, viruses
Autoimmune disorders	Systemic lupus erythematosus, rheumatoid arthritis, thyroiditis, autoimmune lymphoproliferative syndrome, immune-mediated glomerulonephritis

- The viral genome hijacks the host cell's machinery, forcing host cell to replicate the viral genome and produce viral proteins to make new capsids. After maturation, the virus induces host cell apoptosis and propagation of viral particles to neighboring uninfected cells.

Councilman Bodies in Hepatocytes in Viral Hepatitis

In pathology, Councilman body also known as Councilman hyaline body has been named after American pathologist William Thomas Councilman.

- Councilman body is an eosinophilic/pink globule in hepatocytes on hematoxylin and eosin-stained sections examined under light microscope, that represents a hepatocellular apoptosis often surrounded by normal liver parenchyma.
- Apoptotic cells represent membrane-bound cellular chromatin remnants that are extruded into the hepatic sinusoids demonstrated in cases of viral hepatitis, yellow fever and viral hemorrhagic fever. Liver biopsy in viral hepatitis shows apoptosis of virus infected hepatocytes, mild zonal necrosis and lymphocytic infiltration.

Apoptosis of HIV Infected Cells

Significant apoptosis during HIV-1 infection can be attributed to the direct viral killing of peripheral infected mononuclear cells in AIDS patients. In HIV infected persons, viral load is a good predictor of disease progression; the higher the viral load the faster the disease progression.

NEURONAL APOPTOSIS AND FORMATION OF RED NEURONS IN BRAIN

A 'red neuron' is a pathologic finding in the central nervous system, indicative of acute neuronal injury and subsequent apoptosis demonstrated as eosinophilic neuron on observed on hematoxylin and eosin-stained sections under microscope.

- Since neurons are permanent cells, these cells are most susceptible to hypoxic injury often found after 12–24 hours in cerebral stroke.
- The red coloration of red neuron occurs due to pyknosis or degradation of the nucleus and loss of Nissl bodies.

KERATINOCYTE APOPTOSIS IN EPIDERMIS

Keratinocyte apoptosis plays a critical role in regulating epidermal development and restraining carcinogenesis. Keratinocyte apoptosis can also be triggered by ultraviolet radiation and other stimuli.

- The stratum granulosum, the thin middle layer of epidermis, initiates keratinization (constant production of keratin). This process starts with apoptosis of epithelial cells in stratum granulosum of skin.
- The keratinocytes become metabolically inactive with degradation of organelles resulting in constant turnover of differentiated flattened dead squamous cells, that resemble 'protein sacs' containing more than 80% of keratins cross-linked to other cornified envelope proteins.
- Dysfunctional apoptosis occurs in some skin diseases (e.g. psoriasis and skin cancer). Acanthosis, the hallmark of psoriatic skin is an example of diminished epidermal cells apoptosis.

APOPTOSIS OF NEUTROPHILS IN ACUTE INFLAMMATION

Neutrophils respond to acute inflammation and kill bacteria by phagocytosis. Activated neutrophils generate vast amounts of reactive oxygen species, which kill microorganisms and modulate life span as well as clearance of the neutrophils themselves.

- After elimination of bacteria, neutrophil apoptosis occurs to limit destructive capacity of neutrophilic products to the surrounding tissue.
- Apoptosis of neutrophils is important for the resolution of inflammation, as this allows for phagocytosis and removal of senescent cells prior to their necrotic disintegration.
- Apoptotic neutrophils stimulate macrophages, which clear apoptotic cells as well as cell debris, and reduce the inappropriate inflammatory response further.

APOPTOSIS OF PARENCHYMAL ORGAN'S CELLS DUE TO OBSTRUCTION IN DUCTS

Obstruction in ducts of pancreas and parotid glands result in pathologic organ shrinkage by the process of apoptosis of parenchymal cells. After pancreatic duct obstruction, pancreatic acinar cells progressively disappear and pancreatic islets of Langerhans are preserved.

APOPTOSIS OF CELLS WITH DAMAGED DNA

Hypoxia, ionizing radiation, cytotoxic chemotherapeutic drugs and viruses can cause cellular DNA damage, either directly or via production of free radicals. The TP53 tumor suppressor gene recognize cells with DNA damage and analyze whether these can be repaired.

- If DNA repair mechanisms cannot cope with the injured cells, the cell triggers intrinsic mechanisms that induce apoptosis. In these situations, elimination of these cells with DNA damage may be better alternative than risk of malignant transformation in these cells.
- The injurious stimuli can cause apoptosis if the insult is mild, but large doses of the same injurious stimuli may result in necrotic death. In certain cancers, where TP53 tumor suppressor gene is mutated or deleted, the apoptosis is not induced in cells with DNA damage.
- People with **Li-Fraumeni syndrome** have only one functional copy of TP53 tumor suppressor gene, so they are more likely to develop a malignant tumor in early adulthood.
- Follicular lymphoma is a low-grade B cell neoplasm, which usually occurs in elderly patients. About 90% of cases show t(14;18) (q32;q21) chromosomal translocation which juxtaposes the IgH locus on chromosome 14 with BCL-2 gene on chromosome 18 resulting in overexpression of BCL-2. BCL-2, which is located in the mitochondria, promotes cell survival by opposing apoptosis in the follicles. Overexpressed BCL-2 inhibits APAF1 and inactivates caspases leading to survival of neoplastic cells in follicles.

APOPTOSIS OF CELLS WITH ACCUMULATED MISFOLDED PROTEINS

Misfolded proteins may arise due to mutations in the genes encoding these proteins or damage caused by oxygen-derived free radicals. Excessive accumulation of misfolded proteins in the endoplasmic reticulum results in endoplasmic reticulum stress, which culminates in apoptotic cell death. Apoptosis caused by the accumulation of misfolded proteins in the cells has been invoked as the basis of several degenerative diseases of nervous system (Creutzfeldt-Jakob disease, Alzheimer disease, Parkinson disease, Huntington disease and muscle system atrophy) and other organs damage (amyloid deposits in liver, spleen).

APOPTOSIS OF CANCER STEM CELLS

Apoptosis is often a self-defense mechanism for destruction of cells infected with viruses or irreparable DNA damaged cells by CD8+ cytotoxic T cells, thus protecting against neoplastic transformation. Radiation and cytotoxic anticancer drugs induce apoptosis of cancer cells.

Recent Concepts: Nucleolin and Apoptosis

- NCL gene encodes a multifunctional RNA-binding nucleolin protein, that is primarily distributed in the nucleolus (90%), cytoplasm and cell membrane.
- Cell surface nucleolin can bind to various ligands to affect many physiologic functions including ribosomal biogenesis, processing of ribosomal RNA (rRNA), messenger RNA stability, downstream target of several regulation of signal transcription pathway and cell proliferation.

- Nucleolin interacts with DNA repair proteins to maintain genomic stability via stability of apoptosis-related mRNAs by binding to nucleolin RNA-binding domain (RBD) to the 5'- and 3'-UTR of mRNA and inhibit apoptosis. Increased nucleolin expression can also elevate BCL-2 protein levels in cancer cells.
- Nucleolin also interacts with 15 and 6 microRNAs, which are negative regulators of BCL-2 expression.
- Cell surface nucleolin can bind to Fas and block the interaction of Fas/FasL, which prevents cells from entering Fas-induced apoptosis. The interaction of cell-surface nucleolin with ErB1 and RAS also favors cell proliferation.
- Therefore, cell-surface nucleolin can facilitate antiapoptotic phenotype and induce initiation and survival or cancer cells.

LABORATORY DIAGNOSIS

Techniques for detection of apoptotic cells include: cytomorphologic changes (light and electron microscopy), DNA discontinuous fragmentation ladder assay (conventional agarose gel electrophoresis), terminal deoxynucleotidyl transferase (TdT) dUTP nick-end labeling (TUNEL) assay, executioner caspase 3 (immunohistochemistry), annexin V (immunohistochemistry), p53 (immunohistochemistry and RT-PCR, Western blot, enzyme-linked immunosorbent assay, flow cytometry), executioner 3 activation (immunohistochemistry, Western blot, enzyme-linked immunosorbent assay), Fas, TNF-α (tumor necrosis factor α), TRAIL: tumor necrosis-related apoptosis-inducing ligand (RT-PCR, Western blot, immunohistochemistry) and '**cytochrome c**' release (ELISA: enzyme-linked immunosorbent assay).

LIGHT MICROSCOPY

Light microscopy has aided in analyzing the various cytomorphological changes that occur during apoptosis on routinely hematoxylin and eosin-stained sections.

- In the initial stage of apoptosis, the apoptotic cells exhibit cell shrinkage with dark dense eosinophilic cytoplasm, highly condensed chromatin with nuclear pyknosis. In the later stage, cell undergoes fragmentation with formation of apoptotic bodies containing cytoplasmic organelles.
- The apoptotic bodies are phagocytosed by macrophages and surrounding cells within an hour, rendering their appearance very transient. There is essentially no inflammatory response because of these reasons: (a) apoptotic cells do not release their cellular constituents into the surrounding interstitial tissue, (b) apoptotic cells are quickly phagocytosed by macrophages and surrounding healthy cells thus likely preventing secondary necrosis, and (c) phagocytosed apoptotic bodies do not induce production of cytokines.

ELECTRON MICROSCOPY

Electron microscopy is still considered the 'gold standard' for the identification of apoptotic cells. Different cytomorphological features of cells undergoing apoptosis are analysis by transmission electron microscopy (TEM) and scanning electron microscopy (SEM).

- Transmission electron microscopy analysis is essentially qualitative ultrastructural changes in apoptotic cells such as plasma membrane blebbing, chromatin condensation in nucleus and cytoplasmic reorganization, whereas SEM can provide information of the cell surface (extensive plasma membrane blebbing, loss of microvilli), cell–cell and cell–substrate interactions, but it is very difficult to analyze apoptotic features by SEM.
- Extensive plasma membrane blebbing is followed by karyorrhexis and separation of cell fragments into apoptotic bodies by budding. Apoptotic bodies consist of tightly packed cytoplasmic organelles with or without nuclear fragment. Electron microscopy is useful for subsequent biochemical or molecular analysis.

ELECTROPHORESIS

Classical apoptotic cell death can be defined by certain cytomorphological and biochemical characteristics that distinguish it from other forms of regulated cell death. One such feature, which is hallmark of apoptosis, is DNA fragmentation.

- In dying apoptotic cells, DNA is cleaved by an endonuclease that induces fragmentation of chromatin into nucleosomal units, which are multiples of about 180 to 200 bp oligonucleosomal multimers and appear as a 'DNA ladder pattern' of discontinuous DNA fragments, when run on conventional agarose gel electrophoresis.
- DNA ladder remains the hallmark of apoptosis. DNA from apoptotic cell is extracted from the culture and is precipitated with polyethylene glycol (PEG) or agarose or polyacrylamide. The fragmented DNA remains in the supernatant and can be easily subjected for gel electrophoresis or quantification using fluorescent dyes (fluorescein and rhodamine).
- Pulse field gel electrophoresis is a specialized technique for resolving DNA molecules in the range of 50 kb to 10 Mbp. Single cell gel electrophoresis (SCGE) visualizes DNA damage analyzed at the levels of individual apoptotic cell, that exhibits comet-like

structures with small head and large tail. Comet assay has higher sensitivity than DNA ladder assay and TUNEL staining.

FLOW CYTOMETRY

Flow cytometry is one of the most popular and versatile applications for accurate quantification of apoptosis from induction via surface receptors to late stage where DNA fragmentation occurs.

- Apoptotic cells are stained with fluorescent dyes and passed through beam of light of single wavelength.
- Cells flowing through beam of single wavelength scatter light to some extent in the optical and electronic detection apparatus of the flow cytometer.
- Such forward scatter (FSC) versus side scatter (SSC) distinguishes apoptotic cells from nonapoptotic cells and determination of the immunophenotype of cells undergoing apoptosis.

TUNEL ASSAY

Terminal deoxynucleotidyl transferase (TdT) dUTP nick-end labeling (TUNEL) is the most common method used to assay DNA fragmentation in individual cells caused by apoptosis.

- The assay relies on the use of the terminal deoxynucleotidyl transferase, an enzyme that catalyzes attachment of deoxynucleotides, tagged with a fluorochrome or another marker to 3'-hydroxyl termini of DNA double strand breaks. It may also label cell having DNA damaged by other mechanisms than in the course of apoptosis.
- The amount of fluorescence can be detected by fluorescence microscopy, flow cytometry and immunohistochemical techniques.

IMMUNOHISTOCHEMISTRY

Apoptosis competence is central to the prevention of cancer. Gold standard for evaluation of apoptosis is morphologic evaluation. Immunohistochemical detection of apoptotic cells is performed on paraffin-embedded sections by using commercially developed antibodies against a wide range of substrates most importantly cleaved caspase 3, cleaved cytokeratin 18 (c-CK18), cleaved laminin A (c-lam-A), phosphorylated histone 2AX (γ-H2AX), cleaved poly(ADP ribose) polymerase, apoptosis-inducing factor (AIF), p53, annexin V, and M30 neoantigen.

Executioner Caspase 3 Analysis

Caspase 3 belongs to the family of cysteine proteases, which is known as executioner caspase in apoptosis by coordinating the destruction of cellular structures such as DNA fragmentation or degradation of cytoskeletal proteins. Caspase 3 is responsible for the proteolytic cleavage of many key proteins such as the nuclear enzyme poly (ADP-ribose) polymerase (PARP).

- Caspase 3 is generated as zymogen in inactive form. Cleavage and activation of inactive form of procaspase 3 is catalyzed by caspase 8, caspase 9 and granzyme B to generate active caspase 3.
- Caspase 3 antibodies serve as excellent biomarker to monitor induction of apoptosis by detecting the levels of procaspase 3 and its active form.

Monoclonal Antigen M30 Analysis

The monoclonal antigen M30 recognizes a neoepitope of cytokeratin 18, that is produced during the process of apoptosis. It is early indicator of apoptosis in epithelial cells. Monoclonal antigen M30 is immunoreactive in formalin-fixed paraffin-embedded tissue in colon, trophoblastic tissue in human placenta and salivary glands. Monoclonal antigen M30 is absent in nonapoptotic cells.

Annexin V Analysis

Annexin V is a calcium-dependent, phospholipid-binding protein with a high affinity for phospholipid phosphatidylserine, thus can be used a probe for detecting apoptosis.

- The phosphatidylserine residues are normally hidden within the plasma membrane. The appearance of phosphatidylserine residues on the cell is an early event in apoptosis and can be used to detect apoptosis.
- During apoptosis, phosphatidylserine is translocated from the cytoplasmic face of the plasma membrane to the cell surface.

TP53 Gene Mutation Analysis

TP53 gene is a well-defined tumor suppressor gene mapped on chromosome 17p13.1. TP53 gene encodes phosphoprotein that plays a key role in regulating cell proliferation and apoptosis in response to DNA injury. It also suppresses angiogenesis.

- TP53 gene is the most frequently mutated in human cancers. The p53 protein exists as wild type and various types of mutant forms.
- Wild type p53 protein without TP53 mutation is found in normal cells and is critically important in repair of DNA damage. DNA damage activates TP53 gene resulting in either cell cycle arrest allowing time for the cell to repair the damage or apoptosis.
- Loss of TP53 gene function indirectly decreases genomic stability. Manipulation of the apoptotic functions of TP53 gene constitutes an attractive target for cancer therapy.

INTRACELLULAR ACCUMULATION OF SUBSTANCES

Residual effects of reversible cell injury persist in the cell as an evidence of cell injury at subcellular level. One of the manifestations of metabolic derangements in cells is the intracellular accumulation of abnormal amounts of various substances. A normal endogenous substance is produced at a normal rate, but the rate of metabolism is inadequate to remove it. Defective protein folding, packaging and transport, both genetic or acquired, also produce substance accumulation in excess in the cells.

- The intracellular accumulation of substances falls into three categories: (a) one of the normal cellular constituents is accumulated in excess, such as carbohydrates, lipids, proteins and water, (b) one of abnormal substances is accumulated in excess in the cells, either exogenous substance (mineral) or endogenous excess product of metabolism, (c) one of the endogenous or exogenous pigments is accumulated in excess in the cells.
- The intracellular substances may accumulate in the cytoplasm frequently in the phagolysosomes either in transient or permanent manner. These substances may be harmless to the cells, but can be severely toxic to cells on occasion. If the intracellular overload of substance occurs due to systemic derangement, it can be brought under control, the intracellular accumulation is reversible. In genetic disorders, intracellular overload of substance is progressive resulting in secondary tissue/organ damage, that may have a fatal outcome. In some instances, cells may produce the abnormal substance, and in other instances, cells store products of pathologic process elsewhere in the body.
- Most of intracellular accumulation of substances are attributable to three types abnormalities: (a) a normal endogenous substance is produced at a normal or increased rate, but the rate of metabolism is inadequate to eliminate it. For example, fatty change in liver is due to intracellular accumulation of triglycerides, (b) appearance of reabsorption protein droplets in renal tubules occurs due to increased leakage of proteins from the glomerulus in nephrotic syndrome, (c) intracellular accumulation of normal or abnormal endogenous substance due to genetic or acquired defects in the metabolism, packaging, or secretion of these substances.
- For example, genetic defect in the specific enzyme is involved in the metabolism of carbohydrates and lipids leading to intracellular accumulation of these substances largely in lysosomes.
- Misfolding proteins are accumulated in the form of globular eosinophilic inclusions in the endoplasmic reticulum of hepatocytes in cases of α_1-antitrypsin deficiency caused by single amino acid substitution in the enzyme.
- Another example is intracellular accumulations of substances such as carbon or silica particles, which are neither degraded by enzyme or metabolized in the liver. Whatever is the nature and origin of the intracellular accumulations, it implies the storage of some product by individual cells.

Pathology Pearls: Intracellular Accumulations of Substances

- Lipid accumulate in the liver of obese persons and persons with chronic alcoholism.
- Glycogen accumulates in the liver, skeletal muscles, or kidneys in patients with inborn errors of glycogen metabolism and diabetes mellitus.
- Protein accumulates in the proximal renal tubules in patients with proteinuria. Protein accumulation generally appears as discrete eosinophilic cytoplasmic droplets, vacuoles, or aggregates.
- Exogenous and endogenous pigments accumulate in various cells.
  - Exogenous carbon pigment is deposited in alveolar macrophages. When a person gets a tattoo, the pigment is ingested by dermal macrophages, usually without an inflammatory response.
  - Endogenous pigments that accumulate in various cells include lipofuscin (brown pigment formed in the lysosomes of the elderly persons), melanin (brown-black pigment formed during the oxidation of tyrosine to dihydroxy-phenylalanine [DOPA] by tyrosine in melanocytes), hemosiderin (iron-rich yellow brown pigment derived from hemolyzed red blood cells and demonstrated by Perls Prussian histochemical stain) and bilirubin (also derived from hemoglobin but contains no iron). Excess of bilirubin in cells and tissues is called jaundice.
- Hereditary hemochromatosis is a genetic disorder of iron absorption characterized by the deposition of hemosiderin in the liver, spleen, and bone marrow. Patient presents with cirrhosis, diabetes mellitus and skin discoloration (bronze diabetes).

LIPID ACCUMULATION

Lipid accumulation is chemically defined as a substance that is insoluble in water and soluble in alcohol, chloroform and ether. Lipids together with carbohydrates and proteins are main constituents of cells. Cholesterol and triglycerides are lipids, which are easily stored in the body, which are important constituents of cells. These serve as a source of fuel. Lipids include fatty acids, waxes and steroids.

- Compound lipids are complexed with another type of chemical compound and these include lipoproteins, phospholipids and glycolipids. Lipid accumulation results from an imbalance between lipid acquisition and lipid disposal in parenchymal cells of liver, heart and skeletal muscle due to defects in uptake, catabolism or secretion.
- Fatty change in liver is common example. Skeletal muscle may show mild fatty change as a result of ischemia and severe fatty change due to diphtheria.

TRIGLYCERIDE ACCUMULATION INDUCING FATTY CHANGE IN LIVER

Liver is the major organ involved in fat metabolism. Hepatic fat accumulation results from an imbalance between lipid acquisition and lipid disposal, which are regulated through four major pathways: uptake of circulating lipids, *de novo* lipogenesis, fatty acid oxidation (FAO) and export of lipids in the form of very low-density lipoprotein (VLDL).

- Fatty change in liver most often occurs due to accumulation of triglycerides. The triglycerides accumulate when lipoprotein transport is disrupted and/or when fatty acids accumulate in the liver.
- Alcohol abuse, diabetes mellitus and obesity are the most common causes of fatty change in liver. Alcohol interferes with mitochondrial and microsomal function in hepatocytes, leading to an accumulation of lipid.
- Other causes of fatty change in liver include toxins, protein malnutrition (kwashiorkor), anoxia and severe gastrointestinal malabsorption. Tetracycline can cause microvesicular fatty change in liver.

Pathogenesis

Normally, free fatty acids (FFAs) derived from adipose tissue or dietary source are normally transported into hepatocytes, where free fatty acids are esterified to triglycerides, converted into cholesterol or phospholipids, or oxidized to ketone bodies. Some of the free fatty acids are synthesized from acetate within hepatocytes as well. Egress of the triglyceride requires the formation of complexes with apoproteins to form lipoproteins, which are able to enter the circulation.

- Defects in any of the steps of uptake, catabolism, or secretion can lead to accumulation of triglycerides in fatty liver. Alcohol is a hepatotoxin that alters mitochondrial and smooth endoplasmic reticulum function and thus inhibits oxidation of free fatty acids.
- Carbon tetrachloride and protein malnutrition decrease the synthesis of apoproteins. Anoxia inhibits fatty acid oxidation, and starvation increases free fatty acid mobilization from peripheral stores.
- Mild fatty change in liver has no effect on cellular functions. Severe fatty change may transiently impair cellular functions. But in carbon tetrachloride poisoning, fatty change in liver is irreversible.

Surgical Pathology: Fatty Change in Liver

Gross Morphology

Mild fatty change in liver may not affect the gross appearance. Severe fatty change results in enlargement of liver, which becomes progressively yellow on cut surface until it may weigh 3–6 kg. This uniform change is consistent with fatty metamorphosis (fatty change).

Frozen/Cryostat Section and Fat Stains

- Fat cannot be demonstrated in the paraffin-embedded sections because fat is dissolved during processing of tissue in tissue processor.
- Fat can be demonstrated by frozen/cryostat section technique with the fat stains such as Sudan III, Sudan IV, Sudan black, Oil red O and osmic acid.

Light Microscopy

- Initially, hepatocytes show small fat vacuoles around nucleus (mild fatty change or microvesicular) in hematoxylin and eosin-stained sections.
- Progressive accumulation of fat forming vacuoles in the cytoplasm coalesce to create spaces that displace the nucleus toward periphery (severe fatty change).
- Occasionally contiguous cells rupture, and the enclosed fat globules unite to produce so-called fatty cysts.
- Distribution of lipid vacuoles may be diffuse, focal or zonal, midzonal or peripheral depending on severity and etiology. Histology of fatty change in liver is shown in Fig. 1.36.

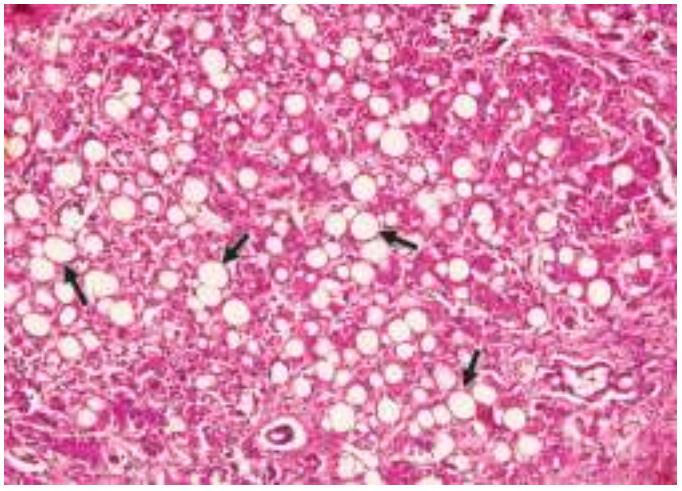

Fig. 1.36: Histology of fatty change in liver. Histologically, fatty liver is characterized by fat accumulation, which is most prominent in the centrilobular zone. Macrovesicular steatosis is the rule. Hepatocytes containing one or numerous fat droplets that displace the nucleus to an eccentric position with abundant clear looking cytoplasm (arrows) (400X).

CHOLESTEROL AND ITS ESTERS ACCUMULATION

Most cells utilize cholesterol for the synthesis of cell membranes without intracellular accumulation. Accumulation of cholesterol and its esters is demonstrated in various disorders such as atherosclerosis, xanthomas, cholesterolosis in gallbladder and Niemann-Pick disease.

Atherosclerosis

Atherosclerosis means hardening (sclerosis) or loss of elasticity of large elastic arteries and medium-sized arteries as a result of fat deposition on their intima.

- Most common sites of atheromatous plaques are abdominal aorta, proximal region of coronary arteries, carotid arteries, vertebral arteries (circle of Willis), iliac arteries, popliteal artery, anterior tibial artery, posterior tibial artery and renal artery; but sparing internal mammary arteries and arteries of upper extremities.
- Major modifiable risk factors of atheromatous plaques include hyperlipidemia, hypertension, tobacco smoking and diabetes mellitus; and nonmodifiable factors are increasing age, male gender, family history of atherosclerosis and genetic abnormalities (ApoA1, ApoE, hepatic lipase and LDL receptor).
- Minor risk factors of atheromatous plaques include obesity, stress type A personality, thrombophilia, high intake of carbohydrates, homocysteinemia, racial factors and infectious agents.
- Atheromatous plaque is composed fibrous cap covering central core comprising smooth muscle cells, foam cells, fibrin, and extracellular matrix material, such as collagen, elastin, glycosaminoglycans, and proteoglycans. Endothelium over the surface of the fibrous cap frequently appears intact.

Xanthomas

Xanthomas are formed due to accumulation of cholesterol or cholesterol esters within macrophages under the skin and tendons on joints (knees and elbows), feet, hands and buttocks.

- Xanthomas can vary in size from pinhead to large grape size, which often appear like a flat mump or yellow to orange. These are usually painless about may be tender or itchy.
- Xanthomas are caused by elevated blood lipids (familial or acquired hyperlipidemia) or fat in the body in the settings of diabetes mellitus, hypothyroidism, primary biliary cirrhosis, nephrotic syndrome, cholestasis and corticosteroid administration.

Gallbladder Cholesterolosis

Gallbladder cholesterolosis is characterized by mucosal villous hyperplasia, excessive accumulation of cholesterol and cholesterol esters in macrophages within the lamina propria and in mucosal epithelium in gallbladder. It is present in 20% of cholecystectomy specimens, usually affecting adult women. It is associated with bile supersaturation with cholesterol but not with increased cholesterol. The gallbladder may be affected in a patchy or diffuse form. Usually, cholesterolosis remains clinically silent.

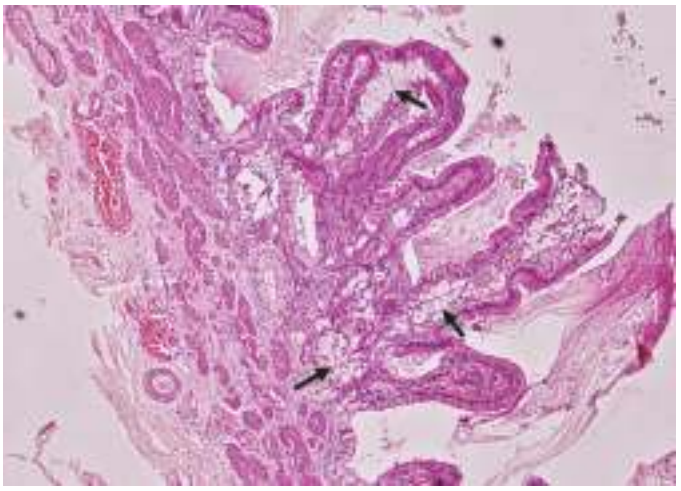

Fig. 1.37: Histology of cholesterolosis in gallbladder. Histologic examination of cholesterolosis shows presence of cholesterol laden macrophages in the lamina propria of the gallbladder mucosa. There is no association with inflammatory changes or presence of gallstones. This finding is incidental without clinical significance (arrows) (100X).

Surgical Pathology: Gallbladder Cholesterolosis

Gross Morphology

Mucosal surface of gallbladder shows yellow, flat deposits, flat or diffuse or speckled appearance (strawberry gallbladder). About 20% of cholecystectomy specimens are associated with cholesterol polyps.

Light Microscopy

- In cholesterolosis, mucosa shows villous hyperplasia with macrophages at the tips of villi and foam cells in the lamina propria and epithelium.
- There is no association with inflammatory changes and cholelithiasis. There may be presence of polypoid lesion with heterotopic bone (osseous metaplasia).
- The changes are usually restricted to gallbladder and not involving extrahepatic bile ducts. Histology of cholesterolosis in gallbladder is shown in Fig. 1.37.

GLYCOGEN ACCUMULATION

Glycogen accumulation is a multibranched polysaccharide of glucose that serves as a buffer to maintain blood glucose levels. It is synthesized from glucose when blood glucose levels are high. It is as an important energy

reservoir in the liver (6–10% of the liver mass) and skeletal muscles (1–2% of skeletal muscle mass).

- In addition to liver and skeletal muscle, glycogen is found in smaller amounts in other tissues such as red blood cells, white blood cells, renal tubules, and some glial cells in brain; except during prolonged starvation. Additionally, glycogen is used to store glucose in the uterus to provide energetic needs of the embryo.
- When energy is required by the body, glycogen is broken down via glycogenolysis into glucose, which then enters the glycolytic or pentose phosphate pathway and then released into the bloodstream.
- In addition to glucagon, cortisol, epinephrine, and norepinephrine also stimulate glycogen breakdown. Periodic acid–Schiff (PAS) is a staining method used to detect polysaccharides such as glycogen, glycoproteins, glycolipids and mucins in tissues. PAS stain with diastase digestion has histochemical specificity for glycogen. Skeletal muscle normally contains glycogen, and is often recommended as a positive control tissue.

GLYCOGEN STORAGE DISEASES

Glycogen storage diseases (GSDS) are the result of deficiency of lysosomal enzymes that cause the alteration of glycogen metabolism (glycogen synthesis or glycolysis) in the liver and skeletal muscle.

- The liver forms of glycogen storage diseases (types 1, 3, 4 and 6) are marked by inability to glycogen to glucose leading to hepatomegaly and hypoglycemia.
- The skeletal muscle forms of glycogen storage diseases (types 2, 3A, 5 and 7) have mild symptoms appearing during strenuous exercise owing to inability to provide energy for skeletal muscle contraction.
- Examples of glycogen storage diseases include von Gierke disease, Pompe disease, Forbes-Cori disease, Cori disease, Anderson disease, McArdle disease, and Hers disease.
- Glycogen storage diseases are given in Table 1.42. Histology of hepatic glycogen storage disease is shown in Fig. 1.38.

Table 1.42 Glycogen storage diseases

Defective Enzyme	Organ Affected	Glycogen Storage in the Affected Organ	Clinical Features
von Gierke disease (GSD type 1)			
Glucose-6-phosphatase or transport system	▪ Liver ▪ Kidney	Increased amount of normal structure	Massive hepatomegaly, failure to thrive, severe hypoglycemia, ketosis, hyperuricemia, hyperlipidemia
Pompe disease (GSD type 2)			
α-1,4-Glucadase (lysosome)	All organs (liver, kidney, skeletal muscle)	Massive increase in amount, normal structure	Hypotonia (floppy baby), hypertrophic cardiomyopathy, cardiorespiratory failure causes death usually before age of two years
Cori disease (GSD type 3)			
Amylo-1,6-glucosidase (debranching enzyme)	▪ Skeletal muscles ▪ Liver	Increased amount, short outer branch	Like type 1, but milder form of disease
Anderson disease (GSD type 4)			
Branching enzyme (α-1,4 → α -1,6)	Liver and spleen	Normal amount, very long outer branches	Progressive liver cirrhosis, hepatocellular failure with fatal outcome before age of two years
McArdle disease (GSD type 5)			
Phosphatase	Skeletal muscles	Moderately increased amount, normal structure	Limited ability to perform strenuous exercise due to painful muscle cramps, otherwise, patient's development normal
Hers disease (GSD type 6)			
Phosphorylase	Liver	Increased amount	Like type 1, but milder form of disease
Tarui disease (GSD type 7)			
Phosphofructokinase	Skeletal muscles	Increased amount, normal structure	Like type 5, but moderately severe disease
GSD type 8 due to hepatic phosphorylase kinase deficiency			
Phosphorylase kinase	Liver	Increased amount, normal structure	Mild hepatomegaly, mild hypoglycemia

Types 1 through 7 are inherited disorder; and type 8 is sex-linked disorder.

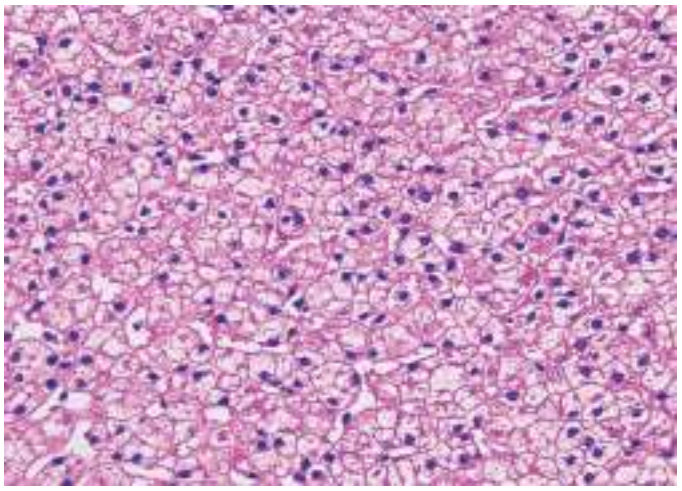

Fig. 1.38: Histology of hepatic glycogen storage disease. Glycogen storage disorders are inborn errors of metabolism with abnormal storage or utilization of glycogen characterized by hypoglycemia, hepatomegaly, stunted growth and chronic lactic acidosis. Histologic examination shows large hepatocytes with prominent cell membrane and glycogenated nuclei with periodic acid–Schiff positive glycogen (400X).

Glycogen Storage Disease Type 0

Glycogen storage disease type 0 (GSD 0) is inherited as an autosomal recessive lysosomal storage disorder, which occurs due to deficiency of glycogen synthase encoded by glycogen synthase 2 (GYS 2) gene. GSD 0 is inherited within families in an autosomal recessive fashion. Normally, glycogen synthase participates in the generation glycogen, that is stored in the liver. Glycogen synthase deficiency leads to low amount of glycogen in the liver resulting in low blood sugar (hypoglycemia) and hyperketonemia.

- **Clinical features:** Early in infancy, patients usually have no symptoms. Any child with a history of needing frequent meals with hypoglycemia and presence of ketone bodies in the urine is suggestive of glycogen storage disease type 0.
- **Laboratory diagnosis:** Genetic testing on blood sample is now available. Aim of treatment for glycogen storage disease type 0 (GSD 0) is to prevent low blood sugar (hypoglycemia) by avoiding fasting. Frequent meals and snacks should be given every 3–4 hours during the day.

von Gierke Disease

Glycogen storage disease type 1 (GSD 1), also called von Gierke disease, is most common autosomal recessive lysosomal glycogen storage disorder caused due to deficiency of glucose-6-phosphatase, in which body cannot break glycogen stored in the liver and skeletal muscle. Normally, glycogen stored in the liver and skeletal muscle is broken down to glucose by glucose-6-phosphatase to generate energy. von Gierke disease is also called type 1 glycogen storage disease.

- **Clinical features:** Patient presents with severe hypoglycemia that coincides with ketonuria, metabolic acidosis and elevated lactate (due to excessive glycolysis) and alanine. Building up of glycogen in liver results in hepatomegaly. Decreased glucose level causes lipolysis resulting in hyperlipidemia. Uricemia is caused by competitive inhibition by lactate of renal tubular urate secretion and increased uric acid production. Patient has growth retardation. Epinephrine and glucagon cannot produce hyperglycemia but result in lipolysis and increased lactate concentration.
- **Laboratory diagnosis:** von Gierke disease is diagnosed by liver biopsy and DNA testing. Patients are treated by cornstarch, allopurinol and granulocytes colony stimulating factor (GCSF).

Pompe Disease

Glycogen storage disease type 2 (GSD 2), also called Pompe disease, is an autosomal recessive lysosomal glycogen storage disorder, which damages skeletal muscle, cardiac muscle, liver and nerves throughout the body. Pompe disease is caused by mutations in the GAA gene, which encodes lysosomal acid α_1-glucosidase and α_4-glucosidase resulting in accumulation of glycogen in the lysosomes of skeletal muscle, cardiac muscle and nerves throughout the body. Normally, lysosomal acid α-glucosidase is involved in glycogen breakdown.

- **Clinical features:** Patient develops intractable hypoglycemia, muscle weakness and cardiomegaly with normal liver functions. Pompe disease is of two types: (a) infantile type and (b) delayed onset type (childhood and juvenile/adult types).
  - **Infantile-onset Pompe disease:** It is most severe form of Pompe disease. Infants are normal at birth, and manifest within the first two to three months with rapidly progressive skeletal muscle weakness, diminished skeletal muscle tone, respiratory problems, feeding problems, hypertrophic cardiomyopathy progressing to cardiorespiratory failure before attaining 3 years of age.
  - **Delayed-onset Pompe disease:** Pompe disease manifests during infancy or early childhood with delayed motor milestones. Juvenile/adult form of Pompe disease presents during in second and seventh decades of life with muscle weakness.
- **Laboratory diagnosis:** Patients with Pompe disease are diagnosed by skeletal muscle biopsy, liver biopsy, lysosomal acid maltase assay and DNA testing. Patients are treated by lysosomal acid maltase replacement.

Cori Disease

Glycogen storage disease type 3 (GSD 3), also known as Cori disease, is an autosomal recessive lysosomal glycogen storage disorder caused due to deficiency of glycogen debranching enzymes (amylo-1,6-gluco--sidase) resulting in storage of abnormal form of glycogen in the liver, heart, or skeletal muscle. Patient presents with stunted growth, hepatomegaly, and hypoglycemia.

- **Clinical features:** Beginning in infancy, any type of GSD III is characterized by low blood sugar (hypoglycemia), hyperlipidemia and elevated blood concentration of liver transaminases and creatinine kinase. As the infant gets older, the child develops stunted growth, hepatomegaly. Liver size returns to normal during adolescence. Some affected persons develop cirrhosis, hepatocellular failure and liver adenoma in life.
- **Laboratory diagnosis:** Beginning in infancy, any type of GSD 3 is characterized by low blood sugar (hypoglycemia), hyperlipidemia and elevated blood concentration of liver transaminases and creatinine kinase.

Anderson Disease

Glycogen storage disease type 4 (GSD 4), also called Anderson disease, is an autosomal recessive trait lysosomal glycogen storage disorder. It is caused by a mutation in GBE1 gene, which encodes glycogen branching enzyme resulting in accumulation of abnormal glycogen in the liver, muscle, and/or other tissues. Normal glycogen branching enzyme is involved in glycogen breakdown in skeletal muscle and liver. Synonyms of GSD 4 are Anderson disease or glycogenosis, amylopectinosis, branching enzyme deficiency and glycogenosis type 4.

- **Clinical features:** Infant presents with failure to thrive, stunted growth and hepatomegaly and cirrhosis progressing to portal hypertension and hepatocellular failure. Death occurs from heart or hepatocellular failure before attaining 5 years of age.
  - In addition, several neuromuscular variants of Anderson disease have been described that may be evident at birth, in late childhood or adulthood.
  - Patient develops isolated muscle involvement with skeletal myopathy and/or dilated cardiomyopathy leading to muscle weakness, fatigue, exercise intolerance, shortness of breath with exertion, edema and cardiac arrhythmias.
  - Neuromuscular variant of GSD 4 in adults, known as polyglucosan body disease, is characterized by dysfunction of the central nervous system (brain and spinal cord) and peripheral nervous system (motor, sensory and autonomic nervous system).
- **Laboratory diagnosis:** Diagnosis of GSD 4 is established by clinical evaluation, history and physical examination. Biopsy obtained from liver, skeletal muscle, heart, skin or peripheral nerve is examined under light microscope, which demonstrates abnormal deposition of amylopectin-like material. Patients are diagnosed by liver biopsy and DNA testing. Patients are treated by liver transplantation.

McArdle Disease

Glycogen storage disease type 5 (GSD 5), also called McArdle disease, is the most common metabolic autosomal recessive lysosomal glycogen storage disorder of skeletal muscle carbohydrate metabolism and one of the most frequent genetic myopathies. It is caused by mutations in PYGM gene located on chromosome 11q13 that codes for the **phosphorylase enzyme**. Normal phosphorylase enzyme causes degradation of glycogen in skeletal muscle for energy. Deficiency of phosphorylase results in accumulation of glycogen in skeletal muscle. Synonyms of GSD 5 are McArdle disease, glycogenosis type 5, myophosphorylase deficiency or muscle glycogen phosphorylase deficiency.

- **Clinical features:** McArdle disease manifests during second or third decade of life. Patient presents with skeletal muscle cramps, muscle stiffness and muscle weakness after strenuous exercise, hypoglycemic seizures or cardiomegaly; increased blood concentration of creatine kinase, myoglobinuria (dark burgundy-colored urine due to presence of myoglobin, a protein found in heart and skeletal muscles), exaggerated increase in ammonia and diminished activity of muscle phosphorylase.
- **Laboratory diagnosis:** Patient is diagnosed by skeletal muscle enzyme assay and DNA testing. Patient is advised to take sucrose prior to strenuous activity.

Hers Disease

Glycogen storage disease type 6 (GSD 6), also known as Hers disease, is a genetic disorder caused by PYG 1 gene mutation and deficiency of the hepatic phosphorylase enzyme resulting in excessive accumulation of glycogen in the liver. Normally, hepatic phosphorylase enzyme is essential to break down glycogen stored in the liver and skeletal muscle and used for energy.

- **Clinical features:** Infant or child presents with failure to thrive, hypotonia, hepatomegaly, ketotic hypoglycemia, elevated hepatic transaminases, hyperlipidemia and low prealbumin level. Most common

complications include short stature, delayed puberty, osteopenia and osteoporosis. Liver fibrosis commonly develops in GSD 6, but cirrhosis and hypertrophic cardiomyopathy rarely develop. Clinical and biochemical alterations may decline with age, but ketosis and hypoglycemia can continue to occur.

- **Laboratory diagnosis:** Diagnosis of Hers disease is established by clinical evaluation, history and physical examination; and molecular testing of **PYG1** gene mutation.

Tarui Disease

Glycogen storage disease type 7 (GSD 7), also known as Tarui disease, is an autosomal recessive lysosomal glycogen storage disorder. It is more often in individuals of Japanese and Ashkenazi Jewish descent equally affecting males and females. It is caused by mutations in the muscle phosphofructokinase gene coding for phosphofructokinase enzyme resulting in deficiency of phosphofructokinase enzyme in skeletal muscle and erythrocytes phosphofructokinase, which leads to reduced amount of energy available to skeletal muscles during exercise.

- **Clinical features:** Tarui disease usually begins in childhood. Patient presents with weakness, pain, stiffness of skeletal muscles during exercise; sometimes associated with nausea, vomiting and dark-burgundy colored urine due to the presence of myoglobin (myoglobinuria). Tarui disease can rarely affect infants and adults.
- **Laboratory diagnosis:** Tarui disease is diagnosed by a skeletal muscle biopsy for the measurement of phosphofructokinase enzyme level or analysis of phosphofructokinase enzyme in red blood cells. Molecular genetic testing is done to analyse mutation in phosphofructokinase gene encoding phosphofructokinase enzyme in Japanese and Ashkenazi Jewish descent. The patients should be advised to avoid strenuous exercise for prevention of skeletal muscle pain and cramps. Consumption of carbohydrates should be avoided. Genetic counseling is recommended for affected individuals and their families.

Glycogen Storage Disease due to Hepatic Phosphorylase Kinase Deficiency

Glycogen storage disease type 8 (GSD 8) is an X-linked recessive hepatic glycogen storage disorder resulting from lack of expression of phosphorylase-β-kinase activity. This is a regulatory enzyme in the activation cascade of glycogenolysis. GSD 8 is mildest form of glycogenoses and characterized by hepatomegaly, increased glycogen in liver, growth retardation and decreased leukocyte phosphorylase, elevation of glutamate-pyruvate transaminase and glutamate-oxaloacetate transaminase, hypercholesterolemia and hyperglyceridemia. Liver shrinkage occurs in response to glucagon.

Glycogen Storage Disease Type 9

Glycogen storage disease type 9 (GSD 9) is an autosomal recessive lysosomal glycogen storage disorder caused by the inability to breakdown glycogen by phosphorylase enzyme in the liver. The signs and symptoms such as hepatomegaly and slow growth begin in the early childhood.

- **Clinical features:** Affected children may have delayed development of milestones (sitting, standing, walking) and mild skeletal muscle weakness. Adolescents may have delayed puberty and liver fibrosis, that can rarely progress to cirrhosis. During prolonged periods of fasting, patient develops hypoglycemia or elevated levels of ketone bodies in the blood (ketosis). Ketones are molecules produced during lipolysis, which occurs when stored sugars are not available. GSD 9 can affect skeletal muscle tissue in children and adults. Patient experiences fatigue, skeletal muscle weakness, skeletal muscle pain, and cramps during strenuous exercise.
- **Laboratory diagnosis:** GSD 9 can cause breakdown of skeletal muscle resulting in release of myoglobin and its excretion in the urine. Myoglobinuria can cause the urine to be red or brown. In a small number of patients with GSD 9 both liver and skeletal muscles are affected, however skeletal muscle problems are usually mild.

Glycogen Storage Disease Type 10

Glycogen storage disease type 10 (GSD 10) is an autosomal recessive lysosomal glycogen storage disorder of glycogen metabolism caused by mutation in PGAM2 gene encoding skeletal muscle phosphoglycerate mutase enzyme. GSD 10 primarily affects skeletal muscles. Patient presents with muscle cramps following strenuous physical activity, recurrent episodes of myoglobinuria as a result of breakdown of skeletal muscle. Untreated cases of myoglobinuria can result in renal failure. In some cases of GSD 10, microscopic tube-shaped structures called tubular aggregates are demonstrated in skeletal muscle fibers. It is not clear how tubular aggregates are associated with the signs and symptoms of the disorder.

PROTEIN ACCUMULATION

Excessive intracellular accumulation of proteins occurs in the settings of protein droplets in proximal tubules in renal disease, Russell bodies in plasma cells, α_1-antitrypsin deficiency, accumulation of cytoskeletal proteins and misfolded proteins in amyloidosis.

INCREASED PROTEIN DROPLETS REABSORPTION IN THE PROXIMAL RENAL TUBULE IN RENAL DISEASE WITH PROTEINURIA

Excessive intracellular accumulation of protein droplets in proximal tubules occurs in renal disease with heavy protein leakage across glomerular filter in renal disease.

- Protein droplets in proximal tubules appear as rounded eosinophilic droplets, vacuoles or aggregates. This change is reversible, if proteinuria diminishes.
- Proteins filtered through glomerular filter are reabsorbed in the proximal tubules via processes that involve at the apical pole of the cells, internalization by receptor-mediated endocytosis involving high molecular proteins (megalin and cubulin) and subsequent lysosomal degradation into constituent amino acids and smaller peptides.

INCREASED PROTEIN PRODUCTION BY PLASMA CELLS FORMING RUSSELL BODIES

Russell bodies are eosinophilic, large, homogenous immunoglobulin-containing hyaline inclusions in the plasma cell undergoing excessive synthesis of a mutant immunoglobulin, which can neither exit nor be degraded in the endoplasmic reticulum.

- Russell bodies lie in distended of rough endoplasmic reticulum, which may be observed in reactive plasmacytosis (e.g. chronic infections) and plasma cell neoplasms on bone marrow aspirates.
- Dilated cisternae of the endoplasmic reticulum resembling Russell bodies are induced in light chain producing myeloma cell lines by transfection of μ heavy chain gene lacking the first constant domain. Plasma cells containing Russell bodies are sometimes referred to a Mott cells.

ACCUMULATION OF CYTOSKELETON PROTEINS

Cytoskeleton of a cell represents network of protein filaments in the cytosol that maintains cell shape, cell movement, cell division, intracellular organization and intracellular transport of organelles and molecules. There are three main components of the cytoskeleton: microtubules, microfilaments and intermediate filaments, along with other proteins that support these components. All three components of cytoskeleton interact with each other noncovalently.

Mallory Hyaline (Mallory-Denk Body)

In histopathology, Mallory hyaline also known as Mallory-Denk body or Mallory body, is an irregular eosinophilic intracytoplasmic inclusion, that represents damaged intermediate filaments (cytokeratins 8 and 18) within hepatocytes in various liver disorders such as alcoholic liver disease, primary biliary cirrhosis, extrahepatic bile duct obstruction, α_1-antitrypsin deficiency, Wilson disease, amiodarone drug-induced liver injury, Indian childhood cirrhosis and nonalcoholic steatohepatitis. Liver disorders associated with Mallory-Denk bodies are given in Table 1.43.

α_1-ANTITRYPSIN PROTEIN ACCUMULATION

The α_1-antitrypsin is an acute phase plasma protein encoded on the proteinase inhibitor locus (Pi) on chromosome 14.

- Normal amount of α_1-antitrypsin protein is synthesized in the liver in normal genotype persons (PiMM phenotype), which inhibits neutrophil elastase. It is most abundant circulating serine protease inhibitor (elastase) secreted by neutrophils during inflammation, which digests the lung parenchyma in tobacco smokers and accelerates the appearance of emphysema symptoms.
- α_1-Antitrypsin deficiency is the most common genetic disorder of liver affecting infants and children. In liver, mutant Z gene in homozygous PiZZ genotype synthesizes mutant Z protein, which folds abnormally and accumulates in endoplasmic reticulum as hyaline globules demonstrated with periodic acid–Schiff (PAS) stain resulting in defective intracellular transport and secretion of proteins in the hepatocytes. Mutated Z protein causes lung disease (emphysema), hepatocellular injury, cirrhosis and hepatocellular carcinoma.

Table 1.43 Liver disorders associated with Mallory-Denk bodies

Category	Disorder
Excessive alcohol consumption	Alcoholic liver disease
Biliary tract disease	▪ Biliary atresia ▪ Extrahepatic bile duct obstruction ▪ Primary biliary cirrhosis ▪ Primary sclerosing cholangitis
Inherited disorders	▪ α_1-antitrypsin deficiency ▪ Abetalipoproteinemia ▪ Glycogen storage disease 1α ▪ Wilson disease
Drug-induced disorders	▪ Ethanol ▪ Amiodarone
Cirrhosis of unknown etiology	▪ Indian childhood cirrhosis ▪ Nonalcoholic steatohepatitis
Hepatocellular tumors	▪ Hepatic adenoma ▪ Hepatocellular carcinoma
Other cause	Focal nodular hyperplasia

- Patients with α_1-antitrypsin deficiency usually develops the first signs and symptoms of lung disease (emphysema) between 20 and 50 years of age.
- Treatment of emphysema includes intravenous administration of prolastin, which replaces α_1-proteinase inhibitor to prevent further lung damage.
- Evaluation for genetic defect involves quantitation of serum α_1-antitrypsin protein and characterization of genetic polymorphism.

PIGMENT ACCUMULATION

Pigments are colored substances which absorb visible light. Pigments are either present in normal cells or introduced from exogenous source. Examples of endogenous pigments synthesized within the body are melanin, bilirubin, hemosiderin, lipofuscin, homogentisic acid. Exogenous pigments introduced from exogenous source include carbon (anthracotic) pigment, tattooing, β-carotene and arsenic. Type of endogenous and exogenous pigments are shown in Table 1.44.

ENDOGENOUS PIGMENTS

Endogenous pigments include melanin, bilirubin, hemosiderin, hematin, lipofuscin, homogentisic acid and Hamazaki-Weissenberg bodies.

Lipofuscin Pigment

The term 'lipofuscin' is derived from the Latin (*fuscus* means brown), thus brown lipid. It is an insoluble pigment, also known as lipochrome or wear-and-tear or aging pigment.

- Lipofuscin is composed of polymers of lipids and phospholipids complexed with proteins, which pigment accumulates in liver, heart muscle, adrenal gland and ganglion cells, producing brown atrophy.
- Lipofuscin is derived from continuing lipid peroxidation of lipids present in cellular membranes as a result of inadequate defenses against activated oxygen-derived free radicals. Lipid peroxides are unstable and breaking down into smaller molecules. Lipofuscin does not injure cells or impair their functions.

Table 1.44 Type of endogenous and exogenous pigments

Endogenous Pigments
Lipofuscin (aging pigment)
Melanin (melanocytes)
Bilirubin (in the settings of hemolytic anemia, cirrhosis, cholestasis)
Hemosiderin (ferritin aggregates)
Hematin
Homogentisic acid
Hamazaki-Wesenberg bodies
Exogenous Pigments
Carbon (anthracotic) pigment
Tattooing
β-Carotene
Arsenic

Pathology Pearls: Lipofuscin Pigment

Light Microscopy

Lipofuscin appears as a yellow brown finely granular pigment in cytoplasm often in perinuclear region in liver, heart muscle, adrenal glands and ganglion cells especially of aging persons or patients with cancer cachexia or severe malnutrition. Histology of myocardium laden with lipofuscin is shown in Fig.1.39.

Histochemistry

Lipofuscin is acid-fast and demonstrated by Sudan black and basic fuscin stains.

Electron Microscopy

Lipofuscin pigment deposition appears as electron dense granules located in a perinuclear region of organs.

Melanin Pigment

Melanin is formed in melanocyte or its precursor derived from neural crest. Melanin biosynthesis begins with the amino acid tyrosine enzyme present in the epidermis, that oxidizes tyrosine to form DOPA (3,4-dihydroxyphenylalanine) in the rate-limiting step of melanin biosynthesis.

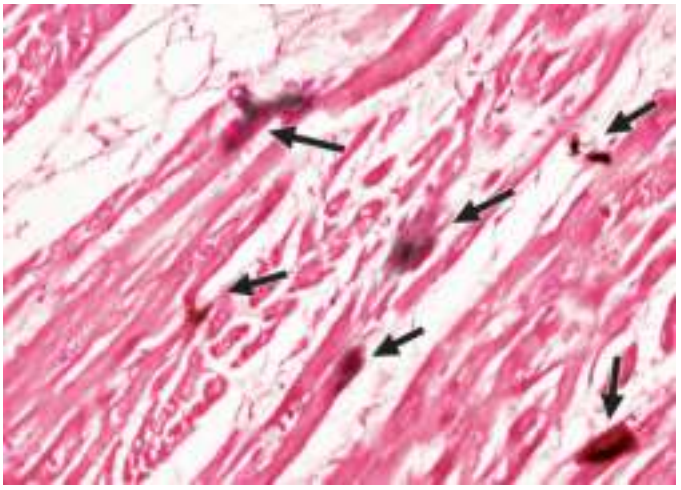

Fig. 1.39: Histology of myocardium laden with lipofuscin. Lipofuscin is fine yellow-brown-golden pigment granules composed of lipid containing residues of lysosomal digestion. It is considered to be one of the aging or 'wear-and-tear' pigments, found in the liver, heart, kidney, retina, adrenal glands, nerve cells and ganglion cells (arrows) (400X).

- Melanin is transferred to adjacent clusters of keratinocytes in the epidermis and macrophages (melanophores) in the dermis.
- Melanin combines with proteins to form melanoprotein. Melanin pigment is responsible for producing color in the body in areas such as skin, hair and eyes.

Hyperpigmentation Disorders

Hyperpigmentation refers to darkening of skin caused by increased melanin, which may be diffuse or focal, affecting face and back of the hands. Ultraviolet rays increase melanin production resulting in hyperpigmentation. Hyperpigmentation is associated with various diseases such as Addison disease, Cushing syndrome. Acanthosis nigricans (hyperpigmentation of intertriginous region associated with insulin resistance), melasma on face during pregnancy, linea nigra on the abdominal region during pregnancy, acne scarring, Peutz-Jeghers syndrome (GIT polyps and hyperpigmented macules on lips), Cronkhite-Canada syndrome and Nelson syndrome (hyperpigmentation, headache, vision impairment and cessation of menstrual cycle in patient with bilateral removal of adrenal glands). Hyperpigmentation associated disorders are given in Table 1.45.

Hypopigmentation Disorders

Hypopigmentation refers to patches of skin that are lighter than the baseline skin color, which occurs due to depletion of melanocyte or melanin, or decrease in the amino acid tyrosine, which is used by melanocytes to manufacture melanin. Genetic disorders caused by mutation in tyrosine gene or OCA2 gene are associated with hypopigmentation. Hypopigmentation is observed in albinism and vitiligo.

Table 1.45 Hyperpigmentation associated disorders

Addison disease (usually associated with elevated melanocyte stimulating hormone)
Cushing syndrome
Acanthosis nigricans (hyperpigmentation of intertriginous region associated with insulin resistance)
Melasma on face during pregnancy
Linea nigra on the abdominal region during pregnancy
Acne scarring
Peutz-Jeghers syndrome (autosomal dominant disorder with GIT polyps and hyperpigmented macules on lips)
Cronkhite-Canada syndrome
Nelson syndrome (hyperpigmentation, headache, vision impairment and cessation of menstrual cycle in patient with bilateral removal of adrenal glands)

- **Albinism:** Albinism is a genetic disorder characterized by the complete or partial absence of melanin production by melanocytes in the epidermis; and associated with vision defects such as photophobia, nystagmus and amblyopia. Oculocutaneous albinism (OC1) results from genetic defect in tyrosinase enzyme.
- **Vitiligo:** Vitiligo is an autoimmune disorder in which cause is an attack by CD8+ cytotoxic T cells on melanocytes in the dermis. Oxidative stress causes cellular disruption including interruption of protein maturation in the endoplasmic reticulum (ER) resulting in the activation of unfolded protein response (UPR) and expression of UPR-regulated chemokines such as interleukin 6 (IL-6) and interleukin 8 (IL-8), which recruit CD8+ cytotoxic T cells, which attack melanocytes in the epidermis. Patient presents with loss of skin color in the form of depigmented, or white patches of skin in any location of the body, that can be focal or multiple in several different areas.

Bilirubin Pigment

Bilirubin is the normal pigment present in bile derived from hemoglobin but contains no iron. RBCs are normally destroyed by reticuloendothelial system (spleen and bone marrow) and liberate hemoglobin, which dissociates to form heme moiety porphyrin and iron and globin.

- Bilirubin derived from porphyrin is an unconjugated (lipid soluble) form, which is conjugated into water-soluble form in the liver by glucuronyl transferase enzyme and excreted into bile. Its normal synthesis and excretion are vital to health.
- Jaundice (yellow discoloration) is a clinical disorder caused by excess of this pigment in the body, which gets deposited in sclerae, mucosae, and internal organs.
- Bilirubin level is increased due to hemolytic anemia (spherocytosis), liver etiology (uptake and conjugation defect of unconjugated bilirubin) and posthepatic obstruction.
  - Hemolytic jaundice is associated with the destruction of red blood cells in hemolytic anemia. In hemolytic disease of newborns, an increase in unbound conjugated bilirubin may result in 'kernicterus' when it enters the central nervous system and dissolves in brain tissue.
  - Conjugated bilirubin is primarily increased in viral hepatitis (hepatocellular injury) and obstructive jaundice (intrahepatic or extrahepatic obstruction of the biliary tract). Bilirubin may accumulate in hepatocytes.

Hemosiderin Pigment

Hemosiderin pigment is a hemoglobin-derived golden brown granular or crystalline pigment, also known as iron pigment. Hemosiderin consists of partially degraded apoprotein, lipid and iron. Iron is stored mostly in the liver, as ferritin and hemosiderin.

- Hemosiderin is a partially denatured form of ferritin present in the form of aggregates in tissues. Apoferritin takes up excess of iron and oxidizes ferrous to ferric form and surrounded by apoprotein known as ferritin. Then ferritin is broken down to hemosiderin.
- Ferritin level in the blood is an index of body iron stores, which is an acute phase reactant protein elevated in inflammatory diseases.
- Hemosiderin is another iron storage protein, which can hold about 35% of iron by weight. Hemosiderin accumulates when iron levels are increased.
- Normally, hemosiderin and ferritin exist in small amounts within tissue macrophages of the iron storage sites such as bone marrow, liver, and spleen, all actively engaged in red cell breakdown.
- Hemosiderin differs from ferritin: (a) unlike ferritin, hemosiderin is visible, water insoluble crystalline protein–iron complex, (b) hemosiderin has higher iron/protein ratio than ferritin, (c) hemosiderin is more stable and less available form of storage iron than ferritin, (d) unlike ferritin, iron in the hemosiderin goes back to metabolic pool of the body in a slow fashion, and (e) iron in hemosiderin is chemically reactive and turns blue-black when exposed to potassium ferrocyanide, which forms the basis for the Perls Prussian blue stain.

Hemosiderosis

Hemosiderosis refers to intracellular storage of hemosiderin located in the fixed macrophages of the bone marrow without associated tissue or organ damage. In congestive heart failure, small hemorrhages occur in the lungs.

- Red blood cells are phagocytosed by alveolar macrophages laden with hemosiderin are known as 'heart failure cells.
- Pulmonary hemosiderosis along with fibrosis is known as **brown induration of lung**. Examples of localized hemosiderosis include organized hematoma, hemorrhagic infarcts and bone fractures.

Hemochromatosis

Hemochromatosis refers to excessive accumulation of hemosiderin primarily within parenchymal cells with accompanying tissue damage, scarring, and organ dysfunction. Excessive iron deposition occurs in primary or secondary hemochromatosis.

- **Primary hemochromatosis:** It is autosomal dominant inborn disorder of iron metabolism resulting in dysregulation of iron metabolism. It most often occurs due to mutation of HFE gene on chromosome 6. Other gene mutations include C282Y, followed by the H63D. Mutations in HFE, C282Y and H63D genes increase iron absorption in the small intestine, excess iron is stored mostly in the form of hemosiderin, primarily in the liver, pancreas, myocardium, and multiple endocrine glands. Perls Prussian blue staining marks the intraparenchymal deposition of hemosiderin. Primary hemochromatosis results in 'bronze diabetes' characterized by micronodular cirrhosis, diabetes mellitus, and skin pigmentation (melanin).
- **Secondary hemochromatosis:** It is most often caused by multiple blood transfusions especially in β-thalassemia major. Iron is deposited in parenchyma of various organs.

Pathology Pearls: Hemosiderin Pigment

Hemosiderin differs from ferritin: (a) unlike ferritin, hemosiderin is visible, water insoluble crystalline protein–iron complex, (b) hemosiderin has higher iron/protein ratio than ferritin, (c) hemosiderin is more stable and less available form of storage iron than ferritin, (d) unlike ferritin, iron in the hemosiderin goes back to metabolic pool of the body in a slow fashion, and (e) iron in hemosiderin is chemically reactive and turns blue-black when exposed to potassium ferrocyanide, which forms the basis for Perls Prussian blue stain.

Light Microscopy

Hemosiderin appears as globular and golden-brown granules. This pigment becomes refractile, when condenser of the microscope is lowered down. Histology of hepatic hemosiderin deposition is shown in Fig. 1.40.

Histochemical Stain

Perls Prussian blue stain is also known as iron stain. Perls Prussian blue stain turns hemosiderin to blue by Prussian blue reaction. Histology of hepatic hemosiderin pigment demonstrated by Perls Prussian blue stain is shown in Fig. 1.41. Distribution of iron in adults is given in Table 1.46. Difference between hemosiderin and ferritin is given in Table 1.47. Hemosiderin is absent in bone marrow macrophages in iron deficiency. It accumulates pathologically in tissues in excess amounts.

Hematin Pigment

Hematin, also known as ferriheme, is a dark bluish or brownish, Perls Prussian blue negative pigment, containing iron in the ferric state, obtained by oxidation of heme.

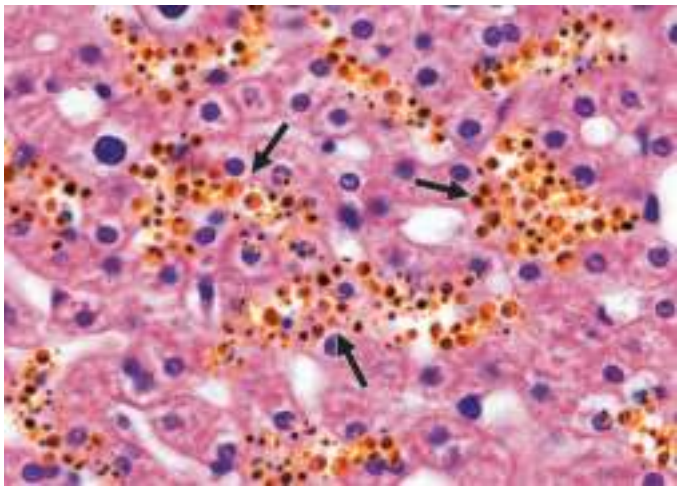

Fig. 1.40: Histology of hepatic hemosiderin deposition. Hemosiderin is a golden-brown iron-containing pigment derived from ferritin, the initial iron storage protein, that tends to be more clumped than melanin. Distinction can be difficult and at times, requiring special iron and melanin pigments. Hemosiderin granules in liver are seen as golden brown finely granular pigment (arrows). In Perls Prussian blue reaction, the tissue section is treated with dilute hydrochloric acid to release ferric ions from binding proteins. These ions will react with potassium ferrocyanide to produce an insoluble blue compound.

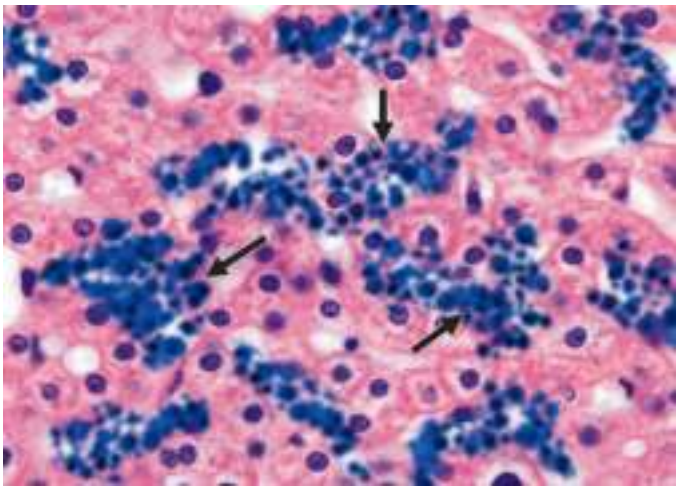

Fig. 1.41: Histology of hepatic hemosiderin pigment demonstrated by Perls Prussian blue stain. The hepatocytes and Kupffer cells are full of granular brown deposits of hemosiderin from accumulation of excess ion in the liver. Hemosiderin granules in liver are demonstrated by Perls Prussian blue stain specific for iron-containing, golden-brown, granular pigment derived from ferritin (arrows). In Perls Prussian blue reaction, the tissue section is treated with dilute hydrochloric acid to release ferric ions from binding proteins. These ions will react with potassium ferrocyanide to produce an insoluble blue compound.

- Hematin is derived from the breakdown of hemoglobin by macrophages in the spleen and bone marrow that have phagocytosed red blood cells (RBCs) in the setting of malaria, methemoglobinemia and schistosomiasis.
- Hematin crystallization is the main mechanism of detoxification of heme that is released in malaria-infected red blood cells as a byproduct of the hemoglobin catabolism by the malarial parasite.
- Functions of hematin include: (a) it inhibits the synthesis of porphyrin, (b) it stimulates the synthesis of globin, (c) it is a component of cytochromes and peroxidases, and (d) it is also used as a reagent.

Homogentisic Acid Pigment

Homogentisic acid is a black pigment that occurs in patients with alkaptonuria, a rare inborn error of metabolism disorder due to homogentisic oxidase deficiency.

- The term alkaptonuria refers to urinary excretion of metabolized homogentisic acid imparting a dark color to urine on standing.

Table 1.46 Distribution of iron in adult male and female

Distribution of Iron Form	Distribution of Iron in Adult Male	Distribution of Iron in Adult Female	Percentage of Total Body Iron
Functional iron			
Hemoglobin (functional iron)	2.4 gm	1.7 gm	65%
Heme enzymes for cellular respiration: functional iron (e.g. cytochromes, catalase, peroxidase, flavoproteins)	0.02 gm	0.015 gm	0.5%
Myoglobin (functional iron)	0.15 gm	0.12 gm	3.5%
Storage/available tissue iron			
Ferritin and hemosiderin (storage iron in bone marrow, liver and spleen)	1.0 gm (0.3–1.5 gm)	0.3 gm (0–1.0 gm)	30%
Plasma iron			
Transferrin-bound iron in plasma	0.004 gm	0.003	0.1%

Total body iron (3.0–5.0 gm)

Table 1.47 Differences between hemosiderin and ferritin

Parameters	Hemosiderin	Ferritin
Solubility in water	Water insoluble crystalline protein–iron complex	Water soluble
Visibility	Visible in tissues	Invisible in tissues
Iron/protein ratio	High	Low
Stability	More stable	Less stable
Storage sites	Bone marrow, liver and spleen	Bone marrow, liver and spleen
Availability form of iron	Less available form of storage iron	More available form of storage iron
Iron going back to metabolic pool	Slow fashion	Rapid fashion
Prussian blue stain	Positive	Negative

- The term **ochronosis** refers to deposition of this pigment prominently in cartilage and connective tissue and other structures (eyes, larynx and bronchi, heart and vessels, prostate, and sweat glands).
- Most symptoms result from joint involvement, which can lead to disabling arthritis as patient ages.

Hamazaki-Wesenberg Bodies

Hamazaki-Wesenberg bodies appear as small, yellow-brown spindle-shaped periodic acid–Schiff (PAS) positive structures in the sinuses of lymph nodes either lying free or as cytoplasmic inclusions deep abdominal mesenteric lymph nodes (most common), superficial lymph nodes and mediastinal lymph nodes. Their significance is not known.

EXOGENOUS PIGMENTS

Exogenous pigments are formed outside the body but found within tissues. Exogenous pigments enter the body in a variety of ways. Examples of exogenous pigments include carbon, asbestos fibers, tattoo ink pigment and metals.

- Copper is the most commonly observed exogenous pigment found in the liver tissue in Wilson's disease. Hematoxylin and eosin-stained tissue section usually does not reveal the presence of copper in liver tissues.
- Two most widely used methods for staining copper are the **rhodanine** and **rubeanic acid stains**, both of which require overnight incubation.
- Shikata stains (orcein and Victoria blue) which stain copper binding protein also require overnight incubation.

Coal Pigment

Coal dust is a fine powdered form of coal, which is created by crushing, grinding or pulverizing of coal. Burning of pulverized coal (powdered coal) in pulverized coal-fired boiler is used to generate thermal energy.

- Because of the brittle nature of coal, coal dust is created during mining, transportation or mechanically handling coal. Coal dust is hazardous to coal workers if it is suspended in air outside controlled environment of crushing grinding and combustion equipment.
- Coal dust (anthracotic pigment) is deposited in the alveolar macrophages, peribronchial lymphatics and hilar lymph nodes. The black streaks seen between lobules of lung beneath the pleural surface are due to accumulation of anthracotic pigment.
- Coal workers' pneumoconiosis, also known as 'black lung disease', is caused by prolonged exposure to coal dust. It develops after the initial mild form of disease known as anthracosis.
  - Prolonged exposure to coal mine dust can cause simple coal workers' pneumoconiosis and complicated coal workers' pneumoconiosis (pulmonary massive fibrosis), chronic bronchitis and emphysema.
  - Coal dust stimulates macrophages to release various products including cytokines, oxygen-derived free radicals and fibroblast growth factors, which are important in the inflammation and complicated coal workers' pneumoconiosis (pulmonary massive fibrosis).

Tattoo ink Pigment

Tattooing is a form of localized exogenous pigment inoculated into the skin. Tattoo ink pigment is phagocytosed by dermal macrophages. It resides in dermal macrophages forever. Inoculated exogenous pigment, as such does not evoke inflammatory response. Most common skin reactions to tattoo ink pigment include a transient acute inflammatory reaction of skin as a result of trauma induced by needles, superficial and deep infections, allergic contact dermatitis, photodermatitis, granulomatous and lichenoid reactions.

EXTRACELLULAR ACCUMULATION OF SUBSTANCES

INTRACELLULAR AND EXTRACELLULAR HYALINE CHANGE

The term 'hyaline' usually refers to an alteration within cells or in the extracellular space, which exhibits a homogenous, glassy, eosinophilic appearance in routine paraffin-embedded histologic sections stained with hematoxylin and eosin. It is widely used as descriptive histologic term rather than a specific marker for cell injury. It is almost always associated with accumulation of a protein in the tissue. Extracellular hyaline can be demonstrated in hyaline arteriosclerosis, uterine leiomyoma, hyaline membrane in the newborn, hyalinization of glomeruli in chronic glomerulonephritis and corpora amylacea in prostate gland. Intracellular and extracellular hyaline change in various disorders is given in Table 1.48.

- Intracellular hyaline change is demonstrated as Russell bodies in plasma cells, reabsorption plasma protein droplets in proximal tubules, tumoral hyaline globules and Mallory hyaline (Mallory-Denk body) in liver disorders.
- Extracellular hyaline change is somewhat more difficult to analyze. Collagenous fibrous tissue in old healed scars may appear hyalinized, but the physiochemical mechanism underlying hyaline change is not clear. In long-standing hypertension and diabetes mellitus, the walls of the arterioles, especially in the kidney, become hyalinized, owing to extravasated plasma protein and deposition of basement membrane material. Hyaline change in the renal arterioles is termed **hyaline arteriolosclerosis**.

Table 1.48 Intracellular and extracellular hyaline change in various disorders

Intracellular Hyaline Change
Mallory hyaline
Russell bodies (e.g. multiple myeloma)
Zenker's hyaline change in rectus abdominis and diaphragm
Crooke's hyaline change in ACTH producing cells
Extracellular Hyaline Change
Hyaline arteriosclerosis
Hyaline change in uterine leiomyoma
Hyaline membrane in the newborn
Hyalinization of glomeruli in chronic glomerulonephritis
Corpora amylacea in prostate

AGGREGATION OF MISFOLDED PROTEINS (AMYLOIDOSIS)

Amyloidosis is fundamentally a disorder of protein misfolding. More than 20 different proteins result in aggregation to form extracellular insoluble fibrils having an antiparallel, β-pleated sheet tertiary structure in organs such as kidney, spleen and liver, resulting in Congo red staining and 'apple green birefringence' under polarized light microscope. Amyloid material appears as beaded fibrillar appearance on electron microscopy.

- Amyloid is composed of fibrillar proteins, and non-fibrillary glycoproteins [amyloid P component also called serum amyloid P (SAP) glycosaminoglycans and apolipoprotein E]. Serum amyloid P component may contribute to stability of amyloid deposits.
- Radioactive iodine labeled SAP is used to assess amyloid deposition in nuclear medicine studies. Irrespective of molecular composition, amyloid always has the same characteristic histologic and ultrastructural appearance. Amyloid is resistant to digestion, which accumulates within tissue, interferes with function and destroys vital organs.
- Important clinical forms of amyloidosis include: (a) primary amyloidosis is a feature of multiple myeloma and characterized by deposits of AL amyloid in the kidneys, blood vessels and heart, which is derived from the immunoglobulin light chains AL, (b) secondary amyloidosis is characterized by deposits of AA amyloid in kidneys, liver and spleen which is derived from serum amyloid associated protein produced by liver in the settings of chronic inflammation, autoimmune disorders and renal cell carcinoma, (c) familial amyloidosis results from deposits of abnormal transthyretin in the nerves, and (d) localized amyloidosis is typical of Alzheimer disease (amyloid deposit in the cerebral cortex) and medullary carcinoma of the thyroid.

RENAL AMYLOIDOSIS

Renal amyloidosis is the most common serious complication in the disease. Kidneys are commonly involved in 80% cases of systemic amyloidosis. Patient develops renal failure associated with fatal outcome.

- Renal amyloidosis occurs due to deposition of amyloid material in primary (AL in multiple myeloma) and secondary amyloidosis (AA in chronic disorders).
  - In primary amyloidosis, κ or λ chains of immunoglobulins synthesized by neoplastic plasma cells are deposited in the glomerular basement membrane and mesangial matrix. These immunoglobulins can be detected in serum or urine by electrophoresis.

- In secondary amyloidosis, amyloidosis is a well-known complication of chronic inflammatory disorder such as tuberculosis, bronchiectasis, rheumatoid arthritis, and osteomyelitis, which stimulate the liver to synthesize AA protein, an acute-phase reactant secreted by the liver. The kidneys (80%), liver, spleen, and adrenals are the most common organs involved in secondary systemic amyloidosis.

- Renal amyloidosis is important cause of nephrotic syndrome in 5% of middle-age adults. About 50% of patients may have proteinuria in the nephritic range and hypertension followed by massive proteinuria in nephrotic range, weight loss, organomegaly, monoclonal light chains in serum or urine.
  - As the renal disease progresses, there will be renal insufficiency and chronic renal failure (small contracted kidneys) over 2–5 years.
  - Renal failure is a common cause of death in amyloidosis. Duodenal biopsy is sensitive technique for diagnosing amyloidosis in chronic kidney disease patients, and highly correlates with renal amyloidosis.

Pathology Pearls: Renal Amyloidosis

Gross Morphology

- Kidney is enlarged, pale, and waxy with smooth surface with firm consistency.
- In advanced cases, the kidneys are contracted and shrunken due to vascular narrowing induced by deposition of amyloid.
- Cut section of kidneys reveals pale firm and waxy amyloid material in the renal cortex.

Light Microscopy

- Glomeruli show thickening of glomerular basement membrane.
- Amyloid material appears as amorphous, homogenous and eosinophilic in mesangial region, tubular basement membranes, renal vessels and interstitial tissue.
- Expansion of mesangial region obliterates the glomerular capillary loops rendering the glomerular filter leaky to plasma proteins and impaired renal functions.
- There is no cellular response to the amyloid deposits. The amount of amyloid in the glomeruli correlate roughly with the clinical manifestations of the disease. Histology of renal amyloidosis is shown in Fig. 1.42.

Amyloid Staining

- Amyloid material in glomerular mesangial matrix, glomerular and tubular basement membrane is demonstrated by Congo red staining under polarized microscopy, which reveals characteristic apple-green birefringence (color of a Granny Smith apple).
- Amyloid material can also be demonstrated by various other stains, i.e. thioflavin T, thioflavin S, methyl violet, crystal violet.
- Pretreatment of tissue with potassium permanganate stained by Congo red demonstrates AL amyloid only but not AA amyloid. Congo red stain in renal amyloidosis is shown in Fig. 1.43. Stains used to demonstrate amyloid material is given in Table 1.49.

Immunofluorescence Microscopy

Immunofluorescence microscopy of renal biopsy reveals non-specific trapping of proteins.

Electron Microscopy

Electron microscopy demonstrates fibrils 7.5–10 nm in diameter with randomly dispersed, nonbranching arrangement in mesangial and subendothelial regions of glomeruli.

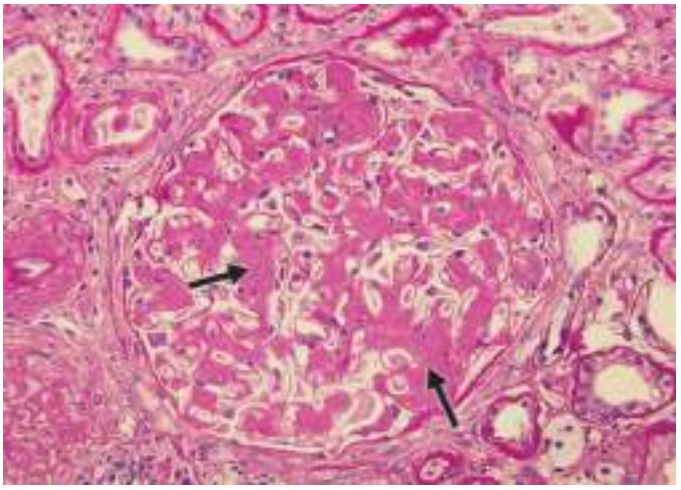

Fig. 1.42: Histology of renal amyloidosis: Initially, amyloid material is deposited in the mesangium and then extending along the inner surface of GBM distorting glomerular lumina. Light microscopy shows amorphous acellular material extending to mesangial matrix and obstructing glomerular lumina (arrows) (400X).

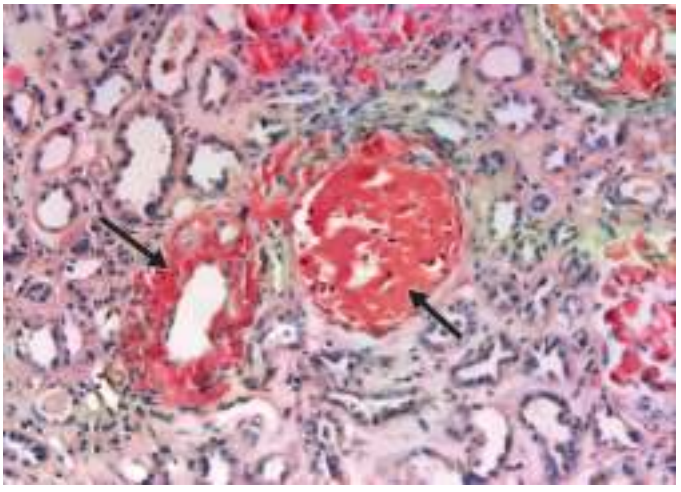

Fig. 1.43: Congo red stain in renal amyloidosis. Amyloid material is stained by Congo red stain. Nodules in diabetic glomerulosclerosis are PAS positive but negative for Congo red stain (arrows) (400X).

Table 1.49 Stains used to demonstrate amyloid material

Amyloid Stain	Color Imparted
Congo red with light microscopy	Rose-pink
Congo red with polarizing microscopy	Apple green birefringence similar to color of Granny Smith apple
Methyl violet (metachromatic stain)	Pink
Crystal violet (metachromatic stain)	Pink
Fluorescent stains: ▪ Thioflavin T ▪ Thioflavin S	Greenish
von Gieson stain	Khaki color
PAS stain	Magenta color

Congo red stain is commonly used to demonstrate amyloid deposits in tissue sections.

SPLEEN AMYLOIDOSIS

Amyloid deposition in the spleen can occur in three major sites: red pulp, white pulp, and blood vessels. Red pulp involvement by amyloid occurs in more than 50% of AL cases but none of the AA cases and produce lardaceous spleen. White pulp amyloid deposition can occur in 70% of the AL and 35% of the AA cases and produce sago spleen. Blood vessels are involved in AL amyloidosis.

- Amyloid involvement of spleen causes moderate to marked splenomegaly weighing 200–800 g, and increases the risk of spontaneous rupture of spleen.
- Amyloid deposit in spleen has two different anatomical patterns such as sago spleen (amyloid deposit in splenic lymphoid follicles with moderate splenomegaly) or lardaceous spleen (amyloid deposit in red pulp with marked splenomegaly).
- In both sago and lardaceous anatomical patterns of spleen due to amyloid deposit, spleen is firm in consistency, and cut surface reveals pale gray, waxy deposits. Comparison between sago and lardaceous spleen in amyloidosis is given in Table 1.50.

Surgical Pathology: Anatomical Patterns of Spleen in Amyloidosis

Sago Spleen

- Amyloid involvement of the spleen occurs in splenic lymphoid follicles resulting in moderate splenomegaly.
- Cut surface of the spleen shows dotted with tapioca-like gray nodules called as 'sago spleen'.
- Sago is an edible starch that is prepared from the pith of an array of tropical palm trees. It is staple food in parts of the tropics.

Lardaceous Spleen

- Alternatively, the amyloid involvement of spleen occurs in the red pulp sparing splenic follicles resulting in marked splenomegaly.
- Gross examination of spleen shows large, firm spleen mottled with waxy discolorations called 'lardaceous spleen'.
- The red pulp of the spleen is composed of connective tissue known as 'cords of Billroth' and many splenic sinusoids that are engorged with blood exhibiting it a red color.
- Primary function of 'cords of Billroth' is to filter circulating blood antigens, microorganisms and defective or worn-out red blood cells. Histology of amyloid deposition in the spleen is shown in Fig. 1.44.

LIVER AMYLOIDOSIS

The liver is almost universally involved in systemic amyloidosis that occurs in myeloma-related (AL) primary amyloidosis and amyloid-associated (AA) secondary or reactive amyloidosis.

- Amyloid deposits occur in the hepatic parenchyma along the sinusoids within the 'space of Disse' or within the walls of blood vessels. As a result of extensive compression of the hepatocytes by amyloid deposits, there may be atrophy of hepatocytes.
- AL amyloid involves the portal vessels as frequently as AA amyloid associated deposit occurs significantly more frequently in the portal stroma, the central vein and the sinusoidal areas.
  - Hepatic dysfunction is usually subclinical and may include hepatomegaly, mild jaundice and rarely severe cholestasis.

Table 1.50 Comparison between sago and lardaceous spleen in amyloidosis

Parameters	Sago Spleen	Lardaceous Spleen
Amyloid deposit	AL (>50%)	AA (70%) and AL (35%)
Amyloid deposit in splenic region	Red pulp	White pulp (lymphoid follicles)
Gross appearance of spleen	Tapioca-like gray nodules	Large firm spleen
Splenomegaly	Marked splenomegaly	Moderate splenomegaly
Consequence	Rupture (more frequent)	Rupture (relatively less frequent)

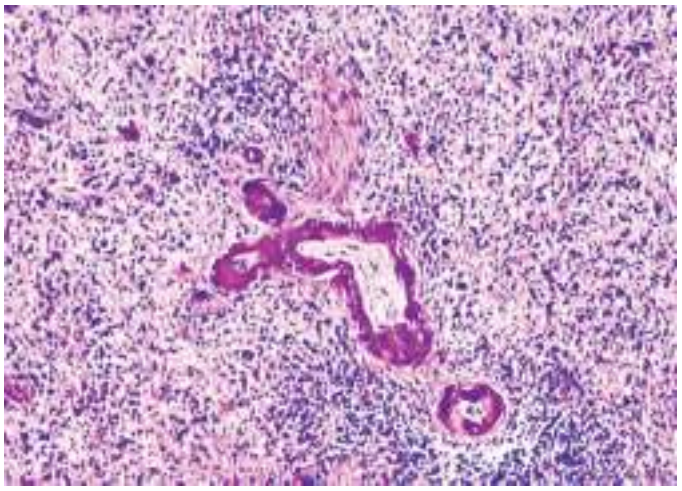

Fig. 1.44: Histology of amyloid deposition in the spleen. Most common types of amyloidosis are AL (primary), AA (secondary), familial ATTR and senile ATTR amyloidosis. Amyloidosis most commonly affects kidneys, liver and spleen. Amyloid deposition in spleen can involve red pulp (AL type), white pulp (AL and AA types) and blood vessels (100X).

- Hepatic amyloidosis can cause portal hypertension, subcapsular hematoma and spontaneous rupture.
- Acute and fulminant hepatic failure have been described as a result of amyloid light (AL) amyloidosis in the setting of multiple myeloma.

Pathologic Features: Liver Amyloidosis

Gross Morphology

The amyloid liver is usually grossly enlarged (as much as 900 gm), pale, and smooth surface, firm consistency. When sectioned, it has sharp rigid edges.

Light Microscopy

- Liver biopsy shows near complete effacement of acinar architecture by sinusoidal and portal deposits extracellular, pale eosinophilic, hyaline amorphous acellular material.
- Amyloid material is initially deposited in the spaces of Disse between the hepatocytes and vascular sinusoids. As more amyloid accumulates, it compresses the hepatic cords and sinusoids.
- The hepatic cords undergo nutritional and pressure atrophy and become displaced or replaced by bands and nodules of amyloid.

FIBRINOID NECROSIS OF ARTERIOLES

Fibrinoid necrosis of arterioles is associated with endothelial damage of small arteries and arterioles characterized by entry and accumulation of serum proteins followed by fibrin polymerization in the blood vessel wall. Accumulated serum proteins and fibrin form an intensely eosinophilic collar that obliterates cellular details of blood vessel. Fibrinoid necrosis lesion is frequent in many acute degenerative and inflammatory disorders of small arteries and arterioles.

HYALINIZATION OF GLOMERULAR BASEMENT MEMBRANE

In long-standing hypertension and diabetes mellitus, the walls of arterioles, especially in the kidney, becomes hyalinized, owing to extravasated plasma protein and deposition of glomerular basement membrane.

DYSGENETIC HYALINIZATION IN SEMINIFEROUS TUBULES

Dysgenetic hyalinization is demonstrated as a diffuse lesion in most seminiferous tubules in the settings of Klinefelter syndrome and cryptorchid testes. Focal hyalinization may be demonstrated in mixed testicular atrophy.

- **Dysgenetic hyalinized seminiferous tubules in Klinefelter syndrome:** During infancy, small seminiferous tubules contain reduced numbers of Sertoli cells and with few or absence of spermatogonia.
  - At puberty dysgenetic Sertoli cells fail to undergo maturation and soon disappear. The seminiferous tubules collapse, exhibiting the appearance of phantom seminiferous tubules. Peritubular cells fail to differentiate resulting in reduction in their numbers, thereby there is no synthesis of elastic fibers and lamina propria.
  - Dysgenesis also involves the interstitium and Leydig cells. The uniform morphology of Leydig cells is altered. Most of Leydig cells contain reduced amounts of lipofuscin granules and lipid droplets. Testosterone secretion is markedly reduced and the resulting hypogonadism is the most salient clinical feature of Klinefelter syndrome.
- **Cryptorchid testis:** In contrast to atrophic collapse observed in Klinefelter syndrome, cross-sections of the dysgenetic hyalinized seminiferous tubules are targetoid in cryptorchid testis. The peritubular cells are arranged into two layers in patients with cryptorchidism. This suggests that atrophic process in cryptorchidism has evolved over a longer period than in Klinefelter syndrome.

PATHOLOGIC CALCIFICATION

Calcification is a process in which calcium builds up in the body tissue, causing the tissue harden. This can be a physiologic or pathologic processes. About 99% of calcium entering the body is deposited in the form of calcium phosphate and calcium carbonates in the bones and teeth. The remaining calcium dissolves in the blood. Dystrophic and metastatic calcification occurs when calcium accumulates in the body cells/tissues, blood vessels or organs. Differences between dystrophic and metastatic calcification are given in Table 1.51.

- Dystrophic calcification is defined as the local deposition of predominantly calcium salts in injured or necrotic tissue that occurs in the setting of pathologic disorders otherwise with normal serum calcium levels. Overtime, ossification may occur at site of dystrophic calcification.
- Metastatic calcification is defined as the local or systemic deposition of predominantly calcium salts in otherwise normal tissues in the setting of hypercalcemia. Lungs are the commonest site for metastatic calcification.
  - Calcification begins in the mitochondria of all organs except kidney. Calcification in kidney begins in the glomerular basement membrane of kidney.
  - The calcium deposits can impair normal functions and cause pain. In hematoxylin and eosin-stained sections, calcium appears as amorphous, basophilic, granular and clumped in the intracellular as well as extracellular sites.
  - Depending on the site involvement, patients can present with skeletal muscle weakness, bone pain, prone to bone fractures, bone spurs, leg new bone deformity such as leg bowing or spine curvature breast lump.
  - Gross morphology of calcified leiomyoma and Monkeberg's medial calcific sclerosis is shown in Fig. 1.45A and B.

DYSTROPHIC CALCIFICATION

Dystrophic calcification occurs in areas of degeneration and necrosis. Some examples of lesions with dystrophic calcification include atherosclerotic plaques, tuberculous lymph node, damaged cardiac valves, hyalinized scars, myositis ossificans, degeneration in leiomyoma, neurocysticercosis and TORCH syndrome.

- TORCH syndrome is characterized by congenital infection with toxoplasmosis, rubella,

Table 1.51 Differences between dystrophic and metastatic calcification

Features	Dystrophic Calcification	Metastatic Calcification
Definition	Calcium deposition in dead or dying tissues	Calcium deposition in in normal tissues.
Calcium metabolism	There is no systemic disturbance of calcium metabolism.	There is systemic disturbance of calcium metabolism
Serum calcium	Normal	Elevated
Organs	Organs affected due to necrosis, i.e. parasitic infections as mentioned and some tumors as mentioned above	Kidneys, lungs, cornea, blood vessels, fundal glands of stomach due to relative alkalinity left after their acid secretions favor it
Causes	▪ Caseous necrosis ▪ Fat necrosis ▪ Cysticercosis (dead parasite) ▪ Filariasis ▪ Hydatid cyst (dead parasite) ▪ Dead fetus (lithopedion) in ruptured tubal pregnancy ▪ Complicated atheromatous plaque ▪ Monkeberg's calcific sclerosis ▪ Venous thrombi (phleboliths) ▪ Damaged cardiac valves ▪ Traumatic myositis ossificans ▪ Hyalinized scar tissue ▪ Leiomyomas undergoing degeneration ▪ Goiter undergoing degeneration ▪ Meningiomas (psammoma bodies) ▪ Serous cystadenoma (psammoma bodies) ▪ Papillary carcinoma thyroid (psammoma bodies) ▪ Pulmonary alveolar microliths	▪ Primary hyperparathyroidism ▪ Secondary hyperparathyroidism secondary to chronic renal disease with phosphate retention ▪ Milk-alkali syndrome ▪ Hypervitaminosis D ▪ Multiple myeloma ▪ Metastatic bone tumors ▪ Prolonged immobilization

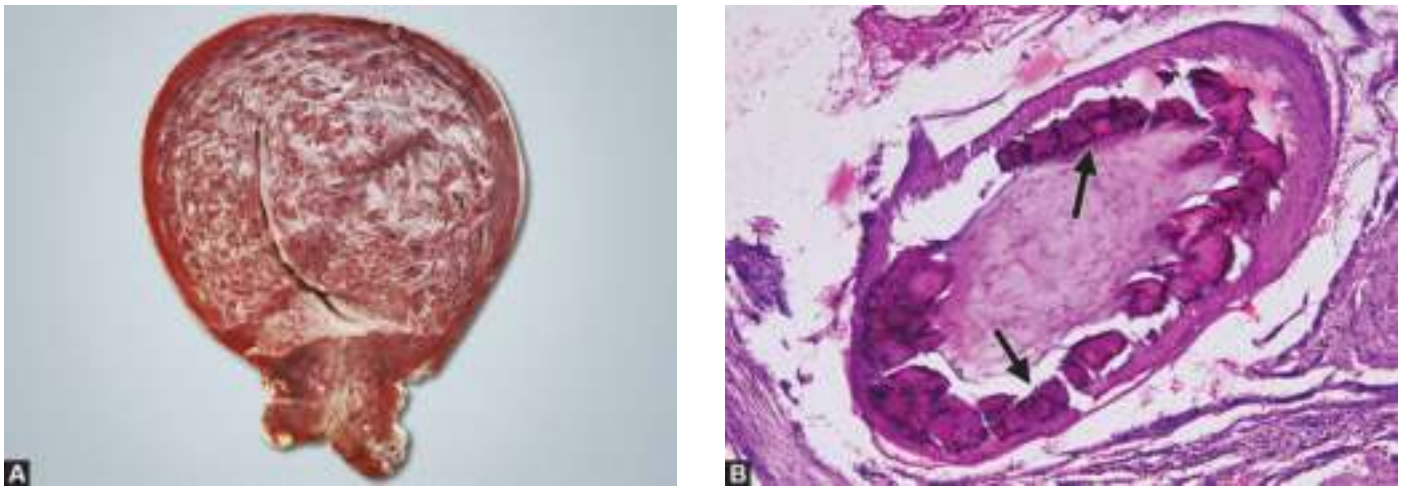

Fig. 1.45: (A) Gross morphology of calcified leiomyoma, (B) Monkeberg's medial calcific sclerosis is a ring-like calcification of the vascular media of small- to medium-sized blood vessels without associated with intimal thickening in the settings of aging, diabetes mellitus and progressive renal failure (arrows) (400X).

cytomegalovirus, herpes simplex and other organisms including syphilis, parvovirus, varicella zoster and Zika virus. TORCH infection can cause spontaneous abortion, premature birth, cerebral calcifications, chorioretinitis and skeletal metaphyseal dystrophy and periostitis.

- Macroscopically, dystrophic calcification appears tiny, white and gritty granules. On histologic examination, calcium is observed as basophilic granules (or sometimes amorphous calcium deposits) either inside or outside of cells.
- Sometimes, single necrotic cells act like grains of sand around which a 'pearl' of calcium is deposited known as psammoma bodies. Psammoma bodies are calcific spherules observed in papillary carcinoma of thyroid, meningioma, and serous cystadenoma, serous cyst borderline tumor and serous cyst adenocarcinoma.
- Disorders associated with dystrophic calcification are given in Table 1.52.

Pathology Pearls: Vitamin D and Vitamin K Role in Calcium Metabolism

- Vitamin D and vitamin K are fat-soluble vitamins and play a central role in calcium metabolism (intestinal and renal calcium absorption).
- Vitamin D promotes the production of vitamin K-dependent proteins, which require vitamin K for carboxylation in order to function properly.

Vitamin D Role in Calcium Metabolism

- Vitamin D, a fat-soluble vitamin, is derived from two sources: dietary foods and synthesis by human skin exposed to sunlight. In the liver, vitamin D is hydroxylated to 25(OH) dihydroxyvitamin D, the main circulating vitamin D metabolite to be analyzed to know vitamin D status.
- Circulating 25(OH)D is further metabolized by kidney into most active form 1,25-dihydroxyvitamin D(1,25[OH]D), also known as calcitriol.
- Vitamin D plays important role in regulating calcium metabolism by increasing intestinal and renal c absorption.

Vitamin K Role in Calcium Metabolism

- Vitamin K regulates calcium metabolism by two mechanisms: (a) it promotes calcification of bones, and (b) it prevents the calcification of blood vessels and kidneys. Vitamin K deficiency can occur due to bile duct obstruction and warfarin therapy (vitamin K antagonist).
- Vitamin K exists in two forms: vitamin K_1 (phylloquinone, mainly found in green leafy vegetables) and vitamin K_2 (menaquinone). Vitamin K stores are limited. Vitamin K_1 is transported to the liver that regulates the production of coagulation factors.
- Vitamin K_2 is transported to extrahepatic tissues such as bone and the blood vessel wall that regulates the activity of matrix Gla protein (MGP) and osteocalcin-vitamin K-dependent proteins. Vitamin K plays important role in carboxylation and functioning of vitamin K-dependent proteins (MGP and osteocalcin).
- When circulating concentrations of vitamin K are insufficient, major proportion of MGP and osteocalcin remain uncarboxylated, which is linked with cardiovascular disease, low bone mineral density (BMD) and osteoporosis.

Pathology Pearls: Mechanism of Dystrophic Calcification

- Dystrophic calcification has its origin in direct cell injury.
- Calcium is deposited in dead or dying tissues.
- Serum calcium concentration is within normal limits. It occurs by two processes: initiation and propagation.

Initiation of Calcification

- The process of dystrophic calcification is thought to start in membrane-bound vesicles within degenerated or necrosed cells.
- When the membrane of a vesicle gets damaged, phosphatase adds phosphate to the calcium forming calcium phosphate that has strong affinity for phospholipids in the cell membrane.
- Now tiny crystals of calcium are released from membrane bound vesicles into the extracellular compartment.

Propagation of Calcification

- Deposition of enough calcium phosphate leads to form clumps, which rearranges itself to generate microcrystals resulting in propagation and more calcium deposition.
- Further deposition of calcium is known as propagation, which depends on level of calcium and phosphate in the extracellular compartment, presence of collagen fibers and other proteins.
- Propagation enhances deposition of calcium. Calcium now binds with osteopontin. Normally, osteopontin participates in mineralization of bone.

METASTATIC CALCIFICATION

The deposition of calcium and phosphate salts in normal tissues is known as metastatic calcification, most often secondary to some derangement in calcium and phosphate metabolism.

- Serum calcium and phosphate concentration is higher than normal range in the settings of advanced stage cancers metastasizing to bones, multiple myeloma, primary/secondary hyperparathyroidism, hypervitaminosis D, milk-alkali syndrome due to excess calcium intake in the form of milk and self-antacid therapy, prolonged immobilization, advanced renal disease with phosphate retention in secondary hyperparathyroidism, and pharmacological agents.
- Most cases of hypercalcemia of malignancy are associated with dysregulation of parathormone (PTH) and PTH-related peptide (PTHrP).
- Under physiologic state, PTH is activated when calcium levels in the blood drop, which leads to increased calcium absorption by renal tubules and the intestine to correct the drop.
- PTHrP, an ectopic hormone, is capable of acting on the same receptors as parathormone. PTHrP is upregulated in breast cancer, lung cancers (small cell lung carcinoma and squamous cell carcinoma), ovarian carcinoma, prostatic carcinoma, hepatocellular carcinoma and adult T cell lymphoma.
- In primary or secondary hyperparathyroidism, the overproduction of parathormone leads to an inevitable increase in serum calcium level as a consequence of calcium released from the bones and increase in absorption of calcium by small intestine under the influence of parathormone.

Table 1.52 Disorders associated with dystrophic calcification

Necrosis
▪ Caseous necrosis ▪ Fat necrosis
Parasitic Disorders
▪ Cysticercosis ▪ Hydatid cyst ▪ Filariasis ▪ Schistosomiasis
Tissue Trauma and Repair
▪ Myositis ossificans (calcium deposition in skeletal muscles after trauma) ▪ Calcium deposition in hyalinized scar
Hamartomas
Hamartomas in the vicinity of the bones
Thyroid Gland Disorders
▪ Multinodular goiter ▪ Papillary thyroid carcinoma (psammoma bodies)
Central Nervous System Disorders
▪ Intrauterine toxoplasma infection of fetus with TORCH syndrome causing acute encephalitis associated with foci of necrosis that become calcified ▪ Neurocysticercosis ▪ Meningioma (psammoma bodies)
Cardiovascular System Disorders
▪ Advanced atheromatous plaque ▪ Venous thrombi ▪ Arteriosclerosis ▪ Scarred cardiac valves
Breast Disorders
▪ Breast carcinoma (calcification demonstrated by mammography) ▪ Breast fat necrosis
Female Genital System Disorders
▪ Degeneration in uterine leiomyoma ▪ Calcium deposition in dead fetus after ruptured tubal pregnancy is called lithopedion ▪ Serous cystadenoma of ovary (psammoma bodies) ▪ Borderline serous tumor of ovary (psammoma bodies) ▪ Serous cystadenocarcinoma of ovary
Metastatic Calcinosis Cutis
Dystrophic calcification under skin in internal malignancy
Other Rare Disorders
▪ Arterial calcification due to CD73 deficiency ▪ Generalized arterial calcification of infancy ▪ Hyperphosphatemic familial tumor calcinosis ▪ Pseudoxanthoma elasticum ▪ Scleroderma ▪ Dermatomyositis ▪ Systemic lupus erythematosus

- The process of metastatic calcification seems to affect renal tubular basement membrane (nephrolithiasis), pulmonary alveolar septa (pulmonary alveolar microlithiasis), cornea, interstitial tissues of the gastric mucosa in fundus region, internal elastic lamina of blood vessels and synovium of joints.
- Metastatic calcification in the lung or kidney may impair functions.
- Adult T cell lymphoma caused by human leukemic virus type 1 synthesizes overproduction of parahormone-related peptides, that has osteoclast overactivity resulting in hypercalcemia in association with bone demineralization.
- Metastatic calcification in kidney causes nephrocalcinosis and renal stones leading to impairment of renal function.
- Metastatic calcification in malignancy is reported in parathyroid carcinoma.
- Etiology of metastatic calcification is given in Table 1.53. Sites of metastatic calcification are given in Table 1.54.

Table 1.53 Etiology of metastatic calcification

Primary hyperparathyroidism
Secondary hyperparathyroidism secondary to chronic renal disease with phosphate retention
Milk-alkali syndrome
Hypervitaminosis D
Multiple myeloma
Metastatic bone tumors
Prolonged immobilization

Table 1.54 Sites of metastatic calcification

Kidney: basement membrane of tubules and tubular lumina
Lung: alveolar cells
Stomach: acid secreting fundal glands
Blood vessels: internal elastic lamina
Eyes: cornea
Joints: synovium causing pain

PULMONARY ALVEOLAR MICROLITHIASIS

Pulmonary alveolar microlithiasis (PAM) is a rare chronic lung disease characterized by deposition of calcium and phosphate in the intra-alveolar region involving bilateral lung parenchyma in the lower and mid zones.

- Exact etiopathogenesis is not fully understood. However, mutation in SLC34A2 gene that codes a sodium phosphate co-transporter in alveolar type 2 pneumocytes resulting in formation and accumulation of microliths rich in calcium phosphate due to impaired clearance is considered the cause of disease.
- Patients with pulmonary alveolar microlithiasis remain asymptomatic till development of hypoxemia and cor pulmonale. In some persons, PAM remains static, while in some persons, PAM progresses to pulmonary fibrosis, respiratory failure and cor pulmonale. Patient presents with dry cough and progressive shortness of breath on exertion.
- Chest radiograph shows dense micronodular opacities giving classical sandstorm appearance. High resolution computed tomography (HRCT) shows microcalcification, subpleural cystic changes and calcified pleura. Lung biopsy shows calcospherites within the alveolar spaces.

CELLULAR BIOLOGY OF AGING

Aging human cells can stop dividing and enter senescence, as a result of cell damage and defective chromosomal telomeres. Cellular aging process is driven at the cellular level by random molecular damage in almost all systems that slowly accumulate with age. Although the cells possess the mechanisms to repair the damage, yet they are not 100% efficient to do so, as their efficiency declines with age.

- Cellular aging is affected by genetic and environmental factors. Genetic abnormalities result in progressive decline in cellular function and viability. Environmental factors induce sublethal injury over years at cellular and molecular level.
- Alternative theories of aging suggest that essential neuroendocrine biological stimuli from brain or endocrine glands are programmed to stop at a certain biological age, resulting in lack of essential trophic factors to maintain cell growth.
- Other proposals suggest inefficient DNA repair, oxygen-derived free radical damage, or failure of protein catabolism as the root cause of aging.
- Cumulative injury theories propose that aging is the result of all cellular impairments sustained throughout life, whether through DNA damage, protein modification, oxygen-derived free radical damage, or disease. Mechanisms of cellular aging is discussed as follows.

Pathology Pearls: Interventions that might Extend Human Life Span

- Clearance of senescent cells
- Elimination of damaged cells
- Telomerase activation
- Activation of chaperones and proteolytic systems
- Dietary restriction, inhibition of mTOR pathway; and activation of AMPK and sirtuin
- Stem cell-based therapies
- Mitohormetics mitophagy
- Anti-inflammatory drugs/blood-borne rejuvenation factors
- Epigenetic drugs

DNA DAMAGE THEORY OF AGING

DNA is a double helix molecule of deoxyribonucleic acid containing a chain of nucleotides winding around a helix axis in a right-handed spiral at 360°. Each helical turn consists of 10 nucleotide base pairs.

- Each nucleotide contains a sugar phosphate backbone and a nitrogen base. Four types of nitrogen bases are (a) purines: adenine (A) and guanine (G); and (b) pyrimidines: thymine (T) and cytosine (C). The order of these nitrogen bases determines DNA instructions or genetic code. The main role of DNA in the cell is the long-term storage of information.
- The DNA damage theory of aging proposes that aging is a consequence of unrepaired accumulation of naturally occurring DNA damage and mitochondrial DNA damage.
- The DNA damage is an alteration in the chemical structure of DNA, such as a break in a strand of DNA, a nucleotide base pair missing from the sugar phosphate backbone of DNA.
- Ultraviolet radiation speeds the natural aging process by breaking down skin's collagen and elastic fibers present in the skin's dermis resulting in early wrinkling.

CELLULAR SENESCENCE

The genetic theory of aging centers on telomeres, which are tandem repeat DNA nucleotide sequences present at the tips of human chromosomes. The number of tandem DNA nucleotide sequences in a telomere determines the maximum life span of a cell, since each time a cell divides, multiple tandem repeat DNA nucleotide sequences are lost.

TELOMERE ATTRITION

Human cells have evolved complex mechanism for regulating cellular life span. Telomerase enzyme, also called terminal transferase, is a ribonucleoprotein that adds a species-dependent telomere repeat sequence (TTAGGG) to the ends of telomeres, which prevent telomere shortening.

- A telomere is a region of repetitive nucleotide sequences of noncoding DNA present at the tips of human chromosomes, that protect the chromosome from damage by preventing their degradation or fusion with neighboring chromosomes thus stabilize the genome and maintain structural integrity during cell division. Each time a cell divides, the telomeres become shorter that the cell can no longer divide. Telomerase is ordinarily inactive in most somatic cells, but can be detected in tumor cells.
- Long telomeres are linked to DNA integrity, normal sperm count/motility and thus fertility occurs in males. Short telomers are linked DNA fragmentation, low sperm count/motility; and thus, infertility occurs in males.
- Telomere length is associated with biological aging, that progressively shortens with each cell division, so that elderly adults have the shortest telomeres. Telomere length can serve as an indication for the biological status of previous cell divisions and DNA damage due to inflammation and oxidative stress.
- Telomeres can also undergo shortening following oxidative stress and chronic diseases, as telomeres are very sensitive to damage by reactive oxygen species (ROS).
- The greatest period of telomere shortening occurs during the first four years of life. Few *in utero* risk factors (i.e. maternal tobacco smoking, large babies for gestational age) accelerate telomeres shortening in infants and young children. In adults, telomere shortening has been associated with development of diabetes mellitus and progression of metabolic syndrome.

ACTIVATION OF TUMOR SUPPRESSOR GENES

Cellular senescence is a stable cell cycle arrest that can be triggered in normal cells in response to many intrinsic and extrinsic stimuli, as well as developmental signals. Cell cycle arrest in senescence is mainly mediated via activation of any one of p53/p21 and p16/pRB tumor suppressor pathways. All these pathways involve many upstream regulators and downstream effectors along with various side branches. Prolonged expressor of any of these four critical components (p53/p21 and p16/pRB) is sufficient to induce cellular senescence.

- Prolonged activation of p53/p21 pathway in response to DNA damage caused by telomere attrition, oxidative stress or oncogenic stress induces cellular senescence.

- The p53, known as 'Guardian of the Genome', plays a central role in inducing cellular senescence. Activation of p53 is dependent on various translation modifications such as phosphorylation, methylation, acetylation, sumoylation and ubiquitination.
- The p21 protein encoded by the CDKN1A gene, is a member of the Cip/Kip family of cyclin-dependent kinase inhibitors (CDKIs) in addition to p27 and p57. The p21 protein is capable of inactivating all CDKIs, thereby inhibiting cell cycle progression.

OXYGEN-DERIVED FREE RADICALS THEORY LINKED TO CELLULAR AGING

Oxygen-derived free radical injury theory proposes that cellular aging is the cumulative result of oxidative damage to biological structures resulting in compromising cellular functions and ultimately short life span. Oxygen-derived free radicals arise primarily as a result of aerobic metabolism. The free radical theory of aging in human is shown in Fig. 1.46.

- Oxygen-derived free radicals such as superoxide anion radical ($O_2^{\bullet -}$), hydroxyl radical ($^{\bullet}OH$), hydrogen peroxide (H_2O_2), nitric oxide, peroxynitrite ($ONOO^-$), lipid peroxide radical (RCOO), and hypochlorous acid (HClO) interact with cellular DNA, proteins and lipids resulting in peroxidation of cell membrane, accumulation of misfolded proteins, oxidative damage and cell death.
- Oxygen-derived free radical scavenging system protect the cells and tissues from adverse effects of oxygen-derived free radicals. Intracellular oxidase enzymes, i.e. superoxide dismutase (SOD) in mitochondria converts oxygen to hydrogen peroxide; and glutathione peroxidase converts hydroxyl ion to hydrogen peroxide. Catalase in peroxisome converts hydrogen peroxide to water and oxygen. Exogenous antioxidants such as vitamin E (α-tocopherol), retinoids, vitamin C (ascorbate) and transport proteins (transferrin, ferritin, lactoferritin, ceruloplasmin) either inhibit synthesis or scavenge oxygen-derived free radicals.

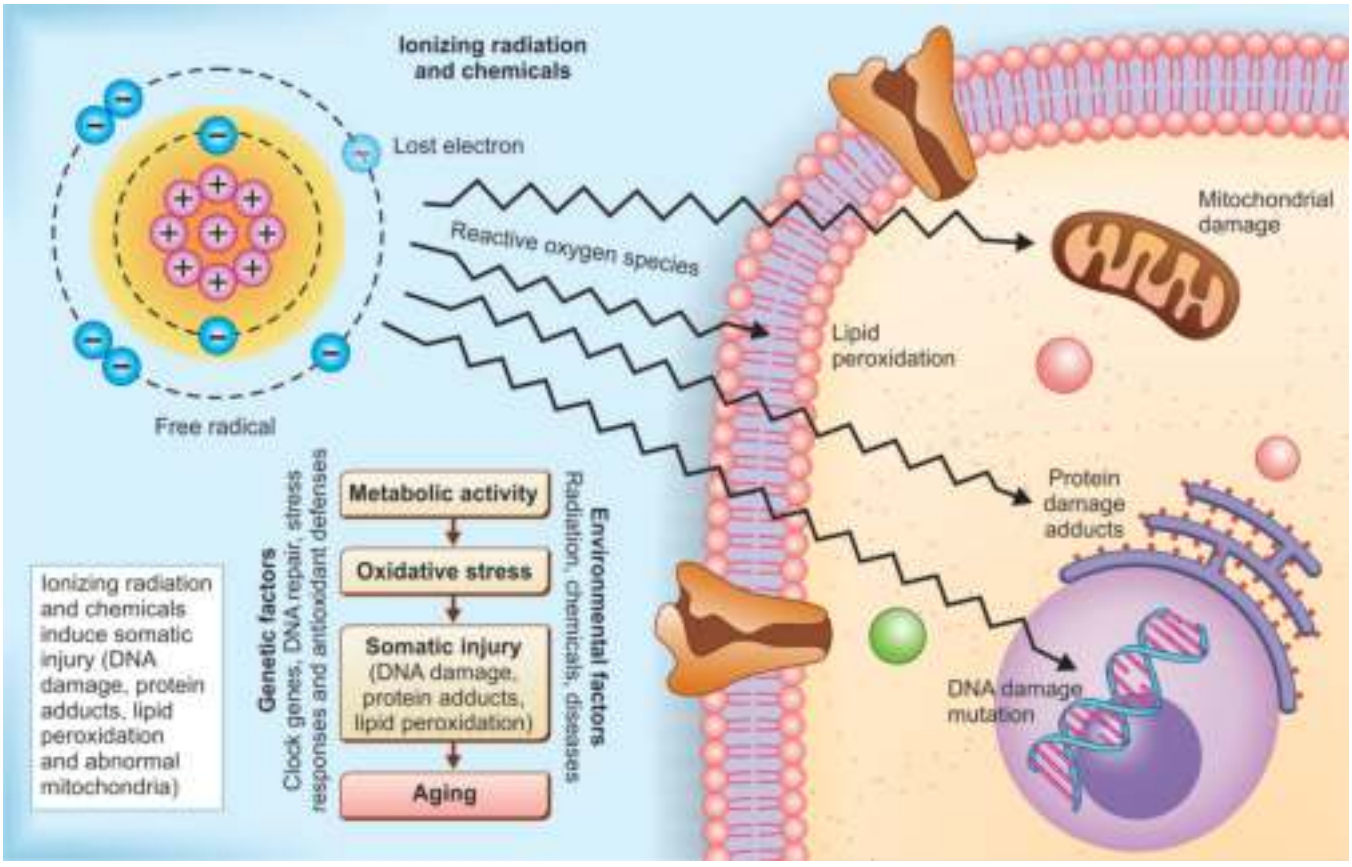

Fig. 1.46: The free radical theory of aging in human. It is caused by accumulation of damage inflicted by reactive oxygen species (ROS). Oxygen-derived free radicals are mainly produced by the mitochondrial respiratory chain as a result of electron transport and reduction of the oxygen molecules. Toxic effects of reactive oxygen species on cellular components lead to accumulation of oxidative damage which causes cellular dysfunction with age.

- Various studies demonstrated that longevity (life span) is enhanced by availability of protective oxygen-derived free radical scavenging system, enhanced expression of antioxidant enzymes and reduced calorie intake, which lead to a decline in the production of reactive oxygen species. On the other hand, decreased oxygen-derived free radical scavenging system, decreased expression of antioxidant enzymes and high calorie intake cause decreased life span.

DEFECTIVE PROTEIN HOMEOSTASIS AND CELLULAR AGING

Three cellular machineries (i.e. translation, folding and clearance of proteins) act in coordinate manner to maintain the stability of the proteome and to ensure its continuous renewal under normal state. Most cytosolic proteins fold spontaneously after synthesis.

- Failure to acquire a proper folding configuration of protein is aided by chaperones and chaperonins, which provide a favorable protein folding environment. Chaperones also assist folding of proteins synthesized in the rough endoplasmic reticulum (ER).
- Misfolded proteins are degraded by the autophagy-lysosome phagocytic system and ubiquitin-proteosome system.
- Altered protein handling is linked to many human diseases known as protein conformational disorders. Recent studies established that both normal folding and degradation of misfolded proteins are implicated in cellular aging.

AGE-RELATED CHANGES IN THE EXTRACELLULAR MATRIX

Extracellular matrix accumulation and/or degeneration due to aging process may alter cellular reparative pathways. The extracellular matrix (ECM) provides a structural framework essential for the functional properties of tissues.

- Each tissue has a three-dimensional organization of the extracellular molecules: proteoglycans, collagen fibers, elastic fibers and structural glycoproteins essential for development and growth. ECM homeostasis is regulated by serine proteases.
- During aging process, interaction of environmental factors and modifications of biosynthesis and degradative processes results in modifications of ECM homeostasis and consequently alterations of tissue functionality. These alterations of tissue functionality are increased during aging process and pathologic processes such as atherosclerosis.
- Intervertebral disc degeneration is driven partially by aging process. During aging, collagen fibers become thicker and less soluble resulting in decline in collagen synthesis. The elastic property of skin is also affected with advancing age, in which elastic fibers become thicker and fragmented.

GENETIC DISORDERS LINKED TO PREMATURE AGING

Premature aging syndromes associated with defective DNA repair system include **Hutchinson-Gilford progeria**, **Werner syndrome** and **Cockayne's syndrome**. In these disorders, skin changes that indicate aging include skin atrophy (skin thinning and loss of elasticity), loss of cutaneous fat and wrinkling.

HUTCHINSON-GILFORD PROGERIA SYNDROME

Hutchinson-Gilford progeria syndrome is an autosomal dominant disorder caused by mutation in LMNA gene encoding protein called lamin A, essential component of nuclear envelope.

- Lamin A protein plays an important role in determining the shape of the nucleus within the cells. Mutation in LMNA is thought to make the nucleus unstable.
- Hutchinson-Gilford progeria syndrome is characterized by rapid appearance of premature aging beginning in childhood.
- Patient presents with early development of cataracts, hair loss, skin atrophy, osteoporosis and atherosclerosis. Patient has a fatal outcome between 13 and 20 years of age.
- Patients are managed with lipid lowering agents and low doses of aspirin to prevent myocardial infarction and cerebral stroke; growth hormone for building height and weight and occupational therapy for stiff joints or hip problems.

WERNER SYNDROME

Werner syndrome, an autosomal recessive disorder, is characterized by the premature aging and cancer predisposition. It occurs due to mutation in the WRN gene, which affects multiple DNA-dependent enzymatic functions, including proteins with ATPase, helicase, and exonuclease activity. Persons develop normally until the end of the first decade. Lack of growth spurt is the first sign during early teen years.

Clinical Features

Patient presents with gray hair, hair loss, voice hoarseness and scleroderma-like skin changes in the 20s; later followed by type 2 diabetes mellitus, bilateral ocular cataracts, hypogonadism, osteoporosis and skin ulcers in the 30s. Myocardial infarction and development of cancer are the most common causes of death in the fifth decade of life with mean age of death in persons with Werner syndrome is 54 years.

Laboratory Diagnosis

The diagnosis of Werner syndrome is established on the basis of following cardinal signs: short stature, bilateral ocular cataracts, premature thinning and/or graying of scalp hair and skin ulcers. Demonstration of biallelic WRN gene mutation on molecular testing establishes the diagnosis of Werner syndrome. Surgical treatment is essential for bilateral ocular cataracts.

Management

In Werner syndrome. it is essential to control type 2 diabetes mellitus, maintenance of normal lipid profile and aggressive treatment of skin ulcers in these patients.

- Malignances should be treated in a standard fashion. Regular exercise, cessation of tobacco smoking and weight control reduce atherosclerosis.
- Annual screening should be performed for type 2 diabetes mellitus, lipid profile analysis, ophthalmologic examination for cataracts, physical examination for malignancies, and history of angina and cerebrovascular disease. It is essential to perform career testing for relatives at-risk and prenatal testing for pregnancies at risk.

COCKAYNE'S SYNDROME

Cockayne's syndrome also known as Weber-Cockayne's syndrome or Neill-Dingwall syndrome is an autosomal recessive disorder characterized by premature aging, failure to thrive, increased photosensitivity, hearing loss, pigmentary retinopathy.

MAMMALIAN SIRTUIN SYSTEM

Mammalian sirtuins are a family of signaling proteins (enzymes) encoded by seven sirtuin genes (SIRT1-SIRT7) implicated a variety of cellular functions ranging from gene silencing over to cell cycle, apoptosis, autophagy and cellular energy homeostasis.

- Homeostasis involves keeping the cells in balance. However, sirtuins can only function in the presence of NAD^+, nicotinamide adenine dinucleotide, a coenzyme found in all living cells.

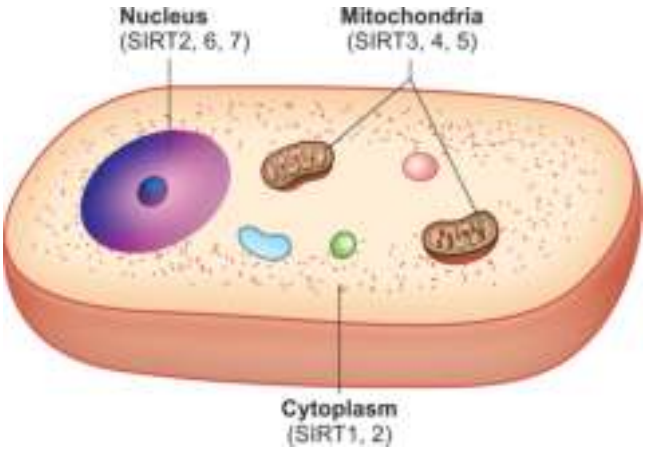

Fig. 1.47: Schematic representation of sirtuins in mammalian cellular compartments. Sirtuins are a family of signaling proteins involved in metabolic regulation.

- Sirtuins are predominantly located in either nucleus (SIRT1, SIRT6 and SIRT7), cytoplasm (SIRT2), or mitochondria (SIRT3, SIRT4 and SIRT5). SIRT1 protein counteracts aging and obesity-related diseases by deacetylating many proteins. SIRT3 deacetylates and regulates many mitochondrial proteins to maintain health.
- Calorie restriction affects the level of specific sirtuins in various tissues. The sirtuin system is involved in mediating the increase in life span by calorie restriction by increasing gluconeogenesis, cholesterol metabolism, fatty acid oxidation, fatty acid mobilization and insulin activity. There is decreased glycolysis and adipogenesis. SIRT3 functions are decreased in aging process and obesity.
- Sirtuins activities and subcellular locations are shown in Fig. 1.47 and Table 1.55.

SIRTUINS IN HEALTH AND DISEASE

SIRT1 protein, the 'master metabolic regulator' is a highly conserved nicotinamide adenine dinucleotide (NAD)-dependent protein deacetylase encoded by SIRT1 gene, which removes acetyl groups from target proteins.

- SIRT1 directly links environmental nutrient signals to cellular metabolic homeostasis. It is expressed in brain, heart, liver, pancreas, spleen, skeletal muscle endothelial tissue and white adipose tissue.
- Activated sirtuins have remarkable property in preventing diseases such as diabetes mellitus, neurodegenerative diseases, and reversing some aspects of aging. Sirtuin is an essential factor, that suppresses

Table 1.55 Subcellular location, enzymatic activity, function, and selected nonhistone target substrates for mammalian sirtuins

Sirtuins Location in Organs	Subcellular Location	Enzymatic Activity	Function
Sirtuin 1 (SIRT1)			
Brain, hypothalamus, heart, kidney, liver, pancreas, spleen, skeletal muscle and white adipose tissue	▪ Nucleus (predominant) ▪ Cytoplasm	Deacetylase	▪ Formation of facultative and constitutive chromatin ▪ Mitochondrial biogenesis ▪ Fatty acid oxidation ▪ Regulation of cholesterol and bile acid homeostasis
Sirtuin 2 (SIRT2)			
Adipose tissue	▪ Cytoplasm ▪ Nucleus (transient)	▪ Deacetylase ▪ Demyristoylase	▪ Promotion of lipolysis in adipocytes ▪ Tumor suppression/promotion ▪ Neurodegeneration
Sirtuin 3 (SIRT3)			
Skeletal muscle, brown adipose tissue, white adipose tissue, heart, kidney, liver	Mitochondria	▪ Deacetylase ▪ ADP-ribosylase	▪ Regulation of mitochondrial activity ▪ Protection against oxidative stress ▪ Tumor suppression
Sirtuin 4 (SIRT4)			
Islets of Langerhans in the pancreas	Mitochondria	▪ ADP ribosylase ▪ Deacetylase ▪ Lipoamidase	▪ Glucose metabolism ▪ Amino acid catabolism ▪ Tumor suppression
Sirtuin 5 (SIRT5)			
Liver	▪ Mitochondria (predominant) ▪ Cytoplasm ▪ Nucleus	▪ Deacetylase ▪ Demanolyase ▪ Desuccinylase ▪ Deglutarylase	▪ Urea cycle ▪ Fatty acid metabolism ▪ Amino acid metabolism
Sirtuin 6 (SIRT6)			
Adipose tissue, skeletal muscle, brain, and heart	Nucleus	▪ ADP ribosylase ▪ Deacetylase ▪ Deacylase	▪ Genomic stability and DNA repair ▪ Glucose metabolism ▪ Lipid metabolism ▪ Inflammation
Sirtuin 7 (SIRT7)			
Adipose tissue and cardiac muscle	Nucleus (nucleolus)	Deacetylase	▪ Ribosome biogenesis ▪ Tumor promotion

cellular senescence-mediated through the age-related telomere attrition, sustaining genomic integrity and promotion of DNA repair. Expression and activity of sirtuins are strongly influenced by dietary, lifestyle or environmental factors.

- Through its deacetylation activity, SIRT1 protein modulates of its downstream pathways by targeting several cellular proteins, such as peroxisome proliferator-activated receptor-γ (PRAR-γ) and its coactivator peroxisome proliferator-activated receptor α (PRAR-α), liver X receptors (LXRs), farnesoid X receptors (FXRs), nuclear factor κ-light-chain enhancer of activated B cells (NF-κB), forkhead transcription factors, protein tyrosine phosphatase (PTP), adenosine monophosphate activated protein kinase (AMPK), CRE-binding protein regulated transcription activator 2 (CRTC2), endothelial nitric oxide synthase (eNOS), myogenic differentiation (MyoD) and transcription factor E2F1.

SIRT1 and Metabolic Diseases

SIRT1 is an important regulator of energy homeostasis in response to nutrient availability. **Liver** is the central regulator of metabolism. Activation of SIRT1 has been shown to be protective against metabolic damage. Hepatic SIRT1 regulates glucose metabolism (gluconeogenesis), lipid metabolism (fat mobilization in white adipose tissue, fatty acid oxidation in the liver and

reverse cholesterol transport), insulin secretion in the pancreas, sensing nutrition availability in hypothalamus, influencing obesity-induced inflammation and modulating activities of cicardian (sleep-wake cycle every 24 hours) clock in metabolic tissues in response to nutritional and hormonal signals.

Glucose Homeostasis

SIRT1 is an important regulator of hepatic glucose metabolism. Hepatic SIRT1 is a key regulator of gluconeogenesis in response to fasting. SIRT1 induces protein gluconeogenic genes and hepatic glucose output through PGC-1α.

- During short-term fasting phase, SIRT1 inhibits TORC2 (also known as CRCT2), a CREB-regulated transcription coactivator that is important for CAMP/CREB-mediated activation of gluconeogenesis genes resulting in reduced gluconeogenesis.
- Prolonged fasting enhances SIRT1-mediated deacetylation and activation of co-activator for numerous transcription factors resulting in increased fatty acid oxidation and improved glucose homeostasis. In addition to TORC2 and PGC-1α, SIRT1 also deacetylates Foxo1 leading to increased gluconeogenesis.

Lipid Homeostasis

Numerous studies demonstrated that hepatic SIRT1 ineracts with a nuclear receptor known as peroxisome proliferator-activated receptor-γ (PRAR-γ) and regulates lipid homeostasis in response to fasting and starvation.

- Hepatic-specific SIRT1 deletion impairs PRAR-γ signaling resulting in decreased fatty acid β-oxidation, whereas hepatic SIRT1 overexpression (upregulation) induces the expression of PRAR-γ targets.
- As hepatic SIRT1 is a regulator of lipid homeostasis, hence pharmacological activation of hepatic SIRT1 may be important for the prevention of obesity-associated metabolic diseases.
- Manipulation of hepatic SIRT1 affects the expression of genes involved in lipid and glucose metabolism.
- Modest hepatic SIRT1 overexpression (upregulation) has protective effect against high fat induced hepatic steatosis and glucose intolerance.

Cholesterol and Bile Acid Homeostasis

SIRT1 regulates hepatic cholesterol and bile acid homeostasis through direct modulation of liver X receptors (LXRs) and farnesoid X receptors (FXRs). LXRs and FXRs are nuclear receptors, that function as important cholesterol and bile acid sensors and regulate cholesterol and bile acid homeostasis.

- Cholesterol homeostasis is vital for proper cellular functions. The cellular cholesterol level reflects the dynamic balance between biosynthesis, uptake, export and esterification—a process in which cholesterol is converted to neutral cholesteryl esters either for fat storage in lipid droplets or for secretion as secretion as constituents of lipoproteins.
- Disturbed cholesterol balance can cause cardiovascular diseases, neurodegenerative diseases and cancers. Since bile acids are detergent-like molecules and toxic to hepatocytes. SIRT1 dysregulation leads to excess of bile acids, which can cause hepatobiliary disease and hepatocellular carcinoma.

Sirtuin 1 and Obesity

Adipose tissue recently emerged as a pivotal organ controlling life span. Obesity is a complex metabolic disorder linked to the development of several diseases associated with insulin resistance, glucose intolerance and hepatic steatosis; in which excess body fat has accumulated as a result of both hypertrophy and hyperplasia of adipocytes.

- Obesity is defined by body mass index (BMI) and further evaluated in terms of fat distribution via the waist–hip ratio and total cardiovascular risk factors. Increased calorie intake causes an expansion of adipocyte size, with subsequent activation of stress pathways leading to metabolic deterioration and decreased insulin sensitivity. The process is associated with increased infiltration by inflammatory cells into the adipose tissue, which contributes to the development of decreased insulin sensitivity.
- SIRT1 has emerged as an important nutrient sensor and regulator of metabolism. Numerous studies have revealed that SIRT1 plays a role in retarding of white adipose tissue (WAT), while stimulating both differentiation and activation of brown adipose tissue as browning of white adipose tissue (WAT), SIRT1 promotes fat mobilization in white adipocytes by repressing the transcription factor 'peroxisome proliferator activated receptor-γ (PPAR-γ). Calorie restriction extends life span of organisms. Upregulation of SIRT1 triggers lipolysis.
- White adipose tissue (WAT) and brown adipose tissue (BAT) have opposite functions.
  - White adipose tissue stores excess energy as triglyceride, and composed of white adipocytes and less capillaries, and white adipocyte which contains a single lipid droplet.
  - Brown adipose tissue is composed of brown adipocytes with more capillaries, and brown adipocyte contains numerous smaller lipid droplets

and much higher number of iron containing mitochondria. BAT activation generates heat from nutrients by non-shivering thermogenesis. BAT is abundant in newborns and helps them to survive cold temperatures. In adults, it has been considered to be absent or at least of no relevance. Recent studies have created interest in adult brown adipose tissue. With increasing as, BAT decreases and body weight increases. Stimulation of BAT appears to be an attractive novel candidate target for the treatment of age-related obesity.

Sirtuins 1 and 6 (SIRT1 and SIRT6) Associated Cardiovascular System in Health and Disease

Oxidative stress represents the common hallmark of cardiovascular disease including atherosclerosis, hypertension, heart failure and other vascular-related diseases.

- SIRT1 and SIRT6 have protective roles against inflammation, and cardiovascular disease including development of atheromatous plaque.
- SIRT1 regulates endothelial homeostasis by modulating endothelial nitric oxide synthase (eNO) activity, p53 angiotensin II type 1 receptor and forkhead box O (FOXO1).
- SIRT2 participates in the hypertension-induced remodeling.
- SIRT3 protects endothelial cells in response to oxidative stress by acting on FOXO3/manganese superoxide dismutase signaling pathway.
- SIRT4 and SIRT7 aggravate cardiac hypertrophy; inhibit proliferation and migration of endothelial–vascular smooth muscle cells.

Sirtuins (SIRT1 and SIRT6) Signalizing in Cellular Redox Status and Oxidative Stress

Cellular redox homeostasis is attained by the regulation of both reactive oxygen species (ROS) and removal from the body. A shift in ROS balance promotes oxidative stress.

- At vascular level, the physiologic functions of SIRT1 and SIRT6 in the control of the cellular redox status are mediated by deacetylation of multiple targets. SIRT1 regulates cellular redox homeostasis mediated by deacetylation of eNOS, FOXOs, CAT, GPx and peroxisome proliferator activated receptor α (PPAR-α) resulting in vascular protection.
- SIRT6 regulates cellular redox homeostasis mediated by nuclear respiratory factor 1 (NRF-1), a transcription activator for gene encoding cytochrome c resulting in vascular protection. Impairment of SIRT1 and SIRT6 results in decreased vascular protection against oxidative stress.

Sirtuins (SIRT1 and SIRT6) Signalizing in Cellular Senescence, Inflammation and Vascular Aging

Oxidative stress and inflammation are main events in the development of vascular aging.

- Changes in arterial vasculature include dilated lumen, endothelial dysfunction, increased endothelial apoptosis, increase in intima—medial thickness, dysregulation of matrix metalloproteinase (MMP), production of inflammatory cytokines and increased reactive oxygen species (ROS).
- Oxidative stress and low-grade inflammation are key features occurring in the arteries with aging process.
- SIRT1 and SIRT6 regulate eNOS via transcriptional and post-transcriptional deacetylation resulting in NO-mediated vascular protection. Impairment of SIRT1 and SIRT6 result in cellular senescence, inflammation and vascular aging.

Sirtuin 6 (SIRT6) Signalizing in Age-related Endothelial Function

SIRT6 plays important role in DNA repair, chromatin compaction, telomerase function and genomic stability resulting in prevention of cellular senescence.

- In endothelial cells, downregulation of SIRT6 occurs during hydrogen peroxide-induced cellular senescence, whereas overexpression of SIRT6 reverses this process.
- Impairment of SIRT6 accelerates cellular senescence via overactive NF-κB signaling. SIRT6 protein silenced by siRNA inhibits endothelial cell replication resulting in endothelial cell senescence. Depletion of SIRT6 causes upregulation of ICAM-1 mRNA, PAI-1 and p21 resulting in decreased eNOS expression and ability to form endothelial cells *in vitro* vessels.

Sirtuin 1 (SIRT1) Signalizing in Glucose Homeostasis and Hyperglycemia

Elevated reactive oxygen species (ROS) and reduced NO bioavailability play important role in the induction and progression of microvasculature and cardiovascular complications during diabetes mellitus.

- The metabolic derangements in diabetes mellitus such as hyperglycemia, dyslipidemia, insulin resistance and hyperinsulinemia induce oxidative stress, apoptosis, vascular permeability and low-grade inflammation through NF-κB signaling pathway.
- Hyperglycemia impairs activity of SIRT1 and SIRT6 resulting in reduction in vascular protection. SIRT1

is a positive regulator of insulin secretion, that triggers glucose uptake and utilization; hence it represents a targeted therapy in diabetes mellitus.
- SIRT1 protects arterial vasculature from hyperglycemia-induced endothelial dysfunction through a mechanism involving the downregulation of PAI-1 and p66 expression.

Sirtuins 1 and 6 (SIRT1 and SIRT6) Signalizing in Preventing Atherosclerosis

SIRT1 protein plays important role in prevention of atherosclerosis. It enhances production of NO.
- SIRT1 reduces oxidized LDL uptake by downregulating Lox1 signaling pathway. SIRT1 prevents foam cell formation by downregulation of LxRs.
- SIRT1 also blocks the NF-κB-mediated inflammatory process, reducing oxidative stress and controlling lysosomal autophagy. SIRT6 prevents synthesis of cholesterol and triglyceride, glycolysis and lipogenesis by downregulating ach3K9 signaling pathway.
- Impairment of SIRT1 and SIRT6 accelerates atherosclerosis by enhancing synthesis of triglyceride and cholesterol, uptake of oxidized LDL, foam cell formation and lysosomal induced autophagy.

Sirtuins 1 and 6 (SIRT1 and SIRT6) Signalizing Networks in the Heart Protection

SIRT1 and SIRT6 protect the heart against cardiac hypertrophy, ischemia/reperfusion injury, oxidative stress, heart failure and autophagy.
- SIRT1 acts by deacetylating NF-κB (nuclear factor κ-light chain-enhancer of activated B cells), FOXO and AKT signaling pathways.
- Similarly, SIRT1 protects cardiomyocytes from oxidative stress of endoplasmic reticulum by deacetylating eukaryotic translation initiator 2α (elf2α) on Lys-141 (K141) and (K143) residues. SIRT6-FOXO3 enhances the transcription of antioxidant genes manganese superoxide dismutase (MnSOD) and CAT.
- SIRT6 protects heart against hypoxic stress by activating AMPK pathway, upregulating BCL-2 and suppressing the activity of NF-κB. SIRT6 inhibits insulin growth factor (IGF)-AKT signaling pathway by targeting c-Jun and deacetylating histone type 3 (H3), acetylated Lys-9 (acH3K9).

Sirtuin 3 (SIRT3) Signalizing in Heart Protection

SIRT3 together with SIRT4 and SIRT5 are located in the mitochondria. SIRT3 preserves mitochondrial metabolic homeostasis via regulation of mitochondrial lysine acetylation, oxidative phosphorylation, boosting antioxidant defense resulting in heart protection.
- SIRT3 also decreases cellular levels of reactive oxygen species. SIRT3 also prevent stress-induced mitochondrial apoptosis of cardiomyocytes.
- Mitochondrial dysfunction plays a central role in various cardiovascular diseases, ranging from hypertrophic cardiopathy, dilated cardiomyopathy, heart failure, pulmonary hypertension, endothelial dysfunction and early development of atherosclerosis.

Sirtuin 7 (SIRT7) Signalizing in Heart Protection

SIRT7 is a master regulator of nuclear-mediated mitochondrial genes. It improves mitochondrial function in cardiac muscle, skeletal muscle, hence protects from cardiomyopathy and skeletal muscle dysfunction. Moreover, SIRT7 gives protection from microvesicular steatosis.

Sirtuins 1, 6 and 7 (SIRT1, SIRT6, SIRT7) and Cancer

Cancer is a leading cause of death worldwide. Hallmarks of cancer include sustained proliferative signaling, evading growth suppressors, resisting apoptotic cell death, enabling replicative immortality, inducing angiogenesis and activating invasion and metastasis.
- SIRT1 and SIRT6 have dual role as tumor promotor and tumor suppressor in caner through epigenetic activity, including their involvement in epithelial-to-mesenchymal transition (EMT), energy metabolism program, invasion and metastasis. SIRT6 has both tumor promotor and suppressor functions.
- SIRT6 is upregulated at mRNA and protein level, and acts as oncogene for cancer cell proliferation.
- SIRT7 is involved in cellular pathways such as regulation of cellular metabolism, genomic stability, aging, stress response, transcription, ribosome biogenesis and tumorigenesis. The oncogenic properties of SIRT7 may be due to its interaction with p53 and upregulation of rRNA synthesis determining rapid growth.
- EMT is a reversible transdifferentiation process that transforms an epithelial cell into mesenchymal cell, providing it with the ability to invade, escape apoptosis, and metastasize to distant organs.
- EMT is of three types: (a) In EMT type 1, mesenchymal cell differentiates into epithelial cells, that has role during embryogenesis and organogenesis, (b) in EMT type 2, mesenchymal cell differentiates into fibroblasts, which is implicated in tissue repair after injury; and (c) EMT type 3 occurs in cancer progression and metastasis.
- EMT is activated by numerous transcriptional factors and epigenetic regulators, including sirtuins (SIRTs), members of the class III histone deacetylase family.

During EMT, there is loss of cell-to-cell adhesion E-cadherin protein, that correlates with high rate of metastasis and poor prognosis.

- Normal cells usually switch from aerobic to anerobic status by changing their glucose metabolism. Energy is essential for rapid and uncontrolled growth and proliferation of cancer stem cells by reprograming of cellular energy metabolism. Cancer stem cells demonstrate glycolysis and glutaminolysis, with an increase and accumulation of glycolytic intermediates, as a fuel for macromolecular synthesis resulting in malignant tumor growth.
- Numerous studies have showed that SIRT1 is significantly elevated in human prostatic carcinoma, acute myelogenous leukemia, primary colon carcinoma and hepatocellular carcinoma. Overexpression of SIRT1 has been observed in nonmelanotic skin cancers including basal cell carcinoma, squamous cell carcinoma, Bowen' disease, and actinic keratosis.
- Based on elevated levels of SIRT1, it has been suggested that SIRT1 serves as a tumor promotor. SIRT1 interacts with p53 and attenuates p53-mediated functions through deacetylation of p53. SIRT1 is involved in epigenetic silencing of DNA hypermethylated tumor suppressor genes (TSGs) in cancer stem cells. SIRT1 also interacts with and deacetylates c-Myc leading to decreased c-Myc stability.

Sirtuins 1 and 2 (SIRT1 and SIRT2) and Neurodegeneration Diseases

- Sirtuins 1 and 2 (SIRT1 and SIRT2) are implicated in numerous biological pathways related to stress response, mitochondrial dysfunction, oxidative stress, misfolded protein aggregation and inflammatory processes that are intertwined with age-related neurodegenerative diseases such as Alzheimer disease, Parkinson's disease, Huntington's disease, amyotrophic lateral sclerosis.
- SIRT1 targets multiple transcriptional regulators, such as p53, FOXO3 and NF-κB. SIRT1 has a protective role against neurodegenerative diseases (Alzheimer disease, Parkinson's disease, Huntington's disease) via its effects in mitochondria. SIRT2 deletion has a protective role against Parkinson's disease and Huntington's disease.

Sirtuin 1 (SIRT1) and Inflammatory Signalizing in Response to Environmental Stress

SIRT1 gives protection against chronic inflammation by regulating the acetylation of nuclear factor κB (NF-κB), a transcription signaling pathway involved in the innate immune response. Sirtuin 1 (SIRT1) plays a key role in resorting homeostasis during stress responses. Inflammation is linked to altered glycolysis and fatty acid oxidation by NAD^+-dependent function of sirtuins.

Clinical Pearls: Vital Signs Observed in Patients

- **Respiratory rate:** The respiratory rate varies with age. The normal respiratory rate in adults is 12–20 breaths/minute. An elevated respiratory rate >22 breaths is poor indicator of respiratory dysfunction in patients with pneumonia, congestive heart failure and chronic obstructive pulmonary disease (COPD).
- **Blood pressure:** Blood pressure is recorded by two readings—systolic blood pressure (ventricular contraction) and diastolic blood pressure (ventricular filling). Blood pressure 120/80 mm Hg is considered normal. The difference between the systolic and diastolic blood pressure is called the **pulse pressure**. Pulse pressure <25 mm Hg indicates low stroke volume. There is no absolute normal value of blood pressure rather, there is a range of blood pressure.
- **Pulse:** The pulse is the result of physical expansion of the artery. The pulse rate is measured at wrist (radial artery) or ankle (posterior tibial artery) or neck (carotid artery) and behind knee (popliteal artery), and recorded as beats per minute. Pulse can be measured by listening directly to the heart beat using a stethoscope. Pulse rate >100 or <60 per minute is defined as tachycardia or bradycardia respectively.
- **Temperature:** An elevated body temperature (>38° C) is an indicator of illness, when proceeded by chills. Fever will increase the heart rate by 10 beats per minute. Hypothermia should be evaluated since it is an important vital sign of severe illness. The absence of fever does not rule out infection. High spiking fever is observed in patients with blood transfusion reaction or drug reactions.
- **Fifth vital sign**: Fifth vital sign refers to pain, pupil size and reactivity to light or oxygen saturation measurement. A pulse oximetry saturation of 90–92% represents a PaO_2 near 60 mm Hg should be the minimal aim of O_2 supplementation. The 90% of oxygen saturation represents the elbow of the hemoglobin saturation curve, and below this number (<90% of oxygen saturation) indicates rapid hemoglobin desaturation. Above this number (>90% of oxygen saturation) indicates little gain in oxygen carrying capacity of hemoglobin.

Clinical Pearls: How to Approach Clinical Problems

- There are many key questions essential for application of basic science information to the clinical settings. The scientific aspect of medicine seeks to gather data in an objective manner for understanding pathophysiologic processes in the light of scientific information and propose rational explanations. A skilled clinician must be able to correlate basic sciences and clinical sciences.

- The history is the most important tool in obtaining diagnosis. All physical examination findings, laboratory findings, imaging studies are first obtained, and then interpreted in the light of the pertinent history.
- In history taking, basic information is gathered related to age, gender, ethnicity, chief complaints, past history, family history, and social history.
- Physical examination includes general appearance, vital signs (blood pressure, heart rate, respiratory rate, height, weight, pain, pupil size and reactivity to light or oxygen saturation measurement) and body systems examination.
  - The presence of specific physical findings can be useful in making differential diagnosis and guiding therapy.
  - Inspiratory crackles may indicate pulmonary edema. Cardiac murmur indicates valvular insufficiency.
  - An S3 gallop indicates left ventricular dysfunction.
  - A pleural or pericardial rub can point to pleuritis or pericarditis. It is important to remember that a normal physical examination does not exclude potentially serious causes of chest pain.
- Laboratory investigations should be carried out, which include complete blood count, chemical panel, electrocardiogram, arterial gas analysis, lipid panel, urine analysis, and Gram staining and blood culture for isolation of bacteria.
- Common types of imaging include: X-rays, CT (computed tomography), MRI (magnetic resonance imaging), ultrasonography and positron emission tomography (PET). Children with infections, trauma and congenital abnormalities require imaging. Brain tumors are detected in children by CT scan and MRI. MRI is the study of choice, although non-contrast CT scan is used initially if intracranial hemorrhage or recent trauma is suspected.
  - Chest radiography is extremely useful in assessing cardiac size and contour, chamber enlargement, pulmonary vasculature and infiltrates the presence of pleural effusions.
  - Ultrasonography is noninvasive and helpful in evaluating biliary tree looking for ureteral obstruction and evaluating vascular strictures, but has limited utility in obese patients. Ultrasonography evaluates fetal and infant brain as long as the fontanelles remain open. It is also done to evaluate lateral ventricles, choroid plexus, thalamus, temporal lobes, and posterior fossa. Ultrasonography is done to assess ventricular enlargement and suspected brain hemorrhage.
  - Computed tomography (CT) is helpful in possible intracranial bleeding, abdominal and/or pelvic masses, and pulmonary processes, it may help delineate the lymph nodes and retroperitoneal disorders. Generally, CT requires radiocontrast dye, which can be nephrotoxic.
  - Magnetic resonance imaging (MRI) identifies soft tissue planes very well and provides the best imaging of the brain parenchyma. When used with gadolinium contrast (which is not nephrotoxic agent) magnetic resonance angiography is useful in delineating vascular structures.
- Cardiac procedures include echocardiography, angiography, and stress treadmill test. Two-dimensional colored echocardiography enables a quantification of shunts, cardiac output and provides a noninvasive assessment of concomitant valvular disease. The presence and extent of ischemic heart disease is determined by monitoring segmental wall motion.
- There are typically four distinct steps to the systemic solving of clinical problems: (a) gathering information with a differential diagnosis and looking for discriminating features to narrow the differential diagnosis and establishing the diagnosis, (b) assessing the severity of the disease (stage), (c) rendering a treatment based on the stage of disease, and (d) following the patient's response to the treatment. Hemodynamic instability disorders include myocardial infarction, cardiogenic shock, tamponade, acute mitral regurgitation, ventricular septum rupture, hypovolemic shock, and septic shock.
- Clinician needs to identify the objectives of therapy, symptom relief, prevention of complications or reduction in mortality.

CHAPTER

2

Inflammation and Tissue Repair

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

INFLAMMATION

- General features of inflammation
- Causes of inflammation
- Type of inflammatory responses
  - Acute inflammatory response
  - Chronic inflammatory response

ACUTE INFLAMMATION

- Vascular events in acute inflammation
  - Hemodynamic changes
  - Increased vascular permeability of postcapillary venules
  - Exudate formation
- Cellular events: leukocytes recruitment to the sites of inflammation
  - Margination of leukocytes
  - Rolling of leukocytes
  - Firm adhesion of leukocytes
  - Transmigration of leukocytes
  - Chemotaxis of leukocytes
  - Activation of leukocytes
- Phagocytosis and clearance of the injurious agents
  - Intracellular microbial killing
  - Leukocyte-induced injury
- Termination of acute inflammatory response
- Chemical mediators of inflammation
  - Plasma protein-derived chemical mediators
  - Cell-derived chemical mediators
- Morphologic patterns of acute inflammation
  - Serous inflammation
  - Fibrinous inflammation
  - Purulent (suppurative) inflammation
  - Pseudomembranous inflammation
  - Hemorrhagic inflammation
  - Gangrenous inflammation
  - Catarrhal inflammation
- Outcome of acute inflammation
  - Complete resolution
  - Tissue destruction
  - Progression to chronic inflammation
  - Healing by fibrosis
- Anti-inflammatory therapeutic agents

CHRONIC INFLAMMATION

- Common causes of chronic inflammation
- Essential morphologic features of chronic inflammation
  - Mononuclear cells infiltrate
  - Tissue destruction
  - Tissue healing by fibrosis
- Cells involved in chronic inflammation
  - Monocytes/macrophages
  - Lymphocytes
  - Other cells involved in chronic inflammation
- Chronic nonspecific inflammation
- Granulomatous inflammation
  - Type of granulomas
  - Multinucleated giant cells
- Systemic effects of inflammation
  - Acute-phase reactants synthesis
  - Clinical manifestations in inflammation
  - Systemic inflammatory response
  - Metabolic alterations in inflammation
  - Release of chemical substances in inflammation
  - Hematologic alterations in inflammation

TISSUE REPAIR

- Normal cell proliferation and tissue growth regulation
  - Tissue proliferative activity
  - Stem cells in tissue homeostasis
- Cell cycle in tissue homeostasis
  - Cell cycle phases
  - Cell cycle regulation
- Cell regeneration: regulation
  - Growth factors and cytokines involved in cell regeneration
  - Signaling mechanisms of cell growth
- Extracellular matrix
  - Structural fibrous proteins
  - Amorphous ground substance
  - Cell adhesion molecules
- Wound healing and tissue repair
  - Hemostasis phase
  - Inflammatory phase
  - Proliferative phase
  - Remodeling phase
- Cutaneous wound healing and tissue repair
  - Cutaneous wound healing and tissue repair by primary intention
  - Cutaneous wound healing and tissue repair by secondary intention
- Factors affecting wound healing and tissue repair
  - Local factors affecting wound healing
  - Systemic factors affecting wound healing
- Complications of wound healing and tissue repair
  - Inadequate granulation tissue
  - Excessive fibrosis
- Healing of bone fracture
  - Type of bone fractures
  - Stages of bone fracture healing
  - Clinical significance
- Regeneration of specific organs
  - Regeneration of liver
  - Regeneration of nervous system

INFLAMMATION

GENERAL FEATURES OF INFLAMMATION

Inflammation is a tissue response to cellular injury in living cells, that results in vascular changes which allow fluid and leukocytes into extravascular tissue. It involves both innate and adaptive immune responses. It localizes and eliminates the causative injurious agent, limits tissue injury and restores tissue to its normal state.

- Within minutes of tissue injury, histamine, nitric oxide and leukotrienes are synthesized. Within hours other chemical mediators (e.g. IL-1, tumor necrosis factor and interferon-gamma (IFN-γ) are synthesized.
- Neutrophil is the predominant cell type of acute inflammation, which reach the injured tissues by margination, rolling, adhesion along vascular endothelium and transmigration. Neutrophils production occurs in bone marrow, which circulates in peripheral blood and migrates in tissues. **Hematopoietic stem cells (HSCs)** produce neutrophils in the bone marrow and undergo maturation in about 1–2 weeks. Majority of neutrophils are released into peripheral blood circulation in the form of segmented forms. Increased demand results in release of immature form of neutrophils. About 50% of the neutrophils circulate in the peripheral blood circulation in the marginating pool; and rest 50% of the neutrophils circulate in the circulating pool. Neutrophils spend <10 hours in the peripheral blood before marginating and reaching tissues, where they spend 1–5 days. Schematic representation of neutrophils production in bone marrow and circulation in peripheral blood migration in tissues is shown in Fig. 2.1.
- Macrophages, lymphocytes and plasma cells are demonstrated in chronic inflammation. Chronic inflammation is nonspecific in majority of cases. There is specific cause of chronic inflammation in tuberculosis, leprosy and syphilis.
- Tissue injury may induce fibrinous inflammation of coelomic cavities, tissue necrosis, and wall thickening of hollow organs. Distinguishing features of neutrophil and macrophage are given in Table 2.1.

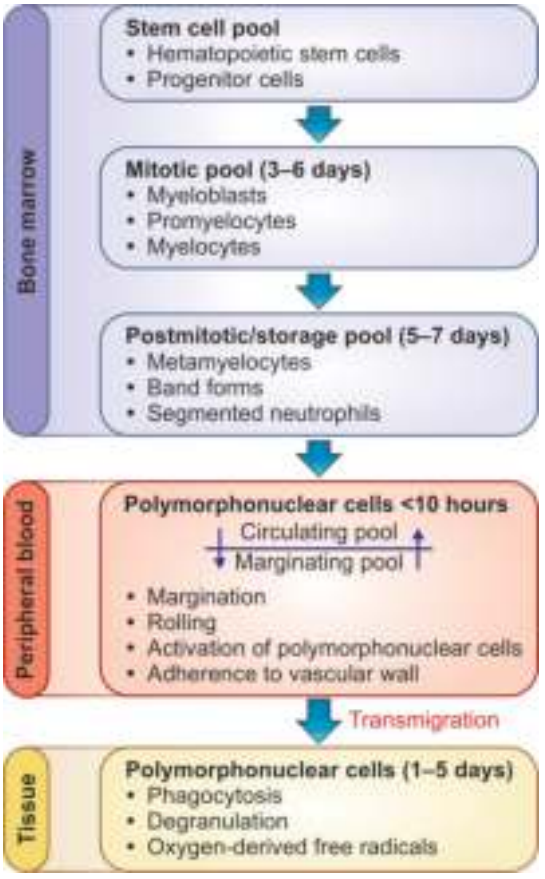

Fig. 2.1: Schematic representation of neutrophils production in bone marrow and circulation in peripheral blood migration in tissues. Hematopoietic stem cells produce neutrophils in the bone marrow and undergo maturation in about 1–2 weeks. Majority of neutrophils are released into peripheral blood circulation in the form of segmented forms. Increased demand results in release of immature form of neutrophils. About 50% of the neutrophils circulate in the peripheral blood circulation in the marginating pool; and rest 50% of the neutrophils circulate in the circulating pool. Neutrophils spend <10 hours in the peripheral blood before marginating and reaching tissues, where they spend 1–5 days.

Table 2.1 Distinguishing features of neutrophil and macrophage

Characteristics	Polymorphonuclear Cell	Macrophage
Cell morphology	Granular leukocyte comprising nucleus with three to five lobes	Macrophage is agranular leukocyte comprising large round nucleus
Antigen presenting function	Neutrophils are phagocytes without antigen presenting capability	Macrophages are antigen-presenting phagocytes to T cells or can act antigen-presenting cells
Immune response	Neutrophils are primarily involved in innate (non-specific) immune response with its phagocytic capability	Macrophages play key roles in innate (non-specific) and adaptive (specific) response by recruitment of lymphocytes

Contd...

Table 2.1 Distinguishing features of neutrophil and macrophage (*Contd...*)

Characteristics	Polymorphonuclear Cell	Macrophage
Site of production	Hematopoietic stem cells (HSCs) in bone marrow	Hematopoietic stem cells (HSCs) in bone marrow inflammation, stem cells in yolk sac or fetal liver during embryogenesis
Maturation of cell	Bone marrow	Tissues
Presence of cell	Neutrophils are normally found in the blood circulation and recruited to the site of infection or injury	Macrophages are found in all tissues
Duration in blood circulation	7–10 hours	20–40 hours (monocytes in blood circulation)
Average life span	Several days (1–-2 days)	▪ Macrophages in inflammation (days or weeks) ▪ Tissue macrophages (months to years)
Numbers in blood circulation	(2.5 × 7.5) × 10^9/L constituting 50–70% of circulating leukocytes	(0.2–0.8 × 7.5) ×10^9/L constituting 2–8% of leukocytes
Numbers in tissues	Mainly present in blood circulation but transient presence in tissues	Present in large numbers in tissues
Receptors on cell membrane	Ly6G, and MPO+ receptors	EMR1+, CD107b+ (Mac-3+) and CD68
Phagocytic function	First to kill bacteria at the site of infection by phagocytosis	Engulfs large pathogens, apoptotic cells, tissue debris, foreign particles
Principal killing mechanisms	Oxidative and nonoxidative mechanisms	Oxidative, nitric oxide, cytokines
Reactive oxygen species	Neutrophils are rapidly induced by assembly of phagocyte oxidase (respiratory burst)	Less prominent
Nitrogen oxide synthesis	Low level or none	Induced following transcriptional activation of iNOS
Cytokine synthesis level	Cytokine low level per neutrophil	Cytokine high level per macrophage, which requires transcriptional activation of cytokine genes
Secretion of lysosomal enzymes	Prominent	Less prominent
Cell activated by products	TNF-α, IFN-γ, GM-CSF, microbial products activate neutrophils	TNF-α, IFN-γ, GM-CSF, microbial products (i.e. LPS) activate macrophages
Important deficiencies	Chronic granulomatous disease, myeloperoxidase deficiency, chemotactic deficiency, and Chédiak-Higashi disease	Lipid storage diseases
Major secretory products	Lysozyme	Over 80; lysozyme, cytokines (TNF-α, IL-1)
Neutrophil extracellular trap (NET)	▪ Neutrophil extracellular traps primarily composed of DNA from neutrophils, which bind pathogens ▪ Neutrophil extracellular traps are rapidly induced by extrusion of nuclear contents	Neutrophil extracellular traps (NET) absent in macrophage
Fate of cell	Neutrophils die after phagocytosis of pathogen and immediately taken by macrophages	Macrophages are also able to engulf apoptotic neutrophils and make use of antimicrobial molecules present in their granule

GM-CSF: Granulocyte-macrophage colony-stimulating factor; IFN: Interferon; TNF: Tumor necrosis factor; LPS: Liposaccharide.

CAUSES OF INFLAMMATION

Each of the injurious stimuli may induce reactions with some distinctive characteristics, but all inflammatory reactions have the same features. When a deficit of water, oxygen, or nutrients occurs or if constant temperature and adequate waste disposal are not maintained, cellular synthesis does not take place. A lack of just one of these basic requirements can cause cell disruption or cell death.

- **Infectious agents:** Bacteria, viruses, fungi, and parasites can cause cell injury or death. Mammal's cells possess family of 'toll-like receptors' and several cytoplasmic receptors, which can detect pathogens

resulting in synthesis of chemical mediators of inflammation. These infectious organisms adversely affect cell integrity, usually by interfering with cell synthesis, producing mutant cells. Human immunodeficiency virus alters the cell, when virus is replicated in the cells.

- **Physical agents:** Mechanical injury (trauma or surgery) includes blunt or penetrating injuries (cutaneous laceration, osseous fracture). Physical injury disrupts cell's organelles (such as mitochondria, nuclei, lysosomes, and ribosomes). Thermal injury includes burns, or frostbite and irradiation.
- **Toxic agents:** Endogenous and exogenous toxic agents cause cell injury. Endogenous toxic agents include genetically determined metabolic errors, gross malformations, and hypersensitivity reactions. Exogenous toxic agents such as alcohol, lead, carbon monoxide (toxic gas), acids, alkali, drugs, chemotherapeutic agents or immunosuppressive drugs alter cellular function.
- **Foreign bodies:** Foreign bodies (sutures, splinters, dirt) elicit inflammation, because foreign bodies cause tissue injuries.
- **Immunologic reactions:** Immunologic reactions induce: (a) hypersensitivity reactions on exposure to environmental antigens such as bee sting or self-antigens, and (b) autoimmune disorders. Since these stimuli cannot be eliminated, hence such immunologic reactions tend to be persistent, and often have features of chronic inflammation, which are important cause of morbidity and mortality.
- **Endogenous causes:** Circulatory system disorders causing acute inflammation include thrombosis, acute myocardial infarction, and hemorrhage. Activation of pancreatic enzymes results in acute pancreatitis. Metabolic products such as uric acid may cause inflammatory response.

TYPE OF INFLAMMATORY RESPONSES

Inflammatory response is expressed through vascular response (arterioles, capillaries and venules) and cellular response coordinated by chemical mediators.

- Increased vascular permeability due to widened intercellular junctions and contraction of endothelial cells by chemical mediators (e.g. histamine, bradykinin and vascular endothelial growth factor) lead to extravasation of proteins, inflammatory cells and red blood cells resulting in formation of exudate. Transudate is poor in protein that occurs due to increased hydrostatic pressure.
- Macrophages and lymphocytes participate in tissue repair either by complete resolution and return of tissue to normal state or formation of scar tissue.
- Septic inflammation caused by pathogens has a protective character. Aseptic inflammation due to sterile chemical agents, radiation has a reparative character.
- Depending on the persistence and extent of tissue injury, clinical symptoms, and the nature of inflammatory response, inflammation may be acute (seconds, minutes to <48 hours), subacute (2–6 weeks) or chronic (several months to years).

ACUTE INFLAMMATORY RESPONSE

Acute inflammatory response is a short-term transient and rapid process occurring in response to tissue injury, usually appearing within seconds, minutes to <48 hours. It dilutes, neutralizes and eliminates the

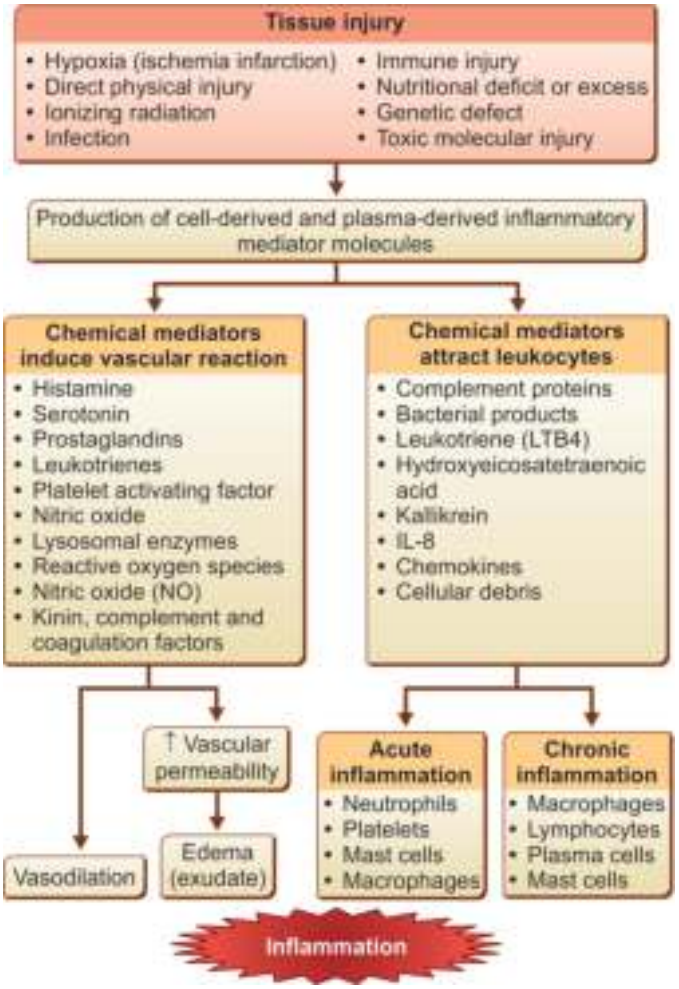

Fig. 2.2: Acute and chronic inflammatory responses. Inflammation is a normal response of the body to protect tissues from infection, injury or disease. Acute inflammation is the initial response of the body to harmful stimuli and achieved by increased movement of plasma and leukocytes (polymorphonuclear cells) from the blood into the injured tissues. Chronic inflammation is characterized by mononuclear cells infiltration, tissue destruction and healing of the tissues from inflammatory response.

injurious agents by exudation of plasma proteins, fluid along with neutrophils. Neutrophils are the dominant players of acute inflammation.

- Neutrophils clear debris and begin the process of wound healing. During mild tissue injury, removal of inflammatory exudate results in restoration of normal tissue architecture (resolution). Transition of acute inflammation to chronic inflammation occurs due to persistent injury.
- Acute inflammatory response is characterized by five **cardinal signs**: **pain**, **redness**, **immobility** (loss of function), **swelling** and **heat**.

CHRONIC INFLAMMATORY RESPONSE

Chronic inflammatory response has the potential to cause tissue destruction, fibrosis and disease, which lasts for days, weeks or years. It is associated with influx of macrophages, lymphocytes and plasma cells, proliferation of blood vessels (angiogenesis), fibrosis (role of fibroblasts, macrophages); and tissue necrosis (organ damage).

- Chronic inflammation is mediated by reactive oxygen species (ROS), hydrolytic enzymes, IFN-γ, other cytokines and growth factors.
- Macrophages and fibroblasts regulate scar tissue formation. Examples of chronic inflammation include tuberculosis, chronic sinusitis, chronic hepatitis, autoimmune diseases (i.e. ulcerative colitis, Crohn's disease).
- Acute and chronic inflammatory responses are shown in Fig. 2.2. Differences between acute and chronic inflammation are given in Table 2.2.

Table 2.2 Differences between acute and chronic inflammation

Parameters	Acute Inflammation	Chronic Inflammation
Pathogenesis of inflammation	Pathogens, trauma, burns	Progression of persistent acute inflammation, foreign bodies, tuberculosis, autoimmune diseases
Onset of inflammation	Immediate (rapid onset within seconds)	Delayed (slow onset)
Cells involved in inflammation	PMN cells	Lymphocytes and macrophages
Chemical mediators	Histamine, prostaglandins, thromboxane A_2 (TXA_2), prostacyclin, leukotrienes, lipoxins	Cytokines (IL-1), growth factors
Immunoglobulin	IgM	IgG
Duration of inflammation	Shorter (lasting for few hours to days)	Longer duration (lasting for weeks, months, or years)
Exudation in inflammation	Present	Absent
Tissue necrosis	Present	Less prominent
Tissue fibrosis	Absent	Present
Angiogenesis	Absent	Present
Outcome of inflammation	Complete resolution, tissue destruction (abscess), progression to chronic inflammation	Scar tissue formation, secondary amyloidosis
Peripheral blood leukocytic response	Neutrophilic leukocytosis	Lymphocytosis or monocytosis

ACUTE INFLAMMATION

Acute inflammation is short-term transient, rapid response to living tissue injury. It is characterized by hyperemia (rubor), pain (dolor), heat (color) and edema/swelling. Predominant cells in acute inflammation are polymorphonuclear cells. Macrophages and mast cells also play important role in acute inflammation. Acute inflammation is a series of processes initiated to limit tissue damage.

- The main features of acute inflammation are vasodilatation, increased vascular permeability and exudation into extravascular tissues, intravascular stasis and leukocyte margination, intravascular activation of polymorphonuclear cells, and activation of platelets.
- During inflammation, central stream of cells (e.g. leukocytes and red blood cells) move to peripheral

cell-free layer of plasma close to vessel wall. This phenomenon is known as margination. Neutrophils of the central column come close to the vessel wall; the phenomenon is known as **pavementing**. Peripherally marginated neutrophils slowly roll over (rolling phase).
  - Transient bond between neutrophils and endothelial cells becomes firmer (adhesion phase). Selectins, integrins and immunoglobulin superfamily adhesion molecules bring about rolling and adhesion of neutrophils over endothelium.
  - Escape of neutrophils with the help of pseudopodia across basement membrane into the extravascular space is known as emigration.
  - After extravasation from the blood, neutrophils migrate toward sites of infection by chemotactic molecules, phenomenon is known as chemotaxis.
- Vasodilatation and increased permeability in acute inflammation are caused by inflammatory chemical mediators. These vascular events participate in delivery of leukocytes (PMNs cells) and plasma proteins to the site of injury.
- Acute inflammation is mediated by chemical mediators such as histamine, nitric oxide, bradykinin, interleukin-1, tumor necrosis factor and interferon-γ, which act on nearby blood vessels.
  - Vasoactive amines (histamine and serotonin) are the first chemical mediators to be released in acute inflammation because they are present in preformed stores in mast cells, basophils, and/or platelets.
  - Resident tissue macrophages recognize inflammatory inducers such as bacterial products, immune complexes, toxins, physical injury, or dead cells and attempt to eliminate them. Macrophages synthesize master cytokines such as IL-1 and TNF-α.
- Chemical mediators are derived from plasma proteins, tissue macrophages, mast cells, platelets and endothelial cells, local injured tissue, and bacterial products. These chemical mediators increase the vascular permeability, with exudation of water, salts and plasma proteins including fibrinogen along with numerous polymorphonuclear cells to eliminate injurious agent.
- Inflammatory inducers, i.e. bacterial products immune complexes, toxins, physical injury activate tissue macrophages resulting in synthesis of cytokines (IL-1 and TNF-α), which activate neutrophils and venular endothelium.
- Glucocorticoids are broad spectrum of powerful anti-inflammatory agents, which downregulate expression of genes encoding proinflammatory cytokines (IL-1 and TNF-α) and nitric oxide synthase. Long-term use of corticosteroids is associated with many side effects including reduced bone densities (osteoporosis), diabetes mellitus, hypertension and cataracts. The prolonged administration of corticosteroids is, therefore, carefully regulated the lowest possible effective dose is prescribed.
- During acute inflammation, neutrophils are recruited at injured site, which eliminate injurious agent, removes cellular debris from injured area. Inflammatory exudates dilute or neutralize the injurious agent. Acute inflammation prevents the spread of infection followed by resolution. Without inflammation, infections would go unchecked and wound would never heal.
- Tissue damage occurs due to liberation of lysosomal enzymes into the extracellular tissue, especially due to prolonged unregulated inflammatory response in chronic inflammation and hypersensitivity reactions. Tissue damage may also occur in space occupying lesions in brain compressing vital structures.
- Acute inflammation has two major components: vascular and cellular responses. Vascular and cellular events in acute inflammation are shown in Fig. 2.3.
  - **Vascular response:** Vascular response depends on nature and severity of inflammatory stimulus, leading to alterations in vascular blood flow and structural changes in the microvasculature (vasodilatation and increased vascular permeability). These vascular changes result in extravasation of plasma fluid and proteins (edema) along with leukocytes to the site of injury.
  - **Cellular response:** In cellular response, inflammatory cells are recruited from circulation, which migrates to the injurious tissue by margination, rolling, adhesion, transmigration to initiate inflammation and eliminate injurious stimulus. Chemotaxis occurs due to endogenous signaling molecules such as lymphokines and exogenous toxins. Neutrophils are dominant cells in acute inflammation during 1–2 days, which phagocytose and degrade injurious agent by lysosomal enzymes, oxygen-derived free radicals and oxidative burst. Macrophages and mast cells play important role in acute inflammation.

VASCULAR EVENTS IN ACUTE INFLAMMATION

Alteration in the microvasculature is the hallmark of acute inflammation that occurs in two phases: hemodynamic changes and alterations in vascular permeability.
- Normally, most of the capillary bed is closed down by precapillary sphincters. In acute inflammation,

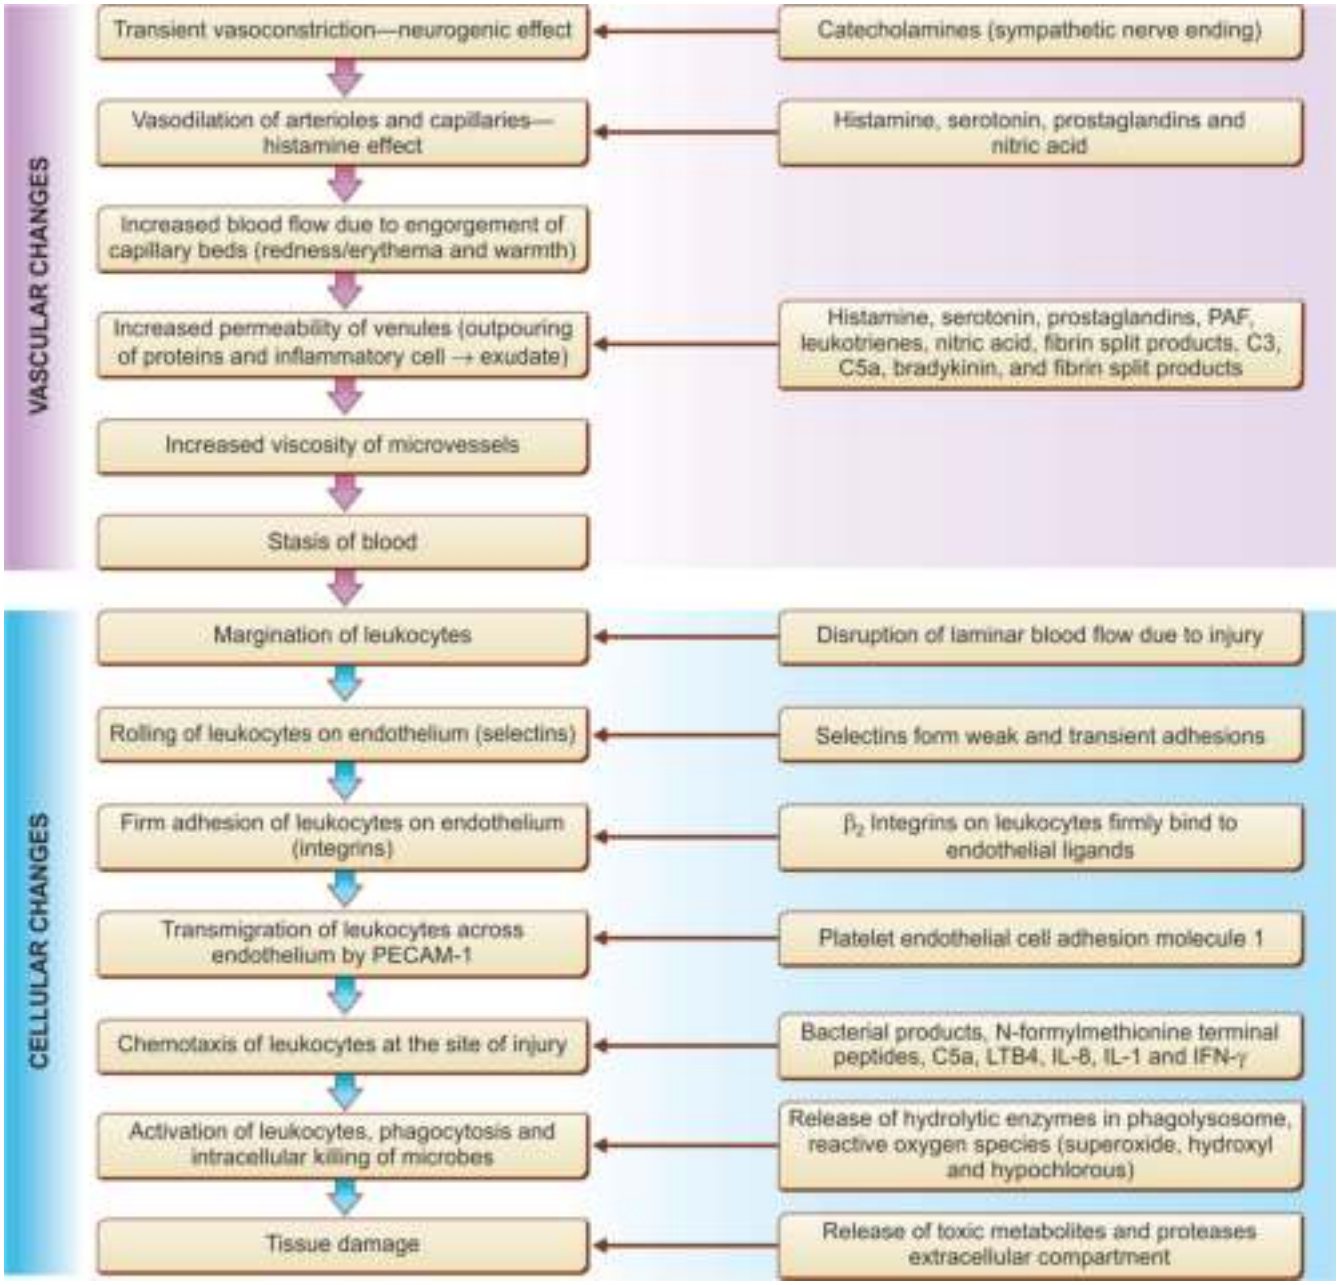

Fig. 2.3: Vascular and cellular events in acute inflammation. Vascular phase is characterized by vasodilatation and increased vascular permeability of the vascular barrier and the process is regulated by chemical mediators. Cellular phase is characterized by neutrophil margination, rolling, adhesion, and emigration to the injured site.

precapillary sphincters open, which cause blood to flow through all capillaries. During acute inflammation, vascular changes start with a transient neurogenic-mediated vasoconstriction of arterioles, which is shortly followed by vasodilatation of arterioles, capillaries, and post-capillary venules leading to increased blood flow to the injured area, which becomes red and warm.

- Under optimal conditions, the inflammatory response remains confined to a localized area (i.e. redness, swelling, heat, pain and loss of function). The four cardinal signs of acute inflammation were described nearly 2000 years ago by Celsius, which include rubor (redness), calor (heat), dolor (pain), and tumor (swelling). Virchow added functio laesa (loss of function) sign.
- Rubor, calor and tumor are mediated by histamine. These cardinal signs result from vascular changes, neutrophilic recruitment to the site of injury, synthesis of chemical mediators, and leukocyte-induced tissue injury. Acute inflammation subsides in <48 hours after elimination of injurious agents.
  - **Rubor (redness):** Inflamed area becomes red due to histamine induced vasodilatation of arterioles

and increased blood flow through all capillaries to the inflamed area in acute inflammation.

- **Calor (heat):** Inflamed area becomes hot due to increased blood flow in the injured area to skin surface, mediated by chemical mediators such as histamine, serotonin, C3a, C5a, prostaglandins (PGI_2, PGD_2, PGE_2, and PGF_2).
- **Dolor (pain):** Certain chemical mediators stimulate sensory nerve endings giving pain. Nerves are also stimulated by stretching due to edema. The inflamed area becomes painful, when touched. Pain occurs due to pressure on nerve endings from swelling; and direct effect of prostaglandin E_2 (PGE_2) and bradykinin effect on nerve endings.
- **Tumor (swelling):** Increased vascular permeability induces tissue swelling due to accumulation of blood and damaged tissue cells. Chemical mediators such as histamine, bradykinin, and prostaglandins increase vascular permeability leading to extravasation of inflammatory exudate into the interstitial tissue and edema formation.
- **Functio laesa (loss of function):** Loss of function occurs due to increased pain and swelling. When swelling and pain are marked, there is partial or complete loss of function of the inflamed structure. This clinical sign was added by Virchow in 1800s.

HEMODYNAMIC CHANGES

Vascular component in acute inflammation comes into play when tissue is damaged by infectious agents, trauma, toxic agents, endogenous product (uric acid), immunological reactions and foreign bodies (sutures, splinters, dirt). Vascular response in acute inflammation includes immediate (e.g. immediate transient and sustained) and late response. Vascular response in acute inflammation is given in Table 2.3.

Transient Vasoconstriction of Arterioles

Initially, rapid transient vasoconstriction of arterioles occurs after minor tissue injury within 30 seconds and is mediated by neurologic and liberation of catecholamines from sympathetic nerve endings. Blood flow is decreased to the site of injury and followed by vasodilatation of microvasculature.

Persistent Progressive Vasodilation of Arterioles and Capillaries

Persistent progressive vasodilation of arterioles and capillaries increases blood flow to injured site within half an hour referred to as active hyperemia responsible for redness (rubor), increased local temperature (heat = calor) and removal of toxins. It is immediate sustained microvasculature response after tissue injury. It starts 2–3 hours after injury and lasts for about 8 hours. It is mediated by chemical mediators synthesized by damaged tissue and mast cells such as histamine, serotonin, and sustained by prostaglandins (PGI_2, PGD_2, PGE_2, $PGF_{2\alpha}$) and nitric oxide.

Progressive Vasodilation of Arteriols and Capillaries and Elevated Local Hydrostatic Pressure and Transudate Formation

Permeability of vascular endothelium is usually normal, but alterations in hydrostatic pressure or oncotic pressure leading to formation of transudate. Normal fluid exchange between blood and extracellular fluid is shown in Fig. 2.4.

- A transudate is clear extravascular ultrafiltrate of plasma with water, dissolved eletrolytes, low protein, low cellularity fluid content mostly albumin and specific gravity <1.012. Formation of transudate due to fluid exchanges between blood and extracellular fluid is shown in Fig. 2.5.

Table 2.3 Vascular response in acute inflammation

Vascular Response Mediated by Neurologic/ Chemical Mediators	Net Effect
Transient vasoconstriction of microvasculature	
Transient vasoconstriction of microvasculature by neurologic mechanism by liberation of catecholamines from sympathetic nerve endings	Blood flow decreased
Vasodilatation of arterioles and capillaries	
▪ Histamine ▪ Serotonin ▪ Vasodilatation is sustained by prostaglandins (PGI_2, PGD_2, PGE_2, $PGF_{2\alpha}$) and nitric oxide	Blood flow increased (redness/erythema and warmth)
Increased vascular permeability of venules	
▪ Histamine ▪ Serotonin ▪ Bradykinin ▪ C3a, C5a ▪ Fibrin split products ▪ Prostaglandins ▪ Leukotrienes ▪ Platelet-activating factor (PAF) ▪ Nitric oxide (NO)	Inflammatory exudate and increased viscosity of blood

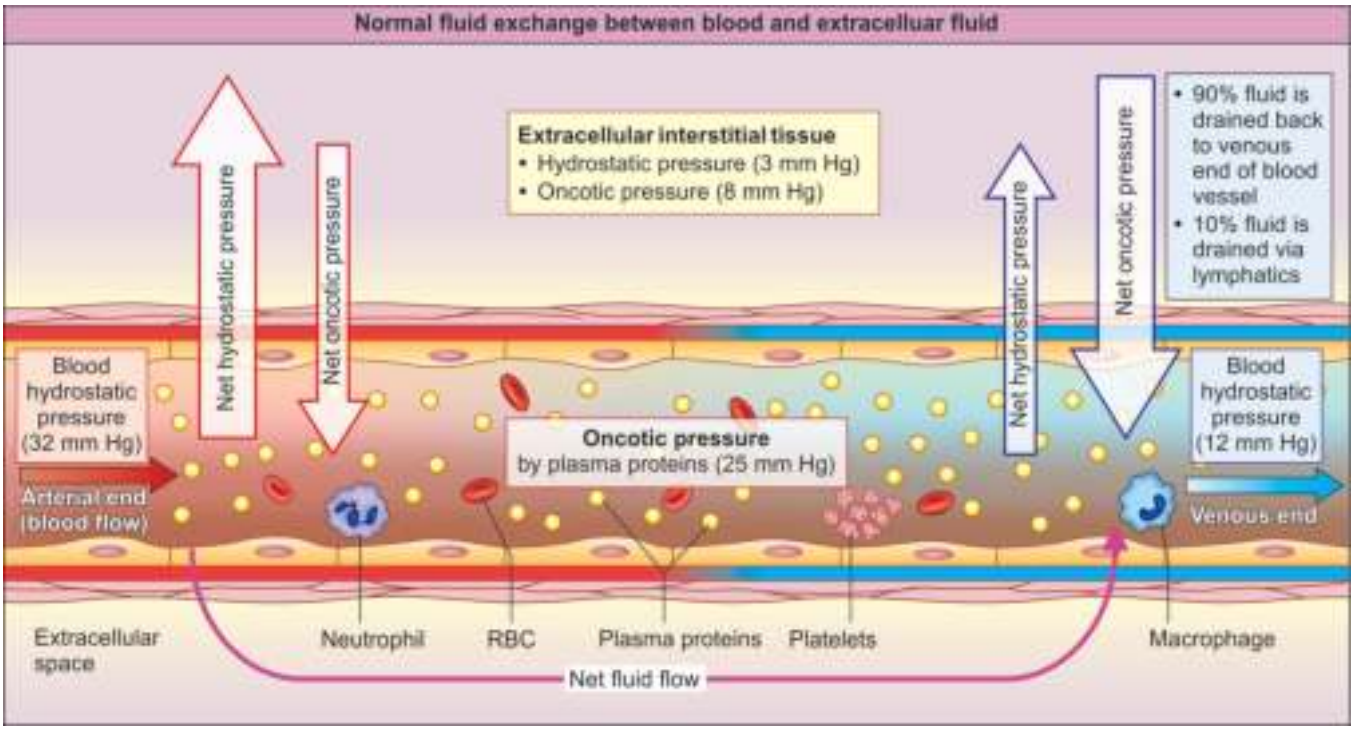

Fig. 2.4: Normal fluid exchange between blood and extracellular fluid. Normal hydrostatic pressure at arterial end of capillary is 32 mm Hg and 12 mm at venous end therefore fluid leaves blood vessel. Oncotic pressure exerted by plasma proteins is 25 mm Hg. At venous end, hydrostatic pressure is less than plasma oncotic pressure, so fluid enters blood vessel. Approximately 90% of fluid is drained back to capillary, while 10% of excess interstitial fluid is drained by lymphatic channels to venous circulation.

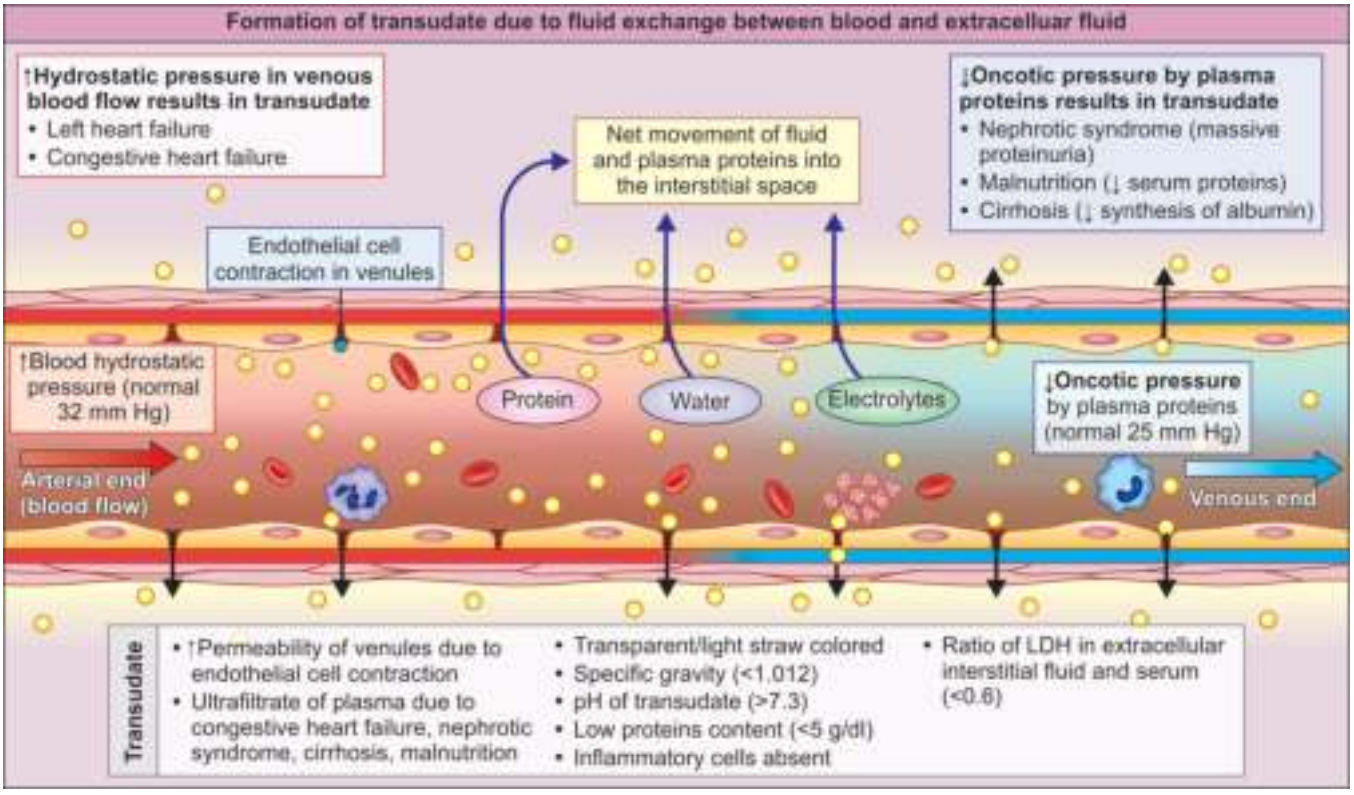

Fig. 2.5: Formation of transudate due to fluid exchanges between blood and extracellular fluid. Transudate is formed as a result of increased hydrostatic pressure or decreased plasma oncotic pressure. Therefore, fluid leaves microvasculature along whole length with no reabsorption. There is low protein loss, so this is a transudate.

- Transudate implies a problem due to alteration of hydrostatic pressure. Transudate is formed when fluid escapes from the normal endothelium of microvasculature. It occurs in non-inflammatory conditions.
- Transudate formation occurs either due to increased hydrostatic pressure (congestive heart failure) or decreased oncotic pressure (decreased protein synthesis in liver diseases, malnutrition, proteins loss in kidney diseases such as nephritic or nephrotic syndrome), and lymphatics obstruction (filariasis). Woman with breast cancer develops edema over arm, which has undergone mastectomy along with removal of lymph nodes and lymphatic channels.

Slowing or Stasis of Blood and Increased Blood Viscosity

Escape of fluid from microvasculature into the interstitial tissue increases the concentration of the red blood cells and blood viscosity leading to slowing of blood flow (stasis). The small vessels are dilated and congested. Leukocytes principally neutrophils now begin to accumulate along the endothelial surface, a process is called 'margination'.

INCREASED VASCULAR PERMEABILITY OF POSTCAPILLARY VENULES

Increased vascular permeability is the hallmark of acute inflammation that affects postcapillary venules. Increased vascular permeability is caused by chemical mediators, bacterial toxins, chemical agents, physical agents, severe burns, thermal injuries, X-rays, ultraviolet rays, leukocyte-induced endothelial injury, widening of venular interendothelial cells and leakage from newly formed vessels.

- Under physiologic state, normal venules are sealed by tight junctions between adjacent endothelial cells. Fluid leaving and entering blood vessels is in equilibrium.
- Increased vascular permeability occurs due to various chemical mediators derived from plasma (fibrin split products, bradykinin, C3a, C5a) and cells (histamine, serotonin, prostaglandins, leukotrienes, platelet-activating factor, nitric oxide).
- Due to widening of interendothelial junctions of postcapillary venules, there will be outside movement of the blood fluid rich in plasma proteins and inflammatory cells from the blood vessels to the site of injury and exudate formation.

Mechanism of Increased Vascular Permeability of Postcapillary Venules

Increased vascular permeability of postcapillary venules is mediated by chemical mediators, bacterial toxins, chemical agents, physical agents, severe burns, thermal injury, X-rays and ultraviolet rays, leukocytes induced, vascular endothelial growth factor and leakage from newly formed blood vessels. Chemical mediators responsible for increased vascular permeability are given in Table 2.4.

Table 2.4 Chemical mediators responsible for increased vascular permeability

Plasma and Cell-derived Components	Chemical Mediators
Plasma-derived chemical mediators	
Coagulation/fibrinolytic systems	Fibrin split products
Kallikrein-kinin system	Kinins (bradykinin)
Complement system	C3a, C5a
Cell-derived chemical mediators	
Mast cells, platelets	Histamine
Platelets	Serotonin
Inflammatory cells	Prostaglandins, leukotrienes, platelet-activating factor
Endothelium	Prostaglandins, nitric oxide, platelet-activating factor

- **Chemical mediators:** Histamine (mast cells, platelets, basophils), serotonin, prostaglandins, complement (C3a, C5a), fibrin split products, prostaglandins, leukotrienes, platelet-activating factor and nitric oxide increase permeability of postcapillary venules resulting in formation of exudate and increased viscosity of blood. Action of chemical mediators on postcapillary venules lasts for 15–20 minutes. Histamine binds and induces intracellular signaling pathway by phosphorylation of contractile myosin cytoskeleton proteins leading to increased vascular permeability.
- **Bacterial toxins, chemical agents, physical agents, and severe burns:** These injurious agents cause necrosis of endothelium of microvasculature. It leads to prolonged vascular leakage of fluid elements into interstitial tissue persisting for several hours to days until the damaged endothelium is thrombosed or repaired.
- **Thermal injury, X-rays and ultraviolet rays:** Delayed prolonged vascular leakage starts 2–12 hours after injury and lasts for several hours or days due to mild to moderate thermal injury, X-rays, and ultraviolet rays.
- **Leukocyte-dependent endothelial injury:** In acute inflammation, leukocytes liberate oxygen-derived free radicals and proteolytic enzymes, which cause detachment of venular endothelial cells leading

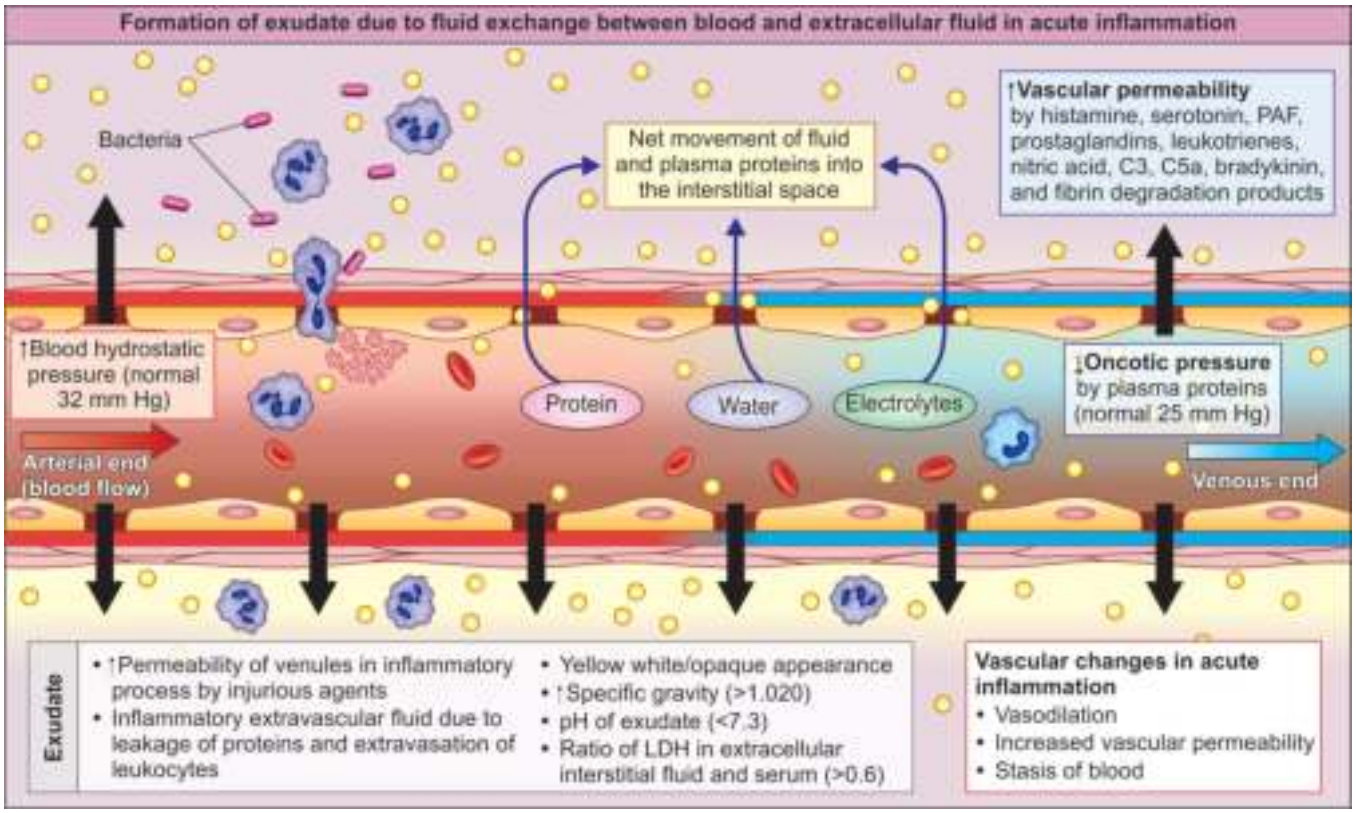

Fig. 2.6: Formation of exudate due to fluid exchange between blood and extracellular fluid in acute inflammation. An exudate is formed due to increased vascular permeability. Protein leaks out of microvasculature, so that there is no osmotic pressure difference between plasma and tissue (plasma oncotic pressure=0), therefore fluid leaves microvasculature. Fluid contains proteins, so this is an exudate.

to increased permeability. It is a delayed vascular response, which persists for hours. Glomeruli and pulmonary capillaries are also injured by this mechanism.

- **Vascular endothelial growth factor (VEGF) related increased vascular permeability:** Vascular endothelial growth factor acts on vesiculovacuolar organelles located close to intercellular junction of venules increase the size and number of these channels leading to increased vascular permeability.
- **Leakage from newly formed vessels:** New vessels formed are responsible for persistent leakage of fluid. Increased expression of receptors for histamine and VEGF further increases vascular permeability.

EXUDATE FORMATION

Exudate formation is a consequence of altered endothelial permeability of postcapillary venules that results in extravasation of plasma proteins and neutrophils into interstitial space. Formation of exudate due to fluid exchange between blood and extracellular fluid in acute inflammation is shown in Fig. 2.6. Acute inflammatory exudate in tissue is shown in Fig. 2.7.

- Starling forces are altered so that there is increased flow of fluid from the vascular system into the interstitium. There are four pressures involved in Starling's law: hydrostatic pressure in the capillary, hydrostatic pressure in the interstitium, oncotic pressure in the capillary and oncotic pressure in the interstitium.

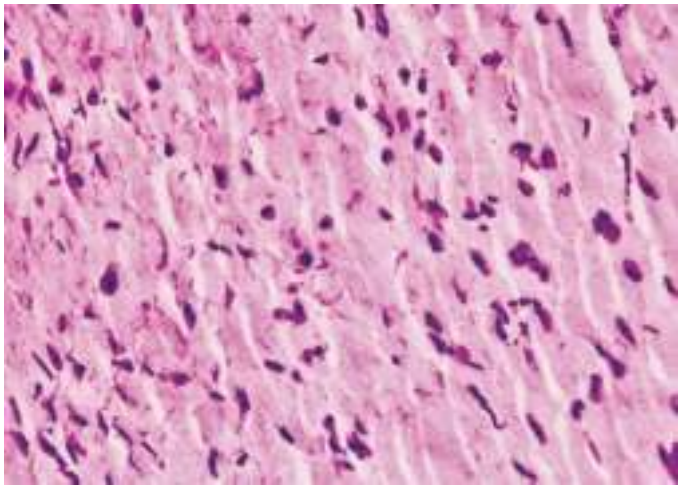

Fig. 2.7: Acute inflammatory exudate in tissue. Exudate is inflammatory in nature that occurs due to vascular permeability caused by the release of inflammatory chemical mediators from the inflamed tissue. Neutrophils are predominant cell type in most exudates, along with some macrophages (400X).

- Normal hydrostatic pressure in capillaries at arterial end is 32 mm Hg and venous end is 12 mm Hg. Osmotic pressure exerted by plasma proteins is 25 mm Hg in capillaries. Due to pressure gradient, hydrostatic blood pressure forces water out of capillaries at the arterial end. At the venous end, 90% of extravasated fluid is drained back in capillaries at venous end due to oncotic pressure exerted by plasma albumin. Remaining 10% fluid in interstitial tissue is drained via lymphatic channels into circulation. When the balance of starling forces is altered, the net result is accumulation of fluid in the interstitial spaces (i.e. edema).
- During acute inflammation, lymph flow is increased, which helps to remove edema fluid from extravascular fluid along with cell debris and microbes. Severe inflammation results in inflammation of lymphatic channels and lymph nodes. There is presence of red streaks near a skin wound due to lymphangitis.

Mechanism of Exudation

Exudation occurs as a result of several mechanisms: endothelial contraction, cytoskeleton reorganization, direct injury to blood vessels, leukocyte-dependent injury and increased transcytosis.

- **Endothelial contraction:** Endothelial cell contraction develops temporary gaps in venules and vascular leakiness, which is mediated by vasoactive chemical mediators (histamine, leukotrienes). These vascular changes occur within 15–30 minutes immediately after injury and persists for short duration.
- **Cytoskeleton reorganization in endothelium:** Reversible endothelial cell retraction occurs at the intercellular junctions due to structural reorganization of cytoskeleton of endothelial cells. The process is mediated by cytokines IL-1 and TNF-α.
- **Direct injury to endothelium**: Chemical agents, severe bacterial infections, radiation and thermal injury induce necrosis of endothelial cells in arterioles, capillaries and venules. Direct injury to endothelium initiates thrombus formation. The process appears immediately after injury and persists for hours to days.
- **Leukocyte-dependent endothelial injury:** In bacterial infections, leukocytes adhere to the endothelium at the site of inflammation. Activation of the leukocytes releases proteolytic enzymes and reactive oxygen species, which cause endothelial injury and increased vascular leakiness. The process mostly affects venules and pulmonary capillaries. Injury to endothelium initiates thrombus formation. The process persists for several hours to 2–12 hours.
- **Increased transcytosis (channels across endothelial cytoplasm):** It is mediated by vascular endothelial growth factor (VEGF) at the site of angiogenesis. The vessels become leaky, which allows plasma proteins, such as fibrin, to be delivered directly to the injury site.

Composition of Exudate

An exudate has a high protein content due to increased vascular permeability of postcapillary venules during acute inflammatory process. Exudate is rich in fibrinogen/fibrin, immunoglobulins, salts, water and neutrophils. Specific gravity is >1020 in exudate. Because the metabolically active leukocytes consume glucose, the glucose content in blood is often greatly reduced.

Exudation and Clinical Correlation

Acute inflammation brings chemical mediators of inflammation to injured site, which act on nearby blood vessels. It is responsible for swelling (edema), pain, and impaired function. Exudate formed in severe burns is life-threatening. Fibrin formation in the injured area aids in localizing the spread of infectious microorganisms. Exudate dilutes bacterial toxins and provide opsonins (IgG, C3b) to assist in phagocytosis. Differences between exudate and transudate are given in Table 2.5.

CELLULAR EVENTS: LEUKOCYTES RECRUITMENT TO THE SITES OF INFLAMMATION

The cellular response in acute inflammation is a multistep process, marked by recruitment of phagocytic cells (e.g. neutrophils and monocytes/macrophages) into extravascular tissue to the site of injury. Steps of leukocyte extravasation include: margination, rolling, and adhesion to endothelium, transmigration across endothelium (leukocyte diapedesis) and migration toward a chemotactic stimulus in tissues. Cellular changes in acute inflammation are given in Table 2.6.

- Neutrophils are the primary leukocytes in acute inflammation, i.e. *Staphylococcus aureus* infection. Macrophages and mast cells also play important role in acute inflammation. On the other hand, macrophages, lymphocytes and plasma cells participate in chronic inflammation.
- The leukocytes first roll, then become activated and adhere to endothelium, then transmigrate across the endothelium, pierce the basement membrane, and migrate to site of injury by chemotaxis. **PECAM-1 (platelet endothelial cell adhesion molecule 1)** synthesized by interendothelial junctions and platelets participate in transmigration of leukocytes.

Table 2.5 Differences between exudate and transudate

Characteristics	Exudate	Transudate
Mechanism	Increased permeability of postcapillary venules in inflammation	Increased hydrostatic pressure or decreased oncotic pressure
Causes	Acute inflammation	Congestive heart failure, hypoproteinemia (malnutrition), nephrotic syndrome (protein loss)
Endothelial permeability	Altered endothelial permeability	Normal endothelial permeability
Fluid nature	Inflammatory extravascular fluid	Ultrafiltrate of blood plasma
Composition	Mainly protein and cellular debris	Mainly water and dissolved electrolytes
Color	Yellowish-white opaque appearance	Transparent/light straw colored
pH	<7.3	>7.3
Specific gravity	>1.020 (due to high proteins content in exudate)	<1.012
Proteins content	High protein content (which raises specific gravity)	Low protein fluid (<5 g/dl)
Glucose concentration	Glucose concentration is low in infections and cancer	Glucose concentration remains same as that of blood
Ratio of LDH levels in fluids and serum	High ratio (>0.6)	Low ratio (<0.6)
Light microscopy	PMN cells in acute inflammation, macrophages and lymphocytes in chronic inflammation	Inflammatory cells absent

Table 2.6 Cellular changes in acute inflammation

Multistep Process	Role
Margination of leukocytes	
Localization of leukocytes from central axial column along the vascular endothelium	Disruption of laminar blood flow due to injury
Rolling of leukocytes	
Rolling (or tumbling) along the vascular endothelium	Selectins form weak and transient adhesions
Firm adhesion of leukocytes	
Leukocytes bind firmly to endothelium	β_2 Integrin on leukocytes firmly bind to endothelial ligands
Transmigration (diapedesis) of leukocytes	
Movement of leukocytes across venular endothelium	PECAM-1 (platelet endothelial cell adhesion molecule 1)
Chemotaxis of leukocytes	
Recruitment of leukocytes at the site of tissue injury site known as chemotaxis	C5a, bacterial products, N-formyl methionine terminal peptides, leukotrienes (LTB4,) hydroxyeicosatetraenoic acid, kallikrein and IL-8, IL-1 and IFN-γ; and cellular debris
Phagocytosis by leukocytes	
Phagocytes (neutrophils and macrophages) eliminate microbes and cellular debris by process of phagocytosis	Opsonization, binding, engulfment, phagolysosome formation, release of hydrolytic enzymes in phagolysosome
Intracellular killing of microbes of leukocytes	
Killing and degradation of microbes in neutrophils	▪ Oxygen-dependent [superoxide, highly reactive hydroxyl molecule, hypochlorous (HOCl)] free radical ▪ Oxygen-independent system (lactoferrin, defensins, bactericidal permeability increasing protein, lysosomal enzyme and major basic proteins)

- Chemoattractants, i.e. bacterial products (peptides with N-formyl methionine termini), plasma proteins (C5a), cells (IL8, LTB4), and cellular debris attract neutrophils to the site of tissue injury. Neutrophils play important role in elimination of injurious agents.
- Selectins are sugar-binding glycoproteins that mediate the initial loose transient adhesion of leukocytes to endothelial cells in acute inflammation. These are found at the cell surface and are not part of the extracellular matrix.

- Selectin family is comprising E-selectins (endothelial cells), P-selectins (platelets and endothelial cells) and L-selectins (leukocytes).
- Leukocytes with the help of their Sialyl-Lewis X (oligosaccharides) bind to E- and P-selectins expressed on vascular endothelial cells that mediate the initial adhesion of leukocytes (primarily neutrophils) to endothelial cells in acute inflammation. P-selectin is a cell adhesion molecule that mediates the margination of neutrophils during acute inflammation.

■ Integrins are a family of transmembrane cell surface receptors that mediate interactions with extracellular matrix components and with other cells. These cell surface glycoproteins transmit mechanical and chemical signals, thereby regulating cellular survival, proliferation, differentiation, and migration.
- The motility of epithelial cells is also regulated by integrin receptors. During inflammation, β_2 integrins form firm adhesion of leukocytes to immunoglobulin family adhesion proteins expressed on vascular endothelium, which are involved in leukocyte recruitment to the injury site in acute inflammation.
- The locomotion of leukocytes is powered by membrane extensions called lamellipodia. It is worth mentioning that slower moving cells, such as fibroblasts, extend finger-like membrane protrusions called filopodia.
- Integrins expressed on various inflammatory cells include lymphocyte function-associated antigen 1 (LFA-1), macrophage antigen 1 (MAC-1), and very late antigen 4 (VLA-4). These bind to Ig family adhesion proteins expressed on endothelium.

■ Emigration is escape of inflammatory leukocytes between endothelial cells into surrounding interstitial tissue, which occurs by margination, rolling, firm adhesion, and transmigration processes. Mechanism of leukocyte emigration is shown in Fig. 2.8.

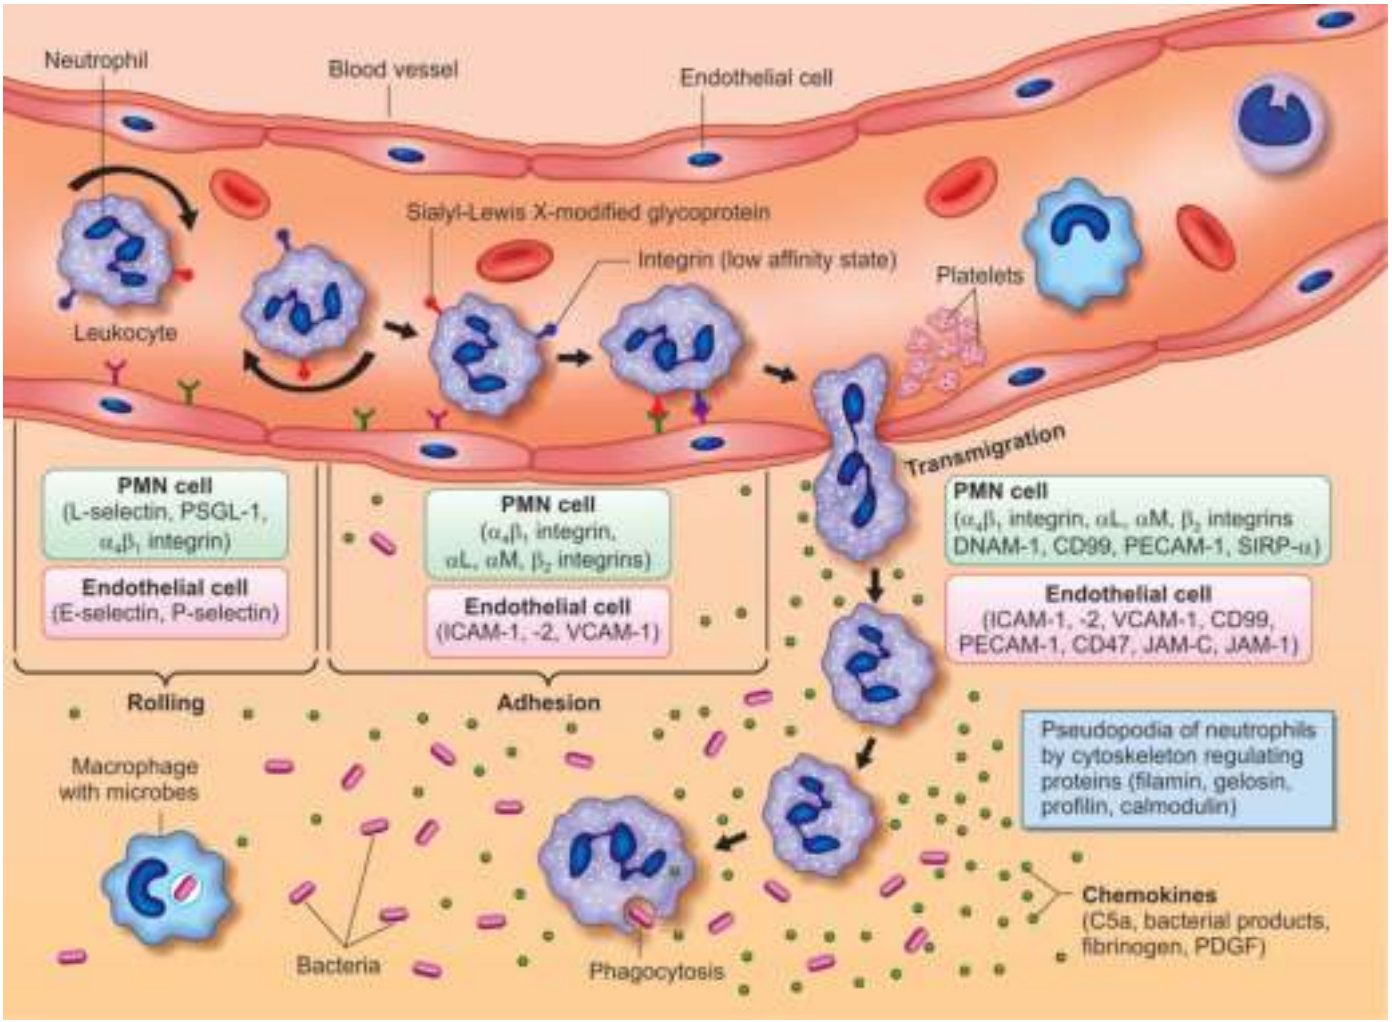

Fig. 2.8: Mechanism of leukocyte emigration. It involves rolling, adhesion, transmigration, chemotaxis and phagocytosis of injurious agent. Rolling is mediated by selectins, firm adhesion by β integrin, and transmigration.

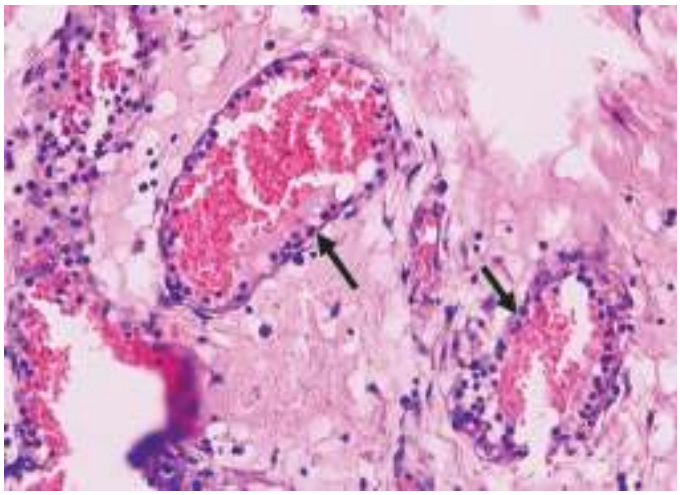

Fig. 2.9: Margination of leukocytes in microvessel. Leukocytes, in contrast to red blood cells fall out of the axial stream in the blood vessel and their attachment to the endothelial cells in the peripheral stream is under the influence of selectins. Margination is the first step in the firm adhesion of leukocytes to the endothelium (arrows) (100X).

MARGINATION OF LEUKOCYTES

Margination occurs due to localization of leukocytes from central axial column along the vascular endothelium. Normally, 50% of neutrophils travel in laminar flow, while remaining 50% are circulating along venular endothelial cells (marginating zone). Red blood cells being smaller in size move faster than large sized white blood cells.

- During acute inflammation, release of chemical mediators (i.e. histamine, leukotrienes and kinins) and cytokines act on endothelial cells of capillaries and leukocytes leading to increased expression of adhesion molecules and slowing down of leukocytes in blood circulation.
- Margination (pavementing) occurs as all leukocytes line the endothelial surface, due to activating and deactivating neutrophilic adhesive molecules. RBCs also aggregate into rouleaux formation ("stacks of coins") in venules. Margination of leukocytes in microvessel is shown in Fig. 2.9.

ROLLING OF LEUKOCYTES

After margination, the leukocytes start rolling (or tumbling) along the vascular endothelium by forming weak and transient adhesions mediated by 'selectins' family of adhesive molecules. Selectin family consists of three types of structurally related selectins.

- E-selectin is found on endothelial cells. P-selectin is expressed on platelets and endothelial cells. L-selectin is present on leukocytes except T cells.
- E-selectin and P-selectin expressed on endothelial cells bind to oligosaccharides such as Sialyl-Lewis X on the surface of leukocytes.
- Selectins mediate the initial adhesion of leukocytes (primarily neutrophils) to endothelial cells in acute inflammation.

Pathology Pearls: Regulation of Selectin Family
E-Selectin (CD62E)
▪ E-selectin (CD62E) is stored in Weibel-Palade bodies of resting endothelial cells. ▪ E-selectin is redistributed along the luminal surface of the endothelial cells, where they mediate the initial adhesion and rolling of leukocytes.
P-Selectin (CD62P)
P-selectin (CD62P) is stored in endothelial Weibel-Palade bodies and platelet α-granules; relocate to the plasma membrane after stimulation by mediators such as histamine and thrombin.
L-Selectin (CD62L)
L-selectin (CD62L) is expressed on all leukocytes except T cells, that bind to endothelial mucin-like molecules such as GlyCam-1.

FIRM ADHESION OF LEUKOCYTES

During inflammation, β_2 integrins expressed over leukocytes firmly bind to ligands expressed on venular endothelium. Normally, β_2 integrins (LFA-1, MAC-1, and VLA-4) are expressed in low concentration on leukocytes. Hence, leukocytes do not adhere firmly to their appropriate ligands endothelial surface, unless activated by chemokines (C5a, LTB_4 and bacterial endotoxins) during acute inflammation. Leukocytic activation leads to increased concentration and conformational changes of β_2 integrins on their surface. Corticosteroids, lithium and catecholamines inhibit activation of adhesion molecules.

- Chemical mediators (chemokines, IL-1 and TNF-α) increase the expression of ligands ICAM (intercellular adhesion molecule) and VCAM (vascular cell adhesive molecule) over vascular endothelium. VCAM also participates in adhesion of eosinophils, monocytes, lymphocytes to venular endothelium.
- Leukocyte β_2 integrin receptor binds to ligands expressed over venular endothelium. During acute inflammation, binding of integrin to heparin sulfate glycosaminoglycans inhibits rolling of leukocytes. Net result is formation of firm adhesion of leukocytes to endothelial surface.
- Endothelial–leukocyte adhesion molecules are shown in Fig. 2.10. Major leukocyte–endothelial cell adhesion molecules are given in Table 2.7. Endothelial/leukocyte adhesion molecules and their major roles are given in Table 2.8.

Clinical Pearls: Defects in Firm Adhesion of Leukocytes to Venular Endothelium

Leukocytic adhesion to venular endothelium is impaired in leukocyte adhesion (LAD1, LAD-2, LAD3) deficiency, diabetes mellitus and patient on steroid therapy and hemodialysis.

Leukocyte Adhesion Type 1 (LAD-1) Deficiency

- Leukocyte adhesion type 1 deficiency occurs due to mutations of ITGB2 gene that causes deficiency of β_2 integrins (LFA-1 and MAC-1) expressed on leukocytes. It impairs adhesion of leukocytes to venular endothelium.
- Patients suffer from recurrent severe bacterial and fungal infections of skin and mucous membranes, gingivitis, peritonitis, tooth loss, delayed wound healing and delayed detachment of umbilical cord in newborns along with infection of the umbilical cord stump (omphalitis).

Leukocyte Adhesion Type 2 (LAD-2) Deficiency

- Leukocyte adhesion type 2 deficiency occurs due to mutations of SLC35C1 gene that causes mild disorder. Infants with LAD-2 develop pneumonia, recurrent bacterial infections such as otitis media, peritonitis, cellulitis. The infections are not life-threatening.
- As affected infant grows older, severe peritonitis is the main infectious complication. Unlike LAD type 1, deficiency infants with LAD type 2 deficiency do not experience a delay in the detachment of the umbilical cord. LAD type 2 deficiency can develop a unique Bombay blood group.
- LAD type 2 deficiency can develop additional features such as diminished muscle tone resulting in hypotonia, distinctive facial features, severe mental retardation and short stature.
- LAD type 2 deficiency may also be known as congenital disorder of glycosylation type 2C due to basic defect in fucose metabolism.

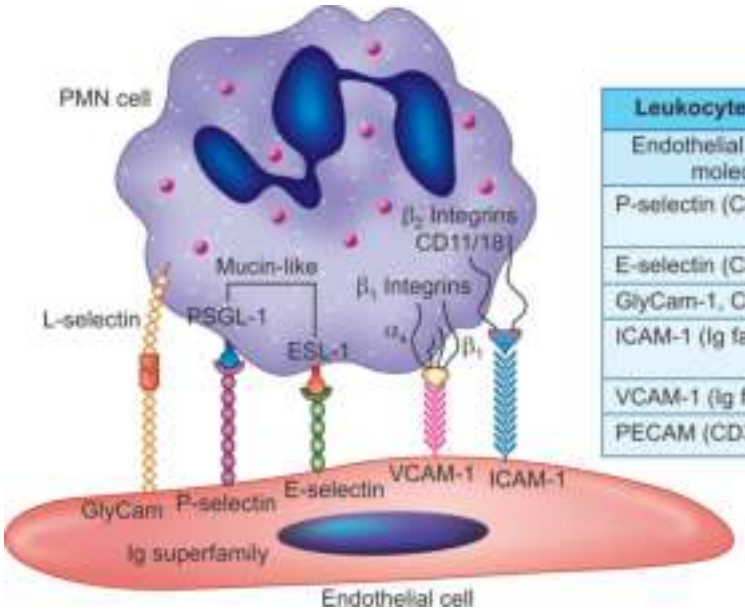
Leukocyte Adhesion Type 3 (LAD-3) Deficiency

- Leukocyte adhesion type 3 (LAD-3) deficiency occurs due to gene mutation in Kindlin-3 encoding a protein essential for all integrins activation. Patients with LAD type 3 deficiency develop recurrent bacterial and fungal infections similar to seen in LAD type 1 deficiency.
- LAD type 3 deficiency can develop life-threatening bleeding complication that resembles a platelet disorder, Glanzmann thrombasthenia. Patient presents with profuse bleeding tendencies especially after surgical procedures, epistaxis, gingival bleeding and /or red- or purple-colored spots on skin. The bleeding tendency usually starts at birth.

TRANSMIGRATION OF LEUKOCYTES

Transmigration is the movement of leukocytes across venular endothelium. It is also known as diapedesis. Transmigration is an essential step in acute inflammation and thus in host defense and healing process.

- Transmigration of leukocytes occurs in venules in all tissues except lung where it occurs via capillaries. Interendothelial junctions of postcapillary venules and platelets synthesize a chemokine known as 'platelet endothelial cell adhesion molecule 1' (PECAM-1).
- PECAM-1 stimulates adherent neutrophils to produce collagenase, elastase, and metalloproteinases leading to focal digestion of venular basement membrane.



Leukocyte and endothelial adhesion molecules

Endothelial adhesion molecule	Leukocyte adhesion molecule
P-selectin (CD62P)	Sialyl-Lewis X PSGL-1
E-selectin (CD62E)	Sialyl-Lewis X
GlyCam-1, CD4	L-selectin (CD62L)
ICAM-1 (Ig family)	Integrins (LFA-1, Mac-1) CD11/CD18
VCAM-1 (Ig family)	VLA-4 integrin
PECAM (CD31)	CD31

Fig. 2.10: Endothelial–leukocyte adhesion molecules. The adhesion of leukocytes to vascular endothelium is the hallmark of the inflammatory process. Endothelial cells express immunoglobulin-like molecules such as ICAM-1, ICAM-2, VCAM-1 and PECAM-1. Which engage leukocyte counter receptor to mediate rolling (L-selectin on leukocytes, E-selectin and P-selectin on endothelium), adhesion mediated by integrin (CD11/CD18, VLA4 on leukocytes) and/or transendothelial migration of neutrophils that occur for several hours after the initiation of inflammatory response.

- Neutrophils start inserting pseudopodia; migrate across resting endothelium into the interstitial tissue spaces towards chemotactic stimulus. Red blood cells also transmigrate along with neutrophils towards site of injury.

CHEMOTAXIS OF LEUKOCYTES

Leukocyte chemotaxis is a critical feature of innate immune response in which movement of neutrophils and macrophages from one site in the body to another site of tissue injury to provide effector functions in response to concentration gradients of extracellular signals.

- Common chemotactic agents are bacterial products, complement (especially C5a), leukotrienes and cytokines (IL-8), which cause leukocyte movement.
- Chemotaxis occurs under the influence of chemotactic mediators derived from various sources: (a) complement proteins (C5a), (b) bacteria and mitochondrial products, particularly of low-molecular weight N-formyl methionine terminal peptides, (c) cell-derived arachidonic acid metabolites (LTB4, hydroeicosatetraenoic acid, kallikrein and IL-8), and (d) chemokines (e.g. IL-1 and IFN-γ); and (e) cellular debris.

- **Binding of chemokines on leukocytes:** Chemotactic chemical mediators bind to seven transmembrane G protein-coupled receptors (GPCRs) family on leukocytes. G protein-coupled receptors mediated signal transduction lead to generation of lipid second messengers and increased cytosolic calcium, which ultimately induce cytoskeleton polymerization and contraction.
- **Enhancement of neutrophilic motility:** Calcium causes contraction of 'cytoskeleton actin regulating proteins' (filamin, gelsolin, profilin and calmodulin), which are necessary for pseudopodia formation that anchor to the ECM. Cytoskeleton actin regulating proteins pull the leukocytes in the direction toward injury site.
- **Recruitment of leukocytes:** Neutrophils predominate in the acute inflammatory infiltrate during first 6–24 hours, which are short lived. Cellular infiltrate is dominated by continuously recruited neutrophils for several days in Pseudomonas infection.
  - Neutrophils undergo apoptosis and disappear after 24–48 hours which are replaced by monocytes/macrophages in 24–48 hours, which survive longer. Inflammation lasting more than a few days attracts macrophages and lymphocytes.

Table 2.7 Major leukocyte–endothelial cell adhesion molecules

Molecules	Distribution	Ligand/Molecule on Cell Type
Selectin family		
P-selectin glycoprotein ligand 1 (CD62P)	Endothelium activated by histamine and thrombin	Sialyl-Lewis on X P-selectin glycoprotein ligand 1 (PSGL-1) and other glycoproteins; neutrophils, monocytes, T cells (memory, effector)
E-selectin (CD62E)	Endothelium activated by IL-1 and tumor necrosis factor (TNF)	Sialyl-Lewis (e.g. cutaneous lymphocyte antigen-1; CLA-1) on glycoproteins; neutrophils, monocytes, T cells (memory, effector)
L-selectin (CD62L)	Neutrophils, monocytes, T cells (naïve), B cells (naïve) and central memory cells	Sialyl-Lewis X/PNAd on GlyCam-1 (glycan bearing cell adhesion molecule 1), CD34, MadCAM-1, others; endothelium (HEV)
Integrin family		
Leukocyte function antigen 1 (leukocyte function-associated antigen 1; LFA-1) (CD11a/CD18)	Neutrophils, monocytes, T cells (naïve), B cells (naïve) and central memory cells	Intercellular adhesion molecule 1 (ICAM-1) (CD54), ICAM-2 (CD102); endothelium cell immunoglobulin family (upregulated when cytokine activated), ICAM-3 (intercellular adhesion molecule 3) (CD50) neutrophil immunoglobulin family
Macrophage antigen 1 (MAC-1) (CD11bCD18)	Neutrophils, monocytes, dendritic cells	Intercellular adhesion molecule 1 (ICAM-1) (CD54), ICAM-2 (CD102); endothelium cell immunoglobulin family (upregulated when cytokine activated), ICAM-3 (intercellular adhesion molecule 3) (CD50) neutrophil immunoglobulin family
VLA-4 (very late antigen 4) (CD49a, CD29)	Monocytes, T cells (naïve, effector, memory)	Vascular cell adhesion molecule 1 (VCAM-1)(CD106); endothelium cell immunoglobulin family (upregulated when cytokine activated)
$\alpha_4\beta_7$ (CD49d, CD29)	Monocytes, T cells (gut, naïve, memory) B cell (gut homing)	Vascular cell adhesion molecule 1 (VCAM-1) (CD106); mucosal adhesion cell adhesion molecule 1 (MadCAM-1); endothelium cell immunoglobulin family in gut and gut-associated lymphoid tissue

PECAM-1 (platelet endothelial cell adhesion molecule 1) (CD31).

Table 2.8 Endothelial–leukocyte adhesion molecules and their major roles

Endothelial Molecule	Leukocyte Receptor	Major Roles
P-selectin (CD62P)	▪ Sialyl-Lewis X ▪ PSGL-1	Rolling of polymorphonuclear (PMN) cells, monocytes, lymphocytes
E-selectin (CD62E)	Sialyl-Lewis X	Rolling and adhesion of leukocytes
GlyCam-1, CD4	L-selectin (CD62L)	Rolling of PMN cells and monocytes
ICAM-1 (Ig family)	Integrins (LFA-1, Mac-1) CD11/CD18	Adhesion, arrest and transmigration of PMN cells, monocytes and lymphocytes
VCAM-1 (Ig family)	VLA-4 integrin	Adhesion of PMN cells, monocytes and lymphocytes
PECAM (CD31)	CD31	Transmigration of all leukocytes through endothelium

- Macrophages participate in clearance of pus, cellular debris, damaged tissue and dead neutrophils. In acute viral infections lymphocytes may be the first cells to arrive. In hypersensitivity reactions, eosinophils may be the main cell type.

- **Impaired chemotaxis:** Chemotaxis is impaired in diabetes mellitus, cancer, sepsis, immunodeficiency disorders and thermal injuries. Patients develop increased susceptibility to infections due to defects in complement proteins, pathologic activation and deficiency of regulatory proteins. Chemotactic factors for various cells in inflammation are given in Table 2.9.

ACTIVATION OF LEUKOCYTES

Leukocytes express on their surface different kinds of receptors that recognize different stimuli. After recruitment of leukocytes to the injured site, microbes, products of necrotic cells and chemical mediators activate the leukocytes. Activated leukocytes participate in phagocytosis and degradation of injurious agents. Chemical mediators amplify the innate and adaptative inflammatory immune responses.

- **Pathogen-associated molecular patterns:** Pathogens contain pathogen-associated molecular patterns (PAMPs) in gram-negative bacteria (e.g. lipopolysaccharides, endotoxin), gram-positive bacteria (peptidoglycan, e.g. lipoprotein, lipoteichoic acid), bacteria with flagella (e.g. flagellin), viruses (e.g. single stranded, double-stranded RNA molecules) and fungi (e.g. zymosan). Pathogen-associated molecular patterns (PAMPs) are shown in Fig. 2.11. Major pathogen-associated molecular patterns (PAMPs) in microbes are given in Table 2.10.
- **Damage-associated molecular patterns:** Necrotic cells/tissues release damage-associated molecular patterns (DAMPs), whereas apoptotic cells typically do not release DAMPs.
  - Stimuli that induce necrosis or severe cellular damage, which results in rapid cell rupture with consequent release of intracellular DAMPs to the extracellular space. DAMPs can then engage cells of immune system and promote inflammation.

Table 2.9 Chemotactic factors for various cells in inflammation

Chemotactic Factor	Source	Chemotaxis for Cells
Formylated peptides	Bacterial products of *Escherichia coli*	Neutrophils
C5a	Activated complement component	Neutrophils
Kallikrein	Product of factor XIIa-mediated conversion of prekallikrein	Neutrophils
Fibrinogen	Plasma protein	Neutrophils
Acetyl-glyceryl-ether-phosphorylcholine (AGEPC), a potent platelet-activating factor (PAF)	▪ Basophils ▪ Mast cells	Eosinophils
PDGF	▪ Platelets ▪ Monocytes ▪ Macrophages ▪ Smooth muscle cells ▪ Endothelial cells	▪ Neutrophils ▪ Macrophages
TGF-β	▪ Platelets ▪ Neutrophils ▪ Macrophages ▪ Lymphocytes ▪ Fibroblasts	▪ Macrophages ▪ Fibroblasts
Fibronectin	Extracellular matrix protein	▪ Fibroblasts ▪ Endothelial cells

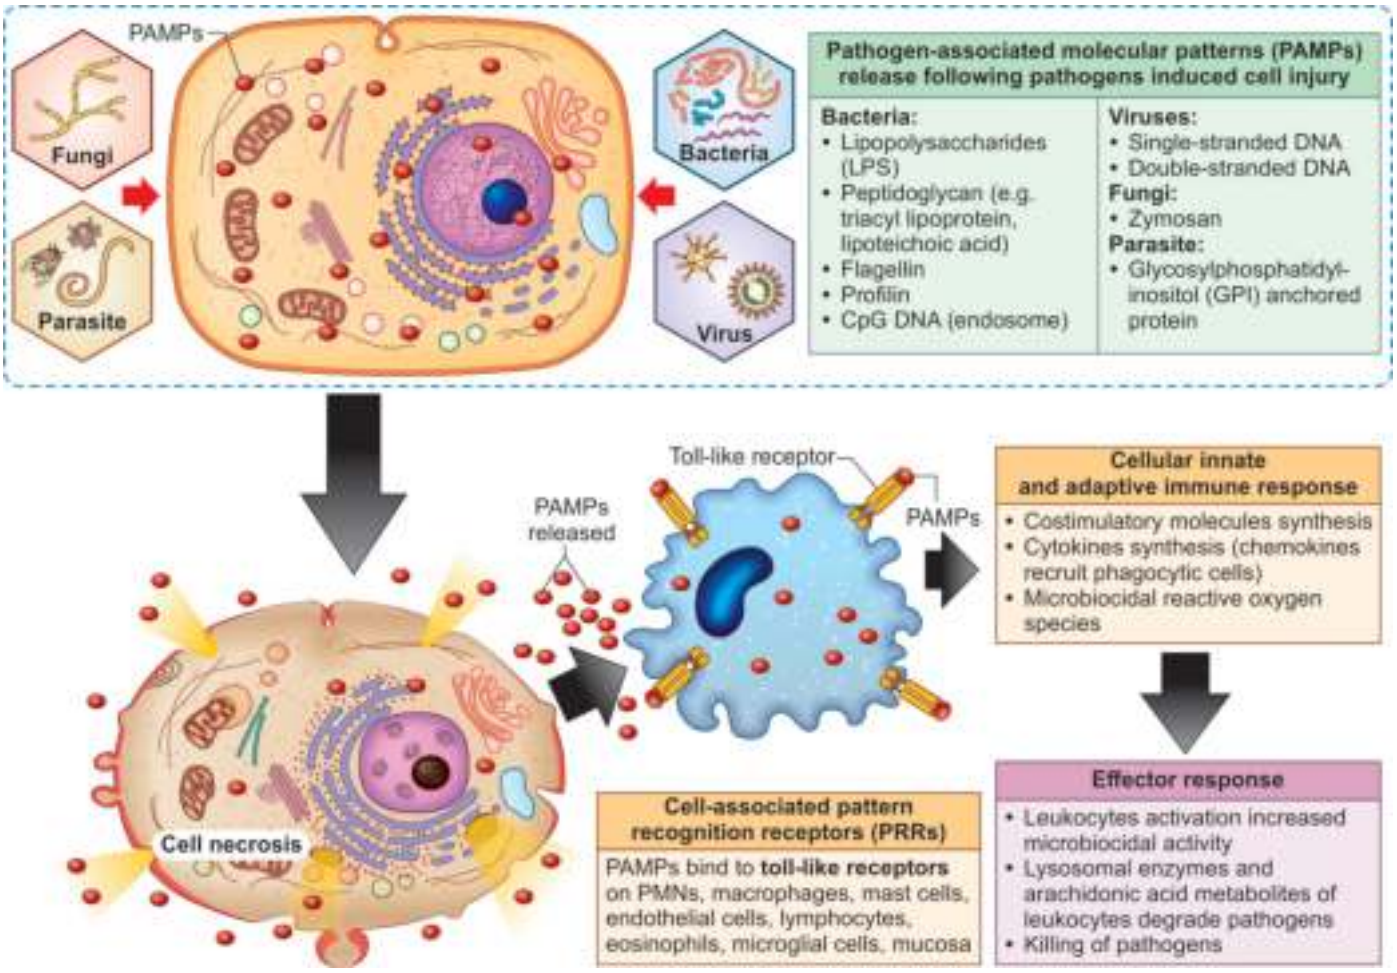


Fig. 2.11: Pathogen-associated molecular patterns. Microbes release PAMPs that bind to the family of pattern recognition receptors (PRRs), i.e. toll-like receptors and mediate innate and adaptive immune responses. Activation of toll-like receptors by specific ligands induces cytokine release and costimulatory molecules that instruct the type on immune response and direct antimicrobial response and tissue injury.

Table 2.10 Major pathogen-associated molecular patterns (PAMPs) in microbes

Pathogens	Pathogen-associated Molecular Patterns (PAMPs)	Tolle-like Receptors
Bacteria		
Gram-negative bacilli	Lipopolysaccharides (LPS), endotoxin	TLR-4
Gram-positive cocci	Peptidoglycan (e.g. triacyl lipoprotein, lipoteichoic acid)	TLR-1, TLR-2, TLR-6
Bacterial flagella	Flagellin	TLR-5
Bacterial profilin	Profilin	TLR-1
Endosome	CpG DNA (immunostimulatory cytosine-guanosine rich DNA sequence ends of DNA)	TLR-2, TLR9
Viruses		
Nucleus	▪ Single-stranded DNA ▪ Double-stranded DNA	▪ TLR-3, TLR-7, TLR-9 ▪ TLR-3
Yeast		
Fungi	Zymosan	TLR-2
Parasite		
Parasite component	Glycosylphosphatidylinositol (GPI) anchored protein	TLR-2

- On the other hand, because mild stimuli that initiate apoptosis (regulated cell death) do not undergo cell rupture and their removal is coordinated by macrophages and surrounding other cells of innate immune system, before release of DAMPs can occur. For this reason, apoptosis is not associated with activation of the immune system. Damage-associated molecular patterns (DAMPs) are shown in Fig. 2.12.

- **Binding of PAMPs and DAMPs to receptors:** PAMPs and DAMPs bind to receptors belonging to the family of pattern recognition receptors (PRRs) and initiate cell signaling leading to enhanced activation of cytokines and reactive oxygen species (ROS). These inflammatory signals can lead to further release of DAMPs, which initiate innate and adaptive inflammatory immune response. Major damage-associated molecular patterns in microbes are given in Table 2.11. Various receptors expressed on leukocytes (macrophages and neutrophils) are discussed below.

Toll-like Receptors on Leukocytes

Toll-like receptors (TLRs) play essential role in the innate immune response against invasion by microorganisms by recognizing pathogen-associated molecular patterns (PAMPs) derived from various microbes.

- Toll-like receptors are expressed on the surface of macrophages, neutrophils, dendritic cells, microglial cells, eosinophils, mast cells, endothelial cells,

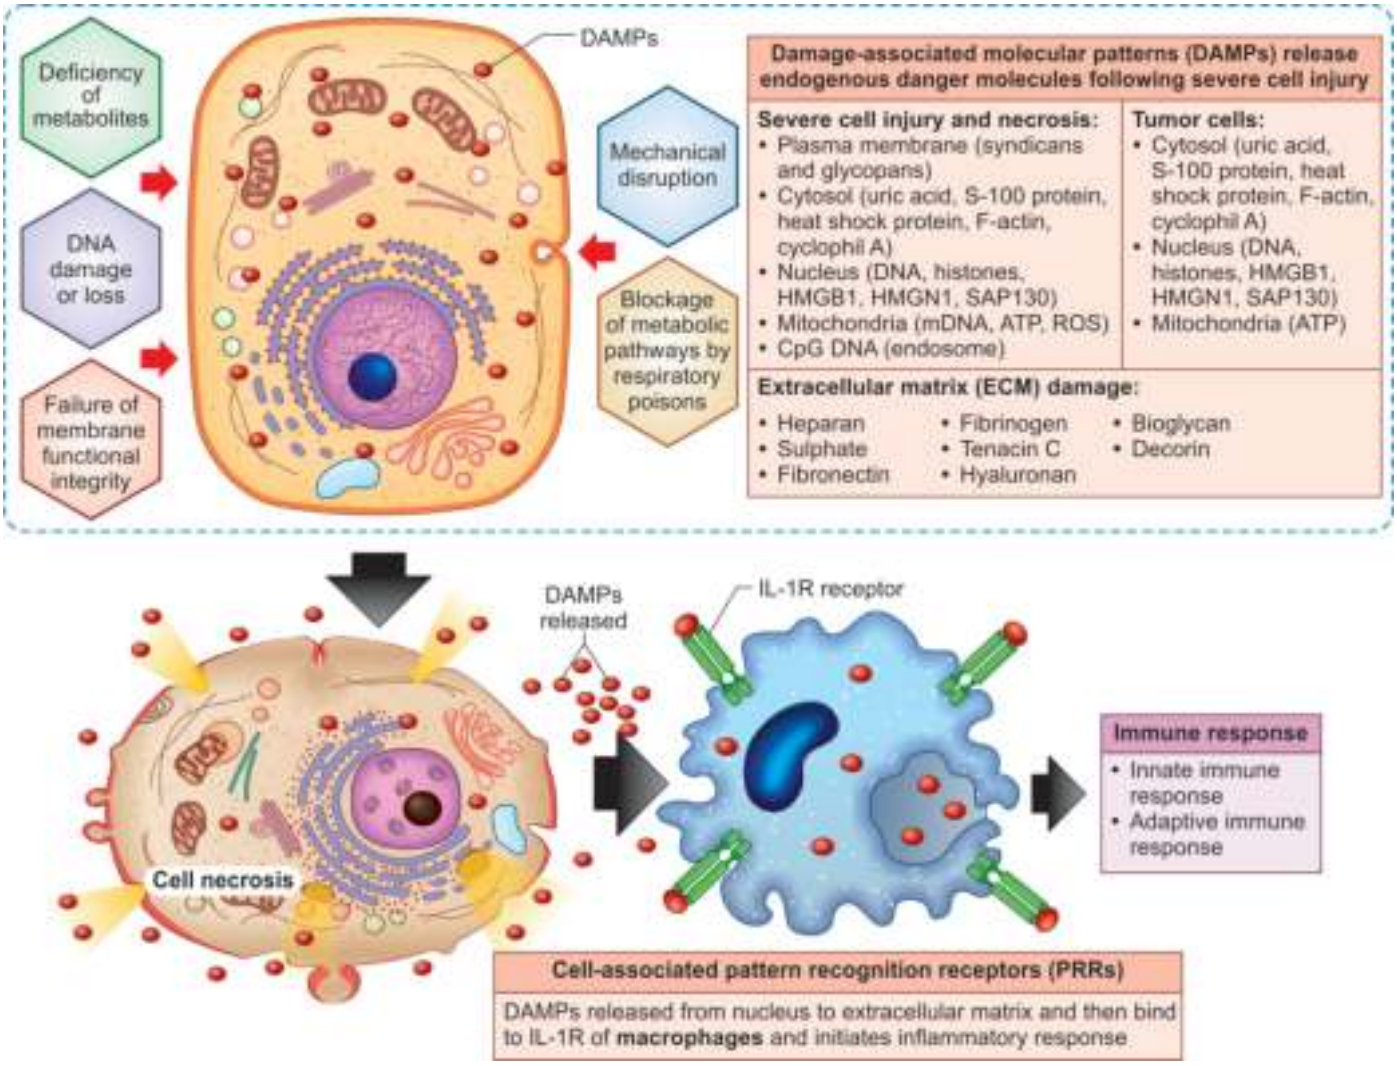

Fig. 2.12: Damage-associated molecular patterns. Necrotic cells release damage-associated molecular patterns (DAMPs), i.e. endogenous danger molecules from damage cells, whereas mild cell injury apoptosis induced cells do not. Stimuli that induce cell necrosis frequently cause severe cellular damage, which leads to rapid cell rupture with consequent release of intracellular DAMPs. DAMPs can then engage cells of the immune system and promote inflammation. On the hand, because stimuli that initiate apoptosis are physiological and relatively mild, apoptotic cells do not rupture and their removal is coordinated by macrophages and other cells of the innate immune system, before release of DAMPs can occur. For this reason, apoptosis is not typically associated with activation of the immune system.

Table 2.11 Major damage-associated molecular patterns (DAMPs) in microbes

Damage-associated Molecular Patterns (DAMPs)	Receptors
Extracellular matrix (ECM) damage	
Heparan sulfate	TLR-4
Fibronectin	TLR-4
Fibrinogen	TLR-4
Tenacin C	TLR-4
Hyaluronan	TLR-2, TLR-4, NLRP-3
Decorin (proteoglycan)	TLR-2, TLR-4
Bioglycan	TLR-2, TLR-4
Plasma membrane damage	
Syndicans	TLR-4
Glycopans	TLR-4
Nucleus damage	
DNA	TLR-9, AIM-2
Histones	TLR-2, TLR-4,
HMGB1	TLR-2, TLR-4, RAGE
HMGN1	TLR-4
SAP130	Mincle
Cytosol damage	
Uric acid	NLRP3, P2X7
S-100 protein	TLR-2, TLR-4, RAGE
Heat shock protein	TLR-2, TLR-4, CD91
ATP	P2X7, P2Y2
F-actin	DAGR-1
Cyclophil A	CD147
Mitochondrial damage	
Mitochondrial DNA	TLR-9
Mitochondrial reactive oxygen species	NLRP-3

mucosal cells and lymphocytes. Each TLR recognizes and binds distinct microbial molecules called pathogen-associated molecular patterns (PAMPs).

- Pathogen-associated molecular patterns present in pathogens include gram-positive cocci (lipoprotein, lipoteichoic acid), gram-negative cell wall lipopolysaccharides (LPS), bacteria with flagella (flagellin) viruses (single-stranded or double-stranded RNA molecules) and fungi (zymosan).
- Toll-like receptor binds and transmits a signal to the nucleus by recruiting intracellular proteins such as MyD88, IRAK-M and TRAF6 to activate the MAP3 kinase/NF-κB signaling pathway and promote the expression of proinflammatory genes leading to production of proinflammatory cytokines.
- Nuclear factor κ-light chain-enhancer of activated B cells (NF-κB) stimulates synthesis of cytokines and increases expression of adhesion molecules. Net result is recruitment and activation of leukocytes. Production of microbiocidal reactive oxygen species (ROS) and lysosomal enzymes kill the microbes. Interferon regulatory factors (IRFs) stimulate antiviral cytokines. TLRs increase baseline inflammatory activity and promote atherosclerosis.
- Toll-like receptors and their actions are shown in Fig. 2.13. Four family of pattern recognition receptors (PRRs), their location and actions are given in Table 2.12.

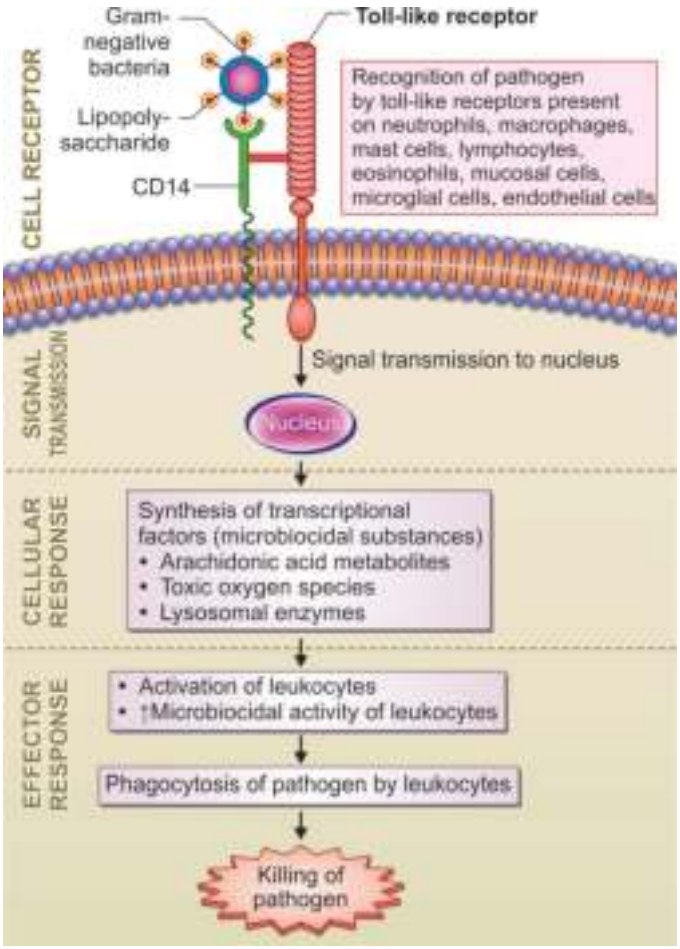

Fig. 2.13: Toll-like receptors and their actions. Toll-like receptors (TLRs) constitute the first line of defense system against microbes. These can recognize both invading pathogen-associated molecular patterns (PAMPs) and endogenous danger molecules released from the damaged cells/tissues (damage-associated molecular patterns—DAMPs). Toll-like receptors play key role in linking innate and adaptive immune response.

Table 2.12 Four family of pattern recognition receptors (PRRs), their location and actions

Toll-like Receptors
TLR1 (macrophages and neutrophils): Lipid and carbohydrates from gram-positive bacteria
TLR2 (macrophages, neutrophils and basophils): Gram-positive bacteria and fungi
TLR3 (macrophages): Nucleic acid derivatives (viral DNA)
TLR4 (macrophages, neutrophils and basophils): Lipopolysaccharides from gram-negative bacteria
TLR5 (macrophages, neutrophils and basophils): Bacterial flagellin
TLR6 (macrophages and neutrophils): Lipid and carbohydrates from gram-positive bacteria
TLR7 (macrophages and neutrophils): Nucleic acid derivatives (viral DNA)
TLR8 (macrophages and neutrophils): Nucleic acid derivatives (viral DNA)
TLR9 (macrophages and neutrophils): Nucleic acid derivatives (viral DNA) and bacterial DNA containing unmethylated CpG motifs
TLR10 (macrophages and neutrophils): Ligand unknown
TLR11 (macrophages and neutrophils): Bacterial profilin
C-type Lectin Receptors
C-type lectin receptors are expressed on the plasma membrane of macrophages and dendritic cells. These receptors detect fungi and elicit inflammatory response
NOD-like Receptors (NLRs) Located in Cytoplasm
NLRs are present in cytoplasm of cell. These recognize microbial products and products of necrotic cells (uric acid)
NLRs signal via cytosolic inflammasome protein, which activates caspase 1. This enzyme cleaves precursor IL-1 to form biologically active form
NLRs inflammatory pathway may participate in pathogenesis of atherosclerosis, gout and obesity associated type 2 diabetes mellitus
RIG-like Receptors (RLRs) for Viral Nucleic Acid
RLRs are located in the cytoplasm of the cell
RLRs detect nucleic acids of viruses that are replicating in the cytoplasm of infected cells
RLRs stimulate the synthesis of antiviral cytokines

Seven α-Helical Transmembrane G Protein-coupled Receptors

Certain bacterial N-formylmethionyl peptides, lipid mediators, chemokines, C5a, platelet-activating factor, prostaglandin E and leukotrienes bind to seven α-helical transmembrane G protein coupled receptors on leukocytes. Cellular changes in leukocytes lead to cytoskeleton changes by signal transduction, increased expression of integrin adhesion molecules resulting in adhesion of leukocytes to endothelium, transmigration and chemotaxis of leukocytes to site of tissue injury by activation of the respiratory burst. Seven α-helical transmembrane G protein-coupled receptors and their actions are shown in Fig. 2.14.

Phagocytic Receptors

Microbes bind to phagocytic receptors leading to killing of bacteria by production of microbiocidal reactive oxygen species, release of lysosomal enzymes, leukocytic activation and killing the microbes. Phagocytic receptors on phagocytes and their actions are shown in Fig. 2.15.

Opsonin Receptors on Leukocytes

Macrophages express opsonin receptors (FcR1, CR1 and C1q), scavenger receptors, macrophage integrin receptors MAC1 (CD11 and CD18). FcR1, CR1, C1q receptors recognize microbes coated by IgG, C3 (classical and alternate pathways) and plasma proteins derived mannose binding lectin (MBL). Scavenger receptors bind microbes and modified low-density lipoprotein (LDL). Opsonin receptors on leukocytes and their actions are shown in Fig. 2.16.

Cytokine Receptors

Cytokine IFN-γ synthesized by NK cells and CD8+ cytotoxic T cells bind to cytokine receptor superfamily on leukocytes. It leads to activation of leukocytes resulting

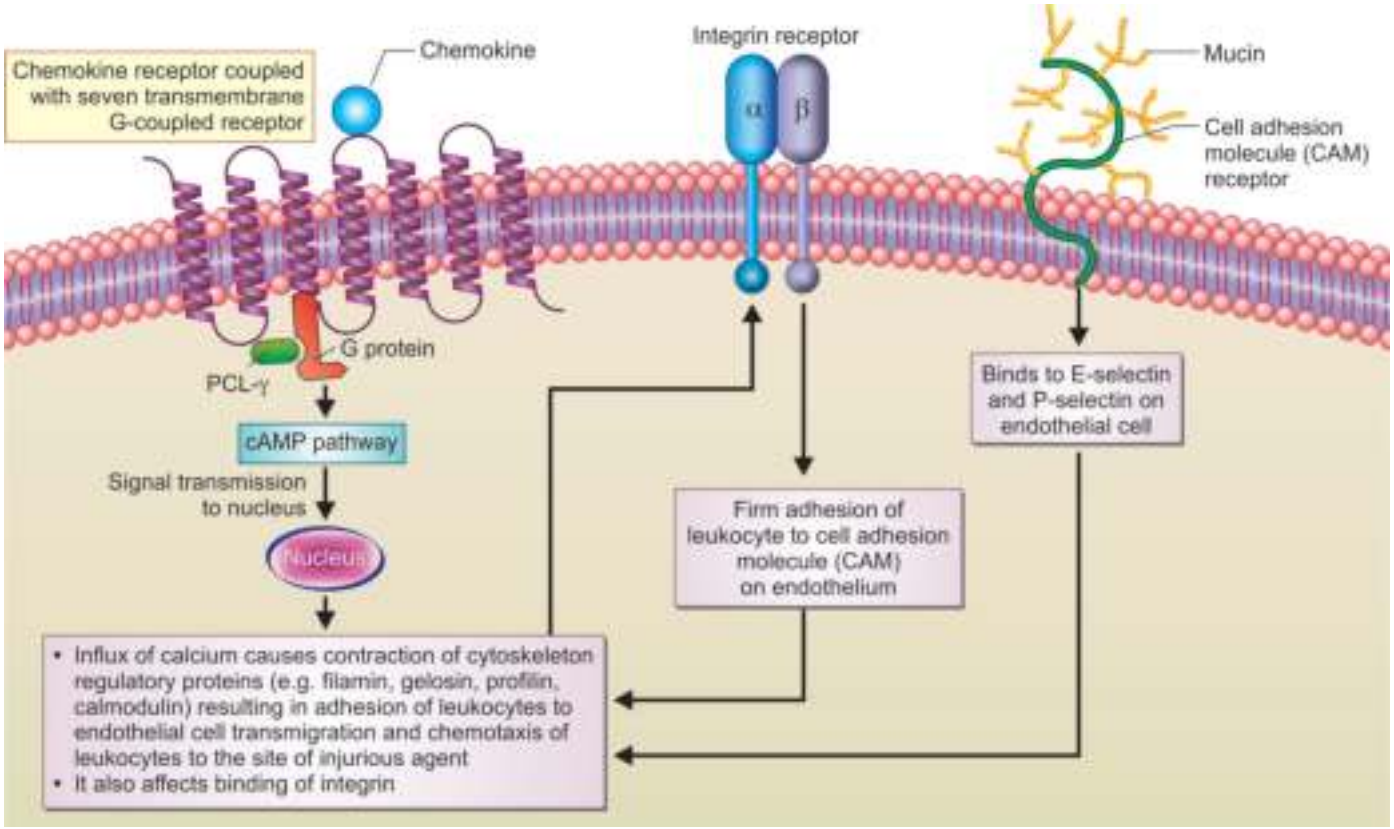

Fig. 2.14: Seven α-helical transmembrane G protein-coupled receptors and their actions. These form the largest superfamily of cell-surface receptors. They respond to wide range of stimulants including light energy, peptides, lipids, sugars and proteins. Increased cytosolic calcium stimulates integrin receptors, which induces firm adhesion of leukocytes to vascular endothelium leading cross-linkage with effector molecules of seven α-helical transmembrane G protein-coupled receptors.

in production of reactive oxygen species, release of lysosomal enzymes and ultimately killing of microbes.

- Signaling by cytokine receptors depends upon their association with the Janus kinases (JAKs), which couple ligand binding to tyrosine phosphorylation of signaling proteins recruited to cytokine receptor complex.
- Among these signaling proteins are unique family of transcription factors such as signal transducers and activators of transcription (STAT). The receptors and their corresponding cytokines have been divided into several families based on their structure and activities. Cytokine receptors on phagocytes and their actions are shown in Fig. 2.17.

PHAGOCYTOSIS AND CLEARANCE OF THE INJURIOUS AGENTS

The process of engulfment of solid particulate material by phagocytic cells (neutrophils and macrophages) is known as phagocytosis. Phagocytes eliminate microbes and cellular debris by process of phagocytosis.

- Activated phagocytes recognize, internalize, release proteolytic enzymes (i.e. lysozyme, protease, collagenase, elastase, lipase, proteinase, gelatinase and hydrolases) and degrade the injurious agent and dead cells by releasing reactive active species (ROS), nitrogen and oxygen species (NO) and lysosomal enzymes in phagolysosomes.
- Phagocytosis involves distinct steps, i.e. recognition, opsonization, binding, engulfment, phagolysosome formation, intracellular killing and degradation of microorganisms by lysosomal enzymes, and reactive oxygen species (ROS). Sequential steps in phagocytosis are shown in Fig. 2.18. Phagocytosis in tissue is shown in Fig. 2.19.
- Enzymes or molecules involved in O_2-dependent phagocytosis are nicotinamide adenosine dinucleotide phosphate (NADPH) oxidase, H_2O_2 activity, superoxide radical and NADPH oxygenase.
- Enzymes or molecules involved in O_2-independent phagocytosis include bactericidal permeability increasing (BPI) protein, lactoferrin, lysozyme, major basic proteins and defensins. A young infant deficient in NADPH enzyme is susceptible to bacterial infections due to impaired phagocytosis.
  - **Opsonization of injurious agent:** Phagocytosis is initiated by the expression of surface receptors

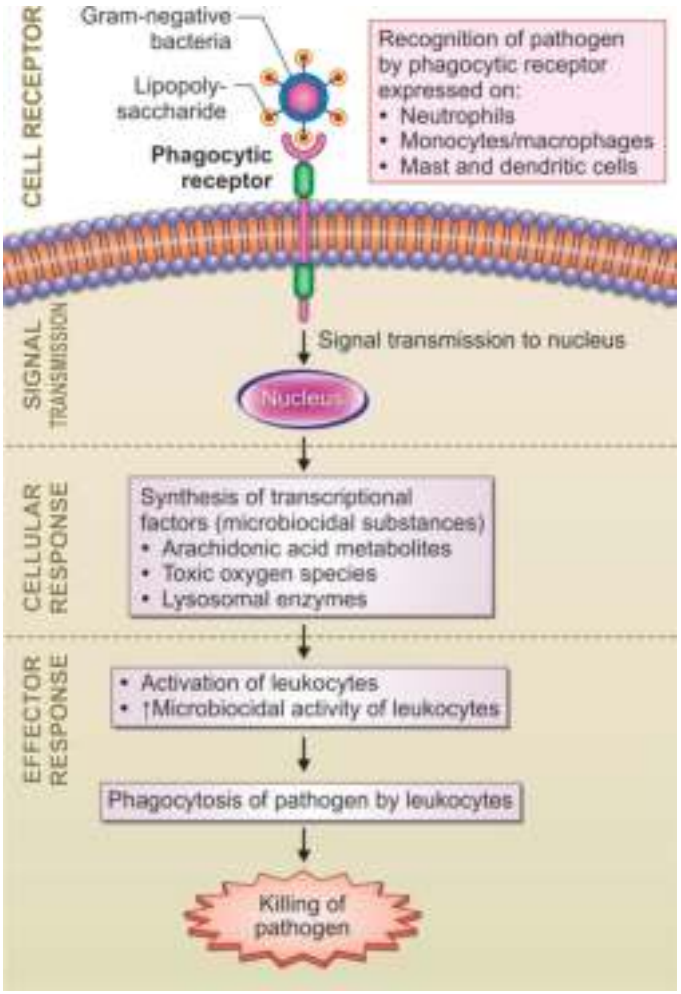

Fig. 2.15: Phagocytic receptors on phagocytes and their actions. Phagocytic receptors are expressed on professional phagocytes such as neutrophils, monocytes/macrophages, and dendritic cells. These professional phagocytes activate signaling pathways resulting in phagocytosis and elimination of pathogens.

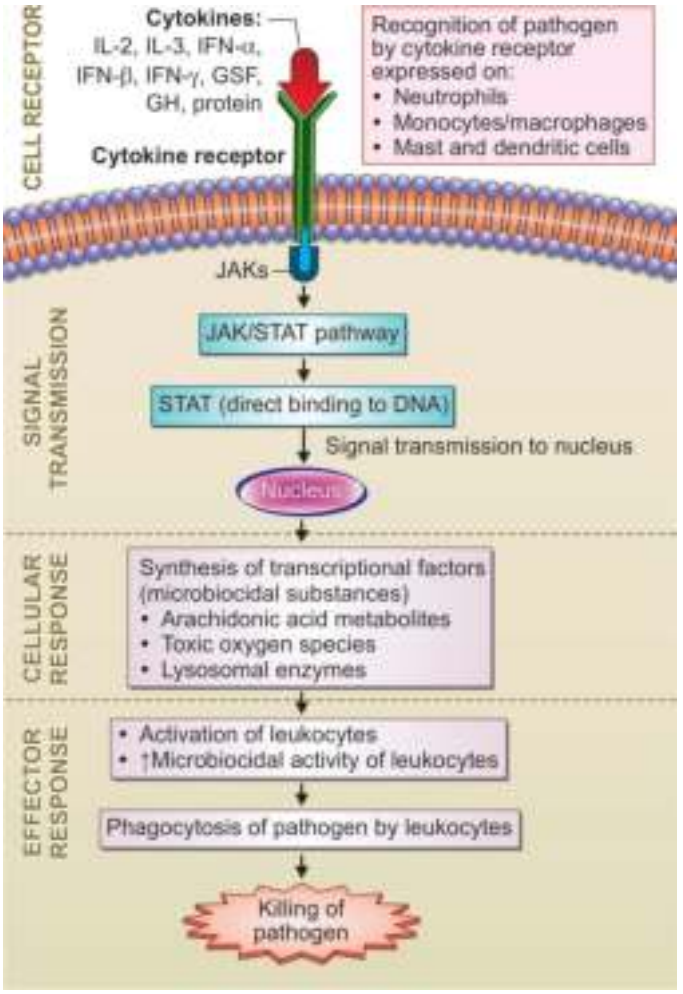

Fig. 2.17: Cytokine receptors on phagocytes and their actions. Professional phagocytes (i.e. neutrophils, monocytes/macrophages and dendritic cells) play a key role innate immunity. The signaling induced by stimuli such as bacterial products, cytokines and inflammatory mediators leads to stimulation of molecules involved in phagocytosis.

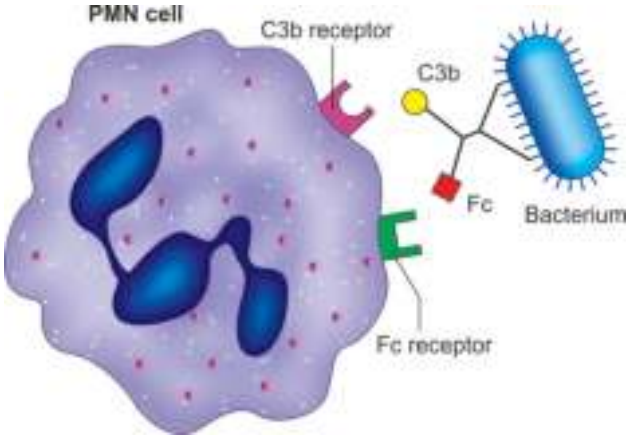

Fig. 2.16: Opsonin receptors on leukocytes and their actions. Function of opsonins is to react with bacteria and make them susceptible to ingestion by phagocytes. Phagocytes express receptors for Fc end of IgG molecule and for the C3a fragment of complement, which recognize and ingest IgG or C3b coated bacteria. Facilitation of phagocytosis is called opsonization. IgG and C3b are called opsonins.

on neutrophils and macrophages. Phagocytosis is further enhanced when the microorganisms are coated with specific proteins, opsonins. Opsonization is a process by which injurious stimulus coated by opsonins, i.e. IgG, C3b and complement mannose-binding lectin (MBL). Opsonization enhances binding of injurious agent to membrane receptors (e.g. FcR1, CR1 and MBL) expressed on activated neutrophils. Defects in opsonization results in 'Bruton's agamma-globulinemia'.

- **Binding opsonized injurious agent to cellular receptors of phagocytes:** Microbes are coated (opsonized) by immunoglobulin (IgG), complement (C3b) and mannose-binding lectin. Opsonized microbes bind to cell-surface receptors of leukocytes. Fc portion of the IgG binds to FcR1 and C3b to FcR1 of leukocytes. Bacterial polysaccharide binds

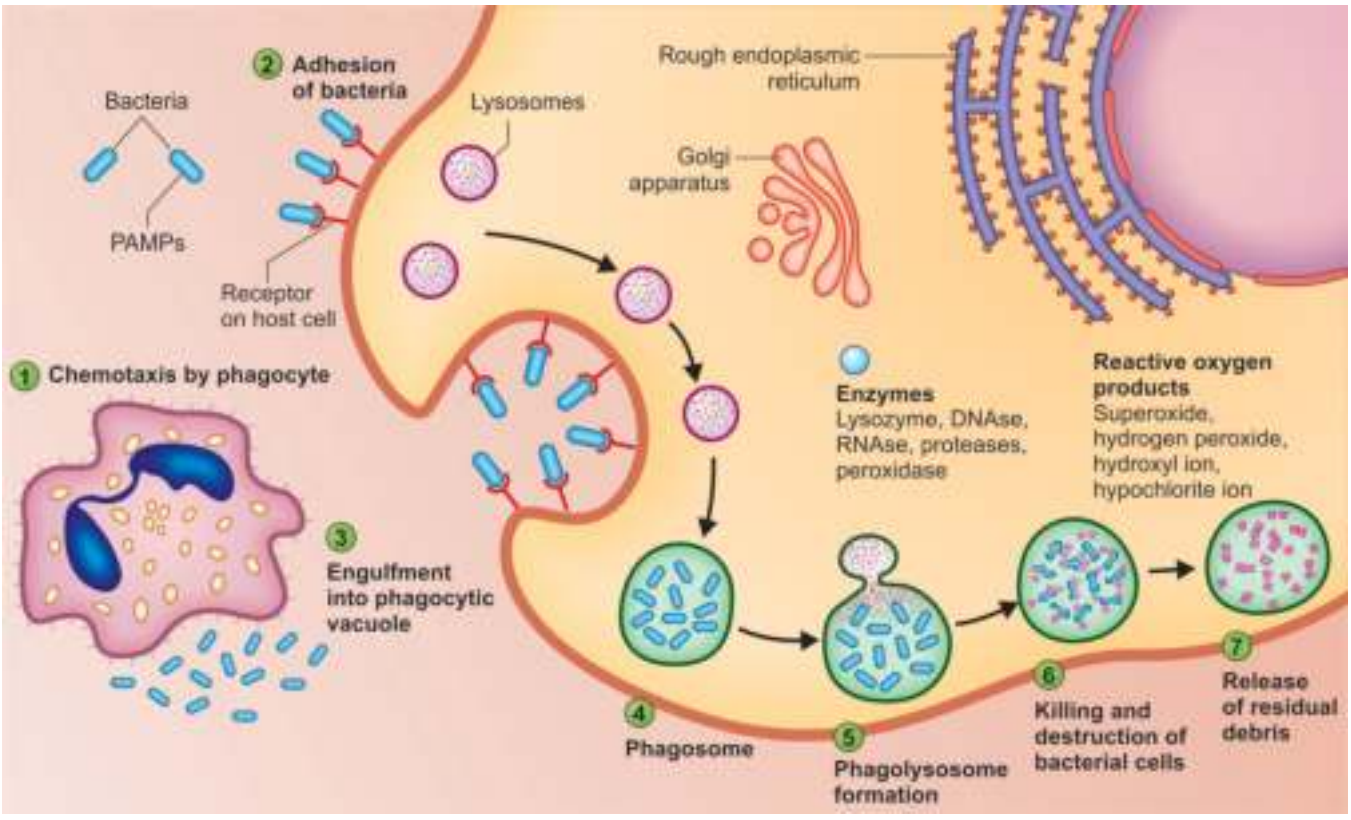

Fig. 2.18: Sequential steps in phagocytosis. The process of phagocytosis involves recognition of injurious agent, adhesion, engulfment, formation of phagosome, maturation of phagosome to transform into a phagolysosome, killing of pathogens by lysosomal enzyme, and reactive oxygen species.

to mannose-binding lectin (MBL) receptors on leukocytes.

- **Engulfment of injurious agent:** Neutrophils push out pseudopodia to surround the injurious agent completely, forming an endocytic phagocytic vacuole (phagosome), driven by polymerization (assembly and disassembly) of actin filaments. Special proteins probably allow final sealing of the leukocytic membrane.
- **Phagolysosome formation:** Phagocytic vesicle fuses with neutrophilic membrane of lysosome to form phagolysosome. In 'Chédiak-Higashi syndrome' a defect in microtubule function prevents phagolysosome formation. Impaired membrane fusion of lysosomes with melanosomes in melanocytes causes 'albinism'.
- **Release of lysosomal hydrolytic enzymes into phagolysosome:** Neutrophils release lysosomal hydrolytic enzymes into the phagolysosome and degrade the pathogens. Products of azurophil and specific granules of neutrophils participate in vascular permeability, chemotaxis and tissue damage in acute inflammation.
- **Degradation of injurious agent:** Degradation of microorganism occurs by intracellular and extracellular organisms. Intracellular mechanism to degrade microorganisms includes oxidative bactericidal mechanism by oxygen-derived free radicals (myeloperoxidase dependent and myeloperoxidase independent), oxidative bactericidal mechanism by lysosomal granules, and nonoxidative bactericidal mechanisms. Extracellular mechanism to degrade microorganisms is mediated by lysosomal granules and immune mechanism.

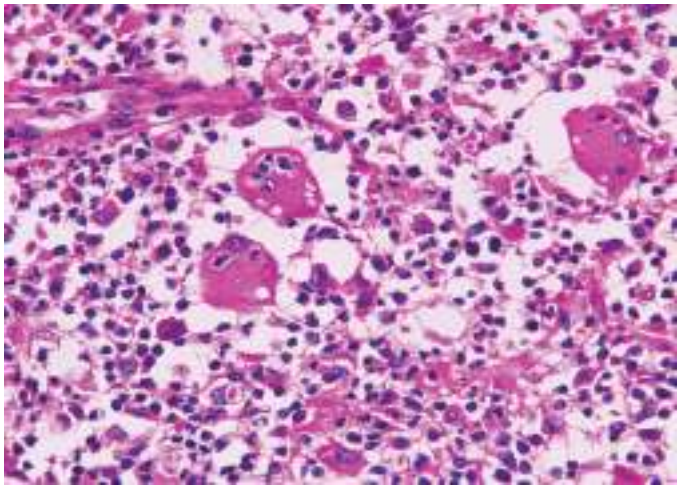

Fig. 2.19: Phagocytosis in tissue. Phagocytosis is a cellular process for ingesting and eliminating particles larger than 0.5 μm in diameter, including microorganisms, foreign substances and apoptotic cells. Phagocytes are showing ingested injurious agent (arrows) (400X).

Pathology Pearls: Defects in Opsonization, Phagocytosis and Phagolysosome Formation, Defective Degranulation and Clinical Correlation

Phagocytosis is impaired due to defects in opsonization and phagolysosome formation, in the settings of leukemias, diabetes mellitus, malnutrition and neonates.

Defects in Opsonization

- Opsonization is a process by which injurious stimulus coated by opsonins, i.e. IgG, C3b and complement mannose-binding lectin (MBL). Opsonization enhances binding of injurious agent to membrane receptors (e.g. FcR1, CR1 and MBL) expressed on activated neutrophils.
- Defects in opsonization results in 'Bruton's agammaglobulinemia', an X-linked inherited agammaglobulinemia is characterized by the absence of mature B cells which in turn leads to severe immunoglobulin deficiency and recurrent infections.

Defective Phagolysosome Formation and Defective Degranulation of Neutrophils

- Chédiak-Higashi syndrome occurs due to mutation in LYST gene located on chromosome 1q42 that encodes a protein essential for assembly of microtubules in the cytoplasm that results in defective fusion of phagosome with lysosome (phagolysosome) and defective degranulation in neutrophils.
- Chédiak-Higashi syndrome is characterized by defective degranulation of neutrophils, impaired microbial killing, and recurrent bacterial infections (*Staphylococcus aureus*) forming soft tissue abscess. Impaired membrane fusion of lysosomes with melanosomes in melanocytes causes 'albinism'.
- Neutrophils contain giant granules due to aberrant organelles. Chédiak-Higashi syndrome also affects platelets (bleeding), melanocytes (albinism), Schwann cells (neuropathy), natural killer cells, and cytotoxic T cells (aggressive lymphoproliferative disorder).

INTRACELLULAR MICROBIAL KILLING

Neutrophils participate in phagocytosis and destruction of microorganisms. When coated with opsonins (e.g. complement and/or immunoglobulin), microorganisms bind to the specific receptors on the surface of the neutrophil and invagination of the cell membrane occurs with the incorporation of the microorganisms into an intracellular phagosome.

- There follows a burst of oxygen consumption and extra oxygen consumed is converted to highly reactive oxygen species (ROS). In addition, cytoplasmic lysosomal enzymes discharge their contents into the phagosome leading to degradation of the ingested microorganisms.
- Bactericidal activity is carried out either via myeloperoxidase (MPO)-dependent enzyme (most effective) or myeloperoxidase (MPO)-independent (less effective) mechanisms.
- Myeloperoxidase is a heme peroxidase expressed mainly in neutrophils and to a lesser degree in monocytes/macrophages.
- In the presence of hydrogen peroxide and halides, myeloperoxidase catalyzes the formation of reactive oxygen species intermediates, including hypochlorous acid (HOCl).
- Oxygen-independent intracellular killing uses preformed cytoplasmic granules containing antimicrobial agents. Superoxide is subsequently converted into hydrogen peroxide (H_2O_2). Antibacterial compounds in the phagolysosome are given in Table 2.13.
  - **Myeloperoxidase dependent bactericidal mechanism:** Activated neutrophils use enzyme myeloperoxidase to generate an array of potent toxic oxidants in the phagosome. During degranulation, hydrogen peroxide is formed by the respiratory burst and a halide particularly chloride. The initial product of MPO-H_2O_2-chloride system in HOCl

Table 2.13 Antibacterial compounds in the phagolysosome

Compounds	Functions
Oxygen-dependent antibacterial compounds	
Superoxide, hydroxyl molecule hypochlorous acid ($HOCl^-$)	▪ Kill intracellular microbes in neutrophils and (not by macrophages) ▪ Deficiency results in recurrent infections
Oxygen-independent antibacterial compounds	
Lactoferrin	Lactoferrin binds iron in neutrophils leading to inhibition of bacterial reproduction
Defensins	Cytotoxic to microbes
Bactericidal permeability increasing protein	Bactericidal permeability increasing protein activates phospholipase, which degrades phospholipids of bacterial cell wall resulting in killing of microbes
Lysosomal enzyme	Lysosomal enzyme hydrolyzes the muramic acid-N-acetylglucosamine bond of bacterial glycopeptides resulting killing of microbes
Major basic proteins	Major basic proteins, cationic protein in eosinophilic granules cytotoxic to helminths

and subsequent formation of chlorine, chloramines, hydroxyl radicals, singlet oxygen and ozone has been proposed.

- **Myeloperoxidase independent bactericidal mechanism:** Mature macrophages lack myeloperoxidase enzyme. Bactericidal activity of mature macrophages is mediated by producing hydroxyl ions and superoxide singlet oxygen. Fenton and Haber and Weiss reactions are a source of oxidative stress. The generation of oxygen-derived free radicals occurs first with the reduction of ferric to ferrous ion and then by Fenton reaction with ferrous iron catalyzing the breakdown of hydrogen peroxide to hydroxyl radicals. Haber-Weiss reaction generates hydroxyl radicals from hydrogen peroxide (H_2O_2) and superoxide catalyzed by iron ions.

Oxygen-dependent Microbial Killing by Generation of Oxygen-derived Free Radicals

Phagocytic cells such as neutrophils, eosinophils monocytes and macrophages phagocytose and kill internalized pathogens by respiratory or oxidative burst. During respiratory burst, phagocytes require energy and oxygen for the generation of a variety of cytotoxic reactive oxygen species. Generation of reactive oxygen species (ROS) in polymorphonuclear cell is shown in Fig. 2.20.

- The phagocytes contain NADPH dependent oxidase enzyme, which transfers one electron to an oxygen molecule to generate oxygen-derived free radicals such as superoxide anion, highly reactive hydroxyl molecule and hypochlorous acid (bleach). Superoxide dismutase reduces the superoxide radical to H_2O_2.
- The superoxide anion dismutases spontaneously in the presence of superoxide dismutase to hydrogen peroxide that serves as the parent product for a variety of other highly reactive metabolites such as hydroxyl radical and hypochlorous acid; which enter phagosome and together with enzymes participate in the killing of phagocytosed pathogens.

Superoxide Anion Free Radical

In resting neutrophils, NADPH oxidase (nicotinamide adenine dinucleotide phosphate oxidase) is present in the plasma membrane as well as cytoplasm. In acute inflammation, NADPH oxidase in the phagolysosome membrane reduces oxygen by the addition of electrons to form superoxide anion.

- **Chronic granulomatous disease of childhood:** Defect in NADPH oxidase activity in neutrophils causes X-linked chronic granulomatous disease of childhood. Disease is characterized by phagocytic cells that ingest but unable to kill certain microorganisms.

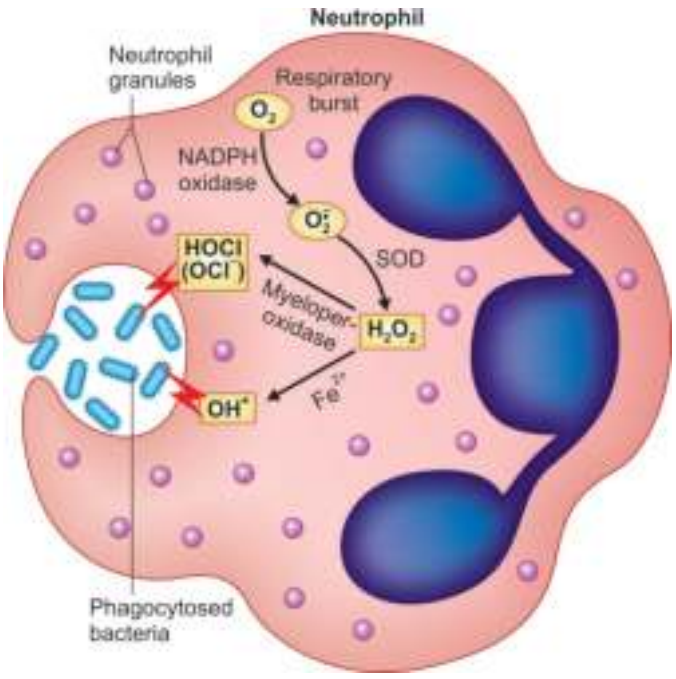

Fig. 2.20: Generation of reactive oxygen species (ROS) in polymorphonuclear cell. Reactive oxygen species are generated in polymorphonuclear cell as a result of engulfment of bacteria during mitochondrial electron transport system. The sequential reduction of oxygen through the addition of electrons leads to formation of a number of ROS including superoxide, hydrogen peroxide, hydroxyl radical ion, and nitric oxide.

- **Nitroblue tetrazolium slide test to detect defect in NADPH oxidase:** Nitroblue tetrazolium (NBT) slide test is used for screening defects in NADPH oxidase. The number of neutrophils with dark cytoplasmic granules of reaction product is counted. Normally, >95% of the granulocytes containing NADPH oxidase are positive for nitroblue tetrazolium. In the abnormal NBT slide test in chronic granulomatous disease, less than 5% of neutrophils are stained.

Highly Reactive Hydroxyl Free Radical

During phagocytosis, superoxide dismutase converts superoxide radical to hydrogen peroxide (H_2O_2). This reaction is neutralized by glutathione peroxidase. Hydrogen peroxide dissociates to generate highly reactive hydroxyl molecule.

Hypochlorous ($HOCl^-$) Free Radical

Myeloperoxidase (MPO) enzyme in phagocytic vacuole combines with H_2O_2 and chloride ions (Cl^-) to form hypochlorous free radicals (HOCl), which kills bacteria by halogenation, in which halide is bound covalently to cellular constituents or by oxidation of proteins and lipids (lipid peroxidation). Patients deficient in myeloperoxidase cannot produce hypochlorous acid, which leads to increased susceptibility to Candida infections. It is rarely associated with recurrent bacterial infections.

Oxygen-independent Microbial Killing

Oxygen-independent microbial killing is much less effective than oxygen-dependent microbial killing.

- **Lactoferrin:** Normally, bacteria require iron for bacterial reproduction. Binding of lactoferrin present in neutrophilic granules to iron leads to inhibition of bacterial reproduction.
- **Defensins:** Defensins are cationic arginine rich granule peptides in neutrophils, which are cytotoxic to microbes.
- **Bactericidal permeability increasing protein:** Bactericidal permeability increasing protein activates phospholipase, which degrades phospholipids of bacterial cell wall leading to killing of microbes.
- **Lysosomal enzyme:** Lysosomal enzyme present in azurophilic granules hydrolyzes the muramic acid-N-acetylglucosamine bond of bacterial glycopeptides leading to killing of microbes.
- **Major basic proteins:** Major basic proteins, cationic proteins in eosinophilic granules are cytotoxic to helminths.

LEUKOCYTE-INDUCED INJURY

Inflammation plays important role to eliminate the initial cause of cell injury as well as the necrotic cells and tissues, but it is itself capable of causing tissue damage by liberation of products by neutrophils and macrophages. During phagocytosis, leukocytes release microbiocidal and other products (e.g. lysosomal enzymes, reactive oxygen species, arachidonic acid products, prostaglandins and leukotrienes) within phagolysosomes, but also into extracellular space causing tissue damage and may amplify the effects of injurious stimulus.

Mechanism of Tissue Damage by Leukocytes

Leukocyte adhesion and emigration are involved in host defense and phagocytosis and thus serve a beneficial role during the mounting of a well-contained inflammatory response. However, in certain situations, leukocytes turn against the host and contribute in tissue damage and organ dysfunction. Leukocyte-induced injury linked inflammatory disorders are given in Table 2.14.

- **Digestion of basement membranes:** During transmigration, leukocytes release elastase and metalloproteinases, which digest the basement membrane.
- **Regurgitation before complete closure of the phagolysosome:** Regurgitation may occur if the phagocytic vacuole remains transiently open to outside before complete closure of the phagolysosomes.
- **Frustrated (regurgitated) phagocytosis:** Deposition of immune complex on the flat surface of glomerular basement membrane activates complement system and recruitment of leukocytes. Leukocytes fail to engulf these immune complexes and release lysosomal hydrolytic enzymes and O_2-derived free radicals leading to glomerular basement membrane injury, increased permeability and proteinuria. After phagocytosis, potentially cytotoxic substances such as urate crystals are released, which damage the membrane of phagolysosomes. Leukocyte-induced injury mechanism is known as 'frustrated (regurgitated) phagocytosis'. In addition, there is some evidence that substances in secondary granules of neutrophils may be directly secreted by exocytosis. After phagocytosis, neutrophils rapidly undergo apoptotic cell death and are digested by macrophages.
- **Chemical mediators induced tissue damage:** Inflammatory chemical mediators produced by phagocytes, such as prostaglandins and leukotrienes play key role

Table 2.14 Leukocyte-induced injury linked inflammatory disorders

Inflammatory Disorders	Cells and Molecules Involved in Injury
Acute inflammatory disorders	
Acute respiratory distress syndrome	Neutrophils
Bronchial asthma	Eosinophils, IgE antibodies
Acute transplant rejection	Lymphocytes, antibodies and complement
Vasculitis	Antibodies, complement, neutrophils
Glomerulonephritis	Antibodies, complement, neutrophils, monocytes
Septic shock	Cytokines
Chronic inflammatory disorders	
Chronic transplant rejection	Lymphocytes, cytokines
Arthritis	Lymphocytes, macrophages and antibodies
Atherosclerosis	Macrophage, lymphocyte?
Pulmonary fibrosis	Macrophages, fibroblasts

in tissue damage. Prolonged severe injury causes necrosis of tissue. Leukocyte-induced injury may cause acute injury (e.g. glomerulonephritis, acute transplant rejection, bronchial asthma, acute adult respiratory syndrome, septic shock, vasculitis) and chronic injury (e.g. chronic graft rejection, atherosclerosis, arthritis and chronic lung disease).

TERMINATION OF ACUTE INFLAMMATORY RESPONSE

Acute inflammatory response is triggered by changes in intracellular chemical mediators that activate stress-sensitive kinases and transcription factors, which regulate the synthesis of proinflammatory and anti-inflammatory cytokines.

- **Gene silencing and reprogramming:** Acute inflammation is associated with gene silencing and reprogramming that induces various effects: (a) downregulation of proinflammatory cytokines (cytokines (IL-1β, IL-8, TNF-α and IFN-γ), (b) upregulation of anti-inflammatory cytokines such as IL-1 receptor antagonist (IL-IRA), TNF-α receptors, IL-6 IL-10, IL-11, IL-12 and LI-13, and (c) resolution of inflammation.
- **Role of interleukins:** Several interleukins such as IL-6 IL-10, IL-11, IL-12 and LI-13 limit acute inflammation by reducing production of TNF-α. This process may occur by preservation of nuclear factor κB (NF-κB), thus blocking cell activation and release of proinflammatory cytokines.
- **Apoptosis of neutrophils:** Neutrophils have a short half-life in tissues, which undergo apoptosis within a few hours after leaving the blood circulation. Anti-inflammatory lipoxins transmit signal to macrophages, which phagocytose apoptotic bodies of neutrophils by programmed death.
- **Downregulation of leukotrienes and upregulation of lipoxins:** Leukotrienes and lipoxins are synthesized by cell–cell interactions (neutrophils-platelets). After an inflammatory response, neutrophils 'switch off' chemical mediators of inflammation such as proinflammatory leukotrienes (LTC_4, LTD_4 and LTE_4), and '**switch on**' actions of anti-inflammatory lipoxins (LXA_4, LXB_4).
  - **Leukotrienes actions:** There is downregulation of proinflammatory leukotrienes (LTC_4, LTD_4 and LTE_4) synthesized by leukocytes and mast cells. Leukotrienes cause vasodilation and increased vascular permeability. These also activate PMNs leukocytes leading to adhesion on venular endothelium, chemotaxis, and generation of oxygen-derived free radicals and release of lysosomal enzymes.
  - **Lipoxins actions:** Lipoxins (LXA_4, LXB_4) are potent anti-inflammatory cytokines that terminate acute inflammation in the first few hours of injurious stimulus by inhibiting adhesion of leukocytes to endothelium as well as chemotaxis. Lipoxins also cause vasodilatation. Lipoxins transmit signal to macrophages, which phagocytose apoptotic bodies of neutrophils by programmed cell death (apoptosis).
- **Glucocorticoids:** Glucocorticoids inhibit many inflammation-associated molecules such as cytokines, chemokines, arachidonic acid metabolites and adhesion molecules. Glucocorticoids suppress vasodilation and inhibit vascular permeability; and decrease emigration of leukocytes into inflammation sites.
- **Kininases:** Kininases in blood circulation degrade the potent proinflammatory mediator bradykinin.
- **Phosphatase:** A phosphatase is an enzyme that removes a phosphate group from a protein and thus acts to modulate the activities of the proteins in a cell, often in response to external stimuli. Protein phosphatase activation attenuates acute inflammation.
- **Transforming growth factor-β (TGF-β):** Apoptotic neutrophils induce TGF-β expression, that suppresses proinflammatory leukotrienes (LTC_4, LTD_4, and LTE_4) and chemokines. TGF-β upregulates synthesis of anti-inflammatory lipoxins (LXA_4, LXB_4) leading to clearance of apoptotic neutrophil debris by macrophages.

CHEMICAL MEDIATORS OF INFLAMMATION

Chemical mediators of inflammation mediate specific response by acting on the blood vessels, inflammatory cells or other cells in tissues. These regulate inflammation and immunity. These are synthesized either at injury site (local synthesis by cells) or plasma derived (distant synthesis).

- **Synthesis of chemical mediators:** Chemical mediators are derived from various sources: (a) plasma (complement system, kinins, and clotting factors), (b) cells (neutrophils, tissue macrophages, endothelial cells of blood vessels, mast cells and platelets), (c) bacterial products, and (d) fibroblasts of damaged tissues in response to tissue injurious stimulus.
- **Properties of chemical mediators:** Chemical mediators have short life span (e.g. seconds to minutes), which possess enzymatic or toxic activity. These have potential to cause harmful effects.
- **Mechanism of actions of chemical mediators:** Chemical mediators bind to specific receptors on single or multiple target cells, and stimulate them to release secondary molecules, which may have direct enzymatic effects and/or systemic toxic effects.

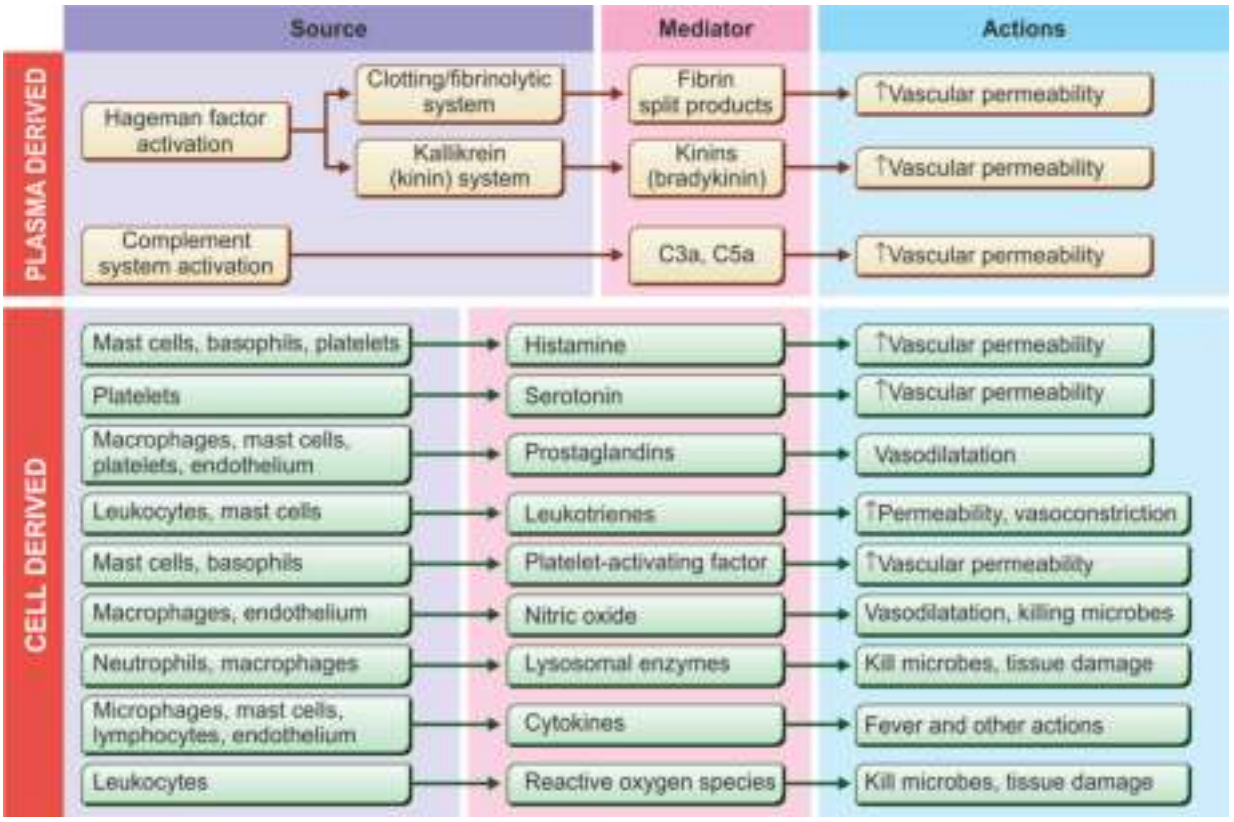

Fig. 2.21: Plasma- and cell-derived chemical mediators and their functions. In response to the inflammatory process, plasma- and cell-derived chemical mediators mediate the inflammatory process by preventing further tissue damage and ultimately resulting in healing and restoration of tissue function.

- **Plasma- and cell-derived chemical mediators—categories:** Chemical mediators are derived from plasma proteins or inflammatory cells. Plasma- and cell-derived chemical mediators and their functions are shown in Fig. 2.21.
  - **Plasma-derived chemical mediators:** These include kinin system, fibrinolytic system, coagulation system, and complement system. These are synthesized by liver.
  - **Cells-derived chemical mediators:** These are synthesized by monocytes, macrophages, lymphocytes, fibroblasts, mast cells, platelets, and endothelial cells of blood vessels. Chemical mediators may be preformed or newly synthesized.
- **Functional categories of chemical mediators:** Chemical mediators produce vascular and cellular changes in inflammation. Based on functions, chemical mediators are classified into following categories: vasoactive, chemotactic and combined chemotactic as well as vasoactive chemical mediators.

Pathology Pearls: Functional Categories of Chemical Mediators

Chemical mediators are categorized according to their actions described as under. Functional categories of chemical mediators and their inflammatory responses are shown in Fig. 2.22 and Table 2.15.

Chemical Mediators with Vasoactive Actions

- **Vasodilation of arterioles and capillaries:** Chemical mediators such as histamine, serotonin, nitric oxide, bradykinin, platelet-activating factor cause vasodilation of microvasculature and sustained by prostaglandins (PGI_2, PGD_2, PGE_2, $PGF_{2\alpha}$) resulting to increased blood flow to injury site. It is responsible for redness (rubor) and increased local temperature (heat—calor).
- **Increased permeability of venules:** Chemical mediators such as histamine, serotonin, bradykinin, anaphylatoxins (C3a, C5a), prostaglandins (PGD_2, PGE_2, $PGF_{2\alpha}$), leukotrienes (LTC_4, LTD_4, LTE_4), platelet-activating factor (PAF) and neuropeptide (substance P) increase the permeability of venules results to inflammatory exudates.

Chemical Mediators with Chemotactic Actions

Chemotactic agents include such as C5a, chemokines, leukotrienes (LTB_4, LTC_4), collagen, fibrin and bacterial peptides (pathogen-associated molecular patterns: PAMPs).

Chemical Mediators with Combined Vasoactive and Chemotactic Actions

Complement system components, cytokines (interferon and interleukins), products of arachidonic acid metabolism, and platelet-activating factor produce vasoactive and chemotactic effects.

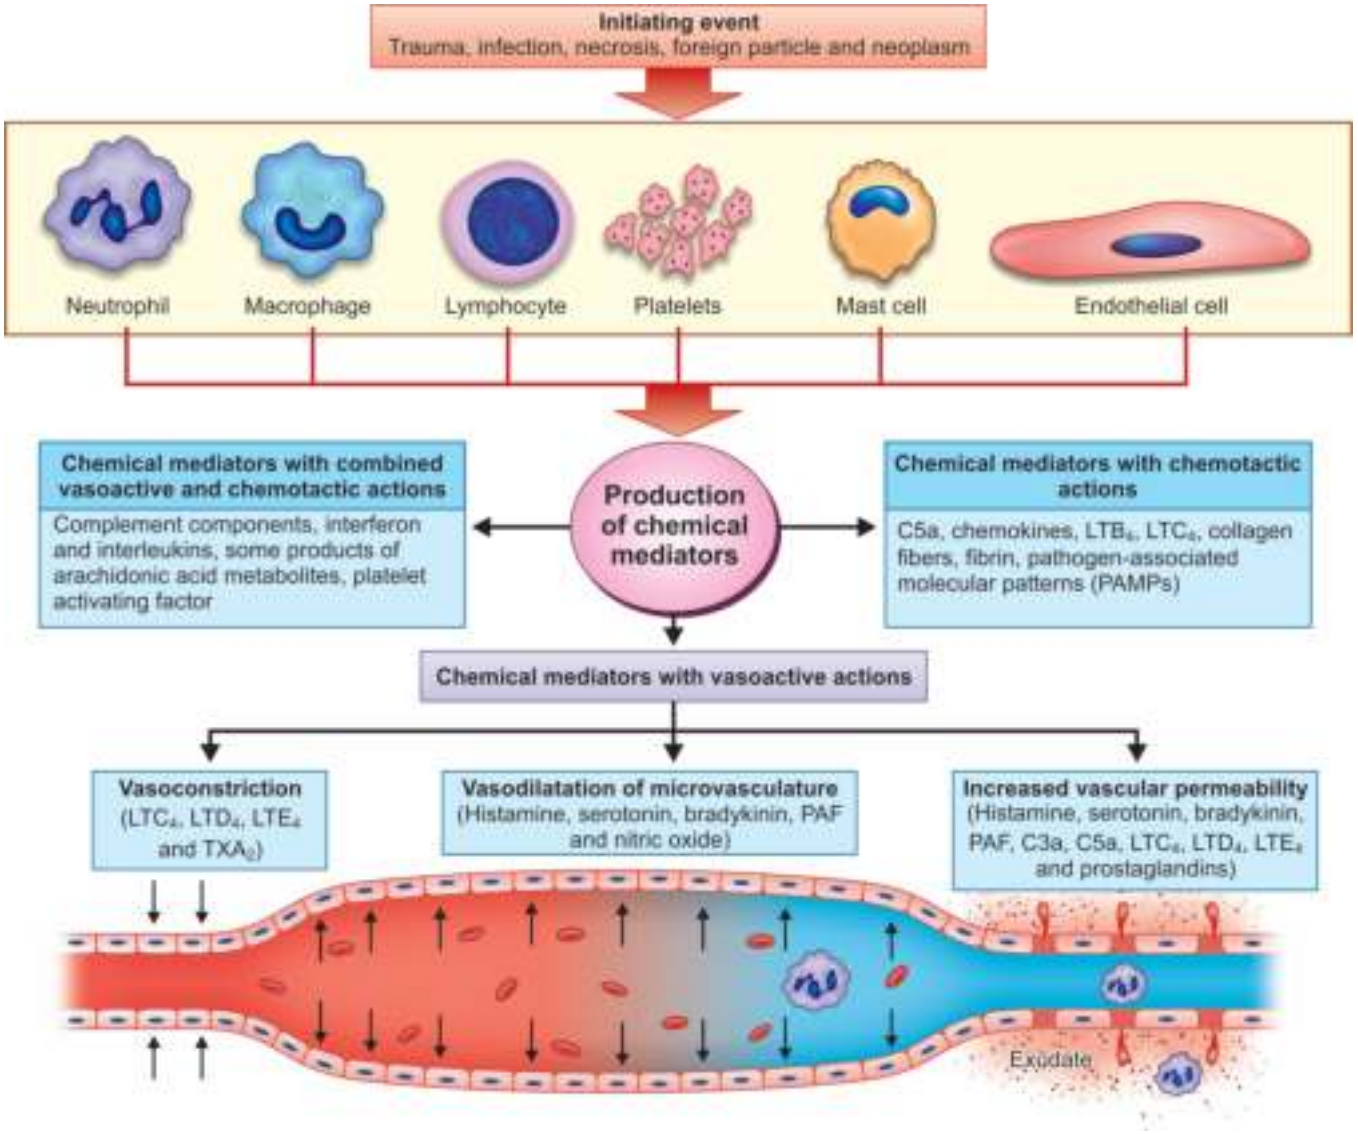

Fig. 2.22: Functional categories of chemical mediators and their inflammatory responses. Functional categories of chemical mediators include chemotactic, vasoactive and combined chemotactic and vasoactive functions.

Table 2.15 Functional categories of chemical mediators

Inflammatory Response	Chemical Mediators	Source
Chemical mediators with vasoactive actions		
Vasodilation of arterioles and capillaries	▪ Histamine ▪ Serotonin ▪ Bradykinin ▪ Platelet-activating factor (PAF) ▪ Nitric oxide ▪ Neuropeptide (substance P)	▪ Mast cells, basophils, platelets ▪ Platelets ▪ Liver (plasma-derived chemical mediators) ▪ Mast cells, basophils ▪ Macrophages, endothelium ▪ Neurons
Vasoconstriction	▪ Leukotrienes (LTC_4, LTD_4, LTE_4) ▪ Thromboxane A_2	▪ Leukocytes, mast cells ▪ Macrophages, mast cells, platelets, endothelium
Increased vascular permeability of venules	▪ Histamine ▪ Serotonin ▪ Bradykinin	▪ Mast cells, basophils, platelets ▪ Platelets ▪ Liver (plasma derived)

Contd...

Table 2.15 Functional categories of chemical mediators (*Contd...*)

Inflammatory Response	Chemical Mediators	Source
	▪ Platelet-activating factor (PAF) ▪ Anaphylatoxins (C3a, C5a) ▪ Prostaglandins (PGD_2, PGE_2, $PGF_{2\alpha}$) ▪ Leukotrienes (LTC_4, LTD_4, LTE_4)	▪ Mast cells, basophils ▪ Liver (plasma derived) ▪ Macrophages, mast cells, platelets, endothelium ▪ Leukocytes, mast cells
Chemical mediators with chemotactic actions		
Chemotaxis of leukocytes	▪ C5a ▪ Chemokines ▪ Leukotrienes (LTB_4, LTC_4) ▪ Collagen fibers ▪ Fibrin (plasma derived) ▪ Pathogen-associated molecular patterns	▪ Liver (plasma derived) ▪ Leukocytes, endothelial cells ▪ Leukocytes, mast cells ▪ Tissues ▪ Liver (plasma derived) ▪ Bacterial peptides
Chemical mediators with combined vasoactive and chemotactic actions		
Vasoactive and chemotaxis of leukocytes	▪ Complement components (C3a, C5a) ▪ Interleukins ▪ Chemokines ▪ LTC_4, LTD_4, LTE_4 ▪ Platelet-activating factor	▪ Liver (plasma derived) ▪ Macrophages, dendritic cells, fibroblasts, hepatocytes ▪ Leukocytes, endothelial cells ▪ Macrophages, mast cells, endothelial cells ▪ Mast cells, basophils

PLASMA PROTEIN-DERIVED CHEMICAL MEDIATORS

Plasma protein-derived chemical mediators mediate inflammatory response. Hageman factor XII synthesized by liver is the key source of vasoactive chemical mediators.

- Hageman factor XII is activated by negatively charged surfaces (collagen, basement membrane), activated platelets and high molecular weight kininogen).
- Hageman factor activates kallikrein (kinin) system resulting in activation of fibrinolytic system, coagulation system (intrinsic pathway) and complement system at the site of injury.
- Kallikrein (kinin) system converts kininogen to bradykinin, which mediates arteriolar dilation, vascular permeability, and pain in acute inflammation.
- Kallikrein (kinin) system is activated by Hageman factor, plasmin and leukocyte protease.
- Kallikrein (kinin) is degraded by kininase and angiotensin converting enzyme (ACE) in the lungs.
- Kallikrein (kinin) system also activates complement system to generate C3, C5a, C5–9, which participate in chemotaxis of leukocytes, opsonization and phagocytosis of microbes. Plasma protein-derived chemical mediators in acute inflammation are shown in Fig. 2.23.

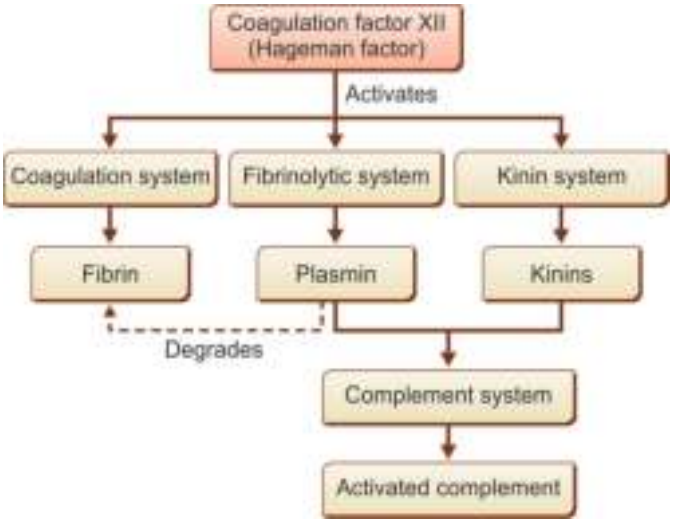

Fig. 2.23: Plasma protein derived chemical mediators in acute inflammation. These chemical mediators include complement system, coagulation cascade and kinin generation. Hageman factor (clotting factor XII) converts plasminogen to plasmin, prekallikrein to kallikrein and activation of the alternative complement pathway and coagulation system.

Fibrinolytic System

Plasminogen activator synthesized by endothelium and leukocytes activates fibrinolytic system, which converts plasminogen to plasmin, which degrades fibrin into fibrin peptides. Fibrinolytic system participates in vascular phase of inflammation is discussed as follows:

- Plasmin activates Hageman factor XII to synthesize plasma proteins related bradykinin (kinin).
- Bradykinin mediates vascular permeability, arteriolar dilation, and pain.
- Fibrinolytic system cleaves C3 to C3a. Plasmin, fibrin peptides, C3a and bradykinin increase vascular permeability.

Coagulation System

Coagulation system and inflammation are tightly linked. During final stage of coagulation, thrombin and

insoluble fibrin are formed. Thrombin and insoluble fibrin bind to seven transmembrane G protein-coupled receptors expressed on platelets, endothelial cells, smooth muscle cells and other cells. Thrombin and insoluble fibrin participate in vascular phase of acute inflammation.

- Thrombin and insoluble fibrin increase expression of adhesion molecule (P-selectin) by mobilization on vascular endothelium. These also induce integrin synthesis, resulting to leukocytic adhesion to vascular endothelium.
- Factor Xa and fibrin peptides increase vascular permeability.
- Factor Xa participates in emigration of leukocytes. Thrombin and fibrin peptides participate in recruitment of leukocytes to the site of injury. Thrombin and fibrin peptides also enhance the synthesis of chemical mediators such as chemokines, prostaglandins, platelet-activating factor, nitric oxide. Coagulation system products and their actions are given in Table 2.16.

Complement System

Complement system consists of a group of soluble plasma proteins synthesized by liver present in its inactive form that interact with one another in three distinct enzymatic-activation cascades, which are numbered C1 to C9 (C3 most abundant). Complement system cascade and its actions are shown in Fig. 2.24.

- Complement system plays important role in acute inflammation. It is a part of the innate and adaptative immune system by contributing to mediation of vascular permeability and vasodilation, leukocyte adhesion and chemotaxis, phagocytosis and cell lysis. C5a, the complement cleavage product is a powerful chemoattractant. C3b and Ic3b act as opsonins to coat bacteria. Many regulatory proteins expressed by mammals prevent inappropriate activation of complement system.
- Three pathways of complement have different triggers at starting points, but all converge at the same place, C3 convertase. This C3 convertase enzyme begins the formation of tiny openings in the cell membrane and the destruction of target pathogen.
- All these three pathways of complement system converge to form C3. C3 convertase enzyme converts C3 molecule into an activator C3b. C3 convertase enzyme and C3b are the central features of complement system activation. Activation of complement produces C3a, C5a and C5–9.

Three Pathways of Complement System

Three pathways of complement system are described as under:

- **Classical pathway of complement system:** Classical pathway of complement system is also known as immunologic pathway, which involves fixation of antibodies (IgG and IgM) and complement (C1). This pathway is rapid and nonspecific. C1q, C1, C1s are converted to form C4, C2, C3.
- **Alternate pathway of complement system:** Alternate pathway of complement system is antibody independent pathway. It is activated by bacteria, fungi, viruses and parasites and venom. Factor B and factor D are converted to C3. Deficiency of C3 affects alternate pathway of complement activation resulting to **recurrent infections** with fatal outcome, until treated.
- **Mannose-binding lectin pathway of complement system:** Mannose-binding lectin pathway of complement system is also antibody independent pathway. It binds mannose (carbohydrate) on pathogen surfaces. It is nonspecific for bacteria and viruses. MBL, MASP-1, MASP-2 are converted to form C4, C2, C3.

Mechanism of Action of Complement System

Mechanism of action of complement system is described as under:

- **C3 convertase enzyme:** It activates complement system and splits C3 into two functionally distinct C3a and C3b. C3a is released, while C3b binds to C5 convertase.

Table 2.16 Coagulation system products and their actions

Coagulation System	Actions
Thrombin and insoluble fibrin	▪ Mobilization of adhesion molecule (P-selectin) and its expression on vascular endothelium ▪ Induction of integrin synthesis, resulting to leukocytic adhesion to vascular endothelium
Factor Xa and fibrin peptides	Increased vascular permeability
Factor Xa	Emigration of leukocytes
Thrombin and fibrin peptides	▪ Recruitment of leukocytes to the site of injury ▪ Enhancing synthesis of chemical mediators such as chemokines, prostaglandins, platelet-activating factor, nitric oxide

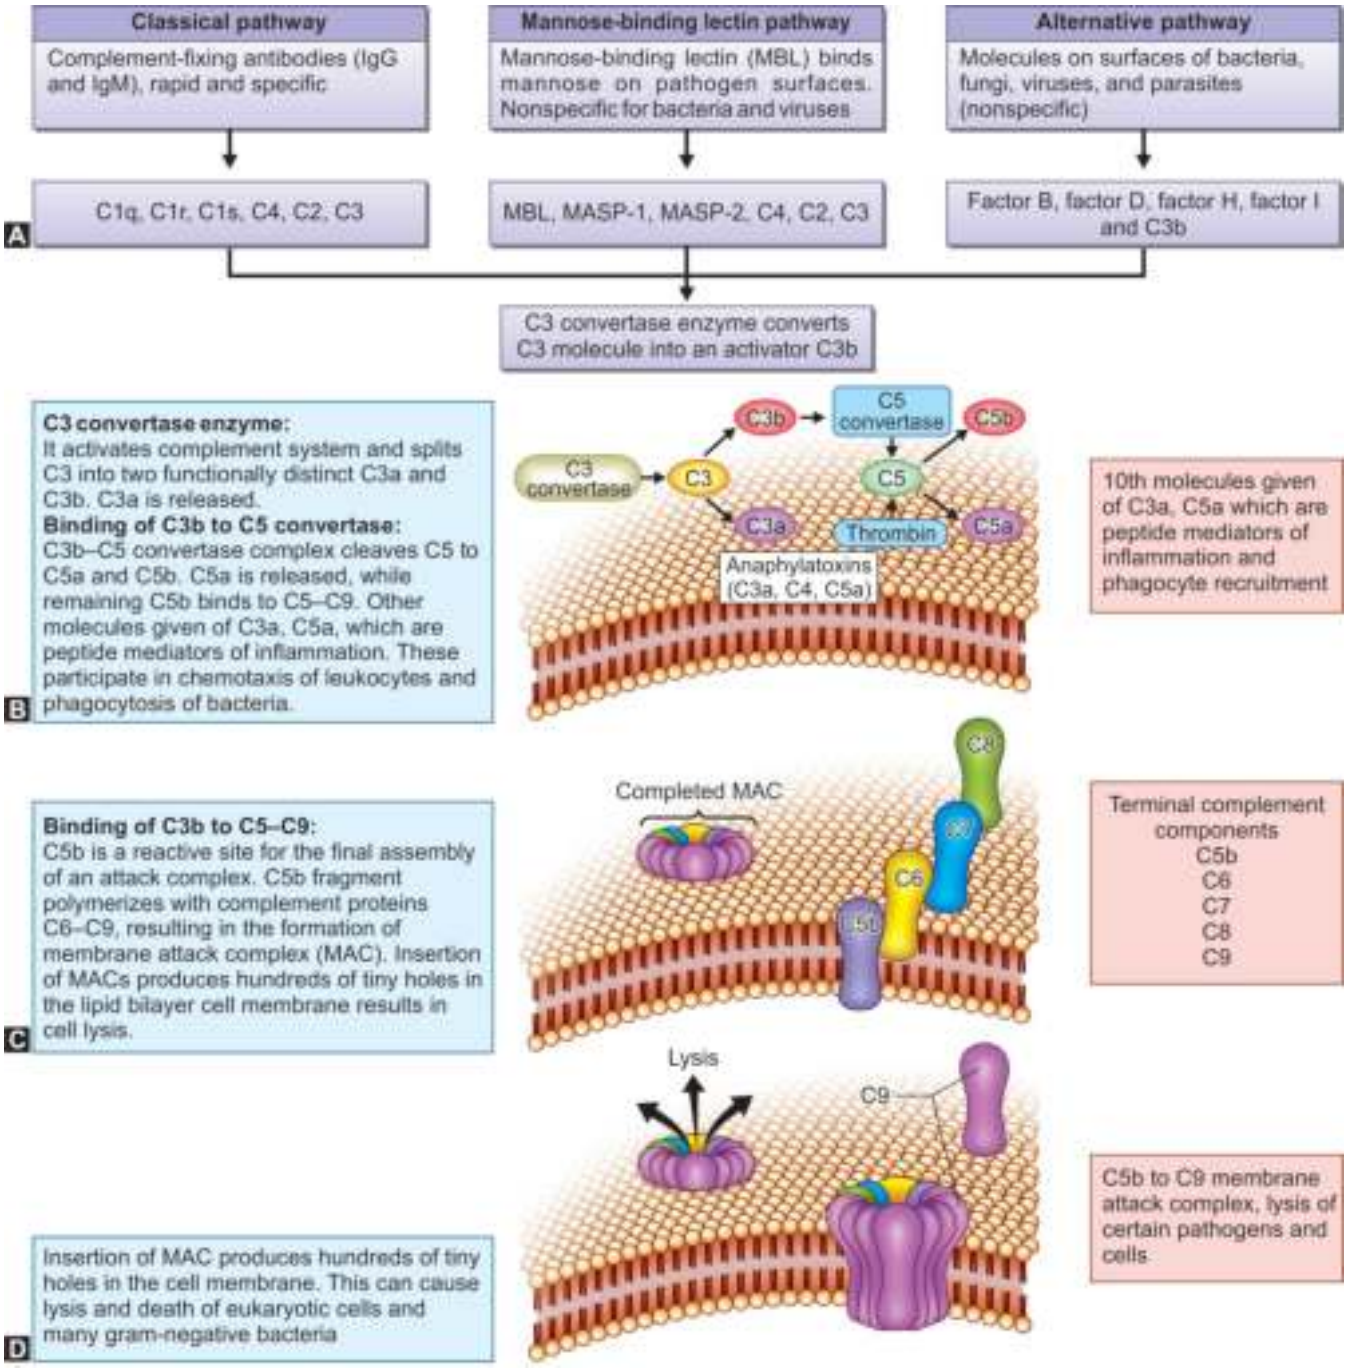

Fig. 2.24: Complement system cascade and its actions. Complement system consists of wide variety of proteins, which perform many functions: (A) defense against pyogenic bacterial infection by opsonization, chemotaxis, activation of leukocytes and degradation of microbes, (B) bridging innate and adaptive immunity, (C) disposal of immune and inflammatory products by clearance of immune complexes from the tissues and removal of apoptotic cells, and (D) MAC produces holes in the cell membrane of bacteria and kill them. The proteins involved in activating the complement system are themselves activated by three convergent pathways termed classical, mannose-binding lectin (MBL) and alternative.

- **Binding of C3b to C5 convertase:** Binding of C3b to C5 convertase forms C3b–C5 convertase complex, which cleaves C5 to C5a and C5b. C5a is released, while remaining C5b binds to C5–C9. C3a, C5a, are peptide mediators of inflammation. These participate in chemotaxis of leukocytes and phagocytosis of microorganisms in acute inflammation.
- **Binding of C3b to C5–C9:** C5b is a reactive site for the final assembly of an attack complex. C5b fragment polymerizes with complement proteins C6, C7, C8, and C9, resulting in the formation of membrane attack complex (MAC). Insertion of MACs produces hundreds of tiny holes in the lipid bilayer cell membrane results in cell lysis.

Pathology Pearls: Complement System Actions

Complement system cascade and its actions are given in Table 2.17. Breakdown products of complement system mediates acute inflammation by following mechanisms:

Opsonization and Phagocytosis

C3b acts as opsonins, which coat the bacteria leading to phagocytosis by neutrophils and macrophages.

Increased Vascular Permeability

C3a and C5a cause increased vascular permeability.

Leukocytic Adhesion, Transmigration and Chemotaxis

- C5a fragment is a chemotactic agent, which mediates the release of histamine from platelet-dense granules.
- C5a induces the expression of leukocyte adhesion molecules.
- C5a participates in transmigration and chemotaxis of leukocytes.

Anaphylactic Shock

- C3a, C5a and C4 are called anaphylatoxins, which stimulate degranulation of mast cells and basophils liberating histamine.
- Histamine causes increased vascular permeability, vasodilatation and smooth muscle contraction. Patient develops '**anaphylactic shock**'.

Synthesis of Arachidonic Acid Metabolites

C5a fragment activates lipoxygenase enzyme, which acts on membrane of neutrophils and monocytes resulting to synthesis of arachidonic metabolites (lipoxygenase pathway).

Membrane Attack Complex (MAC) Formation

- C5b-C9 is a lytic agent for bacteria and target cells, which stimulates arachidonic acid metabolism and produces reactive oxygen metabolites.
- Defective formation of membrane attack complex (MAC) leads to increased susceptibility to Neisseria organisms.

Clinical Pearls: Complement System Disorders

Patients develop increased susceptibility to infections due to defects in complement proteins, pathologic activation and deficiency of regulatory proteins. Disorders of complement system cascade are given in Table 2.18.

Recurrent Infections

- Patient presents with **increased susceptibility to infection** due to deficiency of complement components such as C2, C3, and C5.
- **Defective formation of membrane attack complex (MAC)** leads to increased susceptibility to Neisseria organisms.

Hereditary Angioneurotic Edema

- **Physiologic state:** Normally, classical pathway involves fixation antibodies (IgG and IgM) and complement (C1). C1 is inhibited by plasma protein C1 inhibitor (C1 INH).
- **Pathologic state:** Hereditary deficiency of C1 inhibitor (C1 INH) causes improper activation of C1 by immune complex resulting to excessive breakdown of C4 and C2. Complement C2 molecule generates vasoactive peptide (bradykinin), which produces painless nonpitting edema of soft tissues especially laryngeal edema, which may be life-threatening.

Systemic Lupus Erythematosus

Patient with C2 and C4 deficiencies may develop systemic lupus erythematosus (SLE) due to failure to clear immune complexes.

Paroxysmal Nocturnal Hemoglobinuria

- **Physiologic state:** Glycosylphosphatidylinositol (GPI) anchor regulatory proteins such as CD55, CD59, and C8, which are required for the protection of red blood cells, granulocytes, and platelets from complement-mediated lysis. CD55 known as DAF (decay accelerating factor) cleaves C3b. CD59 known as MIRL (membrane inhibitor reactive lysis) participates in cleaving C5–9.
- **Pathologic state:** PIG-A gene mutation encoding phosphatidylinositol linked membrane proteins leads to uncontrolled activation of complement resulting to recurrent bouts of intravascular complement mediated hemolysis.
  - **Clinical manifestations:** Recurrent bouts of intravascular complement-mediated hemolysis is often marked by the passage of hemoglobin-containing urine on awakening. During hemolytic episodes, patients develop normocytic or macrocytic anemia, accompanied by an appropriate reticulocytosis response. PNH may develop as a primary disorder or evolve from preexisting cases of aplastic anemia.
  - **Laboratory diagnosis:** Flow cytometry demonstrates diminished CD55 and CD59 expression on red blood cells, leukocytes and platelets. Traditional diagnostic test is based on hemolysis in sucrose (sucrose hemolysis test) or acidified serum (Ham test) *in vitro*.

CELL-DERIVED CHEMICAL MEDIATORS

Cell-derived chemical mediators are synthesized by monocytes, macrophages, lymphocytes, fibroblasts, mast cells, platelets, and endothelial cells of blood vessels. These participate in acute inflammation by increasing vascular permeability resulting in extravasation of plasma proteins rich fluid along with inflammatory cells in interstitial tissue '**exudate**'. Cell-derived preformed and newly synthesized chemical mediators are given in Table 2.19.

Vasoactive Amines

Vasoactive amines act directly or indirectly on the vascular system, which are stored as preformed molecules in mast cells or early inflammatory cells. Vasoactive amines include histamine, serotonin and bradykinin. Vasoactive amines chemical mediators are given in Table 2.20.

Table 2.17 Complement system cascade and its actions

Complement System Cascade	Actions
C3b	▪ Opsonization of microbes ▪ Phagocytosis of microbes
C3a and C5a	Increased vascular permeability
C5a	▪ Adhesion of leukocytes ▪ Chemotaxis of leukocytes ▪ Transmigration of leukocytes
C5a	Synthesis of arachidonic acid metabolites (lipoxygenase pathway)
C5b–C9 membrane attack complex (MAC)	Degradation of microbes and enhancing arachidonic acid metabolism and producing reactive oxygen metabolites

Defective formation of membrane attack complex (MAC) leads to increased susceptibility to Neisseria organisms. C3a, C5a and C4 cause anaphylactic shock due to excessive histamine release by mast cells.

Table 2.18 Hereditary and acquired deficiencies of complement linked to diseases in human beings

Complement Deficiency	Associated Disorder
Deficiencies of early complement components, C1, C4, C3	Systemic lupus erythematosus (SLE), glomerulonephritis, polymyositis
C1q	SLE-like syndrome; decreased secondary to agammaglobulinemia
C1r	SLE-like syndrome; dermatomyositis, vasculitis, recurrent infections and chronic glomerulonephritis, necrotizing skin lesions, arthritis
C1s	SLE-like syndrome
C1 inhibitor (C1 INH)	Hereditary angioedema, laryngeal edema. lupus nephritis
C2	Recurrent pyogenic infections, SLE-like syndrome, discoid lupus, membranoproliferative glomerulonephritis, dermatomyositis, synovitis, purpura, Henoch-Schonlein purpura, hypertension, Hodgkin disease, chronic lymphocytic leukemia, dermatitis, herpetiformis, polymyositis
C3 and factor B	Severe recurrent pyogenic bacterial infections, SLE-like syndrome, arthralgias, skin rash
C3b inactivator	Neisseria infections
C3 inactivator	Recurrent pyogenic infections, urticaria
C4	SLE-like syndrome, dermatomyositis-like syndrome, vasculitis
C5	Neisseria infections, SLE
C5 dysfunction	Leiner's disease, gram-negative skin and bowel infections
C6	Neisseria infections, SLE, Raynaud's phenomenon, scleroderma-like syndrome, vasculitis
C7	Neisseria infections, SLE, Raynaud's phenomenon, scleroderma-like syndrome, vasculitis
C8	Neisseria infections, xeroderma pigmentosum, SLE-like syndrome

(1) C2, C3, and C5 deficiency cause recurrent infections. (2) C5b–C9 defective formation of membrane attack complex (MAC) causes Neisseria infections. (3) C2 and C4 deficiency cause improper clearance of immune complex in systemic lupus erythematosus. (4) PIG-A gene mutation encoding phosphatidylinositol linked membrane proteins leading to uncontrolled activation of complement resulting to recurrent bouts of intravascular complement-mediated hemolysis in paroxysmal nocturnal hemoglobinuria. Flow cytometry demonstrating diminished CD55 and CD59 expression on red blood cells, leukocytes and platelets.

- **Histamine:** Histamine is stored in the secretory granules of mast cells, basophils and platelets. Histamine release is triggered by immune complexes, C3a, C5a, IL-1, IL-8, neuropeptide into the extracellular tissues. Histamine also increases secretion of salivary, lacrimal, respiratory and gastric glands. Histamine action on smooth muscle varies with location, which increases intestinal motility. Histamine is responsible for the wheal and flare reaction in skin, pruritus and headache. Histamine mediates acute inflammation, bronchial asthma and anaphylactic shock. Histamine is inactivated by histaminase enzyme.

Table 2.19 Cell-derived preformed and newly synthesized chemical mediators

Source	Chemical Mediators	
Preformed cell-derived chemical mediators		
Stored in the secretory granules of mast cells, basophils and platelets	Histamine	
Stored in dense bodies of platelets	Serotonin	
Neutrophils and macrophages	Lysosomal enzymes	
Newly synthesized cell-derived chemical mediators		
Cyclooxygenase pathway (arachidonic acid metabolites)	▪ Prostaglandins ▪ Prostacyclin (PGI_2)	▪ Thromboxane A_2 (TXA_2)
Lipoxygenase pathway (arachidonic acid metabolites)	▪ Leukotrienes	▪ Lipoxins
Cytokines	▪ Interleukins ▪ Tumor necrosis factor-α (TNF-α) ▪ Chemokines	▪ Interferons (IFN-α, IFN-β, IFN-γ) ▪ Growth factors
Other chemical mediators	▪ O_2-derived free radicals ▪ Nitric oxide (NO) ▪ Platelet-activating factor	▪ Neuropeptides (substance P) ▪ Hypoxia-inducible factor-α (HIF-α)

Table 2.20 Vasoactive amines chemical mediators

Chemical Mediators	Source	Actions
Histamine	Mast cell, basophils, platelets, enterochromaffin cells	▪ Increased vascular permeability (exudate) ▪ Bronchoconstriction (bronchial asthma) ▪ Anaphylactic shock (circulatory collapse)
Serotonin	Platelets	▪ Increased permeability of venules (exudate) ▪ Vasodilation ▪ Increased collagen synthesis
Bradykinin	Plasma proteins (kinin)	▪ Increased vascular permeability (exudate) ▪ Vasodilation ▪ Induction of pain

- **Acute inflammation:** Histamine binds to specific H1 receptors in the vascular wall, inducing endothelial cell contraction gap formation, increasing vascular permeability and edema formation (exudate) in acute inflammation. It occurs due to phosphorylation of contractile myosin and cytoskeleton proteins. Histamine causes smooth muscle relaxation of arterioles resulting in vasodilation.
- **Bronchial asthma:** Histamine is potent fast acting chemical mediator in allergic disorders, which causes smooth muscle contraction of bronchioles. Histamine increases mucus secretion in bronchioles and increases synthesis of 'eotaxin', which attract eosinophils.
- **Anaphylactic shock:** Massive release of histamine may cause circulatory collapse (anaphylactic shock). Patient develops hypotension, tachycardia, circulatory failure, and shock.

- **Serotonin:** Serotonin is stored in dense bodies of platelets during platelet aggregation. Serotonin release is triggered by immune complexes, C3a, C5a, IL-1, IL-8, neuropeptide into the extracellular tissues. Serotonin increases permeability of microvasculature and vasodilatation. It also causes smooth muscle contraction and inhibits gastric secretion.
- **Bradykinin:** Bradykinin is related to plasma proteins known as kinins. Kinin system converts kininogen to bradykinin, which causes vasodilation of peripheral arterioles, increased capillary permeability and induction of pain. In allergy, bradykinin causes prolonged smooth muscle contraction of bronchioles and increased mucus secretion. Bradykinin activates complement system to generate C3, C5a, C5–9, which participate in chemotaxis of leukocytes, opsonization and phagocytosis of microbes.

Neutrophil and Macrophage Lysosomal Enzymes

Macrophages and neutrophils contain lysosomal enzymes in their granules. During inflammation, lysosomal enzymes (preformed chemical mediators) are released at the site of tissue injury resulting in degradation of injurious agents. Liberation of lysosomal enzymes in the interstitial tissue may cause tissue damage.

- **Neutrophils:** Neutrophils contain azurophilic and specific granules. Specific granules are released more easily in extracellular compartment even in low concentration, in comparison to azurophilic granules. Myeloperoxidase, lactoferrin, lysozyme and major basic proteins degrade bacteria and debris within phagolysosomes. Neutral elastases degrade virulence factors of bacteria and thus combat bacterial infection. During acute inflammation, neutrophilic collagenase, hydrolase, protease and elastase degrade extracellular matrix (ECM) composed of collagen fibers, basement membrane, elastin and cartilage. Contents of polymorphonuclear cell granules are given in Table 2.21.
- **Monocytes/macrophages:** Monocytes/macrophages regulate acute and chronic inflammatory response, coagulation/fibrinolytic pathway and immune response. Primary inflammatory chemical mediators of monocytes/macrophages include enzymes (e.g. hydrolases collagenases, elastases, phospholipases), plasminogen activator, complement proteins, chemokines, cytokines, reactive oxygen species, antioxidants, coagulation factors and bioactive lipids, which participate in chronic inflammation.

Arachidonic Acid Metabolites Synthesis by Enzymatic Pathways

Arachidonic acid (AA) is 20-carbon polyunsaturated fatty acid (4 double bonds) obtained from dietary linoleic acid (essential fatty acid). It is present in its esterified form as a component of cell membrane phospholipids of tissue macrophages, mast cells, endothelial cells and recruited leukocytes.

- Tissue injury leads to influx of cytosolic calcium in tissue macrophages, mast cells, endothelial cells and recruited leukocytes.
- Increased cytosolic calcium activates membrane phospholipase A_2 enzyme resulting to synthesis of arachidonic acid known as 'eicosanoids. PGH2 serves as a substrate for cyclooxygenase and lipoxygenase enzymatic pathways. These enzymatic pathways synthesize various arachidonic acid metabolites.
- Generation of arachidonic acid metabolites and their roles in inflammation is shown in Fig. 2.25.
- Arachidonic acid metabolites, their source and actions are given in Table 2.22. The spectrum of reactions to inflammatory cytokines released by mast cells is given in Fig. 2.26.

Cyclooxygenase Pathway

- Cyclooxygenase pathway participate in synthesis of prostaglandins, prostacyclin and thromboxane A_2. Cyclooxygenase pathway is inhibited by anti-inflammatory drugs (NSAIDs and corticosteroids). COX2 inhibitor drugs produce less toxicity than COX1.
- Prolonged administration of nonsteroidal anti-inflammatory drugs may increase risk of arterial thrombosis in people possibly due to reduced

Table 2.21 Contents of polymorphonuclear cell granules

Primary (Azurophilic) Granules	Specific (Heterophilic) Granules	Tertiary Granules
▪ Myeloperoxidase ▪ Acid hydrolases ▪ Cathepsins G, B, D ▪ Defensins ▪ Bactericidal permeability increasing protein ▪ Cationic proteins ▪ Lysozyme ▪ Elastase ▪ Glucuronidase ▪ Mannosidase ▪ Phospholipase A_2	▪ Lysozyme ▪ Lactoferrin ▪ Alkaline phosphatase ▪ Nicotinamide adenine dinucleotide phosphate oxidase ▪ Collagenase ▪ Histaminase ▪ Phospholipase A_2 ▪ Complement activator ▪ CD11b/CD18 ▪ CD11c/CD18	▪ Glucuronidase ▪ Mannosidase ▪ Gelatinase ▪ Plasminogen activator ▪ Cathepsins

Neutrophil functions: Central role in acute inflammation, reactive oxygen species, phagocytosis of microorganisms and tissue debris, mediates tissue injury.

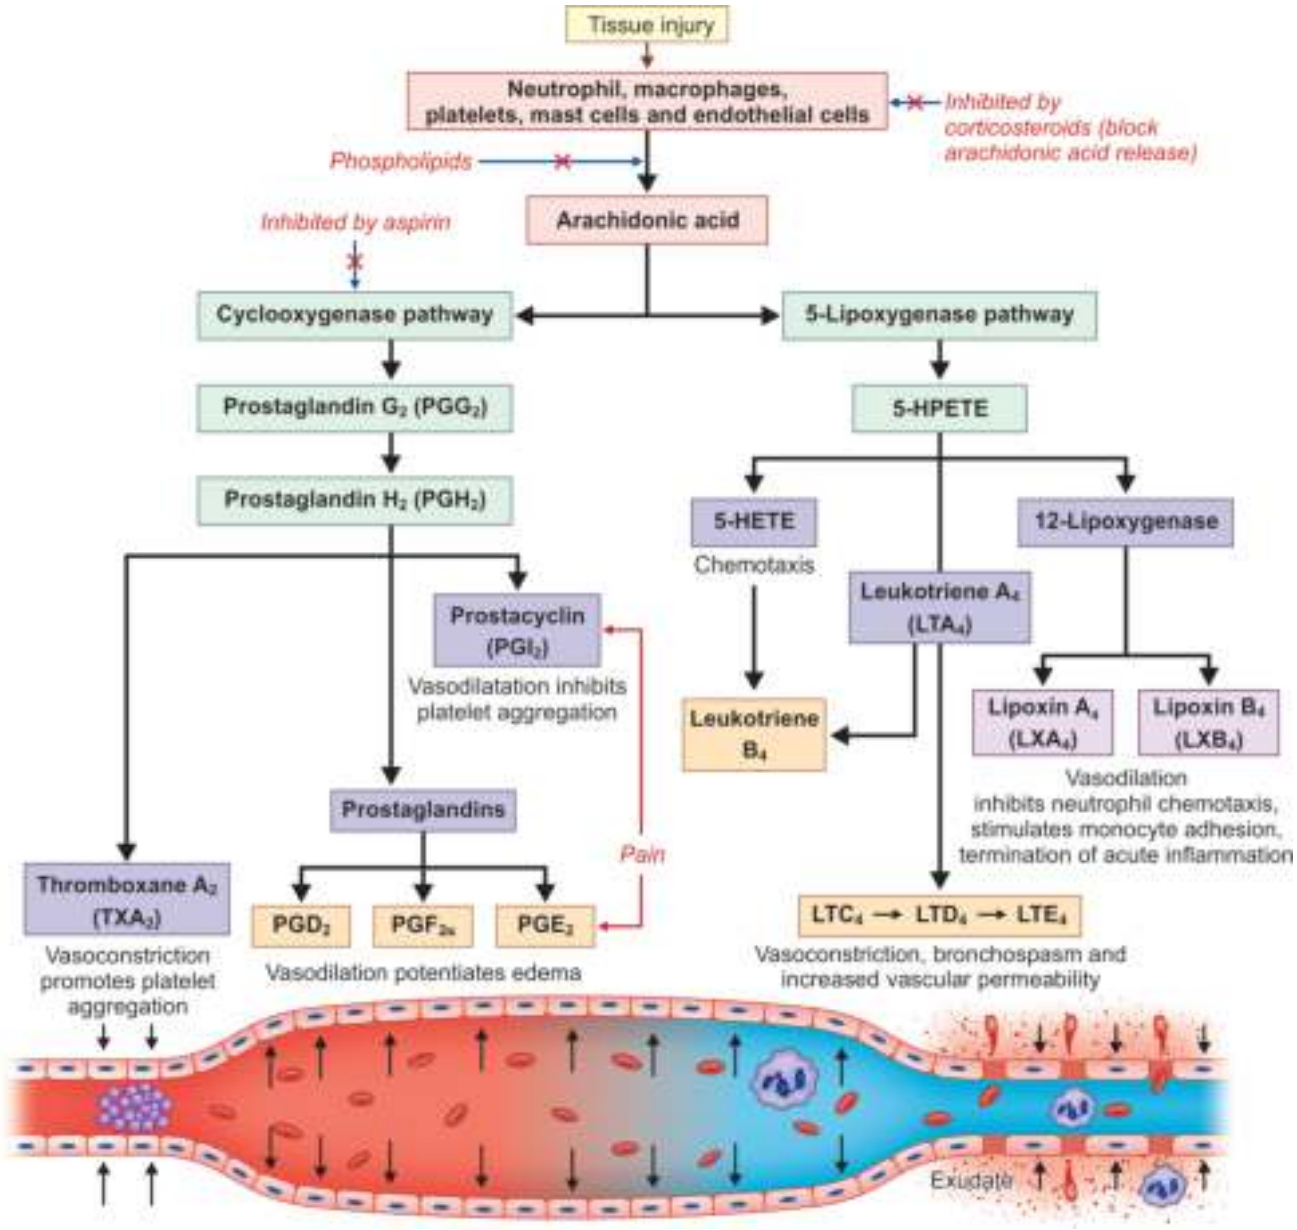

Fig. 2.25: Generation of arachidonic acid metabolites and their roles in inflammation. Arachidonic acid is produced by the actions of phospholipase A_2 on membrane phospholipids (linoleic acid). The arachidonic acid metabolites include prostaglandins, prostacyclin, thromboxane, leukotrienes and lipoxins, which play major role in the pathophysiology of inflammation.

Table 2.22 Arachidonic acid metabolites, their source and actions

Source	Chemical Mediators	Actions
Cyclooxygenase pathway		
Macrophages, endothelial cells, mast cell, platelets	▪ PGD_2 ▪ PGE_2 ▪ PGD_2, PGE_2	▪ Promotes platelets aggregation ▪ Vasodilation ▪ Increased vascular permeability ▪ Pain, fever, edema ▪ Modulation of phagocytic activity of leukocytes
Vascular endothelium (prostacyclin synthase enzyme)	PGI_2 (prostacyclin)	▪ Activating adenylyl cyclase and increases intracellular levels of cAMP ▪ Inhibiting platelets aggregation

Contd...

Table 2.22 Arachidonic acid metabolites, their source and actions (*Contd...*)

Source	Chemical Mediators	Actions
PGI_2 is converted to TXA_2 by thromboxane synthase in platelets	Thromboxane A_2 (TXA_2)	▪ Platelet aggregation (due to activation of guanylyl cyclase increasing intracellular levels of cGMP) ▪ Increased vascular permeability (serotonin released due to interaction of platelets, thrombin and collagen fibers) ▪ Vasoconstriction ▪ Smooth muscle contraction
Lipoxygenase pathway (5) in neutrophils		
Leukocytes and mast cells	▪ LTB_4 (leukotriene) ▪ LTC_4, LTD_4, LTE_4 (leukotrienes)	Adhesion, chemotaxis and activation of neutrophils ▪ Vasoconstriction ▪ Increased permeability of venules ▪ Bronchoconstriction (monteleukast therapeutic agent used to block leukotrienes receptors)
Lipoxygenase pathway (12) in platelets		
Platelets	Lipoxins (LXA_4, LXB_4)	▪ Termination of acute inflammation by inhibiting adhesion, chemotaxis of leukocytes ▪ Vasodilatation

prostacyclin in endothelial cells. Anti-inflammatory agents inhibiting cyclooxygenase pathway are given in Table 2.23.

- **Prostaglandins:** Prostaglandins are synthesized by macrophages, endothelial cells, mast cell and platelets. PGD_2 causes vasodilation, increased vascular permeability and aggregation of platelets. PGE_2 is responsible for pain, fever and edema. PGD_2 and PGE_2 modulate phagocytic activity of leukocytes.
- **Prostacyclin (PGI_2):** Prostacyclin synthase enzyme in vascular endothelium synthesizes prostacyclin. Prostacyclin activates adenylyl cyclase and increases intracellular levels of cAMP. Prostacyclin inhibits platelets aggregation. Prostacyclin participates in vasodilatation, increased vascular permeability and chemotaxis. Prostacyclin enhances the action of other chemical mediators leading to increased vascular permeability and chemotaxis.
- **Thromboxane A_2 (TXA_2):** Thromboxane A_2 is synthesized by platelets with the help of thromboxane synthase enzyme. Thromboxane A_2 activates guanylyl cyclase and increases intracellular levels of cGMP. TXA_2 promotes platelets aggregation and causes vasoconstriction. Thromboxane A_2 mediates smooth muscle contraction. Platelets come in contact with thrombin and fibrillar collagen fibers liberate serotonin resulting in increased vascular permeability.

Lipoxygenase Pathway

Lipoxygenase pathway participates in synthesis of leukotrienes (LTB_4, LTC_4, LTD_4, and LTE_4) and lipoxins (LXA_4, LXB_4). Arachidonic acid metabolites such as leukotrienes and lipoxins are synthesized by cell–cell interactions (neutrophils–platelets) by following mechanisms:

- **5-Lipoxygenase pathway in neutrophils:** Arachidonic acid metabolites of this pathway include leukotrienes and 5-HETE.
  - Leukotrienes (LTC_4, LTD_4, and LTE_4) are synthesized by leukocytes and mast cells. Injurious stimulus activates 5-lipoxygenase enzymatic pathway in neutrophils resulting in synthesis of LTA_4. Simultaneously LTA_4 is converted to leukotrienes, e.g. LTB_4 (chemotactic), LTC_4, LTD_4, and LTE_4.
  - Leukotrienes and histamine have similar actions. Histamine is less potent with rapid action. While leukotrienes are more potent chemical mediator of inflammation, but slow reacting substance of anaphylaxis (SRS-A).
  - Leukotrienes cause vasodilation and increased vascular permeability. Leukotrienes activate PMNs leukocytes leading to adhesion on venular endothelium, chemotaxis, and generation of oxygen-derived free radicals and release of lysosomal enzymes. Mechanism of actions of leukotrienes and therapeutic correlation are given in Table 2.24.
- **12-Lipoxygenase pathway in platelets:** This pathway coverts arachidonic acid to lipoxins (LXA_4 and LXB_4) in platelets. After an inflammatory response, neutrophils 'switch off' chemical mediators of inflammation such as prostaglandins and leukotrienes, and 'switch on' actions of anti-inflammatory **lipoxins**.
  - Lipoxins (LXA_4, LXB_4) terminate acute inflammation in the first few hours of injurious stimulus

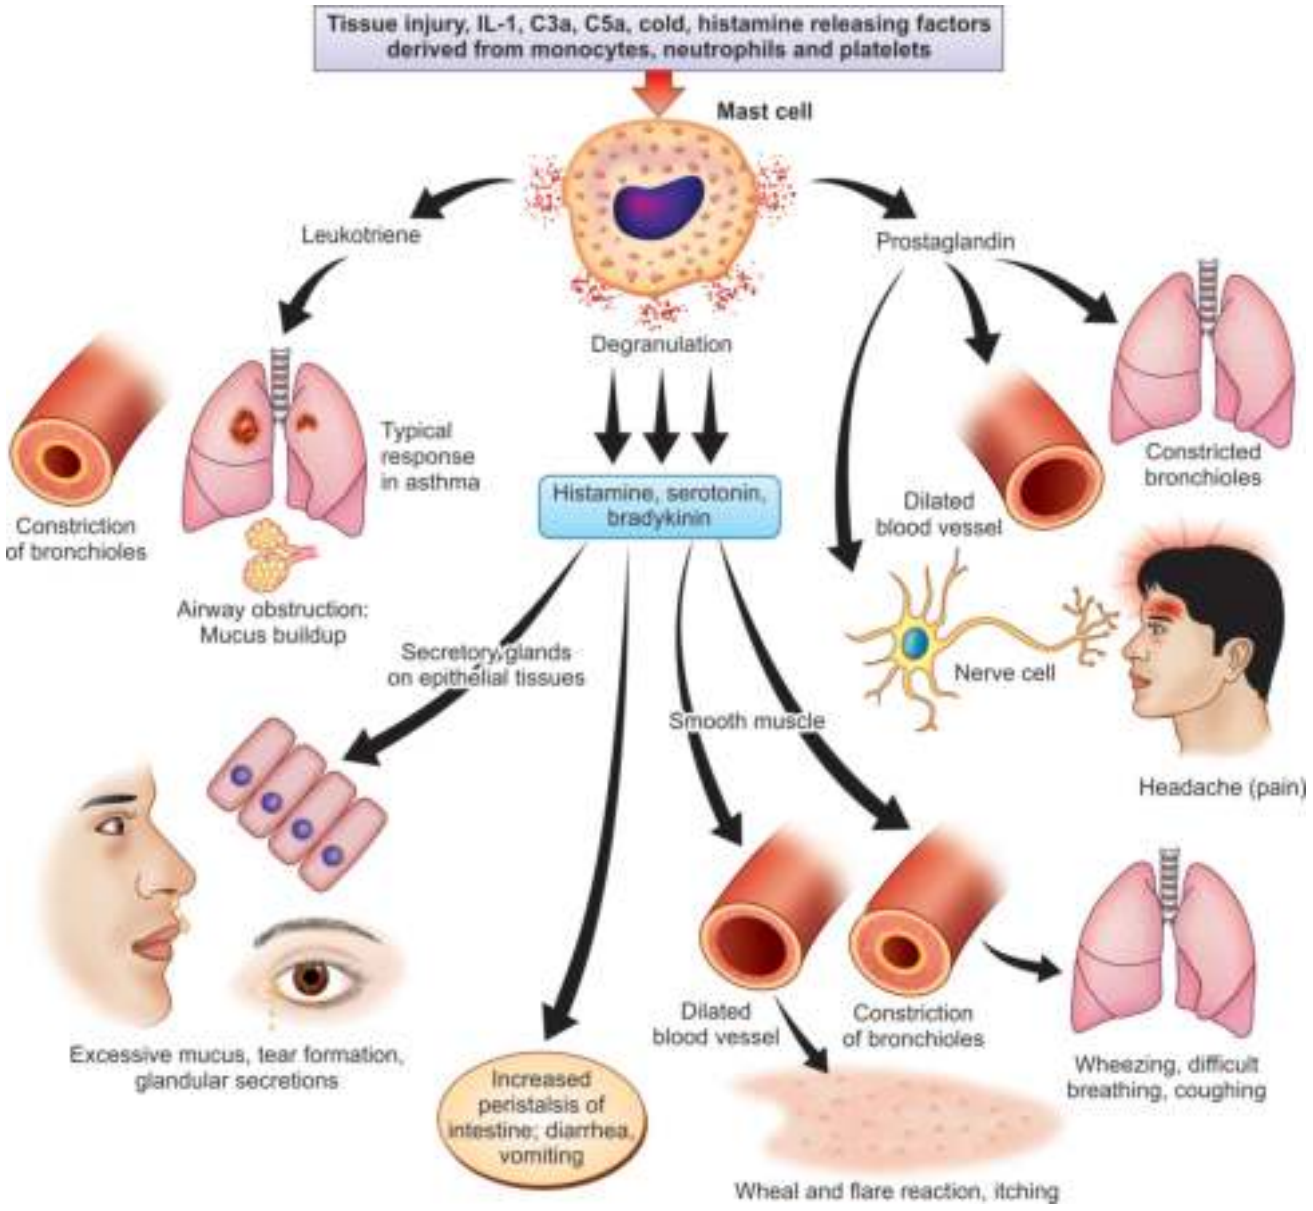

Fig. 2.26: The spectrum of reactions to inflammatory cytokines released by mast cells. These cytokines elicit overlapping extensive effects in target cells. In addition to inflammatory mediators such as histamine, prostaglandins and leukotrienes, mast cells can also synthesize wide variety of cytokines including tumor necrosis factor-α and Th2-associated cytokine such as IL-4, IL-5, IL-6, IL-10 and IL-13, which are important players in the pathogenesis of allergic reactions.

Table 2.23 Anti-inflammatory agents inhibiting cyclooxygenase pathway

Therapeutic Agents	Actions
Aspirin (NSAIDs)	Inhibiting the action of both COX1 and COX2
Meloxicam and carprofen (NSAIDs)	Inhibiting the action of COX2 without toxic effects
Glucocorticoids	Downregulating expression of gene encoding COX2 without toxic effects
Omega-3 fatty acid consumption	Serving as poor substrates for synthesizing prostaglandins

Prolonged administration of nonsteroidal anti-inflammatory drugs may increase risk of arterial thrombosis in people possibly due to reduced prostacyclin in endothelial cells.

Table 2.24 Mechanism of actions of leukotrienes and therapeutic correlation

Leukotrienes Actions	Therapeutic Agent Correlation
LTC_4, LTD_4 and LTE_4 bind to $CystLT_1$ and $CystLT_2$ receptors on bronchial smooth muscles and cause prolonged bronchospasm, increased vascular permeability, and mucus secretion of the asthmatic persons	▪ Monteleukast is used to treat bronchial asthma that blocks cysteinyl leukotrienes receptors ($CystLT_1$ and $CystLT_2$) expressed in bronchial smooth muscles ▪ Zileuton inhibits 5-lipoxygenase pathway that decreases synthesis of LTC_4, LTD_4 and LTE_4 ▪ Dietary fish rich in omega-3 fatty acid serves as poor substrates for synthesis of leukotrienes by lipoxygenase pathway ▪ Nonsteroidal anti-inflammatory drugs are not effective in inhibiting the synthesis of metabolites by lipoxygenase pathway
LTB_4 increases PMNs adhesion to endothelium and recruitment to site of tissue injury	Therapeutic correlation not applicable

Leukotrienes also participate in generation of oxygen-derived free radicals and release of lysosomal enzymes.

by inhibiting adhesion of leukocytes to endothelium as well as chemotaxis in the first few hours. Lipoxins also cause vasodilatation.

- Lipoxins transmit signal to macrophages, which phagocytose apoptotic bodies of neutrophils (programmed death).
- Lipoxins are potent anti-inflammatory chemical mediators that may have therapeutic significance.

Cytokines Synthesis

Cytokines are synthesized by activated macrophages, mast cells and endothelial cells. Cytokines usually act at short range in inflammation, which have multiple effects, such as activation of inflammatory cells resulting in degradation of injurious agents.Cytokines include interleukins, tumor necrosis factor-α, interferons (IFN-α, IFN-β, and IFN-γ), chemokines and growth factors. Cytokines chemical mediators and their actions are given in Table 2.25.

Interleukins Synthesis

Interleukins are soluble proteins synthesized by lymphocytes, monocytes–macrophages, NK cells, fibroblasts, hepatocytes and epithelial cells. Macrophages synthesize IL-1, IL-8, and IL-12. T cells synthesize IL-2, IL-3, IL-4,

Table 2.25 Cytokines chemical mediators and their actions

Source	Specific Cytokine	Actions
Interleukins		
Monocytes–macrophages, lymphocytes, dendritic cells, fibroblasts, hepatocytes and epithelial cells	▪ IL-1 ▪ IL-6 ▪ IL-8	▪ Adhesion, chemotaxis of leukocytes and phagocytosis and synthesis of acute-phase reactants by liver ▪ Synthesis of acute-phase reactants by liver ▪ Chemotaxis of leukocytes
Tumor necrosis factors		
TNF-α synthesis by macrophages, T cells, and NK cells	TNF-α	▪ Adhesion of leukocytes ▪ Synthesis of acute-phase reactants
TNF-β synthesis by T cells	TNF-β	▪ T cell proliferation ▪ Cytotoxic to some tumor cells
Interferons		
Macrophages, T cells, and NK cells	IFN-α	Antiviral activity
Fibroblasts	IFN-β	Antiviral activity
Natural killer cells (NK cells)	IFN-γ	▪ Antiviral activity ▪ Activation of macrophages and T cells during chronic inflammation ▪ Increasing cytotoxicity of natural killer cells

Contd...

Table 2.25 Cytokines chemical mediators and their actions (*Contd...*)

Source	Specific Cytokine	Actions
Chemokines: C-X-C (α), C-C (β), XC (γ) and CX3C		
Leukocytes, endothelial cells	▪ C-X-C (α) ▪ C-C (β-chemokine) ▪ XC (γ-chemokine) ▪ CX3C	▪ Chemotaxis of neutrophils ▪ Chemotaxis of monocytes ▪ Chemotaxis of lymphocytes ▪ Chemotaxis of monocytes and T cells
Growth factors: G-CSF, GM-CSF, IL-7: and IL-13		
Macrophages, neutrophils and T cells. fibroblasts and vascular endothelium	G-CSF	Activation and differentiation of neutrophils
Fibroblasts and vascular endothelium	▪ G-CSF ▪ GM-CSF	▪ Hematopoiesis ▪ Promoting the growth and development of macrophages from undifferentiated precursor stem cells ▪ Activation of natural killer cells and dendritic cells
Stromal cells in bone marrow, dendritic cells, hepatocytes, keratinocytes, neurons and epithelial cells except normal lymphocytes	IL-7	Acting as a growth factor for bone marrow stem cells
T cells	IL-13	Acting as a growth factor for bone marrow stem cells

IL-5, IL-9, IL-10, IL-13, and IL-16. Stromal cells synthesize IL-7. Interleukins mediate communications between leukocytes such as B cells, T cells, NK cells, monocytes, macrophages, hematopoietic cells and many other cell types. IL-2 and IL-4 favor lymphocytes growth. IL-10 and TGF-β disfavor lymphocytes growth. Interleukins, source and their actions are given in Table 2.26.

Table 2.26 Interleukins, source and their actions

Source	Interleukins	Actions
Chemotactic activity		
Monocytes/macrophages	▪ IL-1 ▪ IL-8	▪ Master cytokine stimulating T cells proliferation and IL-2 synthesis ▪ Adhesion of neutrophils ▪ Chemotaxis of neutrophils ▪ Phagocytosis of injurious agent by neutrophils ▪ Induces fever ▪ Chemotaxis of neutrophils
CD4+ T cells	IL-9	Chemotaxis of neutrophils and fever
T-suppressor cells and eosinophils	IL-16	Chemotaxis of T-helper cells
Synthesis of acute-phase reactants		
T cells, B cells, macrophages and fibroblasts	IL-6	Stimulating liver to synthesize acute-phase reactants
Bone marrow stromal cells	IL-11	Stimulating liver to synthesize acute-phase reactants
Synthesis of other cytokines		
T-helper cells	IL-17	Synthesis of IL-6, IL-8 G-CSF and PGE_2
Regulation of lymphocytes		
T cells, NK cells and macrophages	IL-2	▪ Stimulates proliferation of T cells, B cells (immunoglobulin synthesis), and NK cells; activates monocytes ▪ Activated natural killer cells kill of cancer cells, fungi and virally infected cells by antibody-dependent cell-mediated cytotoxicity (ADCC)
T cells	IL-4, IL-13 (Both have similar functions)	▪ IL-4 and IL-13 promoting growth of B and T cells ▪ IL-4 and IL-13 switching B cells to synthesize IgE antibody in type 1 hypersensitivity reactions ▪ IL-4 also enhancing expression of HLA class II antigens

Contd...

Table 2.26 Interleukins, source and their actions (*Contd...*)

Source	Interleukins	Actions
Specific immune response		
T cells	IL-5	▪ IL-5 promotes end-stage maturation of B cells into plasma cells ▪ Priming of basophils to release histamine and leukotrienes and chemotaxis of eosinophils in type 1 hypersensitivity reaction
T cells, B cells, macrophages and fibroblasts	IL-6	▪ Promoting maturation of B and T cells ▪ Inhibiting growth of fibroblasts ▪ Inducing synthesis of acute-phase reactants by liver ▪ Promoting mucus secretion
T cells	IL-9	Proliferation of T cells
T cells	IL-12	Activating T cells and natural killer cells
Monocytes/macrophages	IL-15	Proliferation of T cells and B cells
T cells	IL-10	Inhibiting macrophages, B cells and synthesis of interferons
Growth factors activity		
T cells	IL-3	Acting as a growth factor for tissue mast cells and hematopoietic stem cells
T cells	IL-4	Promoting growth of B and T cells; enhances expression of HLA class II antigens
Stromal cells in bone marrow, dendritic cells, hepatocytes, keratinocytes, neurons and epithelial cells	IL-7	Acting as a growth factor for bone marrow stem cells

Tumor Necrosis Factors Synthesis

Tumor necrosis factor-α (TNF-α, cachectin) is synthesized by macrophages, T cells, and NK cells, which participates in adhesion of leukocytes and synthesis of acute phase reactants in acute inflammation. Tumor necrosis factor-β (TNF-β) is synthesized by T cells, which stimulates T cell proliferation and IL-2 production. It is cytotoxic to some tumor cells. Tumor necrosis factors and their actions are given in Table 2.27.

Interferons Synthesis

Interferons (IFN-α, IFN-β, and IFN-γ) initiate an antiviral state in cells by blocking viral protein synthesis and inhibiting cell growth. When a cell is infected, its nucleus is triggered to transcribe and translate the interferon (IFN). The interferon diffuses out of the infected cells into nearby (uninfected) cells, where it enters the nucleus. IFN activates a gene for synthesizing a peptide that blocks viral replication. It is worth mentioning that IFN does not protect the original cells and that IFN prevents viruses from invading protected cells.

- Macrophages and T cells synthesize interferon-α (IFN-α). Fibroblasts synthesize interferon-β (IFN-β). Interferon-γ (IFN-γ) is synthesized by activated T cells and NK cells. Interferon-α and interferon-β activate natural killer cells. Interferon induces synthesis of antiviral molecules.
- Interferon-γ (IFN-γ) activates macrophages and T cells during chronic inflammation and enhances expression of HLA class II antigens. IFN-γ participates in differentiation of T and B cells, increases the cytotoxicity of natural killer cells, activates neutrophils and stimulates diapedesis. Human interferons (IFNs) are given in Table 2.28. Antiviral activity of interferon is shown in Fig. 2.27.

Chemokines Synthesis

- Chemokines are synthesized by macrophages and endothelial cells. Chemokines are classified into four groups according to the arrangement of the conserved cysteine (CC) residues in the mature

Table 2.27 Tumor necrosis factors and their actions

Characteristics	TNF-α	TNF-β
Principal source	▪ Macrophages ▪ T cells ▪ NK cells	T cells
Actions	▪ Adhesion of leukocytes ▪ Synthesis of acute-phase reactants	▪ T cell proliferation ▪ Cytotoxic to some tumor cells

Table 2.28 Human interferons (IFNs)

Characteristics	IFN-α	IFN-β	IFN-γ
Principal source	All cells	All cells	T lymphocytes (NK cells)
Inducing agent	Viral infection	Viral infection	Antigen
Chromosomal location of gene encoding IFN	22	1	1
Antiviral property	+++	+++	+
Macrophage action	Absent	Absent	++
MHC-I upregulation	+	+	+
MHC-II upregulation	Absent	Absent	+

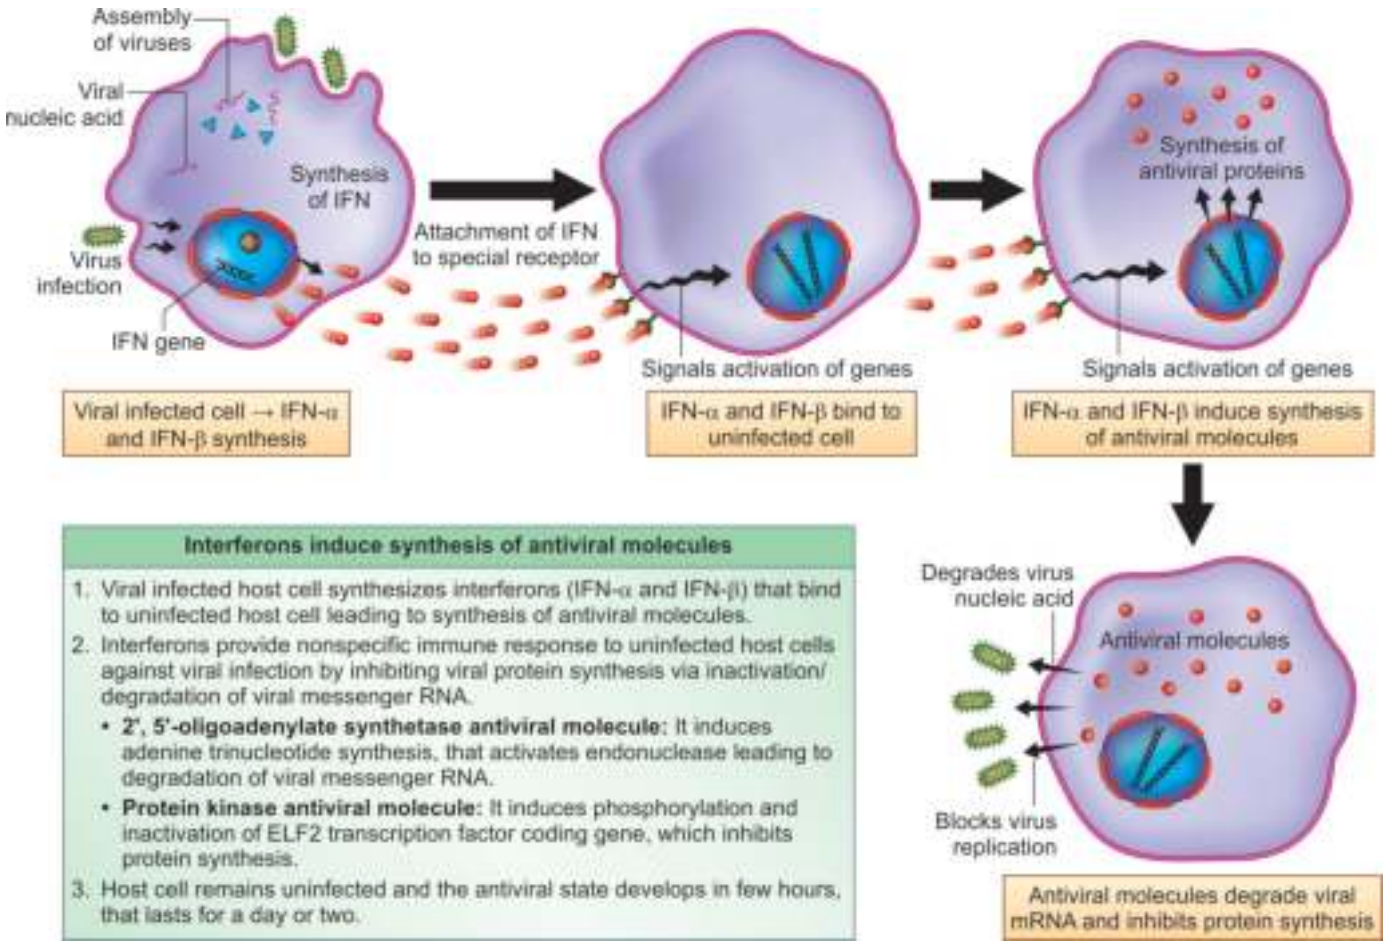

Fig. 2.27: Antiviral activity of interferon. When a cell is infected by a virus, its nucleus is triggered to transcribe interferon (IFN) gene. Interferon diffuses out of the cell and then binds to IFN receptors on nearby uninfected cells, where it induces production of proteins that eliminate viral genes and block viral replication. Note that the original cell is not protected by IFN and that does not prevent viruses from invading the protected cells.

proteins: (a) C-X-C chemokine (α-chemokine), (b) C-C chemokine (β-chemokine), (c) C chemokine (γ-chemokine) and (d) CX3C chemokine.

- Chemokines participate in recruitment of inflammatory cells (neutrophils, monocytes) to the injured site. These also increase the adhesion integrin affinity of leukocytes to ligand on vascular endothelium.
- Chemokines bind to G protein-coupled receptors and exert biological effects. HIV enters into lymphocytes via G protein-coupled receptors (CXCR4, CCR5). Other chemokines include C5a, IL-8 and platelet-activating factor. Chemokines and their actions are given in Table 2.29.

Growth Factors Synthesis

- **Interleukin-4 (IL-4):** It is synthesized by T cells, which promotes growth of B and T cells and enhances expression of HLA class II antigens.

Table 2.29 Chemokines and their actions

Specific Chemokine	Actions
C-X-C chemokine	
α-Chemokine	Activation and chemotaxis of neutrophils
***C-C chemokine (β-chemokine) examples**	
MCP-1 (monocyte chemotactic protein 1)	Chemotaxis of monocytes
RANTES (regulated and named T cell expressed and secreted)	Chemotaxis of lymphocytes
Eotaxin	Chemotaxis of eosinophils or basophils
C chemokine (γ-chemokine)	
Lymphotoxin	Chemotaxis of lymphocytes
CX3C chemokine	
Fractalkine	▪ Chemotaxis of monocytes and T cells ▪ Promoting strong adhesion of monocytes and T cells

**C-C chemokine (β-chemokine) molecule does not attract neutrophils.*

- **Interleukin-7 (IL-7):** It is synthesized by stromal cells in bone marrow, dendritic cells, hepatocytes, keratinocytes, neurons and epithelial cells except normal lymphocytes, which acts as a hematopoietic growth factor for bone marrow stem cells.
- **Interleukin-13 (IL-13):** It is synthesized by T cells, which acts as a growth factor for bone marrow hematopoietic stem cells.
- **Granulocyte colony-stimulating factor (G-CSF):** It is synthesized by macrophages, neutrophils and T cells, which participates in activation and differentiation of neutrophils.
- **Granulocyte-macrophage colony-stimulating factor (GM-CSF):** It is synthesized by fibroblasts and vascular endothelium, which participates in hematopoiesis. GM-CSF promotes the growth and development of macrophages from undifferentiated precursor stem cells. GM-CSF also activates natural killer cells and dendritic cells. Growth factors, source and their actions are given in Table 2.30.

Oxygen-derived Free Radicals Synthesis

Oxygen-derived free radicals (i.e. reactive oxygen species) play key role in microbial killing and tissue injury. Organisms killed by reactive oxygen species are given in Table 2.31.

- Injurious stimulus activates neutrophils and macrophages, which synthesize oxygen-derived free radicals via NADPH oxidase pathway (i.e. superoxide anion ($O_2^{\bullet -}$), hydrogen peroxide (H_2O_2) and hydroxyl

Table 2.30 Growth factors, source and their actions

Source	Growth Factors	Actions
T cells	IL-3	Acting as a growth factor for tissue mast cells and hematopoietic stem cells
T cells	IL-4	IL-4 promoting growth of B and T cells; enhances expression of HLA class II antigens
Stromal cells in bone marrow, dendritic cells, hepatocytes, keratinocytes, neurons and epithelial cells	IL-7	IL-7 acting as a growth factor for bone marrow stem cells
Monocytes/macrophages, neutrophils, T cells, fibroblasts and vascular endothelium	G-CSF	Activation and differentiation of neutrophils
Fibroblasts and vascular endothelium	GM-CSF	▪ Hematopoiesis ▪ Promoting the growth and development of macrophages from undifferentiated precursor stem cells ▪ Activation of natural killer cells and dendritic cells
Stromal cells in bone marrow, dendritic cells, hepatocytes, keratinocytes, neurons and epithelial cells except normal lymphocytes	IL-7	Acting as a growth factor for bone marrow stem cells
T cells	IL-13	Acting as a growth factor for bone marrow stem cells

Table 2.31 Organisms killed by reactive oxygen species

Bacteria	Fungi	Protozoa
▪ *Staphylococcus aureus* ▪ *Escherichia coli* ▪ *Serratia marcescens*	▪ *Candida albicans* ▪ Aspergillus	▪ Plasmodium ▪ *Leishmania donovani* (killed by nitric oxide)

ions (OH). Oxygen-derived free radicals combine with nitric oxide to form nitrogen intermediates.

- Oxygen-derived free radicals play an important role in microbial killing in phagolysosome and tissue injury. These cause damage to vascular endothelium resulting in increased vascular permeability. These also increase synthesis of cytokines and cell adhesion molecules, thus amplify the cascade of inflammatory mediators in acute inflammation.
- Serum, tissue fluids and host cells possess antioxidant mechanisms that protect against these potentially harmful oxygen-derived free radicals. These antioxidants include: (a) ceruloplasmin—copper binding serum protein, (b) transferrin—iron-free fraction of serum, (c) superoxide dismutase enzyme, (d) catalase—H_2O_2 detoxifier and (e) glutathione peroxidase—another powerful H_2O_2 detoxifier.

Nitric Oxide Synthesis

Nitric oxide (NO) is a free radical soluble gas synthesized and released by macrophages and vascular endothelium during conversion of arginine to citrulline by NO synthase. Actions of NO are shown in Fig. 2.28. Mechanism of action of nitric oxide on target cells is given in Table 2.32.

- **Physiologic state:** Nitric oxide, which was previously known as endothelium-derived relaxing factor. It is a free radical soluble gas synthesized in low concentration, which has half-life of seconds (short lived) *in vivo*. Nitric oxide synthase enzyme converts L-arginine to citrulline resulting in release of nitric oxide in vascular endothelium (endothelial inducible nitric oxide—eNO), macrophages (macrophage-inducible iNO) and neurons (nuron inducible nNO).
- **Pathologic state:** During acute inflammation, inflammatory cytokines (IL-1, TNF-α and IFN-γ) and bacterial endotoxin participate in synthesis of nitric oxide.
  - Calcium influx in vascular endothelium and neurons stimulates nitric oxide synthase enzyme resulting in synthesis of nitric oxide. TNF-α and IFN-γ stimulate macrophage-inducible synthase enzyme to synthesize nitric oxide.

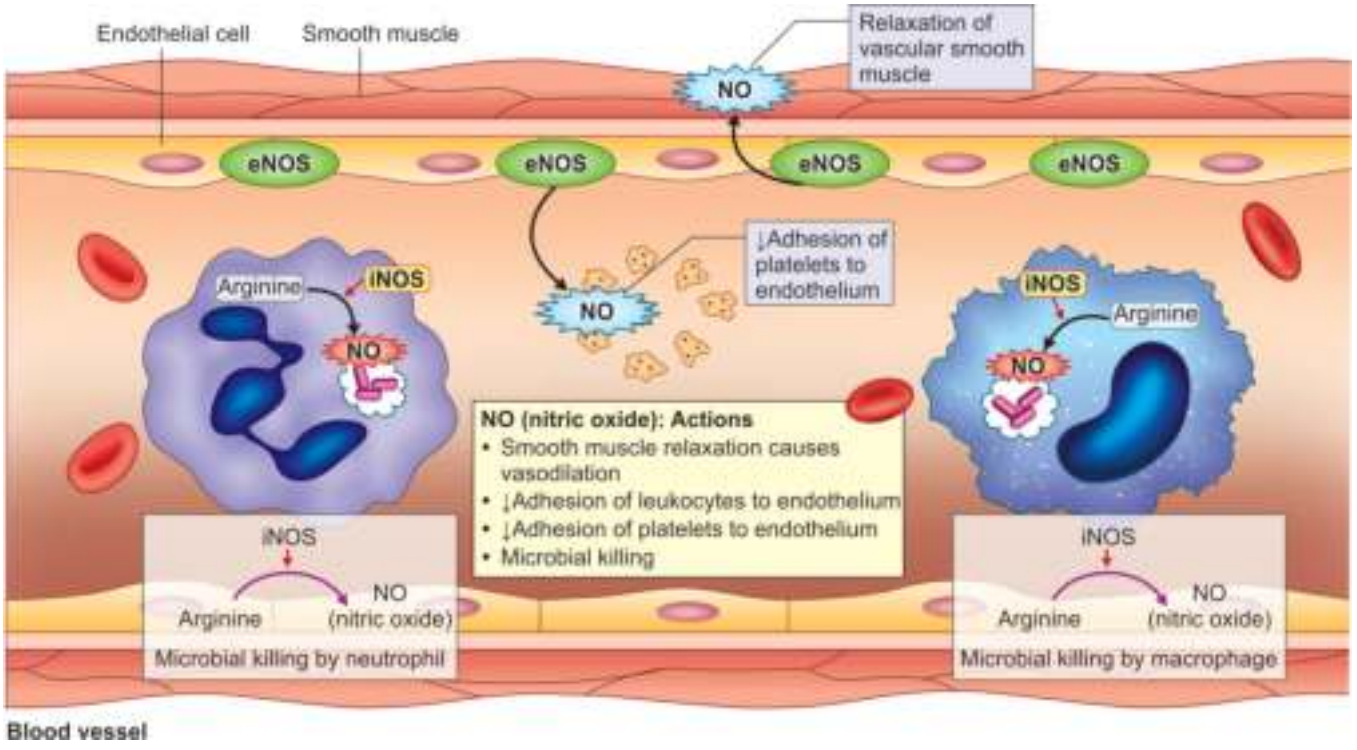

Fig. 2.28: Actions of nitric oxide. Nitric oxide is produced by vascular endothelium and macrophages. Nitric oxide causes vasodilatation and degradation of microbes, inhibits platelets aggregation and thus prevents thrombus formation. Sustained synthesis of nitric oxide in patient with septicemia results in hypotensive shock.

Table 2.32 Mechanism of action of nitric oxide on target cells

Target Organs	Action
Blood vessels	▪ Vasodilatation by relaxation of smooth muscle cells ▪ Hypotensive shock in septic patients
Leukocytes	Decreasing adhesion of leukocytes to vascular endothelium
Platelets	▪ Inhibits platelets aggregation and degranulation ▪ Preventing thrombus formation
Brain	Regulation of neurotransmitter by increasing blood flow to brain
Microbes	Killing of microbes (nitric oxide derived reactive oxygen metabolites toxic to microbes)
Tumor cells	Killing of tumor cells by macrophages

- Nitric oxide acts in paracrine manner on target cells through induction of cyclic guanosine monophosphate (GMP), which initiates intracellular events. Nitric oxide and platelet-activating factor (PAF) have opposite action.

Platelet-activating Factor Synthesis

Platelet-activating factor (PAF) is cell membrane phospholipids synthesized by platelets, mast cells/basophils, neutrophils, macrophages, monocytes, endothelial cells, and vascular endothelium.

- Platelet-activating factor acts via G protein-coupled receptor and can elicit most of the cardinal features of inflammation. Platelet-activating factor and nitric oxide have opposite action.
- Platelet-activating factor increases vascular permeability, smooth muscle contraction of bronchioles (bronchoconstriction), pulmonary edema, hypotension, and wheal and flare in the skin. PAF kills bacteria and tumor cells. PAF enhances leukocyte adhesion, chemotaxis, leukocyte degranulation and the oxidative burst. PAF also stimulates the synthesis of other chemical mediators, particularly eicosanoids.
- Physiologic actions of platelet-activating factor and histamine are similar. Platelet-activating factors and their functions are given in Table 2.33. Differences between nitric oxide and platelet-activating factor are given in Table 2.34.

Neuropeptides Synthesis

Neuropeptides are small proteins synthesized by nerve fibers mainly in lungs and gastrointestinal tract. Neuropeptides are related to kinin family.

Table 2.33 Platelet-activating factors and their functions

Platelet-activating Factor	Functions
Mast cells/basophils derived PAF	▪ Increases vascular permeability leading to edema ▪ Vasoconstriction
Endothelial derived PAF	Priming and chemotaxis of leukocytes
Neutrophils derived PAF	▪ Increasing leukocyte adhesion to endothelium by integrin mediated mechanism ▪ Chemotaxis, degranulation and oxidative burst of leukocytes ▪ Enhances synthesis of eicosanoids by leukocytes
Monocytes/macrophages derived PAF	Adhesion of leukocytes of vascular endothelium
Platelets derived PAF	▪ Platelets aggregation ▪ Thrombus formation

Platelet-activating factor is more potent mediator than histamine.

Table 2.34 Differences between nitric oxide and platelet-activating factor

Characteristics	Nitric Oxide	Platelet-activating Factor
Blood vessels	Vasodilatation	Vasoconstriction and increased vascular permeability
Leukocytes	Inhibits leukocyte recruitment	Enhances chemotaxis, degranulation and oxidative burst
Platelets	Inhibits platelet aggregation	Enhances platelet aggregation
Killing of microbes/tumor cells	Absent	Present
Respiratory bronchi/ bronchioles	No effect	Bronchospasm

- Neuropeptides and bradykinin have similar functions. Neuropeptide synthesis is activated by capsaicin (chiles), which transmits pain signals, regulates blood pressure, modulates vascular permeability; and stimulates secretion of endocrine cells.
- Neuropeptides also synthesize other proinflammatory molecules, which are thought to link the sensing of dangerous stimuli to development of protective host responses. Neuropeptides and their actions are given in Table 2.35.

Hypoxia-inducible Factor Synthesis

Hypoxia-inducible factor-α (HIF-α), a protein released from injured cells, mediates cell injury and inflammatory response. HIF-α activates many genes involved in inflammation, including VEGF, which increases vascular permeability. Local and systemic effects of chemical mediators are given in Table 2.36.

MORPHOLOGIC PATTERNS OF ACUTE INFLAMMATION

Vascular and cellular responses in acute inflammation produce distinctive morphologic patterns in various tissues. Location, cause, and duration of inflammation determine the morphology of an inflammatory reaction. Reactive gliosis is a normal response of the brain to injury and infection but is not visible on the cut surface of the brain at autopsy. Morphologic patterns of acute inflammation are described below.

SEROUS INFLAMMATION

Serous inflammation is a type of acute inflammation characterized by the copious effusion of non-viscous serous fluid, commonly produced by cells of serous membranes but may be derived from blood plasma.

Table 2.35 Neuropeptides and their actions on nerves in lungs and gastrointestinal tract

Transmission of pain signals
Regulation of blood pressure
Modulation vascular permeability
Stimulation of secretion of endocrine cells
Synthesis of other proinflammatory molecules, which are thought to link the sensing of dangerous stimuli to that development of protective host responses

- **Serous inflammation of coelomic cavities:** Serous inflammation occurs in coelomic cavities (e.g. pleural, pericardial and peritoneal cavities) and skin. Serous fluid is yellow and straw colored with scant cells, which is either derived from plasma proteins or secretion of mesothelial cells of serous cavities. Tissue looks dull engorged with blood vessels.
- **Skin blisters:** Skin blisters are caused by burns and viral infection. Serous fluid is accumulated either within or immediately beneath the epidermis of the skin.

FIBRINOUS INFLAMMATION

Deposition of fibrin-rich exudates in meninges and coelomic surfaces (pleura, pericardium and peritoneum) is known as fibrinous inflammation, which occurs as a result of increased vascular permeability due to acute inflammation and malignancy leading to extravasation of fibrinogen over coelomic surfaces. Surface of the heart is covered by shaggy fibrinous exudates giving 'bread and butter' appearance. Fibrinous exudate may be removed by fibrinolysis. Cellular debris is cleared by macrophages. When fibrin is not removed, it may stimulate the growth of fibroblasts and capillaries and thus leading to organization (fibrous strands) and obliteration of the pericardial sac.

Table 2.36 Local and systemic effects of chemical mediators

Local and Systemic Effects	Chemical Mediators
Increased vascular permeability and edema	Histamine, anaphylatoxins (C3a, C5a), bradykinin, leukotrienes (LTC_4, LTD_4, and LTE_4), nitric oxide, platelet-activating factor and neuropeptide (substance P)
Vasodilatation	Histamine, serotonin, bradykinin, platelet-activating factor, nitric oxide
Vasoconstriction	LTC_4, LTD_4, LTE_4, TXA_2
Adhesion of neutrophils to endothelium	C5a, LTB_4, IL-1, TNF-α, chemokines and platelet-activating factor
Chemotaxis of leukocytes and their activation	C5a, LTB_4, IL-1, TNF-α, chemokines and bacterial products
Pain	Prostaglandins, bradykinin, and neuropeptides (substance P)
Fever	Prostaglandins, IL-1 acting on hypothalamic thermoregulatory centers
Bronchoconstriction	Histamine and leukotrienes
Tissue damage	Lysosomal enzymes, oxygen-derived free radicals, hypochlorous acid, prostaglandins, leukotrienes, and nitric oxide

PURULENT (SUPPURATIVE) INFLAMMATION

Pyogenic bacteria such as staphylococci cause liquefactive necrosis of tissue leading to formation of opaque pus due to excessive production of exudate. Pus contains cellular debris derived from damaged tissue and polymorphonuclear cells. The destroyed tissue is restored and eventually replaced by fibrosis. Patient presents with pain induced by bradykinin and edema fluid. Complications of purulent (suppurative) inflammation include thrombophlebitis, massive bacteremia, and septic shock, embolization to various solid organs producing septic infarcts, lymphangitis and lymphadenitis.

- **Abscess in organs:** Abscesses in various organs include skin abscess, brain abscess, pyogenic meningitis, lung abscess, lobar pneumonia, bronchopneumonia, splenic abscess, breast abscess, empyema gall bladder and acute appendicitis. There is danger of perforation of suppurative acute appendicitis; hence early appendectomy is the treatment of choice. Multiple splenic abscess is shown in Fig. 2.29. Histology of acute appendicitis is shown in Figs 2.30 and 2.31. Histology of acute lymphadenitis is shown in Fig. 2.32. Histology of lobar pneumonia is shown in Fig. 2.33.

Fig. 2.29: Splenic abscesses. Splenic abscesses are most commonly seen as complications of infective endocarditis caused by streptococci and staphylococci, which occur in 5% of patients. Splenic abscesses can have a fatal outcome, healing of abscesses or chronic clinical course. (*Courtesy:* Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru, Karnataka).

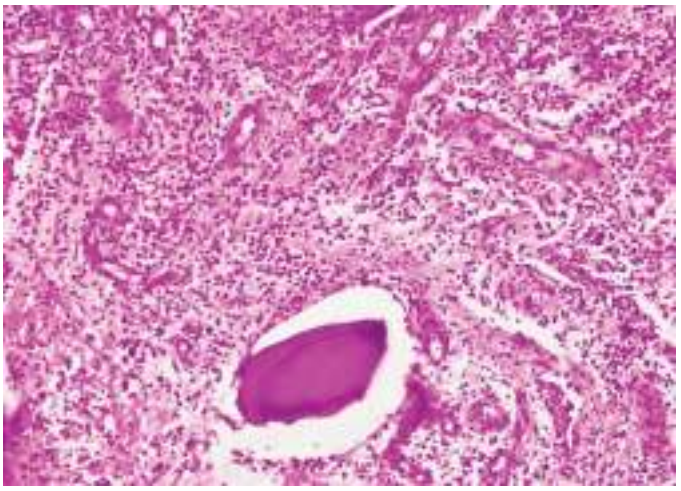

Fig. 2.30: Histology of acute appendicitis. Pathognomonic feature of acute appendicitis on histopathology is predominantly neutrophilic infiltration in muscular coat or all layers of appendix (400X).

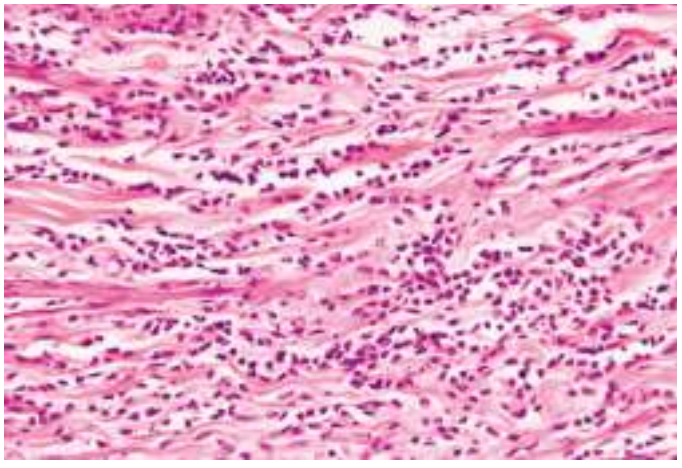

Fig. 2.31: Histology of acute appendicitis. Pathognomonic feature of acute appendicitis on histopathology is predominantly neutrophilic infiltration in muscular coat or all layers of appendix. Pathogenesis includes obstruction of appendiceal orifice and subsequent bacterial infection. Most common symptom is periumbilical pain radiating to the right lower quadrant. On clinical examination, there may be rebound tenderness and percussion pain over McBurney point and guarding (400X).

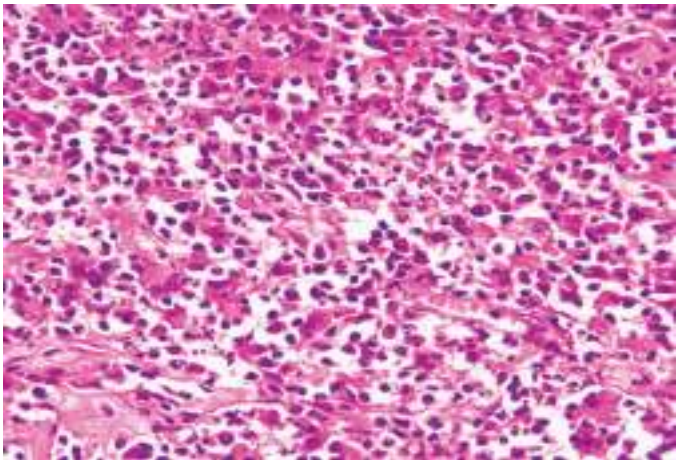

Fig. 2.32: Histology of acute nonspecific lymphadenitis. Acute nonspecific lymphadenitis most commonly affects children in cervical region caused by bacterial infection. Children present with enlarged, painful and tender lymph nodes, redness on overlying skin, low-grade fever and malaise. Microscopic examination of lymph node, is performed will show sinus dilatation followed by accumulation of polymorphonuclear cells, vascular dilatation and edema of the capsule (400X).

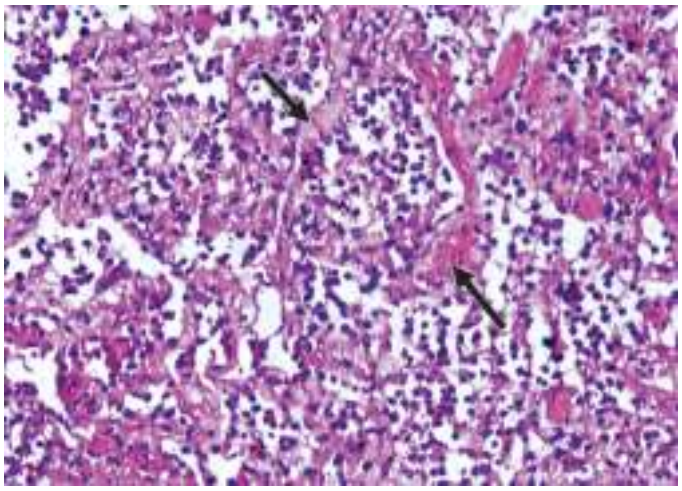

Fig. 2.33: Histology of lobar pneumonia in congestion stage. Lobar pneumonia has four stages: congestion, red hepatization, grey hepatization and resolution. Congestion stage occurs in the first 24 hours, that is characterized histologically by vascular congestion, intra-alveolar fluid, small number of neutrophils, often numerus bacteria. Gross examination reveals heavy and hyperemic lung (arrows) (400X).

- **Cellulitis:** Cellulitis refers to acute diffuse suppurative inflammation caused by streptococci, which synthesize hyaluronidase and streptokinase enzymes that dissolve the ground substances and facilitate the spread of infection in areolar tissue of orbit, pelvis, and subcutaneous tissue.
- **Carbuncle:** Carbuncle is an extensive form of abscess in the back of the neck and scalp due to collection of pus in multiple loci. Patient presents with multiple discharging sinuses at the surface.
- **Furuncle or boil:** Furuncle or boil is small abscess related to hair follicles or sebaceous glands.

PSEUDOMEMBRANOUS INFLAMMATION

Pseudomembrane formation is the term for an acute inflammatory process, in which there is overlay of fibrin and debris on mucous membrane. Deposition of yellow-colored exudate over mucosal surfaces produces a shaggy membrane composed of necrotic tissue. *Corynebacterium diphtheriae* liberates toxin, which forms pseudomembrane in the pharynx and trachea of children leading to severe respiratory distress. *Clostridium difficile* toxin in adults produces pseudomembranous colitis.

HEMORRHAGIC INFLAMMATION

Hemorrhagic inflammation is characterized by bleeding within or around the pancreas. It is usually a complication of acute pancreatitis. Intrapancreatic activation of pancreatic enzymes causes acute inflammation and necrosis of pancreatic parenchyma, pancreatic fat and blood vessel. Patient presents with upper abdominal pain radiating to back, tenderness, fever, nausea, vomiting and rapid pulse.

GANGRENOUS INFLAMMATION

Gangrenous inflammation is seen in ischemic necrosis with superadded bacterial infection in appendix and intestine, which results in partial liquefaction of the tissues by lytic activity of bacteria and inflammatory cells in the affected tissue. Gangrenous inflammation needs to be treated immediately, because it spreads quickly and can be fatal.

CATARRHAL INFLAMMATION

Catarrhal inflammation involves mucosal surfaces (e.g. catarrhal rhinitis, catarrhal conjunctivitis) containing mixture of serous and mucous secretions. Catarrhal inflammation is characterized by increased blood flow to the mucosal blood vessels, edema of the interstitial tissue, and enlargement of the secretory epithelial cells and profuse discharge of mucus and epithelial debris.

OUTCOME OF ACUTE INFLAMMATION

Acute inflammation may have one of the following outcomes (complete resolution, pus formation, fibrosis, and progression to chronic inflammation). Outcome of acute inflammation is shown in Fig. 2.34.

COMPLETE RESOLUTION

Resolution of normal structure and function of tissue occurs without scarring, if the injurious agent is eliminated. Lymphatics and macrophages play central role in complete resolution of acute inflammation (e.g. restoration of structure and function of tissue without scarring).

- Complete resolution occurs with mild injury (bee sting or first-degree burns) to those cells, which are capable to enter the cell cycle (e.g. labile and stable cells). Neutrophil cells start disappearing as a result of apoptosis from injury site. Leukotrienes undergo decay after neutralizing the injurious agent. Normalization of vascular permeability occurs.
- Macrophages phagocytose necrotic cellular debris and apoptotic neutrophils leading to removal from injured site. Edema fluid and proteins are finally drained into the lymphatics. Injured cells with intact supporting stroma undergo regeneration (e.g. labile and stable cells) with restoration of normal structure and function.

TISSUE DESTRUCTION

Oxygen-derived free radicals released by mononuclear cells are injurious to the own tissues as well as invading agents.

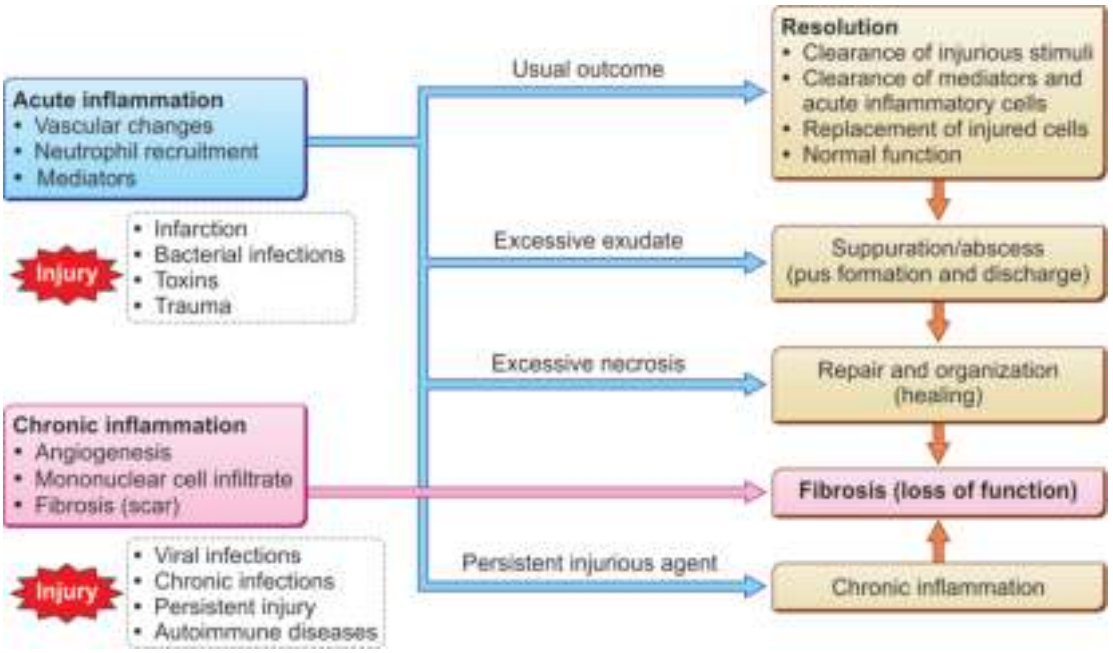

Fig. 2.34: Outcome of acute inflammation. The outcome depends on the type of tissue involved and the amount of tissue destruction has occurred, which are in turn related to the cause of the injury. Outcome of inflammation includes complete resolution by clearance of injurious agent, chemical mediators and replacement of injured cells, suppuration, healing by fibrosis and scar formation, loss of function and chronic inflammation.

- **Skin ulcer:** Loss of surface epithelium or skin results in ulcer formation, which can be caused by acute inflammation of epithelial surfaces (e.g. ulcer of the skin and peptic ulcer).
- **Abscess:** Production of large amounts of thick yellow pus or purulent exudate (PMN cells) by pyogenic bacteria such as *Staphylococcus aureus* is accompanied by significant liquefactive necrosis. The destroyed tissue is restored and eventually replaced by fibrosis.
- **Suppurative fistula:** Suppurative fistula is an abnormal communication between two organs or between an organ and a surface due to suppurative infection.
- **Gastric and duodenal ulcers:** Histologic examination of gastric shows focal destruction of the mucosa and full-thickness replacement of the muscularis with collagen-rich connective tissue.
  - Gastric ulcers are usually single and less than 2 cm in diameter and deep, with its floor covered by debris and neutrophils. Beneath to the ulcer is present in the granulation tissue and dense fibrosis replacing muscle coat. Ulcers on the lesser curvature are commonly associated with chronic gastritis, whereas those on the greater curvature are often related to nonsteroidal anti-inflammatory drugs (NSAIDs).
  - Grossly, chronic peptic ulcers may closely resemble gastric carcinoma. Peptic ulcer may heal by regeneration of mucosa close to its edge. Peptic ulcer may perforate involving full thickness of the wall. Chronic peptic ulcer may persist for years.
  - Therefore, the endoscopist must take multiple biopsies from the edges and bed of any gastric ulcer. Although contraction and scarring of gastric ulcers may occur leading to pyloric stenosis.

PROGRESSION TO CHRONIC INFLAMMATION

Persistent or recurrent acute infection greater than 48 hours progress to chronic inflammation, which occurs when host response fails to degrade the injurious agent (e.g. pathogen, tissue debris and foreign bodies) that incites gradual onset of inflammatory reaction. Chronic inflammation usually occurs as *de novo*, without a preceding acute inflammation.

- Chronic inflammation is characterized by disappearance of neutrophils from the injury site; followed by influx of mononuclear cells (e.g. macrophages, lymphocytes and plasma cells), angiogenesis and fibrosis in the injured tissue. Plasma cells produce immunoglobulins. Some of the macrophages may become multinucleated giant cells.
- Fibroblasts migrate into the injured area and lay down collagen fibers. Consequently, chronic inflammation is almost always accompanied by tissue destruction.

HEALING BY FIBROSIS

Healing by fibrosis is the final result of tissue destruction, with resultant distortion of structure and, in some cases, altered function. Growth factors synthesized by macrophages initiate the subsequent process of repair forming scar composed of primarily of collagen fibers. The scar does not contain parenchymal cells, hence functional impairment may occur.

- **Third degree burns:** Third degree burns occur with extensive injury or damage to permanent cells, which are incapable to regenerate. Fibrous scarring occurs in the areas of damage, forming a scar composed primarily of collagen, which leads to functional impairment of tissue.
- **Fibrinous exudate organization:** Organization occurs in fibrinous inflammation seen in coelomic cavities (pericardium, pleura and peritoneum), in which excessive fibrinous exudates cannot be cleared. Coelomic cavities are organized by growing of capillary loops into the exudates accompanied by fibroblasts and capillaries forming adhesions. Mass of fibrous tissue is called organization.

ANTI-INFLAMMATORY THERAPEUTIC AGENTS

The acute inflammatory response can be treated with anti-inflammatory drugs, which can prevent production of key chemical mediators of inflammation. Phospholipase A2 activity is inhibited by corticosteroids, limiting the production of arachidonic acid and, therefore, the formation of arachidonic acid metabolites. Anti-inflammatory therapeutic agents can be directed at many targets along the eicosanoid biosynthetic cyclooxygenase and lipoxygenase pathways. Anti-inflammatory agents inhibiting cyclooxygenase pathway are given in Table 2.37.

- **Cyclooxygenase pathway:** Various anti-inflammatory therapeutic agents are used to inhibit the action of COX-1 and COX-2 (cyclooxygenase pathway). COX-2 inhibitor drugs produce less toxicity than COX-1 inhibitors.
  - **Nonselective therapeutic agents:** NSAIDs such as aspirin inhibit the action of both COX-1 and COX-2 responsible for blocking production of prostaglandins.
  - **Selective anti-inflammatory therapeutic agents:** Meloxicam and carprofen inhibit the action of COX-2 without toxic effects. Prolonged administration may increase risk of arterial thrombosis in people possibly due to reduced prostacyclin synthesis in endothelial cells, while sparing of COX-1 mediated production of TXA_2 in platelets.
- **Lipoxygenase pathway:** 5-Lipoxygenase pathway is not affected by nonsteroidal anti-inflammatory drugs (NSAIDs). Pharmacological agents such as monteleukast are used to inhibit leukotrienes synthesis or block leukotrienes receptors (e.g. $CystLT_1$ and $CystL_2$), which are useful in the treatment of bronchial asthma. Zileuton inhibits 5-lipooxygenase and thus decreasing synthesis of LTC_4, LTD_4 and LTE_4.
  - **Glucocorticoids:** Glucocorticoids are broad spectrum powerful anti-inflammatory agents, which downregulate expression of genes encoding phospholipase A2, COX-2, proinflammatory cytokines (IL-1 and TNF-α) and nitric oxide synthase. Glucocorticoids also upregulate genes that encode potent anti-inflammatory protein such as lipocortin 1.
  - **Omega-3 fatty acid consumption:** Fish oil is a source of omega-3 fatty acid. Consumption of fish oil (omega-3 fatty acid) may modify inflammatory response. Omega-3 fatty acid serves as poor substrates for synthesizing prostaglandins (cyclooxygenase pathway) and leukotrienes (lipoxygenase pathway). In contrast, omega-3 fatty acid serves as excellent substrate for the synthesis of anti-inflammatory products (e.g. resolvins and protectins).

Table 2.37 Anti-inflammatory agents inhibiting cyclooxygenase pathway

Therapeutic Agents	Actions
Aspirin (NSAID)	Inhibiting the action of both COX-1 and COX-2
Meloxicam and carprofen (NSAIDs)	Inhibiting the action of COX-2 without toxic effects
Glucocorticoids	Down regulating expression of gene encoding COX-2 without toxic effects
Omega-3 fatty acid consumption	Serving as poor substrates for synthesizing prostaglandins

Prolonged administration of nonsteroidal anti-inflammatory drugs may increase risk of arterial thrombosis in people possibly due to reduced prostacyclin in endothelial cells.

CHRONIC INFLAMMATION

Chronic inflammation is an immune reaction to persistent and recurrent injury greater than 48 hours to weeks or months or years. It occurs when host response fails to degrade the injurious agent (e.g. pathogen, tissue debris and foreign bodies) that incites gradual-onset of inflammatory reaction, tissue destruction and attempts tissue repair.

- Chronic inflammation usually occurs as *de novo*, without a preceding acute inflammation. Mononuclear cells (macrophages, lymphocytes, plasma cells) predominate in chronic inflammation. Macrophages accumulate at the site of chronic inflammation as a result of continued recruitment and local proliferation.
- Chronic inflammation occurs in two major histologic patterns: chronic nonspecific inflammation and granulomatous inflammation.
- Granuloma is an aggregation of epithelioid histiocytes surrounded by rim of lymphocytes, plasma cells and fibroblasts. There are two types of granulomas: foreign body granuloma and immune granuloma.
- A nonabsorbable suture left in the body over a long time produces foreign body granuloma. Immune granuloma with central necrosis is seen in tuberculosis.
- Granulomatous inflammation is a pattern of chronic inflammation defined by the presence of granulomas.

COMMON CAUSES OF CHRONIC INFLAMMATION

Chronic inflammation occurs due to persistent infectious agents, prolonged exposure to potentially toxic agents and autoimmune disorders.

- **Progression of acute inflammation:** Persistent acute inflammation period can progress to chronic inflammation accompanied by tissue destruction. Pneumonic focus can induce extensive destruction and cavity formation resulting in extensive fibrosis. Peptic ulcer disease is manifested by acute and chronic inflammatory reactions.
- **Persistent infection:** Chronic inflammation occurs due to persistent infection for longer period by microorganisms with low-virulence resisting elimination by neutrophils resulting in delayed hypersensitivity reaction. Causative organisms include Mycobacterium tubercle bacilli, *Mycobacterium leprae* bacilli, *Treponema pallidum*, cat-scratch disease, fungi, brucellosis, and viruses. All these pathogens cause granulomatous inflammation except brucellosis and viral infections. Later two organisms resist phagocytosis and intracellular killing, but granulomas are absent.
- **Prolonged exposure to potentially toxic agents:** Prolonged exposure to exogenous and endogenous toxic substances may cause chronic inflammation. Exogenous toxic agents inducing chronic inflammation include suture materials, implanted prosthesis, asbestos fibers, silicosis or berylliosis. Necrotic adipose tissue and bone, and uric acid crystals (gouty tophus) are endogenous toxic materials that cause chronic inflammation.
- **Autoimmune disorders:** Autoimmunity is altered long-standing immune response to self-antigens that can result in chronic tissue damage in various organs. Autoimmunity can occur in the settings of Hashimoto's thyroiditis, pernicious anemia, rheumatoid arthritis, contact hypersensitivity reaction (exposure to nickel), ulcerative colitis, Crohn's disease and sarcoidosis.

ESSENTIAL MORPHOLOGIC FEATURES OF CHRONIC INFLAMMATION

Essential morphologic features in chronic inflammation include: (a) disappearance of neutrophils and appearance of mononuclear cells (e.g. macrophages, T cells, B cells, and plasma cells) causing tissue destruction, (b) formation of granulation tissue (proliferation of fibroblasts and angiogenesis), and (c) proliferation of fibroblasts with collagen fibers production leading to tissue fibrosis. Macrophage is the key cell that directs the various cells involved in chronic inflammation. Macrophages play an important role in removal of dead polymorphonuclear cells, presentation of antigenic material and granuloma formation.

MONONUCLEAR CELLS INFILTRATE

Chronic inflammation is characterized by a predominantly mononuclear inflammatory infiltrate composed of macrophages, lymphocytes and plasma cells along with few neutrophils. Mononuclear cells interact dynamically over the course of chronic inflammation. Macrophages are present in higher numbers replacing neutrophils. CD4+ helper T cells predominate in the chronic inflammatory infiltrate. CD8+ cytotoxic T cells are diminished in number.

TISSUE DESTRUCTION

Tissue destruction occurs due to persistent infection that leads to loss of organ function, and healing by fibrosis. Inappropriate activation of macrophages causes tissue destruction in chronic inflammation. Some of the macrophages may become multinucleated giant cells. Fibroblasts migrate into the injured area and lay down collagen.

- Necrotic tissue also stimulates leukocytes to release cell derived chemical mediators. Necrotic cells also activate plasma derived chemical mediators (kinin system, coagulation system, complement system and fibrinolytic system).
- Necrosed cells liberate uric acid at persisting injurious agent. In cellular immune reactions, T cells may directly kill cells. This ongoing tissue destruction can activate the inflammatory cascade by diverse mechanisms, so that features of both acute and chronic inflammation may coexist in certain circumstances.

TISSUE HEALING BY FIBROSIS

Tissue healing occurs by connective tissue replacement of damaged tissue by formation of highly vascular granulation tissue composed of newly formed blood vessels and myofibroblasts (activated fibroblasts) and some inflammatory cells that replace a fibrin clot. Granulomas are not present in granulation tissue. Fibronectin is required for granulation tissue formation. Fibronectin is a cell adhesion glycoprotein which binds collagen, fibrin, and cell surface receptors (e.g. integrins).

- **Angiogenesis:** Angiogenesis is a process of new blood vessels from existing blood vessels by pro-angiogenic factor (VEGF, FGF). It is essential in tissue development, reproduction, and wound healing. Angiogenesis occurs by mobilization of endothelial precursor cells (EPCs) from bone marrow and preexisting blood vessels at the site of injury. Chemotactic factors recruit endothelial cells from preexisting blood vessels to form new blood vessels (angiogenesis).
- **Collagen fibers synthesis:** Growth factors (PDGF, EGF, TGF-α, FGF-β, IGF-1, IL-1 and TGF-β) synthesized by macrophages participate in migration of fibroblasts, their proliferation, and synthesis of collagen fibers in early wound healing (3–5 days). Collagen fibers are the most abundant proteins in the body, which form the major structural component of many organs. Collagen fibers provide tensile strength of healing wounds. Fibrogenic cytokines synthesized by macrophages serve to eliminate injurious agents, and enhance process of tissue repair in chronic inflammation.

CELLS INVOLVED IN CHRONIC INFLAMMATION

Chronic inflammation is characterized by a predominantly mononuclear cell infiltrate (includes monocytes/macrophages, lymphocytes, plasma cells) with a few neutrophils present. Other cells include dendritic cells and eosinophils, tissue fibroblasts and endothelial cells. Neutrophils and macrophages originate from the bone marrow and serve as antigen presenting cells, which are professional phagocytes involved in the innate immunity. Macrophages detect and phagocytose pathogens enhance inflammation and promote tissue repair. Some important cells involved in chronic inflammation are given in Table 2.38.

MONOCYTES/MACROPHAGES

Macrophages are present in acute and chronic inflammation. Monocytes/macrophages are the dominant player of chronic inflammation. Monocytes begin to emigrate into extravascular tissues quite early in acute inflammation. In chronic inflammation, macrophage accumulation persists as a result of continuous recruitment from the circulation and their local proliferation at the site of inflammation. Macrophages regulate lymphocyte responses to antigens and secrete a variety of chemical mediators that modulate the proliferation and function of fibroblasts and endothelial cells.

Macrophage Origin and Distribution

Mononuclear phagocytes (monocytes/macrophages) are derived from a common precursors in the bone marrow, which give rise to monocytes. Blood monocytes migrate and differentiate into tissue macrophages known as reticuloendothelial cells diffusely distributed in the connective tissues in various organs. Macrophages have different names in different tissues, e.g. macrophages in connective tissue, alveolar macrophages in lung, mesangial cells in kidneys, sinus histiocytes in lymph node, Kupffer cells in liver, littoral cells in spleen, microglial cells in brain, osteoclasts in bone, lipophages in adipose tissue. Reticuloendothelial cells distribution in various tissues are depicted in Fig. 2.35 and Table 2.39.

Macrophage Receptors

Some macrophage receptors such as mannose and glucan and scavenger receptors bind cell-wall carbohydrates of bacteria, fungi and yeast. **Toll-like receptors** (TLRs) are present on macrophages, dendritic cells and other immune cells, which recognize different microbial components.

- TLR1, TLR2 and TLR6 recognize lipid and carbohydrates of gram-positive bacteria. TLR3, TLR7, TLR8

Table 2.38 Some important cells involved in chronic inflammation

Immune Cell	Functions	
Reticuloendothelial cell		
Monocyte/macrophage	▪ Antigen-presenting cell (APC) ▪ Phagocytosis and elimination of microorganisms ▪ IL-1 synthesis that activates T cells	▪ Monocyte life span 1–3 days in peripheral blood ▪ Macrophage life span months to years in tissues
T lymphocytes		
T helper cell (Th1)	▪ IL-2 and interferon-γ (IFN-γ) synthesis	▪ Activate macrophages and cytotoxic T cells
T helper cell (Th2)	▪ IL-4 and IL-6 synthesis	▪ B cell activation
T regulatory cell (Treg)	▪ T regulatory cell (Treg) suppresses immune response by inhibiting T cell proliferation and cytokine production	▪ T regulatory cell (Treg) maintains homeostasis and self-tolerance ▪ T regulatory cell (Treg) prevents autoimmunity
Memory T cell	▪ Memory T cell protects against previously encountered pathogen	▪ On re-encounter to specific invading pathogen, memory T cells are quickly converted into a large number of effector T cells to eliminate it
B lymphocytes		
B cell	▪ B cell is precursor of plasma cell that synthesizes immunoglobulins	▪ B cell acts as an antigen-presenting cell to T helper cell (Th2)
Plasma cell	▪ B cell differentiates to form plasma cell	▪ Plasma cell synthesizes IgM and then IgG and IgA immunoglobulins
Natural killer cells (granular lymphoid-like cells)	Unlike lymphocytes lack antigen specific receptors	
Circulating granulocytes		
Neutrophil	▪ Acute inflammatory cell involved in bacterial phagocytosis and killing, neutrophilic granules involved in increased vascular permeability, chemotaxis, killing and digesting extracellular matrix	▪ Neutrophil has 6 hours life span in peripheral blood ▪ Neutrophil has 4 days life span in tissues
Eosinophil	Acute inflammatory cell involved in allergic and parasitic conditions. Eosinophilic granules include major basic proteins	
Basophil	Basophil is circulating cell that gives rise to mast cell. Basophil granules contain histamine	

and TLR9 recognize viral nucleic acid derivatives (viral DNA). TLR9 also recognizes bacterial DNA containing unmethylated CpG motifs.

- TLR4 recognizes lipopolysaccharides of gram-negative bacteria. TLR5 recognizes bacterial flagellin. TLR10 recognizes unknown ligand. TLR11 is present on macrophages and neutrophils, that recognizes bacterial profilin. Pathogen recognition toll-like receptors are given in Table 2.40.

Monocyte/Macrophage Half-life Span

Half-life of blood monocytes is one day, while life span of tissue macrophage is several weeks to two years. If the injurious agent is eliminated, macrophages eventually disappear either by dying off or making their way into the lymphatic channels and lymph nodes.

Macrophage Activation

Activated macrophages have many salient features, which include: increase in cell size, lysosomal enzymes level, metabolic activity, phagocytic activity and secretion of large variety of biologically active products. Activated macrophages synthesize TNF-α, IL-1, chemokines that promote leukocyte recruitment and participate in chronic inflammation, tissue injury and tissue repair.

- Activation of macrophages occurs by immune and nonimmune mechanisms. T cells synthesize interferon-γ (IFN-γ), which activate macrophages by immune mechanism.
- Bacterial endotoxins, necrotic cells, fibronectin-matrix proteins and chemical mediators activate macrophages by nonimmune mechanism.

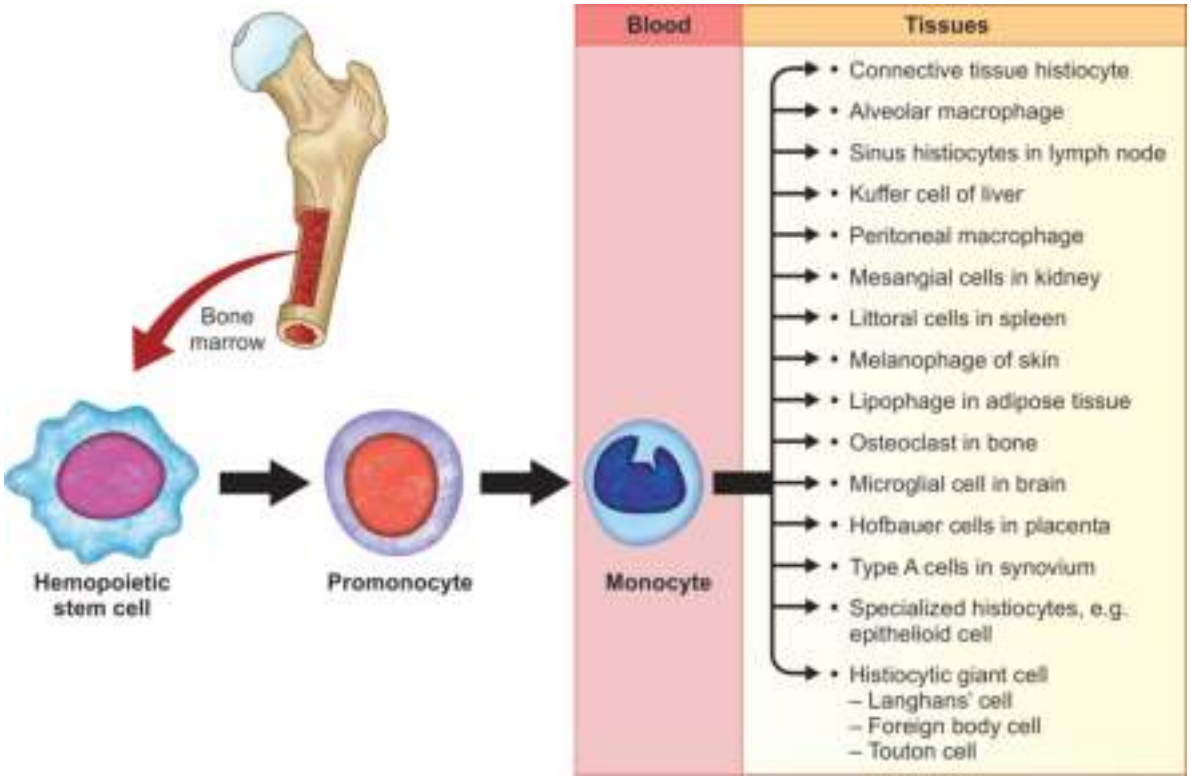

Fig. 2.35: Reticuloendothelial cells distribution in various tissues. The reticuloendothelial system consists of macrophages in tissue descending from the blood monocytes, which are able to perform phagocytosis of foreign materials and particulate material. The tissue component is concentrated in liver (90%), spleen, lymph nodes, bone marrow, lungs and other tissues. Reticuloendothelial system removes immune complexes from the circulation in healthy persons. Reticuloendothelial system has affinity for encapsulated bacteria, such as *Streptococcus pneumoniae*, *Neisseria meningitidis* and *Haemophilus influenzae*.

Table 2.39 Reticuloendothelial cells distribution in various tissues

Tissue	Reticuloendothelial Cells
Blood	Monocytes
Connective tissue	Macrophages
Lung	Alveolar macrophages
Peritoneum	Peritoneal macrophages
Kidney	Mesangial cells
Liver	Kupffer's cells
Lymph nodes	Sinus histiocytes
Spleen	Littoral cells
Placenta	Hofbauer cells
Skin	Melanophages
Brain	Microglial cells
Synovium	Synovial macrophages (type A synoviocytes)
Bone	Osteoclasts
Adipose tissue	Lipophage
Specialized histiocytes	▪ Epithelioid cells ▪ Histiocytic giant cells ▪ Langhans' giant cells ▪ Foreign body giant cells ▪ Touton giant cells

Monocytes/Macrophage Recruitment

Chemotaxis plays key role in migration of circulating monocytes similar to polymorphonuclear cells to injured site by chemokines, where these are called tissue macrophages. Chemokines are derived from macrophages, T cells, bacterial products, products derived from injured tissue (e.g. break down products of collagen, fibronectin), growth factors (PDGF, TGF-α), fibrinopeptides, and complement cascade product (C5a). Sources of chemokines and their role in chemotaxis of macrophages are given in Table 2.41.

Macrophage Proliferation and Immobilization in Tissues

Growth factors derived from necrotic tissue and T cells play important role in proliferation of macrophages leading to increased number of macrophages at persistent injury site. Macrophages engulf particulate material, process and present to CD4+ helper T cells. Activated T cells synthesize IFN-γ, which activates macrophages and transform into epithelioid cells and multinucleated giant cells inflammation. As macrophages lead to formation of fibrous scar tissue; it has been hypothesized that immobilization of macrophages allows resolution of chronic inflammation.

Table 2.40 Pathogen recognition toll-like receptors

Toll-like Receptors (TLRs)	TLRs Expression on Cell	TLRs Recognize Pathogen Component
TLR1	Macrophages and neutrophils	Lipid and carbohydrates from gram-positive bacteria
TLR2	Macrophages, neutrophils and basophils	Lipid and carbohydrates from gram-positive bacteria and fungi
TLR3	Macrophages	Nucleic acid derivatives virus (viral DNA)
TLR4	Macrophages, neutrophils and basophils	Lipopolysaccharides from gram-negative bacteria
TLR5	Macrophages, neutrophils and basophils	Bacterial flagellin
TLR6	Macrophages and neutrophils	Lipid and carbohydrates from gram-positive bacteria
TLR7	Macrophages and neutrophils	Nucleic acid derivatives (viral DNA)
TLR8	Macrophages and neutrophils	Nucleic acid derivatives (viral DNA)
TLR9	Macrophages and neutrophils	Nucleic acid derivatives (viral DNA) and bacterial DNA containing unmethylated CpG motifs
TLR10	Macrophages and neutrophils	Ligand unknown
TLR11	Macrophages and neutrophils	Bacterial profilin

Table 2.41 Sources of chemokines and their role in chemotaxis of macrophages

Source of Chemokines	Examples of Chemokines
Blood cells	Macrophage chemotactic protein 1 (MCP-1)
Bacteria	Bacterial products
Injured tissue	Breakdown products of collagen fibers and fibronectin
Growth factors	PDGF, TGF-α
Fibrinopeptides	Fibrin degradation products (FDPs)
Complement	C5a

Activated Macrophages and their Products

Macrophages possess receptors for IgG and C3b, which process antigen, enhance immune response, and participate in phagocytosis of injurious agent. Activated macrophages synthesize many products, which participate in elimination of injurious agent and initiation of tissue repair by fibrosis and tissue destruction in chronic inflammation. This ongoing tissue destruction can activate the inflammatory cascade by diverse mechanisms, so that features of both acute and chronic inflammation may coexist in certain circumstances.

- Activated macrophages synthesize variety of cytokines such as IL-1, TNF-α, IL-6, IL-8 and monocyte chemoattractant protein 1 (MCP-1). These cytokines attract inflammatory cells at the site of tissue injury. Macrophages synthesize reactive oxygen and nitrogen oxygen species, which are toxic to microbes as well as host cells. Macrophages synthesize neutral proteases, which may cause degradation of extracellular matrix.
- Matrix metalloproteinases (MMPs) are synthesized by polymorphonuclear cells, macrophages, fibroblasts, synovial cells and some epithelial cells. MMPs cause breakdown of type 3 collagen fibers. Deposition of type 1 collagen fibers increase tensile strength by 80%.
- Macrophages synthesize variety of growth factors (PDGF, FGF, and TGF-β), which are involved in proliferation of fibroblasts, deposition of collagen fibers and new blood vessels formation (angiogenesis).
- Macrophages synthesize arachidonic acid metabolites such a prostaglandins and leukotrienes involved in chronic inflammatory process. Macrophage products and their actions are given in Table 2.42. Role of activated macrophages in chronic inflammation is shown in Fig. 2.36.

LYMPHOCYTES

Chronic inflammation is a response to prolonged exposure to injurious stimuli that harm and destroy tissues and promote lymphocytic infiltration into inflamed sites. Lymphocytes have life span of 2 weeks to 2 years. Lymphocytes mediate innate and adaptive immunity.

- There are three main types of lymphocytes: CD8+ cytotoxic T cells, B cells and natural killer cells. B cells produce antibodies that can destroy invading pathogens. CD8+ cytotoxic T cells attack foreign cells, cancer cells and cells infected with virus.
- Natural killer cells represent the major source of interferon-γ, a proinflammatory cytokine acting as a master regulator of different immune cell response.

Table 2.42 Macrophage products and their actions

Inflammatory Mediators	Actions
Cytokines	
TNF-α	Endothelial cell-leukocyte adhesion; can trigger or inhibit apoptosis
IL-1, TNF-α	Chemotaxis of inflammatory cells
IL-1, IL-6	Synthesis of acute phase reactant by liver
IL-2	Autocrine action
IL-8	Leukocyte recruitment
Chemokines	
IL-8 and MCP-1	Chemotaxis of inflammatory cells and paracrine action
Lysosomal enzymes	
Neutral hydrolases	Toxic to extracellular matrix
Acid hydrolase and serine protease	Hydrolyzing the muramic acid-N-acetylglucosamine bond of bacterial glycopeptides leading to killing of microbes
Metalloproteinases (MMPs)	▪ Degradation of type 3 collagen fibers ▪ Deposition of type 1 collagen fibers leading to increased tensile strength
Cell derived arachidonic metabolites	
Prostaglandins	▪ Platelet aggregation ▪ Vasodilatation ▪ Increasing vascular permeability with formation of inflammatory exudate ▪ Modulation of phagocytic activity of leukocytes ▪ Pain ▪ Fever
Leukotrienes	▪ Vasoconstriction ▪ Increased vascular permeability ▪ Bronchospasm
Plasminogen activator	
Plasminogen activator	Cleaves plasminogen to form plasmin, that degrades fibrin strands resulting in dissolution of blood clot
Procoagulant activity	
Procoagulant activity	Activation of coagulation system
Reactive oxygen and nitrogen species	
Superoxide, highly reactive hydroxyl molecule and hypochlorous acid (bleach)	Toxic to microbes and host cells
Reactive oxygen and nitrogen species	
PDGF, FGF, and TGF-β	▪ Fibroblast proliferation ▪ Collagen deposition ▪ Angiogenesis

Metalloproteinases (MMPs) also known as collagenases synthesized by macrophages, neutrophils, fibroblasts, synovial cells and some epithelial cells.

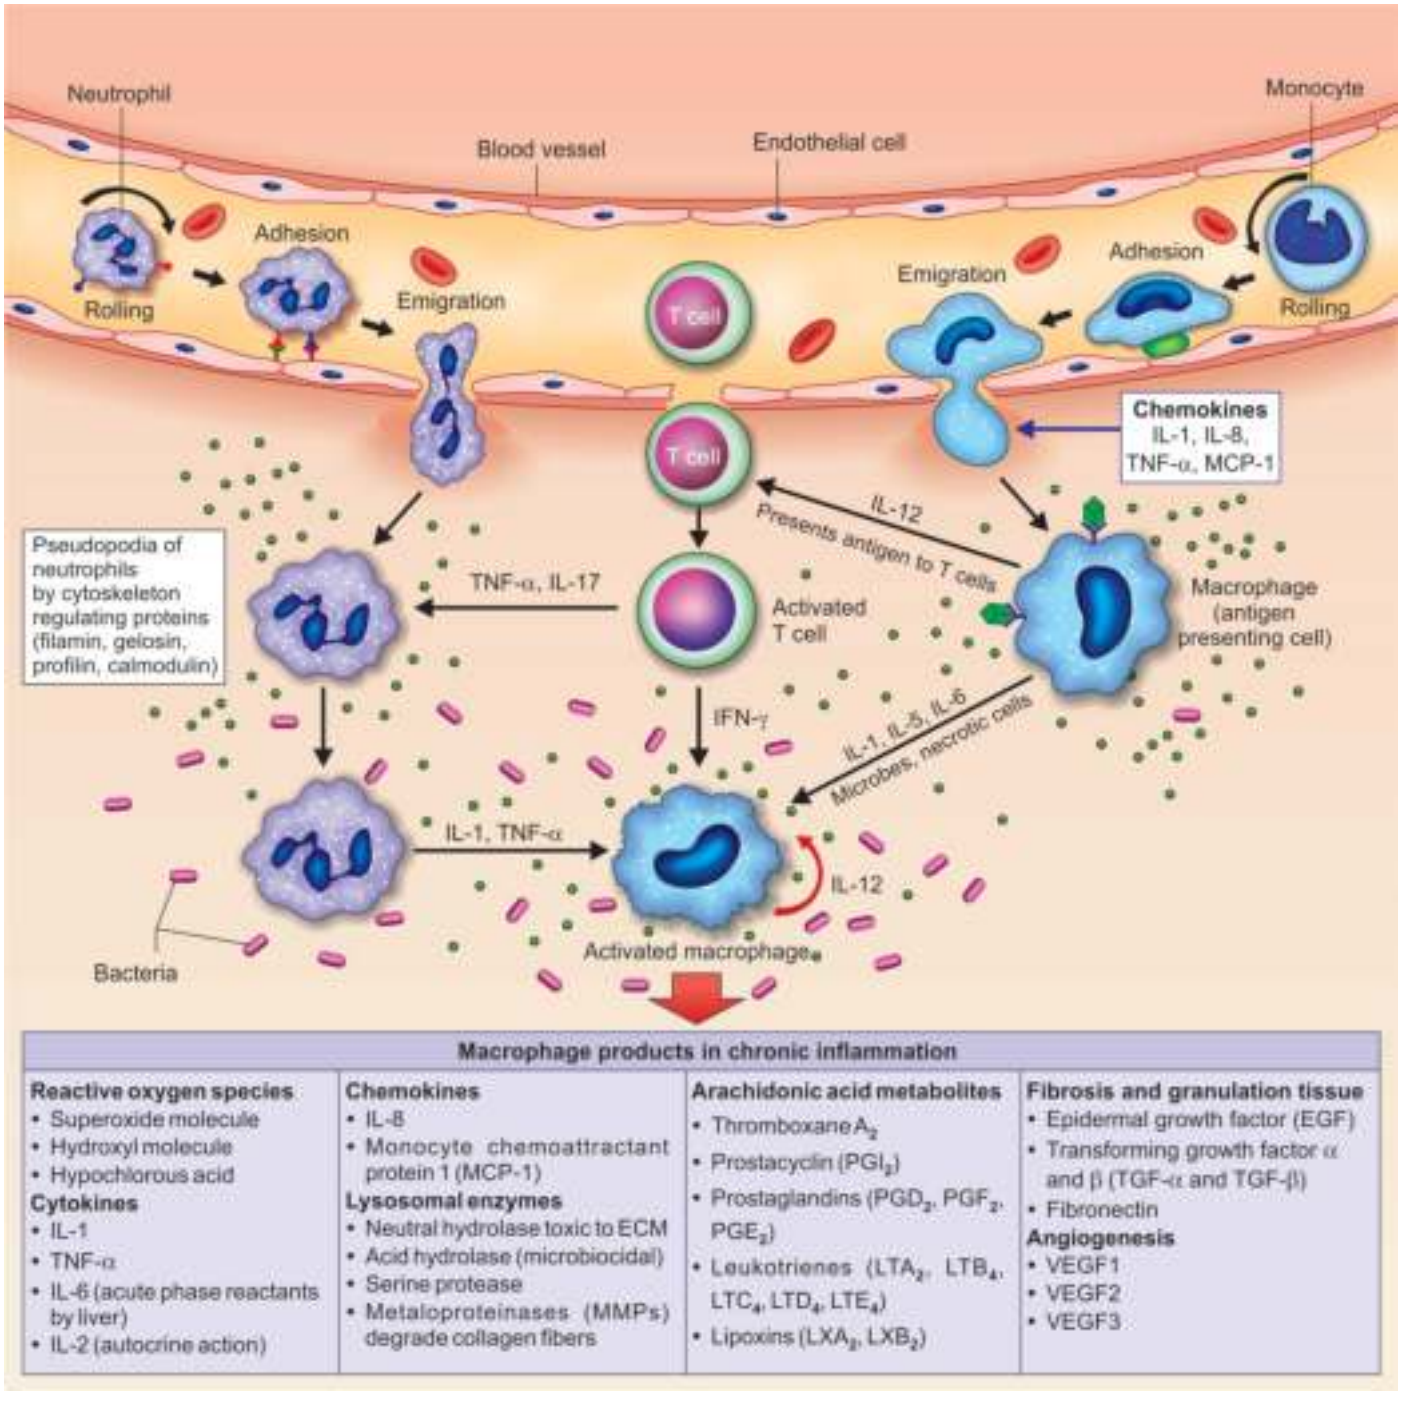
T Lymphocytes

T cells participate in cell-mediated immunity. Activated macrophages display antigens to CD4+ helper T cells. Macrophages synthesize IL-12 that stimulates T cell responses. Activated T cells recruit monocytes from the circulation interferon-γ (IFN-γ) is a powerful activator of macrophages.

- **T helper 1 cell:** T helper 1 (Th1) participates in synthesis of interferon-γ (IFN-γ) and IL-2, which activate macrophages and cytotoxic natural killer cells.
- **T helper 2 cell:** T helper 2 (Th2) synthesizes IL-4 and IL-6 that activates B cell.
- **CD4+ regulatory T cell:** CD4+ regulatory T cell (Treg) suppresses immune response by inhibiting T cell proliferation and cytokine production. Treg maintains homeostasis and self-tolerance. Treg prevents autoimmunity.
- **Memory T cell:** Memory T cell provides protection against previously encountered pathogen. On re-encounter to specific invading pathogen, memory T cells are quickly converted into a large number of effector T cells to eliminate it.

B Lymphocytes and Plasma Cells

B cell is precursor of plasma cell that synthesizes immunoglobulins. B cell acts as an antigen-presenting



Macrophage products in chronic inflammation

Reactive oxygen species	Chemokines	Arachidonic acid metabolites	Fibrosis and granulation tissue
• Superoxide molecule • Hydroxyl molecule • Hypochlorous acid **Cytokines** • IL-1 • TNF-α • IL-6 (acute phase reactants by liver) • IL-2 (autocrine action)	• IL-8 • Monocyte chemoattractant protein 1 (MCP-1) **Lysosomal enzymes** • Neutral hydrolase toxic to ECM • Acid hydrolase (microbiocidal) • Serine protease • Metaloproteinases (MMPs) degrade collagen fibers	• Thromboxane A_2 • Prostacyclin (PGI_2) • Prostaglandins (PGD_2, PGF_2, PGE_2) • Leukotrienes (LTA_2, LTB_4, LTC_4, LTD_4, LTE_4) • Lipoxins (LXA_2, LXB_2)	• Epidermal growth factor (EGF) • Transforming growth factor α and β (TGF-α and TGF-β) • Fibronectin **Angiogenesis** • VEGF1 • VEGF2 • VEGF3

Fig. 2.36: Role of activated macrophages in chronic inflammation. Macrophages are activated by immunological or nonimmunological mechanisms. In inflammation, macrophages perform three major functions: antigen presentation, phagocytosis and immunomodulation through production of various cytokines and growth factors. Macrophages play a critical role in the initiation, maintenance, and resolution of inflammation. Various products synthesized by activated macrophages can induce tissue fibrosis.

cell to T helper cell (Th2). B cells, when stimulated with antigen, become plasma cells. Plasma cells participate in humoral immunity.

- Plasma cells are large cells with amphophilic to basophilic cytoplasm with eccentric nucleus with chromatin arranged in a characteristic cartwheel pattern.
- Plasma cell cytoplasm contains a pale perinuclear zone that on electron microscopy demonstrates an extensive Golgi appratus and centrioles.
- Plasma cells have abundant rough endoplasmic reticulum coupled with a well-develop Golgi appratus, which together are responsible for immunoglobulins synthesis (e.g. IgG, IgA, IgM, IgD and IgE).

Natural Killer Cells

Natural killer cells are large granular, lymphoid-like cells with important functions in innate immunity especially against intracellular viral infections or tumor cells. Unlike T and B lymphocytes, natural killer cells lack antigen-specific receptors. Natural killer cells controlling human viral infections are given in Table 2.43.

Pathology Pearls: Macrophages and Lymphocytes Interaction

- Macrophages can act as antigen-presenting cells to CD4+ helper T cells. Poorly digested antigen is presented by macrophages to CD4+ helper T cells. Interaction between macrophages and CD4+ helper T cells triggers an immune response. As a result, stimulated T cells can secrete interleukin-2 (IL-2), which mediates activation and proliferation of lymphocytes. Interaction between macrophages and helper T cells is shown in Fig. 2.37.
- Cellular activation can also result in secretion of varying effector molecules. For example, T helper cells (Th1) synthesize interferon-γ (IFN-γ), IL-2 and TNF-β, which activate macrophages and cytotoxic CD8+ T cells and also mediate the transformation of monocytes/macrophages to epithelioid cells and multinucleated giant cells. T helper cell (Th-2) secretes IL-4, IL-5, IL-6, IL-10 and IL-13, which activates B cell.
- Contact-mediated activation of macrophages by activated lymphocytes triggers production of reactive oxygen species (ROS), nitric oxide (NO), IL-1 and TNF-α.

Table 2.43 Natural killer cells (NKCs) controlling human viral infections

Human cytomegalovirus
Human herpesvirus 5
Vesicular stomatitis virus (VSV)
Herpes simplex virus (HSV)
Human papillomavirus (HPV)
Human immunodeficiency virus (HIV)
Epstein-Barr virus (EBV)

Natural killer cells are rapid but nonspecific means of controlling viral and other intracellular infections.

OTHER CELLS INVOLVED IN CHRONIC INFLAMMATION

Other cells involved in chronic inflammation include eosinophils, mast cells, neutrophils, platelets and fibroblasts.

Eosinophils

The eosinophil is a specialized cell of the immune system. Eosinophils are particularly prominent in allergic and parasitic infection mediated by IgE, which are recruited by eotaxin chemokine.

- Eosinophilic granules contain major basic protein, a highly cationic protein that is toxic to parasites but also causes lysis of host epithelial cells. Eosinophilia is highly suggestive of response to invasive helminths, arthropods, allergic rhinitis and bronchial asthma.

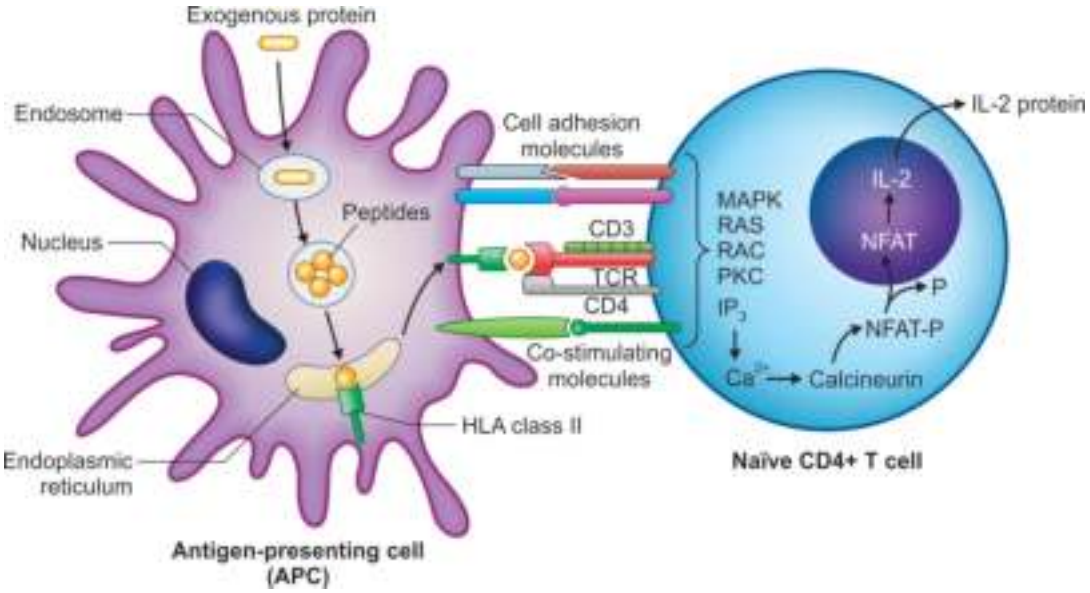


Fig. 2.37: Interaction between macrophages and CD4+ helper T cells. Macrophages interact with CD4+ helper T cells in order to bring about T cell activation in target cells. CD4+ helper T cells play important role in adaptive immunity by activating B cells form plasma cells to secrete immunoglobulins, and activating cytotoxic T cells to kill infected target cells. Macrophages stimulated by T cells need to produce a tumor necrosis factor α (TNF-α) cytokine, which acts on macrophages to produce nitric oxide (NO).

- Eosinophilic specific granules contain preformed chemical mediator, i.e. major basic protein (MBP), which kills only invasive helminths by type 2 hypersensitivity reaction. It has no effect on pinworms and adult worms (*Ascaris lumbricoides*), which are not invasive.
- Eosinophils modulate hypersensitivity reactions with the help of histaminase and arylsulfatase. Histaminase neutralizes histamine, whereas arylsulfatase neutralizes leukotrienes. Eosinophilic red granules contain crystalline material in cytoplasm, which become 'Charcot-Leyden crystals' in the sputum of asthmatic patients. Primary inflammatory mediators of eosinophils are given in Table 2.44.

Mast Cells

Mast cells are widely distributed in connective tissue, which participate in acute and chronic inflammation. Mast cells express surface receptors that bind the Fc portion of IgE antibody. Mast cell contains electron-dense granules, which release histamine, leukotrienes (LTC_4, LTD_4, LTE_4), prostaglandins, and platelet-activating factor (PAF) during allergic reactions to foods, insect venom, or drugs, sometimes mast cells have catastrophic results (e.g. anaphylactic shock). Mast cells may produce cytokines (TNF-α and IL-4), that contribute to fibrosis in chronic inflammation. Mast cells degranulation and their actions are shown in Fig. 2.38. Primary inflammatory mediators of mast cells are given in Table 2.45.

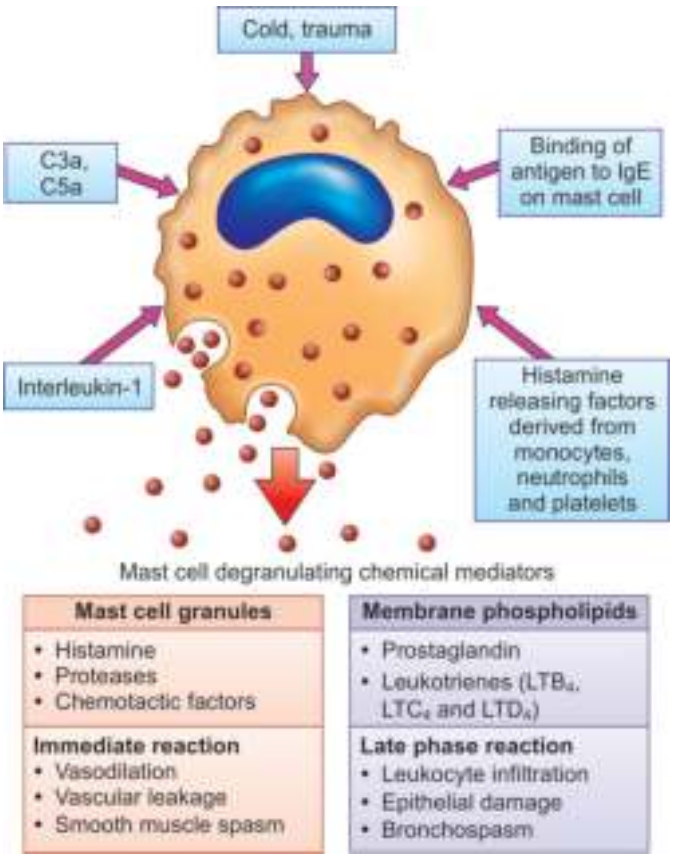

Fig. 2.38: Mast cells degranulation and their actions. Mast cell degranulation is a central event in the development of lesions in urticaria, and histamine levels are elevated in biopsies skin. Upon stimulation by an allergen, mast cells degranulate and release contents into surrounding tissues.

Table 2.44 Primary inflammatory mediators of eosinophils

Specific Mediator	Actions
Reactive oxygen species (ROS)	
Superoxide, highly reactive hydroxyl molecule and hypochlorous acid	These participate in inflammatory reactions
Lysosomal enzymes granules (also known as primary crystalloid granules)	
Major basic proteins (highly cationic protein)	▪ Modulation of hypersensitivity reactions ▪ Killing only invasive helminths by type 2 hypersensitivity reaction ▪ No effect on noninvasive parasites such as pinworms and *Ascaris lumbricoides* ▪ Lysis of host epithelial cells
Histaminase	▪ Modulation of hypersensitivity reactions ▪ Neutralization of histamine
Aryl sulphatase B	Neutralization of leukotrienes
Eosinophil cationic protein	Damaging schistosomula of *Schistosoma mansoni*
Eosinophil peroxidase	Functions unknown
Acid hydrolase	Functions unknown
β-Glucuronidase	Functions unknown
Other inflammatory mediators of eosinophils	
Phospholipase D	Specific functions unknown
Prostaglandins of the E series	Specific functions unknown
Cytokines	Specific functions unknown

Table 2.45 Primary inflammatory mediators of mast cells

Histamine
Leukotrienes (LTC_4, LTD_4, LTE_4)
Platelet-activating factor
Eosinophil chemotactic factors
Cytokines (TNF-α and IL-4)

Neutrophils

Neutrophils characteristically participate in acute inflammation and sometimes present in during chronic inflammation due to ongoing persistent infection for many months in osteomyelitis and tissue damage as a result of chemical mediators produced by activated macrophages and T cells.

Platelets

Platelets regulate vascular permeability and proliferation of mesenchymal cells in chronic inflammation. Platelets also participate in thrombosis and clot formation. Platelets contain primary inflammatory mediators in dense granules and α-granules. Dense granules of platelets contain serotonin, calcium and ADP. Platelets' α-granules contain cationic proteins, fibrinogen and coagulation proteins, platelet-derived growth factors, acid hydrolases and thromboxane A_2.

Fibroblasts

Fibroblasts mediate chronic inflammation and wound healing. These cells are derived from mesoderm or neural crest and differentiate into other connective tissue cells (e.g. adipocytes, smooth muscle cells, chondrocytes and osteocytes).

- Fibroblasts respond to immune signals, which produce extracellular matrix proteins. Fibroblasts interact with lymphocytes, via surface molecules and receptors on fibroblasts and lymphocytes. For example, when CD40 on fibroblasts binds with its ligand on lymphocytes, both cells are activated.
- Fibroblasts synthesize variety of inflammatory mediators that include IL-6, IL-8, cyclooxygenase 2, hyaluronan, PGE_2, CD40 expression, extracellular proteins and matricellular proteins.

CHRONIC NONSPECIFIC INFLAMMATION

Tissue injury and wound healing proceed simultaneously in chronic inflammation. Neutrophils have disappeared from the injury site. There is influx of macrophages, lymphocytes, plasma cells in chronic nonspecific inflammation. Synthesis of cytokines is associated with granulation tissue formation (proliferation of fibroblasts and capillaries) resulting in tissue scarring and architecture distortion.

- Chronic nonspecific inflammation is mediated by the interaction of monocytes–macrophages with lymphocytes. Cytokines synthesized by macrophages and lymphocytes activate each other.
- Macrophages display antigens to B cells resulting in synthesis of antibody-producing plasma cells. Other inflammatory cells such as eosinophils, mast cells, platelets and neutrophils also participate in chronic inflammation.

GRANULOMATOUS INFLAMMATION

Granulomatous inflammation is a distinctive form of chronic inflammation, which develops when acute inflammatory cells are unable to digest the injurious agent (e.g. suture or talc). Fusion of macrophages within the persistent inflammatory lesion results in the formation of granulomas admixed with mononuclear infiltration (macrophages, lymphocytes and plasma cells) and multinucleated giant cells.

- **Granuloma composition:** Granuloma consists of three components: (a) epithelioid cells (activated macrophages) contain eosinophilic cytoplasm and oval or elongate nuclei, which may show folding of nuclear membrane, (b) collar of lymphocytes plasma cells and reactive fibroblasts, and (c) multinucleated giant cells (40–50 microns in size with 20 or more nuclei arranged peripherally) formed by fusion of epithelioid cells. Epithelioid cells show increased endoplasmic reticulum and few phagolysosomes on electron microscopy. Demonstration of granulomas in biopsy specimen has diagnostic significance associated with the persistent inflammatory lesions.
- **Granulomas in granulomatous inflammation:** Granulomas are formed in various pathologic conditions due to bacteria, fungi, parasites, inorganic compounds (silicosis, berylliosis), foreign bodies (sutures, implants, accidents) and sarcoidosis (unknown etiology). Brucellosis and viral infections resist phagocytosis and intracellular killing, but granulomas are absent. Granulomas are seen in secondary or primary chronic granulomatous conditions. Some examples of chronic granulomatous inflammation are given in Table 2.46. Differences between granuloma and granulation tissue are given in Table 2.47.

TYPE OF GRANULOMAS

There are two types of granulomas in granulomatous inflammation: immunologic mediated granulomas (caseating and noncaseating granulomas) and

Table 2.46 Some examples of chronic granulomatous inflammation

Disorder	Characteristics
Persistence of infectious agents due to failure of phagocytosis	
Tuberculosis	Mycobacterium tubercle bacilli induced caseous necrosis, epithelioid granulomas and Langhans' giant cells. AFB may be demonstrated by Ziehl-Neelsen staining
Leprosy	*Mycobacterium leprae* bacilli induced noncaseating granulomas
Syphilis	*Treponema pallidum* induced with gumma (microscopic to grossly visible lesion), with central necrotic cells, surrounded by macrophages and plasma cell infiltrate
Cat-scratch disease	Gram-negative bacteria forms rounded or stellate granuloma containing central granular debris
Prolonged exposure to exogenous and endogenous substances	
Endogenous materials	▪ Necrotic adipose tissue and bone ▪ Uric acid crystals (gouty tophus)
Exogenous materials	▪ Suture materials ▪ Implanted prosthesis ▪ Asbestos fibers ▪ Silicosis ▪ Berylliosis
Autoimmune disorders	
Organ-specific diseases	▪ Hashimoto's thyroiditis ▪ Pernicious anemia ▪ Rheumatoid arthritis
Contact hypersensitivity reactions	Self-antigens altered by exposure to nickel
Diseases of unknown etiology	▪ Ulcerative colitis ▪ Crohn's disease ▪ Sarcoidosis

Table 2.47 Differences between granuloma and granulation tissue

Characteristics	Granuloma	Granulation Tissue
Features	Well circumscribed collection of modified macrophages (epithelioid cells) surrounded by lymphocytes and fibroblasts	Hallmark of healing process composed of proliferation of fibroblasts and new blood vessels formation (angiogenesis) embedded in loose edematous matrix along with inflammatory cells such as neutrophils, lymphocytes and plasma cells
Granulomas	Present	Absent
Multinucleated giant cells	Present	Absent
Conditions	Tuberculosis, tuberculoid leprosy, sarcoidosis, rheumatoid arthritis	Normal physiological response after an injury
Vascularization	Absent	Present due to angiogenesis
Fibroblasts	Minimal	Marked
Cytokines	IL-1, IL-12 and IFN-γ	Angiogenetic and fibrogenic growth factors involved, e.g. VEGF, PDGF, FGF, TNF
Consequence	Damage to host tissues	Physiological process

nonimmunologic mediated granulomas (foreign body granulomas).

- Immunologic granulomas are mediated by lymphocytes. Examples of immunologic mediated granulomas are tuberculosis, leprosy, cat scratch fever, sarcoidosis, histoplasmosis and Hodgkin's disease.
- Nonimmunologic mediated foreign body granulomas are formed by poorly digestible particles seen in silicosis, surgical sutures, implanted prosthesis, asbestosis, and beryllium exposure. Granuloma formation by immunologic and nonimmunologic mechanisms are given in Table 2.48.

Table 2.48 Granuloma formation by immunologic and non-immunologic mechanisms

Granuloma Formation Mediated by Immunologic Mechanism
Tuberculosis
Leprosy
Cat-scratch fever
Sarcoidosis
Histoplasmosis
Blastomycosis
Cryptococcosis
Coccidioidomycosis
Hodgkin's disease (mixed cellularity variant)
Granuloma Formation Mediated by Nonimmunologic Mechanism
Silicosis
Berylliosis
Asbestosis
Surgical sutures
Implanted prosthesis
Foreign body induced pneumonia

Granulomas Formation Mediated by Immunologic Mechanism

Exposure to antigen leads to activation of macrophages resulting in synthesis of IFN-γ, which activates CD4+ helper T cells leads to synthesis of IFN-γ.

- IFN-γ synthesized by activated macrophages and CD4+ helper T cells plays key role in formation of granuloma. IFN-γ activates macrophages to become epithelioid cells. IFN-γ also participates in proliferation and differentiation of T cells.
- Cytokines TNF-α and IFN-γ participate in recruitment of chronic inflammatory cells, granuloma formation and maintenance of tuberculous and systemic fungal granulomas.
- Inhibitors of TNF-α cause the breakdown of granulomas leading to dissemination of disease. Mechanism of caseating and noncaseating granulomas formation is shown in Fig. 2.39. Steps in granuloma formation are shown in Fig. 2.40.

Caseating Granulomas

Tuberculosis is caused by a bacterium called *Mycobacterium tuberculosis*, that often attacks lungs. The bacteria spread from person to person through tiny droplets released into the air via coughing and sneezing.

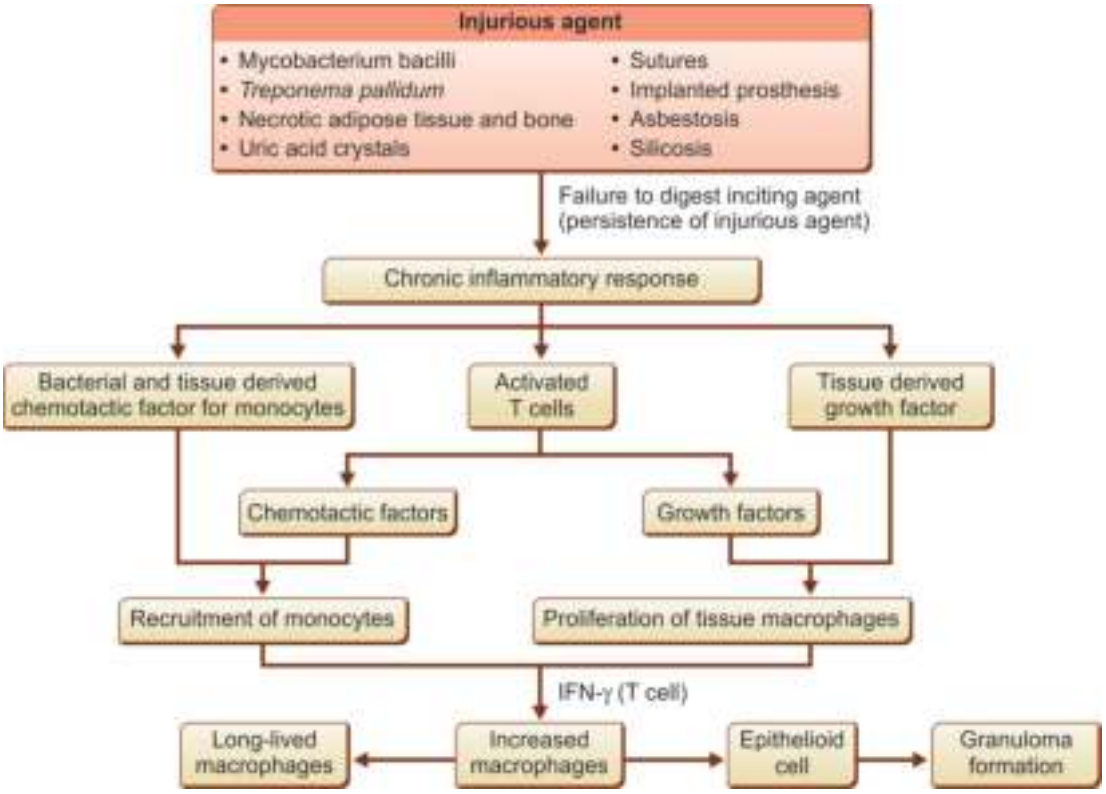

Fig. 2.39: Mechanism of caseating and noncaseating granulomas formation. Granulomas are collection of macrophages, often surrounded by helper-T cells and rim of fibroblasts. Most granulomas fall into one of two categories: caseating with necrotic center; or noncaseating without any necrosis caused by persistent infection. Granulomas are formed when the immune system responds to causative agent, eventually leading macrophage transformation to epithelioid cells, which may bind tightly together, forming granuloma.

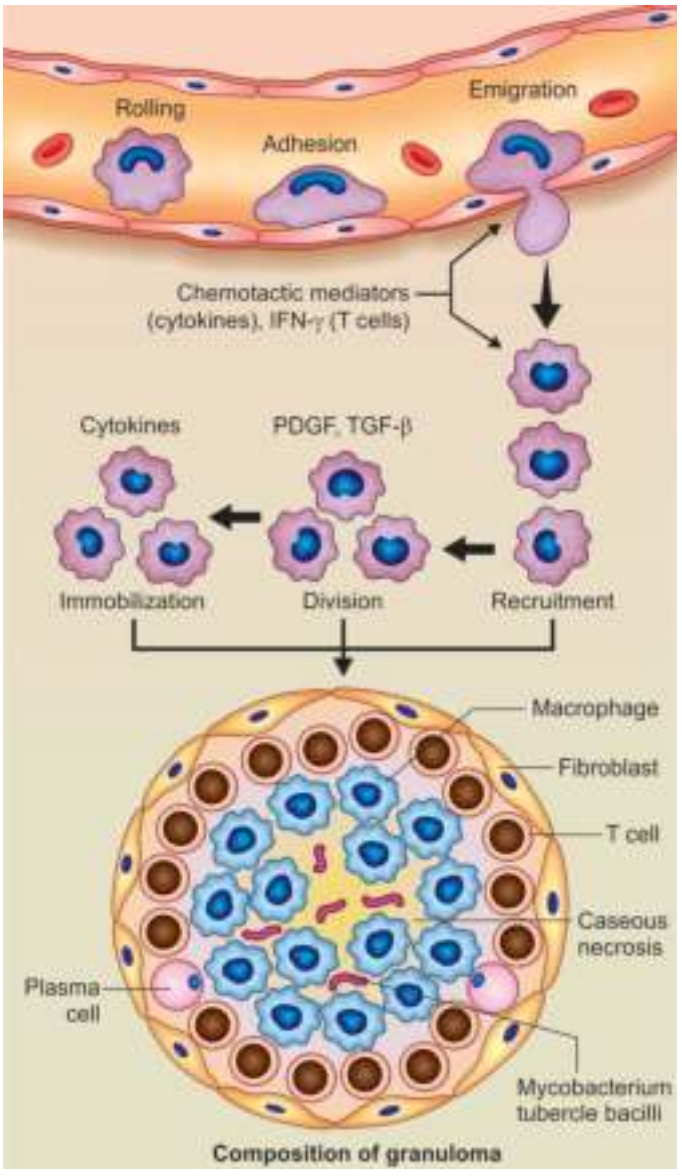

Fig. 2.40: Steps in granuloma formation. Macrophages migrate and accumulate involving cellular recruitment into the site of infection initiate granuloma formation, when the immune system responds to causative agent, eventually leading macrophage transformation to epithelioid cells, which may bind tightly together forming granuloma. A fully formed tuberculous granuloma consists of a central zone of caseating necrosis, surrounded by cellular infiltrate comprising activated macrophages surrounded by a rim of lymphocytes and plasma cells.

Fig. 2.41: Gross morphology of tubercular lymphadenitis. Cut surface tubercular lymphadenitis shows cheesy appearance on cut surface. (*Courtesy:* Department of Pathology, Dr DY Patil Medical College, Pune, Maharashtra.)

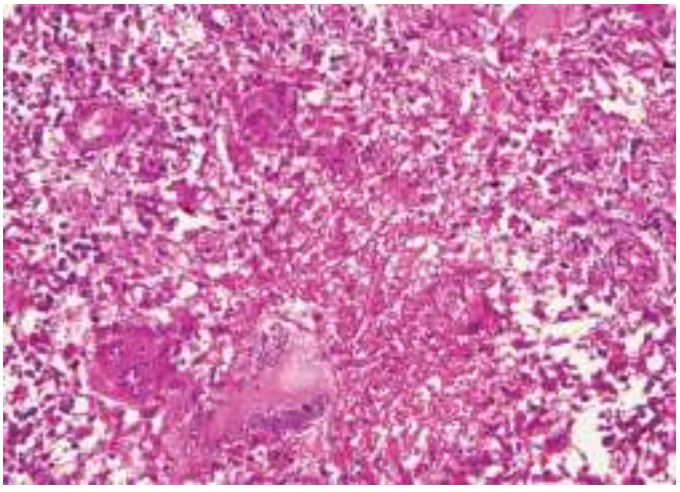

Fig. 2.42: Granulomatous inflammation with multiple Langhans' giant cells. Granulomatous inflammation is seen in bacterial, fungal, protozoal infections and other granulomatous diseases. A granuloma is a focus collection of granulomatous inflammation consisting of microscopic aggregation of macrophages surrounded by a rim of lymphocytes and plasma cells. Langhans' giant cell is formed by the fusion of epithelioid cells that shows an arc of nuclei toward the periphery of the outer membrane giving horseshoe/ring appearance (400X).

- Caseating granulomas are demonstrated in tuberculosis. The caseating granulomas are formed when tubercle bacilli are poorly degraded by macrophages.
- Mycobacterium tubercle bacilli cause caseous necrosis, epithelioid granulomas and Langhans' giant cells with nuclei arranged peripherally in horseshoe/ring form or clustered at two poles in tuberculosis. AFB is seen in macrophages. Mycobacterium tubercle bacillus is strict aerobe. It is acid-fast due to presence of mycolic acid in its cell wall and stained by Ziehl-Neelsen staining (decolorized by 20% H_2SO_4).
- Diagnostic techniques for tuberculosis include: demonstration of acid-fast bacilli (Ziehl-Neelsen stain), culture on Lowenstein-Jensen medium (LJ medium), serological polymerase chain reaction (PCR) technique.
- Gross morphology of tubercular lymphadenitis is shown in Fig. 2.41. Granulomatous inflammation with multiple Langhans' giant cells is shown in Fig. 2.42. Mycobacterium tubercle bacilli stained by Ziehl-Neelsen (ZN) stained in tubercular lymphadenitis are shown in Fig. 2.43.

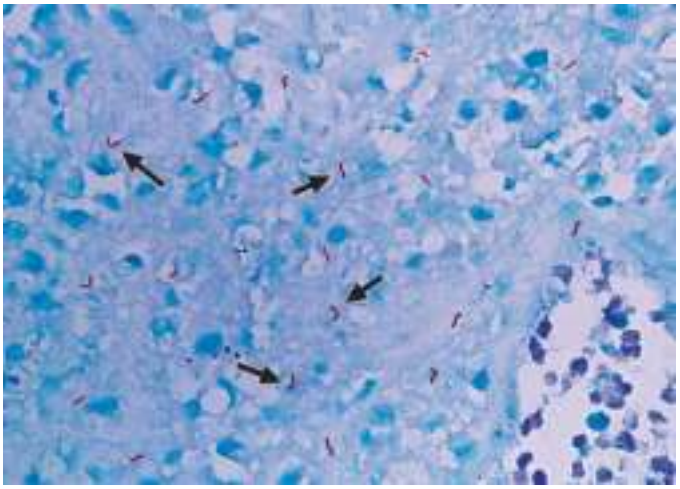

Fig. 2.43: Mycobacterium tubercle bacilli stained by Ziehl-Neelsen (ZN) stained in tubercular lymphadenitis. Ziehl-Neelsen (ZN) stain is a rapid method for detecting acid-fast bacilli (AFB) due to its rapidity, low cost and high predictive values of tuberculosis. Acid-fast bacilli have lipoid capsule that has a high molecular weight and is waxy at room temperature. This makes the AFB impermeable by aqueous-based staining solutions (arrows) (400X).

Noncaseating Granulomas

Persistence of infectious agents due to failure of phagocytosis leads to formation of noncaseating granulomas, which are composed of multinucleated giant cells without caseous necrosis. Noncaseating granulomas are formed due to fungi, cat scratch fever, syphilis, sarcoidosis, schistosomiasis and Hodgkin's disease.

- **Leprosy:** Leprosy is an infectious disease caused by a bacillus, *Mycobacterium leprae*, which multiplies slowly. *Mycobacterium leprae* are transmitted from human body by nasal discharge and digital impregnation of skin, as bacilli can be carried under nails and are inoculated under the skin by scratching. The incubation period is usually 3–5 years. Skin of extremities, mouth, eyes and peripheral nerves involving Schwann cells are commonly involved. The organisms may be demonstrated in bone marrow, liver, spleen and lymph nodes. Macrophages are laden with *Mycobacterium leprae* bacilli. Noncaseating granulomas are present in leprosy.
- **Syphilis:** Syphilis is caused by *Treponema pallidum* with formation of gumma (microscopic to grossly visible lesion), with central necrotic cells, surrounded by macrophages and plasma cell infiltrate. *Treponema pallidum* is the only organism that causes venereal disease transmitted through sexual contact, anogenital and orogenital contact. *Treponema pallidum* is a very tiny organism that is not visible on light microscopy. Thus, it can be identified by its distinct spiral movements on darkfield microscopy. The organism cannot survive outside the body.
- **Deep fungal infections:** Some fungi occur in both the yeast and mycelial forms, which are called dimorphic fungi, which cause pneumonia and disseminated infection. Noncaseating granulomas may be seen in fungal infections (e.g. histoplasmosis, blastomycosis, cryptococcosis, coccidioidomycosis). *Blastomyces dermatitidis* involves skin, bone and genitourinary system. *Coccidioides immitis* disseminates to central nervous system and bone. *Histoplasma capsulatum* involves lungs, liver, spleen and bone marrow. *Paracoccidioides brasiliensis* disseminates to lung, mucosa of mouth and nose; and central nervous system. *Histoplasma capsulatum* is shown in Fig. 2.44. *Cryptococcus neoformans* is shown in Fig. 2.45.
- **Parasitic infections:** Noncaseating granulomas are seen in schistosomiasis. Schistosomiasis, also called

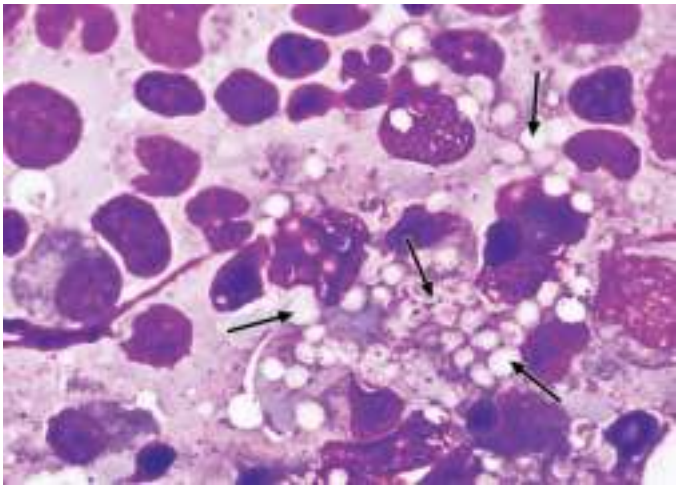

Fig. 2.44: *Histoplasma capsulatum.* Bone marrow demonstrates *Histoplasma capsulatum* as empty spaces in the reticuloendothelial cells in immunocompromised state (arrows) (1000X).

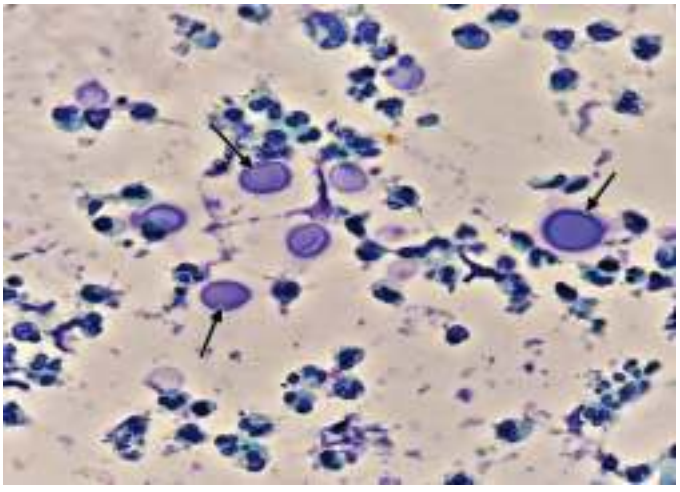

Fig. 2.45: *Cryptococcus neoformans.* Endobronchial ultrasound bronchoscopy (EBUS) demonstrates *Cryptococcus neoformans* (arrows) (400X). (*Courtesy:* Dr. Tushar Kalonia.)

bilharzia, or snail fever or Katayama fever, which is an acute and chronic disease caused by trematode parasitic flatworms of the genus Schistosoma. The parasite may infect intestine or urinary tract. Lack of proper hygiene, swimming or fishing in infested water make the persons vulnerable to infection.

- **Cat-scratch disease:** Cat-scratch disease is a gram-negative bacterial infection spread by infected cats due to cat lick into person's open wounds or bites a person by breaking the surface of the skin. Histologic examination of tissue shows rounded or stellate noncaseating granuloma containing central granular debris.

Granulomas Formation Mediated by Nonimmunologic Mechanism

Prolonged exposure to exogenous and endogenous toxic substances causes chronic inflammation. Granulomas are seen in vicinity of necrotic adipose tissue, necrotic and bone and gouty tophus (uric acid crystals).

Noncaseating Granulomas Formation in Autoimmune Disorders

Noncaseating granulomas are observed in the settings of autoimmune disorders such as Hashimoto's thyroiditis, pernicious anemia, rheumatoid arthritis, contact hypersensitivity reactions, ulcerative colitis, Crohn's disease and sarcoidosis.

- **Hashimoto's thyroiditis:** Hashimoto's thyroiditis is an autoimmune disease characterized by destruction of thyroid follicles by autoantibodies such as antithyroid peroxidase antibody, antithyroglobulin antibody and anti-TSH antibody. Histologic examination reveals noncaseating granulomas along with dense chronic inflammatory infiltrate and destruction of thyroid follicles. Patient presents with diffuse painless thyroid enlargement, transient hyperthyroidism resulting from excessive release of thyroid hormones from damaged thyroid follicles, but later hypothyroidism in 40–50% of cases.
- **Pernicious anemia:** Parietal cells in stomach synthesizes intrinsic factor required for absorption of vitamin B_{12}. Autoantibodies are formed against parietal cells in stomach cause pernicious anemia.
- **Rheumatoid arthritis:** In long-standing cases, rheumatoid nodules are formed in synovium and composed of macrophages, lymphocytes and plasma cells.
- **Contact hypersensitivity reactions:** Self-antigens are altered by exposure to nickel. Patient develops contact hypersensitivity reactions.
- **Ulcerative colitis:** Ulcerative colitis is characterized by ulcerations of mucosa and submucosa with formation of pseudopolyps in colon. Disease begins in the rectum as friable red mucosa and extends in continuity to involve segment or the entire colon, which does not form fistulous tract. Light microscopy shows crypt abscesses due to PMN cells infiltration and noncaseating granulomas. Patient may develop adenocarcinoma. Patient presents with abdominal cramping, diarrhea with blood and mucus, rectal bleeding, and tenesmus (ineffective and painful straining of stool).
- **Crohn's disease:** Crohn's disease is an autoimmune disorder characterized by discontinuous/skipped lesions involving all layers of small or large intestine. On light microscopy, intestinal wall shows noncaseating granulomas along with dense chronic inflammatory infiltrate. Patient presents with colicky pain in right lower quadrant due to intestinal obstruction, diarrhea and anal bleeding. It is located in the terminal ileum (30%), colon and small bowel (50%), colon alone (20%).
- **Sarcoidosis:** Sarcoidosis is an idiopathic disorder in which abnormal immune system leads to formation of noncaseating granulomas and collection of activated macrophages, which trigger an inflammatory response leading to extensive tissue damage and scarring. It is essential to exclude tuberculosis, fungal infection and berylliosis. Schaumann bodies calcium and protein inclusions in noncaseating granuloma in sarcoidosis are shown in Fig. 2.46. Relative frequency of organs involved in sarcoidosis is given in Table 2.49. Differences between sarcoidosis and tuberculosis are given in Table 2.50.

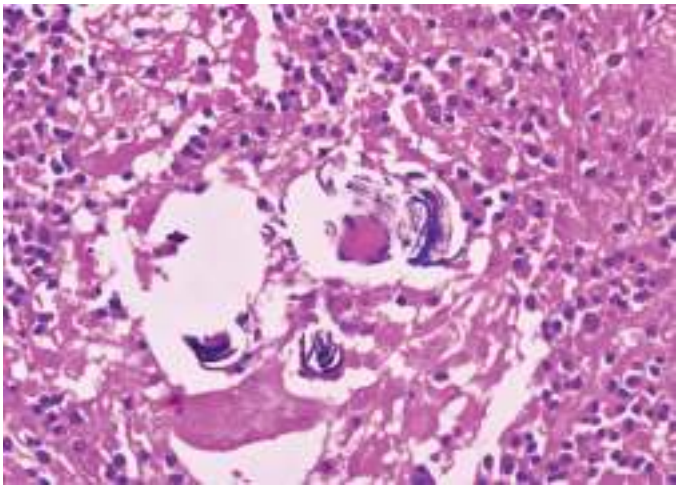

Fig. 2.46: Calcium and protein inclusions in noncaseating granuloma in sarcoidosis. The morphologic feature of sarcoidosis of unknown etiology is noncaseating epithelioid cell granulomas formed by epithelioid cells in any organs especially in intrathoracic lymph nodes and lungs in over 90% of patients. Diagnosis of sarcoidosis is made by exclusion of other systemic granulomatous conditions In pathology, **Schaumann bodies** are calcium and protein laminated inclusions inside of Langhans' giant cells as a part of granuloma in the settings of sarcoidosis, hypersensitivity pneumonitis, and berylliosis (400X).

Table 2.49 Relative frequency of organs involved in sarcoidosis

Organs	Frequency	Comments
Lymph nodes	80%	Hilar, mediastinal, cervical, epitrochlear, preauricular and postauricular lymph nodes
Lungs	80%	Diffuse consolidation without cavities
Liver	70%	Noncaseating granulomas in portal tracts
Skin	30%	Small erythematous nodules on back
Eyes	20%	Lacrimal gland involvement
Heart	20%	Light microscopy showing noncaseating granulomas in heart
Brain	15%	Noncaseating granulomas are present in brain
Spleen	15%	▪ Nodules visible in 15% cases on gross examination ▪ Light microscopy showing noncaseating granulomas in 75% cases
Bone	15%	Destruction of terminal phalanges
Nasal and pharyngeal mucosa and tonsils	10%	Light microscopy showing noncaseating granulomas in these regions
Salivary gland	1%	Bilateral parotid gland enlargement but may involve all salivary glands

Table 2.50 Differences between tuberculosis and sarcoidosis

Characteristics	Sarcoidosis	Tuberculosis
Etiology	Unknown etiology	Mycobacterium tubercle bacilli
Granuloma	Noncaseating granulomas	Caseating granuloma
Cytoplasmic inclusions in giant cells	Presence of Schaumann bodies, asteroid bodies and birefringent crystals	Absence of Schaumann bodies, asteroid bodies and birefringent crystals
Steroid therapy	Improvement	Worsening the disease
Diagnosis	Done by excluding causes of granulomatous lesions	Acid-fast bacilli demonstration

Foreign Body Granulomas

A foreign body granuloma is formed when the immune host system fails to digest the inert foreign body, resulting in the accumulation of macrophages in the tissues. As macrophages surround and isolate the foreign body, some of them will fuse to form multinucleated giant cells. T cells and fibroblasts also participate in this inflammatory response. Foreign bodies can usually be identified in the center of the granulomas, particularly if viewed with polarized light, in which it appears refractile. Foreign body granulomas are shown in Fig. 2.47.

- Substances that cause foreign body granulomas include such as surgical suture materials, implanted prosthesis, minerals and metallic particles (e.g. silica, aluminum, zinc, nickel, calcium, asbestos), carbon pigments in cosmetic tattoo, cosmetic fillers (e.g. collagen, silicon, paraffin and hyaluronic acid), ruptured cyst, hairs, and other biotic and abiotic materials, such as talc, cactus, spins, glass, retained sutures, splinters and natural and artificial hair.
- Natural history of foreign body granuloma varies depending on the etiology. Foreign body granulomas and abscesses due to bovine collagen injections often regress spontaneously within 1–2 years. Other types of foreign body granuloma may persist for decades.

Special Granuloma Formation

Special granuloma formation includes recurrent pyogenic granulomas with satellitosis and Durck's granuloma.

- **Recurrent pyogenic granulomas with satellitosis:** Development of recurrent pyogenic granulomas with multiple satellite lesions is rare and most often associated with trauma or carbon dioxide laser excision of a previous recurrent primary pyogenic granuloma. Pyogenic granuloma with satellitosis is tumor-like non-neoplastic growth of the oral mucosa or skin. Pyogenic granulomas with satellitosis can be demonstrated in cat-scratch fever and lymphogranuloma venereum. Pyogenic granulomas with satellitosis show central neutrophilic infiltrate.
- **Durck's granulomas:** Durck's granulomas are demonstrated in brain containing activated microglia/macrophages appearing at the site of a prior ring hemorrhage in cerebral malaria caused by *Plasmodium falciparum*. Malaria infestation of central nervous system can cause a severe neurological syndrome

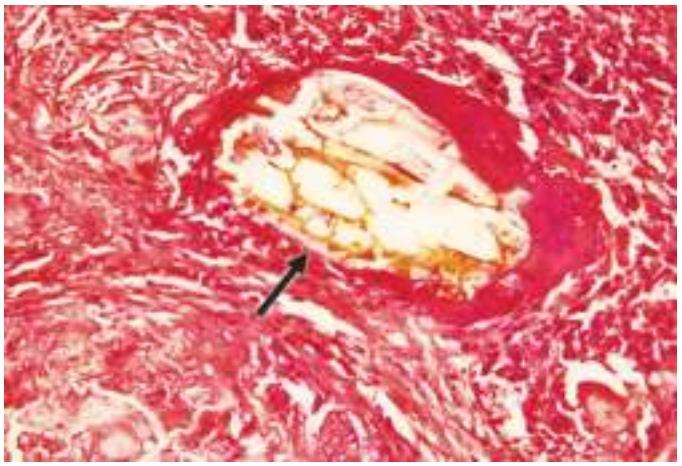

Fig. 2.47: Foreign body granulomas. Foreign body granulomas may develop, when immune system is unable to digest exogenous foreign body, resulting in the accumulation of macrophages. As macrophages surround and isolate foreign body, some of them will fuse to form multinucleated giant cells, T cells and fibroblasts also participate in this inflammatory response (arrow) (400X).

termed cerebral malaria. **Cerebral malaria** is characterized by preferential sequestration of parasitized red blood cells in the cerebral microvasculature. Immunohistochemistry and electron microscopy studies have revealed widespread cerebral endothelial cell activation, focal endothelial damage and necrosis in a patient of cerebral malaria.

MULTINUCLEATED GIANT CELLS

Normally, multinucleated giant cells are present in bone marrow (megakaryocytes), bone (osteoclasts) and placenta (syncytiotrophoblasts). Multinucleated giant cells are formed by fusion of activated macrophages (epithelioid cells) showing multiple nuclei.

- Epithelioid cells are recruited by IL-4 and IFN-γ, which measure 40–50 micron in diameter. Cytoplasm of giant cells is abundant and contains 15 or more small nuclei. Multinucleated giant cells include Langhans' giant cells, foreign body giant cells, Touton giant cells, Reed-Sternberg cells, Aschoff's giant cells, and tumor giant cells.
- Types of multinucleated giant cells are shown in Fig. 2.48A to G. Giant cells in various pathologic disorders are given in Table 2.51. Giant cells seen in bone tumors and tumor-like conditions are given in Table 2.52. Differences between Langhans' giant cell and tumor giant cell are given in Table 2.53.

Langhans' Giant Cells

Langhans' giant cells are large multinucleated cells found in granulomatous inflammatory conditions. These cells are formed by the fusion of epithelioid cells (modified macrophages) oriented around tuberculosis antigen with the multiple nuclei arranged in a horseshoe-shaped pattern in the cell periphery and an eosinophilic cytoplasm, representing the most successful type immune response. Langhans' giant cell in tissue section is shown in Fig. 2.49.

Foreign Body Giant Cells

A foreign body giant cell is a collection of fused macrophages which are generated in response to the presence of a large foreign body formed through signaling from

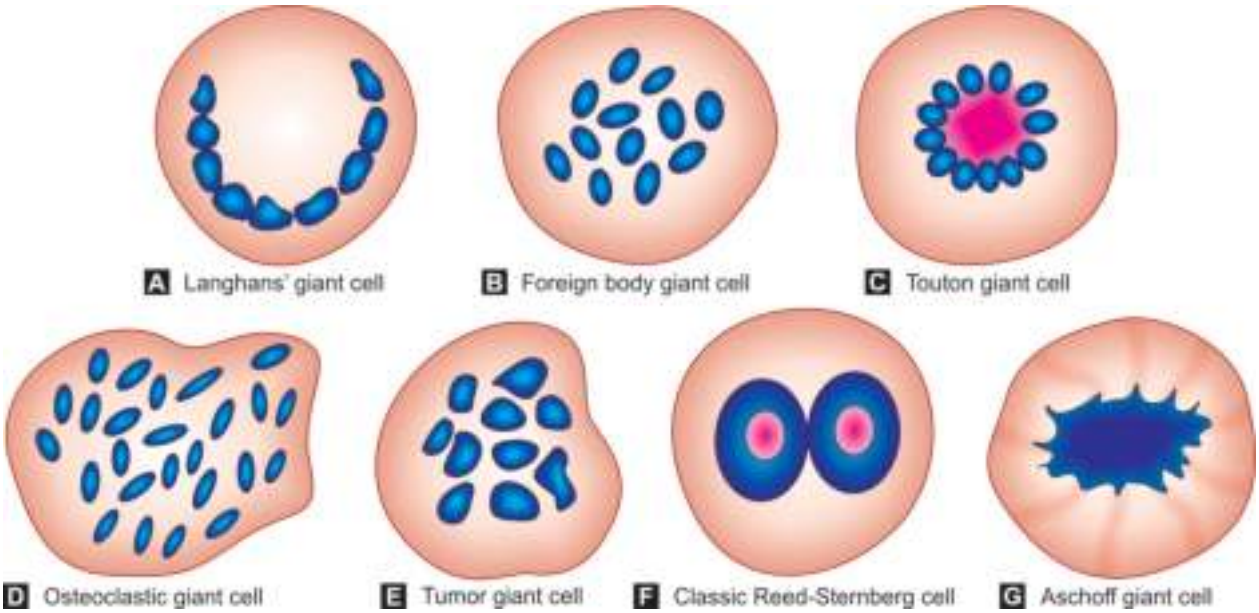

Fig. 2.48: Types of multinucleated giant cells. (A) Langhans' giant cell, (B) foreign body giant cell, (C) Touton giant cell, (D) osteoclastic giant cell, (E) tumor giant cell, (F) classic Reed-Sternberg cell, (G) Aschoff giant cell.

Table 2.51 Giant cells in various pathologic disorders

Pathological Disorder	Morphology and Condition
Langhans' giant cells	
Tuberculosis	Langhans' giant cells contain peripherally arranged nuclei in a horseshoe-shaped pattern
Foreign body giant cells	
Prolonged exposure to exogenous or endogenous substances	Foreign body giant cells show haphazardly scattered nuclei around
Foreign body granulomas present around foreign material	Surgical suture materials, implanted prosthesis, asbestos fibers, silica, beryllium, necrotic adipose tissue, necrotic and bone and gouty tophus (uric acid crystals)
Touton giant cells	
Juvenile xanthogranuloma, xanthoma disseminatum and dermatofibroma	Touton giant cells showing ring of nuclei separating outer foamy cytoplasm
Aschoff's giant cells	
Rheumatic heart disease	Aschoff's nodule composed of swollen eosinophilic collagen fibers, central fibrinoid necrosis surrounded by macrophages, lymphocytes, plasma cells and occasional multinucleated giant cells
Reed-Sternberg cells	
Hodgkin's disease	▪ Popcorn cells (lymphohistiocytic cells) in lymphocytic rich variant ▪ Lacunar cells in nodular sclerosis variant ▪ Classic Reed-Sternberg cells in mixed cellularity variant
Warthin-Finkeldey giant cells	
Measles	Giant cells
Tumor giant cells	
Tumors	Benign and malignant bone lesions
Giant cells in normal tissues	
Bone	Osteoclasts
Bone marrow	Megakaryocytes
Placenta	Syncytiotrophoblastic giant cells

Table 2.52 Giant cells seen in bone tumors and tumor-like conditions

Benign Tumors or Tumor-like Conditions
Osteoclastoma
Benign fibrous histiocytoma
Chondroblastoma
Chondromyxoid fibroma
Fibrous dysplasia
Metaphyseal fibrous defects (nonossifying fibroma)
Aneurysmal bone cyst
Malignant Tumors
Malignant fibrous histiocytoma
Fibrosarcoma
Giant cell variant of osteosarcoma

IL-3 and IL-4. Foreign body giant cell contains up to 200 nuclei within cytoplasm, which produce reactive products associated with phagocytosis and respiratory burst that can degrade the surface of the biomaterial leading to potential failure of the implanted biomaterial.

Touton Giant Cells

Touton giant cells are observed in lesions with high lipid content such as fat necrosis, xanthoma, xanthelasma, xanthogranuloma and dermatofibroma. Touton giant cells contain a ring of nuclei surrounding a central homogenous amphophilic and eosinophilic cytoplasm, while foamy cytoplasm near the periphery of the cell. Touton giant cells are formed by the fusion of macrophage-derived foam cells. It has been suggested that IL-3, IFN-γ and M-CSF may be involved in the production of Touton giant cells, which are positive for CD14, CD68, CD163, factor XIIIa and fascin, suggesting that Touton giant cells are dermal dendrocytes.

Aschoff's Giant Cells

Aschoff giant cells are associated with rheumatic heart disease. Normally, cardiac macrophages are present in small number. But, in rheumatic heart disease,

Table 2.53 Differences between Langhans' giant cell and tumor giant cell

Features	Langhans' Giant Cell	Tumor Giant Cell
Origin	Fusion of epithelioid cells in response to some chronic inflammation	Anaplastic giant cells, dividing nuclei of neoplastic cells
Number of nucleus/nuclei	Containing 20 or more small nuclei—either around the periphery in horseshoe/ring form or clustered at two poles	Prominent nuclei—either single huge polymorphic nucleus or may have two or more nuclei
Nucleus morphology	Normal appearing nucleus, same as macrophage and epithelioid cells	Nucleus hyperchromatic
Size of nucleus	Normal	Large in relation to cells
Associated features	Absent	Showing other features of malignancy

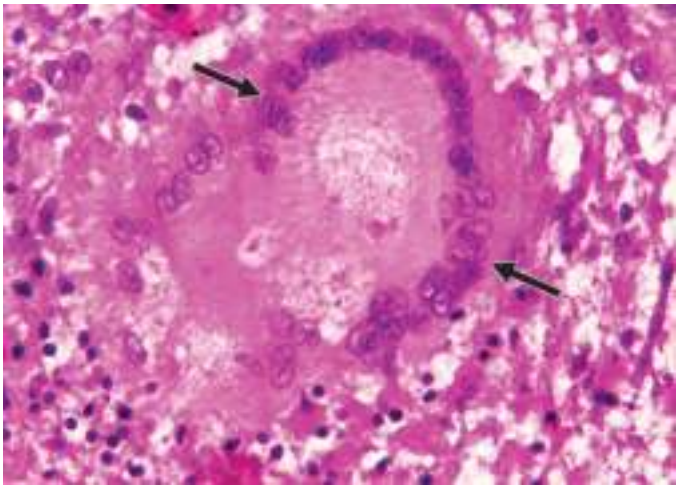

Fig. 2.49: Langhans' giant cell in tissue section. Langhans' giant cell is a large cell characterized by an arc of nuclei toward the periphery of the outer membrane giving horseshoe/ring appearance. The cell is formed by the fusion of epithelioid cells, which are derived from immune cells, called macrophages (arrows) (400X).

macrophage number is increased, which participate in the formation of Aschoff nodule surrounding centers of fibrinoid necrosis. Aschoff giant cells are known as Anitschkow cells, which contain basophilic cytoplasm, up to four nuclei with central band of clumped chromatin that gives caterpillar-like appearance in longitudinal sections also called caterpillar cells, which have owl-eyed appearance in cross sections.

Reed-Sternberg Cells

Diagnostic criteria of Hodgkin disease include demonstration of neoplastic Reed-Sternberg cells in the lymph nodes. Classic, mononuclear, pleomorphic and lacunar variants of Reed-Sternberg cells are demonstrated in various histologic types of Hodgkin disease. Classic Reed-Sternberg cells are seen in mixed cellularity variant of Hodgkin disease. Mononuclear Reed-Sternberg cells can be observed in any variant of Hodgkin disease. Pleomorphic Reed-Sternberg cells are seen in lymphocytic depletion variant of Hodgkin disease. Lacunar Reed-Sternberg cells are observed in nodular sclerosis variant of Hodgkin disease. Lymphohistiocytic Reed-Sternberg cells are sometimes called popcorn cells and seen in nodular lymphocytic predominant Hodgkin disease.

Warthin-Finkeldey Giant Cells

Warthin-Finkeldey giant cells are found in hyperplastic lymph nodes early in the course of measles, systemic lupus erythematosus and HIV-infected persons, as well as in Kimura disease, but rarely observed in lymphoma and non-neoplastic lymph node disorders. Warthin-Finkeldey giant cells have an appearance akin to 'grape-like clusters' or 'Mulberry'. Warthin-Finkeldey giant cells are large cells enclosing multiple, round, regular-sized nuclei having inconspicuous nucleoli.

SYSTEMIC EFFECTS OF INFLAMMATION

In some cases, tissue injury can result in prominent systemic inflammatory manifestations as a result of release of chemical mediators into the circulation.

ACUTE-PHASE REACTANTS SYNTHESIS

Within hours of onset of inflammation, acute phase response is triggered by infection, tissue injury, prostaglandin E, interferons associated viral infection, cytokines synthesis (IL-1, IL-6, and TNF-α), and synthesis of acute-phase reactants by liver such as C-reactive proteins, serum amyloid A, haptoglobin and fibrinogen. These acute-phase reactents reach to the site of inflammation to kill the pathogens by opsonization (CRP and SAA), clearing necrotic cells and activating complement system pathways.

- Acute-phase reactants are analyzed to monitor the progress of disease activity and assess response to therapy in inflammatory disorders (e.g. rheumatoid arthritis, juvenile chronic arthritis, ankylosing

spondylitis, Reiter's syndrome, psoriatic arthropathy, vasculitis, rheumatic fever).

- Measurement of acute-phase reactants is useful to detect complications of a known disease (e.g. immune complex deposition, postsurgical infection).
- Acute-phase proteins and their functions are given in Table 2.54. Measurement of acute-phase reactants in clinical practice is given in Table 2.55.

Immune-mediated Acute-phase Reactants

Immune-mediated acute-phase reactants include C-reactive protein (CRP), mannose-binding lectin (MBL) protein, complement proteins and α_1-acid glycoprotein.

- **C-reactive protein (IL-6):** C-reactive protein has opsonization property, which is a sensitive marker of cell necrosis associated with acute inflammation and disease activity. Its concentration is increased in

Table 2.54 Acute-phase proteins and their functions

Protein	Functions
Immune-related acute-phase reactants	
C-reactive protein	Opsonization
Mannose-binding lectin (MBL)	Opsonization, complement activation
Complement proteins	Inflammatory response to kill pathogens
α_1-Acid glycoprotein	Binding and transport of specific drugs
Antiproteases (antienzymes) acute-phase reactants	
α_1-Antitrypsin (α_1-AT)	Serine protease inhibitor
α_2-Macroglobulin (α_2-M)	Antiprotease
Antioxidants acute-phase reactants	
Ceruloplasmin	Antioxidant and binds copper
Coagulation factors acute-phase reactants	
Fibrinogen	Coagulation cascade
Factor VIII	Coagulation cascade
Other acute-phase reactants	
Serum amyloid A protein	Apolipoprotein
Haptoglobin	Haptoglobin binds hemoglobin
Plasma fibronectin	Tissue repair
Ferritin	Makes iron available for cellular processes and protects lipids, DNA and proteins from toxic effects of iron
Lipopolysaccharide-binding protein (LBP)	Binds to bacterial lipopolysaccharide and presents to cell surface recognition receptors called TLR4 and CD31 and elicits response
Cysteine proteinase inhibitor	Antiprotease

Decreased concentration of acute-phase reactants in acute inflammation include albumin, transferrin, transthyretin (TBPA) and retinol-binding protein (RBP).

Table 2.55 Measurement of acute-phase reactants in clinical practice

Acute-Phase Reactants (Proteins)	Normal Concentration Range	Concentration in Acute Inflammation	Response Time
C-reactive protein	0.0008–0.004 g/L	0.4 g/L	6–10 hours
α-Antichymotrypsin	0.3–0.6 g/L	3.0 g/L	10 hours
α-Antitrypsin	2.0–4.0 g/L	7.0 g/L	24 hours
Orsomucoid	0.5–1.4 g/L	3.0 g/L	24 hours
Haptoglobin	1.0–3.0 g/L	6.0 g/L	24 hours
Fibrinogen	2.0–4.5 g/L	10.0 g/L	24 hours
C3	0.55–1.2 g/L	3.0 g/L	48–72 hours
C4	0.2–0.5 g/L	1.0 g/L	48–72 hours
Ceruloplasmin	0.15–0.6 g/L	2.0 g/L	48–72 hours

disrupted atheromatous plaques in coronary arteries, which may predispose to thrombosis and myocardial infarction. On this basis; anti-inflammatory agents are being administered in these patients to reduce the risk of myocardial infarction. C-reactive protein is excellent marker to monitor of the disease activity in patient suffering from rheumatoid arthritis. C-reactive protein can be analyzed in the serum as a nonspecific marker of inflammation. Serial measurements of c-reactive proteins can be used to monitor progress of an inflammatory disease.

- **Mannose-binding lectin protein:** Mannose-binding lectin (MBL) protein is an acute-phase reactant produced in the liver in response to acute inflammation, which plays key role in complement activation and opsonization of pathogens. MBL recognizes and binds to sugars, such as mannose, fucose and glucose, that are found on the surface of bacteria, viruses and yeast and turning on complement system. Normal serum levels of MBL range from 800 to 1000 ng/ml in healthy Caucasians. MBL protein synthesis is initiated when pattern-recognition molecules bind to the pathogen-associated molecular patterns (PAMPs) on the surface of pathogens or to necrotic or apoptotic cell.
- **α_1-Acid glycoprotein:** α_1-Acid glycoprotein is an acute-phase protein. It is an important plasma protein involved in binding and transport of specific drugs such as diazepam, disopyramide and chlorpromazine. α_1-Acid glycoprotein concentration rises several folds during an acute inflammatory response.

Other Acute-phase Reactants Synthesis

Other acute-phase reactants include serum amyloid A (SAA) protein, haptoglobin, plasma fibronectin ferritin, lipopolysaccharide-binding protein (LBP) and cysteine proteinase inhibitor.

- **Serum amyloid A protein:** Serum amyloid associated protein belongs to a family of apolipoproteins associated with high density lipoprotein (HDL) in plasma produced in the liver. High density lipoproteins are used by macrophages as a source of energy. Prolonged synthesis of SAA results in secondary amyloidosis. Different isomers of serum amyloid associated protein are expressed constitutively at different levels in response to inflammatory stimuli (acute-phase response). SAA can be produced by macrophages in inflammatory tissue. SAA deposition in organs is found in patients with sarcoidosis, rheumatoid arthritis, inflammatory bowel disease (ulcerative colitis, Crohn's disease) and chronic persistent infections.
- **Haptoglobin:** Haptoglobin binds hemoglobin, which is an acute-phase reactant that scavenges hemoglobin in the event of independently of the degree of intravascular or extravascular hemolysis associated with tissue injury process. Haptoglobin prevents iron loss and renal damage. Haptoglobin also acts as antioxidant activity and plays a role in modulating many aspects of the acute phase response. High haptoglobin levels may be a sign of inflammatory disease.
- **Fibronectin and vitronectin:** Fibronectin and vitronectin are also acute phase reactant proteins. Fibronectin plays a role in tissue repair.
- **Ferritin:** Ferritin makes iron available for cellular processes and protects lipids, DNA and proteins from toxic effects of iron.
- **Lipopolysaccharide-binding protein:** Lipopolysaccharide-binding protein binds to bacterial lipopolysaccharide and presents to cell surface recognition receptors called TLR4 and CD31 and elicits response.

Antiproteases (Antienzymes) Acute-phase Reactants

Antiproteases acute-phase reactants include α_1-antitrypsin (ATT) and α_2-macroglobulin.

- **α_1-Antitrypsin:** α_1-Antitrypsin is a serine protease inhibitor produced by liver. It is one of the classical acute-phase response proteins with high serum ATT level indicates state of acute inflammation.
- **α_2-Macroglobulin:** α_2-Macroglobulin is an antiprotease, which functions as an inhibitor of coagulation by inhibiting thrombin. It binds foreign peptides and serves as host defense barrier against pathogens in the plasma and tissues. Its level may be increased in nephrotic syndrome.
- **Cysteine proteinase inhibitor:** Cysteine proteinase inhibitor has antiprotease activity. Human mucous membrane secretions contain a proteinase inhibitor, which is secreted locally inhibits trypsin, chymotrypsin, granulocyte elastase and cathepsin G as well as mast cell chymase and tryptase.

Antioxidants Acute-phase Reactants

Ceruloplasmin is an antioxidant that binds copper. It is an acute-phase plasma protein produced principally by liver and activated monocytes and macrophages. The plasma level of ceruloplasmin nearly doubles in response to inflammation, infection or trauma, which are mediated by cytokines. High ceruloplasmin levels indicate abnormally high levels of copper.

Coagulation Proteins as Acute-phase Reactants

Fibrinogen and factor VIII play key role in coagulation cascade.

- **Fibrinogen:** Fibrinogen plays key role in coagulation cascade, which is a marker of inflammation, which when elevated indicates the presence of inflammation and identifies persons with a high-risk for cardiovascular disorders. Increased synthesis of

fibrinogen promotes red blood cells (RBCs) rouleaux formation, which is the basis of increased erythrocyte sedimentation rate (ESR) in inflammation. In addition, fibrinogen acts as an acute-phase reactant.

- **Factor VIII:** Coagulation factor VIII is an acute-phase reactant protein in humans that plays key role in coagulation cascade. Factor VIII has been recently shown to be transcriptionally responsive to interleukin-6 (IL-6). Elevated levels of factor VIII and von Willebrand factor may indicate endothelial dysfunction and inflammation in different settings including chronic autoimmune diseases, that could serve as potential candidate biomarkers of chronic graft-versus-host disease.

CLINICAL MANIFESTATIONS IN INFLAMMATION

Systemic inflammation-associated clinical syndromes (sepsis and septic shock) have high mortality and remain as challenge in emergency medicine. Systemic inflammation is usually accompanied by changes in body temperature (fever or hypothermia), and lethargy.

Septic Shock

Septic shock is a life-threatening condition that occurs when a systemic infection leads to dangerously low-blood pressure (hypotension), generalized vasodilatation, platelet aggregation, low tissue perfusion and widespread organs dysfunction, particularly lungs, kidneys, liver, and heart. Septic shock can be a complication of infections due to gram-negative bacteria, fungi or viruses (flu or COVID-19).

- Septic shock occurs in concert with activation of monocytes/macrophages and synthesis of large quantity of cytokines IL-1 and TNF-α and activation of neutrophils that interact with the endothelium through pathogen recognition receptors and result in further involvement of cytokines, proteases, kinins, reactive oxygen species (ROS) and nitric oxide.
- Primary site response of these chemical mediators induces microvascular injury and also activates the coagulation and complement cascades which further exacerbate the vascular injury leading to capillary leakage. This cascade of events is responsible for the clinical manifestations of sepsis to septic shock.

Fever

Patient has above normal temperature (>1 to 4°C) due to bacterial products and cytokines, which act as pyrogen. Fever plays important role in providing a hostile environment for bacterial and viral reproduction. More oxygen is available for the oxygen-dependent myeloperoxidase (MPO) system. Mechanisms of fever and therapeutic agent are described as under.

- Exogenous pyrogens released by bacteria or injured cells stimulate macrophages to synthesize IL-1 and TNF-α (endogenous pyrogens). IL-1 stimulates prostaglandin E_2 (PGE_2) synthesis in the hypothalamic thermoregulatory centers, thereby resets the body temperature set point at higher level (fever).
- Profound chills with shivering, sweating and piloerection are associated with fever. Inhibitors of cyclooxygenase (e.g. aspirin) block the fever response by inhibiting PGE_2 synthesis in the hypothalamus.
- Nonsteroidal anti-inflammatory drugs (NSAIDs) including aspirin reduce fever by inhibiting cyclooxygenase and thus blocking prostaglandins synthesis.

Lethargy and other Manifestations

Lethargy, a common feature of the acute-phase response, results from the effects of IL-1 and TNF-α on the central nervous system. Patient presents with increased pulse rate, hypotension, rigors (shivering), chills (search for warmth), anorexia, somnolence, and malaise (probably because of the actions of cytokines on brain cells). There is decreased sweating due to redirection of blood flow from cutaneous to deep vascular beds leads to minimize heat loss.

SYSTEMIC INFLAMMATORY RESPONSE

Systemic inflammatory response is a clinical triad characterized by (a) disseminated intravascular coagulation, (b) cardiovascular failure and hypoglycemia.

- **Disseminated intravascular coagulation (DIC):** Patient develops DIC by the action of bacterial products (lipopolysaccharide) and TNF-α. These bacterial products and TNF-α stimulate endothelial cells to express tissue factor and promote platelets aggregation, which also inhibit anticoagulant mechanism by (a) decreasing synthesis of thrombomodulin by endothelial cells, and (b) decreasing the expression of tissue factor pathway inhibitor (TFPI). This condition is always fatal.
- **Cardiovascular failure:** Cytokines (IL-1 and TNF-α) activate cardiac myocytes and vascular smooth muscle cells to synthesize nitric oxide (NO), which causes heart failure and hemodynamic shock due to loss of perfusion pressure. Patient may develop acute respiratory distress syndrome (ARDS) is neutrophil-mediated endothelial injury characterized by escape of fluid from blood into the lung air spaces.

METABOLIC ALTERATIONS IN INFLAMMATION

Various metabolic alterations can occur in inflammation, which include negative nitrogen balance, skeletal muscle catabolism, glucose metabolism, lipid metabolism, mineral metabolism and acid–base balance.

- **Negative nitrogen balance:** Negative nitrogen balance occurs due to protein catabolism. Metabolic products increase the osmotic pressure in interstitial

space which attracts water and thus contribute to edema (swelling—tumor).

- **Skeletal muscle catabolism:** Skeletal muscle catabolism provides amino acids that can be used in the immune response and tissue repair.
- **Glucose metabolism:** Cytokines (IL-1 and TNF-α) cause liver injury and impair liver function, resulting in a failure to maintain normal blood glucose levels due to lack of glycolysis from stored glycogen. Anaerobe utilization of glucose is increased because of hypoxia with increased formation of lactic acid and pyruvic acid.
- **Lipid metabolism:** Lipid metabolism leads to increased formation of ketone bodies and fatty acids.
- **Mineral metabolism:** There is increased extracellular K^+ concentration in inflammation.
- **Acid–base balance:** Metabolic acidosis occurs as a result of formation of ketone bodies and lactic acid.

RELEASE OF CHEMICAL SUBSTANCES IN INFLAMMATION

Interleukin-1 (IL-1) and tumor necrosis factor α (TNF-α) synthesized by macrophages play a key role in release of norepinephrine, vasopressin and activation of renin-angiotensin-aldosterone system.

HEMATOLOGIC ALTERATIONS IN INFLAMMATION

Hematologic findings in acute inflammation include leukocytosis, leukemoid reactions, leukopenia, monocytosis, lymphopenia, lymphocytosis, eosinophilia and elevated erythrocyte sedimentation rate (ESR).

- **Leukocytosis:** Leukocytosis is defined as an absolute increase in the circulating white blood cell count. In acute inflammation (bacterial infection), cytokines (IL-1, TNF-α) released by leukocytes stimulate bone marrow leading to leukocytosis (TLC 15000–20,000/cu mm). In prolonged infection, colony stimulating factors (CSFs) induce proliferation of myeloid precursors in the bone marrow. There is shift to the left, which is defined as >10% band form neutrophils or the presence of metamyelocytes. Neutrophils contain toxic granules (e.g. prominence of azurophil granules in lysosomes).
- **Leukemoid reactions:** In some cases, bone marrow produces more immature leukocytes in increased number into the circulation (i.e. shift to the left) showing leukocytosis as high as 40,000–100,000/cu mm (leukemoid reactions). It is sometimes difficult to differentiate leukemoid reaction from leukemia.
- **Leukopenia:** Leukopenia is defined as an absolute decrease in the circulating WBC count. Leukopenia is occasionally encountered under conditions of chronic inflammation, especially in patients who are malnourished or who suffer from a chronic debilitating disease such as typhoid fever, viruses, rickettsiae, certain protozoa, disseminated cancer and rampant (difficult to treat) tuberculosis.
- **Monocytosis:** Peripheral blood shows absolute monocytosis in chronic debilitating disease (e.g. tuberculosis, rheumatoid arthritis). There is increase in serum IgG levels.
- **Lymphopenia:** Lymphopenia occurs due to sequestration of B and T cells in lymph nodes, which indicates apoptosis of lymphocytes.
- **Lymphocytosis:** Lymphocytosis is defined as an increase in the absolute peripheral blood lymphocyte count above the normal range (<4,000/μl in children and 9,000/μl in infants) in acute viral infections (infectious mononucleosis, mumps and German measles), whooping cough, tuberculosis, brucellosis and lymphoproliferative diseases.
- **Eosinophilia:** Eosinophilia is demonstrated in bronchial asthma, hay fever and parasitic infestations.
- **Elevated erythrocyte sedimentation rate (ESR):** Increased plasma levels of acute phase reactants accelerate erythrocyte sedimentation rate. ESR index estimated by Wintrobe's tube or Westergren's pipette expressed as mm/hour is important to monitor the activity of many inflammatory diseases such as tuberculosis and rheumatoid arthritis.

TISSUE REPAIR

Tissue repair is a natural process in which architecture and function of the tissue is restored by compensatory regeneration of active resident cells as well as maturation of stem cells, following loss of blood supply, mechanical trauma, surgical procedure, or chemical-induced injury.

- Tissue repair requires the highly coordinated interaction of vascular component, cellular component and chemical mediators.
- If the injured tissue is incapable of complete restoration to original state, tissue repair occurs by laying down of connective tissue and scar formation.
- Fibrosis develops in a tissue space by organization of the inflammatory exudate in chronic inflammation occupying the tissue space by extensive deposition of collagen in the parenchymal organ.

NORMAL CELL PROLIFERATION AND TISSUE GROWTH REGULATION

Size of cell population in adult tissue is determined by rate of cell proliferation, differentiation and apoptosis. Increased cell numbers may result from either increased proliferation or decreased cell death by apoptosis.

- Apoptosis is a physiologic process required for tissue homeostasis, but it can also be induced by a variety of pathologic stimuli (*refer* to Chapter 1).
- Hyperplasia is an increase in the number of cells of a tissue due to increased rate of cell division resulting from increased functional demand, hormonal stimulation. It may be physiologic, compensatory or pathologic conditions (*refer* to Chapter 1).
- Tissue healing occurs by removal of the damaged tissue by phagocytosis, lymphatic drainage of exudates, angiogenesis, and regeneration of residual stem cells, which restore the continuity of the injured tissue.
- Damage to residual stem cells leads to fibrosis resulting in malfunction of organs. Both platelet-derived growth factor (PDGF) and fibroblast growth factor (FGH) participate in migration, proliferation of fibroblasts leading to synthesis and deposition of extracellular matrix leading to wound healing. Most of the organs heal by regeneration and fibrosis.

TISSUE PROLIFERATIVE ACTIVITY

Tissue proliferative activity is a process of replacement of damaged components and returning to normal state, which requires preservation of the basement membrane, residual stem cells and intact extracellular matrix (collagen fibers type 3 and fibronectin). Regeneration is not possible if the stem cells are destroyed.

- Tissue healing involves two processes: (a) proliferation of residual stem cells to replace lost tissue; and (b) migration of residual stem cells into the vacant space.
- Regeneration of cells depends on the ability of cells to replicate (e.g. labile cells, stable cells and permanent cells) and growth factors such as VEGF, FGF-β, and EGF, which stimulate cell division resulting in restoration of tissue to normal.
- The tissues are divided into three groups based on proliferative activity of their cells in the context of the cell cycle, which include labile cells, stable cells and permanent cells. Role of labile, stable and permanent cells in tissue healing is shown in Fig. 2.50. Cells based on proliferative activity in the context of cell cycle are given in Table 2.56.

Labile Cells/Continuous Dividing Cells

Labile cells enter cell cycle continuously and proliferate throughout life. Regeneration of cells is excellent, if stem

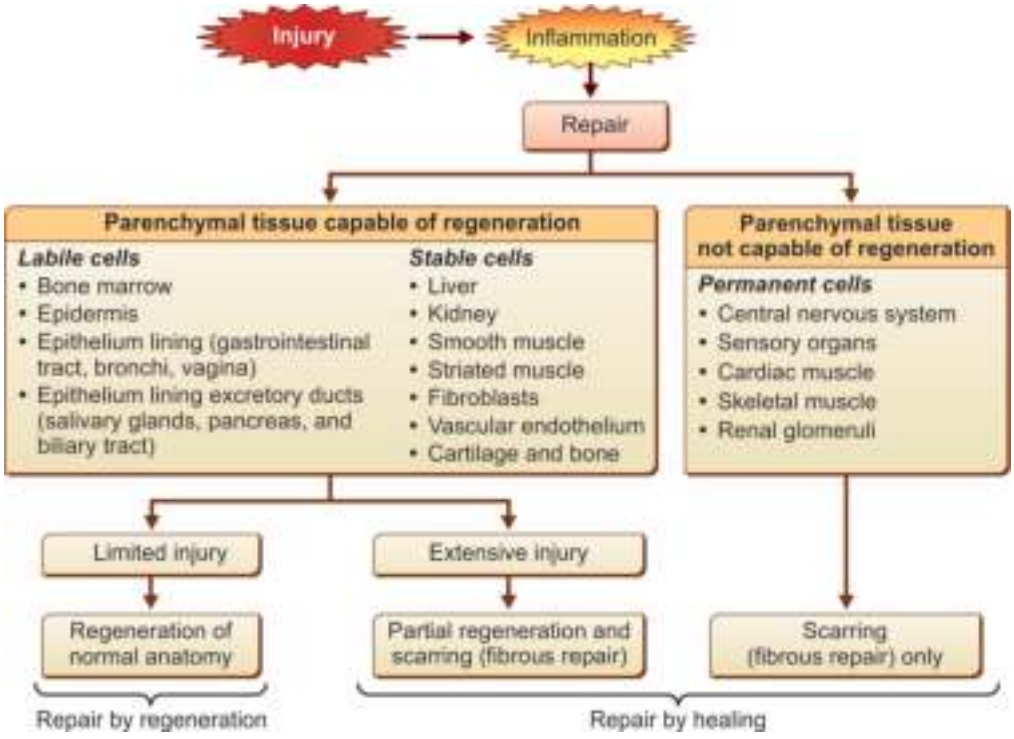

Fig. 2.50: Role of labile, stable and permanent cells in tissue healing. Labile cells in healing and repair process. Parenchymal tissue with labile cells contains stem cells that continuously regenerate new stem cells. Tissue with labile cells repairs by regeneration. Parenchymal tissue with stable cells contains stem cells that reproduce rapidly as a result of injury. Tissues with stable cells repair by regeneration. Tissues with permanent cells do not contain stem cells. Hence, injury to tissues with permanent cells repair by fibrosis only.

Table 2.56 Cells based on proliferative activity in the context of cell cycle

Labile Cells
Bone marrow cells
Epidermis
Epithelium lining gastrointestinal tract, bronchi and vagina
Epithelium lining excretory ducts of salivary glands, pancreas, and biliary tract
Stable Cells
Liver
Kidney
Smooth muscle
Fibroblasts
Vascular endothelium
Cartilage
Bone
Permanent Cells
Brain
Cardiac muscle
Skeletal muscle

cells are not destroyed. Examples of labile cells are bone marrow cells and epithelium lining epidermis, oral cavity, gastrointestinal tract, genitourinary tract, uterus, cervix and vagina, excretory ducts of salivary glands, pancreas, and biliary tract. Organs with labile cells heal by regeneration without fibrosis.

Stable Cells/Quiescent Cells (Facultative Mitotic Cells)

Stable cells normally have little proliferative activity but remain capable of more rapid cell division following injury, e.g. liver, renal tubular epithelium and smooth muscle, fibroblasts, vascular endothelium, cartilage and bone. That is the reason that stable cells regenerate from G0 cells (quiescent) when needed.

Permanent Cells/Nondividing Cells

Permanent cells are irreversibly postmitotic terminally differentiated cells, which are incapable of division and regeneration in postnatal life. Healing occurs by fibrosis. Examples of permanent cells are neurons of central nervous system, sensory organs, renal glomeruli, myocardial muscle, and striated muscle. Injury to adult neurons is replaced by glial cells (gliosis in CNS), cardiac muscle in acute myocardial infarction replaced by fibrosis, and skeletal muscle fibrosis through the differentiation of the satellite cells located beneath myocytes basal lamina.

STEM CELLS IN TISSUE HOMEOSTASIS

Stem cells possess self-renewal properties to generate differentiated cell lineages, which are essential to give rise to these lineages during life. Embryonic and adult stem cells can be used to repopulate damaged cells. Generation and differentiation of stem cells is shown in Fig. 2.51. Stem cell therapy in clinical practice is given in Table 2.57.

Embryonic Stem Cells

Human embryonic stem cells are pluripotent stem cells derived from the inner mass of the blastocyst, an early-stage pre-implanted embryo. Human embryo reaches the blastocyst stage 4–5 days of post fertilization, at which time blastocyst consists of 70–100 cells. The blastocyst, later gets implanted into uterine endometrium. The embryonic stem cells are cultured and used to repopulate damaged cells in various organs such as **β-**embryonic stem cells in diabetes mellitus, myocardial embryonic stem cells in acute myocardial infarction and hepatocyte embryonic stem cells in hepatocellular injury.

- **Totipotent cells:** Totipotent cells are obtained from a fertilized oocyte in a woman's fallopian tube, that can differentiate into embryonic and extraembryonic cells to create an entire human body, which normally results in the birth of new human being.
- **Pluripotent cells:** Pluripotent cells are derived from totipotent cells, which have the potential to differentiate into almost any type of cell (i.e. embryonic stem cells from blastocyst).
- **Multipotent cells:** Multipotent cells can give rise to multiple cell types. Hematopoietic stem cell can change into several types of blood cells.
- **Oligopotent cells:** Oligopotent cell can differentiate into a few cell types (i.e. myeloid or lymphoid progenitor cells).
- **Unipotent cells:** Unipotent cell can only make one cell type itself, which also has the power to self-renewal (i.e. hepatocytes).

Adult Stem Cells

Adult stem cells, also known as somatic cells, are undifferentiated cells that reside among differentiated cells in a tissue or organ throughout the body after development. Adult stem cells possess two distinctive properties: self-renewal and capacity to differentiate into multiple lineages.

- Unlike embryonic stem cells, adult stem cells are multipotent progenitor cells, which possess limited differentiation potential, responsible for replenishing damaged or dead cells due to injury or disease.
- Adult stem cells are located in specialized vascular microenvironments, referred to as the stem cell

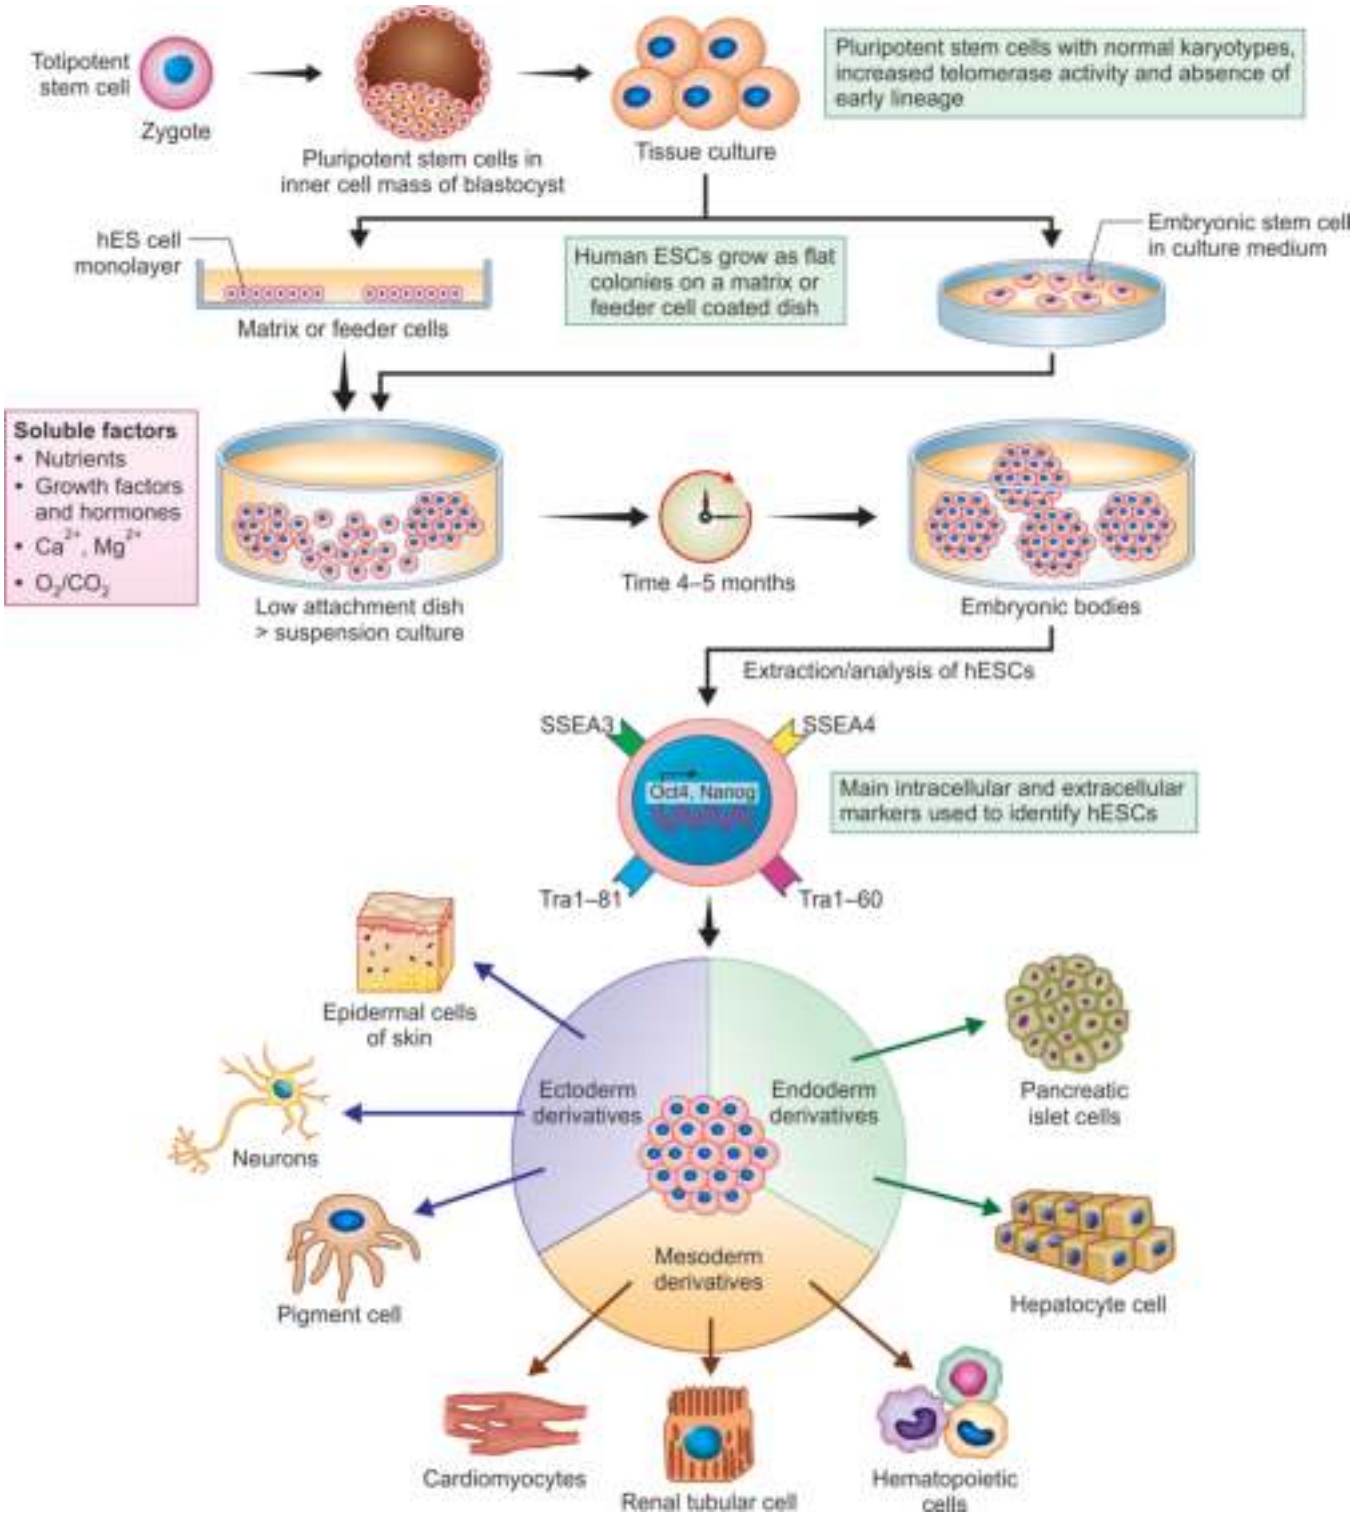

Fig. 2.51: Generation and differentiation of stem cells. Embryonic pluripotent stem cells obtained from inner cell mass of blastocyst are cultured and induced to obtain differentiated cells such as hepatocytes, pancreatic islets of Langerhans' cardiomyocyte and neurons.

niche: bone marrow, liver, epidermis, skeletal muscle, colon and cornea. These niche cells generate or transmit stimuli that regulate stem cell self-renewal and the generation of progeny cells.

- Adult stem cells can be reprogrammed into pluripotent cells, similar to embryonic stem cells, by the transduction of genes encoding embryonic stem cell transcription.

Table 2.57 Stem cell therapy in clinical practice

Disease	Stem Cell Therapy
Embryonic stem cells	
Diabetes mellitus	β-Embryonic stem cells
Myocardial infarction	Myocardial embryonic stem cells
Hepatocellular damage	Hepatocytic embryonic stem cells
Adult stem cells	
Restricted use skin, lining epithelia of gut, cornea and hemato-poietic tissue	Reprogramming of adult stem cells into pluripotent cells, similar to embryonic cells, by the transduction of genes encoding embryonic stem cell trans-cription

Pathology Pearls: Maintenance of Stem Cells

Maintenance of stem cells is achieved by two mechanisms: obligatory asymmetric replication and stochastic differentiation.

Obligatory Asymmetric Replication of Stem Cell

- Obligatory asymmetric replication is also known as symmetric cell division in which one cell is identical to the mother cells and the other cell is totally differentiated one.
- In obligatory asymmetric replication, each stem cell division produces two daughter cells with different cellular fates: one copy of the original stem cell retains self-renewal property, while second cell enters a differentiation pathway into a non-stem cell fate.
- Obligatory asymmetric replication is a key mechanism to ensure tissue homeostasis. In normal stem and progenitor cell, asymmetric cell division balances proliferation and self-renewal with cell cycle exit and differentiation.

Stochastic Differentiation of Stem Cell

- Stochastic differentiation refers to the process in which a father stem cell divides into two differentiated daughter cells.
- In order to maintain the population (stem cell reserve) in the body, a second father cell divides into two stem cells.

Stem Cell Therapy

Both embryonic stem (ES) and induced pluripotent stem (iPS) cells are capable of differentiating into various cell types. Adult stem cells, location and their clinical uses are given in Table 2.58.

- **Embryonic stem cell therapy:** Therapeutic cloning using embryonic stem cells is done by introducing diploid nucleus of an adult cell into an anucleate oocyte. The oocyte is activated, and the zygote divides to become a blastocyst that contains the donor DNA. The blastocyst is dissociated to obtain embryonic stem cells. Differentiated cells of adult tissues can be reprogrammed to become pluripotent by transferring their nucleus to an enucleated oocyte.
- **Induced pluripotent stem cell therapy:** The cells of a patient are placed in culture and transduced with genes encoding transcription factors, to generate induced pluripotent stem cells (iPS cells). The goal of stem cell therapy is to repopulate damaged organs of a patient or to correct a genetic defect, using the cells of the same patient to avoid immunological rejection.

Stem Cells in Tissue Homeostasis

Stem cells have an essential role in tissue homeostasis, repair and regeneration of a tissue or an organ. Stem cells are immature cells having unlimited ability of self-renewal and capacity to differentiate into the specialized cell types. The zygote gives rise to pluripotent cells in the embryo, which gives rise to multipotent tissue-specific stem cells that complete the process of organogenesis during fetal development.

- **Bone marrow stem cells:** Bone marrow consists of two types of stem cells: hematopoietic stem cells and marrow stromal cells.
  - **Hematopoietic stem cells:** Hematopoietic stem cells (HSCs) are pluripotent labile cells involved in the hematopoiesis. Labile cells enter cell cycle continuously and proliferate throughout life. Regeneration of cells is excellent, if stem cells are not destroyed. Hematopoietic stem cells are used in various hematologic disorders. These hematopoietic stem cells are obtained from bone marrow, umbilical cord and blood. Granulocyte macrophage colony stimulating factors administered to obtain hematopoietic stem cells.
  - **Marrow stromal cells:** Marrow stromal cells (MSCs) are multipotent, which do not participate in normal hemostasis. These marrow stromal cells are important for therapeutic applications to generate osteoblasts, chondroblasts, endothelial cells, myoblasts and adipocytes. Marrow stromal cells are obtained and administered to generate cells depending on the tissues.
- **Liver stem cells:** Liver stem cells are present in canals of Hering at the junction between parenchymal hepatocytes and biliary ductal system. Liver stems located in this niche may undergo transformation to bipotential progenitor 'oval cells', which are capable of differentiating into parenchymal hepatocytes and biliary ductular system. Oval cells are prominent in the patients with liver diseases such as recovery phase of fulminant hepatocellular failure, liver tumors, chronic hepatitis and advanced liver cirrhosis.
- **Neural stem cells in brain:** Brain contains neural stem cells (NSCs), also known as neural precursor cells, which are capable to generate neurons,

Table 2.58 Adult stem cells, location and their clinical uses

Location of Stem Cells	Clinical Use
Bone marrow stem cells	
Hematopoietic stem cells	Various hematological disorders
Marrow stromal cells	Generation of osteoblasts, chondroblasts, endothelial cells, myoblasts and adipocytes
Liver stem cells	
Canals of Hering	Oval cells prominent in recovery phase of fulminant hepatic failure, liver tumors, chronic hepatitis and cirrhosis
Neural stem cells	
Subventricular zone (SVZ) and dentate nuclei	Generating of neurons, astrocytes, oligodendrocytes in Parkinson's disease, Alzheimer disease and spinal cord injury
Epidermis stem cells	
Hair follicle bulge, interfollicular areas of epidermis and sebaceous glands	Wound healing
Skeletal muscle stem cells	
Satellite cells located beneath the myocyte basal lamina	Regeneration of injured skeletal muscle
Cardiac muscle stem cells	
Under debate	May be used in injured myocardium
Intestinal stem cells	
Located immediately above Paneth cells in the small intestine, or at the base of the crypts in the colon	Regeneration of crypts of small intestine
Limbal stem cells in cornea	
Located at the junction between the epithelium of the cornea and the conjunctiva	Corneal opacity and correction of photoreceptors

astrocytes and oligodendrocytes. Neural stem cells have been demonstrated in two areas of brain such as subventricular zone (SVZ) and dentate nuclei. Research is in progress for neural stem transplantation in patients suffering from Parkinson's disease, Alzheimer disease and spinal cord injury.

- **Skin epidermis stem cells:** Skin consists of stem cells in the epidermis regions: the hair follicle bulge, interfollicular areas of epidermis and sebaceous glands. Skin epidermis stem cells are regulated by two mechanisms: (a) Wnt pathway stimulates epidermis stem cells, and (b) bone morphogenic protein (BMP) inhibits epidermis stem cells. Bulge area of hair follicle is niche for stem cells. Epidermis stem cells are capable to generate all the cell lineages of the hair follicle. Human skin consists of labile cells capable of high turnover rate of about 4 weeks, which replenish surface epithelial cells in skin wound. These labile cells do not participate in normal hemostasis. Skin epidermis stem cells are shown in Fig. 2.52.
- **Intestinal epithelial stem cells:** Intestinal epithelial stem cells are located immediately above Paneth cells

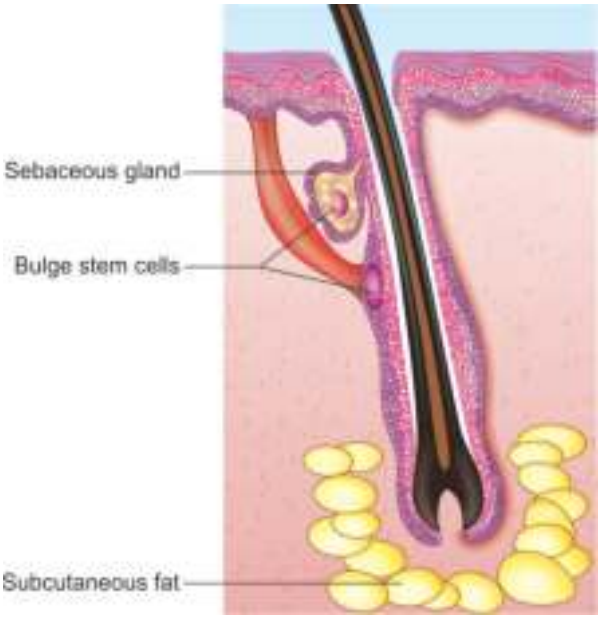

Fig. 2.52: Skin epidermis stem cells. Stem cells are located in the bulge area of the hair follicle, sebaceous glands and lower layer of the epidermis. Stem cells in skin replenish surface epithelial cells after skin wound.

in the small intestine, or at the base of the crypts in the colon. Intestinal stem cells are regulated by Wnt pathway and bone morphogenic protein similar to regulation seen in skin epidermis. Monoclonal proliferation of intestinal stem cell participates in formation of crypts in the villous structures of intestine. Stem cells in crypts of small intestine regenerate crypts in about 3–5 days.

- **Skeletal muscle satellite stem cells:** Skeletal muscle satellite cells are located beneath the myocyte basal lamina, which participate in regeneration of injured skeletal muscle. NOTCH signaling regulate skeletal muscle satellite stem cells by upregulation of δ-like ligands and angiogenesis.
- **Cardiac muscle stem cells:** Presence of cardiac muscle stem cells in myocardium is under debate. It has been proposed that myocardium may contain progenitor cells, which may repair the injured heart. There is no role of these progenitor cells during physiologic aging process.
- **Limbal stem cells in cornea:** The transparency of cornea depends on the integrity of the outermost corneal epithelium, which is maintained by limbal stem cells (LSCs). The limbal stem cells located at the junction between the epithelium of the cornea and the conjunctiva. Hereditary or acquired deficiency of limbal stem cells results in corneal opacity. It can be treated by transplantation of limbal stem cells. Limbal stem cells in cornea are shown in Fig. 2.53.

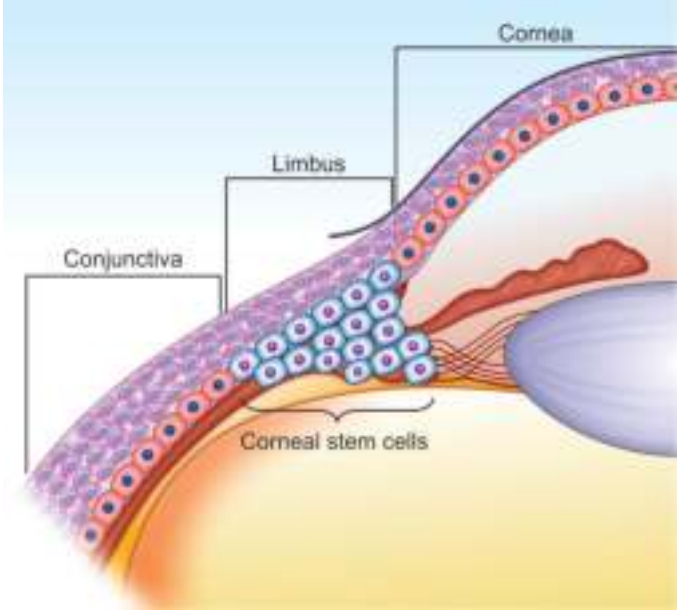

Fig. 2.53: Limbal stem cells in cornea. Limbal stem cells, also called corneal epithelial stem cells are located in the basal epithelial layer of the corneal limbus. These cells form the border between the cornea and sclera. Additionally, these cells also prevent the conjunctival epithelial cells from migrating onto the surface of cornea.

- **Retinal stem cells:** Retinal stem cells persist at the margin of retina, near the junction with the ciliary epithelium. Retinal stem cells transplantation may correct the loss of photoreceptors that occurs in degenerative diseases of the retina.

CELL CYCLE IN TISSUE HOMEOSTASIS

Before division, a cell must double its mass and content. This occurs during the growth phase, called interphase. Chromatin, the small, slender rods of the nucleus that give its granular appearance, begins to form. Replication and duplication of deoxyribonucleic acid occurs during the four phases of mitosis.

- During prophase, the chromosomes coil and shorten, and the nuclear membrane dissolves. Each chromosome is made up of a pair of strands called chromatids, which are connected by a spindle of fibers called a centromere.
- During metaphase, the centromeres divide, pulling the chromosomes apart. The centromeres then align themselves in the middle of the spindle.
- At the onset of anaphase, the centromeres begin to separate and pull the newly replicated chromosomes toward opposite sides of the cell. By the end of anaphase, 46 chromosomes are present on each side of the cell.
- Telophase is the final phase of mitosis—a new membrane forms around each set of 46 chromosomes. The spindle fibers disappear, cytokinesis occurs, and the cytoplasm divides, producing two identical new daughter cells.

CELL CYCLE PHASES

G0, G1, G2, S and M phases of cell cycle are shown in Fig. 2.54. Cell cycle phases comprising G0, G1, G2, and M phases are given in Table 2.59.

- **M (mitotic phase):** Mitotic phase describes the interval between the onset of prophase and conclusion of telophase. The cell undergoes mitosis and cytokinesis or equal division of chromosomes and cell membrane, cytoplasm and organelles between two new daughter cells. Ki-67 is expressed during active phases of cell cycle (G1/M).
- **G1 (pre-synthetic phase):** Following mitosis, the cell enters this phase. Synthesis of RNA, protein, organelles and cyclin-D occurs in G1 phase. The main difference between slowly and rapidly dividing cells is the length of the G1 phase of cell cycle.
- **S (synthetic phase):** Synthesis of DNA, RNA, and protein occurs in S phase. Labile cells undergo mitosis throughout life. Doubling of DNA occurs in this phase.

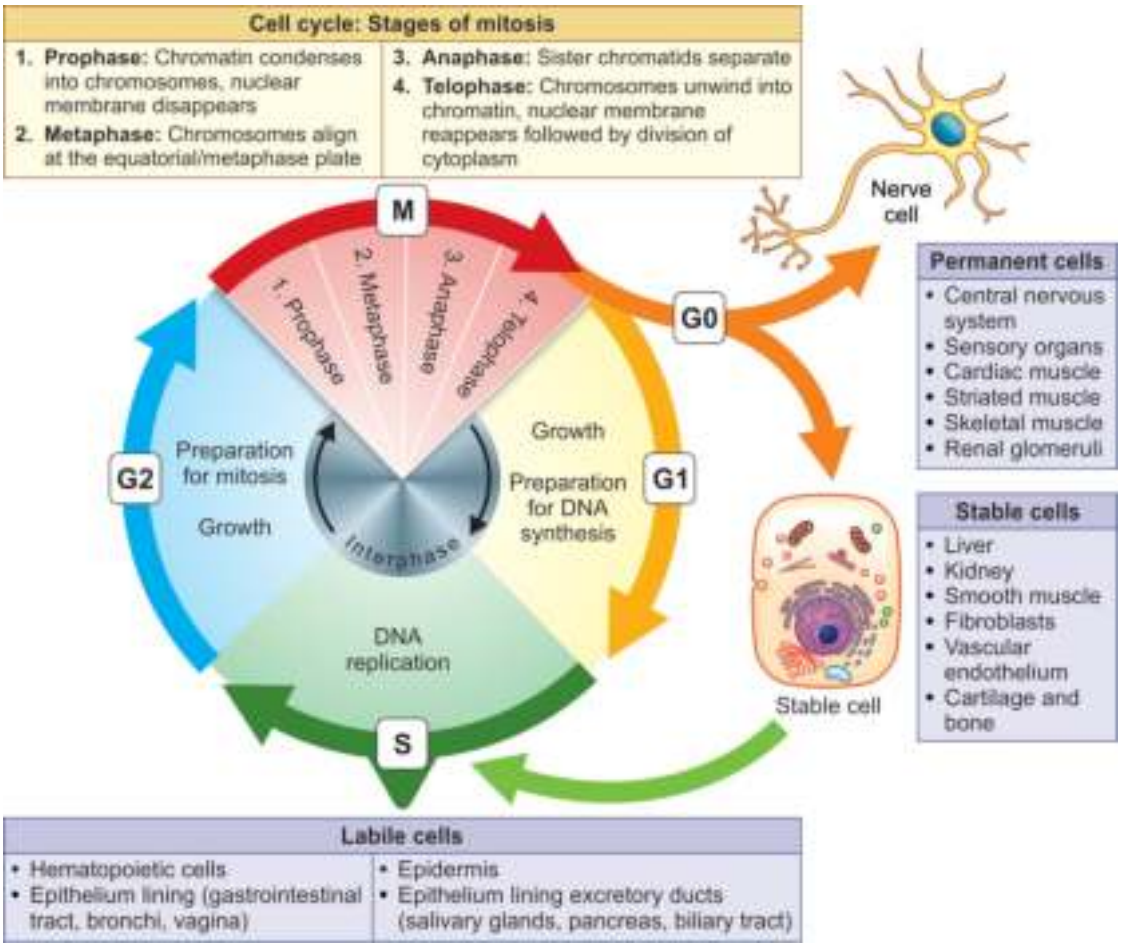

Fig. 2.54: G0, G1, G2, S and M phases of cell cycle. Location of the G1 is the restriction point. G1/S and G2/M are checkpoints of cell cycle. Cells from labile tissues such as bone marrow, epidermis, epithelial lining gastrointestinal tract, bronchi and vagina may cycle continuously.

Table 2.59 Cell cycle phases comprising G0, G1, G2 and M phases

Stage	Major Functions	
G0 phase of cell cycle		
G0 phase	Relatively inactive and nondividing stable state for cell cycle	
Interphase of cell cycle		
G1 phase	▪ Period of cell growth and preparation for DNA synthesis in the cell: G1/S checkpoint	▪ Ki-67 is expressed during active phases of cell cycle (G1/M)
S phase	▪ Period during which DNA is synthesized	▪ Ki-67 is expressed during active phases of cell cycle (G1/M)
G2 phase	▪ In G2 phase the cell grows and prepares for cell division: G2/M checkpoint	▪ Ki-67 is expressed during active phases of cell cycle (G1/M)
M phase of cell cycle		
Prophase	Chromosomes condense and mitotic spindle formed	
Prometaphase	Nuclear envelope disintegrates, spindle microtubules anchor to kinetochores	
Metaphase	Chromosomes align on metaphase plate; spindle-assembly checkpoint	
Anaphase	Sister chromatids separate, becoming individual chromosomes that migrate toward spindle poles	
Telophase	Chromosomes arrive at spindle pole. The nuclear envelope re-forms, and the condensed chromosomes relax	
Cytokinesis	Cytoplasm divides	

1. Ki-67 is expressed during active phases of cell cycle (G1/M). 2. In M phase, the cell undergoes mitosis and cytokinesis or equal division of chromosomes and cell membrane, cytoplasm and organelles between two daughter cells. 3. Proliferation of the cell is only appreciated once cytokinesis has occurred.

- **G2 (pre-mitotic phase):** After completion of nuclear DNA duplication, cell enters G2 phase. Synthesis of tubulin is necessary for formation of mitotic spindle.
- **G0 phase:** G0 phase is the resting phase of stable parenchymal cells. Quiescent cells that have not entered the cell cycle are in the G0 phase. This phase consists of stable and permanent cells. Stable cells may enter cell cycle. Permanent cells do not enter cell cycle.

CELL CYCLE REGULATION

Regulation of the G1, checkpoint (G1 to S) phase is the most critical phase of the cycle. It is controlled by cyclin D and cyclin-dependent kinase 4 (CDK-4). Growth factors activate nuclear transcribing proto-oncogenes to produce cyclin D and CDK-4.

- **Binding of cyclin D to CDK-4:** Cyclin D binds to CDK-4 to form a complex; that causes the cell to enter the S phase by phosphorylation of RB protein. RB proteins normally arrest the cell in the G1 phase. CDK-4 phosphorylates the RB protein causing the cell to enter the S phase.
- **TP53 suppressor gene:** TP53 protein arrests the cell at G2/M phase by inhibiting CDK-4. It prevents RB protein phosphorylation. TP53 protein may provide time for repair of damaged DNA in the cell.
- **BAX gene:** When there is excessive DNA damage, BAX gene is activated, which inhibits BCL-2 anti-apoptotic gene causing release of '**cytochrome c**' from the mitochondria and apoptosis of the cell.

Pathology Pearls: Cyclin-dependent Kinases in Cell Cycle

- Cyclin-dependent kinases (CDKs) are a family of related proteins that bind to specific cyclin proteins to form active protein complexes that can phosphorylates specific target molecules.
- CDKs play a critical role in cell replication, and different CDKs are sequentially activated and inactivated during G1, S, and M phases of the cell cycle.
- CDK4 binds cyclin D at the transition to activate it to phosphorylate the retinoblastoma protein (Rb).
- CDK2 binds cyclin E late in G1 and with cyclin A in S phase to mediate the G2/M transition.
- CDK1 binds cyclin B in G2/M.

CELL REGENERATION: REGULATION

Regeneration is controlled by stimulatory and inhibitory factors. Stimulation is a three-stage processes described as under.

- **Initiation:** Cells in growth arrested phase (G0) are primed for progression to cell division. Initiation is brought about by tissue specific growth factors such as epidermal growth factor (EGF) and platelet-derived growth factor (PDGF). It is worth mentioning that growth factors play important role in cancers.
- **Potentiation:** Nonspecific growth factors such as insulin, hydrocortisone, growth hormone and ACTH stimulate cells which have already been primed by the appropriate initiator to enter S phase.
- **Signaling through integrin:** Signaling through integrin enhances contact of adjacent cells with basement membranes.

GROWTH FACTORS AND CYTOKINES INVOLVED IN CELL REGENERATION

Growth factors (polypeptides) synthesized by macrophages, damaged cells and platelets play important role in the healing process by cell regeneration. These growth factors are chemotactic for white blood cells, fibroblasts and endothelial cells, which also act as mitogens, which increase proliferation of cells in tissue healing process.

Growth factors bind to specific receptors, which deliver signals to the target cells and stimulate the transcription of genes that may be silent in resting cells.

Gene products (i.e. growth factors) activate cell cycle progression, enhance synthesis of cellular proteins and prevent apoptosis resulting in cell growth. Growth factors involved in tissue healing and repair are given in Table 2.60.

- **Platelet-derived growth factor:** Platelet-derived growth factor (PDGF) is synthesized by macrophages, smooth muscle cells, endothelial cells, keratinocytes and many tumor cells. PDGF is stored in platelet granules and released on platelet activation.
  - PDGF binds to specific cell-surface receptors (transmembrane proteins) and induces tyrosine kinase activity in their intracellular domains resulting in conformational changes.
  - PDGF causes migration (chemotaxis) and proliferation of fibroblasts, smooth muscle cells and monocytes to the site of tissue injury.
  - PDGF participates in healing skin wounds by process of wound contraction. It activates hepatic stellate cells in the initial steps of liver fibrosis.
- **Epidermal growth factor (EGF) and transforming growth factor-α (TGF-α):** EGF and TGF-α share common biologic activities.
  - EGF is synthesized by macrophages, keratinocytes, and other inflammatory cells during healing of skin wounds.
  - EGF participates in formation of granulation tissue by promoting the growth of endothelial cells and fibroblasts.
  - EGF stimulates keratinocytes. Amplification of EGFR1 occurs in glioblastoma and cancers of the lung, head and neck, and breast.

Table 2.60 Growth factors involved in tissue healing and repair

Growth Factor Source/Synthesis	Functions
Platelet-derived growth factor (PDGF stored in platelets)	
Macrophages, smooth muscle cells, endothelial cells, keratinocytes synthesize	Migration and proliferation of smooth muscle cells, fibroblasts, endothelial cells and monocytes
EGF and TGF-α (both have similar actions)	
Macrophages, keratinocytes and other inflammatory cells	▪ Stimulation of keratinocytes ▪ Granulation tissue formation as a result of proliferation of fibroblasts and endothelial cells
Fibroblast growth factor-β (FGF-β)	
Macrophages, T cells, endothelial cells, platelets, many other cells	▪ Angiogenesis ▪ Synthesis of extracellular matrix proteins
Transforming growth factor-β (TGF-β)	
Macrophages, T cells, endothelial cells, platelets	▪ Chemotaxis of fibroblasts, macrophages, and lymphocytes ▪ Stimulation of fibroblasts to synthesize collagen fibers ▪ Modulation of repair process by inhibiting collagen degradation ▪ Decreasing the synthesis of metalloproteinase enzymes and enhances protease inhibitor activities
Interleukin-1 (IL-1) and tumor necrosis factor-α (TNF-α)	
Macrophages	▪ Proliferation of fibroblasts, smooth muscle cells, and endothelial cells in wound healing ▪ Chemotaxis of neutrophils ▪ Regeneration of hepatocytes ▪ Synthesis of metalloproteinases and acute-phase reactants
Fibronectin	
▪ Blood plasma	▪ Chemotaxis of fibroblasts and endothelial cells ▪ Angiogenesis and extracellular matrix deposition
Vascular endothelial growth factor (VEGF)	
Endothelial cells and many other cells	▪ Angiogenesis in chronic inflammation and tumors ▪ Healing of wounds
Hepatocyte growth factor (HGF)	
Fibroblasts, endothelial cells, and mesenchymal cells of liver	Proliferation of hepatocytes, epithelia of biliary tract, lungs, kidney, mammary gland and skin
Keratinocyte growth factor(KGF)/fibroblast growth factor 7 (FGF-7)	
Fibroblasts	Migration, proliferation and differentiation of keratinocytes
Insulin growth factor 1 (IGF-1)	
Liver	▪ Synthesis of collagen fibers ▪ Migration of keratinocyte

  - Transforming growth factor-α (TGF-α) is involved in epithelial cell proliferation in embryos and adults. TGF-α also participates in transformation of normal cells to cancer stem cells.
- **Fibroblastic growth factor-β:** Fibroblastic growth factor-β (FGF-β) is synthesized by macrophages, endothelial cells and many other cells.
  - FGF-β stimulates fibroblasts to synthesize extracellular matrix proteins including fibronectin, and epithelialization of skin.
  - FGF-β stimulates endothelial cells to synthesize new vessels (angiogenesis) and participates in development of skeletal and cardiac muscles, and lung maturation.
  - FGF-β differentiates specific lineages of hematopoietic stem cells (HSCs).
- **Transforming growth factor-β:** Transforming growth factor-β (TGF-β) is synthesized by macrophages, T cells, endothelial cells, platelets and many other cells.

- TGF-β is chemotactic for fibroblasts, macrophages and lymphocytes.
- TGF-β stimulates fibroblasts and enhances synthesis of collagen fibers, fibronectin and proteoglycans.
- TGF-β also modulates the repair tissue process by inhibiting collagen degradation by downregulating metalloproteinase enzymes and upregulating protease inhibitor activities. TGF-β causes fibrosis of the lung, kidney, and liver during chronic inflammation.

- **Interleukin-1 and tumor necrosis factor-α:** Interleukin-1 (IL-1) and tumor necrosis factor-α (TNF-α) are synthesized by macrophages.
  - IL-1 and TNF-α promote the proliferation of fibroblasts, smooth muscle cells and endothelial cells.
  - IL-1 and TNF-α are chemotactic for neutrophils at the site of injury.
  - IL-1 and TNF-α are involved in the initiation of liver regeneration.
  - IL-1 stimulates synthesis of metalloproteinases and acute phase reactants.
- **Fibronectin:** Fibronectin is a glycoprotein that links extracellular matrix components (e.g. collagen fibers and proteoglycans) and macromolecules (e.g. heparin and fibrin) to cell surface integrins.
  - Fibronectin participates in chemotaxis of fibroblasts and endothelial cells.
  - Fibronectin promotes angiogenesis (new vessel formation).
- **Vascular endothelial growth factor:** Vascular endothelial growth factor B (VEGF-B) is located in endothelial cells and many other cells.
  - VEGF family comprises VEGF-C and VEGF-D. VEGF-C and VEGF-D bind to VEGF-C and signal through three tyrosine receptors.
  - VEGF is potent inducer of new blood formation during intrauterine life.
  - VEGF plays central role in angiogenesis (capillaries and lymphatic channels) in adults.
  - VEGF promotes angiogenesis in chronic inflammation, healing of wounds, and malignant tumors.
- **Insulin-like growth factor 1:** Insulin-like growth factor 1 (IGF-1) is synthesized by liver. IGF-1 participates in proliferation of collagen fibers and migration of keratinocytes.
- **Hepatocyte growth factor:** Hepatocyte growth factor (HGF) is synthesized by fibroblasts, endothelial cells and mesenchymal cells of liver.
  - HGF participates in proliferation of hepatocytes, epithelia of biliary tract, lungs, kidney, mammary gland and skin.
  - HGF promotes cell scattering, migration, and enhances survival of hepatocytes.

Pathology Pearls: Properties of Vascular Endothelial Growth Factor (VEGF)

- Capillary and lymph duct formation
- Monocyte migration
- Hematopoiesis
- Recruitment of hematopoietic progenitor cells from bone marrow
- Regulation of the endothelial cell pool during development
- Capillary permeability

VEGF and its cognate receptors play multiple roles in the angiogenesis and hematopoietic process.

SIGNALING MECHANISMS OF CELL GROWTH

The process of receptor-mediated signal transduction is activated by the binding of ligands such as growth factors, and cytokines to specific receptors. It leads to expression of specific genes. Biochemical pathways and transcriptional regulation mediate growth factor activity.

Modes of Cell Signaling

According to the source of the ligand and the location of its receptors, there are four modes of cell signaling, i.e. autocrine (in the same cell), paracrine (adjacent cells), endocrine (distant cells) and juxtacrine (cell to cell or cell to extracellular matrix). General patterns of intercellular signaling demonstrating autocrine, paracrine, endocrine, contact-dependent and neurocrine signaling are shown in Fig. 2.55A to E. Signaling mechanisms involved in cell growth in the organs are shown in Table 2.61.

- **Autocrine signaling:** Cells respond to signaling molecules due to synthesis of growth factors, which act on the same cells, so establishing an autocrine loop. Autocrine signaling participates in liver regeneration and proliferation of antigen-stimulated lymphocytes. Cancer cells frequently overproduce growth factors and their receptors, thus stimulating proliferation of own cells through an autocrine loop.
- **Paracrine signaling:** One cell type synthesizes the ligand, which acts on adjacent target cells that express the appropriate receptor. The responding cells are in close proximity to the ligand-producing cells generally of a different type. Paracrine stimulation is common in connective tissue repair of healing wounds, in which a growth factor produced by one cell (e.g. macrophage) has growth effect on adjacent cell (e.g. a fibroblast). Paracrinal signaling is necessary for hepatocyte replication during liver regeneration, and NOTCH effects in embryonic development, wound healing, and renewing tissues.

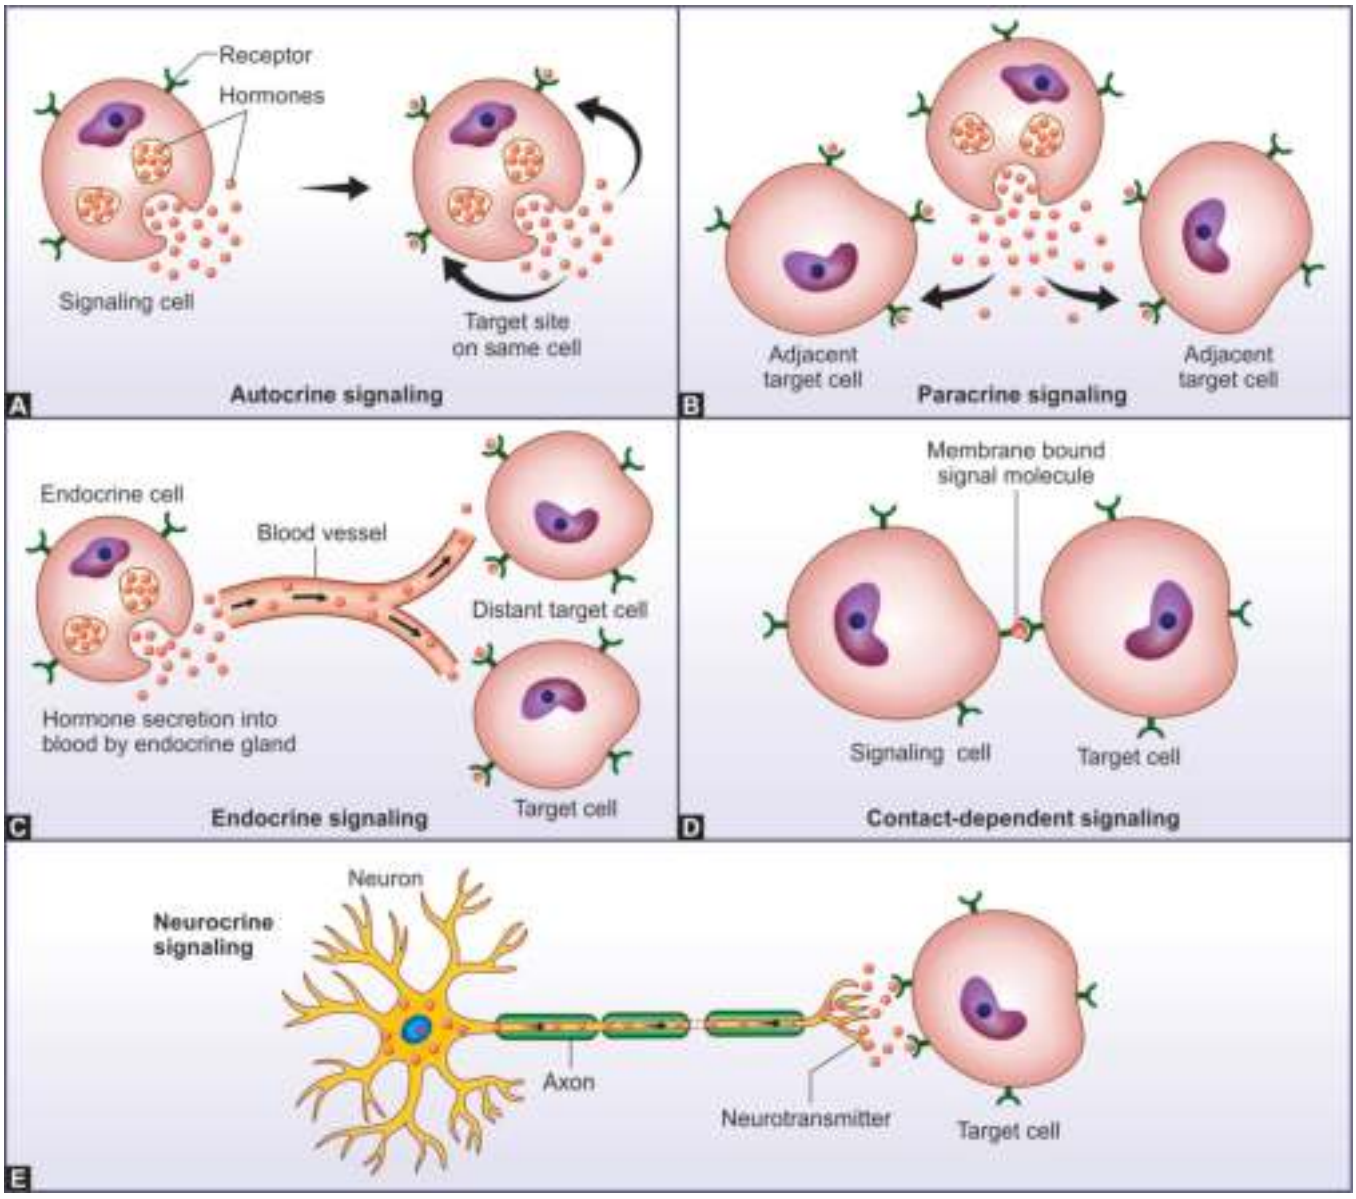

Fig. 2.55A to E: General patterns of intercellular signaling demonstrating autocrine, paracrine, endocrine, contact-dependent and neurocrine signaling.

- **Endocrine signaling:** Hormone synthesized by cells of endocrine organs act on target cells at distant sites from their site of synthesis, being usually carried by blood. Growth factors may also circulate and act at distant sites. Cytokines also act in similar fashion and produce systemic effects of inflammation.
- **Juxtacrine signaling:** Juxtacrine signaling requires close contact in multicellular organisms. There are three types of juxtacrine signaling described as under: (a) Two adjacent cells interact with the help of membrane ligand and membrane protein. (b) Intracellular compartment of two adjacent cells interacts via communicating junction permit relatively small molecules. (c) Two adjacent cells interact via extracellular matrix glycoprotein and membrane protein.

Receptors and Signaling Transduction Pathways

Binding of a ligand to its receptor on cell induces a series of events by which extracellular signals into the cell leading to expression of genes. Behavior of cells in tissue healing process are initiated by three receptor systems that share integrated intracellular signaling pathways: (a) protein tyrosine kinase receptors for peptide growth receptors, (b) seven transmembrane G protein-coupled receptors for chemokines and other factors, and (c) integrin receptors for extracellular matrix. Cell surface receptors and their principal signal transduction pathways are shown in Fig. 2.56.

- **Receptors with intrinsic tyrosine kinase activity:** Receptor tyrosine kinases (RTKs) are enzyme-linked receptors localized on the plasma membrane containing an extracellular ligand-binding domain, a

Table 2.61 Signaling mechanisms involved in cell growth in the organs

Cell Signaling	Mechanism	Regulation of Cell Growth
Autocrine signaling	Cells synthesize molecules, which act on same cells forming autocrine loop	▪ Liver regeneration ▪ Proliferation of antigen stimulated lymphocytes
Paracrine signaling	Cells synthesize molecules, which act on adjacent cells	▪ Connective tissue repair of wound healing ▪ Hepatocyte replication during regeneration ▪ NOTCH effects in embryonic development, wound healing and renewing tissues
Endocrine signaling	Cells synthesize hormones, which act on distant target cells from their site of synthesis	▪ Endocrine glands synthesize hormones, which act on distant target cells ▪ Hepatocyte growth factor acting at distant target cells ▪ Several cytokines produce systemic effects in inflammation
Juxtacrine signaling	Known as contact-dependent signaling (cell to cell or cell to extracellular matrix signaling)	▪ Two adjacent cells interacting with the help of membrane ligand membrane protein ▪ Intracellular compartment of two adjacent cells interacting via communicating junction permit relatively small molecules ▪ Two adjacent cells interacting via extracellular matrix glycoprotein and membrane protein

transmembrane domain, and an intracellular protein-tyrosine kinase domain. The tyrosine kinase receptors are proteins that span cell membrane surfaces, which have critical roles in transducing extracellular signals to the cytoplasm. The tyrosine kinase receptors bind to growth factors such as EGF, TGF-α, HGF, PDGF, VEGF, FGH, c-KIT and insulin and activate tyrosine kinase domain phosphorylates tyrosine amino acid residues. Following intracellular pathways initiate a cascade of events leading to several signaling pathways.

- **MAP kinase signaling pathway:** One of the most common intracellular signaling pathways triggered by RTKs is known as the mitogen-activated protein (MAP) kinase cascade. RTKs can activate RAS, a protein that is tethered to the plasma membrane, by causing it to bind guanosine triphosphate (GTP). Once activated, RAS activates an enzymatic cascade of MAP kinases. This results in potent changes in the cell, such as the alteration of key proteins and changes in gene transcription leading to synthesis of transcriptional factors such as Fos and Jun.
- **RAS phosphatidylinositol 3-kinase signaling pathway:** RAS phosphatidylinositol 3-kinase (PI3) signaling pathway increases concentration of calcium results in activation of serine threonine kinase protein C. Net result is activation of transcription factors.
- **Phosphatidylinsositol 3-kinase (PI3-kinase) signaling pathway:** Phosphatidylinositol 3-kinase (PI3) phosphorylates a membrane phospholipid results in generation of product that activates kinase Akt (also known as protein kinase B). Net result is cell proliferation and survival through inhibiting apoptosis.

- **Seven transmembrane G protein-coupled receptors:** Chemokines, vasopressin, serotonin, histamine, epinephrine, norepinephrine, calcitonin, glucagon, parathormone, corticotropin and rhodopsin bind to seven transmembrane G protein-coupled receptors and trigger cyclic AMP leading to multiple cellular effects.
- **Receptors without tyrosine kinase activity:** Erythropoietin, granulocyte stimulating factor and growth hormone bind to receptors without tyrosine kinase activity and transmit extracellular signals to the nucleus by activating JAK-STAT (Janus kinase) pathway. JAK-STAT pathway activates cytoplasmic transcription factors known as STAT (signal transducers and activation of transcription). Cytokines may also activate MAP kinase intracellular signaling pathway.
- **Nuclear steroid receptors:** Steroid receptors are most often located in the nucleus, which function as ligand-dependent transcription factors. These bind to steroid hormones, thyroid hormone, vitamin D and retinoids. Activated nuclear steroid receptors then bind to specific DNA sequences known as hormone response elements involved in inflammation, atherosclerosis and adipogenesis.
- **Integrin receptors:** Integrin receptors transmit chemical and physical information in the extracellular matrix, which create attachment sites for the actin filaments of cytoskeleton. These integrin receptors activate PI3 kinase and MAP kinase intracellular signaling pathways leading to proliferation and differentiation of cells.

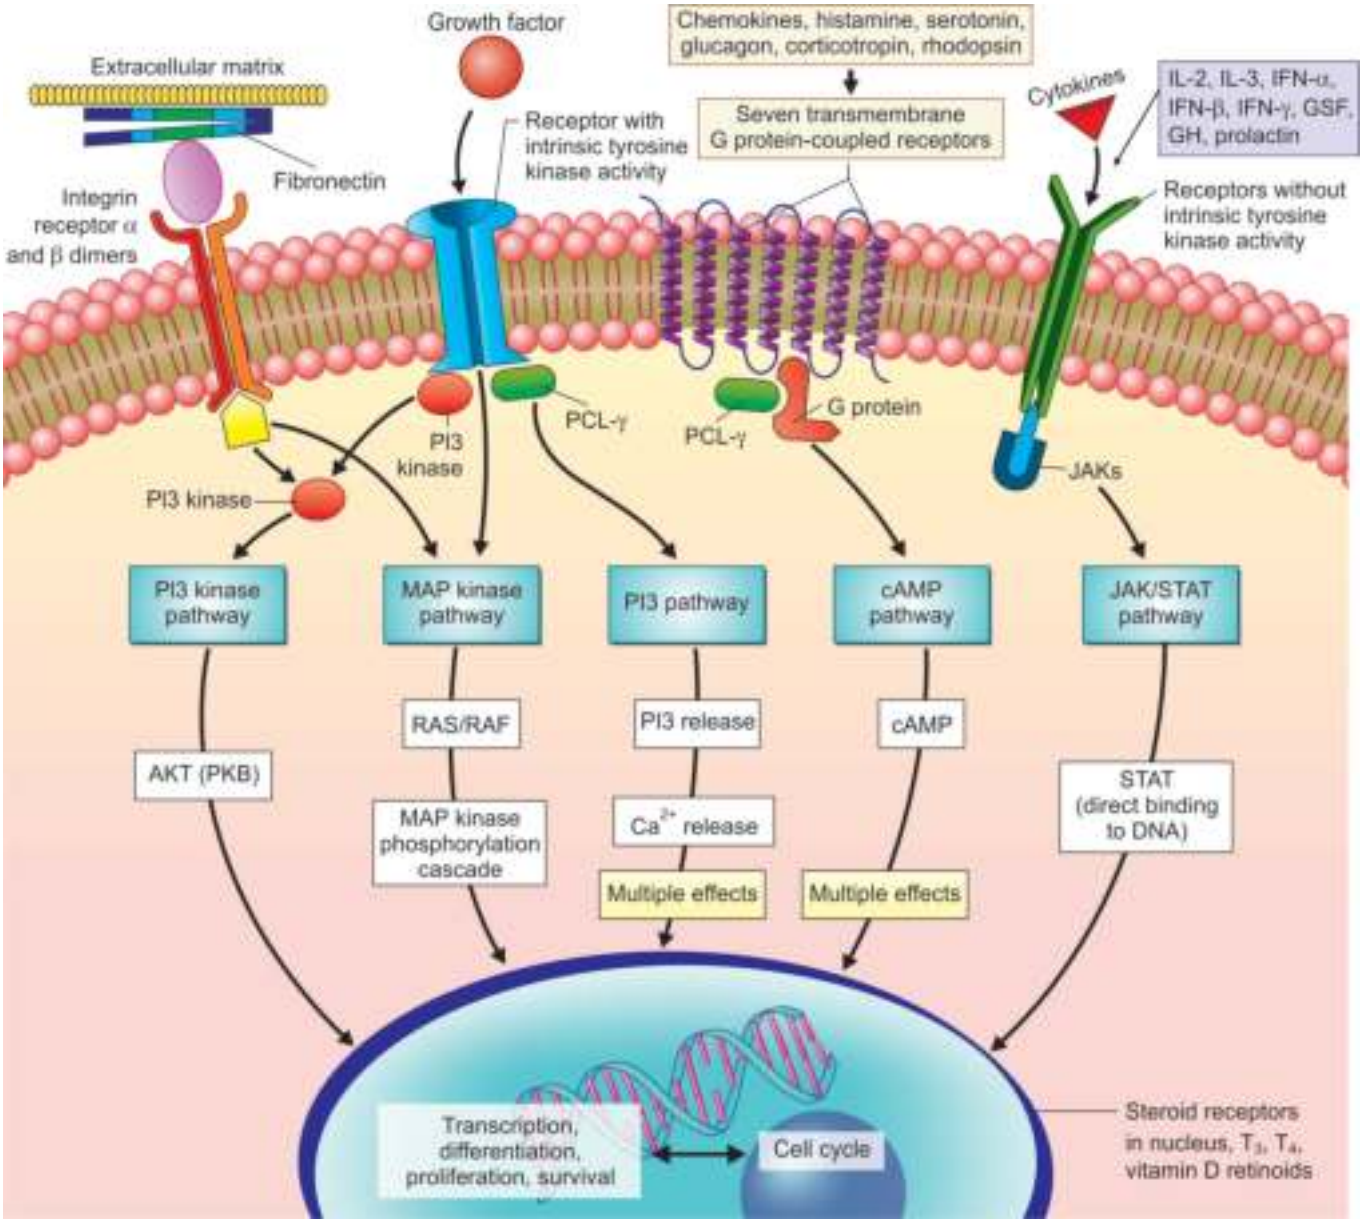

Fig. 2.56: Cell surface receptors and their principal signal transduction pathways. It shows receptors with intrinsic tyrosine kinase activity, seven transmembrane G proteins, and receptors without tyrosine kinase activity. Cyclic adenosine monophosphate (cAMP): Inositol triphosphate (IP3); Janus kinase (JAK); Mitogen-activated protein (MAP) kinase; Signal transducers and activators of transcription (STAT).

Transcriptional Pathway

Transducing signals transmit the information to the nucleus and modulate gene transcription through the activity of transcriptional factors. Transcriptional factors regulating cell proliferation include products of growth promoting genes such as c-Jun and c-Myc, and cell cycle-suppressing TP53.

EXTRACELLULAR MATRIX

Spaces between cells are filled with extracellular matrix (ECM). Epithelial cells rest on a dense sheet of ECM are called the basement membrane. Mesenchymal cells are surrounded by a diffuse ECM. Extracellular matrix plays important role in tissue repair. Extracellular matrix is essential for wound healing, which provides framework for cell migration, cell shape, gene expression and differentiation. ECM also participates in angiogenesis and maintenance of correct polarity for the re-assembly of multicellular structures.

- The ECM is composed of two main classes of interlocking macromolecules: (a) structural fibrous proteins including collagen, elastin, fibronectin and laminin, which have both structural and adhesive functions, and (b) amorphous ground substance is composed of polysaccharide chains of the class

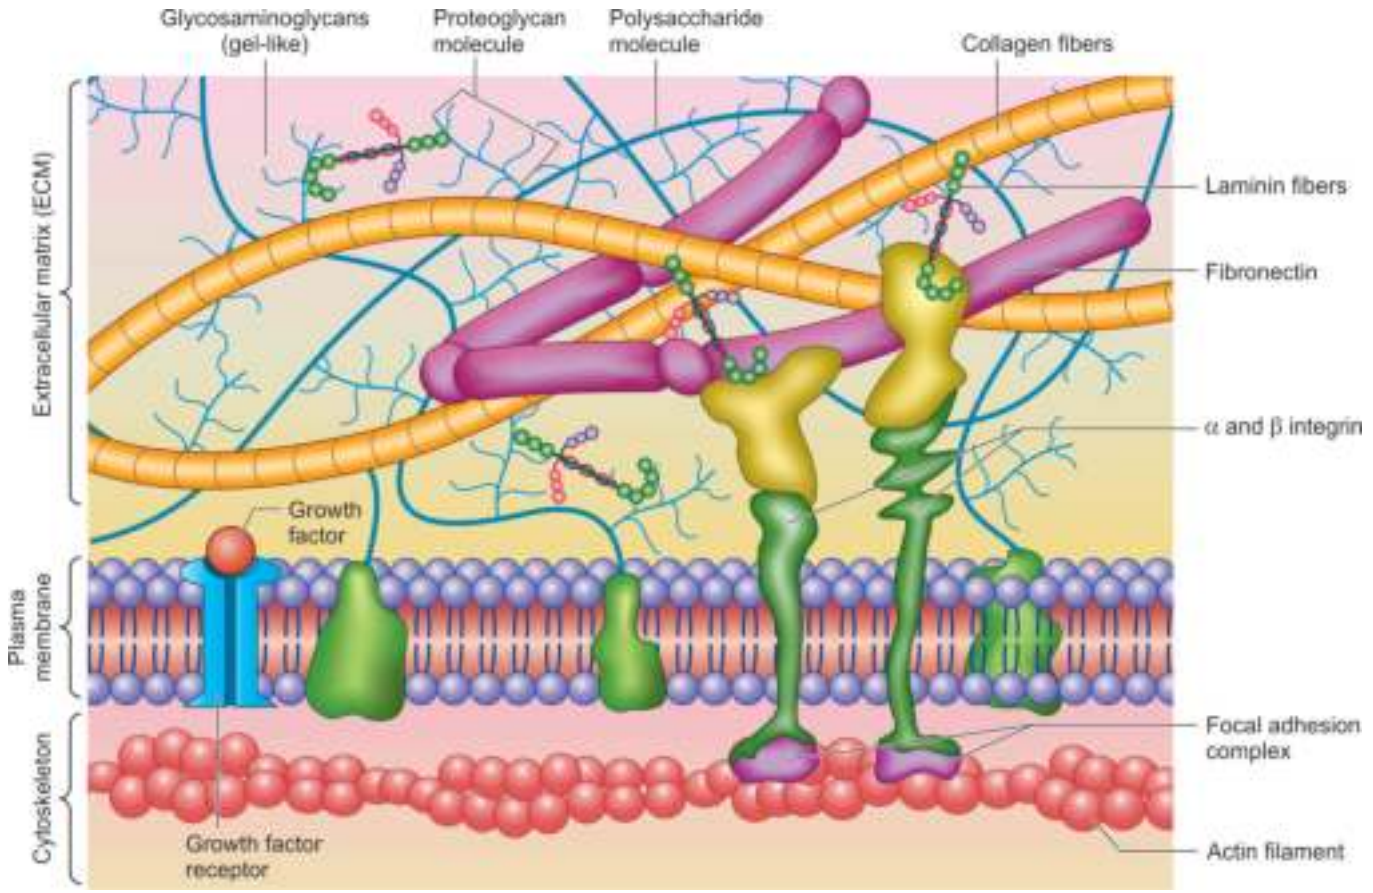

Fig. 2.57: Composition of extracellular matrix (ECM). ECM consists of structural fibrous glycoproteins and amorphous ground substance. Structural fibrous glycoproteins are composed of collagen fibers, fibronectin, laminin, and elastin. These reinforce the ground substance. Amorphous ground substance is a gel-like material composed of glycosaminoglycans (hyaluronic acid, chondroitin sulfate, heparin, and heparan sulfate) and proteoglycans (carbohydrate and proteins). Both epithelial and mesenchymal cells interact with extracellular matrix via integrins.

called glycosaminoglycans (GAGs), which are usually found covalently linked to protein in the form of proteoglycans. Specialized proteins include fibronectin and laminin, which form mesh of fibers embedded in proteoglycans. Hyaluronic acid, dermatan sulfate, keratan sulfate and heparan sulfate belong to the group of sulfated GAGs. Composition of extracellular matrix is shown in Fig. 2.57.

- Four groups of GAGs are distinguished according to their sugars, the type of linkage between sugars and the number and location of sulfate groups: (a) hyaluronan, (b) chondroid sulfate and dermatan sulfate, (c) heparan sulfate, and (d) keratan sulfate.
- ECM macromolecules are secreted locally by fibroblasts and assembled into an organized meshwork in close association with the surface of the cell that synthesizes them.
- Cell surface receptors transduce signals into cells from ECM, which regulate diverse cellular functions, such as cell growth, proliferation, migration, differentiation, survival and some vital role in maintaining cells homeostasis. Functions of extracellular matrix are given in Table 2.62.

Table 2.62 Extracellular matrix functions

Mechanical Support
▪ Cell anchorage ▪ Migration ▪ Maintenance of cell integrity
Control of Growth
Regulation of cell proliferation by signaling mechanism via cellular receptors of the integrin family
Maintenance of Differentiation
Regulation of differentiation of the cells in tissues via acting cell-surface integrin
Scaffoldings for Tissue Renewal
▪ Regeneration of labile and stable cells if intact ECM ▪ Scar formation due to disruption of ECM
Establishment of Tissue Microenvironment
Forming boundary between epithelial cells and underlying connective tissue
Storage of Regulatory Molecules
Storage of growth factors in ECM during regeneration of cells at injured site

STRUCTURAL FIBROUS PROTEINS

Collagen fibers are the most abundant glycoprotein protein in humans (>25% total protein). Variety of genes encode different collagen molecules. Mnemonic, collagen fibers go from hard to soft types in various organs.

- Collagen fibers provide strength and help in organization of extracellular matrix. Rubber-like elastic fibers provide stretchability and resilience to the ECM. Fibronectin has binding sites for cells and other ECM proteins, which links cells to the ECM.
- Sequence of fibronectin such as arginine, glycine, and aspartate binds to cells avidly. Laminin is abundant in basement membranes where it promotes adhesion of many types of cells. Laminin participates in attachment of endothelial and visceral cells to glomerular basement membrane.

Collagen Fibers

Collagen fibers may be fibrillar or nonfibrillar (amorphous) types. Fibrillar collagen types 1, 2, 3; while non-fibrillar collagen (amorphous) types 4–18. Collagen fibers are the most abundant protein in the body, which form the major structural component of many organs and provide tensile strength of healing wounds. Collagen synthesis is shown in Fig. 2.58. Collagen fibrils and their distribution are given in Table 2.63.

- **Biosynthesis:** Various growth factors such as PDGF, EGF, TGF-α, FGF-β, IGF-1, IL-1 and TGF-β participate in proliferation of fibroblasts resulting in synthesis of collagen fibers in early wound healing and tissue repair (3 to 5 days). Some of the fibroblasts also acquire features of smooth muscle cells, including the presence of actin filaments called myofibroblasts.
- **Synthesis of α-chains of collagen fibers:** DNA sends signal to messenger RNA, where splicing occurs, where α-chains of collagen fibrils are formed.

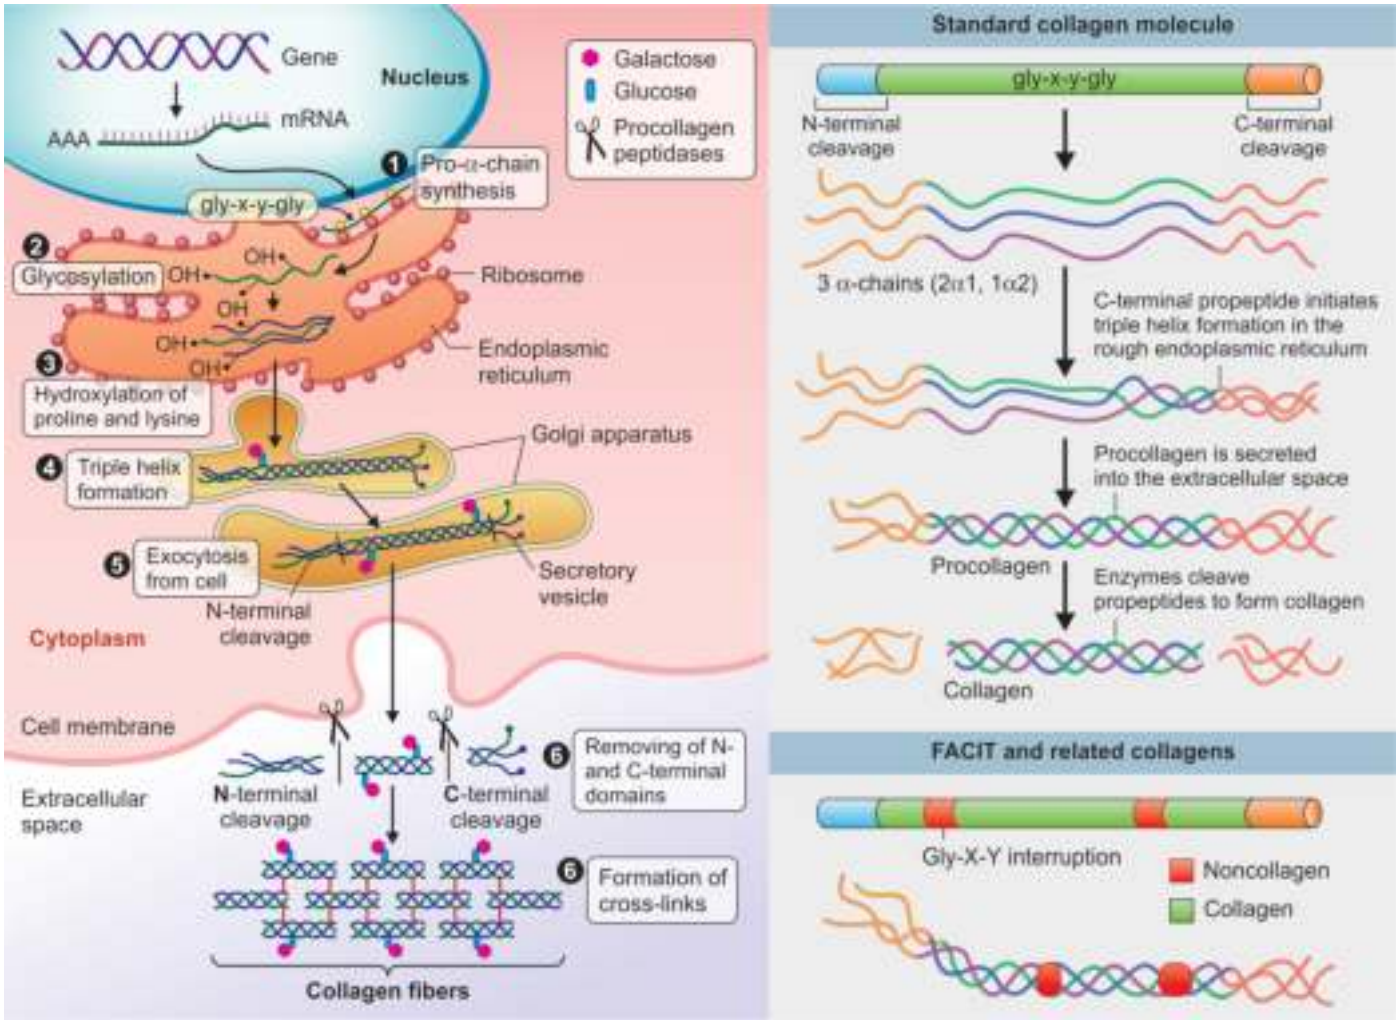

Fig. 2.58: Collagen synthesis. Principal steps in biosynthesis of interstitial collagens include synthesis of pro-α-chains in rough endoplasmic reticulum, aggregation of three pro-α-chains, hydroxylation of lysin and proline residues, secretion of procollagen molecule, cleavage of propeptides, alignment of collagen molecules to form fibrils, and aggregation of fibrils to form collagen fibers.

Table 2.63 Collagen fibrils and their distribution

Collagen Fibrils	Property	Distribution	Genetic Disorders
Fibrillar collagen			
Type 1	Greatest tensile strength	Bones, tendons and skin (90%)	▪ Osteogenesis imperfecta ▪ Ehlers-Danlos syndrome ▪ Arthrochalasia type 1
Type 2	Thin collagen fibrils	Cartilage (50%) and vitreous humor	Achondrogenesis type 2
Type 3	Thin collagen fibrils	Blood vessels, uterus, skin (10%) and granulation tissue	Vascular Ehlers-Danlos syndrome
Type 5	Amorphous fibrils	Cell surfaces, hair and placenta	Classical Ehlers-Danlos syndrome
Type 9	Amorphous fibrils	Soft tissue, blood vessels, cartilage, intervertebral discs	▪ Stickler syndrome ▪ Multiple epiphyseal dysplasia
Basement membrane			
Type 4	Amorphous fibrils	Basement membranes (glomerular basement membrane) and basal lamina	Alport's syndrome
Other molecules			
Type 6	Amorphous microfibrils	Various organs	Bethlem myopathy
Type 7	Anchoring fibrils at dermal-epidermal junctions	Skin	Dystrophic epidermolysis bullosa
Type 9	Amorphous microfibrils	Cartilage and intervertebral disc	Multiple epiphyseal dysplasia
Type 17	Transmembrane collagen	Skin	Benign atrophic generalized epidermolysis bullosa
Types 15, 18	Endostatin-forming collagen	Endothelial cells	Knobloch syndrome type 18 collagen

Ehlers-Danlos syndrome (EDS) is characterized by defects of type 1 and type 3 collagen synthesis and structure. Patients present with hypermobile joints, aortic dissection (most common cause of death), bleeding into the skin (ecchymoses), rupture of the bowel, and poor wound healing.

- **Assembly of collagen fibrils:** Structural unit of collagen is tropocollagen (collagen fibrils) comprising α-chains. Collagen molecules consist of three polypeptide chains arranged in a triple helix, known as α-chains, which combine with proline. Hydroxylation reactions in the rough endoplasmic reticulum convert proline to hydroxyproline; and lysine to hydroxylysine. Ascorbic acid is required in hydroxylation reactions, which leads to assembly of triple helix of α-chains.
- **Stabilization of triple helix of α-chains:** Hydroxyproline residues produce bonds that stabilize the triple helix in the tropocollagen molecule.
- **Cross linkage of collagen fibers:** Transportation of **triple helix α-chains** through Golgi apparatus results in formation of true fibrils in extracellular space.
  - **Oxidation of hydroxylysine** by lysyl oxidase (MMP enzyme) results in cross linkage of α-chains occurs. Lysyl oxidase is a metalloproteinase enzyme containing copper. Fibrils are arranged in 'quarter stagger' mode to form insoluble fibers. Inhibition of lysine oxidation results in malformation of skeleton, and blood vessels seen in Marfan's syndrome.
  - **Cross linkage of collagen fibrils** provide structural stability to tropocollagen, which are relatively resistant to general proteases; slow remodeling by specific collagenases. Decreased cross-linking (e.g. vitamin C deficiency) reduces the tensile strength of collagen. In vitamin C deficiency, the structurally weakened collagen fibers are responsible for a bleeding diathesis (e.g. bleeding into skin and joints) and wound healing and tissue repair. Decreased cross-linking with advancing age leads to decreased elasticity of skin, joints, and blood vessels.

Elastin Fibers

Blood vessels, lungs, skin and uterus require elasticity to perform functions. Collagen fibers provide tensile strength to the tissues. On the other hand, elastic fibers can stretch up to 1.5 times their length and snap back to their original length when relaxed.

- **Composition of elastic fibers:** Elastic fibers consist of a central core made of elastin, surrounded by network of fibrils. Elastic fibers are synthesized by fibroblasts and smooth muscle cells in arteries. Substantial

quantity of elastin is found in aorta, skin, ligaments and uterus.

- **Biosynthesis of elastic fibers:** Elastic fibers are derived from elastic microfibril, which consists of numerous proteins such as microfibrillar-associated glycoproteins, fibrillin and fibrullin. Elastic fibers are also derived from amorphous elastin. Microfibrils scaffold and organize the deposition of amorphous elastin, which also influence the availability of active TGF-β in the ECM. Genetic defect in synthesis of fibrillin causes Marfan's syndrome. Inhibition of lysine oxidation results in malformation of skeleton, and blood vessels seen in Marfan's syndrome.

Fibronectin

Fibronectin is a ligand member of integrin receptor family that links extracellular matrix with the intracellular cytoskeleton. Fibronectin has many functions, which allow it to interact with many extracellular matrix proteins such as collagen, fibrin and heparin, and with specific membrane receptors in respective cells.

- Fibronectin is adhesive glycoproteins that is widely distributed in stromal connective tissue and deposited at the site of tissue injury.
- During the initial phase of tissue healing, fibronectin in the extravasated plasma is cross-linked to fibrin, collagen, and other extracellular matrix components by the action of transglutaminases. This cross-linking of fibronectin to various components provides a provisional stabilization of the wound during the first several hours. Fibronectin, cell debris, and bacterial products are chemoattractants for a variety of cells that are recruited to the wound site over the next several days.

Laminin

Laminin is cell adhesion molecule that interacts with receptors anchored in the plasma membrane of cells adjacent to the basement membranes. Laminin regulates multiple cellular activities and signaling pathways.

AMORPHOUS GROUND SUBSTANCE

Amorphous ground substance is composed of polysaccharide chains of the class called glycosaminoglycans **(GAGs)**, which are usually found covalently linked to protein in the form of proteoglycans. Proteoglycans attract Na^+ and water and expand to form gels that occupy space between cells, which also bind and selectively release growth factors.

- **Glycosaminoglycans (GAGs):** Glycosaminoglycans are long unbranched polysaccharide chains composed of repeating units of disaccharides, e.g. an amino sugar (n-acetyl glucosamine) and a glucuronic acid. Four groups of GAGs are distinguished according to their sugars, the type of linkage between sugars and the number and location of sulfate groups: (a) hyaluronan, (b) chondroid sulfate and dermatan sulfate, (c) heparan sulfate, and (d) keratan sulfate.
- **Proteoglycans:** Proteoglycan molecules in connective tissue form a highly hydrated gel-like amorphous ground substance in which the structural fibrous proteins are embedded. Proteoglycans contain (>50% carbohydrate with some protein, which possess an extracellular and intracellular domain. Proteoglycans interact with collagen, fibronectin, and other ECM molecules. Hydrated gel-like amorphous ground substance absorbs water and also binds and selectively release growth factors. Polysaccharide gel resists compressive forces on the extracellular matrix while permitting the rapid diffusion of nutrients, metabolites, and hormones between the blood and tissue cells.

CELL ADHESION MOLECULES

Cell adhesion molecules enable cells to contact and specifically interact with each other in multicellular organisms. Specialized cell–cell and cell–matrix interactions permit communication between cells and their surrounding environment necessary for development and functional activity. Several different families of receptors mediate these interactions.

Pathology Pearls: Categories of Cell Adhesion Molecules

Cell Junctions

Cell junctions are formed slowly but generate very stable and durable connections such as tight junctions, desmosomes, and gap junctions.

Cell Surface Adhesion Molecules

- Cell surface adhesion molecules include selectins, immunoglobulin-like cell adhesive molecules, and integrins. Their function is adhesion of cells to extracellular matrix or to neighboring cells, rather than cell activation.
- Cell surface adhesion molecules play an important role in acute inflammation, which ensure arrival of cells to the required locations. These are selective and quickly formed. Cell surface adhesion molecules are relatively weak in comparison to cell junctions.

Substrate Adhesion Molecules

Substrate adhesion molecules consist of extracellular matrix molecules and matched receptors, which are expressed on the cell surface.

Family of Cell Surface Adhesion Molecules

Families of cell surface adhesion molecules include selectins, integrins, immunoglobulin (Ig) super family members and cadherins, which are critical in embryonic development, differentiation, migration, inflammation, and wound healing and cancer metastases.

- **Selectin family:** Selectins are cell adhesion molecules mediating initial adhesion of leukocytes (primarily neutrophils) to endothelial cells during acute inflammation.
  - **E-selectins (CD62E):** E-selectins are stored in Weibel-Palade bodies of resting endothelial cells. Upon activation, E-selectins are redistributed along the luminal surface of the endothelial cells, where they mediate the initial adhesion and rolling of leukocytes.
  - **P-selectins (CD62P):** P-selectins are stored in Weibel-Palade bodies of endothelium and platelet α-granules, relocate to the plasma membrane after stimulation by chemical mediators such as histamine and thrombin.
  - **L-selectins (CD62L):** L-selectins are expressed on neutrophils, which bind to endothelial mucin-like molecules such as GlyCam-1.
- **Lectins:** Lectins are expressed on cells and endothelial cells. Glycosyltransferases are lectin-related cell adhesive molecules (CAMs), which transfer monosaccharides to an oligosaccharide chain on an adjacent cell.
- **Immunoglobulin family of cell adhesion molecules:** Intercellular adhesion molecules (e.g. ICAM-1 and ICAM-2) are expressed on the endothelial cells, which bind to integrin expressed on leukocytes.
- **Integrins:** Integrins contain 2α and 2β chains, which belong to immunoglobulin supergene family. The α-chain has ligand binding sites for Ca^{++} and Mg^{++} which are needed for integrin to adhere. During inflammation, integrin participates in adhesion of leukocytes to vascular endothelium leading to chemotaxis of leukocytes to the injury site. Integrin family of proteins is given in Table 2.64.

Table 2.64 Integrin family of proteins

Integrins	Mechanism of Actions
Integrin β_1	▪ Binding of cells by integrin β_1 to extracellular matrix ▪ β-Chain using CD29
Integrin β_2 (Leu CAMs)	▪ Leukocyte adhesion to endothelium by integrin β_2 during inflammation ▪ β-Chain using CD18
Integrin β_3 (cytoadhesion)	Interactions of platelets and neutrophils at inflammatory sites or sites of vascular damage

- **Cadherins:** Cadherins participate in forming stable adhesion, which are expressed on all cells forming solid organs. Cadherin family includes E-cadherin, P-cadherin, N-cadherin and L-cadherin members. E-cadherin is present in desmosomes of epithelial cells. P-cadherin is expressed in placenta. N-cadherin is present in neural tissue. L-cadherin is demonstrated in liver. In adults, cadherins are responsible for tight cell-to-cell associations within tissues. Cadherins are intimately associated with the cytoskeleton, interacting via other proteins with both microfilaments and intermediate filaments, which mediate homotype interactions in zonula adherens, tight junctions, gap junctions, and desmosomes. Cadherins are rapidly degraded by proteases in the absence of Ca^{++}.
- **Cadherin-catenin linkage:** Catenin family includes α-catenin, β-catenin and γ-catenin. The β-catenin is a membrane protein associated with cell adhesion molecules, which link cadherin to the cytoskeleton. If cadherin-catenin linkage is disturbed, cadherin does not work, which leads to disruption of embryonic development especially of brain neural tissue.

WOUND HEALING AND TISSUE REPAIR

Steps of wound healing and tissue repair are acute inflammation, granulation tissue formation, re-epithelialization, collagen accumulation, regression of vascular channels, replacement of granulation tissue with scar formation and wound contraction. Inflammatory infiltrate is removed within 36 hours to 3–4 weeks.

- Granulation tissue becomes a scar as a result of proliferating fibroblasts by laying down collagen which accumulates in the location of the eventual scar. Therefore, granulation tissue is a combination of capillary loops and myofibroblasts involved in wound-healing and tissue repair phenomenon.
- Wound healing and tissue repair occurs in four phases under normal conditions in adults: (a) hemostasis (scab formation), (b) inflammatory phase (inflammation and edema formation), (c) proliferative phase (granulation tissue formation), and (d) remodeling phase and wound contraction with scar formation.
- Granulation tissue is an important component of wound healing and tissue repair process. Wounds can heal by primary intention and secondary intention. Wound edges approximate easily in tissue healing by primary intention. Wound edges do not approximate in tissue healing by secondary intention.
- Tissue repair by connective tissue involves the influx of debris-removing inflammatory cells, formation of

granulation tissue, maturation of granulation tissue, migration and proliferation of fibroblasts forming, fibrosis tissue that is remodeled over time to form a fibrous scar.

- Tissue repair depends on growth factor activity and interaction between cells and extracellular matrix (**ECM**). Extracellular matrix serves many functions: providing support, anchorage for cells, segregating tissues from one other and regulating intercellular communication.
- Tissue repair by connective tissue involves five mechanisms: removal of injured tissue by inflammation, angiogenesis, migration and proliferation of fibroblasts, scar formation and remodeling of connective tissue. Organization refers to replacement of dead tissue or hematoma by granulation tissue, which is seen in hematoma (wound and bone fracture), thrombi, infarcts and fibrinous exudates. Phases of wound healing tissue repair process are given in Table 2.65 and Fig. 2.59. Growth factors, enzymes and other factors regulating wound healing and tissue repair are given in Table 2.66.

HEMOSTASIS PHASE

Hemostasis starts when blood leaks out of the body. The initial phase of tissue repair process, which typically begins with hemorrhage, involves the coagulation of blood resulting from the aggregation and degranulation of platelets and formation of fibrin network within seconds and minutes that fills the gap created by the wound.

- A thrombus, referred to as a scab after drying out, forms on the wounded skin as a barrier to invading microorganisms, which also prevents the loss of plasma and tissue fluid. Thrombus contains fibronectin and growth factors.
- Fibrin network is the basis for a blood clot and serves as a temporary matrix for migratory cells. Platelets release cytokines and growth factors that serve as proinflammatory signals to attract the immune cells to the site of the wound.

INFLAMMATORY PHASE

Inflammation is the second phase of wound healing and tissue repair, that begins immediately after the tissue injury, when injured blood vessels leak transudate causing swelling. Immune cells such as neutrophils and monocytes/macrophages play important role in inflammatory phase of wound healing and repair. Chemical mediators released by injured cells, plasma proteins, tissue macrophages; mast cells, platelets and endothelial cells increase vascular permeability resulting in formation of inflammatory exudates. Polymorphonuclear cells liquefy the injured tissue and remove dead cellular debris. Inflammatory phase of wound healing and tissue repair takes about 72 hours to complete.

- **Neutrophilic infiltration:** Neutrophils are produced from hematopoietic stem cells in the bone marrow and undergo maturation in 1–2 weeks. Majority of neutrophils are released into peripheral blood circulation in the segmented forms. About 50% of

Table 2.65 Phases of wound healing and tissue repair process

Hemostatic Phase	
▪ Platelet aggregation	▪ Coagulation system cascade
Inflammatory Phase	
▪ Polymorphonuclear cell migration	▪ Removal of necrotic debris
Proliferative Phase	
▪ Endothelial proliferation results in granulation tissue formation and angiogenesis ▪ Keratinocyte proliferation results in re-epithelialization of the wound	▪ Fibroblast proliferation results in synthesis of type 3 collagen and extracellular matrix
Remodeling Phase and Wound Contraction (3 Weeks–36 Months)	
▪ Resolution of acute inflammation and dissolution of fibrin clot ▪ Maturation of granulation tissue produced by fibroblasts and endothelial cells that completely fill wound space ▪ Maturation of extracellular matrix (ECM) ▪ Fibroblasts lay down vertically oriented collagen fibers at the wound margin ▪ Metalloproteinases (MMPs) activity can be minimized by binding to specific proteinase inhibitors such as α_1-antitrypsin and α_2-macroglobulin	▪ Progressive re-epithelialization, devascularization, type 1 collagen fibers deposition over next two to three weeks resulting in a dense white scar ▪ Remodeling increases the tensile strength of scar tissue that involves two processes: (a) collagen fibers remodeling by growing in both size and strength to replace fibronectin and hyaluronic acid, (b) vascular maturation and repression ▪ Myofibroblasts are responsible for the contractile process in wound closure

Cytokines and growth factors (e.g. PDGF, VEGF, FGF-2, TGF-α, TGF-β) play key role in wound healing. Phases of wound healing: hemostatic and inflammatory phase (0–3 days), proliferative phase (3–14 days) and remodeling phase and wound contraction (3 weeks–36 months).

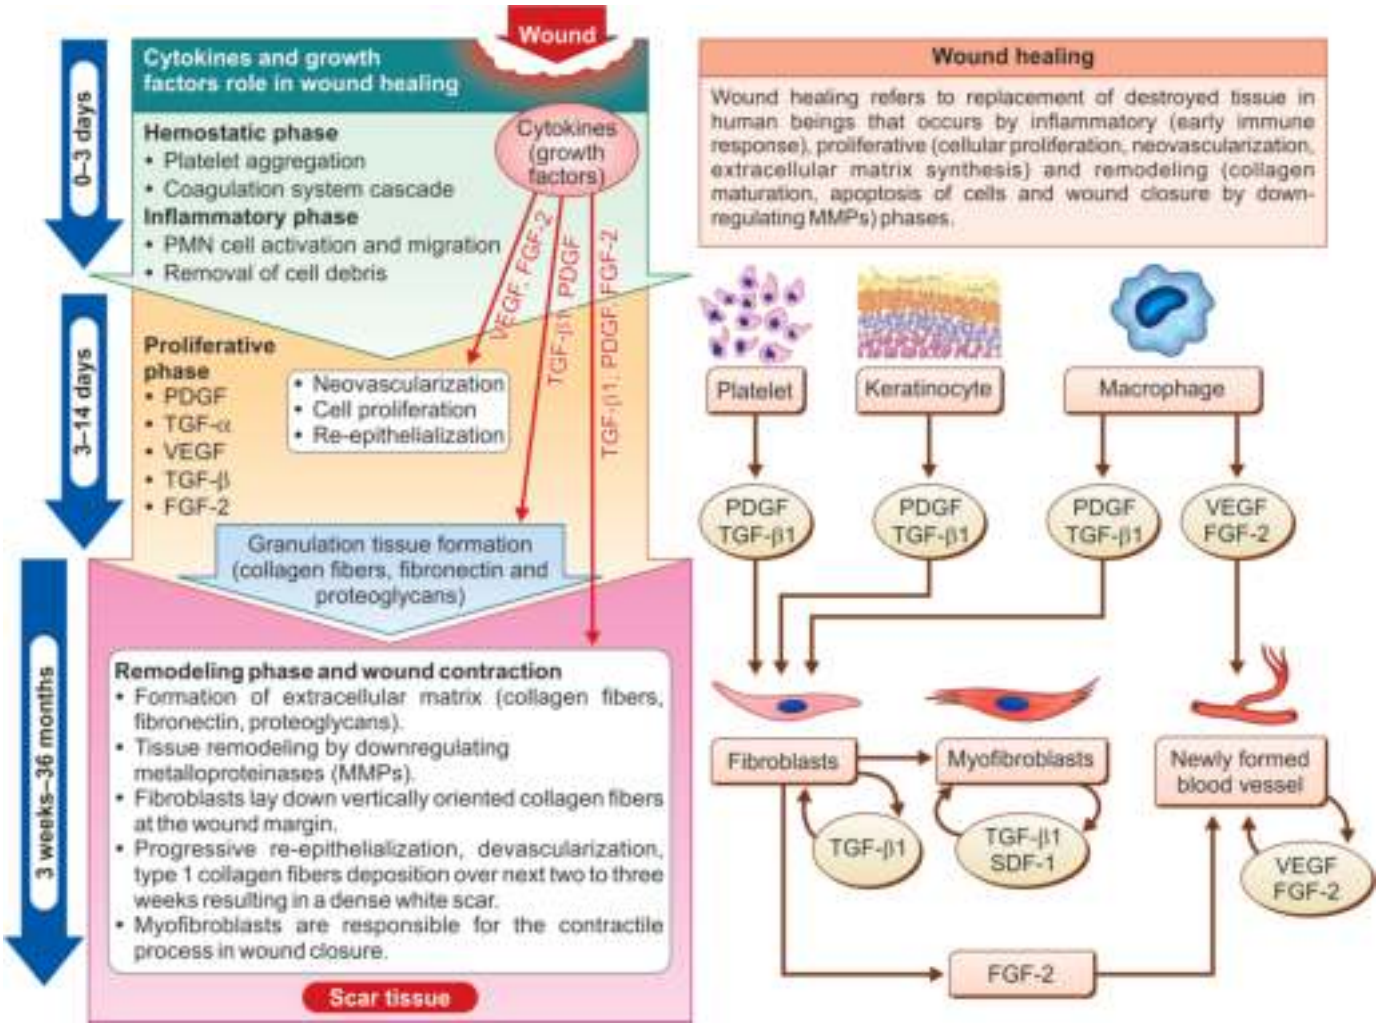

Fig. 2.59: Phases of wound healing and tissue repair process. Wound healing involves influx of necrotic debris removing inflammatory cells, formation of granulation consisting of fibroblasts and delicate capillaries in a loose extracellular matrix, and conversion of said granulation tissue into fibrous tissue that undergoes remodeling over time to form a scar. Numerous cytokines and growth factors are involved in every stage of wound healing however, it appears that transforming growth factor-β is a major factor in matrix protein synthesis and granulation tissue formation.

Table 2.66 Growth factors, enzymes and other factors regulating tissue wound healing and tissue repair

Functions	Growth Factors and Enzymes
Chemotaxis of monocytes/macrophages	PDGF, FGF-β, TGF-β, MCP-1 (CCL2)
Migration of fibroblasts	PDGF, FGF-β, TGF-β, EGFs, CTGF, SDF-1
Proliferation of fibroblasts	PDGF, FGF-β, EGFs, IGF, CTGF, TGF-β
Maturation of new blood vessels during angiogenesis	VEGF-A, VEGF-B, VEGF-C, VEGF-D, angiopoietin 1 and angiopoietin 2, FGFs, HGF
Endothelial cell migration and survival during angiogenesis and lymphangiogenesis	Integrin-α and integrin-β
Inhibiting proliferation of endothelial cells and angiogenesis	ECM protein such as endostatin
Collagen synthesis	TGF-β, PDGFs, IGH, CTGF
Collagen secretion	PDGFs, FGFs, CTGF
Collagen cross-linking and maturation	Lysyl oxidase
Epithelial cell migration and proliferation	KGF, TGF-α, HGH, IGF
Tissue remodeling by movement of surface and stromal cells	Metalloproteinases (MMP-1, MMP-2, MMP-3, MMP-13)
Resolution of tissue repair	IP-8 (CXCL11), IP-10 (CXCL10)

the neutrophils in the peripheral blood circulation are in the marginating pool; and rest 50% circulate in the central column. Neutrophils spend <10 hours in the peripheral blood before marginating and reaching tissues, where they spend 1–5 days. Neutrophils arrive at the wound site within few minutes and continue to accumulate for several days. Neutrophils entrap the microorganisms at the wound site from the beginning of the tissue injury. Neutrophils also amplify the proinflammatory response by releasing their own chemical mediators.

- **Monocytes/macrophages infiltration:** Monocytes arrive at the site of tissue injury within two days, where these cells differentiate into macrophages. Macrophages play key role in phagocytosis of necrotic debris, pathogens and apoptotic neutrophils. Macrophages also produce chemical mediators, e.g. transforming growth factor-β and vascular endothelial growth factor (VEGF) that severe to recruit fibroblasts and endothelial cells that mark the next phase of wound healing and tissue repair.

PROLIFERATIVE PHASE

In proliferative phase of wound healing and tissue repair, wound is rebuilt with new tissue made up of collagen and extracellular matrix.

- Proliferative phase of wound healing and tissue repair includes three components: (a) keratinocytes proliferation and re-epithelialization, (b) endothelial cell proliferation involved in granulation tissue formation and angiogenesis, (c) fibroblasts proliferation involved in collagen synthesis and extracellular matrix formation.
- During proliferative phase of wound healing and tissue repair, re-epithelialization, and the replacement of the blood clot by granulation tissue formation occurs spontaneously. In proliferative stage, specific cells migrate, proliferate and fill the gap created by tissue destruction. It occurs by formation of granulation tissue and angiogenesis. The early extracellular matrix of granulation tissue contains proteoglycans, glycoproteins, and type 3 collagen.
- Granulation tissue is a reddish connective tissue that forms on the surface of a wound, when wound is healing, in which fibroblasts and vascular endothelial cells proliferate and form granulation tissue. Granulation tissue is characterized histologically by the presence and proliferation of fibroblasts, keratinocytes, endothelial cells, formation of new thin-walled capillaries, and inflammatory cell infiltration of the extracellular matrix.
- Angiogenesis is the formation of new blood vessels from the existing vasculature, that is required to support a healing wound environment.

Keratinocytes and Re-epithelialization

Keratinocytes play multiple roles essential for skin repair. Keratinocytes proliferate in the basal layer of the epidermis and start differentiating on their way to the surface, undergoing gradual differentiation, execution of re-epithelialization process by various cytokines and growth factors (epidermal growth factor, transforming growth factor-α and keratinocyte growth factor produced by keratinocytes and fibroblasts) and restoration of epidermal barrier.

- During this process, keratinocytes profoundly change their morphology and start to produce keratin, cytokines, growth factors, interleukins and complement proteins.
- In an autocrine and paracrine fashion, keratinocytes produce signals that regulate more keratinocytes activation that alters gene expression, migration of keratocytes and stimulate nearby fibroblasts.

Endothelial Cells Involved in Granulation Tissue Formation and Angiogenesis

During proliferative phase, the wound defect is filled with highly vascular connective tissue, commonly referred as 'granulation tissue'.

- Granulation tissue typically grows from the base of a wound and is able to fill wounds almost any size.
- The endothelial cells are responsible for revascularization/angiogenesis at the site of wound.
  - Initially, quiescent resident endothelial cells become activated by many angiogenic factors including vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), angiopoietin and transforming growth factors α and β.
  - Once activated, the endothelial cells undergo four events to occur in the formation of new blood vessels (angiogenesis): (a) protease production that breakdown extracellular matrix, (b) chemotaxis, (c) proliferation and (d) remodeling and differentiation.
- Angiogenesis is important for the restoration of the flow of nutrients and oxygen to the wound site, removing waste products, and transportation of leukocytes to the wound site.
- Any errors in the formation of granulation tissue can result in persistence of chronic wound. Foreign bodies at wound site can also result in persistent granulation tissue formation and poor wound healing with excess of macrophages, fibroblasts and capillaries around the foreign material.

Granulation Tissue Formation

Granulation tissue is soft, pink and highly vascular young immature tissue in 3–7 days seen in chronic

inflammation, which fills defects created by liquefaction of cellular debris. Granulation tissue serves as the foundation for scar tissue development. Due to presence of numerous, newly formed capillaries in granulation tissue are fragile. These capillaries bleed easily and permit leakage of plasma proteins and white blood cells into the tissues.

- Granulation tissue is formed by proliferation of fibroblasts, myofibroblasts delicate collagen fibrils, macrophages and vascular endothelial cells. Capillaries arise from adjacent blood vessels by division of endothelial cells in a process termed angiogenesis. Newly formed blood vessels supply blood to the granulation tissue. Granulation tissue supplies antibacterial antibodies and growth factors.
- Macrophages synthesize growth factors and remove cellular debris. If the tissue injury affects deeper layers of tissue, fibroblasts proliferate resulting in synthesis of collagen fibers. Granulation tissue can mature into fibrous tissue (scar formation).
- Healthy granulation tissue appears pink to red due to new blood vessels formation, which is soft to touch, moist in appearance and painless. On the other hand, unhealthy granulation appears dark red in color, painful, easy to bleed with minimum contact, which may be covered by avascular shiny white or yellow fibrous tissue, that impedes wound healing.

Angiogenesis

Angiogenesis is a process of new blood vessels development from existing blood vessels. It is essential in tissue development, and wound healing. Vasculogenesis is the process of blood vessel formation in the embryo occurring by a *de novo* production of endothelial cells by angioblasts (endothelial cell precursors). Mechanism of angiogenesis is shown in Fig. 2.60. The main angiogenic proteins involved in angiogenesis are given in Table 2.67.

- Angiogenesis is regulated by various angiogenic cytokines (e.g. VEGF, FGF).
- Angiogenesis occurs as a result of mobilization of endothelial precursor cells (EPCs) from bone marrow and preexisting vessels at the site of tissue injury.
- Bone marrow EPCs migrate to a site of tissue injury and proliferate to form a mature network by linking with preexisting vessels. Endothelial cells from preexisting blood vessels become motile and proliferate to form capillary sprouts.
- Regardless of the mechanism of angiogenesis, blood vessel maturation requires the recruitment of pericytes and smooth muscle cells to form the periendothelial layer. Mechanism of angiogenesis by following steps is described below:
  - **Sprouting of vessel:** It occurs by separation of pericytes. NOTCH signaling pathway regulates sprouting and branching of new vessels. Growth factors synthesized by extracellular proteins participate in sprouting of vessel process.
  - **Chemotaxis of endothelial cells:** Fibronectin participates in recruitment of endothelial cells toward the site of tissue injury.
  - **Proliferation of endothelial cells:** Endothelial cells proliferate just behind the leading front (tip) of the migrating cells. This function is mediated by growth factors such as VEGF, PDGF, EGF, TGF-α FGF-β, fibronectin, IL-1 and TNF-α. Vascular endothelial growth factor acts on VEGF-1, VEFG-2 and VEGF-3 receptors. Targeted mutations in these receptors result in lack of angiogenesis.
  - **Remodeling and extension of the vascular tube:** Matrix metalloproteinases synthesized by extracellular matrix degrade ECM to permit remodeling and extension of the vascular tube.
  - **Formation of mature blood vessels:** Recruitment of periendothelial cells form the mature blood vessels. This function is mediated by proteins such as fibronectin, VEGF-A, VEGF-B, VEGF-C, VEGF-D, angiopoietin 1 and angiopoietin 2. VEGF-C especially induces hyperplasia of lymphatic vasculature. Targeted mutations in these VEGFs result in lack of angiogenesis.
  - **Modulation of tissue repair:** TGF-β modulation of tissue repair the repair process by inhibiting proliferation and chemotaxis of endothelial cells. TGF-β also suppresses deposition of basement membrane.

Regulation of Angiogenesis by ECM Proteins

Angiogenesis is required by extracellular matrix (ECM) proteins.

- Integrin-α and integrin-β play key role in angiogenesis and its maintenance.
- Extracellular matrix proteins such as thrombospindin 1, SPARC and tenascin destabilize cell–ECM interactions, thus leading to angiogenesis.
- Matrix metalloproteinases and plasminogen activators are essential in tissue remodeling.
- Matrix metalloproteinases and plasminogen activators cleave ECM proteins and release VEGF and FGF-2 leading to induction of angiogenesis.
- On the other hand, ECM protein such as endostatin inhibits proliferation of endothelial cells and angiogenesis.

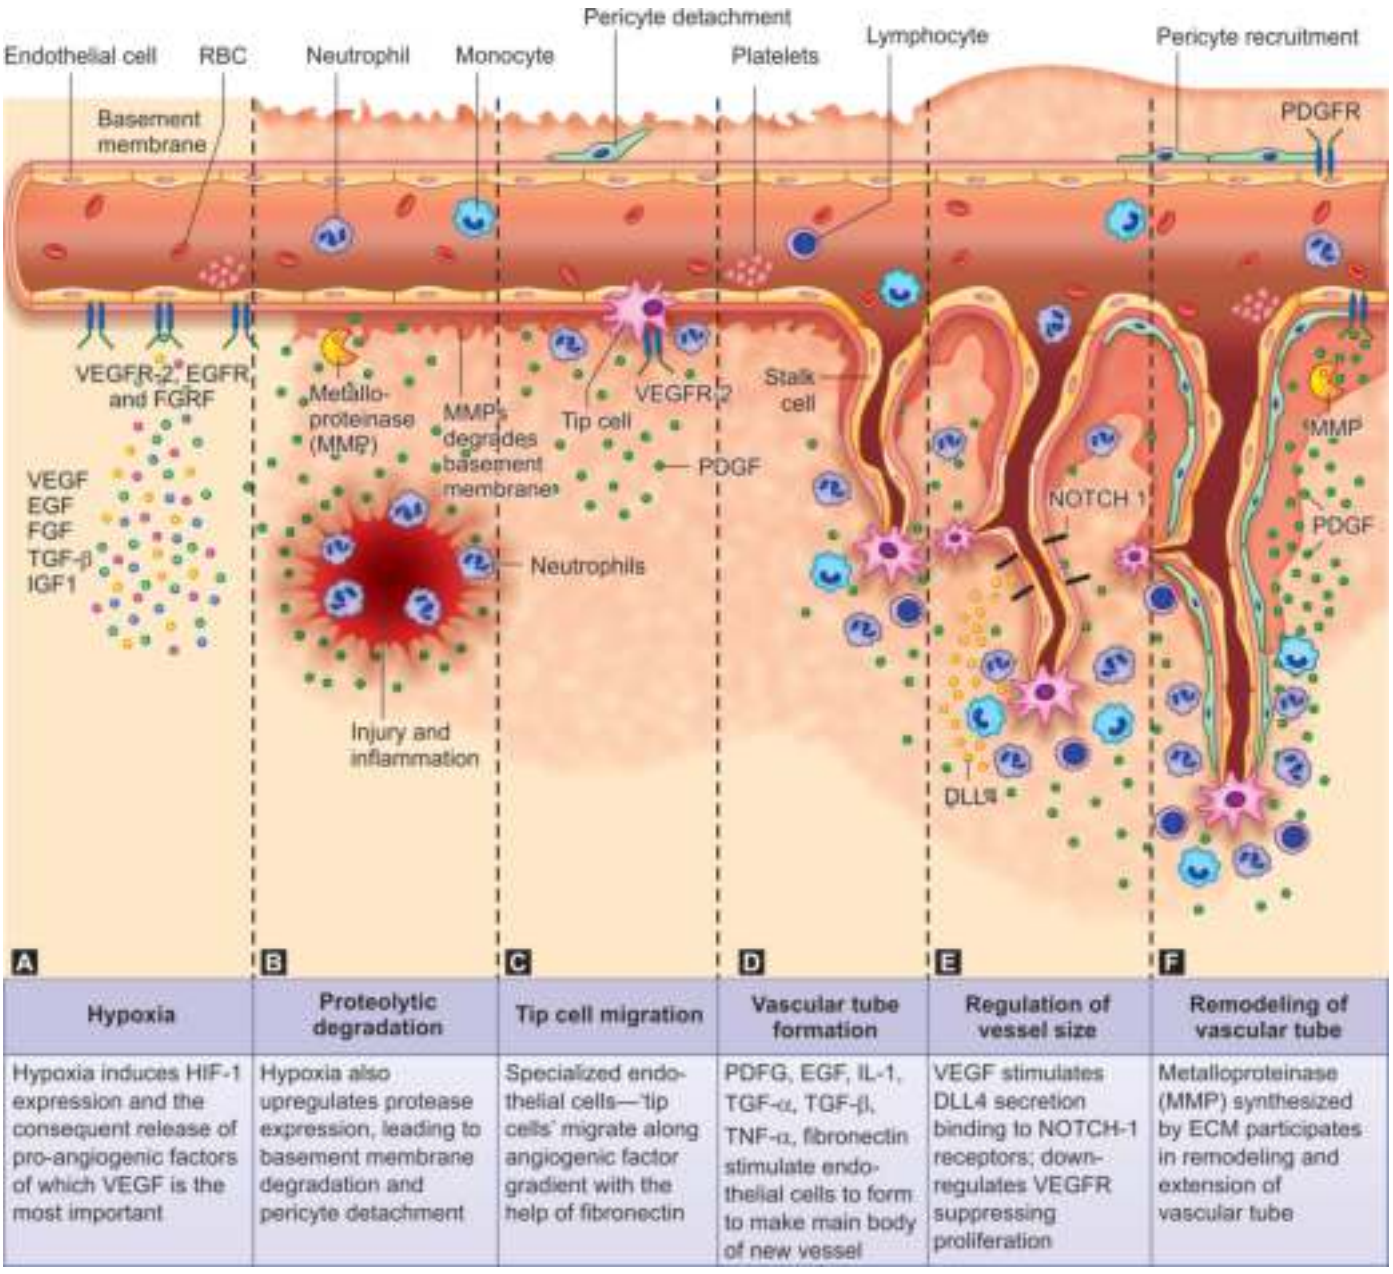

Fig. 2.60: Mechanism of angiogenesis. Endothelial precursor cells are mobilized from bone marrow and pre-existing capillaries. Endothelial cells become motile, proliferate to form capillary sprouts. It is followed by maturation (stabilization) by recruitment of pericytes and smooth muscle to form periendothelial layer. Blockage of DLL4 leads to sprouting, proliferation of endothelial cells, decrease in vascular lumen size and organization. Blockage of VEGF leads to decrease in sprouting, proliferation of endothelial cells, decrease in vascular lumen size and organization.

Interactions between DLL4 and Vascular Endothelial Growth Factor

Vascular endothelial growth factor induces delta 4 (DLL4) that inhibits VEGF signaling. Blockage of DLL4 leads to sprouting, proliferation of endothelial cells, decrease in vascular lumen size and organization. Blockage of VEGF leads to decrease in sprouting, proliferation of endothelial cells, decrease in vascular lumen size and organization.

Fibroblasts Involved in Synthesis of Collagen Fibers and Extracellular Matrix

The primary function of fibroblasts is the maintenance of structural integrity within the connective tissue, granulation tissue and extracellular matrix (ECM) formation. Fibroblasts synthesize transforming growth factor-β that maintains structural integrity within the connective tissue, granulation tissue and ECM synthesis.

Table 2.67 The main angiogenic proteins involved in angiogenesis

Angiogenic Protein Family	Angiogenic Proteins	Protein Receptors
Vascular endothelial growth factor (VEGF) protein family	VEGF-A, VEGF-B, VEGF-C, VEGF-D, VEGF-E and PIGF	VEGFR1 (FLT1), VEGF (KDR, FLK1), VEGFR3 (FLT4)
Fibroblastic growth factor (FGF) protein family	FGF-1 (acidic FGF), FGF-2 (basic FGF)	FGF-1, FGF-2, FGF-3, integrins, heparan sulfate proteoglycans
Platelet-derived growth factor (PDGF) protein family	PDGF-A, PDGF-B, PDGF-C, PDGF-D	PDGF-A, PDGF-B
Angiopoietin (Ang) protein family	Ang-1, Ang-2, Ang-3, Ang-4	Tie-2, Tie-1
Hepatocyte growth factor (HGF) protein family	HGF	c-Met
Hypoxia-inducible factor (HIF) protein family	HIF-α, HIF-β	Aryl hydrocarbon receptor nuclear translocator
Insulin growth factor (IGF) protein family	IGF	IGF-1R, IGF-2
Transforming growth factor-β (TGF-β) protein family	TGF-β1, TGF-β2, TGF-β3	TGFBR1, TGFBR2
Metalloproteinases (MMPs) protein family	MMP	MMP1-MMP23
Tumor necrosis factor (TNF) protein family	TNF	TNF1-TNF18

Angiogenesis inhibitors include thrombospondin 1, thrombospondin 2, interferon-α, interferon-β, angiostatin, endostatin and collage IV fragments.

- Fibroblasts produce and secrete all components of ECM, including structural proteins (collagen fibers, elastic fibers, fibronectin, laminin), adhesive proteins and a space-filling ground substance composed of glycosaminoglycans (GAGs) and proteoglycans.
- Activated fibroblasts, myofibroblasts, and capillary sprouts are abundant in wound healing and tissue repair 3–5 days following injury. These fibroblasts change shape from oval to bipolar as they begin to form collagen and synthesize a variety of extracellular matrix proteins. Neutrophils accumulate in the wound 12–24 hours after injury.
- The extracellular matrix initially consists of weaker form of type 3 collagen during wound healing and tissue repair within 5–7 days that is ultimately replaced by stronger type 1 collagen at the end of wound healing and scar formation. As the amount of collagen in granulation tissue progressively increases, the tissue becomes gradually less vascular and less cellular. Cellularity and edema are diminished with formation of an avascular, hypocellular scar. Mature scar tissue would be visible 2 weeks following injury.

REMODELING PHASE

Remodeling phase, also known as maturation phase of wound healing and tissue repair, is the final phase of the tissue healing process in which granulation tissue and extracellular matrix mature into scar formation leading to increase in tissue tensile strength.

- Sequence of events in scar formation in remodeling phase of wound healing and tissue repair include: (a) resolution of acute inflammation and dissolution of fibrin clot, (b) maturation of granulation tissue produced by fibroblasts and endothelial cells filling wound space, (c) maturation of ECM, (d) fibroblasts lay down vertically oriented collagen fibers at the wound margin, and (e) progressive re-epithelialization, devascularization, collagen deposition over next two to three weeks resulting in a dense white scar.
- Collagen fibers become denser and align according to force as seen in muscle, tendon or ligament. It is known as remodeling. Remodeling increases the tensile strength of scar tissue. Remodeling phase involves two processes: (a) collagen fibers remodeling by growing in size and strength replacing fibronectin and hyaluronic acid, (b) vascular maturation and repression.
- In remodeling phase in wound healing and tissue reapir, fibroblasts regulate the process of wound matrix breakdown by matrix metalloproteinases (MMPs) and synthesis of new ECM. Immature type 3 collagen fibers are replaced by mature type 1 collagen fibers, which are critical to scar formation, integrity and strength. Remodeling phase can continue from 21 days to two years.
- Myofibroblasts are responsible for the contractile process in wound closure.
  - During granulation tissue formation, fibroblasts slowly modulate into myofibroblasts, characterized by bundles of actin microfilaments along their cell's plasma membrane.
  - Prostaglandins, bradykinin, epinephrine and norepinephrine play important role in modulation of contraction by myofibroblasts.

- Eventually, actin binds to the extracellular matrix component fibronectin, attaches to the collagen fibers, retracts and draws collagen fibers toward it. The net result is wound contraction and closure.

- Errors during remodeling phase can cause excessive wound healing leading to formation of hypertrophic scar or keloid or a persistent granulation tissue in chronic wound.

Matrix Metalloproteinases

Matrix metalloproteinases (MMPs) are crucial components in wound healing and tissue repair because enable cells to migrate by degrading extracellular matrix (ECM) proteins. MMPs are synthesized by polymorphonuclear cells, macrophages, fibroblasts, synovial cells and some epithelial cells.

- In addition to cell migration, MMPs can also disrupt cell–cell adhesions and release bioactive molecules stored in the ECM. MMPs degrade collagen fibers type 3 and get replaced by type 1 collagen fibers, and increasing tensile strength to approximately 80% of the original. MMPs cut triple helix collagen into two unequal fragments; which are susceptible to digestion by other macrophages.
- MMPs activity can be minimized by binding to specific proteinase inhibitors such as **α_1-antitrypsin** and **α_2-macroglobulin**. Metalloproteinases synthesized by various cells are given in Table 2.68.

Wound Contraction

Proliferation of myofibroblasts causes progressive wound contraction and deformity. Myofibroblasts are bound together by tight junctions forming syncytia, which express smooth muscle actin, desmin, and vimentin. On the other hand, fibroblasts tend to be spindle cells, surrounded by collagen fibers.

- A mature scar is composed of type 1 collagen fibers. Further changes in scars occur such as cicatrization—a late diminution in size resulting in deformity, calcification and ossification. Fibronectin attaches fibroblasts to collagen fibers.
- Chondronectin binds chondrocytes to type 2 collagen, the matrix of cartilage.
- Laminin binds epithelial cells to the type 4 collagen of basement membranes.
- Osteonectin binds hydroxyapatite and calcium ions to type 1 collagen (bone matrix) and initiates mineralization.

CUTANEOUS WOUND HEALING AND TISSUE REPAIR

Type of wound healing process in the skin depends on the extent of tissue damage. Minimal cutaneous tissue loss involves wound healing by primary intention. Extensive cutaneous tissue loss involves wound healing by secondary intention. Differences between primary and secondary intention of cutaneous wound healing and tissue repair are given in Table 2.69.

- Cutaneous wound healing by primary intention indicates that wound edges have been mechanically brought together. Fibrin occupies the small residual space and initiates steps of wound healing and tissue repair. Surgical clean incised wound with closely apposed margins heals by primary intention leading to minimal scar formation. Collagen deposition is the ultimate source of strength for the healed wound.
- Cutaneous wound healing by secondary intention indicates in which edges are not approximated, requires more extensive granulation tissue growth that fills the defect; myofibroblasts then contract wound, forming a scar and subsequently, more wound contracture is likely to occur.
- There are no fundamental differences between healing by primary and secondary intention, they merely differ in the degree to which the various stages apply. Escape of blood and exudate results

Table 2.68 Metalloproteinases synthesized by various cells

Cell Types	MMPs Synthesis
Proliferating keratinocytes	MMP3, MMP19, MMP28
Migrating keratinocytes	MMP1, MMP10, MMP9, MMP26
Fibroblasts	MMP1, MMP2, MMP3, MMP19, MT1-MMP (membrane-type 1 matrix metalloproteinase)
Endothelial cells	MMP9, MMP2, MMP19, MT1-MMP
Neutrophils	MMP8, MMP9
Macrophages	MMP12, MMP19

MMP1 strongly influences keratinocyte migration at the wound edges. MMP7 regulates neutrophil recruitment. The wound induced by angiogenesis, result of migration and proliferation of endothelial cells, is driven by vascular endothelial growth factor (VEGF) and tumor necrosis factor-α (TNF-α) release through the gelatinases MMP2 and MMP9. MMP-1 is overexpressed in different malignant tumors and is associated with invasion of epithelial ovarian cancer cells, lymph node involvement and metastases.

Table 2.69 Differences between primary and secondary intention of cutaneous wound healing and tissue repair

Parameters	Primary Intention	Secondary Intention
Site	Clean, uninfected surgical incision approximated by surgical sutures	In all natural, open wounds like, abscess, surface wounds in road accidents. Infection may be present
Tissue injury	Limited to superficial layer of epithelium and connective tissues	Extensive, causing cells death and necrosis in larger area; larger defect
Inflammatory reaction	Less intense	More intense for clearing large amount of fibrin, necrotic debris and exudate
Granulomatous tissue	Small amount of granulation tissue is formed	Larger amount of granulation tissue is formed to fill large defect
Wound contraction	Absent	Present due to presence of fibroblasts
Scarring	Less scarring	More scarring
Keloid	Absent	▪ May be formed later transforming into squamous cell carcinoma ▪ Skin appendages destroyed do not regenerate in either type of wound healing

Skin appendages destroyed do not regenerate in either type of wound healing.

in acute inflammatory response at the margins, scab formation and removal of necrotic debris by macrophages, which is followed by epidermal proliferation, contraction of the wound, progressive increase in collagen fibers and loss of vascularity and shrinkage of the scar.

- Cutaneous wound healing and tissue repair is inhibited by superadded infection, foreign body acting as a nidus for inflammation, protein depletion, vitamins depletion, vitamin C deficiency, ischemia and hydrocortisone.

CUTANEOUS WOUND HEALING AND TISSUE REPAIR BY PRIMARY INTENTION

Cutaneous wound healing and tissue repair by primary intention occurs in clean surgical superficial skin wounds with closely apposed edges and minimal tissue loss. Normally, maturation of the epidermis requires an intact layer of basal cells that are in direct contact with one another. Disruption of this contact activates basal cells resulting in migration, proliferation and epithelialization of skin wound. Cutaneous wound healing and tissue repair by primary intention is shown in Fig. 2.61A to D.

- **Contact inhibition of growth and motility:** When epithelial continuity is re-established, migration and cell division cease, and the epidermis resumes its normal cell cycle of maturation and shedding. This process of epithelial growth regulation is referred to as 'contact inhibition of growth and motility'. Such a wound requires only minimal cell proliferation and neovascularization to heal, and formation of a small scar.
- **Wound healing in surgical wound:** Suturing of apposed edges by sutures used for clean surgical wounds. Surgical clean wound with opposed margins heals by primary intention. Epithelial regeneration predominates over fibrosis. Wound healing in surgical wound is fast with minimal scarring/infection. There is regeneration of epidermis. Dermis undergoes fibrous repair. Sutures are taken out on 5–10 days after surgery. Surgical scar provides 80% normal strength. Minimal surgical scarring gives good strength. Maturation of scar continues up to 2 years. Risk of trapping infection under skin produces abscess.

Pathology Pearls: Wound Healing and Tissue Repair by Primary Intention

- **Within 24 hours:** Wound is filled with blood clot. Neutrophils appear at the margin of wound.
- **By third day:** Neutrophils are replaced by macrophages with progressive granulation tissue and collagen deposition at the margins of the incision and epidermal layer thickening due to epithelial cell proliferation and migration along incised wound margin.
- **By fifth day:** Wound incision space is filled with granulation tissue. There is maximum neovascularization. Collagen fibers become abundant and bridge the wound incisional gap. Differentiation of surface cells yields mature epidermal architecture.
- **By first week:** Wound shows continued accumulation of collagen fibers and fibroblast proliferation and regression of vascularity, edema and inflammation.
- **End of first month:** Connective tissue is cellular with intact epidermis. Wound is devoid of inflammatory infiltrate. There is gradual gain in tensile strength overtime. Epidermal appendages do not regenerate.

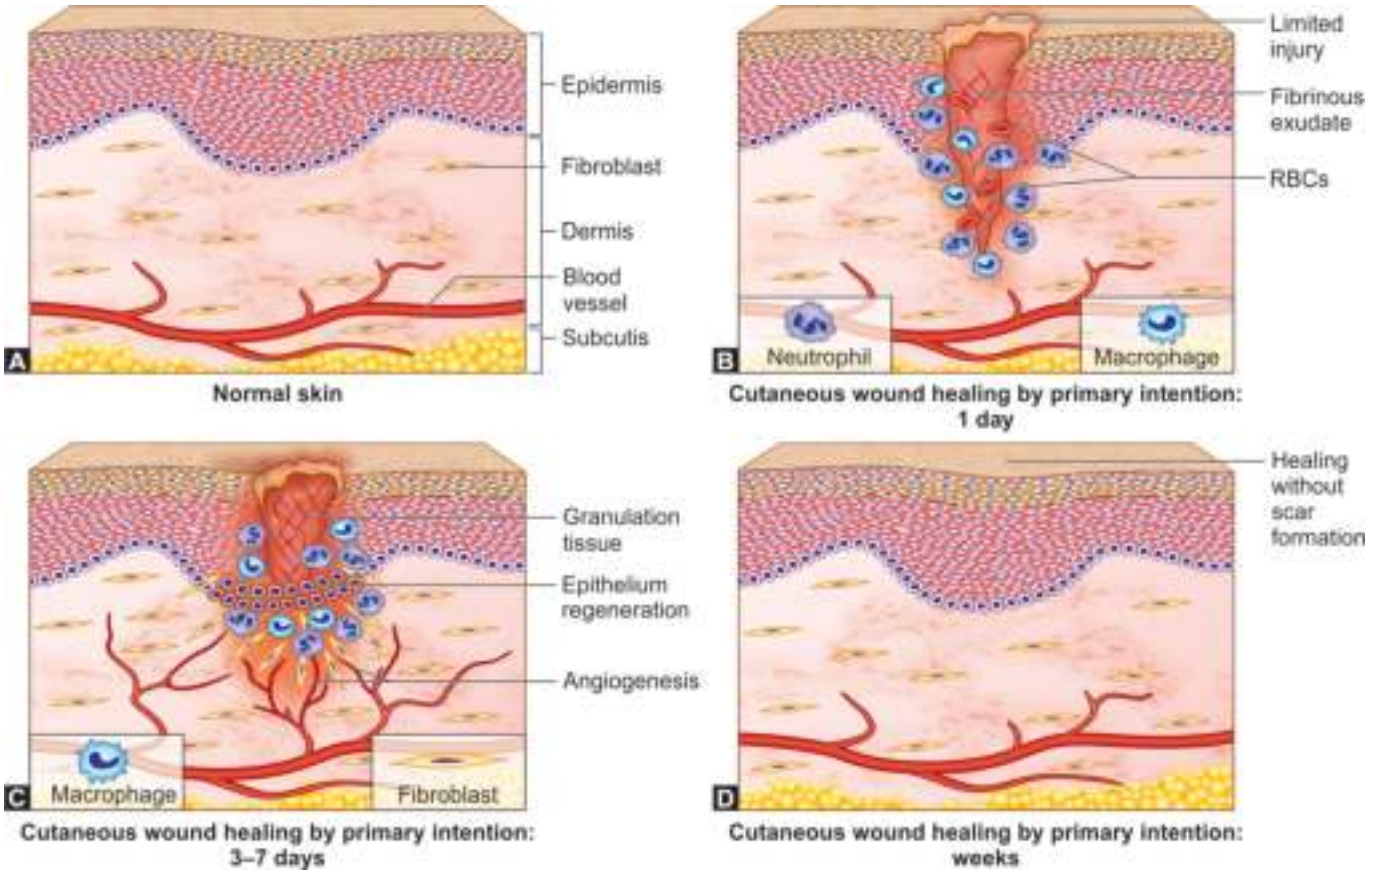

Fig. 2.61A to D: Cutaneous wound healing and tissue repair of skin by primary intention. It occurs in surgical wound with closely opposed edges with minimum tissue loss. Healing requires only minimal proliferation of cells and neovascularization with formation of small scar.

CUTANEOUS WOUND HEALING AND TISSUE REPAIR BY SECONDARY INTENTION

Cutaneous wound healing and tissue repair by secondary intention occurs in open gaping or infected wounds, in which the edges are far apart and in which there is substantial tissue loss. Cutaneous wound healing and tissue repair by secondary intention is shown in Fig. 2.62A to D.

- Healing of cutaneous wound requires extensive cell proliferation and granulation tissue formation. Resorption of granulation tissue is replaced by deposition of collagen-rich scar tissue in settings of open gaping or infected wounds, large third-degree burns, ulcers, tooth extraction, and external bevel gingivectomies. Tissues in the third stage burn do not restore to normal owing to loss of skin, basement membrane and connective tissue infrastructure.
- Extensive proliferation of epithelial cells and formation of granulation tissue are essential for healing of such wounds by secondary intention.
- Cutaneous wound healing and tissue repair is slower in open gaping or infected wounds. Fibrosis predominates over epithelial regeneration. Resorption of granulation tissue is replaced by deposition of collagen-rich scar tissue. There is more inflammatory exudate to remove necrotic tissue. Wound contraction is necessary for tissue repair. Initially, wound contraction occurs, then clot dries to form a 'scab'. Epidermis regenerates in cutaneous wound.
- There is increased susceptibility to infection in the presence of granulation tissue. Cutaneous wound healing and tissue repair by secondary intention takes longer time, which produces a larger scar; not necessarily weaker resulting in fibrosis.

FACTORS AFFECTING WOUND HEALING AND TISSUE REPAIR

Factors accelerating wound healing and tissue repair include ultraviolet light, administration of anabolic steroids, deoxycorticosterone acetate, and growth hormone, rise in temperature and hyperbaric oxygen. Wound healing and tissue repair can be delayed by factors local to the wound itself, including infection, desiccation or abnormal bacterial presence, maceration, trauma, necrosis, pressure and edema. Systemic factors adversely affecting wound healing and tissue repair include age, body type, chronic disease,

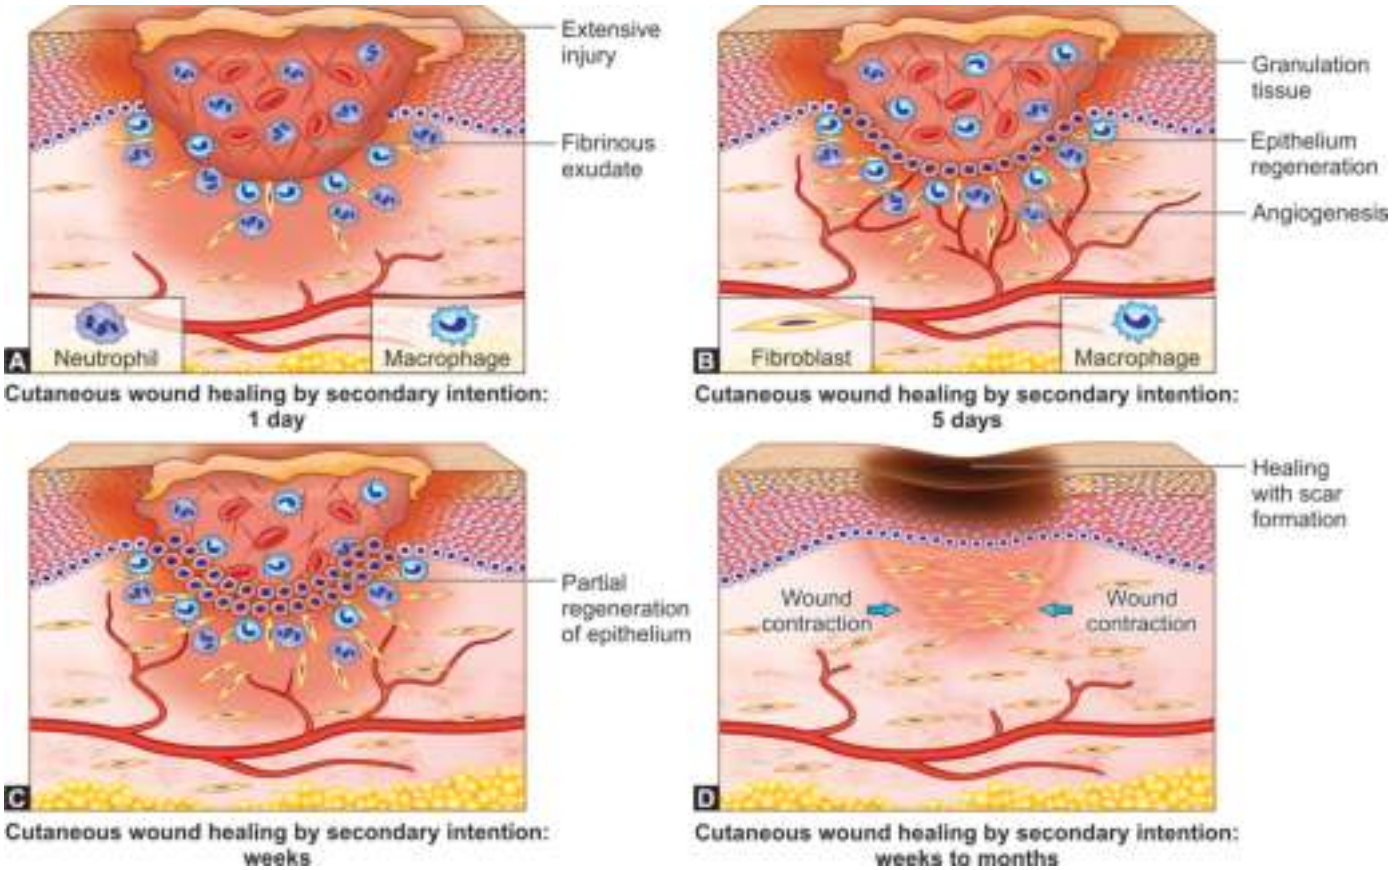

Fig. 2.62A to D: Cutaneous wound healing and tissue repair by secondary intention. It occurs in wound with far apart edges with substantial tissue loss. The wound requires contraction, extensive proliferation of cells and neovascularization. Re-epithelialization of wound starts from the margins with deposition of collagen fibers and granulation tissue leading to resorption of granulation tissue and formation of large scar.

immunosuppression, nutritional status, radiation therapy and vascular insufficiencies.

LOCAL FACTORS AFFECTING WOUND HEALING

Local factors can affect wound healing and tissue repair.

- **Decreased blood supply:** Molecular oxygen is required for collagen synthesis. It has been shown that even a temporary lack of oxygen due to cardiovascular pathology can result in the formation of less stable collagen fibers. Failure of proper collagen synthesis leads to delayed wound healing and weak scars.
- **Type of wound:** Wound healing and tissue repair can be delayed by factors local to the wound itself, including infection, foreign bodies, desiccation, maceration, necrosis, trauma, edema and type of open wound. Large wounds take longer time to heal and linear wound heals faster than circular or rectangular. In addition, wound healing is slower when wounds have infection, necrotic tissue, desiccation (dry), and foreign bodies.
- **Type of injurious agent:** Blunt, crushing or tearing of tissues adversely affect wound healing.
- **Poor apposition of wound margins:** Due to poor opposition of wound margins leads to large hematoma formation, which retards wound healing and tissue repair.
- **Persistent infection in wound:** Wounds in ischemic tissue become infected more frequently. Polymorphonuclear cells and macrophages require oxygen for destruction of microorganisms. *Staphylococcus aureus* is the most common cause of impaired wound healing. Gangrene, suppuration and secondary hemorrhage delayed wound healing and tissue repair.
- **Retention of debris:** Retention of foreign bodies, dirt, sutures, hematoma, and necrotic tissue delayed wound healing and tissue repair.
- **Denervation:** The skin is densely innervated with an intricate network of cutaneous nerves, neurotransmitters and specific receptors which influence a variety if physiological and disease processes. Denervated skin could result in impaired wound healing and tissue repair, such as decubitus ulcers and diabetic foot ulcers.

SYSTEMIC FACTORS AFFECTING WOUND HEALING

Wound healing and tissue repair can be delayed due to systemic factors such as age, body type, nutritional

status, chronic disease, immunosuppression, radiation therapy and vascular insufficiencies.

- **Age of patient:** There are many changes in wound healing capacity that are related to age. Wound healing and tissue repair is delayed in elderly people over the age of 60 years. Due to advancing age, there is decrease in the body's inflammatory response, a delay in angiogenesis and slow the process of epithelialization. Some visible changes to the skin are related to the alteration in melanocytes and decreased function of sebaceous glands. Decreased collagen synthesis is attributed to slower scar formation in the wound healing and tissue repair process.
- **Nutritional status:** Proteins rich in sulfur amino acids are essential for wound healing. Protein deficiency leads to delayed wound healing. In geriatric patient or chronic ailment, poor nutrition can cause delayed wound healing and tissue repair. Inadequate nutrition can occur due to infections. Large pressure injuries induced ulcers require large quantity of protein and calorie. Insufficient protein and calorie intake delayed wound healing and tissue repair.
  - **Vitamins and trace elements deficiency:** Vitamin and trace elements deficiency delayed wound healing.
  - **Vitamin C (ascorbic acid):** It is a powerful, biologic reducing agent. It is necessary for the hydroxylation of proline residues in collagen. Deficiency of vitamin forms an abnormal collagen that lacks tensile strength. Patients with vitamin C deficiency exhibit poor wound healing and tissue repair.
  - **Vitamin A:** Vitamin A stimulates epithelialization, capillary formation, and collagen synthesis. Deficiency of vitamin A retards wound healing.
  - **Vitamin K:** Vitamin K plays an indirect role in wound healing and tissue repair by preventing bleeding disorders. Deficiency of vitamin K retards wound healing and tissue repair.
  - **Vitamin B complex:** Vitamin B complex components are important cofactors in enzymatic reactions that contribute to the wound-healing process. Deficiency of vitamin B complex retards wound healing and tissue repair.
  - **Zinc deficiency:** Zinc leads to defects in removal of type 3 collagen in wound remodeling and causes bleeding in wound resulting to delayed wound healing and tissue injury.
- **Immunosuppression:** Glucocorticoids interfere with collagen formation and thus decrease tensile strength. It is worth mentioning that glucocorticoids along with antibiotic are occasionally used to prevent scar formation (e.g. bacterial meningitis).
- **Vascular insufficiencies:** Blood delivers the necessary components to tissue for wound healing process. Blocked or narrowed blood vessels or diseases of the heart, kidneys and lungs can also cause issues in the body delivering vital wound healing components, including adequate oxygen and white blood cells to wounded tissues.
- **Chronic disease:** Diabetes mellitus is associated with susceptibility to infection, impaired circulation and increasing tissue levels of glucose. Diabetic patients affect circulatory system that may delay wound healing. In renal failure, uremia impairs platelet function leading to diminished hemostasis, the first stage in wound healing.
- **Genetic disorders:** Marfan syndrome and Ehlers-Danlos disease adversely affect wound healing process. Marfan syndrome is a genetic disorder of the connective tissue affecting most notably the skeletal system, cardiovascular system and skin. Ehlers-Danlos disease is characterized by wound dehiscence, increased bleeding tendency due to the blood vessel fragility and delayed wound healing and tissue repair process.

COMPLICATIONS OF WOUND HEALING AND TISSUE REPAIR

The complications of wound healing and tissue repair can be grouped into four categories: (a) inadequate granulation tissue, (b) excessive fibrosis, (c) exuberant granulation tissue, and (d) other complications.

INADEQUATE GRANULATION TISSUE

Granulation tissue is an important component in the wound-healing process. Proliferation of fibroblasts and endothelial cells generates granulation tissue near the wound. The new capillaries make the tissue pink and granular. Cutaneous wounds can heal by primary intention and secondary intention. Granulation tissue matrix fills cutaneous wound that heals by secondary intention. Inadequate granulation tissue can occur due to multiple factors, that cause delayed wound healing and tissue repair.

Wound Dehiscence

Wound dehiscence occurs when a surgical incision following abdominal or cardiothoracic procedures associated with superadded infection reopens either internally or externally within 3–10 days of surgery.

- Several risk factors for wound dehiscence include obesity, malnutrition, tobacco smoking, peripheral vascular disease, cardiopulmonary diseases, anemia, diabetes mellitus, hypertension, cancer, infection, hematoma formation and elderly persons.

- A clean wound will have minimal space between the edges of the wound and commonly form a straight line. One can see holes in the wound dehiscence.
- Wound dehiscence can become life-threatening. Patient has a feeling that wound is ripping apart or giving away with leaking pink or yellow fluid.
- Signs of infection at wound site shows yellow or green pus, swelling, redness or warmth and fever.

Ulceration in Wound

Common causes of ulceration in wound are caused by venous hypertension, dependent edema, peripheral vascular disease, uncontrolled diabetes mellitus, cutaneous necrosis, vasculitis, pyogenic gangrenosum, skin disorders and connective tissue disorders such as rheumatoid arthritis, systemic lupus erythematosus, dermatomyositis, and systemic sclerosis.

- Ulceration in rheumatoid arthritis is usually of rapid onset, associated with pain, tender margin, fever, arthralgia and myalgia.
- Pyoderma gangrenosum is characterized by the appearance of lesions at the site of trauma. Surgical debridement of pyoderma gangrenosum often results in worsening of the ulceration.
- Abnormities of coagulation factors associated with skin necrosis occur due to deficiencies of protein C, protein S, antithrombin III, heparin cofactor 2 including homocysteinemia, increased prothrombin concentration and factor V Leiden mutation.
- *Staphylococcus aureus*, β-hemolytic streptococci, *Streptococcus pyogenes* and opportunistic infections in AIDS can complicate existing ulceration.

Incisional Hernia

Incisional hernia is caused by an incompletely-healed surgical wound. All abdominal surgeries carry higher risk of incisional hernia leading to protrusion of intestine, organ and other tissues. Since, median incisions in the abdomen are frequent in patients undergoing abdominal exploratory surgery, patients develop ventral incisional hernias within three to six months post-surgery due to many reasons such as excessive physical activity, gain considerable weight, pregnancy and increase in abdominal pressure.

- Patient presents with constipation, protrusion in the abdomen at or near the site of a previous incision, nausea, vomiting, fever, pain and abdomen around the protrusion.
- If the protrusion portion of intestine has become trapped within the abdominal wall, the blood supply to the intestine can get cut off leading to necrosis. Imaging techniques are helpful in detection of blockage or actual location of the intestinal protrusion.

EXCESSIVE FIBROSIS

Excessive fibrosis leads to cosmetic scarring, hypertrophic scar and keloid formation. In hypertrophic scar, excessive connective tissue is formed within the original wound and stays within that area. With keloid scars, excessive connective tissue that forms within original wound extends beyond the original wound area. Fibrosis induced by transforming growth factor-β in various organs is given in Table 2.70.

Hypertrophic Scar

A hypertrophic scar is thick, wide and raised scar formed within the original wound and stays within that area due to an abnormal response to wound healing. Hypertrophic scar commonly occurs due to lot of tension around wound in taut skin areas following skin trauma, burns or surgical incisions. Hypertrophic scar can be treated by medication, freezing, injections, lasers and surgery.

Keloid

Keloid is exuberant scar that tends to progress beyond the site of initial injury and recurs after excision, which is thick raised, smooth and hard area much larger than the original wound. Keloid is characterized by changes

Table 2.70 Fibrosis induced by transforming growth factor-β in various organs

Fibrosis in Various Organs	Disorder
Eyes	▪ Graves' disease ▪ Conjunctival cicatrization
Lung	▪ Pulmonary fibrosis ▪ Pulmonary sarcoidosis
Liver	▪ Cirrhosis ▪ Primary biliary cirrhosis
Kidney	▪ Glomerulosclerosis ▪ Interstitial fibrosis
Pancreas	▪ Chronic of fibrosing pancreatitis
Skin	▪ Keloid ▪ Hypertrophic scar ▪ Scleroderma
Endometrium	▪ Endometriosis
Peritoneum	▪ Post-surgical adhesions ▪ Sclerosing peritonitis
Retroperitoneum	▪ Retroperitoneum fibrosis
Bone	▪ Renal osteodystrophy
Bone marrow	▪ Myelofibrosis
Skeletal muscle	▪ Muscular dystrophy ▪ Polymyositis ▪ Dermatomyositis ▪ Eosinophilia myositis

in the ratio of type 3 to type 1 collagen, suggesting a 'maturation arrest' in the healing process.

- Dark-skinned persons are more frequently affected by keloids than light-skinned people. Keloid is formed due to excessive scar tissue as a result of synthesis of collagen in the settings of burns, ear piercing, severe acne scar, scratches and surgical incision site.
- Keloid is most commonly found on the chest, shoulders, earlobes and cheeks including any part of the body. Keloid tends to grow slowly with raised pink, pink red, purple margin causing pain, itching and tenderness. Histologic examination of keloid reveals irregular, thick collagen bundles that extend beyond the confines of the original injury. Histology of keloid is shown in Fig. 2.63.

EXUBERANT GRANULATION TISSUE

Granulation tissue fills the dead space during normal wound healing. Exuberant granulation tissue is an overgrowth of granulation tissue. The proliferation of excess granulation prevents proper wound healing and tissue repair. There are various causes and predisposing factors of exuberant granulation tissue that include infections, and chronic inflammation induced by implanted material (e.g. bandages, casts).

Pyogenicum Granuloma

Pyogenicum granuloma is sometimes also called granuloma pyogenicum. It is a common benign vascular neoplasm that arises in skin and mucous membranes (e.g. lips, eyelids, genital, inside mouth). Scientifically, accurate term for this entity is the lobular capillary hemangioma. Patient presents with grossly visible, 2 cm size solitary, red, friable pedunculated papule that has tendency to bleed.

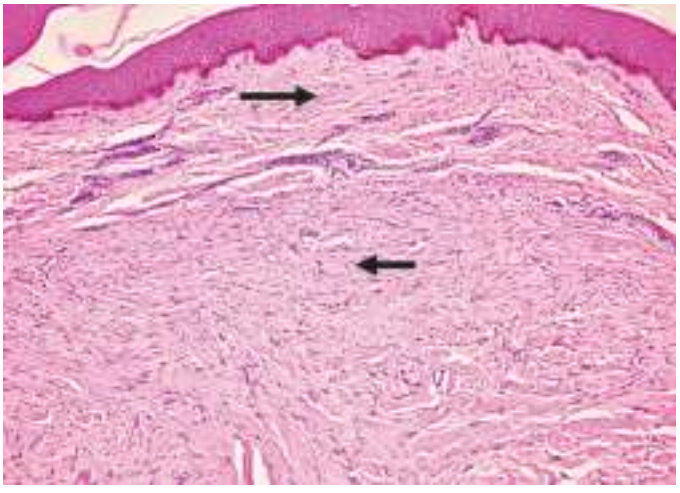

Fig. 2.63: Histology of keloid. Keloid is an exaggerated response to injury that produces abundant collagenous soft tissue, forming a large nodular scar. It often follows trauma to the skin, such as ear-piercing or surgical wounds. It most often occurs in dark-skinned persons especially of African lineage. It tends to recur after resection. Keloid is composed of haphazard fascicles of dense, hyalinized collagen that appear edematous due to dermal mucosubstances in dermis. There is lack adnexal structures. Scattered fibroblasts and myofibroblasts and widely scattered blood vessels are present (arrows) (400X).

Desmoid Tumor

Desmoid tumor is known as aggressive fibromatosis. develop from skeletal muscle, connective tissue, fasciae and aponeuroses in the abdomen as well as neck, shoulders, upper arms and thighs. Desmoid tumor is a low-grade malignancy that occurs in sporadic form and in familial neoplastic syndromes. In about 10–15% of patients with familial adenomatous polyposis (FAP) syndrome, aggressive fibromatosis is a potential manifestation of FAP due to APC gene mutation.

Wound Contracture

Wound contracture can occur during wound healing that leads to severe physical deformity of the wound and surrounding tissues wound contracture is characterized by skin constriction and functional limitations of movements. Wound contracture may be observed after serious burns, crushing injuries, obvious lacerations and avulsion injuries that may occur on the palms, souls and the anterior thorax, which can be severe enough to compromise the movement of joints. Wound contracture results from the proliferation of the specialized fibroblasts termed myofibroblasts.

Proud Flesh

Exuberant granulation tissue, also known as proud flesh, is a frustrated complication of wound healing as a result of extensive growth of the granulation tissue leading to delayed or inhibition of healing process. In severe cases, excessive granulation tissue can lead to the development of significant elevation above the wound edges giving cauliflower-like appearance causing inhibition of epithelial migration.

OTHER COMPLICATIONS

Other complications of cutaneous wound healing and tissue repair include wound infection, epidermal inclusion cyst, hyperpigmentation and malignant transformation.

Wound Infection

Infected wound is a localized defect of the skin or underlying soft tissue in which pathogenic organisms have invaded into viable tissue. Signs of wound infection include yellow-green foul smelling pus discharge, spreading redness around wound edges, increased pain, swelling, fever and lymphadenopathy.

Epidermal Inclusion Cyst

Epidermal inclusion cyst is also called sebaceous, keratin or epidermoid cysts. An epidermal inclusion cyst is lined by stratified squamous epithelium, that appears as a slow-growing mobile, dome-shaped lump filled with keratin material and located just below the surface of skin. It can be located anywhere, but most commonly on the face, followed by the chest or back, scalp, neck, legs, and/or genitalia. It can range in size from 0.5 cm to several centimeters. It has a 'punctum' small-dark-colored opening on the surface of epidermal inclusion cyst, which connects to the cyst located below the skin's surface. Patient can present with pain, redness, swelling and/or drainage. Keratin material can be drained out through the punctum by dermatologist.

Hyperpigmentation over Healed Wound

Hyperpigmentation occurs when the skin affected by an inflammatory disorder and healed scar left after a wound induced by a deep cut or skin burn. Tissue damage also frequently leads to alterations in skin pigmentation in particular to wound hyperpigmentation. The skin remains more pigmented than the normal surrounding skin due to immune cell recruitment to wounds and subsequent recruitment of melanoblasts and melanocytes.

Wound Healing and Malignant Transformation

The relationship between wound healing and development of cancer has been recognized. The mechanisms that regulate wound healing can promote transformation of normal cell to cancer stem cell.

- In addition, chronic inflammation has been associated with malignant transformation in many tissues by enhancing cancer stem cell (CSC) populations, which are highly resistant to current treatments.
- Proinflammatory cytokines and development of signaling pathways are involved in tissue repair, whose deregulation in the tumor microenvironment may promote growth and survival of CSCs.
- Presence of myofibroblastic cells has emerged as common hallmark of wound healing and repair including malignant transformation.
- Both epithelial–mesenchymal transition (EMT) and myofibroblastic differentiation are common occurrences during wound healing, inflammation and fibrosis as well as tumor progression. EMT and myofibroblastic differentiation are regulated by growth factors and signaling pathways.

HEALING OF BONE FRACTURE

Bone fracture is usually accompanied by trauma to adjacent soft tissues with hemorrhage. Healing of bone fracture occurs by the process of organization, while the bone is repaired by regeneration. Pathologic fractures may occur due to osteoporosis, especially steroid induced, metastatic tumors, primary tumors (benign and malignant), Paget's disease, and bone lesions of hyperparathyroidism and osteogenesis imperfecta.

TYPE OF BONE FRACTURES

There are several types of bone fractures. Following terminology is being used in describing basic principles of bone fractures: open, closed, incomplete or partial, complete, stable and displaced bone fracture.

- **Open bone fracture:** An open bone fracture is also called a compound fracture in which there is an open wound, that exposes the bone through the skin near the site of broken bone. Compound bone fractures are extremely painful and patients be shifted to emergency. If not properly treated, open bone fractures can lead to nonlethal, long-term complications such as osteomyelitis and problems in proper bone fracture healing.
- **Closed bone fracture:** A closed bone fracture is a broken bone that does not penetrate the skin. This is also called simple bone fracture. Common causes of closed bone fracture include trauma, motor vehicle accidents, direct blow and repetitive forces such as running. Repetitive forces can induce stress fractures of foot, ankle, tibia or hip bones.
- **Incomplete or partial bone fracture:** This is a crack in the bone that does not completely break the bone into two or more pieces. Incomplete or partial bone fracture occurs as a result of a direct hit to the body or repetitive motions on the muscles that mounts pressure on the bones. Bones are weakest when they are twisted hence prone to partial fracture.
- **Complete bone fracture:** In complete bone fracture, the break goes completely through the bone separating into two or more pieces.
- **Stable bone fracture:** Stable bone fracture occurs when an injury causes the bone to break clean with its segments in alignment and the bone maintains its original position. Stable bone fracture can be induced by physical trauma, osteoporosis and aging process that weaken the bones.
- **Displaced bone fracture:** There is gap between the broken ends of the bone. Repairing a displaced bone fracture may require surgery.

Clinical Pearls: Type of Bone Fractures

Transverse Bone Fracture

A transverse bone fracture occurs when the fracture straight line is perpendicular to the shaft of long bone. This type of bone fracture may be caused by trauma or fall.

Spiral Bone Fracture

In spiral bone fracture, the broken bone resembles a corkscrew or winding staircase because the break happens diagonally across a bone that is longer than it is wide. Spiral; fractures occur in the long bones, usually femur, tibia or fibula, humerus, radius or ulna. Spiral bone fractures are caused by twisting injuries sustained during sports and/or physical trauma or automobile accident.

Greenstick Bone Fracture

- A greenstick bone fracture is a partial fracture that occurs in infants and children as their bones are softer and more flexible.
- The bone bends and breaks but does not separate into two separate pieces.

Stress Bone Fracture

Stress bone fracture is also called hairline fracture, which is tiny crack in the weight-bearing bones of the lower leg and foot caused by repetitive motions such as running. It can be difficult to diagnose with a regular radiograph.

Compression Bone Fracture

- Crushing of bone is called a compression fracture. The broken bone occurs most often in the spine and can cause vertebral body to collapse making it shorter in height.
- Compression bone fracture can lead to slowly worsening severe pain, deformity and restricted movements (bending or twisting). Osteoporosis is the most common cause of compression bone fracture.

Oblique Bone Fracture

An oblique bone fracture occurs when the bone breaks at an angle across the bone, which tends to occur most often in femur or tibia as a result of a sharp blow that comes from an angle due to a fall or trauma. This type of injury causes a visible bone deformity beneath the skin.

Impacted Bone Fracture

An impacted bone fracture occurs when the broken ends of the bone are jammed together by the force of the injury that caused the fracture.

Comminuted Bone Fracture

- A comminuted bone fracture is one in which the broken ends of the bone are shattered into three or multiple pieces.
- Comminuted bone fracture occurs when there is high-impact trauma, such as an automobile accident.

Segmental Bone Fracture

- Segmental bone fractures occur when bone is broken in at least two places, leaving a segment of bone totally separated by two fracture lines.
- Segmental bone fracture can affect any long bone such as femur, tibia, fibula, humerus, radius and ulna, which may take longer time to heal and cause complications.

Avulsion Bone Fracture

An avulsion bone fracture occurs in a bone where a tendon or ligament attaches to the bone that leads to pulling of the bone by a tendon or ligament, which is more common in children than adults. Sometimes a child's ligament can pull hard enough to cause a growth plate to fracture.

STAGES OF BONE FRACTURE HEALING

There are four stages of bone fracture healing: (a) hematoma formation and inflammatory stage, (b) fibrocollagenous callus formation stage, (c) bone callus formation stage, and (d) bone remodeling stage. Healing of bone fracture is shown in Fig. 2.64A to F.

Hematoma Formation and Inflammatory Stage

Initial phase of the bone fracture healing process is considered to be one of the critical determinants of the healing outcome. Hematoma formation and inflammatory stage begins immediately following the bone fracture within 1–5 days.

- The blood vessels supplying the bone and periosteum are ruptured during the bone fracture causing hematoma formation around the bone fracture site. Hematoma clots and forms the temporary frame for subsequent healing of bone fracture.
- With the onset of inflammation, regeneration begins by secretion of proinflammatory cytokines like interleukins (IL-1, IL-6, IL-11, IL-23), tumor necrosis factor-α (TNF-α) and bone morphogenic proteins (BMPs), which stimulate migration of mesenchymal stem cells, endothelial cells and immune cells (monocytes/macrophages and lymphocytes) towards the bone fracture site.
- The immune cells act together to remove necrotic debris, which is followed by early organization due to proliferation of fibroblasts and new capillaries formation (angiogenesis) by vascular endothelial growth factor (VEGF) at the bone fracture site.

Fibrocollagenous Callus Formation Stage

Fibrocollagenous callus formation stage is formed within 5–11 days of bone fracture. Secretion of VEGF leads to angiogenesis at the bone fracture site and within hematoma.

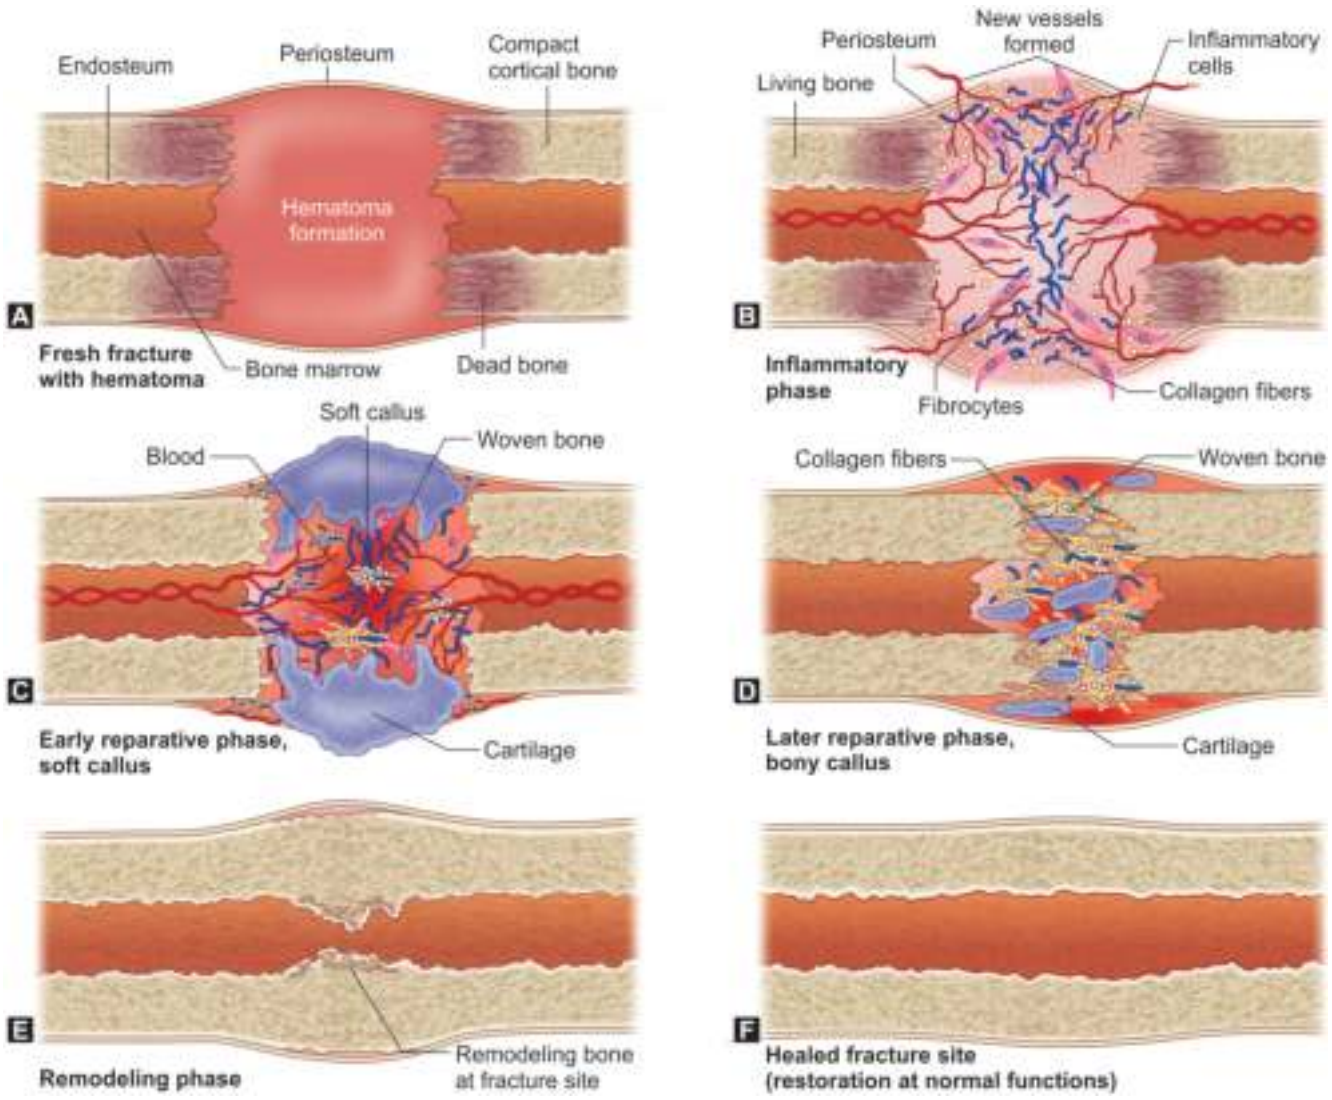

Fig. 2.64: Healing of bone fracture. (A) Hematoma is formed in recent fracture, (B) during inflammatory phase (2–7 days), neovascularization, early fibrosis and woven bone occur, (C) during reparative phase (2–6 weeks), there is gradual decrease in inflammation and granulation tissue. Soft callus is formed. Abundant woven bone is formed. Cartilage appears at the periphery, (D) during later reparative phase, bony callus is formed, (E) during remodeling phase in later months, linear stress causes alignment of new bone and formation of compact bone joining new bone to original bone, (F) bone formation at fracture site and restoration of function occur.

- Fibrin-rich granulation tissue begins to develop. Further mesenchymal stem cells are recruited to the bone fracture site and begin to differentiate to fibroblasts, chondroblasts and osteoblasts driven BMPs.
- As a result, chondrogenesis begins that leads to laying down a collagen-rich fibrocollagenous network spanning the bone fracture ends with a surrounding hyaline cartilage after one week of bone fracture.
- At the same time, adjacent to the periosteum layers, a layer of woven bone is laid down by the osteoprogenitor cells, that bridges the gap.

Bony Callus Formation Stage

The cartilaginous callus begins to undergo endochondral ossification from three weeks onwards at the bone fracture site. RANKL, a transmembrane protein of the TNF is expressed on the surface of osteoblasts and osteoclasts by MMP-7, that stimulates differentiation of chondroblasts, osteoblasts and osteoclasts.

- As a result, the cartilaginous callus is reabsorbed and begins to calcify. Woven bone continues to be laid down in subperiosteal region.
- The newly formed blood vessels continue to proliferate, that allows further migration of mesenchymal stem cells. At the end of this phase, a hard calcified callus of immature bone is formed.

Bone Remodeling Stage

With the continued migration of osteoblasts and osteoclasts, hard calcified callus of immature bone undergoes

repeated bone remodeling termed coupled remodeling within weeks to months of bone fracture.

- The coupled bone remodeling is balance of resorption by osteoclasts and new bone formation by osteoblasts. The center of the callus is ultimately replaced by compact bone, while the callus edges become replaced by laying down of lamellar bone.
- Subsequently, remodeling of the vasculature occurs alongside these changes. The process of bone remodeling lasts for many months ultimately leading to regeneration of the normal bone structure.
- Endochondral ossification process continues, that converts cartilage to bone leading to formation of bony callus, in which the newly formed collagen-rich cartilaginous callus gets replaced by immature bone.
- Final reconstruction in healing of bone fracture occurs months later. Bone fracture site may be almost invisible.

Clinical Pearls: Endochondral and Intramembranous Ossification in Fetus
Endochondral Ossification
Endochondral ossification process plays key role in the formation of bones in the fetus, in which bony skeleton replaces the hyaline cartilage.
Intramembranous Ossification
Intramembranous ossification process in the fetus converts mesenchymal tissue to bone without cartilage formation. This process takes place in the flat bones of the skull in the fetus.

CLINICAL SIGNIFICANCE

Primary bone fracture healing is the reestablishment of the cortex without formation of callus in patients by adequate fixation through reduction, immobilization and rehabilitation. On the other hand, secondary bone fracture healing occurs through inflammatory, fibrocollagenous callus formation, bone callus formation and subsequent bone remodeling.

Factors Adversely Affecting Bone Fracture Healing

Multiple factors adversely affect bone fracture healing, which can broadly categorize into local and systemic categories.

- **Local factors:** Presence of any of local factors predisposes delayed bone fracture healing, which include bone fracture characteristics (i.e. excessive movement, misalignment, extensive damage, large hematoma at bone fracture site, and soft tissue caught within fracture ends), superadded infection (open bone fractures), inadequate blood supply, and avascular necrosis of head of femur and scaphoid, large hematoma and imperfect immobilization.
- **Systemic factors:** Presence of any of systemic factors predisposes to poor bone fracture healing, which include advancing age, obesity, malnutrition, anemia, diabetes mellitus, parathyroid diseases (decreased calcium and phosphate levels), menopause, steroid administration, tobacco smoking and systemic infections.

Complications of Bone Fracture Healing

Early life-threatening complications of bone fracture occur during the first hours or days after the bone fracture include neurovascular injury, visceral injury, hemarthrosis, pneumothorax, rhabdomyolysis, fat embolism, infection, compartment syndrome, deep vein thrombosis, thromboembolism and disseminated intravascular coagulation (DIC). Major complications of bone fracture include wound infection, osteomyelitis, delayed union, nonunion, malunion, premature physeal closure, and fracture associated sarcoma. Consideration of complications of bone fracture healing, it is essential to evaluate and manage these patients in preoperative and postoperative states.

- **Wound infection:** If the overlying skin is breached in any way, the bone fracture is compound, the risk of infection is greatly increased; which is an important adverse factor in the healing process. Patient can develop osteomyelitis.
- **Compartment syndrome:** Compartment syndrome occurs in a case of bone fracture when excessive pressure builds up inside an enclosed anatomical muscle space in the body, which temporarily or permanently compromises the circulation and function of the tissues within that space. Primary symptom of the compartment syndrome is the pain, especially when muscle is stretched, which can be acute or chronic. Anterior compartment of the leg is most common site in acute compartment syndrome. Chronic compartment syndrome is musculoskeletal condition brought on by exercise, that causes recurrent pain and disability.
- **Fat embolic syndrome:** Fat embolic syndrome (FES) is a life-threatening complication in patients with orthopneic trauma especially of long bone fractures due to entry of fat microglobules from the bone marrow cavity into the torn ends of veins and capillaries of the lungs and other sites leading to acute respiratory distress syndrome, cerebral dysfunction and a petechial rash.
  - FES follows closed bone fracture, orthopedic procedures such as intramedullary nailing of the long bones during replacement, severe burns, bone marrow trephine biopsy and liposuction.
  - Patient presents with breathlessness, petechial rash, cerebral dysfunction, oliguria, fever and drowsiness within 24–72 hours between injury and onset.

- Major diagnostic criteria of FES include respiratory insufficiency, cerebral dysfunction and petechial rash; and minor diagnostic criteria of FES include tachycardia, fever, confusion, sustained respiratory rate, retinal hemorrhages, jaundice, renal changes, thrombocytopenia, diffuse alveolar infiltrate and macroglobulinemia.

- **Late complications:** Late complications of bone fracture healing include excess callus formation, delayed union of fracture, malunion of bone fracture (angulation and shortening), nonunion, joint stiffness, myositis ossificans, avascular necrosis, osteomyelitis, septicemia and pseudoarthrosis. Nonunion occurs, if soft tissues such as muscle or fat are interposed between the severed ends. Fibrous union of bone fracture results from excessive movement, infection and ischemia.

REGENERATION OF SPECIFIC ORGANS

The liver has the greatest regenerative capacity of any organ in the body. The nervous system is the only tissue in the body that does not regenerate.

REGENERATION OF LIVER

Liver regeneration is activated spontaneously after hepatocellular injury and can be further stimulated by cell therapy with hepatocytes, hematopoietic stem cells, or mesenchymal cells. Liver regeneration occurs by two mechanisms: proliferation of remaining hepatocytes and repopulation from progenitor cells.

Proliferation of Remaining Hepatocytes

The compensatory proliferation of remaining hepatocytes is the main mechanism of liver regeneration following acute and chronic hepatocellular injury.

- **Priming phase:** IL-6 synthesized by Kupffer cells acts on the uninjured hepatocytes that makes the hepatocytes to receive and respond to growth factor.
- **Growth factor action:** Hepatocyte growth factor (HGF) and TGF-α act on primed hepatocytes. Hepatocytes replication is followed by replication of nonparenchymal cells.
- **Termination phase:** The hepatocytes turn to quiescence. The nature of the stop signal is poorly understood, which may be due to synthesis of TGF-β that inhibits further proliferation of liver parenchyma.

Repopulation from Progenitor Cells

Fulminant hepatic necrosis usually regenerates. Progenitor cells in the liver contribute to repopulation. Patient suffering from chronic viral hepatitis develops cirrhosis. There is development of broad collagenous scars within the hepatic parenchyma. Hepatocytes form regenerative nodules that lack central veins and expand to obstruct blood vessels and bile flow.

REGENERATION OF NERVOUS SYSTEM

Regeneration of nervous system involves the regrowth or repair of nervous tissues, cells or cell products.

- **Regeneration of central nervous system:** Central nervous system comprises permanent cells. In spinal cord injuries, axonal regeneration can be seen up to 2 weeks after injury. Damage to the brain or spinal cord results in proliferation of capillaries and gliosis (permanent scar formation). Gliosis occurs due to proliferation of astrocytes and microglia. After two weeks, axonal regeneration occurs only in the hypothalamohypophyseal portal region, because capillary and glial barriers do not interfere with axonal regeneration. Axonal regeneration seems to require contact with extracellular fluid containing plasma proteins.
- **Regeneration of peripheral nervous system:** Neurons in the peripheral nervous system can regenerate their axons. Patient develops a bulbous lesion known as traumatic neuroma, if cut ends are not in perfect alignment. Light microscopy shows disorganized axons and proliferating Schwann cells and fibroblasts. The nerve is surrounded by dense collagenous tissue, which appears dark blue in this trichrome stain.

CHAPTER 3

Hemodynamic Disorders, Thrombosis, Embolism and Shock

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

EDEMA AND EFFUSIONS

- Pathophysiology of edema
  - Edema caused by sodium and water retention
  - Edema caused by increased capillary hydrostatic pressure
  - Edema caused by reduced capillary plasma oncotic pressure
  - Edema caused by increased capillary permeability
  - Edema caused by lymphatic obstruction
- Composition of the edema fluid
  - Transudate
  - Exudate
  - Lymphedema
  - Non-pitting edema
- Edema: clinical significance
  - Subcutaneous edema
  - Pulmonary edema
  - Ascites
  - Pericardial effusion
  - Hydrothorax
  - Cerebral edema

HYPEREMIA AND CONGESTION

- Hyperemia
- Venous congestion

HEMOSTASIS

- Hemostasis: components
  - Vascular endothelium
  - Platelets
  - Coagulation system cascade
- Hemostasis: stages
  - Primary hemostasis (platelet hemostatic plug formation)
  - Secondary hemostasis (stable hemostatic plug formation)
  - Blood clot retraction
  - Blood clot dissolution (thrombolysis)

HEMORRHAGIC DISORDERS

- Defects in hemostasis
  - Defects of primary hemostasis (platelet defects and von Willebrand disease)
  - Defects of secondary hemostasis (coagulation factor defects)
  - Defects in blood vessels

THROMBOSIS

- Thrombogenesis
  - Vascular endothelial injury
  - Alterations of blood flow
  - Role of platelets
  - Hypercoagulable state
- Thrombotic disorders
  - Inherited thrombotic disorders
  - Acquired thrombotic disorders
- Fate of thrombus
  - Propagation of thrombus
  - Dissolution of thrombus
  - Organization of thrombus
  - Recanalization of thrombus
  - Thrombus embolization
- Thromboembolism
  - Venous thromboembolism
  - Arterial thromboembolism

EMBOLISM

- Pathophysiology of embolism
  - Fat embolism syndrome
  - Air embolism
  - Amniotic fluid embolism
  - Embolism due to exogenous and endogenous materials

INFARCTION

- Factors influencing infarct formation
  - Anatomical pattern of arterial supply
  - Vulnerability of tissues to hypoxia
  - Blood oxygen content
  - Rapid development of infarct
- Types of infarct
  - Pale/white infarct
  - Hemorrhagic/red infarct
  - Brain infarct

SHOCK

- Categories of shock
  - Hypovolemic shock
  - Cardiogenic shock
  - Septic shock
  - Anaphylactic shock
  - Neurogenic shock
- Stages of shock
  - Compensated shock stage
  - Nonprogressive shock stage
  - Progressive decompensated shock stage
  - Irreversible decompensated shock stage

EDEMA AND EFFUSIONS

Edema is swelling caused by accumulation of excessive fluid in body's interstitial tissues. Edema most commonly occurs in the feet, ankles and legs and/or hands where it is referred to as **peripheral edema**. Edema of the feet is sometimes called **pedal edema**. In medical terminology, an **effusion** refers to accumulation of fluid in an anatomic space (**body cavity**) such as pleural cavity between two layers of membrane covering the lungs (pleural effusion) and peritoneal cavity (ascites). Pulmonary edema occurs as a result of excess fluid in the alveoli.

- Excess fluid accumulation occurs due to disorders, which impair functions of cardiovascular system,

liver and kidneys. Edema can occur by four mechnisms: (a) elevated capillary hydrostatic pressure, (b) decreased capillary colloidal osmotic pressure, (c) increased capillary permeability, and (d) obstruction of lymphatic flow.

- Edema can present in numerous forms including unilateral, bilateral, localized or generalized edema.
- In normal health, most of the body's fluids are stored in blood vessels and interstitial spaces outside the cells. In various disorders, excess fluid can accumulate either in one compartment or multiple compartments.
- Anasarca also known as extreme generalized edema is severe, widespread accumulation of fluid in the tissues and cavities of the body at the same time. Causes of edema are given in Table 3.1.

Pathology Pearls: Terminology of Edema and Effusions

- **Peripheral edema:** It occurs due to accumulation of excessive fluid in the subcutaneous interstitial tissues of legs and feet. It is caused by salt retention, cellulitis, congestive heart failure and side effects of medicines. Persistent identification of a swollen leg after pressure from a finger is known as 'pitting edema'.
- **Dependent edema:** It is edema of the legs and lower body affected by gravity which is dependent on a person's position (i.e. edema legs while standing, edema in buttocks and hands while lying down).
- **Cerebral edema:** It refers to accumulation of excessive fluid in the brain.
- **Angioedema:** It occurs due to accumulation of excessive fluid in the deeper layers underneath the skin and on the face. In contrast, hives affect the surface of the skin.
- **Hereditary angioedema:** It is genetic disorder that causes the capillaries to release excessive fluid into the surrounding tissue leading to edema.
- **Papilledema:** It is swelling of the optic nerve as a result of increased intracranial pressure.
- **Macular edema:** It is swelling of the portion of the eyes that perceives central detailed vision (the macula).
- **Lymphedema:** It refers to tissue swelling of arms, legs, genitals, face, neck, chest wall, and oral cavity due to accumulation of protein-rich fluid due to obstruction of lymphatics and lymphatic flow in the settings of tumor emboli, surgical excision of lymph nodes in breast cancer, and 'Milroy' disease.
- **Edema due to venous insufficiency:** Edema can occur in the settings of varicose veins and thrombophlebitis (inflammation of the deep veins of the legs).
- **Edema during pregnancy:** Mild swelling of face, hands or legs can be a sign of **preeclampsia of pregnancy**.
- **Non-pitting edema in myxedema:** Non-pitting edema occurs in myxedema due to accumulation of mucopolysaccharides secondary to overproduction of fibroblasts, which creates a suction force due to enhanced elastic recoil of the extracellular matrix that creates a high negative interstitial fluid pressure.

Table 3.1 Causes of edema

Mechanism	Causes of Edema	
Increased capillary hydrostatic pressure		
Increased vascular volume	▪ Cardiac failure ▪ Renal disease ▪ Pregnancy	▪ Premenstrual sodium retention ▪ Environmental heat stress ▪ Thiazolidinedione therapy
Venous obstruction	▪ Venous thrombosis (thrombophlebitis) ▪ Acute pulmonary edema	▪ Liver disease with portal hypertension
Decreased arteriolar resistance	Calcium channel-blocking drug response	
Decreased capillary colloidal osmotic pressure		
Increased loss of plasma proteins	▪ Protein losing renal disease	▪ Extensive skin burns
Decreased synthesis of plasma proteins	▪ Liver disease ▪ Malnutrition	▪ Starvation
Increased capillary permeability		
Inflammation	Increased vascular permeability	
Tissue injury and burns	Increased vascular permeability	
Allergic reactions	Hives	
Malignancies	▪ Malignant ascites	▪ Malignant pleural effusion
Obstruction of lymphatic flow		
Tumor emboli	Obstructing lymphatic channels and lymphatic flow	
Surgical excision of lymph nodes	Obstructing lymphatic flow	
Milroy's disease	Congenital absence of lymphatic channels	

PATHOPHYSIOLOGY OF EDEMA

Several factors regulate the direction of flow of interstitial fluid including capillary hydrostatic pressure, plasma oncotic pressure, endothelial integrity and the lymphatic system. These factors are thought to driven by Starling's law, which describes fluid movement across capillaries being proportional to capillary permeability, transcapillary hydrostatic pressure differences and transcapillary oncotic pressure differences.

- Normal hydrostatic pressure is 32 mm Hg in capillaries at arterial end, and 12 mm Hg at venous end. Oncotic pressure exerted by plasma proteins is 25 mm Hg throughout length of capillaries. Due to pressure gradient, hydrostatic pressure forces water out of capillaries at the arterial end. At the venous end, 90% of extravasated fluid is drained back in capillaries at venous end due to constant 25 mm Hg oncotic pressure exerted by plasma albumin. Remaining 10% fluid in interstitial tissue is drained via lymphatic channels into venous circulation. Normal fluid exchange between blood and extracellular fluid is shown in Fig. 3.1.
- When the balance of Starling forces is altered, the net result is accumulation of fluid in the interstitial spaces (i.e. edema). Edema can occur due to elevated capillary hydrostatic pressure, reduced capillary plasma oncotic pressure, sodium and water retention, and lymphatic obstruction.

EDEMA CAUSED BY SODIUM AND WATER RETENTION

Total body sodium is the principal determinant of extracellular fluid volume because it is the major cation in the extracellular fluid. The kidneys play an essential role in the regulation of sodium and water. The functioning of the kidneys is efficiently monitored and regulated by hormonal feedback mechanisms involving hypothalamus, juxtaglomerular apparatus and to a certain extent, the heart.

- Renin-angiotensin-aldosterone system (RAAS), antidiuretic hormone (ADH), and atrial natriuretic factor (ANF) provide an elaborate system of checks and balances that regulate body fluid osmolarity, salt concentrations, blood pressure and blood volume.

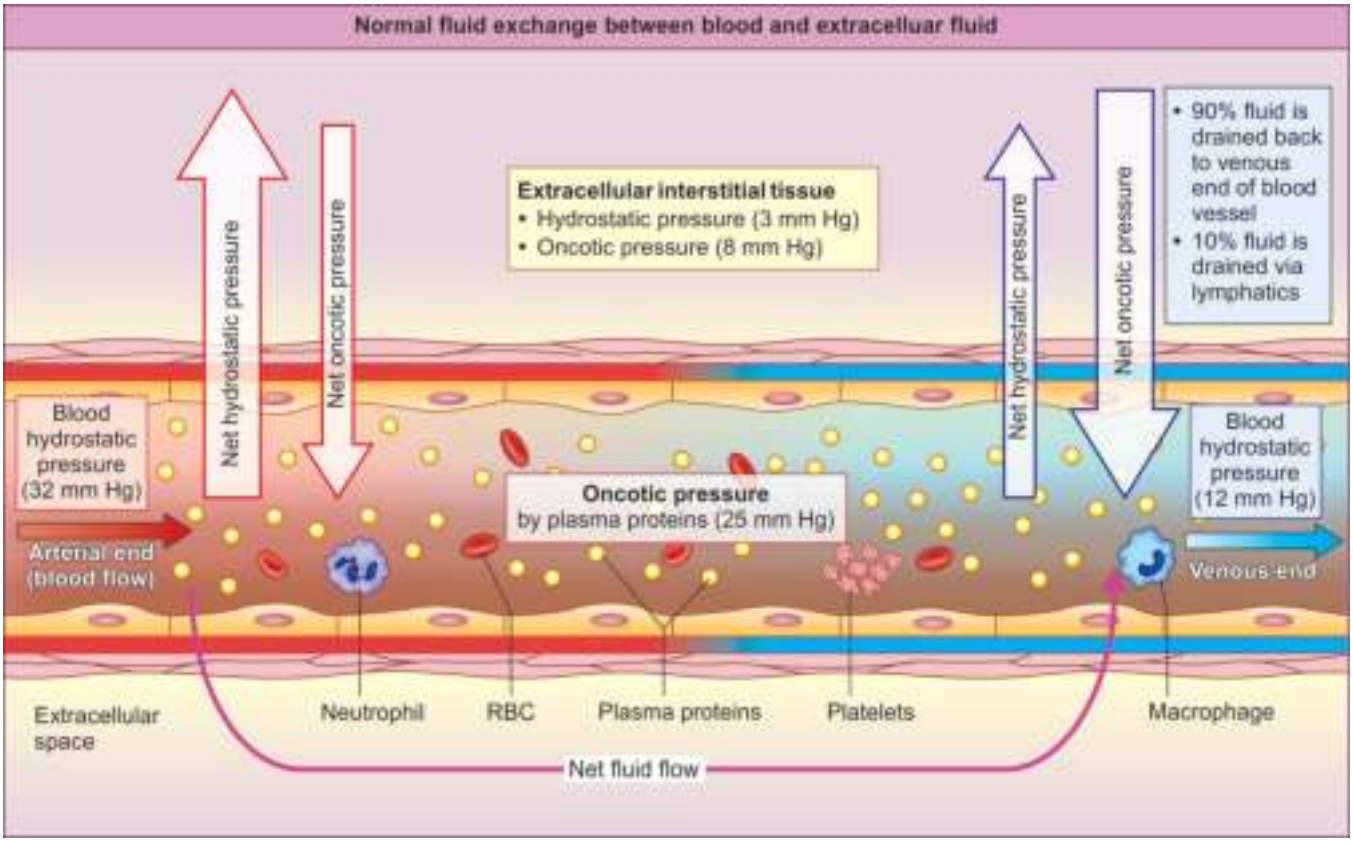

Fig. 3.1: Normal fluid exchange between blood and extracellular fluid. Normal hydrostatic pressure at arterial end of capillary is 32 mm Hg and 12 mm at venous end therefore fluid leaves blood vessel. Oncotic pressure exerted by plasma proteins is 25 mm Hg. At venous end, hydrostatic pressure is less than plasma oncotic pressure, so fluid enters blood vessel. Approximately 90% of fluid is drained back to capillary, while 10% of excess interstitial fluid is drained by lymphatic channels to venous circulation.

- Salt retention occurs whenever renal function is impaired in the settings of primary glomerulopathy and cardiovascular disorders resulting in hypoperfusion of kidneys. When the blood pressure falls, juxtaglomerular cells synthesize renin, which stimulate liver to synthesize angiotensinogen. Lungs convert angiotensinogen to angiotensin I, which is converted to angiotensin II by kidneys.
- Angiotensin II is a potent arteriolar constrictor and it also stimulates adrenal cortex to synthesize aldosterone. Angiotensin II increases peripheral resistance and blood volume leading to regulation of blood pressure via the renin-angiotensin-aldosterone system. Dilution effect of albumin results in decreased plasma oncotic pressure. Atrial natriuretic factor (ANF) is a peptide hormone, which opposes the regulation by RAAS.
- Increased salt retention and obligate water retention causes both elevated capillary hydrostatic pressure as a result of expansion of blood volume, and reduced plasma oncotic pressure leading to edema.

EDEMA CAUSED BY INCREASED CAPILLARY HYDROSTATIC PRESSURE

Increased hydrostatic pressure in vessels exceeds that of plasma oncotic pressure and so that water remains in the tissues in congestive cardiac failure.

- Hydrostatic pressure in capillary has autoregulatory capacity allowing alterations in resistance at the precapillary sphincter and thus determines the arterial pressure forced onto the capillary.
- In contrast, venous end of the capillary has poor autoregulation, and as a result, venous pressure alterations lead to parallel changes in capillary hydrostatic pressure. Venous pressure can enhance expansion of blood volume and obstruction at the venous end.
- Cardiac failure and renal disease lead to expansion of blood volume, while venous blood flow obstruction occurs due to right heart failure ultimately resulting in edema. Local venous obstruction increases capillary hydrostatic pressure in the settings of deep vein thrombosis (DVT) of legs, external compression of deep vein and superior vena cava obstruction.
- Patient develops pulmonary edema due to left-sided heart failure (e.g. systemic hypertension, aortic valve stenosis in rheumatic heart disease). Peripheral edema occurs in right-sided heart failure. Portal hypertension in cirrhosis leads to accumulation of fluid in peritoneal cavity known as '**ascites**'. Clinical manifestations of congestive heart failure are shown in Fig. 3.2.
- Excess fluid accumulation in interstitial tissues is a transudate, which is straw-colored ultrafiltrate of blood plasma composed of mainly water, dissolved electrolytes, and low-protein with specific gravity <1.012.

EDEMA CAUSED BY REDUCED CAPILLARY PLASMA ONCOTIC PRESSURE

Decreased plasma albumin concentration reduces the plasma oncotic pressure in the capillaries, so that water cannot be drained back into the capillary bed at the venous end. Excess fluid accumulation in the interstitial tissue results in transudate formation.

- Reduced plasma oncotic pressure in the capillaries typically occurs due to hypoalbuminemia resulting from massive proteinuria (i.e. nephrotic syndrome), decreased synthesis of albumin in liver in cirrhosis and inadequate albumin in the settings of malabsorption syndrome and kwashiorkor.
- Massive proteinuria, inadequate albumin intake and synthesis can lead to reduced oncotic pressure and ultimately edema. Patient develops anasarca (generalized edema) in nephrotic syndrome.

EDEMA CAUSED BY INCREASED CAPILLARY PERMEABILITY

In normal health, the wall of the normal venules is sealed by tight junctions between adjacent endothelial cells. Normally, fluid leaving and entering microvessels is in equilibrium.

- During acute inflammation, chemical mediators widen interendothelial space resulting in increased vascular permeability in postcapillary venules. Extravasation of inflammatory exudate is accumulated at injury site, which is responsible for swelling (edema), pain, and impaired function.
- Exudate contains proteins content with specific gravity >1020, particularly fibrinogen/fibrin, immunoglobulins, salts, water and neutrophils. Severe injury to microvasculature in severe burns is life-threatening.

EDEMA CAUSED BY LYMPHATIC OBSTRUCTION

In normal health, approximately 90% of extravasated fluid is drained back in capillaries at venous end, and remaining 10% of fluid in interstitial tissue is drained via lymphatics into circulation.

- Lymphatic obstruction prevents drainage of lymph fluid from the tissues into the venous circulation leading to lymphedema and tissue swelling as a result of excess accumulation of protein-rich fluid. Lymphedema and tissue swelling can occur

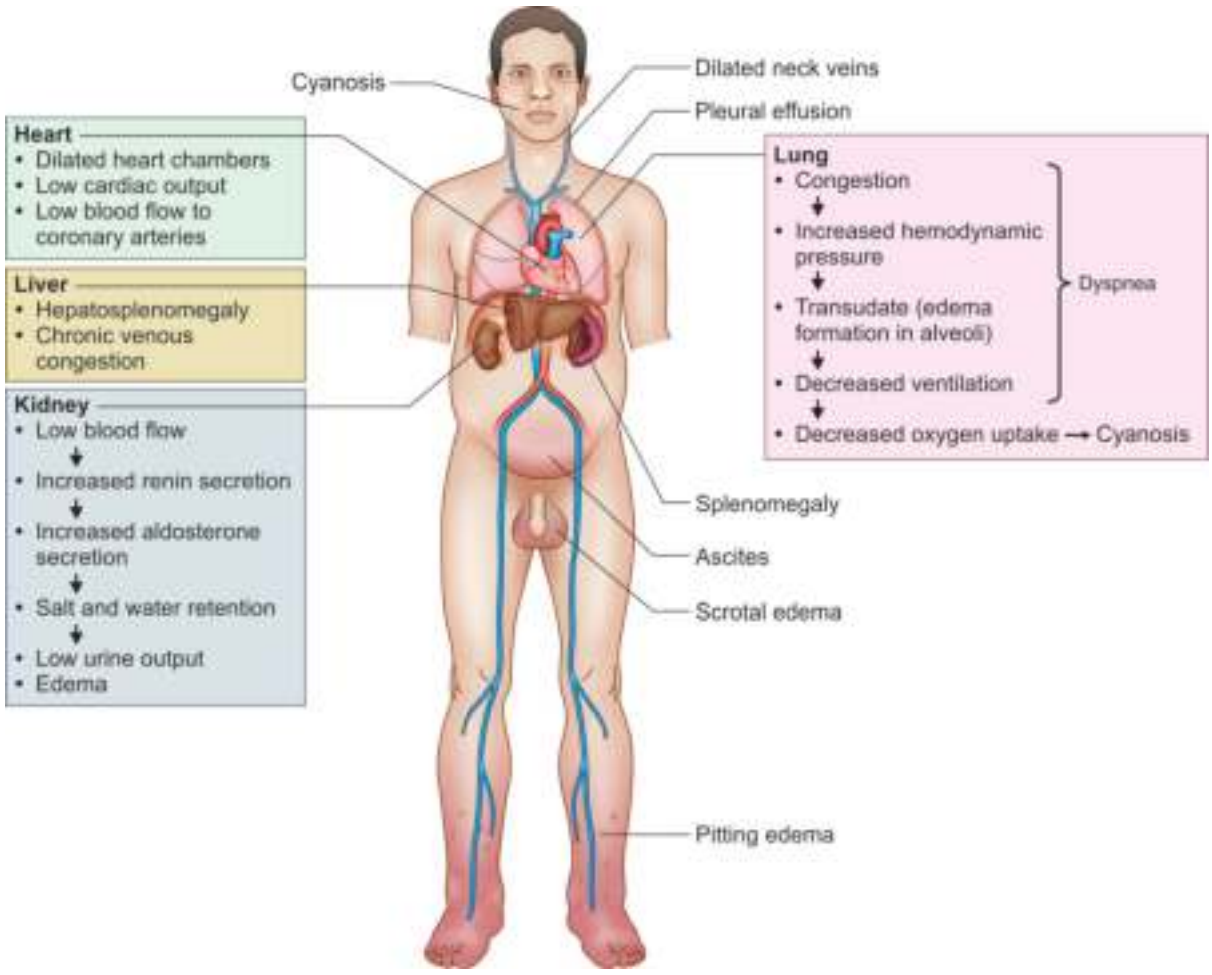

Fig. 3.2: Clinical manifestations of congestive heart failure. Left-sided heart failure results in pulmonary congestion, dyspnea on exertion, dyspnea on lying down (orthopnea), awakening from sleep (paroxysmal nocturnal dyspnea) and cough with frothy sputum. Right-sided heart failure results in systemic venous congestion, peripheral edema over ankles, hepatosplenomegaly and raised jugular venous pressure.

in arms, legs, genitals, face, neck, chest wall, oral cavity. Lymphedema can be either pitting or non-pitting.

- Most common causes of secondary lymphedema include oncologic surgical procedures such as excision of breast cancer along with axillary lymph node dissection, cancer stem cells blocking lymphatic vessels, radiation treatment of surgery (inducing inflammation and fibrosis), and *Wuchereria bancrofti* infestation. *Wuchereria bancrofti* can result in lymphatic obstruction that produces massive lymphedema of the scrotum and lower extremities (elephantiasis). Lymph fluid has high protein content, which may be fibrogenic stimulus in the formation of dermal fibrosis.
- Primary lymphedema is an inherited disorder (Milroy disease) or congenital disorder that causes malformation of lymphatic system, which can be subdivided into three categories: (a) congenital lymphedema is present at birth or recognized within two years of birth, (b) lymphedema praecox occurs at puberty or beginning of third decade, and (c) lymphedema tarda, which begins after 35 years of age. Primary lymphedema is marked by hyperplasia, hypoplasia or aplasia of lymphatic channels.

COMPOSITION OF THE EDEMA FLUID

Edema is a common clinical sign indicating expansion of the interstitial fluid volume. The edema fluid contains predominantly water, but protein and cell-rich fluid can accumulate in cases of infection or lymphatic obstruction. Factors that regulate the size of interstitial fluid compartment include capillary fluid dynamics, interstitial fluid pressure, lymph flow, interstitial compartment compliance, all of which are delicately balanced. Disruption of this delicate balance is caused by common disease processes, which can lead to a better understanding of clinical edema.

TRANSUDATE

A transudate is ultrafiltrate of plasma that occurs due to alterations in Starling's pressure (hydrostatic pressure or oncotic pressure). Permeability of vascular endothelium is usually normal. The noninflammatory edema fluid results from altered capillary hydrostatic or osmotic pressure. Transudate is straw-colored ultrafiltrate of blood plasma with low protein content (<3 g/dl), water, dissolved electrolytes, and specific gravity <1.012, which produces edema in dependent parts (pitting) and body cavity effusions. Formation of transudate due to fluid exchange between blood and extracellular fluid is shown in Fig. 3.3.

EXUDATE

An exudate occurs due to increased permeability of postcapillary venules during acute inflammatory response. Chemical mediators derived from cells and plasma proteins act on nearby vessels and cause increased permeability of microvasculature responsible for swelling (edema), tissue pain, and impaired function. Formation of exudate due to fluid exchange between blood and extracellular fluid in acute inflammation is shown in Fig. 3.4.

- Exudate is rich in plasma proteins (>3 g/dl), fibrinogen/fibrin, immunoglobulins, salts, water and neutrophils with specific gravity exceeding 1.020.
- Exudates formed in severe burns are life-threatening. Fibrin formation at the tissue injury site aids in localizing the spread of infectious microorganisms. Exudates dilute bacterial toxins and provide opsonins (IgG, C3b) to assist in phagocytosis. Comparison of exudate and transudate is given in Table 3.2.

LYMPHEDEMA

Lymphedema occurs due to obstruction of lymphatic channels by tumor emboli, surgical excision of lymph nodes, filariasis and congenital absence of lymphatic channels (Milroy's disease). Filariasis due to *Wuchereria bancrofti* causes lymphangitis and ultimately blockage of lymphatic channels. Scrotal and vulvar lymphedema occurs due to lymphogranuloma venereum. Breast lymphedema occurs due to blockage of subcutaneous lymphatic channels by cancer stem cells. Breast cancer undergoing modified radical mastectomy and lymph nodes dissection develops edema of upper arm due to obstruction of lymphatic drainage. Lymph fluid has high-protein content, which may induce

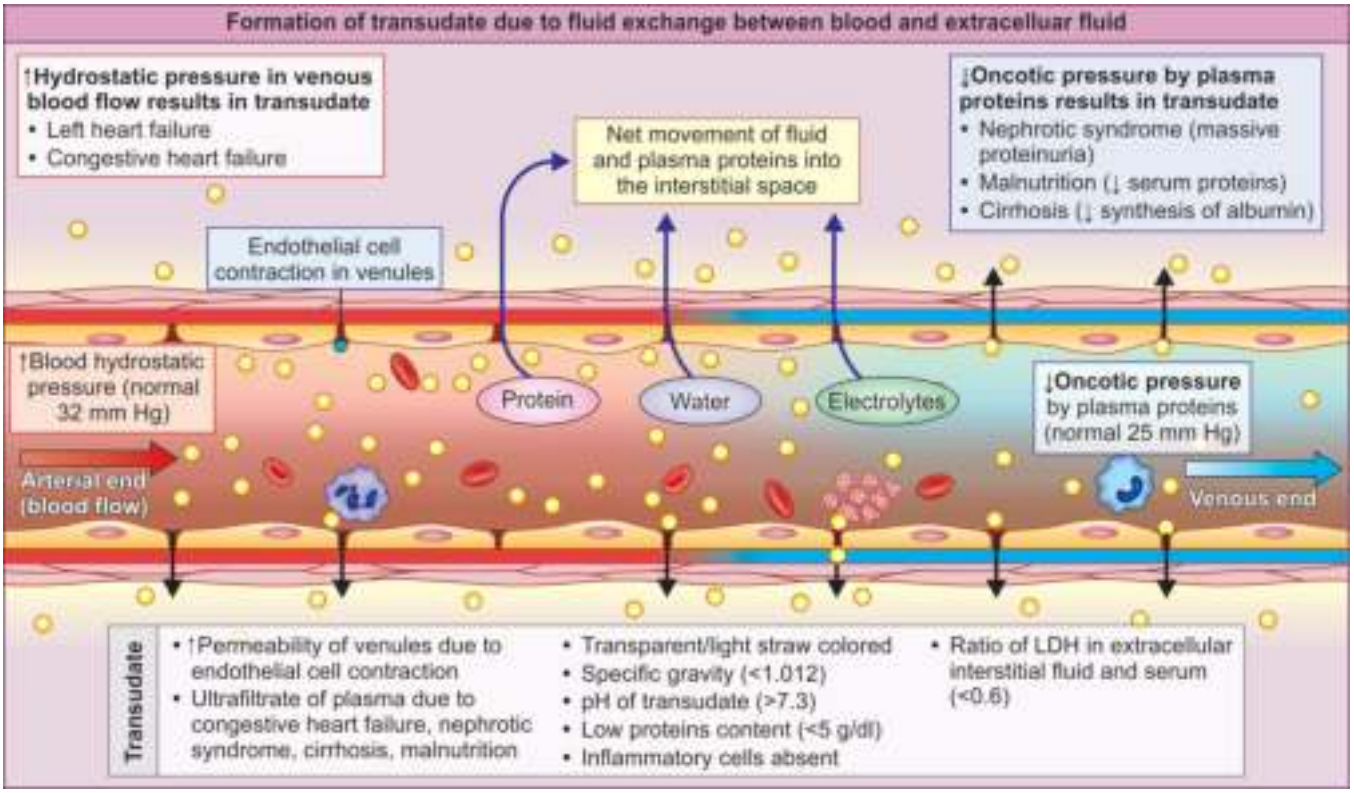

Fig. 3.3: Formation of transudate due to fluid exchange between blood and extracellular fluid. Transudate is formed as a result of increased hydrostatic pressure or decreased plasma oncotic pressure. Therefore, fluid leaves microvasculature along whole length with no reabsorption. There is low protein loss so this is a transudate.

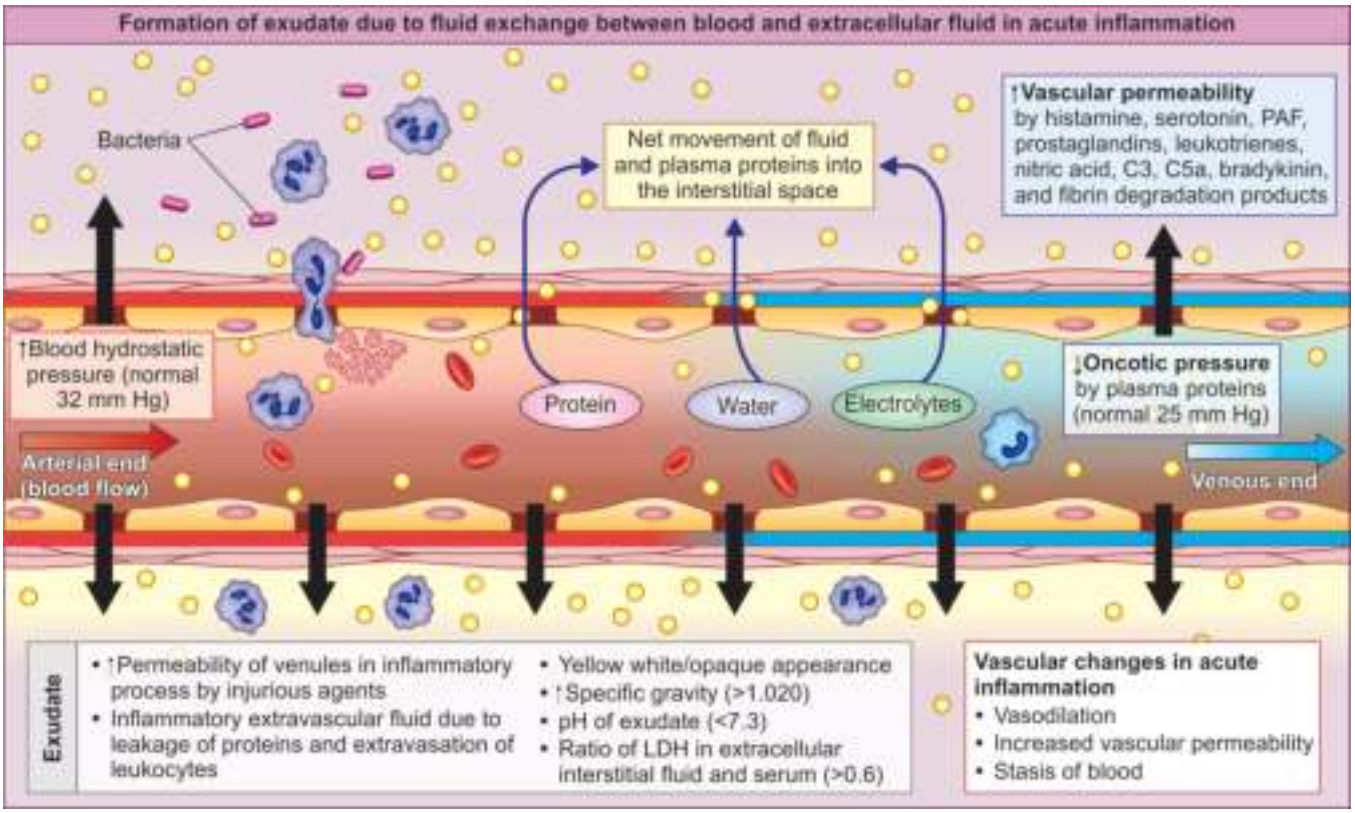

Fig. 3.4: Formation of exudate due to fluid exchange between blood and extracellular fluid in acute inflammation. An exudate is formed due to increased vascular permeability. Protein leaks out of microvasculature, so that there is no osmotic pressure difference between plasma and tissue (i.e. plasma oncotic pressure=0), therefore fluid leaves microvasculature. Fluid contains proteins, so this is an exudate.

Table 3.2 Comparison of exudate and transudate

Characteristics	Exudate	Transudate
Cause	Increased permeability of postcapillary venules in inflammation	Increased hydrostatic pressure or decreased oncotic pressure
Pathologic state	Acute inflammation	▪ Congestive heart failure ▪ Hypoproteinemia (malnutrition) ▪ Nephrotic syndrome (protein loss)
Endothelial permeability	Altered endothelial permeability	Normal endothelial permeability
Fluid nature	Inflammatory extravascular fluid	Ultrafiltrate of blood plasma
Color of fluid	Yellowish-white opaque appearance	Transparent/light straw colored
pH of fluid	Less alkaline (<7.3)	More alkaline (>7.3)
Specific gravity	>1.020 due to raised proteins content in exudate	<1.012
Composition of fluid	Mainly proteins and cellular debris	Mainly water and dissolved electrolytes
Proteins content in fluid	High-protein content, which raise specific gravity	Low protein fluid (<5 g/dl)
Glucose concentration	Low glucose in case of association with infections and cancer	Glucose level in fluid same as that of blood glucose
Ratio of LDH levels in fluids and serum	High ratio (>0.6)	Low ratio (<0.6)
Light microscopy	PMN cells in acute inflammation and later on macrophages and lymphocytes in chronic inflammation	Inflammatory cells absent

fibrogenic stimulus in the formation of dermal fibrosis. Lymphedema can be either pitting or non-pitting.

NON-PITTING EDEMA

Non-pitting edema occurs when excess fluid builds up in the body causing swelling that does not indent when pressure is applied. Non-pitting edema is caused by diseases related to thyroid gland and lymphatic system.

- **Lymphedema:** Lymphedema occurs due to blockage of lymphatic system in the settings of tumor emboli in lymphatic channels, modified radical mastectomy, radiation, and *Wuchereria bancrofti*. Lymphedema can be either pitting or non-pitting. Lymph fluid has high protein content, which may induce fibrogenic stimulus in the formation of dermal fibrosis resulting in non-pitting edema.
- **Myxedema:** Myxedema is severe form of hypothyroidism characterized by swelling of legs and feet including eyelids. Clinical examination of legs reveals non-pitting edema in peritibial region due to deposition of glycosaminoglycans such as hyaluronic acid, chondroitin sulfate and mucopolysaccharide, which binds water, producing non-pitting edema, in particular around feet, hands, eyes and supraclavicular fossae.
- **Graves' disease:** Graves' disease is characterized by nontender diffuse symmetric thyroid gland enlargement with features of thyrotoxicosis, exophthalmos in 60–90%, dermatopathy and constitutional symptoms. Retrobulbar ocular muscles are infiltrated by chronic inflammatory cells. There is deposition of hydrophilic mucopolysaccharides, fibrosis and contractures of extraocular muscles resulting in incoordination of eye movements. Patient presents with proptosis, lid lag, upper lid retraction, and muscle weakness.
- **Lipedema:** Lipedema is an abnormal fat build up in lower body that causes adipose tissue cells to grow and proliferate and increased fluid retention around adipocytes, which results in tender or painful non-pitting edema in legs and feet almost exclusively in women.

EDEMA: CLINICAL SIGNIFICANCE

Edema may be localized in body cavities, e.g. pleural effusion, pericardial effusion or ascites. Generalized edema in nephrotic syndrome is also known as anasarca. Clinically important type of edema is given in Table 3.3. Comparison of cardiogenic and noncardiogenic edema is given in Table 3.4.

Table 3.3 Clinically important type of edema

Type of Edema	Cause
Periorbital edema	Nephritic syndrome (post-streptococcal glomerulonephritis)
Generalized edema (anasarca)	Nephrotic syndrome
Peripheral edema (pitting leg edema)	Left heart failure
Brain edema	Head traumatic injury
Hydropericardium	Viral pericarditis
Hydrothorax	▪ Congestive heart failure ▪ Pleuritis
Ascites	Cirrhosis

Table 3.4 Comparison of cardiogenic and noncardiogenic edema

Characteristics	Cardiogenic Edema	Noncardiogenic Edema
Etiopathogenesis	▪ Left ventricular failure ▪ Myxoma in left atrium ▪ Mitral valve disease ▪ Acute respiratory distress syndrome ▪ Pulmonary vaso-occlusive disease	▪ Aspiration of noxious fluids ▪ Ingestion of drugs or poisons ▪ Inhalation of noxious fluids ▪ Pulmonary infection ▪ Systemic sepsis and trauma
Distribution of edema	Central region	More peripheral
Radiologic findings	▪ Septal lines common ▪ Peribronchial cuffing common ▪ Pleural effusion common ▪ Cardiomegaly present ▪ Pulmonary vasculature diversion in upper lobes	▪ Septal lines less common ▪ Peribronchial cuffing less common ▪ Pleural effusion less common ▪ Cardiomegaly absent ▪ No distribution of pulmonary vasculature

- **Subcutaneous edema:** Patient develops periorbital edema in nephritic syndrome, because proteinuria varies from mild to moderate <3.5 g/24 hours. Patient with nephrotic syndrome presents with generalized edema due to massive proteinuria ≥3.5 g/24 hours. Dependent edema is seen in congestive heart failure.
- **Pulmonary edema:** Congestive heart failure is most important cause of pulmonary edema, which may also occur in left ventricular failure, mitral valve disease, myxoma in left atrium, acute respiratory distress syndrome and pulmonary vaso-occlusive disease. Noncardiac edema causes include aspiration of noxious fluids, ingestion of drugs or poisons, inhalation of noxious fluids, pulmonary infection, systemic sepsis and trauma.
  - **Pathogenesis:** In patients with congestive heart failure, increased venous hydrostatic pressure leads to congestion of alveolar capillaries resulting in accumulation of a transudate in the alveoli. Passage of red blood cells into the alveoli are phagocytosed and degraded by macrophages. Hemosiderin-laden macrophages are known as 'heart failure cells'.
  - **Clinical features:** Patient presents with shortness of breath (dyspnea) on exertion and when recumbent (orthopnea). Patient may awaken from sleep due to sudden episodes of shortness of breath (paroxysmal nocturnal dyspnea). On auscultation, crackling breath sounds (rales) are heard caused due to expansion of fluid-filled alveoli. Right-sided heart failure reveals distended jugular veins, pitting edema of the lower extremities, and tender hepatomegally.
- **Ascites:** Excessive accumulation of serous fluid in the peritoneal cavity is known as **ascites**. Massive proteinuria (≥3.5 g/24 hours) in nephrotic syndrome and chronic liver disease lowers plasma albumin levels results in ascites. Ascites in liver cirrhosis occurs due to decreased synthesis of albumin by liver, the most significant contributor to reduced plasma oncotic pressure, is associated with increased sodium and water retention because of stimulation of the renin-angiotensin system. Portal hypertension in liver cirrhosis results in fluid transudation and increased secretion of hepatic lymph.
- **Pericardial effusion:** Pericardial effusion is collection of fluid in the pericardial sac beyond the 20–50 ml normally present. Pericardial effusion is caused by pericarditis (e.g. serous, fibrinous, suppurative, hemorrhagic or tubercular), metastatic deposits from lung cancer, breast cancer or lymphomas. Tubercular pericardial effusion contains straw/pale colored fluid formed by Mycobacterium tubercle bacilli.
- **Hydrothorax:** Hydrothorax refers to the accumulation of a significant volume of transudate about 200–400 ml within the pleural cavities to be detected by chest radiograph. Transudate is clear, straw colored fluid with low-protein content and low specific gravity. Cardiac failure is the most common cause of hydrothorax, which is usually bilateral.
- **Cerebral edema:** Increased intracranial pressure due to cerebral edema leads to herniation of the brainstem or cerebellar tonsils. Patient presents with projectile vomiting, headache and convulsive seizures.

HYPEREMIA AND CONGESTION

Hyperemia refers to increased blood flow (active hyperemia) or reduced drainage (passive hyperemia congestion) via capillaries and small vessels in a tissue or organ. Active hyperemia is usually a physiologic response to an increased functional demand associated with acute inflammation.

- Congestion refers to the engorgement of an organ with venous blood. Acute passive congestion occurs in shock or sudden right-sided heart failure due to obstruction to venous return or increased back flow from congestive heart failure.
- Deep vein thrombosis (DVT) of the leg veins causes edema of the lower extremity. Thrombosis of the hepatic veins in Budd-Chiari syndrome causes chronic passive congestion within liver. Differences between hyperemia and congestion are shown in Table 3.5.

HYPEREMIA

Hyperemia refers to active engorgement of vascular beds due to increased metabolic activity of tissue that results in localized increased concentrations of carbon dioxide and other metabolites. These metabolic changes act as local stimuli, which cause vasodilatation and increased blood flow to the tissue.

- Hyperemia can occur as a physiologic mechanism within the skin to dissipate heat. There is increased blood flow to gastrointestinal tract after a meal.
- Vascular changes in acute inflammation induces active hyperemia due to neurogenic reflexes and release of vasoactive substances such as histamine and prostaglandins, which promote the delivery of inflammatory metabolites to the injury site. Tissues

Table 3.5 Differences between hyperemia and congestion

Hyperemia	Congestion
Process	
Active process	Passive process
Blood flow	
Increased blood flow due to arteriolar dilatation in inflammation or skeletal muscles during exercise	Blood pooling due to impaired venous blood flow in congestive heart failure or isolated venous obstruction
Edema within organ	
Absent	Present
Gross morphology	
Organs with reddish discoloration due to engorgement with oxygenated blood	Organs blue-red color (cyanosis), due to accumulation of deoxygenated hemoglobin giving nutmeg appearance on gross examination
Light microscopy	
Acute pulmonary hyperemia with engorged capillaries, septal edema and minute intra-alveolar hemorrhage in lobar pneumonia	Chronic pulmonary congestion with alveolar spaces containing numerous hemosiderin-laden macrophages, heart failure cells and thickened septa
Acute liver hyperemia with distended sinusoids and fatty change	Chronic liver congestion with dilated central vein, distended sinusoids, fatty change progressing to cardiac cirrhosis

with hyperemic blood vessels are bright red and warm and there is engorgement of the arterioles and capillaries.

- Hyperemia is fundamental pathophysiologic process leading to overgrowth of epiphysis and early fusion in short stature persons with immature skeleton. Hyperemia with bone fracture healing may result in bone overgrowth.
- In the early acute stage of bacterial pneumonia, the upper lungs become red and microscopically blood vessels and alveolar capillaries are engorged with blood from hyperemia.

VENOUS CONGESTION

Venous congestion refers to the engorgement of an organ with venous blood. Acute passive congestion occurs in shock or sudden right-sided heart failure due to obstruction to venous return or increased backflow from congestive heart failure.

CHRONIC VENOUS CONGESTION IN LIVER

Diffuse venous congestion in the liver results from right-sided heart failure usually due to cardiomyopathy, tricuspid regurgitation, mitral insufficiency, constrictive pericarditis or cor pulmonale. In right-sided heart failure, liver is particularly vulnerable to chronic passive congestion, because the hepatic veins empty into the inferior vena cava. Liver is enlarged and tender.

- **Pathophysiology:** Moderate or severe right-sided heart failure increases central venous pressure, which is transmitted to the liver via the inferior vena cava and hepatic veins. Chronic venous congestion of liver leads to atrophy of hepatocytes, dilatation of sinusoids and centrizonal fibrosis. If severe chronic venous congestion of liver persists, it can progress to cardiac cirrhosis. The basis of hepatocytes cell death is probably sinusoidal thrombosis that propagates to the central veins and branches of the portal vein, causing ischemia. Pitting edema is seen in lower extremities in these patients.
- **Gross morphology:** Nutmeg liver is characteristic of chronic congestion of liver in patients with right-sided heart failure. Dark nutmeg-like spots reflect congestion and dilatation of sinusoids, venules and small hepatic veins in the centrilobular zones, which alternate with pale areas reflecting unaffected surrounding liver tissue in the periportal zones. Gross morphology of chronic venous congestion in liver is shown in Fig. 3.5.
- **Light microscopy:** The central veins and sinusoids are dilated and congested. Surrounding hepatocytes show brownish-yellow discoloration and fatty change. The increased venous pressure leads to dilation of the sinusoids and pressure atrophy of the centrilobular hepatocytes. Long-standing chronic passive congestion of liver leads to bridging fibrosis in extreme cases resulting in cardiac cirrhosis. Histology of chronic venous congestion in liver is shown in Fig. 3.6.
- **Clinical features:** Most patients of chronic venous congestion within liver remain asymptomatic. However, moderate chronic venous congestion causes discomfort in the right upper quadrant due to

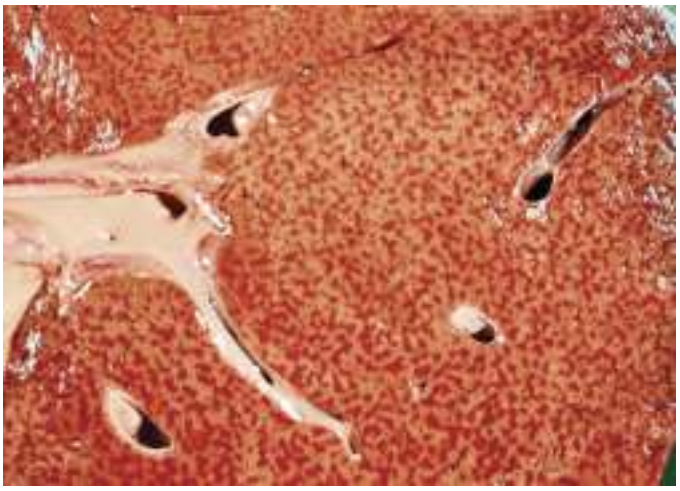

Fig. 3.5: Gross morphology of chronic venous congestion in liver. Nutmeg liver is characteristic of chronic congestion of liver in right-sided heart failure. Dark nutmeg-like spots reflect congestion and dilatation of sinusoids, venules and small hepatic veins in the centrilobular zones. These dark spots alternate with pale areas reflecting unaffected surrounding liver tissue in the periportal zones. Severe and long-standing hepatic congestion can lead to fibrosis, that is called cardiac cirrhosis.

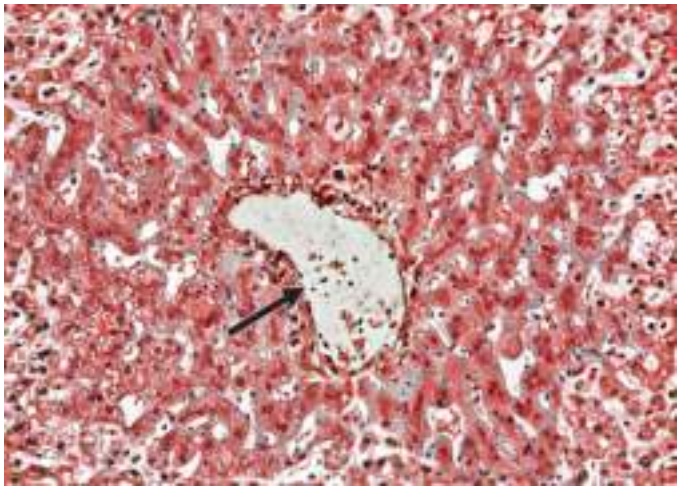

Fig. 3.6: Histology of chronic venous congestion in liver. Histologic findings suggestive of venous outflow impairment (i.e. chronic venous congestion in right-sided heart failure) in liver biopsies include dilatation and congestion of sinusoids and central veins, edema, hepatic cord atrophy and extravasation of red blood cells into the hepatocytes. Sinusoidal dilatation is a fairly common finding (arrow) (400X).

stretching of liver capsule, and tender hepatomegaly. Severe congestion leads to jaundice, massive hepatomegaly and ascites. Infrequently splenomegaly may result. Liver functions are impaired.

- **Diagnosis:** Laboratory test results are moderately abnormal in chronic venous congestion of liver, which include: unconjugated hyperbilirubinemia, elevated aminotransferases and prolonged prothrombin time/international normalized ratio (PT/INR). In addition, a high ascitic total protein content more than 2.5 g/dl plus ascitic albumin concentration more than 1.1 g/dl suggests congestive hepatopathy and differentiates portal hypertension from cirrhosis, in which ascitic total protein content <2.5 g/dl plus ascitic albumin concentration <1.1 g/dl.

BUDD-CHIARI SYNDROME

The cause of Budd-Chiari syndrome is thrombotic occlusion of the major hepatic veins, resulting in hepatomegaly. Thrombus in the hepatic veins cause obstruction to the blood flow to liver leading to chronic venous congestion in the liver. Liver shows severe centrilobular necrosis and hemorrhage as a result of localized obstruction to venous drainage. Zone 1 of liver shows a rim of viable hepatocyte. Budd-Chiari syndrome is shown in Fig. 3.7.

- Budd-Chiari syndrome occurs in the settings of hepatocellular carcinoma, polycythemia vera or other abdominal tumors and pregnant women.
- Less common causes of Budd-Chiari syndrome include paroxysmal nocturnal hemoglobinuria, promyelocytic leukemia, protein C deficiency, protein S deficiency, antithrombin III deficiency and antiphospholipid autoantibodies (lupus anticoagulant).
- Patient of Budd-Chiari syndrome presents with ascites, abdominal pain, hepatomegaly, mild jaundice, edema and eventual hepatic encephalopathy. Acute hepatic failure and death often occur rapidly.

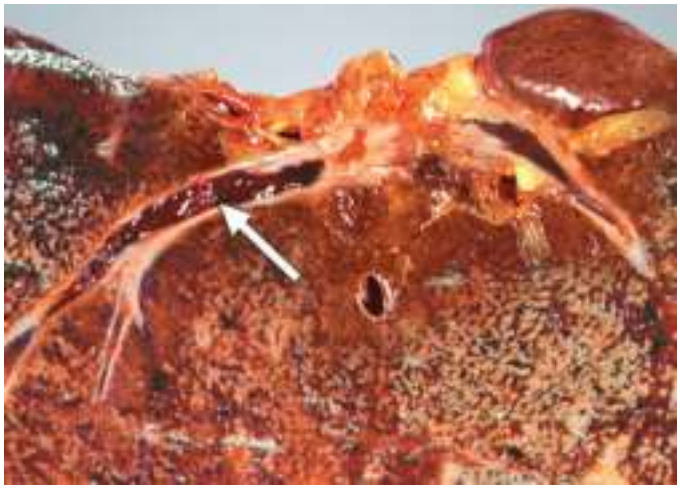

Fig. 3.7: Budd-Chiari syndrome. Budd-Chiari syndrome is characterized by narrowing and obstruction of the outflowing hepatic veins from either large region of the liver or entire liver. Blood clots or congenital webbing occur at the junction of these vessels with large veins that carries the blood from the inferior vena cava to the right atrium of the heart. Budd-Chiari syndrome may begin gradually or abruptly. Patient presents with pain in the upper part of the abdomen, jaundice, hepatomegaly and/or ascites. Thrombus can be seen in the hepatic veins (arrow).

CHRONIC VENOUS CONGESTION OF LUNGS

Chronic venous congestion of lungs is usually caused by left-sided heart failure in the settings of acute myocardial infarction, cardiomyopathies, hypertensive, or valvular heart disease (mitral stenosis, aortic stenosis in rheumatic heart disease), and left atrial myxoma. Pulmonary edema refers to intra-alveolar accumulation of fluid, which is a common complication of left heart failure.

- **Pathophysiology:** Left ventricular failure causes congestion of alveolar capillaries resulting to rupture, passage of red blood cells into the alveoli and accumulation of transudate in the alveoli. Alveolar macrophages degrade red blood cells and accumulate hemosiderin in macrophages. The hemosiderin-laden macrophages are called 'heart failure cells'. In long-standing chronic venous congestion, fibrosis of interstitial tissue and hemosiderin deposition results in brown induration of the lung. The alveoli in the lungs are filled with a smooth to slightly floccular pink material characteristic for pulmonary edema. Capillaries in the alveolar walls are congested with many red blood cells. Pulmonary edema is shown in Fig. 3.8. Heart failure cells in chronic venous congestion of lung are shown in Fig. 3.9.
- **Clinical features:** Patient presents with dyspnea due to pulmonary congestion, orthopnea (difficulty in breathing unless sitting up), frothy white pink sputum, pleural effusion with hydrothorax, weak pulse, cool moist skin as the peripheral vasoconstriction shunts blood to vital organs. Reduction in renal perfusion activates renin-angiotensin-aldosterone system and leading to retention of salt and water, which is less frequent. Cerebral anoxia is less frequent. On auscultation, crackles and wheeze breath sounds are heard.
- **Assay of B-type natriuretic peptide:** Assay of B-type natriuretic peptide is elevated in congestive heart failure, which may aid in the distinction of heart failure from acute coronary syndrome, bronchial asthma, chronic obstructive pulmonary disease, or pulmonary thromboembolism phenomenon, which may also present with dyspnea or pulmonary edema.

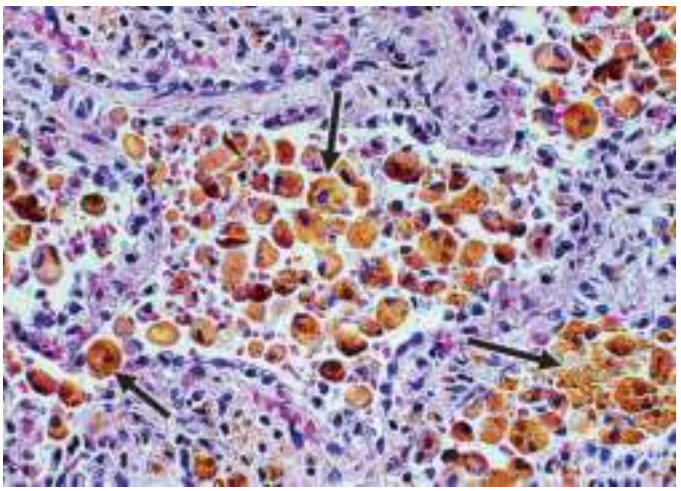

Fig. 3.9: Heart failure cells in chronic venous congestion of lung. Heart failure cells are basically macrophages laden with hemosiderin generated in the alveoli of the lungs of persons with left heart failure or chronic pulmonary edema, when the high pulmonary blood pressure causes breakdown of red blood cells to while passing through the vascular wall (arrows) (400X).

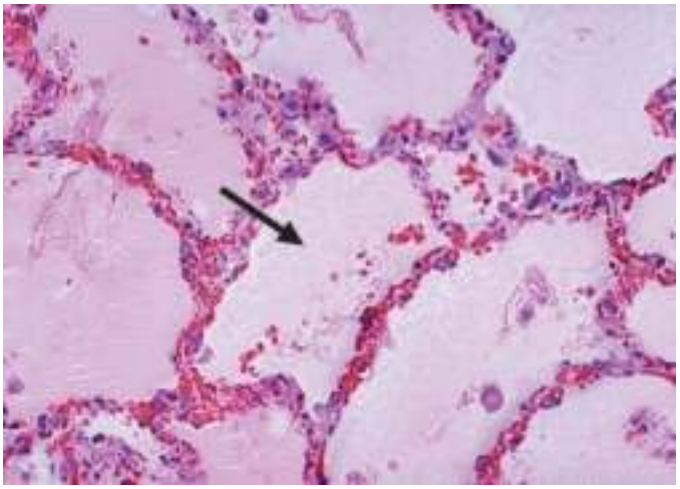

Fig. 3.8: Pulmonary edema. The alveoli in this lung are filled with a smooth to slightly floccular pink material characteristic of pulmonary edema. Alveolar capillaries are congested with many red blood cells. Congestion and edema of the lungs is common in patients with heart failure (arrow) (400X).

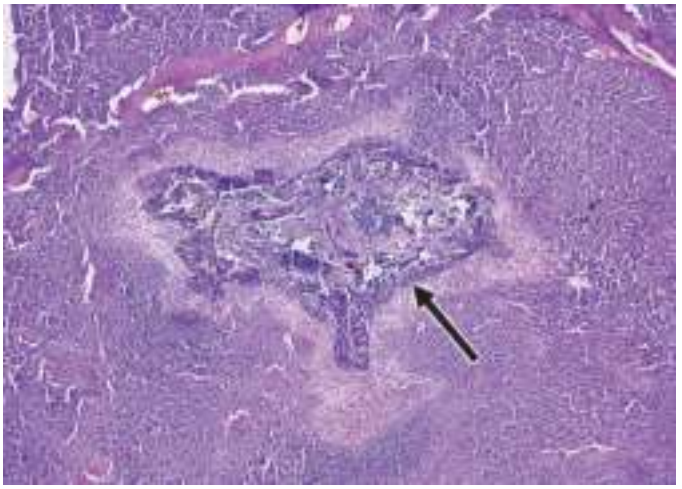

Fig. 3.10: Gamna-Gandy bodies in chronic venous congestion of spleen. Gamna-Gandy bodies or siderotic nodules are formed as a result of organization of hemorrhage with hemosiderin pigment and dystrophic calcification in spleen (arrow) (400X).

CONGESTIVE SPLENOMEGALY

Congestive splenomegaly most often occurs in portal hypertension due to cirrhosis and right-sided cardiac failure with cor pulmonale. Decreased portal venous drainage in these disorders leads to congestive splenomegaly. The increased portal venous pressure causes dilatation of sinusoids, with slowing of blood flow from the cords to the sinusoids that prolongs the exposure of the red blood cells to the macrophages, resulting in excessive trapping and destruction of red blood cells by macrophages in spleen (hypersplenism). Perivascular hemorrhages result in organization and formation of Gamna-Gandy bodies with hemosiderin pigment and dystrophic calcification.

- **Gross morphology**: Spleen shows irregular tan-white fibrous plaques over the purple capsular surface. Cut surface of fibrocongestive splenomegaly shows firm and brown fibrotic nodules termed 'Gamna-Gandy bodies'.
- **Light microscopy:** Gamna-Gandy body is an organized hemorrhage forming nodule with hemosiderin pigment and dystrophic calcification in spleen. Gamna-Gandy bodies in chronic venous congestion of spleen are shown in Fig. 3.10.

HEMOSTASIS

Hemostasis is a host-defense mechanism that protects the integrity of the vascular system after tissue injury, that causes free blood flow in the vascular system by inhibiting activation of platelets, coagulation system and fibrinolytic system.

- Hemostasis has integrating five major components: vascular endothelium, platelets, coagulation proteins, anticoagulant proteins (antithrombin III, protein C, protein S, and tissue factor pathway inhibitor), and fibrinolytic proteins (plasminogen-plasmin system).
- Hemostasis components are generally quiescent, but following tissue injury, these are rapidly activated to stop bleeding at the injured site by formation of a temporary 'platelet plug', activation of coagulation cascade and formation of stable 'fibrin polymer plug'. The clot seals the injured blood vessel and prevents further bleeding.
- Once the injured site starts to heal by regenerating process, the stable fibrin plug slowly undergoes remodeling and dissolution with restoration of normal tissue at the injured site, and maintenance of normal blood flow and vascular integrity.
- Thrombosis is opposite to hemostasis. Bleeding and coagulation disorders are the result of the failure of hemostatic plug formation mechanisms. Hemostasis and thrombosis are regulated by three components: blood vessel, platelets and coagulation system. All components of the hemostatic mechanism exist under resting conditions in an inactive form.

HEMOSTASIS: COMPONENTS

There are various cellular components in the process of coagulation, which include vascular endothelium, platelets and clotting factors.

- Endothelial cells synthesize clotting factors III and IX, while the clotting factor IV comes from the plasma. Factors III, IV and VIII undergo vitamin K-dependent γ-carboxylation of their glutamic acid residues, which allows their binding with calcium and other ions while in the coagulation cascade.
- Platelets are produced by megakaryocytes in the bone marrow, which have structural elements, which include plasma membrane, open canalicular system, spectrin and actin cytoskeleton, microtubules, mitochondria, lysosomes, α- and δ-granules, and peroxisomes. Platelets release proteins involved in formation of primary hemostatic plug to maintain hemostasis.
- The liver produces the majority of the clotting factors that function as procoagulants and anticoagulants.

VASCULAR ENDOTHELIUM

The blood vessel wall is the first-line of defense in maintaining hemostasis. Blood vessel is lined by endothelial cells and supported by subendothelial tissue, which maintains the vascular structural integrity. Subendothelial tissue, an extracellular matrix is composed of collagen, elastin, mucopolysaccharides (including heparan sulfate, chondroitin sulfate), laminin, fibronectin, von Willebrand factor (vWF), vitronectin and thrombospondin, synthesized by the endothelial cells.

- Vascular endothelium forms a barrier between platelets and plasma clotting factors and the subendothelial connective tissue.
- Vascular endothelium inhibits platelet aggregation and coagulation cascade. Disruption of normal laminar flow, imbalance between antithrombotic and prothrombotic molecules synthesized by endothelium result in thrombus formation.
- Vascular endothelium synthesizes antithrombotic (i.e. prostacyclin, ADPase, heparin-like molecules, thrombomodulin) and prothrombotic molecules

(i.e. von Willebrand factor, tissue factor, plasminogen activator inhibitors).

- Antithrombotic properties of vascular endothelium are shown in Fig. 3.11. Prothrombotic properties of vascular endothelium are shown in Fig. 3.12. Antithrombotic and prothrombotic properties of vascular endothelium are given in Table 3.6.

Maintenance of Laminar Blood Flow by Vascular Endothelium

Laminar blood flow dilutes clotting factors and inhibits endothelial cell activation, which increases the inflow of inhibitors of clotting factors. Endothelial cells influence vascular tone, blood pressure, and blood flow by induction of vasoconstriction and vasodilatation. Prostacyclin and nitric oxide cause vasodilation and inhibit platelet aggregation. Laminar blood flow is achieved by secretion of renin, endothelin, endothelial-derived relaxing factor (EDRF) or nitrous oxide (NO), adenosine diphosphatases (ADPase), prostacyclin, and surface enzymes that convert or inactivate other vasoactive peptides such as angiotensin and bradykinin.

Antiplatelet and Anticoagulant Properties of Vascular Endothelium

Intact vascular endothelium is nonthrombogenic that exerts a powerful inhibitory influence on hemostasis by a range of factors of endothelium either synthesizes or expresses on its surface.

Antiplatelet Properties of Vascular Endothelium

For example, platelets adhere to subendothelium tissue rather than vascular endothelium. It is because vascular endothelium synthesizes prostacyclin, endothelial-derived relaxing factor (EDRF) and adenosine diphosphatase (ADPase) enzyme, which inhibit platelet adherence.

- Adenosine diphosphate (ADP) released by platelets play important role in platelet activation and adhesion of platelet to each other.
- Vascular endothelium synthesizes adenosine diphosphatase enzyme (ADPase), which degrades ADP resulting in inhibition of platelets adhesion to subendothelial tissue.

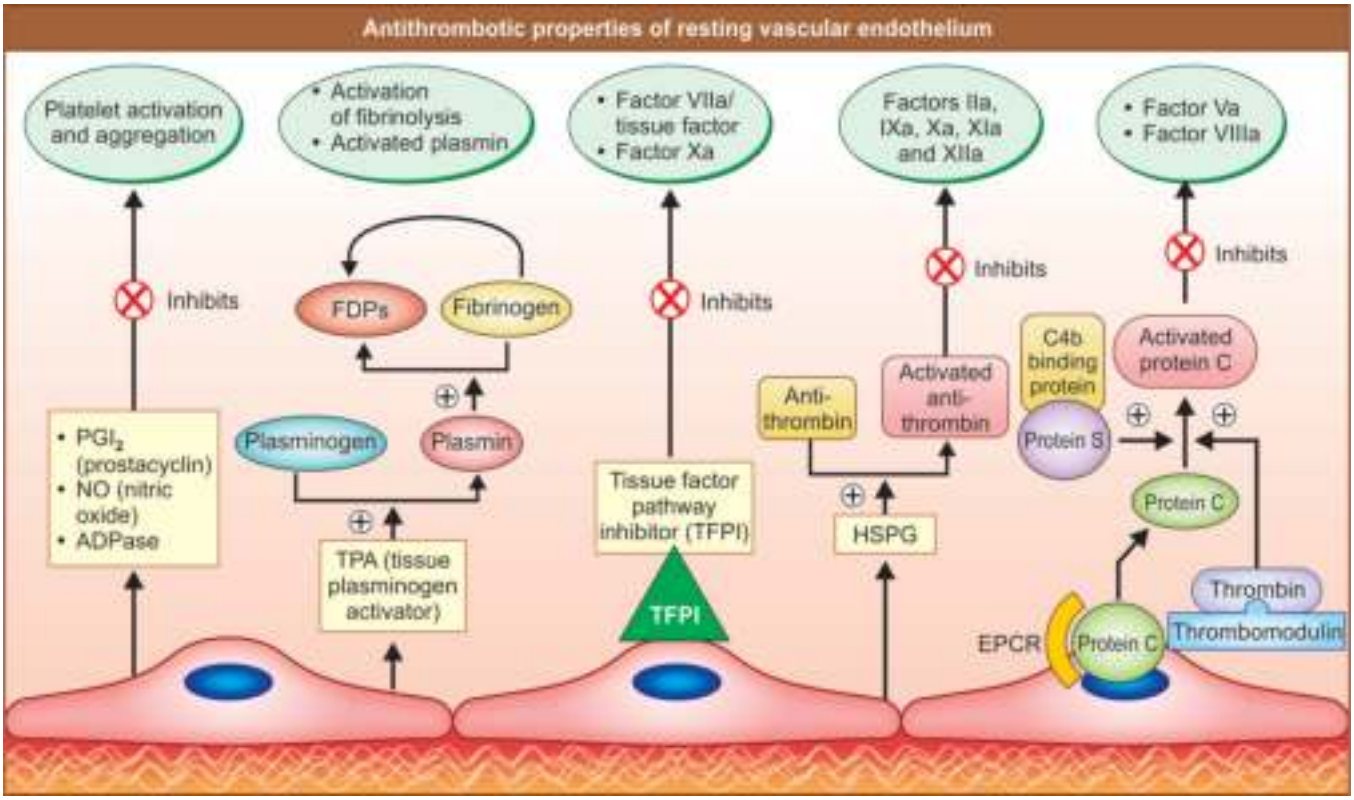

Fig. 3.11: Antithrombotic properties of vascular endothelium. Most important inhibitors of platelet activation generated by endothelial cells are nitric oxide (NO) and prostacyclin (PGI_2). Inhibitors of coagulation generated by endothelial cells are heparin-like molecules, tissue factor pathway inhibitor (TFPI) and thrombomodulin. Heparin-like molecules serve as a cofactor for antithrombin III inactivating several coagulation factors. Tissue factor pathway inhibitor (TFPI) limits the action of tissue factor (TF) and inhibits excessive tissue factor (TF)-mediated activation of coagulation factors VII and X. Thrombomodulin binds thrombin activating protein C and degrades factor Va and factor VIII.

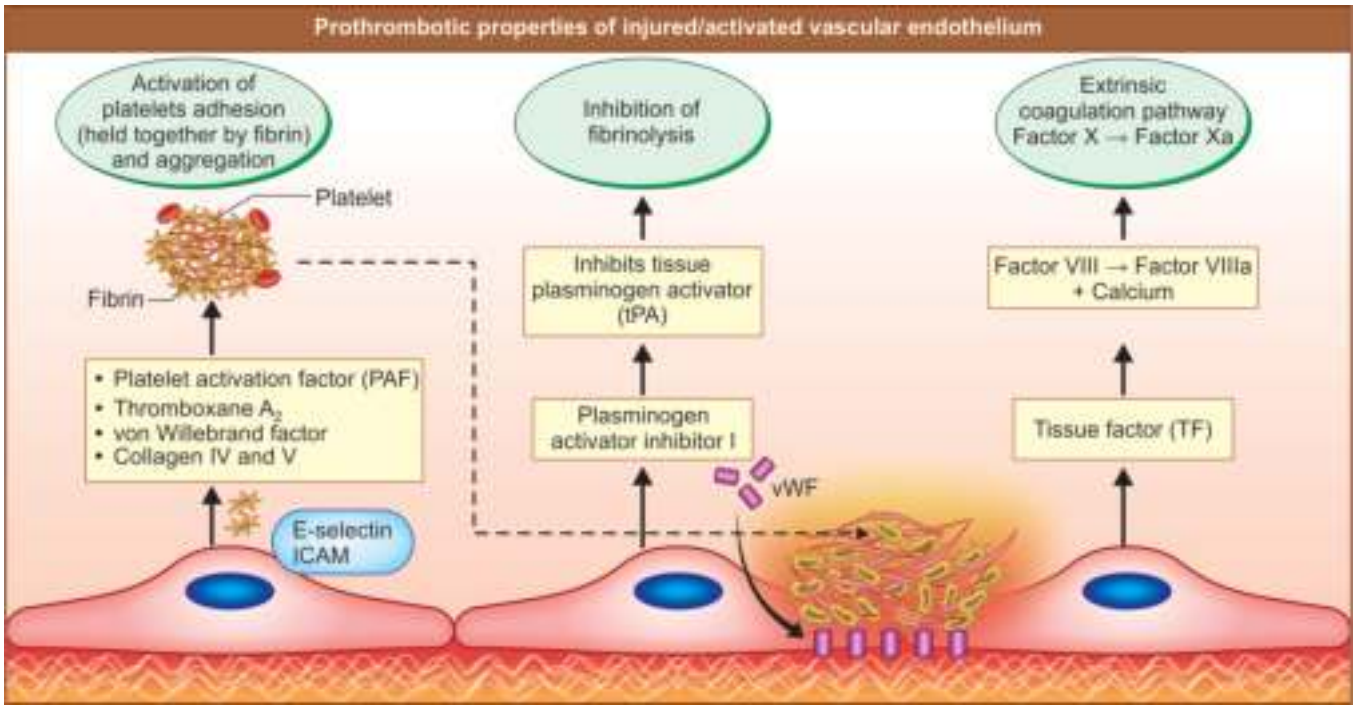

Fig. 3.12: Prothrombotic properties of vascular endothelium. At the site of vascular injury, von Willebrand factor (vWF) binds to the exposed subendothelial collagen. vWF then captures platelets from the bloodstream via the interaction of vWF with GpIb on the platelet surface. The binding of glycoprotein VI with subendothelial collagen leads to further platelet activation, which results in the integrin-mediated platelet adhesion and cellular activation releasing mediators. Thrombin binds to GpIb and activates protease-activated receptor 1 (PAR1) and protease-activated receptor 4 (PAR-4). Adenosine diphosphate (ADP) activates P2Y1 and P2Y2. Thromboxane A_2 (TXA_2) activates thromboxane receptor (TP). Agonists stimulation leads to aIIb-β_3 activation, which binds fibrinogen and mediates platelet aggregation.

Table 3.6 Antithrombotic and prothrombotic properties of vascular endothelium

Component Characteristics	Functions
Antithrombotic functions of vascular endothelium	
Negatively charged endothelial surface	Repels platelets and hemostatic proteins
Nitric oxide (NO)	Vasodilates; inhibits platelet recruitment and accumulation
ADPase (CD39)	▪ Antiplatelet property ▪ Degrades platelet ADP to AMP and adenosine; hence prevents platelet aggregation
Prostacyclin (PGI_2)	▪ Potent vasodilator ▪ Antiplatelet property by inhibiting platelet activation, adhesion and aggregation
Heparin-like molecules (heparan sulphate)	▪ Inhibitor of coagulation ▪ Inhibits fibrin formation (cofactor for antithrombin) and inactivates thrombin, factor X and other clotting factors
Thrombomodulin (TM)	▪ Inhibitor of coagulation ▪ Binds thrombin, enhances activation of protein C, that inhibits the activity of factor V and hence inhibits conversion of fibrinogen to fibrin
Endothelial protein C receptor (EPCR)	EPCR binds protein C; facilitates activation of protein C
Tissue factor pathway inhibitor (TFPI)	TFPI binds tissue factor/factor VIIa/factor Xa complex; inhibits extrinsic pathway of coagulation
Tissue plasminogen activator (tPA)	tPA activates fibrinolytic system
Annexin A2 (TPA receptor A2)	Annexin A2 binds tissue plasminogen activator (tPA) and plasminogen; activates fibrinolysis
Urinary-type plasminogen activator receptor (uPAR)	uPAR binds urinary plasminogen activator and plasminogen; activates fibrinolysis
Prothrombotic functions of vascular endothelium	
Endothelin (ET)	Vasoconstriction of blood vessel

Contd...

Table 3.6 Antithrombotic and prothrombotic properties of vascular endothelium (*Contd...*)

Component Characteristics	Functions
von Willebrand factor (vWF)	▪ Carrier of factor VIII in plasma; facilitates platelet adhesion ▪ Promotes platelet aggregation ▪ Stabilizes factor VIII procoagulant protein
Tissue factor (TF) induced by bacterial toxins, IL-1, TNF-α	▪ Procoagulant property ▪ Initiates fibrin formation, activates factor VII
Plasminogen activator inhibitor 1 (PAI-1)	▪ Procoagulant property ▪ Inhibits activation of fibrinolytic system
Nonhemostatic functions of vascular endothelium	
Selective blood/tissue barrier	Keeps blood cells and macromolecules in blood vessels; allows nutrient and gas exchange
Processing of blood-borne antigens	Contributes to cellular immunity
Basement membrane collagen synthesis	Provides back up protection for endothelial cells
Collagen of the matrix synthesis	Promotes platelet adhesion
Elastin synthesis	Vasodilates and vasoconstricts
Fibronectin synthesis	Binds one cell to another
Laminin	Contributes to platelet adhesion after injury
Vitronectin	Binds one cell to another, possibly promotes platelet adhesion
Thrombospondin (encoded by THBS1 gene)	Adhesive glycoproteins bind one cell to another, possibly promotes platelet adhesion

Normal blood flow dilutes clotting factors, inhibits activation of vascular endothelial cells and enhances inflow of inhibitors of coagulation.

Anticoagulant Properties of Vascular Endothelium

Vascular endothelium synthesizes membrane-associated molecules such as heparin-like molecules, thrombomodulin, tissue factor pathway inhibitor (TFPI) and protease nexin 1, which inhibit coagulation system. Major anticoagulant property of vascular endothelium is via the endothelial expression of thrombomodulin and tissue factor pathway inhibitor (TFPI).

- **Heparin-like molecules:** Heparin-like molecules synthesized by vascular endothelium binds to antithrombin III, which inactivates thrombin, factor Xa and other coagulation factors. Cell-surface heparan sulfate enhances the effect of antithrombin III in forming thrombin–antithrombin complexes.
- **Thrombomodulin:** Thrombomodulin is a natural anticoagulant synthesized by vascular endothelium that acts as a cofactor for thrombin-catalyzed activation of protein C, which inhibits the procoagulant functions of thrombin. Protein C inhibits the activity of factor Va and factor VIIIa, that can no longer convert fibrinogen to fibrin. Heparan sulfate proteoglycan potentiates the activation of antithrombin (AT) 15-fold. Thrombomodulin stimulates the activation of protein C by thrombin 30-fold.
- **Tissue factor pathway inhibitor (TFPI):** Vascular endothelium synthesizes tissue factor pathway inhibitor (TFPI). TFPI rapidly inactivates VIIa and factor Xa in circulation, so limiting conversion of prothrombin to thrombin.
- **Protease nexin 1:** Endothelium also synthesizes protease nexin 1 enhanced by heparan sulfate that inactivates thrombin by covalent binding to the thrombin active sites.

Procoagulant Properties of Vascular Endothelium

Normal vascular endothelium inhibits platelet adherence and coagulation cascade. In contrast to antiplatelet and anticoagulant properties of normal vascular endothelium, injured endothelium induces synthesis of prothrombotic molecules such as tissue factor, plasminogen activator inhibitor and von Willebrand factor (vWF).

Tissue Factor

Tissue factor (TF) triggers coagulation cascade by binding to factor VIIa, and the resulting tissue factor—factor VIIa complex activates the coagulation factors IX and X, ultimately leading to formation of fibrin and blood clot. Vascular endothelium synthesizes endothelin 1 (ET-1), which is a potent vasoconstrictor.

von Willebrand Factor

The von Willebrand factor (vWF) is a carrier of factor VIII in plasma, that stabilizes factor VIII procoagulant protein and facilitates platelet adhesion and aggregation to subendothelial collagen fibers.

Plasminogen Activator Inhibitors

Plasminogen activator inhibitors have procoagulant property, which inhibit activation of fibrinolytic system leading to thrombus formation.

Fibrinolytic Properties of Vascular Endothelium

Vascular endothelium secretes several components involved in fibrinolysis, which include tissue plasminogen activator (tPA) and plasminogen activator inhibitors bound to the endothelial cell surface, which enable assembly of active complexes.

Repair Properties of Vascular Endothelium

After simple minor injury to vascular endothelium, vascular repair process involves migration of adjacent resident proliferation and subsequent proliferation of these cells leading to restoration of functional endothelial monolayer and reestablishment of junctions to reform semipermeable membrane. More severe blood vessel wall injuries require migration and proliferation of smooth muscle cells and fibroblasts. Vascular endothelium secretes platelet-derived growth factor (PDGF), fibroblast growth factor-β and vascular permeability factor. Vascular endothelium is also responsive to PDGF and fibroblast growth factor-β.

Interactive Properties of Vascular Endothelium with Leukocytes

Cell adhesion molecules (CAMs) present on both endothelial cells and leukocytes mediate interaction of vascular endothelium and leukocytes. CAMs play key role in the inflammatory response. Selectins, integrins and immunoglobulin superfamily of receptors mediate rolling, adhesion, emigration and migration of leukocytes from the bloodstream to the site of tissue injury.

PLATELETS

Platelets play a central role in normal hemostasis by forming 'primary hemostatic plug'. Platelets activate coagulation system through the platelet phospholipid complex, which maintain the physical integrity of the vascular endothelium. During platelet activation, platelets release a number of cytokines and chemical mediators via degranulation, which include adenosine diphosphate (ADP), adenosine triphosphate (ATP), serotonin, von Willebrand factor, thromboxane A_2, from dense granules of platelets, which can activate neighboring platelets via ADP and ATP sensitive receptors. Platelet-derived growth factor (PDGF) repairs injured endothelium. Platelet structure is shown in Fig. 3.13.

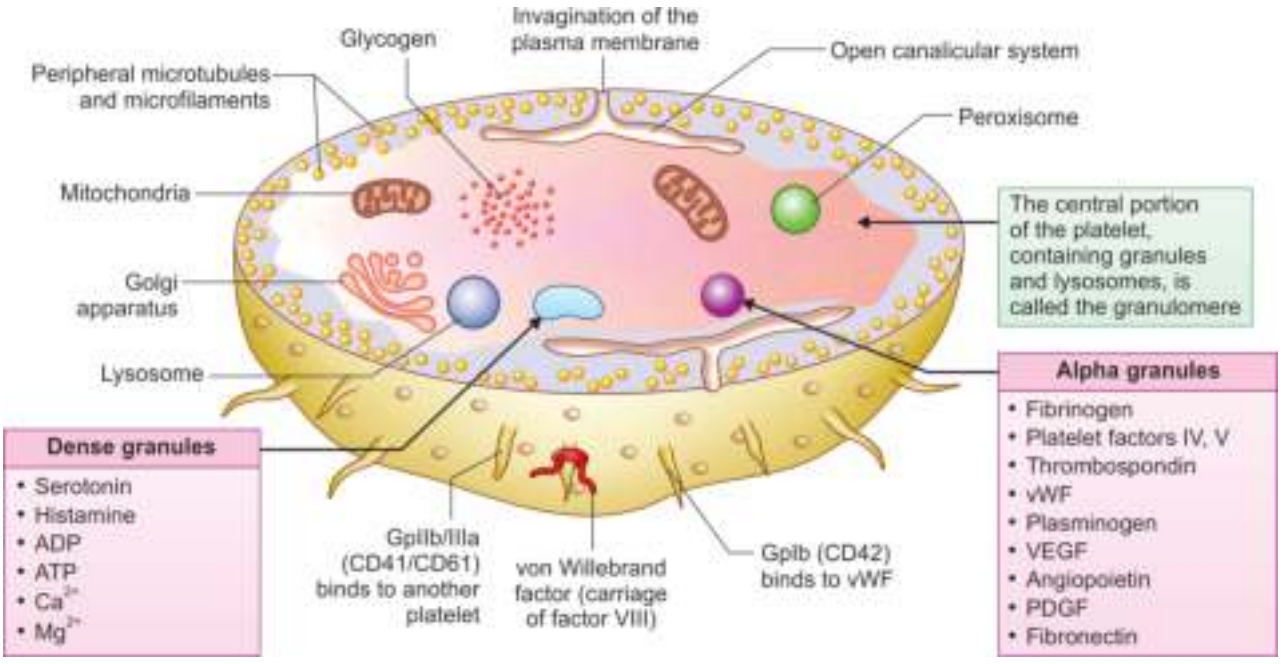

Fig. 3.13: Platelet structure. Platelets are fragments of cytoplasm derived from the megakaryocytes of the bone marrow and then enter the bloodstream. Circulating inactivated platelets are biconvex discoid structures. Platelets regulate hemostasis by forming primary hemostatic platelet plug. Platelets contain two types of granules, i.e. α-granules and dense bodies (dense granules). α-Granules contain fibrinogen, factors V and VIII; platelet-derived growth factor, transforming growth factor β, fibronectin and platelet factor IV. Dense bodies contain adenosine diphosphate (ADP), adenosine triphosphate (ATP), ionized calcium, serotonin and epinephrine.

Thrombopoiesis

Thrombopoietin, vitamin B_{12} and folic acid participate in platelet production in bone marrow. Platelets are formed due to cytoplasmic fragments of megakaryocytes. Thrombopoiesis is shown in Fig. 3.14.

- Megakaryocytes undergo endomitosis to increase ploidy. Megakaryocytes produce platelets by remodeling of cytoplasm into long projections called proplatelets. The lamellipodial and filopodial formation that accompanies platelet activation is driven by the actin cytoskeleton.
- Nearly one trillion, platelets circulate in an adult human. Platelets range in size from less than 5 femtoliters to more than 12 femtoliters; however, the average platelet is about 7.3 femtoliters.
  - Two-thirds of platelets remain in circulation, while one-third is stored in spleen. Recent studies revealed that platelet life span in 3–7 days. Platelet normal count for all ages is 150–450 × 10^9/L.
  - The discoid shape of resting platelets is maintained by a cytoskeleton composed of microtubules, actin filaments, and spectrin-based membrane skeleton.
- Platelets possess several glycoproteins on their surface, which act as adhesive receptors and antigens involved in autoimmune and immune reactions.
  - The main glycoproteins of platelets are the GpIb/IX/V complex, the aIIbβ3 integrin, CD36 (GpIV or GpIIIb), and GpVI. For each of these glycoproteins, several polymorphisms have been described, influencing both platelet function and platelet immunogenicity. The identification and characterization of the gene encoding these glycoproteins by crystallographic studies have contributed to analyze the role of platelet surface glycoproteins.

Platelet Structure

Platelets are membrane bound porous disc-like structures, which express glycoprotein receptors of the integrin family on their surface.

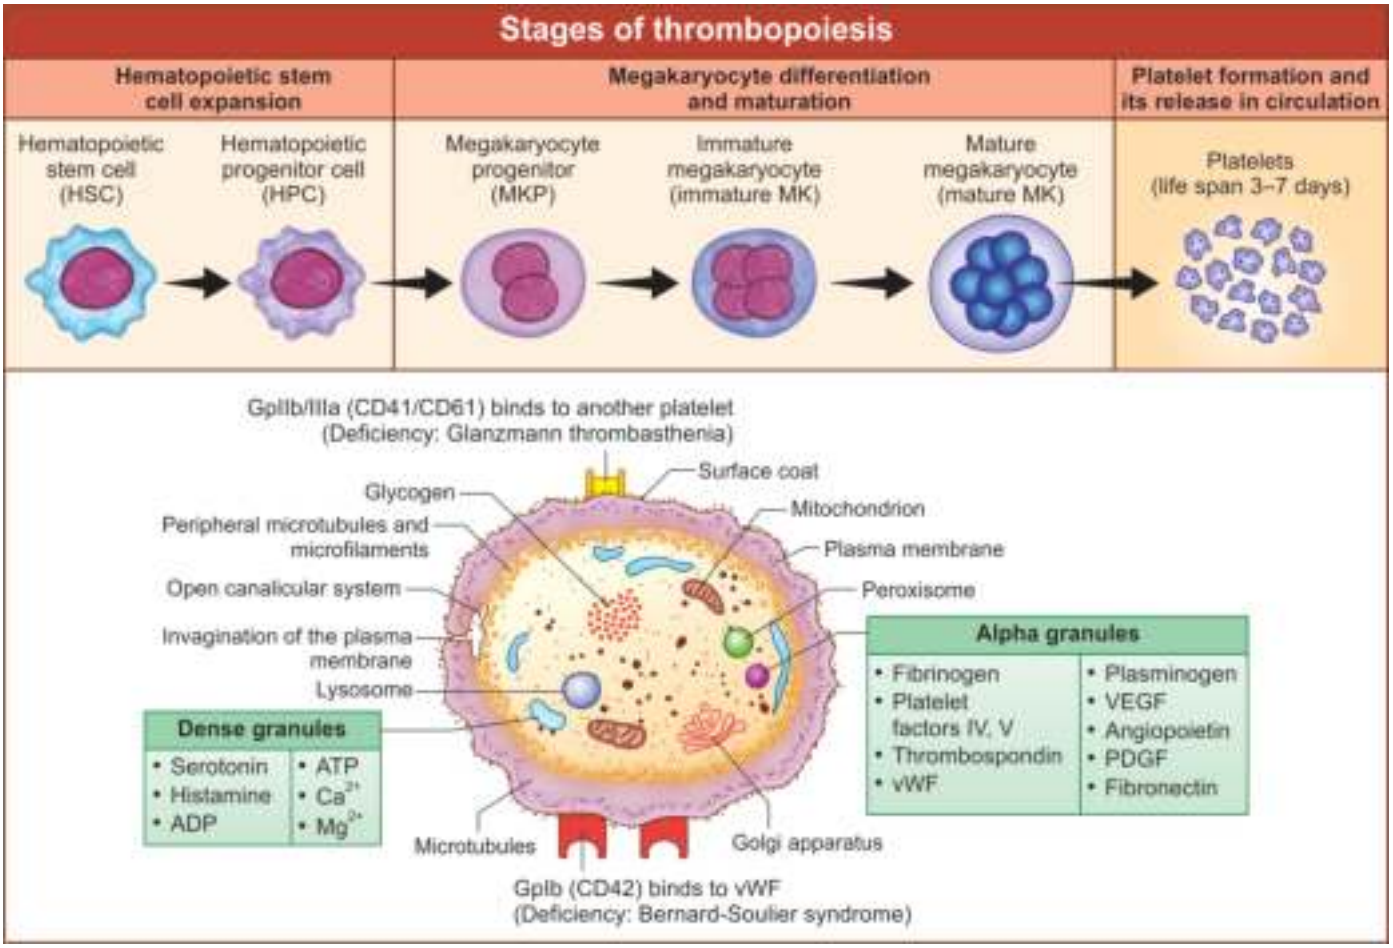

Fig. 3.14: Thrombopoiesis. Platelets are produced by process of thrombopoiesis in the bone marrow. Thrombopoietin produced by liver, which regulates production of platelets in the bone marrow, which stimulates differentiation of common myeloid progenitor cells into promegakaryocytes and then into megakaryocytes that buds off numerous platelets and their release into the circulation. Life span of platelets is 3–7 days. Platelets play important role in formation of primary hemostatic plug.

Table 3.7 Important platelet plasma membrane glycoproteins

Glycoproteins	Copies per Platelet	Receptors
Glycoprotein Ia	$2–4 \times 10^3$	Collagen
Glycoprotein IIa	$5–10 \times 10^3$	Fibronectin, laminin
Glycoprotein Ic	$3–6 \times 10^3$	Fibronectin, laminin
Glycoprotein Ib/IX	$25–30 \times 10^3$	vWF, thrombin essential in the platelet vessel wall interaction
Glycoprotein IIb/IIIa complex	$40–50 \times 10^3$	Fibrinogen, vWF, fibronectin and vitronectin
Glycoprotein IV	Unknown	Collagen, thrombospondin
Glycoprotein V	Unknown	Thrombin

Platelet Plasma Membrane

Plasma membrane of platelets allows adherence of platelets with the help of fibrinogen. Integrin α-IIb-β3 (GpIIb/IIIa) is most abundant glycoprotein on the platelet surface with a number of 60,000–80,000 copies per cell and an additional intracellular pool that is exposed on the surface on activation.

- Platelet plasma membrane glycoproteins function as receptors for different agonists, adhesive proteins, coagulation factors and adjacent other platelets.
- The platelet plasma membrane is a source of phospholipid (prostaglandins synthesis), site of calcium mobilization and localization of coagulant activity to the platelet surface. Important platelet plasma membrane glycoproteins are given in Table 3.7.

Platelet Antigens

Platelets also have many surface specific antigens associated with platelet membrane glycoproteins: HLA class I antigen and ABO group antigen.

Platelet Cytoskeleton

Beneath plasma membrane, platelets contain actin and myosin filaments that cause the platelets to contract. Microtubules maintain the disc-like shape in the resting platelets, but disappear temporarily on platelet aggregation.

Platelet Surface Connecting Canalicular System

The surface-connected canalicular system is formed by invaginations of platelet plasma membrane, that increases the surface area across membrane transport through which platelet granules discharge their contents during the secretory phase of platelet aggregation. The dense tubular system represents the smooth endoplasmic reticulum, which is thought to be site of prostaglandin synthesis and release of calcium ions.

Platelet Organelles and Platelet-specific Storage Granules

Platelet contains many cell organelles (mitochondria, lysosomes, peroxisomes and glycogen granules) and two types of platelet-specific storage dense granules and α-granules. Platelet aggregation results in release of platelet-specific granules.

- **Dense granules:** Dense granules of platelets contain 60% of platelet storage pool of adenosine diphosphate (ADP), adenosine triphosphate (ATP), ionized calcium, bioactive amines (serotonin and histamine) and epinephrine. ADP and ATP play important role in recruitment of platelets and activation of neighboring platelets resulting in platelet aggregation.
- **α-Granules:** α-Granules of platelets contain fibrinogen, von Willebrand factor (vWF), adhesive proteins, platelet factor IV, factor V, β-thrombospondin, plasminogen, vascular endothelial growth factor (VEGF), angiopoietin, platelet-derived growth factor (PDGF), transforming growth factor-β (TGF-β), and fibronectin. Fibrinogen, von Willebrand factor (vWF), adhesive proteins mediate platelet–platelet and platelet–endothelial interactions.

Platelet Function

Platelets play important role in hemostasis, thrombosis and wound healing. Following vascular endothelial injury, platelets become activated in the blood resulting in platelet adhesion to the exposed subendothelial extracellular matrix, platelet hemostatic plug formation, and finally formation of a thrombus consisting of both core and shell. Platelet structure components and their functions are given in Table 3.8. Lysosomal enzymes in platelets are given in Table 3.9.

COAGULATION SYSTEM CASCADE

Platelets initially arrest bleeding by forming temporary primary hemostatic plug in severed blood vessels. Formation of clot by activation of coagulation system is necessary to secure the repair of the damaged blood vessel. Coagulation system pathways are shown in Fig. 3.15.

- On activation, platelets undergo conformational change in shape resulting in synthesis of platelet factor 3 derived from plasma membrane phospholipid of platelets, which serve as catalytic sites for calcium

Table 3.8 Platelet structure components and their functions

Platelet Structure Components	Functions
Platelet membrane	
Glycocalyx	▪ Outermost coat comprising glycolipids, glycoproteins and mucopolysaccharide ▪ Negative charge due to sialic acid residue of proteins and lipids
Plasma membrane	▪ Plasma membrane is composed of glycolipids, cholesterol and glycoproteins ▪ Lipoprotein layer containing platelet factor 3 involved in blood coagulation
Membrane glycoproteins (acting as receptors for cell–cell and ligand–cell interaction)	
Glycoprotein IIb/IIIa	Cross-linking of GpIIb/IIIa to vWF and fibrinogen leading to platelets aggregation. Deficiency of GpIIb/IIIa results in Glanzmann's disease
Glycoprotein Ib–IX	In Bernard-Soulier syndrome, deficiency of GpIb–IX results in bleeding diathesis
Cytoskeleton proteins	
Short actin filament	Present under plasma membrane involved in maintaining discoid shape
Actin microfilament network	Present in cytoplasm
Microtubules	Present in peripheral part of cytoplasm involved in maintaining discoid shape
Dense granule products	
Serotonin (bioactive amine)	Vasoconstriction
Histamine (bioactive amine)	Allergic and inflammatory response
Adenosine diphosphate (ADP)	Recruitment of platelets and activation of neighboring platelets resulting in platelet aggregation
Adenosine triphosphate (ATP)	Agonist for cells other than platelets
Calcium (Ca^{++})	Extracellular source for hemostatic reactions
Magnesium (Mg^{++})	Essential for the movement of sodium, potassium and calcium into and out of cells
α-Granule products	
Fibrinogen	▪ Fibrinogen mediates platelet–platelet and platelet–endothelial interactions ▪ Platelets aggregation and fibrinogen conversion to fibrin
Platelet factor 4	Platelets aggregation
Thrombospondin	Platelets aggregation
Factor V	Platelets adhesion
von Willebrand factor (vWF)	vWF mediates platelet–platelet and platelet–endothelial interactions
Plasminogen	Plasminogen conversion to plasmin, that causes fibrinolysis
VEGF, angiopoietin, PDGF	Angiogenesis
Fibronectin	Plasma form of fibronectin circulates in the blood, and upon tissue injury. Fibronectin is incorporated into fibrin clots to exert effects on platelet function and mediate hemostasis
Osteonectin	Osteonectin is a regulatory protein involved in the adhesion of osteoblasts and platelets to their extracellular matrix and in early stromal mineralization

Table 3.9 Lysosomal enzymes in platelets

and coagulation factors in the intrinsic coagulation system pathway.

- Coagulation system comprises extrinsic and intrinsic pathways, which reflect how clotting occurs in the test tube during tests. Clotting in the body is initiated differently in both coagulation system pathways.
  - **Extrinsic pathway of blood coagulation system:** Tissue factor binds and activates factor VII. Activated factor VII (VIIa) further activates factors X and IX via proteolysis. Activated factor IX (IXa) binds to its cofactor-activated factor VIII (factor VIIIa), which results in activation of factor X (factor Xa). Factor Xa binds to its cofactor-activated factor V (factor Va) and calcium and generates

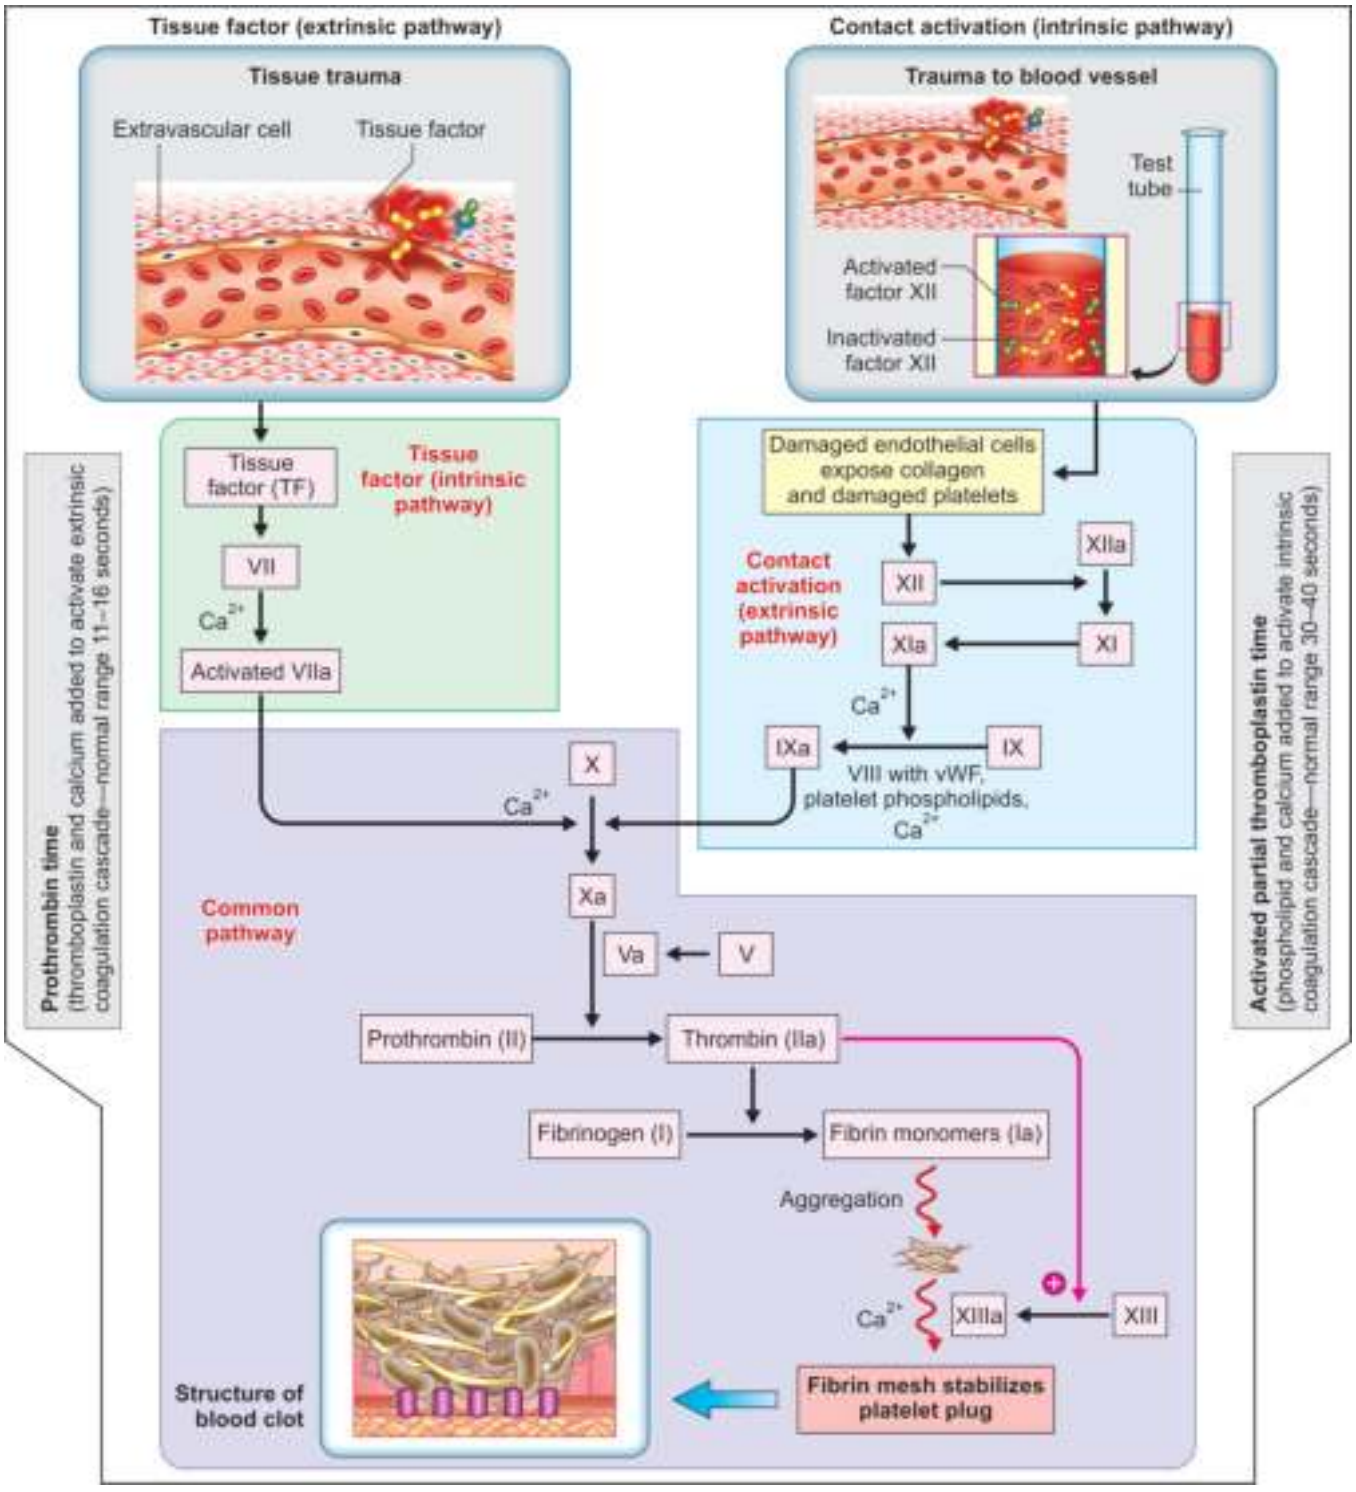

Fig. 3.15: Coagulation system pathways. Coagulation system consists of extrinsic, intrinsic and common pathways, that interact together to form a stable blood clot. Both extrinsic and intrinsic pathways converge to common pathway by independently activating factor X. Extrinsic pathway involves interaction by factor III (i.e. tissue factor) and its interaction with factor VII, whereas factors XII, XI, IX and VIII are utilized in the intrinsic pathway. Then the common pathway uses factors X, V, II, I and XIII leading to formation of a protein web made up of polymerized cross-linked fibrin.

a prothrombinase complex that cleaves the prothrombin into thrombin.

- **Intrinsic pathway of blood coagulation system:** With production of thrombin, factor XI is converted to activated factor XI (factor XIa). Activated factor XI (factor XIa) binds to activated factor VII and tissue factor, and converts factor IX to activated factor IX (factor IXa). Factor IXa activates factor X. Activated factor X (factor Xa) converts factor VIII to activated factor VIII (VIIIa). Factor VIIIa activates

factor X. Activated factor X (factor Xa) binds with activated factor V (factor Va) and converts prothrombin to thrombin. Thrombin acts a cofactor and catalyzes and enhances bioactivity of many of the aforesaid proteolytic pathways.

- **Fibrin clot formation:** Both extrinsic and intrinsic pathways of coagulation cascade converge and convert fibrinogen to fibrin monomers, which polymerizes and forms fibrin polymer mesh leading to cross-linked fibrin clot. This reaction is catalyzed by activated factor XIII (factor XIIIa) that stimulates the lysine and glutamic acid side chains causing cross-linking of the fibrin molecules and formation of stabilized fibrin clot.
- **Blood clot dissolution (tertiary hemostasis):** Activated platelets contract their internal actin and myosin fibrils in their cytoskeleton leading to shrinkage of the blood clot volume. Plasminogen then activates to plasmin, which promotes dissolution of the fibrin blood clot; and restores the blood flow in the blood vessels.

Coagulation Factors

Liver is actively involved in synthesis of coagulation factors, which include factors I, II, V, VII, VIII, IX, X, XI, XIII, and protein C and protein S. Ionized calcium (Ca^{++}) is present in the blood, that is also derived from intracellular source. Phospholipid component is present on surface of the cells including platelets, which provide a surface upon which the chemical reactions of coagulation system can take place.

Thrombin

Thrombin is formed from its precursor prothrombin following tissue injury. Thrombin converts fibrinogen to fibrin in the final stage of blood coagulation cascade. Thrombin is multifunctional serine protease with both procoagulant and anticoagulant properties. Thrombin plays a central regulator of hemostasis and thrombosis.

- Thrombin having procoagulant properties participates in activation of fibrinogen to fibrin, activation of factors V and VIII and platelets.
- Thrombin having anticoagulant properties participates in activation of protein C via thrombomodulin and activation of thrombin activatable fibrinolysis inhibitor (TAFI).
- Thrombin activates platelets causing shape change, generation of thromboxane A_2, ADP release and ultimately platelet aggregation.
- Thrombin also activates the cofactors of coagulation factors V, VIII and XIII. Thrombin bound to thrombomodulin activates protein C. In addition to its procoagulant and anticoagulant activities, thrombin also plays key role in cell growth, activation migration.
- Thrombin plays key role in endothelial cell contraction and acquisition of prothrombin properties, and promotion of cell division.

Tissue Factor

Tissue factor is an integral transmembrane protein found on the surface of vascular cells and many avascular tissues.

- Inflammatory cytokines or endotoxin can upregulate tissue factor on vascular endothelium and monocytes. After blood vessel injury, tissue factor (TF) plays a central role in hemostasis and thrombosis.
- Tissue factor binds to factor VII via calcium ions. Tissue factor (thromboplastin)–factor VIIa complex activates extrinsic pathway of coagulation cascade, which results in fibrin deposition and activation of platelets.
- Tissue factor acts as a cofactor enhancing the proteolytic activity of factor VIIa towards factors IX and factor X.

Factor V

Factor V is plasma procoagulant glycoprotein, that circulates in inactive form. Plasma factor V is predominantly synthesized in the liver. Platelet factor V is synthesized in the megakaryocytes and stored in α-granules of platelets. Factor V interacts with other coagulation proteins including factor X and prothrombin to facilitate the conversion of prothrombin to thrombin to many folds. Factor V is inactivated by activated protein C and its cofactor protein C. Plasma factor V has half-life of approximately 12 hours.

Factor VII

Factor VII is a vitamin K-dependent plasma glycoprotein and serine protease synthesized in the liver. Its main role is to initiate the blood coagulation cascade in conjunction with tissue factor to generate enzyme complex that activates factors X and IX. Activated factor VII has no catalytic activity until bound to tissue factor. Factor VII has half-life of 4–6 hours.

Factor VIII

Factor VIII (antihemophilic factor) is a glycoprotein synthesized in the liver. It is one of the longest and least stable coagulation factors with complex polypeptide composition. Factor VIII circulates in the plasma in a noncovalent complex with von Willebrand factor (vWF), which functions to protect factor VIII from premature proteolytic degradation and concentrate factor VIII at the sites of vascular injury. Factor VIII functions as a cofactor in the blood coagulation cascade for the proteolytic activation of factor X by factor IX, facilitate the conversion of factor X to factor Xa by 200,000-fold. Inactivation of factor VIII also occurs via activated

protein C and its cofactor protein C. Factor VIII has half-life of about 12 hours.

Factor IX

Factor IX (Christmas factor) is a vitamin K-dependent plasma glycoprotein and serine protease, which cleaves factor X in blood coagulation cascade leading to conversion of fibrinogen to fibrin. Calcium binding properties of factor IX are crucial to its normal function and biological activity. Factor VIII together with factor IX proceed to activate factor X. In addition, factor IXa may also activate factor VII. Factor IX has a half-life of 24 hours.

Factor X

Factor X (Stuart-Prower factor) is a vitamin K-dependent plasma glycoprotein and serine protease synthesized in the liver. It plays a central role in the blood coagulation cascade at the point of convergence of the intrinsic and extrinsic pathways of coagulation system. Calcium binding properties of factor X are crucial to its normal function and biological activity. Activated factor X, in conjunction forms a complex on phospholipid surfaces with factor V to form the prothrombinase complex, which converts prothrombin to thrombin. Factor X is inhibited by antithrombin and α_2-macroglobulin. Factor X has half-life of about 36 hours.

Factor XI

Factor XI is a plasma glycoprotein and serine protease, that circulates bound to kininogen. Factor XI is cleaved to active factor XIa by activated factor XIa in the presence of kininogen. Factor XIa activates factor IX in the presence of calcium. Both factor XI and factor XIa bind to platelets. Factor XI has a half-life of about 72 hours.

Factor XII

Factor XII (Hageman factor) is plasma glycoprotein and serine protease synthesized in the liver that circulates in blood as a zymogen. Factor XII may undergo auto-activation to factor XIIa after binding to negatively charged surfaces. Factor XIIa activates prekallikrein to kallikrein that in turn further autoactivates factor XII. Factor XIIa can activate factor XI to promote downstream activation of the blood coagulation cascade.

Factor XIII

Factor XIII (fibrin stabilizing factor) is a **transglutaminase** that forms γ-glutamyl-lysyl amide cross-linking of fibrin, stabilizing the insoluble blood clot against shear stress. As a result, it achieves further protection from degradation of clot in the coagulation cascade. Factor XIII also works on α_2-antiplasmin to cross-link it to fibrin, as a part of its another antifibrinolytic property.

von Willebrand Factor

von Willebrand factor is a glycoprotein synthesized in both endothelium and megakaryocytes involved in primary hemostasis plug formation. Vascular endothelium secretes vWF into the plasma constitutively, but is stored in Weibel-Palade bodies of **α**-granules of platelets. The vWF functions as **carrier protein** for coagulation factor VIII. The vWF functions as adhesive protein involved in vascular endothelial–platelet interaction, via platelet membrane glycoprotein Ib and IIb/IIIa complex. Its function as a adhesive protein is important in setting of high shear stress.

Coagulation System Cascade

Coagulation cascade refers to series of steps that occur during formation of a blood clot after vascular injury by activating clotting factors. There are three pathways of coagulation cascade, which include extrinsic, intrinsic and common pathways. Factor Xa proceeds and forms a link between both extrinsic and intrinsic pathways. Prothrombin time and international normalized ratio (PT–INR) assesses the extrinsic and common pathways of coagulation. Activated partial thromboplastin time (APTT) analyzes factors XII, IX, X, VII, V, II or prothrombin, kininogen and prekallikrein.

Extrinsic Pathway of Coagulation System

Binding of tissue thromboplastin and calcium ions activates factor VII, which further activates factors X and IX via proteolysis. Activated factor IX (IXa) binds with its cofactor-activated factor VIII (factor VIIIa), which results in activation of factor X (factor Xa).

- Activated factor X (factor Xa) binds to its cofactor-activated factor V (factor Va) and calcium and generates a prothrombinase complex that cleaves the prothrombin into thrombin.
- Thrombin first splits off fibrinopeptides A and B from fibrinogen, and then form fibrin monomers, which undergo spontaneous polymerization by hydrogen bonding to form fibrin network. It precedes stabilization of fibrin network by factor XIII (fibrin stabilizing factor) resulting in cross-linking of fibrin network. This product is insoluble and resistant to digestion by plasmin.
- Absence of clotting factors VII, X, V, II, or fibrinogen or presence of inhibitors interfere with conversion of fibrinogen to fibrin, which leads to abnormal prothrombin time. Similarly, abnormalities of fibrinogen and inhibitors of the conversion of fibrinogen to fibrin result in an abnormal thrombin time.

Intrinsic Pathway of Coagulation System

With production of thrombin, factor XI is converted to activated factor XI (factor XIa). Activated factor XI

(factor XIa) binds with activated factor VII and tissue factor, and converts factor IX to activated factor IX (factor IXa), which activates factor X (factor Xa). Platelets provide phospholipid in this process.

- Factor Xa proceeds and forms a link between both extrinsic and intrinsic pathways. Factor Xa binds with factor V and prothrombin. Factor Xa cleaves prothrombin to form thrombin. Thrombin converts fibrinogen into fibrin, which is stabilized by fibrin-stabilizing factor XIII.
- Activated partial thromboplastin time (APTT) analyzes factors XII, IX, X, VII, V, II or prothrombin, kininogen and prekallikrein. Factor XII, kininogen and prekallikrein are essential for normal clotting in the test tube. Activation of factor XII begins, when it is exposed to glass surface in presence of kininogen and prekallikrein. In human, many substances such as collagen, fatty acids, or joint cartilage can activate factor XII (factor XIIa).
- Abnormalities in any one of the following coagulation factors produce an abnormal activated partial thromboplastin time (APTT) such as factors XII, IX, X, VII, V, II or prothrombin, kininogen and prekallikrein. Persons deficient in kininogen and prekallikrein have no significant bleeding disorders.

Stabilized Fibrin Clot Formation

Both extrinsic and intrinsic pathways of coagulation cascade converge and convert fibrinogen to fibrin monomers, which polymerize and form fibrin polymer mesh resulting in cross-linked fibrin clot. This reaction is catalyzed by activated factor XIII (factor XIIIa) that stimulates the lysine and glutamic acid side chains causing cross-linking of the fibrin molecules and formation of stabilized clot.

Anticoagulant Pathways

Natural, physiologic anticoagulants fall into two broad categories: (a) serine protease inhibitors and (b) protein C system that neutralizes specific activated coagulation factors. These anticoagulant systems have physiologic significance. These are active from the initiation of coagulation process until fibrin deposition has occurred.

Serine Protease Inhibitors (SERPINs)

SERPINs are natural **ser**ine **p**roteases **in**hibitor**s**. Serine proteases are controlled by serpins. Serine proteases drive important physiologic processes such as blood coagulation, fibrinolysis inflammation and angiogenesis. Serine protease inhibitors include antithrombin III, heparan cofactor II, protein C inhibitor, plasminogen inactivators and α_2-antiplasmin.

- Out of these, antithrombin III is most important inhibitor of coagulation that inhibits all the coagulation serine proteases (II, VII, IX, X, XI and XII).
- Antithrombin III antagonizes thrombin activity. Heparin-like molecules synthesized by endothelium activates antithrombin III. Hence in clinical practice, heparin is administered to minimize thrombosis.
- Antithrombin III (ATIII) that has anti-Xa activity. ATIII activity/inhibition is enhanced in the presence of heparin and other sulfated glycosaminoglycans.
- Heparin is not normally present in circulation and normally, antithrombin III binds to heparin sulfate on the vascular endothelial cells.

Anticoagulant Protein C System

Protein C is a vitamin K-dependent natural anticoagulant synthesized in the liver and present in circulation. Protein C is the key enzyme that inactivates both coagulation factors Va (cofactor in the activation factor in the prothrombin) and VIIIa (cofactor in the activation factor X). Protein C is activated on the surface of vascular endothelium by thrombin-thrombomodulin endothelial protein C receptor (EPCR). Thrombin thrombomodulin complex is a potent activator of protein C.

Anticoagulant Protein S System

Protein S is a vitamin K-dependent natural anticoagulant present in circulation. It is synthesized in the liver, endothelial cells and megakaryocytes. About 60% of protein S is complexed to C4b binding protein. Only unbound or free protein S is physiologically active. Protein S serves as a cofactor for protein C and enhances its activity of protein C resulting in inhibition of factors V and VIII. Protein S does not require activation.

Fibrinolytic System

The fibrinolytic system is a highly regulated enzymatic process that functions to remove the fibrin clot after the vasculature is repaired, as well as to degrade fibrin clots that form in the blood circulation. The final step in fibrinolytic pathway is the plasminogen-plasmin-mediated cleavage of fibrin creating fibrin degradation products (FDPs).

- Plasminogen is normally present in blood circulation in an inactive form. Plasminogen is activated by tissue-type plasminogen activator (tPA) and urokinase-type plasminogen activator (uPA).
- Urokinase-type plasminogen activator (uPA) is a serine protease that binds to its receptor (uPAR) and catalyzes the conversion of plasminogen into plasmin and activates signaling pathways leading to promote cell migration, proliferation, and survival.
- Tissue-type plasminogen activator (tPA) is synthesized by vascular endothelium in response to thrombin, shear stress and venous occlusion. Tissue-type plasminogen activator is considered the major intravascular activator of plasminogen.

- Tissue-type plasminogen activator converts plasminogen (inactive form) to plasmin (active form) that binds to specific receptors on fibrin strands network and begins degrading the fibrin strands resulting in dissolution of blood clot. Plasmin also degrades fibrinogen, factor V, factor VIII, prothrombin, and factor XII.
- Circulating plasmin is rapidly inactivated by plasmin inhibitor, which limits the fibrinolytic process in the blood clot and prevents it from occurring in the entire circulation.
- Many tissue-type plasminogen activators (alteplase, reteplase, tenecteplase), prepared by recombinant DNA technology, are now available for use in treatment of acute myocardial infarction, acute ischemic stroke, and pulmonary embolism.

HEMOSTASIS: STAGES

The mechanism of hemostasis can be divided into various stages: vascular constriction, formation of a temporary 'platelet plug', activation of the coagulation cascade, thrombin generation and formation of 'fibrin plug'.

- Binding of thrombin to platelet surface receptors along with adenosine diphosphate (ADP) and thromboxane A_2 cause further platelet aggregation. ADP produces conformational changes of the platelets surface GpIIb–IIIa receptors, to which noncleaved fibrinogen binds. Fibrinogen bridges by binding to aggregated platelets together resulting in formation of secondary hemostatic plug. The platelet hemostatic plug is stabilized by polymerized fibrin mesh.
- Hemostasis facilitates formation of blood clot with platelets and fibrin polymer. The blood clot seals the injured blood vessels in the area and prevents further bleeding so that tissue regeneration process takes place. Once the tissue injury starts to heal, the platelets and fibrin polymer plug remodel and get dissolved resulting in restoration of normal tissue at the site of the tissue damage.

PRIMARY HEMOSTASIS (PLATELET HEMOSTATIC PLUG FORMATION)

Hemostasis is a stepwise process for stoppage of bleeding by sequentially vasoconstriction of the blood vessel, formation of a primary hemostatic platelet plug and development of a blood clot.

- Blood clotting process requires the presence of platelets produced by bone marrow, von Willebrand factor generated by the vascular endothelium, and clotting factors synthesized in the liver, using vitamin K.
- Within seconds of vascular injury, von Willebrand factor (vWF) is released by endothelium that binds to platelet receptors. This phenomenon is responsible for adhesion of platelets to the exposed subendothelial collagen fibers.
- Platelets undergo morphologic changes (disc shape to spherical shape) and activation leading to release of adenosine diphosphate (ADP), thromboxane A_2 (TXA_2), serotonin, and epinephrine. ADP and TXA_2 attract additional platelets leading to platelet aggregation. Platelet factor 3, a surface phospholipid accelerates clotting by formation of thrombin.
- Blood clot retraction and its dissolution also play significant role in hemostasis. These processes involve the interaction of substrates, enzymes, protein cofactors released from platelets and vascular endothelium, and calcium ions in the blood.

Transient Vasoconstriction of Microvasculature

Following vascular endothelial injury, there is immediate transient vasoconstriction of adjacent microvasculature via neural stimulation reflex and endothelin chemical mediator released from damaged vascular endothelial cells and release of thromboxane A_2 by platelets. This reduces the blood flow into the damaged area that allows contact activation of platelets. Neural reflex and thromboxane A_2-mediated vasoconstriction in an injured blood vessel is given in Fig. 3.16.

- Vasoconstriction effect is temporary and needs to be supplemented by aggregation of platelets and blood coagulation factors to maintain permanent hemostasis of the injured blood vessels.

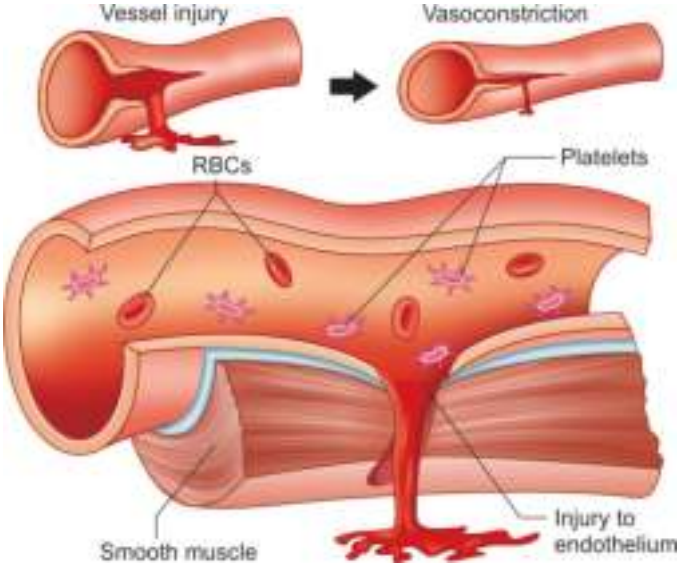

Fig. 3.16: Neural reflex and thromboxane A_2-mediated vasoconstriction in an injured blood vessel. Vasoconstriction of blood vessel occurs due to neural reflex and release of thromboxane A_2 by platelets resulting in reduction of blood flow.

- Patient with genetic deficiency of von Willebrand factor (vWF) or platelet-surface glycoprotein receptors (GpIb) results in defective platelet adhesion and bleeding tendencies, known as **Bernard-Soulier syndrome**.

Platelet Adhesion to Exposed Subendothelial Collagen

Within seconds of tissue injury, endothelial injury exposes subendothelial collagen or noncollagenous microfibrils resulting in platelets adhesion to the subendothelial surface. The von Willebrand factor (vWF) released from Weibel-Palade bodies of the endothelial cells and α-granules of platelets, binds to the platelet-surface GpIb glycoprotein receptors resulting in platelets adhesion to the exposed subendothelial collagen fibers of damaged blood vessels.

Platelets Release Reaction (Secretion)

Subendothelial collagen exposure and local thrombin generation results in release of platelet α-granule contents such as adenosine diphosphate (ADP), serotonin, calcium (Ca^{++}) and fibrinogen, further enhances platelet activation, chemotaxis of additional circulating platelets, platelet aggregation and platelet plug formation.

- Activated platelets stick to each other via bridges formed by the binding of fibrinogen, fibrin or vWF to activated aIIbβ3 integrin.
- The platelet hemostatic plug is extended as additional platelets are activated via the release (secretion) of thromboxane A_2 (TXA_2) generated from arachidonic acid through cyclooxygenase pathway.

Platelet Agonists

Agonist is a substance, which initiates a physiologic response when combined with a receptor. Agonists promoting platelet aggregation, include ADP, thromboxane A_2, epinephrine, collagen, platelet activating factor (PAF) derived from mast cells and basophils. Platelet-derived agonists and their receptors are given in Table 3.10.

- Platelet agonist thromboxane A_2 causes vasoconstriction and promotes platelet aggregation by activating guanyl cyclase, which increases intracellular levels of cGMP. The inhibition of cyclooxygenase pathway by low-dose aspirin is the basis of aspirin therapy for prevention of thrombotic disease.
- Platelet agonists bind to **P2Y12 receptor** (G protein-coupled receptor) on the platelet surface induce GpIIb/GpIIIa expression at platelet surface and induction of signal and conformational and morphologic changes of platelet from a disc shape to a spherical shape.
- Conformational and morphological changes are followed by constriction of the microtubules and releasing contents of the granules (primarily ADP, catecholamine, serotonin and PDGF) into the open canalicular system.
- Pseudopodia develop on the surface of platelet, which contain a network of actin and myosin. The microtubule circumferentially contracts resulting in activation of phospholipids and glycoprotein IIb/IIIa receptors. Internal biochemical changes occur in the platelets resulting in granule secretion.

Table 3.10 Platelet-derived agonists and their receptors

Platelet-derived Agonist	Agonist Receptors
Adenosine diphosphate (ADP)	▪ P2Y1 receptor ▪ P2Y2 receptor
Serotonin	5-HT2 receptor
Platelet activating factor (PAF)	PAF receptor
Thromboxane A_2	TP receptor

Agonist is a substance, which initiates a physiological response when combined with a receptor.

Platelet Aggregation Inhibitors

Prostacyclin (PGI_2) synthesized in the vascular endothelium is a potent vasodilator, which prevents platelet aggregation. TXA_2 causes vasoconstriction and promotes platelet aggregation. Both prostacyclin and TXA_2 perform balanced function for modulating platelet function. In hemostasis, fibrinolysis and fibrin degradation products (FDPs), compete with fibrinogen for binding to platelet membrane and interfere with platelet aggregation. Fibrin degradation products attract leukocytes (neutrophils and monocytes).

Pathology Pearls: Platelet Activation

- Platelet activation *in vivo* can be part of the hemostatic response to vascular injury or a pathologic response to drugs or disease.
- Collagen, thrombin, and ADP are critical platelet agonists, causing granule exocytosis, activation of the aIIbβ3 integrin, and platelet aggregation.
- Once platelet aggregation begins, the close proximity of the adjacent platelets allows contact-dependent and contact facilitated interactions that promote growth and stability of the platelet mass.
- Achieving a platelet hemostatic plug that is large enough to be stable but small enough to avoid vascular occlusion is the result of tight regulation of initial intracellular signaling events and the presence of molecules on the platelet surface that help limit the extent of platelet activation.
- Platelet receptors and signaling events have provided targets for the development of antiplatelet agents, which are in widespread clinical use. It is reasonable to expect that new discoveries in the basic science of platelets will lead to the identification of new targets and new approaches to the manipulation of platelet behavior *in vivo*.

Hematology Pearls: Platelet Plug Formation (Primary Hemostasis)

Resting platelets maintain low levels of cytoplasmic calcium via uptake by dense tubular system (DTH) and active extrusion, probably via a calcium pump. These mechanisms oppose a passive diffusion of intracellular calcium. With platelet activation, platelets increase intracellular cytoplasmic calcium due to release of calcium from the dense tubular system and increase in calcium influx. Formation of primary platelet plug is shown in Figs 3.17 and 3.18.

- Platelet agonists such as adenosine diphosphate (ADP) and thromboxane A_2 released from platelets, play important role in platelet aggregation and initial hemostatic platelet plug formation, that stops bleeding.
- Platelet agonist in the presence of calcium stimulates high-affinity fibrinogen receptors to bind activated glycoprotein IIb/IIIa on the surface of platelet and linked platelets. Fibrinogen binds horizontally to two platelets by peptide sequences at the terminal end of its γ-chain and α-chain in the D domains, one γ-chain to GpIIb receptors of each platelet.
- Fibrinogen, thus becomes a bridge between the two platelets. Initial platelet hemostatic plug is reversible, unstable and easily dislodged, when ADP release is minimal. It is worth mentioning that PGI_2 and nitric oxide (NO) released from vascular endothelial cells inhibit platelet aggregation.
- Leukocytes and RBCs are also present in hemostatic plug. Leukocytes adhere to vascular endothelium and produce inflammatory response.

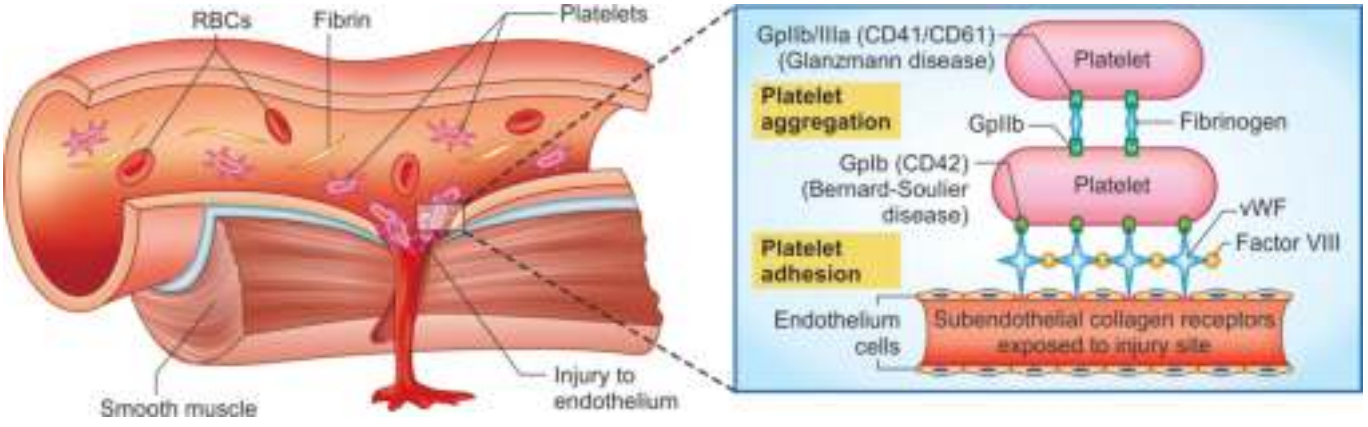

Fig. 3.17: Formation of primary platelet plug. Platelets adhere to be exposed collagen fibers due to binding of von Willebrand factor to platelet receptors. Activated platelets release ADP and TXA_2 resulting in attraction of additional platelets and aggregation.

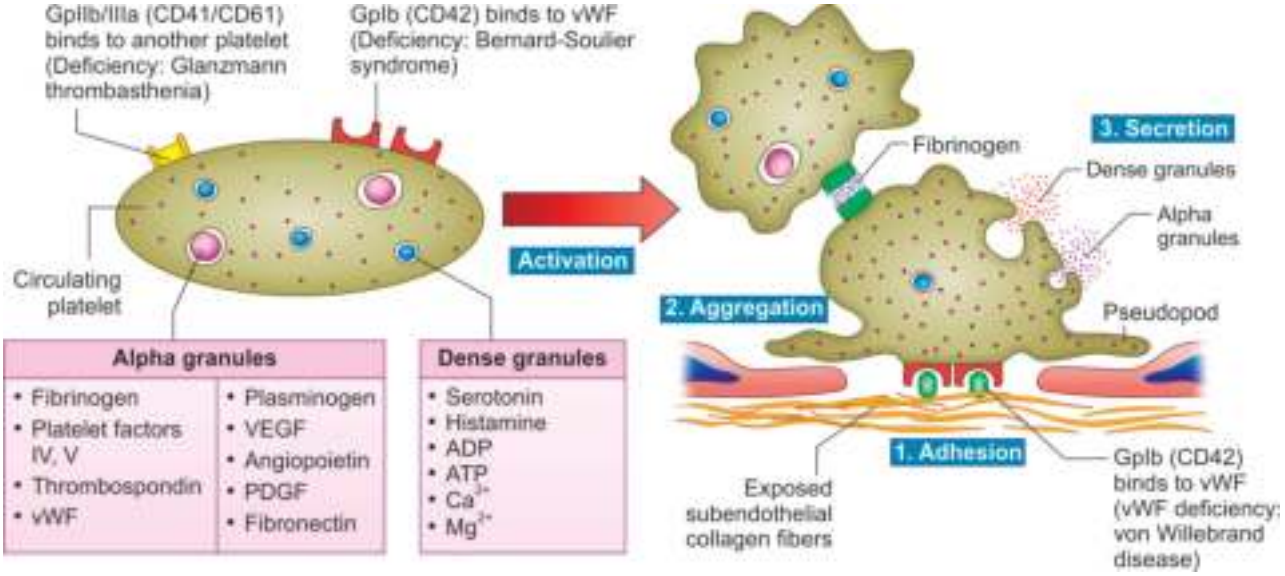

Fig. 3.18: Formation of platelet hemostatic plug. Platelet activation involves three overlapping mechanisms. (a) Adhesion of platelets to the exposed subendothelium is mediated by the binding of von Willebrand factor (vWF) to glycoprotein, i.e. GpIb/IX (CD42) resulting in initiation of signal for activation of platelets, (b) Exposure of GpIIb/IIIa (CD41/61) to the fibrinogen receptor on the platelet surface permits for platelet aggregation, (c) At the same time, platelets synthesize their granule contents, which facilitate further activation.

SECONDARY HEMOSTASIS (STABLE HEMOSTATIC PLUG FORMATION)

Finally, close contact between platelets in the growing platelet plug, along with a fibrin meshwork help to perpetuate and stabilize the platelet plug. Formation of stable hemostatic plug is shown in Figs 3.19 and 3.20.

- Coagulation system cascade results in formation of insoluble polymerized fibrin mesh. Secondary hemostasis refers to the coagulation system cascade of enzymatic reactions that ultimately leads to the conversion of fibrinogen to fibrin monomers. Fibrin monomers are then cross-linked into insoluble polymerized fibrin strands that serve to stabilize the loose platelet hemostatic plug formed in primary hemostasis. Vascular injury activates intrinsic and extrinsic pathways of coagulation system. Intrinsic pathway of coagulation begins in blood circulation by activation of circulating factor XII. Extrinsic pathway of coagulation system is activated by cellular lipoprotein known as tissue factor including platelet phospholipids.

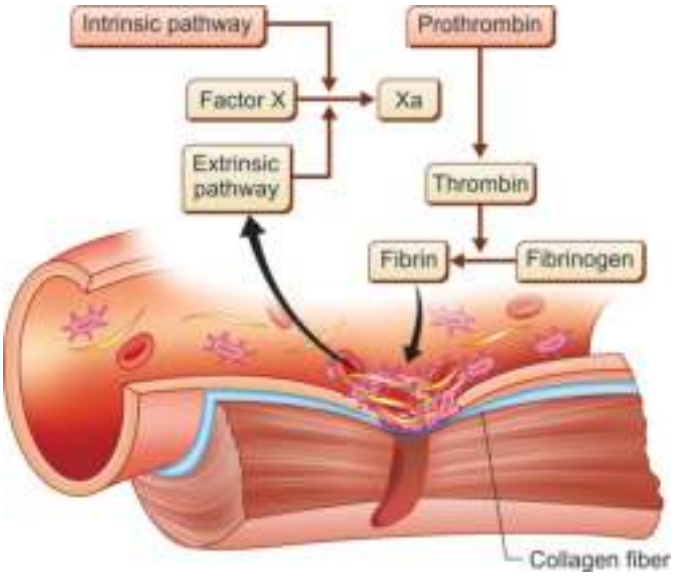

Fig. 3.19: Formation of stable hemostatic fibrin plug. Blood coagulation occurs by intrinsic and extrinsic pathways as a result of vascular injury. Both these coagulation pathways lead to activation of factor X, conversion of prothrombin to thrombin. Thrombin converts fibrinogen to fibrin. Fibrin stabilizing factor stabilizes fibrin leading to holding of clot by insoluble fibrin strands.

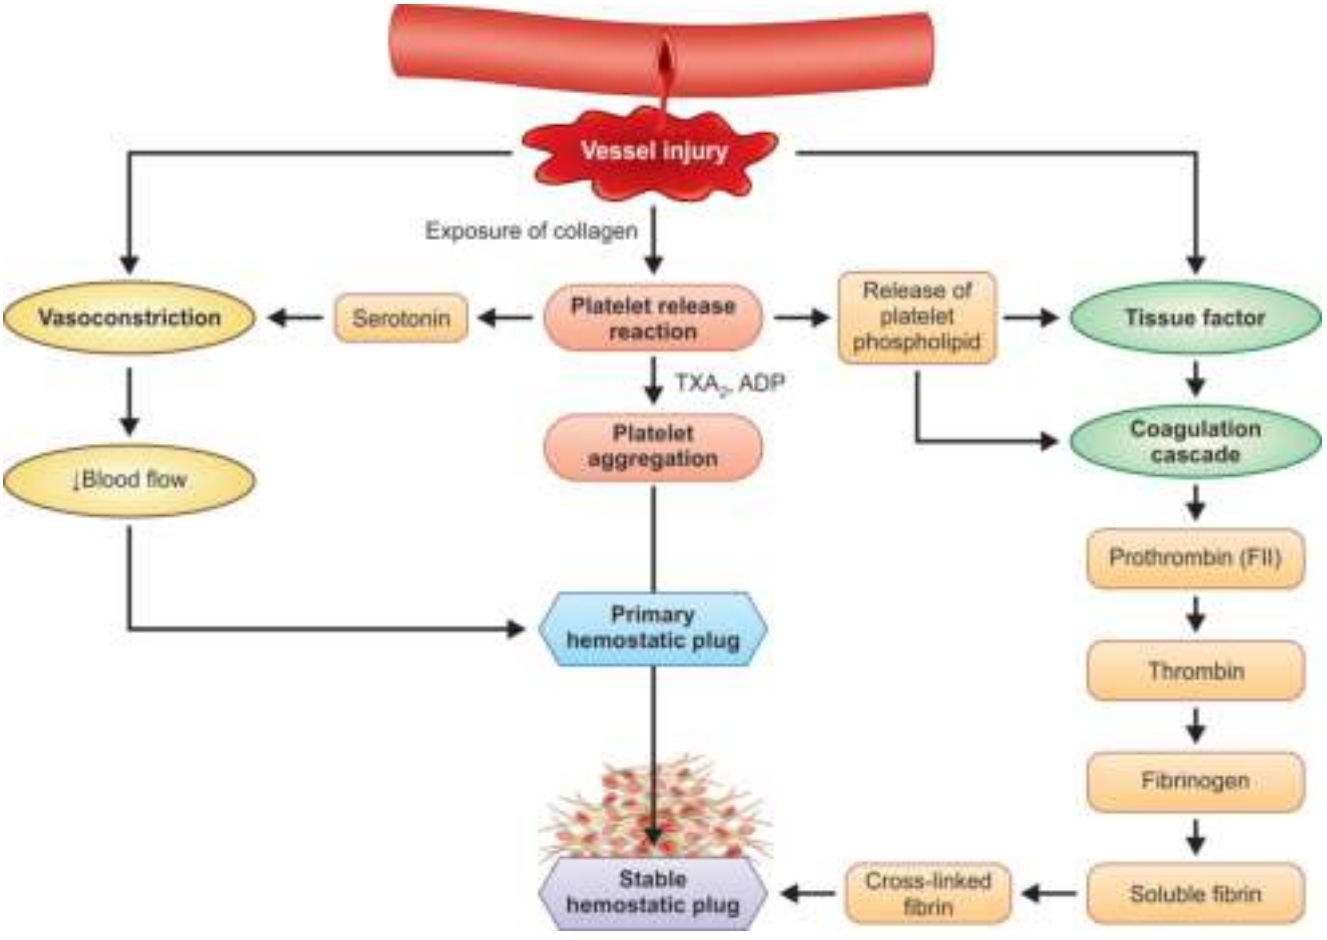

Fig. 3.20: Formation of stable hemostatic fibrin plug. During primary hemostasis, after vasoconstriction, platelets adhere and aggregate to form a platelet hemostatic plug around the site of injury. Then in the secondary hemostasis, platelet hemostatic is reinforced by a protein mesh made up of polymerized cross-linked fibrin.

- Calcium, factor X, factor V, platelet phospholipids combine to form prothrombin activator, which then converts prothrombin to thrombin. The terminal steps in both intrinsic and extrinsic pathways of coagulation system are same.
- Thrombin converts fibrinogen to fibrin strands stabilized by fibrin stabilizing factor (factor XIII) that create the secondary hemostatic stable plug of insoluble polymerized fibrin strands, blood clot, with platelets and red blood cells resulting in stoppage of bleeding.
- Binding of thrombin to platelet surface receptors along with adenosine diphosphate (ADP) and thromboxane A_2 (TXA_2) cause further platelet aggregation resulting in formation of stable hemostatic plug.
  - ADP produces conformational changes of the platelets surface GpIIb–IIIa receptors, to which noncleaved fibrinogen binds.
  - Cross-linking of fibrin by fibrin stabilizing factor XIII holds the blood clot and results in activation of platelets and fibrinolytic pathways. Plasmin dissolves fibrin strands in the course of wound healing.
  - Additionally, thrombin interacts with nonhemostatic systems to promote cellular chemotaxis, fibroblast growth factor and wound healing and tissue repair.
- Vascular endothelium also undergoes a series of changes moving from its resting phase with predominantly anticoagulant properties to a more active procoagulant properties.

BLOOD CLOT RETRACTION

Blood clot retraction occurs within 20–60 minutes after a blood clot is formed, which contributes to hemostasis. Activated platelets contract their internal actin and myosin fibrils in their cytoskeleton leading to shrinkage of the blood clot volume. Actin and myosin in the cytoskeleton of activated platelets that are trapped in the blood clot, contract and pull the blood clot towards platelets. This phenomenon causes squeezing serum from the blood clot leading to shrinkage of blood clot. Blood clot retraction requires large numbers of platelets, and failure of blood clot retraction is indicative of a low-platelet count. Blood clot retraction is shown in Fig. 3.21.

BLOOD CLOT DISSOLUTION (THROMBOLYSIS)

Blood clot dissolution (thrombolysis) begins immediately after blood clot formation. This allows blood flow to be reestablished and permanent blood vessel repair to take place. The process by which a blood clot dissolves is known as **fibrinolysis**. Blood clot dissolution requires a sequence of steps controlled by plasminogen activators and inhibitors. Blood clot dissolution or lysis is shown in Fig. 3.22.

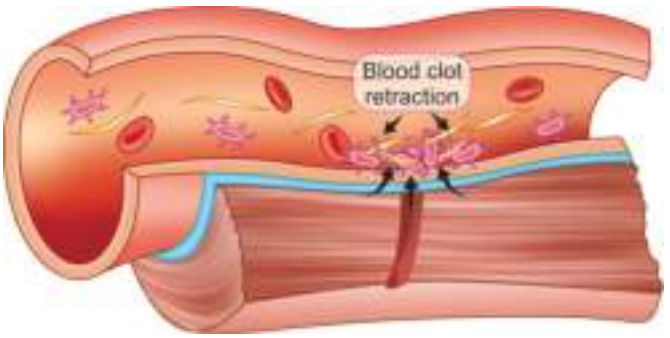

Fig. 3.21: Blood clot retraction. Within a few minutes after a blood clot is formed at injured site, actin and myosin in the platelets that are trapped in the blood clot begins to contract. As a result, fibrin strands of the blood clot are pulled towards the platelets, thereby squeezing serum (plasma without fibrinogen) from the blood clot and causing it to shrink to become smaller.

- Plasminogen activators such as tissue plasminogen activator (tPA) and urokinase plasminogen activator (uPA) circulate in the plasma as a reversible complex with plasminogen activator inhibitor 1 (PAI-1).
  - When the fibrin clot is formed, tPA and uPA bind to the fibrin clot and convert plasminogen to plasmin.
  - Then elastase, cathepsin G and uPA derived from neutrophils, monocytes/macrophages, and high shear stress including plasmin result in lysis of the cross-linked fibrin into fibrin degradation products (FDPs).

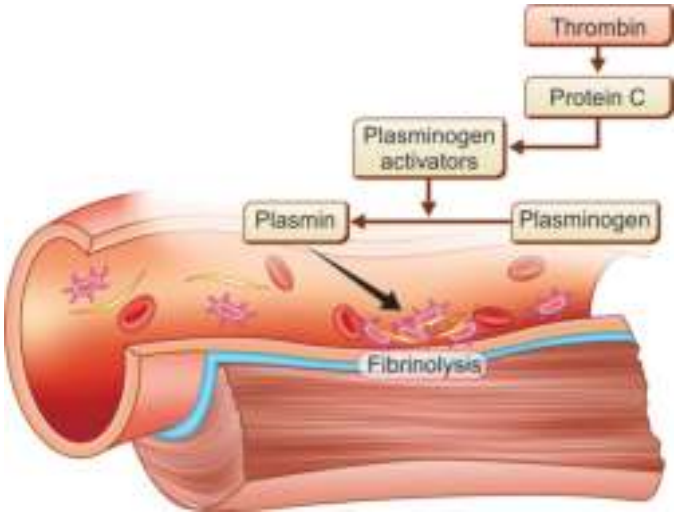

Fig. 3.22: Blood clot dissolution (thrombolysis). Blood clot dissolution begins immediately after a blood clot is formed. This process begins with activation of plasminogen, an inactive precursor of the proteolytic enzyme, and plasmin. After the formation of blood clot, large amounts of plasminogen are trapped in the blood clot. tPA released from injured tissues and vascular endothelium converts plasminogen to plasmin. Plasmin digests the fibrin strands, causing the clot to dissolve.

- To binding of plasminogen activator inhibitor 1 (PAI-1) fibrin can irreversibly inhibit plasminogen activators.

- Blood clot dissolution (thrombolysis) is inhibited by release of plasminogen activator inhibitor 1 (PAI-1) by platelets; and elastase and cathepsin G from white blood cells that become trapped on the thrombus, which directly breakdown fibrin; the plasminogen activation by tissue plasminogen activator (tPA) and urinary plasminogen activator (uPA). The thickness and porosity of fibrin fibers also determines structural stability and susceptibility to thrombolysis. Lp(a), a homologue of plasminogen that can inhibit tPA-mediated plasminogen activation.

Clinical Pearls: Recombinant Tissue Plasminogen Activator (tPA) used in Clinical Practice

- Tissue plasminogen activator functions by catalyzing the conversion of plasminogen to plasmin, the primary enzyme involved in dissolving blood clots.
- Recombinant biotechnology has allowed to manufacture tissue plasminogen activator such as alteplase, reteplase and teneplase in the laboratories.
- Recombinant tissue plasminogen activators are administered in ischemic cerebral stroke within 3 hours of onset, and myocardial infarction. If there is delay of more than 1 to 2 hours before percutaneous transluminal coronary angioplasty, severe pulmonary thromboembolism causing severe instability due to pressure in heart, and deep vein thrombosis (DVT).

HEMORRHAGIC DISORDERS

Spontaneous bleeding can be caused by primary or secondary structural defects in the blood vessel wall, platelet disorders, coagulation disorders. Three most common hereditary bleeding disorders are hemophilia A (factor VIII) deficiency, hemophilia B (factor IX deficiency) and von Willebrand disease. Causes of inherited and acquired abnormalities of hemostasis are given in Table 3.11.

Table 3.11 Causes of inherited and acquired abnormalities of hemostasis

Inherited Abnormalities of Secondary Hemostasis		
Hemophilia A	▪ X-linked recessive disorder ▪ Decreased or depletion of coagulation factor VIII deficiency ▪ Activated partial thromboplastin time (APTT) prolonged	▪ Severity and risk of bleeding depend on severity of deficiency of factor VIII ▪ About 5–20% of patients develop inhibitors of factor VIII due to treatment
Hemophilia B	▪ X-linked recessive disorder ▪ Decreased or depletion of coagulation factor IX	▪ An activated partial thromboplastin time (APTT) prolonged ▪ About 1–3% of patients develop inhibitors to factor IX due to treatment
Hemophilia C	▪ Decreased or depletion of coagulation factor XI ▪ Autosomal recessive disorder	▪ Common in Ashkenazi Jews ▪ 1:8 Heterozygotes ▪ 1:90 Homozygotes
Afibrinogenemia	▪ Complete absence of fibrinogen–homozygous gene mutation ▪ Prothrombin time and international normalized ratio (PT–INR) prolonged	▪ Activated partial thromboplastin time (APTT) prolonged ▪ Thrombin time (TT) prolonged ▪ Some patients have severe bleeding with minor challenges than hemophiliacs
Hypofibrinogenemia	▪ Patient has fibrinogen level 50% of normal level–heterozygous gene mutation with mild bleeding ▪ Thrombin time (TT) prolonged	▪ Activated partial thromboplastin time (APTT) prolonged ▪ Prothrombin time and international normalized ratio (PT–INR) prolonged
Dysfibrinogenemia—structural abnormality	▪ Structural abnormality of fibrinogen–usually heterozygous state ▪ About 50% of patients have no clinical bleeding, 25% of cases with clinical bleeding; and 25% of cases develop thrombosis	▪ Prothrombin time normal ▪ Activated partial thromboplastin time (APTT) normal ▪ Thrombin time (TT) prolonged ▪ Fibrinogen levels variable
von Willebrand disease (some cases)	Decreased vWF leads to decreased stability and function of factor VIII	

Contd...

Table 3.11 Causes of inherited and acquired abnormalities of hemostasis (*Contd...*)

Acquired Abnormalities of Secondary Hemostasis	
Vitamin K deficiency	Impaired synthesis of coagulation factors II, VII, IX and X; and natural anticoagulant protein C and protein S
Liver disease	Impaired synthesis of coagulation factors I, II, V, VIII, IX, X, XI; and natural anticoagulant protein C, protein S and antithrombin C
Disseminated intravascular coagulation (DIC)	Multiple coagulation factors deficiencies especially fibrinogen depletion; as well as thrombocytopenia
Nephrotic syndrome	Loss of antithrombin III and antiplasmin in urine along with massive proteinuria
Multiple myeloma and amyloidosis	Consumption of coagulation factor X
Direct oral administration of anticoagulants for therapeutic purpose	Oral anticoagulants antagonize thrombin

Table 3.12 Common clinical manifestations of hemorrhagic disorders

Organs	Clinical Manifestations	
Skin, mucosal or serosal surfaces	▪ Petechiae (pin-point sized lesions) ▪ Ecchymoses (bruises)	▪ Purpura (systemic disease characterized by numerous petechiae and ecchymoses)
Gastrointestinal tract	▪ Hematemesis (blood in vomiting) ▪ Hematochezia (fresh blood in stool)	▪ Melena (blackened blood in the stool, caused by exposure of blood to hydrochloric acid in the gastric region)
Respiratory tract	▪ Epistaxis (nose bleeding)	▪ Hemoptysis (expectoration of blood)
Genitourinary tract	▪ Metrorrhagia (excessive uterine bleeding)	▪ Hematuria (blood in the urine)

- Patients suffering from hemorrhagic disorders often present with only mild bleeding due to traumatic injuries or surgical procedures. However, some patients have life-threatening bleeding. Blood can be released from the circulation to the exterior of the body or into surrounding tissues, hollow organs or body cavities. Common clinical manifestations of hemorrhagic disorders are given in Table 3.12.
- Simple screening tests can be performed to find out the cause of the bleeding by taking family history that provides information whether the bleeding tendency is hereditary or acquired. Clinical examination can reveal the type of bleeding. Platelet count can be done to exclude thrombocytopenia. Coagulation tests, such as prothrombin time and international normalized ratio (PT–INR) and activated partial thromboplastin time (APTT) can supplement initial information concerning deficiency states of coagulation disorders. Bleeding time is often prolonged in patients suffering from von Willebrand disease, thrombocytopenia or thrombocytopathy. Further testing of platelets and coagulation factors is required in tertiary hospitals.

DEFECTS IN HEMOSTASIS

Defects in hemostasis lead to susceptibility to bleeding (also known as hemorrhagic diathesis). Bleeding may result from abnormalities in platelets, coagulation factors and blood vessels.

- Bleeding diathesis is classified into disorders of primary hemostasis caused by platelet abnormality, and secondary hemostasis caused by defects in the extrinsic and/or intrinsic and common pathways of coagulation system cascade, and hyperfibrinolysis (when there is increased clot degradation).
- Although clinical features may overlap. Mucocutaneous bleeding (e.g. petechiae, epistaxis and gastrointestinal bleeding) is associated with disorders of primary hemostasis. Bleeding into potential spaces (e.g. hemarthrosis and bleeding in skeletal muscles) is characteristic of disorders of secondary hemostasis.
- Diagnostic workup of a hemorrhagic diathesis begins with a detailed clinical history, family history, clinical examination, complete blood count, and a coagulation panel, which typically allows the bleeding disorder to be classified as one of primary or secondary hemostasis. Specialized studies are performed to determine the specific etiology of disorder so that treatment can be initiated.
- Treatment of hemorrhagic diathesis may include transfusion of blood products and replacement of specific coagulation factors or administration of adjuvant medications (e.g. desmopressin or tranexamic acid).

Pathology Pearls: Clinical Findings in Hemorrhagic Disorders

- **Erythema:** Erythema is an inflammatory redness of the skin.
- **Purpura:** Purpura is a diffuse superficial hemorrhage in the skin up to 1 cm in diameter.
- **Petechial hemorrhages:** Petechial hemorrhages are pinpoint hemorrhages occur in the skin, mucous membranes (conjunctiva), which represent the rupture of capillaries or arterioles and occur in conjunction with coagulopathies or vasculitis. In bacterial endocarditis, microemboli from infected cardiac valves may cause rupture of capillaries and arterioles results in pinpoint hemorrhages under nails known as Janeway's lesions.
- **Ecchymosis:** Ecchymosis is a larger diffuse superficial hemorrhage in the skin and subcutaneous tissue (a 'black and blue' mark). Following hemorrhage, skin shows purple discoloration, turning green and then yellow before resolution. These changes reflect progressive oxidation of bilirubin released from the hemoglobin of degraded erythrocytes. A 'black eye' is a good example of an ecchymosis.
- **Hematoma:** Hematoma is localized extravascular accumulation of clotted blood within a tissue or organ. Hemorrhage into skeletal muscles can be merely painful or fatal, if hematoma is located in the brain.
- **Hemorrhage in body cavities:** Hemorrhage refers to discharge of blood from the vascular compartment into the extravascular body spaces or to the exterior. Hemorrhage may occur in the pleural cavity, pericardial sac, peritoneal cavity or a synovial space. Cardiac tamponade occurs when the pressure in the pericardial sac rises to exceed the filling pressure of the heart.
- **Hemopericardium:** Pericardial fluid may accumulate rapidly, particularly with hemorrhage caused by a ruptured myocardial infarct, dissecting aortic aneurysm due to intimal tear, or trauma. Dissecting aortic aneurysm occurs due to weakening of the aortic media (cystic medial necrosis) or hypertension.
- **Hemarthrosis:** Bleeding into the joint cavity is known as hemarthrosis. It is most often caused by hemophilia. Repeated bleeding in joint cavity may cause deformities and may limit the mobility of the joints.
- **Hematemesis:** Hematemesis is presence of blood in vomitus. Massive hematemesis is a frequent cause of death in patients with esophageal varices in alcoholic cirrhosis, who has portal hypertension. Bleeding occurs due to increased intravascular hydrostatic pressure.
- **Hemoptysis:** Hemoptysis is coughing up blood.
- **Hematochezia:** Hematochezia is passage of bloody stools caused by lower gastrointestinal hemorrhage.
- **Hematobilia:** Hematobilia is bleeding into the biliary passages, a complication of trauma or neoplasia.
- **Hematocephalus:** Hematocephalus is an intracranial infusion of blood.
- **Melena:** Melena (black stool) is a symptom of upper gastrointestinal bleeding. Blood from ruptured esophageal varices or a peptic ulcer is partially digested by hydrochloric acid. Hemoglobin is transformed into a black pigment (hematin), which imparts a typical "coffee-grounds" color to the stool.

DEFECTS OF PRIMARY HEMOSTASIS (PLATELET DEFECTS AND VON WILLEBRAND DISEASE)

Hemostasis refers to the response to vascular injury that produces a platelet clot at the injured site. Primary hemostasis serves to immediately limit bleeding through the formation of a loose primary hemostatic platelet plug.

- Platelets play key role in primary hemostasis. Initial platelet adhesion, activation and aggregation upon tissue injury, stimulates coagulation factors and other potent mediators to achieve hemostasis. Defects in primary hemostasis are generally associated with mucocutaneous bleeding, characterized by epistaxis, ecchymosis, genitourinary bleeding or gingival bleeding. Platelet count and platelet function tests are performed to assess primary hemostasis.
- The von Willebrand factor (vWF) is an adhesive plasma glycoprotein, which performs its primary hemostatic functions through binding to factor VIII, platelets surface glycoproteins, and constituents of connective tissue. The vWF acts as a stabilizer of factor VIII in the blood circulation.
  - Defects in vWF concentration or activity are very common, affecting about 1% of the population. The von Willebrand disease is an inherited bleeding disorder in which the blood does not clot properly.
  - Patient presents with excessive bleeding from tissue injury or after surgery or dental procedure, epistaxis, hematuria, easy bruising, heavy menstrual bleeding and heavy bleeding during delivery and postpartum period.

DEFECTS OF SECONDARY HEMOSTASIS (COAGULATION FACTOR DEFECTS)

Secondary hemostasis is defined as the formation of insoluble, cross-linked fibrin by activated coagulation factors in coagulation system cascade, specifically thrombin. Fibrin stabilizes the primary platelet plug at the injury site, where the primary hemostatic platelet plug is insufficient alone to limit hemorrhage.

- The most common inherited defect of secondary hemostasis is hemophilia A (factor VIII deficiency). Failure to stabilize primary platelet plug results in hemorrhagic diathesis. Patient presents with hemarthrosis soft tissue bleeding, hematomas, or retroperitoneal bleeding in hemophilia A.

- Two screening tests are most often done in the initial assessment of secondary hemostasis. Both prothrombin time and international normalized ratio (PT–INR) and activated partial thromboplastin time (APTT) are performed on plasma separated from whole blood collected in test tube containing sodium citrate anticoagulant.

DEFECTS IN BLOOD VESSELS

Vascular bleeding disorders can result from primary or secondary defects in blood vessels, typically causing petechiae, purpura and bruising except hereditary hemorrhagic telangiectasia, which can cause serious blood loss. Vascular bleeding may occur in the setting of defects in vascular and perivascular collagen in Ehlers-Danlos syndrome, and hereditary connective tissue disorders (Marfan's syndrome, pseudoxanthoma and osteogenesis imperfecta). Vascular bleeding may be a prominent feature of scurvy, immunoglobulin A associated vasculitis during childhood. Tests of hemostasis are usually normal in vascular bleeding disorders.

Atherosclerotic Aneurysm Rupture

Atherosclerosis means hardening (sclerosis) or loss of elasticity of large elastic arteries and medium-sized arteries due to atheromatous plaque formation. Severe atherosclerosis may so weaken the wall of the abdominal aorta that it balloons to form an aneurysm, which may rupture and bleed into the retroperitoneal space. The atherosclerotic aneurysm may be demonstrated by ultrasonography and MRI.

Mycotic Aneurysm Rupture

Mycotic aneurysm occurs in the root of aortic arch and its descending branches, due to direct extension from aortic valve endocarditis. Emboli from infective endocarditis may involve cerebral blood vessels result in hemorrhage into the basal ganglia, extending into the subarachnoid space.

Berry Aneurysm Rupture

The most common site of berry aneurysm formation is between the anterior communicating and the anterior cerebral arteries in the circle of Willis.

- Berry aneurysm develops as saccular lesions (1.0–1.5) at site of congenital defects in smooth muscle of the arterial wall, which occurs in 10–15% of patients with adult polycystic kidney disease.
- Rupture of berry aneurysm causes subarachnoid hemorrhage. Patient presents with history of severe headache, nuchal rigidity from irritation of the meninges.

Aortic Dissection

Aortic dissection can occur due to systemic hypertension, atheromatous plaque, trauma to chest, pregnancy, Marfan's syndrome (missense mutations of the fibrillin gene 1 located on chromosome 15 causing defective cross linkage), Ehlers-Danlos syndrome (defective synthesis of procollagen fibers) and copper deficiency (cofactor in lysyl oxidase participating in collagen fibers). Aortic dissection rupture causes massive bleeding associated with fatal outcome.

Infections and Cancers

Certain infections (e.g. pulmonary tuberculosis) and invasive cancers may erode blood vessels and allow hemorrhage to occur. Malignant tumors that arise in organs (e.g. ovaries, gastrointestinal tract, or lung) adjacent to body cavities may shed cancer stem cells into these spaces, which invariably results in malignant effusion.

Capillary Fragility in Vitamin C Deficiency

Vitamin C deficiency is associated with capillary fragility and bleeding, owing to a defect in the supporting connective tissue structures. Vitamin C is essential for cross linkage of collagen fibrils gives structural stability to tropocollagen. Patient presents with bleeding diathesis (e.g. bleeding into skin and joints) and poor wound healing.

Traumatic Injury to Blood Vessels

Hemorrhage occurs depending on the severity of traumatic injury. Damage to the large blood elastic vessels or heart causes massive hemorrhage associated with fatal outcome. Blunt trauma to capillaries causes ecchymosis.

Bleeding and Coagulation Disorders

Severe decrease in the number of platelets (thrombocytopenia) or a deficiency of a coagulation factor (e.g. factor VIII in hemophilia A) is associated with spontaneous hemorrhage into various parts of the body without apparent injury.

Gastrointestinal Tract Disorders

A person may exsanguinate into an internal cavity, as in gastrointestinal hemorrhage from a peptic ulcer disease (arterial hemorrhage) or esophageal varices (venous hemorrhage). In such cases, fresh blood may fill the entire gastrointestinal tract. Bleeding into a serous cavity can also result in the accumulation of a large amount of blood, even to the point of exsanguination.

THROMBOSIS

Thrombosis is intravascular coagulation of blood, often causing significant interruption of blood flow. A thrombus is blood clot formed from constituents of blood (coagulation factors, platelets, red blood cells) in the circulatory system (blood vessels, cardiac chambers and valvular cusps) during life. Most important factor in thrombus formation is vascular endothelial injury. Alterations of blood flow (turbulence blood flow) and hypercoagulability of blood also play a role in thrombus formation. Size and shape of thrombus depends on its site of origin in veins or an artery. Virchow's triad contributing to thrombosis is shown in Fig. 3.23.

- Thrombus is attached to the site of its formation and remains there, and interrupting blood flow to organs due to partial or complete occlusion of blood vessels.
- Hemostasis is a physiologic phenomenon, whereas thrombosis is usually a pathologic phenomenon that precedes embolism with serious complications. However, embolism may have antecedent causes other than thrombosis.
- Thromboembolism remains a leading cause of mortality and disability. Thrombi may partially or completely obstruct arteries or veins leading to local ischemic complications.
  - Thromboembolic phenomenon can be life-threatening by causing myocardial infarction, cerebrovascular infarction and pulmonary embolism.
  - Embolus is intravascular solid, liquid or gaseous mass carried in the blood from its origin and lodged in another site.
  - Infarct is localized area of ischemic tissue necrosis generally caused by an impaired blood supply.

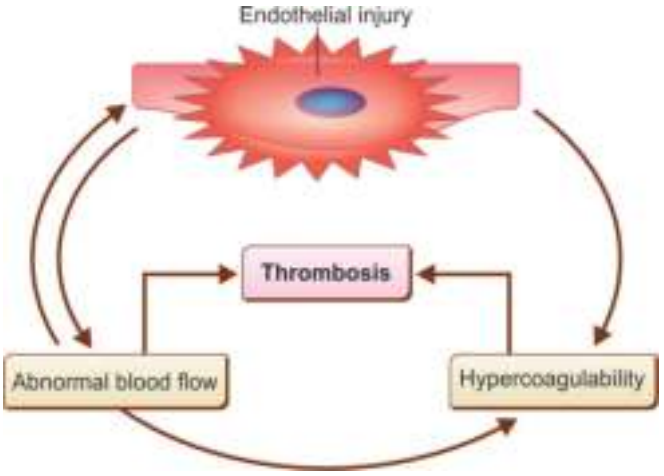

Fig. 3.23: Virchow's triad contributing to thrombosis. Three factors of Virchow's triad include endothelial injury, stasis of blood flow, the presence of hypercoagulable state. It is named after the renowned German physician Rudolf Virchow (1821–1902). Thrombus is a solid mass of blood formed within the cardiovascular system involving the interaction of endothelial cells, platelets and the coagulation cascade.

- A thrombus is the final product of the blood coagulation step in hemostasis, which occurs in cardiovascular system leading to obstruction of blood flow. A blood clot is formation of semi-solid mass in blood vessels that helps control bleeding.

THROMBOGENESIS

Thrombosis occurs when there is a breakdown in the balance between thrombogenic factors and protective antithrombogenic factors. Thrombogenesis results from the interaction of platelets, damaged vascular endothelial cells, and the vascular coagulation system cascade. Intravascular thrombogenesis is influenced by a complex interplay of procoagulant, anticoagulant and fibrinolytic factors.

VASCULAR ENDOTHELIAL INJURY

Vascular endothelial cells line the entire circulatory system, from the heart to the smallest capillaries. Vascular endothelium forms a barrier between platelets and plasma clotting factors and the subendothelial connective tissue. In normal health, vascular endothelium inhibits platelet aggregation and coagulation cascade including protein C and protein S pathway, thus plays a crucial role in providing the proper hemostatic balance.

- Vascular endothelium controls coagulation system by regulating the expression of binding sites for anticoagulant factors (i.e. prostacyclin, ADPase, heparin-like molecules, thrombomodulin) and procoagulant factors (i.e. von Willebrand factor, tissue factor, plasminogen activator inhibitors including platelet adhesion molecules inducing platelet adhesion) on the endothelial cell surface.
- Vascular endothelial damage can be caused by hemodynamic forces, hyperlipidemia, cigarette smoke, immune complex, bacterial toxins, irradiation, direct trauma and various mutagens.
- Vascular endothelial injury favors thrombus formation through disruption of normal laminar flow and coordinated induction of procoagulant and suppression of anticoagulant mechanisms.

Increased Synthesis of Procoagulant Molecules

Vascular endothelial injury upregulates procoagulant molecules (i.e. von Willebrand factor, tissue factor, plasminogen activator inhibitors including platelet adhesion molecules). Increased expression of platelet adhesion molecules enhances adhesion of platelets on injured vascular endothelium. Tissue factor activates coagulation system. Plasminogen activator inhibitors inhibit fibrinolytic system. Tumor necrosis factor

suppresses synthesis of thrombomodulin, vascular endothelial anticoagulant cofactor, and induced the expression of tissue factor, which is a procoagulant cofactor.

Decreased Synthesis of Anticoagulant Molecules

Vascular endothelial injury downregulates anticoagulant molecules such prostacyclin (PGI_2), nitric oxide, adenosine diphosphatase enzyme, heparin-like molecules and thrombomodulin. Prostacyclin and nitric oxide (NO), potent inhibitors of platelets. Loss of prostacyclin and nitric oxide promotes platelets aggregation. Loss of adenosine diphosphatase enzyme is not able to degrade adenosine diphosphate (ADP) that results in platelets aggregation. Loss of heparin-like molecules and thrombomodulin activate coagulation system.

ALTERATIONS OF BLOOD FLOW

Blood flow within cardiovascular system can be either laminar (physiologic state) or turbulent (pathologic state). Laminar blood flow is smooth constant, and streamlined, whereas turbulent blood flow is irregular and chaotic. In laminar blood flow, platelets circulate in central column separated from subendothelial collagen by plasma. Laminar blood flow dilutes clotting factors by fresh blood. Laminar blood flow increases the inflow of inhibitors of clotting factors, and inhibits vascular endothelial cell activation.

- Blood vessel wall damage due to atherosclerosis, hypertension or vascular anomalies is a major predisposing factor for arterial thrombosis, by inducing turbulent blood flow, which allows platelets adhesion to injured vascular endothelium. Consequently, hyperactivity of platelets also plays a role in the pathogenesis of **thrombus formation** within arteries, veins and cardiac chambers. Both arterial and venous thrombosis can reduce or totally impede blood flow.
- Turbulent blood flow disrupts laminar blood flow bringing platelets in contact with vascular endothelium. Turbulent blood flow prevents dilution of clotting factors by fresh flowing blood and retards inflow of clotting factors inhibitors resulting in buildup thrombi. Turbulent blood flow promotes vascular endothelial cell activation resulting in thrombus formation and leukocytic adhesion.

ROLE OF PLATELETS

Platelets are essential in the initial stages of thrombus formation, because they adhere and aggregate at the site of exposed subendothelial extracellular matrix in injured blood vessel and then serve as a surface for coagulation system cascade, the overall rate which determined the final structure of fibrin.

- Following severe injury to vascular endothelium, platelets adhere to exposed subendothelial extracellular matrix, which is mediated by von Willebrand factor (vWF). Soon after platelet adhesion; platelets release adenosine diphosphate (ADP), catecholamine, serotonin and platelet-derived growth factor (PDGF) into the open canalicular system.
- Platelet aggregation is promoted by ADP, thromboxane A_2, epinephrine, collagen, and platelet activating factor (PAF) derived from mast cells and basophils. Then integrin, glycoprotein IIb/IIIa becomes receptor for fibrinogen, which forms bridges between adjacent platelets leading to formation of initial reversible hemostatic platelet plug, when ADP release is minimal.
- On the surface of stimulated platelets, coagulation system cascade is accelerated that stabilize primary hemostatic platelet plug by polymerized fibrin leading to generation of thrombus.

Clinical Pearls: Agonists, Promoters and Inhibitors of Platelets Aggregation

Agonists Promoting Platelets Aggregation

- **Platelets aggregation:** Platelets aggregation is promoted by ADP, thromboxane A_2, epinephrine, collagen, platelet activating factor derived from mast cells and basophils.
- **Thromboxane A_2:** Thromboxane A_2 is generated from arachidonic acid through cyclooxygenase pathway. Thromboxane A_2 causes vasoconstriction and promotes aggregation of platelets by activating guanyl cyclase, which increases intracellular levels of cGMP. The inhibition of cyclooxygenase by low-dose aspirin is the basis of aspirin therapy for prevention of thrombotic disease.

Inhibitors of Platelets Aggregation

- **Prostacyclin:** Prostacyclin (PGI_2) synthesized by endothelium is a potent vasodilator and prevents platelet aggregation. TXA_2 causes vasoconstriction and promotes platelets aggregation. Both prostacyclin and TXA_2 perform balanced function for modulating platelets function.
- **Fibrin degradation products:** Under physiologic state, intravascular platelets aggregation is also prevented by fibrin degradation products, but after vascular endothelial injury, hemostatic plug is formed. Leukocytes and RBCs are also present in hemostatic plug. Leukocytes adhere to endothelium and produce inflammatory response.
- **Thrombin:** Thrombin stimulates leukocytic adhesion and cleaves fibrinogen into fibrin. Fibrin degradation products attract leukocytes (neutrophils and monocytes).

HYPERCOAGULABLE STATE

Hypercoagulable state or thrombophilia is the increased tendency of blood to form thrombus. It is less frequent cause of thrombus formation that may occur in settings of hereditary or acquired disorders. Hereditary causes

of hypercoagulable state are given in Table 3.13. Acquired causes of hypercoagulable state are given in Table 3.14.

Inherited Hypercoagulable State

Inherited hypercoagulable state occurs due to factor V Leiden mutation (most common), prothrombin gene mutation, deficiencies of natural anticoagulant proteins (i.e. antithrombin III, protein C and protein S), elevated levels of fibrinogen or dysfunctional fibrinogen (dysfibrinogenemia, abnormal fibrinolytic system and elevation of plasminogen activator inhibitor 1 (PAI-1).

Acquired Hypercoagulable State

Acquired hypercoagulable state occurs due to prolonged immobilization, hormonal replacement therapy, oral contraceptive pills, pregnancy, obesity, recent trauma or surgery, central venous catheter placement, mucin secreting tumors, some medications used to treat cancer (i.e. tamoxifen, bevacizumab, thalidomide and lenalidomide), heparin-induced thrombocytopenia, antiphospholipid antibody syndrome, myeloproliferative disorders (i.e. polycythemia vera or essential thrombocythemia), previous history of deep vein thrombosis (DVT) or pulmonary embolism, paroxysmal nocturnal hemoglobinuria, nephrotic syndrome and HIV/AIDS.

Table 3.13 Hereditary causes of hypercoagulable state

Common Mutations
Factor V Leiden mutation (abnormal factor V resists degradation by protein C)
Prothrombin G20210A (factor II) mutation
Methyl tetrahydrofolate reductase (MTHFRC677T) mutation
Rare Mutations
Antithrombin III mutation
Protein C mutation
Protein S mutation
Very Rare Mutations
Dysfibrinolysis

Table 3.14 Acquired causes of hypercoagulable state

High-risk Disorders
Myocardial infarction
Atrial fibrillation
Prosthetic valve
Trauma (surgery, fracture, burns)
Disseminated intravascular coagulation (DIC)
Malignant tumors (mucin secreting tumors)
Heparin-induced thrombocytopenia (HIT)
Antiphospholipid antibody syndrome (lupus anticoagulant syndrome)
Low-risk Disorders
Nephrotic syndrome (urinary loss of antithrombin III)
Hyperestrogenic state (pregnancy)
Oral contraceptive use
Tobacco smoking
Sickle cell anemia

THROMBOTIC DISORDERS

In normal health, hemostatic balance exists between procoagulant, anticoagulant and fibrinolytic systems. Numerous inherited and acquired thrombotic disorders can tip the balance in favor of coagulation leading to thrombus formation in arteries and veins. Thrombi can obstruct blood flow and cause dysfunction of organs. Comparison between inherited and acquired thrombophilia is given in Table 3.15. Laboratory diagnosis of thrombophilia is given in Table 3.16.

- Common manifestations of thrombotic disorders include deep vein thrombosis (DVT) and life-threatening pulmonary thromboembolism. Coronary artery disease can cause myocardial infarction. Occlusion of mesenteric arteries lead to gangrene gut. Occlusion of arteries supplying brain can lead to cerebral stroke.
- Most of the inherited thrombotic disorders do not begin to cause an increased risk of thrombosis until young adulthood, although thrombus can form in blood vessels at any age. Women may have a history of multiple spontaneous abortions.
- Hereditary thrombophilia is a prothrombotic familial syndrome caused by deficiency of a number of anti-thrombotic proteins, including antithrombin III, protein C, and protein S. Hereditary thrombophilia is characterized by recurrent venous thrombosis and thromboembolism, which most often occurs in adolescents or young women.
- Patients should be investigated in the settings of history of thrombosis at young age, unexplained recurrent episodes of thromboembolic phenomenon, strong family history of thrombosis in the first-degree relatives, recurrent abortions and pregnancy associated thrombi in women.

INHERITED THROMBOTIC DISORDERS

Significant advances in identification of etiologies of inherited thrombotic disorders associated with recurrent arterial or venous thrombosis have been recently

Table 3.15 Comparison between inherited and acquired thrombophilia

Feature	Inherited Thrombophilia	Acquired Thrombophilia
Common causes	▪ Factor V Leiden mutation ▪ Prothrombin G20210A gene mutation ▪ Antithrombin III deficiency ▪ Protein C (PC) deficiency ▪ Protein S (PS) deficiency	▪ Autoimmune disorders ▪ Antiphospholipid syndrome (lupus anticoagulant causing pregnancy loss)
Family history of thrombophilia	Present (family member with known thrombophilia)	Absent
Venous thromboembolism	Unprovoked venous thromboembolism or with minor risk factor	Unprovoked venous thromboembolism
Site of thrombosis	Recurrent venous thromboembolism in <50 years	Thrombosis at unusual sites especially in patient >50 years (e.g. splanchnic region)
Clinical manifestations	Skin necrosis associated with vitamin K antagonists	Late or recurrent pregnancy loss

Table 3.16 Laboratory diagnosis of thrombophilia

Laboratory Test	First Diagnostic Step	Comments
Activated protein C resistance (APCR)/factor V Leiden (FVL)	Deficient factor V Leiden (FVL) coagulation based functional assay	DNA analysis for factor V Leiden mutation
Prothrombin G20210A mutation (FII G20210A)	DNA analysis	Measurement of protohemin (FII) activity in plasma should not be used to screen thrombophilic patients for this mutation due to its inability to clearly distinguish carriers from noncarriers of the mutation
Antithrombin (AT) deficiency	Functional chromogenic assay	Measurement of antithrombin antigen by an immunoassay in order to classify the type of deficiency as type 1 or 2
Protein C deficiency	Functional chromogenic assay	Measurement of protein C antigen by an immunoassay in order to classify the type of deficiency as type 1 or 2 or 3
Protein S (PS) deficiency	Functional coagulation-based assay	Measurement of protein S antigen by an immunoassay in order to classify the type of deficiency as type 1 or 2 or 3
Antiphospholipid antibodies (aPLAs): LA, ACL and anti-β2-Gp1	▪ Lupus anticoagulant: a panel of screening two or more assays and at least one confirmatory assay ▪ ACL and anti-β2-Gp1: enzyme immunosorbent assays for both IgM and IgG isotopes	Repeat testing for a positive test result with at least 12 weeks apart in order to confirm a positive test result
Increased factor VIII level (FVIII >159%)	Coagulation or chromogenic functional assay	Repeat testing 3 to 6 months after initial testing
Homocysteinemia	Plasma level of homocysteine	Repeat testing in case of questionable or borderline test result or to confirm a positive test result
Dysfibrinogenemia	Screening assays: thrombin time (TT) and replitase time (RT), functional fibrinogen level correlated with von Clauss fibrinogen level	Parallel analysis of functional and immunoreactive fibrinogen as confirmatory assays

reported. A point mutation in coagulation factor (factor V Leiden) results in resistance to activated protein C probably represents the most common genetic risk factor for venous thrombosis. Homocysteinemia is a metabolic disorder linked to both arterial and venous thrombosis. Many patients with recurrent thrombosis will have more than one genetic risk factor. Thrombophilias in approximate descending order of probability are given in Table 3.17.

Factor V Leiden Mutation

Mutation of factor V Leiden has been named after the city in Netherlands, which is the most common cause of hereditary thrombophilia. Risk of hereditary thrombophilia is greatly increased during pregnancy and following oral contraceptive intake.

- **Molecular genetics:** Abnormal factor V protein is formed due to specific point mutation by substitution of glutamine for normal arginine at position 506,

Table 3.17 Thrombophilias in approximate descending order of probability

Blood protein/platelet defects leading to thrombosis
Antiphospholipid syndrome
Factor V Leiden mutation (abnormal factor V resists degradation by protein C)
Other factor V mutations
Sticky platelet syndrome
Plasminogen activator inhibitor 1 (PAI-1) mutation
Prothrombin G20210 mutation
Methylene tetrahydrofolate reductase (MTHFRC677T) mutation
Antithrombin III mutation
Protein C mutation
Protein S mutation
Heparin cofactor II mutation
Plasminogen mutation
Factor XII mutation
Dysfibrinogenemia
Homocysteinemia
Lipoprotein (a)
Tissue plasminogen activator mutation
Tissue factor pathway inhibitor mutation

which alters the cleavage site targeted by activated protein C. Abnormal factor V protein becomes resistant to cleavage by protein C. As a result, an important antithrombotic counter-regulatory mechanism is lost. There is increased generation of prothrombinase complex and thrombin generation.

- **Clinical features:** Patient presents with recurrent deep vein thrombosis (DVT). Factor V Leiden mutaion predisposes to unchecked thrombosis especially in deep veins of leg.
- **Laboratory tests:** Laboratory tests for factor V Leiden mutation include activated protein C resistance assay and genetic analysis by polymerase chain reaction.

Prothrombin G20210A Mutation

Prothrombin is the precursor of thrombin. Normally, prothrombin protein is produced to assist hemostasis. The prothrombin G20210A mutation is the second most common cause of inherited risk factor for thrombosis that leads to elevated plasma levels of prothrombin, which demonstrates a higher risk for arterial and venous thrombotic events.

- **Single point mutation** in prothrombin gene occurs due to a single nucleotide change (G to A) in the 3′-untranslated regions at position 20210. It is more commonly seen in Caucasians and individuals of African Americans.
- Prothrombin testing is done by taking a blood sample and using a genetic test to look at the prothrombin gene. DNA is isolated from blood cellular components and the prothrombin gene is analyzed to see if there is a mutation in the DNA code.

Methylene Tetrahydrofolate Reductase (MTHFRC677T) Mutation

Methylene tetrahydrofolate reductase (MTHFRC677T) gene mutation results in mild elevation of homocysteine levels in 5–15% of White and East Asia populations. Elevated levels of homocysteine inhibit antithrombin III and thrombomodulin. There is increased risk of thrombosis. Increased levels of homocysteinemia are also associated with an increased risk of neural tube defects and possibly a number of diverse neoplasms. Increased homocysteine can be reduced by dietary supplementation with folic acid and vitamins B_6 (pyridoxine) and B_{12} (cobalamin).

Increased Concentration of Factor VIII, Factor IX, Factor XI, or Factor I

Increased levels of factor VIII (antihemophilic globulin A), factor IX (antihemophilic globulin B), factor XI (antihemophilic globulin C), or factor I (fibrinogen) are also associated with increased venous thrombosis.

Increased Concentration of Factor VIII

Higher levels of factor VIII increase the risk of thrombosis especially in African-Americans, which also correlate with acute phase reactant synthesis, estrogen usage, pregnancy and after aerobic exercise. Elevated factor VIII level may cause activated protein C resistance. In contrast, low levels of factor VIII correlate with bleeding in hemophilia patients.

Increased Concentration of Factor IX

Factor IX is a vitamin K-dependent glycoprotein that plays a key role in hemostasis. Factor IX is activated through intrinsic pathway as well as extrinsic pathway of coagulation system.

- Factor XI, when activated by factor XIa or factor VIIa tissue factor, converts factor X into Xa and accelerated by factor VIIIa, calcium ions and a phospholipid membrane, which eventually results in formation of fibrin clot.
- Elevated factor IX levels increase risk of deep venous thrombosis (DVT) after adjustment for factors VIII, XI and other known risk factors.
- Various studies revealed that enhanced level of factor IX occur with advancing age and in women on oral contraceptive pills. In contrast, deficiency of factor IX leads to hemophilia B.

Increased Concentration of Factor XI

Factor XI is a vitamin K-dependent protein that plays a role in hemostasis. Factor XI is activated through intrinsic pathway of coagulation system cascade involved in the creation of a stable fibrin clot. Elevated factor IX levels increase the risk of venous thrombosis after adjustment with factor VIII, factor IX and other known factors.

Increased Concentration of Factor I

Factor I (fibrinogen) is a protein synthesized in the liver. Major physiologic function of fibrinogen is the formation of polymerized fibrin that binds to platelets and some plasma proteins in a hemostatic plug. Elevated fibrinogen levels increase risk of blood clots associated with higher risk of heart disease, blood vessel dysfunction and cerebral stroke.

Antithrombin III, Protein C and Protein S Deficiency

Vitamin K-dependent clotting factors (II, VII, IX and X), protein C and protein S are synthesized by liver. Antithrombin III synthesis is not vitamin K-dependent. In normal health, antithrombin III, protein C and protein S prevent thrombus formation.

- Hereditary deficiency of antithrombin III and protein C have an autosomal dominant pattern of inheritance with identical clinical manifestations of thrombosis.
- Approximately, 50% reduction in the plasma concentration of protein C results in venous thrombosis and recurrent thromboembolic pulmonary phenomenon in adolescents or early life. Diagnostic tests of hemostasis used for detection of congenital thrombotic disorders are given in Table 3.18.

Antithrombin III Deficiency

Antithrombin III is a protein in the blood synthesized in the liver that inhibits thrombus formation by binding to heparin on endothelial cells and forming a complex with thrombin (thrombin-antithrombin) thus inhibiting coagulation cascade.

- Qualitative defects of antithrombin III describe mutations, which either affect heparin binding site, reactive site or has pleomorphic effects.
- Homozygous antithrombin III deficiency is incompatible with life unless affecting the heparin-binding site.
- Persons with antithrombin III deficiency present with venous thrombosis and less likely with arterial thrombosis.

Protein C Deficiency

Protein C interacts with thrombomodulin to become activated protein C. Activated protein C inactivates coagulation factors V and VIII leading to inhibit coagulation system cascade. Protein C deficiency can cause thrombosis in teenagers.

- Protein C and protein S deficiency can be inherited or acquired in the stetting of liver dysfunction, vitamin K antagonists, renal failure, disseminated intravascular coagulation (DIC) and active thrombosis.
- Protein C is rapidly consumed in disseminated intravascular coagulation. A total lack of protein C is usually associated with death *in utero*.
- Newborns with total absence of protein C suffer from purpura fulminans neonatalis. Repeated infusions of prothrombin complex help in keeping these children alive.
- The half-life of protein C is shorter than half-life of other vitamin K-dependent coagulation factors.

Protein S Deficiency

Protein S enhances the effect of activated protein C. Protein S deficiency is linked to develop thrombus formation. Protein S deficiency can be classified as type 1 (reduced quantity of protein C), type 2 (low activated protein C activity) and type 3 (low free protein S to increased binding to the complement factor C4b). Interaction of protein S with C4b is an active phase reactant linked to coagulation, inflammation and autoimmunity.

Dysfibrinolysis

Dysfibrinolysis occurs due to dysfibrinogenemia, plasminogen deficiency, tissue plasminogen activator (tPA) deficiency, elevated plasminogen activator inhibitor 1 (PAI-1) and factor XII deficiency.

Table 3.18 Diagnostic tests of hemostasis used for detection of congenital thrombotic disorders

Diagnostic Test	Type of Assay	Application
Protein C (PC)	Functional clotting and/or chromogenic assays	Congenital deficiency of protein C
Protein S (PS)	Functional clotting and/or antigenic assays	Congenital deficiency of protein S
Antithrombin III (AT-III)	Chromogenic or antigenic assays	Congenital deficiency of antithrombin III
Activated protein C resistance (APCR)	Activated partial thromboplastin time (APTT) or Russell's viper venom time (RVVT)	Congenital or acquired thrombophilia (APCR, FVL—factor V Leiden)

- Plasminogen deficiency clinically appears similar to protein C deficiency associated with thrombosis during teen-age years.
- Plasminogen activator inhibitor I (PAI-1) and deficient tissue plasminogen activator are linked to diabetes mellitus, inflammatory bowel syndrome and coronary arteriosclerosis.
- In patients with functional changes in fibrinogen (dysfibrinogenemia) are linked to thrombosis or bleeding.

Sticky Platelet Syndrome

Sticky platelet syndrome is an autosomal dominant thrombophilic disorder characterized by increased *in vitro* platelet aggregation after low concentrations of ADP and/or epinephrine. Antiphospholipid antibodies bind to phospholipid molecules in the blood and induce autoimmune reaction resulting in platelets sticking together. Clumping of platelets causes the build-up of blood clots in blood vessels.

ACQUIRED THROMBOTIC DISORDERS

Patients with acquired hypercoagulable states are more likely to develop venous and arterial thrombosis than healthy individuals. Venous thrombosis and pulmonary embolism are associated with significant morbidity and mortality. Acquired hypercoagulable states associated with increased risk of thrombosis are given in Table 3.19.

Table 3.19 Acquired hypercoagulable states associated with increased risk of thrombosis

Acquired Hypercoagulable States Leading to Abnormal Platelet Functions
Atheromatous plaque
Diabetes mellitus
Hyperlipidemia
Tobacco smoking
Thrombocytosis
Acquired Hypercoagulable States Leading to Abnormal Coagulation System Cascade
Congestive heart failure
Postsurgical state
Immobilization
Use of oral contraceptives
Pregnancy
Heparin-induced thrombocytopenia (HIT)
Antiphospholipid syndrome
Thrombotic thrombocytopenic purpura (TTP)
Nephrotic syndrome (loss of antithrombin III and antiplasmin in urine)
Myeloproliferative disorders

Antiphospholipid Syndrome

Antiphospholipid syndrome (APS) is most common acquired thrombophilia associated with high titers of circulating antibodies (IgG) directed against cell membranes, and phospholipids, which may cause arterial or venous thrombosis and recurrent miscarriages. Proposed mechanism of thrombosis in antiphospholipid antibody syndrome is given in Table 3.20. Common sites of arterial and venous thrombosis in antiphospholipid syndrome are given in Table 3.21.

- *In vitro* antiphospholipid antibodies interfere with the assembly of phospholipid complexes and thus

Table 3.20 Proposed mechanism of thrombosis in antiphospholipid antibody syndrome

Interference with endothelial phospholipids and thus prostacyclin release
Inhibition of prekallikrein, thus inhibition of fibrinolysis
Inhibition of thrombomodulin, thus protein C and protein S activity
Activated protein C resistance (nonmolecular)
Interaction with platelet membrane phospholipids
Direct inhibition of protein S
Inhibition of endothelial cell tissue plasminogen activator release
Inhibition of annexin-V, a cell surface protein that inhibits tissue factor—also referred to as 'placental anticoagulant protein (serine only)
Induction of monocyte release of tissue factor

Table 3.21 Common sites of arterial and venous thrombosis in antiphospholipid syndrome

Arterial Thrombi
Coronary arteries
Cerebral arteries
Retinal arteries
Brachial artery
Mesenteric arteries
Peripheral (extremity) arteries
Aorta
Placental arteries (recurrent miscarriage)
Venous Thrombi
Deep vein thrombosis (DVT)/pulmonary embolism (PE)
Intracranial veins
Retinal vein
Inferior vena cava
Renal vein
Hepatic vein (Budd-Chiari syndrome)
Portal vein
Placental veins (recurrent miscarriage)

inhibit coagulation. However, *in vivo*, the antibodies induce a hypercoagulable state.

- Antiphospholipid syndrome antibodies are being tested, which include lupus anticoagulant, anti-cardiolipin and anti-β_2 glycoprotein. Lupus anticoagulant leads to prolongation of coagulation analyzed by activated partial thromboplastin time (APTT) *in vitro*.
- Antiphospholipid antibodies may also occur secondary to systemic lupus erythematosus, rheumatoid arthritis, and drugs (e.g. phenytoin and cocaine). The most common thrombotic event is deep vein thrombosis (DVT). Any person with cerebral stroke and rheumatological disorder should be screened for antiphospholipid antibody syndrome.
- Patient with antiphospholipid syndrome presents with recurrent venous especially in deep veins of legs or arterial thrombi. But renal, hepatic, and retinal veins are also susceptible. There is history of repeated miscarriages, cardiac valvular vegetations, or thrombocytopenia.

Heparin-induced Thrombocytopenia Syndrome

Heparin is widely used for treatment and prophylaxis of thromboembolism in clinical practice. Heparin-induced thrombocytopenia (HIT) is a serious complication of administration of low-molecular weight heparin products. A fall in platelet counts and hypercoagulable state characterize heparin-induced thrombocytopenia. Patients are prone to thromboembolic complications linked to morbidity and mortality. Two types of heparin-induced thrombocytopenia syndrome include: type 1 HIT and type 2 HIT syndrome.

Type 1 Heparin-induced Thrombocytopenia Syndrome

Type 1 heparin-induced thrombocytopenia syndrome is a nonimmune-mediated reaction, which is more common than type 2 HIT, which can occur within a day of heparin therapy. This is mild reaction that results in mild to moderate drop of platelets. Type 1 HIT syndrome is not associated with any complications and platelet counts will spontaneously normalize even if heparin is continued, which is not a contraindication to future heparin use.

Type 2 Heparin-induced Thrombocytopenia Syndrome

Type 2 heparin-induced thrombocytopenia is an immune-antibody mediated reaction in patients that results in severe drop of platelet counts (often <50% of baseline) within 5–10 days of heparin administration.

- In normal person, platelet factor 4 is positively charged and stored in α-granules of the platelets, which is released upon platelet activation. Platelet factor 4 binds to the negatively charged heparin-like substance present on vascular endothelium. Platelet factor 4 can also bind to exogenous heparin with a much higher affinity than endogenous heparan.
- Platelet factor 4 binding to exogenous heparin may trigger the formation of IgG, IgA or IgM antibodies specific to the heparin–PF4 complex. IgG attached to the heparin–platelet factor 4 (PF4) complex binds to the Fc receptor on the platelet surface and leads to platelet activation. Repeated cycles of platelet activation leads to release prothrombotic substances such as thrombin and platelet factor 4 leading to severe hypercoagulable state. Continuous chain can be broken on discontinuation of heparin and initiation of treatment.
- Most characteristic clinical finding in type 2 HIT is thrombocytopenia that occurs due to destruction of IgG-coated platelets by reticuloendothelial cells. Simultaneously, activated platelets lead to platelets aggregation leading to arterial and venous thrombosis and simultaneous low-platelet count.
- The most common complications of type 2 HIT are deep vein thrombosis (DVT) and pulmonary thromboembolism within the first 10 days. However, prothrombotic state persists up to 30 days after withdrawal of heparin.
- However, if a patient has been exposed to heparin within last 100 days, antibodies may remain in the body, causing an immune reaction to manifest as soon as day one of re-exposure to heparin.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is characterized by widespread clotting with resultant consumption of platelets and coagulation factors, especially factors II, V, and VIII, and fibrinogen. Pathophysiology of DIC is shown in Fig. 3.24. Causes of DIC are given in Table 3.22.

- Disseminated intravascular coagulation (DIC) occurs as a result of release of tissue thromboplastin (tissue factor) or activation of the intrinsic pathway of coagulation, as well as secondary activation of the fibrinolytic system.
- Clinical manifestations of DIC are thrombotic phenomena in small blood vessels of multiple organs and hemorrhage.
- Hematologic findings in disseminated intravascular coagulation include microangiopathic hemolytic anemia with fragmented red blood cells

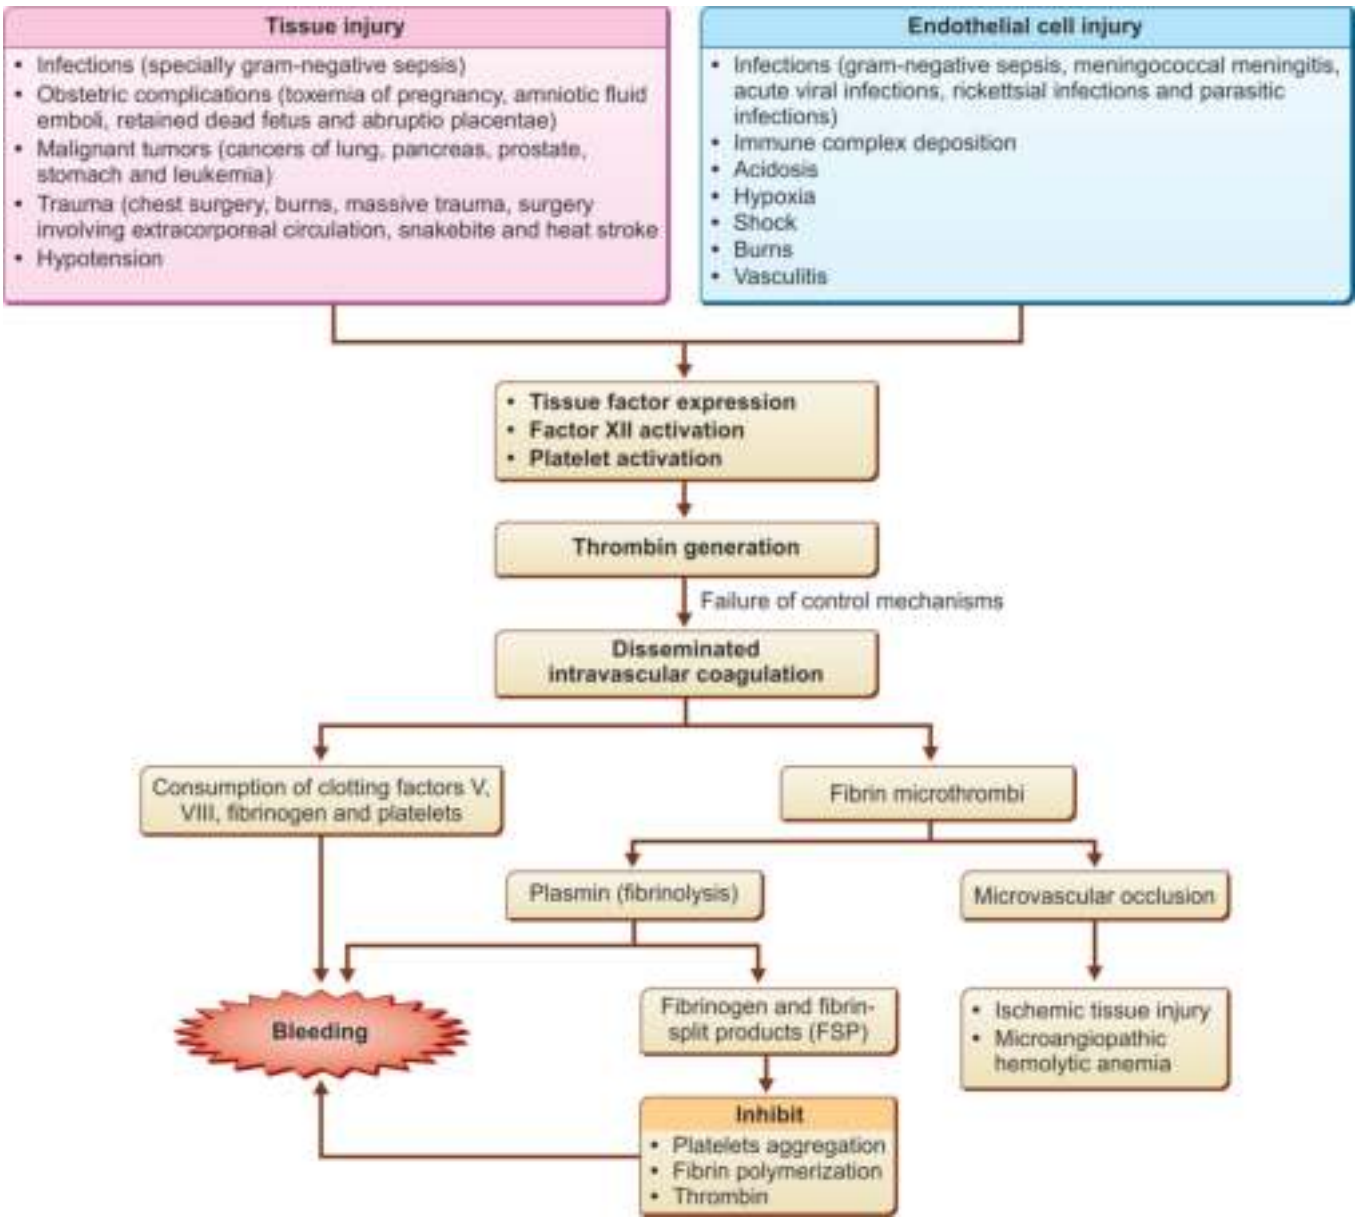

Fig. 3.24: Pathophysiology of disseminated intravascular coagulation (DIC). DIC is triggered by tissue injury, endothelial injury or combination of both these processes, and characterized by widespread activation of coagulation leading to formation of blood clots throughout the bloodstream, occlusion of small vasculature, organ dysfunction, consumption of coagulation factors and platelets, and life-threatening hemorrhage.

(schistocytes), increased fibrin and fibrinogen degradation (split) products, thrombocytopenia and prolonged bleeding time, prothrombin time and international normalized ratio (PT–INR), activated partial thromboplastin time (APTT), and thrombin time (TT).

Procoagulant Substance Secreting Malignant Tumors

Malignancy is the second most common acquired hypercoagulable state that leads to a prothrombotic state through the production of procoagulant factors (tissue factor and cancer procoagulant factor) and the interaction of cancer stem cells with blood and vascular endothelium.

- Blood stasis from malignant tumor compression, paraproteinemia, and cytokine release pose an additional risk for thrombus formation.
- Cancer procoagulant factor is elevated in 85% of cancer patients. Procoagulant factor activates factor X thus causing hypercoagulable state in cancer patients. Polycythemia vera poses a thrombotic risk in addition to hyperviscosity. Migratory thrombophlebitis as a consequence of visceral malignancy is known as Trousseau syndrome.

Table 3.22 Causes of disseminated intravascular coagulation

Cause	Mechanism
Obstetric complications	▪ Toxemia of pregnancy ▪ Amniotic fluid emboli ▪ Retained dead fetus ▪ Abruptio placentae (premature separation of placenta)
Metastatic cancers	▪ Lung carcinoma ▪ Pancreatic carcinoma ▪ Prostate carcinoma ▪ Gastric carcinoma ▪ Leukemia
Infectious agents	▪ Gram-negative sepsis ▪ Meningococcal meningitis ▪ Acute viral infections ▪ Rickettsia infections (e.g. Rocky Mountain spotted fever) ▪ Parasitic infections (e.g. malaria)
Trauma or surgery	▪ Chest surgery ▪ Burns ▪ Massive trauma ▪ Snake bite ▪ Surgery involving extracorporeal circulation ▪ Heat stroke
Shock	▪ Septic shock ▪ Severe hypovolemic shock
Immunological mechanism	▪ Immune complex disease ▪ Hemolytic transfusion reactions

FATE OF THROMBUS

Thrombosis is process of formation of mass in circulation from the constituents of flowing blood, mass is called as thrombus.

- Thrombosis involves activation of platelets and coagulation system cascade leading to conversion of soluble fibrinogen to fibrin, which is polymerized and converted to insoluble fibrin.
- Thrombus formation can have one of five outcomes: propagation, dissolution, organization, recanalization and embolization to distant organs.
- Occasionally, instead of organization of thrombus, the central portion of thrombus undergoes enzymatic digestion as a result of the release of lysosomal enzymes from trapped leukocytes and platelets, which occurs in large thrombi formed in cardiac chambers or abdominal aortic aneurysm. If the bacterial seeding occurs, it is called mycotic aneurysm. Fate of thrombus is shown in Fig. 3.25A to D.

PROPAGATION OF THROMBUS

Platelet activation at the site of disrupted atheromatous plaque is an initial step in the thrombus formation. Activated platelets release adenosine diphosphate (ADP), serotonin and thromboxane A_2, which promote platelets activation further. This self-amplifying process results in thrombus propagation, in which increase in size of thrombus occurs due to accumulation of additional platelets and fibrin. Propagation of thrombus results in occlusion of the blood vessel.

DISSOLUTION OF THROMBUS

Fibrinolysis refers to the process of dissolution of the blood clot formed by activation of hemostatic pathways either in hemostasis in physiologic response to vascular injury or dissolution of thrombosis in pathologic response to vascular injury. Dissolution of thrombus occurs when the fibrinolytic mechanisms break up the thrombus and restoration of blood flow in the blood vessel. Tissue plasminogen activator (tPA), synthesized by vascular endothelium, converts plasminogen to plasmin in the vicinity of the thrombus.

- Plasmin is a fibrinolytic enzyme, which splits fibrin strands (fibrinolysis) and dissolves relatively small thrombus resulting in restoration of blood flow.
- Streptokinase enzyme can directly activate plasmin, which can dissolve occlusive thrombi. Activation of Hageman factor links the fibrinolytic system, coagulation system, complement system, and kinin system.

ORGANIZATION OF THROMBUS

Older thrombi undergo organization, due to ingrowth of vascular endothelial cells, fibroblasts, smooth muscle cells into the fibrin-rich thrombus. Contraction of these cells leads to incorporation of smaller thrombus in the subendothelial region of the blood vessel wall. Organized thrombus is firm and grayish white in color resulting in obliteration of lumen of blood vessel.

RECANALIZATION OF THROMBUS

The process of recanalization of the deep vein of the lower limbs after an episode of deep vein thrombosis (DVT) is a part of the natural evolution of the remodeling of the venous thrombosis in patients on anticoagulant therapy with heparin and vitamin K inhibitors. Recanalization is a process that initially involves adhesion of the thrombus to the wall of deep vein of lower extremities and inflammatory response in the blood vessel wall resulting in organization and subsequent contraction of the thrombus, neovascularization, spontaneous lysis of areas within the thrombus and restoration of partial blood flow.

THROMBUS EMBOLIZATION

Thrombus embolism occurs when a blood clot or thrombus formed in a blood vessel breaks loose and circulate in the bloodstream and blocks another blood vessel leading to infarction of organs at a distant

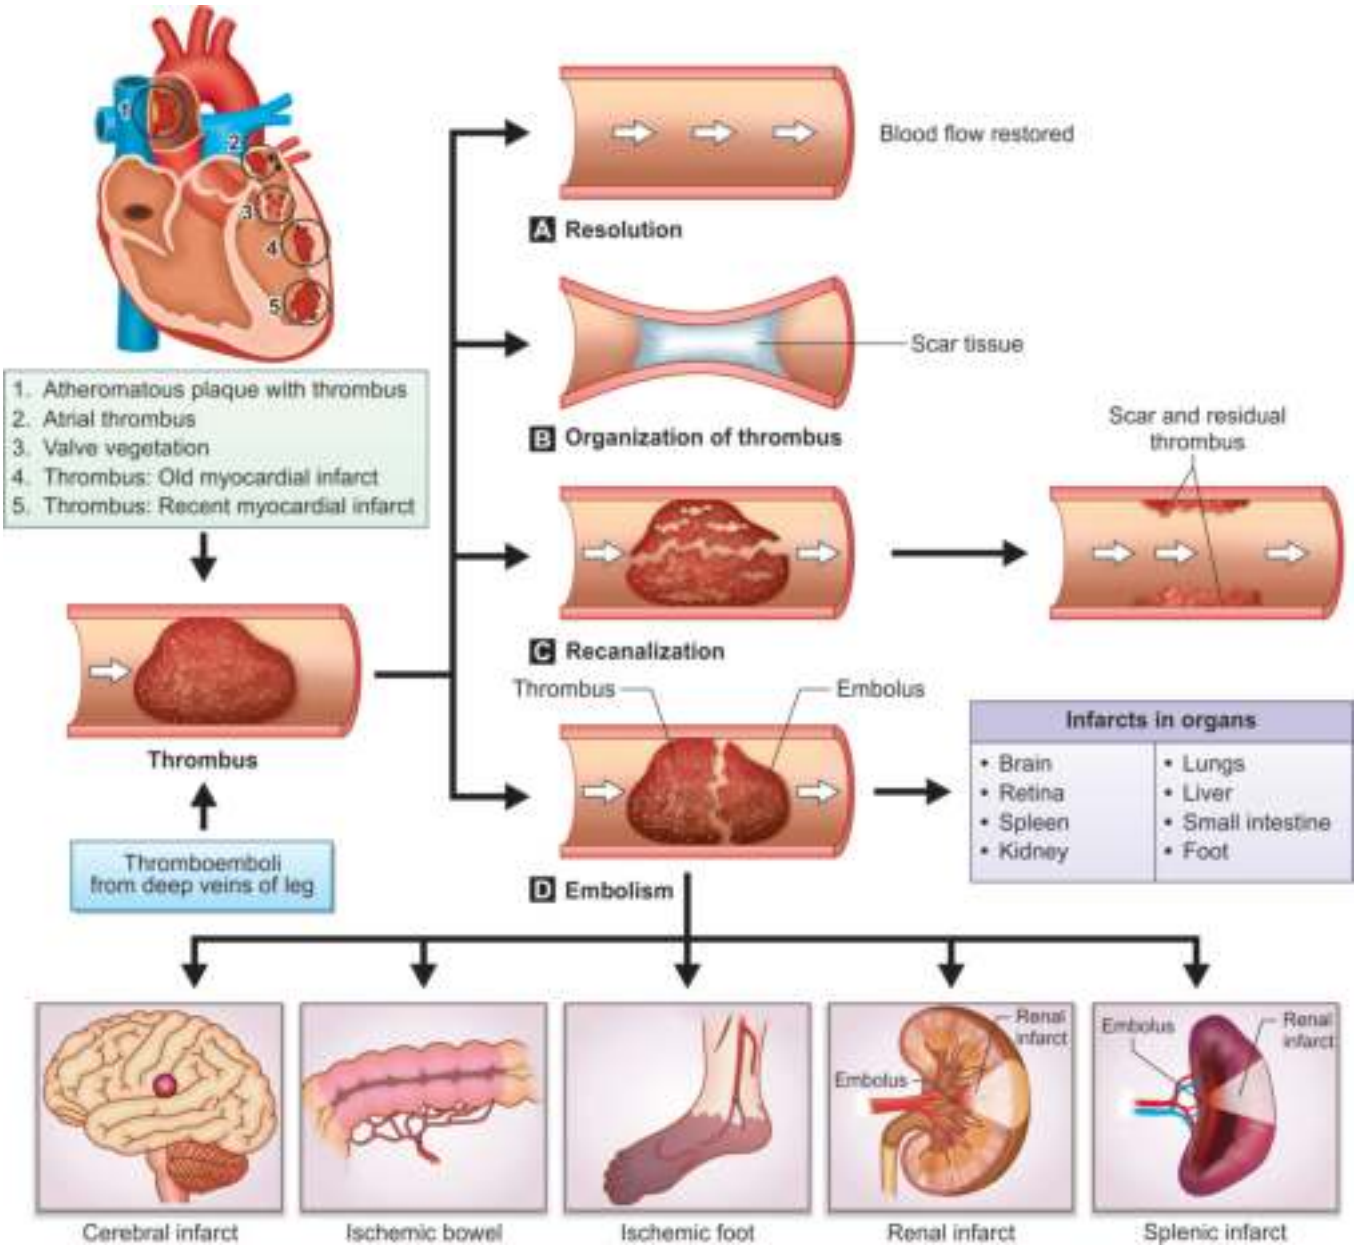

Fig. 3.25A to D: Fate of thrombus. The main outcomes of thrombosis are resolution, organization, recanalization, occlusion, embolism and propagation. Thromboembolism can cause cerebral stroke, ischemic bowel disease, peripheral vascular disease, renal infarct and splenic infarct.

site such as brain, kidney, intestine and lower limbs and even death. The thromboemboli may enter coronary arteries resulting in myocardial infarction. Venous thrombi may cause pulmonary embolism with fatal outcome.

THROMBOEMBOLISM

Thromboembolism refers to formation of a blood clot or thrombus in a blood vessel that breaks loose and is carried by the blood stream to obstruct another blood vessel.

- The blood clot or thrombus may obstruct a blood vessel in the lungs (pulmonary embolism), heart (myocardial infarction), brain (cerebral stroke), legs (deep vein thrombosis), and less common in gastrointestinal tract (gangrene gut) and kidneys (renal infarct). Thromboembolism is important cause of morbidity and mortality especially in adults.
- There are two main categories of thromboembolism depending on type of blood vessel affected: venous and arterial thromboembolism. Patients are treated with anticoagulants, aspirin and vasodilators.
  - Venous thromboembolism occurs in veins, which includes deep vein thrombosis (DVT) and pulmonary embolism (PE). Risk factors of venous thromboembolism include bed confinement and sitting for a long time without movement.

- Arterial thromboembolism occurs in arteries, that causes restriction of blood flow and oxygen leading to ischemia of organ. Risk factors of arterial thromboembolism are generally different.

Pathology Pearls: Arterial and Venous Thrombi

- Thrombi may be formed in arteries and veins during life. There are two main types of thrombi: arterial thrombus and venous thrombus. The risk factors of arterial thrombus and venous thrombus are generally different.
- The composition, physical properties, and evolution of arterial and venous thrombi are likely to differ mainly due to various local conditions and time since formation.
- Outcome of thrombi includes lysis of thrombus, propagation, organization, recanalization and embolization. Differences between arterial and venous thrombi are given in Table 3.23.

Arterial Thrombi

- Risk factors of arterial thrombi include cigarette smoking, diabetes mellitus, hypertension, hyperlipidemia, family history of arterial thrombosis and older age.
- Platelets play key role in the development of arterial thrombi formed at relatively high wall shear rates, generating what are often termed 'white thrombi'.
- Arterial thrombus is most often superimposed on an ulcerated atheromatous plaque in large elastic and medium-sized arteries (i.e. abdominal aorta and coronary arteries).
- Arterial thrombi commonly arise from the rupture of atherosclerotic plaque and exposure of procoagulant components such as collagen and lipid-rich activated macrophages being tissue factor in coronary, cerebral and other arteries supplying organs.
- Arterial thrombus grows in the direction of the blood flow (propagation) resulting in tissue infarction and ischemia either directly or indirectly through embolization.

Venous Thrombi

- Venous thrombi are attributed to a combination of hypercoagulable state together with injured or activated endothelium of veins, turbulent blood flow, blood stasis during surgery and immobilization, fracture, obesity, history of deep vein thrombosis (DVT), inherited disorders, autoimmune disorders (e.g. Crohn's disease), central venous catheter, pregnancy, and oral contraceptive pills.
- Most common sites of venous thrombi are deep veins of lower leg (90%), dural sinuses of skull, pelvic veins and portal tributaries.
- In contrast, venous thrombi are formed under low shear rate and mainly composed of red blood cells (RBCs) and fibrin (i.e. red thrombi).

Pathology Pearls: Postmortem Blood Clots

- Thrombosis is the formation of a solid mass by the constituents of blood within vascular system. Thrombus should not be confused with a blood clot, which occurs in nonflowing blood. A postmortem blood clot is defined as coagulation of blood after death. Postmortem blood clots may be confused with venous thrombi.
- Postmortem blood clots are gelatinous with dark red due to settling down of red blood cells by gravity giving 'red currant jelly' appearance.
- Yellow chicken fat cell-free supernatant resembles melted and clotted chicken. In contrast to thrombi; postmortem clots are not attached to the blood vessel wall. Differences between antemortem thrombus and postmortem blood clot are given in Table 3.24.

VENOUS THROMBOEMBOLISM

Venous thromboembolism occurs when a blood clot or thrombus breaks off and blocks a vein—a blood vessel that brings blood in need of oxygen back to heart.

- Venous thrombi are formed in areas of less active blood flow due to stasis of venous blood especially in immobilized patients, which extend in the direction of blood flow (i.e. toward heart). Propagating tail of venous thrombi may not be well attached to vascular endothelium resulting in fragmentation creating an embolus.
- Venous thrombi are occlusive, which often create a long cast of the lumen of vein. The venous thrombi are dark red with a higher concentration of red blood cells (RBCs) along with fair number of platelets and leukocytes than arterial thrombi. Lines of Zahn are not prominent in venous thrombi. Anticoagulant therapy with heparin and warfarin prevents formation of venous thrombi.
- Venous thromboembolism often starts in the lower extremities with a condition known as deep vein thrombosis (DVT) below knee joint (most common in 90%). Less common sites of venous thromboembolism include superior saphenous, periprostatic, ovarian or uterine veins, hepatic veins, renal veins, and dural sinuses. If the venous thrombus breaks off and lodges in the lung, it causes life-threatening condition known as pulmonary thromboembolism, which can be fatal depending on the location of the embolus and the degree of blood flow obstruction in lungs.
- The broader term venous thromboembolism denotes deep vein thrombosis (DVT), pulmonary embolism (PE) or a combination of the two conditions (called DVT/PE). Venous thromboembolism can involve

Table 3.23 Differences between arterial and venous thrombi

Parameters	Arterial Thrombi	Venous Thrombi
Blood flow	Formed in rapid blood flow in heart chambers or arteries	Formed in slow blood flow in veins (deep veins of leg)
Location of thrombus	Coronary, cerebral, iliac, femoral arteries and heart chambers in active blood flow	Superficial saphenous veins, deep veins of legs, popliteal veins, femoral veins, hepatic veins, renal veins and dural sinuses in less active blood flow
Pathogenesis	Vascular endothelial injury (atheromatous plaque), turbulent blood flow (e.g. bifurcation of vessel and aortic aneurysm) and hypercoagulable states	Stasis of venous blood especially in immobilized patients, disseminated cancers, pregnancy, antithrombin III deficiency and intravenous cannula
Progression of thrombus	Growing in a retrograde direction from the point of attachment	Venous thrombi formed in the lower extremities propagating toward the heart may cause pulmonary artery embolization
Vessel occlusion	Partial or complete occlusion of vessels	Occlusive and often creating a long cast of the lumen of vein
Gross morphology	Gray white friable with alternating pale and red areas	Dark red with a higher concentration of red blood cells along with fair number of platelets and leukocytes
Light microscopy	▪ Lines of Zahn prominent (pale area composed of platelets held together by fibrin; and red areas composed predominantly of RBCs) ▪ Inflammatory changes in arteries absent	▪ Lines of Zahn not prominent or absent ▪ Inflammatory changes in veins present known as 'thrombophlebitis
Complications of thrombus	Infarction of organs such as heart, brain, kidney, spleen, lower limb	Pulmonary thromboembolism, edema, skin ulcers and poor wound healing
Therapy	Aspirin and anticoagulant therapy	Anticoagulants heparin and warfarin

Thrombosis is diagnosed by taking medical history, physical examination, ultrasonography, CT and MRI scan, hematologic tests and venography.

Table 3.24 Differences between thrombus and postmortem blood clot

Features	Thrombus	Postmortem Clot
Cause	Pathologic disorders	Dead person, sedimentation and settling down of blood components due to gravity
Location	Present in any blood vessel in the body	Present in dependent part in relation to the body kept after death
Shape	May or may not fit their vascular contours	Taking the shape of vessels or its bifurcation
Attachment to the vessel wall	Strong attachment of thrombus to vessel wall	Weak attachment of postmortem clot to vessel wall
Gross morphology	Dry, granular, firm, and friable	Gelatinous, soft and rubbery; two layer—currant jelly dark appearance in red cell-rich lower and a chicken fat appearance in cell-poor upper layer
Light microscopy	Lines of Zahn present	Lines of Zahn absent

other deep and superficial veins of the body. Less common sites of venous thromboembolism include upper extremities, liver, kidneys and brain.

- Risk factors of venous thromboembolism include family history of venous thromboembolism, obesity, older age, chronic diseases (e.g. heart disease, lung, disease, inflammatory bowel disease and cancer), injury to a vein due to trauma or major surgery, use of a central venous catheter, bed confinement, sitting for long time with crossed legs and intake of estrogen based contraceptive pills.

Clinical Pearls: Venous Thromboembolism

The symptoms of venous thromboembolism depend on location of embolus, extent of blood flow obstruction and ischemia of organ.

- **Deep vein thrombosis (DVT) in legs:** Patient presents with throbbing, cramps, swelling, pain, hardened veins, warmth and redness in the affected leg.
- **Pulmonary embolism:** Patient presents with sudden shortness of breath, rapid breathing, chest pain, hemoptysis and bluish discoloration of the lips or finger (cyanosis).

- **Central nervous system venous thrombosis:** Patient presents with headache, facial dropping, limb weakness, difficulty in speaking and in some cases, seizures.
- **Portal vein thrombosis:** Patient presents with pain and swelling in the upper abdomen, nausea and persistent fever.
- **Renal vein thrombosis:** Patient presents with pain in the flank or lower back, decreased urine output, hematuria and swelling of the lower limbs.

Deep Vein Thrombosis

Deep vein thrombosis (DVT) is most common in the deep veins of the calf region that frequently propagates in the femoral and iliac veins, from where it embolizes to the lungs leading to life-threatening pulmonary thromboembolism characterized by sudden onset of shortness of breath and clear lungs. Venous thrombi may cause venous inflammatory changes. Inflammation of veins with thrombus formation is known as '**thrombophlebitis**'.

Risk Factors

Risk factors of deep vein thrombosis include joint replacement, immobility, surgical trauma, intravenous cannula and catheterization, varicose veins, polycythemia, disseminated malignancies; and thrombophilia (factor V mutation, lupus anticoagulant, protein C and S deficiency, antithrombin III deficiency).

- In pregnant women, weight of the fetus on femoral blood vessels slows down blood venous return. Hormonal changes and stress precipitates thrombi formation. During childbirth, thromboplastin released from amniotic fluid results into activation of coagulation system.
- Hormonal replacement therapy and therapy for carcinoma prostate increase the risk of deep vein thrombosis.
- Following orthopedic surgery (knee or hip replacement, pelvic surgery) or cardiac surgery increase the risk of DVT.

Clinical Features

Patient with deep vein thrombosis presents with swelling in one or rarely both legs, pain in calf region, red discoloration of affected leg and feeling of warmth in the affected leg. DVT can occur without noticeable symptoms in 50% of cases.

- In medicine, **Homan's sign** is considered to be sign of DVT that is defined by discomfort behind the knee upon forced dorsiflexion of the foot.
- One should keep in mind that pain and swelling in affected leg may also occur as a result of rupture of gastrocnemius muscle, osteoarthritic cyst (Baker's cyst) of knee joint and anterior compartment syndrome (skin split).
- **Superficial venous thrombus** causes swelling, edema and tenderness along the course of vein in the affected area, iliofemoral venous thrombus is formed during puerperium.
- **Migratory thrombophlebitis** is defined by formation of venous thrombus in the lower extremities, embolization and propagation as toward the heart leading to pulmonary embolization.

Diagnosis

Diagnosis of deep vein thrombosis (DVT) is established by a combination of clinical history, ECG (sinus tachycardia) and imaging techniques (e.g. radiographic venogram and ultrasonography), which provide the most specific diagnostic investigation. **Wells score system** for deep vein thrombosis consists of clinical criteria with a single point awarded for criteria. Wells score system for DVT is given in Table 3.25.

Management

High-risk patients of DVT should be identified and offered prophylactic treatment with oral anticoagulants or low-molecular heparin. Immediate systemic administration of heparin anticoagulant is the standard treatment for DVT. Prolonged warfarin anticoagulant therapy is advised in patients developing recurrent DVT.

Table 3.25 Wells score system for deep vein thrombosis (DVT)

Clinical Findings	Score System
Paralysis, paresis or recent orthopedic casting of lower leg	1
Recently bedridden >3 days or major surgery within past four weeks	1
Localized tenderness in deep vein system	1
Swelling of entire leg	1
Calf swelling 3 cm greater than other leg (measured 10 cm below the tibial tuberosity)	1
Pitting edema greater in the symptomatic leg	1
Collateral nonvaricose superficial veins	1
Active cancer or cancer treated within 6 months	1
Alternative diagnosis more likely deep vein thrombosis (Baker's cyst, cellulitis, muscle damage, superficial venous thrombosis, post-phlebitis syndrome, inguinal lymphadenopathy, external vein compression)	2

Total score points 3–8 have high probability of DVT; and 1–2 score points have moderate probability of DVT.

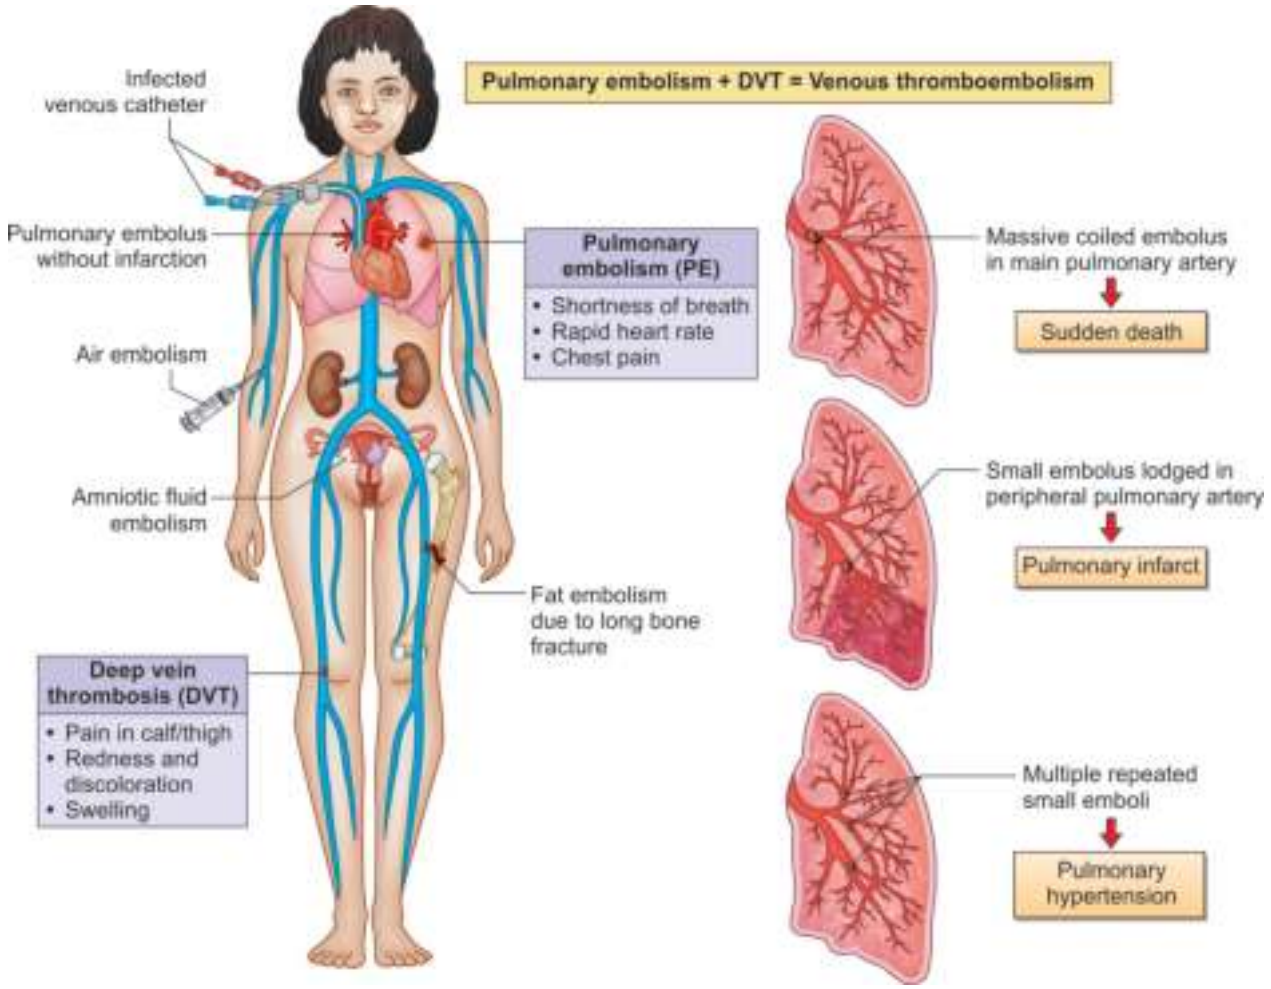

Fig. 3.26: Pulmonary embolism. It usually occurs when a blood clot called DVT in leg, travels through the bloodstream and becomes lodged in the blood vessels of the lung. This restricts blood flow to the lungs, lowers oxygen levels in lungs, increases blood pressure in the pulmonary arteries and affects other organs. Large or multiple blood clots in the lungs can be life-threatening.

Pulmonary Embolism

Pulmonary embolism (PE) is most important cause of sudden death, which most often results from thrombus formation in the deep veins of lower extremity or rarely from other deep veins of the body.

- Pulmonary embolism blocks pulmonary blood flow resulting in severe pressure increase in the pulmonary artery and right ventricle.
- Right heart strain occurs only with the most severe, large emboli that results in sudden onset of shortness of breath and fatal outcome. Pulmonary embolism is shown in Fig. 3.26. Wells diagnostic criteria of pulmonary embolism are given in Table 3.26.

Sources of Pulmonary Emboli

Sources of pulmonary emboli include thrombi in right heart (septal infarction, atrial fibrillation), tumor emboli, air embolism, pelvic veins thrombi (following pelvic or prostate surgery), fat emboli (fractures of long bones) and thrombi in deep veins of lower extremities.

Table 3.26 Wells diagnostic criteria of pulmonary embolism

Variables in Pulmonary Embolism	Wells Scoring System (Point)
Previous DVT or pulmonary thromboembolism	1
Present clinical signs of deep vein thrombosis (painful unilateral swollen warm leg)	1
Surgery or immobilization within the past four weeks (1 point)	1
Heart rate ≥100 beats/minute	1
Hemoptysis	1
Patient with active cancer disease	1
Alternative diagnosis less likely than pulmonary thromboembolism	1

Wells scoring system: 0–1 point: Low clinical probability of pulmonary thromboembolism; 2–6 points: Intermediate clinical probability of pulmonary thromboembolism; and ≥7 points: High clinical probability of pulmonary thromboembolism.

Predisposing Factors

Venous thrombosis is associated with stasis blood flow seen in elderly, debilitated, or chronically bedridden persons, joint replacement surgery, contraceptive oral pills, obesity, inherited and acquired hypercoagulable state, and congestive heart failure.

Pathophysiology

In immobilized patients, thrombi are formed most commonly in the lower extremities (deep veins of legs, femoral vein). Thrombi may also form in pelvic veins or inferior vena cava in some cases. Fragments of thrombi travel through the venous circulation and settle in branches of pulmonary artery.

Clinical Features

Pulmonary emboli may differ in size (small size, intermediate and large saddle thrombus). Clinical features of pulmonary embolism are related to the size of emboli reaching lungs.

- **Small pulmonary emboli:** Small emboli are less clinically significant. Patient presents with sudden onset of dyspnea and tachycardia. Auscultation may be normal or few rales and diminished breath sounds.
- **Intermediate size pulmonary emboli:** Intermediate size emboli increase pulmonary artery pressure leading to pulmonary hypertension. Patient may develop cor pulmonale (right-sided heart failure).
- **Large saddle thrombus:** A large venous embolus occluding the major pulmonary artery branches (bifurcation of the pulmonary artery) is known as saddle thrombus, which has sudden fatal outcome.
- **Emboli occluding pulmonary artery:** Emboli occlude pulmonary artery and decrease blood flow to pulmonary parenchyma and may cause hemorrhagic infarction in less than 10% cases of thromboembolism.
  - Pulmonary infarct is a wedge-shaped infarct located just beneath the pleura.
  - Patient presents with sudden shortness of breath, rapid breathing, chest pain, hemoptysis and bluish discoloration of the lips or finger (cyanosis).

Diagnosis

A computed tomography (CT) angiogram is standard imaging technique to establish pulmonary embolism in 95% of cases. Lower extremity Doppler ultrasound is excellent test. D-dimers testing is sensitive test in fresh new clots. D-dimers are metabolic breakdown products of fibrin. Plasmin chops up fibrin into the D-dimers.

Management

The standard of care in pulmonary embolism is administration of low molecular weight heparin and oxygen support. Later warfarin should be advised for 3–6 months after the use of heparin. Thrombolytic agents are administered in patients with hemodynamically unstable (hypotension), which activate plasminogen to plasmin. Plasmin dissolves only fresh clots. That is the reason thrombolytic agents are useful within 12 hours of myocardial infarction.

ARTERIAL THROMBOEMBOLISM

Arterial thrombi are formed in areas of active blood flow in cardiac chambers, large elastic (aorta) and muscular arteries (coronary, cerebral arteries) at the site of vascular endothelial injury, which tend to grow in a retrograde direction from the point of attachment.

- Arterial thromboembolism occurs when a blood clot or thrombus breaks off and causes partial/complete blockage of an artery that carries oxygen-rich blood from the heart to the rest of the body.
  - Partial blockage of an artery by a thrombus restricts blood flow and oxygen and induces ischemia of organ. Complete occlusion of an artery induces tissue death.
  - Arterial thromboembolism obstructing arteries supplying lower extremities below knee joints leads to ischemia and induce sudden pain, absence of arterial pulses, and a cold limb. In some cases, the limb must be amputated.
  - Arterial thromboembolism can also obstruct mesenteric artery supplying intestine produce hemorrhagic infarcts (gangrene gut). Some persons may develop myocardial infarction and cerebral stroke.
- Less common sites of arterial thromboembolism include kidneys, intestine and eyes. Arterial thromboembolism obstructing the end arteries supplying kidney and spleen produce wedge-shaped pale infarcts.
- Arterial thromboembolism is strongly linked to hyperlipidemia, hypertension, diabetes mellitus, cigarette smoking, sedentary lifestyle, recent surgery, previous stroke of cardiovascular disease, mitral stenosis and atrial fibrillation, stasis of blood flow (e.g. sickle cell anemia) and hypercoagulable state (e.g. antithrombin III deficiency, protein C deficiency, protein S deficiency, lupus anticoagulant).

Clinical Pearls: Arterial Thrombi inducing Tissue/Organ Infarction

Sudden pain is characteristic symptom of arterial thromboembolism. The most common forms of organ damage can be recognized by the following signs and symptoms.

Myocardial Infarction

- Cardiovascular disease is the leading cause of morbidity and mortality in developed countries.

- Most acute cardiovascular events are attributable to arterial thrombosis. Thrombi superimposed on ulcerated atheromatous plaque in coronary can cause myocardial infarction.
- Patient presents with chest pain, shortness of breath, profuse sweating, weakness, nausea, vomiting and palpitations.

- Atheromatous disruption through erosion or rupture creates a prothrombotic environment through activation of procoagulant factors, platelet activation by von Willebrand factor (vWF), platelet aggregation leading to thrombus formation. Simultaneously, enzymatically mediated processes that mediate endogenous fibrinolysis maintains the patency of the arteries.
- Interplay between the prothrombotic and antithrombotic pathways determines clinical outcome. If prothrombotic pathway predominates, the thrombus may propagate resulting in occlusion of the arteries.
- Thrombus achieves structural stability and resistance to dislodgement and thrombolysis through the cross-linked fibrin to vascular endothelium, thereby provide structural stability to the thrombus.

Cerebral Stroke

- Occlusion of the middle cerebral artery due to arterial thromboembolism is the most common site of arrest of arterial emboli in branches of the carotid artery resulting in cerebral infarction (liquefactive necrosis as brain lacks proteins).
- Thrombi at the junction of the internal and external carotid arteries are the causes of thrombotic brain infarcts and can also be a site of origin of emboli. Patient presents with sudden difficulty in walking, speaking and understanding, as well as paralysis or numbness of the face, arm and leg.

Peripheral Vascular Disease (Limb Infarction)

- Arterial thromboembolism obstructing arteries of leg leads to sudden pain, absence of pulses, and a cold limb.
- Patient presents with numbness, tingling sensation, pain, skeletal muscle weakness and spasm, and decreased arterial pulse in the affected lower extremity. In some cases, the limb must be amputated.

Thrombi in the Arteries

Arterial thrombosis occurs with partial or complete occlusion within large elastic and medium-sized arteries in the settings of ulcerated atheromatous plaques in abdominal aorta, coronary, cerebral and femoral arteries, which can cause systemic thromboembolism.

- Turbulence of blood flow at bifurcation of common iliac artery and abdominal aortic aneurysm can result in thrombosis. Atheromatous plaque with thrombus formation in coronary artery is shown in Fig. 3.27.
- Thrombi formed the junction of the internal and external carotid arteries may emboli to produce brain infarct (liquefactive necrosis). Ischemia in brain does not produce coagulative necrosis as it lacks proteins.

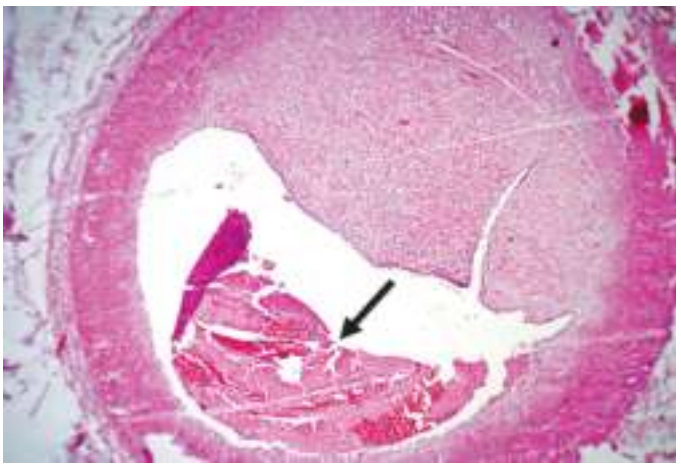

Fig. 3.27: Atheromatous plaque with thrombus formation in coronary artery (arrow) (400X). The development of atheromatous plaque and its rupture, erosion and calcification are hallmarks of atherosclerotic vascular disease. Atheromatous plaque rupture is defined by fibrous cap disruption whereby the overlying thrombus is in continuity with the underlying necrotic core.

- Arterial thrombi also undergo structural changes as thrombi grow.
  - Evolution of ST segment elevation myocardial infarction leads to doubling of the fibrin content in coronary artery thrombus each hour during clinically manifesting ischemia, whereas the relative platelet content halves each hour.
  - The structural changes in thrombus have been associated with formation of a dense, stiff fibrin network that impairs responsiveness to antiplatelet therapy and thrombolysis over time.
- Arterial thrombi are gray white and friable. Histologic examination of mature arterial thrombi demonstrates alternating pale and red areas. Pale areas of thrombus are composed of platelets held together by fibrin, while red areas are composed predominantly of red blood cells. This layering results in the '**lines of Zahn**'.

Mural Thrombi in Cardiac Chambers

Mural thrombi are formed in the left ventricle of patients due to transmural myocardial infarction.

- Mural thrombi are formed in the left atrium in rheumatic heart disease (RHD) patients with mitral stenosis and atrial fibrillation. Mural thrombi are also formed in congestive cardiomyopathy.
- Mural thrombi usually in cardiac chambers adhere to the endocardium and termed mural thrombi. Thrombi may also be formed on cardiac valvular vegetations such as infective endocarditis and nonbacterial thrombotic endocarditis.
- Mural thrombi can also develop in the settings of noninfective verrucous Libman-Sacks cardiac vegetations in systemic lupus erythematosus patients and myxoma in cardiac chambers.

EMBOLISM

Embolus is detached mass (e.g. thrombus, fat, gas, amniotic fluid), that is circulating to distant organs and eventual trapping within the vasculature resulting to partial or complete occlusion of cardiovascular system leading to dysfunction of organs. Origin of thrombi causing embolization in various organs are given in Table 3.27.

- Detachment of fragments of thrombi originating from veins (deep vein in legs, femoral vein) or heart (cardiac vegetations, myxoma) or atheromatous plaques travel in the arterial system. One-third of patients with a left atrial or left ventricular myxoma die from tumor embolization to the brain. Emboli obstruct the blood flow and cause ischemic damage of organs.
- Paradoxical emboli originate in the venous circulation and bypass the lungs, but gain access through an incompletely closed foramen ovale (most common) or atrial septal defect into the systemic circulation.
- Thromboembolism refers to obstruction of a blood vessel by a blood clot or thrombus that has dislodged from another site in the circulation.

PATHOPHYSIOLOGY OF EMBOLISM

The embolus may be a thrombus, fat globule (fat embolism), a bubble of air or other gas (gas embolism), amniotic fluid (amniotic fluid embolism) and embolism due to miscellaneous exogenous and endogenous materials. Two of the most serious conditions caused by an embolism are pulmonary embolism and cerebral stroke.

FAT EMBOLISM SYNDROME

Fat embolism syndrome refers to presence of emboli comprising of fat microglobules in the circulation, which is most often a consequence of severe trauma with long bone fractures such as femur with abundant fatty bone marrow. It can also be seen with extensive trauma to fat laden tissues, burns, and very rarely with orthopedic procedures. Fat embolic syndrome is shown in Fig. 3.28.

Pathogenesis

On long bone fracture, bone marrow fatty fragments enter the circulation, lodge in small blood vessels of the lung, skin, kidneys, brain and other organs producing ischemia and hemorrhage, which results in the clinical manifestations. Fat microglobules are converted into fatty acids, which damage vascular endothelium resulting in formation of platelet thrombi in areas of injury. Causes of fat embolism are given in Table 3.28.

Clinical Features

Patient develops potentially fatal fat embolism syndrome within 24–72 hours, which is characterized by pulmonary distress, cutaneous petechial hemorrhages, and various neurologic manifestations. Gurd and Wilson diagnostic criteria for fat embolism syndrome and laboratory findings are given in Table 3.29.

- **Pulmonary manifestations:** Patient develops dyspnea and tachypnea due to presence of fat microglobules in pulmonary capillaries leading to hypoxemia.
- **Petechial hemorrhage:** Patient develops petechial hemorrhage over the chest and upper extremities due to thrombocytopenia from platelet adhesion to microglobules of fat.
- **Neurologic manifestations:** Numerous petechial hemorrhages are produced by fat emboli in the brain, particularly in white matter known as '**brain purpura**'. Patient develops neurologic manifestations such as loss of consciousness, cerebral edema and herniation within a week in less than 10% of cases with fatal outcome. Fat emboli inducing petechial hemorrhages in brain are shown in Fig. 3.29.

Table 3.27 Origin of thrombi causing embolization in various organs

Origin of Thrombi	Embolization to Organs
Thrombi in deep veins of leg	Pulmonary thromboembolism
Mural thrombi in left ventricle	Systemic thromboembolism
Trauma to bone marrow	Fat embolism
Entry of excess air during intravenous fluid infusion, cardiothoracic surgery, delivery and trauma to veins during surgery of head and neck	Air embolism
Divers and ascent during flights	Decompression sickness
Amniotic fluid entry in circulation during delivery	Amniotic fluid embolism
Ulcerated atheromatous plaques	Atheroembolism
Tumor fragments (myxoma heart)	Tumor fragment emboli

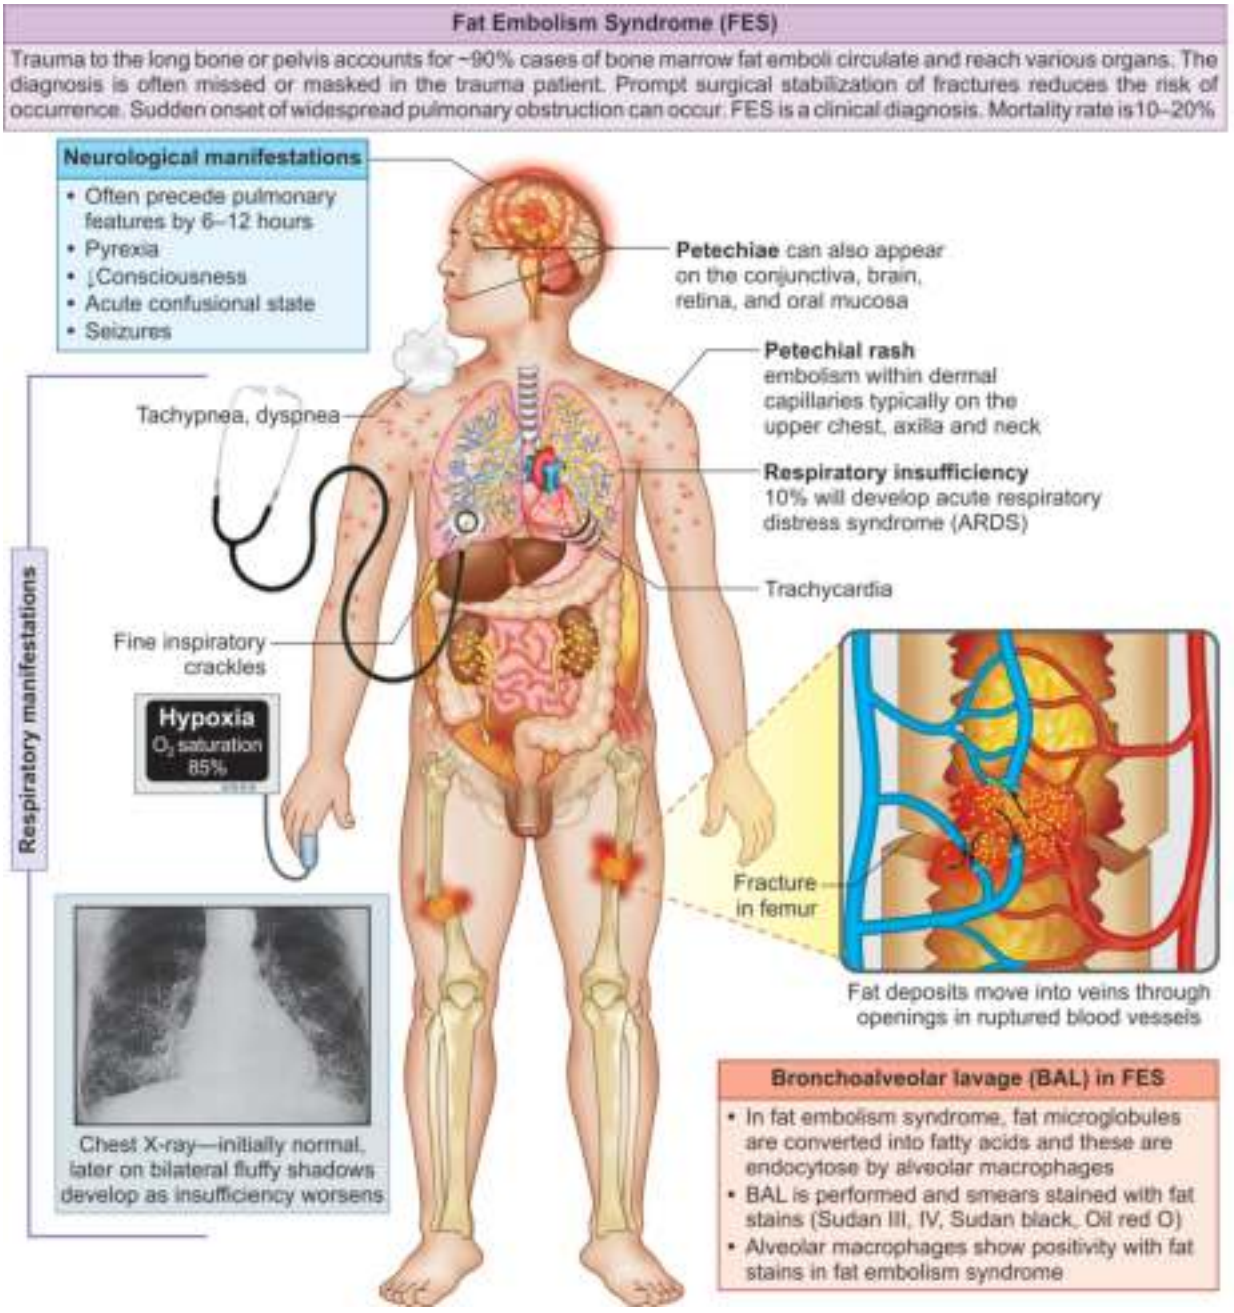

Fig. 3.28: Fat embolic syndrome. Fat embolism is characterized by fat globules within microcirculation, while fat embolic syndrome is the systemic manifestation of fat embolism, characterized by pulmonary insufficiency due to occlusion of blood flow, neurologic symptoms, anemia, thrombocytopenia and a rash. Fat embolic syndrome is most often associated with orthopedic trauma.

Laboratory Diagnosis

Bronchoalveolar lavage is done to demonstrate fat in alveolar macrophages by staining with fat stains, e.g. Sudan III, Sudan V, Sudan black and Oil red O. In fat embolism syndrome, fat microglobules are converted into fatty acids, which are taken by the alveolar macrophages. In autopsy specimens, frozen section examination reveals fat globules within the pulmonary arterioles demonstrated by fat stains. Examination of paraffin-embedded sections stained with hematoxylin and eosin reveals rounded clear holes due to dissolution of fat during processing in the small pulmonary arterial branch of lung characteristic for fat embolism syndrome.

AIR EMBOLISM

Air embolism results from the introduction of excess of air into the circulation leading to blood flow obstruction.

Table 3.28 Causes of fat embolism

Fracture of long bones
Soft-tissue trauma
Liposuction
Bone marrow infarction complicating hemoglobinopathy
Bone marrow harvest
Fatty liver induced by viral hepatitis
Pancreatitis
Intravenous injection of various oils by accident or intention
Breast augmentation
Periurethral injection to treat stress incontinence

Table 3.29 Gurd and Wilson diagnostic criteria for fat embolism syndrome and laboratory findings

Major Diagnostic Criteria
Skin (petechial hemorrhages)
Respiratory symptoms (tachypnea, dyspnea, bilateral inspiratory crepitations, hemoptysis, bilateral diffuse patchy shadowing on chest radiograph)
Neurological signs (confusion, drowsiness, coma)
Minor Diagnostic Criteria
Tachycardia (heart rate >120 per minute)
Pyrexia >38.5°C
Retinal petechial hemorrhages and fat emboli
Renal changes (anuria or oliguria)
Jaundice
Unexplained thrombocytopenia and low hemoglobin
Erythrocyte sedimentation rate increased
Fat macroglobulinemia
Fat globules in urine
Fat globules in sputum

- Patient presents with distal ischemic injury, pulmonary air embolism—sudden death, convulsions and deep coma.
- Air embolism occurs as a consequence of penetrating chest injury, clumsily performed criminal abortion, intravenous infusion of fluids and deep-sea divers.
- Air embolism occurs when atmospheric air may enter the blood circulation as a result of incision of intracranial vein during head and neck surgery. Inspiration process produces a suction effect by causing negative pressure in these veins leading to frothing of blood in right ventricle and impairment of cardiac functions.
- Penetrating chest injury leads to entry of air into the ruptured vessels resulting in air embolism.

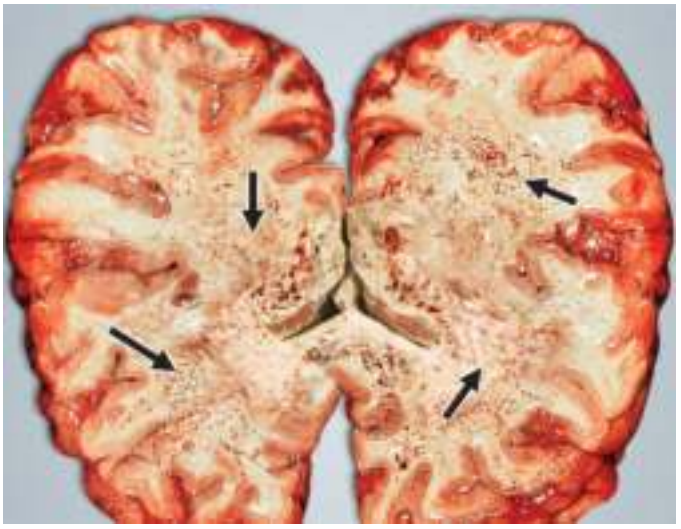

Fig. 3.29: Fat emboli inducing petechial hemorrhages in brain. The patient died due to multiple fractures of both legs in a motorcycle accident. The fat emboli caused petechial hemorrhages in the white matter throughout the brain, resulting in coma and death. The macroscopic appearance of cerebral malaria is identical to this (arrows).

Pneumothorax due to rupture of a pre-existing subpleural bleb or pulmonary embolism is responsible for dyspnea and pleuritic pain. Due to improper monitoring of intravenous infusion, excess of air (more than 100 cc) may result in air embolism.

Clinical Pearls: Decompression Sickness (Caisson Disease)

- Decompression sickness is a form of air embolism observed in deep-sea divers due to sudden change in atmospheric pressure, who return to the surface too rapidly.
- Insoluble nitrogen coming out of blood forms multiple gas emboli obstructs blood flow to skeletal system, central nervous system and other tissues.
- Patient presents with musculoskeletal pain in joints, muscle and bones called 'bends'.
- Obstruction to circulation leads to small infarcts. Nitrogen has an affinity for adipose tissue; hence obese persons are at increased risk for Caisson disease.

AMNIOTIC FLUID EMBOLISM

Amniotic fluid embolism refers to the entry of amniotic fluid containing fetal squamous cells, lanugo hair, vernix, and mucin following tear in the placental membranes may gain access to uterine and cervical veins into the maternal circulation, which occurs during labor or immediate postpartum period.

- Patient develops abrupt onset of dyspnea, cyanosis, hypotension and bleeding manifestations as a result of amniotic fluid emboli contents.
- Amniotic fluid embolism is most often confirmed at autopsy by histopathologic examination, which

reveals presence of squamous epithelial cells, lanugo hair, fat globules, mucinous material, marked pulmonary edema, diffuse alveolar damage and fibrin clots in the blood vessels.

Neonatal Respiratory Distress Syndrome in Amniotic Fluid Embolism

Diffuse alveolar damage with hyaline membranes is a feature of neonatal respiratory distress syndrome in amniotic fluid embolism.

- Severe damage to alveolar-capillary membrane by amniotic fluid emboli contents leads to formation of hyaline membrane and pulmonary edema.
- Due to impaired exchange of gases across alveolar-capillary membrane, patient develops dyspnea and cyanosis.
- Pulmonary edema in neonatal respiratory distress syndrome does not resolve. Neonate presents with signs of respiratory distress.

Disseminated Intravascular Coagulation in Amniotic Fluid Embolism

Amniotic fluid embolism is one of the major obstetric causes of disseminated intravascular coagulation (**DIC**) as a result of activation of coagulation system. Patient presents with bleeding manifestations due to consumption of coagulation factors and fibrin (i.e. defibrinating syndrome) results in formation of microthrombi with ischemic changes in various organs. There is sudden onset of cyanosis and shock, followed by coma and death.

EMBOLISM DUE TO EXOGENOUS AND ENDOGENOUS MATERIALS

Embolism may be caused by fragments of tumors such as clear cell carcinoma of kidney, lung carcinoma and malignant melanoma.

- Atherosclerosis means hardening (sclerosis) or loss of elasticity of large elastic arteries and medium-sized arteries due to atheromatous plaque formation. Emboli of atheromatous plaque material to distant sites may result in infarction (spleen, kidney, small intestine).
- Various exogenous and endogenous substances may act as emboli, which include fragments from tissue and placenta.
- Other emboli are formed by parasites, bullets, sutures and barium contrast media.

INFARCTION

An infarct is an area of necrosis resulting from ischemia caused by obstruction of arterial or venous blood supply in a particular tissue or organ such as myocardium, brain, lung, kidneys, spleen, bowel, ovaries, testes, and lower limb.

- Ischemia produces coagulative necrosis in solid organs rich in proteins such as heart, kidney and spleen. Coagulative necrosis refers to light microscopic changes in the dead or dying cells as a result of ischemia.
- Cellular outlines are maintained but structural details are lost. Widespread tissue necrosis is called an 'infarction'. **Liquefactive necrosis** occurs in brain (proteins deficient in brain) and suppurative infections.
- Intravascular causes of organ infarction include arterial occlusion by thrombotic or embolic events (99% of all infarcts), local vasospasm and expansion of an atheromatous plaque occluding lumen.
- Extravascular causes of organ infarction include arterial occlusion due to compression by a tumor, twisting of the blood vessels: testicular torsion and bowel volvulus, edema inducing ischemia of hernial sac entrapment, and traumatic rupture of the blood vessels. Causes of infarction depending on blockage of blood vessel are given in Table 3.30.

FACTORS INFLUENCING INFARCT FORMATION

Factors that influence development of organ infarct include the nature of blood supply, rate of development of the vascular occlusion and the vulnerability of tissue or organ to hypoxia and the blood oxygen content.

ANATOMICAL PATTERN OF ARTERIAL SUPPLY

Extent of tissue injury due to ischemia depends on the anatomical pattern of arterial supply of the tissue or organ. There are four patterns of arterial supply to various organs described as under.

Organs Infarct with Single Arterial Supply Without Rich Anastomoses

Some organs such as kidney, spleen and retina have single arterial supply without significant anastomosis. Occlusion of arteries supplying these organs produce white (pale) infarcts.

Table 3.30 Causes of infarction depending on blockage of blood vessel

Lesion	Artery Involved	Infarct in Organ
Blockage of arteries		
Atherosclerosis	▪ Coronary arteries ▪ Cerebral arteries ▪ Renal arteries	▪ Myocardial infarction ▪ Cerebral stroke ▪ Renal infarct
Thromboembolism in arteries (originating in heart and blood vessels)	▪ Coronary arteries ▪ Renal arteries ▪ Splenic artery	▪ Myocardial infarction ▪ Renal infarct ▪ Splenic infarct
External pressure on arteries	Arteries of organ	Organ infarct
Blockage of arteries and veins		
Strangulated hernia	Mesenteric vessels	Gangrene intestine
Volvulus intestinal loop	Mesenteric vessels	Gangrene intestine
Intussusception	Mesenteric vessels	Gangrene intestine
Torsion testes	Testicular vessels	Testicular infarct
Blockage of small arteries		
Microthromboemboli (originating from infective endocarditis)	Renal artery branches	Renal infarct
Sickle cell anemia	Renal peritubular capillaries in the medulla due to the low O_2 tension in the medulla	Renal infarct
Bed sores	Occlusion of skin, small vessels	Gangrene of affected skin
Decompression sickness	Dissolved gases forming microemboli occluding vessels	Infarcts of organs

Organ Infarct with Single Arterial Supply with Rich Anastomoses

Intestine supplied by superior and mesenteric arteries has multiple anastomoses. Large bowel has arterial blood supply from more than one artery. Splenic flexure and rectosigmoid junction are the most common sites of infarcts in colon. These are less vascularized areas known as 'watershed regions', which include splenic flexure (junction of the superior and inferior mesenteric arteries) and rectosigmoid junction (junction of left colic and sigmoid—superior rectal branches of the inferior mesenteric artery).

Organs Infarct with Dual Blood Supply

Lungs and liver have dual blood supply, hence less prone to ischemia.

- Liver receives blood supply from portal vein and hepatic artery. Occlusion of portal vein may produce **red infarct** as liver keeps on receiving arterial supply from hepatic artery.
- Lung is supplied by pulmonary and bronchial arteries. Occlusion of pulmonary artery by emboli produces red infarct, because lung keeps on receiving blood from bronchial artery. Hemorrhagic lung infarct is raised, wedge-shaped area with red blue discoloration that extends to the pleural surface. Majority of lung infarcts are located in the lower lobes. Perfusion is greater than ventilation in the lung's lower lobes. Patient develops dyspnea or pleuritic chest pain on inspiration, expiratory wheezing, tachycardia, productive cough (sputum may be blood-tinged), low-grade fever and pleural effusion (fibrinous exudate).

Organs Infarct with Parallel Blood Supply

Forearm is supplied by radial and ulnar arteries running in parallel pattern. Vitality of forearm due to occlusion of one artery is maintained by alternative another artery.

VULNERABILITY OF TISSUES TO HYPOXIA

Ischemic injury depends on the type of cells or tissues undergoing ischemic necrosis. Hypoxia adversely affecting tissues in descending order include neurons, myocardium, liver, skeletal muscle and fibroblasts. Vulnerability of cells/tissues/organs) to ischemic irreversible cell injury are given in Table 3.31.

Nervous System

Complete interruption of blood supply to brain causes irreversible damage to neurons within 3–5 minutes. Cerebellum's Purkinje cells and hippocampus area are more susceptible to ischemic injury.

Table 3.31 Vulnerability of cells/tissues/organs to ischemic irreversible cell injury

Organs	Cells/Tissues	Duration of Development of Irreversible Cell Injury
Nervous system	Neurons (cerebellum Purkinje fibers and hippocampus region most susceptible to ischemic injury)	3–5 minutes
Heart	Myocardium	20–30 minutes
Liver	Hepatocytes	1–2 hours
Skeletal muscle	Skeletal muscle fibers	Many hours
Fibrous tissues	Fibroblasts	Resistant to ischemic changes

Myocardium and Liver

Ischemic necrosis of myocardial cells and hepatocytes cause irreversible cell death within 1–2 hours.

Skeletal Muscles

Ischemic necrosis of skeletal muscle cells causes irreversible cell death within many hours.

BLOOD OXYGEN CONTENT

Blood oxygen content and cardiovascular system play important role in maintenance of arterial supply to the tissues. Disorders of blood and cardiovascular system adversely affect the arterial supply to the tissues or organs, which include blood loss, shock, sickle cell anemia, cardiac failure and atheromatous plaques in large elastic and medium size arteries. Complete occlusion of arteries produces more severe ischemic necrosis of tissues or organs.

RAPID DEVELOPMENT OF INFARCT

Sudden occlusion of arteries produces more severe and rapid ischemic tissue injury, because tissue or organ takes more time for development of collateral blood supply.

TYPES OF INFARCT

Infarct is gross manifestation of coagulative necrosis in organs, which is of two types, i.e. pale/white infarct and hemorrhagic/red infarct depending on the consistency of the tissue. Infarcts may be recent or healed lesion. Infarcts are classified based on the color, age, and presence or absence of microbial infection.

- Based on color, there are two types of infarcts, i.e. pale/white infarcts, and hemorrhagic/red infarcts. Pale/white infarcts occur in kidneys, spleen and heart. Hemorrhagic/red infarcts are common in lungs, small intestine, ovaries and testes. Differences between pale/white and hemorrhagic/red infarcts are given in Table 3.32.
- Septic (infective) infarcts occur when bacterial vegetations from a heart valve embolize or when microbes seed an area of necrotic tissue. Such infarcts are converted into abscess with a corresponding greater inflammatory response. Septic infarcts get

Table 3.32 Differences between pale/white and hemorrhagic/red infarcts

Comments	Pale/White Infarcts	Hemorrhagic/Red Infarcts
Arterial circulation	Single arterial supply	Dual arterial supply
Etiology	Occlusion of artery by thrombi, emboli, complicated atheromatous plaque and vasospasm	Occlusion of artery or vein by thromboembolic phenomenon or torsion
Consistency of organ	Solid consistency	Loose texture organs permitting blood
Organs involved	Heart, kidneys, spleen, digits of lower limb (cystic infarct in brain)	Lung, small intestine, testis and ovaries
Morphology of infarcts	▪ Small size infarcts ▪ Wedge shaped, with the occluded vessel at the apex and the periphery of the organ forming the base	▪ Large-sized infarcts ▪ Well circumscribed, firm and dark red infarcts
Shape of infarct	Zone of hyperemic at the periphery of infarct sharply defines margins	Margin of infarct not well defined. Fibrinous exudates present on serous membrane of organs
Edema in organ	Absent in organs	Present in organs
Light microscopy	Coagulative necrosis in all solid organs except brain*	Coagulative necrosis in all organs involved

**Liquefactive necrosis in brain occurs, because brain is deficient in proteins.*

organized. Bland infarcts are sterile (non-infective). No organisms are demonstrated in these infarcts.

PALE/ WHITE INFARCT

Pale/white infarct is secondary to the sudden occlusion of a vessel, which most common occurs in solid organs such as heart, kidney, and spleen. Increased density of solid tissue prevents RBCs from diffusing through necrotic tissue.

- Pale/white infarct produces wedge-shaped with apex pointing to the site of obstruction, and the base of infarct at the periphery of the organ.
- The cellular debris of pale/white infarct is degraded by neutrophils, and later by macrophages. Granulation tissue eventually forms, which is to be replaced ultimately by a scar.

Myocardial Infarct

Myocardial infarct is most often caused by ischemia related to coronary artery occlusion involving >75% of lumen by atheromatous plaque. Coronary artery occlusion causing myocardial infarction is shown in Fig. 3.30A and B.

- Major risk factors of atherosclerosis are hyperlipidemia, hypertension, tobacco smoking and diabetes mellitus.
- The coronary vessels most commonly involved in decreasing order of frequency are anterior descending branch of left anterior discending (LAD) of left coronary artery in 50%, right coronary artery (RCA) in 30% and left circumflex artery (LCA) in 20%. Atheromatous plaques are observed in proximal part of anterior descending artery.
- Complete occlusion of coronary artery produces transmural myocardial infarct. Partial coronary artery occlusion leads to subendocardial infarct limited to the interior one-third to inner half of the left ventricle. Due to severe reduction of blood flow in coronary artery causes circumferential myocardial infarct.

Renal Infarct

Renal infarct refers to ischemic necrosis due to occlusion of interlobar or larger branches of the renal artery most often caused as a result of thromboembolism. Patient presents with sudden onset of flank pain and hematuria.

Pathogenesis

The microthrombi originating from mural endocardium in the settings of acute myocardial infarction, and infective endocarditis can occlude renal artery resulting in renal infarct. Less common causes of renal artery occlusion inducing renal infarct include severe atheromatous plaque and sickle cell nephropathy. Sickling of red blood cells may occur in peritubular capillaries in the medulla due to the low O_2 tension in the medulla leading to renal ischemia. The glomeruli are conspicuously congested with sickle cells.

Gross Morphology

Irregular wedge-shaped pale/white infarcts are present in the renal cortex within one week. Old renal infarcts have a V-shaped appearance due to scar tissue. Apex of renal infarct is pointing towards cortex and base towards medulla.

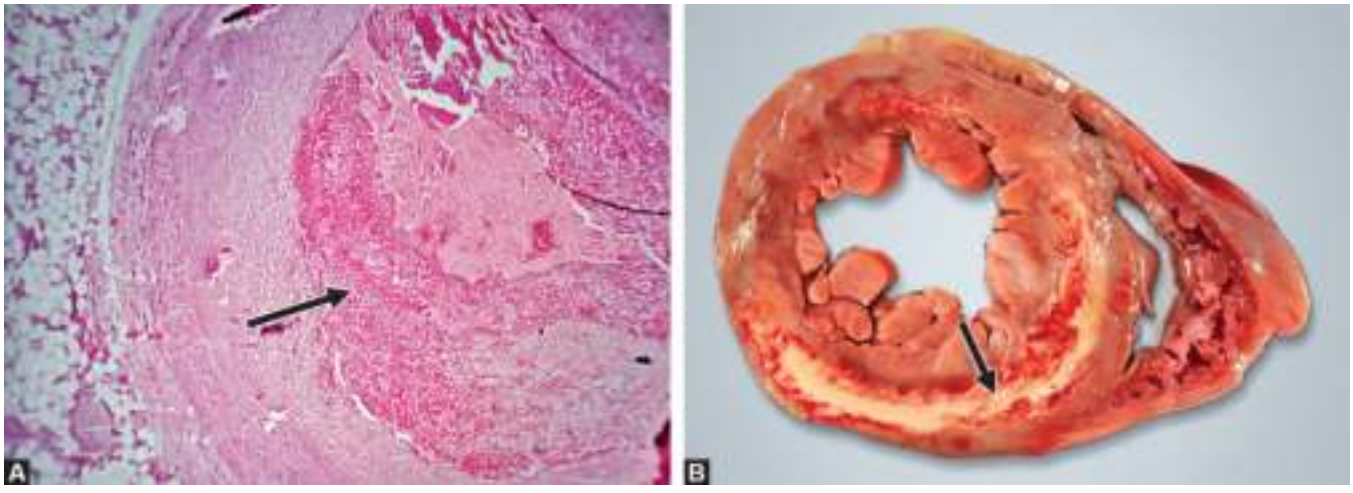

Fig. 3.30A and B: Coronary artery occlusion causing myocardial infarction. (A) Complicated atheromatous plaque with thrombus formation and complete occlusion of coronary artery (arrow) (400X), (B) myocardial infarct (arrow). Coronary artery occlusion can lead to myocardial infarction. The immediate and most common cause of coronary artery obstruction is the thrombus formation or rupture of atheromatous plaque. Patient presents with chest pain, pain radiating to jaw, neck or back and shortness of breath.

Light Microscopy

Histopathologic examination of renal infarct shows coagulative necrosis. Cellular outlines of renal tubules and glomeruli are maintained with loss of structural details. There is presence of polymorphonuclear cells in acute inflammatory phase followed by macrophages in later phase in the margin of renal infarct.

Splenic Infarct

Splenic infarct refers to ischemic necrosis due to occlusion of splenic artery and its branches most often caused as a result of thromboembolism.

- The microthrombi originating from the heart such as mural endocardium in the settings of acute myocardial infarction and infective endocarditis occlude splenic artery leading to splenic infarct.
- Splenic pale/white infarcts are most often multiple and wedge-shaped in appearance.
- Histopathologic examination of splenic infarct shows coagulative necrosis. Cellular outlines are maintained with loss of structural details. There is presence of polymorphonuclear cells in acute inflammatory phase followed by macrophages in later phase in the margin of splenic infarct. Gross morphology of pale/white infarct in spleen is shown in Fig. 3.31.

HEMORRHAGIC/RED INFARCT

Hemorrhagic/red infarct may result from either arterial or venous occlusion, which occurs principally in the loose-textured well vascularized organs such as lungs, small intestine, ovaries, and testis. Splenic vein occlusion due to thrombosis causes hemorrhagic/red infarct in spleen. Hemorrhagic infarct allows RBCs to diffuse through necrotic tissue. Gross examination reveals wedge-shaped hemorrhagic/red infarct with dark red to purple discoloration extending to the surface of organ.

Fig. 3.31: Gross morphology of pale/white infarct in spleen. Infarct is a localized area of tissue necrosis caused by arterial occlusion and is usually seen in the spleen, kidney and heart. Pale/white infarct lacks hemorrhage and limited red blood cells accumulation, when compared to hemorrhagic infarct (arrow). (*Courtesy:* Department of Pathology, Sapthagiri Institute of Medical Sciences, Bengaluru.)

Pulmonary Hemorrhagic/Red Infarct

Each lung receives blood supply from pulmonary and bronchial arteries. Pulmonary artery embolism produces wedge-shaped area of hemorrhagic/red infarct extending to the pleural surface. Hemorrhagic/red infarct area receiving constant blood supply from normal bronchial arteries, and allows RBCs to diffuse through necrotic tissue. Gross examination of pulmonary infarct reveals wedge-shaped area of hemorrhage extending to the pleural surface due to embolus in one of the pulmonary artery tributaries. Pulmonary hemorrhagic/red infarct is shown in Fig. 3.32.

Intestinal Hemorrhagic/Red Infarct

Small intestine has rich blood supply with extensive collateral circulation. Occlusion of mesenteric artery causes hemorrhagic/red infarct. Volvulus (segment of gut twisting on its mesentery) and strangulated hernial sac cause infarct in small intestine. Red blood cells diffuse through necrotic tissue. On gross examination, hemorrhagic/red infarcts are sharply circumscribed, firm, and dark red to purple. Gross morphology of

Fig. 3.32: Pulmonary hemorrhagic infarct. A wedge-shaped pulmonary hemorrhagic infarct is seen extending to pleural surface (arrow). Hemorrhage in pulmonary infarct is attributed to the dual arterial blood supply of lung. Deep vein thrombosis (DVT) is the most common source of pulmonary embolism.

Fig. 3.33: Gross morphology of ischemic bowel disease (gangrene intestine). External surface shows dusky blackish discoloration. Ischemic bowel disease represents an irreversible cell injury that occurs due to sudden occlusion of arterial blood supply by a thrombus leading to ischemia involving short or long segments of bowel. Splenic flexure (Griffiths point) and rectosigmoid junction (Sudek's point) are watershed areas prone to ischemia.

Fig. 3.34: Liquefactive necrosis in brain. Cut surface of the brain shows liquefactive necrosis with formation of cystic spaces on resolution of infarct (arrow). Liquefactive necrosis is type of necrosis which results in a transformation of the tissue into liquid viscous mass as a result of lysosomal release of digestive enzymes.

ischemic bowel disease (gangrene intestine) is shown in Fig. 3.33.

Hemorrhagic/Red Infarct of Testis or Ovaries

Torsion of testis or ovary and postoperative adhesions may cause venous occlusion results in hemorrhagic/red infarcts giving a bluish discoloration.

Pale/White Myocardial Infarct Undergoing Hemorrhagic/Red Infarct

Myocardial infarct is an example of white/pale infarct, but a hemorrhagic/red infarct occurs following spontaneous reperfusion of infarct area due to therapeutically induced lysis of the occluding thrombus.

BRAIN INFARCT

Cerebrovascular diseases are the most common group of central nervous system disorders. Complicated atheromatous plaques in arteries supplying brain at the bifurcation of carotid arteries, emboli arising from cardiac mural thrombi, vegetations of infected endocarditis valves, clumps of malignant tumor cells, bubbles of air, or droplets of fat into middle cerebral artery cause cerebral ischemia leading to liquefactive necrosis and formation of cystic spaces containing creamy necrotic debris in the brain.

Watershed Areas in Brain

Cerebral infarction occurs in the boundary zone between the territories supplied by middle cerebral and anterior cerebral arteries. Watershed areas of the arterial territory are most remote from the patent arterial stems and thus most vulnerable to the effects of cerebral underperfusion.

Gross Morphology

Brain does not contain proteins; hence ischemia produces liquefactive necrosis resulting in formation of cystic spaces containing creamy liquid necrotic debris by hydrolytic enzymes. Liquefactive necrosis in brain is shown in Fig. 3.34.

Light Microscopy

Microscopically, the cystic space in brain infarct contains necrotic cell debris, macrophages filled with phagocytosed material. The cyst wall is formed by proliferating capillaries, inflammatory cells, and neuroglial cells (gliosis) in brain.

SHOCK

Shock is a life-threatening clinical state as a result of decreased blood flow throughout the body resulting in reduced perfusion of tissues, impaired oxygenation of tissues and multiple organs failure. Shock may result from significant blood loss, severe allergic reaction, severe bacterial infections, severe/third degree burns,

Table 3.33 Type and causes of shock

Type of Shock	Causes	
Major types of shock		
Hypovolemic shock	▪ Severe trauma, major surgery, obstetrical related massive blood loss ▪ Severe burns ▪ Dehydration due to vomiting and diarrhea	▪ Diabetic precoma state ▪ Vasodilation (severe allergic reaction and bacterial sepsis)
Cardiogenic shock	▪ Myocardial infarction ▪ Ventricular arrhythmias ▪ Cardiomyopathy ▪ Cardiac tamponade (hemopericardium)	▪ Acute valve in competence ▪ Dissecting aortic aneurysm ▪ Massive pulmonary embolism
Shock associated with systemic inflammation	▪ Septic shock due to gram-positive, gram-negative bacterial infections resulting to vasodilatation, and fungal infections	▪ Anaphylactic shock: Type 1 hypersensitivity (excessive histamine resulting to vasodilatation)
Shock related to uncommon condition		
Neurogenic shock	▪ Spinal administration of anesthetic agent ▪ Spinal cord injury	▪ Head injury
Endocrine shock	▪ Adrenal failure	▪ Myxedema

Table 3.34 Pathologic findings in organs in shock

Organ	Pathologic Findings
Brain	Edema and focal ischemic changes
Heart	Subendocardial infarct
Lungs	Edema, hemorrhage, hyaline membranes
Kidneys	Acute tubular necrosis
Liver	Centrilobular congestion and necrosis
Intestine	Mucosal petechiae, foci of necrosis

dehydration, and cardiac failure. Type and causes of shock are given in Table 3.33. Pathologic findings in organs in shock are given in Table 3.34.

CATEGORIES OF SHOCK

There are mainly five categories of shock, which include hypovolemic shock, cardiogenic shock, septic shock, anaphylactic shock and neurogenic shock. Pathophysiologic findings in hypovolemic, cardiogenic and endotoxic shock are given in Table 3.35.

Table 3.35 Pathophysiologic findings in hypovolemic, cardiogenic and endotoxic shock

Characteristics	Hypovolemic Shock	Cardiogenic Shock	Endotoxic Shock
Cardiac output	Decreased	Decreased	Increased
Peripheral vascular resistance	Increased	Increased	Decreased
Left ventricle end diastolic pressure	Decreased	Increased	Decreased

HYPOVOLEMIC SHOCK

Hypovolemic shock is characterized by circulatory collapse due to acute reduction of blood volume resulting in circulatory dysfunction and inadequate tissue perfusion, which most often occurs due to acute blood loss >20% of blood volume or reduction of body fluids.

Etiopathogenesis

Hypovolemic shock is categorized into two subtypes: hemorrhagic hypovolemic shock and nonhemorrhagic hypovolemic shock.

- **Hemorrhagic hypovolemic shock:** Common causes of hemorrhagic hypovolemic shock include gastrointestinal tract bleed (e.g. esophageal varices, peptic ulcer disease, diverticulosis), trauma, ruptured abdominal atheromatous aneurysm, tumor eroding into major blood vessel and spontaneous bleeding due to prolonged anticoagulant use.
- **Nonhemorrhagic hypovolemic shock:** Common causes of nonhemorrhagic hypovolemic shock include severe/third degree burns, **Stevens-Johnson syndrome**, fluids loss from severe diarrhea or vomiting, intestinal obstruction, peritonitis and acute pancreatitis. Shifting of fluid in pleural cavity, pericardial cavity or peritoneal cavity can also cause nonhemorrhagic hypovolemic shock.

Pathophysiology

In hypovolemic shock, body's compensatory mechanism cannot maintain circulation for a long time. Blood pressure starts declining dramatically.

- **Compensatory mechanism:** In the initial phase of hypovolemic shock, body tries to compensate for fluid loss and maintains tissue/organ perfusion by

increasing cardiac output, sodium and water retention, synthesis of antidiuretic hormone.

- Decreased blood supply to kidney leads to synthesis of renin, which stimulates liver to release angiotensinogen, which form angiotensin I and converted to angiotensin II in lungs.
- Angiotensin II increases peripheral resistance and stimulates aldosterone production by adrenal cortex.
- Aldosterone acts on distal convoluted tubules of kidneys to absorb sodium and water. Compensatory mechanism in controlling hypovolemic shock by regulating of blood pressure is shown in Fig. 3.35.

- **Failure of compensatory mechanism:** If compensatory mechanism fails, blood pressure continues to drop leading to hypotension and cessation of tissue perfusion. Cardiac ischemia and arrhythmias may develop.

Clinical Features

Patient develops metabolic acidosis, cyanosis, cold clammy skin, thready pulse, tachycardia, perspiration, and renal failure associated with decreased urine output (oliguria).

Laboratory Diagnosis

Blood biochemistry in hypovolemic shock shows increased potassium, blood urea nitrogen and creatinine. During hemorrhage, there is no initial effect on hemoglobin and hematocrit concentration. Plasma is replaced

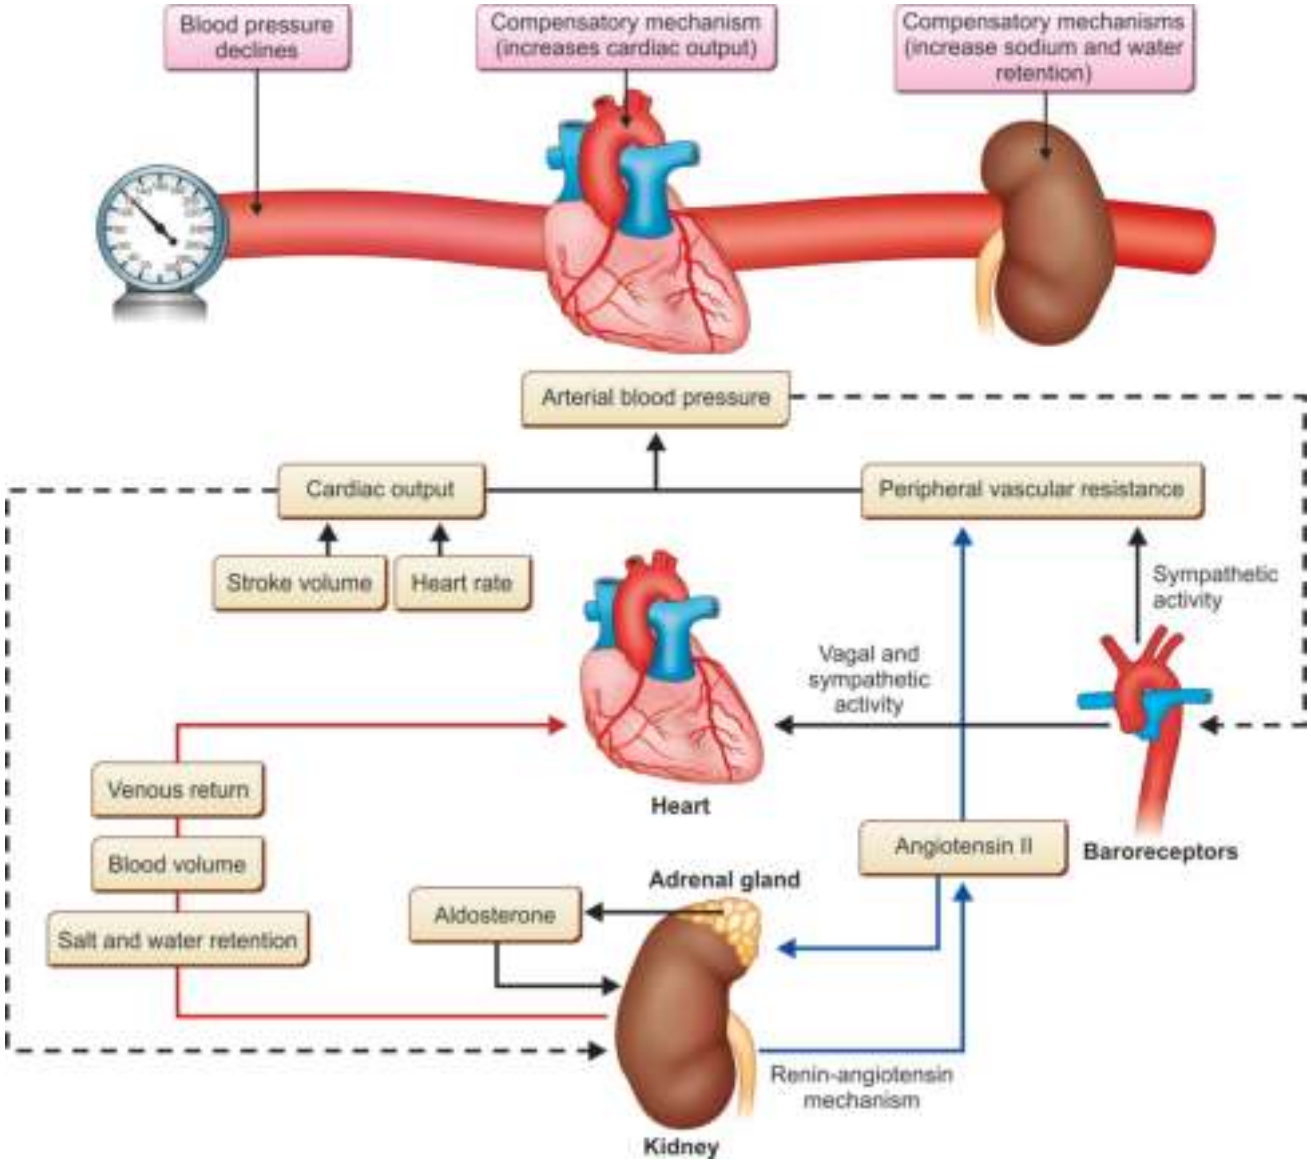

Fig. 3.35: Compensatory mechanism in controlling hypovolemic shock by regulating of blood pressure. The solid lines represent the mechanisms for kidneys and baroreceptor control of blood pressure through changes in cardiac output and peripheral resistance. The dashed lines represent the stimulus for regulation of blood pressure by baroreceptors and kidney.

first with fluid from interstitial space. Absolute neutrophilic leukocytosis is the first hematologic sign of hemorrhage. RBCs production response in the bone marrow begins in 5–7 days after hypovolemic shock.

CARDIOGENIC SHOCK

Cardiogenic shock is a life-threatening condition in which heart suddenly cannot pump out enough oxygen rich blood to the vital organs to meet body's demand most often caused by myocardial infarction.

- Other causes of cardiogenic shock include viral myocarditis, cardiomyopathies, cardiac arrhythmias, pulmonary embolism, severe mitral insufficiency, rupture of papillary muscles or chordae tendineae, rupture of ventricular free wall aneurysm, cardiac tamponade and rarely atrial myxoma.
- Patient presents with dyspnea as a result of pulmonary edema, cold, clammy skin due to vasoconstriction, hypotension, and rapid weak pulse due to compensatory response to decreased cardiac output. Clinical presentation varies related to organ involved and finally development of renal failure.

SEPTIC SHOCK

Septic shock is a serious condition that occurs when a body wide infection leads to life-threatening low-blood pressure, an altered mental state with organs dysfunction. Septic shock can be caused by bacteria and fungi.

- Septicemia with gram-negative organisms (*Escherichia coli*) originating from a urinary tract infection is the most common cause of septic shock. The invading bacteria are responsible for the release of endotoxin, a lipopolysaccharide (LPS), which binds to the surface of monocytes/macrophages.
- Septic shock due to gram-positive bacteria occurs in immunocompromised patients and persons undergoing invasive procedures. *Staphylococcus aureus* releases toxic molecules (so-called superantigens) resulting in 'toxic shock syndrome'. Septic shock causes multiple organs dysfunction syndrome (MODS) characterized by systemic shut down of vital processes and lactic acidosis, which requires major intervention to maintain homeostasis. Multiple organs dysfunction is most common cause of death.
  - At first, septicemia (bacteremia) begins with weakness, chills, and a rapid heart and respiratory rate. Left untreated, toxins produced by bacteria can damage the small blood vessels resulting in leakage of fluid into the surrounding tissues.
  - Final diagnosis of septicemia (bacteremia) is made by culturing the organisms from the blood. Major pathogenic pathways of septic shock are shown in Fig. 3.36. Synthesis of chemical mediators in varying quantity in septic shock stages are given in Table 3.36.

Pathogenesis of Septic Shock

Infectious microorganisms in the blood circulation induce dysregulated homeostatic response by synthesis of proinflammatory and counter-inflammatory cytokines causing hemodynamic decompensation in septic shock. Both immune activation and immunosuppression are present in septic shock.

- Severity of immune response depends on interactions between host innate response and pathogen characteristics. Closely interrelated host's inflammatory response and coagulation system play central role in the pathophysiology of septic shock.
- Abnormalities in macrovascular, microvascular endothelial cells and mitochondrial function contribute to the hemodynamic changes and organs failure in septic shock patients. Sepsis mortality increases with successive failure of organs.

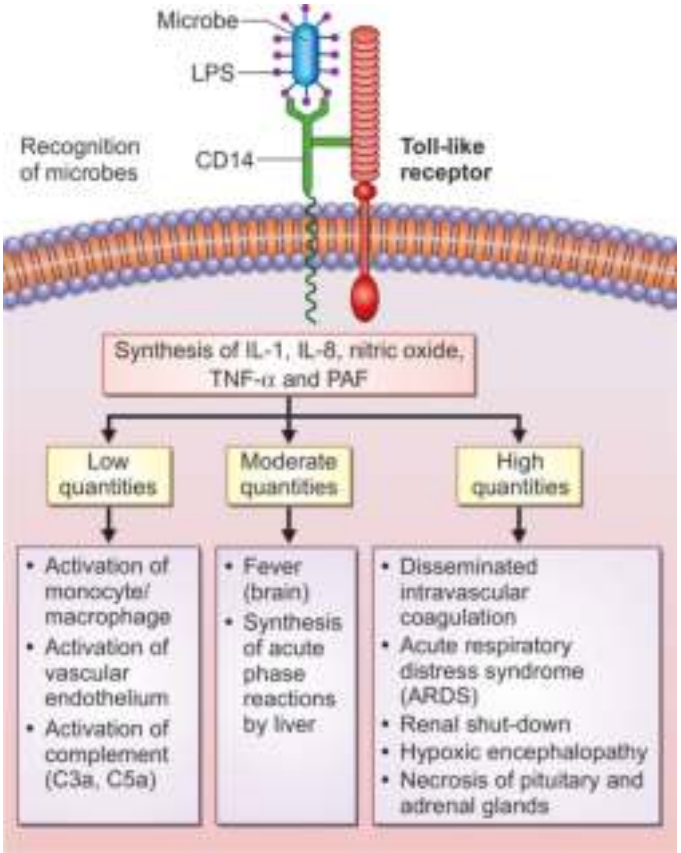

Fig. 3.36: Major pathogenic pathways of septic shock. Microbes release pathogen-associated molecular patterns (PAMPs) that bind to receptors belonging to the family of pattern recognition receptors (PRRs) and initiate cell signaling leading to enhanced activation of cytokines in varying quantity and reactive oxygen species (ROS). Depending on the quantity of cytokines, patient develops clinical manifestations.

Table 3.36 Synthesis of chemical mediators in varying quantity in septic shock stages

Quantity of Chemical Mediators	Chemical Mediators Actions	Net Effect
Chemical mediators in low quantity	▪ Activation of neutrophils and monocytes, endothelial cells and complement system ▪ Endothelial injury releases nitric oxide (NO) and prostacyclin, which cause vasodilatation and increase blood flow of skin vessels	Local inflammation (increased cardiac output and rebounding pulse)
Chemical mediators in moderate quantity	▪ Fever (cytokine action on brain) ▪ Acute phase reactants synthesis ▪ Leukocytosis (cytokine action on bone marrow)	Systemic effects of inflammation
Chemical mediators in high quantity	▪ Low cardiac output and decreased peripheral resistance ▪ Endothelial injury activates both coagulation pathways forming thrombi in small vessels and disseminated intravascular coagulation (DIC) ▪ Acute respiratory distress syndrome (damage to alveolar-capillary damage) ▪ Activation of alternative complement pathway stimulates mast cell release of histamine (vasodilator), which causes significant pooling of blood resulting in relative hypovolemia and impaired tissue perfusion	Septic shock

Proinflammatory and Anti-inflammatory Cytokines Synthesis Role in Septic Shock

Microorganisms contain pathogen-associated molecular patterns (PAMPs), which bind to the family of pattern recognition receptors (PRRs), i.e. toll-like receptors and mediate innate and adaptive immune responses.

- The best-known human pattern recognition receptors are ubiquitous toll-like receptors (TLRs), a highly diversified family of cell surface of cytoplasmic receptors for a number of microbial invaders and endogenous danger signals.
- Toll-like receptors activation, via multiple signaling pathways, leads to translocation of nuclear factor κB (NF-κB), a central regulatory transcriptor factor for several inflammatory target genes, including proinflammatory cytokines such as tumor necrosis factor α (TNF-α) and interleukin-1 (IL-1) and costimulatory molecules that instruct the type of immune response and direct antimicrobial response and tissue injury. TNF-α and IL-1 cytokines trigger the pathologic manifestations of septicemia: leukocytic activation and transmigration, severe vascular endothelial injury and increased capillary permeability leading to hypovolemia and exposure to tissue factor (TF) and other circulating coagulation factors.
- Injurious stimuli that induce severe cellular damage results in rapid cell rupture with consequent release of intracellular DAMPs to the extracellular space. Circulating necrotic cells release damage-associated molecular patterns (DAMPs), which can engage cells of immune system and promote inflammation leading to similar manifestations of septicemia *via* pattern recognition receptors (PRRs), i.e. DAMP receptors. Since ischemia and necrosis most often accompany infection.
- Proinflammatory cytokines play important role in the pathophysiology of septic shock. Immunosuppression in septicemia partially results from synthesis of anti-inflammatory cytokines and lymphocyte apoptosis. Toll-like receptors activation results in upregulation of signal transduction pathways, which leads to endonuclease activation and apoptosis.
- Interestingly, immune cells recognize foreign danger signals within themselves by toll-like receptors (TLRs) and nod-like receptors (NLRs) having similar functions and induce synthesis of cytokines like IL-1, IL-6, IL-8, IL-18, TNF-α, IFN-β and high morbidity group box-1 products (HMGB-1). There is also increased production of reactive oxygen species (ROS), prostaglandins and platelet activating factor (PAF), which induce vascular endothelial injury triggering the pathologic manifestations of septicemia: leukocytic activation, transmigration, cytokines synthesis, activation of complement system, severe vascular endothelial injury, increased capillary permeability leading to hypovolemia and exposure to tissue factor (TF), other circulating coagulation factors and thus causing cellular and multiple organs damage.

Inflammation and Activation of Coagulation System Cascade

There are substantial cross-links between inflammation and coagulation system. Vascular endothelial cell injury leads to release of tissue factor that activates coagulation system cascade resulting in rapid generation of thrombin, that converts fibrinogen to fibrin.

- Coagulation system cascade is balanced by early fibrinolysis via increased expression of plasminogen activator, that is counterbalanced by upregulation of plasminogen activator inhibitor 1 (PAI-1).
- Coagulation system is an essential protective response to microbial infection. The formation of fibrin nets trap activated platelets, microorganisms and leukocytes. Bacteria trapped by fibrin nets in a region of decreased nutrient supply, bacterial trapping in fibrin nets limits both local bacterial growth and hematogenous spread to organs. The majority of human microorganisms employ fibrinolytic properties to evade these fibrin nets.
- When overwhelmed, procoagulant and anticoagulant responses to microbial infection can accelerate consumptive coagulopathy and disseminated intravascular coagulation (DIC) leading to blockage of small blood vessels and thus multiorgan failure.

Vascular Endothelial Activation and Injury

Toxic microbial products of infection, proinflammatory mediators, reactive oxygen species (ROS), activated host leukocytes, complement activation (C3 and C5a), platelet activating factor synthesis, and inducible nitric oxide synthase, all exert direct effects on vascular tone, integrity and vascular endothelial cell signaling resulting in vasodilatation and massive leakage of capillaries and thus resulting in systemic hypotension.

Metabolic Abnormalities in Septic Shock

Glucose uptake by insulin-dependent tissues is mediated by insulin, which activates GLUT-4 transporters.

- Hyperglycemia is one of the most common metabolic derangements in patients presenting with septicemia resulting from altered glycogen metabolism and profound insulin resistance.
- Hyperglycemia modifies inflammatory response by enhancing production of proinflammatory tumor necrosis factor-α (TNF-α) cytokine and reactive oxygen species (ROS). Hyperglycemia decreases neutrophil function leading to decreased bactericidal activity.
- **Waterhouse-Friderichsen syndrome** is a life-threatening disorder due to severe bacterial infection, and characterized by disseminated intravascular coagulation (DIC), bleeding into adrenal gland associated with adrenal insufficiency and profound septic shock. Metabolic abnormalities in septic shock are given in Table 3.37.

Multiple Organs Failure in Septic Shock

The common denominator in septic shock is impaired utilization of oxygen by the tissues resulting from systemic hypotension, thrombosis in small blood vessels, disturbed perfusion of microcirculation, interstitial edema and inflammatory and immune reaction-mediated tissue injury. Septic shock patients most often manifest single or multiple organs failure such as kidneys, lungs and liver. Mortality in these patients has been roughly double for each additional organ system failure. Recovery of organ system failure is possible on reversal of the underlying insult and associated host inflammatory response.

- **Renal manifestations:** Septic shock patients experience acute kidney injury as a result of impaired blood flow. Renal parenchymal cells express toll-like receptors (TLRs), which may be activated by endotoxin. Elevated levels of cytokines (e.g. TNF-α), coagulation factors and inflammatory chemical mediators and neuroendocrine mediators in septic patients. Prognosis depends on severity of acute kidney injury.
- **Pulmonary manifestations:** Septic shock patients can manifest with acute pulmonary injury induced by pathogens reaching either from environment or systemic circulation.
  - Binding of endotoxin to toll-like receptors induce signaling pathways leading to necrosis of pulmonary parenchyma and disruption of

Table 3.37 Metabolic abnormalities in septic shock

Physiological Changes in Septic Shock	Metabolic Impact	
↑Gluconeogenesis, glycolysis	Hyperglycemia	
↑Protein catabolism	Altered circulating amino acids	
↑Lipolysis	▪ ↑Triglycerides	▪ ↓Lipoprotein
↓Micronutrients	Oxidative stress	
↑Neuroendocrine activation	▪ ↑Catecholamines	▪ ↑Counter-regulatory hormones
↑Cortisol	Hyperglycemia	
↑Catecholamine release	▪ ↑Gluconeogenesis	▪ ↑Glycolysis
↑Cytokine release	Hyperglycemia and insulin resistance	
Impaired oxygen utilization	↑Reactive oxygen species	

alveolar-capillary membrane leading to non-cardiogenic edema.
- There is increased production of danger-associated molecular patterns (DAMPs), which cause leukocyte activation, vascular endothelial cell dysfunction and interstitial edema as well as activation of platelets and coagulation factors.
- Progressive pulmonary dysfunction leads to pulmonary shunt with refractory hypoxemia, contributing to multiple organs dysfunction.

- **Cardiac manifestations:** Sepsis disrupts functions of cardiovascular system such as vascular tone and capillary integrity.
  - Increased synthesis of inflammatory cytokines contributes to peripheral arterial dilatation, diffuse capillary leakage, decreased contractility and reflux tachycardia.
  - Patient manifests with dilatation of both ventricles, decreased ejection fraction, diastolic dysfunction and decreased cardiac output. Elevated concentrations of TNF-α, IL-2 and IL-6 can induce adverse effects on myocardium.
- **Neurological manifestations:** Septic shock patients develop encephalopathy due to blood–brain barrier disruption, central nervous system inflammation, leukocyte recruitment, increased production of nitric oxide (NO) and vasoactive substances, and neuromotor dysfunction.

ANAPHYLACTIC SHOCK

Anaphylactic shock is a clinical syndrome of severe type 1 hypersensitivity reaction mediated by immunoglobulin E (IgE) resulting in cardiovascular system collapse and severe bronchospasm as a result of massive release of histamine.

- Immediate type 1 hypersensitivity can occur within seconds to minutes after presentation of the inciting antigen (allergen) such as drugs (e.g. nonsteroidal anti-inflammatory drugs, penicillin), food (e.g. milk, fish, shellfish, eggs) and insect stings.
- Patient develops hypotension, dizziness, respiratory distress, tachycardia, weak and rapid pulse, circulatory failure, and shock.

NEUROGENIC SHOCK

Neurogenic shock is most often associated with acute injury to the brain or spinal cord. The underlying mechanism is the disruption of the autonomic nervous system pathway resulting in decreased vascular resistance and changes in vagal tone.

- In high spinal cord injury, there is failure of sympathetic outflow and adequate vascular tone. There is loss of function below the site of spinal cord injury.
- Clinical examination reveals flaccid paralysis distal to injury site, loss of sympathetic nervous system, relative bradycardia, hypotension, vasodilatation,

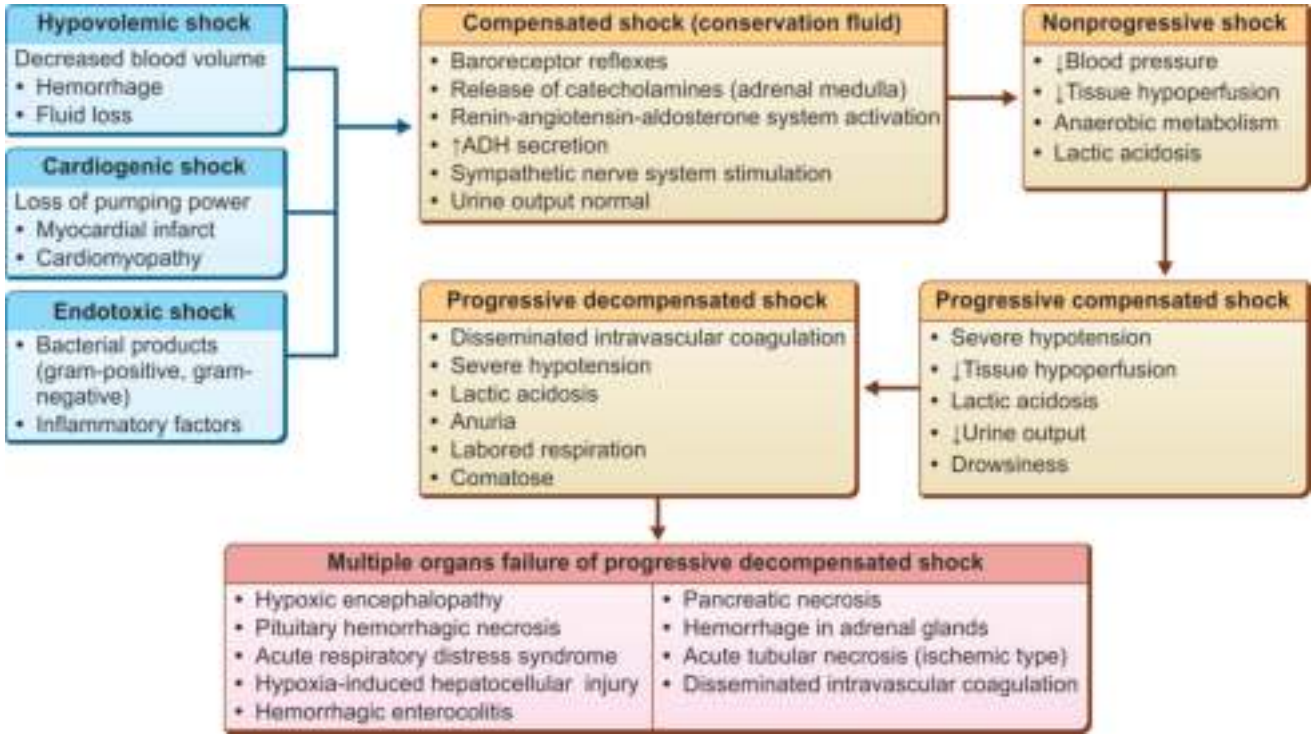

Fig. 3.37: Schematic representation of shock. The illustration shows etiology, pathogenesis and consequences of shock. Shock is a life-threatening medical condition as a result of insufficient blood flow throughout the body. There are many causes of shock, each of which can be caused by a number of different events.

warm, pink, dry skin, loss of urinary bladder control and priapism.

STAGES OF SHOCK

Stages of shock, etiology, pathogenesis and consequences are shown in Fig. 3.37.

- **Compensated shock stage:** In compensated shock stage, neurohormonal mechanism plays important role in this stage.
  - Compensatory mechanisms such as baroreceptor reflexes, release of catecholamines by adrenal medulla, activation of renin-angiotensin axis, antidiuretic hormone release and generalized sympathetic stimulation of tachycardia, increased peripheral vasoconstriction and conservation of fluid by kidneys lead to maintenance of perfusion of vital organs.
  - On clinical examination, level of conscious, respiratory rate, blood pressure and urine output are normal. There is mild lactic acidosis.
- **Nonprogressive shock stage:** Nonprogressive shock stage is characterized by persistent hypotension, vasodilatation, tissue hypoperfusion, anaerobic glycolysis, lactic acidosis. Clinical examination reveals low blood pressure, increased pulse rate, increased respiratory rate and decreased urine output.
- **Progressive decompensated shock stage:** Progressive decompensated shock stage is characterized by widespread tissue hypoxia, anaerobic glycolysis, excessive production of lactic acid, metabolic lactic acidosis, decreased tissue pH, blunting of vasomotor response, peripheral pooling of blood and decreased cardiac output. Compensatory mechanisms are no longer adequate. Clinical examination reveals reduced urine output, drowsy state, increased respiratory rate, increased pulse rate and hypotension.
- **Irreversible decompensated shock stage:** Irreversible decompensated shock stage is characterized by anoxic vascular endothelial cell injury, disseminated intravascular coagulation (DIC), widespread tissue anoxia, lysosomal enzyme leakage, aggravation of shock and complete renal shut down. Clinical examination reveals anuria, severe hypertension, comatose state, labored respiration, increased pulse rate and lactic acidosis. Multiple organs damage and metabolic disturbances are so severe that survival is not possible. Multiple organs involvement in irreversible decompensated shock are given in Table 3.38.

Table 3.38 Multiple organs involvement in irreversible decompensated shock

Organ	Morphology of Organ
Brain	Hypoxic encephalopathy
Pituitary gland	Pituitary hemorrhagic necrosis
Lungs	Acute respiratory distress syndrome
Liver	Hypoxia-induced hepatocellular injury
Intestine	Hemorrhagic enterocolitis
Pancreas	Pancreatic necrosis
Adrenal glands	Hemorrhage in adrenal glands
Kidneys	Acute tubular necrosis (ischemic type)
Blood	Disseminated intravascular coagulation

CHAPTER 4

Immunopathology

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

IMMUNE SYSTEM

- Types of immune responses
  - Innate (inborn, natural, nonspecific) immune response
  - Adaptive immune response
- Active versus passive immunity
  - Active immunity
  - Passive immunity
- Components of immune system
  - Communicating body compartments
  - Cells of immune system
  - Lymphatic system

INNATE IMMUNE RESPONSE

- Components of innate immune system
  - Host three lines of defense
  - Barriers for pathogens
  - Immune cells of innate immune system
  - Soluble mediators
  - Cellular receptors for microbes and damaged cells
  - Responses of innate immune system

ADAPTIVE IMMUNE RESPONSE

- Antigens and immunogens
  - Antigenicity and immunogenicity
  - Categories of antigens
  - Antigen and immunogen
  - Superantigens
  - Molecular mimicry and autoimmunity
  - Antigen and host relationship
- Components of adaptive immune system
  - Immune cells
  - Lymphoid tissues/organs
  - Major histocompatibility complex
  - Cytokines
- T cell- and B cell-mediated immune responses
  - Development of B cells and T cells
  - Functions of B cells and T cells
  - Creation of antigen-binding T cell receptors and B cell receptors
  - Exposure of host to antigens
  - Co-operation in immune cells against antigens
  - Antigen processing and presentation by antigen-presenting cells (APCs)
- T cell and cell-mediated adaptive immune response
  - CD4+ helper T cell and cell-mediated adaptive immune response
  - CD8+ cytotoxic T cells and cell-mediated cytotoxicity
  - CD4+, CD25+, FOXP3+ regulatory T cells
  - Natural killer cells kill viruses and cancer stem cells
- B cells and humoral adaptive immune response
  - B cell activation and differentiation
  - Synthesis of immunoglobulin
  - Classes of immunoglobulin
  - Primary and secondary immune responses
  - Selected monoclonal antibody-based drugs

VACCINES AND IMMUNIZATION

- Vaccines
  - Vaccines preparation
  - DNA vaccine
  - RNA vaccine

IMMUNODEFICIENCY DISEASES

- Primary immunodeficiency diseases
  - B cell defects: primary immunodeficiency diseases
  - T cell defects: primary immunodeficiency diseases
  - Combined T cell and B cell defects: primary immunodeficiency diseases
  - Phagocytic dysfunction: primary immunodeficiency diseases
  - Complement system defects: primary immunodeficiency diseases
- Secondary immunodeficiency diseases
  - Acquired immunodeficiency syndrome

HYPERSENSITIVITY REACTIONS

- Type 1 hypersensitivity reaction
  - Categories of IgE-mediated type 1 hypersensitivity reaction
  - Bronchial asthma
- Type 2 hypersensitivity reaction
  - Antibody-dependent cellular cytotoxicity
  - Complement-mediated with increased susceptibility to phagocytosis of target cells
  - Anti-receptor antibody-mediated type 2 hypersensitivity reaction
- Type 3 hypersensitivity reaction
  - Pathogenesis of immune complex-mediated tissue injury and organs damage
- Type 4 hypersensitivity reaction
  - CD8+ cytotoxic T cell and cell-mediated immune response
  - CD4+ helper T cells and macrophages-mediated type 4 hypersensitivity reactions
- Type 5 hypersensitivity reaction
  - Graves' disease

IMMUNOLOGIC TOLERANCE

- T cell immunologic tolerance
  - T cell immunologic tolerance in central lymphoid organs
  - T cell immunologic tolerance in peripheral lymphoid organs
- B cell immunologic tolerance
  - B cell immunologic tolerance in central lymphoid organs
  - B cell immunologic tolerance in peripheral lymphoid organs

AUTOIMMUNE DISEASES

- Specific autoimmune diseases
  - Systemic lupus erythematosus
  - Scleroderma
  - Sjögren syndrome
  - Polymyositis
  - Dermatomyositis
  - Mixed connective tissue disease
  - Polyarteritis nodosa
  - Rheumatoid arthritis
  - Goodpasture syndrome
  - Graves' disease
  - Myasthenia gravis
  - Pemphigus vulgaris

TISSUE/ORGAN TRANSPLANTATION IMMUNOLOGY

- Immunology of transplant rejection
  - Distinguishing self- and non-self-antigen
  - Pathophysiology of transplant rejection
- Clinical stages of transplant rejection
  - Hyperacute transplant rejection
  - Acute transplant rejection
  - Chronic transplant rejection
- Graft-versus-host disease (GVHD)
  - Pathogenesis
    - Acute and chronic graft-versus-host disease
- Finding eligible donor–recipient match
- ABO blood group compatibility
- Tissue typing
  - Cross-matching
  - Panel of reactive antibody test
  - Serological screening
- Prevention of transplant rejection
  - Immunosuppressive drugs
  - Adverse effects of immunosuppressive drugs

AMYLOIDOSIS

- Chemical nature of amyloid
  - Amyloid light chain amyloidosis
  - Amyloid-β precursor protein associated amyloidosis
  - Transthyretin protein associated amyloidosis
  - β_2-Microglobulin protein hemodialysis associated amyloidosis
  - Endocrine glands–proteins associated amyloidosis
- Organs involved in amyloidosis
  - Renal amyloidosis
  - Liver amyloidosis
  - Spleen amyloidosis
  - Cardiac amyloidosis
  - Gastrointestinal tract amyloidosis
  - Skin amyloidosis
  - Nervous system amyloidosis
  - Respiratory system amyloidosis
- Laboratory diagnosis of amyloidosis
  - Histochemical stains

IMMUNE SYSTEM

Immunology is the branch of medicine and biology concerned with development of immunity against invading pathogens (bacteria, viruses, fungi, parasites).

- Immune system is composed of a number of specialized organs, cells and molecules that conducts surveillance of the body, which is activated by inflammatory inducers that indicate the presence of pathogens or tissue damage.
- Immune system plays important role in providing defense against infectious microbes, noninfectious substances and products of damaged cells, which is mediated by sequential and coordinated immune responses that are called innate (natural or native) and antigen-specific adaptive immunity.
- When an antigen attacks the host system, two distinct, yet interrelated, branches of the immune system are active: innate (nonspecific) and adaptive (specific) immune response. It should be noted that both innate and adaptive immune responses do not work independently. Moreover, most of the immune responses involve the activity and interplay of both the humoral and cell-mediated immune responses, which recognize foreign materials, neutralize and eliminate them.
- Innate (nonspecific) immune response provides initial defense against infections that does not require previous sensitization that is mediated by neutrophils, macrophages, dendritic cells (DCs), natural killer cells (NK cells), mast cells and innate lymphoid cells. Adaptive immune responses develop later and require activation of T cells, B cells, natural killer cells (NK cells), dendritic cells (DCs). Dendritic cells act as an important conduit between the innate and adaptive immune systems.
- Adaptive/specific immune response has again two divisions: humoral immunity and cell-mediated immunity, which are induced by different types of lymphocytes and function to eliminate different types of pathogens.
  - In humoral immunity, B cells secrete antibodies that prevent infections and eliminate extracellular microbes.
  - In cell-mediated immunity, CD4+ helper T cells activate macrophages and neutrophils to eliminate phagocytosed pathogens, or CD8+ cytotoxic T cells directly kill viruses and cancer stem cells.
- Immune-mediated disorders may be localized or system to a particular organ.
  - Major immune-mediated disorders include: hypersensitivity reactions, autoimmune disease (systemic or limited to a specific organ), immunodeficiency diseases and immunologic complications of solid organs and hematopoietic stem cells (HSCs) transplantation.
  - Hypersensitivity reaction is an exaggerated, misdirected expression of certain immune responses. There are main four types of hypersensitivity reactions including fifth type of hypersensitivity reaction.
  - Autoimmunity involves abnormal immune response to self-antigens against own proteins.
  - A deficiency or loss in immune function is called immunodeficiency.
- Cellular and humoral components of innate and adaptive immune responses are shown in Fig. 4.1. Cellular components of innate (nonspecific) and adaptive immune responses are shown in Fig. 4.2. Overview of diseases of the immune system is shown in Fig. 4.3. Importance of the immune system in health and disease is given in Table 4.1.

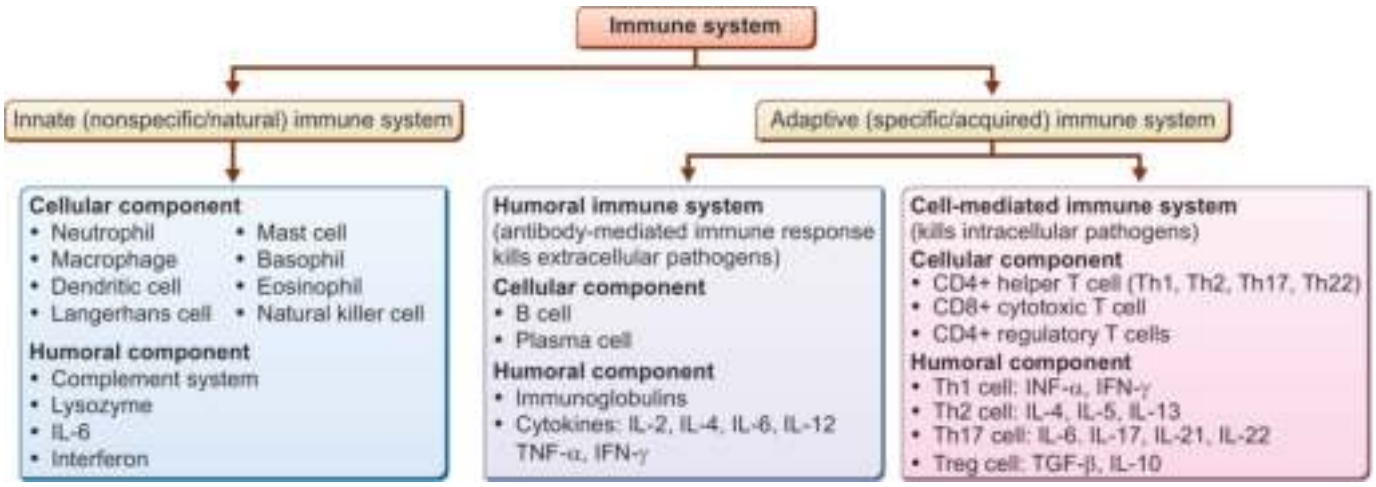

Fig. 4.1: Cellular and humoral components of innate and adaptive immune responses. The innate immune system is the first to respond to pathogens and does not retain immunologic memory of previous exposure to pathogens. Innate system consists of physical and chemical barriers, and cellular components such as monocytes/macrophages, mast cells, neutrophils, eosinophils, basophils, dendritic cells and natural killer cells. Components of the adaptive immune system include fundamental immune cells and molecules: B cells, T cells, immunoglobulins and major histocompatibility complex (MHC).

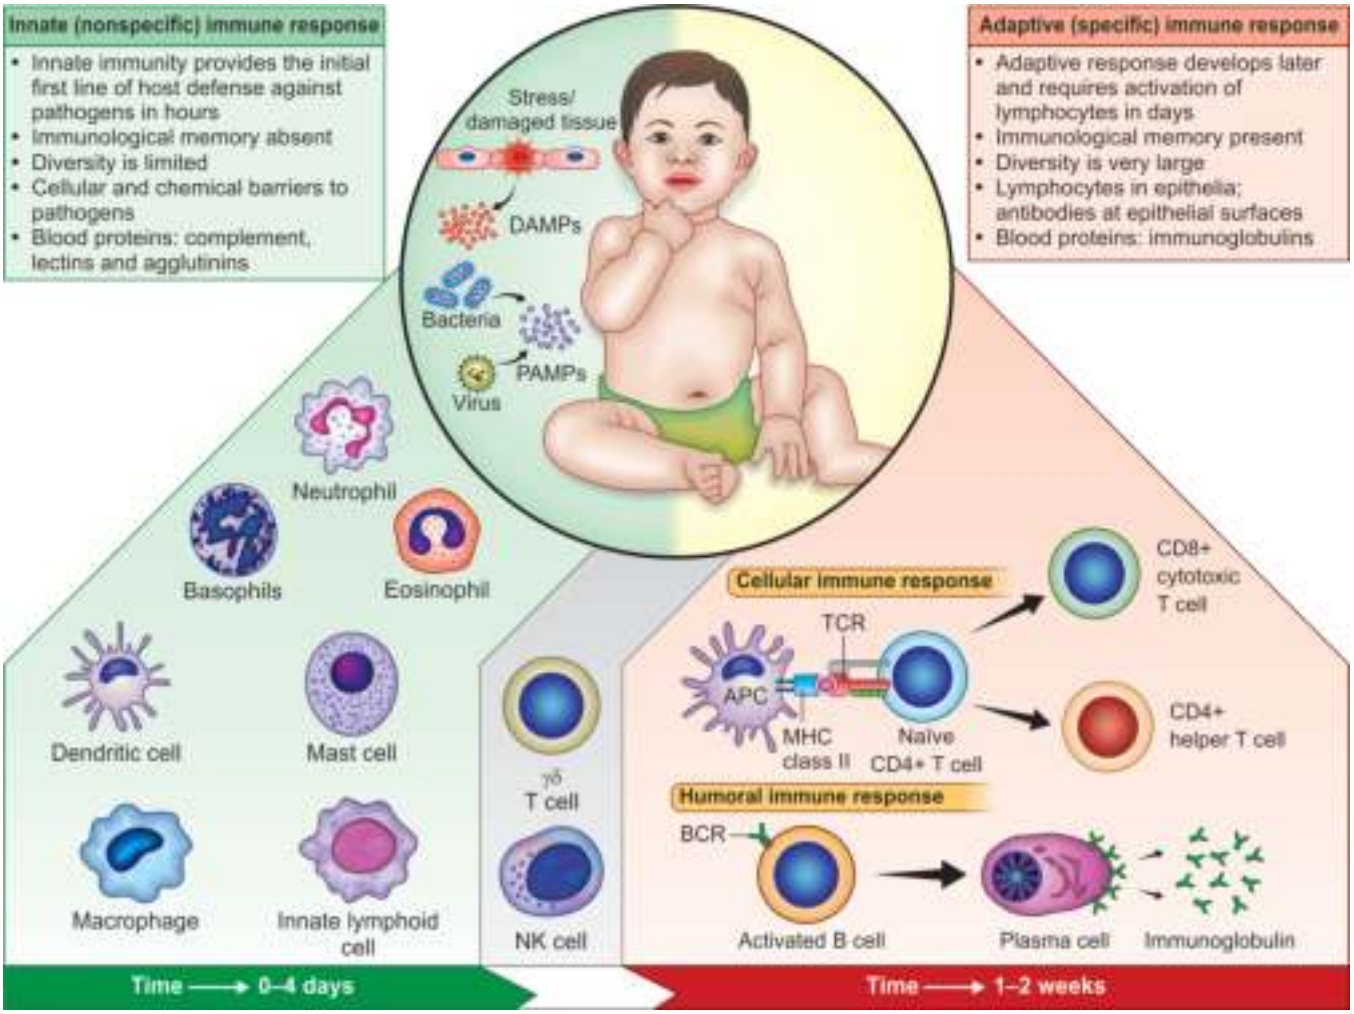

Fig. 4.2: Cellular components of innate and adaptive immune responses. Immune cells of the innate (nonspecific) immune system include macrophages, dendritic cells, neutrophils, basophils, mast cells and innate lymphoid cells. Cells involved in the adaptive immune response include T cells (e.g. CD4+ helper T cells, CD8+ cytotoxic T cells and CD4+ regulatory T cells) and B cells including antibody secreting plasma cells.

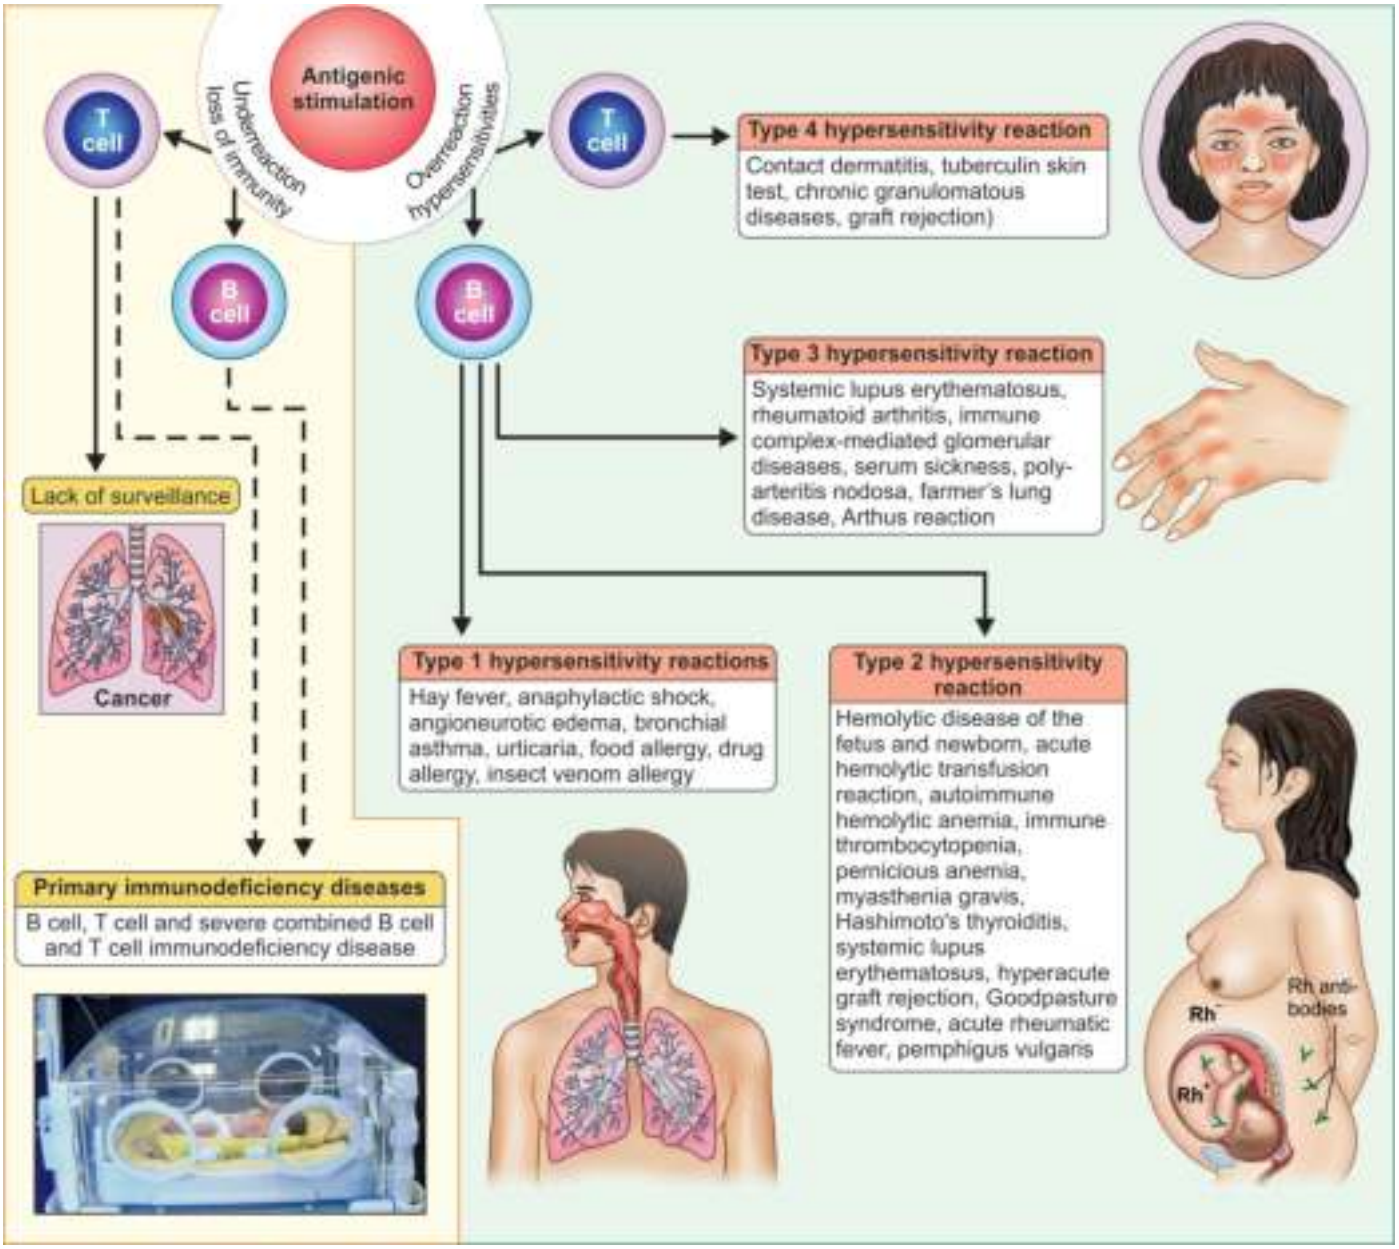

Fig. 4.3: Overview of diseases of the immune system. T cells and B cells provide necessary protection against infection and disease. Immune system can cause serious and debilitating disorders to immune stimuli. Lack of surveillance of immune system causes immunodeficiency diseases, hypersensitivity reactions, autoimmune diseases and carcinomas. Types 1, 2 and 3 hypersensitivity reactions are mediated by antibodies (IgG or IgM). Type 4 hypersensitivity reaction is mediated by T cells, which release cytokines, chemokines, macrophages and CD8+ cytotoxic T cells rather antibodies.

Table 4.1 Importance of the immune system in health and disease

Immune System Functions in Health	Immune System Impairment and Associated Disease
Defense against infections	Susceptibility to infections that can protect against infections
Defense against malignancies	Potential for immunotherapy of malignancies
Immune system can induce cell injury and inflammation	Immune system can cause hypersensitivity reactions (types 1, 2, 3, 4), autoimmune disorders and other inflammatory disorders
Immune system recognizes and responds to tissue/organ graft and newly introduced proteins	Immune system responses are barrier to tissue/organ transplantation and gene therapy

Pathology Pearls: Terminology used in Immunology

- **Adaptive immunity:** It refers to immune response to the first exposure to a pathogen or vaccination, that has memory.
- **Antigen:** It is nonself or foreign protein that binds to an antibody and triggers the immune response.
- **Antigen determinant (epitope):** It is one of the chemical groups recognized by a single type of lymphocyte.
- **Antigen-presenting cell (APC):** It is an immune cell that detects, engulfs and informs the adaptive immune response about an infection by presenting the processed antigen on the cell surface.
- **Antigen presentation:** It is binding of processed antigen to the protein-binding cleft (groove) of a major histocompatibility complex molecule.
- **Antigen processing:** It refers to internalization and digestion of antigen in an antigen-presenting cell (APC).
- **Antigen receptor on lymphocytes:** It has two-chain by which lymphocytes recognize antigen.
- **Allergen:** It is an antigen that induces allergic reaction.
- **Antibody-dependent cell cytotoxicity:** The cytotoxicity of certain lymphocytes that attack a target cell bound by IgG.
- **Autoimmune response:** It refers to inappropriate immune response to host cells or self-antigens.
- **Cell-mediated immune response:** It is adaptive immune response that is carried by T cells.
- **Clone:** It is a group of lymphocytes sharing the same antigen receptor.
- **Clonal expansion:** It refers to the growth of a clone of selected lymphocytes corresponding to specific BCR or TCR variant.
- **Clonal selection:** It refers to stimulating growth of lymphocytes that have specific receptors.
- **Constant region of immunoglobulin:** Constant region is a subdivision of a heavy chain that has the same amino acid sequences.
- **CD8+ cytotoxic T cell:** It has ability to induce apoptosis in target cells via perforin and granzyme and releases cytokine to enhance the immune response.
- **CD4+ helper T cell:** It is a cell of the adaptive immune system that binds to antigen-presenting cell (APC) via MHC class II molecules that secretes cytokines to enhance other immune responses involved in activation of both B cell and T cell.
  - **CD4+ helper T cell (Th1 cell):** It secretes cytokines that enhance the activity of macrophages and other cells.
  - **CD4+ helper T cell (Th2 cell):** It secretes cytokines that induce B cells to differentiate into antibody secreting plasma cells.
- **Dendritic cell:** It is immune cell that processes antigen material and presents it on the surface of other cells to induce an immune response.
- **Effector T cell:** Lymphocyte that has differentiated to effector cell, which has direct adverse effect on pathogen.
- **Epitope:** Epitope is a small component of an antigen that is specially recognized by antibodies, B cells, and T cells; the antigenic determinant.
- **Humoral immune response:** It is adaptive immune response that is regulated by activated B cells and antibodies.
- **Immunological memory:** It is the ability of the adaptive immune response to mount a stronger and faster immune response upon re-exposure to a pathogen.
- **Immunologic tolerance:** It is acquired ability to prevent an undesirable or harmful immune response to a detected foreign body known not to cause autoimmune disease or to self-antigens.
- **J-chain (joining chain):** J-chain is a protein produced by B cells and plasma cells that connects a monomer to form dimer or pentamer.
- **Lymph:** It is a watery fluid that bathes tissues and organs with protective white blood cells and does not contain red blood cells.
- **Major histocompatibility complex (MHC):** It is a gene cluster whose proteins present antigen to T cells.
  - **Major histocompatibility complex (MHC) class I:** It is found on most cells of the body, it binds to molecule on CD8+ cytotoxic T cells.
  - **Major histocompatibility complex (MHC) class II:** It is found on macrophages, dendritic cells, Langerhans cell and B cell, it binds to molecule on CD4+ helper T cells.
- **Memory T cell:** It is antigen specific long-lived immune cell (B cell or T cell) that does not differentiate into effector cell during the primary immune response but can immediately become effector cell upon future re-exposure to the same antigen.
- **Opsonization:** Opsonization refers to coating of antigen by antibody that enhances phagocytosis by a macrophage.
- **Papain:** Papain is cysteine protease commonly found in papaya, that digests proteins into fragments.
- **Polyclonal immune response:** It refers to response by multiple clones to a complex antigen with many determinants.
- **Plasma cell:** It is an immune cell that arises from B cell and secretes antibodies.
- **CD4+ regulatory T cell (Treg):** CD4+ regulatory T cell suppresses local inflammation and inhibits the secretion of cytokines, antibodies and other stimulatory immune factors; involved in immune tolerance.
- **Secretory piece:** Secretory piece is a polypeptide that attaches to a dimer (IgA) when it passes through epithelial cells in mucosal regions.
- **Somatic recombination:** Somatic recombination or V(D)J recombination is the process for generating antibody diversity.
- **Variable region of immunoglobulin:** Variable region is subdivision of a heavy chain or light chain that has different amino acid sequences, responsible for antigen recognition and binding.

TYPES OF IMMUNE RESPONSES

There are two fundamental types of immune responses: innate (inborn, natural, nonspecific) and adaptive (specific) immune response. Innate immune response

recognizes pathogen-associated molecular patterns (PAMPs). These PAMPs are recognized by pattern recognition receptors (PRRs), mainly expressed in the innate immune cells. PRRs can also recognize host molecules containing damage-associated molecular patterns (DAMPs) that are often released from damaged cell by invading pathogens. Innate and adaptive immune responses are shown in Fig. 4.4. Comparison of innate and adaptive immune responses is given in Table 4.2.

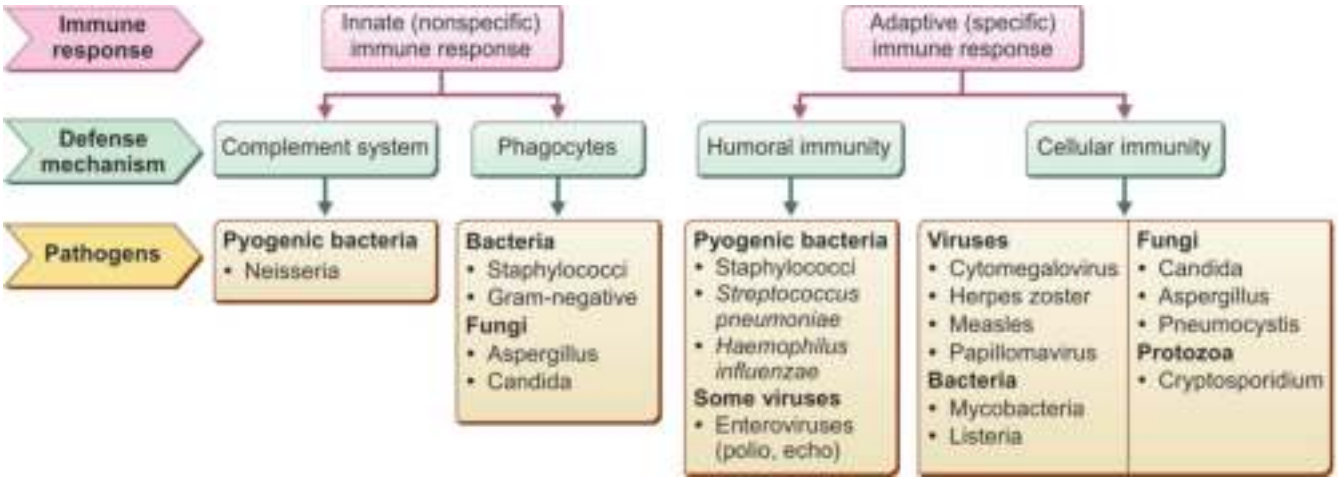

Fig. 4.4: Host innate and adaptive immune responses. Innate immunity is the defense system with person is born that protects against all pathogens. Innate immune system involves first line of defense physical and chemical barriers that keep harmful substances entering body. Adaptive immune responses are carried out by T cells and B cells. There are two broad classes of adaptive immune responses: humoral immunity (B cell) and cell-mediated immunity (T cell).

Table 4.2 Comparison of innate and adaptive immune responses

Characteristics	Innate Immune Response	Adaptive Immune Response
Presence	Innate immunity (inborn) exists in the body	Adaptive immunity is created in response to a foreign substance
Inheritance	Inherited from parents and passed to offspring	Adaptive immunity is not inherited from parents and passed to offspring
Specificity	Nonspecific immunity	Specific immunity
Diversity	Limited diversity to recognize pathogens and molecules encoded by germline genes	High diversity to recognize very large molecules encoded by somatic recombination of gene segments in lymphocytes generated randomly and there is specific immune response for each unique antigen
Speed of immune response	Faster response and fights any foreign invader	Slow response and fights only specific infection
Stimuli	Lipopolysaccharide (endotoxin), bacterial peptidoglycans	Protein antigens
Major cells involved	Macrophages, neutrophils, dendritic cells (DCs), natural killer cells (NK cells), mast cells and innate lymphoid cells	T cells, B cells, natural killer cells (NK cells), dendritic cells (DCs)
Cellular and chemical barriers	Skin, mucosal epithelia, antimicrobial molecules, phagocytes, cells, toxic granules, inflammation and fever	T cells and B cells in lymph nodes, spleen, mucosa-associated lymphoid tissue (MALT), antibodies secreted by plasma cells on the epithelial surfaces
Potency	Limited and lower potency	High potency
Time span	Innate immunity once activated against a specific antigen; innate immunity remains throughout the life	The span of developed adaptive immunity can be lifelong or short

Contd...

Table 4.2 Comparison of innate and adaptive immune responses (*Contd...*)

Characteristics	Innate Immune Response	Adaptive Immune Response
Defense	Epithelial lining (skin, mucous membranes), phagocytes, inflammation and fever	Cell killing, tagging of antigen by antibody for removal
Specificity	Nonspecific immune response (specificity for molecules and molecular patterns (PAMPs) associated with microbes, damaged host cells or foreign particles)	Highly specific immune response and can discriminate between microbes and nonmicrobial antigens, and their molecular structures
Pathogen recognition	General patterns on pathogens; nonspecific immune response	Specific immune response to individual microbes and antigens (antigens/antigen–antibody complex)
Self versus nonself discrimination	Innate immunity is based on self- versus nonself-antigens discrimination, so it has to be perfect	Adaptive immunity is not as good as the innate immunity, failure to discriminate self and nonself-antigens result in autoimmune diseases
Immunologic memory	Innate immunity cannot react with equal potency upon subsequent exposure to same antigen	Adaptive immunity has immunologic memory subsequent exposure to specific pathogens which have encountered before
Response to repeated infection	Similar immune response with each exposure	Immunologic memory, more rapid and efficient immune response with subsequent exposure
Blood proteins	Complement, lectins and agglutins	Immunoglobulins
Complement activation	Alternative and lectin pathways	Classical pathway
Molecular components	Cytokines (IFN-α, IFN-β, TNF-α, IL-1, IL-6, IL-10, IL-12, IL-15, IL-18), complement system, soluble chemical mediators, acute phase reactants	Antibodies, cytokines (IFN-γ, TNF-β, IL-2, IL-4, IL-l5, IL-13 lymphotoxin), complement system proteins
Effects	Local and systemic effects	Usually, local effects
Roles in disease	Systemic disorders	Local tissue injury
Inhibitors	Corticosteroids	Cyclosporine

INNATE (INBORN, NATURAL, NONSPECIFIC) IMMUNE RESPONSE

Innate immunity is essential in providing immediate and nonspecific first line defense for fighting against invading pathogens before adaptive immune response has developed.

- Components of innate immune response include physical barriers (i.e. tight junctions in the skin, epithelial and mucosal surfaces including mucus coating cells), epithelial and phagocytic cell enzymes (i.e. lysozyme), phagocytes (i.e. neutrophils, monocytes, macrophages, natural killer cells, dendritic cells and mast cells) and complement system to the site of tissue injury. It does not confer long-lasting immunity.
- Research on innate immune response has been focused on pathogen recognition receptors (PRRs) and signaling pathways. Necrotic cells release damage-associated molecular patterns (DAMPs), which lead to cell rupture with consequent release of intracellular DAMPs. Members of pathogen recognition receptors (PRRs) recognize diverse pathogens invasion or danger signals from release of DAMPs and initiate innate immune system signaling pathways, leading to proinflammatory cytokines synthesis, which in turn instructs development of adaptive response.
- Pathogen-associated molecular patterns (**PAMPs**) and damage-associated molecular patterns (**DAMPs**) mediated signaling and induction of an innate immune response usually results in resolution of infection.
- Toll-like receptors (**TLRs**) on phagocytes bind to bacterial lipopolysaccharide (LPS, or endotoxin) and induce innate immune response. Phagocytosis and activation of complement system are more rapid resulting in destruction of pathogens.

ADAPTIVE IMMUNE RESPONSE

Adaptive immune response is acquired that takes time for optimum reactivity, which is mediated by B cells and T cells and their products in response to specific antigens. Lymphocytes express highly diverse receptors that can recognize a vast number of antigens. Adaptive immune system mediated by different cells and molecules provide two types of immune responses dependent on the functions of B cells and T cells: humoral immune response (defense against extracellular microbes)

Table 4.3 Categories of adaptive immune response

Features	Humoral-mediated Immune Response	Cell-mediated Immune Response
Mechanism	Antibody-mediated immune response	Cell-mediated immune response
Cell type	B cells	T cells
Mode of action	Antibodies in serum	Direct cell-to-cell contact or soluble products screened by cells
Purpose	Primary defense against bacterial infection	Defense against viral and fungal infections, intracellular organisms; and graft rejection

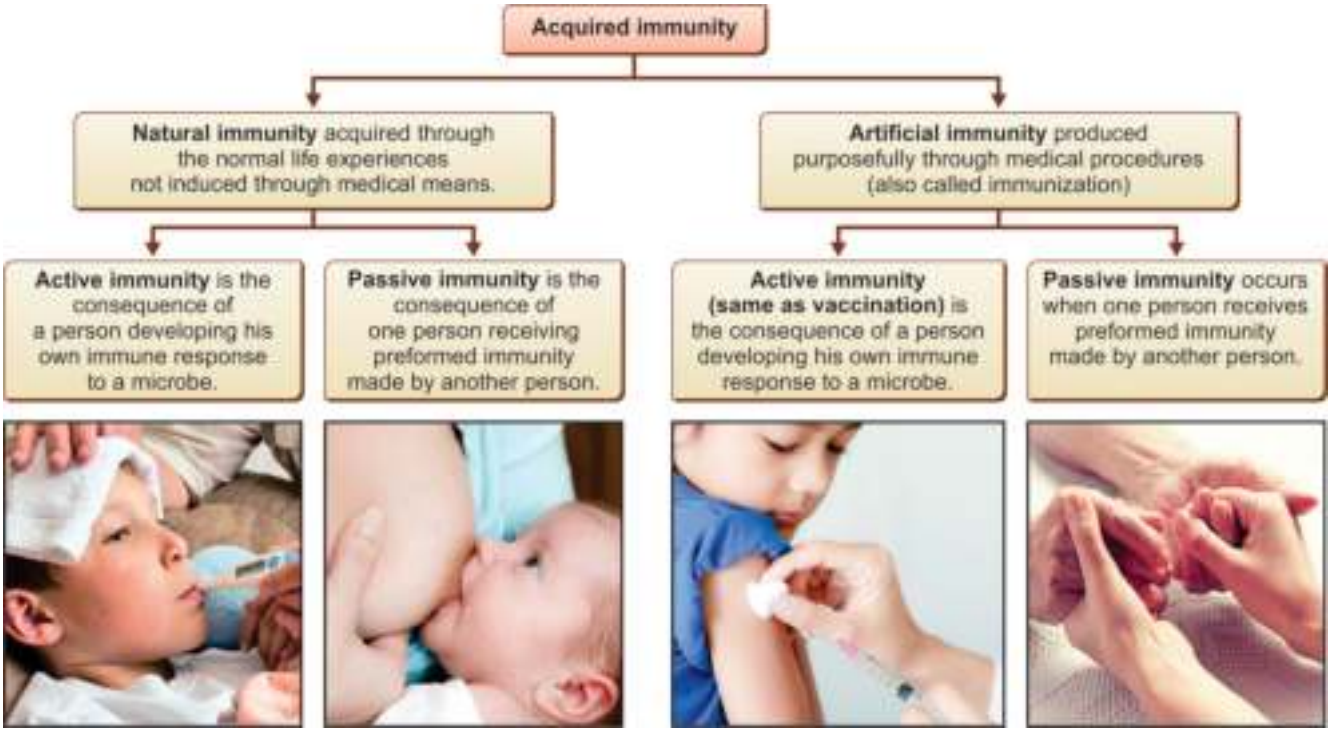

Fig. 4.5: Categories of acquired immunity. Natural immunity, which occurs during normal course of life, is either active (acquired from an infection and then recovering) or passive (antibodies donated by mother to fetus to her child). Artificial immunity is acquired through medical practices and can be active (vaccination with antigen), to stimulate an immune response) or passive (immune therapy with serum containing antibodies).

and cell-mediated immune system (defense against intracellular microbes). Categories of adaptive immune response are given in Table 4.3.

Adaptive Humoral Immune Response

Membrane-bound immunoglobulin on the surface of B cells serves as the cell's receptor for antigen, and is known as the B cell receptor (BCR). In humoral immune response, B cells recognize different antigens and induce immunoglobulins synthesis by plasma cells bind to antigens and prevent infections and eliminate extracellular microbes. B cell activation also initiates a cascade of intracellular signaling leading to the internalization of antigen for processing and presenting to CD4+ helper T cells. Categories of acquired immunity are given in Fig. 4.5.

Pathology Peals: Comparison of Acquired Immune Responses

Comparison of types of acquired immune response is given in Table 4.4.

Active Natural Type of Acquired Immune Response

- Active natural type of immune response is obtained in course of daily life. Antigens or pathogens enter body naturally.
- Body generates an immune response to antigens. Immunity may be lifelong (**chickenpox** or **mumps**) or temporary (**influenza** or **intestinal infections**).

Active Artificial Type of Acquired Immune Response

Active artificial type of immune response is obtained in response to an antigen. Immunity can be lifelong (oral polio vaccine) or temporary (tetanus toxoid) due to formation of antibodies.

Passive Natural Type of Acquired Immune Response

- Passive natural type of immune response is obtained by passage of neutralizing antibodies from mother to the fetus via placenta or breastfeeding (colostrum).
- There is no immune response to antigens.
- Immunity is usually short-lived (weeks to months). It provides protection for 6–12 months until child's immune system develops.

Passive Artificial Type of Acquired Immune Response

- Preformed antibodies (antiserum) are introduced into body by injection.
- Snake antivenom injection from horses or rabbits are administered in persons with snakebite.
- Immunity is short lived (half-life of three weeks). Host immune system does not respond to antigens.

Adaptive Cell-mediated Immune Response

In adaptive cell-mediated immune response, T cell receptor (TCR) on CD4+ helper T cell recognizes antigens (peptides) bound to the major histocompatibility complex (MHC/HLA) class II molecules on the surface of antigen-presenting cells (APCs) and activate macrophages to eliminate phagocytosed intracellular microbes and kill infected cells. CD8+ cytotoxic T cells recognize antigens on the virus infected cells and directly cause their elimination. CD4+ regulatory T cells (Tregs) suppress immune response to self-antigens.

Pathology Pearls: Immunologic Memory in Adaptive Immune System

- Immunologic memory to specific pathogens is most important characteristic of adaptive immunity that can provide long-lasting defense and protection against recurrent infections by inducing intense immune response on subsequent exposure to the same antigen.
- Vaccination is a good example of adaptive immune response. Vaccination exposes body to the antigen to induce antibodies synthesis specific to attenuated pathogen. Body acquires a memory to the virus without experiencing illness. The concept of immunologic memory is due to the body's ability to make antibodies against different antigens.
- Some breakdowns in the immunologic memory system can lead to autoimmune diseases.
- Molecular mimicry of a self-antigen by a infectious pathogen may trigger autoimmune diseases as a result of cross-reactive immune response against the infection. One example of a pathogen that uses molecular mimicry to hide from immunologic defenses is Streptococcus infection in which patient develops rheumatic heart disease.

ACTIVE VERSUS PASSIVE IMMUNITY

Active immunity is conferred by a host response to infectious microbes or microbial antigen, whereas passive immunity is achieved by transfer of antibodies or T cells specific for the infectious microbes. Both types of immune responses provide resistance to specific microbial antigens, but only active immune response generates immunologic memory. Therapeutic passive transfer of immunoglobulins, but not lymphocytes are performed routinely. Passive transfer of antibodies occurs during pregnancy from mother to the fetus. Differences between active and passive immunity are given in Table 4.5.

ACTIVE IMMUNITY

Active immunity means immune response caused by a disease agent. Natural active immunity develops as a result of disease process, which creates memory, takes time and is lasting. Artificial active immunity develops as a result of vaccination of person. Vaccines include inactivated toxins, killed microbes, parts of microbes, and viable but weakened microbes. Vaccines stimulate a protective immune response without causing the disease. Active immunity is usually permanent by creating memory.

PASSIVE IMMUNITY

Passive immunity develops, when a patient receives antibodies from another person. Natural passive immunity comes from the mother.

- Artificial passive immunity is acquired through medical procedures such as administration of human antiserum in patients (short-lived immunity).
- Artificial active immunity is the same as administering a vaccine (long lived immunity against an infectious agent that may be encountered in the future).

COMPONENTS OF IMMUNE SYSTEM

The immune system consists of three overlapping lines of defense: first line, second-line and third-line. A fourth component, the extracellular fluid surrounds the first three lines of defense and allows constant communication between all areas of the body. Lymph nodes, spleen, and thymus participate in defense mechanisms.

- White blood cells formed in the bone marrow participate in elimination of injurious agents by inducing inflammation and specific immune response. White blood cells travel freely due to

Table 4.4 Comparison of types of acquired immune response

Type of Immune Response	Mode of Acquisition	Immunoglobulin Synthesis	Duration of Immune Response
Active acquired immune response			
Active natural immune response	Infection by pathogens	IgG synthesis present (IgG half-life of 23 days)	Lifelong immune response in immunocompetent host (memory cells life span is in years)
Active artificial immune response	Vaccination	IgG synthesis present (IgG half-life of 23 days)	Lifelong immune response in immunocompetent host (memory cells life span is in years)
Passive acquired immune response			
Passive natural immune response	Transfer from mother *in vivo* to infant or colostrum	IgG synthesis absent	Short-long immune response
Passive artificial immune response	Transfer of antibodies preparations to non-immune persons	IgG synthesis absent	Short-long immune response

Table 4.5 Differences between active and passive immunity

Characteristics	Active Immunity	Passive Immunity
Duration of immune response	Active immunity is usually permanent that occurs when person comes in contact with living or dead microbes	Passive immunity lasts for a few weeks to months that occurs due to administration of ready-made antibodies for immunization
Immune response	Slow immune response because it takes time to generate antibodies	Immediate and quick immune response
Duration of immune response	Long lasting	Short lived
Side effects	No side effects	Passive immunity can induce reactions
Clinical aspect	Used for prophylaxis to increase resistance (BCG vaccination for prophylaxis of tuberculosis)	▪ Treatment of acute infections ▪ Breastfeeding (colostrum rich in abundant IgA) ▪ Fetus receives some antibodies from mother through placenta during pregnancy

close interrelationship among blood, lymphatic channels and reticuloendothelial system.

- Communication between cells of the immune system is facilitated by the release of chemical mediators from inflammatory cells and injured tissue, which drive inflammatory response, increased blood flow, recruitment of white blood cells to the site of tissue injury, initiate fever and destroy necrotic cells. Complement system acts in nonspecific or specific ways to lyse cells that has been identified as foreign.
- Pathogen-associated molecular patterns (PAMPs) on phagocytes (neutrophils and macrophages) recognize pathogens, phagocytose and degrade them.
- For purposes of immunologic study, the body is divided into three compartments: the blood, lymphatic system and the reticuloendothelial system. Fourth compartment is extracellular fluid compartment surrounding tissue cells.

COMMUNICATING BODY COMPARTMENTS

Tissue cells are in direct contact with blood vessel, lymphatic system, reticuloendothelial system and extracellular fluid. Blood cells formed in the bone marrow is called **hematopoiesis**, which begins in the yolk sac during embryogenesis. Later, the function is taken over by liver and lymphatic organs and finally bone marrow. Hematopoietic stem cells (HSCs) in the bone marrow differentiate to produce WBCs, RBCs and platelets. Blood cells are dispersed in the plasma.

CELLS OF IMMUNE SYSTEM

Principal cells of the immune system include lymphocytes (B cells and T cells), antigen-presenting cells—APC (e.g. dendritic cells, macrophages, follicular dendritic cells), and granulocytes (neutrophils, eosinophils and basophils).

- Immune cells originate in the bone marrow from pluripotent hematopoietic stem cells (**HSCs**), which give rise to a common myeloid progenitor cell leading to generation of major myeloid cell types (neutrophils, eosinophils, basophils, dendritic cells, mast cells, and monocytes/macrophages), the erythrocytes and megakaryocytes (which generate platelets).
- Pluripotent hematopoietic stem cells (HSCs) also give rise to common lymphoid progenitor cell, which

differentiates to major lymphoid cell types (B cells, T cells, and natural killer cells).

- The extracellular compartment is protected by humoral immune response, in which immunoglobulins produced by B cells induce elimination of extracellular pathogens and prevent spread of intracellular infections. The activation of B cells and their differentiation leads to formation of immunoglobulin-secreting plasma cells.
- Cell-mediated immune response is primarily mediated by mature T cells, antigen-presenting cells (macrophages, dendritic cells, Langerhans' cells) and the release of cytokines in response to antigen. T cells involved in cell-mediated immune response rely on antigen-presenting cells that contain membrane-bound MHC class molecules in order to recognize intracellular target antigens.
- Antigen-presenting cells (APCs) capture and display antigen to lymphocytes. Dendritic cells activate CD4+ helper T cells and induce cell-mediated immune response. Follicular dendritic cells display antigens to B cells to induce humoral immune response.
- Monocytes differentiate to become tissue macrophages. Macrophages function in the effector phase of cell-mediated immunity, which serve an important role as phagocytes in engulfing and killing microbes.

LYMPHATIC SYSTEM

The lymphatic system parallels the circulatory system and transports lymph through lymphatic channels to draining lymph nodes, which returns interstitial tissue fluid to systemic circulation and drains away excess inflammatory exudate fluid present in inflamed tissue. It also concentrates and processes invading pathogens and initiates specific immune response through phagocytes, lymphocytes and antibodies.

- Lymph is made up of water, dissolved salts and 2–5% proteins (antibody and albumin), which transports lymphocytes, fats, cellular debris and pathogens. Lymphatic channels permeate all parts of the body except the central nervous system, bone, placenta and thymus gland.
- Lymphoid organs and tissues with immune functions can be classified into primary and secondary.
  - Primary (central) lymphoid organs include bone marrow and thymus gland.
  - Secondary (peripheral) organs and tissues include lymph nodes, spleen, MALT (mucosa-associated lymphoid tissue, SALT (skin-associated lymphoid tissue) and GALT (gut-associated lymphoid tissue in Peyer's patches).

EXTRACELLULAR FLUID COMPARTMENT

Extracellular fluid (ECF) surrounds all cells in the body, which is composed of blood plasma, interstitial fluid, lymph and transcellular fluid (e.g. cerebrospinal fluid, synovial fluid, aqueous humor, serous fluid and gastrointestinal tract fluid). The interstitial fluid and the blood plasma are the major components of the extracellular fluid. ECF contains nutrients from capillaries by diffusion and holding waste products as a result of cellular metabolism. In general, the elevation of extracellular fluid increases the preload, which eventually contributes to the generation of hypertension.

INNATE IMMUNE RESPONSE

Innate immune system is immediate (nonspecific, inborn, or natural) first line of defense system against infection that responds to pathogens in a generic way, which does not confer long-lasting or protective immunity. Anatomic and chemical barriers are the first line of defense against pathogens. Innate immune system is also required to initiate specific adaptive immune response. Two principal types of reactions of the innate immune system are inflammation and antiviral defence. The specificity of the innate immunity is different from adaptive (specific) immunity. It does not react against the normal host cells.

- **Type of immune response:** Innate immune system responds in the same way to repeated encounters with the same infectious microbe. On the contrary, adaptive immune response mounts stronger and effective immune responses to each successive encounter with an infectious microbe.
- **Specificity:** Innate immune system responds to a limited number of microbial molecules such as pathogen-associated molecular patterns (**PAMPs**). It also recognizes molecules called damage-associated molecular patterns (**DAMPs**), that are released from the damaged or necrotic host cells. The subsequent immune response to DAMPs serves to eliminate the damaged or necrotic host cells and to initiate the process of tissue repair. Innate immune response occurs even in sterile injury in acute myocardial infarction as a result of cessation of arterial supply to the heart.
- **Receptors encoded by genes:** Innate immune system recognizes particular identical antigen receptors

expressed on the host cells such as macrophages. These antigen receptors are encoded by inherited genes. On the contrary, T and B cells in adaptive immune system recognize antigen receptors encoded by inherited genes formed by somatic rearrangement of gene segment during development and differentiation of B cells and T cells.

- **Distribution of receptors:** There are about 100 types of innate immune receptors which can recognize 1000 PAMPs and DAMPs on all cells of the same lineage. On the contrary, there are only two types of specific receptors in the adaptive immune response. B cells possess immunoglobulin (Ig) receptors and T cells have T cell receptors (TCRs). Because of their diversity, B cell and T cell receptors can recognize millions of different antigens.
- **Unable to discriminate self- and nonself-antigens:** Sensor cells express pattern recognition receptors (PRRs) that provide an initial discrimination between self- and nonself-antigens. Innate immune response does not recognize healthy host cells. Molecules expressed on healthy host cells inhibit innate immune reactions. Sensor cells induce an inflammatory response by producing chemical mediators such as chemokines and cytokines. Adaptive immune response is initiated by the activation of antigen-specific T cells and B cells. T cell responses to self-antigens can inflict tissue damage either directly or indirectly.

COMPONENTS OF INNATE IMMUNE SYSTEM

Components of the innate immune system include physical barriers (tight junctions in the skin, epithelial and mucous membrane including mucus itself, anatomical barriers, phagocytic cell enzymes (i.e. lysozyme) and immune cells (i.e. neutrophils, macrophages, mast cells, natural killer cells and dendritic cells).

HOST THREE LINES OF DEFENSE

The multilevel, intercommunicating network of host protection against of pathogens invasion can be organized into three lines of defense.

- First line of defense is the anatomical barrier provided by the body's epithelial surfaces. Epithelial surfaces of the body provide the first line of defense barrier against infection. Epithelial cells and phagocytes produce several kinds of antimicrobial proteins.
- Second line of defense is the chemical barrier, enzymatic system and complement system which act as an immediate antimicrobial barrier near the epithelia.
- If the pathogen overcomes these barriers, third line of defense—adaptive (specific) immune system is brought handle invading pathogens. Major components of the host defenses are shown in Fig. 4.6 and Table 4.6.

First Line of Defense

First line of defense is an inborn and nonspecific immune system comprising anatomical, chemical barriers provided by skin and mucous membranes lining respiratory system, gastrointestinal tract, urogenital system and other systems.

- Anatomical and chemical barriers prevent entry of pathogens. A ciliated pseudostratified columnar epithelium with mucus producing goblet cells is important in trapping debris and bacteria. The bacteria are then propelled to the esophagus and swallowed. Alveolar macrophages are important part of the host defense. As a part of the cough reflex, the muscles of the chest wall and diaphragm are important in clearing secretions from the respiratory tree.

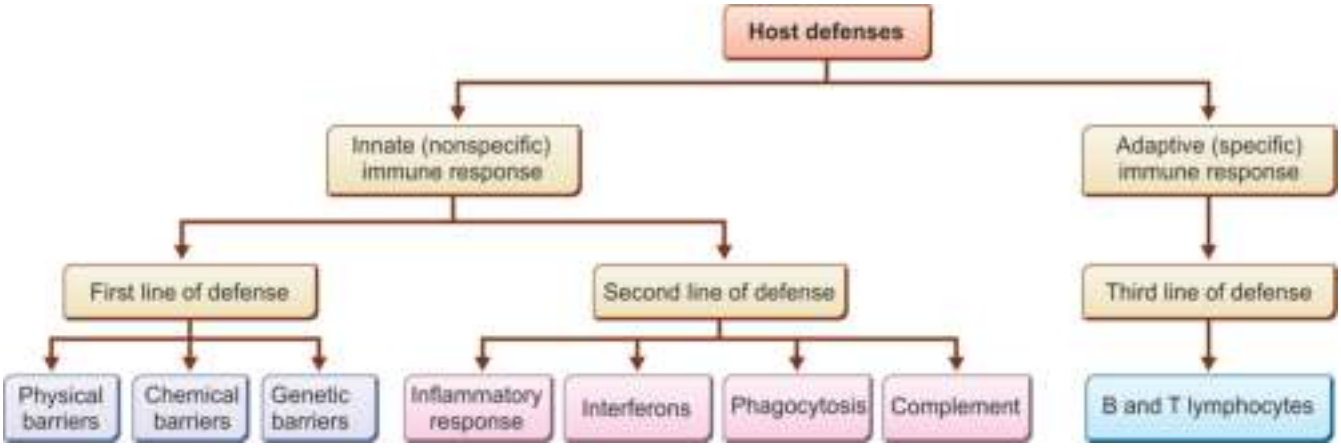

Fig. 4.6: Major components of the host defenses. Defenses are classified into two categories: innate and nonspecific; and acquired and specific. These can be further subdivided into the first, second and third lines of defense. Each of the defense is characterized by a different level and type of protection. The third line of defense is responsible for specific immunity.

Table 4.6 Major components of the host defenses

Lines of Defense	Comments
First line of defense: natural immune system	
▪ Physical barriers: skin, tears, coughing, sneezing ▪ Chemical barriers: low pH, lysozyme, digestive enzymes ▪ Genetic barriers: resistance inherent in genetic makeup of host (pathogen cannot invade)	First line of defense (innate host defense) prevents entry of pathogens in body
Second line of defense: natural immune system	
▪ Cellular component: mast cells, neutrophils, macrophages ▪ Humoral component: complement system, lysozyme, interferon	▪ Direct cell-cell contact results in secretion of soluble products ▪ Defense against fungal infections, intracellular organisms, tumor antigens and organ graft rejection
Third line of defense: adaptive immune system	
▪ Cellular component (B cells, T cells, plasma cells) ▪ Humoral component (antibodies, cytokines)	Adaptive (specific) host defense against pathogens

- Viral infections can disrupt the function of the respiratory epithelium allowing bacteria to enter areas that are normally sterile. A bronchogenic carcinoma can obstruct a bronchus. Superadded infection can arise distal to the obstruction. Compromise of the action of the chest muscles by trauma or abdominal surgery can affect the cough reflex.
- Infectious agents that successfully penetrate the physical barriers are then engaged by the cells and soluble factors of the innate immune system. There is no creation of memory cells that normally react immediately if same pathogen enters the body in the future.
- The innate immune system is also responsible for triggering activation of the adaptive immune system. The immune cells and products of the adaptive immune system reinforce the defense mounted by the innate immune system.

Second Line of Defense

Second line of defense comprises phagocytic cells (mast cells, neutrophils, macrophages), complement system, inflammatory chemical mediators and antimicrobial proteins such as complement, lysozyme, interferon and antibodies. Second line of defense does not create memory cells that normally react immediately if same pathogen enters the body in the future.

Third Line of Defense

Third line of defense is an acquired and specific immune response against invader pathogens. It is dependent on the function of cellular component (T cells, B cells, plasma cells), and humoral component (antibodies and cytokines). Third line of defense also creates memory cells that permit the immune system to immediately react if same pathogen enters the body in the future. Lymphoid organs such as the spleen, lymph nodes, and thymus are also intimately involved in these defense mechanisms.

BARRIERS FOR PATHOGENS

Nonspecific inborn or innate immunity is present at the time of birth, which provides different types of barriers to entry of the foreign agents in our body. Disruption in barriers for pathogens leads to infection.

- Patient with severe burns is susceptible to infections. Blockage of ducts in the salivary glands and lacrimal glands, intestine and genitourinary tract are at greater risk for infection.
- Bacteria in trachea are easily aspirated into the lung. Antibiotic use selects out bacteria such as *Pseudomonas aeruginosa*, *Enterobacter* species, and *Klebsiella* species.
- Supine position and reduction of stomach acidity allow bacteria to traverse the stomach and ascend the esophagus.
- Endotracheal ventilation gives direct access for organisms to the lungs. Abdominal surgery compromises the diaphragm and the cough reflex. Unwashed hands of health care workers can readily transmit bacteria from patient to patient.
- A lung abscess may arise as a result of bacterial pneumonia; aspiration of stomach fluid and oral bacteria; compression of a bronchus by a carcinoma. Right middle lobe pneumonia progresses to abscess formation due to lung parenchyma necrosis. Usually aerobic/facultative bacteria, e.g. *Klebsiella* species., *Staphylococcus aureus*, or *Pseudomonas aeruginosa*.
- Barriers to portal entry of pathogens are shown in Fig. 4.7. Barriers in first and second line of defense in innate immunity are shown in Table 4.7.

Anatomical Barriers

The skin and mucous membranes of the respiratory and gastrointestinal tract have several defenses.

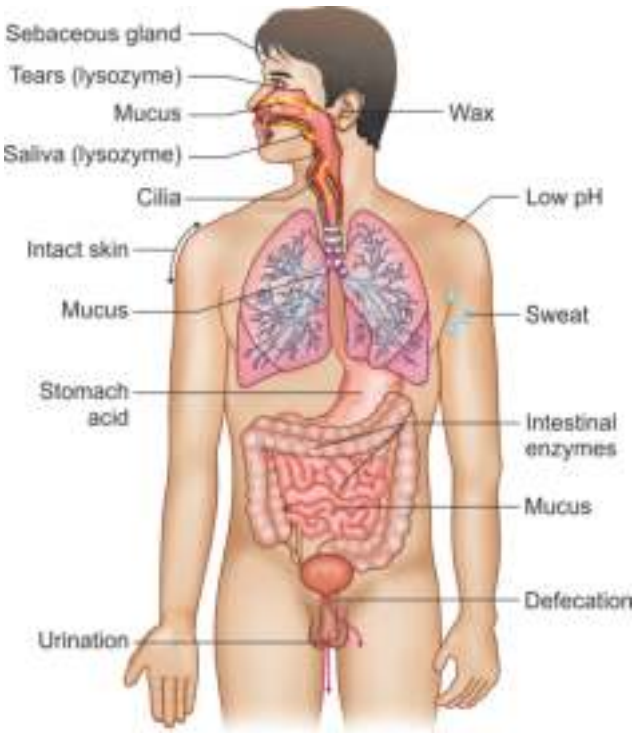

Fig. 4.7: Physical and chemical barriers to portal entry of pathogens. The skin, mucous membranes and endothelia throughout the body serve as physical barriers that prevent pathogens from reaching potential sites of infection. Chemical barriers such as enzymes in sweat, saliva and semen kill pathogens on body surfaces.

- Skin's outer most layer stratum corneum impregnated with insoluble keratin proteins is highly impervious to most pathogens. Sweat glands flush out microbes.
- The epithelial lining of the airways contains a brush border of cilia to entrap and propel particles upward toward the pharynx.
  - Sneezing due to irritation of nasal passages expels pathogens.
  - Coughing triggered by irritation of bronchi, trachea and larynx remove foreign irritants.
- Genitourinary tract gives partial protection by flushing out pathogens in urine.

Chemical Barriers

Chemical barriers against infection include enzymes in saliva, tears and mucous membranes and skin surface that break down the surface bacteria.

- **Skin: Dermcidin** synthesized by skin has antibacterial activity by lysing bacterial membranes. High lactic acid and electrolyte concentration of sweat and the skin's acidic pH and fatty acid content have antibacterial property. Sebaceous secretions have antimicrobial property.
- **Eyelids:** Meibomian glands of the eyelids lubricate the conjunctiva with an antimicrobial secretion.

Table 4.7 Barriers in first and second line of defense in innate immunity

Component	Function
Anatomical barriers prevent the entry of pathogens	
Skin	Skin epidermis
Nose	Hairs and cilia
Mucosa lining respiratory, gastrointestinal, and urogenital tracts	Mucosal lining secretes proteins and enzymes, absorbs metabolic substrates prevent microbial entrance
Antimicrobial peptides causing destruction of invading pathogens	
Skin	▪ Dermcidin (lysis of bacterial wall), sweat (rich in lactic acid, electrolytes), keratin, sebum (unsaturated fatty acids and hyaluronic acid): antibacterial actions ▪ Skin stratum corneum impregnated with insoluble keratin proteins is highly impervious to most pathogens
Eye	▪ Meibomian glands secretion lubricates the conjunctiva has antimicrobial property ▪ Lysozyme in tears has antimicrobial property
Salivary gland	Saliva contains lysozyme, which hydrolyzes the peptidoglycan in the wall of bacteria
Gastrointestinal tract	Hydrochloric acid by parietal cells and enzymes
Respiratory tract	Mucus secretion by lining mucosa in respiratory tract (mucociliary apparatus, sneezing and coughing)
Urogenital system	▪ Semen containing antibacterial secretion, flushing and acidity of urine ▪ Vaginal acidic pH (antibacterial action)
Phagocytic cells act as barriers	
Bone marrow	Macrophages, granulocytes, natural killer cells (NK cells kill infected cells and tumor cells, activation of macrophages through cytokine production)
Blood	Monocytes, neutrophils, eosinophils

Contd...

Table 4.7 Barriers in first and second line of defense in innate immunity (*Contd...*)

Component	Function
Lymph nodes	Tissue macrophages and natural killer cells (NK cells) kill carcinoma cells and virus infected cells
Liver	Macrophages (Kupffer cells)
Spleen	Macrophages, natural killer cells (NK cells) kill carcinoma cells and virus infected cells
Lymphoid cells	Innate lymphoid cells mediate immune response and regulate tissue homeostasis and inflammation
Endothelial/epithelial cells	Microbial recognition, cytokine production
Cytokines	
TNF-α, IL-1, chemokines	Mediate immune response and inflammation
IFN-α	Involved in resistance to viral infection
IFN-γ	Involved in resistance to intracellular pathogen infection and activation of macrophages
IL-12	Stimulates IFN-γ production by NK cells and T cells
IL-15	Stimulates NK cells
IL-10	Regulates and controls the inflammation process
TGF-β	Regulates and controls the inflammation process
Serum proteins	
Coagulation system	Localization of damage or infected tissue
Complement system	Opsonization, destruction of pathogens and T cell activation
Kallikrein-kinin system	Regulation of inflammation, coagulation system, pain cell proliferation, vasodilatation and blood pressure
C-reactive proteins and collectins	Opsonization of pathogens and complement activation
Cellular receptors	
Toll-like receptors (TLRs)	Recognize a variety of microbial components
NOD-like receptors (NDRs)	Sense bacterial components present in the cytoplasm
C-type lectin receptors (CLRs)	Recognize sugar moieties of bacteria and fungi
RIG-1-like receptors (RLRs)	Sense viral RNA

Cells derived preformed chemical mediators: histamine and serotonin.
Cells derived newly synthesized chemical mediators: prostaglandins, prostacyclin PGI2, TXA2, leukotrienes, lipoxins, cytokines (interleukins, TNF, chemokines, growth factors), oxygen-derived free radicals, nitric oxide, platelet activating factors and substance P.

Lysozyme enzyme in tears hydrolyzes the peptidoglycan in the wall of bacteria.

- **Salivary glands:** Lysozyme enzyme in saliva hydrolyzes the peptidoglycan in the wall of bacteria and protects from the pathogens.
- **Gastrointestinal tract:** Hydrochloric acid synthesized by gastric parietal cells that provides protection against many pathogens that are swallowed. Intestinal and bile secretions also cause destruction of pathogens.
- **Genital tract:** Semen contains an antibacterial chemical substance. Vagina has a protective acidic pH maintained by normal flora has protective against pathogens.

Reticuloendothelial System

Reticuloendothelial system is network of connective tissue reticular fibers enmeshing each cell inhabited by macrophages, which connects one cell to another within a tissue or organ. Macrophages attack and phagocytose pathogens that have managed to bypass the first line of defense. Monocytes migrate and differentiate into tissue macrophages, which are diffusely distributed in the connective tissues.

IMMUNE CELLS OF INNATE IMMUNE SYSTEM

There are many types of immune cells, that work to defend and protect the human body. Cells of the innate immune system originate from the pluripotent hematopoietic stem cells (HSCs) in the bone marrow that give rise to common myeloid progenitor and common lymphoid progenitor cells.

- Common myeloid progenitor cell gives rise to major myeloid cell types (neutrophils, eosinophils and basophils, monocytes/macrophages, dendritic cells and mast cells), erythrocytes and megakaryocytes.

- Common lymphoid progenitor cell gives rise to major lymphoid cells (T cells, B cells and natural killer cells).

Neutrophils

Neutrophils are produced from pluripotent hematopoietic stem cells (HSCs) in the bone marrow, that proliferate and differentiate through various stages, i.e. myeloblast, myelocyte, metamyelocyte, band form and mature neutrophils well equipped with an armory of granules, which release potent mixture of hydrolytic enzymes into phagolysosome which are lethal to microorganisms, but can also cause tissue damage.

- Neutrophils contain two types of granules: azurophil (primary) and specific (secondary) granules. Products of azurophil and specific granules of neutrophils participate in vascular permeability, chemotaxis and tissue damage.
  - Azurophil granules of neutrophils contain myeloperoxidase, lysosome-derived bactericidal factors, acid hydrolases, neutral proteases (collagenase, proteinase 3, elastase), nonspecific defensins, cathepsin D and phospholipase A_2.
  - Specific (secondary) granules of neutrophils contain high levels of iron-binding protein lactoferritin, collagenase, type 4 gelatinase, plasminogen activator, histaminase, alkaline phosphatase, leukocyte adhesion molecules and phospholipase.
  - Tertiary granules contain gelatinase of neutrophils.
- Neutrophils are pivotal effector cells of innate immune response and the first line of defense for eliminating pathogens in the tissues and clearing debris in acute inflammation. Neutrophils exit from the vascular compartment involving coordinated process: intravascular rolling, adhesion, transmigration along the activated vascular endothelial cells and basement membrane of the venules.
- Once neutrophils have traversed this vascular barrier, these are primed for the rapid detection of microbes and damaged tissue in the extracellular space. Neutrophils undergo sequential phases of highly coordinated chemotaxis towards tissue injury site leading to degradation of injurious agent. During mild tissue injury, inflammatory exudate is removed resulting to restoration of normal tissue architecture (resolution). Transition to chronic inflammation occurs in cases of persistent injurious agent.

Eosinophils

Eosinophil arises from the hematopoietic stem cells (HSCs) in the bone marrow and takes about eight days to mature through various stages, i.e. myeloblast, eosinophilic myelocyte, metamyelocyte, band form cell and mature eosinophil.

- The eosinophil migrates from the bone marrow into circulation leading to recruitment in target tissues/organs with the help of chemokine (eotaxin).
- Eosinophilic granules contain four major proteins: major basic protein (MBP) killing parasites and epithelial cells, eosinophilic cationic protein (ECP), eosinophil peroxidase (EPO) and eosinophil-derived neurotoxin (EDN), which are involved in phagocytosis, killing invasive helminths, antigen presentation to reticuloendothelial cells and platelet interaction. The action of **EPO** also leads to oxidative burst, a crucial step in phagocytosis.

Macrophages

Macrophages can be found in almost all organs in the body such as lungs, liver, brain, lymph nodes, spleen, kidneys, skin, adipose tissue, peritoneum, synovium, placenta, and bone; they have special functions in each organ.

- Macrophages are efficient phagocytic cells of the innate immune system that phagocytose and secrete both proinflammatory chemical mediators (e.g. tumor necrosis factor, IL-1, IL-6, IL-8 and IL-12), and antimicrobial mediators. In addition, macrophages play an important role in eliminating damaged cells, necrotic debris, foreign materials and tumor cells.
- Macrophages and dendritic cells function as antigen-presenting cells (APCs), which present peptide antigens derived from the digested bacteria on the major histocompatibility complex (MHC) class II and activate specific adaptive cell-mediated immunity by activating CD4+ helper T cells.
- Macrophages present antigens to CD4+ helper T cells within tissues, while dendritic cells can activate naïve T cells to become effector CD4+ helper T cell, which are most powerful antigen-presenting cells (APCs).

Dendritic Cells

The mononuclear phagocytic cells such as dendritic cells and macrophages are closely related immune cells, which play central roles in antimicrobial defense and maintenance of organ integrity.

- Dendritic cells (DCs) are present in those tissues that remain in contact with the external environment,where dendritic cells sense self- and non-self antigens.
- Dendritic cells are present in skin, and inner lining of the nose, lungs and gastrointestinal tract. Dendritic cells can also be present in an immature state in the bloodstream.
- The different subtypes of dendritic cells include: Langerhans' cells (skin), plasmacytoid dendritic cells, interdigitating dendritic cells, and myeloid-

derived dendritic cells. Dendritic cells are characterized by distinct origins, receptors and varying functions.

- Dendritic cells can activate naïve T cells to become effector CD4+ helper T cells, and are most powerful antigen-presenting cells (**APCs**), while macrophages present antigens to CD4+ helper T cells.
- Dendritic cells also act as bridge between the innate immune system and specific adaptive immune response.
- The main differences between dendritic cells and macrophages include: (a) macrophages contribute to initiation of the inflammatory response, whereas dendritic cells get activated with inflammatory response to become antigen-presenting cells, and (b) macrophages do not die following activation while dendritic cells die after achieving their effector function.

Mast Cells

Mast cells are found in mucous membranes and connective tissues throughout the body, which originate from pluripotent progenitor cells in bone marrow, differentiate into progenitor cells and then mature mast cells under the influence of the c-KIT ligand, stem cell factor (SCF), and other cytokines. Under normal conditions, mature mast cells do not circulate in the bloodstream.

- The cytoplasm of the mast cell contains large granules that store inflammatory chemical mediators such as histamine, heparin, a variety of cytokines, chondroitin sulfate and neutral proteases.
- Mast cells can be activated by allergens, pathogens and physiologic chemical mediators. Activated mast cells release chemical mediators such as histamine and cytokines by two major pathways: (a) preformed chemical mediators are present in the granules, and (b) metabolism of arachidonic acid is produced through activation of a phospholipase. Intracellular Ca^{2+} and cyclic AMP are central to the initiation of these events. Mast cell degranulation may occur through C3a, C5a, and even by some microorganisms that can act directly on cell surface receptors.
- Mast cells play an important role in the physiologic functions (e.g. wound healing, defense against pathogens via the inflammatory response, vascular homeostasis, innate and adaptive immune responses, angiogenesis and venom detoxification), and pathophysiology of various disorders (e.g. allergy, bronchial asthma, anaphylaxis and autoimmunity).

Natural Killer Cells

Natural killer cells (NK cells) are derived from large granular lymphocytes. NK cells do not rearrange T cell receptor or immunoglobulin genes from their germline configuration. Immunophenotyping of natural killer cells includes CD16, CD56 and CD57.

- Natural killer cells express activating and inhibitory receptors to distinguish between healthy and infected cells. NK cells express activating receptors that recognize ligands on virus infected cells or malignant tumor cells.
- Natural killer cells are effector lymphocytes of the innate immune system, which control several types of malignant tumors and viral infections by limiting their spread and subsequent tissue damage. Recent studies revealed important insights into NK cells function in normal immune surveillance and NK cell receptor biology that has led to remarkable results in treated human malignancy.
- Natural killer cells do not require priming or prior activation in contrast to CD8+ cytotoxic T cells. NK cells can kill target cells by two major mechanisms: (a) cytotoxic granule-dependent signaling pathway and (b) death receptor signaling pathway. In both mechanisms, the target cell dies as a result of the activation of a battery of cytotoxic proteases within the target cell, called caspases.

Cytotoxic Granule-dependent Signaling Pathway of Natural Killer Cells

In the cytotoxic granule-dependent signaling pathway, binding of the natural killer cells to the surface of the virally infected cell triggers the extracellular release of perforin (pore-forming protein) and **granzyme** (diverse collection of proteases) from natural killer cell cytotoxic granules.

- Perforin polymerizes within the target cell membrane to form transmembrane channels that permit entry of granzyme into the target cell.
- Granzyme induces apoptotic cell death through activation of caspase protease cascade, either by directly processing and activating caspases, or through release of 'cytochrome c' from mitochondria that activates the 'apoptosome' pathway to caspase activation.

Death Receptor Signaling Pathway of Natural Killer Cells

In death receptor signaling pathway, membrane bound Fas ligand (FasL) on natural killer cell engages and trimerizes surface Fas receptor on the target cell.

- Engagement of surface Fas receptors on target cells recruits the adaptor protein Fas-associated death domain (**FADD**) to the death-inducing signaling complex (**DISC**) and followed by activation of caspase 8 on the cell surface receptors.

- Caspase 8 then promotes further caspase activation through directly processing other caspases, or via the mitochondrial apoptosome pathway similar to granzymes. Apoptosis occurs as a result of the activation of several 'executioner caspases 3, 6, 7, that coordinate apoptotic cell death through restricted proteolysis of numerous cellular proteins.

Intraepithelial Lymphocytes

Intraepithelial lymphocytes (IELs) contain subsets of innate-like T cell located above the basement membrane and in between intestinal epithelial cells, that evoke innate and adaptive immune responses to provide rapid protection to intestinal epithelium and promote sustained tolerance against dietary and microbial antigens. In the intestine, T cells express variable T cell antigen receptors with unknown antigen specificities.

SOLUBLE MEDIATORS

Soluble mediators of innate immune system include: cytokines, chemokines, pattern recognition receptors (PRRs), antimicrobial peptides, and complement system, which provide protection in the initial phase of contact with pathogens and prevent potentially harmful infections.

Opsonins

The process of engulfment of solid particulate material by phagocytic cells (neutrophils and macrophages) is known as phagocytosis, which is composed of four interrelated phases: chemotaxis, opsonization, engulfment and digestion.

- Opsonins are extracellular proteins, which react with bacteria and make them more susceptible to ingestion by phagocytes (neutrophils and macrophages).
- Examples of opsonins include specific IgG and C3b molecule of complement system. C3b is derived upon complement system activation by either classical pathway or the alternative pathway of complement system.

Complement System

Complement system consists of a group of soluble plasma proteins synthesized by liver present in its inactive form that interact with one another in three distinct enzymatic-activation cascades. These are numbered C1 to C9 (C3 most abundant).

- Complement system proteins play key role in innate and adaptive immunity. In innate immunity, complement proteins defend against foreign pathogens by opsonization, chemotaxis, and activation of leukocytes through cytolysis by C5b–C9 membrane attack complex.
- Recent studies revealed that complement system plays a key role in adaptive immunity by modulating and modifying the T cell response. All these studies suggest that complement system constitutes a critical link between the innate and adaptive immune responses.

Complement System Pathways

Complement system can be activated through three pathways: classical, alternative, and mannose-binding lectin, which have different triggers at starting points, but all converge at the same place, C3 convertase. This enzyme begins the formation of tiny openings in the cell membrane and the destruction of target pathogen. Pathways of complement system activation are shown in Fig. 4.8.

- **Classical pathway:** Classical pathway of complement system activation is also known as immunologic pathway, which involves fixation of antibodies (IgG and IgM) and complement (C1). C1q, C1, C1s are converted to form C4, C2, C3.
- **Alternative pathway:** Alternative pathway of complement system is antibody-independent pathway of complement system activation, which is accelerated by properdin in the presence of pathogens such as bacteria, fungi, viruses and parasites and venom. Factor B and factor D are converted to C3. Deficiency of C3 affects alternate pathway of complement activation resulting to recurrent infections with fatal outcome, until treated.
- **Mannose-binding lectin pathway:** The mannose-binding lectin pathway of complement system uses soluble receptors that recognize microbial surfaces to activate the complement system cascade, which is also antibody-independent pathway. It binds mannose (carbohydrate) on pathogen surfaces. It is nonspecific for bacteria and viruses. MBL, MASP-1, MASP-2 are converted to form C4, C2, C3.

Complement System Activation

All three activated complement system pathways converge to form C3. C3 convertase enzyme converts C3 molecule into an activator C3b. C3 convertase enzyme and C3b are the central features of complement system activation. Activation of complement system produces C3a, C5a and C5–9. Functional protein classes in the complement system are given in the Table 4.8. Mechanism of action of complement is described as under:

- **C3 convertase enzyme:** C3 convertase activates complement system and splits C3 into two functionally distinct C3a and C3b. C3a is released, while C3b binds to C5 convertase.

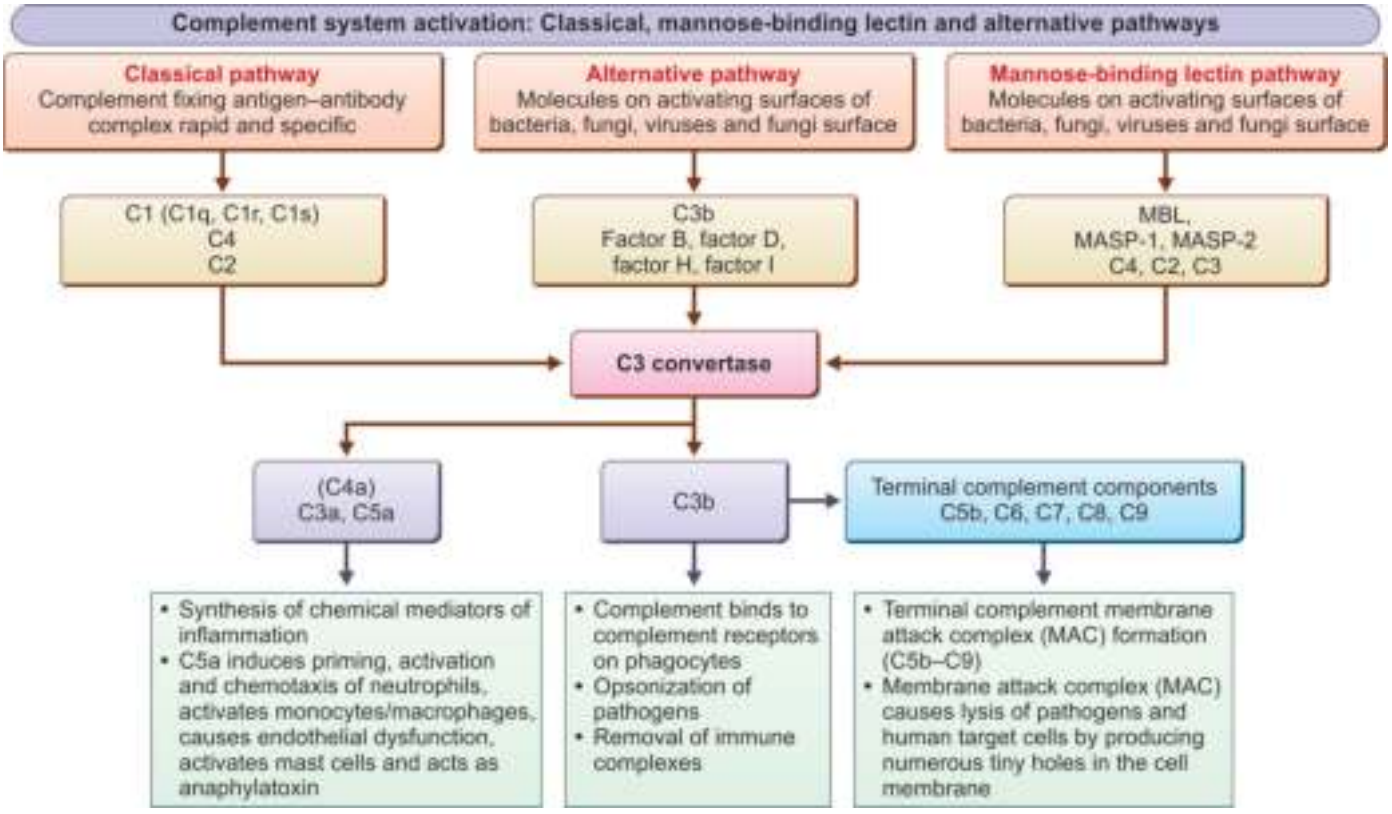

Fig. 4.8: Pathways of complement system activation. Complement system involves classical, alternative and mannose-binding lectin pathways. Common aim of complement system pathways is to yield C3 convertase, which facilitates the cleavage of C3, which in turn cleaves C5 to yield C5b. C5b hence forms a complex with C6, C7, C8 and C9 to form C5b–C9, also known as the membrane attack complex (MAC) that leads to lysis of pathogen plasma membrane and target cells.

Table 4.8 Functional protein classes in the complement system

Characteristics	Protein Classes of Complement System
Binding to antigen–antibody complexes and pathogen surface	C1q
Binding to mannose on bacteria	Mannose-binding lectin (MBL)
Activating enzymes	C1r, C1s, C2b, D, MASP1, MASP2
Membrane binding proteins and opsonins	C4b, C3b
Peptide mediators of inflammation	C5a, C3a, C4a
Membrane attack proteins	C5b, C6, C7, C8, C9
Complement receptors	CR1, CR2, CR3, CR4, C1qR
Complement-regulatory proteins	C1INH, C4bp, CR1, MCP, H, I, P, CD59

- **Binding of C3b to C5 convertase:** C3b–C5 convertase complex cleaves C5 to C5a and C5b. C5a is released, while remaining C5b binds to C5–C9. Other molecules include C3a and C5a, which are peptide clinical mediators of inflammation. These participate in chemotaxis of leukocytes and phagocytosis of bacteria.
- **Binding of C3b to C5–C9:** C5b is a reactive site for the final assembly of an attack complex. C5b fragment polymerizes with complement proteins C6, C7, C8, and C9, resulting in the formation of membrane attack complex (MAC). Insertion of MACs produces hundreds of tiny holes in the lipid bilayer cell membrane results in cell lysis.

Complement System: Actions

Breakdown products of complement system mediate acute inflammation by following mechanisms. Complement system cascade and its actions are given in Table 4.9.

- **Opsonization and phagocytosis:** Complement system activation generates cleavage products,

Table 4.9 Complement system cascade and its actions

Complement System Cascade	Actions
C3b	▪ Opsonization of microbes ▪ Phagocytosis of microbes
C3a and C5a	Increased vascular permeability
C5a	▪ Adhesion of leukocytes ▪ Transmigration of leukocytes ▪ Chemotaxis of leukocytes
C3a, C5a and C4	Anaphylactic shock (due to excessive release of histamine)
C5a	Synthesis of arachidonic acid metabolites (lipoxygenase pathway)
C5b–C9 membrane attack complex (MAC)	Degradation of microbes and enhancing arachidonic acid metabolism and producing reactive oxygen metabolites

Defective formation of membrane attack complex (MAC) leads to increased susceptibility to Neisseria organisms.

mainly C3b and C4b, which are deposited on the surface of the cells and recognized by phagocytes that express receptors for these proteins. C3b acts as opsonins, which coat the bacteria leading to phagocytosis by neutrophils and macrophages.

- **Increased vascular permeability:** Both C3a and C5a induce smooth muscle contraction and increased vascular permeability. C3a and C5a also act on endothelial cells lining blood vessels to induce expression of cell adhesion molecules.
- **Leukocytic adhesion, transmigration and chemotaxis:** C5a fragment is a chemotactic agent, which mediates the release of histamine from platelet-dense granules, which induces the expression of leukocyte adhesion molecules resulting in adhesion, transmigration and chemotaxis of leukocytes.
- **Anaphylactic shock:** C3a, C5a and C4 are called anaphylatoxins, which stimulate degranulation of mast cells and basophils liberating histamine. Histamine causes increased vascular permeability, vasodilatation and smooth muscle contraction. Patient develops 'anaphylactic shock'.
- **Synthesis of arachidonic acid metabolites:** C5a fragment activates lipoxygenase enzyme, which acts on membrane of neutrophils and monocytes resulting to synthesis of arachidonic metabolites via lipoxygenase pathway.
- **Membrane attack complex (MAC):** C5b–C9 is a lytic agent for bacteria and target cells, which stimulates arachidonic acid metabolism and produces reactive oxygen metabolites. Defective formation of membrane attack complex (MAC) leads to increased susceptibility to Neisseria organisms.

Inflammatory Cytokines: Messenger Molecules of Immune System

Cytokines released from innate immune cells play a vital role in regulating immune response in health and disease. The key proinflammatory cytokines such as IL-1, IL-6, IL-12, IL-16, TNF-α, IFN-α and IFN-γ are intracellular soluble messengers,which initiate signaling pathways via type 1 cytokine receptors (CCR1) and coordinate of all cell systems.

- **Chemokines** released by macrophages and dendritic cells recruit effector cells to the site of infection, which induce systemic reaction known as the acute-phase response.
- **TNF-α** is an important cytokine that triggers local containment of infection that induces shock when released into systemic circulation. Cytokines, principal source and cellular targets are given in Table 4.10.

Table 4.10 Cytokines, principal source and cellular targets

Inflammatory Cytokine	Principal Cell Source(s)	Principal Cellular Targets
Tumor necrosis factor-α (TNF-α)	Macrophages, T cells, mast cells	T cell proliferation, IL-2 production and cytotoxic to some malignant tumor cells
Tumor necrosis factor-β (TNF-β)	T cells	T cell proliferation, IL-2 production and cytotoxic to some malignant tumor cells
Tumor necrosis factor (TNF) family members	Macrophages, T cells, mast cells	▪ Vascular endothelial cells activation, neutrophils adhesion, activation, chemotaxis of leukocytes and phagocytosis ▪ Acute inflammation and activation of coagulation system ▪ Acute-phase proteins synthesis in liver ▪ TNF acts on hypothalamus to induce fever ▪ Muscle and fat catabolism (cachexia) ▪ Apoptosis of many cells

Contd...

Table 4.10 Cytokines, principal source and cellular targets (*Contd...*)

Inflammatory Cytokine	Principal Cell Source(s)	Principal Cellular Targets
Interleukin-1 (IL-1)	Macrophages, dendritic cells, endothelial cells, some epithelial cells, mast cells	▪ Endothelial cells activation, inflammation, coagulation ▪ IL-1 acts on hypothalamus to induce fever ▪ Acute-phase proteins synthesis in liver ▪ T helper 17 (Th17) cells differentiation
Interleukin-2 (IL-2)	Macrophages, T cells and natural killer cells	▪ Proliferation of B cells, T cells, and natural killer cells ▪ Monocytes activation
Interleukin-3 (IL-3)	T cells	Acts as growth factor for tissue mast cells and hematopoietic stem cells
Interleukin-4 (IL-4)	T cells	▪ Promotes growth of B cells and T cells ▪ Enhancing expression of MHC class II molecules
Interleukin-5 (IL-5)	T cells	Promotes end stage maturation of B cells into plasma cells
Interleukin-6 (IL-6)	T cells, monocytes/macrophages, and endothelial cells	▪ Promotes maturation of B cells and T cells ▪ Synthesis of acute-phase proteins from liver ▪ B cells proliferation and formation of antibody-producing plasma cells
Interleukin-7 (IL-7)	Stromal cells in bone marrow, dendritic cells, hepatocytes, keratinocytes, neurons and epithelial cells except normal lymphocytes	Acting as a growth factor for hematopoietic stem cells in bone marrow
Interleukin-10 (IL-10)	Macrophages, dendritic cells, T cells	Macrophages and dendritic cells: inhibition of cytokine and chemokine production, reduced expression of costimulators and class II MHC molecules
Interleukin-12 (IL-12)	Dendritic cells, macrophages	IFN-γ synthesis by natural killer cells and T cells, increased cytotoxic activity T cells and T helper 1 (Th1) cells differentiation
Interleukin-13 (IL-13)	T cells	Acting as a growth factor for hematopoietic stem cells in bone marrow
Interleukin-15 (IL-15)	Macrophages, others	Proliferation of natural killer cells and T cells
Interleukin-18 (IL-18)	Macrophages	IFN-γ synthesis by natural killer cells and T cells
Interferon-α (IFN-α)	B cells and macrophages	Antiviral activity, increased MHC class II molecules and natural killer cells activation
Interferon-β (IFN-β)	Fibroblasts	Antiviral activity
Interferon-γ (IFN-γ)	T cells and natural killer cells	Antiviral activity, activation of macrophages, increased MHC class II molecules
Chemokines	Macrophages, dendritic cells, endothelial cells, T cells, fibroblasts, platelets	▪ C–X–C (α-chemokine): chemotaxis of neutrophils ▪ C–C (β-chemokine): chemotaxis monocytes ▪ XC: (γ-chemokine): chemotaxis of lymphocytes ▪ CX3C: chemotaxis of monocytes and T cells
TGF-β	Many cell types	Inhibition of inflammatory T cells: differentiation of Th17, CD4+ regulatory T cells
G-CSF	Macrophages, neutrophils and T cells, fibroblasts and vascular endothelium	Hematopoiesis, activation and differentiation of neutrophils
GM-CSF	Fibroblasts and vascular endothelium	▪ Promoting the growth and development of macrophages from undifferentiated precursor stem cells ▪ Activation of natural killer cells and dendritic cells

Acute Phase Reactants Synthesis

Acute phase reactants are inflammatory markers synthesized in liver that exhibit changes in serum concentration by >25%, in response to inflammatory cytokines such as IL-6, IL-1 and TNF-α.

- Acute phase reactants cause several adverse systemic effects such as fever, anemia of chronic disease, anorexia, lethargy, weakness, somnolence, leukocytosis, amyloidosis, increased cortisol, decreased thyroxine, decreased serum iron and cachexia.
- Increased production of acute phase reactants is a sensitive indicator of inflammation, which can occur prior to the development of an inflammatory leukogram. Concentration of acute phase reactants during acute inflammation is given in Table 4.11.

CELLULAR RECEPTORS FOR MICROBES AND DAMAGED CELLS

Pathogen recognition receptors (**PRRs**) are a class of germline encoded transmembrane receptors found on macrophages, dendritic cells and epithelial cells that recognize different types of pathogen-associated molecular patterns (**PAMPs**).

- The activation of **PRRs** is critical for the initiation of innate immunity, which plays a key role in first line defense until more specific adaptive immunity is developed. PRRs differ in the signaling cascade and host defenses, which are activated by their engagement in various tissues.
- Currently identified PRR families are toll-like receptors (TLRs), nucleotide-binding and oligomerization domain-like receptors (NLRs), retinoic acid-inducible gene-I-like receptors (RLRs) and AIM2-like receptor (ALR). AIM2-like receptors are found in hematopoietic cells, that recognize the presence of double-stranded DNA (dsDNA) of microbial or host cellular origin.

Table 4.11 Concentration of acute phase reactants during acute inflammation

Acute Phase Reactants	Function
Marked increase in concentration	
C-reactive protein	Fixation of complement and opsonization of pathogens
Mannose-binding lectin	Fixation of complement
α_1 Glycoprotein	Transpiration of protein
Serum amyloid P component	Precursor of amyloid component
Moderate increase in concentration	
α_1 Protease inhibitors	Inhibition of bacterial proteases
α_1 Antichymotrypsin	Inhibition of bacterial proteases
C3, C9 and factor	Enhancement of complement function, opsonization, destruction of pathogens and T cell activation
Ceruloplasmin	Oxygen scavenger
Fibrinogen	Localization of damage or infected tissue
Haptoglobin	Hemoglobin binding protein
Fibronectin	Cell attachment
Angiotensin	Blood pressure

Pathology Pearls: Cell-associated Pattern Recognition Receptors

- After entering the tissues, many microbes are recognized, ingested, and killed by phagocytes via a cell-associated pattern recognition receptors (PRRs).
- The cell-associated pattern recognition receptors enhance function of phagocytic cells. PRRs induce production of antimicrobial proteins, cytokines and chemokines, PRRs differentiate phagocytic cells to a more active state.
- G protein-coupled receptors on phagocytes link microbe recognition with increased efficiency of intracellular killing.
- Microbial recognition and tissue damage initiate an inflammatory response.
- Toll-like receptors represent an ancient pathogen-recognition system.
- Mammalian toll-like receptors are activated by many different pathogen-associated molecular patterns.
- TLR-4 recognizes bacterial lipopolysaccharide in association with the host accessory protein MD-2 and CD14.
- TLRs activate NF-κB, AP-1 and IRF transcription factors to induce the expression of inflammatory cytokines and type 1 interferons.
- The NOD-like receptors are intracellular sensors of bacterial infection and cellular damage.
- NLRP proteins react to infection or cellular damage through an inflammasome to induce cell death and inflammation.
- The RIG-I-like receptors detect cytoplasmic viral RNAs and activate mitochondrial antiviral signaling protein (MAVS) to induce type 1 interferon production and proinflammatory cytokines.
- Cytoplasmic DNA sensors signal through STING signaling to induce production of type 1 interferons.
- Activation of innate sensors in macrophages and dendritic cells triggers changes in gene expression that have far-reaching effects on the immune system.
- Toll-signaling in Drosophila is downstream of a distinct set of pathogen-recognition molecules.
- TLR and NOD genes have undergone extensive diversification in both invertebrates and some primitive chordates.

Toll-like Receptors

Macrophages, neutrophils, dendritic cells, microglial cells, eosinophils, mast cells, endothelial cells, mucosal cells and lymphocytes express toll-like receptors (TLRs) within wall of phagocytes.

- Toll-like receptors such as TLR1, TLR2, TLR4 and TLR6 are expressed on cell surface. Toll-like receptors such as TLR3, TLR7 and TLR8 are expressed in endosomes. Endosomal TLRs (TLR3, TLR7 and TLR8) respond only to nucleic acids.
- All TLRs contain a ligand-binding domain composed of leucine-rich motifs and a cytoplasmic signaling, toll-like interleukin-1 receptor (TIR) domain.
- Toll-like receptors on phagocytic cells provide defense against invasion by microorganisms. Different TLRs on phagocytic cells respond to many different structurally diverse products of microbes, which engulf and degrade pathogens. Binding of a particular class pathogen to TLRs initiates innate immune response against microbes by relaying a signal to the nucleus and activating synthesis of transcriptional factor resulting in synthesis of immune molecules known as interleukins. It is the first step to activate both the innate (nonspecific) and specific (adaptive) immune responses.
- Currently 10 TLRs are known to exist on human cells. Each TLR can recognize distinct microbial molecules known as pathogen-associated molecular patterns (PAMPs). Each TLR recognizes and binds distinct microbial molecules called pathogen-associated molecular patterns (PAMPs).
- Toll-like receptors and their actions are shown in Fig. 4.9. Toll-like receptors and their ligands are given in Table 4.12. Pathogen-associated molecular patterns (PAMPs) are given in Table 4.13.

NOD-like Receptors and the Inflammasome

The nucleotide-binding oligomerization domain-like receptors (NOD-like receptors, i.e. NLRs) sense pathogen-associated molecular patterns (PAMPs) that enter the cell cytoplasm via phagocytosis and also sense damage-associated molecular patterns (DAMPs) associated with severe cell stress.

- NOD-like receptors (NLRs) bind to PAMPs and DAMPs and play key role in regulating innate immune response. NLRs can cooperate with toll-like receptors (TLRs) and play key role in regulation of inflammatory response and apoptosis.
- NOD-like receptors (NLRs) are expressed in macrophages, dendritic cells and lymphocytes. NLRs constitute a large family of intracellular pathogen recognition receptors (PRRs) such as NOD1, NOD2 and NOD3. NOD1 and NOD2 recognize peptidoglycan components common to both gram-positive and gram-negative bacteria. Both NOD1 and NOD2 activate MAPK and NF-κB pathways in production of proinflammatory cytokines.

C Type Lectin Receptors

C type lectin receptors (CLRs) are expressed on monocytes, macrophages and dendritic cells, which recognize mannose, fucose and glucan carbohydrate moieties present in bacteria, fungi and viruses. Pathogen recognition by CLRs leads to pathogen internalization, and degradation; and subsequent antigen presentation. CLRs play key roles in regulation of innate and specific adaptive immunity.

RIG-1-like Receptors

RIG-1-like receptors (RLRs) are intracellular receptors for RNA viruses, which sense viral RNA and triggers

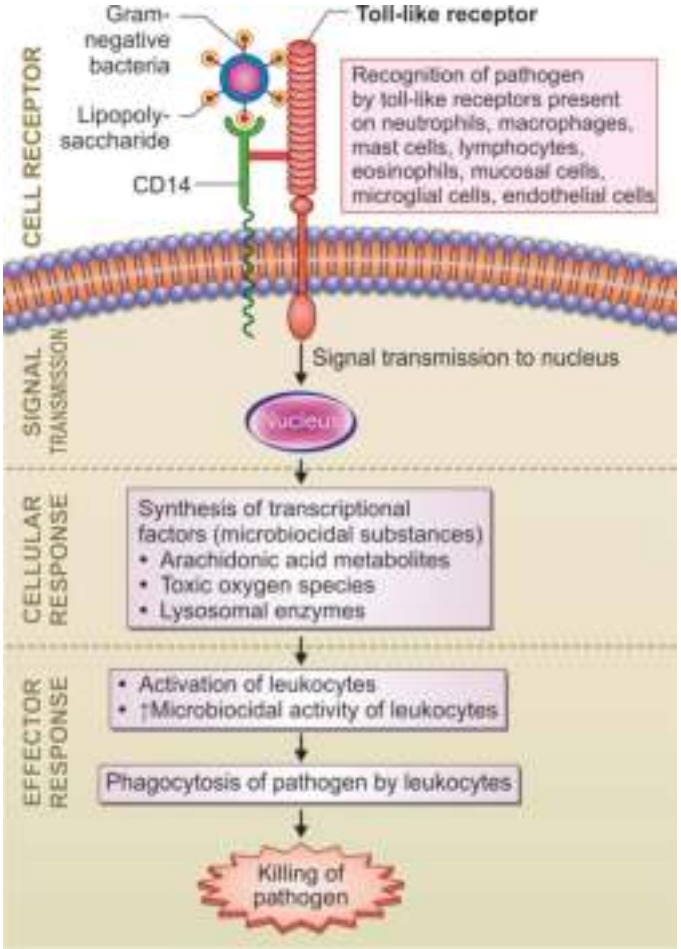

Fig. 4.9: Toll-like receptors and their actions. TLR binds and relays a signal to the nucleus resulting in activation of nuclear synthesis of transcription factors (chemical mediators) such as arachidonic acid metabolites and cytokines amplifying the inflammatory reactions, and production of microbiocidal reactive oxygen species and lysosomal enzymes killing the microbes.

Table 4.12 Toll-like receptors and their ligands

Receptor	Ligand (PAMPs)	Origin of Ligand	Location of Toll-like Receptors
TLR1	Triacyl lipopeptides and soluble factors	Bacteria, mycobacteria, *Neisseria meningitidis*	Plasma membrane
TLR2	Heat shock protein 70, peptidoglycan, lipoprotein/lipopeptides, HCV core and nonstructural 3 protein	Host gram-positive bacteria, various pathogens, hepatitis C virus	Plasma membrane
TLR3	Double-stranded RNA	Viruses	Endosome
TLR4	Lipopolysaccharides, envelope protein and Taxol	Gram-negative bacteria, mouse mammary-tumor virus	Plasma membrane
TLR5	Bacterial flagellin	Bacteria	Plasma membrane
TLR6	Zymosan, lipoteichoic acid, diacyl lipopeptides	Fungi, gram-positive bacteria, mycoplasma	Plasma membrane
TLR7	Single-stranded RNA (ssRNA), imidazoquinoline	Viruses, synthetic compounds	Endosome
TLR8	Single-stranded RNA (ssRNA), imidazoquinoline	Viruses, synthetic compounds	Endosome
TLR9	CpG-containing DNA	Bacteria, malaria and viruses	Endosome
TLR10	Not determined	Not determined	Plasma membrane
TLR11	Profilin-like molecule	*Toxoplasma gondii*	Plasma membrane

Toll-like receptors such as TLR1, TLR2, TLR4, LR5, TLR6, TLR10 and TLR11 are expressed on cell surface. Toll-like receptors such as TLR3, TLR7, TLR8 and TLR9 are expressed in the endosomes.

Table 4.13 Pathogen-associated molecular patterns (PAMPs)

Pathogens	Pathogen-associated Molecular Patterns
Gram-negative bacterial cell wall	Lipopolysaccharides (LPS)—endotoxin
Gram-positive bacteria cocci	Peptidoglycan such as lipoprotein, lipoteichoic acid
Bacteria with flagella	Flagellin
Viruses	Single-stranded or double-stranded RNA molecules
Fungi	Zymosan

innate and specific adaptive immunity mainly through the rapid induction of type 1 interferons (IFNs) and inflammatory cytokines. Viral RNA is a potent inducer of innate immune response, which is recognized by cytoplasmic RNA helicase or toll-like receptors (TLRs). The RLR family is composed of three members: RIG-1, melanoma differentiation-associated protein 5 (MDA5) and laboratory of genetics and physiology 2 (LGP-2).

G Protein-coupled Transmembrane Receptors

G protein-coupled transmembrane receptors are embedded in the plasma membrane of leukocytes.

- G protein-coupled transmembrane receptors bind to extracellular molecules (e.g. hormones and neurotransmitters) and transmits into intracellular responses leading to production of secondary messengers involved in regulation of many physiologic functions such as taste, smell, sight, neurotransmission, pain perception and cardiac output.
- Most leukocytes express more than one G protein-coupled transmembrane receptors on their surface and sense wide range of chemokines and chemoattractants leading to leukocyte movement during immune responses.

Mannose Receptors

Mannose receptors are pattern recognition receptors (PRRs) primarily expressed on tissue macrophages and dendritic cells, which recognize and bind to microbial structures bearing mannose, fucose and N-acetylglucosamine on their surface. Mannose receptors play key roles in host defense via phagocytosis and degradation of microbes, and provides a link between innate and specific adaptive immunity.

RESPONSES OF INNATE IMMUNE SYSTEM

Innate immune system is the first line of host defense against invasive pathogens by discrimination of 'nonself' from 'self'-antigens, which consists of physical, chemical, cellular and humoral defenses against pathogens. The main purpose of the innate immune response is to prevent the spread of pathogens throughout the body.

Signaling in Innate Immunity and Inflammation

Inflammation is the immune response to harmful stimuli such as pathogens, damaged cells, irradiation and toxic compounds, and acts by removing injurious stimuli and initiating healing process. Innate immune cells, neutrophils, macrophages, dendritic cells, mast cells and natural killer cells express pattern recognition receptors (PRRs), which bind to pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs) released from injured cells leading to recognition of invading pathogens and their destruction. Activated PRRs initiate signaling cascades that trigger the release of factors that promote recruitment of leukocytes to the tissue injury site.

Antiviral Defense

Innate immune response is the first line defense against invading viral pathogen. Interferon molecules such as IFN-α and IFN-β are produced and secreted from the infected cells upon virus infection and recognition. Interferon molecules, then act as signaling/communication molecules to induce antiviral and antiproliferative response in the neighboring cells so that those cells become refractory to infection.

Pathogen-associated Molecular Patterns Signaling inducing Innate Immunity

Pathogen recognition receptors (PRRs) are a class of germline encoded receptors that recognize pathogen-associated molecular patterns (PAMPs) of innate immune system. Examples of **PAMPs** include lipopolysaccharide (LPS) of gram-negative bacteria, lipoteichoic acids (LTA) of gram-positive bacteria, peptidoglycans and lipoproteins. Upon PAMP recognition, PRRs present on the cell surface or intracellularly signal to the host, the presence of infection by pathogens triggers pro-inflammatory and antimicrobial responses by activating a multitude of intracellular signaling pathways, including adaptor molecules, kinases and transcription factors. Pathogen-associated molecular patterns are shown in Fig. 4.10.

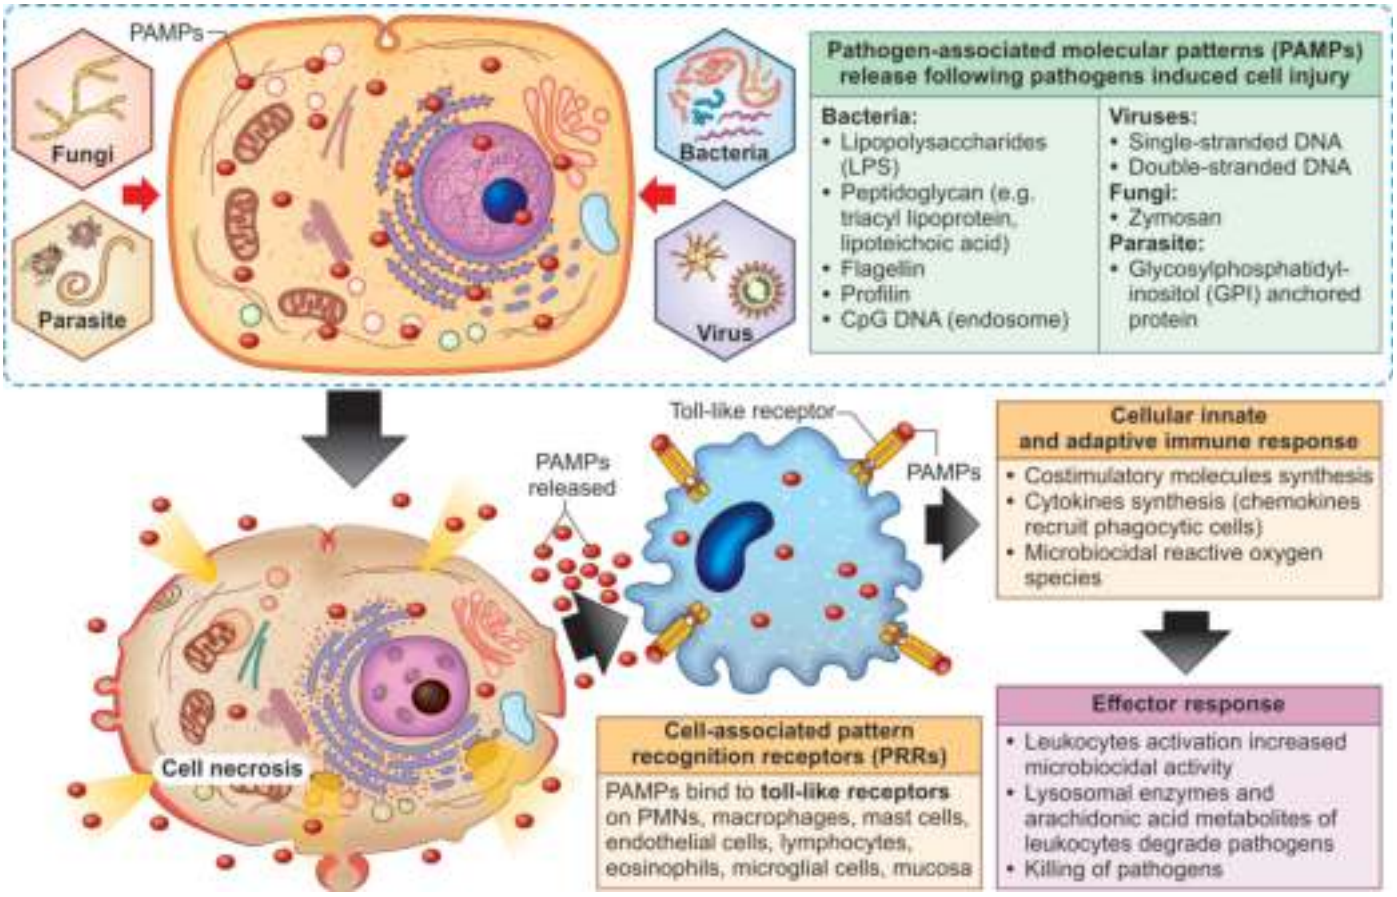

Fig. 4.10: Pathogen-associated molecular patterns. Microbes release PAMPs that bind to the family of pattern recognition receptors (PRRs), i.e. toll-like receptors and mediate innate and adaptive immune responses. Activation of toll-like receptors by specific ligands induces cytokine release and costimulatory molecules that instruct the type on immune response and direct antimicrobial response and tissue injury.

Damage-associated Molecular Patterns Signaling inducing Innate Immunity

Damage-associated molecular patterns (DAMPs) are endogenous danger molecules that are released from damaged cells that activate the innate immune system by interacting with pattern recognition receptors (PRRs). Necrotic cells release their cellular contents from organelles and nucleus (RNA, DNA and nucleotides) as well as IL-1. ATP, HMGB1, uric acid and heat shock proteins (HSPs) that recruit and activate neutrophil, macrophages and dendritic cells, thereby contributing to host defense and inducing a highly inflammatory response by binding to PRRs. Damage-associated molecular patterns (DAMPs) are shown in Fig. 4.11.

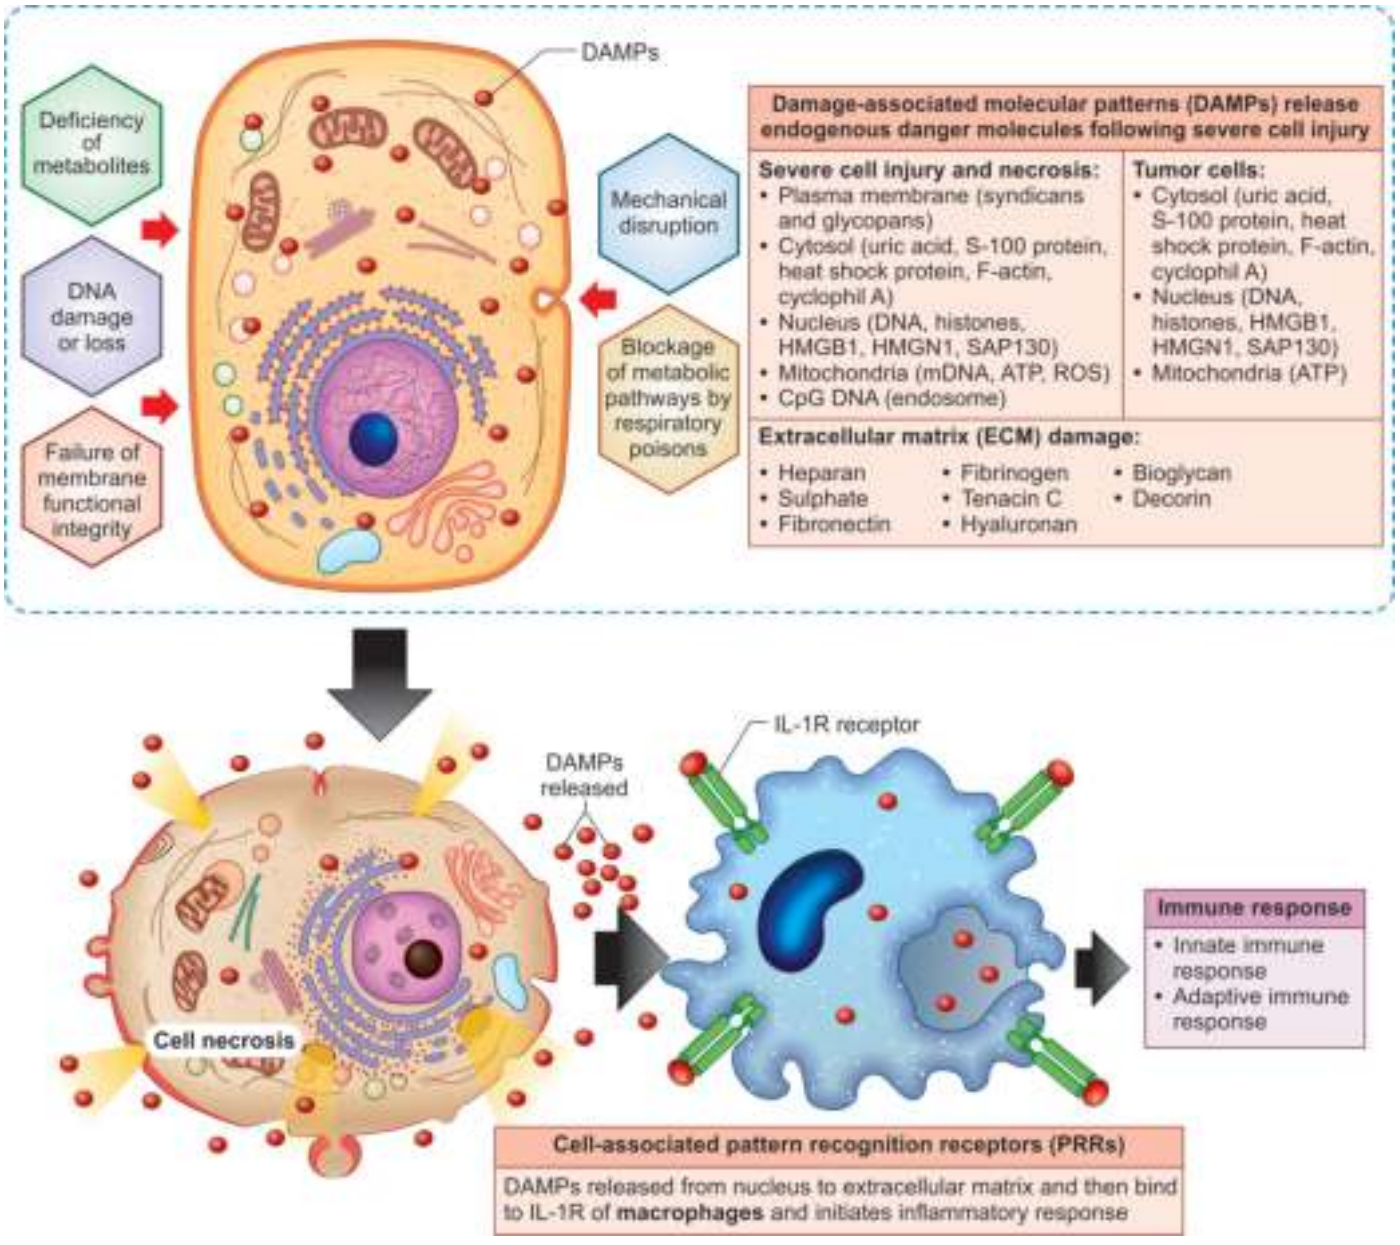

Fig. 4.11: Damage-associated molecular patterns (DAMPs). Necrotic cells release damage-associated molecular patterns (DAMPs), i.e. endogenous danger molecules from damage cells, whereas mild cell injury apoptosis induced cells do not. Stimuli that induce cell necrosis frequently cause severe cellular damage, which leads to rapid cell rupture with consequent release of intracellular DAMPs. Damage-associated molecular patterns can then engage cells of the immune system and promote inflammation. On the other hand, because stimuli that initiate apoptosis are physiologic and relatively mild, apoptotic cells do not rupture and their removal is coordinated by macrophages and other cells of the innate immune system, before release of DAMPs can occur. For this reason, apoptosis is not typically associated with activation of the immune system.

ADAPTIVE IMMUNE RESPONSE

Adaptive immune response provides highly specific protection against pathogens, which involves T cells, B cells, natural killer cells (NK cells), dendritic cells (DCs). T cells and B cells are indistinguishable by light microscopy using conventional stains but can only be distinguished by the presence of different surface proteins on T cells and B cells. Dendritic cells act as an important conduit between the innate and adaptive immune systems.

- Adaptive immune response consists of distinct steps: recognition of antigen, activation of T cells and B cells, their interrelationship with macrophages and elimination of antigen (effector phase). Immune response declines as a result of apoptosis of antigen-stimulated T cells or B cells leading to restoration of homeostasis. Antigen-presenting cells (APCs) which survive and are responsible for immunologic memory.
- Two types of adaptive (specific) immunity include: humoral immunity and cell-mediated immunity, which are induced by different types of lymphocytes and function to eliminate different types of pathogens.
  - In humoral immunity, B cells secrete antibodies that prevent against entry of pathogens and eliminate extracellular microbes. B cells recognize many different antigens and develop into antibody secreting plasma cells.
  - In cell-mediated immunity, CD4+ helper T cells activate macrophages and neutrophils to eliminate phagocytosed pathogens. CD8+ cytotoxic T cells directly kill infected cells. CD4+ helper T cells recognize antigens on the surfaces of the antigen-presenting cells (APCs) and secrete cytokines, which stimulate different mechanisms of adaptive immunity and inflammation.
- CD8+ cytotoxic T cells recognize antigens on infected cells and eliminate them. CD4+ regulatory T cells suppress immune responses to self-antigens.

Pathology Pearls: Key Features of Adaptive Immune Response

Recognition of Antigen

Adaptive immune system has been ability to identify antigen and distinguish between self- and nonself-antigens.

Specificity

- Adaptive immune system mounts a highly specific response against distinct antigens, which allows immune system to respond to newly encountered antigens.
- Fine specificity exists because individual lymphocytes express membrane receptors that can distinguish subtle differences in structure between distinct epitopes.

Specialization

- Adaptive immune system generates responses that are optimum for defense against different types of microbes.
- Cells of adaptive (specific) immune system include lymphocytes (B cells and T cells), monocytes/macrophages, Langerhans' cells of skin, and dendritic cells of lymphoid tissue.

Diversity

- Diversity is one of the key characteristics of adaptive immune system that enables immune system to respond to a large variety of distinct antigens.
- Lymphocyte repertoires of 3×10^7 different clonotypes protect human against infections while avoiding unwanted immune responses against self-peptides and innocuous antigens. Another important source of diversity in the immune system is due to the genes encoding major histocompatibility complex (MHC) molecules.
- For an adaptive immune response to be induced, the proteins of a pathogen need to be degraded into peptides, which are subsequently bound to major compatibility complex molecules on the surface of antigen-presenting cells (APCs).
- The resulting MHC peptides can be recognized by T cell receptors. Each person expresses three classical MHC class I (HLA-A, HLA-B, HLA-C) and three MHC class II gene pairs coding for the α- and β-chains of HLA-DP, HLA-DQ, HLA-DR.
- Diversity of the lymphocyte receptors occurs as a result of evolution of somatic diversification mechanisms. Genes coding for the V, D and J segments of the lymphocyte receptors are somatically rearranged and imprecise joining of the gene segments, addition of nucleotides and somatic hypermutation subsequently contribute to the diversity of lymphocytes that can bind their ligands with great specificity.

Clonal Expansion of Lymphocytes

- The clones of lymphocytes with different specificities are present in an unimmunized person. Lymphocytes activated by antigen give rise to clones of antigen-specific effector cells that mediate adaptive immunity. Clonal expansion increases number of antigen-specific lymphocytes from a small number of naïve B cells and T cells.
- Clone refers to population of B cells and T cells with identical antigen receptors are presumably derived from one precursor cell. Each antigen selects a pre-existing clone of specific B and T cells and stimulates the proliferative and differentiation of that clone.

Immunologic Memory

- Lymphocytes activated by antigen proliferate in the peripheral lymphoid organs, generating effector cells and immunologic memory.
- Adaptive immune system has memory that leads to enhanced responses to repeated exposures to the same antigens. Some of B cells and T cells become memory cells that recognise the same antigen in the future.

- The immune response to the first exposure to antigen called primary response that is initiated by naïve B and T cells that are encountered antigen for the first time. Subsequent encounter with same antigen leads to secondary immune response.

Nonreactivity of Adaptive Immune System to Host Cells (Self-tolerance)

- Adaptive immune system prevents injury to the host during immune responses to foreign antigens.
- Immunologic unresponsiveness is also called tolerance. Tolerance to self-antigens is maintained by many mechanisms: (a) elongation of lymphocytes that express membrane receptors specific for some self-antigens, and (b) inactivation of self-reactive lymphocytes or suppression of lymphocytes by the actions of regulatory cells.
- Abnormalities in the maintenance of self-tolerance lead to immune responses against the self (autologous) antigens, which may induce autoimmune disorders.

Contraction of Adaptive Immune Response and Homeostasis

Contraction of adaptive immune response and homeostasis prevent injury to the host during responses to foreign antigens.

ANTIGENS AND IMMUNOGENS

In immunology, antigen is a macromolecule of high molecular weight >10,000 daltons, which can trigger an immune response in the host by activating leukocytes that provide protection. Antigens may be present on invaders, such as microorganisms, cancer stem cells and transplanted organs.

ANTIGENICITY AND IMMUNOGENICITY

Antigen has two distinct properties: antigenicity (immunologic reactivity) and immunogenicity. Antigenicity is the ability to combine specifically with the final products of the immune response, i.e. secreted immunoglobulins and/or surface receptors on T cells. Immunogenicity is defined as the ability of cells/tissues to provide an immune response and its generally considered to be an undesirable physiologic response.

Antigenicity

Antigenicity refers to ability of an antigen to combine specifically with final products of antibodies and/or T cell receptors (TCRs). Antigenicity depends on recognition of antigen, size of antigen and complexity of cell or molecule.

- **Antigen motifs:** Each antigen may contain several motifs that are recognized by immune system and each motif is an epitope within an antigen to which antigen receptor binds. Epitope or antigenic determinant is the smallest unit of antigenicity present on antigen, that is capable of sensitizing T cells and B cells and reacting with specific site of B cell receptor (BCR) or T cell receptor (TCR). Antigen and its several motifs are shown in Fig. 4.12.
- **Antigen epitopes:** Antigen has two types of epitopes: (a) sequential or linear epitope with sequence of few amino acids residues, and (b) conformational or nonsequential epitope with flexible region of complex antigens having tertiary structures. T cells recognize sequential epitopes, while B cells bind to the conformational epitopes.
- **Hapten-carrier molecule:** Small molecules cannot act as antigen by themselves. Binding of antigen with small carrier molecule known as **hapten** produce immune response.
  - Hapten molecule has molecular weight of <1,000 MW. Hapten size is too small to trigger an immune response alone but can be immunogenic when it attaches to a larger carrier molecule, such as host serum protein.
  - Hapten-carrier complex is capable of inducing immune response in the body. Simple hapten contains only one epitope, while complex hapten contains two or more epitopes.

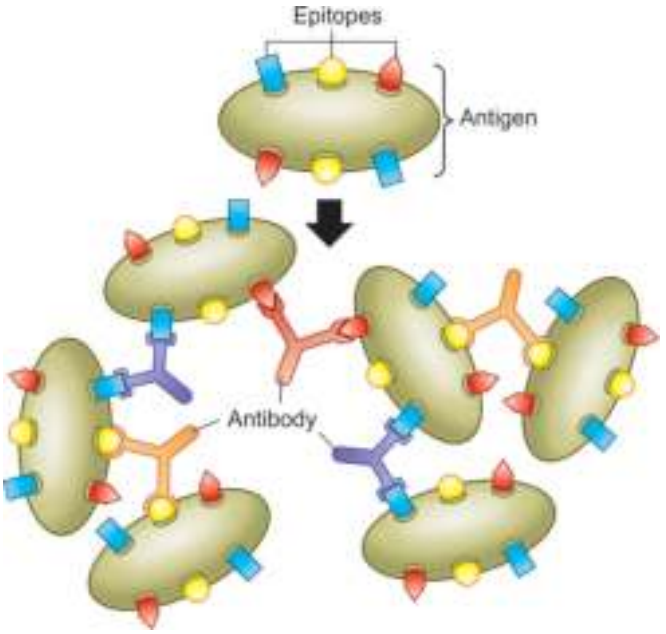

Fig. 4.12: Antigen and its several motifs. Antigen is a macromolecule that reacts with components of the immune system. Antigen may contain several motifs that are recognized by immune cells. Three different antibodies bind to different epitopes of the same antigen.

Immunogenicity

Immunogenicity is the ability of an antigen to induce humoral or cell-mediated immune responses. The substance that satisfies this property is called **immunogen**.

- **Adjuvant:** Adjuvant is a substance that enhances the immunogenicity of an antigen. Adjuvant is added to the **vaccine** to increase the immunogenicity of the vaccine antigen. Adjuvant delays release of vaccine, enhances phagocytosis, activates CD4+ helper T cells and induces granuloma formation.
- **Factors influence immunogenicity:** Factors influencing immunogenicity include: size of the antigen, chemical nature of antigen, susceptibility of antigen to tissue enzymes, structure complexity, foreignness to the host, optimal dose, route of antigen administration, repeated number of doses of antigens, multiple antigens, effect of prior administration of antibody and genetic factors.

Pathology Pearls: Properties of Antigens

Characteristics of antigens are shown in Fig. 4.13A and B. The hapten-carrier phenomenon is shown in Fig. 4.14A and B.

Chemical Nature of Antigen

Antigen and immunogen can be either proteins, polysaccharides, lipids or nucleic acids, which are cell surfaces or membrane bound antigens.

- **Proteins:** These are powerful antigens because of high-molecular-weight and structural complexity.
- **Lipopolysaccharides:** These are endotoxins, capsular polysaccharides of pneumococci.
- **Polysaccharides:** These are too small to be antigenic. But in the case of red blood cells, protein or lipid carrier gives rise to an increase in their size. Polysaccharides are present in the form of side chains and give rise to antigenicity. Red blood cell surface antigens are glycoproteins.
- **Nucleic acids:** These are nonimmunogenic except for single-stranded DNA, simpler structure, molecular flexibility, and rapid degradation.
- **Polypeptide hormones:** These hormones act as weak antigens.
- **Nucleoproteins:** These act as strong antigens.
- **Lipids:** These are nonimmunogenic except cardiolipin.

Molecular Weight of Antigen

- Higher the molecular weight, better the molecule acts as an antigen. The number of epitopes is directly proportional to the size of antigen.
- Haptens are small molecules, which need to combine with the larger carrier molecule to be immunogenic.
- Large molecules of antigens with molecular weight **>10,000** daltons act as good immunogenic because these antigens are easily phagocytosed and processed by antigen-presenting cells (APCs) resulting in increased synthesis of antibodies.

Molecular Structure

- Structural stability of the antigens is essential and always required.
- Antigens with structural stability act as strong immunogen. If the structure is unstable, it acts as poor immunogen.

Routes of Entry

- Route of entry of antigens also influences the immune response. Antigen interaction with skin results in localize reaction.
- Environmental antigens enter the body via respiratory system and gastrointestinal tract.
- Antigens in the form vaccines are administered via subcutaneous or intramuscular routes.

Dose of Immunogen

For adequate immune response, there is always a need for optimum dose of antigen, otherwise, there may be no reaction with a smaller dose.

Genetic Host Reaction

An immune response gene influences the immune response, that varies in different persons.

CATEGORIES OF ANTIGENS

Many native endogenous antigens present in the host play important role in both health and disease, which classified as autologous, heterologous, and homologous antigens (iso-antigens).

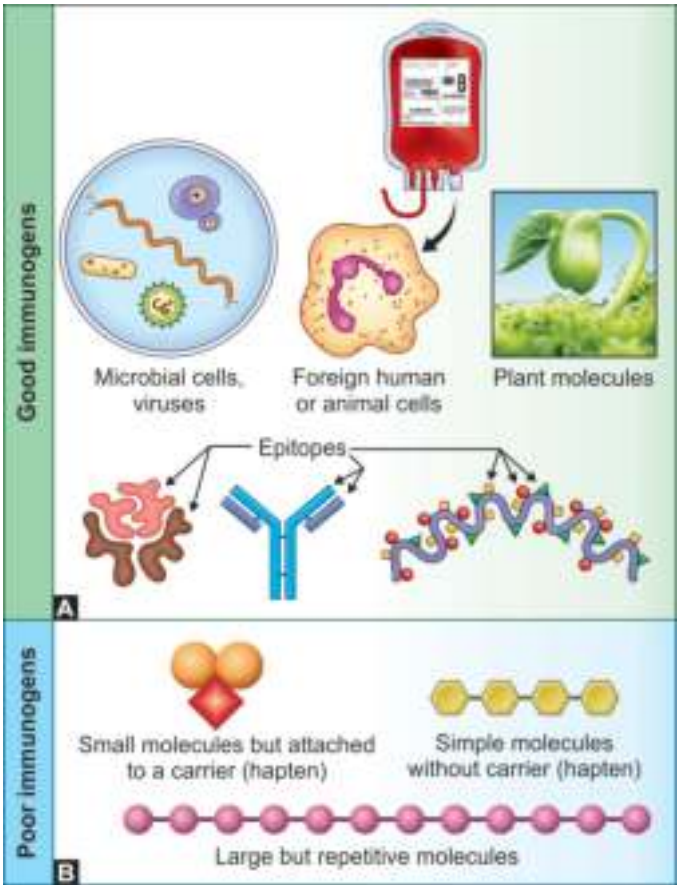

Fig. 4.13: Characteristics of immunogens. (A) Microbial cells, foreign human or animal cells and viruses make good immunogens, (B) complex molecules with several epitopes also make good immunogens. Poor immunogens include small molecules not attached to carrier molecule.

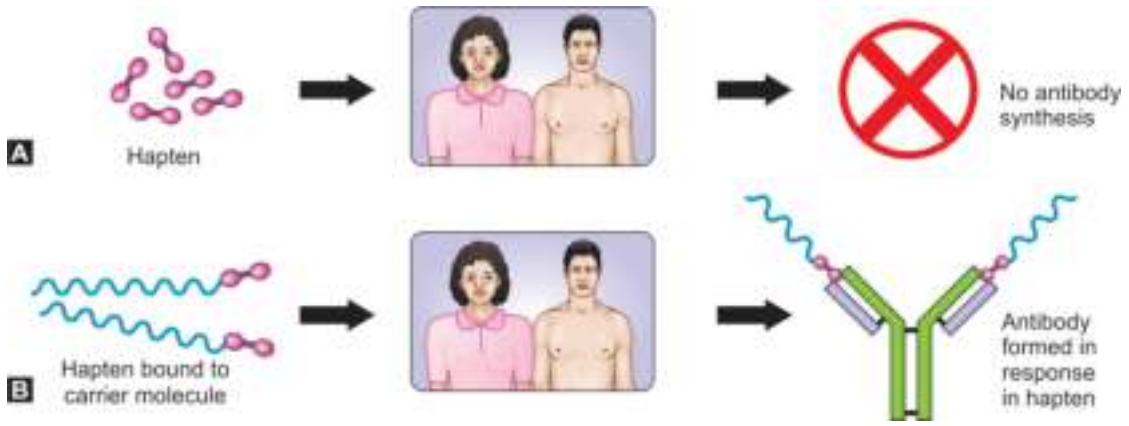

Fig. 4.14: The hapten-carrier phenomenon. (A) Hapten molecule is too small to trigger an immune response, (B) binding of hapten with carrier triggers an immune response.

Exogenous Antigens

Exogenous antigens enter the body through inhalation or ingestion, which are found on the surface of pathogens in the extracellular compartment. Molecular components of the pathogens inside cells are nonself antigens.

Endogenous Antigens

Endogenous antigens are generated inside the cell as a result of the cell metabolism, in which the epitopes are generated as a result of the regular metabolism of self-antigens. Autoantigens are already present within the host's own normal constituents. In normal person, autologous antigens are recognized as 'self-antigens', which do not elicit immune response. This state is known as tolerance. Endogenous autoantigens mistakenly are recognized as non-self-antigens, which are and not able to distinguish between self- and non-self-antigens by the immune system, that results in the destruction of self-tissues, causing autoimmune diseases.

Heterologous Antigens

Heterologous antigens enter the body from outside such as bacteria, viruses, snake venom, certain foods and cells from other persons. Allergens cause damage to host tissue as a consequence of the immune response. Heterologous antigens can induce cross-reaction resulting in genesis of certain disease. Cross reactivity occurs between M proteins present in certain strain of β-hemolytic *Streptococcus pyogenes* and determinant present in heart and joints resulting in genesis of acute rheumatic fever.

Homologous Antigens

Homologous antigens distinguish the tissue components of one person from another. Expression of homologous antigens is genetically regulated, which can be seen from the mode of inheritance of one important group of such antigens, e.g. the ABO blood group system.

Neoantigens

Neoantigens are expressed on the surface of the infected cells by oncogenic viruses. Tumor neoantigens may play an important role in helping the body to induce immune response against the cancer stem cells. Neoantigens arise via mutations that alter amino acid coding sequences. Some of these mutated peptides can be expressed, processed and presented on the cell surface and subsequently recognized by CD8+ cytotoxic T cells.

ANTIGEN AND IMMUNOGEN

The terms antigen and immunogen are most often used interchangeably. When an antigen binds to a receptor molecule of antibodies, B cells and T cells, it may or may not elicit a B cell (humoral/antibody) and/or a T cell-mediated immune response. Immunogens can be categorized into good and poor.

- Antigen that evokes a powerful immune response is called a good immunogen. Immunogenicity refers to the ability of an antigen to induce cellular and humoral immune response, whereas **antigenicity** the ability to bind with antibodies and/or T cell surface receptors (TCRs).
- Antigen–antibody interaction is optimal when the epitope, or antibody recognition/binding site on the antigen is open to the surroundings and therefore available for the antibody to bind.

Pathology Pearls: Good Immunogens Versus Poor Immunogens

Good Immunogens

- Microbial cells, foreign human or animal cells and viruses make good immunogens. Complex molecules with several epitopes also make good immunogens.

- Epitope is a small specific portion of antigen that is recognized by B cells and T cells. The epitope recognized by T cell receptors (TCRs) is often buried. The antigen must first be broken down into peptide fragments. The epitope peptide binds to a self-molecule, an MHC molecule.
- The T cell receptor (TCR) binds to a complex of MHC molecule and epitope peptide. Cells, viruses and large molecules can have numerous antigenic determinants. A given microorganism has many such epitopes, all of which stimulate individual specific immune response.

Poor Immunogens

- Poor immunogens include small molecules not attached to carrier molecule, which may be simple, complex and repetitive. Widely distributed, 'cytochrome c' is generally poor immunogen.
- Protein molecules have large number of different amino acid residues, whereas nucleic acids have a small number of different nucleotide bases. Therefore, large diversity can be obtained in epitopes of protein molecules than the nucleic acids.

Pathology Pearls: Antigens Versus Immunogens

Similarities between Antigens and Immunogens

- Antigen and immunogen are two types of molecules that bind to the components of the immune system, including antibodies, surface receptors of B cell and T cell.
- Moreover, antigen and immunogen can be either proteins, polysaccharides, lipids or nucleic acids.

Differences between Antigens and Immunogens

- **Inducing adaptive immune response:** An antigen refers to a substance specifically bind to antibodies or surface of receptors of B cells (BCRs) and T cells (TCRs), while, an immunogen is an antigen capable of inducing humoral or cell-mediated adaptive immune responses. It is the main difference between antigen and immunogen.
- **Immunogenicity:** Antigens can be either immunogenic or nonimmunogenic while immunogens are immunogenic. Not all antigens are immunogens, but all immunogens are antigens.
- **Type of molecules:** Antigens can be either proteins, polysaccharides, lipids or nucleic acids, while immunogens are normally proteins and large polysaccharides.
- **Haptens:** Haptens are low-molecular-weight molecules, which bind to antibodies, while haptens become immunogenic when binding to large carrier molecules.

SUPERANTIGENS

Conventional antigens are only recognized by specific CD4+ helper T cells having T cell receptor (TCR) with a corresponding shape that corresponds to a peptide of that antigen bound to MHC class molecules. Superantigens, on the other hand, bind directly to the outside of MHC class II molecules and TCR and activate many CD4+ helper T cells without being processed within antigen-presenting cells (APCs). Specific TCR is not required for activation of CD4+ helper T cells. Conventional antigen and superantigen presentation pathways are shown in Fig. 4.15A and B.

- Superantigens are a family of unusual antigenic proteins that interact with exceedingly large number of CD4+ helper T cells and excessive activation of immune system. Activation of very large numbers of CD4+ helper T cells results in the secretion of excessive amounts of inflammatory cytokine IL-2.
- Superantigens can span both MHC II receptors and some T cell receptors (TCRs) resulting in excessive secretion of TNF-α, platelet activating factor (PAF), IL-1, IL-2, IL-6 and IL-8. Excessive production of these cytokines leads to induce inflammatory response leading to massive influx of potent chemical mediators that cause endothelial damage, acute respiratory distress syndrome, disseminated intravascular coagulation (DIC), shock and multiple organs failure seen with pathogen-associated molecular patterns (PAMPs)-induced inflammation. It is also suggested that superantigens may be implicated in rheumatoid arthritis.
- Superantigens such as pyrogenic toxin bypass the standard antigen presentation mechanism and uncontrolled cytokine release results in toxic shock syndrome (TSS).
- Superantigens are actually a form of virulence factor present in group A *Streptococcus pyogenes*, *Escherichia coli*, Epstein-Barr virus, *Chlamydia pneumoniae*, *Campylobacter jejuni*, Coxsackie B4 nuclear antigen, hepatitis C virus and poliovirus, which overstimulate T cells leading to produce serious illness.
- Whole T cell subpopulations can be activated by superantigens independently of antigen specificity.

MOLECULAR MIMICRY AND AUTOIMMUNITY

Molecular mimicry is a mechanism by which infectious or chemical agents may induce autoimmunity, which occurs when similarities between foreign and self-peptides favor an activation of autoreactive B cells and T cells by a foreign-derived antigen in a susceptible person. Molecular mimicry is unlikely to be the only underlying mechanism for autoimmune responses; however, autoimmune responses can be induced by breach in central intolerance, nonspecific bystander activation, or persistent antigenic stimuli leading to autoimmune diseases. Host genetic constitution, exposure to pathogens and environmental chemical agents are additional links to understanding of molecular mimicry. Molecular mimicry and some examples of homologies and tissue antigens as potential cross-reacting T cell epitopes are given in Table 4.14.

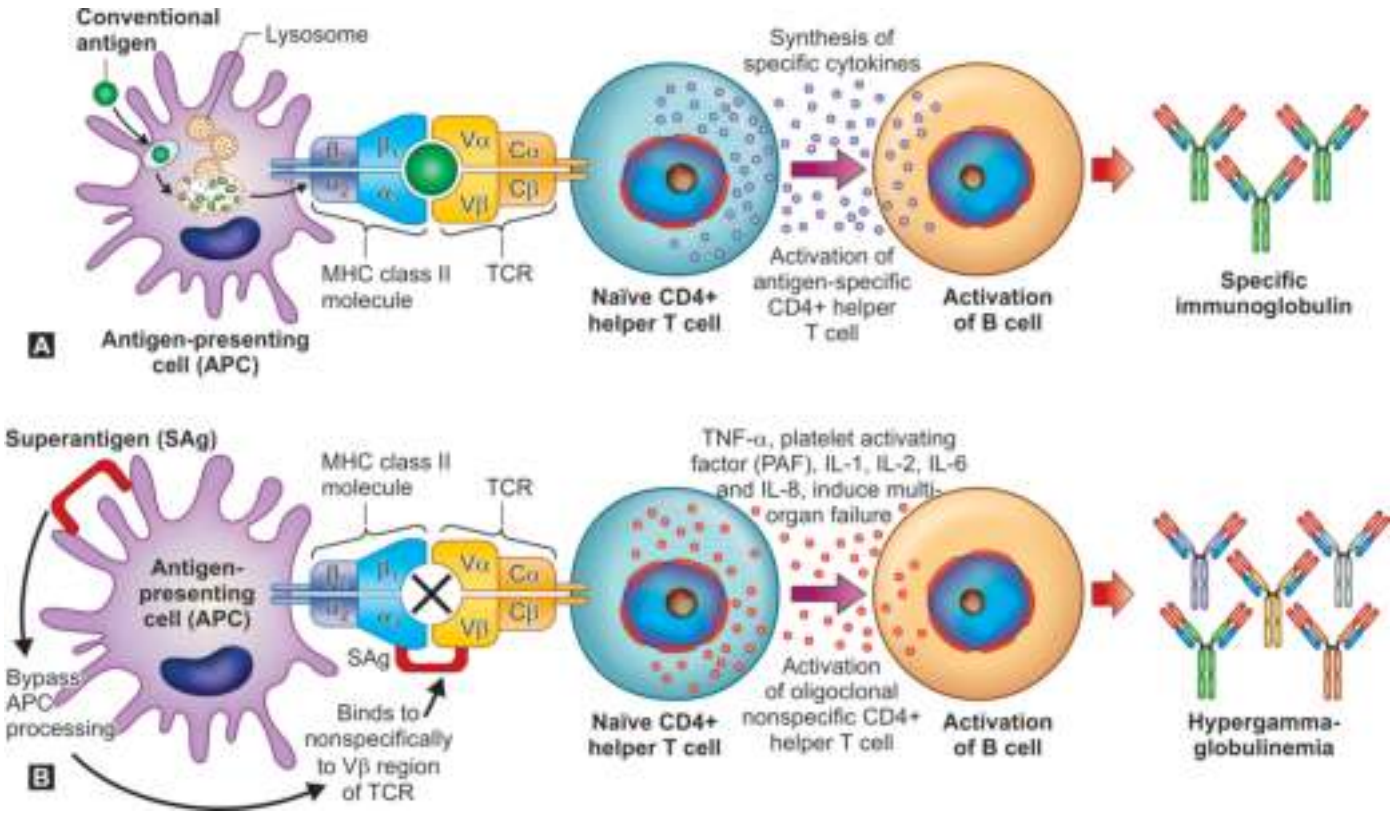

Fig. 4.15: Conventional antigen and superantigen presentation pathways. (A) Conventional antigen is processed into short peptides and presented on MHC class II molecules to one numerous naïve CD4+ helper T cells. (B) In contrast, superantigen bypasses antigen-presenting cell and directly crosslinks TCR and MHC class II molecules outside its peptide binding site leading to oligoclonal T cell activation, massive release of cytokines and multiorgan failure.

Table 4.14 Molecular mimicry and some examples of homologies and tissue antigens as potential cross-reacting T cell epitopes

Microbial Antigen	Self-tissue Antigens Cross-reactivity	Disease Produced as a Result of Molecular Mimicry
Group A *Streptococcus pyogenes*	Cardiac myosin	Rheumatic fever
Escherichia coli	HLA-DRB1* 04:01 allele	Rheumatoid arthritis
Epstein-Barr virus	Myelin basic protein	Multiple sclerosis
Chlamydia pneumoniae	Myelin basic protein	Myelin basic protein
Campylobacter jejuni	Myelin-associated gangliosides and glycolipids	Guillain-Barré syndrome
Coxsackie B4 nuclear antigen	Glutamate decarboxylase present in pancreas islets cells	Insulin-dependent diabetes mellitus
Hepatitis C virus	Glutamate decarboxylase present in pancreas islets cells	Insulin-dependent diabetes mellitus
Poliovirus	Acetylcholine receptor	Myasthenia gravis

Clinical Pearls: Molecular Mimicry and Rheumatic Fever

- Antibodies to the M protein of *Streptococcus pyogenes* cross-react with antigenic determinants of the host. By binding to the endothelium of the heart valves these antibodies initiate an inflammatory response resulting in healing with fibrosis of cardiac valves.
- Patient presents with pharyngitis due to group A Streptococcus. Antibody response occurs against specific antigenic determinant (M protein) on the bacterium.
- Antibodies cross-react with same antigenic determinant found in heart tissue, which promote complement deposition and the inflammatory response.
- Following inflammatory response, healing results in thickened and deformed cardiac valves.

ANTIGEN AND HOST RELATIONSHIP

Based on the antigen–host relationship, antigens can be classified into two groups: (a) self-antigens

(autologous antigens), and (b) nonself-antigens (foreign antigens).

- Biologic classes of antigens are categorized: (a) T cell-dependent antigens are presented by antigen-presenting cells (APCs) to CD4+ helper T cells which lead to T cell activation, and (b) T cell-independent antigens such as bacterial capsule, flagella and lipopolysaccharide do not require the help of APCs and CD4+ helper T cells. Differences between T cell-dependent and T cell-independent antigens are given in Table 4.15.
- Introduction of antigen into a host may give rise to one or more of basic reactions such as synthesis of immunoglobulins, clonal proliferation of T cells and immunologic tolerance.
- Immunity is categorized into humoral (antibody-mediated) and cell-mediated immunity. Immune responses acquired through B cells and T cells can be classified into natural immunity and artificial immunity.
- B cells and T cells are important components of the immune system, which possess cell surface receptors known as BCR and TCR respectively. Both **BCR and TCR** possess unique binding sites, but differ in the process of the recognition of antigens.
- B cell receptor (BCR) is a membrane-bound immunoglobulin molecule on the B cell surface serves as the cell's receptor for soluble antigen.
- T cell receptor (TCR) is a complex of integral membrane proteins that participate in the activation of T cells in response to an antigen when displayed on HLA class I and class II molecules. Recognition of antigens by the TCR and BCR of the immune system is given in Table 4.16.

Table 4.15 Differences between T cell-dependent and T cell-independent antigens

Characteristics	T Cell-dependent Antigens	T Cell-independent Antigens
Structure	Complex-protein in nature	Simple lipopolysaccharide, capsular polysaccharide and flagella
Immunogenicity	Immunogenic over wide range of dose of antigens	Dose-dependent immunogenicity
Immunologic memory	Memory present	No memory
Antigen processing step	Antigen processing required	Antigen processing not required
Antigen metabolism	Rapid metabolism of antigen	Slow metabolism of antigen
Activation of B cell clonality	Activation of B cell monoclonality	Activation of B cell polyclonally
Activation of B cell	Activation of cell mature B cells	Activation of cell mature and immature B cells
Affinity and switch-over	B cells stimulated T cell-dependent antigen undergo affinity and switch-over	B cells stimulated T cell-dependent antigen do not undergo affinity and switch-over
Antibody classes synthesis	All classes of immunoglobulin	IgM synthesis

Table 4.16 Recognition of antigens by the T cell receptor (TCR) and B cell receptor (BCR) of the immune system

Pattern Recognition Receptors	HLA System	T Cell Receptor (TCR)	B Cell Receptor (BCR)
Receptor location			
Cell surface, cytoplasmic secreted	Cell surface	TCR is integral membrane proteins	Transmembrane receptor protein secreted on cell surface
Receptor recognition			
PAMPs/DAMPs	Each HLA class molecule can bind many different peptides	HLA class molecule specifically recognized by TCR	Highly soluble antigen specifically recognized by BCR
Protein diversity in an individual			
10–100s	12 for classical HLA class molecule	Millions	Millions
Genes			
Each protein individually encoded, low polymorphism	Each protein individually encoded, extremely polymorphic	Genetic recombination creates diversity	Genetic recombination creates diversity

Humoral Immune Response

Humoral immune response is mediated by immunoglobulin molecules that are secreted by plasma cells. B cells that reognize antigens (e.g. proteins, lipids, polysaccharides amd small molecules) undergo proliferation and differentiation into plasma cells that synthesize different classes of antibodies (IgG, IgA, IgM, IgD and IgE) with distinct functions. Immunoglobulins circulate in tissue fluids (blood and lymph) and provide humoral immunity. Some of B cells become memory cells that recognise the same antigen in the future.

- Each clone of B cells expresses a cell surface antigen receptor, which is a membrane-bound form of antibody, with a unique antigen specificity.
- Many different types of antigens, including proteins, polysaccharides, lipids, and small molecules, are capable of eliciting humoral immune response.
- The response of B cells to protein antigens requires activating signals from CD4+ helper T cells. B cells can respond to many nonprotein antigens without the participation of CD4+ helper T cells.
- Each plasma cell secretes antibodies that have the same antigen-binding site as the cell surface antigen receptor that first recognizes the antigen.
- Polysaccharides and lipid antigens stimulate secretion of immunoglobulin M (IgM). Protein antigens induce the production of antibodies of different classes (IgG, IgA, IgE) from a single clone of B cells, which serve distinct functions.
- CD4+ helper T cells also stimulate B cell to produce antibodies with increased affinity for the antigen. This process, called 'affinity maturation', improves the quality of the humoral immune response, which combats microbes in many ways.
- Antibodies bind to microbes and prevent them from infecting cells, thus neutralizing the microbes. In fact, antibody-mediated neutralization is the only mechanism of adaptive immunity that stops an infection before it is established; that is why eliciting the production of potent antibodies is a key goal of vaccination.
- IgG antibodies coat microbes and target them for phagocytosis because phagocytes (neutrophils and macrophages) express receptors for parts of IgG molecules. IgG and IgM activate the complement system, and complement products promote phagocytosis and destruction of microbes.
- Immunoglobulin A (IgA) is secreted on mucosal epithelia and neutralizes microbes in the lumens of mucosal tissues, such as the respiratory and gastrointestinal tracts, thus preventing inhaled and ingested microbes from infecting the host.
- Maternal immunoglobulin G (IgG) is actively transported across the placenta and protects the newborn until the baby's immune system becomes mature. Most IgG antibodies have half-lives in the circulation of approximately 3 weeks, whereas other classes of antibodies have half-lives of just a few days.
- Some antibody-secreting plasma cells migrate to the bone marrow or mucosal tissues and live for years, continuing to produce low levels of antibodies, which provide immediate protection if the microbe returns.
- Antibodies have binding sites that affix tightly to an antigen and hold it in place for agglutination, opsonization, complement fixation, and neutralization.

Cell-mediated Immune Response

Cell-mediated immunity (CMI) attributable to population of specific T cells is the principal mechanism whereby intracellular bacteria are eliminated by macrophages activated by interferon-γ derived from T cells. When T cells are activated by an antigen, T cells differentiate into CD4+ helper T cells, memory T cells, CD8+ cytotoxic T cells and CD4+ regulatory T cells. CD8+ cytotoxic T cells eliminate exogenous viruses and cancer stem cells. Cell-mediated hypersensitivity is responsible for graft rejection (**heart, eye, liver, and kidney**). Because cell-mediated immune response is able to recognize self and nonself. Therefore, immunosuppression therapy is given lifelong in such cases.

Immunologic Tolerance

Immunologic tolerance is the prevention of an immune response against a particular antigen, which occurs in two forms: **central** and **peripheral**. Fetus-maternal immunologic tolerance is the prevention of a maternal immune response against a developing fetus. Introduction of antigen to the host during fetal or neonatal life can induce specific immunologic tolerance. A second exposure to such antigen is not followed by antibody synthesis or proliferation of sensitized lymphocytes.

COMPONENTS OF ADAPTIVE IMMUNE SYSTEM

The cells of the immune system originate in the bone marrow from pluripotent hematopoietic stem cells (HSCs), which give rise to two types of progenitors, which include: **common lymphoid progenitor** gives rise to major lymphoid cell types (T cells, B cells and natural killer cells) and **common myeloid progenitor** gives rise to major myeloid cell types (neutrophils, eosinophils, basophils, dendritic cells, mast cells, monocytes/macrophages) as well as erythrocytes and platelets generating megakaryocytes.

- Components of the adaptive immune system include: immune cells (T cells, B cells, macrophages, antigen-presenting cells, innate lymphoid cells), lymphoid

tissues/organs, major histocompatibility complex (MHC) and cytokines.

- Adaptive immune responses are initiated in the secondary lymphoid organs (i.e. lymph nodes, spleen and the mucosa-associated tissues in the Peyer's patches of gut) in response to interaction of recirculating T cells and B cells with cognate antigens, whether delivered by dendritic cells in the case of T cells or free antigens in the case of B cells.

IMMUNE CELLS

The adaptive immune system is highly dependent on cells of the innate immune system for the purpose of knowing when to respond, how to respond and for how long.

- Cells of adaptive immune system include monocytes-macrophages, Langerhans' cells of skin, dendritic cells of lymphoid tissue, and lymphocytes (B cells and T cells). Immunocompetent cells include T cells, B cells, natural killer cells (NK cells) and antigen-presenting cells (APCs).
- Adaptive immune response involves the interactions of these cells to foreign proteins or antigens found in pathogens. B cells and T cells develop specific protein receptors for antigen. Effector cells are T cells, granulocytes and macrophages that eliminate antigens.
- Adaptive immune system uses receptors that are generated *de novo* through random gene rearrangement and recombination in response to each infectious agent that is encountered these receptors of the immune cells. Immune cells of adaptive immune system require instruction from the cells of innate immune system for responding to particular antigen.
- Phagocytes (granulocytes and monocytes) that normally circulate in the blood are recruited at the site of tissue injury. Granulocytes phagocytose and eliminate microbes. Macrophages phagocytose and kill microbes.
- Antigen-presenting cell, naïve CD4+ helper T cell and B cell interactions are shown in Fig. 4.16. Some important cells of the immune system are given in Table 4.17. Differences between B cells and T cells are given in Table 4.18. Antigen-responsive T cells and B cells are given in Table 4.19.

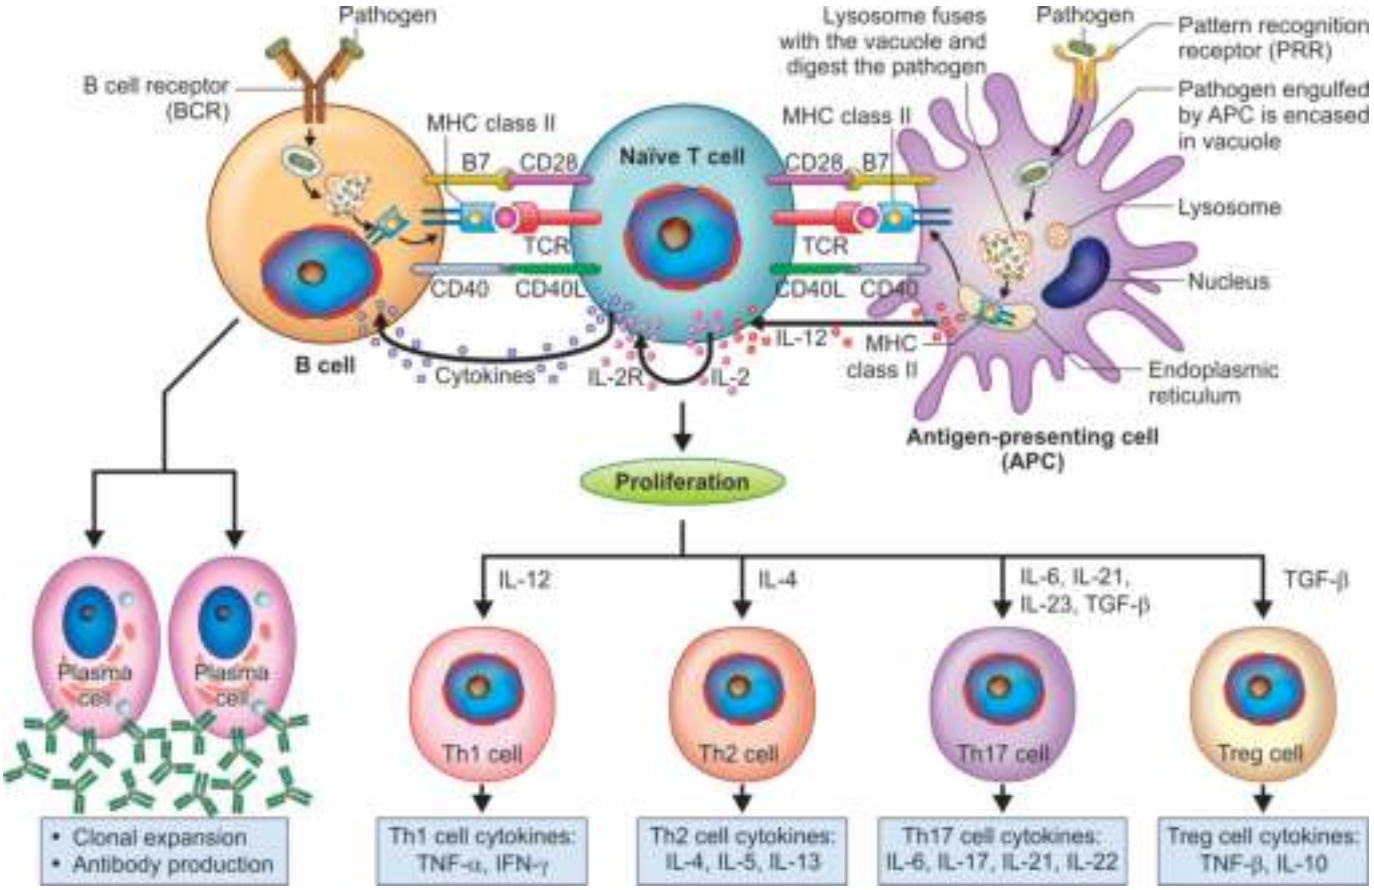

Fig. 4.16: Antigen-presenting cell, naïve CD4+ helper T cell and B cell interactions. When antigen-presenting cell activates naïve CD4+ helper T cell in the peripheral lymphoid tissue, T cell can differentiate into Th1, Th2, Th17 and CD+ regulatory T cells (Treg). Activated CD4+ helper T cell activates B cells, which differentiate to antibody secreting plasma cells. Activated CD4+ helper T cell also activates macrophages and CD8+ cytotoxic T cells.

Table 4.17 Some important cells of the immune system

Immune Cell	Mechanism	Function
Reticuloendothelial Cell		
Macrophage	Macrophage functions as antigen-presenting cell (APC) and synthesizes cytokine IL-1 that activates T cells	Phagocytosis and elimination of microorganisms
CD4+ Helper T Cells, CD8+ Cytotoxic T Cells and CD4+ Regulatory T Cells		
T helper cell (Th1)	Th1 cell synthesizes cytokines (TNF-α, IL-6 and IFN-γ), inhibits activation macrophage and cytotoxic T cells; and activate and differentiation of T cells and B cells	Phagocytosis and elimination of intracellular Mycobacterium extracellular bacteria and viruses
T helper cell (Th2)	Th2 cell synthesizes cytokines IL-4, IL-5, IL-6 and IL-13, which activate B cells	Phagocytosis and elimination of extracellular pathogens (helminths); allergic responses and bronchial asthma
T helper cell (Th9)	Th9 cell synthesizes cytokine IL-9	Allergic inflammation, autoimmunity and carcinoma
T helper cell (Th17)	Th17 cell synthesizes cytokines (IL-17, IL-21 and IL-22)	Phagocytosis and elimination of bacteria (Salmonella) and fungi; bronchial asthma
T helper cell (Th22)	Th22 cell synthesizes cytokine IL-22	Skin immunity, tissue regeneration, Crohn's disease and carcinoma
T helper cell (TFM)	T helper cell (TFM) synthesizes IL-4 and IL-21	Antibody cross-switching, affinity, maturation and auto-immunity
T regulatory cell (Treg)	Treg cell synthesizes cytokines IL-10 and TGF-β	Suppression of lymphocytes, maintenance of immune self-tolerance and tissue homeostasis; and prevention of autoimmunity
Memory T cell	Memory T cell protects against previously encountered pathogen	On re-encounter to specific invading pathogen, memory T cells are quickly converted into a large number of effector T cells to eliminate pathogen
Cytotoxic T cells	Infected cell presents microbial antigen to cytotoxic T cells	Killing of virus infected cells and cancer stem cells
γ and δ T cells	γ and δ T cells differentiate into CD8+ cytotoxic T cells	Killing of cancer stem cells
B Cell and Plasma Cell		
B cell	B cell acts as an antigen-presenting cell (APC) to T helper 2 (Th2) cell	B cell is precursor of plasma cell that synthesizes immuno-globulins, which neutralizes microbes, phagocyte microbes and activate complement
Plasma cell	B cell differentiates to form plasma cell, which synthe-sizes IgM and then IgG and IgA immunoglobulins	Plasma cell synthesizes immunoglobulins (IgG, IgA, IgM, IgD and IgE)

Table 4.18 Differences between B cells and T cells

Characteristics	B Cells	T Cells
Origin	Hematopoietic stem cells	Hematopoietic stem cells
Site of maturation	Bone marrow and lymphoid organs	Thymus gland
Distribution in lymph nodes	Cortex (germinal follicles and medullary cords) of lymph nodes	Paracortical areas of lymph nodes
Distribution in spleen	Germinal centers of follicles in spleen	Periarteriolar lymphoid sheaths in spleen
Differentiation (product of antigenic stimulation)	Plasma cells and memory cells	T-helper cells, T-suppressor cells, cytotoxic T cells and T memory cells

Contd...

Table 4.18 Differences between B cells and T cells (*Contd...*)

Characteristics	B Cells	T Cells
Circulation in blood	Low numbers (10–20%)	High numbers (60–70%)
Immune cell surface markers	Immunoglobulin receptor	T cell receptor
MHC molecules	MHC-I and MHC II	MHC-I and MHC II
Fc receptors	Present	Absent
Electron microscopy	Microvilli present	Smooth surface
Requires antigen-presenting cells with MHC	No	Yes
General functions	Production of antibodies to inactivate, neutralize target antigens	Cell function in regulating immune functions killing 'foreign cells', hypersensitivity, synthesize cytokines
Immunological markers	CD19, CD20, CD21, CD22	CD1, CD2, CD3, CD4, CD5, CD6, CD7, CD8

Table 4.19 Antigen-responsive T cells and B cells

Cells	Characteristics	Markers	Functions
Antigen-responsive T cells			
CD4+ helper T cells	CD4+ helper T cells activate APCs through peptide class II MHC complexes	CD2+, CD3+, CD4+, TCR+ (T cell receptor)	▪ **Distribution:** blood (35–60%), lymph node (50–60%) and spleen (50–60%) ▪ CD4+ helper T cells activate B cells proliferation, differentiation (class-switch antibody production), activate macrophages and stimulate inflammation
CD8+ cytotoxic T cells	Recognition of antigen presented by class I MHC antigens	CD2+, CD3+, CD8+, TCR+ (T cell receptor)	▪ **Distribution:** blood (15–40%), lymph node (15–20%) and spleen (10–15%) ▪ CD8+ cytotoxic T cell secrete lymphokines and kills viral, tumor nonself-organ transplant
CD4+ regulatory T cells	Recognition of antigen presented by class I MHC antigens	CD2+, CD3+, CD25+, FOXP3+ TCR+ (T cell receptor)	▪ **Distribution:** blood (rare), lymph node (10%) and spleen (10%) ▪ Suppression of T cell and B cell response, maintenance of immune self-tolerance and tissue homeostasis; and prevention of autoimmunity
Mucosa-associated invariant T cells	Helper and cytotoxic functions in GIT	CD3+, CD8+	**Distribution:** blood (5%), lymph node (rare) and spleen (rare)
γ and δ T cells	γ and δ T cells differentiate into CD8+ cytotoxic T cells	CD45 and CD27	Killing of cancer stem cells
Antigen-responsive B cells			
Follicular B cells	Humoral immunity (antibody production)	Fc receptors, class II MHC, CD19+, CD23+	▪ **Distribution:** blood (5–20%), lymph node (20–25%) and spleen (40–50%) ▪ Surface immunoglobulin diverse specifications for many types of molecules
Marginal zone B cells	Humoral immunity (antibody production)	IgM+, CD27+	▪ **Distribution:** blood (2–3%), lymph node (3–5%) and spleen (7–10%) ▪ Surface immunoglobulin limited specifications for a restricted set of molecules
B1 cell	Humoral immunity (antibody production)	IgM+, CD27+, CD20+, but CD70 negative	▪ **Distribution:** blood (1–3%), lymph node (rare) and spleen (rare) ▪ Surface immunoglobulin limited specifications for a restricted set of molecules

Immunological markers on T cells are CD1, CD2, CD3, CD4, CD5, CD6, CD7 and CD8.

T Cells

T cells are the major components of adaptive immune system. Once produced from pluripotent hematopoietic stem cells (HSCs) in the bone marrow, T progenitor cells migrate to the thymus gland to mature and become T cells.

- While in the thymus gland, the developing T cells start expression of T cell receptors (TCRs) and other CD4+ and CD8+ receptors. All T cells express TCRs and either CD4+ or CD8+, not both. Hence, some T cells express CD4+, and other express CD8+. Unlike antibodies, TCRs can bind to antigens directly.
- T cell receptors can recognize antigens that are bound to certain molecule, called major histocompatibility complex (MHC) class I and class II. Both MHC class I and class II molecules are membrane-bound surface receptors on antigen-presenting cells (**APCs**) such as dendritic cells (DCs) and macrophages. CD4+ and CD8+ receptors play key role in T cell recognition and activation by binding to either major histocompatibility complex class I and class II molecules.
- T cells undergo rearrangement causing limitless recombination of a gene that expresses T cell receptors. The process of rearrangement permits for binding diversity. The binding diversity of T cells could potentially cause accidental attacks against host self-cells and molecules due to some rearrangement configurations can accidently mimic a host's self cells, molecules and proteins. Mature T cells should recognize only foreign antigens combined with self-major histocompatibility complex molecules in order to mount an appropriate immune response.
- In order to ensure T cells will function properly, once they become mature and have been released from the thymus gland, T cells undergo two selection processes.
- The positive selection and negative selection processes protect host cells and tissues against own immune response. Without these selection processes, autoimmune disorders would be much more common.
  - In positive selection, T cells in the thymus gland that bind moderately to major histocompatibility complexes (MHC class I and class II molecules) receive survival signals to distinguish between self-proteins and nonself-proteins.
  - However, T cells, whose T cell receptors (TCRs) bind too strongly to histocompatibility complexes (MHC class I and class II), and will likely be self-reactive, which are killed in the process of negative selection.
- After positive and negative selection, host is left with three types of mature T cells: CD4+ helper T cells, CD8+ cytotoxic T cells, and CD4+ regulatory T (Treg) cells. T cells directly eliminate infected host cells by activating other immune cells, producing cytokines and regulating immune response.
- CD4+ helper T cells express CD4+ receptors, and help in the activation of CD8+ cytotoxic T cells, B cells and other immune cells. CD8+ cytotoxic T cells express CD8+ receptors, which remove virus infected cells and cancer stem cells. CD4+ regulatory T cells (Treg cells) express CD4+ and another receptor called CD25, which can distinguish between self- and nonself-molecules, hence reduce the risk of development of autoimmune diseases.
- Naïve CD4+ helper T cells that arise in the bone marrow and mature in thymus gland, which preferentially migrate to secondary lymphoid tissues such as lymph nodes and spleen, where naïve T cells become activated by antigens and differentiate into effector T cells. Activated CD4+ helper T cells preferentially migrate to inflamed tissue, where these cells provide defense against microbial infections. Memory CD4+ helper T cells preferentially migrate to inflamed tissue and mucosal tissue.
- When naïve T cell encounters a recognizable antigen-presenting cell (APC), the naïve cell receives extracellular stimulatory signals to undergo maturation. There are three types of signals, which include: TCR, BCR and cytokine signals. If a T cell receives all these three signals, it will undergo maturation to become an effector T cell. If a T cell only receives one of the signals (TCR or BCR), it will become useless. Effector T cells have relatively short life span and carry out functions to regulate adaptive cell-mediated immune response.

CD4+ Helper T Cells

CD4+ helper T cells possess receptors that bind to peptides displayed by the body's class II major histocompatibility complex (MHC) molecules. CD4+ helper T cells synthesize different cytokines that play diverse roles in inducing immune response.

- Activated CD4+ helper T cells secrete cytokines that recruit macrophages and CD8+ cytotoxic T cells to the injured tissue site.
- After interacting with the appropriate MHC II receptors, CD4+ helper T cells become type 1 (Th1) and type 2 (Th2) helper cells that regulate immune system. Th1 cell activates CD8+ cytotoxic T cells. Th2 cell synthesizes cytokines, which stimulate B cells to form antibody forming plasma cells.

CD8+ Cytotoxic T Cells

CD8+ cytotoxic T cells are effector cells that destroy virus-infected cells, cancer stem cells and tissue grafts through a process called **apoptosis**, while sparing

neighboring healthy cells. Apoptosis occurs when a cell's internal organelles are destroyed causing them to die from the inside out. CD8+ cytotoxic T cells express CD8+ glycoprotein on the cell surfaces that bind to protein fragments displayed by the body's major histocompatibility complex (MHC) class I molecules. CD8+ cytotoxic T cells participate in cell-mediated immunity that can reject tissue grafts. CD8+ cytotoxic T cells can induce apoptosis and cell death by process involving release of perforins forming holes in cell membrane and granzymes causing enzymatic breakdown.

CD4+, CD25+, FOXP3+ Regulatory T (Treg) Cells

CD4+, CD25+, FOXP3+ regulatory T (Treg) cells are specialized subtypes of T cells that act to suppress immune system, thereby maintaining homeostasis and self-tolerance. It has been observed that regulatory T cells are able to inhibit T cell proliferation and pro-inflammatory cytokines production and play a critical role in preventing autoimmunity.

γ and δ T Cells

γ and δ T cells are a unique T cell subpopulation that are rarely present in secondary lymphoid organs, but are present in skin, intestine and lungs. γ and δ T cells synthesize cytokines that make key contributions to antitumor immune responses in these tissues. Four subsets of human γ and δ T cells have been identified based on expression of CD45 and CD27 cell surface markers: naïve, effector, memory and terminally differentiated cells.

Memory T Cells

Memory T cells are antigen-specific T cells that persist long-term after an infection has been eliminated, which are rapidly converted into numerous effector T cells upon subsequent exposure to specific familiar invading antigen, thus providing a quick response to past infection. Memory T cells primarily reside in peripheral blood. However, vast majority of memory T cells reside in lymphoid tissues, intestine, skin and lungs.

B Cells

B cells play a central role in adaptive humoral immune response. B cell arises from common lymphoid progenitor that expresses recombination activating genes such as RAG1 and RAG2. There are four main B cell types through development stages of pro-B cell, pre-B cell: transitional/immature B cells, naïve cells, plasma cells and memory B cells.

- Early B cell development is antigen-independent phase, characterized by the ordered rearrangement of IgH and IgL chain loci, and Ig proteins themselves play critical role in regulation of B cell development.
- In the antigen-dependent phase, after formation and maturation in the bone marrow, the naïve B cells move into the lymphatic system to circulate throughout the body. Each B cell has numerous distinctive surface antigen-specific receptors that are inherent to the host's DNA. Naïve cell expresses membrane-bound antibodies on its cell surface.
- In the lymphatic system, when naïve B cell encounters an antigen that matches membrane-bound antibodies on their cell surface leading to maturation and division to become either a memory B cell or an effector B cell, which is called an antibody secreting plasma cell. Antibodies can bind to antigens directly.
- Memory B cells express the same membrane-bound antibody on their surface as the original naïve B cell, or the parent B cell. Plasma cells lack membrane-bound antibody on their surface. Plasma cells secrete antibodies, which provide protection against pathogens. Antibodies may directly neutralize pathogens.
- When the activated B cell divides and differentiates, both plasma cells and memory B cells are produced. B cells produce antigen-specific antibodies that may directly neutralize viral particles or that can act indirectly triggering other effector mechanisms such as phagocytosis, activation of complement system including antibody-dependent cellular cytotoxicity (ADCC), or blocking secreted virulence factors. Immunoglobulins can prevent tumorigenesis by attacking oncogenic viruses and cancer stem cells.
- B cells can have antitumor activities through the recognition of tumor specific antigen and antibody production, antigen-presenting cell (APC) or direct killing of cancer stem cells.
- Different subsets of memory B cells and plasma cells can be identified based on expression of immunoglobulin subtypes (IgA, IgG, IgD, IgM, IgE).
- CD40 expressed on B cells bind to CD40L (CD40 ligand) of T cells. T cells perform a number of specific cellular responses such as assisting B cells and killing foreign cells such as Mycobacterium tubercle bacilli. Interaction of B cells and T cells participates in cell-mediated immunity.
- B cell also expresses a specialized receptor, called **B cell receptor (BCR)**, which plays key role in binding, internalization and processing of antigen leading to initiate signaling pathways and synthesis of cytokines.

Immature/Transitional B Cells in Bone Marrow

Like T cells, immature/transitional B cells are formed from the multipotent hematopoietic stem cells (HSCs)

in the bone marrow and follow a pathway through lymphoid stem cell and lymphoblast. Transitional/immature B cells become mature in the bone marrow. B cell maturation occurs through positive selection for B cells with normal functional receptors.

- Negative selection is then used to eliminate self-reacting B cells that minimizes the risk of auto-immunity. Negative selection of self-reacting B cells can involve elimination by apoptosis, or modification of the antigenic receptors so B cells are no longer self-reactive (i.e. induction of anergy in the B cell).
- Immature B cells that pass the negative selection in the bone marrow travel to the spleen for the final stages of maturation. There, immature/transitional B cells become naïve mature B cells (i.e. mature B cells that have not yet been activated). B cells are activated, when their B cell receptor (BCR) binds to either soluble or membrane bound antigen and trigger downstream signaling cascade.
- One important difference between **TCRs** and **BCRs** is the way they can interact with antigen isotopes. TCRs can only react with antigenic epitopes that are presented within the antigen-binding cleft of MHC class I molecules or MHC II class II molecules. On the contrary, BCRs react with free antigenic epitopes displayed on the surface of intact pathogens without presentation with MHC class molecules.
- Another important difference is that TCRs only recognize antigenic protein epitopes, whereas BCRs can recognize antigen epitopes associated with different molecular classes (e.g. proteins, poly-saccharides and lipopolysaccharide).

Naïve B Cells

Differentiation of immature/transitional B cells to naïve mature B cells is dependent on strong BCR signaling. A naïve B cell is a mature B cell that has not been exposed to antigen and not yet been activated in the peripheral (secondary) lymphoid organs/tissues.

- Naïve B cells circulate through peripheral blood and lymphatic system and enter peripheral lymphoid organs/tissues (spleen, tonsils, lymph nodes, Peyer's patches and mucosal tissues) close to the T cell zone.
- Naïve B cells express high levels of IgD and CD23, intermediate levels of IgM and CD21. Once exposed to an antigen, the naïve B cell either becomes a memory B cell or a plasma cell that secretes antigen-specific antibodies.
- Memory B cells do not secrete antibody until activated by specific antigen. If a naïve B cells have not encountered an antigen, they again enter circulation and undergo apoptosis in the absence of BCR survival signal.

Activated B Cells

If naïve B cells encounter antigen and receive help from CD4+ helper T cells, activated B cells remain in the B cell zone of peripheral (secondary) lymphoid organs and initiate a germinal center response.

- B cells interact with other immune cells such as CD4+ helper T cells that secrete cytokines. Soluble antigens bind to the B cell receptor (BCR) complex and get internalized and degraded into peptides.
- Peptide MHC class complexes bind to T cell receptor (TCR) on CD4+ helper T cells that stimulate cytokines release essential for differentiation into antibody secreting plasma cells.

Plasma Cells

Plasma cells develop from B cells in bone marrow, which synthesize large amounts of immunoglobulins (e.g. IgG, IgA, IgM, IgD and IgE) in response to encounter with antigen. Plasma cells play a significant role in the adaptive immune response. B cells and plasma cells are the main cells responsible for humoral immunity.

- Blimp-1, IRF4, and XBP1 transcription factors are known to be essential for the differentiation of mature B cells into plasmablasts and then mature plasma cells.
- Plasmablasts are most immature cells of the plasma cell lineage that can proliferate and secrete small quantity of immunoglobulins. Mature plasma cells lack proliferative ability but secrete large quantity of immunoglobulins.
- Plasma cells have basophilic abundant cytoplasm and an eccentric nucleus with heterochromatin in a characteristic 'cartwheel appearance'. Plasma cells contain cytoplasmic inclusions called Russell bodies.

Memory B Cells

Memory B cells are able to persist in quiescent state over decades in the bloodstream and germinal centers of the secondary lymphoid organs (most abundant in spleen).

- Memory B cells maintain memory for a given antigen without the need for constant antigenic stimulation. Memory B cells are primed to react quickly and vigorously on subsequent stimulation by the cognate antigen. B cells in the marginal zone express CD27 marker.
- IgG+ and IgM+ memory B cells have a distinct function. IgG+ memory B cells predominantly differentiate into plasma cells, whereas IgM+ memory B cells predominantly enter the marginal zone of lymphoid tissue and secrete IgM and class-switched subsets.

Natural Killer Cells

Natural killer cells (NK cells) are derived from bone marrow, differentiate and mature in bone marrow, lymph nodes, spleen, tonsils and thymus gland and appear as large lymphocytes with numerous cytoplasmic granules in the peripheral blood.

- Natural killer cells do not display antigen specificity. Their cytotoxicity is neither MHC restricted nor antibody dependent. Immunophenotyping shows CD16+ (Fc receptor for IgG) and CD56+.
- Natural killer cells are 'first line of defense' against viruses, fungi and cancer stem cells. Fas ligand (FasL) expressed on the NK cells binds to fas protein expressed on the surface of carcinoma cells, fungi.
- Natural killer cells can kill target cells by two major mechanisms: death receptor and granule-dependent (perforin and granzymes) pathways. In both cases, the target cell dies as a result of the activation of a battery of cytotoxic proteases within the target cell, called caspases.
- Functional activity of natural killer cells is regulated by balance between signals from activating NKG2D family and inhibitory receptors. NKG2D receptors recognize surface molecules induced by various kinds of stress like infection and DNA damage.
- Natural killer cells inhibitory receptors recognize major compatibility complex (MHC) class I molecules expressed on all healthy cells, that prevent NK cells from killing normal cells. Virus infected cells and cancer stem cells enhance expression of ligands for activating receptors and reduces expression of class I MHC molecules which favors cytotoxicity by NK cells.

Macrophages

Monocytes constitute 2–8% of white blood cells, which are derived from a common precursor in the bone marrow. Monocytes migrate and differentiate into tissue macrophages. In the early development, as in fetal life, precursors in the yolk sac and fetal liver give rise to monocytes that seed tissues to generate specialized tissue resident macrophages.

- Tissue macrophages are distributed in the connective tissues. Half-life of blood monocytes is one day, while life span of tissue macrophage is several months or years. If the injurious agent is eliminated, macrophages eventually disappear either dying off or making their way into the lymphatic channels and lymph nodes.
- Macrophages are largest phagocytes (big eaters) that participate in specific-immune reactions. In addition, they process and present antigen (along with human leukocyte antigen (HLA) class II antigens) to CD4+ helper T cells leading to phagocytosis and degradation of injurious agent.
- Chemokines are the major chemical mediators of macrophage chemotaxis derived from mononuclear cells (macrophages, T cells), bacterial products, derived from injured tissue (e.g. break down products of collagen, fibronectin), growth factors (PDGF, TGF-α), fibrin peptides, and complement system cascade product (C5a).
- Macrophages possess receptors for IgG and C3b, which process antigen, enhance immune response, and participate in phagocytosis of injurious agent. Macrophages synthesize a variety of cytokines (IL-1 and TNF-α), acid hydrolases, neutral proteases, oxygen-derived free radicals and prostaglandins.
- TNF-α, IFN-γ and matrix proteins (fibronectin) activate macrophages, to become epithelioid cells with abundant cytoplasm resulting in formation of epithelioid cell granulomas and multinucleated giant cells in tuberculous and systemic fungal infections. TNF-α inhibitors can cause the breakdown of granulomas leading to dissemination of the disease.
- Macrophages express opsonin receptor (FcR1, CR1 and C1q), scavenger receptors, macrophage integrin receptors (MAC1 CD11 and CD18). FcR1, CR1, C1q receptors recognize microbes coated by IgG, C3 (classical and alternate pathways) and plasma proteins derived mannose-binding lectin (MBL). Scavenger receptors on macrophages bind to microbes and modified low-density lipoprotein (LDL).
- Macrophages enhance immune response by activation of endothelium (vascular response) and leukocytes (cellular response). Macrophages also participate in delayed hypersensitivity reactions, which may be capable of directly killing cancer stem cells.
- Reticuloendothelial cells distribution in various tissues are given in Table 4.20. Macrophage products and their actions are shown in Fig. 4.17. Macrophage surface structures are given in Table 4.21. Sources of chemokines and their role in chemotaxis of macrophages are given in Table 4.22. Macrophage products and their actions are given in Table 4.23. Complement receptor on macrophage is shown in Fig. 4.18.

Antigen-presenting Cells

Antigen-presenting cells (APCs) include dendritic cells in lymphoid tissue, Langerhans' cells in skin and macrophages. APCs express large quantities of cell surface HLA class II antigens. APCs capture antigens for display to B cells and T cells. Dendritic cells initiate T cell response. Follicular dendritic cells display antigens to B cells and initiate humoral immune

response. Macrophages perform in the effector phase of cell-mediated immunity. APCs have poor phagocytic function. APCs may be either professional or non-professional types.

Table 4.20 Reticuloendothelial cells distribution in various tissues

Tissue	Reticuloendothelial cells
Blood	Monocytes
Connective tissue	Macrophages
Lung	Alveolar macrophages
Peritoneum	Peritoneal macrophages
Kidney	Mesangial cells
Liver	Kupffer's cells
Lymph nodes	Sinus histiocytes
Spleen	Littoral cells
Placenta	Hofbauer cells
Skin	Melanophages
Brain	Microglial cells
Synovium	Synovial macrophages (type A synoviocytes)
Bone	Osteoclasts
Adipose tissue	Lipophage
Specialized histiocytes	▪ Epithelioid cells ▪ Histiocytic giant cells ▪ Langhan's giant cells ▪ Foreign body giant cells ▪ Touton giant cells

- Professional APCs express MHC II molecules and interact with native T cells. Examples of professional APCs are macrophages, dendritic cells, Langerhans' cells of skin certain activated epithelial cells.
- Non-professional APCs do not express MHC II molecules; hence APCs do not interact with native T cells, and are stimulated by interferon. Examples of nonprofessional APCs are fibroblasts, endothelial cells, thyroid follicular cells, glial cells and β cells of pancreas.

Table 4.21 Macrophage surface structures

Characteristics	Macrophage Surface Molecules
Antigenic presentation	CD40
Facilitated uptake	▪ Fc receptor for IgG ▪ Complement receptor for C3b (CR1)
Adhesion molecules	▪ LFA3 ▪ ICAM 1
Bacterial adhesion	▪ Lipopolysaccharide (LPS) receptor ▪ Toll-like receptor (CD14) ▪ Mannose receptor ▪ Scavenger receptor ▪ Glycan receptor
Cell activation	▪ IFN-γ receptor ▪ TNF-α receptor
Co-stimulators	▪ B7 family of molecules ▪ MHC I molecule ▪ MHC II molecule

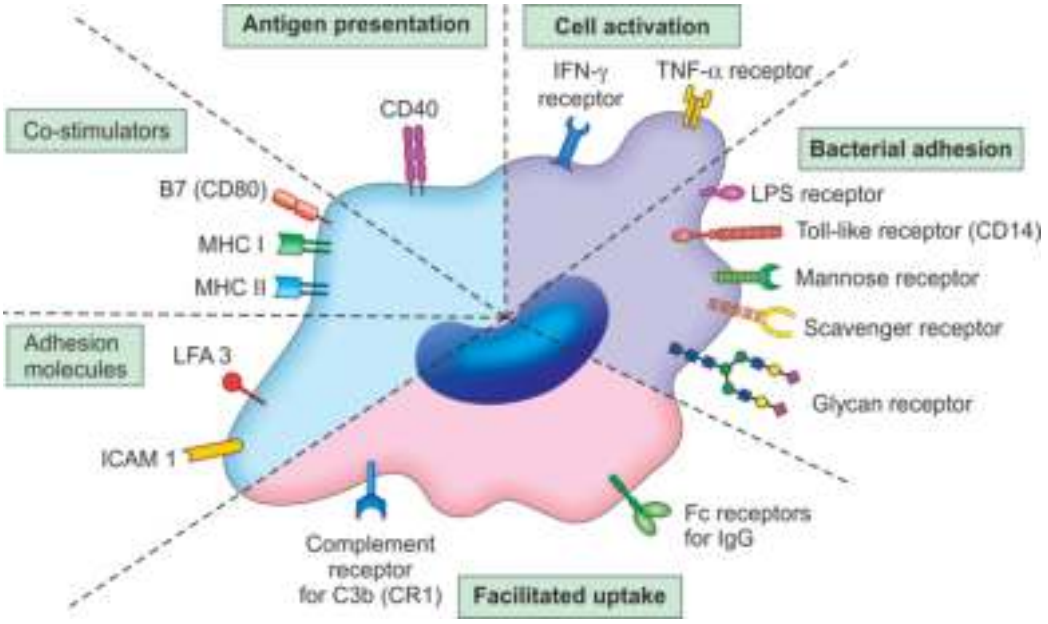

Fig. 4.17: Macrophage surface structures mediate cell function. Bacteria and antigens either bind directly to receptors or bind through antibody or complement receptors (opsonization) and can be phagocytosed; the cell is activated and presents antigen to T cells. The dendritic cell shares many of these characteristics.

Table 4.22 Sources of chemokines and their role in chemotaxis of macrophages

Source of Chemokines	Examples of Chemokines
Blood cells	Macrophage chemotactic protein 1 (MCP-1)
Bacteria	Bacterial products
Injured tissue	Breakdown products of collagen fibers and fibronectin
Growth factors	PDGF, TGF-α
Fibrinopeptides	Fibrin degradation products (FDPs)
Complement	C5a

- Professional and nonprofessional APCs are given in Table 4.24. APCs expressing class II MHC molecules and presenting antigens to CD4+ helper T cells are given in Table 4.25.

Dendritic Cells

Dendritic cells have dendritic cytoplasmic processes and distributed throughout the tissues with reticulo-endothelial system, which cells express large quantities of cell surface MHC class II antigens.

- The most efficient 'antigen-presenting cells' (APCs) are dendritic cells in lymph nodes, which process and present the antigen to lymphocytes resulting in clonal expansion of lymphocytes. Dendritic cells initiate adaptive immune system. In contrast to macrophages, dendritic cells are poorly phagocytic; however, like macrophages, dendritic cells are antigen-presenting cells (APCs) to lymphocytes.
- Dendritic cells originate from common precursor cell of the myeloid lineage in the bone marrow and further differentiates into subsets: classical dendritic cells and plasmacytoid dendritic cells. Inflammatory

Table 4.23 Macrophage products and their actions

Inflammatory Mediators	Actions	
Cytokines		
IL-1, TNF-α	Chemotaxis of inflammatory cells	
IL-6	Synthesis of acute phase reactant by liver	
IL-2	Autocrine action	
Chemokines		
IL-8, MCP-1	Chemotaxis of inflammatory cells and paracrine action	
Lysosomal enzymes		
Neutral hydrolases	Toxic to extracellular matrix	
Acid hydrolase, serine protease	Hydrolyzing the muramic acid-N-acetylglucosamine bond of bacterial glycopeptides leading to killing of microbes	
Metalloproteinases (MMPs)*	▪ Degradation of type 3 collagen fibers	▪ Deposition of type 1 collagen fibers leading to increased tensile strength
Cell-derived arachidonic metabolites		
Prostaglandins	▪ Platelet aggregation ▪ Vasodilatation ▪ Increasing vascular permeability with formation of inflammatory exudate	▪ Modulation of phagocytic activity of leukocytes ▪ Pain ▪ Fever
Leukotrienes	▪ Vasoconstriction ▪ Increased vascular permeability	▪ Bronchospasm
Plasminogen activator		
Plasminogen activator	▪ Cleaves plasminogen to form plasmin, that degrades fibrin strands resulting in dissolution of blood clot ▪ Activation of coagulation system	
Reactive oxygen and nitrogen species		
Superoxide, highly reactive hydroxyl molecule and hypochlorous acid (bleach)	Toxic to microbes and host cells	
Growth factors, fibrogenic and angiogenic factors		
PDGF, FGF, and TGF-β	▪ Fibroblast proliferation ▪ Collagen deposition	▪ Angiogenesis

**Metalloproteinases (MMPs) also known as collagenases synthesized by macrophages, neutrophils, fibroblasts, synovial cells and some epithelial cells.*

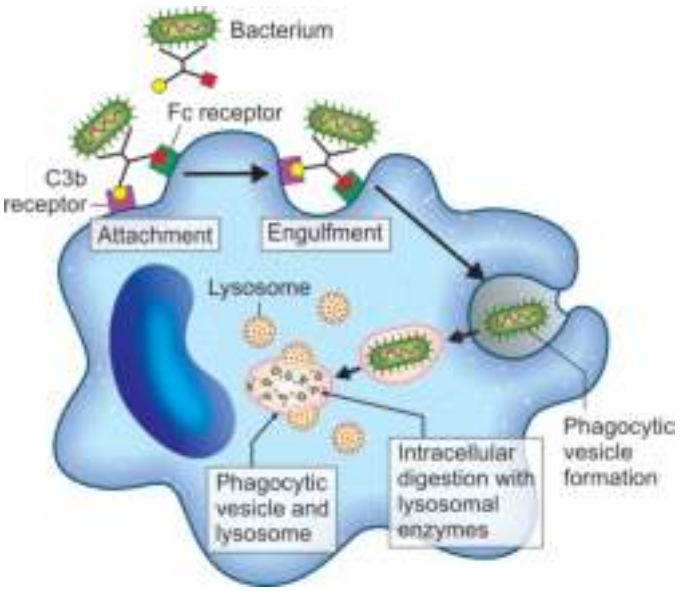

Fig. 4.18: Complement receptor on macrophage. One function of the complement is to aid phagocytosis. Complement proteins attract phagocytes to engulf a foreign organism. The organism is enclosed in a phagocytic vesicle, which then merges with a lysosome. Lysosomal enzymes digest the organism.

dendritic cells may arise from monocytes in inflamed tissues.

- Classical dendritic cells are capturing protein antigens of microbes that enter through epithelia and presenting the antigens to CD4+ helper T cells that induce adaptive immunity. Classical dendritic cells synthesize inflammatory cytokine IL-12.
- Plasmacytoid dendritic cells produce the antiviral interferon (IFN) cytokine in response to viruses and may capture blood-borne microbes and transmit these antigens to the spleen for predation to T cells.

Langerhans' Cells of Skin

Like dendritic cells, Langerhans' cells of the skin express MHC class II antigens. Electron microscopic examination, Langerhans' cells contain 'Birbeck granules' and 'tennis racket-shaped cytoplasmic structures.

Innate Lymphoid Cells

Innate lymphoid cells (ILCs) are innate counterparts of T cells derived from common lymphoid progenitor cells. ILCs do not express the diversified antigen

Table 4.24 Professional and nonprofessional antigen-presenting cells (APCs)

Characteristics	Professional Antigen-presenting Cells	Nonprofessional Antigen-presenting Cells
Examples of antigen-presenting cells	▪ Dendritic cells ▪ Langerhans' cells of skin ▪ Macrophages ▪ Certain activated epithelial cells	▪ Fibroblasts and endothelial cells ▪ Thyroid follicular cells ▪ Glial cells ▪ β Cells of pancreas
MHC II expression	Present	Absent
Interaction with native T cells	Yes	No
Cytokines required or not for stimulation	Cytokines not required	Cytokines (interferon) required

Table 4.25 Antigen-presenting cells (APCs) expressing class II MHC molecules and presenting antigens to CD4+ helper T cells

Antigen-presenting Cells	Functions
Monocytes	▪ Derived from bone marrow and present in blood ▪ Precursors to macrophage-lineage and cytokines release
Tissue macrophages	▪ Possess Fc and C3 receptors ▪ Initiate inflammatory response ▪ Possess antibacterial, antiviral and antitumor properties
Langerhans' cells	▪ Reside in spleen, lymph nodes and other organs. These are activated by interferon-γ and tumor necrosis factor ▪ Transport antigen to lymph nodes
Dendritic cells	▪ Present in lymph nodes and tissues ▪ Efficient antigen-presenting cells
Microglial cells	▪ Present in central nervous system ▪ Cytokines synthesis
Kupffer's cells	▪ Present in liver ▪ Filter particles (viruses) from blood

Monocytes, tissue macrophages, Langerhans' cells, dendritic cells, microglial cells, Kupffer's cells express class II MHC molecules and present antigens to CD4+ T cells.

receptors expressed on T cells and B cells. ILCs are present in gastrointestinal tract, respiratory system as well as oral cavity.

- Three groups of innate lymphoid cells include cytotoxic ILC, innate lymphoid tissue inducer cells and noncytolytic ILC, which have been defined based on shared expression of surface markers, transcription factors and effector cytokine production.
- In response to pathogenic tissue damage, innate lymphoid cells (ILCs) contribute to tissue immune response (i.e. homeostasis, pathogen clearance) via the secretion of effector signaling cytokines and the regulation of both innate and adaptive immune cells. ILCs are especially present in mucosal barriers, where they are exposed to allergens, pathogens and commensal microbes.

LYMPHOID TISSUES/ORGANS

The lymphoid organs of immune system are divided into primary (central) and secondary (peripheral) lymphoid systems. The primary lymphoid organs are the thymus and bone marrow, where immune T and B cells differentiate and mature respectively, and then migrate to secondary (peripheral) lymphoid organs, lymph nodes, spleen, mucosa-associated lymphoid tissue (MALT), skin-associated lymphoid tissue (SALT) and gut-associated lymphoid tissue (GALT) in Peyer's patches in which immature cells interact with each other and process antigens. Primary and secondary lymphoid organs are given in Table 4.26.

Pathology Pearls: Development of Lymphoid Organs

- Thymus gland is formed due to migration of cells of pharyngeal pouches into the chest.
- B cell and T cell precursors originate early in the embryonic life in the yolk sac and eventually migrate to the bone marrow and thymus gland.
- Precursor B cells and T cells arise from pluripotent hematopoietic stem cells (HSCs). B cells start maturation in bone marrow and complete maturation in spleen.
- Precursor T cell migrates to thymus gland for maturation.
- T cells and B cells interact with each other and with accessory cells and antigens in secondary lymphoid organs.
- Bone marrow contains B cells (90%) and T cells (10%). Lymph nodes contain B cells (40%) and T cells (60%). Spleen contains B cells (45%) and T cells (55%).

Primary Lymphoid Organs

Bone marrow and thymus gland are primary (central) lymphoid organs. Thymus gland nearly fills the region over the midline of the upper thoracic region in newborn babies. It progressively becomes small in size in adults.

Table 4.26 Primary and secondary lymphoid organs

Primary (Central) Lymphoid Organs
▪ Bone marrow (site for origin of B cells and T cells from pluripotent hematopoietic stem cell and maturation and migration of B cells to secondary lymphoid organs)
▪ Thymus gland (site of maturation of T cells)
Secondary (Peripheral) Lymphoid Organs
▪ Lymph nodes
▪ Spleen (site for complete maturation of B cells)
▪ Mucosa-associated lymphoid tissue (MALT)
▪ Skin-associated lymphoid tissue (SALT)
▪ Gut-associated lymphoid tissue (GALT) in Peyer's patches

T cells and B cells interact with each other and with accessory cells and antigens in the secondary lymphoid organs.

- Children are born without a thymus gland suffer from DiGeorge syndrome characterized by severe immunodeficiency disorder. During embryonic and fetal development, bone marrow pluripotent hematopoietic stem cells (HSCs) produce B cells and T cells. Precursor T cells and B cells undergo further development or maturation at different sites.
- B cells start maturation in the stromal cells of bone marrow, and then migrate for complete maturation in the spleen. Mature B cells produce antibodies and T cells synthesize cytokines that mediate and coordinate both cellular and humoral immune responses.
- Immature T cells migrate in the thymus gland (cortex and medulla) for differentiation and maturation.

Secondary Lymphoid Organs

After maturation of B cells in bone marrow and T cells in thymus gland, mature lymphocytes reach the secondary (peripheral) lymphoid organs via circulation. Secondary lymphoid organs comprise lymph node, spleen, tonsils, mucosa of appendix and 'Peyer's patches' of small intestine. Cellular and humoral immune responses occur in the secondary (peripheral) lymphoid organs and tissues; effector and memory cells are generated in peripheral lymphoid organs.

Lymph Nodes

Lymph nodes are peripheral lymphoid organs, which mount immune responses to antigens in intercellular fluid and lymph, absorbed either through the skin (superficial lymph nodes) or from internal viscera (deep lymph nodes). Each lymph node has its own arterial supply and venous drainage.

- Beneath the collagenous capsule is the subareolar sinus, which is lined by with phagocytic cells. Naïve

lymphocytes migrate from the blood circulation through vascular endothelial venules into lymph nodes, where these cells are activated by distinct antigens. Activated lymphocytes exit the lymph nodes via the afferent lymphatic system.

- The cortex of lymph node contains aggregates of B cells (primary follicles), most of which are stimulated to form secondary follicles.
- The paracortical region of lymph node contains mainly T cells, many of which are associated with the interdigitating cells (antigen-presenting cells).
- The medulla of lymph node contains both T cells and B cells as well as most of the plasma cells. These lymphoid cells are organized into cords of lymphoid tissue. Lymphocytes and antigens from surrounding tissue spaces or adjacent lymph nodes pass into the sinus via the afferent lymphatic system. Lymphocytes can leave the lymph node through the efferent lymphatic vessel.

Spleen

Spleen is a secondary lymphoid organ which also regulates the destruction of red blood cells, which consists of white pulp and red pulp. Spleen contributes to the maturation of red blood cells by pitting function, which has ability to remove solid particles from the cytoplasm of red blood cells without causing injury to the cell membrane. The spleen responds predominantly to blood-borne antigens. Blood enters the spleen via the trabecular arteries, which give rise to the many-branched central arteries. Some of trabecular arteries end in the white pulp, supplying the germinal centers and mantle zones, but most empty into or near the marginal zones.

- **White pulp:** The white pulp contains germinal centers and is surrounded by the marginal zone, which contains numerous macrophages, antigen-presenting cells (APCs), slowly recirculating B cells, T cells and natural killer cells around splenic arteriole. Dendritic cells present antigens to T cells, where T and B cells interact at the edges of white pulp lymphoid follicles, generating antibody-secreting plasma cells found mainly within the sinuses of red pulp.
- **Red pulp:** The red pulp contains capillaries venous sinuses separated by splenic cords. Blood enters the tissue via the trabecular arteries, which give rise to the many-branched central arteries. T cells are distributed in the periarteriolar sheaths of the spleen. Red pulp stores red blood cells.

Tonsils, MALT, GALT and SALT

Tonsils, appendix, mucosa-associated lymphoid tissue (**MALT**) and gut-associated lymphoid tissue (**GALT**) in Peyer's patches of small intestine are secondary lymphoid organs, which respond to antigens that have penetrated the surface mucosal barriers.

- **Tonsils:** The tonsils are small masses of secondary lymphoid organs located in the pharynx, which function similarly to other types of secondary lymphoid organs and also capture antigens from respiratory tract pathogens.
- **Mucosa-associated lymphoid tissue (MALT):** Lymphoid cells stimulated by antigen in Peyer's patches migrate via the regional lymph nodes and thoracic duct into the blood stream and then to lamina propria of the gut and probably other mucosal surfaces (lungs). Thus, lymphocytes stimulated on the mucosal surface may become distributed throughout the MALT.
  - Many commensal bacteria reside in the small intestine. The mucus-secreting epithelium provides an innate barrier to microbial invasion.
  - Bowel specialized epithelial cells promote transport of antigens from the lumen into the underlying tissues.
  - Dendritic cells, T cells and macrophages in the lamina propria provide innate and specific (adaptive) immune defense against invading microbes. Immunoglobulin A (IgA) is produced in large quantity in the mucosal tissues that is transported into the lumen, where it binds and neutralizes microbes.
- **Gut-associated lymphoid tissue (GALT):** GALT is a component of the mucosa-associated lymphoid tissue (MALT) which works in the immune system to protect the body from pathogens invasion in the gut.
- **Skin-associated lymphoid tissue (SALT):** SALT responds to antigens that have penetrated the skin barrier.

MAJOR HISTOCOMPATIBILITY COMPLEX

Human leukocyte antigen (HLA) system is a cluster of genes located on the short arm of chromosome 6, known as the 'major histocompatibility complex' (MHC) in human.

- MHC (HLA) system codes for proteins that differentiate between self and nonself cells. The biologic role of HLA system is clinically important in immune response and solid organ transplantation, where HLA typing and lymphocyte cross-matching of donor and recipient are now widely used to predict tissue compatibility and to prevent allograft rejection.
- Molecular HLA allele typing is routinely performed to provide MHC (HLA) class I and MHC (HLA) class II allele matching in unrelated donor hematopoietic stem cell (HSC).

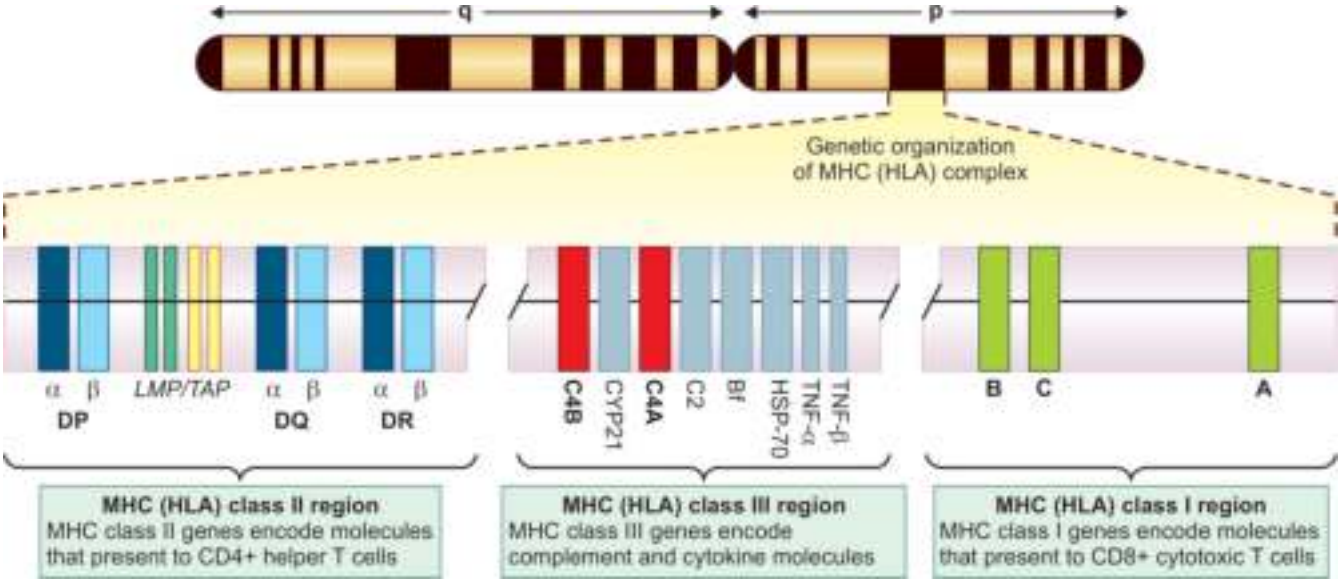

Fig. 4.19: Genetic organization of major histocompatibility complex (human-leukocyte antigen). Loci HLA-A, HLA-B and HLA-C are class I MHC genes encode molecules that present antigen to CD8+ cytotoxic T cells. Loci HLA-DP, HLA-DQ and HLA-DR are class II MHC genes encode molecules that present to CD+ helper T cells. LMP (large multifunctional protease) and TAP (transport associated with antigen presentation) genes encode LMP and TAP molecules that are involved in antigen processing.

- All nucleated human cells express MHC (HLA) class I molecules, whereas MHC (HLA) class II molecules are displayed primarily on macrophages, dendritic cells, Langerhans' cells, B cells, and some T cells. Two major classes of MHC (HLA) antigens are separated on the basis of structure and tissue distribution. MHC class I molecules present antigen to CD8+ cytotoxic T cells. MHC class II molecules that present antigen to CD4+ helper T cells.
- Genetic organization of major histocompatibility complex (human-leukocyte antigen) is shown in Fig. 4.19. Comparison of major histocompatibility complex, i.e. HLA class I and HLA class II molecules is given in Table 4.27.

Major Classes of HLA Genes

The class I region on chromosome 6 contains the classical HLA-A, HLA-B and HLA-C genes that encode the heavy chains of class I molecules. The class II region on chromosome 6 consists a series of subregions, each containing A and B genes encoding α- and β-chains, respectively. HLA-DP, HLA-DQ and HLA-DR genes

Table 4.27 Comparison of major histocompatibility complex, i.e. HLA class I and HLA class II molecules

Characteristics	HLA Class I Molecule	HLA Class II Molecule
HLA molecules expression on various cells	Most nucleated human cells	▪ Macrophages ▪ Dendritic cells ▪ Langerhans' cells ▪ B cells ▪ CD4+ helper T cells
Loci	▪ HLA-A ▪ HLA-B ▪ HLA-C	▪ HLA-DP ▪ HLA-DQ ▪ HLA-DR ▪ HLA-DN ▪ HLA-DO
Location of peptide binding cleft	Present between α_1 and α_2	Present between α_1 and β_1
Functions	Present endogenous antigen to cytotoxic T cells involved in tissue/organ graft rejection and killing of virus-infected cells	Present endogenous antigen to CD4+ helper T cells, which synthesize cytokines
Diagnostic technique	Standard serologic techniques used for identification of HLA-A and HLA-B antigens with the aim to predict the likelihood of long-term graft survival	Standard serologic techniques or mixed lymphocyte reactions are used for identification of HLA-DP, HLA-DQ, and HLA-DR antigens

1. *GlyCAM 1 facilitates lymphocyte recirculation by providing a receptor for leukocyte attachment to high endothelial venules.*
2. *Both class I and class II MHC molecules contain peptide-binding clefts and invariant portions that bind CD8 (α_3 domain of class I) or CD4 (the β-domain class II).*

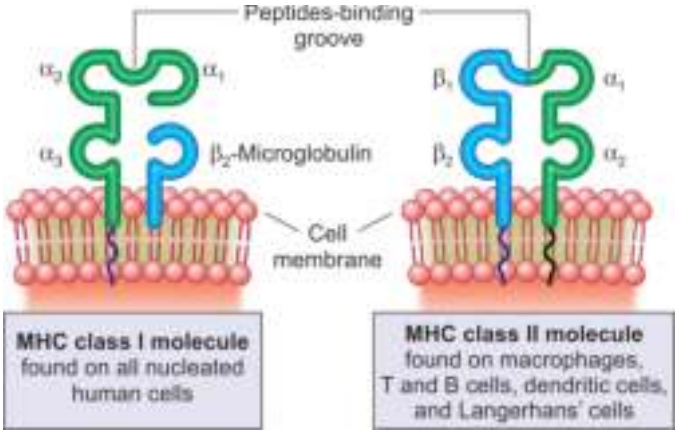

Fig. 4.20: Structure of MHC (HLA) class I and class II molecules. MHC class I and class II molecules play a pivotal role in the adaptive immune response. Both classes of MHC molecules share the task of presenting peptides on the cell surface for recognition by naïve CD4+ helper T cells and CD8+ cytotoxic T cells.

encode HLA class II molecules found on the surface of antigen-presenting cells (APCs) that present peptides to CD4+ helper T cells, class III region on chromosome 6 does not encode HLA molecules, but contains genes for complement system components (C2, C4, factor 4B), 21-hydroxylase, tumor necrosis factors (TNFs) and some others. Structure of MHC (HLA) class I and class II proteins is shown in Fig. 4.20.

MHC (HLA) Class I Molecules

The heavy chain of MHC class I molecules is encoded by genes at HLA-A, HLA-B, and HLA-C loci. HLA class I molecules are found on almost all nucleated human cells that present antigens from inside.

- MHC (HLA) class I molecules are heterodimers consisting of a 44-kilodalton polymorphic transmembrane glycoprotein-α and a 12-kilodalton nonpolymorphic molecule β_2-microglobulin. The later β_2-microglobulin molecule lacks a membrane component and is noncovalently associated with the larger heavy chain. Structural polymorphism occurs primarily in the extracellular domains of the α-chain.
- MHC (HLA) class I molecule is recognized by CD8+ cytotoxic T cells, which are involved in organ graft rejection and cell-mediated killing of virus-infected cells. Standard serologic techniques are used for identification of HLA-A and HLA-B antigens with the aim to predict the likelihood of long-term organ graft survival.

MHC (HLA) Class II Molecules

In humans, MHC (HLA) class II molecules are encoded by multiple different loci HLA-DP, HLA-DQ, HLA-DR, HLA-DN, and HLA-DM, identified by standard serologic techniques or by mixed lymphocyte reactions.

- MHC (HLA) class II molecules play an important role in immune system, which are essential in the defense against infection and important in organ transplantation medicine.
- MHC (HLA) class II molecules are chiefly found on immunocompetent professional antigen-presenting cells such as macrophages, dendritic cells, Langerhans' cells, B cells, and some T cells (CD4+ helper T cells). MHC (HLA) class II molecules consist of α- and β-chains, and are recognized by CD4+ helper T cells.
- Antigen-presenting cells (APCs) present antigen to CD4+ helper T cells, because of their ability to process endocytose antigens and partly possessing cell surface proteins that bind to T cell surfaces. CD4+ helper T cells become activated to synthesize an array of cytokines.
- Despite the essential function of HLA class II molecules in immune defense against pathogens, some alleles are frequently linked to autoimmune diseases.

Clinical Aspect of MHC (HLA) System

The array of HLA alleles on a homologue of our chromosome 6 is known as a haplotype. An individual inherits one HLA haplotype from each parent. Identical twins have the identical haplotype. Therefore, the preference of organ transplantation is performed as follows: identical twins > sibling > unrelated donor. The procedure carried out to match HLA proteins of donor and recipient is called tissue typing. When HLA types are matched properly, the survival of transplanted organs increases dramatically.

Organ Transplants

Autograft refers to grafting of own tissue from one region to another region (skin graft). Organ graft performed between identical twins is known as isograft. Organ graft performed between individuals of same species, but with different MHC (HLA) alleles, is known as allograft (allogenic graft). Success of the allograft depends upon matching and immunosuppressive drugs. Xenograft is referred to graft between animals of different species.

MHC (HLA) Class I and II Molecules Associated Diseases

MHC (HLA) class II molecules play an important role in immune defense against pathogens; however, some alleles are frequently linked to immune-mediated disorders.

- HLA-DR1 and HLA-DR4 predispose to rheumatoid arthritis, systemic lupus erythematosus and type 1 diabetes mellitus, whereas HLA-DR2 confers susceptibility to multiple sclerosis.
- Similarly, HLA-DQ2 and DQ8 are linked to celiac disease.

Table 4.28 MHC (HLA) class I and II molecules associated disorders

HLA Class	Diseases
MHC (HLA) class I molecules linked disorders	
B27 is now called B*2701–2725 according to revision by WHO in 2010	▪ Ankylosing spondylitis ▪ Psoriatic arthritis ▪ Reiter's syndrome
B8	▪ Graves' disease (hyperthyroidism) ▪ Myasthenia gravis
CW6	Psoriasis
B21	Behçet's disease
MHC (HLA) class II molecules linked disorders	
DR2	▪ Multiple sclerosis ▪ Narcolepsy ▪ Goodpasture's syndrome
DR3	▪ Type 1 diabetes mellitus ▪ Dermatitis herpetiformis ▪ Chronic active hepatitis ▪ Sjögren's syndrome ▪ Graves' disease
DR4	▪ Pemphigus vulgaris ▪ Rheumatoid arthritis ▪ Type 1 diabetes mellitus
DR8	Type 1 diabetes mellitus
DQ1	Pemphigus vulgaris
DQ2 and DQ8	▪ Celiac disease ▪ Type 1 diabetes mellitus

- HLA-B27 antigen is associated with almost 90% of cases of ankylosing spondylitis. HLA-B8 is linked to Graves' disease and myasthenia gravis. HLA-CW6 is associated with psoriasis.
- Specific HLA antigens are also associated with uveitis, and Reiter syndrome (urethritis, conjunctivitis, and arthritis), as well as with many other entities. MHC (HLA) class I and II molecules associated disorders are given in Table 4.28.

CYTOKINES

Cytokines are soluble proteins synthesized by lymphocytes (lymphokines), monocytes-macrophages (monokines), and NK cells, as well as other cell types. They act as effector molecules influencing the behavior of B cells, T cells, natural killer cells, monocytes, macrophages, hematopoietic stem cells, and many other cell types synthesize interleukins, growth factors, interferons and tumor necrosis factors involved in immune response. Role of cytokines in specific immune response is given in Table 4.29.

Table 4.29 Role of cytokines in specific immune response

Cytokine	Actions
Interleukins	
IL-6	Maturation of B and T cells
IL-15	Proliferation of T cells and B cells
IL-9	Proliferation of T cells
IL-12	Activates T cells and natural killer cells
IL-5	Maturation of B cells to plasma cells
IL-3	Acts as a growth factor for hematopoietic stem cells
IL-4	Promotes growth of B and T cells; enhances expression of HLA class II antigens
IL-7	Acts as a growth factor for bone marrow stem cells
Interferon	
IFN-γ	▪ Activates macrophages and T cells during chronic inflammation ▪ Enhances expression of HLA class II antigens ▪ Differentiation of T cells and B cells ▪ Increases the cytotoxicity of natural killer cells ▪ Activates neutrophils and stimulates diapedesis
Tumor necrosis factors	
TNF-α and TNF-β	▪ Stimulate T cell proliferation ▪ IL-2 synthesis ▪ Cytotoxic to some tumor cells

- **Interleukins' specific immune response:** IL-6 promotes maturation of B and T cells. IL-15 causes proliferation of T cells and B cells. IL-9 causes proliferation of T cells. IL-12 activates T cells and natural killer cells. IL-5 promotes maturation of B cells to plasma cells.
- **Interleukins as growth factors:** IL-3 acts as a growth factor for hematopoietic stem cells. IL-4 promotes growth of B and T cells; enhances expression of HLA class II antigens. IL-7 acts as a growth factor for bone marrow stem cells.
- **Interferon-γ (IFN-γ):** IFN-γ also activates macrophages and T cells during chronic inflammation, which enhances expression of HLA class II antigens. IFN-γ participates in differentiation of T cells and B cells, and increases the cytotoxicity of natural killer cells. IFN-γ activates neutrophils and stimulates diapedesis.
- **Tumor necrosis factors α and β (TNF-α and TNF-β):** TNF-α and TNF-β stimulate T cell proliferation and IL-2 production and destroy cancer stem cells.

T CELL- AND B CELL-MEDIATED IMMUNE RESPONSES

Immune cells play an important role in adaptive immune response, which includes T cells, B cells, monocytes-macrophages, Langerhans' cells of the skin, and dendritic cells of lymphoid tissue. Both B and T cells may respond to the same antigen, the way the signal is presented as fundamental.

DEVELOPMENT OF B CELLS AND T CELLS

Both B cells and T cells are derived from pluripotent hematopoietic stem cells (HSCs) in the bone marrow, which differentiate into two distinct lymphoid progenitor cells, then to precursor T cells and B cells. B cells develop in bone marrow mature in spleen. Immature T cells develop in bone marrow and migrate to thymus gland for maturation.

- During development, both B cells and T cells develop millions of genetically different clones through independent segregation, random genetic rearrangement and recombination. B cells have antibody (Ig) receptors and T cells have smaller unrelated glycoprotein molecule T cell receptors (TCR) called CD markers. Lymphocytes with self-reactive receptors are normally eliminated during development or functionally inactivated (known as anergy).
- After maturation naïve lymphocytes (i.e. T cells and B cells) migrate from bone marrow and thymus gland, to the peripheral lymphoid tissues/organs such as lymph nodes, spleen, mucosa-associated lymphoid tissue (MALT), gut-associated lymphoid tissue (GALT) in Peyer's patches and skin-associated lymphoid tissue (SALT) throughout the body, and serve as defense force against pathogens.
- Adaptive immune responses are initiated by antigen and antigen-presenting cells (APCs) in the secondary lymphoid tissues. Lymphocytes encounter and respond to antigen in the peripheral lymphoid tissues. Mucosal surfaces have specialized immune structures that orchestrate responses to environmental microbial encounters. Stages of B cells and T cells development in bone marrow and thymus gland are shown in Fig. 4.21.

FUNCTIONS OF B CELLS AND T CELLS

Lymphocytes constitute 20–40% of white cells, which include T cells (60–70%), B cells (10–20%) and natural killer cells (15%), identified by cell surface glycoproteins specific for both cell type and stage of differentiation by use of a panel of monoclonal antibodies. Lymphocytes play key roles in adaptive immune response.

- Lymphocytes consist of distinct classes with different functions and protein products. Subsets of T cells include CD4+ helper T cells, CD8+ cytotoxic T cells, and CD4+ regulatory T cells.

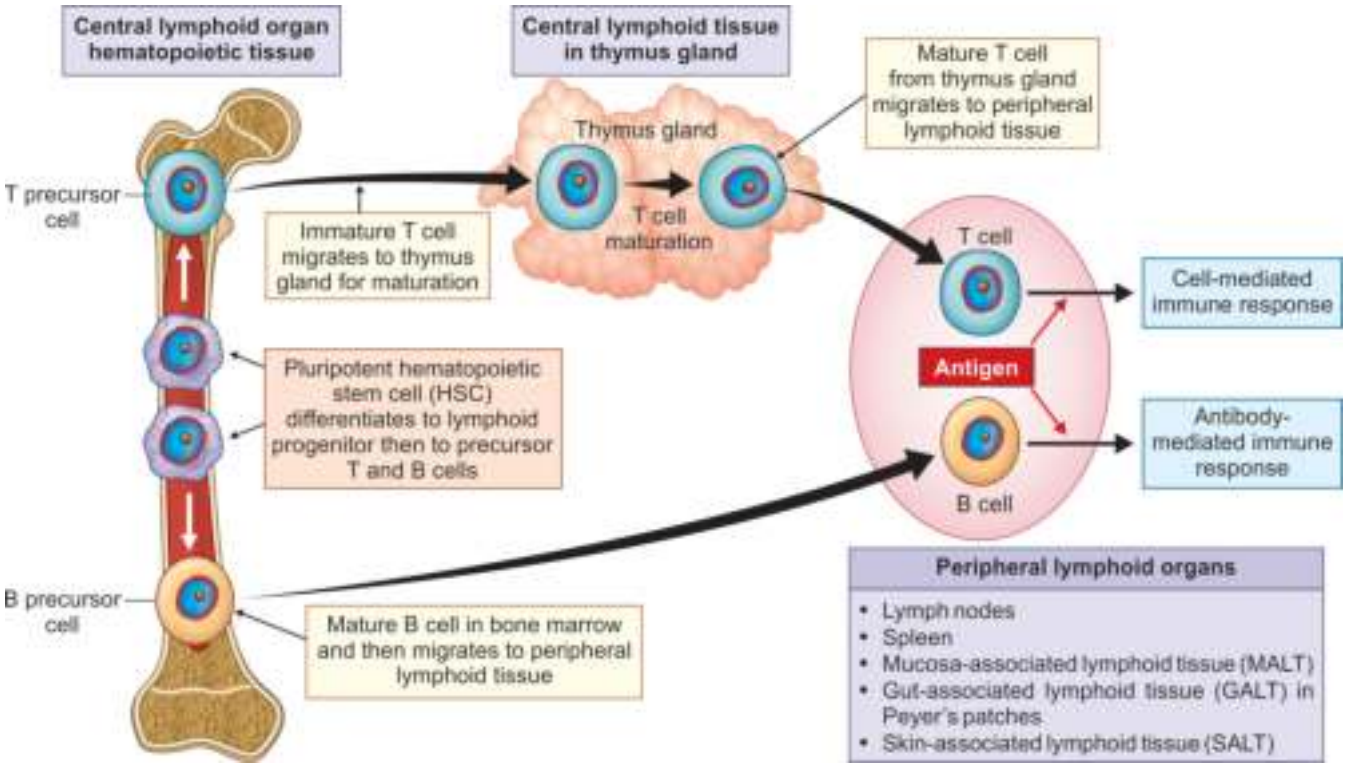

Fig. 4.21: Stages of B cells and T cells development in bone marrow and thymus gland. B cell and T cell are derived from pluripotent hematopoietic stem cells in the bone marrow. T cells migrate to thymus gland for maturation. (a) Stages of B cell development: B cell development starts with rearrangement of the heavy-chain locus in the bone marrow. Immature B cells migrate to the spleen for maturation. There are three subsets of mature B cells: follicular B2 cells, marginal zone B cells and B1 cells. Following exposure to antigens, B cells differentiate into antibody-producing plasma cells. Follicular B2 cells may remain plastic and can differentiate to B1 cells upon self-reactivity of B cell antigen receptor. (b) Differentiation of CD4+ helper T cell subsets: after activation by antigen-presenting cells, CD4+ T cells can differentiate into several T cell subsets: Th1, Th2, Th17 and CD4+ regulatory T cells. The differentiation of each T cell subset is regulated by different transcription factors.

- T cells orchestrate cell-mediated immunity and regulate B cell responses to most antigens. B cells can be transitional/immature, naïve B cells, plasma cells and memory B cells.
- Mature lymphocytes in peripheral lymphoid organs respond to diverse foreign antigens and recirculate in the blood and lymph. Some immature B cells leave the bone marrow and complete their maturation in the spleen. B cells and T cells recognize distinct type of antigens and differentiate into effector cells whose functions are to eliminate the antigens.
- Naïve CD4+ helper T cells engage MHC II molecules on antigen-presenting cells (APCs) and become activated. Clones of the activated CD4+ helper T cell, in turn activate B cells and CD8+ cytotoxic T cells. CD4+ regulatory T cells prevent autoimmune response.
- B cells develop into antibody secreting plasma cells to fight infection. Antibodies protect against extracellular pathogens and their toxic products. Natural killer cells (NK cells) attack any foreign cells including cancer cells.
- Inherited and acquired defects in the immune system result in increased susceptibility to infection. Understanding adaptive immune response is important for control of allergies, autoimmune diseases, and the rejection of transplanted organs. Vaccination is the most effective means of controlling infectious diseases.

CREATION OF ANTIGEN-BINDING T CELL RECEPTORS AND B CELL RECEPTORS

Each lymphocyte produces its own unique receptor, which is structurally organized so that it responds to a different antigen. There is small amount of DNA that encodes the production of B cell receptor (BCR) and T cell receptor (TCR). It is possible for a gene to produce BCR and TCR. Antibodies and T cell receptors are composed of constant and variable regions that provide different functions.

- Therefore, the millions of unique antigen-binding molecules on T cells and B cells are created by a process of gene rearrangement which occur in the primary lymphoid organs (bone marrow and thymus gland) in cells within the lymphoid lineage. B cells and T cells sense the presence of antigens in their environment.
- **Antigen receptor genes** are assembled by somatic gene rearrangements of incomplete receptor gene segments. The gene segments are referred to be as V (variable), D (diversity) and J (joining) and when they are randomly recombined by the action of the RAG genes (recombination activating genes), they are spliced together to create the RNA coding for the N-terminal amino acids in the variable domains of the BCR and TCR.
- Terminal deoxynucleotidyl transferase (TdT) is a DNA polymerase present in the immature pre-B cells and pre-T cells. TdT randomly inserts N-nucleotides to the V (variable), D (diversity), and J (joining) gene segment during gene rearrangements, therefore TdT plays a vital role in the development of the adaptive immune system.
- The immunoglobulin heavy-chain (IgH) and T cell receptor β-chain genes rearrange first in B cell and T cell lineages respectively. Both loci require two recombination events to assemble functional genes; D (diversity) to J (joining) recombination occurs first followed by V (variable) to DJ (diversity and joining) recombination. BCR and TCR recognize antigens by fundamentally different mechanisms.
- Structure of TCR and BCR is shown in Fig. 4.22A and B. Immunotyping of surface markers of human T cells and B cells is shown in Fig. 4.23. V(D)J somatic recombination of the heavy chain immunoglobulin (IgH) and light chain immunoglobulin (IgL) gene segments is shown in Fig. 4.24.

Pathology Pearls: Key Features of Lymphocytes

T Cell Receptor (TCR) and B Cell Receptor (BCR)

- One important difference between TCRs and BCRs is the way they can interact with antigen isotopes.
- TCRs can only react with antigenic epitopes that are presented within the antigen-binding cleft of MHC class I or MHC class II molecules.
- On the contrary, BCRs react with free antigenic epitopes displayed on the surface of intact pathogens without presentation with MHC.
- TCR spans the membrane and projects variable binding regions into extracellular space to bind processed antigens via MHC molecules on antigen-presenting cells (APCs).
- BCR is embedded in the membranes of B cells and bind to a variety of antigens through their variable regions. The signal transduction region transfers the signal in the cell.

Cluster of Differentiation (CD) System

- Lymphocytes possess protein markers on their surfaces that are named using the CD system to delineate particular cell type or stage of differentiation.
- Subsets of lymphocytes are defined by the CD surface markers that the cells carry helper T cells express CD4. On the other hand, suppressor T cells express CD8.
- Markers for T cells include CD1, CD2, CD3, CD4, CD5, CD6, CD7 and CD8. Markers for B cells include CD19, CD20, CD21 and CD22.
- Normal ratio of CD4+ helper T cells to CD8+ cytotoxic T cells are 2:1. This ratio is altered to 0.5:1 or less in acquired immune deficiency syndrome. T cells participate in specific acquired immunity.

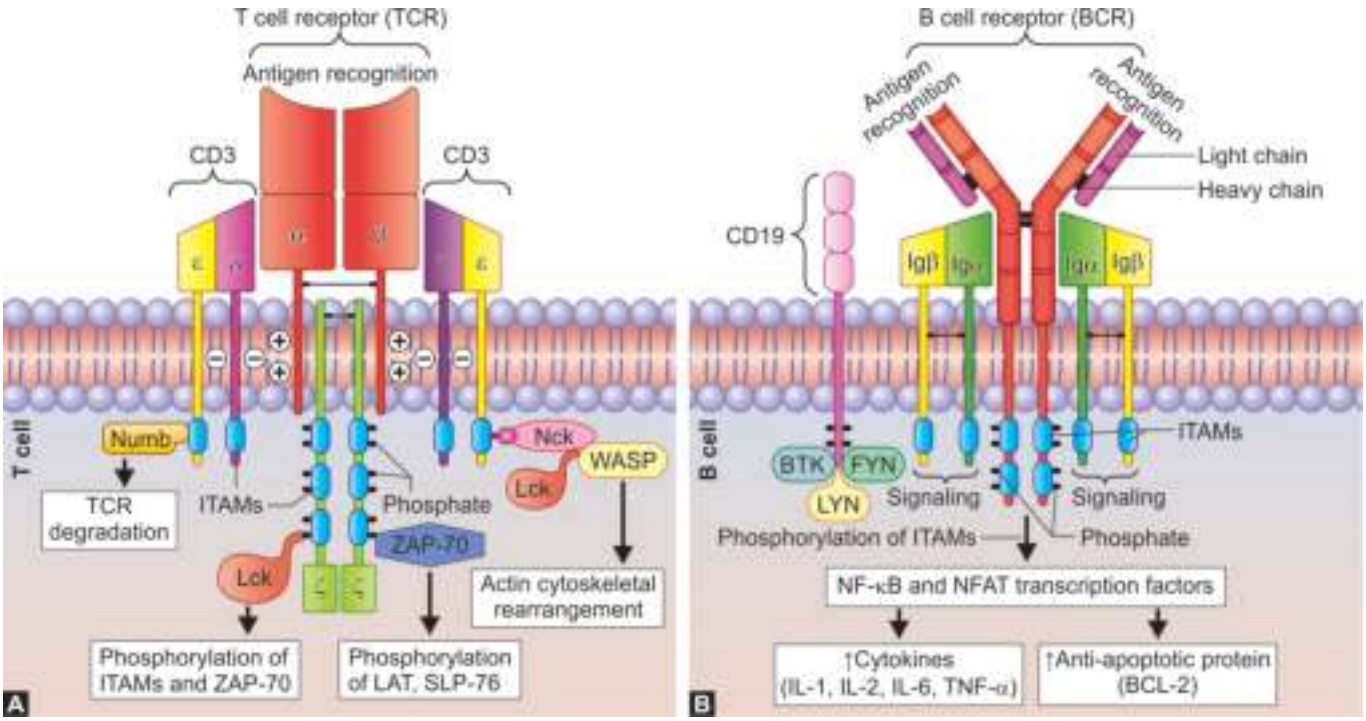

Fig. 4.22A and B: Structure of T cell receptor (TCR) and B cell receptor (BCR). Both TCR and BCR possess unique binding sites. TCR recognizes antigens when displayed to major compatibility complex (MHC). BCR detects and binds to soluble, free and unprocessed antigen. Both TCR and BCR are activated to initiate an immune response to specific binding of their receptors to antigens expressed of tumor cells and viruses.

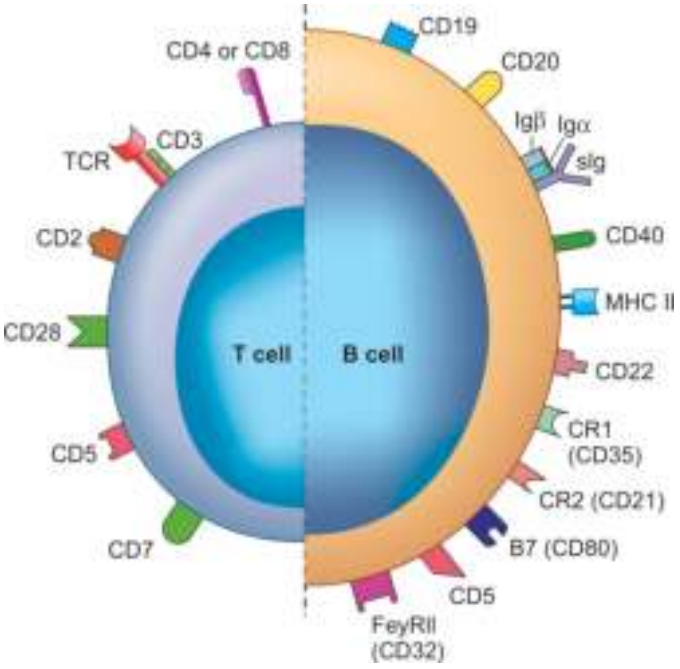

Fig. 4.23: Immunotyping of surface markers of human T cells and B cells. Expression of different markers allows the separation/differentiation of T cells and B cells express CD3, CD4, CD8, or CD25 markers. Immature B cells express CD19, CD20, CD34, CD38 and CD45R, but not IgM. Mature B cells express CD19 and IgM. Activated B cells express CD30, a regulator of apoptosis. Memory B cells express CD20 and CD40. Plasma cells lose CD19 but gain CD78.

Postulates of the Clonal Selection Hypothesis

T cells and B cells with self-respective receptors are normally eliminated during development or these lymphocytes are functionally inactivated. Each lymphocyte bears a single type of receptor with a unique specificity.

- Interaction between a foreign molecule and a lymphocyte receptor capable of binding that molecule with high affinity results in activation of lymphocyte.
- The differentiated effector cells derived from an activated lymphocyte will bear receptors of identical specificity to those of the parental cell from which that lymphocyte has been derived.
- Lymphocytes bearing receptors specific for ubiquitous self-molecules are deleted at an early stage in lymphoid cell development and are therefore absent from the repertoire of mature lymphocytes.

Clonal Selection in Lymphoid Organs

All T cells originate from pluripotent hematopoietic stem cells in the bone marrow and generate a large population of immature progenitors and migrate to thymus gland for maturation. The thymocytes progress from double negative thymocytes to become double positive thymocytes (CD4+ and CD8+) and finally to single positive (either CD4+ or CD8+).

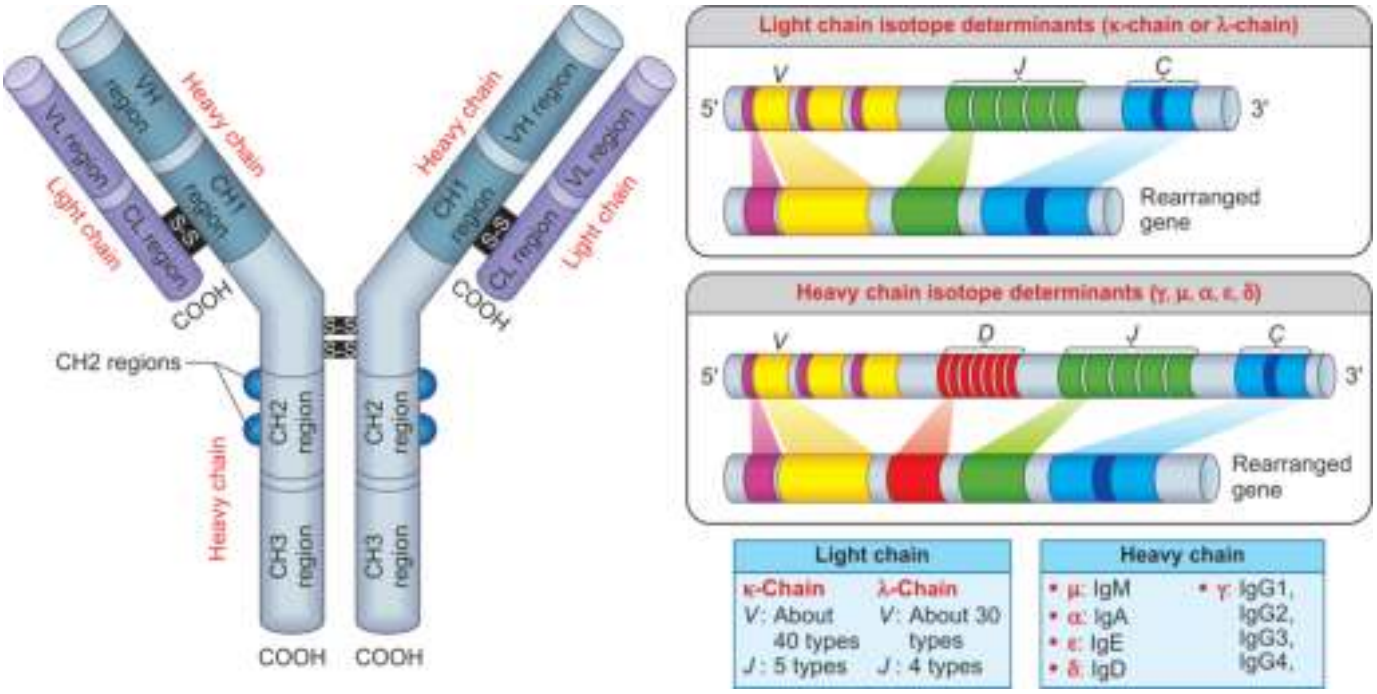

Fig. 4.24: V(D)J somatic recombination of the heavy chain immunoglobulin (IgH) and light chain immunoglobulin (IgL) gene segments. The immunoglobulin IgH locus is organized in gene segments: the variable (V), diversity (D) and joining (J) and constant (C) gene segment. The variable (V) region comprising the V, D and J gene segments is generated by random recombination of these sequences. As IgL lacks diversity (D) gene segment, similar rearrangement of variable (V) and joining (J) genes occurs in IgL.

- Clonal selection is used during negative selection to eliminate lymphocytes that may be able to bind with self-antigens.
- During T cell differentiation, the naïve T cell undergoes proliferation by clonal expansion and differentiation into memory T cells and effector T cells. Many subsets of CD4+ helper T cells are generated during T cell differentiation and perform different functions for the immune system.
- Clonal selection of T cells and B cells can occur by two mechanisms: antigen-independent and antigen-dependent. Overview of the antigen-dependent and antigen-independent clonal selection of lymphocytes diversity in lymphoid organs is shown in Fig. 4.25A and B.

Clonal Selection of Lymphocytes by Antigen-independent Mechanism

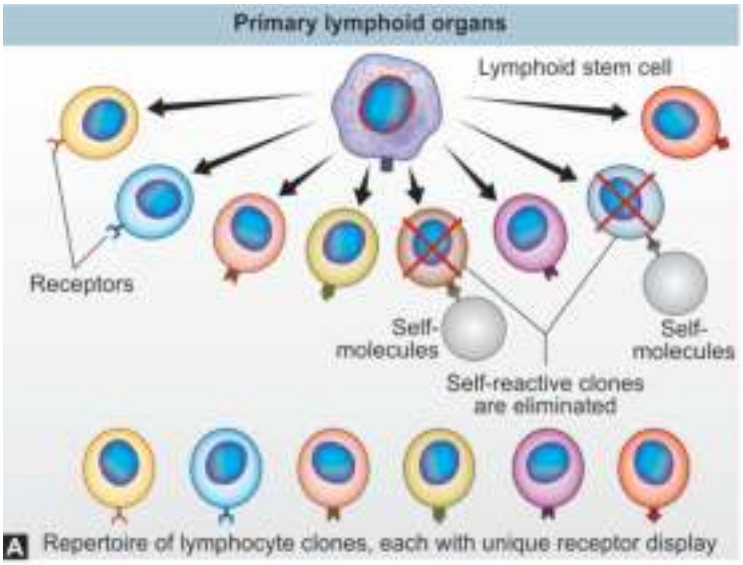
Hematopoietic stem cells (HSCs) in bone marrow participate in the production of lymphocytes. During development, hematopoietic stem cell undergoes rapid cell division to form numerous progenies.

- During this period of cell differentiation, random rearrangements of genes encoding cell surface protein receptors take place. Differentiation leads to formation of large array of genetically distinct cells known as **clones**. Each clone bears a different receptor. Each receptor is specific to react with only a single type of foreign antigen.
- During differentiation, lymphocyte clones harmful to self-molecules formed are eliminated from the pool of diversity known as immune tolerance.
- The specificity for a single molecule is programed into the lymphocyte, which is set for the life of a given clone. The net result is an enormous pool of mature but naïve lymphocytes, which are ready for further differentiation under the influence of certain immune stimuli.

Clonal Selection of Lymphocytes by Antigen-dependent Mechanism

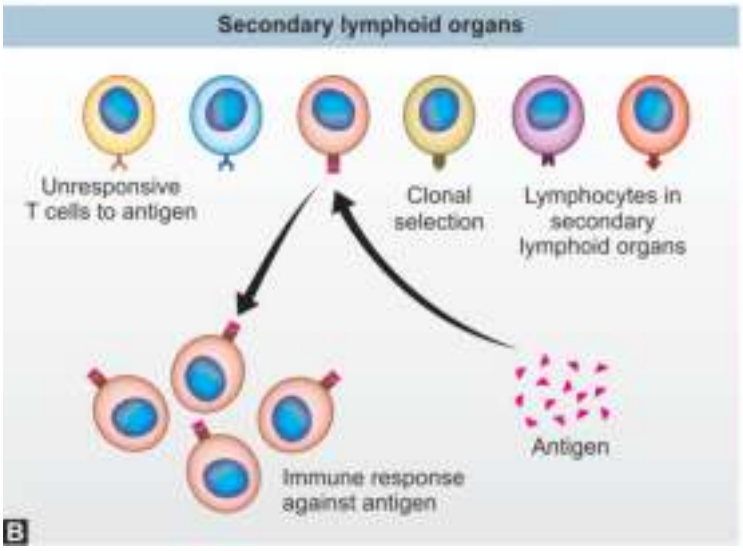
Lymphocytes come to populate the lymphoid organs, which will finally encounter antigens. These antigens activate the immune function. Entry of a specific antigen selects only the lymphocyte clones the carrier matching surface receptors, which triggers immune response, which varies according to the type of lymphocyte involved.

- B cell and T cell receptors function in identification, communication, and development. When receptors on B cells and T cells interact with antigenic determinant specific to it, the lymphocyte becomes activated and divides to form a clone of cells.
- B cells and T cells are derived from hematopoietic stem cell, and exhibit the same specificity for antigenic determinant. B cells and T cells are transformed to responder cells and memory cells.



Antigen-independent clonal selection of lymphocytes

- B cell and T cell originate in hematopoietic stem cells in bone marrow. B cell undergoes maturation and migrates to spleen for maturation. T cell migrates to thymus gland for maturation.
- During antigen-independent period of cell differentiation, random rearrangements of genes encoding cell surface protein receptors take place.
- Differentiation leads to formation of large array of genetically distinct cells known as clones.
- Each clone bears a different specific receptor, which reacts with only a single type of foreign antigen.
- During differentiation, lymphocyte clones harmful to self-molecules formed are eliminated from the pool of diversity known as immune tolerance.
- The specificity for a single molecule is programed into the lymphocyte. It is set for the life of a given clone. The net result is an enormous pool of mature but naïve lymphocytes, which are ready for further differentiation under the influence of certain immune stimuli.



Antigen-dependent clonal selection of lymphocytes

- Lymphocytes come to populate the lymphoid organs, which finally encounter antigens.
- Antigens trigger the immune function by clonal selection of lymphocyte matching surface receptors.
- Immune response triggered by antigens varies according to the type of lymphocyte involved.
- B cell and T cell receptors function in identification, communication, and cell development. When receptors on B cells and T cells interact with antigenic determinant specific to it, the lymphocyte becomes activated and divides to form a clone of cells.
- B cells and T cells are derived from a single parental cell, and exhibit the same specificity for antigenic determinant.
- B cells and T cells are transformed to responder cells and memory cells.
- The process by which diversity is generated in clonal selection. Immune tolerance or tolerance to self occurs during this time.

Fig. 4.25A and B: Overview of the antigen-dependent and antigen-independent clonal selection of lymphocytes diversity in lymphoid organs. T cell progenitors originating from pluripotent hematopoietic stem cell (HSC) migrate to thymus gland for maturation. During development, pluripotent hematopoietic stem cell undergoes differentiation and genetic rearrangement to produce immature progenitors of lymphoid lineage in primary lymphoid organs with many different antigen surface receptors. Those immature progenitors of lymphoid lineage that bind to antigens from the host own tissues are eliminated, while the rest immature lymphocytes mature into inactive lymphocytes.

- Diversity of T cells and B cells occurs by the process of clonal selection. Immune tolerance or tolerance to self occurs during this time.

EXPOSURE OF HOST TO ANTIGENS

Antigen is a substance capable of stimulating an adaptive immune response, specifically activating B cells and T cells. There are different types of antigens on the basis of origin: exogenous antigens (e.g. pollen, food allergen, aerosols), endogenous antigens (e.g. bacteria, viruses), and autoantigens (self-proteins such as nucleic acids can induce autoimmunity).

- An antigen that is not yet processed by an antigen-processing cell (APC) is known as **native antigen**. Each antigen has several antigenic determinants or epitopes. An immunoglobulin has at least two binding sites that can bind to specific antigens. Antigen combines with the immunoglobulin according to the lock and key mechanism.
- Antigen-specific activation of lymphocytes involves the specific receptors on B cells and T cells, which differ in the process of the recognition of antigens. B cell receptor (BCR) detects and binds soluble antigens that are present freely, whilst T cell receptor (TCR) only recognizes antigens when displayed on major histocompatibility complex (MHC), i.e. MHC (HLA) class molecules. Both B cell receptor (BCR) and T cell receptor (TCR) repertoires are generated through identical processes of V(D)J recombination,

exonuclease trimming of germline genes and random addition of nontemplate encoded nucleotides.

CO-OPERATION IN IMMUNE CELLS AGAINST ANTIGENS

Immune cells participating in specific immune response comprise T cells, B cells, Langerhans' cells of the skin, dendritic cells of lymphoid tissue and monocytes/ macrophages, Both B and T cells may respond to the same antigen, the way the signal is represented.

- B cells can recognize the antigen irrespective of the form antigen is presented. B cells are capable to bind free antigen in solution, antigen present on the membrane of cells and antigens insolubilized in various ways.
- In contrast, T cells can only bind antigen present on the membrane of cells. CD4+ helper T cells bind to

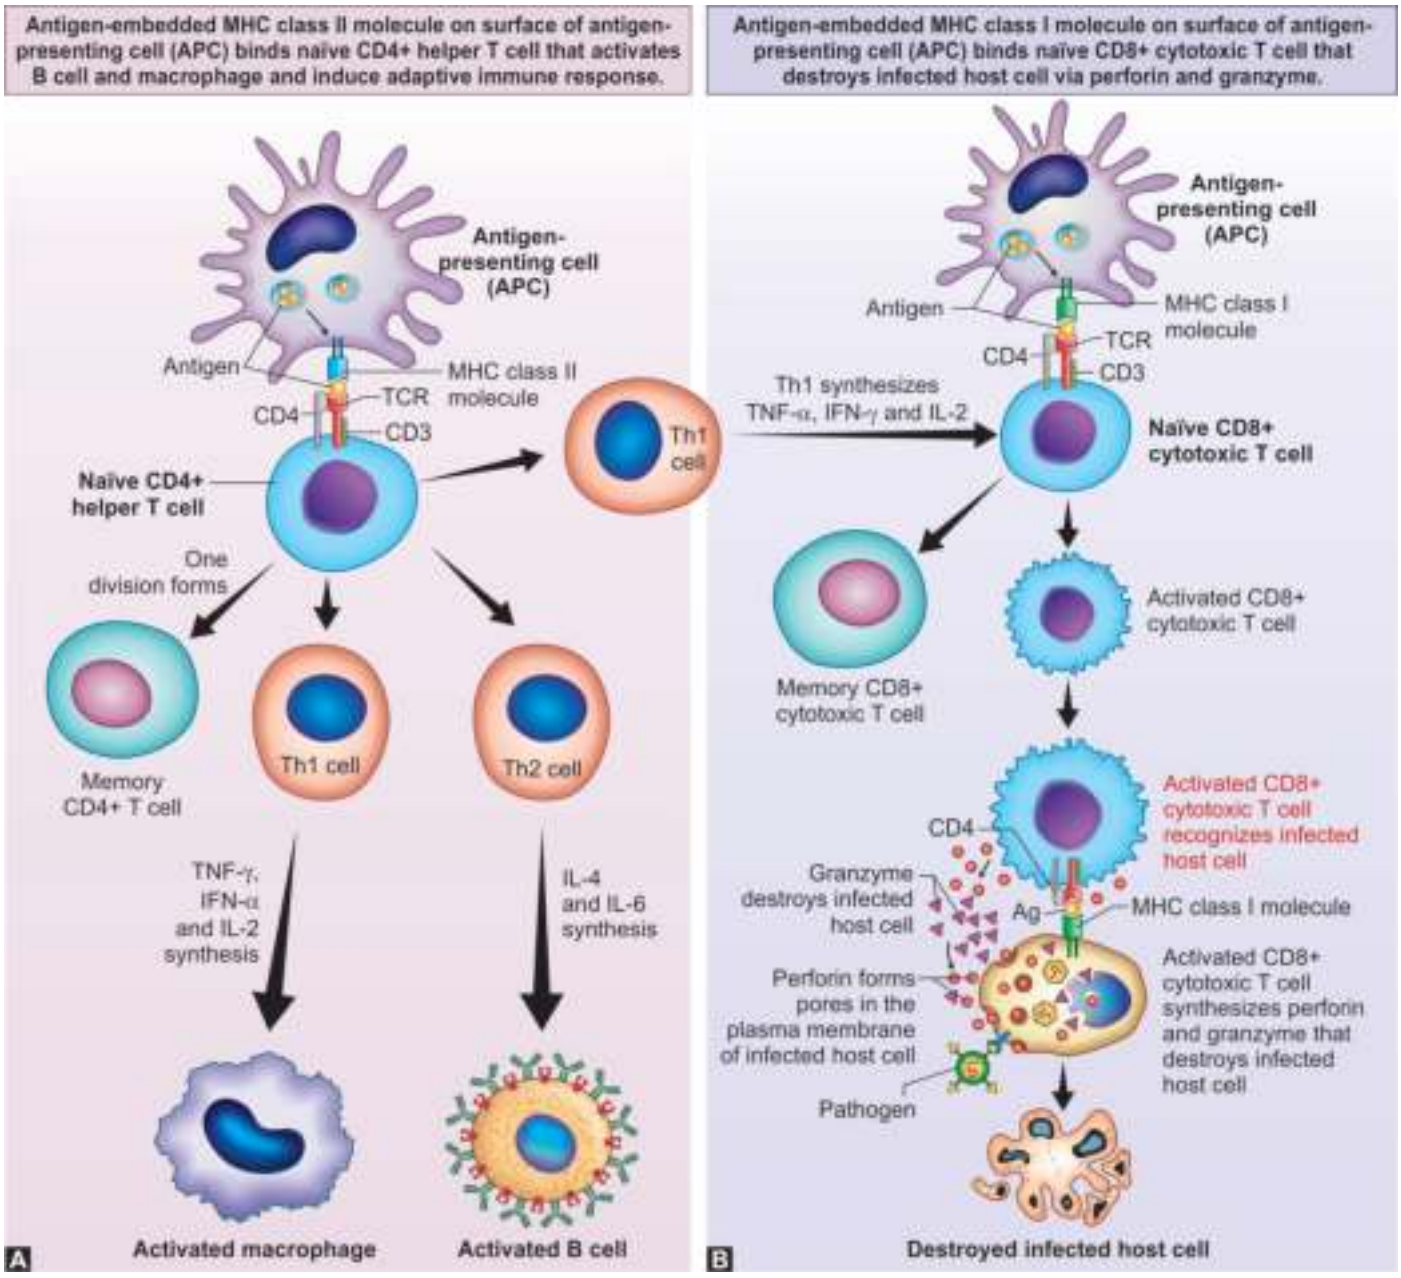


Fig. 4.26: Antigen-embedded different MHC class molecules on surface of antigen-presenting cells and their binding to naïve CD4+ helper T cells or CD8+ cytotoxic T cells. (A) When naïve CD4+ T cell interacts with antigen-presenting cell (APC), both cells release cytokines. In response to cytokines the cloned activated helper T cells produce different cytokines that activate B cells and naïve CD8+ cytotoxic T cells, which become CD8+ cytotoxic T cells. (B) When CD8+ cytotoxic T cells interact with the MHC class I molecule–epitope complex on an infected cell, CD8+ cytotoxic T cells synthesize perforins and granzymes, which kill infected host cells. Perforins induce pores in the plasma membrane and granzymes enter the cell and break down proteins causing lysis of infected cell.

antigen that has been processed by antigen-presenting cells (with the exception of superantigens). Antigen is presented to macrophages with the help of second signal provided by a glycoprotein on the surface of the antigen-presenting cell (APC) that is coded for a gene sequence within major histocompatibility complex (MHC).

ANTIGEN PROCESSING AND PRESENTATION BY ANTIGEN-PRESENTING CELLS

With the exception of superantigens, T cells recognize antigen that has been processed in the same way within antigen-presenting cells (APCs).

- Antigens enter the major fluid compartments. Fluid movement from the intravascular compartment to interstitial and intracellular compartments occur in the capillaries. Antigen-presenting cells (APCs) (dendritic cells and macrophages) process antigen and present to either CD4+ helper T cells or CD8+ cytotoxic T cells depending on type of antigen.
- Antigen derived from the cytoplasm (e.g. viral proteins) is processed by MHC class I molecules to CD8+ cytotoxic T cells. Antigen-presenting cells (dendritic cells and macrophages) process exogenous antigen make small fragments of antigen by MHC class II molecules then to CD4+ helper T cells.
- Some antigens may directly stimulate B cells to form antibody secreting plasma cells and memory B cells. Memory B cells have long life span over 40 years that is regulated by the BCL-2 gene, which is present only in the memory B cells. Antigen-embedded different MHC class molecules on surface of antigen-presenting cells and their binding to naïve CD4+ helper T cells or CD8+ cytotoxic T cells are shown in Fig. 4.26A and B.

Antigen Presentation by Antigen-presenting Cells with MHC Class II Molecules

Exogenous antigen (foreign proteins peptide) is endocytosed by antigen-presenting cells (APCs). The α- and β-chains of MHC class II molecule assemble in the rough endoplasmic reticulum of cell. Invariant (inv) protein synthesized by endoplasmic reticulum directs assembled MHC class II molecules in the endosome, where it binds with endocytosed antigen (foreign protein peptide).

- Assembling of α- and β-chains MHC class II molecule complexed with a membrane bound invariant (inv) protein dictate the folding of MHC class II molecule and prevent premature binding of proteins to MHC class II molecule before the latter reach the location of the intracellular processed antigen. In the endosome, there occurs limited proteolysis of antigen (foreign protein peptide) and lysis of invariant (inv) protein.
- Then MHC class II molecule is transported along with foreign protein peptide and presented to antigen-presenting cells (APCs). Processing and presentation of antigen byAPCs in association with MHC class II molecule are shown in Fig. 4.27.

Antigen Presentation by Antigen-presenting Cells with MHC Class I Molecules

Viral coded proteins presented on the surface of cells expressing MHC class I molecule undergo proteolysis with the formation of peptides, some of which are recognized by T cell receptors (TCRs). Some viral proteins are degraded by proteasome leading to release of viral peptides.

- The viral peptides transported to endoplasmic reticulum of the infected cell bind with MHC class I heavy chains followed by complexing with β_2-macroglobulin.
- MHC class I molecule and viral peptides are transported via Golgi apparatus. Then viral particles are presented on infected surface in association with

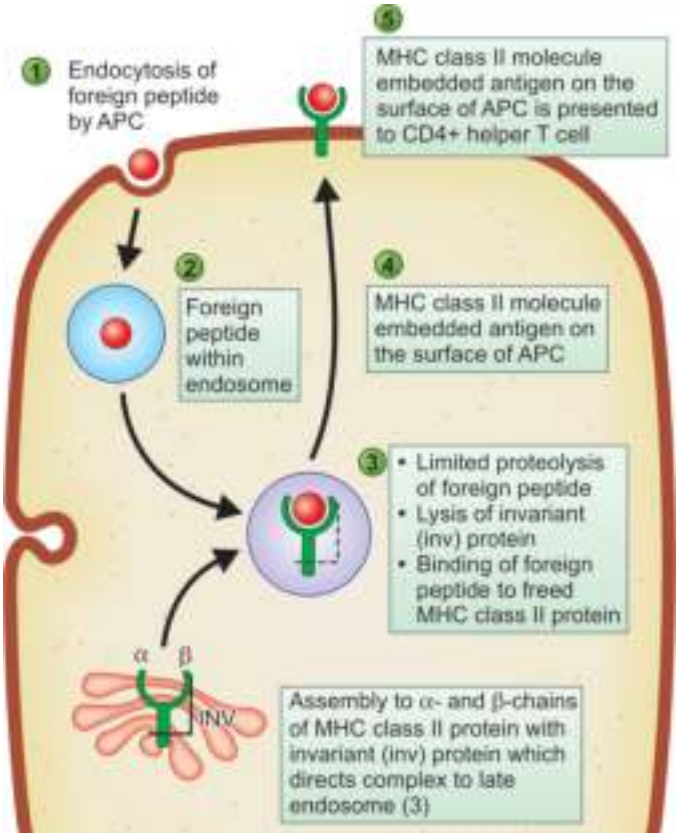

Fig. 4.27: Processing and presentation of antigen by antigen-presenting cells (APCs) in association with MHC class II molecule to CD4+ helper T cells. Antigen-presenting cells (APCs) with MHC class II molecule is essential for the activation of CD4+ helper T cells. APCs ingest pathogens by the process of phagocytosis, degrades them in the phagolysosome, process protein antigens, select the most antigenic/immunodominant epitopes with MHC class II molecule for presentation to CD4+ helper T cells.

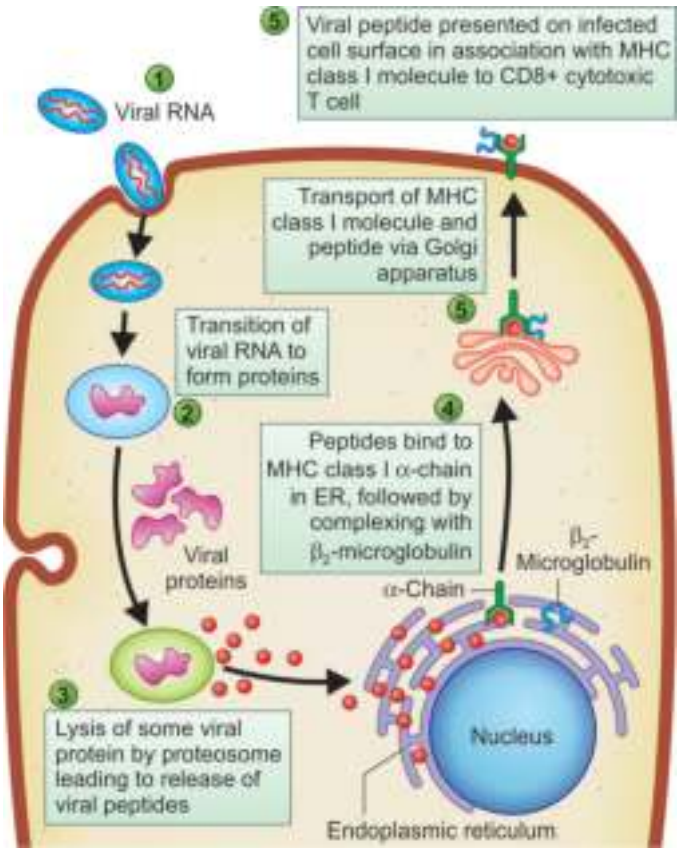

Fig. 4.28: Processing and presentation of antigen by antigen-presenting cells (APCs) in association with MHC class I molecule to CD8+ cytotoxic T cells. MHC class I molecule carries peptides of foreign protein into the cell surface. Once embedded in the surface, a signal is transmitted to CD8+ cytotoxic T cells that foreign protein inside the cell.

MHC class I molecule. Processing and presentation of antigen-presenting cells (APCs) of antigen in association with MHC class I molecule are shown in Fig. 4.28.

T CELL AND CELL-MEDIATED ADAPTIVE IMMUNE RESPONSE

B cells and T cells are the major components of adaptive immune system. Pluripotent hematopoietic stem cell (HSC) differentiates to lymphoid progenitor cell then to precursor T cells and B cells in the bone marrow.

- B cell develops in the bone marrow and matures in spleen and then migrates to peripheral lymphoid tissue. Once produced from hematopoietic pluripotent stem cells in the bone marrow, T progenitor cells migrate to the thymus gland and go through a series of developmental stages that ensures both function and tolerance before T cells leave and become functional components of the adaptive immune response.
- In thymus gland, thymic epithelial cells present MHC class molecules to untrained thymocytes (double negative for CD4 and CD8 receptors). Thymocytes that successfully bind with MHC class molecules continue to develop (positive selection), while those thymocytes fail to bind to MHC class molecules undergo apoptosis (negative selection). Thymocytes that survive by positive selection become double positive (CD4+ and CD8+ receptors). The surviving thymocytes move to the thymic medulla, where they encounter antigen-presenting cells (APCs). These APCs present self-antigens from other body cells. Thymocytes that bind with self-antigens undergo apoptosis, which indicates that thymocytes will attack body cells. This process is called negative selection. Cell signals cause self-tolerant thymocytes to express either the CD4 or CD8 receptor. Those cells express CD4 receptor becomes CD4+ helper T cells, while those cells express the CD8 receptors become CD8+ cytotoxic T cells.
- Mature T cell from thymus gland migrates to peripheral lymphoid tissue such as lymph nodes, spleen, mucosa-associated lymphoid tissue (MALT), gut-associated lymphoid tissue (GALT) in Peyer's patches and skin-associated lymphoid tissue (SALT).
- Mature T cells become activated by recognizing processed foreign antigen in association with a self-MHC class molecule and start dividing rapidly by mitosis. This proliferation of T cells is known as clonal selection, which is essential to make the adaptive immune response strong enough to effectively eliminate a pathogen. Clonal selection is the process of antigen binding only to those T cells that have receptors specific to the antigen. Overview of adaptive cellular and humoral immune response is shown in Figs 4.29 and 4.30.

CD4+ HELPER T CELL AND CELL-MEDIATED ADAPTIVE IMMUNE RESPONSE

Upon uptake, conventional antigen is processed into short peptides by antigen-presenting cell (APC), and then presented MHC class II molecule to naïve CD4+ helper T cells. Cytokines synthesized by CD4+ helper T cells play diverse roles in the immune response.

- Antigen-presenting cells (APCs) synthesize IL-12 that activates CD4+ helper T cells leading to differentiation into CD4+ T helper type 1 (Th1) cell. IL-4 synthesized by naïve CD4 helper T cell results in differentiation into CD4+ T helper type 2 (Th2) cell. Transforming growth factor β, IL-6, IL-21 and IL-23 lead to activation of CD4+ T helper type 17 (Th17) cell. Activated CD4+ helper T cells also differentiate into CD4+ T helper type 17, CD4+ regulatory T cells (Tregs), memory

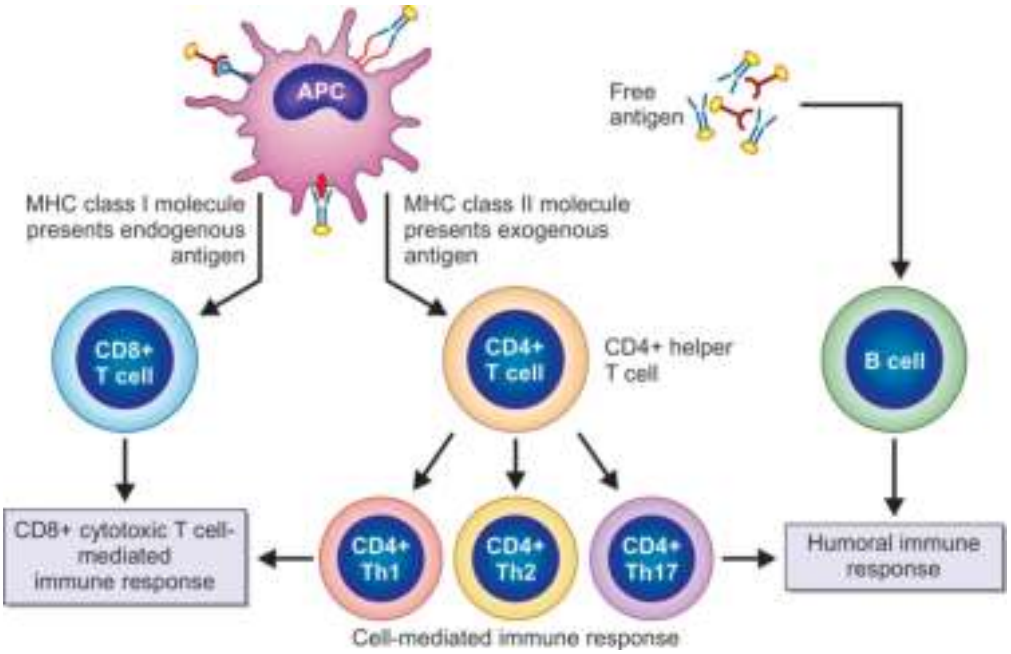

Fig. 4.29: Overview of adaptive cellular and humoral immune response. Activation of CD4+ helper T cells by antigen, leads to their differentiation into subsets of helper T cells (Th1, Th2, Th17, Treg cells) and memory T cells assisting other CD8+ cytotoxic T cells that eliminate foreign cells. T cells also synthesize cytokines that regulate cell-mediated immune response. B cell participates in antibody-mediated immune response.

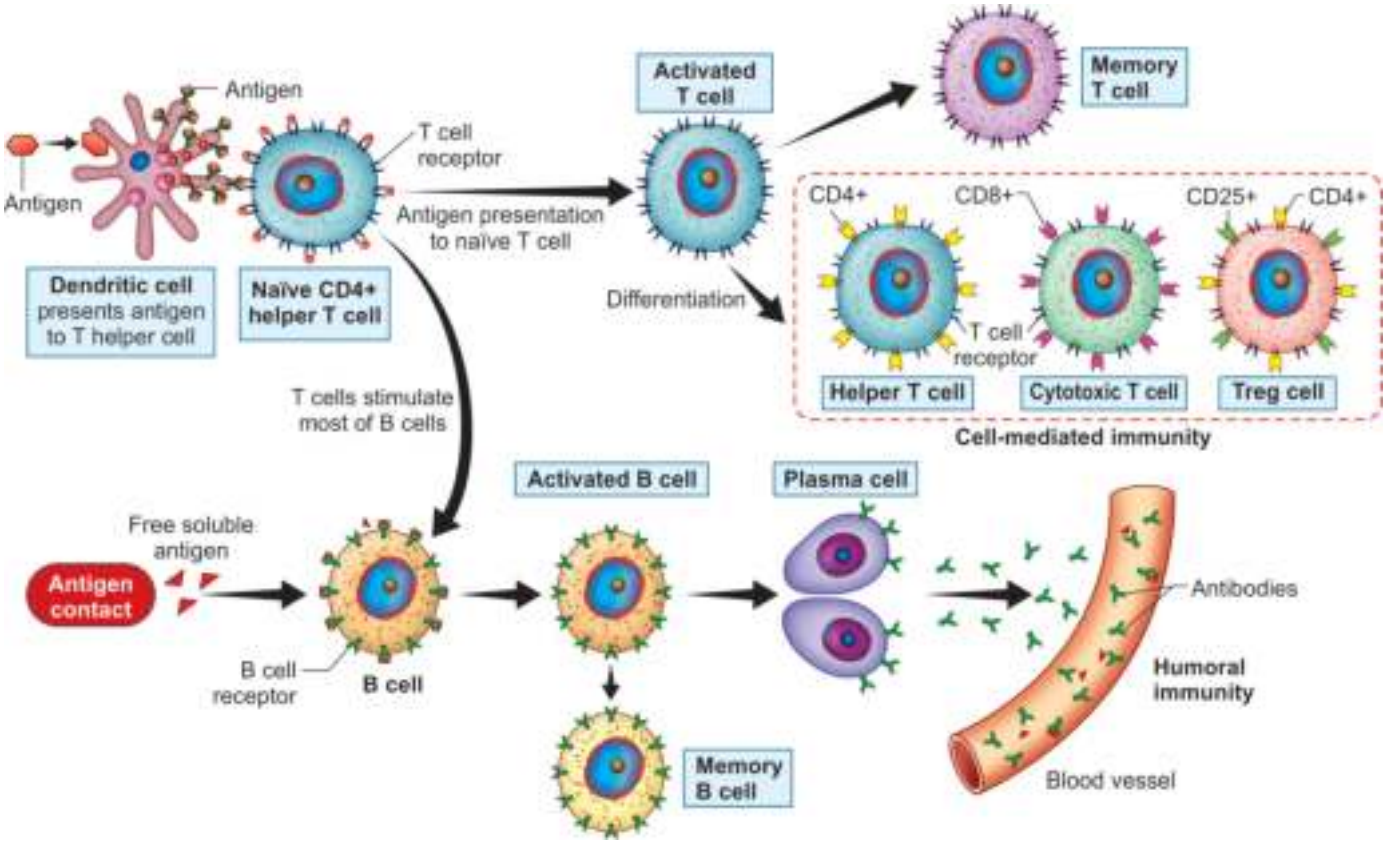

Fig. 4.30: Overview of cellular and humoral adaptive immune system. An adaptive immune system is based on clonally diverse T cells and B cells that can recognize specific pathogens and provide protective immunological memory against subsequent encounter to same pathogen in vertebral species. T cell is involved in cell-mediated immunity and B cell carry out humoral immunity. Antigen-presenting T cell and naïve CD4+ helper T cell leads to clonal proliferation and differentiation of activated CD4+ helper T cells to effector T cells and memory T cells. CD4+ helper T cells also stimulate B cells, which differentiate to effector B cells, antibody secreting plasma cells and memory B cells.

T cells. Differentiation of each T cell subset is regulated by different transcription factors.

- CD4+ helper T cells assist CD8+ cytotoxic T cells that eliminate foreign infected cells or cancer stem cells. CD4+ helper T cells activate macrophages.
- CD4+ helper T cells also activate B cells, which undergo cell division resulting in formation of many plasma cells, which synthesize five classes of immunoglobulins circulating in tissue fluids (blood and lymph) providing humoral immunity.
- Immunoglobulins differ in size and function, which include IgG, IgA, IgM, IgD and IgE. Antibody opsonizes microbes for phagocytosis both directly via Fc receptors and indirectly via complement system activation. The Fab (fragment antigen-binding) part of the antibody binds specific antigen on the microbe and varies from one antibody to another. Some of plasma cells become memory plasma cells that recognize the same antigen in the future. CD4+ helper T cell differentiates into subsets is shown in Fig. 4.31.

Naïve CD4+ Helper T Cell Activation and Differentiation

Antigen-presenting cells (macrophages or dendritic cells) are found in large number in lymphoid tissues, which detect invading foreign antigens (microbes) and present them to CD4+ helper T cells, which recognize the antigen and initiate the specific immune response. Interaction between macrophages and CD4+ helper T cells is shown in Fig. 4.32. Activation of CD4+ helper T cell by antigen-presenting cell (APC) is shown in Fig. 4.33. APCs and CD4+ T cell interaction inducing adaptive immune response are given in Fig. 4.34.

- Naïve CD4+ helper T cells engage MHC II molecule on APCs, where naïve CD4+ helper T cells are activated by antigen to proliferate and differentiate into effector T cells and memory T cells. Some of effector T cells and memory T cells migrate into the peripheral tissue at the site of infection. Superantigens present in Staphylococci, Group A Streptococci) and Epstein-Barr virus can also activate CD4+ helper T cells by binding to MHC class II molecule on antigen-presenting cells without being processed by APCs.
- When naïve CD4+ helper T cells engage MHC class II molecule on APCs, both naïve CD4+ helper T cell and APC release cytokines such as TNF-α, IL-1 and IL-6. Clones of the activated CD4+ helper T cell, in turn, activate B cells and naïve CD8+ cytotoxic T cells, which become activated CD8+ cytotoxic T cells.
- On stimulation of CD4+ helper T cells differentiate to Th1, Th2, Th17 and CD4+ regulatory T cell (Treg

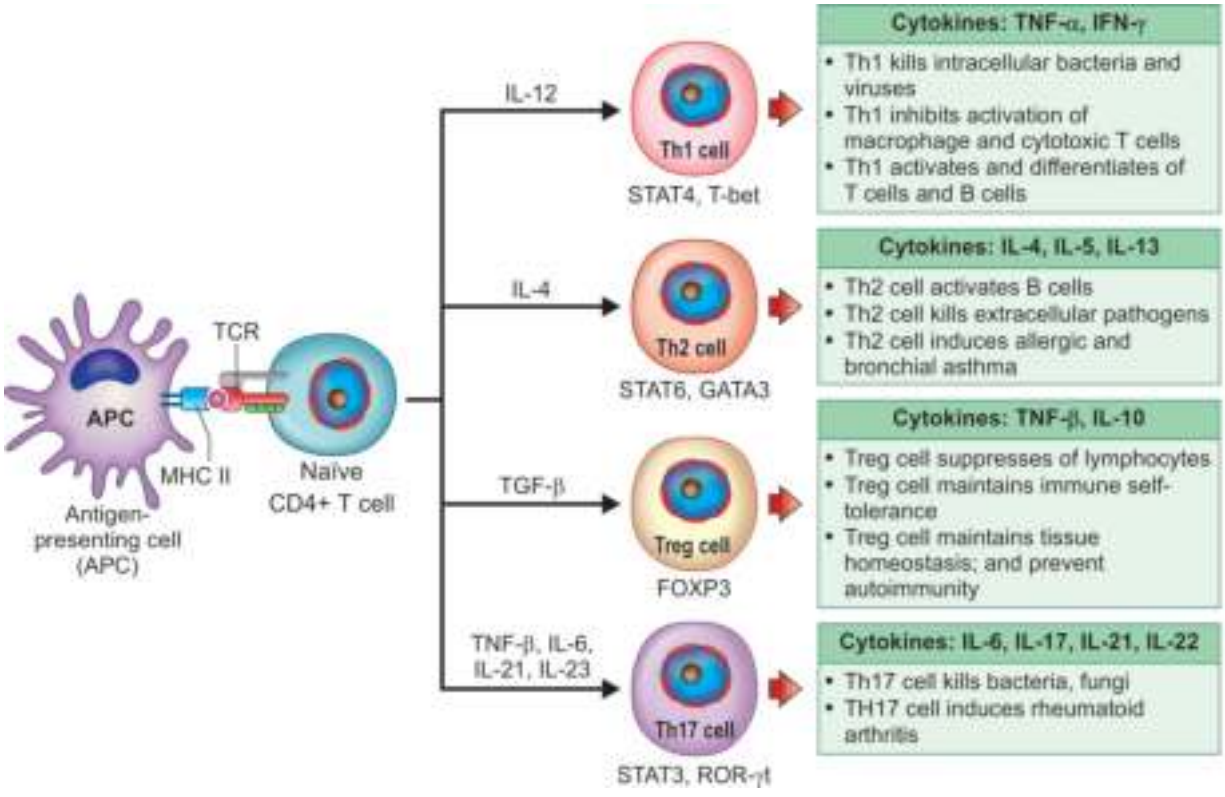

Fig. 4.31: Differentiation of CD+ helper T cell subsets/after activation by antigen-presenting cells, CD4+ helper T cell can differentiate into several subsets: T helper 1 (Th1), T helper 2 (Th2), T helper 17 (Th17) and CD4+ regulatory T (Treg) cells. The differentiation of each helper T cell subset is regulated by different transcription factors.

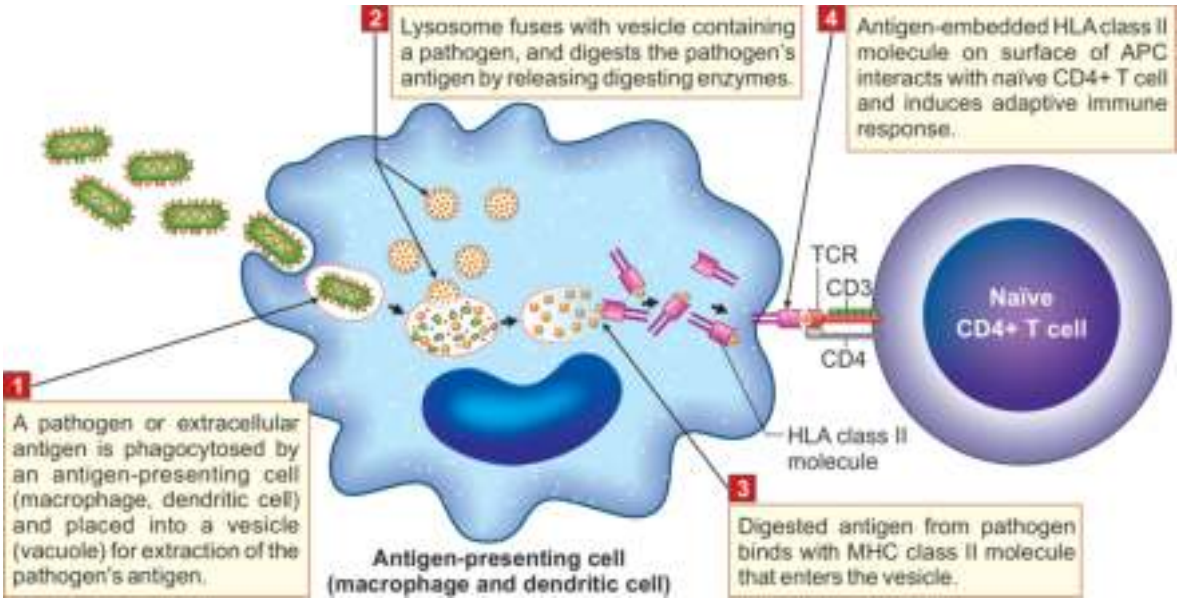

Fig. 4.32: Interaction between macrophages and CD4+ helper T cells. A macrophage takes up antigen, process and presents it with the MHC class II protein. This is recognized by the T cell receptor (TCR) of a specific population of CD4+ helper T cells and CD8+ cytotoxic T cells. CD4+ helper T cell is the key coordinator of adaptive immune response. CD4+ helper T cells play important role in adaptive immunity by activating B cells to form immunoglobulins secreting plasma cells. CD4+ helper T cell activate macrophages that secrete various cytokines. CD4+ helper T cells activate CD8+ cytotoxic T cells that recognize MHC class I molecule on cells that are not part of the immune system and destroy them too. Memory T cells are retained for future use.

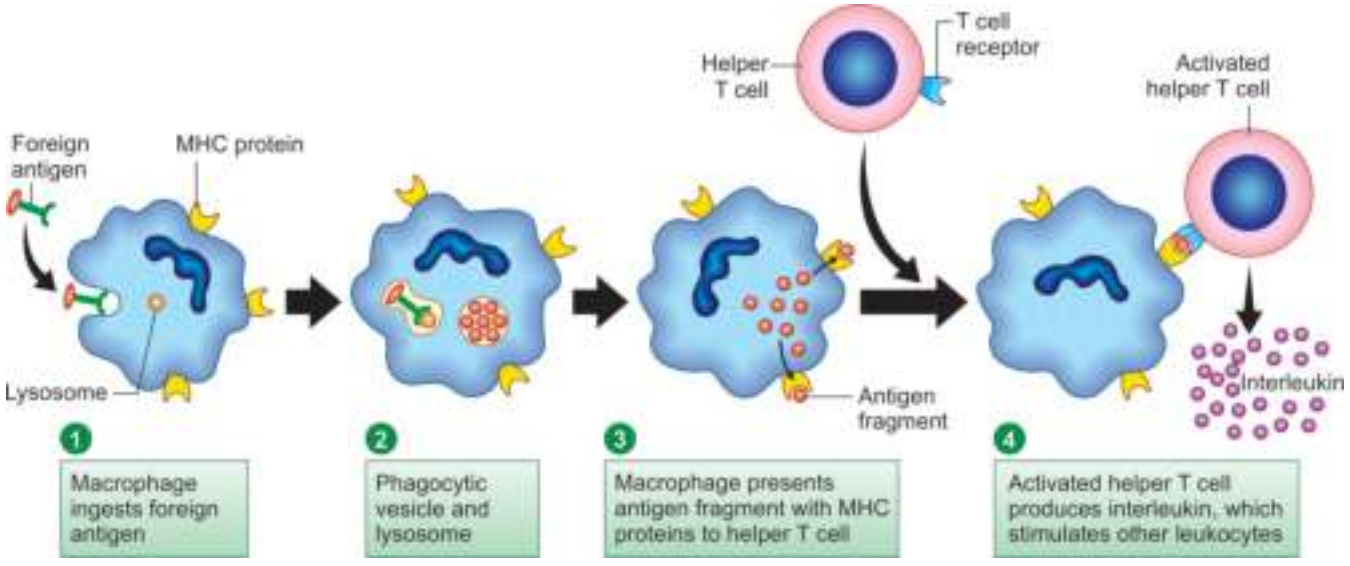

Fig. 4.33: Activation of CD4+ helper T cell by antigen-presenting cell (APC). An antigen-presenting cell (APC), a macrophage displays digested foreign antigen on its surface along with self-major histocompatibility complex (MHC) antigen. A helper T cell is activated by contact with this complex and synthesizes stimulatory interleukins.

cell) subsets, which synthesize cytokines: INF-α and IFN-γ (Th1 cell), IL-4, IL-5 and IL-13 (Th2 cell), IL-6, IL-17 and IL-21, IL-22 (Th17 cell) and TGF-β and IL-10 (Treg cell). CD4+ helper T cell type 1 (Th1) is involved with elimination of intracellular pathogens and is associated with organ-specific autoimmunity. CD4+ helper T cell type 2 (Th2) mounts immune response to extracellular parasites, including helminths, and plays major role in induction and persistence of bronchial asthma as well as other allergic diseases.

- IL-12 is critical cytokine that initiates the downstream signaling pathway to develop Th1 cells. IL-12 is synthesized in large amounts by APCs through the pattern recognition receptors (PRRs). IL-12, in turn induces natural killer cells (NK cells) to produce IFN-γ. IFN-γ is essential for the activation of mononuclear

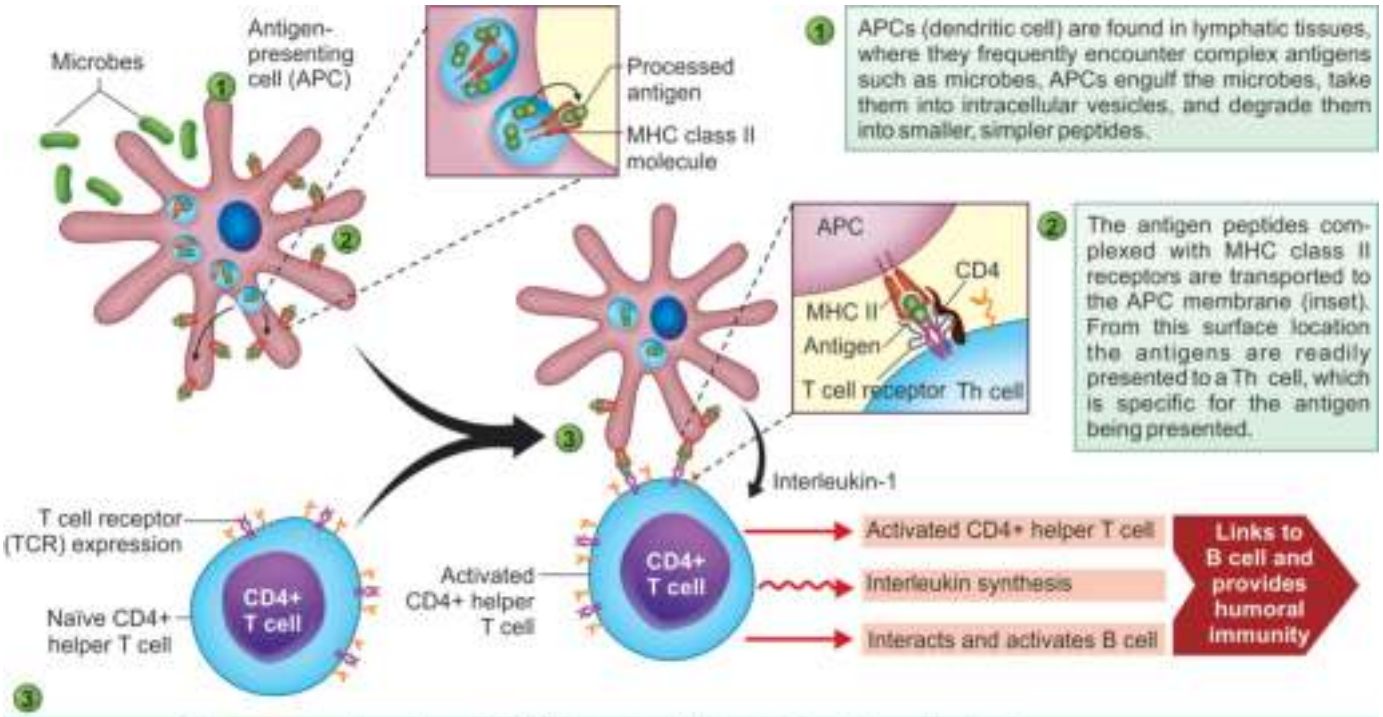

Fig. 4.34: Antigen-presenting cells (APCs) and CD4+ helper T cell interaction inducing adaptive immune response. Naïve CD4+ helper T cells engage MHC class II molecules on antigen-presenting cells (APCs) and become activated. Activated CD4+ helper T cells differentiate into subsets (Th1, Th2, Th17 and Treg cells). Activated CD4+ helper T cells, in turn activate B cells to form antibody secreting plasma cells. Activated CD4+ helper T cells activate CD8+ cytotoxic T cells, which destroy pathogen.

phagocytes, including macrophages, microglial cells, thereby resulting in enhanced phagocytic activity.

- Amplification of T cell response is mediated by growth factor IL-2 within hours of activation of T cells following recognition of antigen by T cell receptor.
- Significance of IL-2 synthesis following tissue rejection is underlined by the effectiveness of drug cyclosporine A, which is widely used to prevent rejection of allogenic transplants. Cyclosporine A blocks the transcription of IL-2 gene, which normally follows T cell activation.

Pathology Pearls: Superantigens Activate Naïve CD4+ Helper T Cell

- Superantigens are present in Staphylococci, Group A Streptococci) and Epstein-Barr virus, that can also activate naïve CD4+ helper T cell by binding to MHC class II molecule on antigen-presenting cells without being processed by APCs, and activate T cells via T cell receptor (TCR).
- Interaction of superantigens and TCR leads to massive influx of potent chemical mediators that can cause blood vessel damage, toxic shock syndrome and multiple organs failure. It is also suggested that superantigens may be implicated in rheumatoid arthritis.
- Whole T cell subpopulations can be activated by superantigens independently of antigen specificity.

CD8+ CYTOTOXIC T CELLS AND CELL-MEDIATED CYTOTOXICITY

Armed CD8+ cytotoxic T cells are essential in host defense against pathogens that reside in the cytosol, the commonest of which are the **viruses**. CD8+ cytotoxic T cells can kill any cell harboring such pathogens by recognizing foreign peptides that are transported to the cell surface bound to MHC class I molecule. CD8+ cytotoxic T cells can kill CSCs and reject tissue grafts. CD8+ cytotoxic T cells kill virus infected host cells by releasing two types of preformed cytokines protein: pore-forming perforin and cytotoxic granzymes.

- **Perforins** are proteins that can punch holes in the membranes of target cells. First the perforins cause ions to leak out of target cells and create a passageway for granzymes to enter. **Granzymes** enter and break down proteins causing death of virus infected cell and CSCs through a process called **apoptosis**. These properties allow CD8+ cytotoxic T cell to attack and destroy any cell that is infected with a cytosolic pathogen.
- A membrane-bound molecule, Fas ligand (FasL) expressed by CD8+ cytotoxic T cells, is also capable of inducing apoptosis by binding to FasR expressed by some target cells. CD8+ cytotoxic T cells also secrete interferon-γ (IFN-γ), which is inhibitor of MHC class I molecule expression and macrophage activation. CD8+ cytotoxic T cells kill virus infected target cells with great precision, sparing adjacent normal cells. This precision is critical in minimizing tissue damage while allowing the elimination of infected cells.

CD4+, CD25+, FOXP3+ REGULATORY T CELLS

CD4+, CD25+, FOXP3+ regulatory T cells (Tregs) are specialized subpopulation of T cells that act to suppress immune response, thereby maintaining homeostasis and involved in self-immunologic tolerance. CD4+ regulatory T cells limit the activation of other CD4+ helper T cells and prevent autoimmune response.

NATURAL KILLER CELLS KILL VIRUSES AND CANCER STEM CELLS

Natural killer cells (NK cells) are derived from large granular lymphocytes. Immunophenotyping of natural killer cells include CD16, CD56 and CD57. NK cells attack viruses and cancer cells.

- NK cells can kill target cells by two major mechanisms: the death receptor and granule-dependent pathways. In both cases, the target cell dies as a result of the activation of a battery of cytotoxic proteases within the target cell, called caspases.
- In the granule-dependent pathway, several proteolytic enzymes called **perforins** and **granzymes** are delivered to the target cells, promoting the activation of a family of death inducing proteases called caspases.
  - Perforin is a pore-forming protein in the plasma membrane of target cell.
  - Granzyme induces cell death mediated CD8+ cytotoxic T cells and natural killer cells.

B CELLS AND HUMORAL ADAPTIVE IMMUNE RESPONSE

B cells have an essential role in host defense via the production of the antibody-mediated immune response to microorganisms. Persons lacking B cells fail to produce antibodies and are prone to serious infectious diseases.

- Major players of humoral immune response are B cells, which develop in the bone marrow and undergo maturation in the spleen. Just like T cells, B cells also learn not to react to body's own antigens, which do not react to self-molecules, hence are eliminated or ignored.
- Similar to T cells, B cells are formed in billions of variations, each carrying a unique surface receptor protein, called B cell receptor (BCR), which are actually membrane-bound immunoglobulins. B cell receptor contains two chains: heavy chains and light chains. The existence of BCR variations means that the body already has all the antibodies, it can possibly synthesize right type of immunoglobulin from the start. For resource management purposes, it makes sense not to produce all of antibodies in large quantity.
- Antigen-binding site on immunoglobulin is made of variable (V), diversity (D), joining (J) protein segments encoded by genes of same name: heavy chains (all three segments) and light chains (V, J segments).
- The majority of mature B cells, namely the follicular B cells circulate and enter into secondary lymphoid tissues/organs, the same locations as mature T cells, where B cells expect encounter with the pathogens. T cells and B cells are usually separated into defined T cell and B cell zones within secondary lymphoid tissues/organs.
- Upon antigen recognition by the membrane-bound receptors, B cells proliferate to increase their numbers and differentiate to secrete their specific antibody as one of the five immunoglobulin classes: IgG, IgA, IgM, IgD and IgE.
- Activated B cells undergo first rounds of proliferation and differentiation, giving rise to the first batch of plasma cells producing mainly IgM and small quantity of IgD antibodies. Some of activated B cells committed to become memory B cells.
- Second batch of plasma cells produces better antibodies and live longer than the first batch. These plasma cells synthesize antibodies of different classes (predominantly IgG) which neutralize the pathogen in many different ways. Upon re-exposure to the pathogen, memory B cells mount a much faster immune response. Plasma cells are formed within hours, producing huge amounts of the best possible antibody within days, destroying the pathogen so quickly that no signs of illnesses are noticeable.

Pathology Pearls: Stages of B Cell Development

- Both B cells and T cells are derived from pluripotent hematopoietic stem cell (HSC) in the bone marrow, which differentiates to lymphoid progenitor cell then to precursor B cells and T cells.
- B cell starts maturation in bone marrow and complete maturation in spleen through various developmental stages: pro-B cell, pre-B cell, immature B cell, naïve B cell and mature B cell.
- Pro-B cells undergo the rearrangement of immunoglobulin heavy chains. Pre-B cells express pre-B cell receptor (BCR) for successful production of a complete heavy chain.
- Signals through the pro-B cell to pre-B cell stage facilitate the survival and proliferation of pre-B cells.
- Pre-B receptor signaling inhibits further heavy locus rearrangement and enforces allelic exclusion.
- The functional rearrangement of immunoglobulin (Ig) light chain genes results in the expression of cell surface IgM of immature B cells.
- Immature B cells arriving in the spleen turnover rapidly and require cytokines and positive signals through B cell receptor for maturation and long-term survival.
- Immature B cells that express autoreactive BCR with a high-affinity change their specificity or immature B cells are deleted (central tolerance) before they leave the bone marrow.
- Receptor editing generates a different light chain and changes the specificity of the BCR.
- B cells that recognize self-antigens in the bone marrow or that fail to generate non-self-reactive BCR might undergo death by apoptosis.
- Mature B cells that recognize self-antigens in peripheral lymphoid tissues in the absence of signals from CD4+ helper T cells become unresponsive (anergy) or undergo death by apoptosis (peripheral tolerance).
- In the follicles of secondary lymphoid organs, naïve B cells recognize rapid proliferation, forming a germinal center.
- Activated B cells in germinal centers differentiate into long-lived antibody secreting plasma cells or memory B cells. B-1 cells are innate lymphocyte subset of B cell lymphocytes that arise early in development.

B CELL ACTIVATION AND DIFFERENTIATION

Mature naïve B cells form a primary follicle in the cortical region of lymph node. When the B cell encounters and binds an antigen, it changes its structure and functions. Interaction of antigen and B cell leads to proliferation of B cell, generating several clones resulting in formation of germinal center. The lymphoid follicle is now called a secondary lymphoid follicle.

- Series of events occur following antigen binding that lead to B cell activation. Ig-α, Ig-β and CD19 are intracellular side chains of the B cell receptors that cluster when two B cell receptors are cross-linked to an antigen.
- BTK, FYN and LYN proteins phosphorylate tyrosine kinase residues on immunoreceptor tyrosine bases activation motif (ITAM) units that lead to synthesis of transcription factors like nuclear factor κB-light chain enhancer of activated B cells (NF-κB), nuclear factor of activated T cells (NFAT cells). NF-κB and NFAT transcription factors increase gene expression coding for cytokines (IL-1, IL-2, IL-6, TNF-α) and upregulation of BCL-2 antiapoptotic cell surface markers.
- Complement fragment C3d can bind an antigen and then can be bound by molecule CD21 complement receptor type 2 (CR2) on a B cell. B cell can also be activated, when B cell has a receptor that is bound to an antigen.
- Activated B cell differentiates into plasma cells that secrete their specific antibody as one of the five immunoglobulin classes: IgG, IgA, IgM, IgD and IgE. Activation of B cells and immunoglobulins secreting plasma cells is shown in Fig. 4.35.

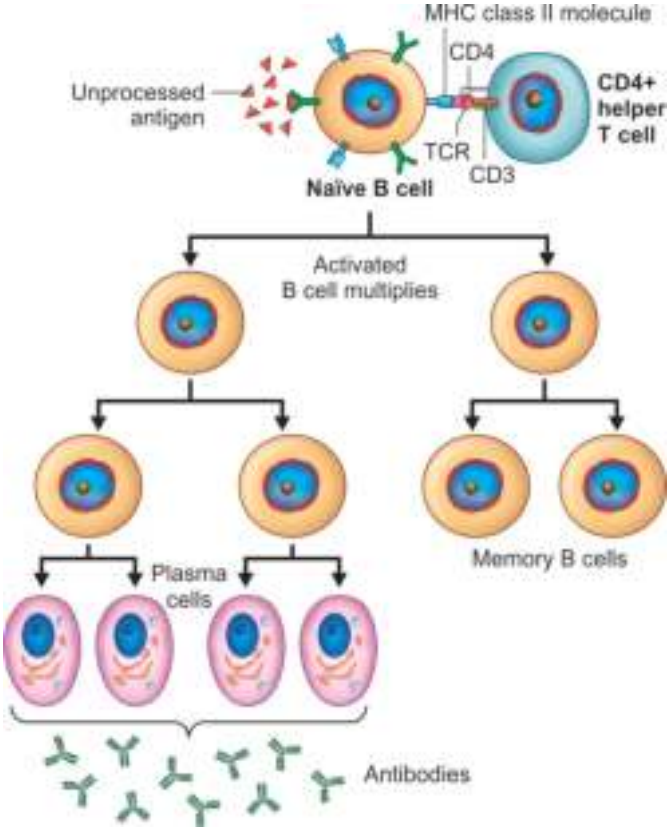

Fig. 4.35: Activation of B cells and immunoglobulins secreting plasma cells. Before a B cell can be activated by CD4+ helper T cell, the B cell must bind to receptor, endocytose and process the same antigen. B cell uses MHC class II molecule to present the processed antigen to CD4+ helper T cell. T cell receptor binds to the MHC class II molecule/antigen complex. There is costimulation of the B cell by CD4+ helper T cell. There is costimulation by cytokines released by CD4+ helper T cell. B cell undergoes proliferation resulting in formation of B memory cells and antibody secreting plasma cells.

- B cell presents an antigen on major histocompatibility complex (MHC) class II molecule to a CD4+ helper T cell. On activation, CD4+ helper T cell expresses CD4L on its surface, which binds CD40 on the B cell. CD40L and CD40 binding leads to expression of a cytokine receptor on B cell and causes T cell to release cytokines IL-4, IL-5 and IFN-γ. The type of cytokine determines what type of antibody the B cell will produce by activation-induced cytidine deaminase. IL-4 and IL-5 cytokines participate in synthesis of IgE. IFN-γ participates in synthesis of IgG.
- CD4+ helper T cell transmits additional signals in the form of interleukins and B cell growth factors. The linked receptors and the chemical stimuli serve to activate B cell. Such activated signals increase in cell metabolism, resulting in cell enlargement, proliferation and differentiation. Immunophenotyping of B cells include CD19, CD20, CD21 and CD22.
- Activated B cell undergoes numerous mitotic divisions, which expand the clone of B cells bearing this specificity and produce memory B cells and antibody secreting plasma cells. Memory B cells are persistent, long-term memory B cells that can react with the antigen on future exposures.
- The plasma cells are short lived, active secretory cells that synthesize and release antibodies. These antibodies (here is IgM) have same specificity as the immunoglobulin (Ig) receptor and circulate in the fluid compartments of the body, where they react with the same antigens and microbes.
- Immunoglobulin is a large Y-shaped protein molecule consisting of four polypeptide chains—two identical light chains and two identical heavy chains bound by disulfide bonds. Each chain of immunoglobulin consists of a variable region (V) and a constant region (C). The variable regions of light and heavy chains with ends form the antigen-binding fragments (Fabs) that bind with a unique specificity to an antigen. The crystalline fragment (Fc) determines the location and function of the antibody molecule. Different immunoglobulin classes engage different mechanisms to neutralize antigen.

SYNTHESIS OF IMMUNOGLOBULIN

Immunoglobulins are synthesized by three mechanisms: (a) T cell-dependent B cell activation and immunoglobulin synthesis, (b) T cell-independent B cell activation and immunoglobulin synthesis, and (c) collaboration of antigen-presenting cells (**APCs**), B cells and T cells and immunoglobulins synthesis. CD4+ helper T cell-dependent and -independent B cell activation and immunoglobulin synthesis are shown in Fig. 4.36A and B.

- In T cell-dependent B cell activation and immunoglobulin synthesis, B cell recognizes and internalizes an antigen and presents it to CD4+ helper T cell that is specific to the same antigen. CD4+ helper T cell interacts with the antigen presented by B cell, which activates and stimulates T cell to induce the production of cytokines, that activate the B cells. The activation of B cell triggers proliferation and differentiation into B cells and plasma cells that produce different classes of antibodies as a result of class switching. Memory B cells are also produced.
- In T cell-independent B cell activation and immunoglobulin synthesis, antigens have repeated epitopes that can induce B cell recognition and activation without involvement of CD4+ helper T cells. A second signal, such as interaction of toll-like receptors (TLRs) with pathogen-associated molecular patterns (PAMPs), is also required for activation of B cell.

CD4+ Helper T Cell-dependent B Cell Activation and Immunoglobulin Synthesis

Costimulatory signaling molecules are needed for B cell activation. Once the antigen is expressed in the membrane of B cells, both B cells and CD4+ helper T cells come in contact with each other that leads to release of cytokines especially IL-1 and IL-6. The collaboration between B cells and CD4+ helper T cells is essential for the initiation of B cell growth and differentiation into immunoglobulins-secreting plasma cells. Immunoglobulin production initiates with IgM. If antigenic stimulus continues, the constant region of IgM is changed to IgG, IgE or IgA but the variable region that binds to the antigen will remain.

CD4+ Helper T Cell-independent B Cell Activation and Immunoglobulin Synthesis

B cells can produce immunoglobulins by antigenic stimulus without the collaboration of CD4+ helper T cells and antigen-presenting cells (APCs). These antigens are present in some bacteria in the form of polysaccharides or lipopolysaccharides but never proteins, which are large polymeric molecules with repeating antigenic determinants. Bacterial antigens can react directly with B cell receptor (BCR) by cross-linking the cell surface immunoglobulin stimulating several BCRs at the same time, and so antigenic stimulus initiates immunoglobulin production especially IgM but not any other immunoglobulin. Once activated the B cell proliferates into antibody secreting plasma cells.

Immunoglobulin Synthesis Through Collaboration of APCs, B Cells and T Cells

Antigens can also bind to antigen-presenting cells (e.g. macrophages and dendritic cells), which express

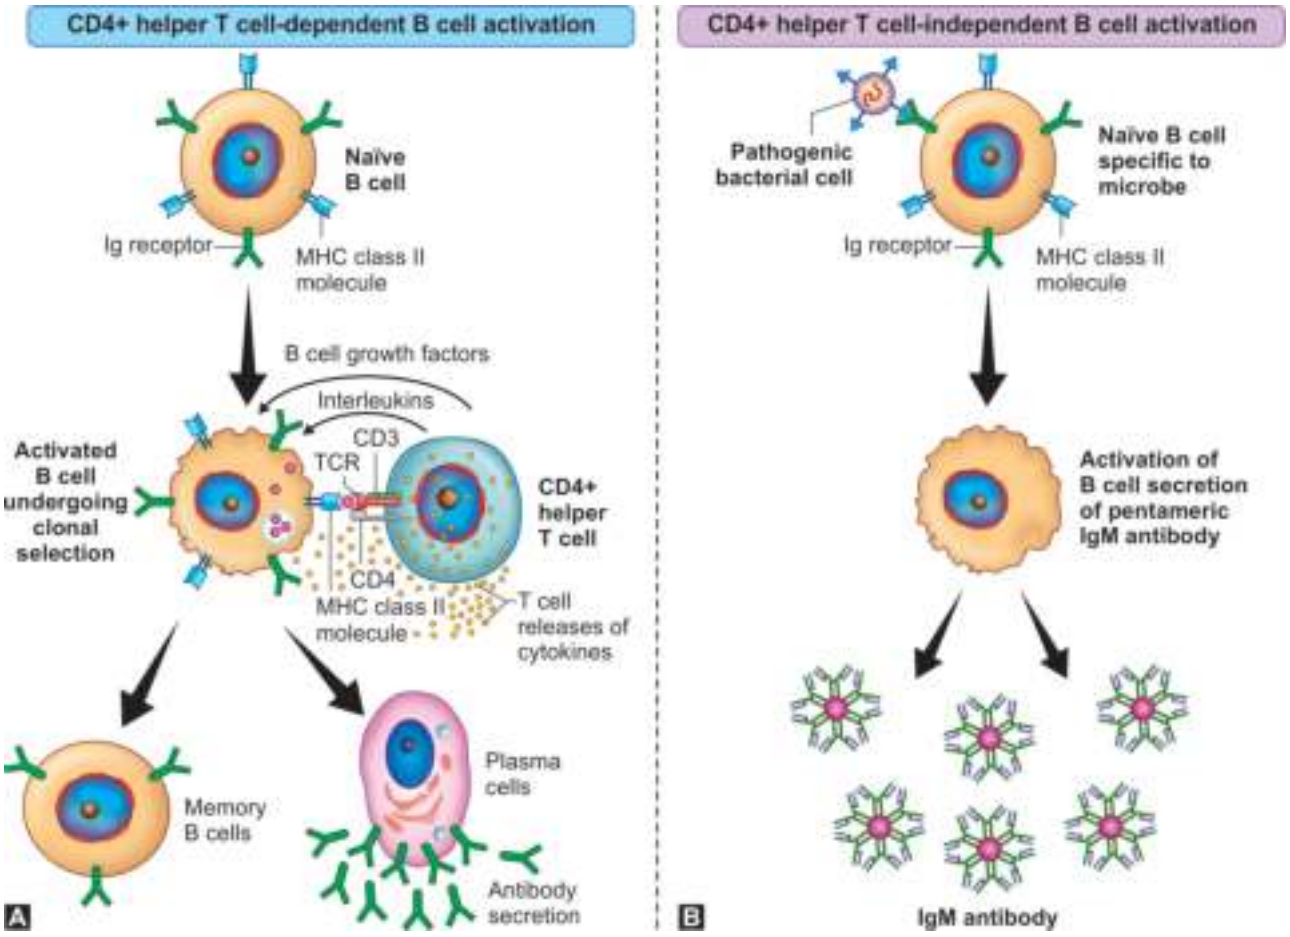

Fig. 4.36A and B: Sequence of events in T cell activation and differentiation into different types of T cells. (A) CD4+ helper T cell-dependent B cell activation: after initially binding an antigen to the B cell receptor (BCR), the B cell internalizes the antigen and presents it on MHC class II. The CD4+ helper T cell recognizes the MHC class II molecule–antigen complex and activates the B cell. As a result, memory B cells and plasma cells are made. (B) CD4+ helper T cell-independent B cell activation: naïve B cell specific to pathogenic bacteria gets activated that results in IgM synthesis.

MHC class II molecule in their membranes. Macrophages and dendritic cells present antigen (epitopes) to the CD4+ helper T cells.

- Antigen is phagocytosed inside a vesicle and transported to the lysosomes, where antigen will be degraded to fragments by different lysosomal enzymes. Fragments of the degraded antigen will bind to MHC (HLA) class II molecule and are transported to the macrophage membrane, where antigenic fragment will be recognized by CD4+ helper T cells. It should be noted that T cell receptor (TCR) cannot recognize antigen, which is not associated with HLA class II molecule.
- Activation of CD4+ helper T cells requires the performance of antigen-presenting cells (APCs) and MHC (HLA) class II molecule. When antigen-presenting cells (APC) and CD4+ helper T cells interact, both cells are activated that synthesize cytokines, which lead to stimulation and clonal proliferation of CD4+ helper T cells. Stimulation of CD4+ helper T cells is mediated by MHC class II molecule and the different epitopes of the same antigen and enhanced by the release of IL-4.
- At this stage, CD4+ helper T cells can stimulate B cells for immunoglobulin production. Some of the B cells are transformed into plasma cells which secrete immunoglobulins, and some other B cells remain as memory B cells. Memory B cells have long life span, i.e. regulated by the BCL-2 gene, which is present only in the memory B cells.

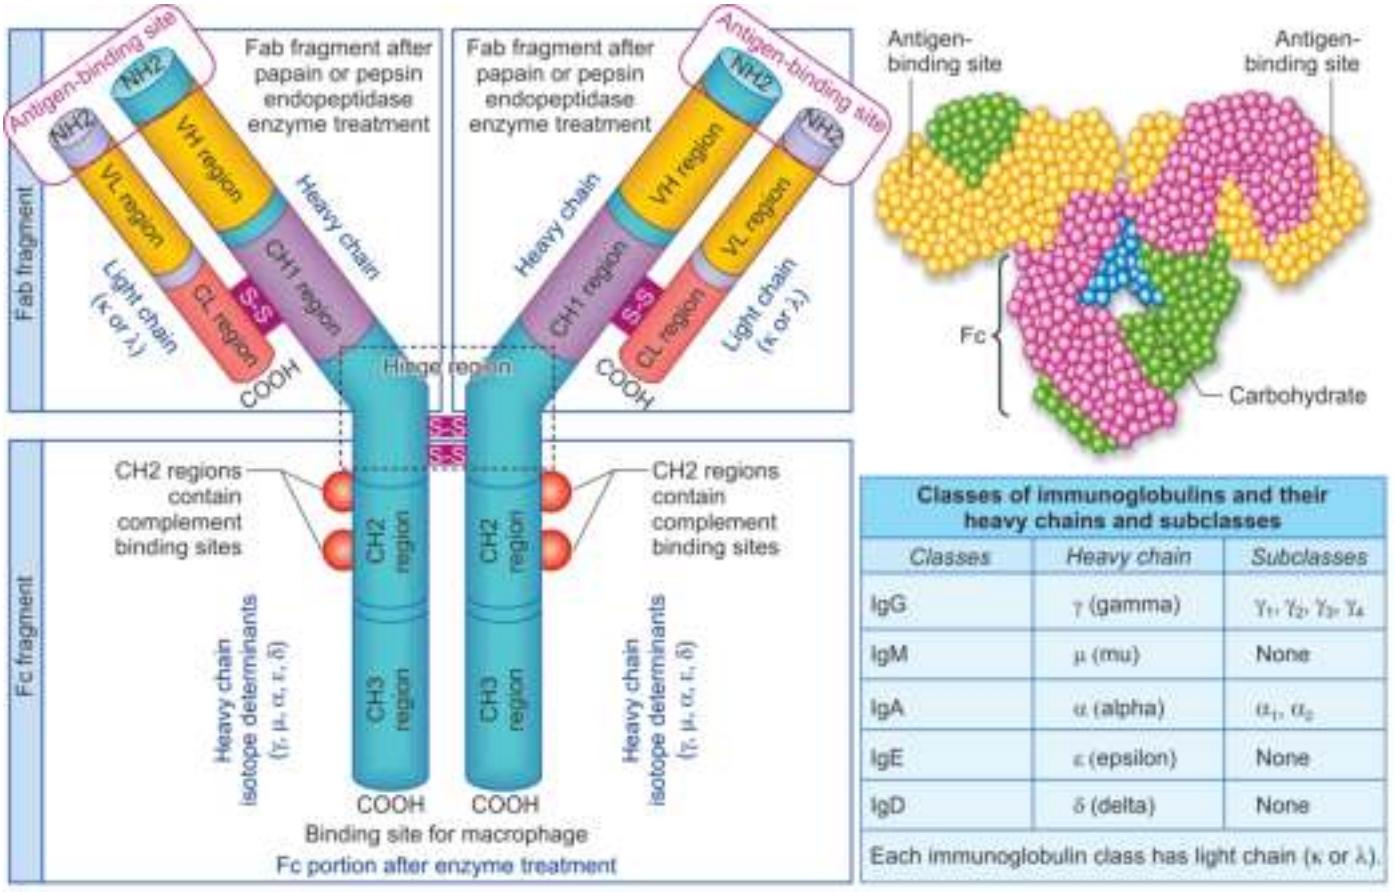
CLASSES OF IMMUNOGLOBULIN

CD4+ helper T cells stimulate B cell differentiation and antibody secreting plasma cells. Plasma cells produce five classes of immunoglobulins (antibodies), which differ in size and function. These include IgG, IgA, IgM, IgD and IgE.

- Depending on the class of immunoglobulin involved, their operations include: agglutination and lysis (IgM), opsonization of pathogens for phagocytosis both directly via Fc receptors and indirectly via

complement system activation by classical pathway, blocking entry the microorganisms from respiratory tract, gastrointestinal tract, eyes and urinary tract (IgA), killing of virus infected cells via antibody-dependent cell cytotoxicity (ADCC) and neutralization of bacterial toxins.

- The Fab (antigen-binding fragment) of antibody binds to specific antigen on the pathogen. The Fc (fragment crystallizable) is identical in all immunoglobulins of the same class/subclass that activates complement system leading to chemotaxis of phagocytes to the site of infection and increased capillary permeability in order to facilitate immunoglobulins passage from the blood circulation to the tissues.
- IgG is present throughout the tissue fluids, which provides long-term immunity. IgA provides protection in body secretions. IgM predominates in plasma. IgD is expressed on B cells as an antigen receptor. IgE binds to tissue cells and induce inflammation. Basic structure of immunoglobulin molecule classes is shown in Fig. 4.37. Characteristics of immunoglobulins' classes are shown in Fig. 4.38. Characteristics of immunoglobulins' classes and their functions are given in Table 4.30.



Classes of immunoglobulins and their heavy chains and subclasses

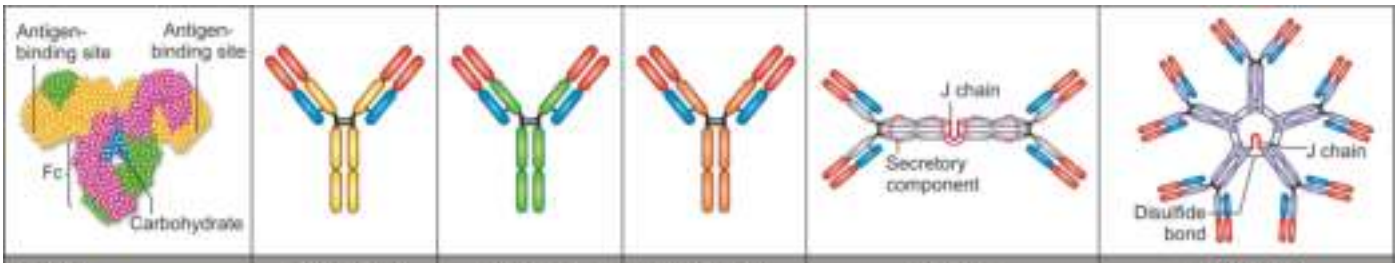
Classes	*Heavy chain*	*Subclasses*
IgG	γ (gamma)	γ_1, γ_2, γ_3, γ_4
IgM	μ (mu)	None
IgA	α (alpha)	α_1, α_2
IgE	ε (epsilon)	None
IgD	δ (delta)	None

Each immunoglobulin class has light chain (κ or λ).

Immunoglobulin structure

1. Immunoglobulin consists of 2 heavy chains and 2 light chains joined together by disulfide bonds.
2. Each heavy chain consists of a variable region (VH) and constant region encompassing functional domains named CH1, CH2 and CH3. Each light chain has a variable region (VL) and a constant region (VC).
3. The carboxy (–COOH) end of both the heavy chains and light chains is highly conserved, the amino acid sequence is very similar for all immunoglobulins of the same class: IgG, IgM, IgA, IgE or IgD.
4. Both the heavy chains and light chains at the amino (–NH2) end of proteins are highly variable, which allows for the development of specific antigen-binding sites.
5. Enzyme will cleave the immunoglobulin molecule at several points in the hinge region, resulting in three fragments: one Fc fraction crystallizable and two Fab fragments (antigen-binding fraction). Hinge region is a flexible amino acid stretch in the central portion of the heavy chains of the IgG or IgA immunoglobulin classes, which link these two chains by disulfide bonds.
6. Papain cleaves the heavy chain CH2 domains above the disulfide bond that connect heavy chains and yields three different fragments. Pepsin endopeptidase enzyme cleaves IgG heavy chains at a point below the disulfide bond that links two heavy chains. The resulting fragment consists of two Fab fragments linked together by heavy chain disulfide bonds.

Fig. 4.37: Basic structure of immunoglobulin molecule. Immunoglobulin contains two identical heavy chains and two identical light chains. Bonded together by disulphide bonds, it forms the Y-shaped molecule.



Forms	Monomer	Monomer	Monomer	Dimer	Pentamer

Triggers mast cell degranulation	–	–	Present	–	–

Fig. 4.38: Characteristics of immunoglobulin classes. IgG is most abundant immunoglobulin in serum and extracellular fluids, which combats pathogens and toxins within body tissues. IgG crosses placenta. IgA is most abundant immunoglobulin in mucous membranes, which protects external surfaces of the body. IgM is the first immunoglobulin produced during an immune response, which is present both in fluids and secretions. IgD immunoglobulin is found on the surface of B cell plasma membrane. IgA and IgM have an additional component referred to as the secretory component, which is required to transport across the epithelial cell barrier. IgE mediates immediate hypersensitivity reactions.

Table 4.30 Characteristics of immunoglobulins' classes and their functions

Characteristics	IgG	IgD	IgE	IgA	IgM
Composition	Monomer	Monomer	Monomer	Dimer, monomer, secretory	Pentamer
Heavy chains	Gamma (γ)	Delta (δ)	Epsilon (ε)	Alpha (α)	Mu (μ)
Subclasses	IgG1, IgG2, IgG3, IgG4	Not applicable	Not applicable	IgA1, IgA2	Not applicable
Number of antigen binding sites	2	2	2	2 or 4	10
Molecular weight (daltons)	150,000	180,000	200,000	385,000	900,000

Contd...

Table 4.30 Characteristics of immunoglobulins' classes and their functions (*Contd...*)

Characteristics	IgG	IgD	IgE	IgA	IgM
Present in	Blood, lymph and intestine	Surface of receptor on B cells	Basophils and mast cells	Glandular secretions (sweat, tears, saliva, mucus of gut, and digestive juices)	Blood and lymph
Total antibody % in serum	80%	0,001%	0.002%	13%	6%
Average life span in serum (days)	23	3	2.5	6	5
Crosses placenta	Yes	No	No	No	No
Fixation of complement or not	Yes	No	No	No	Yes
Binding of immunoglobulin to various cells	Phagocytes	Not applicable	Mast cells and basophils	Epithelial cells	Not applicable
Biological functions	Long-term immunity memory antibody neutralizing toxins by activating complement and viruses	Receptor on B cells for antigen recognition	Antibody against allergy and parasitic infections	Secretory antibody on mucous membrane giving local protection against pathogens	First antibody to be secreted synthesized in response to antigen and serving as B cell receptor

Pathology Pearls: Structure of Immunoglobulin

Heavy Chains and Light Chains in Immunoglobulin

- Immunoglobulin contains two identical heavy chains and two identical light chains, where the light chains can consist of either a κ- or λ-chain.
- The hinge region is a flexible amino acid stretch in the central part of the heavy chains of the IgG and IgA classes, which links these two heavy chains and light chains by disulphide bonds.
- Heavy chain isotopes include monomer (IgG), dimer (IgA) and pentamer (IgM). J chain connects monomers to form dimers and pentamers. J chains are synthesized by B cells and plasma cells. Secretory piece might be attached to a dimer is it passes through epithelial cells commonly found in saliva and tears.
- Papain digests IgG into two Fab fragments, each of which can bind antigen and a single Fc segment.

Variable and Constant Regions in Immunoglobulin

- Heavy and light chains of immunoglobulins can be separated functionally into variable (V) domains that bind antigens and constant (C) domains that specify effector functions such as activation of complement system or binding to Fc receptors.
- Constant regions contain the same amino acid sequences, while variable regions have different amino acid sequences.
- Variable domains are created by means of a complex series of gene rearrangement events, and can then be subjected to somatic hypermutation after exposure to antigen to allow affinity maturation.

Framework and Hypervariable Regions of Immunoglobulin

- Variable region of immunoglobulin is composed of two parts: the framework and hypervariable region. The framework region is structurally similar. But hypervariable regions are extremely diverse.
- Hypervariable regions allow for the synthesis of variety of antibodies, and in turn allow the immune system to recognize and protect against a wide variety of antigens.

IgG Immunoglobulin

IgG immunoglobulin has a molecular weight of 150,000 daltons with two antigen-binding sites, which makes up 75% of antibodies that is present throughout the tissue fluids and bloodstream.

- IgG has four subclasses: IgG1, IgG2, IgG3 and IgG4, which differ in constant regions. IgG serves as opsonin and activates classical complement system pathway. IgG has two binding sites, which activates complement system.
- Of all the immunoglobulins, only IgG can cross placental barrier, which provides immunity to fetus. IgG provides long-term immunity, which is predominant antibody of the secondary response.
- Decreased levels of IgG can be manifested in primary or secondary IgG deficiencies. Significant increase in IgG levels occur in the settings of inflammatory diseases (hepatitis, rubella, and infectious mononucleosis), collagen disorders (rheumatoid

Table 4.31 Properties of human IgG subclasses

Property	IgG1	IgG2	IgG3	IgG4
Normal serum concentration (mg/dl)	540 mg/dl	210 mg/dl	58 mg/dl	60 mg/dl
Half-life in days	21	20	7	21
Fc binding capacity on phagocytes	+	Absent	+	+/–
Activation of classical complement pathway	++	+	+++	–
Capacity to cross placenta	+++	+	++	+/–
Antibody activity	Protein antigens (e.g. diphtheria and tetanus)	Protein antigens (e.g. Pneumococcus, *Haemophilus influenzae*)	Protein antigens (e.g. diphtheria and tetanus)	Protein antigens (e.g. Pneumococcus, *Haemophilus influenzae*)

arthritis and systemic lupus erythematosus) and hematologic disorders (polyclonal gammopathy, monoclonal gammopathy, monocytic leukemia and Hodgkin disease). Properties of human IgG subclasses are given in Table 4.31.

IgE Immunoglobulin

IgE immunoglobulin has molecular weight of 200,000 daltons with two antigen-binding sites. IgE is present in small amount and largely bound to mast cells and to basophils in tissues. Subsequent exposure to antigen leads to release of histamine resulting in type 1 hypersensitivity reactions. IgE production is induced by IL-4. IgE immunoglobulin mediates immediate hypersensitivity reactions that are responsible for symptoms of hay fever, bronchial asthma, hives and anaphylactic shock. IgE binds to Fc receptors on the membranes of blood basophils and tissue mast cells. Cross-linkage of Fc receptor bound IgE molecule by antigen induces degranulation of basophils and mast cells. A variety of pharmacologically active chemical mediators present in the granules are released giving rise to clinical manifestations.

IgD Immunoglobulin

IgD immunoglobulin is monomer with molecular weight of 180,000 daltons and present in small amount in blood. IgD is expressed on B cells as an antigen receptor, which participates in activation of B cells. IgD is found alongside IgM antibody, that signals maturation of B cells.

IgA Immunoglobulin

IgA immunoglobulin has molecular weight of 385,000 daltons with four antigen-binding sites, which has two subclasses: IgA1 and IgA2, which differ in constant region. IgA provides protection in body secretions and bloodstream.

- IgA serves as opsonins for neutrophils, eosinophils and some macrophages. It is major class of antibody in the mucous membranes in gastrointestinal tract, respiratory tract, saliva and tears. IgA does not activate complement system and its half-life is six days.
- Decreased levels of IgA can be manifested in primary or secondary IgG deficiencies, which can occur in the settings of infectious diseases (tuberculosis and actinomyces), collagen disorders (rheumatoid arthritis and systemic lupus erythematosus), hematologic disorders (polyclonal gammopathy, monoclonal gammopathy) and liver diseases (chronic active hepatitis and Laënnec's disease).

IgM Immunoglobulin

IgM is the first class of antibody to be formed by B cell in response to an initial encounter with an antigen (e.g. primary immune response), which has molecular weight of 900,000 daltons with 10 antigen-binding sites predominantly present in plasma.

- IgM penetrates poorly into the tissues on account of larger size, which works against carbohydrate and lipid antigens.
- IgM neutralizes microorganisms especially viruses in intravascular compartments aided by its 10 binding sites.
- IgM activates complement system and lyses microorganisms or remove antigen–antibody complexes by complement receptors on phagocytic cells.

Pathology Pearls: Free Immunoglobulin Functions

Free immunoglobulin functions have binding sites that affix tightly to an antigen and hold it in place for agglutination of bacteria and viruses, opsonization of bacteria to facilitate their subsequent phagocytosis by phagocytes (neutrophils and macrophages), complement fixation (activation of complement system), agglutination of foreign cells, and neutralization (block attachment) of viruses and toxins released by bacteria. Summary of the

actions of free immunoglobulins is shown in Fig. 4.39A to F. Specific immunoglobulins used in diagnosis are given in Table 4.32.

Opsonization

Antigen (microbe) is covered with antibodies that enhances its ingestion and lysis by phagocytic cells.

Neutralization

IgG inactivates viruses by binding to their surface and neutralize toxins by blocking their active sites.

Agglutination

- Antibodies cause antigens (microbes) to clump together. IgM is more effective than IgG (bivalent).
- Agglutination of red blood cells (hemagglutination) is used to determine ABO blood types and to detect influenza and measles viruses.

Complement System Activation

Both immunoglobulins (IgG and IgM) trigger the complement system which results in cell lysis and inflammation.

Antibody-dependent Cell Cytotoxicity (ADCC)

- Antibody coated target cell is recognized by Fc receptors of lymphoid cells.
- Binding occurs between lymphoid and antibody coated target cells leads to lysis of target cells by natural killer cells. This mechanism is known as antibody-dependent cytotoxicity.

Table 4.32 Specific immunoglobulins used in diagnosis

Feature	IgG	IgM	IgA
Agglutination	+	+++	Negative
Complement fixation	+	+++	+
Time of appearance after first exposure to antigen	3–7 days	2–5 days	3–7 days
Time to reach peak titer (days)	7–21 days	5–14 days	7–21 days

PRIMARY AND SECONDARY IMMUNE RESPONSES

The first exposure to a pathogen or antigen to the immune system produces a primary immune response with a gradual increase in antibody titer low intensity. Subsequent exposure to the same pathogen or antigen elicits a highly intensified secondary immune response or anamnestic response due to the presence of memory of the first encounter. Primary and secondary immune responses are carried out with the help of T cells and B cells. Primary and secondary immune responses are shown in Fig. 4.40. Differences between primary and secondary immune responses are given in Table 4.33.

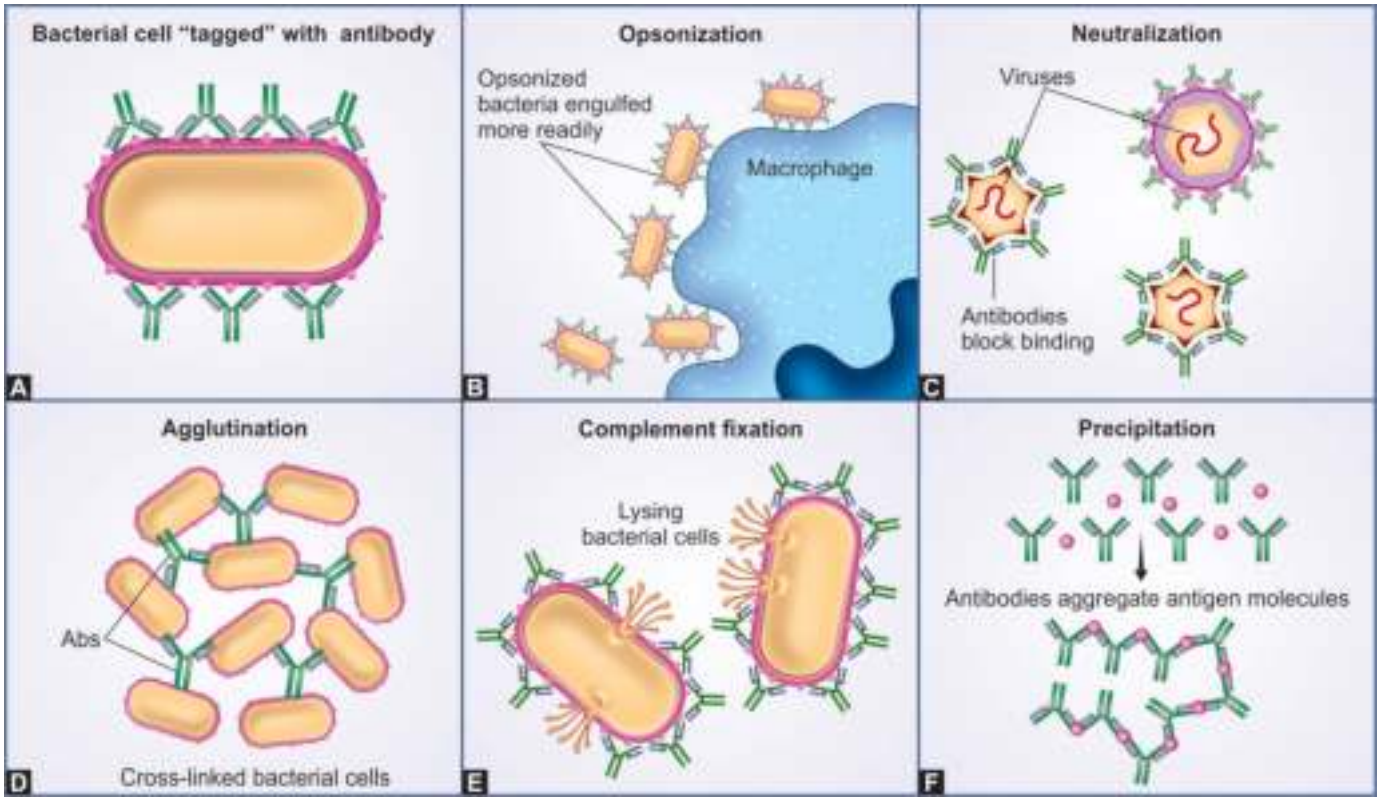

Fig. 4.39A to F: Functions of immunoglobulins. Immunoglobulins are glycoprotein molecules produced by plasma cells. Immunoglobulins act by recognizing and binding to specific antigens, such as bacteria or viruses, and aiding in their destruction by opsonization, neutralization, agglutination, and complement activation.

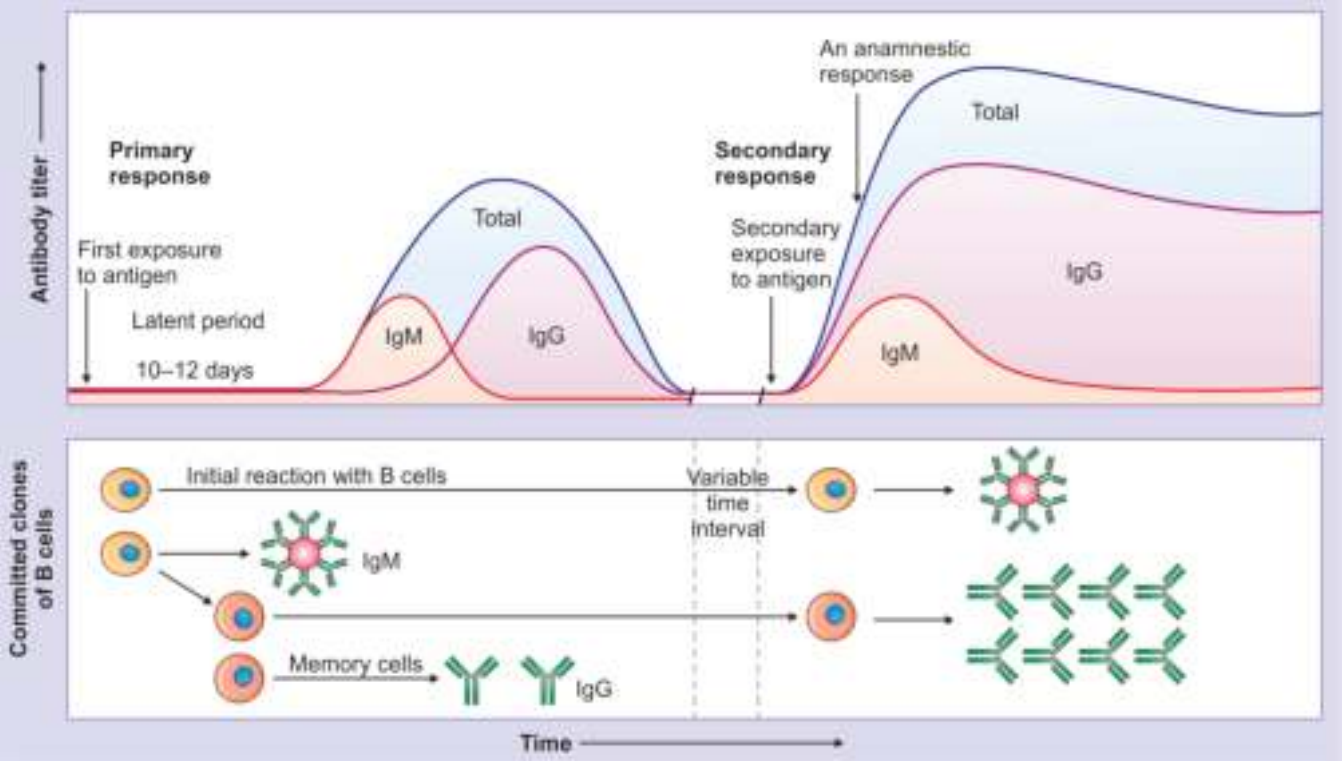

Fig. 4.40. Primary and secondary immune responses. The pattern of antibody titer and subclasses as monitored during initial and subsequent exposure (top). A view of the B cell responses that account for this pattern (bottom). It shows clonal selection by production of memory B cells and the predominant antibody class occurring during first and second contact with antigen. Note that residual B memory cells remaining from the primary response are ready to act immediately, which produces the rapid rise of antibody levels in the secondary period.

Table 4.33 Differences between primary immune response and secondary immune response

Primary Immune Response	Secondary Immune Response
First exposure to antigen results in synthesis of IgM	Second exposure to same antigen results in synthesis of IgG
Animal takes longer duration to respond	Animal takes shorter duration to respond
Response declines rapidly	Response lasts for longer duration
Immune response feeble	Immune response strong

Primary Immune Response

When an antigen is presented to the immune system for the first time, a primary immune response is produced in the lymph nodes and spleen. Memory B cells and T cells are produced during the primary immune response, which is characterized by slow immune response in which characterized by slow short-lasting immune response, IgM is predominating over IgG. Memory cells will remember each epitope's structure of antigen for future infections.

Secondary Immune Response

When an individual has been in contact with any antigen, and has produced memory B cells, if the same antigen enters host again, a secondary immune response is produced in the bone marrow followed by the lymph nodes and spleen. Secondary immune response is faster, more effective and long-lasting. During secondary immune response IgM levels are same as in primary immune response. But IgG levels are much higher and remain longer. Other immunoglobulins are also produced, such as IgA and IgE in the secondary immune response.

Pathology Pearls: Decline in Immune Responses and Immunologic Memory

- CD4+ regulatory T cells (Treg cells) help to end an immune response. After elimination of infectious microbe, majority of activated CD4+ helper T cells undergo apoptosis thus returning the immune system to its basal state called homeostasis.
- Decline of immune response occurs due to cessation of essential stimuli by infectious microbe. Activation of lymphocytes results in generation of long-lived memory cells which may survive for years after the injurious microbe.
- Immunological memory is the ability of the immune system recognize an antigen that has previously encountered and initiate quick and robust immune response.

SELECTED MONOCLONAL ANTIBODY-BASED DRUGS

Monoclonal antibodies (MABs) are pure forms of immunoglobulins produced in hybridoma cells, which may be tailored to high specifications and have numerous applications in medicine and research.

- Monoclonal antibodies can be hybridized with plant or bacterial toxin to form immunotoxin complexes that attach to a target cell and poison it. The most exciting prospect of this therapy is that it can target a specialized cancer stem cells and spare normal cells.
- Monoclonal antibody-based drugs are currently employed in the treatment of breast carcinoma, colorectal carcinoma, lung carcinoma, non-Hodgkin's lymphoma (NHL) and acute myelogenous leukemia. Selected monoclonal antibody-based drugs used in various disorders are given in Table 4.34.

Table 4.34 Selected monoclonal antibody-based drugs used in various disorders

Chemical Name of Drugs	Used in Treatment of Disorder
Transtuzumab	Breast carcinoma
Rituximab	Non-Hodgkin's lymphoma
Bevacizumab	Colorectal carcinoma and lung carcinoma
Ganitumab	Acute myelogenous leukemia
Omalizumab	Bronchial asthma
Infliximab	Crohn's disease
Palivizumab	Respiratory syncytial virus

At the end of a generic name, –mab indicates that the drug is a monoclonal antibody.

VACCINES AND IMMUNIZATION

Immunization is a process by which a person becomes protected against a specific disease through vaccination without becoming infected, which is based on the property of 'memory' of the immune system. **Edward Jenner** showed resistance to the specific disease because of presence of memory cells in cases of smallpox, which increases herd immunity, protection provided by mass immunity in a population.

- Vaccine is administered through needle injections or oral route to stimulate the body's immune response against diseases. Boosters (additional doses) are often required. Vaccination is performed for therapeutic purpose. Vaccination of patients at high-risk group requires specific vaccinations is given in Table 4.35.
- Active immunization is synonymous with vaccination and provides an antigenic stimulus that does not cause disease but can produce long-lasting, protective immunity.
- In passive immunization, preformed serum globulins and specific immune globulins pooled from donated serum are administered to achieve quick immune response in patients at risk for prevention of infection. Antiserum and antitoxins from animals are occasionally used. Antitoxin is administered against snake venom.
- Genetic engineering vaccine preparation techniques include cloning of antigens, recombinant attenuated microbes, and DNA based vaccines. Recombinant DNA technology has allowed the production of antigenic polypeptides of pathogen in bacteria or yeast on large scale, e.g. hepatitis B vaccine, which is prepared from yeast.

Table 4.35 Vaccination of patients at high-risk group require specific vaccinations

Chronic Medical Conditions related to Heart, Respiratory System, Kidneys and Liver	
▪ Pneumococcal polysaccharide vaccine	▪ Influenza vaccine
Immunosuppression State	
▪ Pneumococcal polysaccharide vaccine	▪ Influenza vaccine
Splenectomy or Spleen Dysfunction	
▪ *Haemophilus influenzae* type B vaccine (Hib vaccine) ▪ Pneumococcal polysaccharide vaccine	▪ Influenza vaccine ▪ Meningococcal C vaccine, then A, C W135, Y one month later
Hemodialysis of Patients	
Hepatitis B vaccine (HBV)	
Hemophilic Patients	
▪ Hepatitis B vaccine	▪ Hepatitis A vaccine
Injecting Drug Addicts	
▪ Hepatitis B vaccine	▪ Hepatitis A vaccine
Homosexual Men	
▪ Hepatitis B vaccine (HBV)	▪ Hepatitis A vaccine (HAV)

Pathology Pearls: Vaccination

- Live attenuated vaccines should not be used in immunocompromised patients.
- An attenuated vaccine contains microbes that replicate in host tissues but do not usually cause disease, e.g. polio live vaccine. Disease can occur in immunocompromised individuals (e.g. AIDS).

- An inactivated killed vaccine contains microbes that are unable to replicate, hence safe to use in all patients (e.g. polio, HAV and cholera vaccine).
- A **toxin** such as tetanus toxin is active and immunogenic and causes disease. A toxoid (e.g. tetanus toxoid) used in vaccination is inactive but is still immunogenic. Formalin is used for inactivation (diphtheria, pertussis and tetanus).
- Immunity to the polymer of ribose and ribitol-5-phosphate (PRP) capsule of *Haemophilus influenzae* is T cell-independent and the immune response is poor.
- The polymer of ribose and ribitol-5-phosphate (PRP) conjugated to tetanus toxoid is converted to a T cell-dependent antigen and is immunogenic as a conjugate vaccine (*Haemophilus influenzae* type B vaccine (Hib vaccine).

VACCINES

Vaccines help and protect children and adolescents from serious, often fatal illnesses.

- First generation vaccines are prepared by use of live and weakened or killed pathogens. Examples are smallpox vaccine and polio vaccine.
- Second generation vaccines are prepared by use of defined protein antigens or recombinant protein antigens such as hepatitis B surface antigen.
- Third generation vaccines are prepared from DNA that codes for specific proteins from a pathogen.

VACCINES PREPARATION

Vaccine is a preparation of antigenic proteins of pathogens or inactivated/weakened pathogens is introduced into the body. The antibodies produced against these antigens would neutralize the pathogen during actual infection.

- The vaccines also generate memory B cells and T cells that recognize the pathogen quickly on subsequent exposure.
- Louis Pasteur worked on cholera vaccine and later developed a vaccine against rabies. Other vaccines developed include diphtheria, tetanus, pertussis (whooping cough), tuberculosis (BCG) and hepatitis B vaccine.
- There is no effective vaccine in newly emergent diseases such as HIV/AIDS and malaria. Immunotherapeutic vaccines for malignant tumors—critically are needed as therapies.
- Strategies in vaccine design are shown in Fig. 4.41A to C. Comparison of attenuated vaccine, inactivated vaccine and DNA vaccine is shown in Table 4.36.

Pathology Pearls: Types of Vaccines

Live-attenuated Vaccines

Live-attenuated vaccines are prepared from weakened attenuated cells or viruses that are able to reproduce but have lost virulence.

Killed or Inactivated Vaccines

Killed vaccines are prepared by inactivation of viruses that do not reproduce disease but are antigenic.

Toxoid Vaccines

Toxoid vaccines are prepared by acellular or subunit components of microbes such as surface antigens or neutralized toxins.

DNA Vaccines

- There is new approach to immunization and immunotherapy by injecting piece of DNA containing the gene for the antigen of interest.
- There is generation of desired immune response (CD4+ helper T cells, CD8+ cytotoxic T cells, and B cells).
- Global use of DNA vaccines needs population safety.

DNA VACCINE

Vaccines against infectious agents excel at inducing antibodies and provide immune protection against most viruses and bacteria. Exceptions are intracellular organisms such as *Mycobacterium tuberculosis*, malarial parasite, *Leishmania donovani*, and HIV-protection depends more on cell-mediated immunity. There is new approach to immunization and immunotherapy by injecting piece of DNA containing the gene for the antigen of interest. There is generation of desired immune response (CD4+ helper T cells, CD8+ cytotoxic T cells, and B cells). Global use of DNA vaccines needs population safety.

Manufacture of DNA Vaccine

Direct introduction of a plasmid DNA encoding an antigenic protein is expressed within cells of the host. Naked DNA is simply DNA sequences inserted into bacterial plasmids (simple, extrachromosomal rings of DNA found in bacterial cells) and injected into the host. It is neither a chemical formulation nor a viral coat or envelope structure surrounds it. Preparation of DNA vaccine is shown in Fig. 4.42A to E. Currently approved bacterial vaccines are given in Table 4.37. Currently approved viral vaccines are given in Table 4.38.

- **Isolation of DNA:** DNA sequence coding for a specific protein is isolated from the genome of the infectious organism.

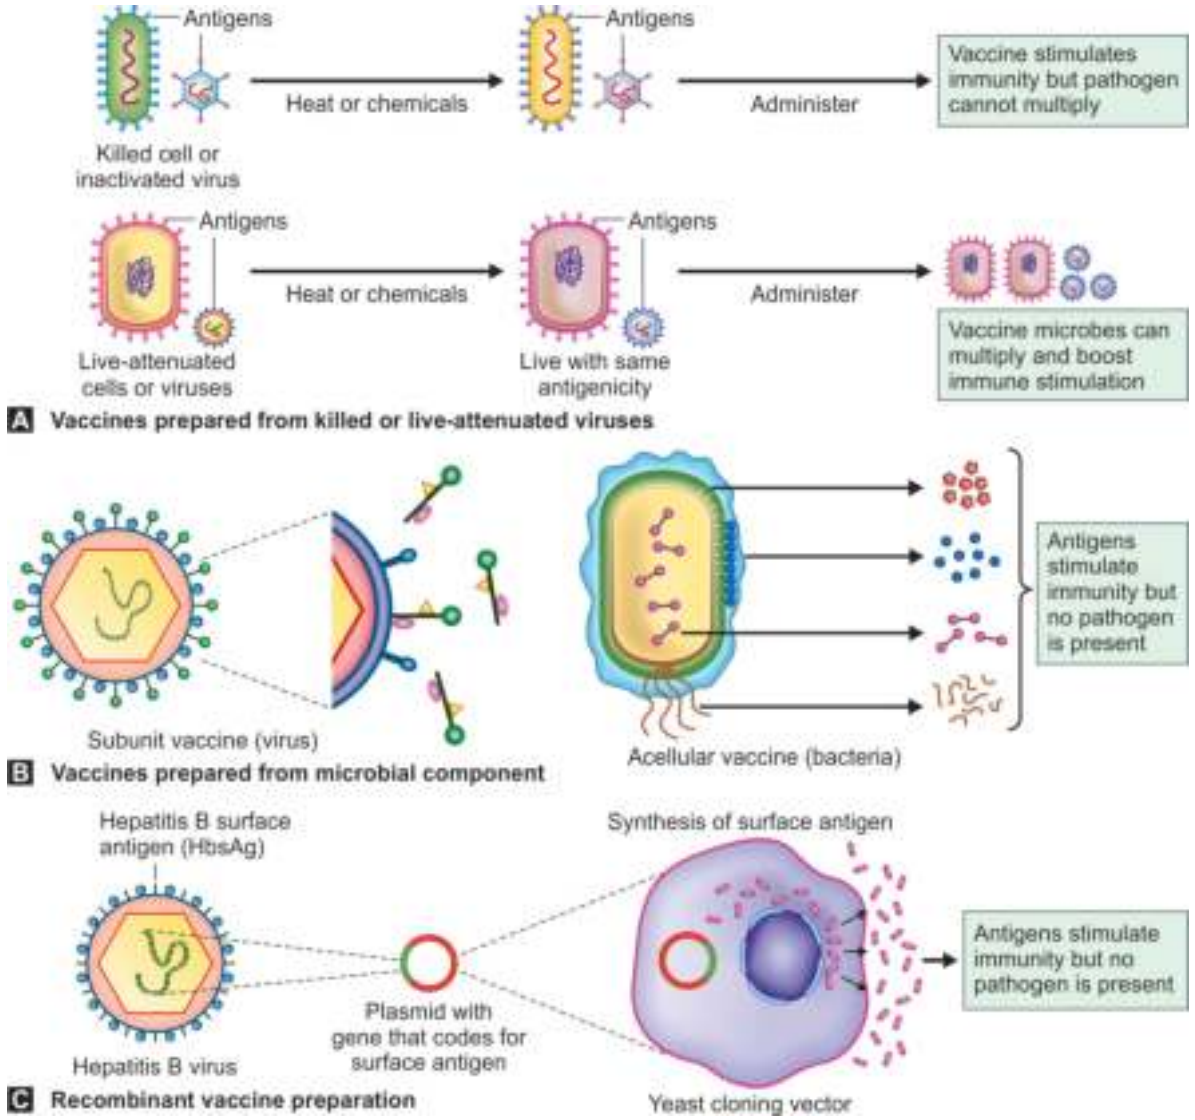

Fig. 4.41: Strategies in vaccine design. (A) Whole cell or viruses are killed or attenuated, (B) a cellular or subunit vaccines are prepared by disrupting the microbes to release various molecules or cell parts that may be isolated and purified, (C) recombinant vaccines are prepared by isolating a gene for the antigen from the pathogen (e.g. hepatitis B virus) and splicing into a plasmid. Insertion of the recombinant plasmid into a cloning host (yeast) leads to increased synthesis of viral surface antigen for vaccine preparation.

Table 4.36 Comparison of attenuated vaccine, inactivated vaccine and DNA vaccine

Characteristics	Attenuated Vaccine	Inactivated (Killed) Vaccine	DNA Vaccine
Production	Virulent human pathogen cultured through different hosts	Inactivation of virulent pathogen by chemicals, irradiation with γ-rays	Easily manufactured and purified
Booster dose requirement	Generally requiring only, a single booster	Requiring multiple boosters	Single injection of DNA vaccine sufficient
Relative stability	Less stable	More stable	Highly stable
Type of immune response	Humoral and cell-mediated immune response	Mainly humoral response	Humoral and cell-mediated immune response
Reversion tendency	May revert to virulent form	Cannot revert to virulent form	Cannot revert to virulent form

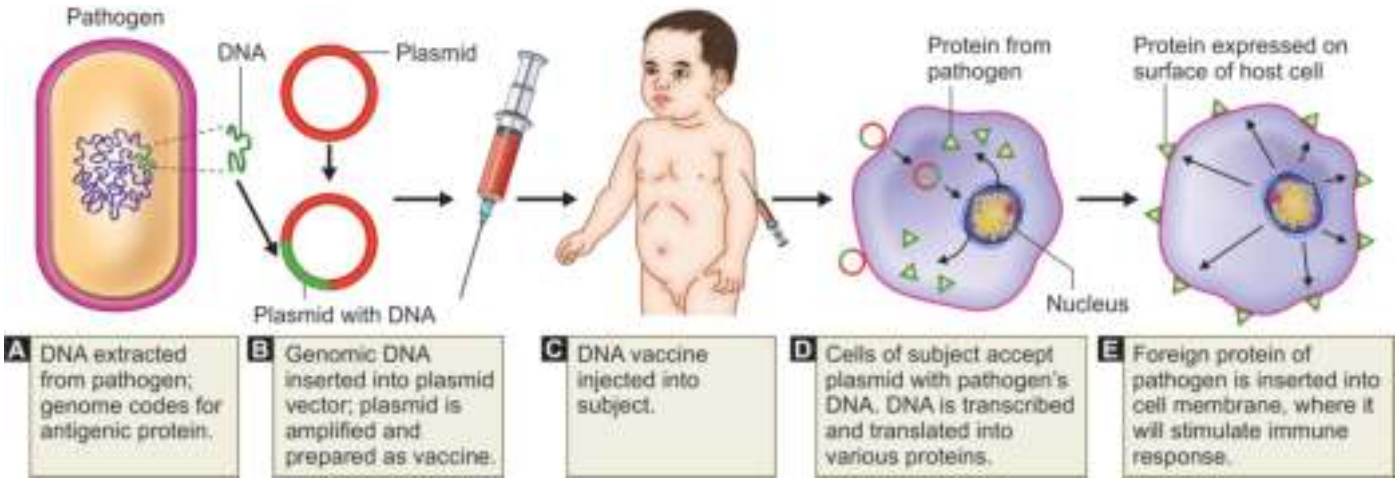

Fig. 4.42A to E: DNA vaccine preparation. DNA that codes for the protein is extracted from the pathogen genome. Extracted genomic DNA of pathogen is inserted into plasmid vector for amplification of DNA and preparation of vaccine. DNA vaccine is injected into the subject. Subject cells accept plasmid with extracted pathogen DNA. DNA is transcribed and transplanted into various proteins. Foreign protein of pathogen is inserted into cell membrane and stimulate immune response.

Table 4.37 Currently approved bacterial vaccines

Obtained from Bacteria	Routes of Administration	Recommended Usage
Vaccines containing killed whole bacteria		
Cholera	Subcutaneous route	Travelers
Plague	Subcutaneous route	Travelers
Vaccines containing live-attenuated bacteria		
Tuberculosis (BCG)	Intradermal route	High-risk persons
Typhoid	Oral route	Travelers
Acellular vaccines containing capsular polysaccharide		
Anthrax	Subcutaneous route	Military personals
Meningococci (meningitis)	Subcutaneous route	High risk infants and military personnel
Haemophilus influenzae (meningitis)	Intramuscular route	Infants and children
Pneumococci (pneumonia)	Intramuscular route/subcutaneous route	Immunocompromised persons
Pertussis containing recombinant protein	Intramuscular route	Newborn and children
Toxoid vaccines (formaldehyde-inactivated bacterial exotoxins)		
Diphtheria	Intramuscular route	Children
Tetanus	Intramuscular route	Children
Pertussis	Intramuscular route	Children
Botulism	Intramuscular route	Only in exposed persons working in laboratories

- **Eukaryotic promoter and terminator:** Eukaryotic promoter and terminator are added. Bacteria and viruses have different promoters for transcription than do eukaryotes. So, a eukaryotic promoter must be added so that a human cell can begin transcription. A terminator is also necessary—exact sequence for the protein is copied and nothing more.
- **Integration of DNA into plasmid vector:** Gene encoding antigenic protein of interest is cloned into a bacterial plasmid and engineered to augment the expression of inserted antigenic protein in mammalian cells. DNA is integrated into a plasmid vector.
- **Plasmid transformed into bacteria:** Plasmid is transformed into bacteria such as *E. coli*. Plasmid then becomes part of the bacteria's DNA, which has two major units: (a) Plasmid backbone contains origin of replication (ori) that delivers adjuvant, mitogenic activity and cloning sites for insertion of genes of interest. Antibiotic resistance gene confers antibiotic selected growth in *E. coli*. (b) Transcription unit is

Table 4.38 Currently approved viral vaccines

Obtained from Viruses	Routes of Administration	Recommended Usage
Vaccines prepared from inactivated virus		
Poliomyelitis (Salk)	Intramuscular route	Children (administered as first choice)
Rabies	Intramuscular route	Victims of animal bites
Influenza	Intramuscular route	High risk persons
Japanese encephalitis	Subcutaneous route	Endemic areas and laboratory persons
Hepatitis A	Intramuscular route	Travelers
Vaccines prepared from live-attenuated virus		
Adenovirus	Oral route	Military persons
Polio (Sabin)	Oral route	Children
Measles (rubeola)	Subcutaneous route	Children
Mumps	Subcutaneous route	Children
Rubella	Subcutaneous route	Children
Chickenpox (varicella)	Subcutaneous route	Children
Rotavirus (Rota Teq)	Oral route	Infants at risk
Smallpox (live vaccinia virus, not attenuated variola)	Multiple punctures	Since 2003, vaccine administered for voluntary health workers
Yellow fever	Subcutaneous route	Travelers, military persons
Influenza	Inhalation route	Same for inactivated
Subunit viral vaccines		
Hepatitis B*	Intramuscular route	Children from birth and health workers at risk
Influenza	Intramuscular route	Same for inactivated
Human papillomavirus*	Intramuscular route	Prevention of HPV infection
Recombinant vaccines		
Hepatitis B*	Intramuscular route	Used more than subunit but subunit for same groups
Pertussis	Intramuscular route	Newborn and children

**Hepatitis B and human papillomavirus vaccines are also prepared by recombinant methods.*

viral promoter/enhancer sequences such as antigen cDNA and termination–polyadenylation sequences.

- **Bacterial growth:** Many more copies of the plasmid containing the infectious organism's DNA must be produced.
- **Purification of plasmid DNA from bacteria:** Plasmid DNA is purified from the bacteria. All the other bacterial DNA and debris are separated from the plasmid vector. This plasmid can now be used to produce the infectious organism's proteins inside a person.

RNA VACCINE

RNA vaccine consists of copy of a molecule called messenger RNA (mRNA) that codes for a disease-specific antigenic protein produce an immune response. RNA vaccines are faster, cheaper and safe. Production of RNA vaccines is laboratory based and the process could be standardized and scaled allowing quick immune responses to large outbreaks and epidemics. A major advantage of RNA vaccines is that RNA can be produced in the laboratory from DNA template using a readily available materials such as chicken, eggs or other mammalian cells.

IMMUNODEFICIENCY DISEASES

Immunodeficiency diseases occur when one or more components system such as lymphocytes (T cell, B cell or combined T cell and B cell), phagocytes (neutrophils or macrophages), and complement system is defective. Immunodeficiency diseases can be primary or secondary.

- **Primary immunodeficiency** diseases are caused by genetic mutation that adversely affects the immune system.
- **Secondary immunodeficiency** diseases occur due to loss of previous functional immune system as a consequence of acquired immunodeficiency syndrome (AIDS), immunosuppressive drugs, starvation, malnutrition, infectious agents, chemotherapy, radiation, hematopoietic tumors and transplants. Patient develops numerous opportunistic infections and malignancies in AIDS.
- In normal health, CD8+ cytotoxic T cells, natural killer cells (NK cells), and macrophages recognize and destroy cancer cells by means of immune surveillance. Failure of immune system results in survival of cancer stem cells. Genetic alteration transforms normal cells to cancer stem cells due to activation of oncogenes or mutation of tumor suppressor genes, irradiation and viral infections.

PRIMARY IMMUNODEFICIENCY DISEASES

Primary immunodeficiency diseases occur due to congenital defects in B cell or T cell or combined (B and T cells). Combined defects in B cells and T cells lead to severe combined immunodeficiency disease (SCID). Patient lacks adaptive immune response associated with fatal outcome by two years of age without replacement of bone marrow or gene therapy.

- Defects in humoral immunity often cause with recurrent sinopulmonary infections with encapsulated bacteria (*Haemophilus influenzae*), parasitic infections (Giardia), chronic diarrhea and failure to thrive.
- Defects in cellular immunity lead to opportunistic infections (*Pneumocystis jirovecii*), disseminated viral infections (CMV, Epstein-Barr virus), failure to thrive, diarrhea, persistent and oral thrush.
- Defects in phagocytosis present with recurrent abscesses, oral ulcers, and severe pneumonias (catalase positive *Staphylococcus aureus*). Nitroblue tetrazolium (NBT) test is done to screen patients with chronic granulomatous disease.
- Phagocytic defects cause chronic granulomatous disease (NADPH oxidase defect), Chédiak-Higashi syndrome (abnormal phagosome formation) and leukocyte adhesion deficiency (absence of leukocyte adhesion molecules).
- Defects in complement proteins cause hereditary angioedema (C1-INH deficiency), systemic lupus erythematosus (C2 and C4 deficiency), paroxysmal nocturnal hemoglobinuria (PIG-A gene mutation encoding phosphatidylinositol-linked membrane proteins) and recurrent bacterial meningitis due to defective membrane attack complex (C5b–C9 deficiency).
- Primary immunodeficiency diseases involving lymphocytes are shown in Fig. 4.43. Classification of immunodeficiency diseases is given in Table 4.39. Primary immunodeficiency diseases are given in Table 4.40.

Pathology Pearls: Warning Signs of Immune Deficiency

- Recurrent infections of ear (otitis media), sinuses and lungs (pneumonias) within one year.
- History of abscesses in skin and deep organs
- History of little response to antibiotics
- History of persistent oral thrush (Candida infections), characterized by white, adherent, painless, discrete or confluent patches in the mouth, tongue or esophagus
- History of failure to thrive
- Family history of early childhood deaths
- Patient needs intravenous administration of antibiotics

B CELL DEFECTS: PRIMARY IMMUNODEFICIENCY DISEASES

Primary immunodeficiency diseases due to B cell deficiency include X-linked agammaglobulinemia (Bruton agammaglobulinemia), transient hypogammaglobulinemia of infancy, common variable unclassifiable immunodeficiency, selective IgA deficiency, selective IgM deficiency, selective IgG subclasses deficiency, immunodeficiency with hyper-IgM syndrome, secondary B cell immunodeficiency associated with drug, protein-losing states and X-linked lymphoproliferative disorder.

X-Linked Agammaglobulinemia (Bruton Agammaglobulinemia)

X-linked agammaglobulinemia (Bruton agammaglobulinemia) is characterized by complete lack of immunoglobulin due to defect in B cell maturation, in which naïve B cells cannot mature to plasma cells due to mutation of Bruton tyrosine kinase (BTK) gene.

Pathogenesis

In normal health, BTK gene located on the long arm of the X chromosome, encodes protein that participates in maturation of pre-B cells to B cells transforming into antibody secreting plasma cells. Mutation of BTK gene results in impaired maturation of pre-B cells to B cells. There is an absence of both mature B cells in peripheral blood and plasma cells in lymphoid tissues. Patient has absence of plasma cells leading to failure of synthesis of immunoglobulins. Cell immunity is not affected. Serum analysis reveals absence of immunoglobulins.

Clinical Features

X-linked agammaglobulinemia affecting male infants of 5–8 months of age, usually does not manifest

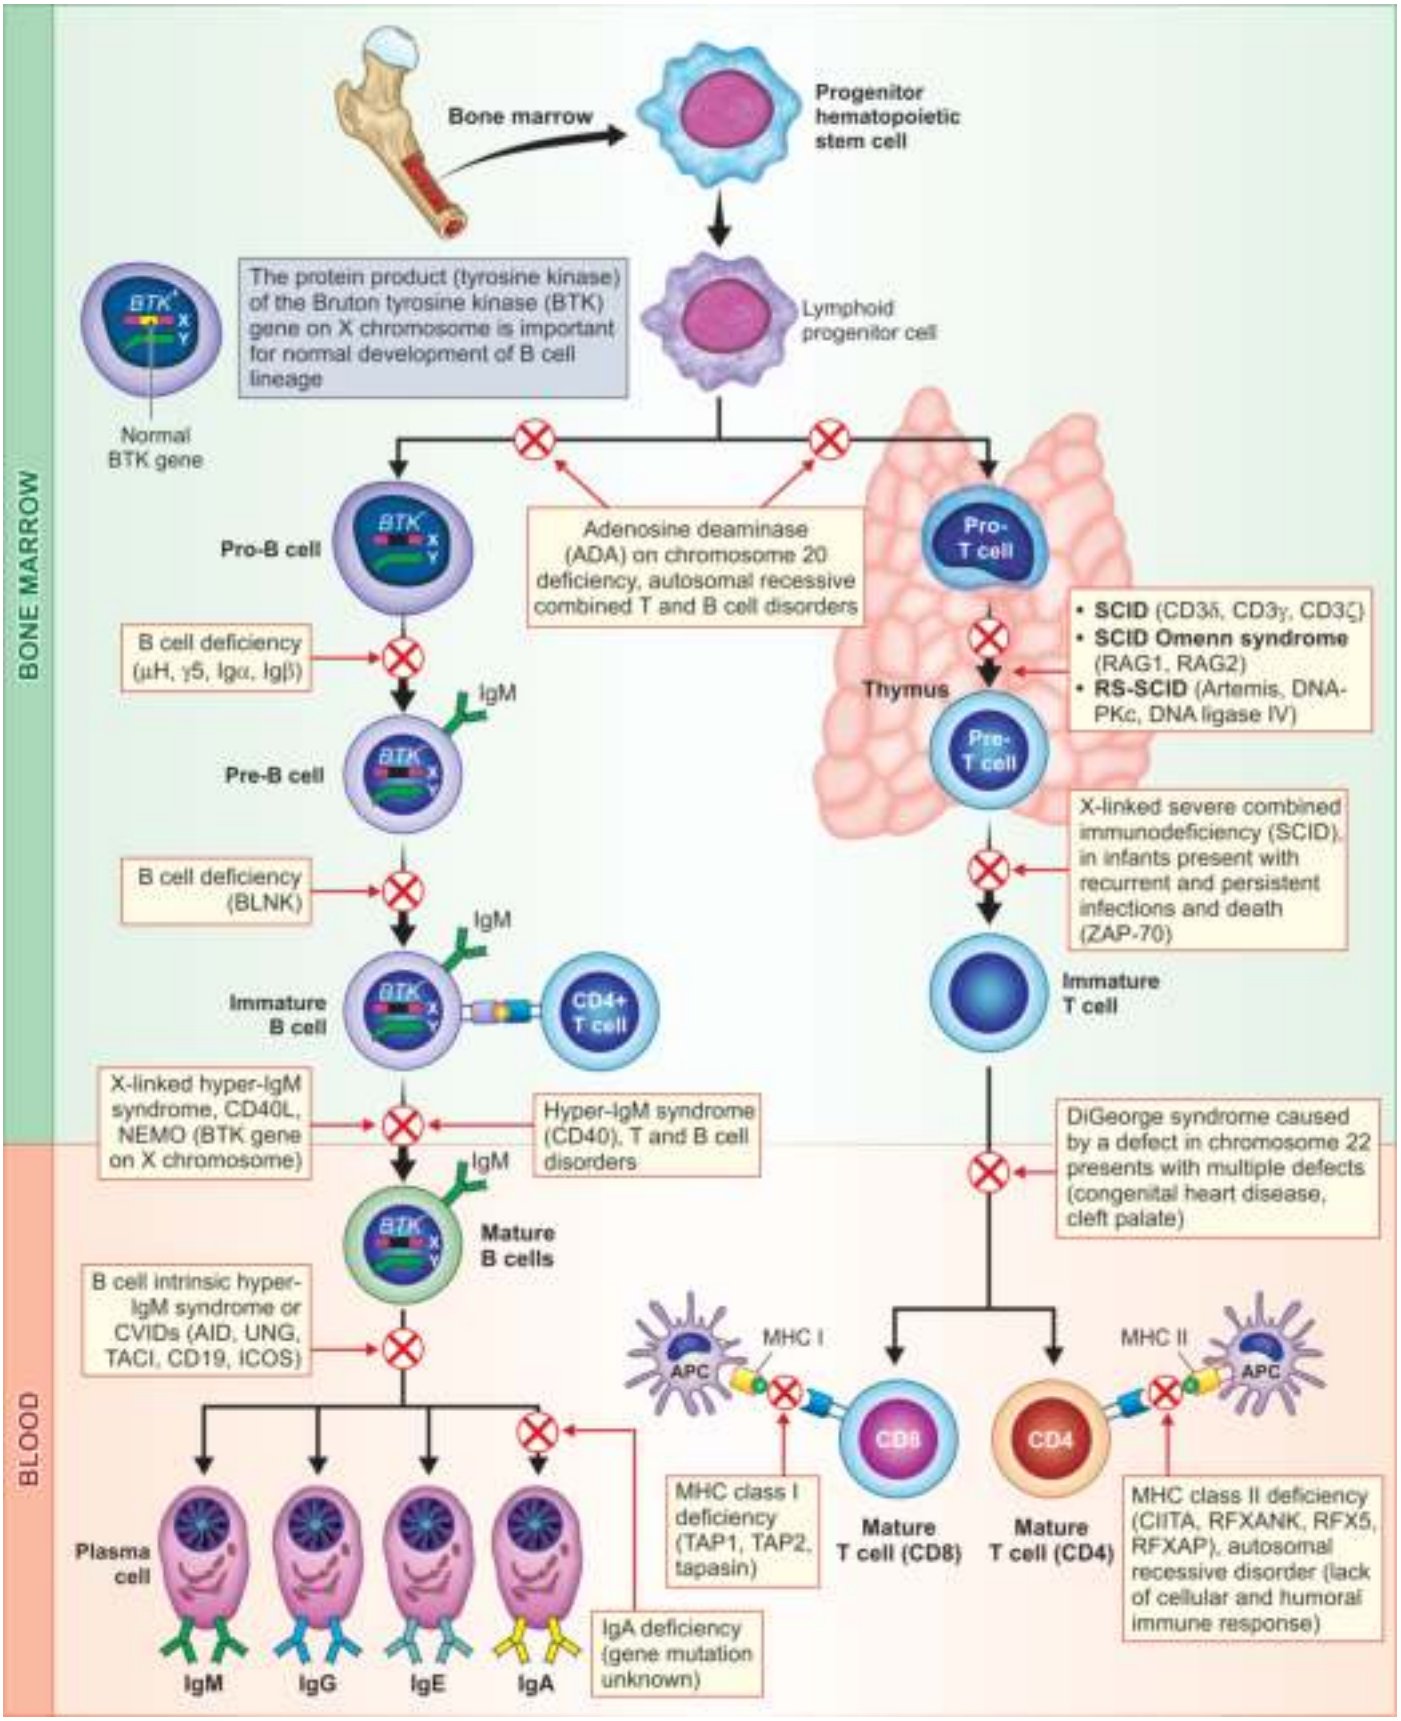

Fig. 4.43: Primary immunodeficiency disorders involving lymphocytes. Primary immunodeficiency diseases are genetically determined immunodeficiencies with immune and nonimmune defects resulting in severe infections that recur more frequently.

Table 4.39 Classification of immunodeficiency diseases

B Cell Defects: Primary Immunodeficiency Diseases
X-linked agammaglobulinemia of Bruton (lack of B cells with deficient antibody production associated with recurrent life-threatening bacterial infections)
Transient hypogammaglobulinemia of infancy
Common variable unclassifiable immunodeficiency (block in CD4+ helper T cell [Th17] differentiation, hypoglobulinemia, defective IgG, IgA; variable IgM associated with recurrent bacterial infections)
Selective IgA deficiency (MHC linked disorder, defect in class switch associated with mild infections of respiratory and gastrointestinal tract)
Selective IgM deficiency (defect in class switch associated with recurrent pyogenic infections)
Selective IgG subclasses deficiency
X-linked hyper-IgM syndrome (defective CD40 ligand, susceptibility to bacteria, *Pneumocystis jirovecii*, *Cryptosporidium parvum* infections)
Secondary B cell immunodeficiency associated with drug, protein-losing states
X-linked lymphoproliferative disorder [SAP (SH2D1A)] mutation, inability to control B cell growth and susceptible to EBV-driven B cell tumors, fatal infectious mononucleosis)
T Cell Defects: Primary Immunodeficiency Diseases
DiGeorge syndrome (congenital thymic hypoplasia associated with defective development of T cells in thymus gland linked to recurrent life-threatening fungal and viral infections)
T cell deficiency associated with purine nucleoside phosphorylase deficiency
T cell deficiency associated with absent membrane glycoprotein
T cell deficiency associated with absent class I or class II MHC antigens or both (base lymphocyte syndrome)
Chronic mucocutaneous candidiasis with or without endocrinopathy
Combined T Cell and B Cell Defects: Primary Immunodeficiency Diseases
Severe combined immunodeficiency diseases (RAG1/RAG2 deficiency, ADA deficiency, PNP deficiency, autosomal recessive-linked, sporadic associated with recurrent life-threatening infections)
Wiskott-Aldrich syndrome (immunodeficiency with eczema and thrombocytopenia, X-linked disorder, defective WASP gene, impaired T cell activation responses, susceptible to encapsulated extracellular bacteria, HSV, EBV infections)
Immunodeficiency with thymoma
Immunodeficiency with ataxia-telangiectasia (autosomal dominant disorder, defective cell-cycle kinase domain of ATM, T cells reduced, low IgA and IgE and susceptible to respiratory tract infections)
Immunodeficiency with short-limbed dwarfism
Immunodeficiency with adenosine deaminase deficiency
Immunodeficiency with nucleotide phosphorylase deficiency
Biotin-dependent multiple carboxylase deficiency
Phagocytic Dysfunction: Primary Immunodeficiency Diseases
Chronic granulomatous disease associated with recurrent infections with bacteria that are sensitive to killing by oxygen dependent mechanisms due to lack of oxidative burst for bacterial killing, i.e. absence of production of reactive oxygen species (e.g. hydrogen peroxide)
Chédiak-Higashi syndrome (autosomal recessive disorder, defective intracellular transport protein encoded by LYST, inability to kill bacteria)
Myeloperoxidase deficiency
Severe congenital neutropenia associated with recurrent life-threatening infections
Hyper-IgE syndrome (Job syndrome characterized by defective STAT3, block in CD4+ T cell (Th17) differentiation, elevated IgE, susceptible to extracellular bacteria and fungi)
Elevated IgE defective chemotaxis, and recurrent infections
Tuftsin deficiency disease in children associated with infections

Contd...

Table 4.39 Classification of immunodeficiency diseases (*Contd...*)

Complement System Defects: Primary Immunodeficiency Diseases
Defective production in C2, C3, and C5 associated with recurrent life-threatening bacterial infections
Defective production of C2 and C4 associated with development of systemic lupus erythematosus due to improper clearance of immune complex
Defective production of C5b–C9 membrane attack complex (MAC) associated with recurrent disseminated infections with Neisseria infections
Hereditary deficiency of C1 inhibitor (C1 INH) associated with laryngeal edema
PIG-A gene mutation encoding phosphatidylinositol-linked membrane proteins (paroxysmal nocturnal hemoglobinuria due to uncontrolled activation of complement associated with recurrent bouts of intravascular complement mediated hemolysis)

Table 4.40 Primary immunodeficiency diseases

Defects in Lymphocytes and other Molecules	Disorder	Comments
Defects in maturation of lymphocytes		
B cell	X-linked agammaglobulinemia of Bruton	▪ Lack of B cells and plasma cells ▪ Loss of BTK tyrosine kinase ▪ Recurrent life-threatening bacterial and viral infections
T cell	DiGeorge syndrome	▪ Thymic hypoplasia ▪ Autosomal dominant
T cell	Bare lymphocyte syndrome	Defect in MHC class II promoter
T cell, B cell and NK	Severe combined immuno-deficiency syndrome (SCID)	▪ RAG 1/RAG 2 (lack of TCR or Ig rearrangement) ▪ Adenosine deaminase (ADA) and purine nucleoside phosphorylase (PNP) deficiency which affects development of T cells and B cells due to toxic metabolites ▪ JAK3 and IL-2R-γ deficiency (defective signals from IL-2, IL-4, IL-7, IL-9, IL-15) ▪ ZAP-70 deficiency results in defective signal from TCR
Defects in activation and function of lymphocytes		
B cell	Hyper-IgM syndrome	▪ Deficiencies of CD40, CD40 ligand and NEMO ▪ Absence of isotope switching and/or somatic hypermutation plus T cell defects ▪ Recurrent life-threatening bacterial infections (*Pneumocystis jirovecii*, *Cryptosporidium parvum*)
B cell	Common variable immuno-deficiency	▪ ICOS deficiency ▪ Defective IgA and IgG production ▪ Recurrent life-threatening bacterial and viral infections
B cell	Selective IgA deficiency	▪ MHC class molecules-linked disorder ▪ Absence of IgA synthesis ▪ Recurrent life-threatening respiratory tract infections
T cells and NK cells	X-linked lymphoproliferative disorders	▪ SAP (SH2D1A) mutant ▪ Disruption in regulation of B cell growth ▪ Epstein-Barr B cell tumors, fatal infectious mononucleosis
CD4+ helper T cells (Th17)	Hyper-IgE syndrome (Job syndrome)	▪ Defective STAT3 ▪ Blockage in CD4+ helper T cell (Th17) differentiation ▪ Elevated IgE ▪ Recurrent extracellular bacterial and fungal infections

Contd...

Table 4.40 Primary immunodeficiency diseases (*Contd...*)

Defects in Lymphocytes and other Molecules	Disorder	Comments
CD4+ helper T cells	MHC class II deficiency	▪ Lack of CD4+ helper T cells ▪ Lack of MHC class II expression ▪ Recurrent respiratory and skin infections
CD8+ cytotoxic T cells	MHC class II deficiency	▪ Lack of CD8+ cytotoxic T cells ▪ TAP mutation ▪ Lack of MHC class I expression ▪ Recurrent pathogen infections
Immunodeficiencies associated with systemic manifestations		
T cells and platelets	Wiskott-Aldrich syndrome	▪ X-linked disorder ▪ Defective WASP gene encoding cytoskeleton protein (CD43) ▪ Impaired T cell activation and CD8+ regulatory T cells dysregulation ▪ Recurrent encapsulated extracellular bacterial and viral infections (e.g. HSV, EBV)
B cells and T cells	Ataxia-telangiectasia	▪ Autosomal recessive disorder ▪ Mutation of cell-cycle kinase domain of ATM, low IgG and IgE ▪ Recurrent life-threatening respiratory tract infections
Phagocytic immunodeficiencies		
Neutrophils	Chédiak-Higashi syndrome	▪ Autosomal recessive disorder ▪ Defect in killing of bacteria due to mutation in LYST gene coding for defective intracellular transport protein
	Severe congenital neutropenia	▪ Autosomal dominant disorder or sporadic/ELA2 mutation, HAX1 mutation, Gfi1 mutation ▪ Severe neutropenia, developmental arrest of myeloid precursors usually at promyelocytic stage and increased apoptosis
	Myeloperoxidase (MPO) deficiency	▪ Neutropenia associated with frequent fungal infections especially *Candida albicans*
	Neutrophil specific granule deficiency	▪ Autosomal recessive/C/EBP-epsilon mutation ▪ Absence of defensin and gelatinase enzyme in specific granules results in recurrent infections
	Cyclic neutropenia	▪ Autosomal dominant disorder or sporadic/ELA2 mutation ▪ Fluctuations between normal granulocyte counts and severe neutropenia with 21-day periodicity and increased apoptosis in myeloid precursors
	Glucose-6-phosphatase deficiency	▪ Autosomal recessive/G6PC3 mutation ▪ Increased susceptibility to apoptosis
	P14 deficiency	▪ Autosomal recessive/p14 (MAPBPIP) mutation ▪ Defective lysosome function, neutropenia, hypogammaglobulinemia, short stature and hypopigmentation
	Leukocyte adhesion deficiency I (LAD-I)	▪ Autosomal recessive/TBG2 mutation ▪ Defective integrin β_2 (CD18) ▪ Defective adhesion and migration
	Leukocyte adhesion deficiency II (LAD-II)	▪ Autosomal recessive/GDP-fucose transporter mutation leads to congenital disorder of fucosylation ▪ Granulocytes unable to bind to selectins on endothelium ▪ Defective adhesion and migration
	Leukocyte adhesion deficiency III (LAD-III)	▪ Autosomal recessive/RASGRP2 mutation ▪ Defective integrin activation ▪ Defective adhesion and migration ▪ High peripheral blood neutrophil count with severe bleeding

Contd...

Table 4.40 Primary immunodeficiency diseases (*Contd...*)

Defects in Lymphocytes and other Molecules	Disorder	Comments
Macrophages	WHIM deficiency	▪ Autosomal recessive/autosomal dominant/CXCR4 mutation ▪ Warts, hypogammaglobulinemia, infections and myelokathexis
	Wiskott-Aldrich deficiency (WAS deficiency)	▪ X-linked/WAS mutation ▪ Dysfunctional actin polymerization in hematopoietic cells, defects of cell activation, adhesion, migration and phagocytosis
	Rac2 deficiency	▪ Autosomal dominant disorder/Rac2 mutation ▪ Abnormal granulocyte chemotaxis, respiratory burst and degranulation ▪ High neutrophil counts
	Chronic granulomatous disease	▪ Autosomal recessive disorder ▪ Phagocytes unable to produce superoxide linked to defective oxidative burst for bacterial killing
	Many disorders affecting macrophage functions	Defect in release of macrophage-activating factors, migration, phagocytosis and killing of pathogens
Complement protein deficiencies		
Complement cascade protein deficiencies	▪ C2, C3 and C5 deficiencies	▪ Recurrent infections with select groups of bacteria with polysaccharide capsules
	▪ C2, and C4 deficiencies	▪ Systemic lupus erythematosus due to improper clearance of immune complex
	▪ C5b–C9 membrane attack complex (MAC) deficiency	▪ Recurrent disseminated infections with Neisseria infections
	▪ Hereditary C1 inhibitor (C1-INH) deficiency	▪ Laryngeal edema
	▪ PIG-A gene mutation encoding phosphatidylinositol-linked membrane proteins	▪ Uncontrolled activation of complement leads to paroxysmal nocturnal hemoglobinuria (PNH) characterized by recurrent bouts of intravascular complement-mediated hemolysis

until after the six months of age due to persistence of maternal antibodies. Patients develop recurrent bacterial especially sinopulmonary infections such as pneumococci, staphylococci, streptococci and *Haemophilus influenzae*. These patients are usually resistant to viral infections except Coxsackie virus and ECHO virus.

Laboratory Diagnosis

There is an absence of both mature B cells in peripheral blood and plasma cells in lymphoid tissues. Lymph nodes lack well defined germinal centers. T cells are unaffected.

X-Linked Hyper-IgM Syndrome

X-linked hyper-IgM syndrome is more common than autosomal variant. In normal health, cytokine is necessary for immunoglobulin class switching to IgG, IgA or IgE X-linked. Hyper-IgM syndrome occurs due to mutated CD40L on CD4+ helper T cells or CD40 receptor on B cells. Second signal cannot be delivered to CD4+ helper T cells during B cells activation. Consequently, cytokine necessary for immunoglobulin class switching is not produced, and the patients have normal or increased concentration of IgM, and low levels IgG, IgA or IgE, hence prone to pyogenic infections.

Selective IgA Deficiency

Selective IgA deficiency is inherited disorder characterized by inability of IgA secreting B cells to mature into IgA producing plasma cells. Other immunoglobulin levels remain within normal limits.

- Patients are usually asymptomatic, but may also be associated with frequent episodes of diarrhea and recurrent infections especially those involving mucosal surfaces.
- The patients lacking in IgA may develop anaphylactic reactions to transfused blood due to increased IgE concentration. This sensitization can result in susceptibility to anaphylaxis on subsequent blood transfusion.

Selective IgM Deficiency

Selective IgM deficiency is a rare immunodeficiency disorder that has been reported in association with

serious recurrent pyogenic infections, such as bacteremia. The disorder can affect infants, children and adults, who have normal IgG subclasses and IgA, normal vaccination responses, absence of T cell defects and absence of causative external factors. Patient presents with recurrent otitis media, chronic sinusitis, bronchitis, bronchiectasis, pneumonia and urinary tract infections. Adults with selective IgM deficiency are at risk of developing allergic and autoimmune diseases.

Selective IgG Subclass Deficiency

IgG is the main immunoglobulin in human blood that provides protection against many infectious agents. IgG is a combination of four subclasses: IgG1 (60–70%), IgG2 (20–30%), IgG3 (5–8%) and IgG4 (1–3%).

- Normally, subclasses IgG1 and IgG3 are effective against toxins produced by *Corynebacterium diphtheriae* and *Clostridium tetani*. In contrast, IgG2 subclass is effective against polysaccharide capsule of certain disease-producing *Haemophilus influenzae* and *Streptococcus pneumoniae*.
- The term 'selective IgG subclass deficiency' refers to significant decrease in the serum concentrations of one or more subclasses of IgG in a patient whose total IgG concentration is within normal range. Occasionally, patients may suffer from infections.

Transient Hypogammaglobulinemia of Infancy

Transient hypogammaglobulinemia of infancy (THI) is a primary immunodeficiency disorder caused by a transient drop of levels of IgG in an infant between 5 months to 2 years of age. IgG levels typically return to reference range between 2 and 6 years of age.

- Clinically, THI is characterized by recurrent infections, although some infants may be asymptomatic.
- Treatment with antibiotics and replacement immunoglobulin therapy is of foremost importance in the management of symptomatic infants.

Common Variable Immunodeficiency

Common variable immunodeficiency (CVID) is a primary immunodeficiency disease characterized by low levels of protective immunoglobulins and an increased risk of infections in children and adults.

- The hallmark of CVID is recurrent or severe bacterial and viral infections of upper airway, sinuses and lungs. Respiratory tract infection can result in pneumonia, chronic bronchitis and bronchiectasis.
- Patient presents with chronic cough, runny nose, fatigue, fever, diarrhea, painful swollen joints in the knee, ankle, elbow or wrist, lymphadenopathy and splenomegaly. In addition, persons with CVID, there is higher risk of developing malignant tumors.

X-Linked Lymphoproliferative Syndrome

X-linked lymphoproliferative (XLP) syndrome is primary immunodeficiency disorder characterized by a defective immune system.

- Persons with X-linked lymphoproliferative syndrome exposed to Epstein-Barr virus can result in severe, life-threatening fulminating hepatitis. There is increased risk of developing various infections, lymphoid malignancies and other abnormalities. In most cases, patient presents with fatigue, epistaxis and infections anytime between 6 months to 10 years of age.
- Diagnosis of XLP syndrome is based on clinical manifestations, laboratory findings and identification of genetic mutations.

T CELL DEFECTS: PRIMARY IMMUNODEFICIENCY DISEASES

Primary immunodeficiency diseases due to T cell defects include DiGeorge syndrome, also known as congenital thymic aplasia and chronic mucocutaneous candidiasis with or without endocrinopathy, T cell deficiency associated with purine nucleoside phosphorylase deficiency; T cell deficiency associated with absent membrane glycoprotein, and T cell deficiency associated with absent MHC class I or class II antigens or both (base lymphocyte syndrome). Deficiency in cell-mediated immunity is associated with recurrent viral, fungal and protozoal diseases.

DiGeorge Syndrome (Congenital Thymic Hypoplasia)

In both DiGeorge syndrome (congenital thymic hypoplasia) and Nezelof syndrome, there is failure of maturation of T cells, but B cells remain unaffected. Majority of persons with DiGeorge syndrome have deletion of a small piece of chromosome 22 known as 22q11.2, which is also known as 22q11.2 deletion syndrome.

Pathogenesis

In DiGeorge syndrome, aberrant embryonic development of third and fourth branchial arches, results in congenital thymic hypoplasia and parathyroid glands as well as anomalies of aortic arch, mandible and ear. It can be summed up by **CATH22**, which denotes cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia and microdeletion of chromosome 22q11. In about 30% of cases, DiGeorge syndrome is also associated with behavior disorders and psychosis (bipolar disorder and schizophrenia) that develop during adolescence.

Clinical Features

DiGeorge syndrome affected children develop recurrent infections (bacterial, fungal and viral), pneumonias and tetany from hypoparathyroidism with hypocalcemia,

breathing problems, developmental disabilities, congenital cardiac defects, cleft lip and palate.

Chronic Mucocutaneous Candidiasis

Chronic mucocutaneous candidiasis is characterized by persistent or recurrent symptomatic Candida infection occurs due to inherited T cell defects and low levels of immunoglobulins in childhood, that affects mucosal sites, skin, and nails. It can be either autosomal dominant or autosomal recessive inheritance pattern.

- Autosomal dominant chronic mucocutaneous candidiasis is associated with gain-of-function mutations of **STAT1** gene resulting in IL-17 deficiency, which is associated with malfunctioning of endocrine glands such as hypothyroidism, hypoparathyroidism, hypoadrenalism and type 1 diabetes mellitus. Patients can develop autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED) syndrome, in which there is mutation of AIRE gene.
- Chronic mucocutaneous candidiasis usually presents before the age of three years with one or more of the symptoms: chronic oral thrush, napkin dermatitis, paronychia, widespread crusted plaques on the scalp, trunk, hands and feet, stenosis of esophagus, larynx or vagina and increased susceptibility to infection with dermatophyte fungi (tenia) and human papillomavirus.
- Chronic mucocutaneous candidiasis may lead to premature death due to disseminated Candida infection, sepsis, pneumonia or mycotic aneurysms. Patients are more prone to develop carcinomas of skin, nose, ear and esophagus.

COMBINED T CELL AND B CELL DEFECTS: PRIMARY IMMUNODEFICIENCY DISEASES

Primary immunodeficiency diseases due to combined T cell and B cell defects include severe combined immunodeficiency disease, Wiskott-Aldrich syndrome, immunodeficiency with ataxia-telangiectasia, immunodeficiency with thymoma, immunodeficiency with short-limbed dwarfism, immunodeficiency with adenosine deaminase deficiency, immunodeficiency with nucleotide phosphorylase deficiency and biotin-dependent multiple carboxylase deficiency.

Severe Combined Immunodeficiency Syndrome

Severe combined immunodeficiency syndrome (SCID) is X-linked disorder or an autosomal recessive disorder caused by mutations in different genes involved in the development and function of B cells and T cells. Infants with SCID appear healthy at birth but are highly susceptible to severe infections due to defective combined humoral and cell-mediated immunity. X-linked SCID occurs due to defects in IL-2 receptor. Swiss type SCID occurs due to adenosine deaminase (ADA) deficiency. Death occurs during the first year of life unless given immunoglobulin and bone marrow transplantation. SCID is often called 'bubble boy disease' since 1970s and 1980s, when world knew David Vetter, a boy with X-linked SCID, who survived for 12 years in a plastic, germ-free bubble.

- **X-linked SCID:** In normal health, MHC class II molecules are essential for activation of CD4+ T helper cells and cytokine production. Cytokine signaling is essential for proliferation and maturation of T cells and B cells.
  - In normal health, enzyme ADA prevents formation of toxic products to lymphocytes.
  - Defect in cytokine IL-2 receptor plays important role in pathogenesis of X-linked SCID.
  - Patients are treated by enzyme ADA replacement therapy (polyethylene glycol-modified bovine ADA (PEG-ADA) and bone marrow transplantation.
- **Swiss type SCID:** Approximately 50% of Swiss type SCID patients have autosomal recessive inheritance due to ADA deficiency.
  - In normal health, ADA protects T cells from toxic metabolic products.
  - ADA deficiency results in accumulation of deoxyadenosine, which in turn leads to buildup of deoxyadenosine triphosphate (dATP) in all cells, which inhibits ribonucleotide reductase enzyme and prevents DNA synthesis, hence cells are unable to divide. Accumulation of toxic metabolic products makes the T cells nonfunctional.
- **Radiosensitive SCID:** Mutations in genes encoding proteins involved in nonhomologous end joining DNA repair pathway prevent resolution of rearrangement intermediates by ionization radiation, which is called radiosensitive-sensitive SCID. Patients have very few T cells and B cells due to failure of DNA rearrangement. Patients develop carcinoma.
- **Omenn syndrome:** Omenn syndrome (leaky SCID) was first described by **Gilbert Omenn** in 1965, partial or impaired V(D)J recombinational activity occurs due to mutations in either in RAG1 or RAG2 genes encoding small quantity of RAG protein. Protein loss through the skin and gastrointestinal tract leads to generalized metabolic derangements.
  - Patient presents with chronic diarrhea, failure to thrive, recurrent infections (*Pneumocystis jirovecii*, cytomegalovirus) lymphadenopathy, hepatomegaly, erythroderma, desquamation, alopecia, and loss of eyebrows, including eyelashes. Tissue damage occurs due to abnormal expansion of Th1 and Th2 cells.
  - Patient outcome is fatal unless corrected by bone marrow transplantation. Laboratory investigations

include normal T cell count, depressed T cell proliferation to antigens, depressed humoral immunity, normal natural killer cells, hypereosinophilia, elevated serum IgE.

Pathology Pearls: Mechanisms of Severe Combined Immunodeficiency (SCID)

Lymphocyte Precursor Cell Death due to Purine Metabolism Defects

Adenosine deaminase (ADA) or purine nucleoside phosphorylase (PNP) deficiency results in accumulation of toxic products, which adversely affect developing B cells and T cells.

Defective Signaling through the Common γ-Chain Dependent Cytokine Receptors

- Several cytokine receptors share the common γ-chain subunit: IL-2 (peripheral T cell homeostasis), IL-4 (class-switch recombination), IL-7 (T cell development), IL-9 (hematopoiesis), IL-15 (natural killer cell development, NK cell requires TAM receptor and IL-15 R) and IL-21 (B cell maturation).
- Mutations in the common γ-chain result in absence of both mature T cells and NK cells. This is the most frequent form of SCID called SCIDX1.
- Because Janus kinase 3 (JAK3) mediates signaling from the γ-chain receptors, mutations in JAK3 result in a SCID phenotype that is undistinguishable from SCIDX1. KAK3 mutation is autosomal recessive SCID. γ-Chain mutation is X-linked SCID. IL-7Rα-chain deficient SCID lacks T cells but has B cells and natural killer cells.

Defective V(D)J Rearrangement

- Mutations in either RAG1 or RAG2 genes impair the development of T cells and B cells and not natural killer cells. SCID patients lack T cells and B cells but natural killer cells are present.
- Omenn syndrome (leaky SCID) was first described by Gilbert Omenn in 1965, partial or impaired V(D)J recombinational activity occurs due to mutations in either in RAG1 or RAG2 genes encoding small quantity of RAG protein. Protein loss through the skin and gastrointestinal tract leads to generalized metabolic derangements.

Defective pre-TCR/TCR Signaling

- T cells are key mediators in mounting an effective adaptive cell-mediated immune response. T cell signaling is essential in T cell development.
- Thymocytes bearing TCR with a high affinity for self-peptide MHC complex undergoes apoptosis (negative selection), whereas those bearing low-affinity TCR survive and differentiate into mature T cells (positive cells), which ensures only those T cells that are self-tolerant survive while eliminating the self-reactive T cells.
- Abnormal TCR rearrangement results in low-affinity limited repertoire TCRs. Dysregulation of this pathway can cause defective T cell survival and activation.

Clinical Features

Severe combined immunodeficiency disorder patient presents with failure to thrive and increased susceptibility to bacterial, fungal, and viral infections. There is increased risk for development of carcinomas. Graft-versus-host disease occurs as a result of blood transfusions. Patient lacks no adaptive immune response with fatal outcome by two years of age without bone marrow transplantation or gene therapy based on maturation of donor lymphoid progenitor cells. Thymic hypoplasia with absent or greatly reduced thymic lymphoid component, hypoplasia of lymph nodes, tonsils, and other lymphoid tissues.

Treatment

Treatment is sterile isolation of baby and stem cell transplantation. Gene therapy is a technique by which faulty gene is replaced by a normal healthy gene. Normal ADA gene is isolated, cloned and inserted into retrovirus vector, which has a packing sequence but no viral genes. Bone marrow cells of the patient are aspirated, and treated with retrovirus containing ADA gene. These bone marrow cells treated with retrovirus containing ADA gene are reinjected into the patient. T cells in bone marrow now become fully functional normal ADA gene and hence the immune system. Patient is observed for expression of normal gene. Gene therapy in severe combined immunodeficiency (SCID) disease is shown in Fig. 4.44.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome is X-linked disorder associated with defects in both B cell and T cell functions (i.e. humeral and cellular immunity) due to mutation in WASP gene, which is characterized by low levels of IgM, recurrent infections, thrombocytopenia and eczema.

- Both T cells and platelets show absence of certain surface glycoprotein (CD43), which is ligand for intercellular adhesion molecule 1 (CAM-1). It has been suggested that a defect of glycosylation especially sialylation of these cell surfaces.
- Serum IgM level is low keeping in view of poor response to polysaccharide antigen. IgA and IgE concentrations are raised. However, IgG level remains within normal range.

Clinical Features

Patient presents with eczema, thrombocytopenia, bloody diarrhea, recurrent infections and poor antibody response to polysaccharide antigens. Patient has fatal outcome before six years of age due to bleeding, infection or malignancy (most often lymphoma).

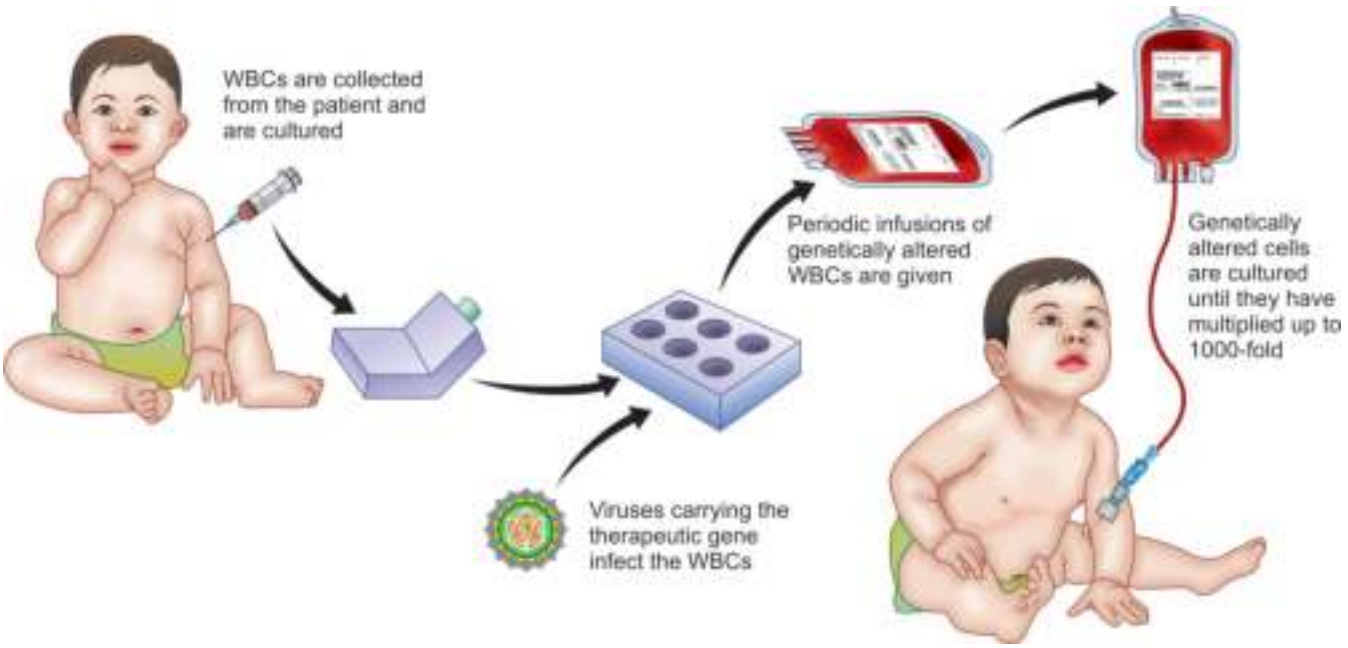

Fig. 4.44: Gene therapy in severe combined immunodeficiency (SCID). Gene therapy for SCID involves isolation and molecular correction of gene mutations in the patients' own pluripotent hematopoietic stem cells (HSCs), followed by transplantation of the functional cells back into the SCID patients.

Ataxia-Telangiectasia

Ataxia-telangiectasia is autosomal recessive trait associated with chromosomal breakages. There is increased risk of development of malignant neoplasm especially lymphomas.

- Patient presents with triad of features: (a) cerebellar degeneration and spinocerebellar atrophy, (b) dilated blood vessels on the flexor surface of forearms and conjunctiva, and (c) diminished resistance to infection.
- Cerebellar degeneration and spinocerebellar atrophy lead to appearance of choreoathetoid movements in early life. Dilated blood vessels are present on the flexor surface of forearms and conjunctiva.
- Diminished resistance to infection occurs due to decreased plasma levels of IgA and IgE and impaired cell-mediated immunity. Affected patients are prone to recurrent infections of sinuses and respiratory tract resulting to bronchiectasis.

PHAGOCYTIC DYSFUNCTION: PRIMARY IMMUNODEFICIENCY DISEASES

Phagocytes (neutrophils, macrophages) are cells that protect the body by phagocytosis and destroying harmful foreign particles, microbes and dead cells. Primary immunodeficiency diseases due to phagocyte defects include chronic granulomatous disease and leukocyte adhesion deficiency syndrome.

Defects in Adhesion of Leukocytes

Leukocytic adhesion is impaired in diabetes mellitus and patient on steroid therapy and hemodialysis. Under physiologic state, **β_2-integrins** (LFA-1 and Mac-1) expressed on leukocytes participate in adhesion of leukocytes to venular endothelium. Gene mutation of LAD-I causes deficiency of β_2-integrins resulting in recurrent bacterial infections, delayed wound healing and delayed separation of umbilical cord in newborns. Gene mutation of LAD-II causes mild disorder. LAD-III deficiency is characterized by both severe bacterial infections and a severe bleeding disorder.

Defects in Chemotaxis of Leukocytes

Chemotaxis is the directed migration of a cell in response to a chemical stimulus, which uses cytokines and chemokines to attract neutrophils and macrophages to the site of tissue injury, ensuring that pathogens in the area will be eliminated. Chemotaxis is impaired in diabetes mellitus, cancers, sepsis, immunodeficiency disorders and thermal injuries.

Defects in Opsonization of Injurious Agents

Opsonization is a process by which injurious stimulus coated by opsonins, i.e. IgG, C3b and complement mannose-binding lectin (MBL).

- Opsonization enhances binding of injurious agent to membrane receptors (e.g. FcR1, CR1 and MBL) expressed on activated neutrophils.

- Defects in opsonization results in 'Bruton's agammaglobulinemia', an X-linked inherited agammaglobulinemia is characterized by the absence of mature B cells which in turn leads to severe immunoglobulin deficiency and recurrent infections.

Defects in Phagocytosis

Phagocytosis is impaired in leukemias, diabetes mellitus, malnutrition, neonates and Chédiak-Higashi syndrome. Mutation in LYST gene is associated with Chédiak-Higashi syndrome. In normal health, phagocytic vesicle fuses with neutrophilic membrane of lysosome to form phagolysosome. LYST gene located on chromosome 1q42 encodes a protein essential for assembly of microtubules in the cytoplasm. Mutation in LYST gene results in defective fusion of phagosome with lysosome (phagolysosome).

- Chédiak-Higashi syndrome also causes defective degranulation of neutrophils, dysfunctional platelet (bleeding), impaired membrane fusion of lysosomes with melanosomes (albinism), Schwann cells (neuropathy), natural killer cells, and CD8+ cytotoxic T cells (aggressive lymphoproliferative disorder).
- In Chédiak-Higashi syndrome, neutrophils contain giant granules due to aberrant organelles. Defective degranulation of neutrophils leads to impaired microbial killing, and recurrent bacterial infections (*Staphylococcus aureus*) forming soft tissue abscess.

COMPLEMENT SYSTEM DEFECTS: PRIMARY IMMUNODEFICIENCY DISEASES

Primary immunodeficiencies due to complement proteins deficiency include hereditary angioedema, deficiency of C3, deficiency of membrane attack complex (MAC), and C2 deficiency or C4 deficiency secondary to autoimmunity.

- Complement system consists of wide variety of proteins, which perform many functions: (a) defense against pyogenic bacterial infection by opsonization, chemotaxis, activation of leukocytes and degradation of microbes, (b) bridging innate and adaptive immunity and (c) disposal of immune and inflammatory products by clearance of immune complexes from the tissues and removal of apoptotic cells. The proteins involved in activating the complement system are themselves activated by three convergent pathways termed classical, alternative and mannose-binding lectin (MBL).
- In complement system cascade, C3b participates in opsonization and phagocytosis of microbes. C3a and C5a play key role in adhesion, transmigration and chemotaxis of leukocytes. C3a and C5a increase capillary permeability. C5a acts on lipoxygenase pathway to synthesize arachidonic acid metabolites. C5b–C9 membrane attack complex (MAC) degrades of microbes via enhancing arachidonic acid metabolism and producing reactive oxygen metabolites.
- Patients develop increased susceptibility to infections due to defects in complement proteins, pathologic activation and deficiency of regulatory proteins. Defective formation of membrane attack complex (MAC) leads to increased susceptibility to Neisseria organisms. C3a, C5a and C4 deficiency leads to anaphylactic shock due to excessive release of histamine. Deficiency of complement system cascade linked to diseases in human beings is given in Table 4.41.

Recurrent Infections

Patient presents with increased susceptibility to infection due to deficiency of complement proteins such as C2, C3, and C5. Defective formation of membrane attack complex (MAC) leads to increased susceptibility to Neisseria organisms.

Hereditary Angioneurotic Edema

In normal health, classical pathway involves fixation antibodies (IgG and IgM) and complement (C1). C1

Table 4.41 Deficiency of complement system cascade linked to diseases in human beings

Disorder	Complement System Cascade Defects
Recurrent infections	C2, C3, and C5 deficiency
Neisseria infections	C3b-inactivator, C6, C7 and C8 deficiency, and C5b–C9 defective formation of membrane attack complex (MAC)
Laryngeal edema	Hereditary deficiency of C1 inhibitor (C1 INH)
Systemic lupus erythematosus (SLE)	C1, C2, C3, C4, C5 and C6, deficiency leads to improper clearance of immune complex
Paroxysmal nocturnal hemoglobinuria	▪ PIG-A gene mutation encoding phosphatidylinositol linked membrane proteins leading to uncontrolled activation of complement resulting to recurrent bouts of intravascular complement mediated hemolysis ▪ Flow cytometry demonstrating diminished CD55 and CD59 expression on red blood cells, leukocytes and platelets

is inhibited by plasma protein C1 inhibitor (C1 INH). Hereditary deficiency of C1 inhibitor (C1 INH) causes improper activation of C1 by immune complex resulting in excessive breakdown of C4 and C2. Complement C2 molecule generates vasoactive peptide (bradykinin), which produces painless non-pitting edema of soft tissues especially laryngeal edema, which may be life-threatening.

Systemic Lupus Erythematosus

Patient with C1, C2, C3, C4, C5 and C6 deficiency may develop autoimmune disease systemic lupus erythematosus (SLE) resulting from failure to clear immune complexes.

Paroxysmal Nocturnal Hemoglobinuria

In normal health, glycosylphosphatidylinositol (GPI) anchor regulatory proteins such as CD55, CD59, and C8, which are required for the protection of red blood cells, granulocytes, and platelets from complement-mediated lysis. CD55 known as DAF (decay accelerating factor) cleaves C3b. **CD59** known as membrane inhibitor reactive lysis (MIRL) participates in cleaving C5–9.

Gene Mutation

PIG-A gene mutation encoding phosphatidylinositol linked membrane proteins leads to uncontrolled activation of complement system resulting to recurrent bouts of intravascular complement-mediated hemolysis.

Clinical Features

Paroxysmal nocturnal hemoglobinuria (PNH) is often marked by the passage of hemoglobin-containing urine on awakening. During hemolytic episodes, patients develop normocytic or macrocytic anemia, accompanied by an appropriate reticulocyte's response. Paroxysmal nocturnal hemoglobinuria may develop as a primary disorder or evolve from preexisting cases of aplastic anemia.

Laboratory Diagnosis

Flow cytometry demonstrates diminished CD55 and CD59 expression on red blood cells, leukocytes and platelets in cases of paroxysmal nocturnal hemoglobinuria. Traditional diagnostic test has based on hemolysis in sucrose (**sucrose hemolysis test**) or acidified serum (**Ham test**) *in vitro*.

SECONDARY IMMUNODEFICIENCY DISEASES

Secondary immunodeficiency diseases are more frequent than primary immunodeficiency diseases. Secondary immunodeficiency diseases occur in the settings of malnutrition, cancer, aging, immunosuppressive agents and acquired immunodeficiency syndrome (AIDS). Causes of secondary immunodeficiency diseases are given in Table 4.42.

Table 4.42 Causes of secondary immunodeficiency diseases

Cancers
Chemotherapeutic drugs
Exposure to radiation
Malnutrition
Splenectomy
Immunosuppressive therapies
Infections
Aging process
Acquired immunodeficiency syndrome (AIDS)

ACQUIRED IMMUNODEFICIENCY SYNDROME

Acquired immunodeficiency syndrome (AIDS) is a chronic potentially life-threatening condition caused by the human immunodeficiency virus (HIV). HIV is transmitted by sexual contact, infected blood, sharing needles in drug addicts and vertical transmission from mother to fetus/child during pregnancy, childbirth or breastfeeding.

- HIV enters the body through mucosal tissues and blood and first infects CD4+ helper T cells, dendritic cells. Langerhans' cells, and macrophages. The infection becomes established in lymphoid tissues, where it remains latent for long periods until activated by cytomegalovirus or Epstein-Barr virus (EBV).
- CD4+ helper T cells play a central role in immune response. HIV targets CD4+ helper T cells resulting in marked depletion (<200 cells/mm^3). Cellular and humoral immunity are impaired. These patients are susceptible to opportunistic infections and carcinomas. The vast majority of AIDS cases in the United States and Europe are caused by infection with the retrovirus HIV-1.
- Without medication, it may take years before HIV weakens immune system to the point of developing AIDS, that causes profound immunosuppression leading to opportunistic infections, secondary neoplasms, and neurologic manifestations.
- There is no cure for HIV/AIDS, but medications can control infection and prevent progression of the disease. Antiviral treatments for HIV have reduced AIDS mortality around the world.
- HIV infection is diagnosed by enzyme-linked immunosorbent assay (ELISA) test; Western blot and direct assessment of viral RNA.

Pathology Pearls: HIV Evasion Mechanisms

- The rapid rate of mutations enables the HIV antigens to escape immune recognition. HIV makes 10 billion copies/day leading to depletion of CD4+ helper T cells.
- HIV integrates into host genome resulting in formation of abnormal proteins. It can remain hidden in resting cells.
- There is downregulation of MHC class I process, impairment of Th1 response of CD4+ helper T cells. HIV infects central nervous system, where antibodies have poor penetration.
- Disrupted immune system fails to control intracellular HIV infection. These reasons also contribute to the difficulty of HIV vaccine research.

Structure of HIV

Human immunodeficiency viruses are about 100–140 nm in diameter. HIV-1 and HIV-2 are members of the family of retroviruses. Retroviruses use RNA to encode their genetic information rather than DNA, as human cells do.

- HIV is composed of a capsid core, which contains the genetic material that has been surrounded by a lipid envelope, in which are embedded the trimeric transmembrane glycoprotein (gp41) to which the surface glycoprotein (gp120) is attached. These viral proteins (gp41 and gp120) are responsible for attachment to the host cell and are encoded by env gene of viral RNA genome.
- Beneath the envelope, is the matrix protein p17, the core proteins p6 and p24 and the nucleocapsid protein p7 (bound to the RNA). All these proteins are encoded by viral gag gene. Within the viral core, lies two copies of positive-sense, viral RNA genome (diploid RNA genome), together with protease, integrase and reverse transcriptase enzymes encoded by the viral pol gene.
- There are several other proteins with various immunomodulatory or regulatory functions in both HIV-1 and HIV-2 including **vif** (viral infectivity factor), **vpr** (viral protein R), **tat** (transactivator transcription), **rev** (regulator of expression of viral protein) and **nef** (negative regulatory factor). An additional **vpu** (viral protein U) is present in HIV-1 and not in HIV-2. Similarly, **vpx** (viral protein X) is present only in HIV-2 and not in HIV-1.
- HIV infects CD4+ helper T cells via high-affinity interaction between the virion envelope glycoprotein (gp120) and the CD4 molecule.
  - HIV integrates into host DNA (CD4+ helper T cells, macrophages, microglial cells) and undergoes high rate of mutation. The infection of CD4+ helper T cells is assisted by the T cell coreceptor called CXCR4; while HIV infects monocytes by interacting with CCR5 coreceptor.
  - HIV can remain dormant within cell for many years, especially memory CD4+ helper T cells. HIV induces a cytokine environment that helps in replication of virus. Either way, this subset of CD4+ helper T cells could become a target for eradicating HIV.
- HIV-1 can cause AIDS in people worldwide. HIV-2 has been isolated in West Africa, India. HIV-2 causes AIDS much more slowly than HIV-1 but otherwise clinically similar. By damaging the immune system, HIV interferes with body's ability to fight infection and disease. Structure of human immunodeficiency virus (HIV) is shown in Fig. 4.45. Summary of HIV-1 gene products and their functions is given in Table 4.43.

Routes of Transmission

Routes of transmission of human immunodeficiency virus include homosexual or bisexual men (75%), intravenous drug abusers (15%), multiple blood transfusion recipients (2%), hemophilic patients (1%) and transplacental route. Risk of human immunodeficiency virus has been greatly diminished by screening donor blood for anti-HIV antibodies, HIV p24 antigen, and HIV-1 RNA. HIV screening and heat inactivation of HIV in factor VIII concentrates have become universal in hemophilic patients.

Sexual Transmission

Sexual transmission is most common mode of transmission of HIV infection. In more than 75% cases, HIV is carried in the semen, and enters the recipient's body through abrasion in rectal or oral mucosa or by direct contact with mucosal lining cells.

Parenteral Transmission

Parenteral transmission occurs in individual's intravenous drug abusers, random recipients of blood transfusion. Mechanism of viral transmission includes sharing of needles, syringes and blood transfusion products contaminated with HIV.

Vertical Transmission

Mother-to-infant transmission is the major cause of pediatric AIDS. Infected mothers can transmit the infection to their offspring by three routes: (a) *in utero* by transplacental spread, (b) during delivery through an infected birth canal, and (c) after birth by ingestion of breast milk. These routes of transmission during birth (intrapartum) and in the immediate period thereafter (peripartum) is considered to be the most common mode of transmission. Higher the risk of transmission is associated with high maternal viral load and low CD4+ helper T cell counts as well as chorioamnionitis.

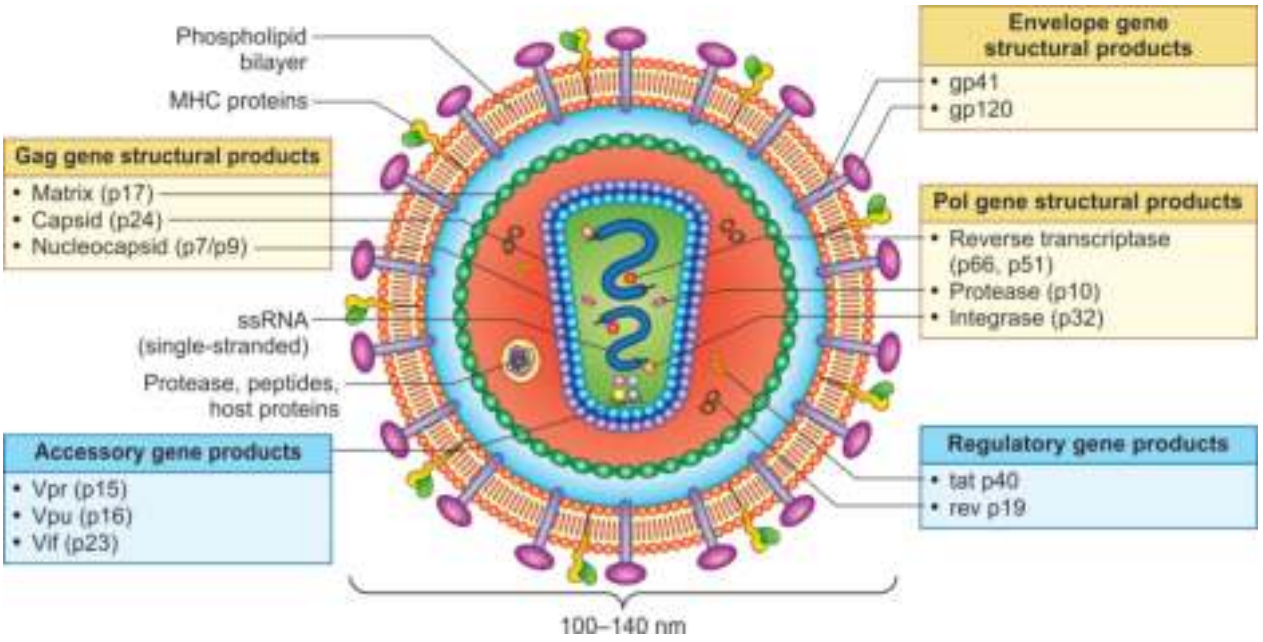

Fig. 4.45: Structure of human immunodeficiency virus (HIV). Each HIV virion is composed of numerous glycoproteins such as gp120 and gp41. The gp41 is a transmembrane molecule that crosses the lipid bilayer of the envelope. The gp120 is nonvalently associated with gp41 and serves as the viral receptor for CD4+ helper T cells of host. The viral envelope also contains some host-cell membrane proteins such as MHC class I and class II molecules. Within the envelope is viral core, or nucleocapsid, which includes a layer of protein called p17 and inner layer protein called p24. The HIV genome consists of two copies of double-stranded RNA (ssRNA), which are associated with two molecules of reverse transcriptase p64 and nucleoid proteins p10, a protease and p32 integrase. These glycoproteins play a vital role when HIV binds to and enters certain target cells.

Table 4.43 Summary of HIV-1 gene products and their functions

Viral Gene	Viral Protein	Designation	Function
Structural proteins			
gag gene	Capsid (CA)	p24	Viral capsid 24 plays a key role in pathogenesis of HIV that mediates gag oligomerization and assembly
	Nucleocapsid (NC)	p7	Viral nucleocapsid p7 is an RNA binding protein that packages the genome in the core; mediates gag oligomerization and assembly
	HIV budding p6	p6	HIV budding p6 is essential for budding of viral particles from plasma membrane that promotes membrane fusion of nascent virions via PTAP-Tsg101 recruitment of the ESCRT complex binds Vpr protein and packages it in the core
env gene	Surface envelope glycoprotein (SU)	SU, gp120	Surface envelope protein gp120; binds to CD4 receptor and chemokine receptors on target cell
	Transmembrane envelope glycoprotein (TM)	gp41	Transmembrane envelope gp41 protein; mediates fusion via fusion peptide
pol gene	Reverse transcriptase (RT)	p66, p51	RNA-dependent-DNA-polymerase converts viral ssRNA to linear DNA
	Integrase (IN)	p32	Integrase p32 protein facilitates integration of HIV DNA into host genome; involved in dynein-mediated transport of the RTC
	Protease (PR)	p10	Protease p10 protein play key role in cleavage of polyprotein components of gag-pol
Regulatory proteins			
tat gene	Trans-activator of transcription (Tat)	p40	Activator of transcription of HIV ssRNA is essential for virus replication
rev gene	Regulator of virions protein expression (Rev)	p19	Regulator of virion p19 protein is a post-transcriptional regulation of viral genes; including export of viral RNA from the nucleus

Contd...

Table 4.43 Summary of HIV-1 gene products and their functions (*Contd...*)

Viral Gene	Viral Protein	Designation	Function
Accessory proteins			
vpr gene	Viral protein R (vpr)	p15	Viral p15 protein assists in nuclear transport of HIV post-entry; induces G cell cycle arrest in infected cells
vpu gene	Viral protein U (vpu)	p16	Viral p16 protein enhances the release of virus particles by counter-acting the interferon-induced restriction factor tether in; promotes CD4 degradation
vif gene	Virion infectivity factor (vif)	p23	Viral p23 protein counteracts the anti-viral activity of APOBEC3 protein group. The latter protein groups are HIV restriction factors that hypermutate HIV genomes and render them nonfunctional

There are several other proteins with various immunomodulatory or regulatory functions in both HIV-1 and HIV-2 including vif (viral infectivity factor), vpr (viral protein R), tat (transactivator transcription), rev (regulator of expression of viral protein) and nef (negative regulatory factor). An additional vpu (viral protein U) is present in HIV-1 and not in HIV-2. Similarly, vpx (viral protein X) is present only in HIV-2 and not in HIV-1.

HIV Life Cycle

Life cycle of HIV comprises binding of HIV to CD4+ helper T cells, fusion of HIV gp120 to host cell membrane, internalization of HIV into host cell, synthesis of proviral DNA, entry of viral DNA into CD4+ helper T cells and creating new virus particles virions. Active viral replication is associated with more infection of cells and progression to AIDS. HIV does not infect the naïve T cells, which contain an enzyme, which inactivates the viral genome. With the activation of T cells, there is upregulation of NF-κB causing cell lysis. Life cycle of HIV is shown in Fig. 4.46.

Binding, Fusion and Internalization of HIV Glycoprotein (gp120) to Host Cell Membrane

The main attachment receptor for HIV is the CD4 molecule belonging to immunoglobulin superfamily, that is present on the CD4+ helper T cells, macrophages and microglial cells.

- The HIV-1 cell's envelope surface glycoprotein (gp120) initially binds to CD4+ molecule, which triggers a conformational change in the host cell membrane and virus envelope that allows binding of the co-receptor (i.e. CCR5 on macrophages and CXCR4 on CD4+ helper T cells), which is required for fusion between host cell membrane and virus envelope.
- Macrophages possess the CCR5 co-receptor, hence HIV strains requiring the CCR5 co-receptor for entry into the macrophages, also referred to as '**macrophage-tropic**' although macrophages also infect CD4+ helper T cells. Certain mutations in the CCR5 receptor are associated with totally resistant to some strains of HIV in homozygotes in the absence of the CCR5 molecule on their macrophages. But heterozygotes with mutation of CCR5 receptor develop a more slowly progressive disease.
- The 'lymphotropic' HIV strains use CXCR4 co-receptor on lymphocytes, for binding and entry into the host cells. So far, CXCR4 co-receptor deficient persons have not been found.

Proviral DNA (Double-stranded DNA) Synthesis

All retroviruses encode reverse transcriptase enzyme that reads the viral RNA sequence and transcribes into double-stranded deoxyribonucleic acid (ssDNA), which is then integrated, via the action of the integrase enzyme into the host cell genome.

- The provirus DNA or viral integrated dsDNA then acts as a template for viral genomic and messenger RNA (mRNA) transcription by the host cell's nucleic acid replicating machinery.
  - Recombination between these two RNA strands during viral replication, coupled with error-prone action of the reverse transcriptase enzyme, gives rise to the extreme genetic diversity of human immunodeficiency virus (HIV).
  - Integration of the provirus double-stranded DNA (dsDNA) into human genome of host cell establishes infection.
- Viral replication is enhanced by coinfection with other microorganisms, inflammatory cytokines and cellular activation. During cellular replication, provirus is transcribed by the host cell RNA polymerase II enzyme, and translated into proteins by viral messenger RNA, genomic RNA and cellular RNAs.

Creation of New Virus Particles

The gag-pol precursor polypeptide encoded by viral messenger RNA, is cleaved by viral-encoded protease enzyme to produce the gag and pol viral proteins.

- In addition, viral messenger RNA is also spliced to produce other viral proteins **tat, rev, vif, vpr** for

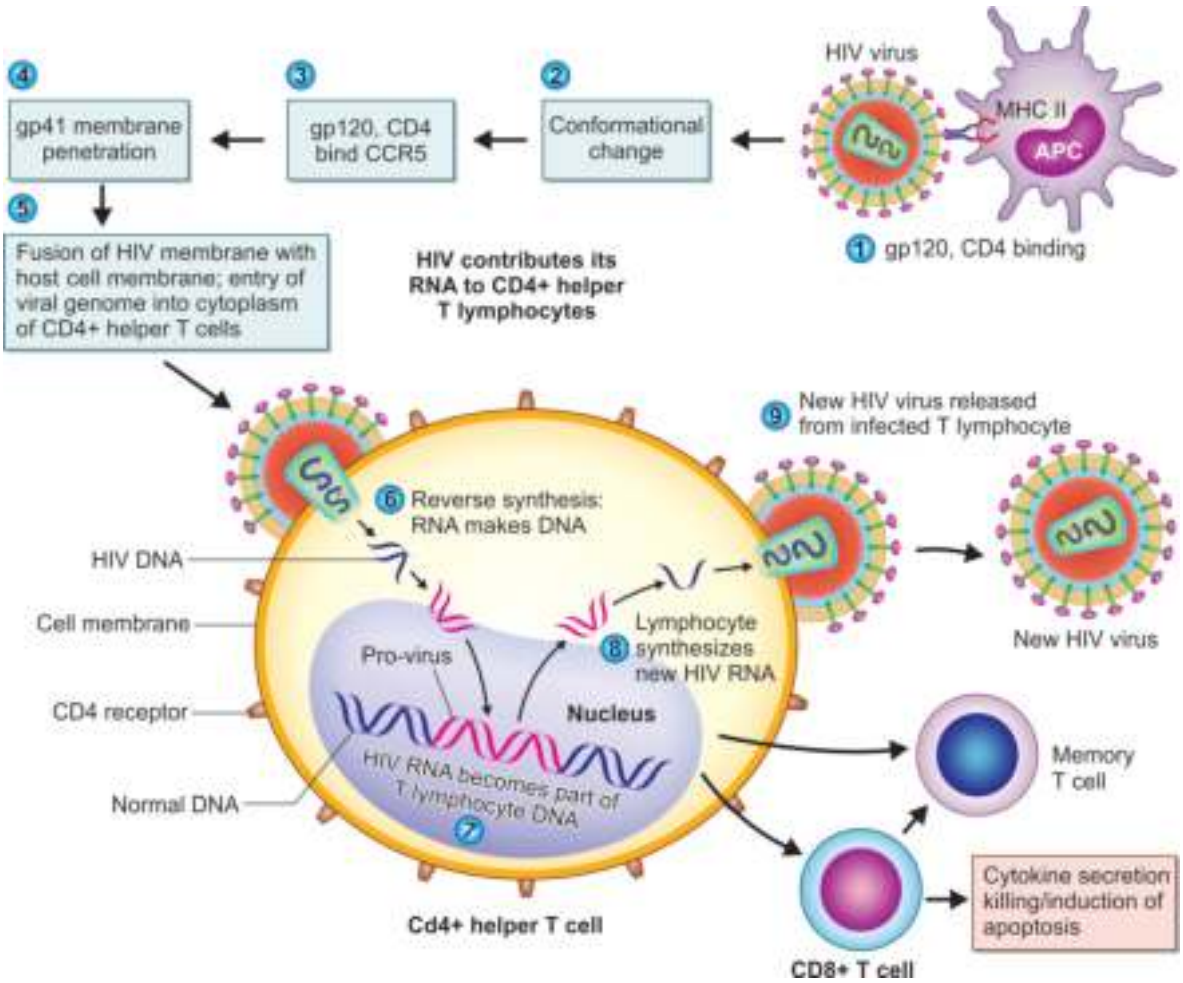

Fig. 4.46: Life cycle of human immunodeficiency virus (HIV) in the host cell. Various stages of the HIV life cycle in the host cell are: binding, fusion, reverse transcription, integration, replication, assembly and budding. HIV uses CD4+ helper T cells to replicate and each infected CD4+ helper T cells produces hundred of new copies of new HIV particles. The process is called the HIV life cycle. Each replication cycle only lasts for one to two days.

HIV-1, as well as the env precursor polypeptide. Ultimately, the env precursor polypeptide is cleaved by host cellular proteases, producing the envelope glycoproteins (gp120 and gp41).

- These viral proteins, together with the replicated diploid viral genomic RNA, are assembled and enveloped by budding through the host cell membrane, producing complete human immunodeficiency virus (HIV) virions.
- The new HIV virions (virus particles) are released from the CD4+ helper T cell. HIV is found in blood, semen, vaginal secretions, breast milk, and saliva.

HIV Natural History and Immunopathogenesis

In normal health, CD4+ helper T cells play important role in cell-mediated response, recognize antigens and utilize major histocompatibility complex (MHC) class II molecules. CD4+ helper T cells are differentiated according to the type of 'help'. Th1 cells activate CD8+ cytotoxic T cells, which utilize major histocompatibility complex (MHC) class II molecules to destroy infected cells. Th2 cells activate B cells, promoting antibody-mediated immunity.

- HIV integrates into host DNA (CD4+ helper T cells, dendritic cells, Langerhans' cells, and microglial cells of the central nervous system). Host mounts cell-mediated and humoral immune responses against HIV. Cell-mediated immune response is most important against HIV. Antibodies have many roles to control HIV infection. But these antibodies are less effective in controlling HIV infection as compared to cell-mediated immune response by two mechanisms: (a) antibodies formed against proteins on surface of virus block attachment of the virus to the host cell receptor, and (b) antibody-dependent cell-mediated cytotoxicity (ADCC) occurs by binding of Fc portion of antibody to natural killer cells (NK cells) leading to destruction of infected cells by indirect mechanism.
- The pathology of HIV infection is usually characterized by declining CD4+ helper T cell counts in the

peripheral blood, wasting disease and neurological disease. The neurological disease is related to infection of macrophages and microglia.

- Three stages of HIV infection include: (a) primary infection (acute HIV infection), (b) clinical latent infection (chronic HIV), and (c) acquired immunodeficiency syndrome (AIDS). There is no permanent cure for HIV. Symptoms depend on the stage of HIV infection.
- Antiretroviral therapy (ART) can slow or prevent HIV from advancing from one stage to the next. In primary HIV infection, about 50% of infected persons remain asymptomatic. Rest symptomatic infected persons present with fever and lymphadenopathy.
- HIV disease may be asymptomatic for many years. Before fully developed AIDS occurs, there is acute illness resembling infectious mononucleosis; a long latent phase followed by generalized lymphadenopathy; and a chronic HIV stage marked by fever, weight loss and diarrhea, illness and then AIDS as a result of disruption of immune system by HIV.
- HIV seropositivity begins soon after initial HIV infection. Antibodies to the proteins encoded by the genes of retroviral gag, env and pol regions can be demonstrated, especially antibodies to the gp120 and p24 proteins. Initial HIV infection occurs with mild illness in 70% of cases. HIV infection can also be demonstrated by amplification of viral genetic sequences by polymerase chain reaction (PCR) or by viral culture.
- The late stage, defined as AIDS, is marked by HIV infection complicated by specified secondary opportunistic infections or malignant neoplasms.

Seroconversion and Acute HIV Infection Stage

After seroconversion, when anti-HIV antibodies in response to acute HIV infection are detectable, patients remain asymptomatic for 2–15 years. During this stage, viral replication continues at a high rate up to 1010 infectious virions/day, leading to infection of 108–109 CD4+ helper T cells/day. Simultaneously, there is rapid turnover of CD4+ helper T cells.

- The rapid turnover of CD4+ helper T cells and its enormous diversity underlie the difficulty in producing antiretroviral drugs with long-term efficacy and development of an effective vaccine against HIV.
- Depletion of HIV-infected CD4+ helper T cells occurs through several mechanisms: (a) HIV has direct cytopathic effect, (b) CD8+ cytotoxic T cells destroy HIV-infected cells, and (c) lymphocytic activation and cytokines cause apoptosis of CD4+ helper T cells. Over this period, there is steady decline in the CD4+ helper T cell count.
- Some infected persons present with flu-like illness such as fever, headache, muscle aches and joint pain, cough, night sweats, skin rash, sore throat, lymphadenopathy, diarrhea and weight loss within two to four weeks after HIV infection. Symptoms may persist for few weeks. High number of infectious virions and rapid depletion of CD4+ helper T cells lead to progression of the disease.

Chronic HIV Infection Stage

Chronic HIV infection stage is also called asymptomatic HIV infection or clinical latency. HIV is still active but viral load is low. Persons remain asymptomatic during this stage. Without taking antiretroviral therapy (ART), some persons may progress to the next stage faster. Persons can transmit HIV to others during this stage. At the end of this stage, viral load goes up and the CD4+ helper T cell goes down. Persons who take antiretroviral therapy may never progress to next stage (i.e. AIDS).

Acquired Immunodeficiency Syndrome (AIDS)

Acquired immunodeficiency syndrome is the most severe stage of HIV infection, that disrupts immune system leading to opportunistic infections and tumors. CD4+ helper T cell count drops below 200 cells/mm. Persons can have a high viral load, that is very infectious. Without antiretroviral therapy, persons with AIDS can survive for three years.

Opportunistic Infections in AIDS

Decline in immune status parallels the decline in CD4+ helper T cells number and function. Loss of CD4+ helper T cells results in failure of normal Th1 response and cell-mediated immunity that is necessary for controlling intracellular infections.

- Children have a high incidence of opportunistic bacterial infections, such as otitis media, sepsis, chronic salivary gland enlargement, *Mycobacterium avium-intracellulare* complex function, and pneumonias, including lymphoid interstitial pneumonia and *Pneumocystis jirovecii* pneumonia.
- HIV causes direct injury to nervous system (encephalopathy and peripheral neuropathy), kidney (nephropathy), heart (cardiomyopathy), and gonads in both sexes (hypogonadism) and gastrointestinal tract (dysmotility and malabsorption). HIV causes indirect injury to various organs by opportunistic infections and malignant tumors as a consequence of immunosuppression. Opportunistic infections and malignant tumors associated with AIDS are shown in Fig. 4.47. Opportunistic infections in AIDS are given in Table 4.44.

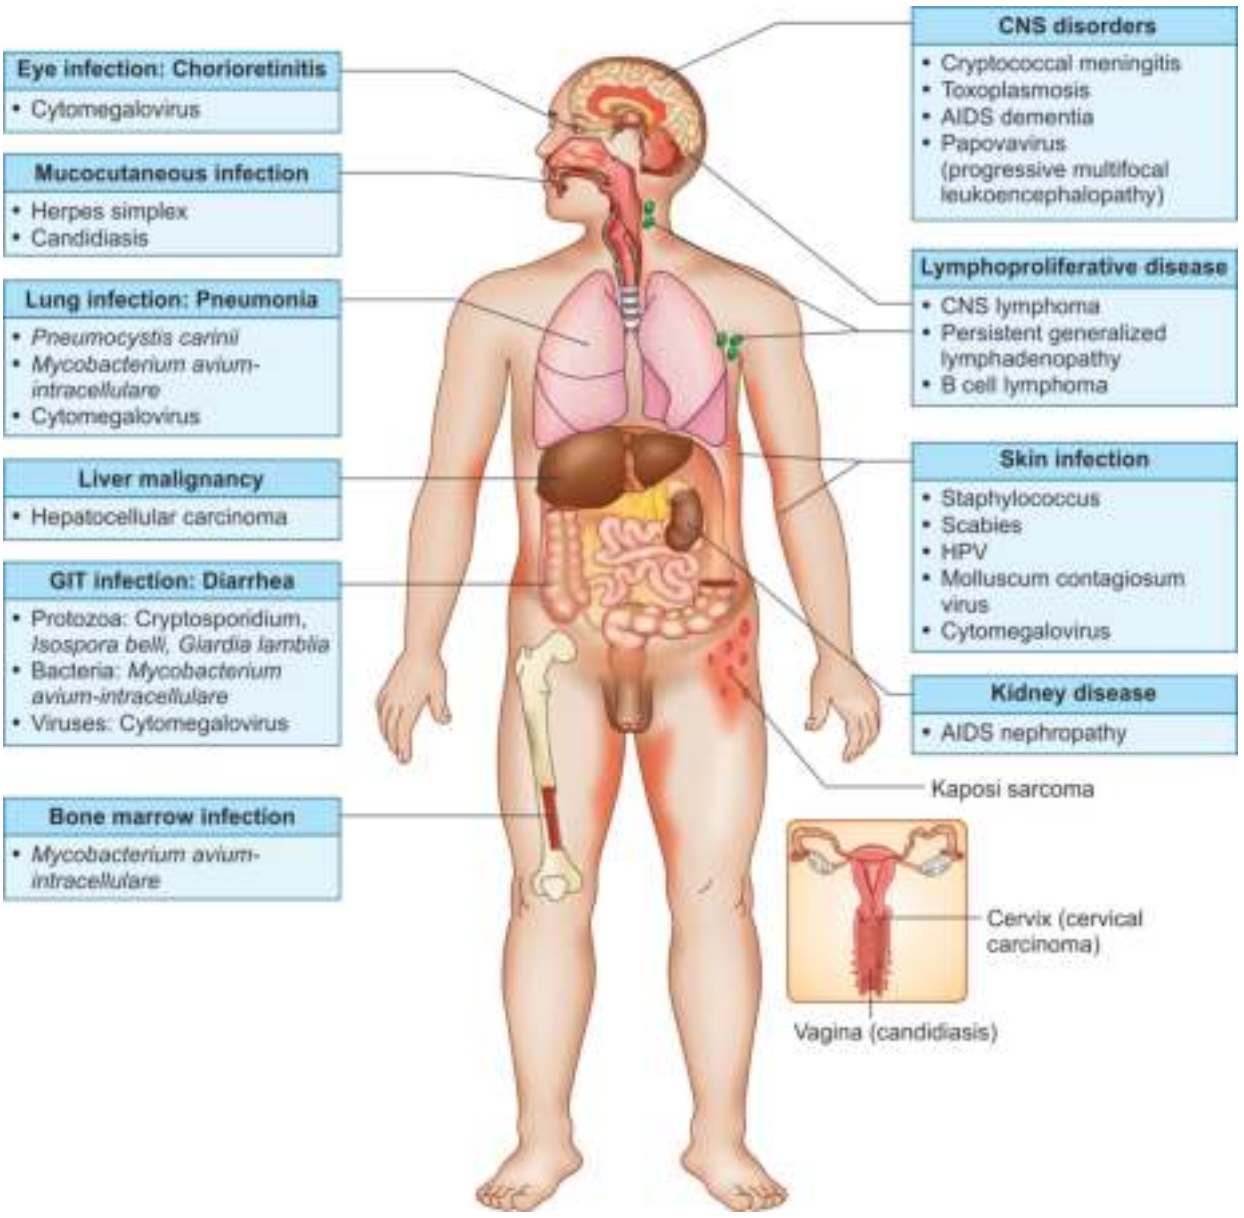

Fig. 4.47: Opportunistic infections and carcinomas associated with human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS). HIV damages the immune system that fails to fight of opportunistic infections. HIV-related opportunistic infections include *Streptococcus pneumoniae*, Salmonella infection, candidiasis, tuberculosis and toxoplasmosis. HIV/AIDS patients are at risk of development of Kaposi sarcoma, non-Hodgkin lymphoma, Hodgkin disease, cervical carcinoma and carcinomas of the lung, liver, mouth, throat and anus.

Table 4.44 Opportunistic infections in AIDS

Organs Involved	Opportunistic Infections
Central nervous system	▪ Cryptococcus (meningitis) ▪ *Toxoplasma gondii* (AIDS dementia) ▪ Papovavirus (progressive multifocal leukoencephalopathy)
Eye (chorioretinitis)	Cytomegalovirus
Mucocutaneous (recurrent aphthous ulcers, angular cheilitis, necrotizing ulcerative gingivitis and periodontitis)	▪ Viral infections (herpes simplex virus, herpes zoster virus, cytomegalovirus) ▪ Fungal infections (*Candida albicans*, *Histoplasma capsulatum*, *Cryptococcus neoformans* and aspergillosis) ▪ Bacterial infections (*Escherichia coli*, *Enterobacter cloacae*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*)

Contd...

Table 4.44 Opportunistic infections in AIDS (*Contd...*)

Organs Involved	Opportunistic Infections
Lungs consolidation (pneumonia)	▪ *Pneumocystis jirovecii* ▪ *Mycobacterium avium-intracellulare* ▪ Cytomegalovirus
Skin (dermatitis, folliculitis and impetigo)	▪ Staphylococcus ▪ Scabies ▪ Human papillomavirus ▪ Molluscum contagiosum ▪ Cytomegalovirus
Small intestine (malabsorption syndrome)	▪ Protozoa (Cryptosporidium, *Isospora belli*, *Giardia lamblia*) ▪ *Mycobacterium avium-intracellulare* ▪ Cytomegalovirus
Large colon	Colitis by opportunistic infections
Kidneys	HIV nephropathy
Vagina	*Candida albicans*
Bone marrow	*Mycobacterium avium-intracellulare*

Pathology Pearls: Opportunistic Infections in AIDS

Fungal Infections

- Fungal infections are a major cause for opportunistic pneumonitis in immunocompromised persons.
- Gross examinations of lungs show irregular yellowish-gray infiltrate with a granular dry and firm on cut surface.
- Opportunistic infections in AIDS include *Pneumocystis jirovecii, Mucor* species, *Candida albicans*, Cryptosporidium, Coccidioides, *Cryptococcus neoformans*, and *Histoplasma capsulatum.*

Bacterial Infections

Bacterial infections include Mycobacterium tubercle bacilli both typical and atypical such as *Mycobacterium avium-intracellulare*.

Viral Infections

- Cytomegalovirus is member of the herpes family, which may cause retinitis, blindness, colitis, pneumonia and infection of adrenal glands.
- Patients are prone to herpes simplex virus, varicella zoster virus, JC virus, Epstein-Barr virus and poxviruses.

Protozoal Infections

Patient with HIV infection may develop giardiasis, leishmaniasis and toxoplasmosis.

Pneumocystis jirovecii

- *Pneumocystis jirovecii* causes pneumonia in immunocompromised persons.
- Patient presents with fever, non-productive cough (viscous sputum), dyspnea, weight loss and night sweats.
- *Pneumocystic jirovecii* may invade liver, spleen and kidney in minority of cases.

Cancers in AIDS

Decline in immune status parallels the decline in CD4+ helper T cells number and function results in failure of normal Th1 response and cell-mediated immunity that is necessary for prevention of development of tumorigenesis. HIV dysregulates immune system, activates cellular genes or proto-oncogenes or inhibit tumor suppressor genes resulting in genomic instability. HIV may also induce abnormalities of endothelial and epithelial cells resulting in development of malignant tumors. HIV / AIDS-related malignant tumors are given in Table 4.45.

Kaposi Sarcoma

Kaposi sarcoma is most often associated with acquired immunodeficiency syndrome (AIDS) especially in male homosexual persons. Kaposi sarcoma is vascular neoplasm involving mucocutaneous, lymphatic, gastrointestinal tract and lungs.

- Kaposi sarcoma is caused by human herpesvirus 8 (HHV) also known as Kaposi sarcoma herpesvirus (KSHV). HHV-8 encodes proteins that interfere with the p53 and pRb tumor suppressor pathways.
- Human herpesvirus 8 (HHVS) and HIV induce angiogenic and inflammatory cytokines responsible for tumor progression.
- Patient presents with reddish purple macules in distal lower extremities. AIDS-associated Kaposi sarcoma often involves lymph nodes and disseminates widely to viscera early in its course.

Lymphomas Associated with HIV

Lymphomas associated with HIV include Burkitt's lymphoma, diffuse large B cell lymphomas (HHV-8), immunoblastic lymphoma (primary CNS), primary

Table 4.45 HIV/AIDS-related malignant tumors

Organs	Cancers
AIDS defined carcinomas	
Skin	Kaposi sarcoma (HHV8), vascular tumor that may involve mucocutaneous, lymphatic, gastrointestinal tract, and pulmonary sites
Central nervous system	Immunoblastic lymphoma HHV8
Lymph nodes	▪ Burkitt's lymphoma (associated with translocations of MYC gene on chromosome 8, surface IgM, CD19, CD20, CD10, and BCL-6, phenotype consistent with a germinal center B cell origin involving CNS, jaw and facial bones of orbit) ▪ Diffuse large B cell lymphoma (CD20 positive, occurs due to dysregulation of BCL-6 at chromosome 3q27) ▪ Primary effusion lymphomas (pleural and peritoneal effusion having clonal IgH gene rearrangements, absence of lymphadenopathy) ▪ Plasmablastic lymphoma ▪ Persistent generalized lymphadenopathy
Cervix	Cervical carcinoma (HPV)
Less common carcinomas	
Anal region	Anal carcinoma (HPV)
Liver	Hepatocellular carcinoma
Lymph node	▪ Hodgkin's disease mixed cellularity EB virus in 70% cases) CD15+, CD30+ ▪ Hodgkin's disease depletion type (EB virus) CD15+, CD30+
Conjunctiva	Squamous cell carcinoma of conjunctiva
Uterus	Leiomyosarcoma (pediatric age group)

Extranodal involvement occurs in central nervous system, liver, bone marrow and gastrointestinal tract.

effusion lymphomas (pleural and peritoneal effusion having clonal IgH gene rearrangements), plasmablastic lymphoma (advanced stage) and Hodgkin's disease. Extranodal involvement occurs in central nervous system, liver, bone marrow and gastrointestinal tract.

- **Burkitt's lymphoma:** Burkitt lymphoma is associated with reciprocal chromosome translocation t(8;14) involving the heavy chain c-Myc oncogene on chromosome 8 and heavy immunoglobulin chain locus on chromosome 14. Expression of surface IgM, CD19, CD20, CD10, and BCL-6 phenotyping is consistent with a terminal center B cell origin neoplasm involving CNS, jaw and orbit.
- **Primary effusion lymphoma:** Primary effusion lymphoma is malignant large B cell lymphoma associated with pleural or peritoneal effusion in the absence of lymphadenopathy in advanced HIV infection or older adults. The tumor cells are often anaplastic in appearance and typically fail to express surface B or T cell markers, but have clonal IgH gene rearrangements. In all cases, the tumor cells are infected with KSHV/HHV-8, which appears to have a causal role.
- **Plasmablastic lymphoma (PBL):** Plasmablastic lymphoma is diffuse proliferation of neoplastic cells most of which are resembling B immunoblasts affecting oral cavity in AIDS persons of 50 years age group. Immunophenotyping reveals positivity with CD138, CD38, and IRF4/MUM1. PBL also shows positivity with CD79a in 50–85% cases.
- **Hodgkin's disease (mixed cellularity type):** More than 50% of patients present as stage III or IV disease. Males are more affected than females with peak in young adults and again in adults older than 55 years of age. EB virus plays role in the pathogenesis of Hodgkin's disease. On histopathologic examination of lymph node, tumor is composed of Reed-Sternberg cells admixed with T lymphocytes, macrophages, plasma cells and eosinophils. Immunophenotyping of Reed-Sternberg cells reveals positivity with CD15 and CD30 in 70% of cases.
- **Hodgkin's disease (lymphocytic depletion type):** Hodgkin's disease (lymphocytic depletion type is more common in older males. EB virus plays role in the pathogenesis of Hodgkin's disease. On histopathologic examination of lymph node, it is composed of Reed-Sternberg cells and paucity of background reactive cells. Immunophenotyping of Reed-Sternberg cells reveals positivity with CD15 and CD30 more common in older males. HIV-infected individuals in developing countries often present with advanced disease.

Other Cancers

Patient may develop hepatocellular carcinoma, HPV-related carcinomas of cervix and anus including lymphoma of central nervous system.

Lymphomatoid Granulomatous

Lymphomatoid granulomatous is an angiocentric and angiodestrictive lymphoproliferative disease involving extranodal sites and composed of EBV positive B cells along with reactive T cells. It has a spectrum of histologic grade and clinical aggressiveness, which is related to the proportion of large B cells.

HIV Testing for Persons

Recommended groups for HIV testing include homosexual men, commercial sex workers, unprotected sex, illness or fever without cause, high-risk needle sharing, perinatal exposure and patient request. Purpose of HIV testing includes blood safety, blood donation safety, identification of asymptomatic individuals and diagnosing clinically suspected cases. HIV testing is useful for prophylaxis, management and treatment of HIV-related illnesses.

WHO Definition of AIDS Patient

An adult or adolescent (>12 years) is considered to have AIDS if a test for HIV antibody is positive and one or more of the following conditions is/are present, which include >10% weight loss or cachexia with diarrhea/fever or both, cryptococcal meningitis, pulmonary or extrapulmonary tuberculosis, Kaposi sarcoma, neurological impairment, esophageal candidiasis, life-threatening or recurrent pneumonia with/without known etiology and invasive cervical carcinoma.

Laboratory Testing

Samples are collected with universal precautions for HIV testing include blood, serum, plasma, saliva or urine. Approximately 3–5 ml of blood sample may be taken as whole or anticoagulated blood. Specimen should be transported and processed within 24–48 hours. If serum/plasma has been separated then it should be refrigerated at –20 degree for a week.

Window Period

The window period in untreated HIV infection begins at the time of infection, which can last 4–8 weeks. During window period, a person is infected, infectious and viremic, with a high viral load and a negative HIV antibody test. The point when the HIV antibody test becomes positive is called the **point of seroconversion**. Window period in untreated HIV infection is shown in Fig. 4.48.

Reporting Procedure

Results of HIV testing is kept confidential. At least three screening HIV testing should be performed, which can be negative or positive or intermediate. Negative HIV report is mentioned if the initial screening report is

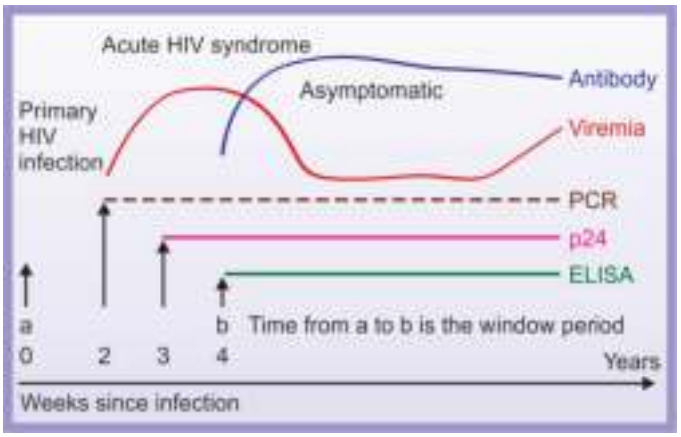

Fig. 4.48: Window period in untreated HIV infection. Normal HIV blood tests detect the presence of antibodies in human body as a part of their immune response to fight HIV. In most cases, HIV persons develop antibodies to HIV within 28 days of infection. During this period, HIV persons experience the so-called 'window period', the antibodies have not been produced in high quantity to be detected by standard tests and when the HIV persons may not show clinical signs of HIV infection but can transmit the disease to others.

nonreactive. At least three screening tests show reactive positive results concordantly, subsequent sample is retested before reporting. Discordant results by three screening tests, follow-up samples to retest at 2 weeks, 3 months, 6 months, 12 months before report dispatched. If the HIV result remains indeterminate even after a year, the person is considered to be HIV negative.

Screening of HIV Infection

Screening of HIV infection is done by analysis of enzyme-linked immunosorbent assay (ELISA) and particle agglutination (PA), antigen capture and immune complex disassociation methods. Screening of HIV infection is given in Table 4.46.

Confirmatory Tests for HIV Infection

HIV infection is confirmed by Western blot, immunofluorescence, nucleic acid testing, HIV RNA detection and HIV DNA detection. Confirmatory tests for HIV infection are given in Table 4.47. Testing of body fluids for HIV is given in Table 4.48.

- **Enzyme-linked immunosorbent assay (ELISA) test:** ELISA test is done for HIV infection. False positive ELISA test is seen in persons immunized against influenza vaccine up to 3 months, presence of rheumatoid factor, chronic alcoholism, HLA-DR antibodies in multigravida, autoimmune disorders and hemodialysis. False negative ELISA test is seen in advanced AIDS and during window period in 6–20% of cases. Unusual serotypes may give rise to negative results in screening. ELISA test for HIV infection

Table 4.46 Screening of HIV infection

Testing Categories	Analyte Detection	Use
ELISA	IgG/IgM	Standard screening using spectrophotometry
Simple ELISA	IgG/IgM	No special equipment required
Rapid ELISA	IgG/IgM	Results obtained in 10–30 minutes
Particle agglutination (PA)	IgG/IgM	ELISA with visual read out of particle clumping
Antigen capture	p24	HIV p24 detection
Immune dissociation	p24	Disrupts p24 antigen–antibody complex permitting capture

Table 4.47 Confirmatory tests for HIV infection

Testing Categories	Analyte Detection	Use
Western blot technique	IgG	Confirmation of HIV infection
Immunofluorescence (IF) microscopy	IgG	Confirmation of HIV infection
Nucleic acid technique (NAT)	HIV RNA	PCR used to detect HIV nucleic acid in donor screening
HIV RNA detection technique	HIV RNA viral load	Useful in resolving indeterminate cases
HIV DNA detection technique	HIV DNA	RT-PCR used to detect HIV DNA in neonatal diagnosis

Table 4.48 Body fluids for HIV testing

Source	ELISA	Rapid ELISA	Western Blot	Immunofluorescence (IF)	Nucleic Acid Testing (NAT)
Whole blood	+	+	–	–	–
Dried blood	+	–	–	–	–
Plasma	+	+	+	+	+
Serum	+	+	+	+	+
Oral fluid	+	–	+	–	–
Urine	+	–	+	–	–

using HIV antibody against immobilized antigens is given in Table 4.49.

- **Particle agglutination assays:** Particle agglutination assays are based on the ability of sera containing HIV antibodies to cross-link small particles containing HIV antigen on the surface. It has high sensitivity and specificity and easy to perform. Its disadvantages include subject to reader interpretation and no permanent records available.
- **Nucleic acid test (NAT):** NAT is adjunct but not a replacement of serological tests. Various formats include PCR and RT-PCR, NASBA (nucleic acid sequence-based amplification) and bDNA (branched-chain DNA). NAT is best in detecting HIV during seronegative period, which has a small window period. Its disadvantage is its high cost.
- **Rapid visual test (tri-dot test)**: Rapid visual test (tri-dot test) is a visual rapid and sensitive immunoassay

Table 4.49 Enzyme-linked immunosorbent assay (ELISA) test for HIV infection using HIV antibody against immobilized antigens

Generation of ELISA	Component	Approximate Window Period	Advantages
First generation	Infected cell lysates	63 days	Laboratory diagnosis of HIV infection
Second generation	Recombinant proteins and peptides	42 days	Decreases false positive
Third generation	Sandwich with laboratory antigen	22 days	Short window period
Fourth generation	p24 antigen sandwich	16 days	Short window period

for differential detection of HIV-1 and HIV-2 antibodies (IgG) in human serum against antigens (gp41 C terminal of gp120 and gp36). Principle of rapid visual test is based on reaction of immobilized antigens with antibodies present in the serum. Conjugate binds to the Fc portion of the HIV antibody to give distinct pinkish purple dot against a white background. Results are confirmed by assay be performed on fresh samples.

- **Immunofluorescence (IF) microscopy:** Immunofluorescence identifies the presence of antibodies by their specific ability to react with antigens on infected cells. Characteristic staining pattern of reactivity provides additional specificity to the interpretation. Conditions interfering with immunofluorescence microscopy include lipemia, hyperfibrinogenemia, paraproteinemia and autoimmune disease.
- **Radioimmunoprecipitation:** Radioimmunoprecipitation (RIPA) identifies antibodies by their ability to react with radiolabeled antigens, which helps to resolve indeterminate Western blot in early infection.
- **CD4+ helper T cells count:** CD4+ helper T cell count is the best indicator for immediate state of the immune system. Normal CD4+ helper T cell count (500–1600 IU/L) and CD8+ cytotoxic T cell count (375–1100 IU/L) (CD4+/CD8+) ratio ranges from 0.9–1.9. It correlates very well with level of immunologic tolerance. CD4+ helper T cell count is performed at every 3–6 months interval. CD4+ helper T cell count is most reliable short-term indicator of disease progression. Changes in CD4+ helper T cells and CD8+ cytotoxic T cells occur over the time span of an HIV infection and its relationship to AIDS diagnosis. CDC classification of HIV categories is given in Table 4.50.
- **CDC classification of HIV categories:** CDC classification of HIV categories includes CD4+ helper T cell count, asymptomatic acute HIV infection, symptomatic HIV infection and AIDS associated with opportunistic infection and carcinomas. Gradual loss of CD4+ helper T cells over the time span of an HIV infection and its relationship to AIDS diagnosis is shown in Fig. 4.49.

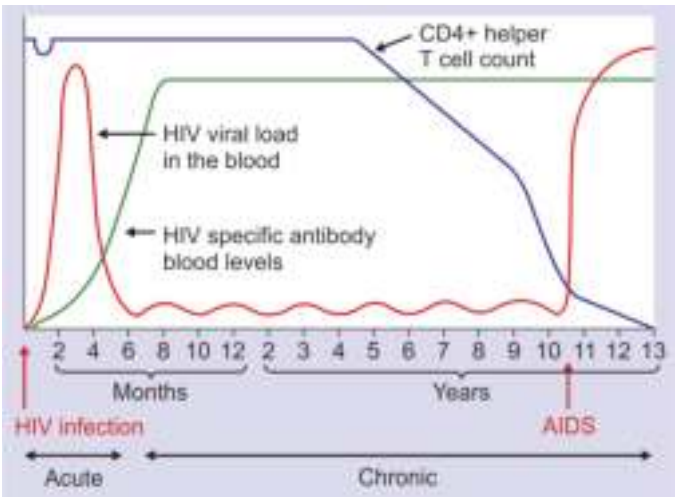

Fig. 4.49: Gradual loss of CD4+ helper T cells over the time span of an HIV infection and its relationship to AIDS diagnosis. The hallmark of human immunodeficiency virus (HIV) infection is gradual loss of CD4+ helper T cells and imbalance of CD4+ helper T cell homeostasis, high HIV viral load and HIV specific antibody with progressive impairment of immunity that results in death. HIV infection in human is caused by two related yet distinct HIV-1 and HIV-2 viruses. HIV-1 is more virulent than HIV-1 and permits the host to mount less effective adaptive immune response.

HIV RNA Determination

HIV RNA determination is highly sensitive and precise, which becomes essential component in monitoring HIV infection. It predicts the outcome of CD4+ T cell count in future. It provides very important prognostic information. During therapy levels of HIV RNA must be measured every 3–4 months.

- **HIV RNA viral loads after infection:** It can be used to assess the viral set point and predict the likelihood of progression to AIDS in the next 5 years. The higher the viral set point, there is rapid fall of CD4+ helper T cell count and rapid progression of HIV infection to AIDS.
- **Rate of disease progression:** It is determined by the patient's viral load. With levels between 1,000 and 10,000 viral copies, the likelihood of AIDS in 5 years is 8%. At 10,000 to approximately 50,000, the likelihood is 26%. At 50,000 to <100,000 it is 49%. Between 100,000 to 1,000,000 the likelihood is 62% at 5 years.

Table 4.50 CDC classification of HIV categories

CD4+ T Cell Count Categories	A. Asymptomatic Acute HIV Infection	B. Symptomatic HIV Infection	C. AIDS Indicator State (Opportunistic Infections and Cancers)
>500/µl	A1	B1	C1
200–499/µl	A2	B2	C2
<200/µl	A3	B3	C3

HIV Vaccines

There are a number of factors that cause development of an HIV vaccine to differ from the development of other classic vaccines. Classic vaccines mimic natural immunity against reinfection generally seen in individuals recovered from infection; there are almost no recovered AIDS patients.

- Most vaccines provide protection against disease, not against infection. HIV infection may remain latent for long periods before causing AIDS. Most effective vaccines are whole-killed or live-attenuated organisms; killed HIV-1 does not retain antigenicity and the use of a live retrovirus vaccine raises safety issues.
- Most vaccines provide protection against infections through mucosal surfaces of the respiratory or gastrointestinal tract; the great majority of HIV infection is through the genital tract.

HYPERSENSITIVITY REACTIONS

Immune system protects our body from outside harmful invaders such as bacteria, viruses and fungi. Hypersensitivity reactions occur when the normally protective immune system responds abnormally in response to an exogenous antigen or allergen, potentially harming the body, whereas autoimmune diseases arise from an abnormal immune response to endogenous substances (**autoantigens**).

- A symptomatic hypersensitivity reaction only occurs in sensitized persons, who must have had at least one prior asymptomatic exposure with the offending exogenous antigen.
- Hypersensitivity reactions are commonly classified into four types by Gell and Coombs: IgE-mediated type 1, IgG-mediated type 2, immune complex-mediated type 3 and cell-mediated type 4. Types 1, 2, and 3 are known as immediate hypersensitivity reactions, which require the active production of IgG, IgM and IgE antibodies by plasma cells, the terminally differentiated B cells. Type 4 hypersensitivity is delayed type of cell-mediated that occurs due to interaction of T cells and macrophages.
  - Type 1 hypersensitivity reaction is an immediate immune reaction mediated by immunoglobulin E (IgE) attached to mast cells, which degranulate in response to subsequent exposure to soluble antigen or allergen and release histamine and other chemical mediators leading to tissue injury. Examples of type 1 hypersensitivity reaction are hay fever (allergic rhinoconjunctivitis due to inhaled allergens), urticaria (hives), eczema, food allergy (nuts, shellfish, eggs, wheat), drug allergy (penicillin), insect venom allergy (bee, wasp), angioneurotic nonpitting subcutaneous edema over face, bronchial asthma, anaphylaxis (cutaneous and anaphylactic shock) and anaphylactic transfusion reactions (in patients with IgA deficiency).
  - Type 2 hypersensitivity reaction refers to an immediate antibody-mediated hypersensitivity reaction in which antibodies (IgG or IgM) are directed against cellular or extracellular matrix antigens with the resultant cellular functional loss or damage to tissue antibody-dependent cellular cytotoxicity (ADCC) mechanisms (e.g. autoimmune hemolytic transfusion reaction, hemolytic disease of the fetus and newborn, autoimmune hemolytic anemia, immune thrombocytopenia, drug-induced neutropenia and agranulocytosis, Hashimoto's thyroiditis, pernicious anemia, hyperacute transplant rejection, rheumatic fever, Goodpasture syndrome, Graves' disease, Lambert-Eaton myasthenic syndrome, pemphigus vulgaris, bullous pemphigoid).
  - Type 3 hypersensitivity reaction is an immediate immune complex-mediated hypersensitivity reaction, which causes tissue damage (skin, joints, blood vessels and glomeruli) due to antigen–antibody complex deposition. Examples of type 3 hypersensitivity reactions are polyarteritis nodosa, drug-induced hypersensitivity vasculitis, post-streptococcal glomerulonephritis, IgA nephropathy, membranous glomerulonephritis, systemic lupus erythematosus, serum sickness, Arthus reaction, hypersensitivity pneumonitis.
  - Type 4 hypersensitivity reaction is delayed type of cell-mediated hypersensitivity reaction that occurs at least 48 hours after exposure to an antigen, which involves sensitized CD4+ helper T cells, which release (cytokines, chemokines), macrophages and CD8+ cytotoxic T cells. Delayed hypersensitivity and epithelioid cell granulomas play a pivotal role in tissue damage observed during infections with slow-growing intracellular pathogens such as *Mycobacterium tuberculosis* (tuberculosis), *Mycobacterium leprae* (leprosy) and *Histoplasma capsulatum*. Examples of type 4 hypersensitivity reaction are contact dermatitis, tuberculin skin test reaction and granulomatous inflammation.
  - Type 5 is stimulatory hypersensitivity reaction, in which antibodies act as agonists for cell surface

receptors present on a cell, which a hormone would normally activate. Antibodies formed against thyroid-stimulating hormone receptors of thyroid follicular cells lead to **Graves' disease**. Comparison of different hypersensitivity reactions is given in Table 4.51.

Table 4.51 Comparison of different hypersensitivity reactions

Type 1 Hypersensitivity Reaction	Type 2 Hypersensitivity Reaction	Type 3 Hypersensitivity Reaction	Type 4 Hypersensitivity Reaction
Response time			
Less than 30 minutes (15–30 minutes)	Less than 8 hours (minutes to <8 hours)	Less than 8 hours (3–8 hours)	24 to 72 hours (acute cases). More than one week in chronic cases
Antigens			
Non-self (heterologous)	Self (autologous cells)	Self or non-self	Self or non-self
Antibody's role			
IgE	IgG, IgM	IgG, IgM	T cells (none Ig)
Complement system's role			
No	Yes or no	Yes	No
Cells involved in initiation			
Mast cells and basophils	None	None	APC, T helper cell 1
Inflammatory cells			
Eosinophils	Neutrophils	Neutrophils	Macrophages, T cells, keratinocytes
Mechanism			
First allergen exposure: IgE binds to mast cells	IgG, IgM antibodies cause cell injury by three mechanisms	Insoluble antigen–antibody (IgG, IgM) complexes are deposited in vessel wall and serosal surfaces or other tissues	Direct destruction of target antigenic cells by binding of cytotoxic T cells, FAS-related induction of apoptosis, and/or release of perforins and granzymes
Subsequent exposure to same allergen causes mast cell degranulation and release histamine, PAF and other chemical mediators that cause itching, bronchospasm, wheezing, shortness of breath and anaphylactic shock	▪ Direct cellular cytotoxicity ▪ Complement-mediated induced phagocytosis ▪ Autoantibodies block/inactivate cell surface receptors	▪ Immune complexes activate complement system resulting in chemotaxis of neutrophils ▪ PMN cells attempt to phagocytose immune complex resulting in liberation of hydrolytic enzymes and chemical mediators causing tissue damage	▪ T cell cytokine response activates macrophages and results in epithelioid granulomas formation (IFN-γ and TNF-α) ▪ T cell cytokine response activates mast cells (IL-3 and IL-5), synthesis of vasoproliferative factors (IL-3. and IL-8)
Chemical mediators			
▪ Early phase: histamine, ECF, PAF, heparin ▪ Late phase: LTC4, LTD4, LTDE4, TXA2, and prostaglandins	C3a, C5a: chemotaxis of neutrophil	C3a, C5a: chemotaxis of neutrophils	Monocyte chemotactic factors (MCF), monocyte inhibitory factors (MIF), IFN-γ, TNF-α, IL-3, GM-CSF
Target tissue			
Vascular endothelium, bronchial smooth muscle	Blood or tissue cells	Vascular endothelium and epithelial cells	Modified self, infected cells, allografts

Contd...

Table 4.51 Comparison of different hypersensitivity reactions (*Contd...*)

Type 1 Hypersensitivity Reaction	Type 2 Hypersensitivity Reaction	Type 3 Hypersensitivity Reaction	Type 4 Hypersensitivity Reaction
Primary results			
Vascular permeability, transudation, erythema, edema, wheal, bronchospasm, wheal and flare	Blood or tissue cell lysis, phagocytosis, inflammation, decreased serum complement	Necrotizing vasculitis (fibrinoid necrosis) vasoconstriction, thrombi, necrosis, decreased serum complement	Erythema, induration, granuloma formation
Histology			
Eosinophils Basophils	Antibody and complement	Complement and neutrophils/ macrophages	Monocytes/macrophages, lymphocytes
Beneficial effects			
Antiparasitic response and toxin neutralization	Direct lysis and phagocytosis of extracellular bacteria (gram-positive) and other susceptible bacteria and virus neutralization	Acute inflammatory neutrophils recruitment at the site of extracellular microbes and their clear microbes	Protection against fungi, intracellular bacteria (*M. tuberculosis*) and viruses, other intracellular pathogens
Pathologic disorders			
▪ Hay fever ▪ Urticaria ▪ Food allergy ▪ Drug allergy ▪ Insect venom allergy ▪ Angioneurotic edema ▪ Bronchial asthma ▪ Anaphylactic shock	▪ Autoimmune hemolytic anemia ▪ Immune thrombocytopenia ▪ Acute hemolytic transfusion reaction ▪ Hemolytic disease of the fetus and newborn ▪ Hashimoto's thyroiditis ▪ Pernicious anemia ▪ Systemic lupus erythematosus ▪ Hyperacute graft rejection ▪ Acute rheumatic fever ▪ Goodpasture syndrome ▪ Myasthenia gravis ▪ Pemphigus vulgaris ▪ Bullous pemphigoid	▪ Systemic lupus erythematosus ▪ Rheumatoid arthritis ▪ Immune complex-mediated glomerular diseases ▪ Serum sickness ▪ Arthus reaction ▪ Polyarteritis nodosa ▪ Farmer's lung disease	▪ Contact dermatitis ▪ Tuberculin skin test ▪ Chronic granulomatous diseases (tuberculosis, leprosy, *Histoplasma capsulatum*, sarcoidosis, Crohn's disease)

TYPE 1 HYPERSENSITIVITY REACTION

Type 1 hypersensitivity reaction is also known as an immediate reaction mediated by immunoglobulin E (IgE) attached to mast cells, which degranulate in response to subsequent exposure to soluble antigen or allergen and release histamine and other chemical mediators leading to tissue injury.

- Examples of IgE-mediated type 1 hypersensitivity reaction are hay fever (allergic rhinoconjunctivitis due to inhaled allergens), urticaria (hives), eczema, food allergy (nuts, shellfish, eggs, wheat), drug allergy (penicillin), insect venom allergy (bee, wasp), angioneurotic nonpitting subcutaneous edema over face, bronchial asthma, anaphylaxis (cutaneous and anaphylactic shock) and anaphylactic transfusion reactions in patients with IgA deficiency.
- **Anaphylaxis** is a rapid generalized immunologic reaction after exposure to antigens in a sensitized person, with at least two clinical manifestations: (a) airway compromise from swelling or wheezing, (b) hypotension or cardiovascular collapse, and (c) diffuse cutaneous findings (urticaria, angioedema, +/− erythroderma).
- Anaphylactoid reaction presents similar to anaphylaxis, expressed by similar chemical mediators, but not triggered by IgE and not necessarily due to prior exposure to the inciting antigen. Urticaria refers to diffuse patchy erythematous pruritic skin rashes with raised borders. Angioedema is nonpitting subcutaneous edema over face, mouth or peri-airway tissue.
- Type 1 hypersensitivity reaction is also referred to as atopy, which is triggered within minutes of subsequent exposure to a variety of environmental antigens such as pollen and house dust mite. Immediate hypersensitivity reaction has strong genetic link and caused by an overproduction of IgE. Common allergens classified by portal of entry associated with type 1 hypersensitivity reactions are given in Table 4.52.

Table 4.52 Common allergens classified by portal of entry associated with type 1 hypersensitivity reactions

Portal of Entry	Allergens
Inhalation	Plant pollens (rye grass, ragweed, timothy grass, birch trees), dust mold spores, dander, animal hair, formalin, drugs
Ingestion	Food (milk, peanuts, wheat, shellfish, soya beans, nuts, eggs), food additives, drugs (aspirin, penicillin, sulphonamide)
Contact	Cosmetics, heavy metals, detergents, formalin, rubber, solvents, dyes
Injections	Hymenopterans venom (bee, wasp, ant, dust mites, cockroach calyx), drugs, vaccines, foreign serum, enzymes, hormones

CATEGORIES OF IgE-MEDIATED TYPE 1 HYPERSENSITIVITY REACTION

Categories of IgE-mediated type 1 hypersensitivity reactions include allergic (atopic) and anaphylaxis. Allergic (atopic) disorders most commonly affect the nose, eyes, skin and lungs, which include conjunctivitis, atopic dermatitis, urticaria, angioedema and allergic bronchial asthma. Anaphylaxis is a severe, potentially life-threatening allergic reaction, which can occur within seconds or minutes of exposure to allergens. Categories of IgE-mediated type 1 hypersensitivity reactions are given in Table 4.53.

Allergic (Atopic) Reactions

Allergic (atopic) reactions include hay fever (allergic rhinitis), bronchial asthma, urticaria (hives), eczema, food allergy, drug allergy. A positive family history of allergy is found in 50% of atopic individuals. Tissue damage and necrosis are present in acute inflammation, while absent in atopic reactions.

Allergic Rhinitis (Hay Fever)

Allergic rhinitis (hay fever) is most common disorder in adults, which is a seasonal reaction to airborne inhaled plant pollen or molds or house dust. Antigens inhaled react with the IgE attached to mast cells/basophils in the nasal mucosa, thereby triggering the release of histamine stored in cytoplasmic granules. Histamine increases the permeability of mucosal blood vessels, causing edema and sneezing. The targets are typically respiratory membranes. Patient presents with nasal congestion, sneezing, coughing, profuse mucus secretion, itchy red and teary eyes and mild bronchoconstriction.

Bronchial Asthma

Bronchial asthma is characterized by episodes of impaired breathing due to severe bronchoconstriction. The airways are responsive to minute amounts of inhaled allergens. Thick mucus plugs are present in airways. Patient presents with shortness of breath, wheezing, cough and ventilatory rales, which may have

Table 4.53 Categories of IgE-mediated type 1 hypersensitivity reactions

Diseases	Clinical Manifestations
Allergic (atopic) reactions	
Hay fever (allergic rhinitis) seasonal reaction to airborne inhaled plant pollen or molds or house dust	Nasal congestion, sneezing, coughing, profuse mucus secretion, itchy red and teary eyes and mild bronchoconstriction
Bronchial asthma	Bronchoconstriction and increased mucus secretion
Urticaria (hives)	Skin hives
Eczema (atopic dermatitis)	Itchy inflammation of skin characterized by dry scaly lesions on the face, scalp, neck, and inner surfaces of the limbs and trunk
Food allergy	Cramping, vomiting, diarrhea and abdominal pain
Drug allergy (penicillin, sulphonamide, aspirin, opiates, contrast media)	Affecting 5–10% of hospitalized patients
Anaphylaxis	
Cutaneous anaphylaxis (injection of allergen)	Wheal and flare reaction
Anaphylactic shock (injection of antibiotics or serum administration)	Acute potentially life-threatening characterized by rapidly progressive urticaria, bronchospasm, laryngeal edema, vasodilatation, increased vascular permeability, intravascular volume depletion and vascular shock with fatal outcome within a few minutes

fatal outcome. Bronchial asthma has been discussed in details under type 1 hypersensitivity reaction.

Atopic Dermatitis

Atopic dermatitis is an itchy inflammatory disease of skin, known as eczema. Sensitization occurs through ingestion, inhalation and occasionally skin contact with allergens. It usually begins in infancy with reddened, vesicular, encrusted skin lesions followed by dry scaly lesions on the face, scalp, neck, and inner surfaces of the limbs and trunk during in children and adults.

Food Allergy

Food allergens enter via ingestion, but can affect respiratory tract and skin. Gastrointestinal tract symptoms include vomiting, diarrhea and abdominal pain. In severe cases, young children present with failure to thrive and growth retardation.

Drug Allergy

Approximately 5–10% of hospitalized patients may develop drug allergy. Compounds implicated most often are antibiotics (penicillin), sulphonamide, aspirin, opiates, contrast media used in imaging techniques. Some forms of penicillin sensitivity occur due to the presence of small amounts of drug in meat, milk and other foods. Exposure to penicillium mold in the environment also causes drug allergy.

Anaphylaxis

Clinical types of anaphylaxis seen in human beings include cutaneous and systemic anaphylaxis. Cutaneous anaphylaxis is the wheal and flare reaction to the injection of allergen. Systemic anaphylaxis is an acute potentially life-threatening type 1 hypersensitivity reaction, which typically occurs within minutes but can occur up to an hour after re-exposure to the offending antigen. Clinical manifestations of anaphylactic shock are shown in Fig. 4.50.

- The allergens and route of entry are variable, i.e. injection of antibiotics or serum administration.
- Anaphylaxis is characterized by rapidly progressive urticaria (vascular swelling in the skin accompanied by itching), bronchospasm, laryngeal

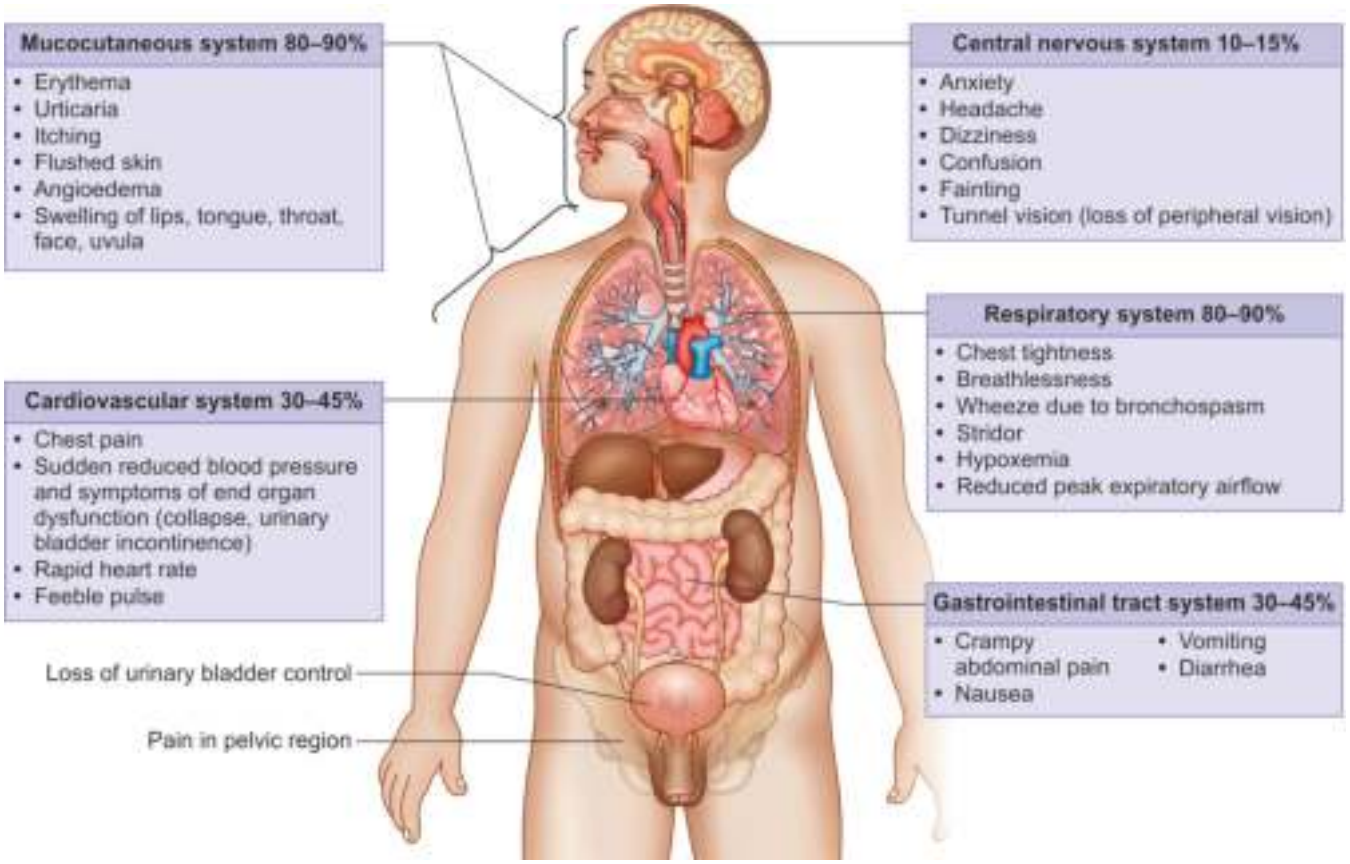

Fig. 4.50: Clinical manifestations of anaphylactic shock. Anaphylaxis is a serious, potentially life-threatening multi-systems allergic reaction on exposure to allergens such as foods, insect stings, medications. Anaphylactic shock is a complication of anaphylaxis that occurs when the blood pressure drops very low leading to poor tissue perfusion of the body. Patient presents with faintness, fat, shallow breathing, wheezing, fast heartbeat, clammy skin, confusion and low of consciousness.

edema, and vascular shock with fatal outcome within a few minutes.
- Children are more likely to experience food-related anaphylaxis, who develop severe stomach cramps, nausea, and diarrhea.
- Adults are more likely to experience anaphylaxis related to antibiotics, radiocontrast media, anesthetic agents and insect stings. Bee venom containing several allergens and enzymes may create sensitivity after exposure leading to anaphylaxis.

BRONCHIAL ASTHMA

Bronchial asthma is an example of type 1 hypersensitivity reaction, which occurs due to increased responsiveness of the airways to a variety of stimuli. Mast cells degranulation release chemical mediators, which stimulate bronchial mucus production and bronchoconstriction.
- Mast cells play central role in the development of type 1 hypersensitivity reaction. Mast cells are derived from circulating basophils and present near blood vessels and nerves in subepithelial tissue.
- Degranulation of mast cells and basophils is triggered by various stimuli such as anaphylatoxins (C4a, C3a, C5a), IL-8, physical stimuli (heat, cold and sunlight), drugs (morphine, codeine), bee venom (mallettin, adenine) and calcium ionophores.
- Mast cells release preformed and newly synthesized chemical mediators such as histamine, serotonin, leukotrienes and eosinophilic chemoattractant factor A (ECF-A) responsible for clinical manifestations of bronchial asthma.
- Differences between extrinsic and intrinsic bronchial asthma are given in Table 4.54. Pathogenesis of type 1 hypersensitivity reaction is shown in Fig. 4.51.

First Time Exposure to Antigen (Sensitization)

First time exposure to exogenous antigen (via skin, inhalation or ingestion), antigen processing cells (macrophages, dendritic cells) process the allergen (antigen) and present to CD4+ helper T cells that stimulate B cells to form immunoglobulin secreting plasma cells, which synthesize IgE that binds to high affinity Fc receptors on the surface of tissue mast cells and basophils.
- CD4+ helper T cells synthesize interleukins (IL-4, IL-5, and IL-6).
  - IL-5 that primes basophils to release histamine and leukotriene. IL-5 participates in maturation, chemotaxis, activation, and survival of eosinophils.
  - IL-6 promotes mucus production.
  - IL-4 switches B cells to IgE antibody synthesis.
- **Tumor necrosis factor-α** synthesized by macrophages activates neutrophils, attracts monocytes/macrophages and enhances production of other cytokines by T cells.

Subsequent Encounter to Same Exogenous Antigen

Subsequent encounter with same provocative dose of allergen (antigen) that binds to the IgE–mast cell complex results in influx of calcium, which is crucial process. Free antigen binds to two adjacent IgE antibodies (cross-linking) and triggers the mast cell degranulation leading to synthesis of preformed and newly synthesized chemical mediators.
- The reaction is amplified by platelet activating factor (PAF) that causes platelet aggregation and release of histamine, heparin and vasoactive and chemotactic factors attract eosinophils and neutrophils which release various hydrolytic enzymes that cause necrosis.
- Cell-bound IgE on the surface of mast cells and basophils of sensitized persons binds a substance

Table 4.54 Differences between extrinsic and intrinsic bronchial asthma

Characteristics	Extrinsic Asthma	Intrinsic Asthma
Definition	Caused by type 1 hypersensitivity reaction induced by exposure to an extrinsic antigen	Caused by diverse nonimmune mechanisms as a result of intrinsic stimuli
Age of clinical presentation	Childhood	Adult
Family history	Present	Absent
Preceding allergic reactions	Present in the form of rhinitis, urticaria, and eczema	Absent
Drug hypersensitivity	Absent	Present
Serum IgE level	Increased serum IgE level	Normal serum IgE level
Skin test	Positive skin test	Negative skin test
Emphysema	Unusual	Common
Associated chronic bronchitis	Absent	Present
Examples	▪ Atopic/allergic asthma ▪ Occupational asthma ▪ Allergic bronchopulmonary aspergillosis	Aspirin ingestion, pulmonary infection especially viral, cold, inhaled irritants, stress, exercise

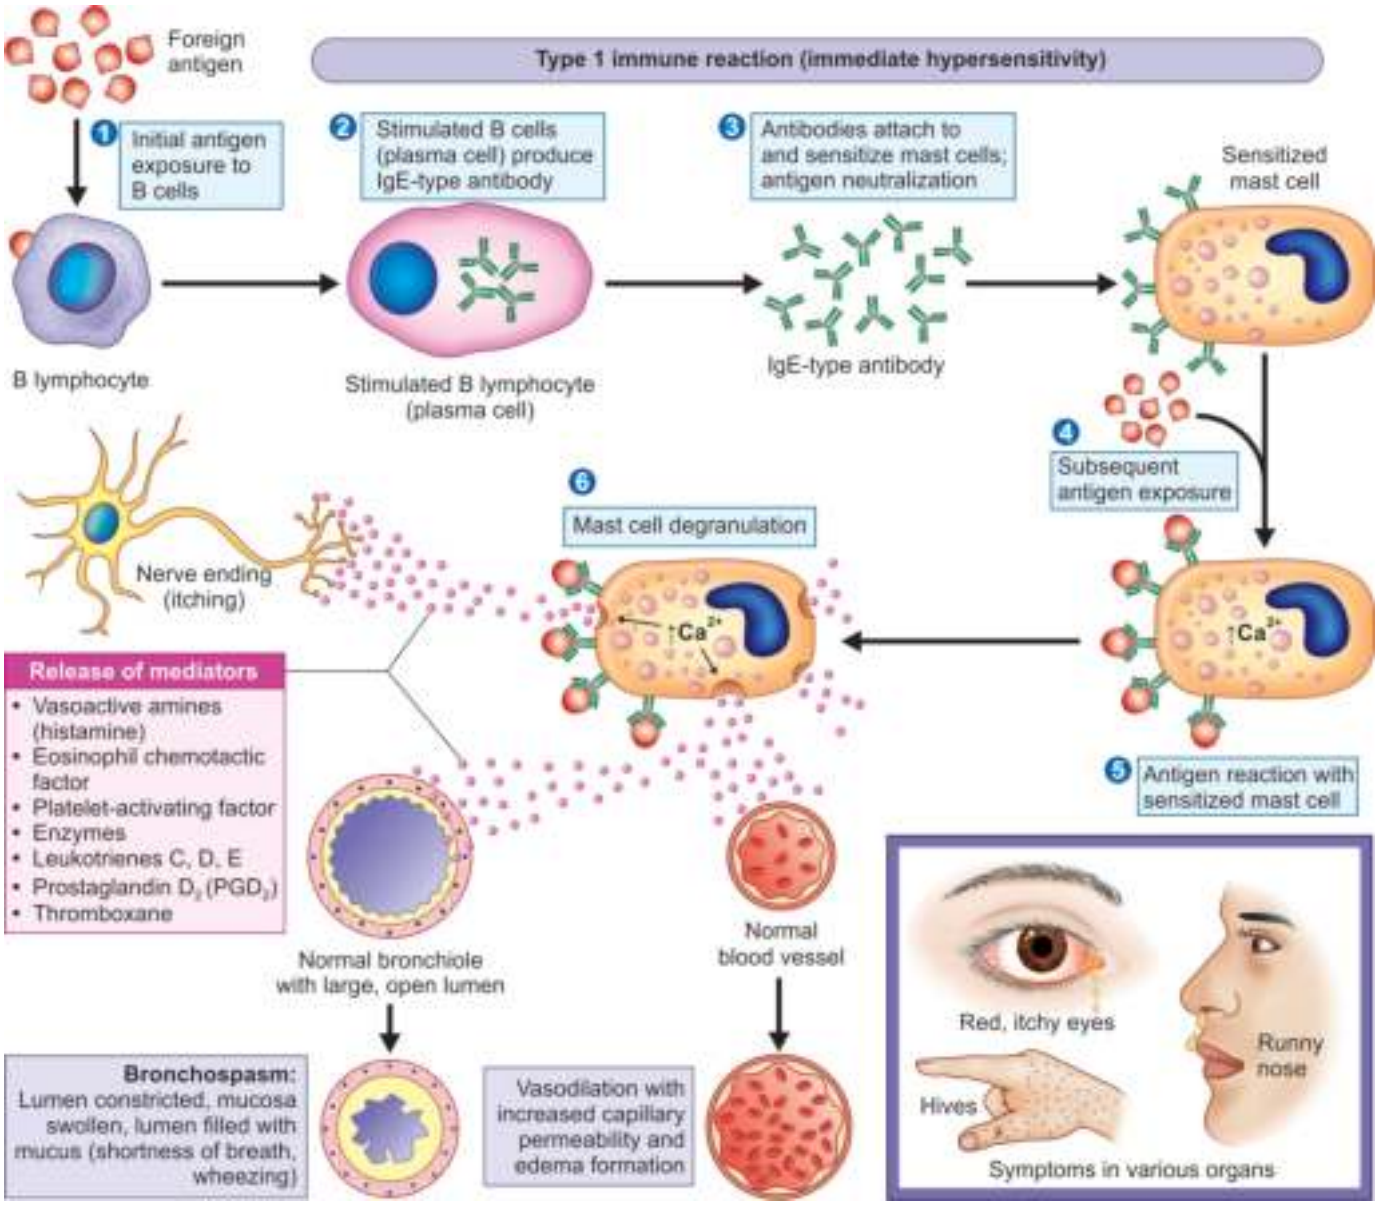

Fig. 4.51: Type 1 hypersensitivity reactions. Initial exposure to antigen (sensitizing dose) stimulates synthesis of IgE antibody. This IgE binds to surface of mast cells. On subsequent exposure to same antigen (provocative dose), it binds with IgE antibody attached to the mast cells and stimulate mast cells to release cytoplasmic granules containing chemical mediators responsible for itching, bronchospasm, wheezing, shortness of breath and anaphylactic shock.

called histamine releasing factor possibly produced by macrophages and B cells causing further release of histamine.

- Mast cells degranulation and their actions are shown in Fig. 4.52. Mast cells preformed and newly synthesized chemical mediators and their actions are given in Table 4.55.

Preformed Chemical Mediators of Mast Cells

Mast cells release preformed chemical mediators such as histamine, serotonin, leukotrienes, prostaglandin, platelet activating factor (PAF), heparin, tryptase and eosinophilic chemotactic factor (ECF), which induce smooth muscle contraction of bronchi, abdominal cramps, peripheral vasodilation, increased vascular permeability, hypovolemia and hypotension.

- Mast cell degranulation is preceded by increased Ca^{++} influx, which is crucial process. The reaction is amplified by platelet activating factor (PAF) that causes platelet aggregation and release of histamine, heparin and vasoactive and chemotactic factors attract eosinophils and neutrophils which release various hydrolytic enzymes that cause tissue necrosis.

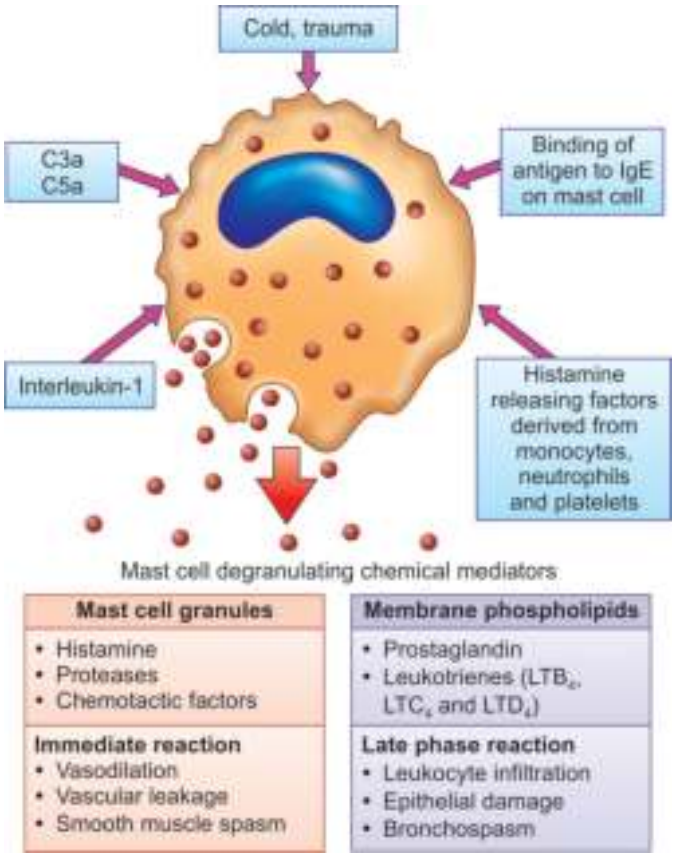

Fig. 4.52: Mast cells degranulation and their actions. Mast cell degranulation is a central event in the development of lesions in urticaria, and histamine levels are elevated in biopsies skin. Upon stimulation by an allergen, mast cells degranulate and release contents into surrounding tissues.

- The chemical mediators cause the **early phase** of allergic reactions that appears within minutes after exposure to the antigen. Late phase of allergic reactions may begin several hours after exposure to antigen.
- Cell-bound IgE on the surface of mast cells and basophils of sensitized persons binds a substance called histamine releasing factor possibly produced by macrophages and B cells causing further histamine release.
  - **Histamine:** Histamine is synthesized by mast cells, basophils and platelets,which is the most profuse and fastest-acting allergic chemical mediator. Histamine causes constriction of the smooth muscle layer of the bronchiole and intestine, thereby causing labored breathing. Histamine increases mucus secretion and synthesis of 'eotaxin', which attract **eosinophils**.
  - **Mast cell enzymes:** Mast cells release neutral protease, chymase, tryptase and hydrolytic enzymes, which cause tissue damage and proteolysis. These enzymes synthesize kinins and C3a. Tryptase is a good marker of mast cell activation.
  - **Eosinophilic chemotactic factor A (ECF-A):** Eosinophilic chemotactic factor A participates in chemotaxis of eosinophils and neutrophils. Major basic protein synthesized by eosinophils and hydrolytic enzymes by neutrophils cause significant tissue damage/necrosis in the late phases of allergic reactions.
  - **Kininogenase:** Kininogen causes vasodilation, vascular permeability and edema.

Newly Synthesized Chemical Mediators of Mast Cells

Mast cells also synthesize new chemical mediators such as leukotrienes, prostaglandins, platelet activating factor, adenosine, bradykinin and cyclic nucleotides.

- **Leukotrienes:** Leukotrienes are 1000 times more potent than histamine, but their actions are similar to histamine. LTC_4 and LTD_4 cause bronchoconstriction, increase vascular permeability and mucus secretion of respiratory airways. LTB_4 is chemotactic for eosinophils, PMN cells, basophils and monocytes.
- **Prostaglandins:** PGD_2 and $PGF_{2\alpha}$ cause bronchoconstriction. PGD_2 enhances histamine release from basophils, and causes edema and pain. PGD_2 inhibits platelet aggregation, whereas $PGF_{2\alpha}$ promotes platelet aggregation.
- **Platelet activating factor:** Platelet activating factor (PAF) causes bronchoconstriction, increased vascular permeability, and chemotaxis as well degranulation of eosinophils and neutrophils.
- **Adenosine:** Adenosine causes bronchoconstriction, which potentiates IgE-induced mast cell mediator release.
- **Bradykinin:** Bradykinin causes bronchoconstriction and increased vascular permeability.
- **Cyclic nucleotides:** Cyclic nucleotides modulate type 1 hypersensitivity reaction.

Phases of Allergic Reactions

Phases of allergic reactions are of two types: immediate and late. Immediate and late response in allergic reactions is given in Table 4.56.

Immediate Response in Allergic Reaction

Immediate allergic response occurs due to release of histamine, chemotactic factors for eosinophils, and proteases resulting into intense immediate reactions within 5–30 minutes. These chemical mediators produce tissue swelling by increasing vascular permeability, hypersecretion of bronchial mucosal glands and bronchoconstriction. Eosinophils are recruited in the tissues, which may be demonstrated by histopathologic examination of biopsy taken from allergic reaction site. Peripheral blood shows eosinophilia.

Table 4.55 Mast cells preformed and newly synthesized chemical mediators and their actions

Mediators	Actions	
Preformed chemical mediators of mast cells		
Histamine	▪ Bronchoconstriction ▪ Increased mucus secretion	▪ Synthesis of 'eotaxin', which attracts eosinophils
Enzymes (neutral protease, chymase and tryptase)	Tissue damage	
Eosinophil chemotactic factor A (ECF-A)	Chemotaxis of eosinophils	
Kininogenase	▪ Vasodilatation	▪ Increased vascular permeability and edema
Newly synthesized chemical mediators of mast cells		
Leukotrienes	▪ LTC_4, LTD_4 and LTE_4 (bronchoconstriction, increase vascular permeability and mucus secretion of respiratory airways)	▪ LTB_4 (chemotactic for eosinophils, PMN cells, basophils and monocytes)
Prostaglandins	▪ PGD_2 and $PGF_{2\alpha}$ cause bronchoconstriction	▪ PGD_2 stimulates basophils to release histamine that results in edema and pain
Platelet activating factor (PAF)	▪ Bronchoconstriction ▪ Increased vascular permeability	▪ Chemotaxis of eosinophils and neutrophils and degranulation
Adenosine	▪ Bronchoconstriction	▪ Potentiates IgE-induced mast cell mediator release
Bradykinin	▪ Bronchoconstriction	▪ Increased vascular permeability
Cyclic nucleotides	Modulation of immediate hypersensitivity reaction	

Table 4.56 Immediate and late response of allergic reactions

Parameters	Immediate Response	Late Phase Response
Onset of response	Within 5–30 minutes	Within 2–24 hours and lasts for several days
Chemical mediators	Histamine, chemotactic factors for eosinophils, and proteases	Prostaglandins and leukotrienes
Clinical manifestations	Tissue swelling by increasing vascular permeability, hypersecretion of bronchial mucosal glands and bronchoconstriction	Tissue destruction (mucosal and epithelial tissue)

Late Response in Allergic Reaction

Late allergic response occurs due to the synthesis and release of prostaglandins and leukotrienes, which enhance and prolong acute inflammatory reaction. Time interval between previous and subsequent exposure to same allergen can be many years. Allergen enters the body and produces changes in bronchopulmonary tree within 2–24 hours and lasts for several days. The tissues are infiltrated by eosinophils, neutrophils, monocytes and CD4+ helper T cells. Tissue destruction (mucosal and epithelial tissue) occurs in bronchopulmonary tree.

Actions of Chemical Mediators on Bronchopulmonary Tree

Chemical mediators synthesized by mast cells participate in bronchoconstriction, increased vascular permeability and chemotaxis of eosinophils. It is worth mentioning that histamine binds to histamine H1 receptors and induces bronchoconstriction and increased vascular permeability. Actions of chemical mediators in type 1 hypersensitivity reaction are given in Table 4.57.

- **Smooth muscle contraction:** Histamine, leukotrienes (LTC_4, LTD_4, and LTE_4), platelet activating factor (PAF), and prostaglandins intensify response by causing bronchoconstriction. Leukotrienes also act on alveoli.
- **Vascular changes:** Histamine, leukotrienes (LTC_4, LTD_4, and LTE_4), platelet activating factor (PAF), neutral protease and PGD_2 act on blood vessels. Histamine, prostaglandins and bradykinin increase vascular permeability resulting in fluid leakage into alveoli.
- **Cellular infiltration:** IL-4, IL-5, IL-6, TNF-α, LTB_4 and ECF-A participate in chemotaxis of eosinophilic and neutrophils.

Table 4.57 Actions of chemical mediators in type 1 hypersensitivity reaction

Chemical Mediators	Actions
Histamine, leukotrienes (LTC_4, LTD_4, and LTE_4), PAF, and prostaglandins	Bronchoconstriction
Histamine, prostaglandins and bradykinin	Increased vascular permeability
IL-4, IL-5, IL-6, TNF-α, LTB_4 and ECF-A	Chemotaxis of eosinophils and neutrophils

Pathology Pearls: Histologic Changes in Bronchial Asthma

Bronchi/Bronchioles Changes

Bronchi/bronchioles changes include bronchial smooth muscle hypertrophy, hyperplasia of goblet cells, thickening and hyalinization of basement membranes.

Bronchial Wall

Bronchial wall is infiltrated by eosinophils, mast cells, macrophages and lymphocytes.

Bronchial Lumen

- Bronchial mucosa shows edema, focal ulceration. Bronchial lumen is occluded with mucus plugs containing whorl-like accumulations of epithelial cells.
- 'Curschmann's spirals' and crystalloids of eosinophils-derived 'major basic protein and cationic proteins' coalesce to form 'Charcot-Leyden crystals' demonstrated in the sputum of bronchial asthma patients.

Clinical Pearls: Bronchial Asthma

Clinical Features

- Bronchial asthma attack may last for hours or even days.
- Due to narrowing of airways, patient presents with sudden dyspnea, episodic expiratory wheezing (inspiratory in severe cases), and tightness in the chest, nocturnal coughing, and tachypnea with use of accessory muscles for breathing.
- After the bronchial asthmatic attack is over, there is prolonged coughing up of tenacious secretions.
- Anteroposterior diameter of chest is increased due to air trapping and increase in residual volume. Initially, patient develops respiratory alkalosis. If bronchospasm is not relieved, patient may develop respiratory acidosis. Such patients need tracheal intubation and mechanical ventilation.

Complications

- Patient may develop pneumothorax, pneumomediastinum, status asthmaticus and fatal outcome.
- When severe acute asthma is unresponsive to therapy. Patient is referred to as status asthmaticus.
- Light microscopy of lung in status asthmaticus often shows a bronchus containing a luminal mucous plug, submucosal gland hyperplasia, smooth muscle hyperplasia, basement membrane thickening, and increased numbers of eosinophils.

Therapeutic Agents

- Therapeutic agents such as epinephrine, isoproterenol and phenoxybenzamine increasing intracellular cAMP provide relief in bronchial asthma.
- Therapeutic agents such as norepinephrine, phenylephrine, propranolol, acetylcholine and carbachol decreasing intracellular cAMP or stimulate cGMP aggravate these allergic conditions. Relationship between allergic symptoms and cyclic nucleotides are given in Table 4.58.

Diagnostic Tests

Diagnosis of allergy can be made by skin scratch testing. IgE estimation and histamine release test on basophils.

- **Skin scratch testing:** The forearm or back is mapped and then injected with a selection of allergen extracts. The allergist must be fully aware of potential anaphylaxis attacks triggered by these injections. Approximately 20 minutes after antigenic challenge, histamine-mediated wheal-and-flare response is studied depending on size on a scale of 0 (no reaction) to 4+ (>1.5 cm).
- **Radioallergosorbent test (RAST):** Radioallergosorbent test is used to detect specific IgE antibodies in serum formed against suspected allergen.

Table 4.58 Relationship between allergic symptoms and cyclic nucleotides

Allergic Symptoms	Molecular Level	Therapeutic Agent	Mechanism of Action
Improvement of allergic symptoms	Elevation of cyclic-AMP	▪ Epinephrine or isoproterenol ▪ Phenoxybenzamine	▪ Stimulation of β-adrenergic receptors ▪ Blockage of α-adrenergic receptors
Worsening of allergic symptoms	Lowering of cAMP or elevation of cGMP	▪ Norepinephrine, or phenyl-epinephrine ▪ Propranolol ▪ Acetylcholine or carbachol	▪ Stimulation of α-adrenergic receptors ▪ Blockage of β-adrenergic receptors ▪ Stimulation of γ-cholinergic receptors

- **Enzyme-linked immunosorbent assay (ELISA) test:** Enzyme-linked immunosorbent assay test is used to estimate IgE antibodies in an atopic condition. IgE elevation is also seen in multiple myeloma and helminths infestations.

Therapeutic Correlation

Various drugs are administered to interrupt allergic response at certain points, i.e. interfering action of histamine, release of chemical mediators from mast cells; and inflammation. Therapeutic agents used to relieve bronchopulmonary symptoms in bronchial asthma are given in Table 4.59.

- **Antihistaminic drugs:** Antihistaminic drugs such as azelastine, cetirizine, desloratadine, and fexofenadine are beneficial in patients of bronchial asthma. These drugs act by blocking receptors expressed on mast cells thus inhibit mast cell degranulation. These drugs have some side effects.
- **Glucocorticoids and disodium cromoglycate:** These agents prevent mast cells degranulation by inhibiting transmembrane influx of calcium ions needed to trigger mast cells degranulation.
- **Singulair or accolate agents:** These agents block the leukotriene receptors expressed on target cells. It is worth mentioning that leukotrienes cause bronchoconstriction.
- **Zileuton agent:** Zileuton drug prevents synthesis of prostaglandins, TXA_2 and prostacyclin by inhibiting cyclooxygenase pathway.
- **Terbutalin or albuterol agents:** These are short acting bronchodilators derived from isoproterenol.
- **Theophylline agent:** Theophylline inhibits cAMP-phosphodiesterase and intracellular Ca^{++} release resulting in elevation of cyclic adenosine monophosphate (cyclic AMP) in the cells. Through the action of protein kinase A enzyme, cyclic AMP activates target enzymes in the cells and opens ion channels in the cell membrane. The final result is smooth muscle relaxation and bronchodilation.
- **Desensitization therapy:** Administration of purified allergens repeatedly block the primary sensitization process. Desensitization by injecting purified allergens and drug therapy to prevent allergy is shown in Fig. 4.53. The blocking antibody mechanism for allergic desensitization is shown in Fig. 4.54.

Table 4.59 Therapeutic agents used to relieve bronchopulmonary symptoms in bronchial asthma

Therapeutic Agents	Mechanism of Action
Antihistaminic drugs	Blocking receptors expressed on mast cells
Glucocorticoids and disodium cromoglycate	Preventing mast cells degranulation by inhibiting transmembrane influx of calcium ions needed to trigger degranulation
Singulair or accolate agents	Blocking the leukotriene receptors expressed on target cells (leukotrienes cause bronchoconstriction)
Zileuton agent	Preventing synthesis of prostaglandins, TXA_2 and prostacyclin by inhibiting cyclooxygenase pathway
Terbutaline or albuterol agents	Short acting bronchodilators derived from isoproterenol
Theophylline agent	▪ Elevation of cAMP by inhibiting cAMP-phosphodiesterase ▪ Inhibiting intracellular Ca^{++} release
Desensitization therapy	Administration of purified allergens repeatedly to block the primary sensitization process

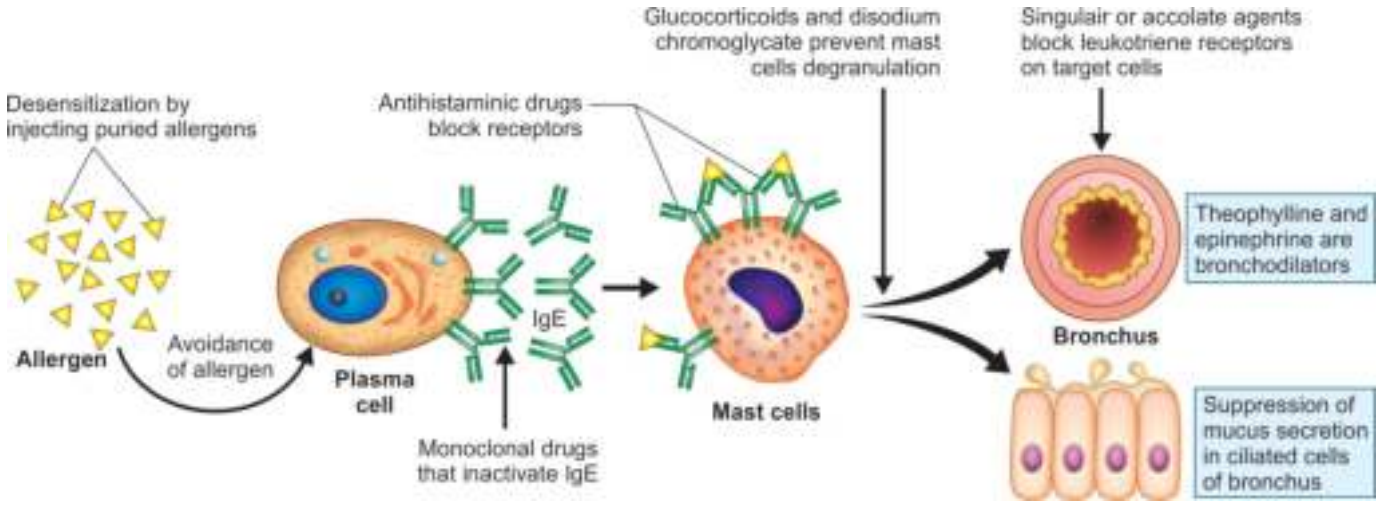

Fig. 4.53: Desensitization by injecting purified allergens and drug therapy to prevent allergy. Type 1 hypersensitivity is interrupted by injecting purified allergens and various drugs to prevent mast cells degranulation that interrupt release of inflammation inducing chemical mediators.

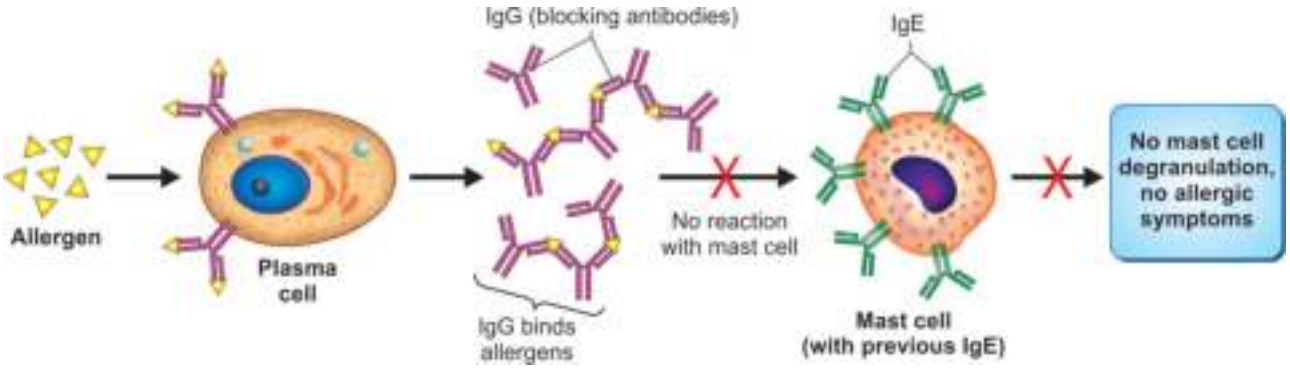

Fig. 4.54: The blocking antibody mechanism for allergic desensitization. An injection of allergen causes IgG antibodies to be formed instead of IgE; these blocking antibodies cross-link and effectively remove allergen before it can react with IgE in the mast cells.

TYPE 2 HYPERSENSITIVITY REACTION

Type 2 hypersensitivity reaction is also known as cytotoxicity hypersensitivity reaction. Antigen-presenting cells (macrophages and dendritic cells) process cell-bound antigen either self antigen (intrinsic) or planted (extrinsic usually a drug such as benzylpenicillin or methyldopa) antigen bound to cell membrane or basement membrane; and present to CD4+ helper T cells resulting in production antibody secreting plasma cells.

- IgG and IgM mistakenly bind to surface antigens on the cells in the body, which are responsible for a number of autoimmune disorders limited to a particular organ/tissue damage in one of three mechanisms: (a) antibody-dependent cellular cytotoxicity, (b) complement-mediated increased susceptibility to phagocytosis of target cells, and (c) Fc-receptor-mediated antibody-dependent cytotoxicity.
- Examples of type 2 hypersensitivity reaction include autoimmune hemolytic transfusion reaction, hemolytic disease of the fetus and newborn, autoimmune hemolytic anemia, immune thrombocytopenia, drug-induced neutropenia and agranulocytosis, Hashimoto's thyroiditis, pernicious anemia, hyperacute transplant rejection, rheumatic fever, Goodpasture syndrome, Graves' disease, Lambert-Eaton myasthenic syndrome, pemphigus vulgaris, bullous pemphigoid.
- Clinical features, diagnostics and treatment of type 2 hypersensitivity reaction depend on the underlying etiology. Diagnosis may involve autoantibody testing and Coombs' test. Pathogenesis of type 2 hypersensitivity reaction is shown in Fig. 4.55A to C.

ANTIBODY-DEPENDENT CELLULAR CYTOTOXICITY

Preformed antibodies IgG or IgM in low concentration bind to cell bound intrinsic antigen and coat it. Fc portion of IgG or IgM binds to Fc receptors on cytotoxic leukocytes such as natural killer cells (most important), macrophages, neutrophils and eosinophils. These cytotoxic leukocytes release hydrolytic enzymes and oxygen-derived free radicals resulting to tissue damage. Antibody-dependent cellular cytotoxicity mechanism in type 2 hypersenstivity reaction does not involve fixation of complement. Diseases caused by antibody-dependent cellular cytotoxicity (ADCC) mechanism in type 2 hypersensitivity reaction are given in Table 4.60.

Antibody-dependent Cellular Cytotoxicity Disorders

Antibody-dependent cellular cytotoxicity disorders include systemic lupus erythematosus, Hashimoto's thyroiditis, and acute rheumatic fever. Treatment involves anti-inflammatory and immunosuppressive agents.

Systemic Lupus Erythematosus

Autoantibodies develop to range of nuclear antigens in systemic lupus erythematosus (SLE), and causes non-organ specific autoimmune disease. Defective clearance of apoptotic cells and immune complexes are important contributors to the development of SLE. The loss of immune tolerance, increased antigenic load, excess CD4+ helper T cell, defective B cell suppression and shifting of CD4+ T helper 1 cell (Th1 cell) and CD4+ T helper 2 cell (Th2 cell) immune responses leads to B cell hyperreactivity and production of pathogenetic autoantibodies. Finally, certain environmental factors may be required to trigger the disease.

Hashimoto's Thyroiditis

Hashimoto's thyroiditis often affects HLA-DR5 and HLA-B5 persons, which is an autoantibody dependent lymphocytic cytotoxicity disorder, in which anti-TSH receptor autoantibody of IgG class to cell surface antigen stimulate natural killer cells, lymphocytes, which destroy sensitized cells. Circulating autoantibodies (anti-TSH receptor, anti-thyroglobulin, anti-peroxidase, anti-microsomal and anti-iodine receptor autoantibodies) are demonstrated in Hashimoto's thyroiditis.

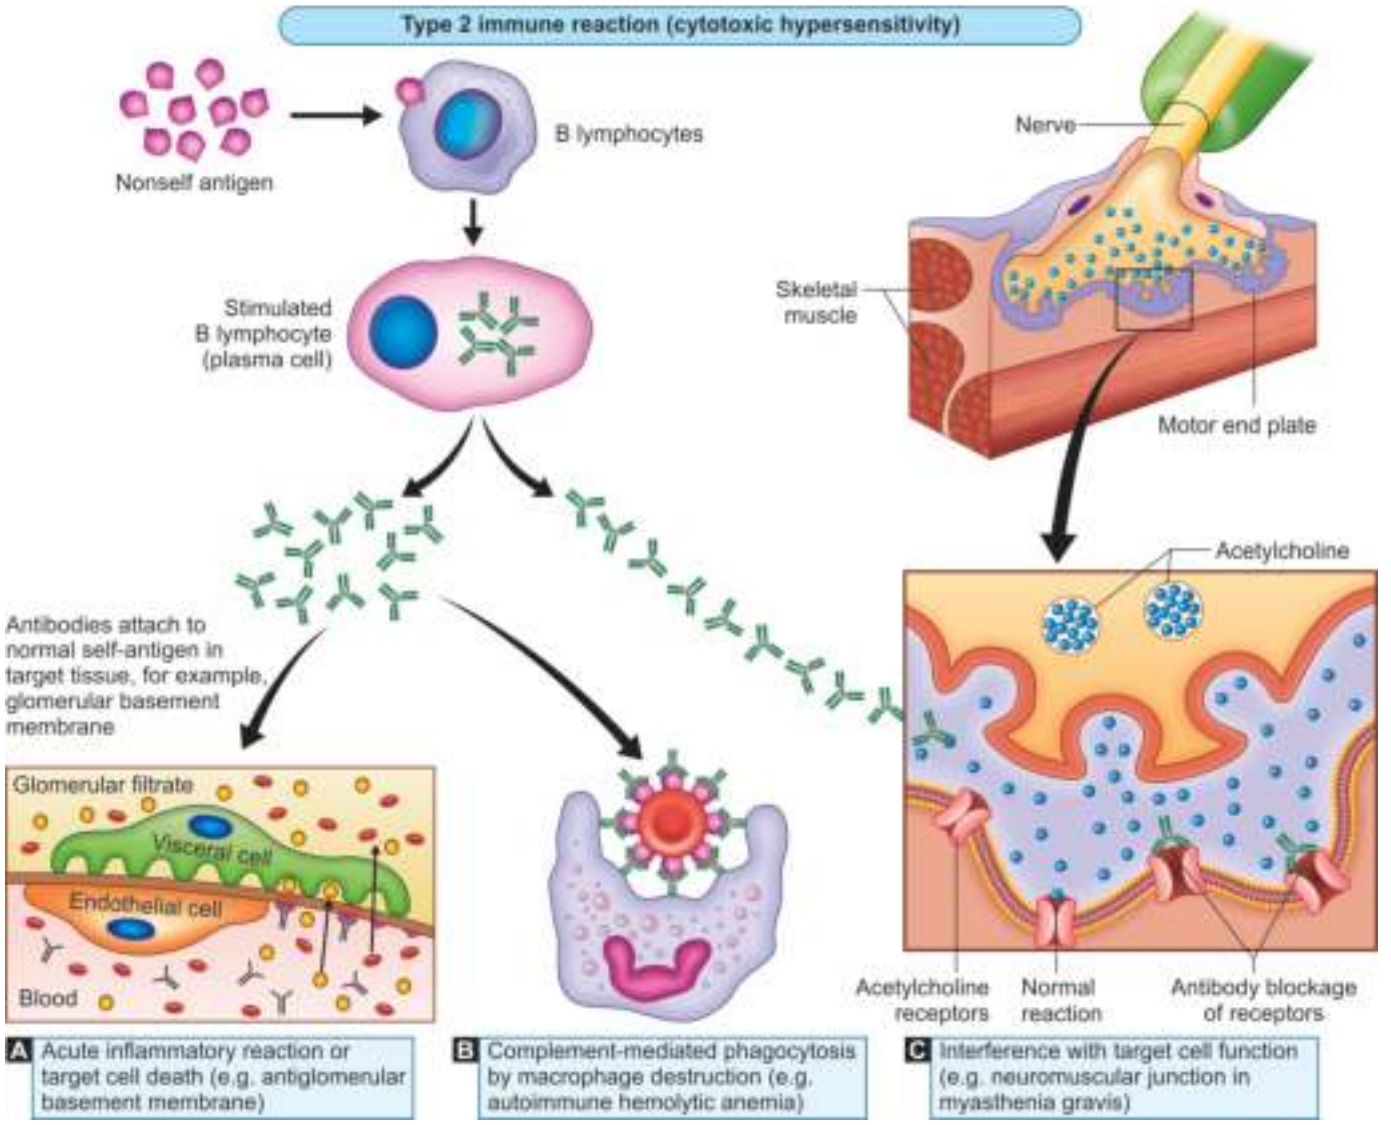

Fig. 4.55: Pathogenesis of type 2 hypersensitivity reaction. (A) Target tissue inflammation or cell death. Antibodies attach to target antigen, which is destroyed by inflammation (glomerular basement membrane) or phagocytosis (RBCs), (B) complement-mediated phagocytosis by macrophage resulting in tissue damage, (C) interference with target cell function. Antibodies attach to target cell receptors and interfere with function (blockage of signal transmission from nerves to muscle in myasthenia gravis.

Table 4.60 Diseases caused by antibody-dependent cellular cytotoxicity (ADCC) mechanism in type 2 hypersensitivity reaction

Disease	Target Antigens	Characteristics
Systemic lupus erythematosus	▪ Systemic ▪ Nuclear antigens (DNA to anti-DNA)	Inflammation of many organs, antibodies against red and white blood cells, platelets, clotting factors, nucleus DNA
Hashimoto's thyroiditis	Thyroid gland	Destruction of the thyroid follicles
Acute rheumatic fever	Antibodies against streptococcal cell wall cross react with myocardial and joint antigens	Pancarditis and migratory polyarthritis

Type 2 and 3 hypersensitivity reactions participate in the pathogenesis of systemic lupus erythematosus.

Acute Rheumatic Fever

Autoantibodies develop against streptococcal cell wall (Group A Streptococcus-β hemolyticus) cross react with myocardial antigens and joints. This multisystem autoimmune disorder affecting periarteriolar connective tissue.

- Patient develops pancarditis, transient mild migratory polyarthritis, chorea, erythema marginatum and subcutaneous nodules.
- Diagnostic tests for acute rheumatic fever include detection of circulating antibody against the tissues involved and the presence of antibody in the lesion (biopsy) by immunofluorescence microscopy.

COMPLEMENT-MEDIATED WITH INCREASED SUSCEPTIBILITY TO PHAGOCYTOSIS OF TARGET CELLS

Complement-mediated with increased susceptibility to phagocytosis of target cells is also known as complement-fixing antibody-mediated cytotoxicity. Antibodies (IgG, IgM) bind to fixed antigens localized to tissue, platelets and red blood cell membranes resulting in complement activation by classical pathway. The cells opsonized by antibodies and complement proteins are destroyed by splenic macrophages. Serum complement is characteristically decreased in these patients. Diseases caused by complement-mediated with increased susceptibility to phagocytosis of target cells in type 2 hypersensitivity reactions are given in Table 4.61.

Goodpasture Syndrome

Goodpasture syndrome is characterized by nephritic syndrome and pulmonary hemorrhage (hemoptysis). Goodpasture antigen is normally present in glomerular basement membrane and lung alveoli. Autoantibodies cross react with antigens located in glomerular basement membrane and pulmonary alveoli. Immunofluorescence study reveals smooth and linear staining pattern due to antibody and complement in renal and lung basement membrane of Goodpasture syndrome.

Drug-induced Autoimmune Hemolytic Anemia or Thrombocytopenia

Sometimes a drug or its metabolite such as benzylpenicillin may bind firmly to the cell surface to give a highly immunogenic epitope. Individuals produce IgG cytotoxic autoantibodies to their own drug coated red blood cells or platelets resulting in their destruction, especially in the spleen. Patients present with anemia and thrombocytopenia-related manifestations.

Warm Antibody-mediated Autoimmune Hemolytic Anemia

IgG autoantibody is reactive at 37°C '**warm autoantibody**' and causes autoimmune disorders. IgM autoantibody is active at 4°C, which becomes less active at higher temperature; but is still able to bind complement and agglutinate red blood cells at the temperature 30°C of the peripheral tissues (e.g. hands, feet, nose and ears).

- RBCs coated by IgG or IgM autoantibodies become bound to receptors on macrophages because they have receptors for the Fc fragments of immunoglobulins. Once activated, complement system cascade leads to the destruction of the red blood cells through formation of a membrane attack complex (MAC).
- IgM antibodies, which are powerful agglutinins, may agglutinate red blood cells in the red pulp of spleen, resulting in cellular destruction. IgM may also activate complement, resulting in cellular lysis.
- Such autoantibodies are detected by Coombs' test (agglutination test).

Table 4.61 Diseases caused by complement-mediated with increased susceptibility to phagocytosis of target cells in type 2 hypersensitivity reactions

Disease	Target Antigens	Characteristics
Goodpasture syndrome	Goodpasture antigen in noncollagenous proteins in basement membrane of kidney glomeruli and lung alveoli	Antibodies to basement membrane of glomeruli and alveoli
Drug-induced (benzylpenicillin) autoimmune hemolytic anemia or thrombocytopenic purpura	RBCs or platelets membrane proteins	Antibodies to surface RBCs or platelets. Opsonization and phagocytosis of RBCs and platelets
Warm antibody-mediated hemolytic anemia IgG autoantibody is reactive at 37°C	RBCs coated by IgG or IgM autoantibodies become bound to receptors of macrophages because they have receptors for the Fc fragments of immunoglobulins	Antibodies to surface RBCs
Blood transfusion reactions	IgG or IgM antibodies attach to the foreign cells of donor, resulting in complement fixation	The resultant formation of membrane attack complexes lyses the donor cells
Hemolytic disease of newborn or erythroblastosis fetalis	RBCs membrane proteins (Rh blood group antigen)	Opsonization and phagocytosis of RBCs results in hemolytic disease of newborn

Blood Transfusion Reactions

In blood transfusion reactions, recipient humans may become sensitized to special antigens on the surface of red blood cells of donor humans. Most common type 2 hypersensitivity reaction occurs when mismatched blood is transfused to the recipient's ABO typing or IgM antibodies attach to the foreign cells, resulting in complement fixation, formation of membrane attack complexes and lysis of donor cells. Crossmatching of donor and recipient blood is necessary to determine which transfusions are safe to perform.

Hemolytic Disease of Fetus (Erythroblastosis Fetalis) or Newborn

Hemolytic disease of fetus or newborn most commonly occurs with Rh blood group incompatibility between mother and fetus, which occurs when the mother is Rh– and baby is Rh+, having inherited an allele for one of the Rh antigens from the father. An Rh –ve person, if exposed to Rh +ve blood, will form specific IgG antibodies against the Rh antigens. Therefore, Rh group should also be matched before transfusion. Hemolytic disease of the fetus or newborn is shown in Fig. 4.56.

- **During first pregnancy, at birth of newborn:** A small quantity of fetal red blood cells usually leaks across the placenta into the maternal bloodstream. Upon exposure to Rh antigen, the mother's immune system responds by making anti-Rh antibodies. Because the baby is already born, it suffers no damage. Prevention of hemolytic disease of fetus or newborn involves therapy with Rh immune globulin after first delivery.
- **During subsequent pregnancy:** The maternal antibodies cross the placenta into the fetal red blood cells. If the second foetus is Rh+, the ensuring antigen–antibody reaction causes hemolysis of fetal RBCs.
  - The result is hemolytic disease of fetus or newborn (HDN). Newborn baby develops severe anemia and jaundice.

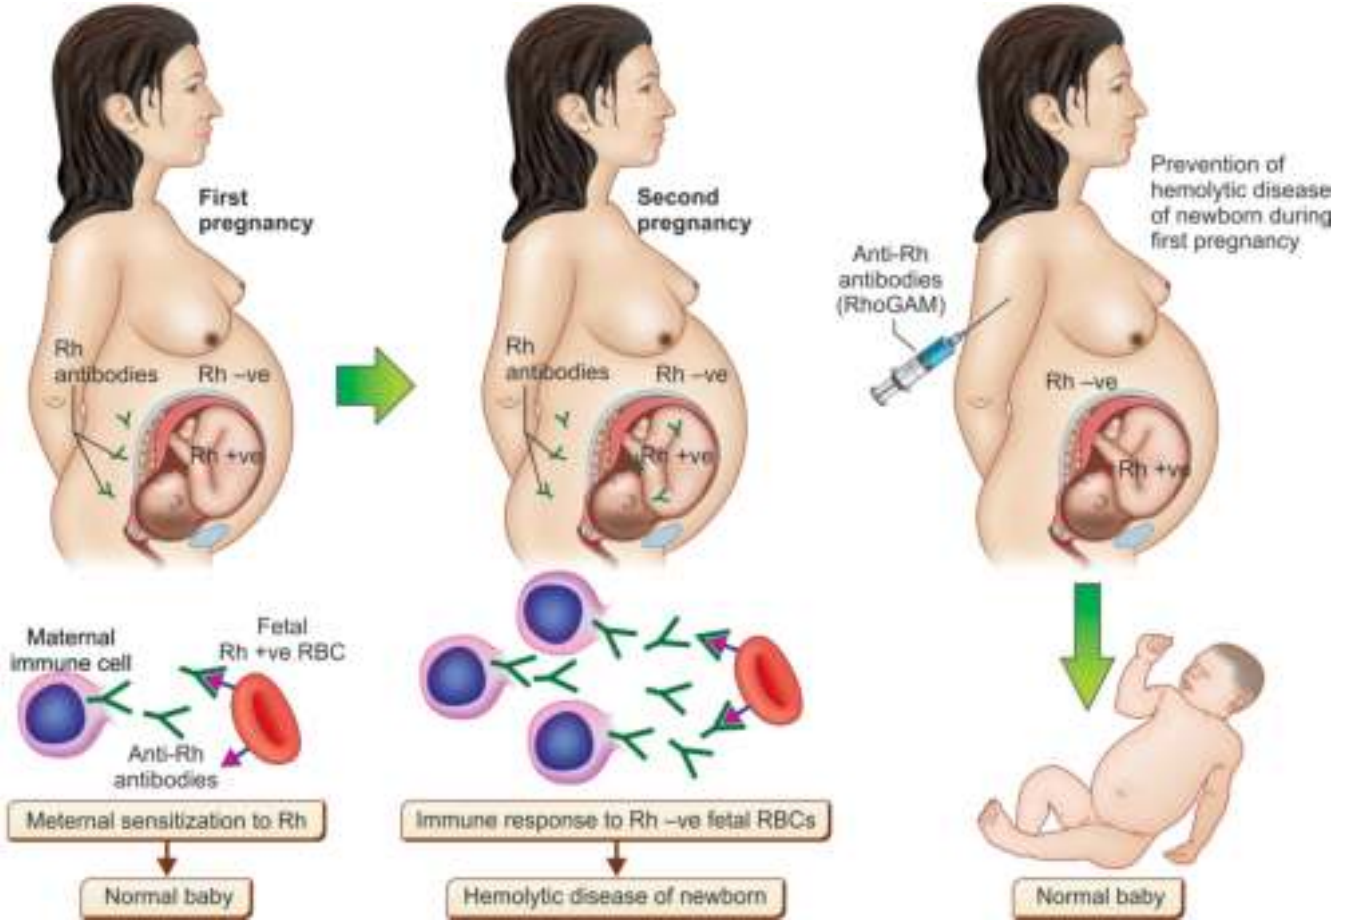

Fig. 4.56: Hemolytic disease of the fetus or newborn. Rh factor incompatibility can cause lysis of red blood cells. A naturally occurring red blood cell incompatibility results when a fetus Rh +ve develops within Rh –ve mother, initial sensitization of the maternal immune system occurs when fetal blood passes the placental barrier. In most cases, the fetus develops normally. However, a subsequent pregnancy with Rh +ve fetus results in a severe fetal red blood cells hemolysis. Control of incompatibility is done by administration of anti-Rh antibody (RhoGAM) to Rh –ve mothers during pregnancy to inactivate and remove any Rh factor that may be transferred from the fetus in maternal circulation. In some cases, anti-Rh antibody (RhoGAM) is administered before sensitization occurs.

- Development of cardiac failure in newborn is called erythroblastosis fetalis.
- Direct Coombs' test detects IgG and/or C3b attached to RBCs. Indirect Coombs' test detects antibodies in serum (e.g. anti-D).

ANTI-RECEPTOR ANTIBODY-MEDIATED TYPE 2 HYPERSENSITIVITY REACTION

In some persons, autoantibodies are formed against cell surface receptors, which impair normal cellular functions of receptors without causing cell injury. Examples of anti-receptor antibody-mediated type 2 hypersensitivity reaction include Graves' disease, myasthenia gravis, insulin-resistant diabetes mellitus, pernicious anemia, pemphigus vulgaris, Lambert-Eaton myasthenic syndrome and rheumatoid arthritis. Diseases caused by anti-receptor antibody-mediated type 2 hypersensitivity reaction are given in Table 4.62.

Graves' Disease

Antibodies to the TSH receptor are seen in patients with Graves' disease an autoimmune disorder that mimic the action of TSH, but are not regulated by natural negative feedback controls, which leads to thyroid follicular hyperplasia and increased synthesis of thyroid hormones resulting to features of hyperthyroidism.

- Patient also develops **exophthalmos** due to infiltration by lymphocytes in retrobulbar ocular muscles in 60–90%.
- Circulating autoantibodies demonstrated in Graves' disease are thyroid stimulating immunoglobulin (**TSI**) mimicking TSH), thyroid growth immunoglobulin (**TGI**), antimicrosomal and antithyroglobulin.

CTL4 or PTPN22 gene mutation increases risk of Graves' disease.

Myasthenia Gravis

Myasthenia gravis is a type 2 hypersensitivity disorder caused by autoantibodies that bind to the acetylcholine receptors in the motor end plates of skeletal muscles. The autoantibodies bind to postsynaptic receptors and block neurotransmission resulting to progressive skeletal muscle weakness involving particularly the external ocular, eyelids and proximal limb muscles. Myasthenia gravis may cause death due to respiratory muscles paralysis. Pathogenesis of myasthenia gravis is shown in Fig. 4.57A and B.

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome (LEMS) is a rare autoimmune disease of presynaptic neuromuscular transmission due to impaired acetylcholine and autoantibodies directed against calcium channel, which results in the gradual onset of muscle weakness in patients associated with small cell lung carcinoma. Paraneoplastic syndrome manifestations of small cell lung carcinoma are often mistaken for myasthenia gravis.

Insulin-resistant Type 2 Diabetes Mellitus

Antibody inhibits binding of insulin to the insulin receptors on adipose cells and skeletal muscles leading to insulin-dependent diabetes mellitus.

- Obesity, lack of physical activity, cigarette smoking, and genetic predisposition contribute to insulin-dependent diabetes mellitus. Patient develops hyperglycemia prone to ketoacidosis.

Table 4.62 Diseases caused by anti-receptor antibody-mediated type 2 hypersensitivity reaction

Disease	Target Antigens	Characteristics
Graves' disease	Thyroid gland	Antibodies against thyroid-stimulating hormone receptors
Myasthenia gravis	Acetylcholine receptors at neuromuscular junction	Antibody inhibits acetylcholine binding, down-modulation receptors
Insulin-dependent diabetes mellitus	Pancreas	Antibodies cause destruction of insulin secreting cells
Pernicious anemia	Stomach lining	Antibodies against intrinsic factor synthesized by parietal cells prevent transport of vitamin B_{12}
Pemphigus vulgaris	Desmoglein-3 proteins in intercellular junctions of epidermis	Antibody-mediated activation of proteases, disruption of intercellular adhesions results in skin vesicles (bullae)
Lambert-Eaton myasthenic syndrome	Calcium channels	Antibodies to calcium channels formed in patients with Lambert-Eaton myasthenic syndrome associated with small cell carcinoma of the lung resulting to muscle weakness
Rheumatoid arthritis	Fc portion of IgG	Rheumatoid factor represents multiple antibodies directed against the Fc portion of IgG and is seen in patients with rheumatoid arthritis and many other collagen vascular diseases

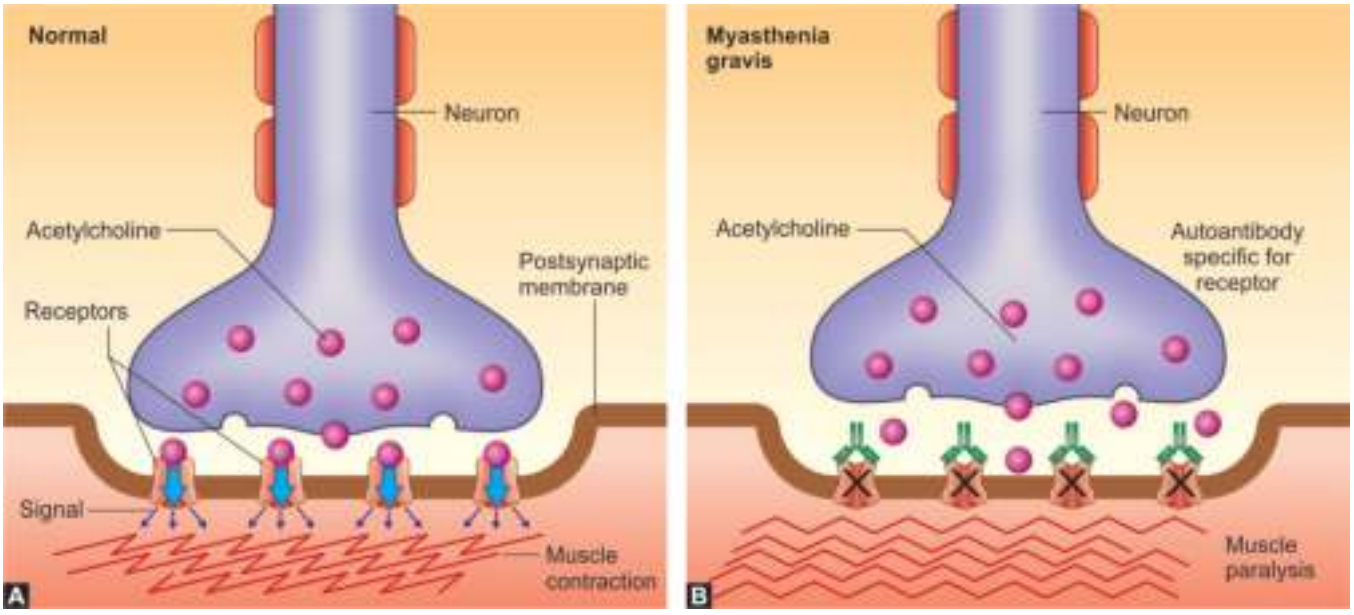

Fig. 4.57: Mechanism for involvement of autoantibodies in myasthenia gravis. (A) Normal neuromuscular junction, (B) in myasthenia gravis, antibodies formed against receptors on the postsynaptic membrane block them so that acetylcholine cannot bind resulting in inhibition of muscle contraction.

- Diagnostic tests such as standard fasting blood glucose and glycosylated hemoglobin (HbA1c) measure the average amount of glucose in the bloodstream over a period of three months in diabetic patients. HbA1c is analyzed in percentages, under 5.7% is considered healthy, a result 5.7–6.4% suggests prediabetes and higher than 6.5% is diabetes mellitus.

Pernicious Anemia

Pernicious anemia is important cause of megaloblastic anemia resulting from vitamin B_{12} deficiency due to lack of intrinsic factor (IF) normally synthesized by gastric parietal cells. Impaired intrinsic factor production can occur in adults due to autoimmune destruction of gastric parietal cells, which synthesize intrinsic factor. Gastrectomy can significantly reduce the production of intrinsic factor.

Rheumatoid Arthritis

Rheumatoid arthritis is an autoimmune disease that causes painful swelling of bilateral joints of the fingers, hands, wrists, knees, ankles, feet and toes.

- A number of genetic and environmental factors play role in the pathogenesis of rheumatoid arthritis.
- Rheumatoid factor (RF) represents multiple antibodies directed against the Fc portion of IgG and seen in patients with rheumatoid arthritis and many other collagen vascular diseases.
- Patients present with pain, swelling, stiffness and tenderness in many joints, stiffness especially in the morning hours, fatigue, weakness and fever.
- About 80% of rheumatoid arthritis cases are positive for rheumatoid factor (RF). Antibodies to cyclic citrullinated peptides are demonstrated in 60–70% of patients. Elevated erythrocyte sedimentation rate confirms inflammation of joints.

Pemphigus Vulgaris

Autoantibodies to desmoglein-3 disrupt intercellular junctions in epidermis are found in patients with pemphigus vulgaris, an autoimmune skin disorder associated with formation of blistering (vesicles). Immunofluorescence study reveals smooth and linear staining pattern in pemphigus vulgaris (skin intercellular protein, desmosomes).

TYPE 3 HYPERSENSITIVITY REACTION

Type 3 hypersensitivity reaction, also referred to as immune complex-mediated reaction, is characterized by immune complex deposition, complement fixation, and localized inflammation of tissues/organs. Examples of type 3 hypersensitivity reaction include Arthus reaction, serum sickness, systemic lupus erythematosus, immune complex-mediated glomerular diseases (poststreptococcal glomerulonephritis, membranous glomerulonephritis and lupus nephropathy), and polyarteritis nodosa. Clinical features, diagnostics and treatment of disorder related to type 3 hypersensitivity reaction dependent on the underlying etiology.

PATHOGENESIS OF IMMUNE COMPLEX-MEDIATED TISSUE INJURY AND ORGANS DAMAGE

Normally, antigen–antibody immune complexes formed in small quantity are cleared by reticuloendothelial

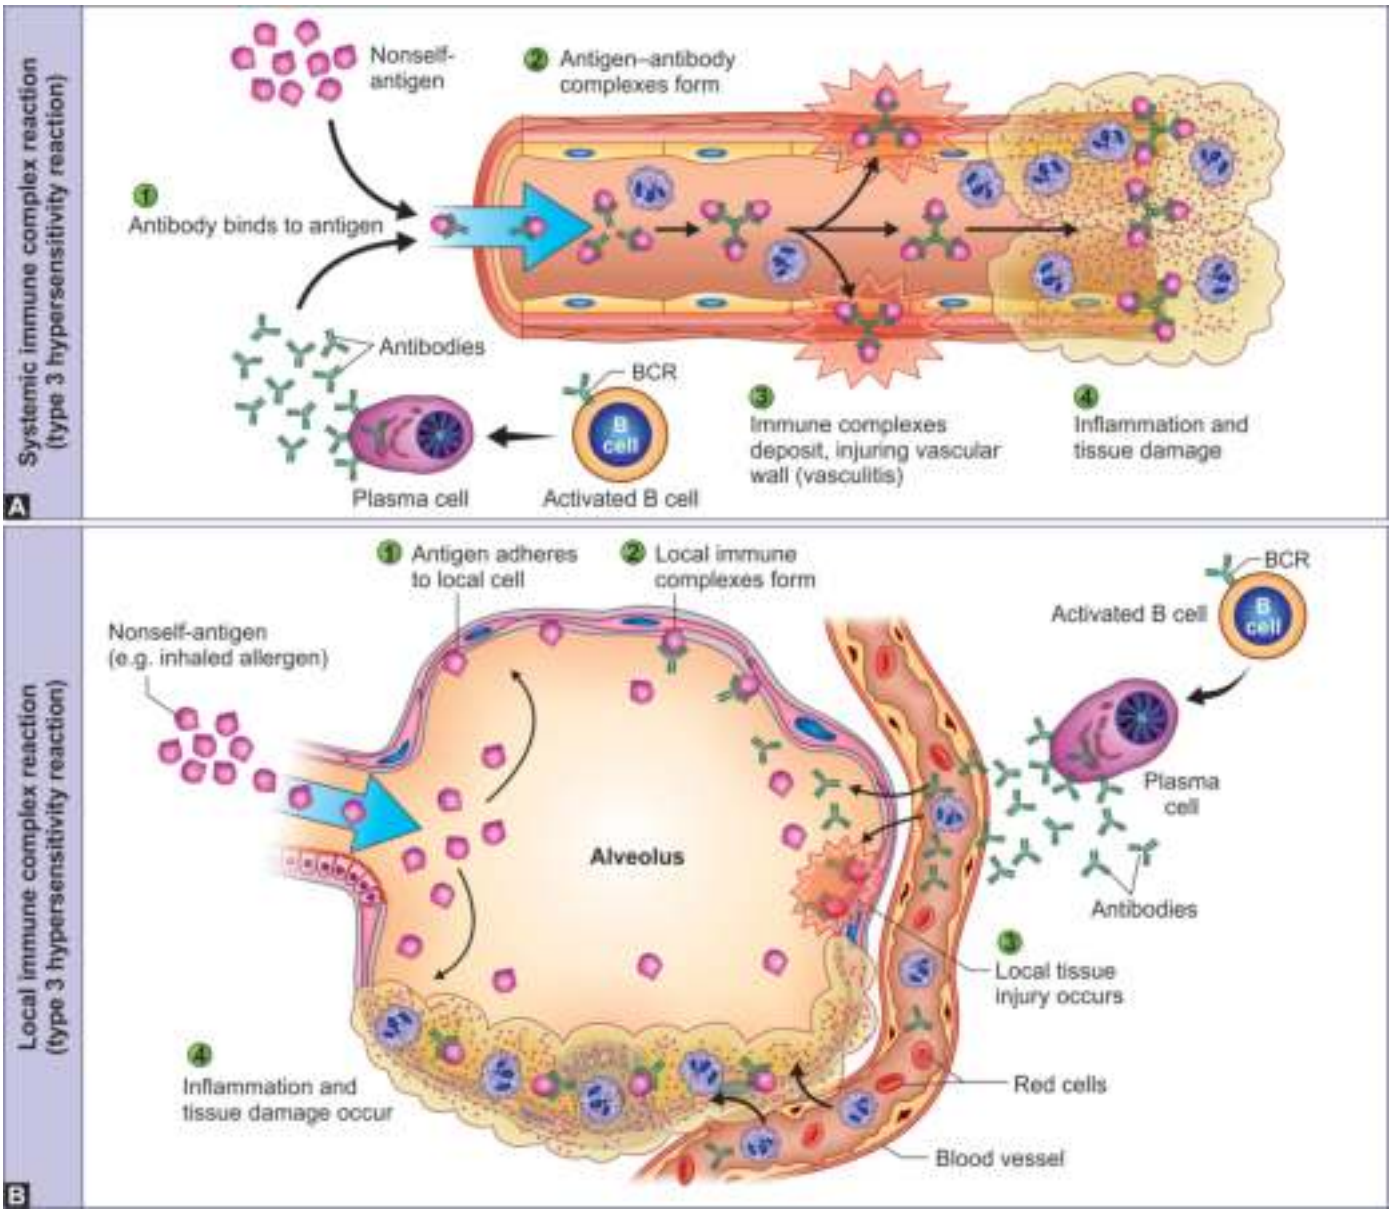

Fig. 4.58: Pathogenesis of type 3 hypersensitivity reaction. Antigen and antibody bind together to create an immune complex. (A) Systemic immune complex reaction. Antibody binds to nonself-antigen and enter circulation. Antigen–antibody complexes are formed. (B) Local immune complex occurs following injection of antigen or organ transplantation.

system. Pathogenesis of type 3 hypersensitivity reaction is shown in Fig. 4.58A and B. Antigen–antibody immune complex-mediated tissue injury is shown in Fig. 4.59.

- Antibodies (IgG or IgM) are formed against soluble antigen (serum or drug) in large quantity and trapped in membranes of various organs (skin, kidney, lung, blood vessels, and joints) in pathologic state such as persistent infections, inhaled allergens (farmer's lung) and self-antigens (systemic lupus erythematosus).
- Immune complex activates the complement system. C3a and C5 attract neutrophils, which release hydrolytic enzymes resulting in tissue injury. Serum complement is decreased.
- Injury to vascular endothelium leads to activation of intrinsic coagulation pathway resulting in formation of microthrombi in small vessels.
- Activation of the kinin system causes vasodilation and edema. Oxygen-derived free radicals, prostaglandins and kinins to incite chronic destructive inflammatory response. Macrophages infiltration in later stages may be involved in the healing process.
- Immunofluorescence microscopy reveals immune complex deposits in biopsy specimens. Serum complement level is decreased in these patients. Immune complex formation and site of deposition are given in Table 4.63. Immune complex deposition induced organs damage is shown in Fig. 4.60.

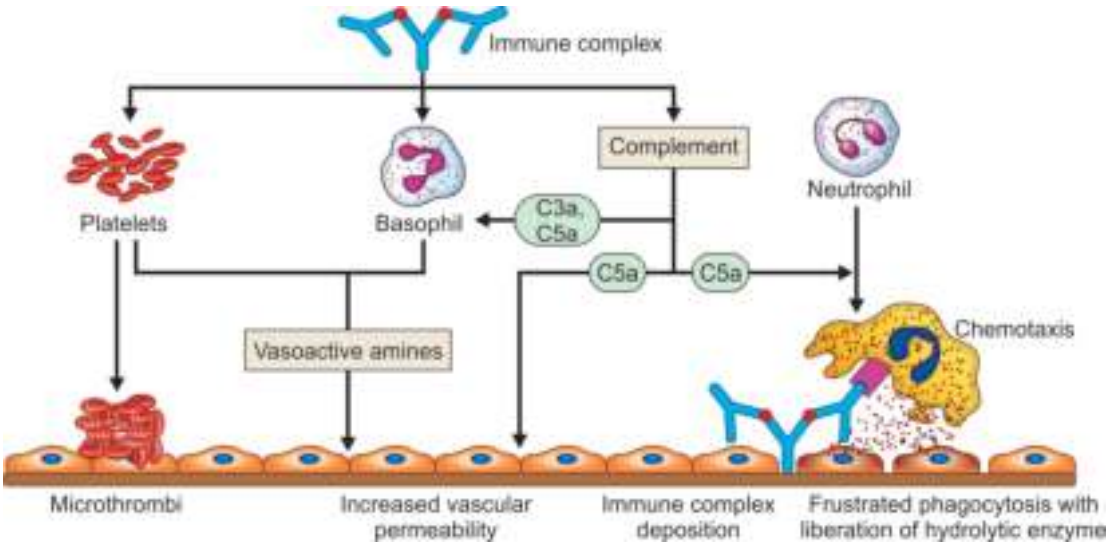

Fig. 4.59: Antigen–antibody Immune complex-mediated tissue injury. Antigen–antibody immune complexes circulating or deposited in perivascular region can damage tissues by triggering inflammation resulting in increased vascular permeability, liberation of hydrolytic enzymes and formation of microthrombi.

Table 4.63 Immune complex formation and sites of deposition

Circumstances	Etiology	Sites of Deposition
Persistent infections	Microorganism products	Blood vessels and glomeruli
Inhaled allergens (farmer's lung)	Exposure to thermophilic actinomyces in air	Lungs: IgG class, although IgM may also be involved in the formation of immune complex
Autoimmune disorders	Endogenous (self) antigens	Immune complex deposition in blood vessels, glomeruli and joints in SLE

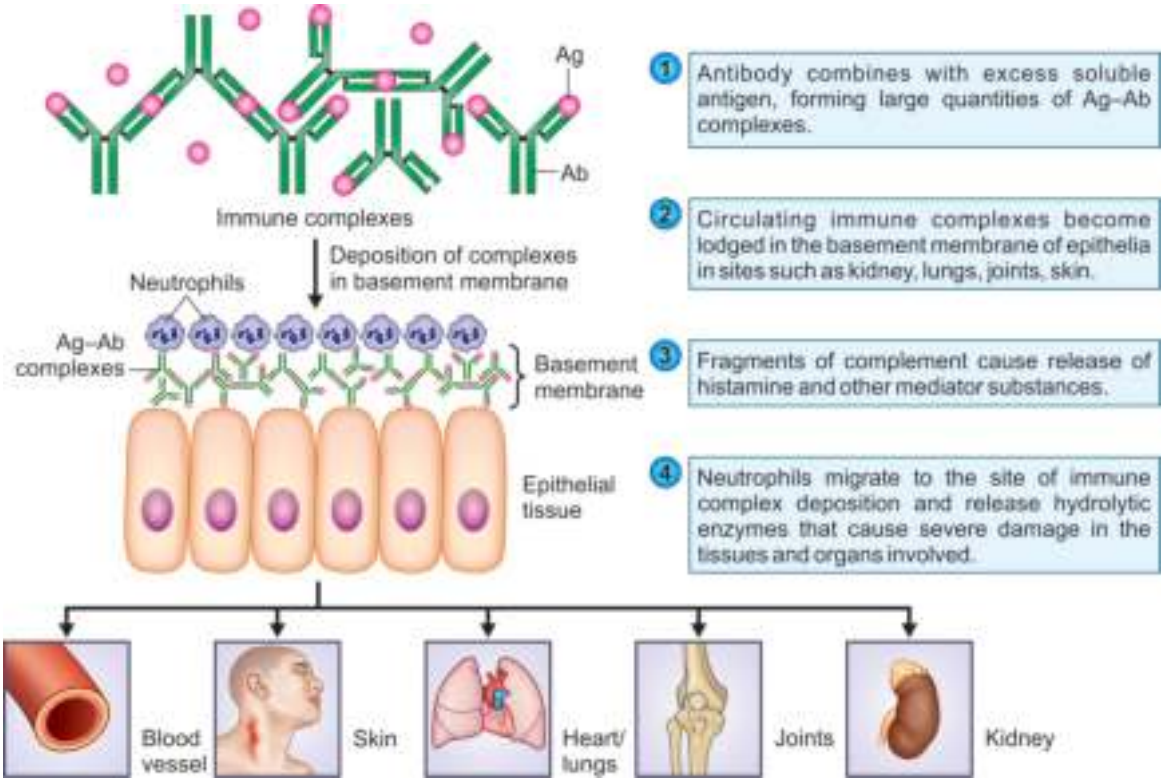

Fig. 4.60: Diseases caused by type 3 hypersensitivity reactions. In type 3 hypersensitivity, an abnormal antigen–antibody complexes, which trigger activation of complement system by classic pathway leading to damage of various tissues such as skin, joints, blood vessels.

- There are two kinds of immune complex-mediated type 3 hypersensitivity reactions, i.e. localized (Arthus reaction) and systemic immune-complex mediated type 3 hypersensitivity reactions.
- Localized (Arthus) reaction occurs at the site of injected drug or booster immunization.
  - Systemic immune-complex-mediated type 3 hypersensitivity reaction occurs when repeated antigen challenges cause systemic distribution of the immune complexes and subsequent inflammation of joints, lymph nodes and kidney. Diseases caused by type 3 hypersensitivity reactions are given in Table 4.64. Differences between Arthus reaction and serum sickness are given in Table 4.65.

Localized (Arthus Reaction) Type 3 Hypersensitivity Reaction

Arthus reaction is a localized immune complex-mediated type 3 hypersensitivity reaction that occurs when exogenous antigen is introduced, either by vaccination against tetanus and diphtheria or by organ transplant, in the presence of an excess of preformed antibodies (usually IgG, but IgM may be involved). Antigen–antibody immune complexes are deposited in the skin that activates complement system leading to local inflammation and tissue necrosis. Patient presents with localized swelling, erythema, hemorrhage, sometimes superficial skin necrosis a few hours after booster vaccination.

Table 4.64 Diseases caused by type 3 hypersensitivity reactions

Disease	Target Antigens	Organs Damage
Localized type 3 hypersensitivity reactions		
Arthus reaction	Various foreign proteins	Cutaneous vasculitis (IgG class, although IgM may also be involved)
Systemic type 3 hypersensitivity reactions		
Serum sickness	Various proteins such as foreign serum proteins (horse antithymocyte globulin)	Arthritis, vasculitis, nephritis
Systemic lupus erythematosus	Nuclear antigens (DNA to anti-DNA)	Lupus nephritis, skin lesions, arthritis
Polyarteritis nodosa	Hepatitis B virus antigen	Systemic vasculitis
Poststreptococcal glomerulonephritis	Streptococcal cell wall antigen, may be planted in glomerular basement membrane	Nephritis
Farmer's lung	Inhaled allergens (exogenous organic dust)	Lungs involvement
Reactive arthritis	Bacterial antigens (Yersinia)	Acute arthritis

Type 2 and 3 hypersensitivity reactions participate in the pathogenesis of systemic lupus erythematosus.

Table 4.65 Differences between Arthus reaction and serum sickness

Characteristics	Arthus Reaction	Serum Sickness
Disorder	Localized immune complex due to antibody excess	Systemic immune complex disorder due to antigen excess resulting to injury
Onset	4–10 days after exposure to antibody	5–7 days after entry of antigen, e.g. exogenous (horse serum, streptococcal infection) or endogenous (systemic lupus erythematosus)
Subtypes	No subtypes	Acute and chronic serum sickness
Mechanism of organ damage		Complement activation, platelet aggregation
Organs involved	Skin only	Joints, skin, heart, blood vessels, serosal surfaces
Morphology of organs	Fibrinoid necrosis of blood vessels	Immune complex-mediated necrotizing vasculitis, fibrinoid necrosis of blood vessels, proliferation of endothelial and mesangial cells
Immunofluorescence microscopy	Deposits comprising fibrinogen, complement and immunoglobulin	Granular deposits of immune complex comprising of immunoglobulin and complement
Clinical features	Dyspnea, flu-like symptoms and lung fibrosis (chronic case)	Fever, arthralgia, urticarial, lymphadenopathy and proteinuria

Systemic Immune-complex-mediated Type 3 Hypersensitivity Reaction-induced Diseases

Systemic immune-complex-mediated type 3 hypersensitivity reactions occur when repeated antigen challenges cause systemic distribution of the immune complexes and subsequent inflammation of joints, lymph nodes and kidney. Examples are serum sickness, polyarthritis nodosa, drug-induced hypersensitivity vasculitis, lupus nephritis, IgA nephropathy, membranous glomerulonephritis, post-streptococcal glomerulonephritis, hypersensitivity pneumonitis.

Serum Sickness

Serum sickness is a classic example of type 3 hypersensitivity reaction, which usually develops as a complication of antivenom or antitoxin administration therapeutically for passive immunization against microorganisms.

- Antivenom and antitoxin containing animal proteins or serum causing serum sickness include: (a) equine anti-snake venom and anti-spider venom, (b) equine or bovine antirabies antitoxin and equine botulinum antitoxin.
- Serum sickness can be induced by drugs such as penicillin or amoxycillin or cephalosporins.
- Antigen–antibody complexes are deposited in the tissues/organs that activate complement system resulting in systemic inflammation and tissues/organs damage.
  - Patient develops symptoms such as fever, skin rashes, arthralgia, edema of hand, headache, blurred vision, abdominal pain, vomiting and diarrhea within one to two weeks following exposure to antivenom or antitoxin or drug.
  - Urine analysis may show mild proteinuria.
  - Prognosis is excellent once the offending agent is withdrawal.

Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is systemic vasculitis involving small- and medium-sized arteries affecting many organs especially the skin, peripheral nerve, gut, kidney and heart.

- Most cases of PAN occur in the 4th or 5th decade, although it can occur at any age. Males are more affected than women. A minority of patients with PAN have an active hepatitis B infection. In rest of the cases, the disease is idiopathic in nature.
- After several weeks or months. patient develops nonspecific symptoms such as fever, malaise, weight loss, anorexia and abdominal pain and other symptoms related to involved organs such as skin, kidney, nerves and gastrointestinal tract. Many patients develop hypertension and elevated erythrocyte sedimentation rate.

Drug-induced Hypersensitivity Vasculitis

Drug-induced hypersensitivity vasculitis is caused by use of various pharmaceutical agents such as penicillin, cephalosporin, sulphonamide, thiazide-type diuretics, phenytoin and allopurinol. Vasculitis causes changes in the walls of blood vessels, including thickening, weakening, narrowing and scarring. Withdrawal of the offending agent alone is often sufficient to induce prompt resolution of clinical manifestations, obviating the requirement for immunosuppressive and anti-inflammatory drugs.

Lupus Nephritis

Systemic lupus erythematosus (SLE) is an autoimmune disorder involving multiple systems such as blood vessels, glomeruli and joints. Anti-DNA antibodies are formed against endogenous (self) antigen.

- Lupus nephritis, one of the most serious manifestations of SLE clinically evident in 50–60% of patients usually arises within five years of diagnosis. Evaluating renal functions (blood urea nitrogen, serum creatinine urinalysis, 24 hours urine test for creatinine and protein excretion) in SLE patients are important because early detection and treatment of renal involvement can significantly improve renal outcome.
- Patients may present with fatigue, fever, skin rashes, arthritis, serositis, central nervous system disease and renal manifestations.
- Histologic examination of renal biopsy shows class I (minimal mesangial lupus nephritis), class II (mesangial proliferative lupus nephritis), class III (focal lupus nephritis) or class IV (diffuse lupus nephritis) and class V (membranous lupus nephritis). Laboratory tests for SLE disease activity include: antibodies to double-stranded DNA (dsDNA), complement protein (C3, C4), erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).

IgA Nephropathy

IgA nephropathy is an autoimmune disease arising from consequences of increased circulating levels of IgA1 with galactose-deficient hinge-region O-glycans and deposition of immune complexes in mesangial region. However, aberrant glycosylation is unable to induce glomerular injury on its own. Patients with IgA nephropathy seem to produce anti-GalNAc antibodies against defective IgA1.

- Immune complex deposition in the glomeruli leads to type 3 hypersensitivity reaction which ultimately damages the kidneys.
- Patient presents with repeated episodes of gross or microscopic hematuria, flank pain, hypertension, variable proteinuria and swelling over ankles.

Table 4.66 Different names of hypersensitivity pneumonitis according to the causative antigen

Different Name	Causative Antigen
Farmer's lung	Moldy hay containing spores of thermophilic actinomycetes
Air conditioner lung	Thermophilic bacteria
Byssinosis	Textile workers due to inhalation of cotton fibers, linen and hemp develop bronchial asthma-like presentation
Pigeon breeder's lung, also called bird fancier's disease	Proteins from serum and features, and excreta
Maple bark stippler's lung	Fungal spores
Hot tub lung	Liquid or solid droplets in the air contaminated by nontuberculous Mycobacterium or other infectious agents

- Clinical markers associated with poor prognosis include: heavy proteinuria, low serum albumin, diastolic hypertension, male sex and age below 30 years.

Membranous Glomerulonephritis

Membranous glomerulonephritis (MGN) is most common cause of nephrotic syndrome affecting mainly adults than children, which is characterized by thickening of the glomerular basement membrane marked by marked proteinuria and generalized edema.

- About 80–85% of MGN cases are idiopathic. Remaining MGN cases are secondary and caused by malignancy, infectious agents and autoimmune diseases.
- In secondary MGN, successful treatment of the underlying cause may be curative.
- Patients with primary MGN may experience spontaneous remission, persistent proteinuria of variable degree, or progression to renal failure.

Poststreptococcal Glomerulonephritis

Poststreptococcal glomerulonephritis results from the body's immune system fighting off the group A streptococcal throat and skin infections, usually in children.

- Patient presents from passage of dark, reddish-brown urine, oliguria, edema around periorbital region and face, fatigue, mild anemia, hypertension, and proteinuria in nephritic range.
- Most patients, who develop poststreptococcal glomerulonephritis recover within a few weeks without any complications. Renal failure rarely occurs more common in adults than children.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis, also known as extrinsic allergic alveolitis, is immunologically induced inflammation of lung parenchyma and respiratory failure in response to inhalation of a large variety of natural and chemical antigens such as spores of bacteria, fungi, hay, grain, sugarcane bark, animal excreta and chemical antigens.

- Antigen exposure results in early development of type 3 immune complexes, and later followed by type 4 hypersensitivity reactions.
- Histologically, it is characterized by lung parenchymal inflammation with fibrosis and poorly formed non-necrotizing granulomas predominantly in middle to upper lobes of lung; and usually bilateral involvement.
- Disease may be diagnosed by radiographs and lung biopsy. Different names of hypersensitivity pneumonitis according to the causative antigen are given in Table 4.66.

TYPE 4 HYPERSENSITIVITY REACTION

Compared to antibody-mediated types 1, 2 and 3 hypersensitivity reactions, type 4 hypersensitivity reaction is mediated by T cells and macrophages. Specifics of type 4 hypersensitivity reactions include: T cell involvement, transplant rejection, tuberculin skin test for tuberculosis and contact dermatitis. Type 4 hypersensitivity reactions involve two major mechanisms: (a) T cell sensitization and (b) pre-sensitized T cell response.

- T cell sensitization response occurs by skin penetration by antigen, uptake of the antigen by Langerhans cell, migration to lymph nodes and formation of sensitized T cells.
- Pre-sensitized T cell response occurs after repeated contact with the antigen by T lymphocytes (CD8+ cytotoxic T cells and CD4+ helper T cells).
  - CD8+ cytotoxic T cells recognize antigens on target cells and induce cell-mediated cellular cytotoxicity resulting in direct cell destruction.
  - CD4+ helper T cells recognize antigens on antigen-presenting cells (APCs) and release of inflammatory cytokines (e.g. TNF-α and IFN-γ). Macrophages activation results in phagocytosis of target cells. Pathogenesis of type 4 hypersensitivity reactions is shown in Fig. 4.61.

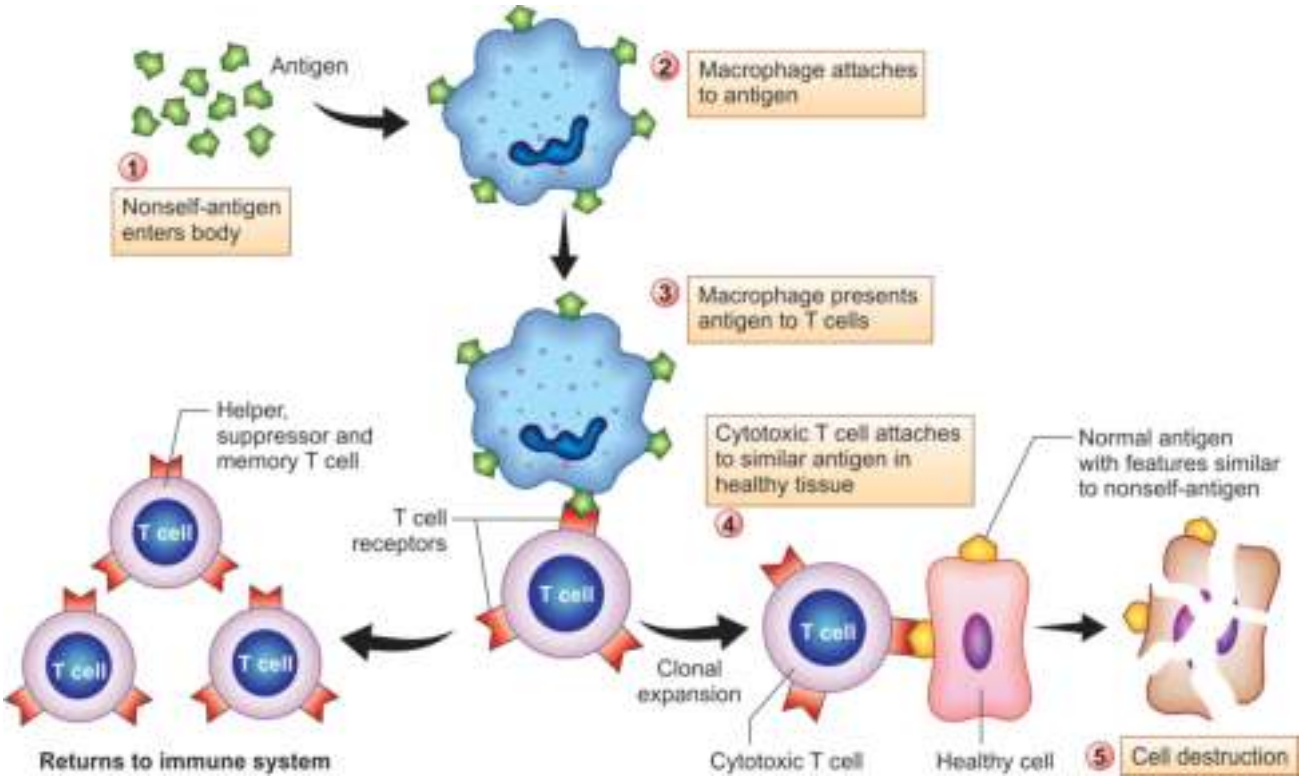

Fig. 4.61: Pathogenesis of type 4 hypersensitivity cell-mediated reaction. Macrophage capture antigen and present to T cells, thus sensitizing these T lymphocytes. Some of these lymphocytes become CD8+ cytotoxic T cells. These CD8+ cytotoxic T cells attack the antigen, where present. Other lymphocytes become T helper cells, T-suppressor cells and memory cells.

CD8+ CYTOTOXIC T CELL AND CELL-MEDIATED IMMUNE RESPONSE

CD8+ cytotoxic T cells, like CD4+ helper T cells are generated in the thymus gland and express T cell receptor (TCR). However, rather than CD4 molecule, CD8+ cytotoxic T cells express a dimeric co-receptor composed of one CD8-α and one CD8-β chain.

- CD8+ cytotoxic T cells recognize peptides presented by MHC class I molecules, found on all nucleated cells. CD8 heterodimer binds to α-region of MHC class I molecule during T cell/antigen-presenting cell interactions.
- CD8+ cytotoxic T cells play important role in immune defense against intracellular pathogens (viruses and bacteria) and tumor surveillance.

Pathophysiology

When CD8+ cytotoxic T cells recognize an antigen and become activated, which kill the intracellular virus or cancer stem cells by three mechanisms: (a) synthesis of cytokines, (b) synthesis of perforins and granzymes, and (c) Fas/FasL interactions.

- **Cytokines synthesis:** CD8+ cytotoxic T cells synthesize cytokines such as TNF-α and IFN-γ, which have antiviral, antimicrobial and antitumor effects. The antiviral activity of interferon is shown in Fig. 4.62.
- **Perforin and granzymes synthesis:** CD8+ cytotoxic T cells release cytotoxic granules containing perforins and granzymes. Perforin forms pore in the plasma membrane of the target cells, that allows entry of granzymes leading to cleaving of proteins inside the target cells, shutting down the production of viral proteins and ultimately resulting in apoptosis of the target cells.
- **Fas/FasL interaction:** CD8+ cytotoxic T cells cause destruction of target cell via Fas/FasL interactions. Activated CD8+ cytotoxic T cells express FasL on the cell surface, which binds to its Fas receptor on the surface of the target cell resulting in the activation of caspase cascade, which induce apoptosis of the target cell.

CD4+ HELPER T CELLS AND MACROPHAGES-MEDIATED TYPE 4 HYPERSENSITIVITY REACTIONS

Type 4 hypersensitivity reactions, also known as delayed-type hypersensitivity reactions (DTH), provide host defense against intracellular pathogens (e.g. Mycobacterium, fungi and certain parasites. Type 4 hypersensitivity reactions are mediated by monocyte/macrophages and CD4+ memory T cells either due to exogenous or autoantigens, rather than antibodies.

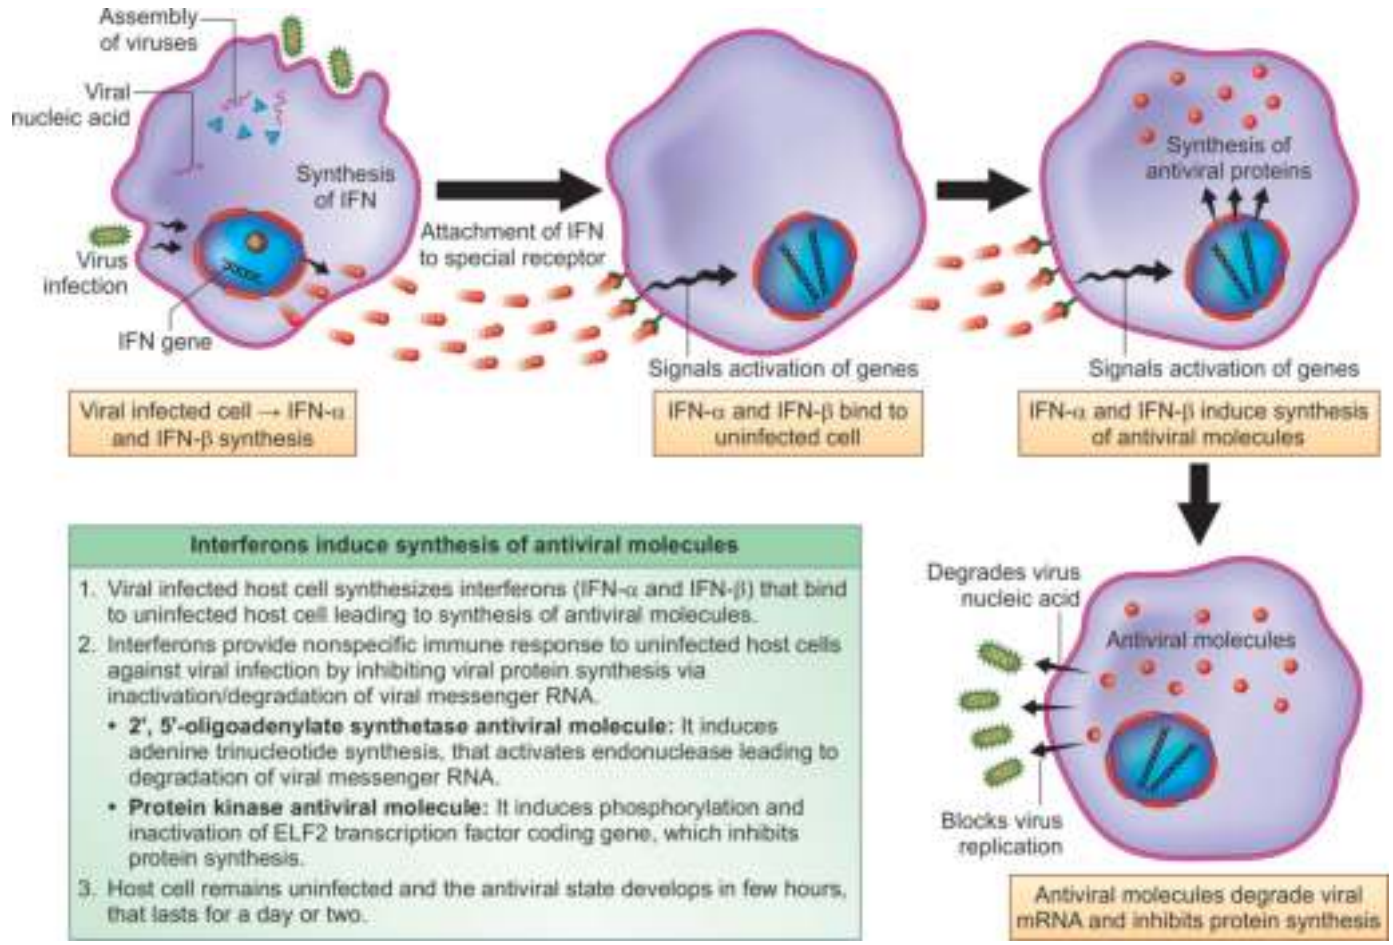

Fig. 4.62: The antiviral activity of interferon. When a cell is infected by a virus, its nucleus is triggered to transcribe interferon (IFN) gene. Interferon diffuses out of the cell and then binds to IFN receptors on nearby uninfected cells, where it induces production of proteins that eliminate viral genes and block viral replication. Note that the original cell is not protected by IFN and that does not prevent viruses from invading the protected cells.

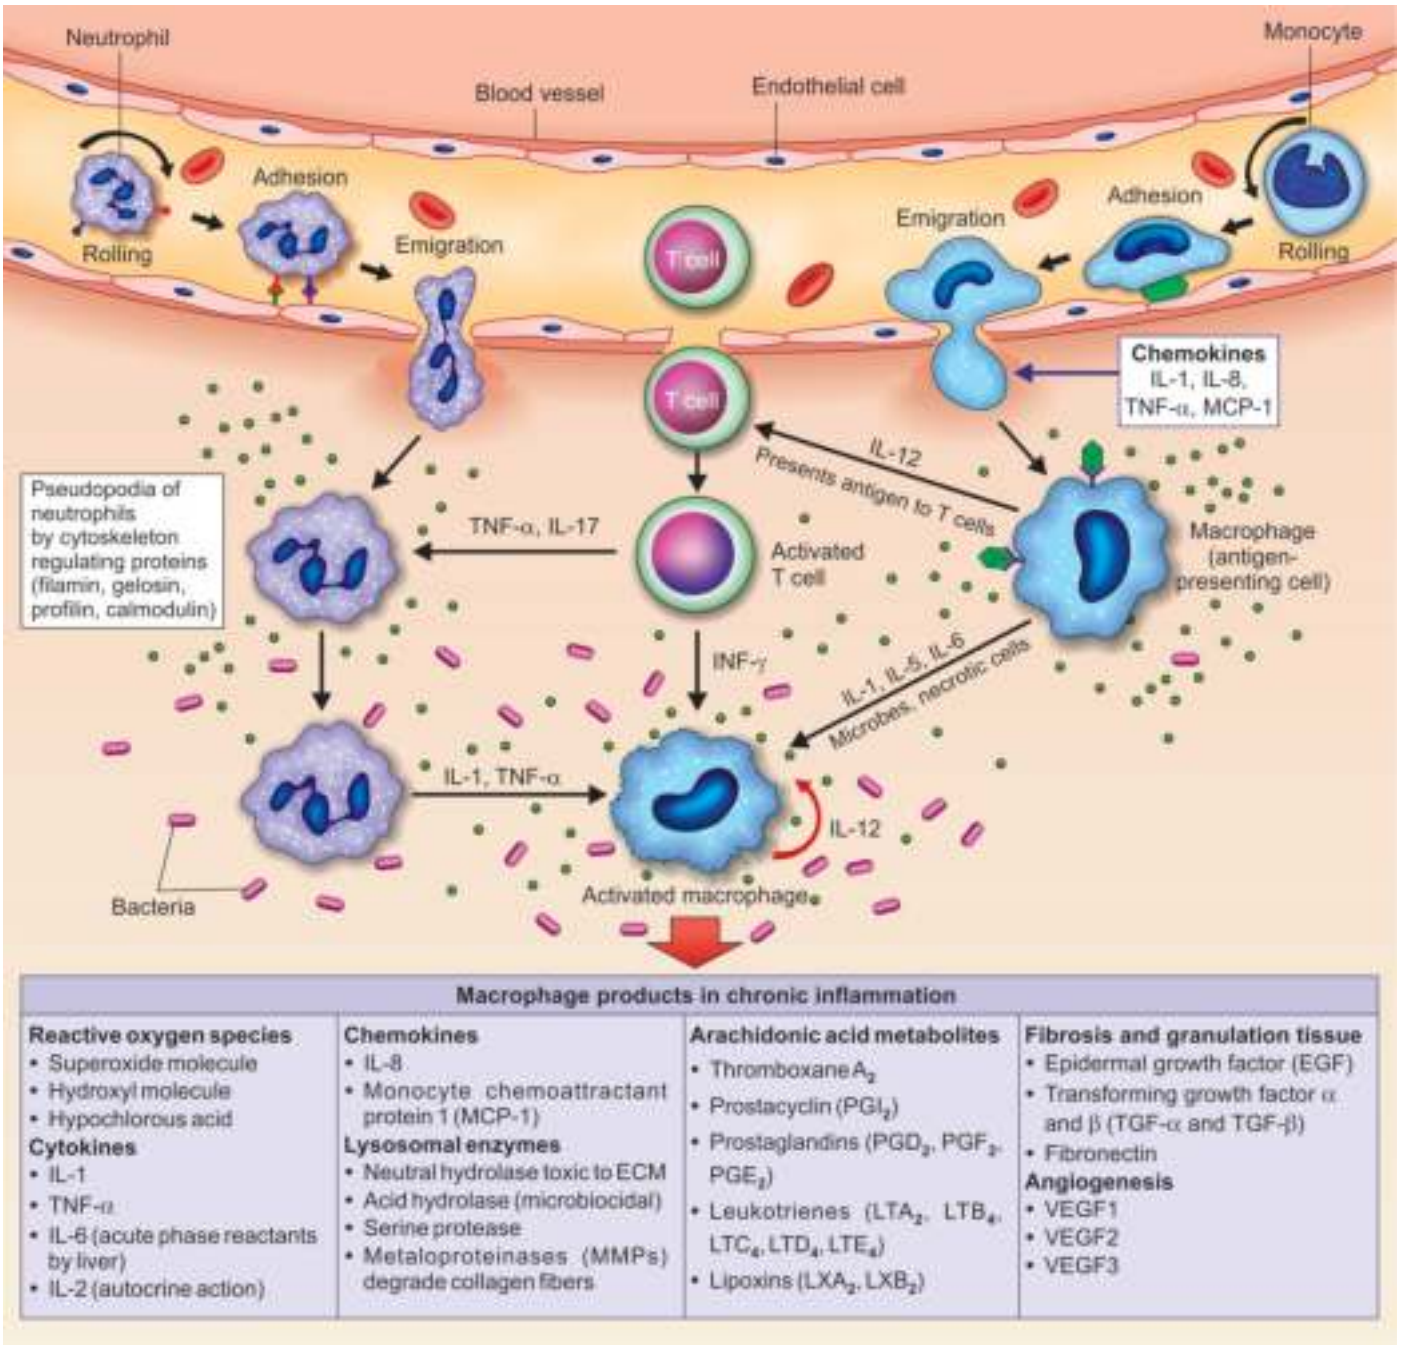
- Delayed-type hypersensitivity reaction to exogenous antigens involves CD4+ helper T cells and antigen-presenting cells (APCs) such as macrophages, Langerhans' cells and dendritic cells, all synthesize cytokine IL-12, which activates CD4+ memory T cells and differentiate to Th1 effector cells, which synthesize various cytokines such as monocyte chemotactic factor, IL-2, interferon-γ (IFN-γ).
- IFN-γ is a central mediator of delayed hypersensitivity and powerful activator of macrophages. IFN-γ further augments the differentiation of Th1 cells. IL-2 has autocrine and paracrine action and causes proliferation of antigen-specific T cells and activation of macrophages, which accumulate and induce a local inflammatory response in a sensitized person. Role of activated macrophages in chronic inflammation is shown in Fig. 4.63.
- Delayed-type hypersensitivity reaction to autoantigens can be seen in type 1 diabetes mellitus, which is an autoimmune cell-mediated destruction of insulin secreting pancreatic β cells.
- One important cytokine is IL-1, which promotes the release of the acute phase reactants of the liver, which increases the proliferation of T cells. IL-1 acts on the hypothalamic thermoregulatory center to induce fever, which is responsible for some of the systemic symptoms of delayed type of hypersensitivity.
- Type 4 hypersensitivity reactions can be classified into three categories depending on the time of onset and clinical and histologic presentation, which include contact dermatitis, tuberculin reaction and granulomatous hypersensitivity. Categories of type 4 hypersensitivity reactions are given in Table 4.67.

Contact Dermatitis

In contact dermatitis, small antigens such as **heavy metals** (nickel, chromium), **plant** (ivy oak), **organic chemicals**, **cosmetics**, **cyanoacrylate adhesive photographic developer** and **primula paint** penetrate the skin combine with tissue protein '**hapten**' and act as a **hapten–protein complex**; which stimulate cell-mediated immune response. Subsequent exposure to these



Macrophage products in chronic inflammation

Reactive oxygen species	Chemokines	Arachidonic acid metabolites	Fibrosis and granulation tissue
• Superoxide molecule • Hydroxyl molecule • Hypochlorous acid **Cytokines** • IL-1 • TNF-α • IL-6 (acute phase reactants by liver) • IL-2 (autocrine action)	• IL-8 • Monocyte chemoattractant protein 1 (MCP-1) **Lysosomal enzymes** • Neutral hydrolase toxic to ECM • Acid hydrolase (microbiocidal) • Serine protease • Metaloproteinases (MMPs) degrade collagen fibers	• Thromboxane A_2 • Prostacyclin (PGI_2) • Prostaglandins (PGD_2, PGF_2, PGE_2) • Leukotrienes (LTA_2, LTB_4, LTC_4, LTD_4, LTE_4) • Lipoxins (LXA_2, LXB_2)	• Epidermal growth factor (EGF) • Transforming growth factor α and β (TGF-α and TGF-β) • Fibronectin **Angiogenesis** • VEGF1 • VEGF2 • VEGF3

Fig. 4.63: Role of activated macrophages in chronic inflammation. Macrophages are activated by immunological or nonimmunological mechanisms. Various products synthesized by activated macrophages participate in tissue injury and fibrosis.

Table 4.67 Categories of type 4 hypersensitivity reactions

Type	Antigen and Site	Reaction Time	Clinical Appearance	Histology
Contact dermatitis	Epidermal contact with organic chemicals, poison ivy, heavy metals	48–72 hours	Eczema	Lymphocytes. Followed by macrophages; edema of epidermis
Tuberculin Test	Intradermal route (tuberculin or lepromin test)	48–72 hours	Local induration, swelling and swelling with or without fever	Lymphocytes and macrophages
Granulomatous inflammation	Persistent antigen or foreign body presence, *Mycobacterium tuberculosis* and leprosy	21–28 days	Hardening	Epithelioid cell granuloma, giant cells with or without necrosis

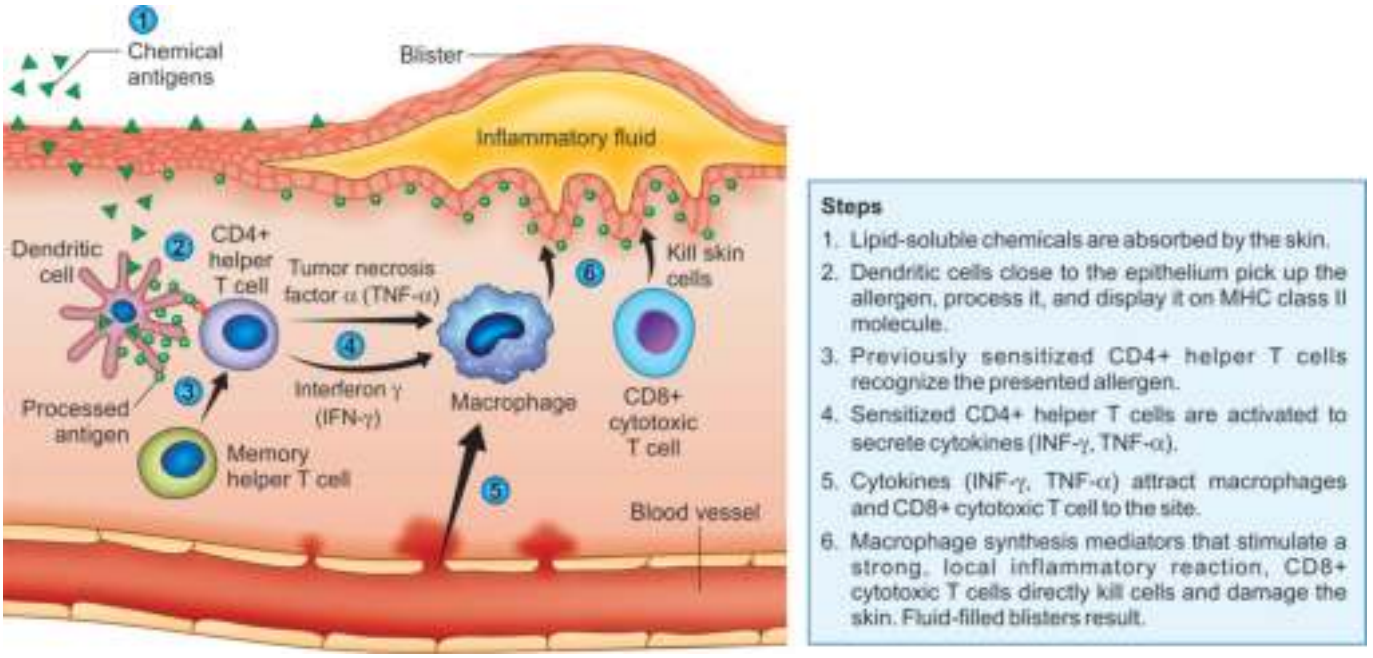


Fig. 4.64: Genesis of contact dermatitis. Contact dermatitis from poison oak, is showing various stages of involvement: blisters, scales and thickened patches. Lipid-soluble chemicals are absorbed by the skin. Dendritic cells close to epidermis pick up the allergen, process it.

substances induces eczema within 48–72 hours. Also, keratinocytes, which express MHC class II molecules and intercellular adhesion molecule 1 (ICAM-1), produce cytokines (IL-1, IL-6, IL-8), that help in the establishment of the contact hypersensitivity reaction. Histologic examination reveals lymphocytic infiltration around dermal blood vessels, together with dermal and epidermal edema leading to vesicle formation. Contact dermatitis is shown in Fig. 4.64.

Tuberculin Skin Test: Type 4 Hypersensitivity Reaction

Tuberculin skin test—type 4 hypersensitivity reaction is a localized inflammatory reaction develops within 48–72 hours in patients with tuberculosis (TB) or vaccinated against tuberculosis. Patients are injected tuberculin (purified protein derivative of tubercle bacillus) via intracutaneous route. Tuberculin skin test induces skin induration, swelling and redness resulting from fibrin deposition is marked by accumulation of lymphocytes, monocytes, and small numbers of neutrophils around small blood vessels (i.e. perivascular cuffing). Other antigens from *Mycobacterium leprae* and *Leishmania tropica* can also cause a similar reaction.

Granulomatous Inflammation Type 4 Hypersensitivity Reactions

Granulomatous inflammation type 4 hypersensitivity reaction results from the persistence of intracellular pathogens or other antigens including silica, beryllium, talc within macrophages, which are unable to process and digest, that leads to development of granulomas as occur in tuberculosis cases in more than 3 weeks.

- Granuloma is defined as an aggregation of modified macrophages (epithelioid cells) surrounded by lymphocytes and fibroblasts. Epithelioid cells may differentiate into multinucleate giant cells. Langhans' giant cells show peripherally arranged nuclei seen in tuberculosis. Epithelioid cell granulomas in tubercular lymphadenitis are shown in Fig. 4.65.
- Examples of granulomatous hypersensitivity include tuberculosis, leprosy, syphilis, blastomycosis, histoplasmosis, toxoplasmosis, leishmaniasis, sarcoidosis, Crohn's disease, rheumatoid arthritis, inorganic antigens (zirconium, inert minerals like silica), autoimmune diseases (e.g. type 1 diabetes mellitus, multiple sclerosis, rheumatoid arthritis and Guillain-Barré syndrome).
- Corticosteroids and other immunosuppressive agents are used in treatment. Examples of granulomatous inflammation type 4 hypersensitivity reactions are given in Table 4.68.

Type 1 Diabetes Mellitus

Type 1 diabetes mellitus results from the autoimmune destruction of islets of Langerhans β cells of the endocrine, pancreas, that lead to insulin deficiency. The process of autoimmune destruction of pancreatic β cells results in granuloma formation in genetically susceptible persons under the triggering effect of one or more environmental factors and usually progresses over a period of many months to years.

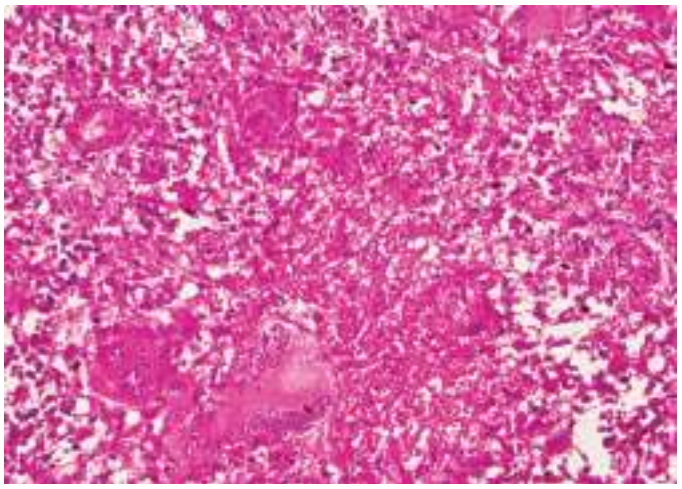

Fig. 4.65: Tubercular lymphadenitis. Hematoxylin and eosin-stained section of involved lymph node shows epithelioid cell granulomas, caseous necrosis and Langhans' cells. Epithelioid cell granuloma can be defined as specifically and structurally organized collection of epithelioid cells, macrophages, lymphocytes and dendritic cells. Dendritic cells are important because these cells present antigens to CD4+ helper T cells in the lymph nodes, in which activated T cell immune response can subsequently be developed. The signaling events lead to the formation of epithelioid cell granuloma, caseous necrosis and Langhans cells, the hallmark of tuberculosis (100X).

Multiple Sclerosis

Multiple sclerosis is a chronic neurodegenerative disease targeting the central nervous system (CNS), which is believed to be autoimmune in nature. Disease is mediated by autoreactive lymphocytes that crosses the blood–brain barrier and enter the CNS, where they cause local perivascular inflammation and tissue damage that results in demyelination, gliotic scarring, axonal loss and paralysis. Patient can develop granulomatous panuveitis.

Rheumatoid Arthritis

Human parvovirus B19 is a causative agent of rheumatoid arthritis, which is characterized by the presence of autoantibodies known as rheumatoid factor (RF) and anticitrullinated peptide antibodies (ACPA), which includes the anticyclic citrullinated peptide antibody or anti-CCP.

- Rheumatoid factor has been recognized as a feature of many persons with rheumatoid arthritis.
- T cells and macrophages are recognized as two critical cellular components involved in rheumatoid arthritis by inducing chronic arthritis with granulomatous inflammation, destruction of articular cartilage and bones.
- Signs and symptoms of rheumatoid arthritis may include tender, warm, swollen joints. Joint stiffness that is usually worse in the morning hours and after inactivity, fever, fatigue and anorexia.

Crohn's Disease

Crohn's disease is a type of inflammatory bowel disease (IBD) that causes inflammation of ileum and colon, often with granulomas, fibrosis, and stricture formation, which leads to abdominal pain, severe diarrhea, fatigue, weight loss and malnutrition.

Guillain-Barré Syndrome

Guillain-Barré syndrome is an autoimmune progressive granulomatous disease that affects the nerves (polyneuritis) causing skeletal muscle weakness and loss of sensation, sometimes progressive to complete paralysis, skeletal muscle weakness begins in the legs and spreads to the arms and body.

Tissues/Organs Transplant Rejection

The four classes of transplants or grafts are determined by the degree of MHC class molecules similarity between graft and host, which include: (a) autografts (one part of body to another), (b) isografts (between identical twins), (c) allografts (between two members of same species), and (d) xenografts (between two different species).

Table 4.68 Granulomatous inflammation type 4 hypersensitivity reactions

Disease	Specificity of Pathogenic T Cells	Clinicopathological Manifestations
Type 1 diabetes mellitus	Antigen of pancreatic islets β cells (insulin, glutamic acid decarboxylase, others)	Insulitis (chronic inflammation in islets destruction of β cells, diabetes)
Multiple sclerosis	Protein antigens in CNS myelin (basic proteins, proteolytic proteins)	Demyelination in CNS with perivesicular inflammation, paralysis, ocular lesions
Rheumatoid arthritis	Unknown antigens in joint synovium (type 2 collagen)	Chronic arthritis with inflammation, destruction of articular cartilage and bones
Peripheral neuropathy (Guillain-Barré syndrome)	Protein antigens of peripheral nerve myelin	Neuritis, paralysis
Crohn's disease (inflammatory bowel disease)	Unknown antigen may be derived from intestinal microbes	Chronic inflammation of ileum and colon, often with granulomas, fibrosis, stricture formation

- All major organs may be successfully transplanted. Allografts require tissue match (MHC class molecules must correspond); rejection is controlled with drugs.
- CD4+ cytotoxic T cells directed against foreign cells of a grafted tissue; involves recognition of foreign major histocompatibility complex (MHC) class molecules and rejection of tissue/organ.
- Graft rejection can be minimized by tissue matching procedures, immunosuppressive drugs, and use of tissues that do not provoke a type 4 hypersensitivity reaction.

TYPE 5 HYPERSENSITIVITY REACTION

Type 5 hypersensitivity reaction is sometimes considered as a subtype of type 2 hypersensitivity reaction, in which antibodies combine with target receptors present on a cell surface, that induces cells to proliferate, differentiate and enhances overactivity of the cells.

- Graves' disease is autoimmune disease named after Robert J Graves, and an example of type 5 hypersensitivity reaction due to circulating autoantibodies, in which excess synthesis of thyroid hormones results in hyperthyroidism.
- It is postulated that long-acting thyroid stimulating autoantibodies mimic TSH and bind to thyroid stimulating hormone (TSH) receptor present on thyroid follicular cell surface and activate excess production and secretion of thyroid hormone and thyroglobulin that is mediated via-3′, 5′-cycle adenosine monophosphate (cyclic AMP), resulting in excess iodine uptake, protein synthesis, and thyroid gland growth, which is responsible for Graves' disease.

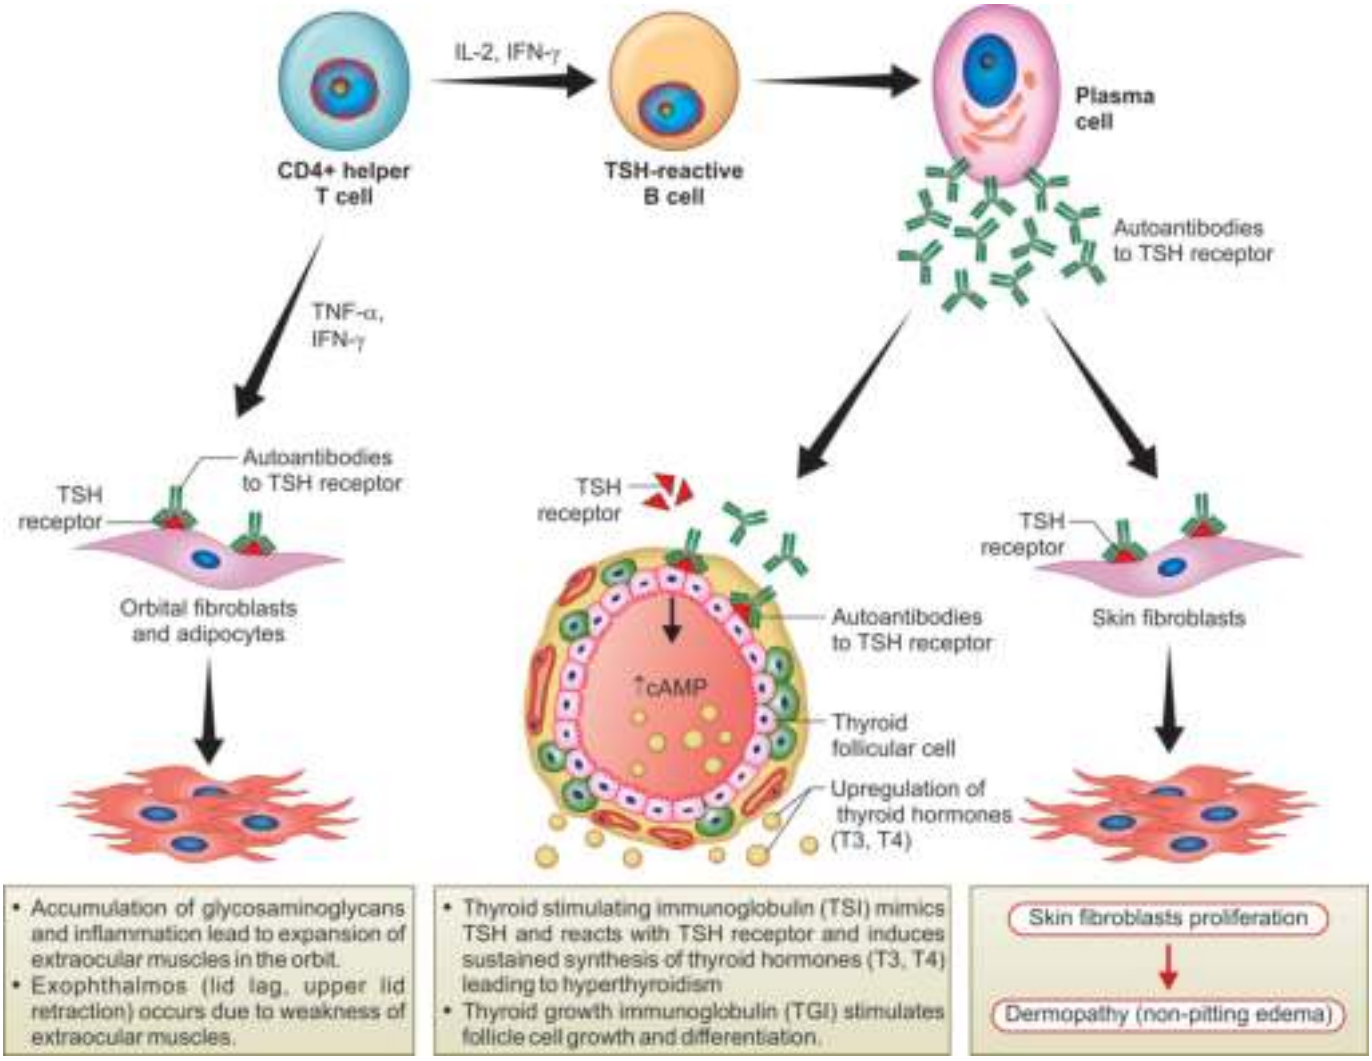

Fig. 4.66: Pathogenesis of Graves' disease. Graves' disease is an autoimmune disorder that results in the overproduction of thyroid hormones. Women are more affected than men in the age group 30–50 years. Graves' disease can cause features of hyperthyroidism, ophthalmopathy, dermopathy, combination of genes and virus trigger the immune system to produce excess of thyroid stimulating immunoglobulin (TSI) and thyroid growth immunoglobulin (TGI), TSI mimics TSH and reacts with TSH receptors and induces sustained synthesis of thyroid hormones. TGI stimulates thyroid follicle growth and differentiation.

GRAVES' DISEASE

Graves' disease is usually a disease of young usually female patients, who present with heat intolerance, tachycardia, tremors, weight loss and orbitopathy. Pathophysiology of thyroid-associated orbitopathy (TAO) is thought to an autoantibody-mediated reaction that can affect orbital and periorbital soft tissue. Long standing thyroid-associated orbitopathy features lid retraction, proptosis and vertical diplopia. Pathogenesis of Graves' disease is shown in Fig. 4.66.

IMMUNOLOGIC TOLERANCE

Thymus gland and bone marrow are sites of maturation for T and B cells respectively, which play important role in humoral and cell-mediated immunity against pathogens.

- Immunologic tolerance is a state of unresponsiveness to various environmental allergens and gut microbes in which T and B cells remain alive but cannot exert effector functions against a particular antigen, hence it provides protection against invading pathogens.
- Immunologic tolerance is classified into central and peripheral tolerance depending on where the state is originally induced in central lymphoid organs such as bone marrow and thymus gland, and peripheral lymphoid organs such as lymph nodes, spleen, mucosa-associated lymphoid tissues, tonsils, lymphoid tissues and organs. B cells and T cells become either immune competent or tolerant towards encountered antigens.
  - Central immunologic tolerance develops very early in life, in which immune system learns to discriminate self- from nonself-antigens, that prevents development of autoimmune diseases in normal persons.
  - Peripheral immunologic tolerance is the key to prevent over-reactivity of the immune system to various environmental antigens. CD4+ regulatory T cells (Treg cells) that inhibit CD4+ helper T cells or CD8+ cytotoxic T cells are involved in the development of peripheral immunologic tolerance.
- Central immunologic tolerance occurs by clonal deletion of autoreactive lymphocyte clones before these cells develop into fully immunocompetent B cells in bone marrow and T cells in thymus gland. It is the main, way the immune system learns to discriminate self- from nonself-antigens.
- T cell development involves positive or negative selection and lineage commitment, which depends on expression of TCR repertoire and exposure to MHC class molecules. T cells possess high affinity receptors for self-antigens.
  - Positive selection of T cells occurs first when naïve T cells are exposed to antigens in the thymus gland. T cells, which possess receptors with sufficient affinity for self-MHC class molecules are selected. Other T cells that do not express sufficient affinity to self-antigens will undergo a deletion process known as death by negligence, which involves apoptosis of the cells.
  - Negative selection of T cells with a very high affinity for self-MHC class molecules is induced to anergy or lineage divergence to form CD4+ regulatory T cells.
- When immunologic tolerance breaks down, individuals can develop autoimmune disease. In genetically predisposed individuals, autoimmunity may be triggered as a result of the failure of intrinsic tolerance mechanisms and/or environmental exposure triggers such as infection. To prevent self-tissue destruction, T cells and B cells are eliminated in primary and secondary lymphoid organs. This process is called central and peripheral immunologic tolerance.
- Immunologic tolerance depends on the concerned action of a variety of mechanisms that operate at different sites and stages of T cell and B cell development. The different ways in which the immune system prevents activation of autoreactive lymphocytes causing tissue damage are listed, along with specific mechanism and where such immunologic tolerance predominantly occurs.
- Factors influencing immunologic tolerance comprise structure of molecule, stage of differentiation when lymphocyte first encounter the epitopes, site of the encounter and nature of the cell presenting the epitopes.
- Central and peripheral immunologic tolerance of T cells and B cells is shown in Fig. 4.67. Positive and negative selection of T cells during development in thymus gland is shown in Fig. 4.68. Central and peripheral immunological; tolerance of B cells is shown in Fig. 4.69. Layers of immunologic tolerance are given in Table 4.69. Factors influencing immunologic tolerance are given in Table 4.70.

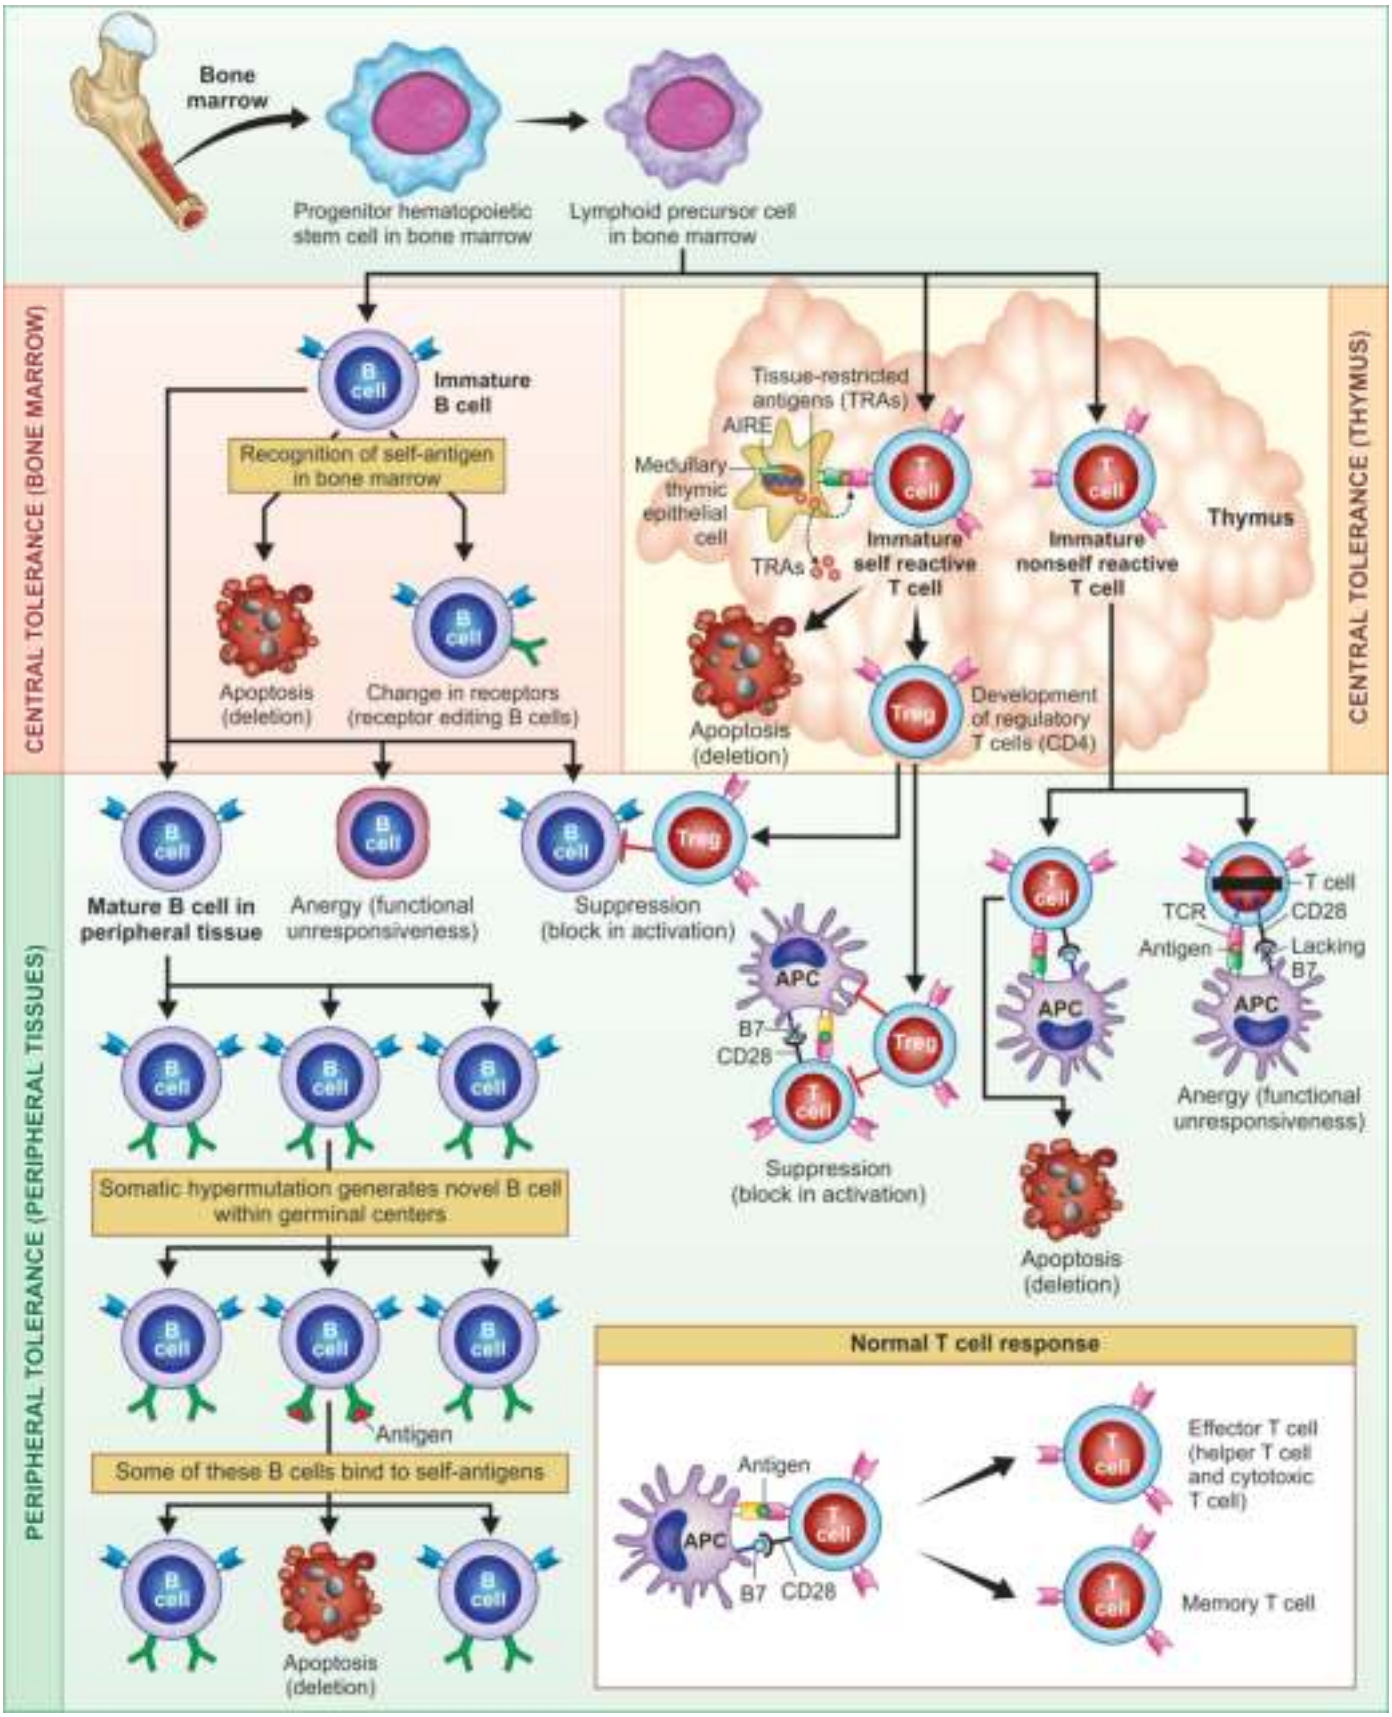

Fig. 4.67: Central and peripheral immunologic tolerance of T cells and B cells. Induction of immunologic tolerance refers to the regulatory education of both B cells and T cells, when occurs in both central organs (bone marrow and thymus gland) and peripheral organs (lymph nodes, spleen and mucosa-associated lymphoid tissue).

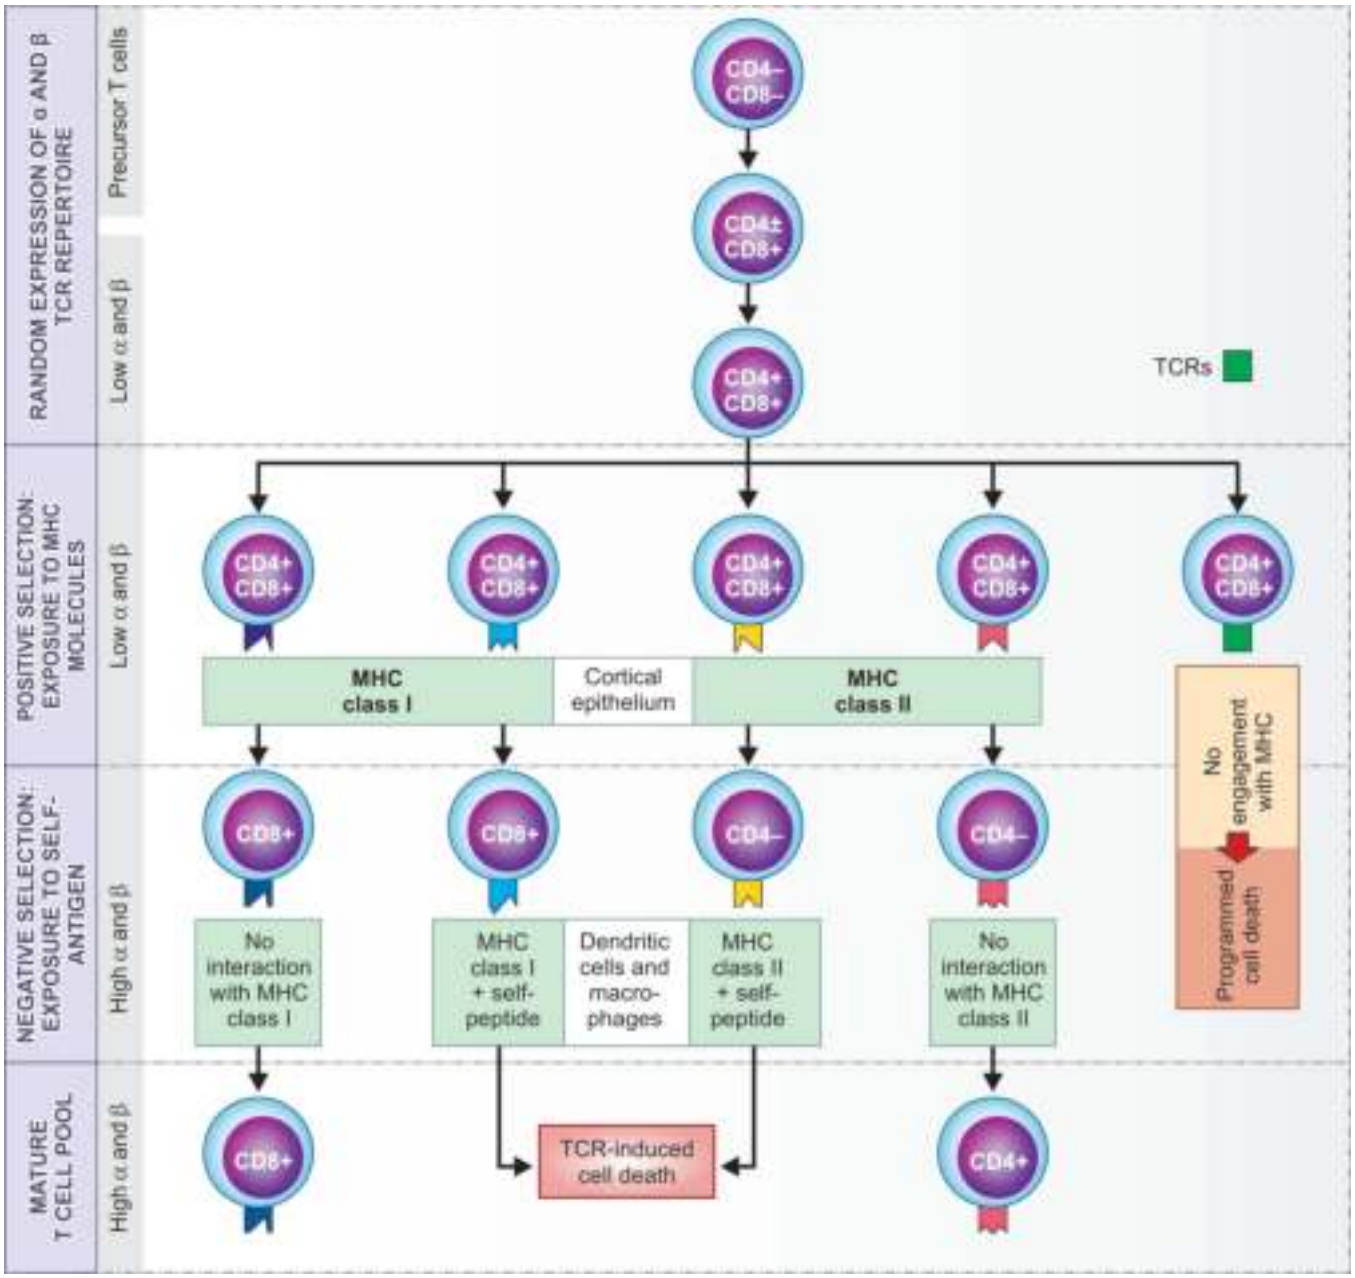

Fig. 4.68: Positive and negative selection of T cells during development in thymus gland. T cell progenitors develop in the bone marrow migrate to thymus gland. Early T cells are CD4 negative and CD8 negative (double negative thymocytes). After TCR rearrangement in the thymus gland, double negative thymocytes differentiate into CD4+ and CD8+ (double-positive thymocytes). Following interaction with self-peptide MHC complex class I molecules, thymocytes become CD8+ cytotoxic T cells. Thymocytes interacting with self-peptide MHC class II molecules become CD4+ helper T cells.

T CELL IMMUNOLOGIC TOLERANCE

T cell immunologic tolerance is a state of unresponsiveness of T cells towards specific self- or nonself-antigens. T cells and B cells with receptors specific for self-antigens are deleted in lymphoid cell development in bone marrow and thymus gland during fetal and early neonatal periods. This process is called central immunologic tolerance that allows elimination of self-reactive B cells and T cells in the tissues by negative selection. Lymphocytes that do not receive survival signals undergo apoptosis.

- T cells function as effector cells as well as regulator cells of the immune system. T cells become educated in the thymus gland and dependent on self-MHC class molecules for survival.
- The subset of T cell receptors that receive the correct antigen signals will leave the thymus gland and circulate in the peripheral lymphoid tissues. Some CD4+ helper T cells receive signals in the thymus

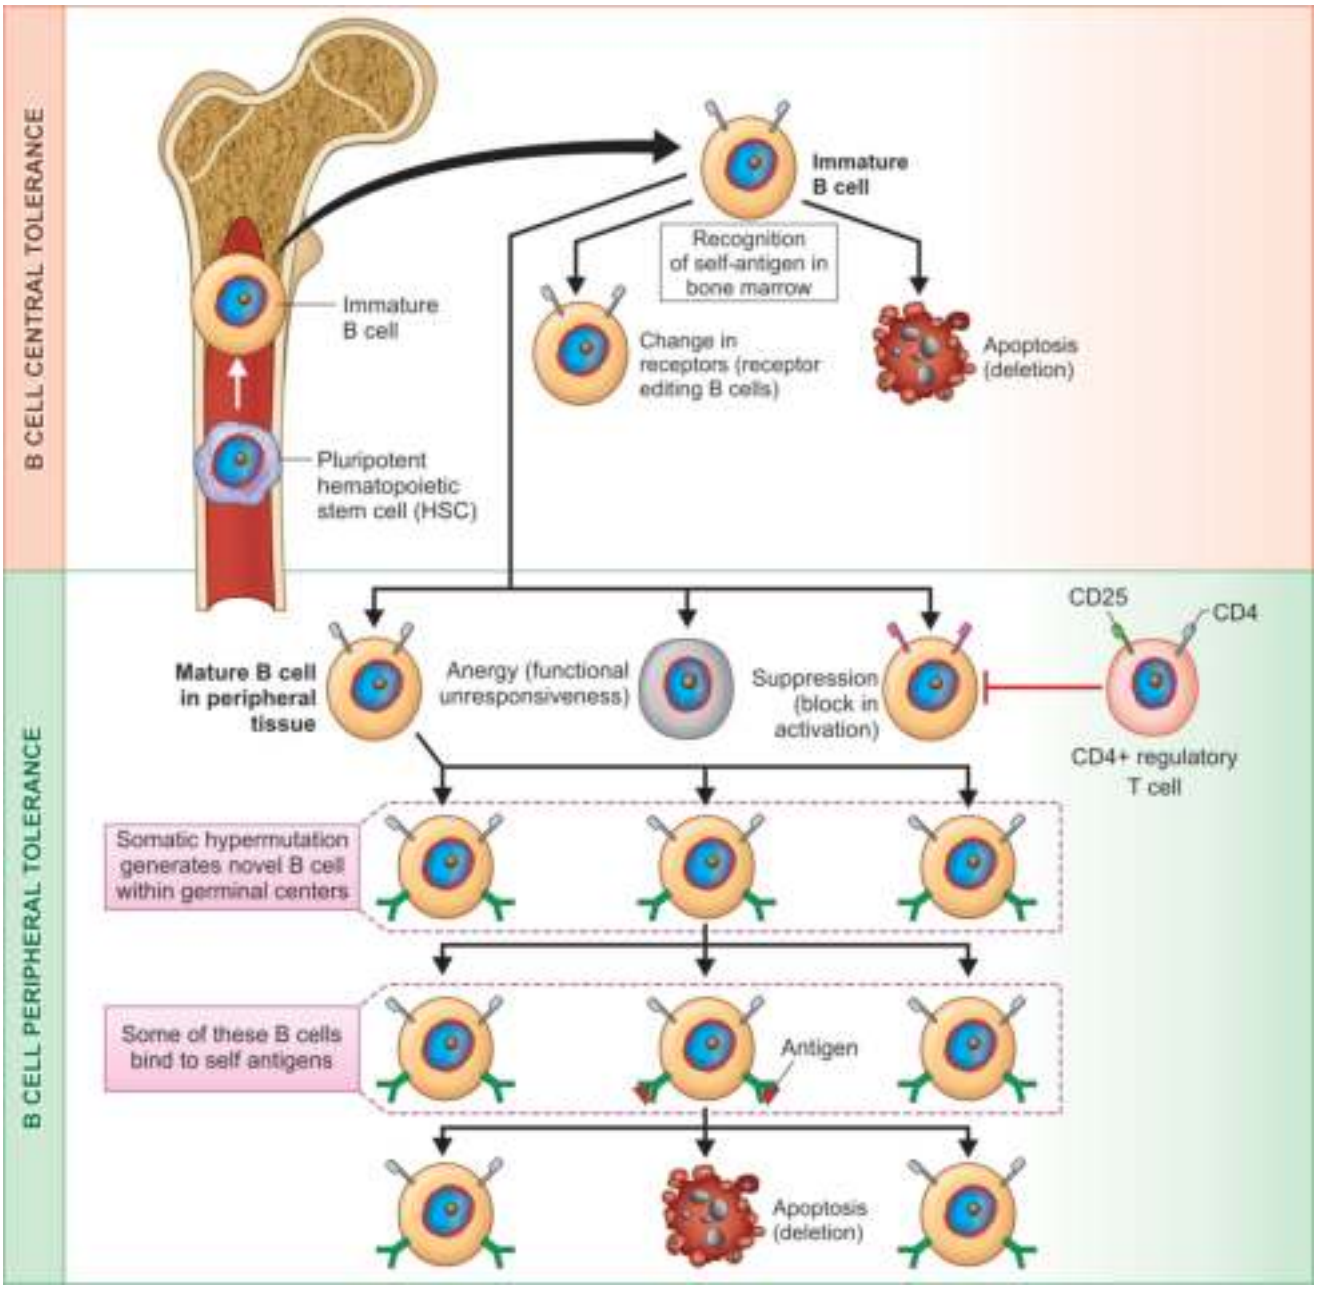

Fig. 4.69: Central and peripheral immunologic tolerance of B cells. Peripheral tolerance occurs after central tolerance. It takes place in the periphery after B cells egress from primary lymphoid tissues/organs. Its main purpose is to ensure that self-reactive B cells which have escaped central tolerance do not cause autoimmune diseases.

gland that select them to differentiate into CD4+ regulatory T cells, which express FOXP3 transcription factor and suppress the immune response by direct and indirect mechanisms.

- Through elimination of autoreactive T cells and B cells, central immunologic tolerance ensures that the immune system does not attack self-peptides hence prevent development to autoimmune diseases.
- Normal individuals are tolerant to their own antigens (self-antigen). Immunologically privileged sites are brain, eye, testis, uterus (fetus). Immunologic tolerance in pregnancy allows mother to gestate a genetically distinct offspring with an alloimmune response mutated enough to prevent miscarriage. Central and peripheral immunologic tolerance of T cells is shown in Fig. 4.70.

T CELL IMMUNOLOGIC TOLERANCE IN CENTRAL LYMPHOID ORGANS

Double negative (CD4 and CD8 negative) T cell progenitors migrate from bone marrow and enter the thymic cortex and rearrange their receptors to

Table 4.69 Layers of immunologic tolerance

Type of Tolerance	Mechanism	Site of Action
Central tolerance	▪ Deletion ▪ Editing	▪ Thymus gland (T cells) ▪ Bone marrow (B cells)
Antigen segregation	Physical barrier to self-antigen access to lymphoid system	Peripheral organs (e.g. thyroid gland, pancreas)
Peripheral anergy	Cellular inactivation by weak signaling without co-stimulus	Secondary lymphoid organs
Regulatory T cells	Suppression by cytokines intercellular signals	Secondary lymphoid tissue and sites of inflammation; multiple tissues in steady state
Functional deviation	Differentiation of CD4+ regulatory T cells that limits inflammatory cytokine secretion	Secondary lymphoid tissue and sites of inflammation
Activation-induced cell death	Apoptosis	Secondary lymphoid tissue/organs and sites of inflammation

Table 4.70 Factors influencing immunologic tolerance

Factors Affecting Response	Favoring Immune Response	Favoring Tolerance
Physical form of antigen	Large aggregated complex molecules properly processed	Soluble aggregates-free simple small molecules not processed
Route of administration of antigen	Subcutaneous and sometimes intramuscular route	Oral or sometimes intravenous route
Dose of antigen	Optimum dose	Ranging from small to large dose

Immunologic tolerance of host depends on heredity, age, gender and health.

become CD4+ and CD8+ (double positive thymocytes) independent on MHC class molecules.

- T cells expressing an αβ complex receptor must interact with self-peptide MHC class molecules to survive. Cells are instructed to repress expression of either CD4 or CD8 and to develop into single positive T cells. Cells that interact strongly with MHC class molecules on thymic epithelia receive a survival signal (positive selection). Depending on which MHC class molecules are recognized, T cells will display (single positivity) either CD4 (CD4+ helper T cells) or CD8 (CD8+ cytotoxic T cells).
- CD4+ helper T cells that recognize self-antigens expressed on thymocytes in the context of MHC class II molecules undergo apoptosis. The key factor in determining positive and negative selection is the strength of the antigen recognition by the maturing T cell.
- T cells with a receptor that bind with high-avidity to autoantigens on thymic epithelia undergo apoptosis leading to negative selection. T cells with a receptor that bind with low-avidity to autoantigens lead to positive selection. CD4+ regulatory T cells (Treg CD4+ and CD25+) that are autoantigen-specific are generated by intermediate degrees of binding.
- The autoantigens are host tissue proteins expressed on thymic epithelia under regulation of the transcription factor autoimmune regulator (AIRE). Many T cells are deleted in the thymus gland, only a fraction is present in peripheral lymphoid tissues or organs.
- The autoimmune regulator (AIRE) protein is part of a complex that regulates the expression of tissue-restricted antigens (TRAs) in medullary thymic epithelial cells (MTECs). Peptides derived from these antigens are displayed on the cells in the absence of functional autoimmune regulator (AIRE). These self-reactive T cells are not eliminated; which can enter tissues where the antigens continue to be produced and cause organ-specific autoimmunity including autoimmune polyglandular syndrome type 1 (APS1), which cause damage to parathyroid and adrenal glands.

T CELL IMMUNOLOGIC TOLERANCE IN PERIPHERAL LYMPHOID ORGANS

When self-reactive T cells leave the central lymphoid organs and settle in peripheral lymphoid tissue such as lymph nodes, spleen, MALT (mucosa-associated lymphoid tissue) and SALT (skin-associated lymphoid tissue), peripheral immunologic tolerance ensures that these self-reactive T cells are eliminated, and become anergic (functionally unresponsiveness to antigen).

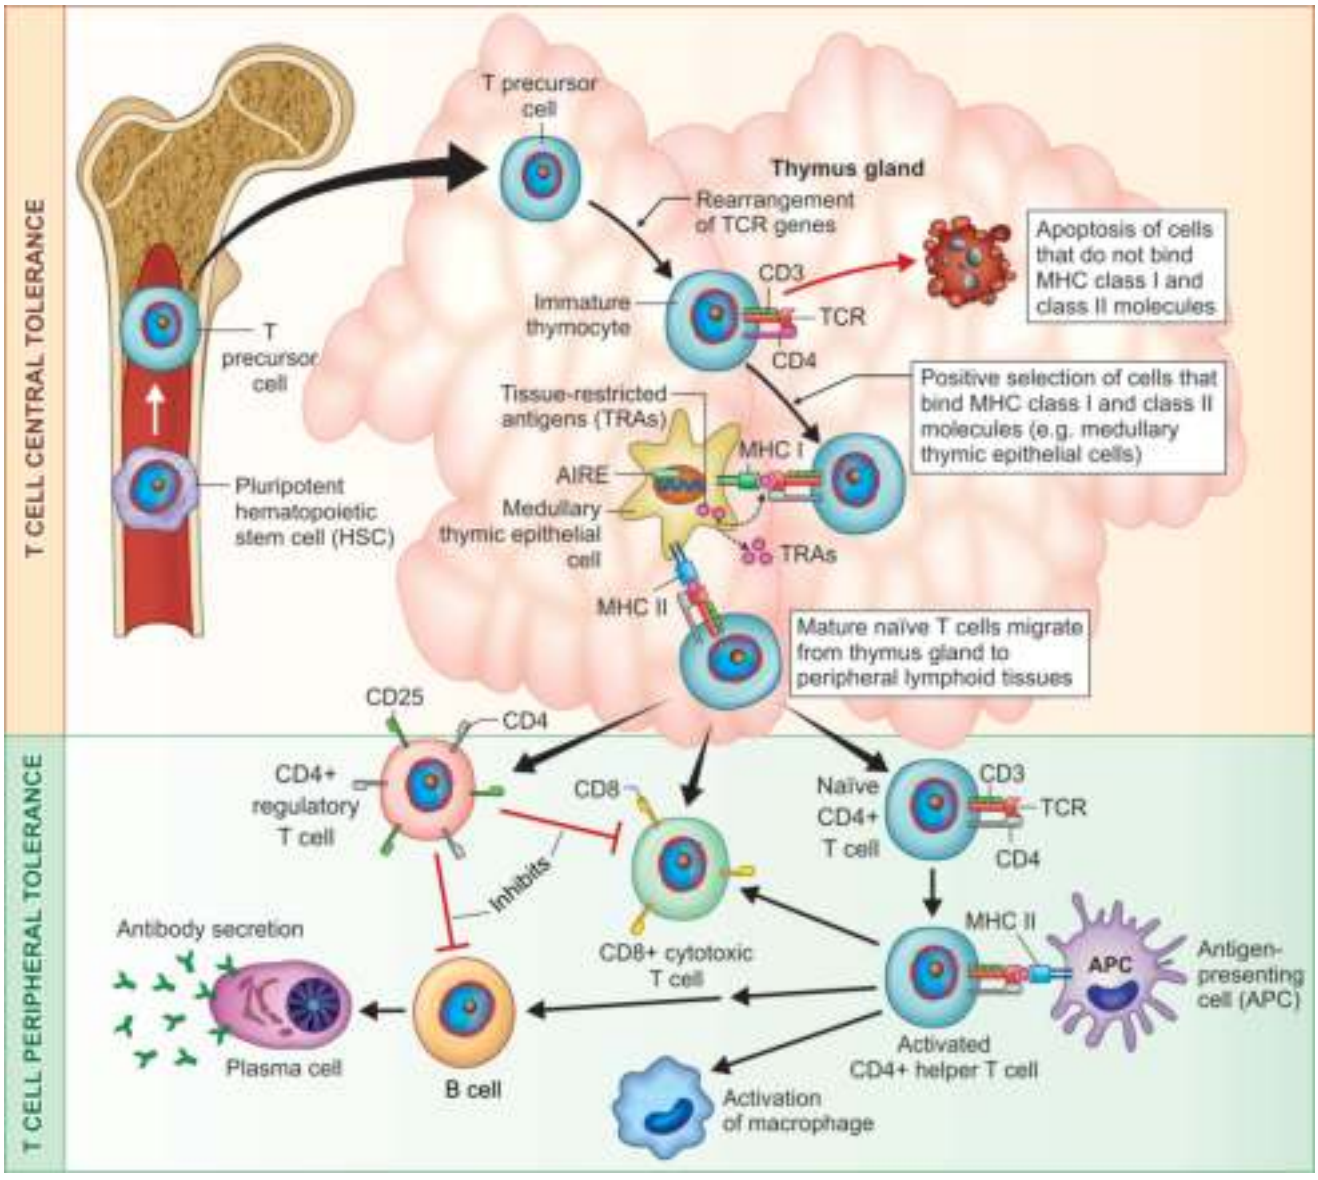

Fig. 4.70: Central and peripheral immunologic tolerance of T cells. After positive or negative selection three types of mature T cells are left: CD4+ helper T cells, CD8+ cytotoxic T cells and CD4+ regulatory cells. CD4+ helper T cells are involved in activating CD8+ cytotoxic T cells, and macrophages (particularly via the secretion of the cytokine interferon-γ) and obligatory for most B cell response.

- Several autoreactive clones of T cells are found in the peripheral blood of healthy persons. Autoreactive clones of T cells potentially activated, undergo proliferation in the setting of subacute bacterial endocarditis, which can lead to emergence of self-reactive clones of T cells that cause damage to kidneys.
- Peripheral immunologic tolerance occurs through one of these mechanisms: clonal deletion, ignorance, anergy and immune regulation.

Clonal Deletion

In fetal life, all T cells and B cells that recognize 'self'-antigens are eliminated by apoptosis. Fas-mediated apoptosis plays a critical role in the removal of mature autoreactive B cells and T cells.

- Fas-mediated apoptosis plays a key role in immune-privileged sites (e.g. central nervous system, eyes and testes). FasL is expressed on antigen-presenting cells, activated T cells and some other cells. Even foreign antigens accessing these tissues do not generally trigger immune responses.
- IL-2 is a cytokine predominantly secreted by activated CD4+ helper T cells essential for T cell homeostasis. IL-2 cytokine suppresses excessive T cell response by inducing activation-induced cell death (AICD) via caspase pathway and elicits the function of CD4+ FOXP3+ T regulatory cells (Tregs).

- Insufficient production of key transcription activators (e.g. NF-κB, AP-1, NFAT-1) during T cell activation reduces IL-2 production. Transcription suppressors (e.g. **CREM**) can also reduce the transcriptional activity of the IL-2 gene promoter resulting in T cell anergy.

Antigen Sequestration (Ignorance)

Autoreactive T cells may remain unresponsive by ignoring self-antigens located in immunologically privileged sites such as brain, eye (vitreous humor), testis, uterus (fetus), because these organs have low immunogenicity (i.e. low-binding affinity). These autoreactive T cells have the potential to be activated under certain circumstances and therefore pose a threat to the host.

- Sympathetic autoimmune ophthalmia is a severe inflammatory damage to both eyes, caused by release of sequestrated ocular self-antigens into the circulation, where these self-antigens eventually activate peripheral autoreactive T cells.
- Immune system is not normally exposed to ocular antigens, but trauma to a single eye releases autologous antigen that activate immune cells resulting in severe granulomatous inflammation of both eyes.

Clonal Anergy

Normally, both B cells and T cells require two signals for activation: (a) one set of signal for recognition of peptide antigen in association of MHC class molecule on the surface of antigen-presenting cells, and (b) second set of costimulatory signals provided by antigen-presenting cells. Lack of second signal switches the cell off.

- Certain T cell associated molecules such as CD28 must bind to their ligands B7–1 (CD80) and B7–2 (CD86). Anergy is a state of unresponsiveness induced by activation upon self-antigen recognition.
- Autoreactive T cells can be made unresponsive to antigens if the T cells engage MHC class molecule on an antigen-presenting cell (signal 1) without engagement of costimulatory molecules such as B7–1 (CD80), B7–2 (CD86) and IL-2 (signal 2).

Immune Regulation Achieved by the Action of Regulatory T Cells (Tregs)

'Induced' CD4+ and CD25+ regulatory T cells (iTregs) play an important role in maintaining immunological unresponsiveness to self-antigens and in suppressing immune responses deleterious to the host.

- 'Induced' regulatory T cells are also produced in the peripheral lymphoid organs rather than in the thymus gland, which have similar effector functions as natural regulatory CD4+ regulatory T cells.
- Patient with genetic CD4+ regulatory T cells (Tregs) dysfunction develops lymphadenopathy and inflammatory infiltrates consisting of autoreactive T cells in multiple organs. During active inflammation, CD4+ regulatory T cells do not provide protection to immune system function.

Peripheral Suppression by CD4+ Regulatory T Cells

Cells which recognize self-antigens develop into CD4+ regulatory T cells, which also express CD25+, α-chain of IL-2 receptor and transcription factor of the family FOXP3.

- CD4+ regulatory T cells synthesize IL-4, IL-10 and TGF-β, which have ability to downregulate function of autoreactive T cells.
- IPEX (immune dysregulation, polyneuropathy, enteropathy) is X-linked syndrome of systemic autoimmunity caused by mutations in FOXP3 gene, which codes for a member of the forkhead transcription factor family, expressed primarily in CD4+ and CD25+ regulatory T cells.

Pathology Pearls: Clinical Significance of Immunologic Tolerance

- **Induction of immunologic tolerance** is done to prevent allogenic grafts, treatment of autoimmune diseases and allergic diseases; and limiting tumor growth.
- **Termination of immunologic tolerance** is done to treat malignant tumor and infectious diseases by enhancing first and second signals.
- **Rheumatoid arthritis** is an autoimmune disease mainly affecting the joints. Clinical significance of cytotoxic T lymphocytes-associated antigen 4 (CTLA-4) is used a biologic response modifier to treat these patients significantly reducing joint inflammation.
- **CTLA-4** is a molecule expressed on activated T cells that firmly binds to costimulatory molecules on antigen-presenting cells (APCs), which decreases the function of T cells.
  - A fusion protein consisting of CTLA-4 using monoclonal antibodies (abatacept or belatacept) is used in rheumatoid arthritis and other transplantation in clinical practice.
  - **CTLA-4** is constitutively expressed on cancer stem cells and can trigger apoptosis upon ligand interaction. There is also an interest in blocking CTLA-4 using monoclonal antibodies (e.g. ipilimumab) to inhibit tumor tolerance.

B CELL IMMUNOLOGIC TOLERANCE

Immunologic tolerance for B cells is a state in which B cells do not initiate an immune response to an antigen. Central immunologic tolerance is the main way by which immune system learns to discriminate self- from

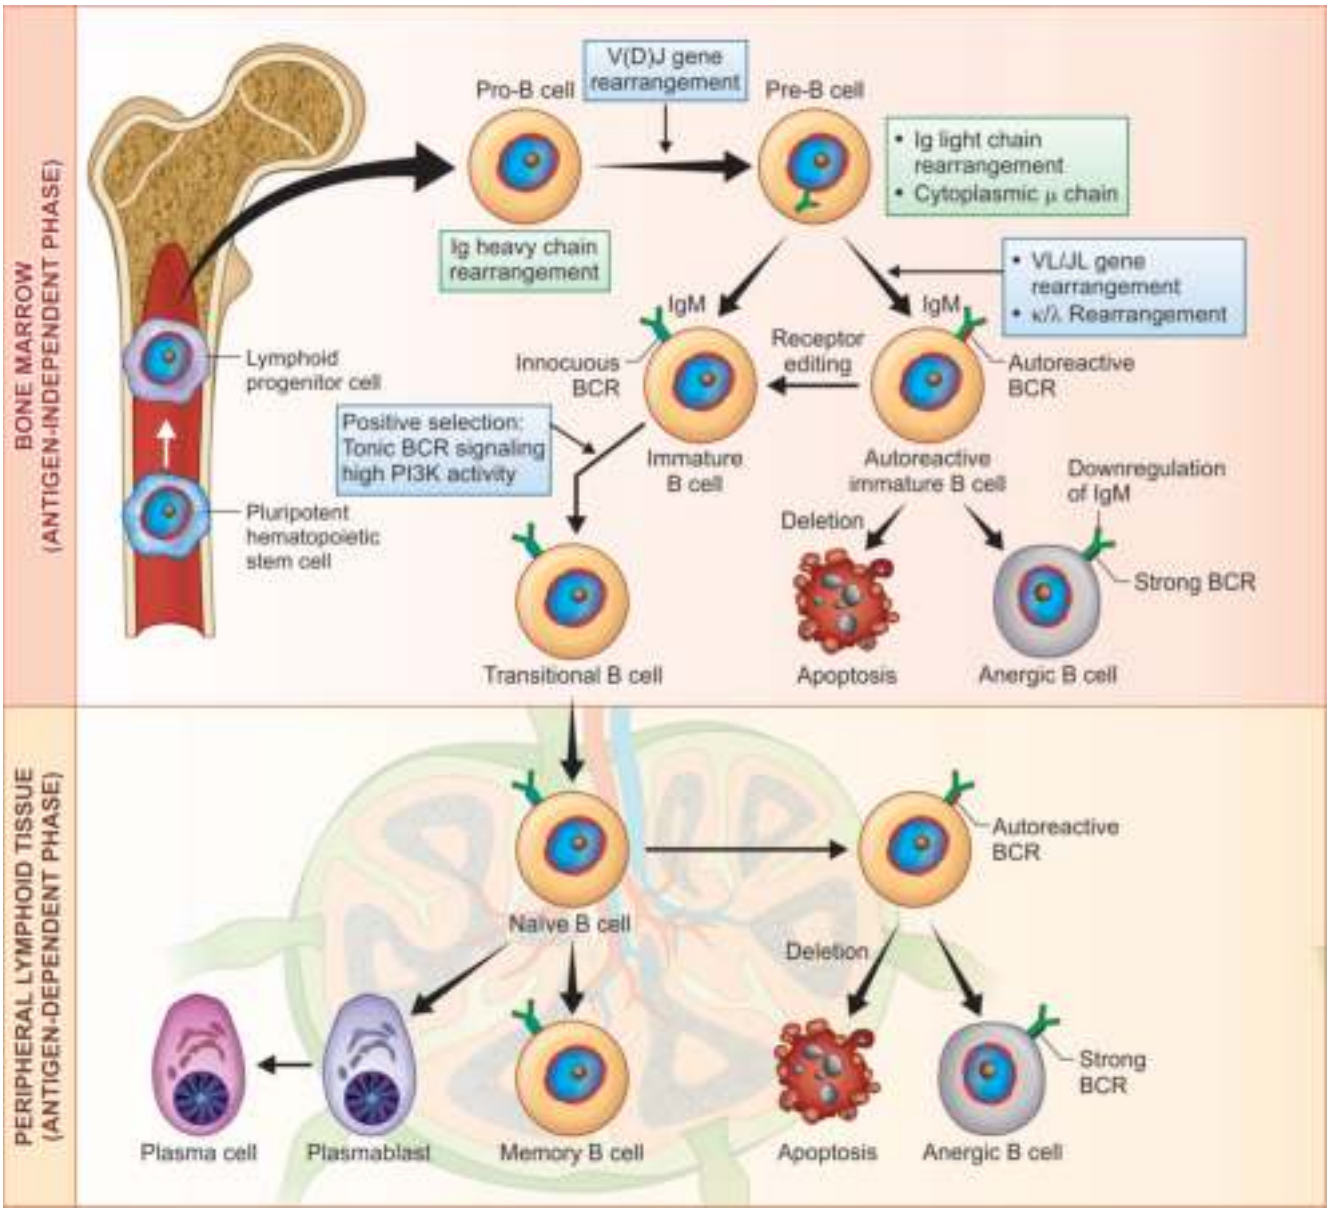

Fig. 4.71: Central and peripheral immunologic tolerance of B cells. Both clonal and anergy are mechanisms utilized in the central as well as peripheral lymphoid organs. Strength of BCR signaling affects the fate of the B cells undergoing tolerance. Receptor editing occurs primarily in the bone marrow. Transitional B cells are found in the bone marrow and spleen. Peripheral immunologic tolerance is primarily found in splenic transitional B cells, which depends on tonic BCR signaling thresholds and survival signals from BAFF.

nonself-antigens. Peripheral immunologic tolerance is key to prevent over-reactivity of the immune system to various environmental antigens (e.g. allergens and gut microbes). Central and peripheral immunologic tolerance of B cells is shown in Fig. 4.71.

B CELL IMMUNOLOGIC TOLERANCE IN CENTRAL LYMPHOID ORGANS

During normal B cell development in the bone marrow, set of processes assist in induction of B cell central immunologic tolerance.

- Education of B cells and elimination of autoreactive B cell clones is somewhat different from that of T cell central immunologic tolerance.
- B cells are still immature when they relocate from bone marrow to spleen T cell zones.
- Autoreactive B cells are not necessarily deleted during negative selection in the bone marrow. B cells that recognize autologous antigens, which are eliminated via apoptosis or become unresponsive (anergic).
- Autoreactive B cells that escape negative selection become part of a maximally-diverse immune system.

Pathology Pearls: B Cells Immunologic Tolerance in Central Lymphoid Organs

- Immunologic tolerance inhibits the potentially destructive immune responses of lymphocytes to host tissues. B cell immunologic tolerance is regulated at the stage of immature B cell development by receptor editing and apoptosis mechanisms.
- Receptor editing involves recombination of immunoglobulin light chain gene leading to secondary rearrangements that can alter antigen receptor specificity by replacing one light chain with another.
- B cell receptor (BCR) signaling in immature B cells promotes the positive selection of B cells with unligated receptors through a phosphoinositide-3 kinase (PI3K)-dependent pathway, whereas BCR ligation promotes negative selection in part through inhibiting this pathway and probably also by downregulating B cell receptor (BCR) levels.
- Increasing number of single gene defects have been described that inhibit central tolerance for B cells in human beings leading to human autoimmune diseases and in several primary immunodeficiencies caused by single gene mutations.

B CELL IMMUNOLOGIC TOLERANCE IN PERIPHERAL LYMPHOID ORGANS

B cell immunologic tolerance in peripheral lymphoid tissues normally occurs when B cells encounter cognate antigen in a way that leads to 'unproductive' BCR (B cell receptor) signaling and induce anergy. Its main purpose is to ensure that autoreactive B cells which have escaped central immunologic tolerance do not cause autoimmune disease.

- Imperfect T cell peripheral immunologic tolerance causes autoimmune disease. T cell-dependent B cell activation requires help from preactivated cognate autoreactive T cells. T cell-independent B cell activation can be achieved by autologous antigens.
- Microbial antigens structurally similar to autologous antigens can lead B cells to produce cross-reactive antibodies in a phenomenon known as molecular mimicry. B cells hypermutate their receptors on activation, so there is a second chance that B cells may become autoreactive to induce autoimmune disease.

AUTOIMMUNE DISEASES

Autoimmune reactions cause disease, when immune system is not able to distinguish self- from nonself-antigens. Autoantibodies or host T cells attack against self-antigens in tissues or organs, which may be systemic or organ-specific. Susceptibility to autoimmune diseases appears to be influenced by gender and genes in the MHC. Autoimmune diseases are mediated by types 2, 3 and 4 hypersensitivity reactions, which commonly affect females. Autoimmune diseases include systemic lupus erythematosus, rheumatoid arthritis, Hashimoto thyroiditis, type 1 diabetes mellitus, myasthenia gravis, autoimmune hemolytic anemia, Sjögren syndrome, and multiple sclerosis.

Pathology Pearls: Pathogenesis of Autoimmune Diseases

- Mechanism of autoimmune disorders occurs by breakdown of peripheral tolerance.
- There is no evidence of breakdown of central tolerance. A number of possible mechanisms may mediate autoimmunity. Pathogenesis of autoimmune diseases is shown in Fig. 4.72.

Genetic Predisposition

- Susceptibility to autoimmune disease is influenced by genes in the major histocompatibility complex (MHC).
- Some HLA antigens are associated with increased incidence of certain autoimmune disorders. For example, there is increased incidence of **Hashimoto's thyroiditis** in HLA-DR5 and HLA-B5 positive individuals.

Environmental Factors

Some viruses may initiate autoimmune reactions in genetically susceptible persons. Some viruses trigger autoimmune islet cell destruction result in **type 1 diabetes mellitus**.

Exposure of Cryptic Self and Epitope Spreading

- Cryptic self means hidden epitopes or protein that has not been exposed during embryonic life.
- Generally, each self-protein in the body expresses few epitopes to T cells during embryonic development, thus, T cells are either deleted in the thymus or undergo anergy in the peripheral organs. But sometimes during adult life, the protein may present some uncommon epitopes, which may lead to autoimmune reaction.

Host Antigens Recognized as Nonself

- Host antigens are recognized as nonself, if modified by viral infection, inflammation, and trauma or forming complex with a drug.
- Examples of host antigens include thyroglobulin, lens protein, and spermatozoa. A foreign antigen may share a common structure with a host antigen.

Release of Sequestered Antigens

Spermatozoa and ocular antigens are completely sequestrated during development, which act as foreign bodies, when these come in contact with systemic circulation resulting immune response.

Autoantibodies

Many autoimmune disorders show presence of autoantibodies directed against host tissue. The demonstration of autoantibodies is presumptive and not entirely conclusive in the diagnosis of autoimmune nature of disorders.

Dysfunctional Immunoregulation

- Autoimmune disorders are caused by following mechanisms: (a) there may be increased in CD4+ helper T cells function, or decreased in CD8+ cytotoxic T cells function. (b) EB virus may activate B cells resulting in polyclonal antibody synthesis.
- Superantigens (TSST, Staphylococcus) activate a large pool of CD4+ helper T cells in antigen-independent manner without relation to their epitope's specificity. (c) There may be thymic defects of T cell.

Breakdown of T Cells Anergy

Antigen-presenting cells express B7 ligands that synthesize IL-2 that stimulates Th1 cells as in case of **multiple sclerosis**.

Failure of Apoptosis

Failure of apoptosis allows persistence and proliferation of autoreactive T cells in peripheral tissues.

SPECIFIC AUTOIMMUNE DISEASES

Autoimmune diseases encompass a group of loosely related conditions, most of which feature fibrinoid necrosis in connective tissue due to antinuclear antibodies (ANAs) and various other autoantibodies. Selected

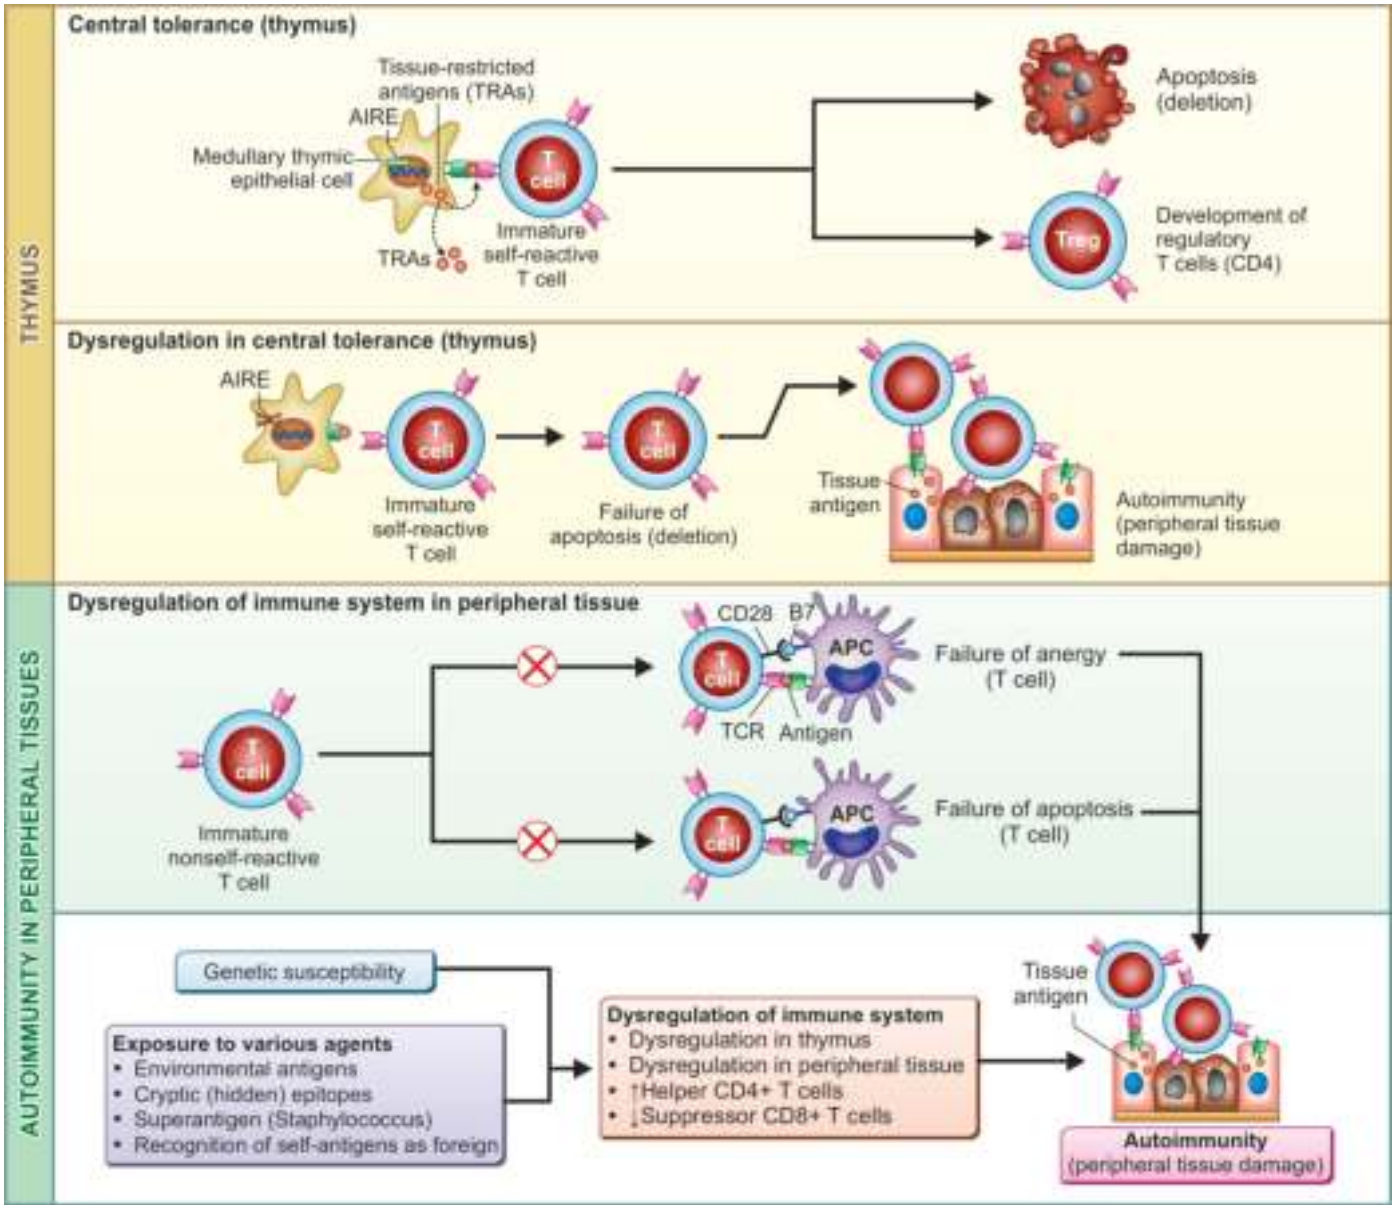

Fig. 4.72: Pathogenesis of autoimmune diseases. Autoimmune diseases result from susceptibility of genes that may interfere with self-immune tolerance and injurious stimuli leading to influx of lymphocytes into the tissue. Activation of lymphocytes causes tissue damage.

autoimmune diseases with autoantibodies reacting only with antigens in the affected organs are given in Table 4.71. Therapeutic strategies in autoimmune diseases are given in Table 4.72.

Table 4.71 Selected autoimmune diseases with autoantibodies reacting only with antigens in the affected organs

Disease	Organ or Tissue	Type of Hypersensitivity	Characteristics
Endocrine system			
Hashimoto's thyroiditis	Thyroid gland	2	Antibodies against thyroid peroxidase and thyroglobulin causing destruction of thyroid follicles
Graves' disease	Thyroid gland	2	Antibodies against thyroid-stimulating hormone receptor (TSH receptor) on thyroid follicular cells resulting in excess of T3 and T4 hormones and thus hyperthyroidism
Primary myxedema	Thyroid gland	2	Antibodies against thyroid peroxidase
Type 1 diabetes mellitus	Pancreas	2	Antibodies (glutamic acid decarboxylase 65, insulin, insulinoma-associated 2[IA-2] and zinc transporter 8[ZnT8]) against islet cell cytoplasmic antigen; causing destruction of insulin secreting β cells of islets of Langerhans
Addison disease	Adrenal gland	2	Antibodies against surface antigens on steroid producing cells; microsomal antigens
Male infertility	Testes	2	Antibodies against surface antigens on spermatozoa
Skin			
Pemphigus vulgaris	Skin	2	Antibody-mediated activation of proteases cause disruption of intercellular junction cadherin adhesion protein in prickle layers of epidermis results in skin vesicles (i.e. bullae)
Bullous pemphigoid	Skin	2	Antibodies against epidermal-dermal basement membrane
Vitiligo	Skin	2	Antibodies against surface antigens on melanocyte
Discoid lupus erythematosus	Skin	2	Antibodies against nuclear antigen
Connective tissue			
Rheumatoid arthritis	Joints	3, 4	Antibodies formed against collagen IgG (rheumatoid factor)
Ankylosing spondylitis	Joints	2	Antibodies (multiple connective tissue proteins) against sacroiliac and spinal apophyseal joints
Systemic lupus erythematosus	Multiple organs involvement	2, 3	Antibodies formed against nuclear antigens (DNA-anti DNA)
Scleroderma (excess collagen deposition in organs)	Systemic involvement	2	Antibodies formed against many intracellular organelles such as DNA topoisomerase, centromeres
Dermatomyositis	Dermis and skeletal muscle	2	Antibodies against extractable nuclear antigen
Neuromuscular system			
Myasthenia gravis	Neuromuscular junction	2	Antibody formed against acetylcholine receptors at neuromuscular junction resulting in inhibiting acetylcholine binding and downregulation of receptors
Multiple sclerosis	Neural tissue	2, 4	T cells and antibodies (myelin basic protein) sensitized to surface antigens on myelin sheath resulting in destroy neurons

Contd...

Table 4.71 Selected autoimmune diseases with autoantibodies reacting only with antigens in the affected organs (*Contd...*)

Disease	Organ or Tissue	Type of Hypersensitivity	Characteristics
Eyes			
Sjögren syndrome	Lacrimal gland, salivary gland and thyroid gland	2	Antibodies (SS-A, SS-B) against antigens on lacrimal gland, salivary gland, thyroid gland and nuclei of cells
Phacogenic uveitis	Lens	2	Antibodies against lens
Sympathetic ophthalmia	Uveal tract	2	Antibodies against uveal tract antigen
Hepatobiliary system			
Primary biliary cirrhosis	Liver	2	Antinuclear antibodies formed against bile duct cells
Cardiovascular system			
Antinuclear cytoplasmic antibody (ANCA)-mediated vasculitis	Blood vessels	2	ANCA-mediated vasculitis resulting in neutrophil degranulation and inflammation of vessels
Rheumatic fever	Heart	2	Antibodies to group A streptococci cross react with heart tissue and major joints (molecular mimicry)
Renal system			
Immune complex-mediated glomerulonephritis	Kidneys	2, 3	Immune complexes formed in excess and deposition in glomerular basement membrane
Goodpasture syndrome	Kidney glomeruli and lung alveoli	2	Antibodies to Goodpasture antigen in noncollagenous proteins in basement membrane of glomeruli and alveoli
Hematological system			
Idiopathic neutropenia	Neutrophils	2	Antibodies formed against surface antigen present on neutrophils
Idiopathic lymphopenia	Lymphocytes	2	Antibodies formed against surface antigen present on lymphocytes
Autoimmune hemolytic anemia	Red blood cells	2	Antibodies formed against surface antigen present on RBCs resulting in opsonization and phagocytosis of RBCs and thus hemolysis, anemia
Autoimmune thrombocytopenic purpura	Platelets	2	Antibodies formed against platelet membrane proteins resulting in opsonization and phagocytosis of platelets and thus thrombocytopenia
Pernicious anemia	Gastric parietal cells		Antibodies against intrinsic factor synthesized by parietal cells prevent transport of vitamin B_{12}

Table 4.72 Therapeutic strategies in autoimmune diseases

Target	Therapeutic Strategies
Self-reactive lymphocytes	▪ Inhibition of lymphocyte function (cytotoxic drugs, cyclosporine A, corticosteroids) ▪ Reinduction of anergy (peptide therapy) ▪ Removal of co-stimulation (anti-CD28 antibodies) ▪ Induction of inhibitory T cells (oral feeding of antigen)
Tissue damage	Anti-inflammatory drugs (corticosteroids)
Organ dysfunction	▪ Replacement therapy (joint replacement) ▪ Renal dialysis ▪ Thyroxine administration in hypothyroidism ▪ Insulin administration in diabetes mellitus

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is an autoimmune chronic inflammatory disease characterized by a generalized dysregulation and hyperactivity of B cells, with production of autoantibodies to individual's own DNA, RNA, and autologous proteins, leads to immune complex formation and deposition in glomeruli, skin, lungs, joints synovium, mesothelium (serous membranes) and other organs. Renal involvement is most common complication of SLE, which can occur at all ages, but is more common in young women during childbearing age.

Pathogenesis

Autoantibodies are formed against individual' own double-stranded DNA and soluble nuclear Sm (Smith) antigen part of nucleosome. High titers of these autoantibodies are nearly pathognomonic for systemic lupus erythematosus.

- Insoluble aggregates of immune complex are deposited in vessel walls, serosal surfaces, and other extravascular sites, and bound to complement.
- The antigen–antibody complement complexes are highly chemotactic for neutrophils, which release lysosomal enzymes and other chemical mediators (prostaglandins, kinins, and oxygen-derived free radicals) leading to tissues/organs damage.

Clinical Features

Patient with systemic lupus erythematosus (SLE) presents with fever, malaise, lymphadenopathy, and weight loss. Recent clinical manifestations in systemic lupus erythematosus are shown in Fig. 4.73. Clinical and immunologic domains of systemic lupus erythematosus are given in Table 4.73.

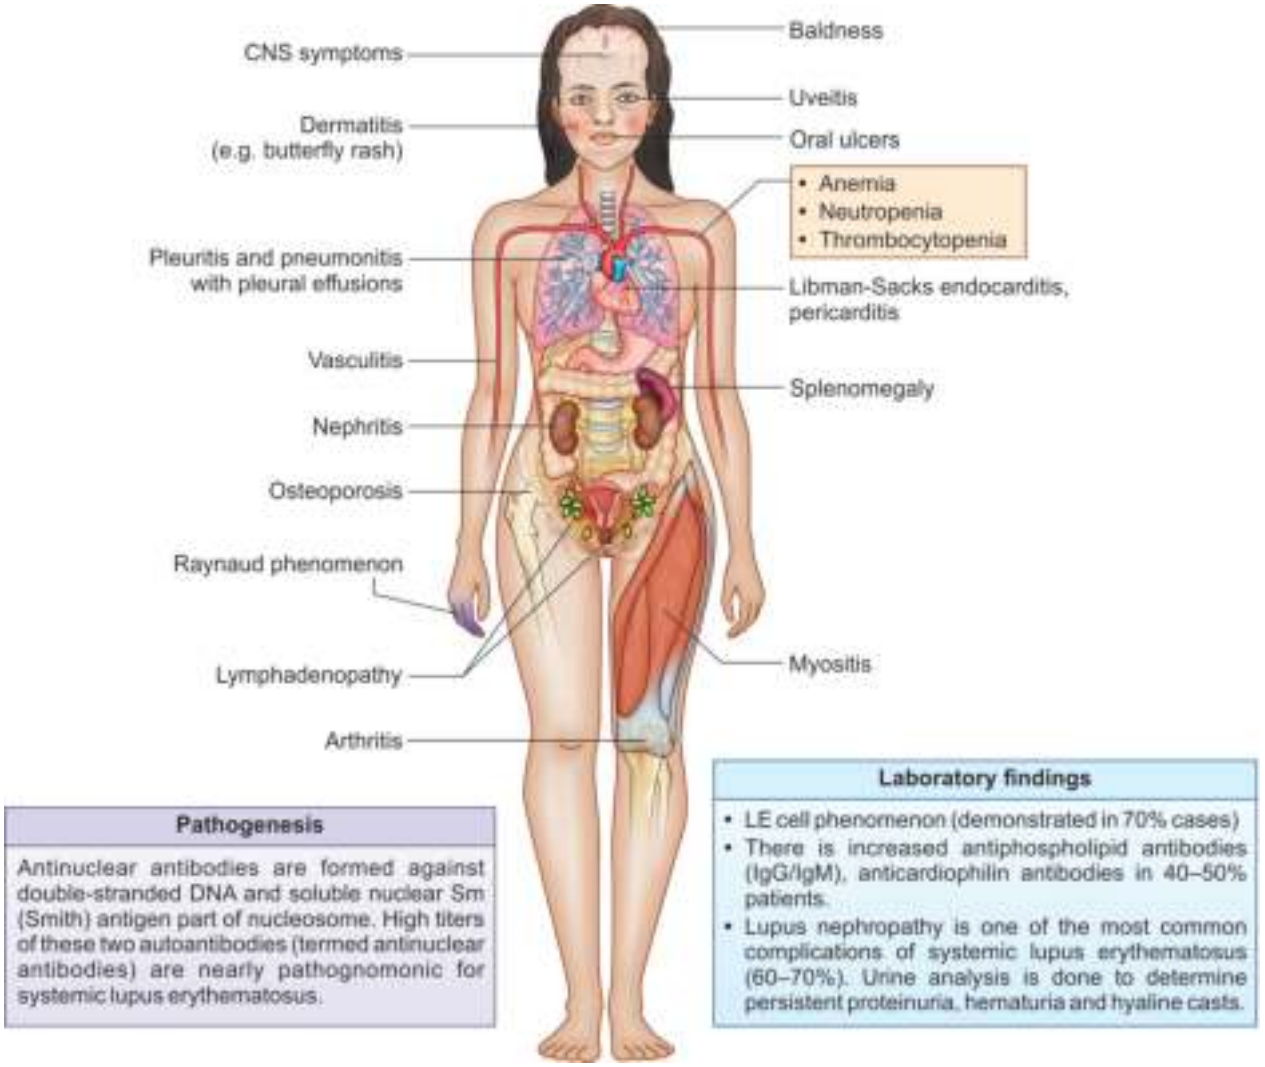

Fig. 4.73: Clinical systemic manifestations and systemic lupus erythematosus (SLE). Patients with systemic lupus erythematosus present with fever, malaise, arthralgias, headache, loss of appetite, weight loss. Red, butterfly-shaped rash over cheeks and nose often following exposure to sunlight. Signs and symptoms may develop suddenly or slowly, that may be mild or severe; temporary or permanent. An antinuclear antibody (ANA) blood test measures the presence of antibodies that are directed against body's cells, a sign of systemic lupus erythematosus.

Table 4.73 Recent clinical and immunologic domains of systemic lupus erythematosus

Domain	Criteria
Clinical domains	
Constitutional symptoms	Fever >38.3°C
Hematologic manifestations	▪ Leukopenia ▪ Thrombocytopenia ▪ Autoimmune hemolytic anemia
Neuropsychiatric manifestations	▪ Delirium ▪ Psychosis ▪ Seizures
Ophthalmic fundus examination	Yellowish, cotton wool-like lesions (cytoid bodies)
Skin	▪ Butterfly rash over the base of the nose and malar eminences ▪ Inflammation of superficial blood vessels responsible for telangiectasis (spider vein), red lines and painful bumps
Cervical lymph nodes	Lymphadenopathy
Spleen	Splenomegaly
Mucocutaneous manifestations	▪ Alopecia ▪ Ulcers in mucous membranes of nose, throat, and mouth ▪ Subacute cutaneous lupus erythematosus (SCLE)/discoid lupus erythematosus (DLE) ▪ Acute cutaneous lupus erythematosus (ACLE)
Cardiovascular manifestations	▪ Acute pericarditis ▪ Pericardial effusion ▪ Libman-Sacks endocarditis ▪ Immune complex-mediated vasculitis ▪ Vasospasm of small blood vessels of fingers (Raynaud's phenomenon)
Pulmonary manifestations	▪ Pleuritis ▪ Pleural effusion ▪ Diffuse interstitial pulmonary fibrosis
Musculoskeletal system manifestations	Painful, swollen, but nonerosive arthritis of hands, knees and seldom spine, tenderness and stiffness in two or more joints for at least 30 minutes in the morning
Renal manifestations including renal biopsy histology finding depending on damage to the glomeruli	▪ Urine analysis: Presence of >0.5 g/24 hours by 24-hour urine or equivalent spot urine protein to creatinine ratio ▪ Class II: Mesangial proliferative lupus nephritis ▪ Class III: Focal lupus nephritis/IV (diffuse lupus nephritis) ▪ Class IV: Diffuse lupus nephritis ▪ Class V: Membranous lupus nephritis
Female genital system	Repeated spontaneous miscarriages attributable to antibody-mediated inhibition of tPA activity necessary for trophoblastic invasion of the uterus
Immunologic domains	
Antiphospholipid antibody syndrome (IgG)	▪ Anticardiophilin antibodies (IgA, IgG, or IgM) at medium or high titer (>40 APL, GPL, or MPL) or anti-β_2-GP1 antibodies (IgA, IgG, or IgM) ▪ Lupus anticoagulant positive ▪ Spontaneous abortion ▪ Recurrent arterial or venous thromboses (deep veins, portal vein, pulmonary artery) ▪ Prolonged activated partial thromboplastin time (APTT)
Complement system proteins	▪ C3 or C4 low ▪ C3 and C4 low
Systemic lupus erythematosus specific antibodies	▪ Anti-Sm antibodies ▪ Anti-Ds antibodies in an immunoassay with demonstrated ≥90% specificity for systemic lupus erythematosus

- **Skin manifestations:** Patient develops butterfly skin rash over the base of the nose and malar eminences, often is accentuated by sun exposure. When superficial blood vessels become inflamed, patient may develop telangiectasis (spider vein), red lines and painful bumps. A biopsy of sun exposed skin that is not involved with a rash will demonstrate immune complex deposition in systemic lupus erythematosus (SLE).
- **Mucocutaneous manifestations:** Patient can develop ulcers in the mucous membranes particularly in the nose, throat, and mouth.
- **Musculoskeletal manifestations:** Most people develop painful, swollen, but nonerosive arthritis. Joints are asymmetrically involved such as hands, knees and seldom spine. Nonspecific muscle pain is another common symptom.
- **Raynaud phenomenon:** Raynaud phenomenon is manifested by vasospasm of small vessels, most often of the fingers.
- **Pulmonary manifestations:** Patient develops diffuse interstitial pulmonary fibrosis, manifested as interstitial pneumonitis or diffuse fibrosing alveolitis.
- **Serous membranes involvement:** Patient develops inflammation and effusion of pericardium and pleura. Pleurisy leads to pain during inspiration.
- **Heart:** Nonbacterial cardiac vegetations are present on both sides of the mitral valve leaflet (most common) and tricuspid valve (less frequent), which are known as 'Libman-Sacks' endocarditis.
- **Blood vessels:** Immune complex vasculitis can occur in any organ.
- **Spleen:** In the spleen, perivascular fibrosis with concentric rings of collagen around splenic arterioles results in a characteristic onion-skin appearance.
- **Reproductive system manifestations:** Repeated spontaneous miscarriages are sometimes the first sign of the disease, which is attributable to antibody-mediated inhibition of tissue plasminogen activator (tPA) activity necessary for trophoblastic invasion of the uterus.
- **Antiphospholipid antibody syndrome:** One-third of patients with systemic lupus erythematosus (SLE) possess elevated concentrations of antiphospholipid antibodies.
  - Prolonged activated partial thromboplastin time (APTT), recurrent arterial or venous thromboses (deep veins, portal vein, pulmonary artery), and spontaneous abortion is highly suggestive of the antiphospholipid antibody syndrome.
  - Current treatment includes anticoagulation therapy (aspirin, heparin, and warfarin) and immunosuppression in refractory cases.
- **Central nervous system and ocular manifestations:** Patient develops neurologic and psychiatric manifestations. Ophthalmic fundus examination shows yellowish, cotton wool-like lesions (cytoid bodies).
- **Lupus nephropathy:** Lupus nephritis is one of the most common complications of systemic lupus erythematosus (60–70%). Immune complexes (DNA-anti-DNA) may localize in glomeruli by deposition from the circulation, formation *in situ*, or both, which cause activation of complement system by classical pathway resulting in damage to tubules and interstitium. Decreased serum C3 level correlates with disease activity. In general, the more immune complex deposition and the more cellular proliferation, the worse the renal disease. Renal changes are highly variable.

Laboratory Diagnosis

In diagnostic pathology, hematoxylin body or 'LE body' is a dense homogenous, basophilic structure easily stained with hematoxylin. Hematoxylin body or LE body consists of degraded nuclear material from injured glomerular cells into the urinary space and phagocytosed by renal tubular epithelial cell, along with autoantibodies and a limited amount of cytoplasm. Hematoxylin body also called LE body in the involved glomeruli in systemic lupus erythematosus is shown in Fig. 4.74.

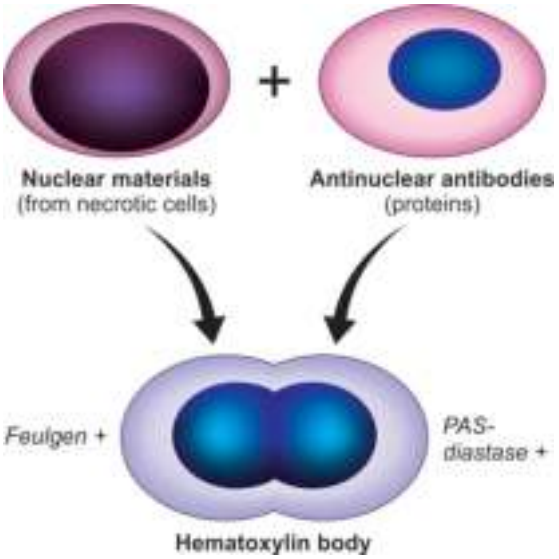

Fig. 4.74: Hematoxylin body also called LE body in the involved glomeruli in systemic lupus erythematosus. In diagnostic pathology, hematoxylin body or 'LE body' is a dense homogenous, basophilic structure easily stained with hematoxylin. It consists of degrades nuclear material from injured glomerular cells into the urinary space and phagocytosed by renal tubular epithelial cell, along with autoantibodies and a limited amount of cytoplasm.

- **LE cell phenomenon:** LE cell is performed *in vitro*, which is possibly mediated by an ANA known as antinucleosome-specific autoantibody. LE cells are formed in a mixture of mechanically damaged neutrophils and autoantibody-containing patient serum. LE test is positive in about 70% of SLE cases and has now been largely replaced by more sensitive determinations.
- **Antiphospholipid antibodies:** Antiphospholipid antibodies are present in 40–50% patients. There is an increase level of IgG/IgM anticardiophilin antibodies. Lupus anticoagulant antibodies interfere with blood coagulation resulting in increased clotting time.
- **Serum complement concentration:** Serum complement level is often greatly decreased, especially in association with active renal involvement. Immune complexes at dermal–epidermal junction are demonstrable in skin biopsies.
- **Urine analysis:** Urine analysis is done to determine persistent proteinuria, hematuria and hyaline casts in lupus nephritis.
- **Hematologic tests:** Reticulocytes count is increased as the patient may develop autoimmune hemolytic anemia. Peripheral blood smear shows leukopenia (lymphopenia), and thrombocytopenia. Bleeding time is prolonged.
- **Immunofluorescence microscopy:** Immunofluorescence microscopy is done to demonstrate antinuclear antibodies against DNA, histone proteins, non-histone proteins bound to RNA, nucleolar antigens. Anti-Smith (Sm) antigen antibodies are formed against dsDNA-pathognomonic of SLE.

SCLERODERMA

Scleroderma is an autoimmune disease of connective tissue characterized by progressive systemic sclerosis. Inflammation stimulates fibroblasts to synthesize excessive collagen fibers, which frequently occurs in skin, hence the name scleroderma: Greek word *sclero* meaning hard and Greek word *derma* meaning skin. Scleroderma occurs most frequently in young women (25 to 50 years), which involves widespread fibrosis in skin, gastrointestinal tract (especially the esophagus), heart, muscle, lung and kidney.

Clinical Pearls: Local and Systemic Scleroderma

There are two main categories of scleroderma: localized and generalized. Each category is comprised of several conditions.

Local Scleroderma

- Local scleroderma is restricted to skin. The initial edema may last for several weeks or months. Skin thickening develops over a course of 3 years, and then the symptoms gradually stabilize or even reverse.
- Local scleroderma occurs in two forms: morphea scleroderma and linear scleroderma.
  - **Morphea scleroderma:** Patient presents with discrete oval patches on trunk, face, or extremities, where skin is dry and thick. These lesions become pale in center and purplish around the edges.
  - **Linear scleroderma:** Patient presents with discolored line or band on legs, arms or forehead.

Systemic Scleroderma

- Systemic sclerosis has a slow-onset that begins as CREST syndrome, but it may eventually involve internal organs.
- Tissues most at risk are digestive tract, the heart and circulatory system, kidneys, lungs, musculocutaneous system, especially synovial membranes in joints and around tendons. It can be fatal. It has three major subtypes.
  - **Limited scleroderma:** Limited scleroderma begins in CREST syndrome, and it is only progressive.
  - **Systemic scleroderma:** Systemic scleroderma is more sudden onset and earlier involvement of internal organs.
  - **Sine scleroderma:** Sine scleroderma does not involve the skin at all. It only involves organs.

Clinical Features

Patient initially presents with skin changes (fixed facial appearance), painful joints, and dysphagia (esophagus involvement).

- **Facial expression:** Skin involvement in scleroderma results in fixed facial expression. There is thickening, tightening and rigidity of facial skin, with small constricted mouth and narrow lips, in atrophic phase of scleroderma.
- **Sclerodactyly:** Sclerodactyly is present (claw-like appearance of the hand). Raynaud phenomenon is seen in approximately 75% of patients. Fingers are partially fixed in significant position, terminal phalanges become atrophied, fingers are pointed and ulcerated.
- **Esophageal fibrosis:** Esophageal fibrosis in scleroderma results in dysphagia. Interstitial pulmonary fibrosis is a serious complication.
- **Renal involvement:** The kidneys are involved in more than half of patients with scleroderma, which show marked vascular changes, often with focal hemorrhage and cortical infarcts. Among the most severely affected vessels are the interlobular arteries, arcuate arteries and afferent arterioles showing marked thickening consisting of dense laminated matrix, rich in elastic fibers and small amount of collagen fibers. Early fibromuscular thickening of the subintima causes luminal narrowing, followed by fibrosis. Hypertension often occurs in scleroderma.
- **Pulmonary involvement:** Pulmonary interstitial fibrosis is a serious complication in scleroderma.

Laboratory Diagnosis

Autoantibodies virtually specific for scleroderma include: (a) Scl70 nonhistone nuclear protein (topoisomerase) in 70% cases, (b) nucleolar autoantibodies (primarily against RNA polymerase) and (c) anticentromere antibodies, which are also associated with the "CREST" variant of the disease. CREST syndrome is a less severe variant of systemic sclerosis (scleroderma) is characterized by calcinosis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia.

Clinical Pearls: CREST Syndrome

- **C stands for calcinosis:** It refers to accumulation of calcium deposits in the skin especially in fingers.
- **R stands for Raynaud's phenomenon:** It is a result of impaired circulation and vascular spasm in the hands.
- **E stands for esophageal dysmotility:** It refers sluggishness of the digestive tract and chronic gastroesophageal reflux.
- **S stands for sclerodactyly:** It is hardening of fingers, a result of the accumulation of scar tissue in the hands.
- **T stands for telangiectasis:** It is discoloration of the skin caused by permanently stretched and damaged capillaries. It is also known as 'spider veins.

SJÖGREN SYNDROME

Sjögren syndrome is an autoimmune disorder, characterized by keratoconjunctivitis sicca and xerostomia in the absence of other connective tissue disease. Sjögren syndrome most often affects women in their late middle age.

Pathogenesis

Antinuclear autoantibodies formed are directed against soluble nuclear nonhistone proteins, especially the antigens SS-A and SS-B in patients with Sjögren syndrome. Autoantibodies to DNA or histones or salivary gland are rare.

Clinical Features

Patient with Sjögren syndrome presents with triad of xerostomia (dry mouth), keratoconjunctivitis sicca (dry eyes) and any one of autoimmune disorders such as rheumatoid arthritis (most common), scleroderma, Hashimoto's thyroiditis or polymyositis. Bilateral salivary glands show enlargement. Salivary gland shows diffuse infiltration by lymphocytes and plasma cells obscuring the parenchyma, which may mimic lymphoma. In some cases, it can lead to malignant lymphoma of salivary gland.

Laboratory Diagnosis

Serum electrophoresis in Sjögren syndrome reveals significant polyclonal hypergammaglobulinemia (a broad-based elevation of serum γ-globulins). Antinuclear autoantibodies against soluble nuclear nonhistone proteins SS-B is highly specific, however against SS-A is less specific.

POLYMYOSITIS

Polymyositis is related to direct muscle cell damage produced by CD8+ cytotoxic T cells, which involves the proximal muscles of the extremities. Initially, healthy muscle fibers are surrounded by CD8+ cytotoxic T cells and macrophages, followed by degeneration of muscle fibers. Increased serum creatine kinase and frequent presence of ANAs (anti-Jo-1, an antibody against histidyl-tRNA synthetase) are characteristic. Histologic examination of muscle biopsy reveals necrotic muscle cells along with lymphocytic infiltrate.

DERMATOMYOSITIS

Dermatomyositis is an immune-mediated disorder involving capillaries that results in obliteration of capillaries supplying skin and skeletal muscle leading to ischemic injury. Involvement of capillaries of skin leads to reddish-purple rash over exposed areas of the face and neck, hence condition is called dermatomyositis in a middle-aged man. There is increased risk of development of squamous cell lung carcinoma. Immunofluorescence microscopy demonstrates C5b–9 proteins (i.e. membrane attack complex) in the walls of capillaries.

MIXED CONNECTIVE TISSUE DISEASE

Mixed connective tissue disease (MCTD) shares many clinical features with other connective tissue disorders, but renal involvement is uncommon, which most often occurs in women (peak 35–40 years). Patient presents with joints pain, myositis, Raynaud phenomenon and esophageal hypomotility. There is increased titer of specific ANAs (anti-nRNP). Immunofluorescence microscopy reveals speckled nuclear appearance on morphologic ANA analysis.

POLYARTERITIS NODOSA

Polyarteritis nodosa is an immune complex-mediated vasculitis and characterized by segmental fibrinoid necrosis of small and medium arteries of many organs, which most often occurs in men. Small and medium arteries undergo ulceration and thrombosis resulting in aneurysms and infarction of organs. Histopathologic changes at different stages of disease process may show acute or chronic or healing stage.

Pathogenesis

Polyarteritis nodosa is mediated via type 3 hypersensitivity reaction, through antigen–antibody complexes, in

which antineutrophilic cytoplasmic autoantibodies are formed resulting in liberation of hydrolytic enzymes and damage to blood vessels. Hepatitis B virus (30–40%) and intravenous amphetamines play important role in its pathogenesis. Drugs, such as sulfonamides and penicillin, may form immunogenic hapten–protein complexes.

Organs Involved

Organs involved in polyarteritis nodosa include renal arteries (85%), coronaries (75%), hepatic arteries (75%), mesenteric arteries (60%), musculocutaneous arteries (40%), arteries of central nervous system, peripheral nervous system, retina, pancreas and skin.

Clinical Features

Patient presents with abdominal pain, hypertension, uremia, polyneuritis, allergic asthma, urticaria or skin rash, splenomegaly, fever, leukocytosis, and proteinuria. Involvement of lungs results in chest pain, cough, dyspnea, and hemoptysis. Severe dyspnea and eosinophilia occur in 20% of patients.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis is a chronic inflammatory autoimmune disorder that primarily attacks synovium of peripheral joints (interphalangeal and metacarpophalangeal joints) and the surrounding muscles, tendons, ligaments, and blood vessels. Knee joints are also involved with formation of subcutaneous nodules. Partial remissions and unpredictable exacerbations mark the course of this potentially crippling disease.

- Subcutaneous nodules are raised, firm, nontender present in the olecranon bursa and along extensor surface of arm. The skin slides freely over subcutaneous nodules. Rheumatoid arthritis is three times more common in women than men, which can occur at any age, but the peak onset is ages 30–60 most often in HLA-DR4 positive individuals.
- Approximately 80% of patients with classic rheumatoid arthritis are positive for rheumatoid factor (**RF**) demonstrated in serum, which represents multiple antibodies, principally IgM, but sometimes IgG or IgA, directed against the Fc fragment of IgG. Rheumatoid factor is useful in diagnosis. Significant titers of RF are also found in patients with related collagen vascular diseases, such as systemic lupus erythematosus, scleroderma, and dermatomyositis. Clinical manifestations of rheumatoid arthritis are shown in Fig. 4.75.

Morphologic Changes in Joints

Progressive changes in rheumatoid arthritis include synovial inflammation, hyperplasia, hypertrophy,

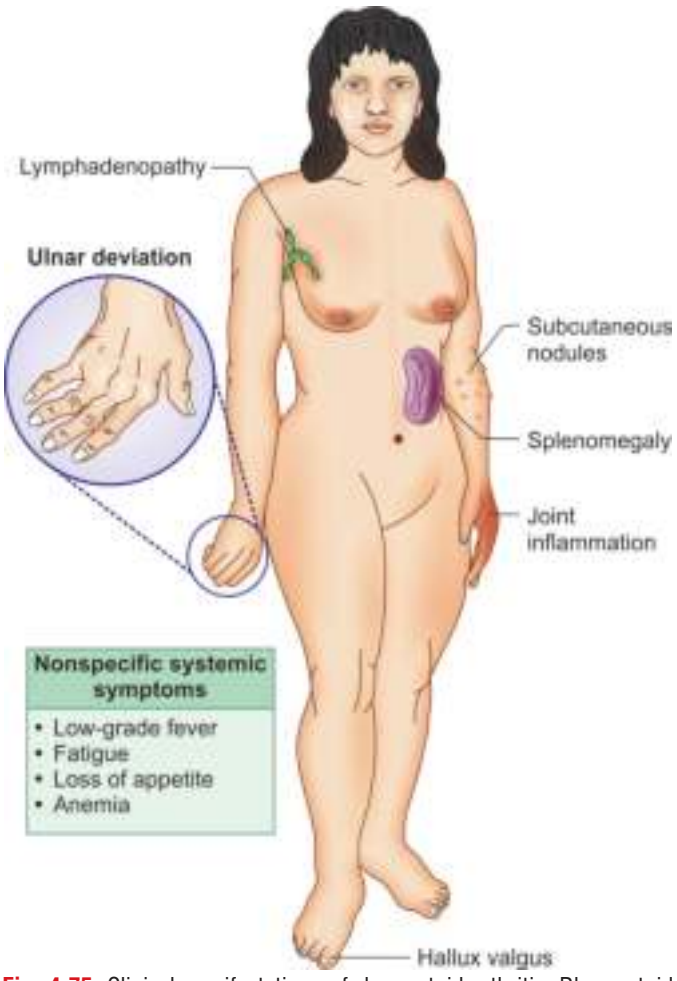

Fig. 4.75: Clinical manifestations of rheumatoid arthritis. Rheumatoid arthritis is a chronic inflammatory autoimmune disorder that primarily attacks synovium of interphalangeal and metacarpophalangeal joints and surrounding muscles, tendons, ligaments, and blood vessels with formation of subcutaneous nodules present in the olecranon bursa and along extensor surface of arms. Patient presents with nonspecific systemic symptoms, lymphadenopathy, ulnar deviation, subcutaneous nodules and painful joints.

formation of numerous villi (fronds), formation of pannus (granulation tissue) invading articular cartilage, subchondral bone results in destruction of joint capsule and bone, which is followed by fibrous ankylosis and calcification.

- **Stage I of rheumatoid arthritis:** Synovitis develops from congestion and edema of the synovial membrane and joint capsule. Initially, synovium shows acute inflammation followed by infiltration by lymphocytes and plasma cells. Synovial cells undergo hyperplasia and hypertrophy resulting in formation of numerous villi and frond-like folds.
- **Stage II of rheumatoid arthritis:** Formation of pannus (thickened layers of granulation tissue), which covers and invades articular cartilage and subchondral bone, which eventually erodes and destroys the joint capsule and bone.

- **Stage III of rheumatoid arthritis:** Fibrous ankylosis (fibrous invasion of the pannus and scar formation that occludes the joint space) occurs. Bone atrophy and misalignment cause visible deformities and restrict movement, leading to muscle atrophy, imbalance and, possibly, partial dislocations.
- **Stage IV of rheumatoid arthritis:** Fibrous tissue calcifies, resulting in bony ankylosis (fixation of a joint) and total immobility. Pain associated with restricted joint movement may restrict active joint use and cause fibrous or bony ankylosis, soft tissue contractures, and joint deformities. Subcutaneous nodules develop in approximately one-third of patients of rheumatoid arthritis.

Clinical Features

Patient of rheumatoid arthritis presents with fatigue, malaise, anorexia, weight loss, fever, and myalgia, bilateral symmetrical swelling and stiffness of joints especially in the morning or after inactivity.

- Chronic inflammatory changes occur in proximal interphalangeal and metacarpophalangeal joints of the hands.
- Patient develops ulnar deviation of fingers resulting from synovitis of ligaments. Minimal radial deviation of the wrist may occur.
- Extra-articular manifestations include effusions (pleura, pericardium), vasculitis, and anemia of chronic disease, neurologic manifestations, lymphadenopathy and secondary reactive amyloidosis.

GOODPASTURE SYNDROME

Goodpasture syndrome is life-threatening autoimmune disorder characterized by nephritic syndrome and pulmonary hemorrhage (hemoptysis). Goodpasture antigen is normally present in glomerular basement membrane and lung alveoli. Autoantibodies cross react with antigens located in glomerular basement membrane and pulmonary alveoli resulting in renal failure and pulmonary hemorrhage. Immunofluorescence study reveals smooth and linear staining pattern due to antibody and complement in Goodpasture syndrome (renal and lung basement membrane).

GRAVES' DISEASE

Graves' disease is type 5 hypersensitivity reaction (anti-receptor mediated) also considered type 2 hypersensitivity reaction. Antibodies to the TSH receptors are observed in patients with Graves' disease, an autoimmune disorder that mimics the action of TSH, but is not regulated by natural negative feedback controls, which leads to follicular glandular hyperplasia and increased synthesis of thyroid hormones resulting in hyperthyroidism. Patient also develops exophthalmos due to infiltration by lymphocytes in retrobulbar ocular muscles in 60–90%.

MYASTHENIA GRAVIS

Myasthenia gravis is an antibody mediated type 2 hypersensitivity reaction disorder. Antibodies bind to the postsynaptic acetylcholine receptors in the motor end plates of skeletal muscles and block neurotransmission resulting to progressive muscle weakness involving particularly the external ocular, eyelids and proximal limb muscles, which may cause death by respiratory muscles paralysis.

PEMPHIGUS VULGARIS

Pemphigus vulgaris is an acantholytic disease caused by autoantibodies against various epidermal cell proteins commonly presenting with flaccid blisters, mucosal erosions in oral cavity and genitalia and scaling. Average age of onset is 40–60 years. IgG autoantibodies to desmoglein-1 (skin) or desmoglein-3 (mucosa) disrupt intercellular junctions in epidermis found in patients with pemphigus vulgaris. Histologic examination of lesion shows intradermal acantholysis with intact basal layer (**tombstone sign**) and intradermal eosinophils. Immunofluorescence study reveals intercellular IgG and C3 as smooth and linear staining pattern in pemphigus (skin intercellular protein, desmosomes).

TISSUE/ORGAN TRANSPLANTATION IMMUNOLOGY

In clinical practice, the term transplantation generally refers to the transfer or replacement of cells, tissues, or organs from one individual to another. Organ transplantation is the treatment of choice for end stage organ failure.

- Transplants are broadly classified as solid organ or hematopoietic stem cell (**HSC**) transplants and within these classifications are categorized according to the relationship of the donor and the recipient.
- Adverse immune responses can be suppressed by immunosuppressant drugs, radiation, or recipient T cell depletion. These processes, however, can result in clinically significant immunodeficiency state.
- Immune system poses a significant barrier to successful organ transplantation when tissue/organ is transferred from donor to the recipient.
- Transplant rejection occurs as result of triggering immune response to destroy the transplanted tissue/

organ. Long-term survival of the transplant can be maintained by manipulating the immune system to reduce the risk of transplant rejection.

- For a successful transplant, recipient and donor must be properly matched for HLA antigens and blood group to minimize the risk of transplant rejection. Tissue typing is done to know how the recipient's blood serum reacts to donor cells. Immunosuppressive drugs are administered to damp immune system and to prevent and treat transplant rejection.

Pathology Pearls: Several Types of Tissues/Organs Transplantation
Autograft
One's own tissue is grafted to another part, e.g. skin autograft in the individual.
Isograft
Graft between identical twins is known as isograft. Donor and recipient are genetically identical.
Allograft (Allogenic Graft)
▪ Transplantation of tissues/organs from a donor to a non-genetically identical individual of the same species. ▪ Allografts are most common type of transplants.
Xenograft
Graft between animals of different species is known as xenograft (e.g. monkey to human).
Hematopoietic Stem Cell Transplant
▪ Hematopoietic stem cells (HSCs) are used as transplants to treat leukemias and other hematological disorders. ▪ HSCs can be harvested either directly from the bone marrow or from the preserved umbilical cord from consenting mothers following childbirth.

IMMUNOLOGY OF TRANSPLANT REJECTION

Transplant rejection response is initiated mainly by host cells that recognize the foreign HLA antigens of the graft, either directly on antigen-presenting cells (APCs) in the transplant or indirectly after uptake and presentation by APCs.

- There are three mechanisms of graft rejection: hyperacute rejection, acute vascular rejection and chronic rejection.
- Preformed and *de novo* donor-specific antibodies (**DSAs**) are central in pathogenesis of hyperacute, acute and chronic transplant rejection.

DISTINGUISHING SELF- AND NONSELF-ANTIGEN

When the immune system encounters a foreign pathogen, it mounts an attack against pathogen to protect the body from infection. To prevent an attack on our own cells and tissues (autoimmunity), the immune system is able to differentiate between our own healthy tissues and foreign invaders.

- Foreign invaders are presented to the immune system in the form of small molecules called **antigens**. Detection of these nonself-antigens will trigger the immune response and stimulate the production of antigen-specific antibodies that mark the infected cells for destruction by immune system and help in amplification of immune response.
- The human leukocyte antigen (**HLA**) system is a complex of genes on chromosome 6 in humans, which encode cell surface proteins responsible for the regulation of the immune system. These cell–surface proteins are found on the surface of all cells and act as 'self-markers' instructing the immune system not to trigger an immune response.
- Each person has own specific set of HLA proteins, based upon their unique genetic makeup that the immune system has learnt not to react. Any cell that does not display these HLA proteins can be identified as nonself by the immune system and will be treated as foreign invader.

PATHOPHYSIOLOGY OF TRANSPLANT REJECTION

Transplant rejection occurs when the recipient's immune system attacks the donor's transplant and begins destroying the transplanted tissue/organ. The transplant rejection can be divided into two phases: (a) initial sensitization phase in which antigen reactive lymphocytes in the recipient's lymph node proliferate in response to the donor's alloantigens and (b) later an effector phase in which the recipient's sensitized effector cells mediate immune destruction of the transplant.

- The immune system is triggered by the presence of donor's own unique set of HLA proteins, which the recipient's immune system will identify as foreign invader.
- The degree of similarity between the HLA genes of the recipient and donor is known as histocompatibility; the more genetically compatible the recipient and the donor, and the more tolerant the recipient's immune system should be to the transplant.
- However, unless the recipient and the donor are genetically similar as in identical twins, there is always be some degree of **transplant rejection**. Non-self HLA proteins, other surface proteins on

Table 4.74 Comparison of acute and chronic transplant rejection

Characteristics	Acute Transplant Rejection	Chronic Transplant Rejection
Stage of rejection	Acute transplant rejection is second stage of rejection	Chronic transplant rejection is third stage of rejection
Onset	Acute transplant rejection occurs within days or suddenly after cessation of immunosuppressive drugs	Chronic transplant rejection occurs over months to years
Components	Acute transplant rejection consists of two components: (a) Acute cellular component comprises CD4+ helper T cells and CD8+ cytotoxic T cells. (b) Antibodies-mediated vasculitis	Chronic transplant rejection does not consist of CD4+ helper T cells and CD8+ cytotoxic T cells. It is characterized by progressive dysfunction of the organs
Mechanism	Acute transplant rejection is mediated by CD4+ helper T cells, CD8+ cytotoxic T cells and antibodies	Chronic transplant rejection shows presence of macrophages, lymphocytes, plasma cells and eosinophils
Morphology	Acute transplant rejection of kidney transplant shows injury to tubules and vascular endothelium resulting in exfoliation of tubular cells in lumen and necrotizing vasculitis. The blood vessels of kidneys are thrombosed resulting in ischemic changes	Arterioles undergo fibrosis of renal vessels leading to ischemic injury to organ

the donor's transplant can also be identified as a foreign antigen and induce immune response. Some patients may develop graft-versus-host disease (GVHD).

CLINICAL STAGES OF TRANSPLANT REJECTION

Transplant rejection can be classified into three types: hyperacute, acute and chronic, which are differentiated by how quickly the recipient's immune system is activated and the specific aspect of immune system involved. Comparison of acute and chronic transplant rejection is given in Table 4.74.

Pathology Pearls: Patterns of Renal Transplant Rejection

Hyperacute Transplant Rejection

- Hyperacute transplant rejection is mediated by preformed antibodies in recipient's plasma as a result of ABO incompatibility between donor and recipient.
- Classic type 2 hypersensitivity reaction results in immune complex formation locally and occluding small blood vessels in transplant.

Acute Vascular Transplant Rejection

- Acute early transplant rejection is antibody-mediated partly by destruction of renal tubules by CD8+ cytotoxic T cells.
- Acute late-onset transplant rejection occurs within 11 days and 6 weeks after transplant, which occurs in patients, who have been immunosuppressed with prednisolone and azathioprine. Florid vascular damage occurs mediated by antibody-complement system.

Chronic Transplant Rejection

Fibromuscular hyperplasia of small and medium-sized arteries with continuing endothelial injury resulting in ischemic necrosis of glomeruli (? immune mechanism).

HYPERACUTE TRANSPLANT REJECTION

Hyperacute transplant rejection occurs within minutes or hours after a transplantation due to preformed antibodies in the recipient that match foreign antigens of the donor.

- The preformed antibodies could have been generated as a result of multiple pregnancies and prior blood transfusions before transplantation. Preformed antibodies react with vascular endothelial cells of blood vessels of the transplant, causing neutrophilic vasculitis, fibrinoid necrosis, extensive thrombosis of small vessels resulting in ischemic damage and rapid transplant rejection.
- Patient presents with sudden cessation of urine output, along with fever and pain in the area of the transplant site. Hyperacute solid organ transplant rejection is shown in Fig. 4.76.

ACUTE VASCULAR TRANSPLANT REJECTION

Acute transplant rejection occurs within six months after transplantation. Some degree of acute vascular transplant rejection occurs in all transplantations, except between identical twins. Recipients are at higher risk within first three months of transplant.

- Acute vascular transplant rejection is caused by formation of antibodies following the detection of nonself-antigens in the donated transplant. If diagnosed early enough, acute transplant rejection can be treated by immunosuppressive therapy to prevent permanent damage to the transplant in some cases.
- Acute transplant glomerulopathy develops in 4–10% of allogeneic transplant. Blood vessels of transplant are destroyed by CD8+ cytotoxic T cells and antibodies resulting in acute vascular transplant rejection. Acute vascular transplant rejection is a complication that

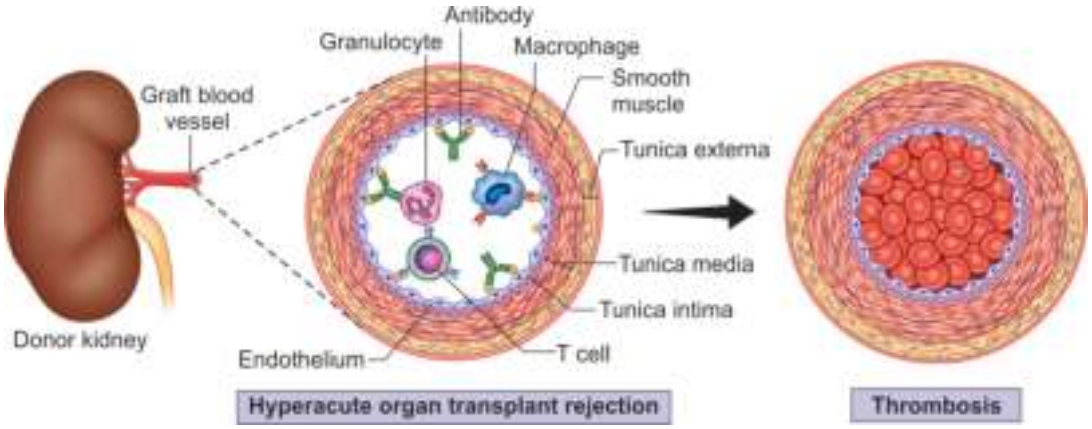

Fig. 4.76: Hyperacute solid organ transplant rejection. Hyperacute rejection occurs before vascularization of the graft, which happens a few minutes or first few days after the organ transplant when antigens are completely unmatched or recipient. The chance of hyperacute rejection is greatest when a recipient possesses preformed anti-ABO blood group antibodies. The transplanted kidney becomes grossly mottled and cyanotic. Capsule bulges out due to marked edema and rupture of the graft may occur. Histologically, renal biopsy evaluation shows endothelial damage with associated sparse polymorphonuclear cells infiltrate followed by widespread capillary thrombosis and necrosis, interstitial hemorrhage, The organ must be removed right way so the recipient does not have fatal outcome. Plasmapheresis may be used to remove circulating antibodies from the blood.

occurs after renal transplantation and is sometimes resistant to anti-rejection therapy resulting in poor prognosis. Recognition of alloantigens in organ graft occurs by direct and indirect pathways described as under: Pathogenesis of renal graft rejection by direct and indirect pathways is shown in Fig. 4.77A and B.

Acute Transplant Rejection by Direct Pathway

Donor's MHC class I and class II are recognized by host (recipient) CD8+ cytotoxic T cells and CD4+ helper T cells. CD4+ helper T cells undergo proliferation and synthesize cytokine IFN-γ, which activates macrophages leading to damage to renal tubules. T cells responding to transplant antigens differentiate to CD8+ cytotoxic T cells that kill renal transplant blood vessels and tubules. Acute cellular transplant rejection occurs within days to weeks to months after transplantation. Pathogenesis of acute transplant rejection by direct pathway is shown in Fig. 4.78.

Clinical Features

Patient presents with abrupt onset of azotemia and oliguria, which may be associated with fever and graft tenderness.

Histologic Examination

Histologic examination of rejected transplant shows edema, interstitial infiltrates of lymphocytes (CD4+ helper T cells and CD8+ cytotoxic T cells) and macrophages. Tubules show lymphocytic infiltration and tubular necrosis.

Acute Transplant Rejection by Indirect Pathway

When antibody-mediated mechanisms are prominent, it may show evidence of arteritis with thrombosis and cortical necrosis. Antibody-mediated rejection of solid transplant is a significant cause of morbidity and mortality. It is difficult to treat these cases. Acute transplant rejection by indirect pathway affects recipients sensitized with pre-transplant donor-specific antibodies (DSAs) to human leukocyte antigen (HLAs) or post-transplant *de novo* HLA or non-HLA antibodies.

Risk Factors

Risk factors for acute transplant rejection include younger age, female gender, prior sensitization to orthoclone (OKT3) monoclonal antithymocyte antibody used for induction therapy in renal transplantation, cytomegalovirus seropositivity, pregnancy, previous blood transfusions, surgical procedures, pre-transplant cardiac support with ventricular assist device and pretransplant or post-transplant hemodialysis.

Pathogenesis

Recipient antigen-presenting cells (APCs) recognize and pick-up graft antigens and activate CD4+ helper T cells, which synthesize IFN-γ, resulting in damage to renal blood vessels. CD4+ helper T cells also stimulate B cells to synthesize antibodies. Antibody binding to antigen activates complement system via classical pathway which cause vascular endothelial injury of renal vessels. Immunological detection of C4d deposition (specific marker for the presence of antidonor recipients) in allografts has evolved as a sensitive and specific diagnostic tool for antibody-mediated transplant rejection.

Diagnosis

Gold standard tissue staining technique for C4d (specific marker for the presence of antidonor recipients) is immunofluorescence (IF) using a monoclonal antibody.

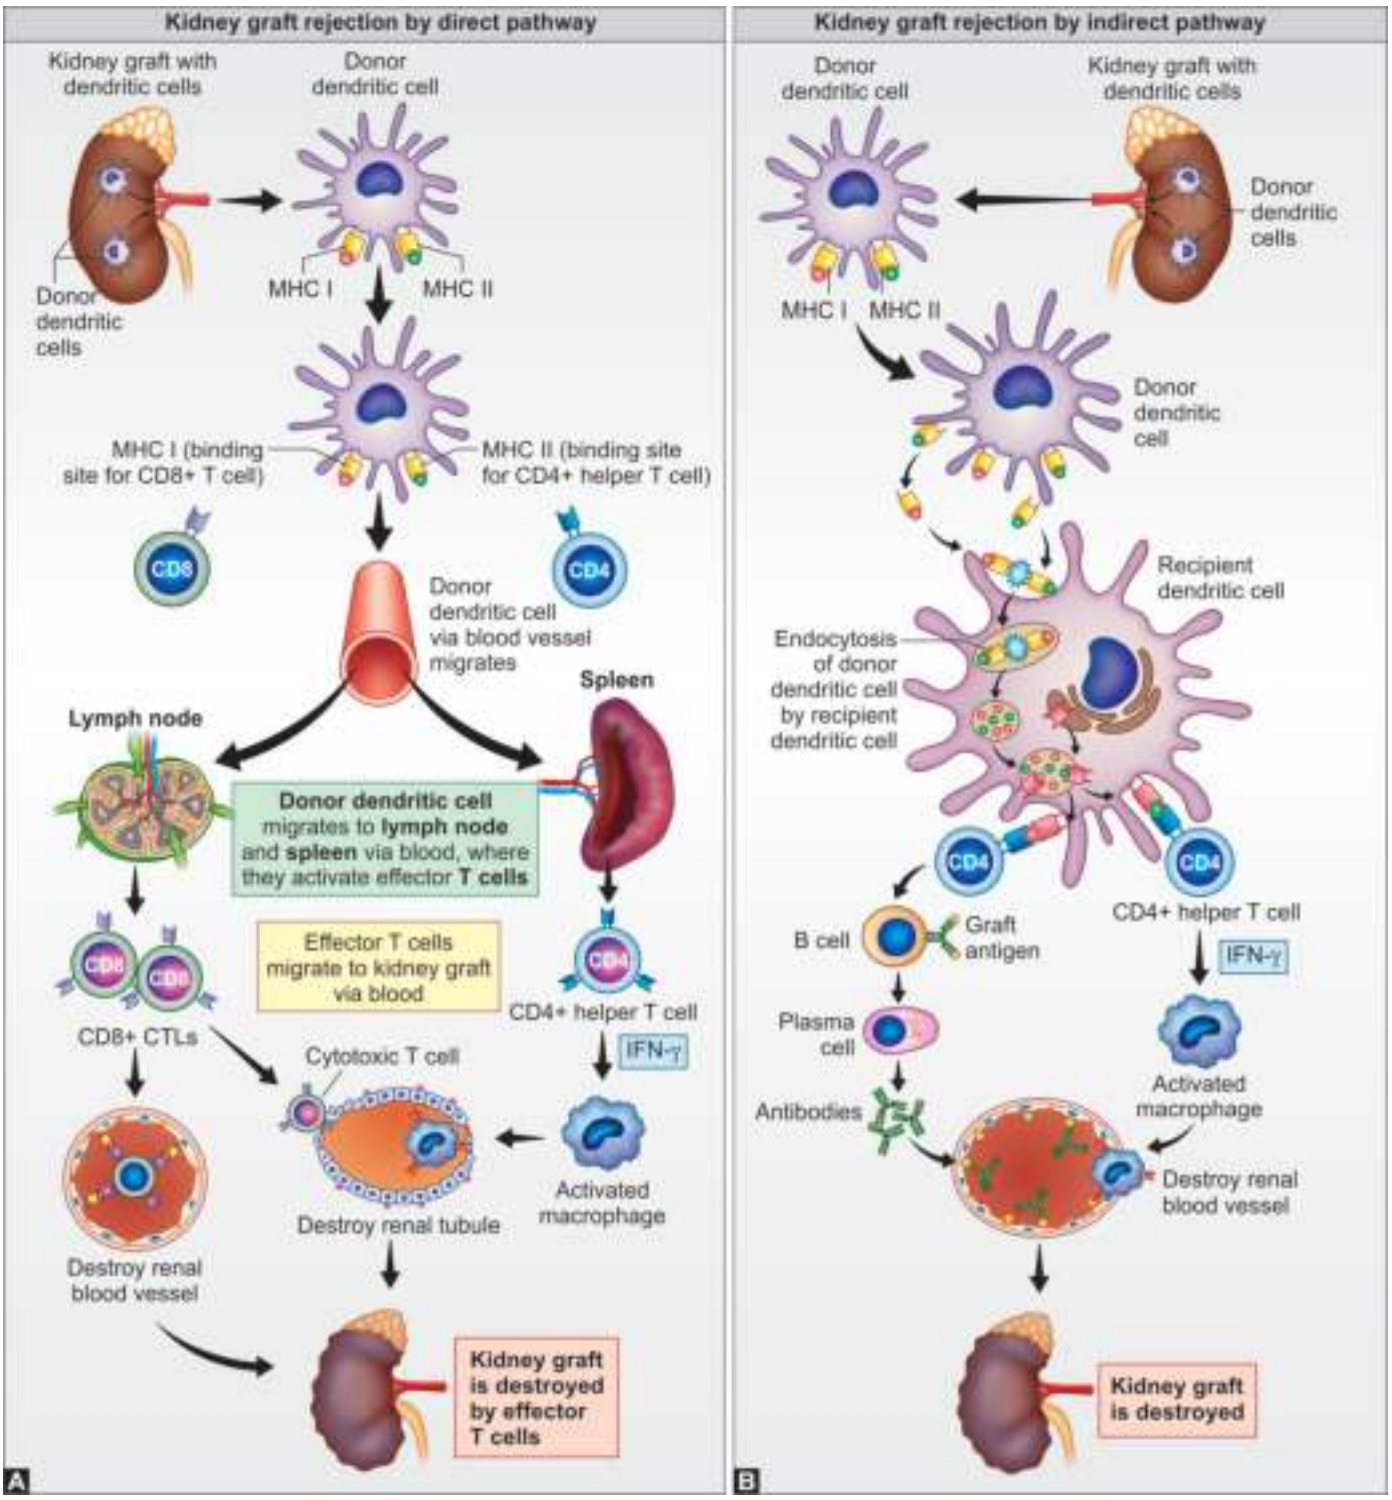

Fig. 4.77: Pathogenesis of renal graft rejection by direct and indirect pathways. Graft rejection occurs when the recipient's immune system attacks the donated renal graft leading to graft destruction. Immune response is triggered by the presence of the donor's own unique set of HLA class molecules, which are recipient's immune system will identify as foreign. The main difference between direct and indirect alloantigen recognition stems from the origin of the antigen-presenting cell (APC). (A) In direct alloantigen recognition, involved antigen-presenting cells are derived from the donor renal graft, (B) in indirect alloantigen recognition, the antigen-presenting cells of recipient are involved.

CHRONIC TRANSPLANT REJECTION

Chronic transplant rejection is primarily caused by antibody-mediated vascular damage within months to years after successful transplantation. It commonly manifests as scarring of the transplant, which can occur months to years after acute transplant rejection has subsided.

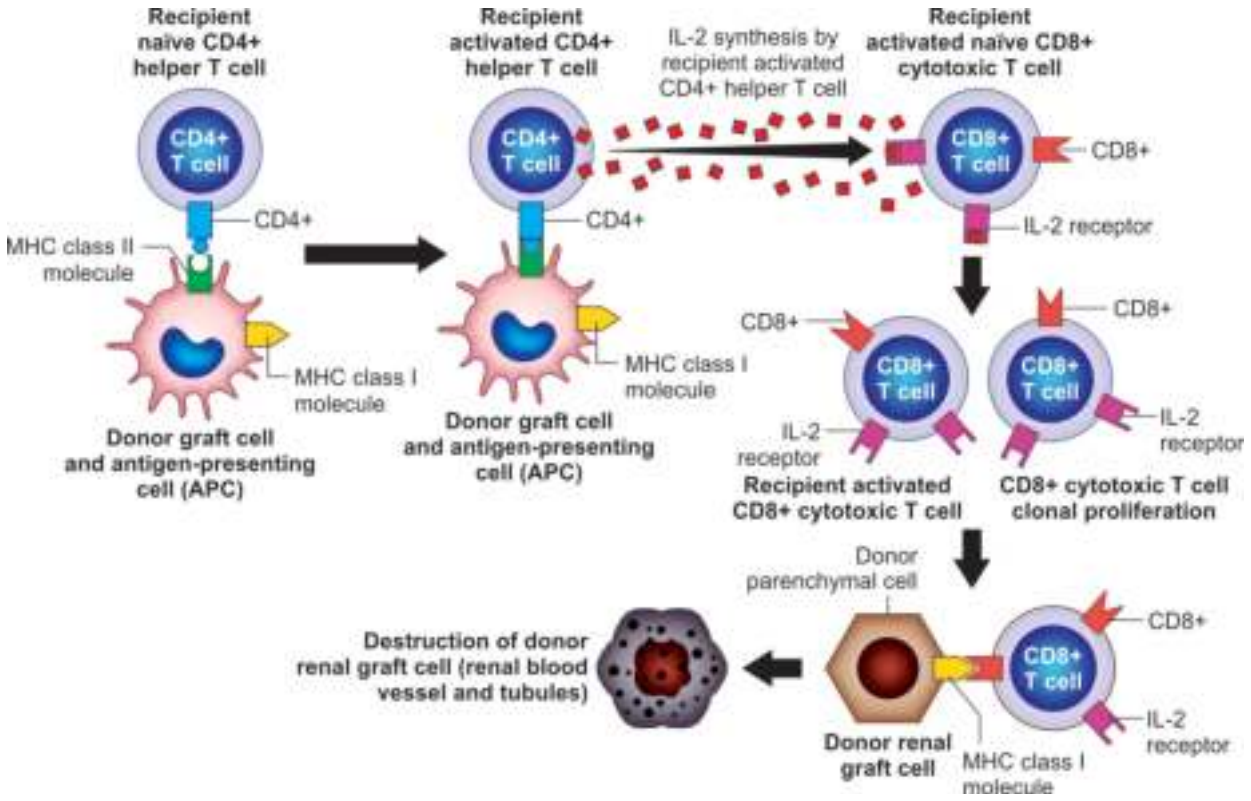

Fig. 4.78: Direct pathway of acute graft rejection of kidney graft. Donor organ cell and antigen-presenting cell (APC) interacts with CD4+ helper T cell of recipient leading to activation of CD4+ helper T cell and synthesis of IL-2 cytokine that activates CD8+ cytotoxic T cell of recipient. It is followed by interaction of CD8+ cytotoxic T cell of recipient with transplanted donor kidney organ resulting in destruction of renal blood vessels and tubules in the recipient.

- Chronic transplant rejection is characterized by arteriosclerosis, glomerulosclerosis, and tubular atrophy-cell reaction and synthesis of cytokines induce proliferation of vascular smooth muscle cells especially kidney transplantation.
- At present, there is no cure for chronic transplant rejection other than removal of the transplant.

Pathogenesis of chronic solid organ transplant rejection is shown in Fig. 4.79.

GRAFT-VERSUS-HOST DISEASE

Graft-versus-host disease (GVHD) is a significant problem, when hematopoietic stem cell (HSC)

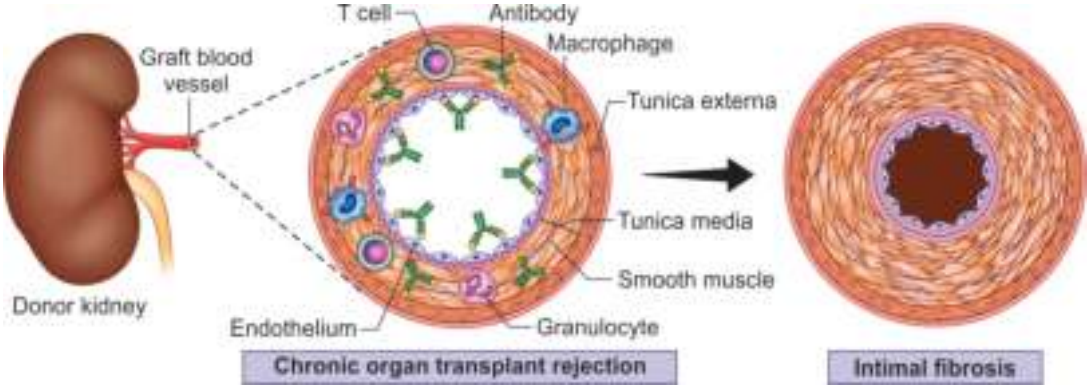

Fig. 4.79: Pathogenesis of chronic solid organ transplant rejection. Chronic graft rejection of solid organs is defined as the loss of allograft function several months after transplantation. The transplanted organ may still be in its place, but persistent immune system attacks on the allo-MHC class molecules expressed by its component cells have gradually caused the organ to lose functioning. The main histological finding in biopsies of rejected solid organs is arteriosclerosis that induces a progressive narrowing of blood vessels of solid graft. This is typically referred to as a vasculopathy or organ graft vascular disease. This entity is usually accompanied by parenchymal fibrosis of graft.

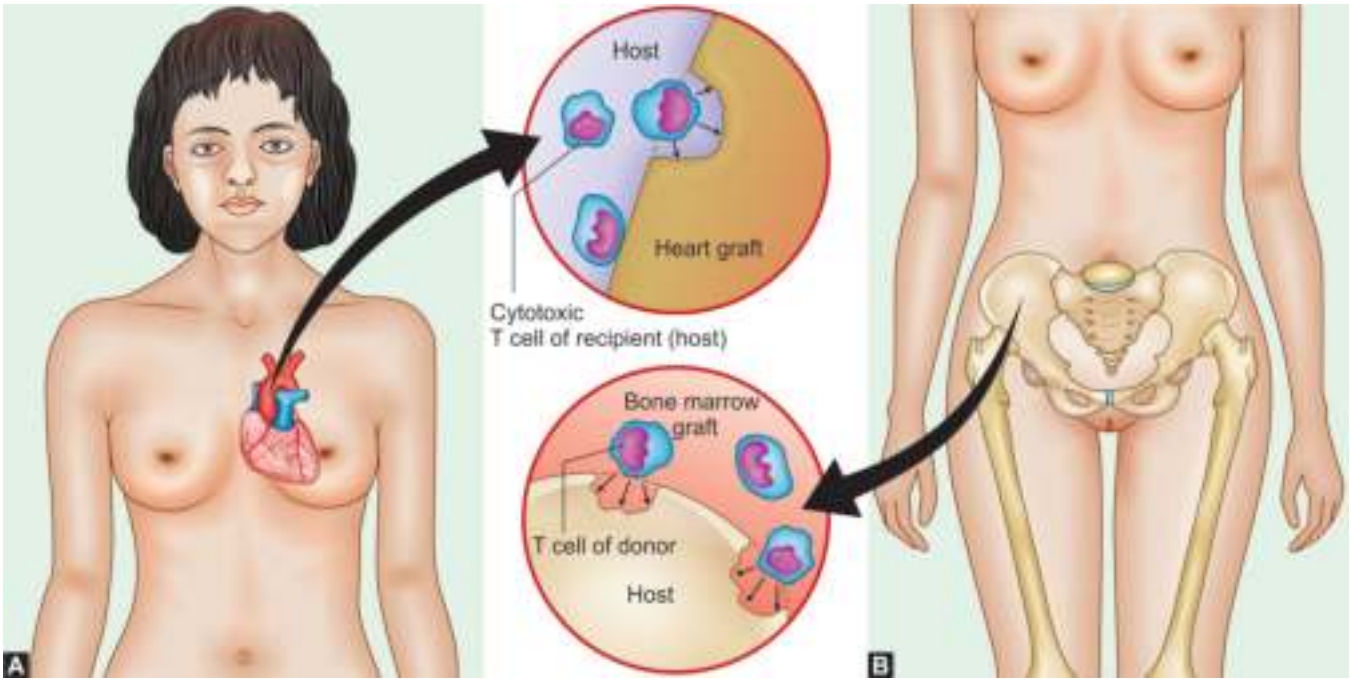

Fig. 4.80: Potential reactions in organ transplantation. (A) CD8+ cytotoxic T cells of host immune system encounter the cells of donated organ (heart) and mediate the organ rejection, (B) grafted bone marrow contains endogenous T cells that recognize host's tissues as foreign and mount an attack on many tissues and organs. The recipient will develop symptoms of graft-versus-host disease.

transplantation is performed in patients of aplastic anemia, acute leukemia and immunological deficiency. CD8+ cytotoxic T cells from transplant directly damage recipient host cells. GVHD can also occur when a patient with severe combined immunodeficiency disease (SCID) is transfused blood containing HLA-incompatible lymphocytes.

- **Billingham's criteria for transplant rejection:** Billingham's described criteria for graft-versus-host disease. A donor graft has immunocompetent cells. Recipient possesses antigens foreign to graft. A recipient who is unable to mount immune response.
- **Classification of GVHD:** There are two types of graft-versus-host disease: acute GVHD occurs in <100 days and chronic GVHD occurs in >100 days. Potential reactions in organ transplantation are shown in Fig. 4.80A and B.

PATHOGENESIS

CD8+ cytotoxic T cells from graft directly damage host epithelial cells of skin, gastrointestinal mucosa and liver. Cytokines from graft CD4+ helper T cells recruit macrophages, which damage host epithelial cells of skin, gastrointestinal mucosa (duodenum, ileum and colon) and liver. Clinically, GVHD manifests as pruritic rash, diarrhea, abdominal cramps, anemia, hepatosplenomegaly and liver dysfunction. Elevation of serum bilirubin and liver enzymes signals the hepatic involvement.

Acute Graft-versus-host Disease (GVHD)

Acute GVHD develops by priming of immune response, activation and expansion of donor; and effector phase.

- **Priming of immune cells:** Immunosuppression damage occurs in several tissues including liver and gut. Gut damage is very important in the pathogenesis. Mucosa of gut becomes permeable resulting in synthesis of IL-1 and TNF-α. There is upregulation of adhesion molecules, MHC antigens and increased recognition of host antigens by T cells. Entry of bacterial product, i.e. lipopolysaccharide (LPS) from systemic circulation aggrevates acute graft-versus-host disease.
- **Donor's cells activation and expansion:** T cells recognize the antigens presented by APCs in the presence of costimulatory molecules (CTLA-4: B7, CD28). Both CD4+ helper T cells and CD8+ cytotoxic T cells can initiate acute GVHD reaction. This depends on allogenic component of host.
- **Effector phase:** Along with T cells, natural killer cells (NK cells) secrete cytokines that continue to stimulate other cells and cause damage tissue. The Fas/FasL pathway and perforin/granzyme pathway play important role in this effector phase to induce acute GVHD.

Chronic Graft-versus-host Disease (GVHD)

Pathogenesis of chronic GVHD remains obscure. Role of development of autoantibodies is still not clear. Synthesis of cytokines by Th2 cells play role in the

pathogenesis of chronic GVHD. Immune dysregulation causing immunodeficiency and autoantibodies to several cell surface and intracellular proteins lead to autoimmunity. Various theories have been proposed in its pathogenesis.

- **Breakage of immune tolerance to self-antigens:** Damage to thymus epithelium dysregulates central immunologic tolerance by generation of CD4+ helper T cells from donor stem cells.
- **CD4+ and CD25+ regulatory T cells reduction:** These cells are reported to be reduced in chronic GVHD via synthesis of cytokines such as TGF-β and IL-10.
- **Role of B cells and their antibodies:** Increased levels of BAFF drive B cell autoimmunity. There is development of antibodies to minor histocompatibility proteins encoded by Y chromosome in a male recipient receiving transplant from a female. There may be role of amplification of autoimmune responses and in epitope spreading of autoreactive T cell and B cell.
- **Fibrotic change:** Synthesis of TGF-β and IL-13 produce fibrotic change. Recruitment of macrophages and other cells to the site causes tissue damage. There is C3 deposition at the dermoepidermal junction in skin.

Pathology Pearls: Organs Involved in Acute GVHD

- Acute GVHD occurs within 100 days of transplant.
- Most commonly seen is a triad involvement of liver (hepatitis), skin (dermatitis) and duodenum (enteritis).
- Other systems may be involved causing pneumonitis, hemorrhagic cystitis, thrombocytopenia and anemia.

Skin Manifestations

- Patient presents with maculopapular rash, erythema, bullae, and desquamation.
- Skin epidermal cells are infiltrated by lymphocytes.
- Duodenal mucosa shows lymphocytic infiltration.

Liver Manifestations

- Patient presents with symptoms related to hepatitis.
- Liver shows lymphoid cells in portal triad invading and attacking hepatocytes, bile ducts epithelial cells and vascular endothelial cells.

Duodenum Manifestations

- Patient presents with diarrhea (green, water, mucoid stool; may contain cells and fecal casts), intestinal bleeding and crampy abdominal pain.
- Barium studies show increased transit time and loss of haustral folds.
- Light microscopy reveals single cell necrosis/apoptotic bodies at the base of the crypts or glands.

Pathology Pearls: Organs Involved in Chronic GVHD

- Chronic GVHD may follow acute GVHD or *de novo.* It is one of the problems affecting the long-term survivors of allogenic graft. GVHD affects liver and colon.
- Liver biopsy shows lymphocytic infiltration in portal triad, fibrosis and loss of bile ducts. Histology of colonic biopsy shows lymphocytic infiltration, glandular degeneration and mucosal atrophy with loss of glands.
- Other organs may be involved. Patient may develop cholestasis, oesophageal reflux and strictures, dryness and stenosis of vagina, polymyositis, fasciitis, myasthenia gravis, nephrotic syndrome and positive autoimmune serology. Organs involved and clinical manifestations in chronic GVHD are given in Table 4.75.

Diagnostic Modalities

Demonstration of donor derived lymphocytes in the areas of tissue destruction in biopsy specimens, viz. dermoepidermal junction, crypts of gut epithelium, bone marrow, etc.

- DNA polymorphism studies are done using VNTR analysis fingerprinting.

Table 4.75 Organs involved and clinical manifestations in chronic GVHD

Organs	Clinical Manifestations
Gastrointestinal tract	Dysphagia, pain, vomiting, diarrhea, abdominal pain
Skin	Skin rash (lichenoid, sclerodermatous, hyper-/hypopigmented, flaky) and alopecia
Oral and ocular organs	Sjögren's syndrome related to lacrimal gland destruction and reduced tear flow, dry and painful eyes, conjunctivitis, corneal ulcers
Liver	Increased transaminases, hyperbilirubinemia, cirrhosis
Lungs	Bronchiolitis obliterans, organizing pneumonia
Hematologic/immune system	Cytopenias, dysfunction
Serous membrane	Pericarditis and pleuritis

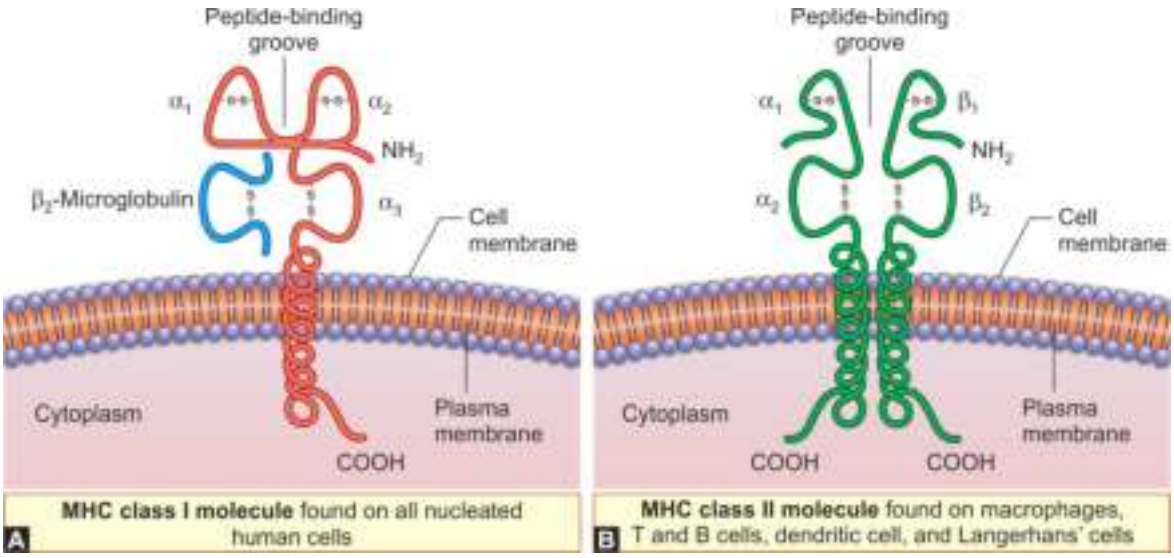

Fig. 4.81: Structure of major histocompatibility complex (MHC or HLA) class I and class II molecules. MHC class I and class II molecules play a pivotal role in the adaptive immune response. Both classes of MHC molecules share the task of presenting peptides on the cell surface for recognition by naïve CD4+ helper T cells and CD8+ cytotoxic T cells.

- **Polymerase chain reaction (PCR)** with donor HLA-DR sequence is specific primers.
- **Fluorescence *in situ* hybridization (FISH)** using Y-chromosome specific DNA probe combined with IHC using monoclonal antibodies define cellular phenotypes.
- **Demonstration of one-way HLA** match between the donor and the recipient is performed.

FINDING ELIGIBLE DONOR–RECIPIENT MATCH

Transplant rejection can be minimized by matching the donor and recipient for compatibility prior to transplantation. Transplantation is successful in properly matched donor and recipient. Compatibility between donor and recipient is assessed using a panel of tests.

Pathology Pearls: Renal Transplantation

- The likelihood of transplant rejection is increased with increasing MHC disparity.
- In addition to **MHC matching**, two additional compatibility tests are performed for renal transplant recipients. Kidneys are also matched for **ABO blood** group antigens.
- For renal transplants, overall rate of **transplant failure** in the first year is 10%, and overall rate of transplant failure at 5 years is 35%.
- The last level of matching is performed by cross-matching assay, which determines whether there is pre-existing antibody in the recipient to donor histocompatibility antigens.
- The determination of donor MHC antigens and antibody to ABO blood group antigens is important for preventing renal transplant rejection.

ABO BLOOD GROUP COMPATIBILITY

The donor and recipient are tested for compatible blood groups prior to organ transplantation. This is the first test to be performed as the organ transplant will be rapidly rejected if the blood groups do not match. ABO compatibility is not necessary in young children undergoing transplantation and also hematopoietic stem cell (HSC) transplantation. When kidneys are transplanted into ABO-incompatible recipients, only 50% of these cases develop impaired renal function one year post-transplant period.

TISSUE TYPING

Tissue typing is carried out to match major histocompatibility complex (MHC or HLA) proteins of donor and recipient on the surface of cells. When HLA types are matched properly, the survival of transplanted organs increases dramatically. Family members, in particular siblings, are often the best major histocompatibility complex (MHC or HLA) matches due to genetic similarity. Structure of major histocompatibility complex (MHC or HLA) class I and class II molecules is shown in Fig. 4.81A and B.

Pathology Pearls: Major Histocompatibility Complex

- Success of organ transplants and skin grafts depends on a proper matching of histocompatibility antigens that occur on all cells of the body.
- Chromosome 6 of mouse contains a cluster of genes known as the major histocompatibility complex, which in human is called human leukocyte antigen (HLA) complex. The alleles of HLA genes are codominant.

- The products of these genes determine histocompatibility, i.e. compatibility between donor and recipient tissues in transplants. The array of HLA alleles on a homologue of our chromosome 6 is known as a haplotype.
- An individual inherits one HLA haplotype from each parent. The large number of alleles at this locus ensures that only identical twins have the identical haplotype.
- The best HLA matches would occur within a family.
- Therefore, the preference order for transplants is as follows: identical twin > sibling parent > unrelated donor.

CROSS-MATCHING

Blood samples are taken from both the donor and the recipient for cross-matching, in which the cells of the donor are mixed with the blood serum of the recipient. If the recipient's antibodies attack donor cells, they are considered a **positive crossmatch** and the transplantation will not be suitable due to increased risk of hyperacute transplant rejection.

PANEL OF REACTIVE ANTIBODY TEST

The blood serum of patients awaiting transplantation are analyzed for **reactive antibodies** against a random panel of cells.

- Previous exposure to foreign tissue by multiple pregnancies or blood transfusion or prior transplantations, are likely to increase the number of HLA antibodies in the bloodstream.
- The more the HLA antibodies present, the higher the panel reactive antibody level denoted to the patient, and greater chance of transplant rejection.
- If the panel reactive antibody levels are high, it may be more difficult to find a match and a higher dosage of immunosuppressive drugs may be required by the recipient.

SEROLOGICAL SCREENING

Pre-transplantation serological screening of donor and recipient is essential for patients undergoing hematopoietic stem cell (HSC) transplantation. Serological testing is performed to know the immune status of both donor and recipient against a number of clinically significant infectious organism including viruses like human immunodeficiency virus (HIV), cytomegalovirus (CMV), and Epstein-Barr virus (EBV), thus determining potential for reinfection or reactivation upon immunosuppressive therapy. Donor and recipient are often matched according to the CMV and Epstein-Barr virus status.

PREVENTION OF TRANSPLANT REJECTION

The chances of transplant rejection may be reduced by good matching between donor and recipient, and suppression of immune response of the recipient.

IMMUNOSUPPRESSIVE DRUGS

Solid organ transplantation immunosuppressive medications have revolutionized the field of transplantation. Generally, immunosuppressive drugs damp the immune system either globally by suppression of T cell reactivity or causing death of reactive T cells to prevent transplant rejection. Immunosuppressive drugs are required for any form of transplantation across MHC barriers. The likelihood of transplant rejection is increased with increasing MHC disparity.

- Various immunosuppressive drugs are given to the recipient including azathioprine, cyclosporine A, tacrolimus (FK506), rapamycin and biological immunosuppression monoclonal antibodies.
- Immunosuppressive drugs are administered in two phases: (a) induction phase involves high dose, and (b) maintenance phase involves using a drug in the long-term at a lower dose.

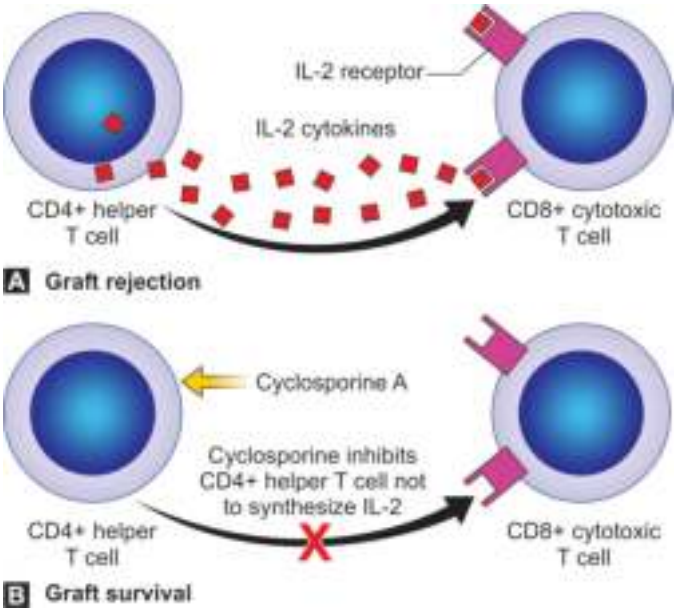

Fig. 4.82. The action of cyclosporine A in preventing transplant rejection. Cyclosporine A drug administration to prevent organ graft rejection. (A) CD4+ helper T cell synthesizes IL-2 that binds to IL-2 receptor on CD8+ cytotoxic T cell leading to graft rejection. (B) Cyclosporine A is administered to prevent graft rejection. Cyclosporine A inhibits CD4+ helper T cells not to synthesis IL-2 that fails to stimulate CD8+ cytotoxic T cell resulting in graft survival.

- The combination of immunosuppressive drugs, and dosage administered, will vary depending on the type of transplant and the chosen treatment regime. If a patient experiences an episode of acute transplant rejection by using immunosuppressive drugs, the dosage is also likely to be increased. Side effects of drugs can also cause alternative drugs to be used.
- The action of cyclosporine A in preventing transplant rejection is shown in Fig. 4.82A and B. Immunosuppressive drugs used in transplant recipient are given in Table 4.76.

ADVERSE EFFECTS OF IMMUNOSUPPRESSIVE DRUGS

Adverse effects of immunosuppressive treatment comprise **nephrotoxicity**, **infection**, **hyperlipidemia**, **hypertension**, and neoplasia risk. Adverse effects of immunosuppressive drugs in recipient of transplant are given in Table 4.77.

Table 4.76 Immunosuppressive drugs used in transplant recipient

Drug	Product	Mechanism
Azathioprine	Azathioprine metabolized to 6-mercaptopurine	▪ Inhibits T cell-mediated transplant rejection ▪ Interferes with enzyme involved in nucleic acid synthesis ▪ Inhibiting proliferation of T cells
Cyclosporine A	Fungal product first-line of drug used in prevention of allograft rejection	▪ Has no effect on the replicating cells of bone marrow ▪ Penetrates antigen-sensitive cells in the G0 and G1 phase ▪ Inhibits RNA polymerase leading to blockage of synthesis of IL-2 by T helper cells
Tacrolimus (FK506)	Fungal product	Inhibits synthesis of lymphokines by recipient T helper cells
Rapamycin	Fungal macrolide	Interferes with the intracellular signaling pathways of the IL-2 receptor
Biological immunosuppression	▪ Monoclonal antibodies ▪ Toxin subunit of riacin conjugated with monoclonal antibodies ▪ Lymphokine (IL-2) complexed with diphtheria toxin	▪ Monoclonal antibodies directed against CD4+ helper T cells (anti-CD4), CD25 molecule and IL-2 receptors expressed on CD4+ regulatory T cells ▪ Targeted against CD25 molecule expressed on activated CD4+ regulatory T cells ▪ Locks IL-2 receptors on activated CD4+ regulatory T cells and kills the cells

Table 4.77 Adverse effects of immunosuppressive drugs in recipient of transplant

Adverse Effects	Findings
Acute nephrotoxicity (cyclosporine A induced)	▪ Vacuoles formation in proximal tubules and hyalinization of arterioles ▪ Interstitial fibrosis and tubular atrophy
Infections risk	Cytomegalovirus infection common
Hypertension (cyclosporine A induced)	Hypertension following renal transplant (50% cases) associated with vasoconstriction
Hyperlipidemia	Present in 60% post-transplant cases increasing risk of cardiovascular deaths in 30% cases
Post-transplant neoplasia	Squamous cell carcinoma, B cell lymphoma especially associated with Epstein-Barr virus, Kaposi's sarcoma and cervical carcinoma

AMYLOIDOSIS

Amyloidosis is fundamentally a disorder of abnormal folding of normal soluble proteins, formation of insoluble fibrils having an antiparallel, β-pleated sheet tertiary structure, and deposition in the extracellular tissue in one or many body organs, systems and soft tissues. Amyloidosis may be localized or systemic. It is not a single disease entity but rather a diverse group of inherited or acquired disorders.

- Amyloid material is resistant to digestion, hence accumulated within tissue, interferes with function and destroys vital organs. Amyloid is deposited between the endocardium and the basement

membrane of blood vessel walls that involves microvasculature of any organ including great blood vessels of the brain. Initial clinical manifestations of amyloidosis include weakness, fatigue, and weight loss. Later life-threatening manifestations depend on organ involved.

- Amyloid deposits in spleen can cause splenic rupture and severe hemorrhage.
  - Amyloid deposition in the liver can cause decreased synthesis of coagulation factors in patients with advanced liver disease.
  - Patient with renal involvement develops nephrotic syndrome progressing to renal failure.
  - Amyloid deposition in subendocardial region produces restrictive cardiomyopathy resulting in cardiac arrhythmias associated with fatal outcome.
- Sometimes, amyloid deposits are limited to a single organ. Amyloid deposits are nodular and encountered in the lungs, larynx, skin, urinary bladder, tongue, and the region about the eyes may be involved. In some of these cases, infiltrates of plasma cells may be found, and the amyloid is of AL type.
- Several factors participate in the misfolding of proteins, which include: (a) increased concentration soluble proteins in chronic inflammation, (b) impaired excretion of soluble proteins in long-term hemodialysis, (c) genetic predisposition due to gene mutations, and (d) limited proteolysis may generate a protein that forms amyloid fibrils (amyloid associated Alzheimer's disease).
- Amyloid is composed of fibrillar proteins, and nonfibrillary glycoproteins [amyloid P component also called serum amyloid P (SAP), glycosaminoglycans and apolipoprotein E]. Serum amyloid P component may contribute to stability of amyloid deposits.
- Amyloid material is demonstrated by Congo red staining and apple green birefringence under polarized light microscope. Radioactive iodine labeled SAP is used to assess amyloid deposition in nuclear medicine studies. Irrespective of molecular composition, amyloid always has the same characteristic histologic and ultrastructural appearance.

Pathology Pearls: Physical Nature of Amyloid

Amyloid deposits typically contain three components: amyloid protein fibrils, amyloid P component and sulfated glycosaminoglycans (GAGs).

Amyloid Protein Nonbranching Fibrils

- Amyloid protein fibrils constitute 90% of the amyloid structure. Regardless of their derivation, all amyloid deposits are composed of nonbranching fibrils, measuring 7.5–10 nm in diameter.
- Each of these nonbranching fibrils of amyloid is made up of two filaments of polypeptide chains, which are folded in ribbon-like twisted "**β-pleated sheet fibrils**" extending over the length of the fibril.
- Amyloid protein nonbranching fibrils bind to proteoglycans, glycosaminoglycans, heparan sulphate, dermatan sulphate and plasma proteins.
- **Congo red** binds to these nonbranching fibrils produces a red-green dichromatism (birefringence) under polarized light, which is commonly used to demonstrate amyloid in tissues.

Amyloid P Component

- In addition, amyloid protein fibrils deposits are intimately associated with the amyloid P (pentagonal globular rod-like structure) component (AP), a glycoprotein related to normal serum amyloid P (SAP).
- P component is very similar to serum C reactive protein, which constitutes 10% of amyloid material.

Sulfated Glycosaminoglycans

- Sulfated glycosaminoglycans (GAGs) are small but constant component.
- Amyloid fibrils and amyloid AP are closely associated with GAGs, complex carbohydrates of connective tissue.
- The presence of abundant charged sugar groups in these adsorbed proteins give the deposits staining characteristics resembling starch (amylose).

CHEMICAL NATURE OF AMYLOID

Out of more than 20 biochemically distinct forms of amyloid proteins identified, there are two, chemically distinct types of amyloid protein fibrils designated amyloid light chain (AL), and amyloid associated (AA). There are several minor types unrelated to AL or AA such as amyloid-β, transthyretin, β_2-microglobulin, procalcitonin. Classification of amyloidosis is given in Table 4.78. Differences between primary and secondary amyloidosis are given in Table 4.79.

AMYLOID LIGHT CHAIN AMYLOIDOSIS

Amyloid light chain (AL) amyloidosis results from aggregation of misfolded proteins of either kappa (κ) or lambda (λ) light chains synthesized by monoclonal plasma cells in multiple myeloma that are deposited in tissues as amyloid fibrils. The light chains (either κ or λ) undergo aggregation, probably because they contain amino acid residue that destabilize the domain structure. Pathogenesis of amyloidosis (AL type) is shown in Fig. 4.83. Bronchopulmonary amyloidosis is shown in Table 4.80.

- In the immunocyte-associated form, perivascular and vascular localizations are common. Amyloid

Table 4.78 Classification of amyloidosis

Associated Disorders	Major Amyloid Protein	Precursor Protein	Organs Involved
Primary amyloidosis			
Multiple myeloma, immunoblastic lymphoma	AL (immunoglobulin light chains or fragments)	Ig light chain, κ- or λ-chain	Systemic amyloidosis (kidney, heart, tongue, bone marrow and peripheral nerves)
Heavy chain disease	AH	Ig heavy chain	Systemic amyloidosis (kidney, heart, tongue, bone marrow and peripheral nerves)
Reactive (secondary) amyloidosis			
Chronic inflammation, autoimmune diseases and some malignancies	AA (serum amyloid protein, an acute phase reactant)	Serum AA (Apo)	Systemic amyloidosis (kidney, liver and spleen)
Hemodialysis associated amyloidosis			
Chronic renal failure	$A\beta_2M$	β_2-Microglobulin	Systemic amyloidosis (synovium, carpel tunnel syndrome and tongue)
Hereditary and familial associated amyloidosis			
Familial amyloid nephropathy (FAN) with urticaria and deafness, familial amyloidotic cardiomyopathy	ATTR	Transthyretin	Systemic amyloidosis (peripheral nerves, autonomic nerves, heart, and kidney)
Familial amyloidotic polyneuropathy	AApoAI	Apolipoprotein AI	Systemic amyloidosis (heart, skin, kidney, nerves, liver, larynx, and blood vessels)
Familial amyloidotic neuropathy	AApoAII	Apolipoprotein AII	Localized amyloidosis (kidney)
Hereditary cerebral hemorrhage with amyloid	ACys	Cystatin C	Localized amyloidosis (cranial blood vessels)
Familial amyloidosis with cranial neuropathy and corneal lattice dystrophy	AGel	Gelsolin	Systemic amyloidosis (cranial nerves, peripheral nerves, cornea, and kidney)
Endocrine system associated amyloidosis			
Medullary thyroid carcinoma	ACal (calcitonin amyloid)	Procalcitonin	Localized amyloidosis (thyroid gland)
Senile changes associated amyloidosis			
Alzheimer's disease	Aβ	Aβ protein precursor (AβPP)	Localized amyloidosis (nervous system)
Alzheimer disease	Aτ	τ (tau)	Localized amyloidosis (brain)
Amyloid cardiomyopathy	TTR	Transthyretin	Localized amyloidosis (myo-cardium)
Atrial amyloid of aging	AANF	Atrial natriuretic factor	Localized amyloidosis (cardiac atria)
Prion disorder associated amyloidosis			
Creutzfeldt-Jakob disease, Gerstmann-Sträussler-Scheinker disease, fatal familial insomnia with amyloid	AprP	Prior protein	Localized amyloidosis (central nervous system)

In addition to major amyloid substance listed, all amyloid deposits also comprise amyloid P glycoprotein as a common constituent.

Table 4.79 Differences between primary and secondary amyloidosis

Parameters	Primary Amyloidosis	Secondary Amyloidosis
Etiology	Multiple myeloma, immunoblastic lymphoma	▪ Chronic inflammation (tuberculosis, chronic osteomyelitis, bronchiectasis) ▪ Autoimmune disorders (rheumatoid arthritis, ulcerative colitis, regional enteritis, dermatomyositis, scleroderma, ankylosing spondylitis) ▪ Cancers (Hodgkin's disease and renal cell carcinoma)
Chemical nature	AL (amyloid light chain)	AA (amyloid associated) due to misfolding of AA fibrils as a result of defective proteolysis
Organs involved	▪ Mesoderm derived structures such as peripheral nerves, heart, lung, skin, tongue, thyroid gland, joints and gastrointestinal tract. ▪ Parenchymal organs also involved (liver, spleen, kidney, heart)	Parenchymal organs (spleen, liver, kidney, adrenals, and lymph nodes)
Frequency	More common	Less common

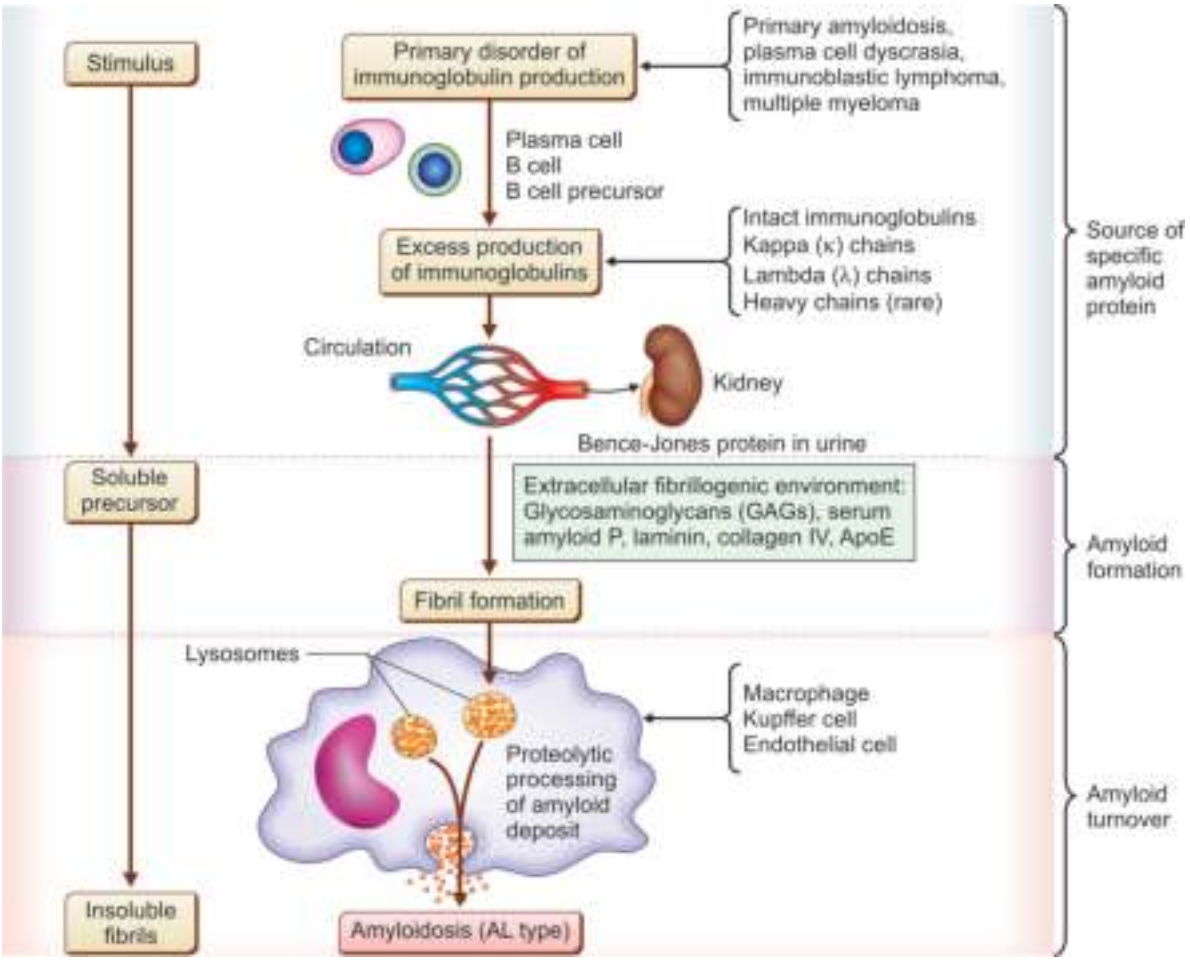

Fig. 4.83: Pathogenesis of amyloidosis (AL type). Primary disorders of B cells/plasma cells such as multiple myeloma leads to synthesis of excessive immunoglobulins. In the extracellular fibrillogenic environment, fibrils are formed. These fibrils are processed by macrophages resulting in amyloid deposition.

Table 4.80 Bronchopulmonary amyloidosis

Bronchopulmonary Amyloidosis	Amyloid Protein	Clinical Features
Diffuse parenchymal involvement as part of systemic amyloidosis	AL	▪ Cardiopulmonary failure ▪ Poor prognosis
Nodular parenchymal involvement limited to the lungs	AL	Often asymptomatic
Tracheobronchial involvement limited to the major airways	AL	▪ Dyspnea ▪ Wheeze ▪ Requires repeated resection

light chain (AL) amyloidosis occurs in 30% cases of multiple myeloma or B cell lymphomas. AL amyloidosis involves multiple organs, including heart (75%), kidneys (65%), liver (15%), soft tissues (175%), peripheral and/or autonomic nervous system (10%) and gastrointestinal tract (5%). Localized amyloid tumor may be found in the respiratory tract.

- Presenting symptoms of systemic AL amyloidosis are often consequence of advanced irreversible organ damage mimicking other common diseases of the older population, thus majority of patients are misdiagnosed. Affected patients have fatal outcome within a few months after diagnosis despite treatment. Hematopoietic stem cell (HSC) transplantation is preferred in 20% of cases. Chemotherapy is administered in patients, who have not undergone hematopoietic stem cell transplantation.

AMYLOID ASSOCIATED (AA) AMYLOIDOSIS

Amyloid associated (AA) amyloidosis is also known as reactive amyloidosis secondary to chronic inflammatory diseases, e.g. tuberculosis, bronchiectasis, chronic osteomyelitis, autoimmune diseases (rheumatoid arthritis, ankylosing spondylitis, dermatomyositis, scleroderma, regional enteritis, ulcerative colitis) and malignancies (e.g. Hodgkin's disease and renal cell carcinoma).

- **Amyloid associated (AA)** fibril, an acute phase reactant synthesized by liver (1,000-fold) under stimulation by **interleukin-1 (IL-1)** released from activated macrophages is derived from serum amyloid associated (SAA).
- **Denaturing of SAA** releases a subunit termed **apoSAA**, which renders it amyloidogenic. In contrast to AL protein derived from immunoglobulin light chain, the amino acid sequence of AA proteins is identical in all patients, regardless of the underlying disorder.

Pathophysiology

Normally SAA in chronic inflammation is degraded to soluble end products by the action of monocyte associated serine esterases. When degradation process is inhibited, insoluble end products form amyloid material. Defective proteolysis may produce misfolded, incompletely degraded SAA, leading to aggregation and deposition as AA fibrils in tissues/organs.

- Amyloid associated (AA) Amyloidosis involves liver, spleen, kidney, adrenal glands, and lymph nodes. However, no organ system is spared. Vascular involvement may be widespread. The liver and spleen are often enlarged, and become firm, and rubbery.
- The kidneys are usually enlarged. Sections of the spleen have large, translucent, waxy areas where the normal Malpighian bodies are replaced by pale amyloid, producing the sago spleen. Clinically significant involvement of the heart is rare. Pathogenesis of AA amyloidosis is shown in Fig. 4.84.

Pathology Pearls: Mediterranean Fever

- Mediterranean fever is autosomal recessive disorder characterized by attacks of fever accompanied by inflammation of pleural, peritoneal and synovial surfaces.
- Patient develops widespread tissue involvement such as kidneys, blood vessels, spleen, and respiratory tract. It is indistinguishable from reactive systemic amyloidosis.
- The amyloid fibril proteins are made up of amyloid associated (AA) proteins.
- Normal gene product '**pyrin**' inhibits neutrophils in acute inflammation.
- Mutation of gene product 'pyrin' leads to vigorous tissue damaging inflammatory response due to minor trauma.

AMYLOID-β PRECURSOR PROTEIN ASSOCIATED AMYLOIDOSIS

Amyloid-β precursor protein (APP) associated amyloidosis is derived from a much larger transmembrane glycoprotein called amyloid precursor protein, protein product of chromosome 21, which is deposited in cerebral blood vessels of Alzheimer's disease. Amyloid deposits contain fibrils of β-amyloid (Aβ-protein resides on chromosome 21) derived from larger Aβ-protein precursor (AβPP), which is a normal cell membrane constituent.

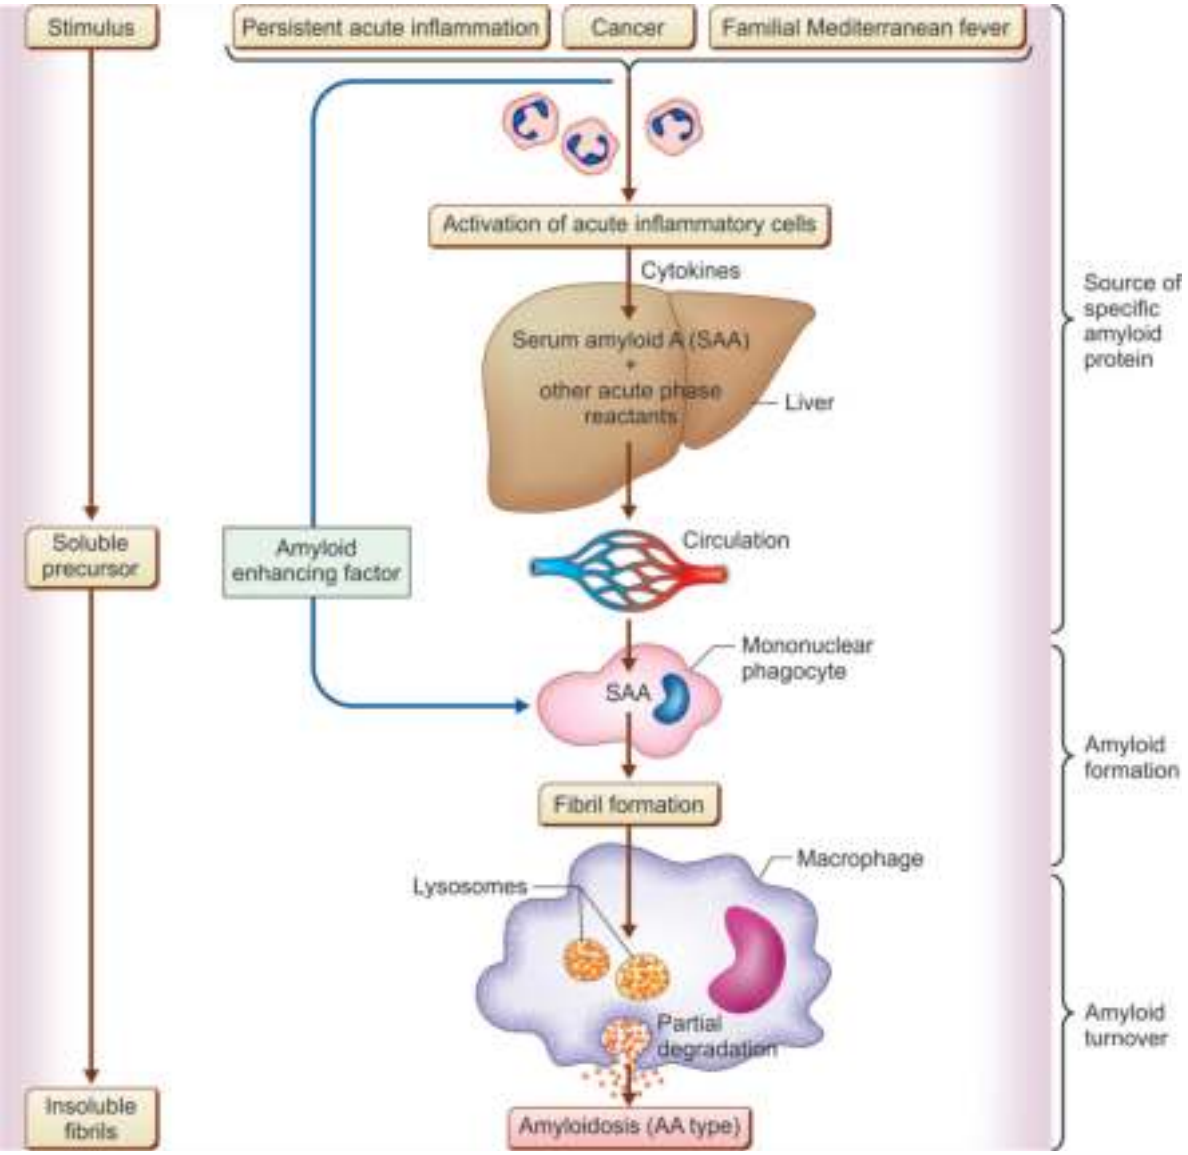

Fig. 4.84: Pathogenesis of amyloid associated (AA) amyloidosis. It is associated with the activation of polymorphonuclear leukocytes and macrophages, which in turn leads to the synthesis and release of acute phase reactants by the liver, including SAA. This SAA is released in association with amyloid-enhancing factor (AEF) by intact macrophages. This released product complexes with glycosaminoglycans and SAP as AA amyloid. The deposit is then processed by macrophages.

TRANSTHYRETIN PROTEIN ASSOCIATED AMYLOIDOSIS

Transthyretin (TTR) protein is a normal serum protein that transports thyroxine and retinol. Mutation in the genes encoding TTR protein is associated with amyloidosis affecting various tissues, including transthyretin amyloidosis and familial autosomal dominant polyneuropathy involving peripheral nerves and autonomic nervous system.

- **Amyloid of aging** is also known as senile systemic amyloidosis affecting 8th and 9th decades of elderly persons. Amyloid fibrils derived from **mutant form** of TTR protein are deposited in heart resulting in restrictive cardiomyopathy. In addition to heart, lungs, pancreas or spleen may be affected, suggesting that it is a systemic disorder.
- Hereditary amyloidosis is characterized by peripheral sensory and motor neuropathy, often autonomic neuropathy, and cardiovascular and renal amyloid. Carpal tunnel syndrome and vitreous abnormalities may occur. The fibrils in these familial polyneuropathies are made up of mutant ATTRs (transthyretin amyloidosis).
- Acquired transthyretin (TTR) protein is increased in insulinoma, glucagonoma and gastrointestinal carcinoids due to synthesis of transthyretin by these neoplasms.

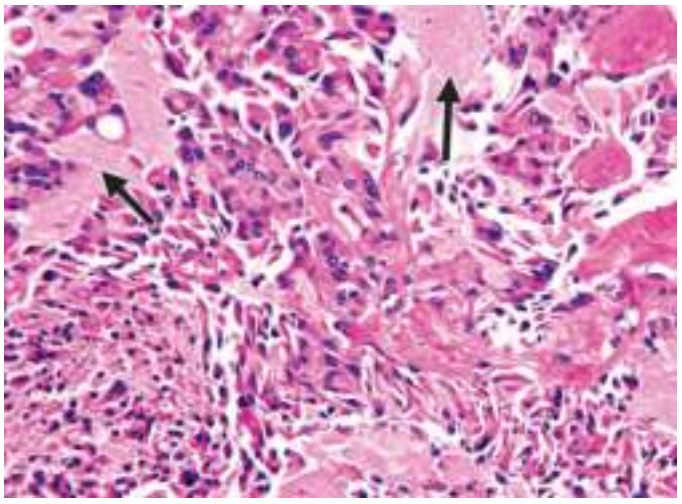

Fig. 4.85: Amyloid deposits in medullary carcinoma thyroid. The tumor is composed of round to polyhedral granular cells arranged in trabecular, glandular, carcinoid-like patterns. The tumor cells are separated by a distinctly fibrovascular stroma containing amyloid material representing deposition of procalcitonin (arrows) (400X).

β_2-MICROGLOBULIN PROTEIN HEMODIALYSIS ASSOCIATED AMYLOIDOSIS

The systemic amyloid deposition of β_2-microglobulin, a component of the MHC class molecules and a normal serum protein, occurs as a complication of long-term dialysis in patients with chronic renal failure due to increased concentration in serum. This protein does not pass-through conventional dialysis membranes. About 60–80% of patients on long-term dialysis develop amyloid deposition in the synovium, joints and tendon sheaths result in destructive arthropathy.

ENDOCRINE GLANDS–PROTEINS ASSOCIATED AMYLOIDOSIS

Microscopic deposits of localized amyloid deposit may be found in certain endocrine lesions, e.g. medullary thyroid carcinoma (amyloid-derived from procalcitonin), pheochromocytoma, undifferentiated carcinoma of stomach, islets of Langerhans in pancreas in type 2 diabetes mellitus (islet amyloid polypeptides or amylin) and islets tumors of pancreas (amyloid-derived from islet amyloid polypeptides). Amyloid deposits in medullary carcinoma of thyroid gland are shown in Fig. 4.85.

ORGANS INVOLVED IN AMYLOIDOSIS

Amyloid associated (AA) amyloidosis most commonly affects kidneys, liver and spleen. Amyloid light chain (AL) amyloidosis involves multiple organs including the heart (75%), kidneys (65%), soft tissues (15%), peripheral and/or autonomic nervous system (10%) and gastrointestinal tract (55%).

RENAL AMYLOIDOSIS

Kidneys are commonly involved in 80% cases of systemic amyloidosis. Patients present with proteinuria in nephritic/nephrotic range and ultimately go into chronic renal failure in a span of two years with fatal outcome. Renal failure is a common cause of death in amyloidosis.

- Renal amyloidosis occurs due to deposition of amyloid material in primary (AL in multiple myeloma) and secondary amyloidosis (AA in chronic disorders).
- Kappa (κ) or lambda (λ) chains of immunoglobulins synthesized by neoplastic plasma cells are deposited in the glomerular basement membranes and mesangial matrix, which immunoglobulins can be detected in serum or urine by electrophoresis.
- Amyloidosis is a well-known complication of chronic inflammatory disorders such as tuberculosis, bronchiectasis, rheumatoid arthritis, or osteomyelitis, which stimulate the production of amyloid from the serum amyloid A (SAA) protein, an acute-phase reactant secreted by the liver.

Surgical Pathology: Renal Amyloidosis

Gross Morphology

- Kidneys are enlarged and pale. Cut section of kidneys reveals firm and waxy surface.
- In advanced cases, the kidneys are contracted and shrunken due to vascular narrowing induced by deposition of amyloid.

Light Microscopy

- Renal amyloidosis shows amyloid deposits primarily affecting glomeruli and renal blood vessels, often causing marked vascular narrowing.
- Peritubular tissue is also involved. Amyloid nephropathy is shown in Fig. 4.86.
- Glomeruli show thickening of glomerular basement membrane. Amyloid material appears as amorphous, homogenous and eosinophilic in mesangial region, tubular basement membranes, renal vessels and interstitial tissue.
- Expansion of mesangial region obliterates the glomerular capillaries loops rendering the glomerular filter leaky to plasma proteins and impaired renal functions. There is no cellular response to the amyloid deposits.

Electron Microscopy

Electron microscopy reveals deposition of 7–10 mm thick amyloid fibrils in subendothelial region of glomerular basement membrane, mesangial matrix, tubular basement membrane and arterioles.

Histochemical Staining to Demonstrate Amyloid

- Amyloid material in glomerular mesangial matrix, glomerular and tubular basement membrane is demonstrated by Congo red staining under light microscopy, which reveals characteristic apple-green birefringence (color of a Granny Smith apple) under polarized microscopy.

- Amyloid material can also be demonstrated by various other stains, i.e. thioflavin T, thioflavin S, methyl violet, crystal violet.
- Pretreatment of tissue with potassium permanganate stained by Congo red demonstrates AL amyloid only but not AA amyloid. Congo red staining for amyloid deposition in the kidney in a case of diabetic glomerulosclerosis is shown in Fig. 4.87.

LIVER AMYLOIDOSIS

Amyloidosis is a well-known complication of chronic inflammatory disorders such as tuberculosis, bronchiectasis, rheumatoid arthritis, or osteomyelitis, which stimulate the production of amyloid from the serum amyloid A (SAA) protein, an acute-phase reactant secreted by the liver.

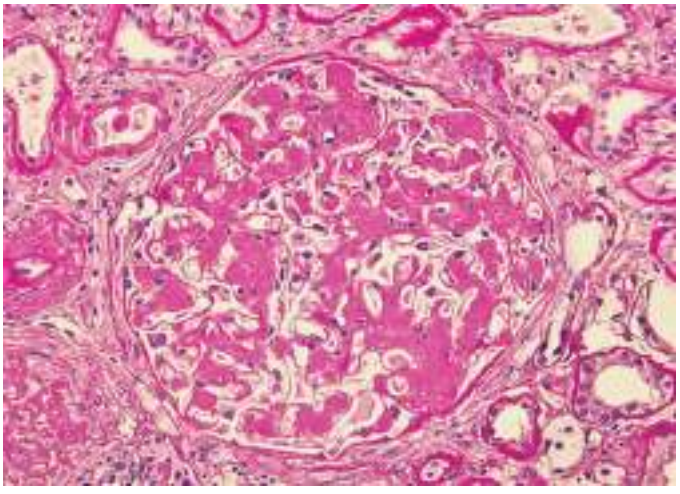

Fig. 4.86: Amyloid nephropathy: initially, amyloid material is deposited in the mesangium and then extending along the inner surface of GBM distorting glomerular lumina. Light microscopy shows amorphous acellular material extending to mesangial matrix and obstructing glomerular lumina (400X).

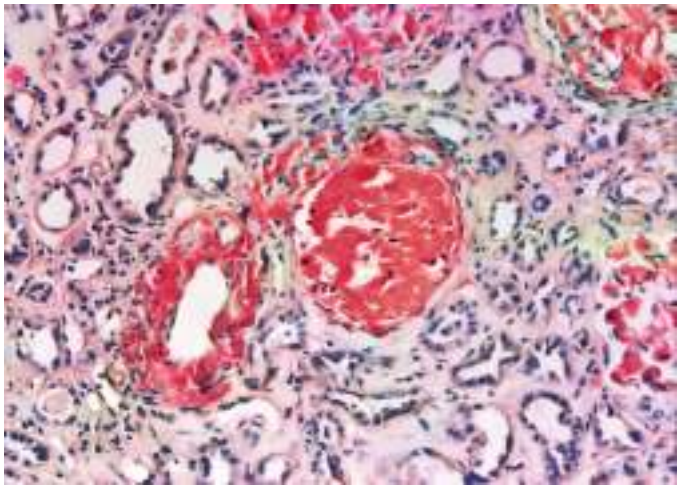

Fig. 4.87: Congo red staining for amyloid deposition in the kidney in a case of diabetic glomerulosclerosis. In histology and polarizing microscopy, Congo red is used to amyloid material in the tissues. Congo red stained preparations of tissue with amyloid material gives apple green birefringence indicative of the presence of amyloid fibrils (400X).

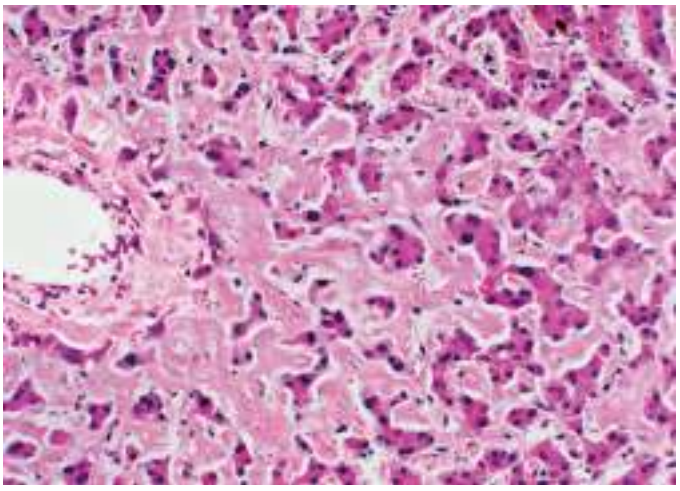

Fig. 4.88: Amyloid deposition in the liver. Histologic examination of liver shows amyloid deposition in the space of Disse between the hepatocytes and vascular sinusoids leading to compression of hepatic cords (400X).

- Liver is grossly enlarged (as much as 900 g), pale, and smooth surface, firm consistency. When sectioned, it has sharp rigid edges.
- On histologic examination, amyloid material is initially deposited in the '**space of Disse**' between the hepatocytes and vascular sinusoids. As more amyloid accumulates, it compresses the hepatic cords and sinusoids. The hepatic cords undergo nutritional and pressure atrophy and become displaced or replaced by bands and nodules of amyloid. Histologic features of amyloid liver are shown in Fig. 4.88.

SPLEEN AMYLOIDOSIS

Amyloidosis of the spleen often causes moderate or even marked enlargement (200–800 g). Amyloidosis of the spleen has two different anatomical patterns such as 'sago spleen' or 'lardaceous spleen'. In both the patterns, amyloid spleen is firm in consistency, and cut surfaces reveal pale gray, waxy deposits. Amyloid deposit in spleen is shown in Fig. 4.89.

- **Sago spleen:** Most commonly, the amyloid deposition is limited to the splenic follicles, resulting in the gross appearance of a moderately enlarged spleen dotted with tapioca-like gray nodules so-called sago spleen.
- **Lardaceous spleen:** Alternatively, the amyloid deposits may spare the follicles and mainly infiltrate the red pulp sinuses, producing a large, firm spleen mottled with waxy discolorations so-called lardaceous spleen.

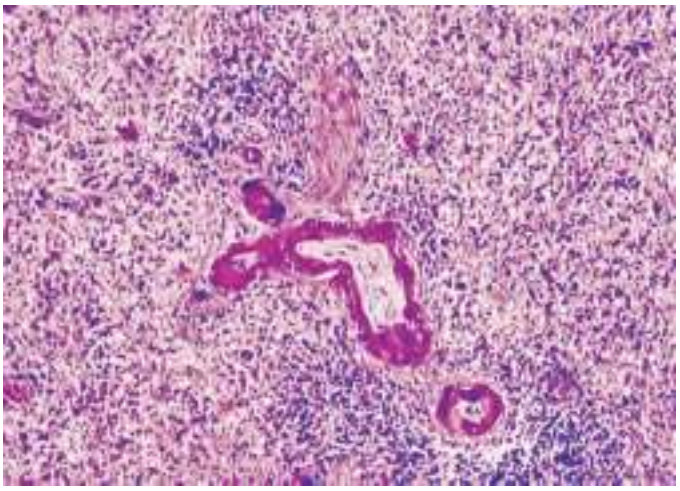

Fig. 4.89: Amyloid deposition in the spleen. Amyloid deposition in the spleen can occur in three major sites: red pulp, white pulp and blood vessels. Amyloid deposition in the red pulp of spleen demonstrates only AL protein in more than 50% of cases. Amyloid deposition in the white pulp of spleen can demonstrate either AL protein in 70% or AA protein in 35% of cases. In this case, amyloid deposition is seen in the blood vessels (100X).

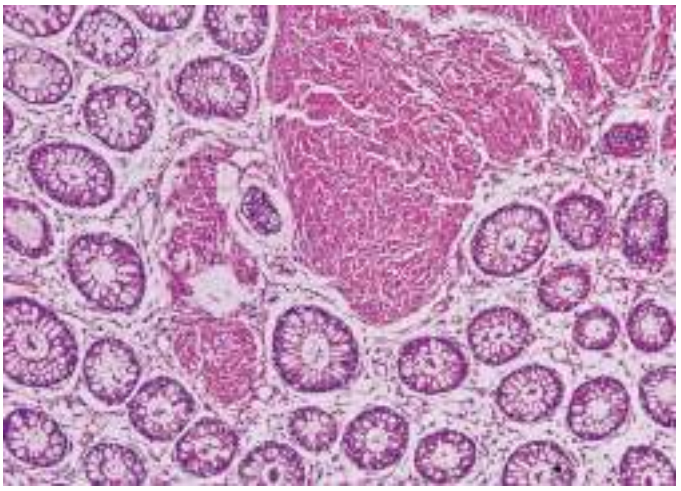

Fig. 4.90: Amyloid deposits in colorectal mucosa. In the colorectal mucosa, amyloid deposition is most often seen around blood vessels or diffusely in the lamina propria. Amyloid deposit is composed of AA protein. Subepithelial amyloid deposit may mimic collagenous colitis (400X).

CARDIAC AMYLOIDOSIS

Heart involvement may accompany systemic amyloid deposition usually associated with immunocyte dyscrasias or localized organ involvement (amyloidosis of aging). Amyloid deposits may cause minimal to moderately enlarged heart.

- Gross morphologic examination of cardiac amyloidosis reveals gray-pink dewdrop-like subendocardial elevation, particularly evident in the atrial chambers.
- Histologic examination reveals amyloid deposits located between the myocardial fibers eventually causing pressure atrophy or in the walls of the coronary arteries, which reduces the heart's ability to fill with blood in between heartbeats. When amyloidosis affects the electrical system of heart, heart's rhythm may be disturbed.

GASTROINTESTINAL TRACT AMYLOIDOSIS

The alimentary tract may be involved at any level, from the tongue to the rectum (submucosa). There may be direct involvement of gut or of autonomic nervous system. In amyloidosis of tongue (interstitial tissue) amyloid infiltrates the capillary walls and narrows the lumens of some of them; resulting in macroglossia. Lesions in the gut may cause obstruction, ulceration, protein loss, malabsorption, diarrhea and hemorrhage. Biopsy is taken from gingiva and rectum to demonstrate amyloid. Amyloid deposits in rectum are shown in Fig. 4.90.

SKIN AMYLOIDOSIS

Skin involvement occurs in primary amyloidosis. Patients present with slightly raised, waxy papules/plaques which are usually clustered in the axillae, anal or inguinal regions, which are seldom pruritic. Gentle rubbing of skin may induce purpuric bleeding into skin. Cutaneous may occur in secondary amyloidosis.

NERVOUS SYSTEM AMYLOIDOSIS

Cranial nerves are generally spared except for those involving pupillary reflexes. Neurologic manifestations include peripheral neuropathy, postural hypotension, inability to sweat; Adie pupil, hoarseness and sphincter incompetence. 25% of patients suffer from 'carpal tunnel syndrome' due to compression of nerves supplying fingers. This may cause severe pain especially during night, numbness and tingling of the fingers.

RESPIRATORY SYSTEM AMYLOIDOSIS

Amyloidosis can involve nasal sinuses, larynx, trachea, bronchi and alveolar septa. Pulmonary amyloidosis results from plasma cell production of monoclonal free immunoglobulin light chains (AL amyloid), which are either produced in the bone marrow and subsequently deposited in the lungs or pleura (systemic AL amyloidosis) or produced in the lungs.

- Diffuse parenchymal pulmonary amyloidosis usually presents with dyspnea, cough, hemoptysis, or a combination of these symptoms. The deposition of amyloid protein causes alveolar membrane and

capillary damage, which ultimately results in impaired gas exchange.

- Tissue biopsy is essential and green-yellow-orange birefringence under polarized light microscopy after Congo red staining is the gold standard for the diagnosis and typing of pulmonary amyloidosis, which is important and helpful for differentiated it from other diseases.

LABORATORY DIAGNOSIS OF AMYLOIDOSIS

No single set of clinical signs or symptoms points unequivocally to amyloidosis. When one suspects amyloidosis, the diagnosis ultimately rests on its histologic demonstration in biopsy specimens (heart, liver, skin, kidney, small intestine, sural nerve, rectum, gingiva, and tongue) and fine needle aspiration of abdominal fat. Biochemical tests, urine analysis, imaging techniques are also performed.

- Formalin fixed frozen sections are used to differentiate primary from secondary amyloid fibrils. Monoclonal antibodies are prepared to demonstrate different components of amyloid protein fibrils, amyloid P component and sulfated glycosaminoglycans (GAGs).
- Ultrastructurally, all forms of amyloid (AA, AL, ATTR types of amyloid) consist of interlacing bundles of parallel arrays of fibrils, which have a diameter of 7–13 nm. The protein in the amyloid fibrils contains a large proportion of crossed β-pleated sheet structure.
- Organs involved and clinical manifestations of amyloidosis are given in Table 4.81. Various stains used to demonstrate amyloid material are given in Table 4.82.

HISTOCHEMICAL STAINS

Iodine solution applied to cut surface of organ. Amyloid typically stains mahogany-brown. Application of dilute sulfuric acid leads to color reaction changes to blue ('starch-like' reaction).

Congo Red Stain

Congo red stain is the most common stain applied on formalin fixed biopsy specimens or aspirates to demonstrate amyloid. When the sections stained with Congo red are viewed under light microscopy, amyloid material imparts a pink or red colored hyaline-like material. Apple green birefringence is observed under polarized light. The fibrillary deposits organized in one plane have one color, and those organized perpendicular to that plane have the other color. This reaction is shared by all forms of amyloid and is caused by the crossed β-pleated configuration of amyloid fibrils.

Metachromatic Stains

Metachromasia refers to the coloring of a tissue constituent in a color different from that of the dye applied,

Table 4.81 Organs involved and clinical manifestations of amyloidosis

Organ Involvement	Clinical Manifestations
Tongue	Macroglossia
Esophagus	Megaesophagus and loss of peristalsis
Stomach	▪ Amyloid deposits in submucosa with loss of gastric rugae ▪ Amyloid deposit may be localized to antrum ▪ Stomach becomes rigid simulating linitis plastica leading to diminished or absence of stomach peristalsis
Small intestine	▪ Amyloid deposits in diffuse pattern (more common) causing broadened flat undulated mucosal folds (mucosal atrophy) leading to impaired motility ▪ Multiple small amyloid deposits causing small bowel dilatation and pseudo-obstruction
Colon	Pseudopolyps
Liver	Hepatomegaly
Spleen	Splenomegaly
Heart	Congestive heart failure with cardiomegaly
Kidney	Nephritic/nephrotic syndrome leading to chronic renal failure
Skin	Waxy papules
Brain	▪ Alzheimer's disease (dementia) caused by toxic Aβ deposits in neurons ▪ Amyloid precursor protein coded by chromosome 21 associated with Down's syndrome
Bone marrow	Plasmacytosis in multiple myeloma and osteolytic lesions in bones
Serum and urine	Monoclonal Ig and light chains

Table 4.82 Stains used to demonstrate amyloid material

Amyloid Stain	Color Imparted
Congo red stain examined under light microscope	Pink
Congo red stain examined under polarizing microscope	Apple green
Fluorescent stains (thioflavin T, thioflavin S)	Greenish fluorescence
Methyl violet (metachromatic stain)	Rose pink
Crystal violet (metachromatic stain)	Pink
PAS stain (metachromatic stain)	Magenta color
Von Gieson stain (metachromatic stain)	Khaki color

which takes place due to polarization, when certain negatively charged groups on the tissues react with cationic dyes. Metachromatic stains for amyloid protein include methyl violet, crystal violet, toluidine blues, periodic acid–Schiff and Van Gieson stains.

- **Methyl violet stain:** It is best used on frozen sections to demonstrate amyloid. Amyloid stains red purple/violet against a blue background. Addition of ammonium oxalate to methyl violet accentuates the metachromatic effect. Methyl green is used as counter stain in methyl violet method to demonstrate amyloid, which imparts purple red color.
- **Crystal violet stain:** Crystal violet stains amyloid a violet color against a blue background. Formic acid-crystal violet method accentuates the metachromatic effect.
- **Periodic acid-Schiff stain:** Amyloid appears magenta pink against background.
- **Von Gieson stain:** Amyloid stains khaki in a yellowish background.

Cotton Dye Sirius Red F3B

Cotton dye Sirius red F3B is a polyazo dye used principally in staining methods for amyloid and collagen. Cotton dye stains amyloid as red and exhibits apple green birefringence under polarized light.

Thioflavin T and Thioflavin Blue Stains

Fluorescein thiocyanate is used for immunofluorescence microscopy. Thioflavin T stain is not entirely specific to demonstrate amyloid. Thioflavin blue stain stains glycosaminoglycans of amyloid to appear blue, which allow amyloid to fluoresce green.

CHAPTER

5

Genetic Disorders

Vinay Kamal, Anubhav and Vigyat

LEARNING OBJECTIVES

HUMAN GENOME

- Human genome project
- Basic structure of DNA double helix molecule
  - Nuclear DNA and mitochondrial DNA
  - Nucleotide base pairs in DNA
  - Deoxyribonucleic acid (DNA) packaging
  - Ribonucleic acid

GENETICS AND MOLECULAR BIOLOGY

- DNA: chemical basis of hereditary
- Human DNA: genetic units
- Human chromosomes

THE NUCLEUS AND DNA REPLICATION

- Organization of the nucleus and its DNA
- DNA replication

GENE EXPRESSION, TRANSCRIPTION, TRANSLATION AND PROTEIN FOLDING

- Central dogma of biology
- Genetic code
- Transcription
- Translation
  - Protein folding
  - Denaturing of protein
  - Protein misfolding and aggregation

DNA DAMAGE AND REPAIR SYSTEMS

- DNA damage mechanisms
- DNA repair mechanisms
- Genetic disorders and faulty DNA repair systems

CHROMOSOMAL DISORDERS

- Changes in autosome chromosome number and structure
- Disorders of autosomal chromosome
  - Down syndrome (trisomy 21)
  - Edward syndrome (trisomy 18)
  - Patau syndrome (trisomy 13)
  - Cri-du-chat (5p minus, cat-cry) syndrome
  - DiGeorge syndrome
- Sex chromosome deviation
  - Barr bodies
  - X chromosome inactivation
- Disorders of sex chromosome
  - Klinefelter syndrome (trisomy 47, XXY)
  - Turner syndrome (monosomy 45, X/XO)
  - Jacob syndrome (trisomy XYY)
  - Triple X syndrome (47, XXX) and other multi-X chromosome anomalies

HUMAN GENE STRUCTURE AND MUTATIONS

- Gene structure
- Gene mutations
- Human genetic disorders

MENDELIAN (MONOGENIC) DISORDERS (SINGLE-GENE MUTATION)

- Modes of inheritance of Mendelian disorders
  - Autosomal dominant inheritance
  - Autosomal recessive inheritance
  - X-linked recessive inheritance
  - X-linked dominant inheritance
  - Mitochondrial inheritance
  - Codominant inheritance
  - Mendelian traits
- Autosomal dominant disorders
- Autosomal recessive disorders
- X-linked recessive disorders
- X-linked dominant disorders
- Mitochondrial DNA mutations associated disorders

BALANCED POLYMORPHISM

- Genetic disorders conferring resistance to infectious diseases
  - Hemoglobinopathies and resistance to malaria
  - Enzymopathies and resistance to malaria
  - Red blood cell-associated antigenic polymorphism and resistance to malaria
  - Cystic fibrosis and resistance to cholera
  - Tay-Sachs disease and resistance to tuberculosis
  - Phenylketonuria and lower risk for miscarriages
  - Niemann-Pick type C disease and resistance to flaviviruses such as Ebola and Marburg viruses
  - Myasthenia gravis and resistance to rabies virus
  - Congenital disorder of N-linked glycosylation (glycosidase 1 deficiency) and resistance to viral infections
  - Sickle cell anemia and susceptibility to pneumococcal infections
  - Hemosiderosis and susceptibility to typhoid fever

POLYGENIC AND MULTIFACTORIAL DISORDERS

- Diabetes mellitus type 2
- Essential hypertension
- Neural tube defects
- Developmental dysplasia of the hip

GENETIC POLYMORPHISM

- Single nucleotide polymorphism (SNP)
- Copy number variations
- Repetitive DNA sequence causing polymorphism

DISORDERS OF SEXUAL DIFFERENTIATION

- 46, XX karyotype testicular disorder of sexual development
- 46, XX karyotype female with normal ovaries and uterus but male or ambiguous genitalia
- 46, XY disorder of sexual differentiation
- Mixed genitalia and sex organs (46, XX ovotesticular disorder of sexual differentiation)
- Sex chromosome disorder of sexual differentiation [children may have either one X chromosome (XO) or an extra chromosome (XXY)]
- Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome
- Pseudohermaphrodite

GENOME IMPRINTING DISORDERS

- Prader-Willi syndrome
- Angelman syndrome

DIAGNOSTIC APPROACH OF GENETIC DISORDERS

- History and physical examination
- Pedigree construction
- Genetic testing
- Types of genetic testing
- Molecular genetic testing: methodology
- Biochemical genetic testing: methodology

HUMAN GENOME

Features of a person depend on genes present in DNA inherited from both the parents. Each gene synthesizes specific proteins. The genes are transmitted from the one generation to the next generation.

- Study of genes and the laws is known as '**genetics**'. The study of genetics consists of three major subdisciplines: transmission genetics, molecular genetics, and population genetics.
- Transmission genetics encompasses the basic principles of hereditary in which traits are transmitted from one generation to the next generation. Transmission genetics also addresses the relation between chromosomes and heredity, the arrangement of genes on chromosomes, and gene mapping.
- Applications of molecular diagnostics include: (a) diagnosis of genetic disorder, (b) prediction of disease progression, (c) paternity and forensic analysis, and (d) gene therapy and therapeutic design in management. Terminology used by geneticist is given in Table 5.1.

Table 5.1 Terminology used by geneticist

Term	Description
Allele	▪ Alternative of a gene present at a given locus ▪ Dominant allele is expressed even if it is paired with a recessive allele ▪ Recessive allele is only visible when paired with another recessive allele
Aneuploidy	Presence of extra copies of chromosome in addition to the normal pair (trisomy seen in Down syndrome and Klinefelter's syndrome) or deficient in number of chromosome (monosomy seen in Turner syndrome)
Anticodon	Consecutive sequence of three nucleotides on a tRNA molecule that is complementary to a specific codon on an mRNA molecule
Base substitution mutation	Base substitution mutation changes the base of a single DNA nucleotide
Cell nucleus	Carries genetic information
Central dogma of biology	The process by which the information in genes flows into the proteins: DNA→RNA→Proteins
Chromosome	Storage units of genes (condensed version of chromatin)
Chromatin	Substance consisting of DNA and associated protein
Chromosomal banding techniques	Demonstration of light and dark strips of chromosomes on staining with Giemsa stain (G-banding) and quinacrine fluorescence (Q-banding)
Codominance	Type of dominance in which two versions of a trait are expressed in the same individual
Codon	Three adjacent base nucleotide sequences in mRNA that code for specific amino acid production or start/stop signal during translation (consecutive sequence of three nucleotides on an mRNA molecule that corresponds to a specific amino acid)
Complete linkage	When two genes located on same chromosome are close to each other, so no crossing takes place and two are transmitted intact
Conservative gene mutation	Replacement of one amino acid with a biochemically similar amino acid
Deletion	▪ Small deletion of one or more nucleotide bases within a gene in DNA and large deletion removes an entire gene or several neighboring genes, hence alters function of the resulting protein(s) ▪ Insertion of intercalating agents into DNA molecule results in single nucleotide deletion ▪ Deletion can arise from strand slippage in DNA replication or from unequal crossing over
Diploid	Cells that carry two gametes (XX in females and XY in males)
DNA	Deoxyribonucleic acid contains the genetic instructions, which specify the biological development of all cellular forms of life
DNA polymerase	Enzyme that functions in adding new nucleotides to a growing strand of DNA during DNA replication
DNA replication	Process of duplicating a molecule of DNA
Duplication mutation	A piece of DNA is abnormally copied one or more times resulting in alteration in function of protein
Dominant	An allele that influences the appearance of the phenotype even in the presence of an alternative allele

Contd...

Table 5.1 Terminology used by geneticist (*Contd...*)

Term	Description
Epigenetics	Study of changes in the regulation of gene activity and expression that are not dependent on gene DNA sequence
Exon	Coding region of a gene (DNA), that codes for a particular translation of protein (one of the coding regions of an mRNA molecule that remain after splicing)
Expanding nucleotide repeats	Expanding nucleotide repeats are short DNA sequences that are repeated a number of times, in which the number of copies of the sequence increases
Frameshift mutation	▪ Insertion or deletion that alters the reading frame of a gene resulting in production of nonfunctional protein ▪ Reading frame consists of groups of three nucleotide bases, and each code for one amino acid ▪ Insertion, deletions and duplications can frameshift mutations
Forward mutation	Changes the wild-type phenotype to a mutant phenotype
Gain-of-function mutation	Gain-of-function mutation causes the appearance of a new trait or function or causes the appearance of a trait in inappropriate tissue or at an inappropriate time
Gene	Basic unit of genetic information determining the inherited characters (functional length of DNA that provides the genetic information necessary to build a protein)
Gene expression	Protein synthesis (gene product) is tightly controlled and regulated (active interpretation of the information coded in a gene to produce a functional gene product)
Genetic code	Combination of nucleotides that build different codons
Genome	Entire DNA content (set of chromosomes) in cell (entire complement of an organism's DNA; found within virtually every cell)
Genotype	The observed alleles for an individual's genetic constitution (DNA sequencing) at a genetic locus with respect to a single character or a set of characters
Haploid	Cells that contain a single copy of the genome (half the number of chromosomes) in replicating germ cells (gametes) such as ova and sperm during meiosis
Haplotype	Series of alleles on a single chromosome
Helicase	Enzyme that functions to separate the two DNA strands of a double helix during DNA replication
Heterozygous	Genotype with two different alleles at a locus of a gene for one trait
Histone	Family of proteins that associate with DNA in the nucleus to form chromatin
Homozygous	Genotype with two identical alleles of a gene for a single trait
In-frame deletion or insertion	Deletion or insertion of a multiple of three nucleotides that does not alter the reading frame
Incomplete linkage	Incomplete linkage occurs when crossover takes place in closely located genes (82% representing parental, while 18% recombinant)
Intron	Intron is noncoding region of a gene (DNA) present between two exons (pre-mRNA transcript) that may be removed during splicing
Insertion	▪ Addition of one or more nucleotide bases alters the number of DNA bases in a gene by adding a piece of DNA resulting in protein made by the gene, that may not function proper ▪ Insertion can arise from strand slippage in DNA replication or from unequal crossing over. Insertion of intercalating agents into DNA molecule causes single nucleotide insertion
Intragenic suppressor mutation	Intragenic suppressor mutation suppresses the effect of an earlier mutation within the same gene
Intergenic suppressor mutation	Intergenic suppressor mutation suppresses the effect of an earlier mutation in another gene
Karyotype	Orderly arrangement of photographs of chromosomes from a single cell; used in genetic counseling to identify chromosomal disorders
Lethal mutation	Lethal mutation causes premature death
Ligation	Process of joining two DNA molecule ends. It involves creating a phosphodiester bond between 3'-hydroxy of one nucleotide and 5'-phosphate of another nucleotide
Linkage disequilibrium	Allelic association when closely linked alleles are inherited together during many generations

Contd...

Table 5.1 Terminology used by geneticist (*Contd...*)

Term	Description
Locus	▪ Location of a gene on the chromosomes in genome ▪ Each locus contains two genes except for sex chromosomes
Loss-of-function mutation	Complete or partial loss of function
Non-conservative gene mutation	Replacement of one amino acid with a biochemically dissimilar amino acid
Missense mutation	A missense mutation alters the coding sequence (i.e. sense codon changes into different codon), so one amino acid is substituted for another amino acid in the protein made by a gene
Mitosis	Process by which a cell separates its duplicated genome into two identical halves
Meiosis	Process that transforms one diploid into four haploid cells
Messenger RNA (mRNA)	Nucleotide molecule that serves as an intermediate in the genetic code between DNA and protein
Molecular diagnostics	The use of DNA, RNA, mRNA to identify and /or characterize disease caused by infectious agents or gene abnormalities
Mutation	Permanent change in the genetic sequence (such as mispairing of base in DNA replication and spontaneous depurination and deamination)
Mutation rate	Mutation rate is the frequency of mutation influenced by genetic and environmental factors. Some mutations occur spontaneously
Mutagenic agents	▪ Intercalating agents insert into the DNA molecule and cause single nucleotide insertions and deletions. ▪ Oxidative reactions alter the chemical structures of bases ▪ Ionizing radiation alters nucleotide base structures and breaking phosphodiester bonds ▪ Ultraviolet light produces light pyrimidine dimers, which block DNA replication
Neutral mutation	A neutral mutation alters the amino acid sequence of a protein but does not change the function of the protein
Nonsense mutation	A nonsense mutation changes a sense codon into a nonsense codon, which altered DNA sequence causing premature termination of translation; but there is no substitution of one amino acid for another.
Nuclear envelope	Membrane that surrounds the nucleus; consisting of a double lipid-bilayer
Nuclear pore	One of the small, protein-lined openings found scattered throughout the nuclear envelope
Nucleolus	Small region of the nucleus that functions in ribosome synthesis
Nucleosome	Unit of chromatin consisting of a DNA strand wrapped around histone protein
Penetrance	Proportion of individuals of a particular genotype (allele of a gene) that express its phenotypic effect in a given environment
Phenotype	Observable characteristics of a specific gene or set of genes
Point mutation	Substitution of a single DNA base by another
Polymorphism	A variation in the base sequence of DNA
Polypeptide	Chain of amino acids linked by peptide bond
Polyribosome	Simultaneous translation of a single mRNA transcript by multiple ribosomes
Promoter of gene	Region of DNA that signals transcription to begin at that site within the gene
Proteins	Proteins are made up of amino acids
Protein expression	Different proteins are expressed in different cells according to the function of the cell
Proteome	Full complement of proteins produced by a cell (determined by the cell's specific gene expression)
RFLP (restriction fragment length polymorphism)	Variation in the size of DNA fragments generated by restriction enzymes
Recessive	An allele that influences the appearance of the phenotype only in the presence of another identical allele
Reverse mutation	Changes a mutant phenotype back to the wild-type phenotype
Ribonucleic acid (RNA)	Single-stranded nuclei acid that carries out the instructions coded in DNA

Contd...

Table 5.1 Terminology used by geneticist (*Contd...*)

Term	Description
Ribosomal polymerase	Enzyme that unwinds DNA and then adds new nucleotides to a growing strand of RNA for the transcription phase of protein synthesis
Ribosomal RNA (rRNA)	RNA that makes up the subunits of a ribosome
STR (short tandem repeats)	Short sequences of DNA, normally 2–5 nucleotide base pairs, that are repeated numerous pairs, that are repeated numerous times
Silent mutation	A silent mutation produces a sense codon into a synonymous codon, that encodes the same amino acid; there is no change in amino acid sequence of the protein
Spliceosome	Complex of enzymes that serves to splice out the introns of a pre-mRNA transcript
Splicing	Complex of enzymes that serves to splice out the introns of a pre-mRNA transcript
Suppressor mutation	Suppressor mutation suppresses the effect of an earlier mutation at a different site
Telomere	Region of repetitive DNA at the end of a chromosome
Transcription	Process during which a DNA sequence of a gene is copied to make RNA molecule
Transcriptome	Set of all RNA molecules transcribed in a cell
Transfer RNA (tRNA)	Molecules of RNA that serve to bring amino acids to a growing polypeptide strand and properly place them into the sequence
Transgene	A foreign gene that is introduced randomly somewhere in the genome
Transition	Base substitution in which a purine replaces a purine or a pyrimidine replaces a pyrimidine
Translation	Process during which a mRNA molecule is used to assemble amino acids into polypeptide chains
Transversion	Base substitution in which a purine replaces a pyrimidine or a pyrimidine replaces a purine
Triplet	Consecutive sequence of three nucleotides on a DNA molecule that, when transcribed into an mRNA codon, corresponds to a particular amino acid
VNTR (variable number of tandem repeats)	Variable number of tandem repeats of identical nucleotide sequences lined up one after another that vary in number from one individual to another

HUMAN GENOME PROJECT

Human Genome Project (HGP) was an International Scientific Research Project (1990–2003) with a goal to discover the complete set of 20,000–25,000 human genes and make them accessible for further biological study, and determine the complete sequence of three billion DNA bases in the human genome.

- **Genome sequencing:** Genome sequencing can provide nucleotide sequence of an individual's DNA. The primary purpose of genome sequencing is to determine the order of the four chemical building blocks called 'nucleotide base pairs' that make up DNA molecule; and to obtain information on medical value for future care, that can help in prevention of disease. Scientists can use DNA sequencing information to determine which stretches DNA contain genes and which stretches carry regulatory instructions, turning genes on or off.
- **Whole genome sequencing:** Whole genome sequencing can detect single nucleotide base variation, insertions/deletions, copy number changes and large structural variants. Human genome sequencing is performed by two methods: (a) the older, classical chain termination method is also known as 'Sanger method', (b) newer human genome DNA sequencing methods are high throughout sequencing (HTS) techniques or next-generation sequencing techniques, that can process a large number of DNA molecules quickly.

BASIC STRUCTURE OF DNA DOUBLE HELIX MOLECULE

Deoxyribonucleic acid (DNA) is a double helix molecule, while RNA is a single helix molecule. Both DNA as well as RNA have sets of nucleotides that contain genetic information. DNA molecule contains the instructions, an organism needs to develop, live and reproduce.

- The human genome is organized into chromosomes and wrapped in histone proteins, condensed into chromatin and arranged in nucleosomes. Histone modifications affect the chromatin state and gene expression.

- The nucleosome has 146 nucleotide base pairs surrounding the histone octamer. The chromatosome has 166 nucleotide base pairs surrounding histone octamer and binding the H1 histone. Nucleosome and chromatosome contain active genes.
- Solenoid defines the packing of DNA as a 30 nm fiber of chromatin and results from the helical winding of at least five nucleosome strands. Genes are less active in solenoid and 30 nm fiber of chromatin.
- Chromatin remains in interphase and chromosome in the metaphase. Structure of double-stranded DNA molecule is shown in Fig. 5.1. DNA packaging is shown in Fig. 5.2. Structure of histone is shown in Fig. 5.3.

NUCLEAR DNA AND MITOCHONDRIAL DNA

Nearly every cell in human body has similar DNA. Most DNA is located in the cell nucleus (where it is called nuclear DNA) having 3.2 billion nucleotide base pairs, but a small amount of circular DNA composed of 16,569 nucleotide base pairs is present in the mitochondria, where it is called mitochondrial DNA (**mtDNA**).

- Nuclear DNA has two copies of a gene per cell, while mitochondrial cell contains 100–1000 copies of a gene per cell. The mitochondrial DNA contains 2 ribosomal RNAs (rRNAs), 22 transfer RNAs (tRNAs) and 37 genes, which code for 13 proteins.

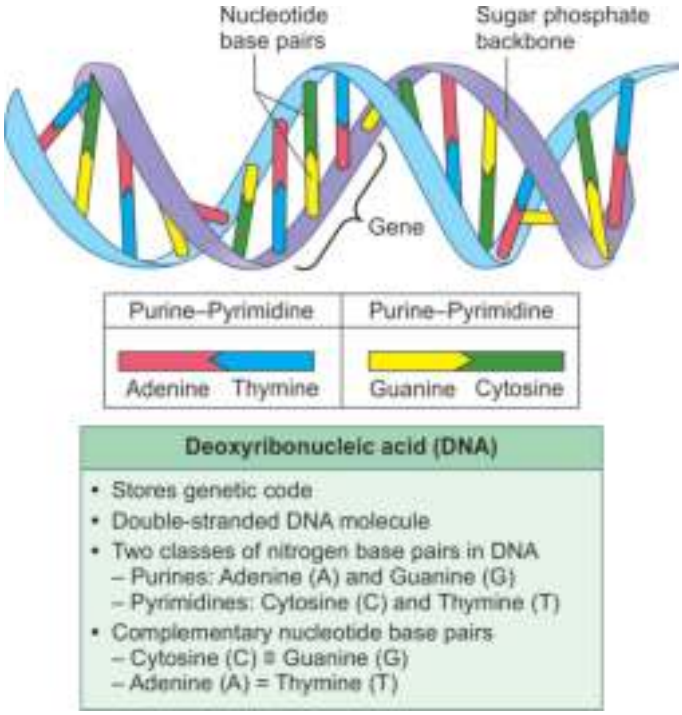

Fig. 5.1: Structure of double-stranded DNA molecule. Double-stranded DNA molecule is composed of two linear strands that run opposite to each other, or anti-parallel, and twist together. Each DNA strand within the double helix is a long, linear molecule composed of smaller units called nucleotides that form a chain.

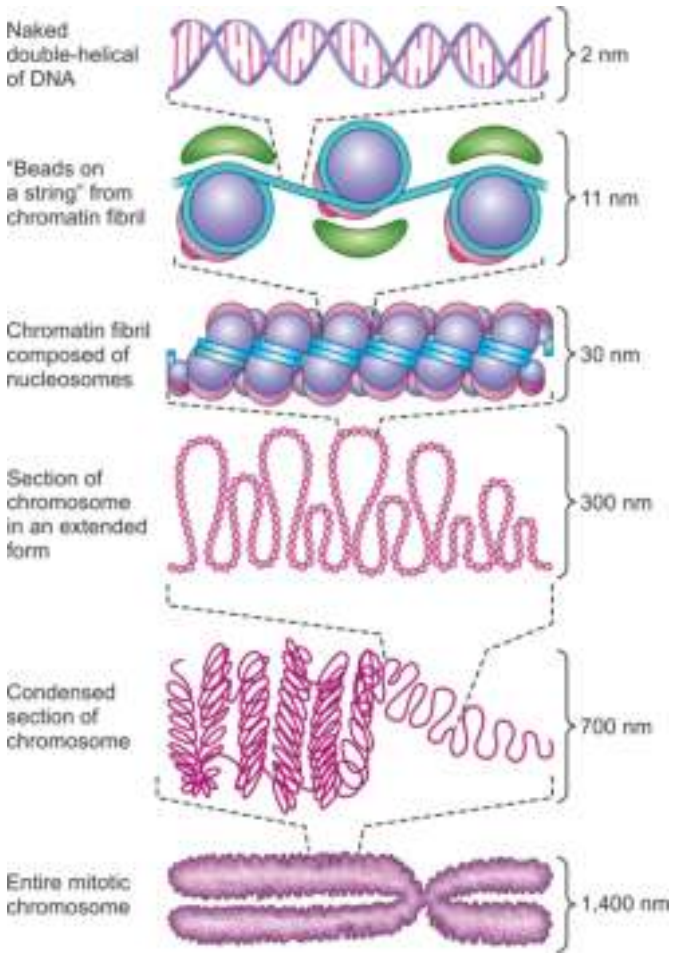

Fig. 5.2: DNA packaging. The process starts when DNA is wrapped around special positively charged protein molecules called histone octamer. The combined loop of DNA and protein is called a nucleosome (10 nm). Then nucleosomes are packaged into a thread, which sometimes described as 'beads on a string'. The end result is a fiber known as chromatin (30 nm) resulting in chromosome.

Each mitochondrion contains several copies of mitochondrial DNA.

- The codons are identical in nuclear DNA and mitochondrial DNA, except that mitochondrial DNA contains 60 codons for amino acids and 4 for stop codons. Transcription of mitochondrial DNA is continuous, as opposed to the discontinuous transcription of nuclear DNA. Comparison of nuclear and mitochondrial DNA is given in Table 5.2.

NUCLEOTIDE BASE PAIRS IN DNA

DNA molecule is composed of four chemical building blocks: adenine, guanine, cytosine and thymine. Each molecule is linked to other molecules, forming a chain.

- The DNA consists of two chains of nucleotides held together by hydrogen bonds. The purine nucleotides, adenine and guanine cross-link by hydrogen bonds to the pyrimidines, thymine and cytosine. Because

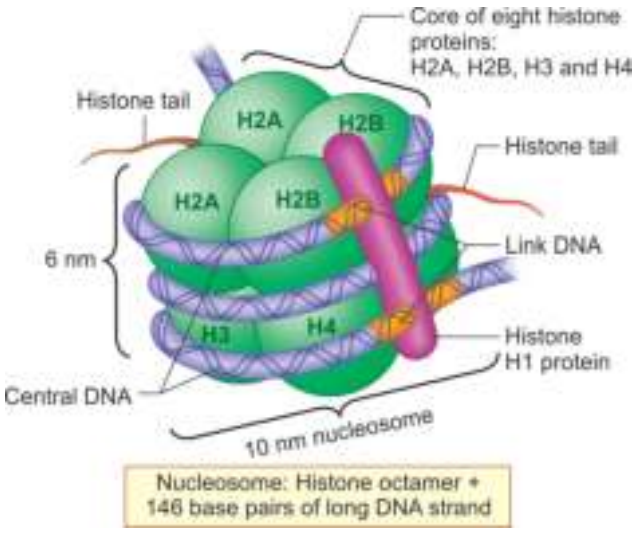

Fig. 5.3: Structure of histone. Histone is positively charged and highly basic proteins composed of amino acids, e.g. 'lysine' and 'arginine'; and found in nuclei that package and order the DNA into structural units called nucleosome. These are the chief protein components of chromatin, acting as spools around negatively charged DNA winds, and playing a role in gene regulation.

of this cross-linking, the nucleotide sequence of one strand of DNA sets the other strand's sequence.

- Separating the two DNA strands allow complementary nucleotides to bind to each DNA strand, which copies the DNA and replicates. Comparison of purine and pyrimidine is given in Table 5.3.

DEOXYRIBONUCLEIC ACID (DNA) PACKAGING

Negatively charged double-stranded DNA is coiled around a set of 8 highly basic histone proteins forming the nucleosome, which is the building block of chromatin packaging. **Histone proteins** contain '**lysine**' and '**arginine**' **amino acids**.

- Main function of the histone octamer is to compact DNA and regulates chromatin, therefore impacting gene regulation. DNA–protein complexes can be packaged by forming coils of nucleosomes, called chromatin fibers.
- The chromatin fibers are condensed into two strands of a replicated chromosome during mitosis (cell division) and visible under electron microscope.
- Chromatids connected by a centromere are called **sister chromatids**. Nonhistone proteins are additional set of proteins required for packaging of chromatin at higher level, i.e. chromatin fibers and chromosomes.
- Heterochromatin protein 1 and polycomb are common nonhistone proteins, which play a key role in regulation of gene expression.
- Both histone and nonhistone proteins provide structure to the DNA. The basic difference between histone and nonhistone proteins is in the structure they provide. Histone proteins are the spools around which DNA winds, whereas nonhistone proteins provide the scaffolding structure.

RIBONUCLEIC ACID

The structure of ribonucleic acid (RNA) is similar to DNA except that it has one strand instead of two. RNA also contains a series of four nucleotide base pairs except that one of these nucleotide base pairs is different from DNA. RNA uses a nucleotide base called uracil (**U**) (also called 5-methyl uracil) instead of thymine (**T**) in the DNA. It has ribose instead of deoxyribose. Comparison of structure of DNA and RNA is shown in Fig. 5.4 and Table 5.4.

- Messenger RNA (mRNA) records information from DNA and carries it to ribosomes for protein synthesis.
- Ribosomal RNA (rRNA) makes up about 60% of ribosomal structure. In RNA, every nucleotide

Table 5.2 Comparison of nuclear and mitochondrial DNA

Characteristics	Nuclear DNA	Mitochondrial DNA
Location of DNA	Nucleus	Mitochondria
Shape of DNA	Linear	Circular
Number of copies	2 copies per cell	100–1000 copies per cell
Number of nucleotide base pairs in DNA	3.2 billion	16,569
Number of genes	20,000 to 25,000	37
Genes code for	Majority of genome proteins	13 proteins, 2 ribosomal RNAs, and 22 transfer RNAs
Codons	Three letter sequence of mRNA nucleotides to specific amino acid, AUG is the codon for methionine; and start codons are UGA, UAA and UAG	60 codons for amino acids and 4 for stop codons
Transcription	Discontinuous	Continuous

Genetic code is universal.

Table 5.3 Comparison of purine and pyrimidine

	Purine	Pyrimidine
Main	A purine is a heterocyclic aromatic organic compound, consisting of a pyrimidine ring fused to an imidazole ring	Pyrimidine is a heterocyclic aromatic organic compound similar to benzene and pyridine, containing two nitrogen atoms at positions 1 and 3 of the six-member ring. It is isomeric with two other forms of diazine
Function	Production of RNA and DNA, proteins and starches, the regulation of enzymes and cell signaling	Production of RNA and DNA, proteins and starches, the regulation of enzymes and cell signaling
Nucleobases	Adenine and guanine	Cytosine, thymine, uracil
Structure	A pyrimidine ring fused to a imidazole ring. Contains two carbon-nitrogen rings and four nitrogen atoms	Contains one carbon-nitrogen ring and two nitrogen atoms
Melting point	214°C, 487 K, 417°F	20–22°C
Type of compound	Heterocyclic aromatic organic compound	Heterocyclic aromatic organic compound
Molecular formula	C5H4N4	C4H4N2

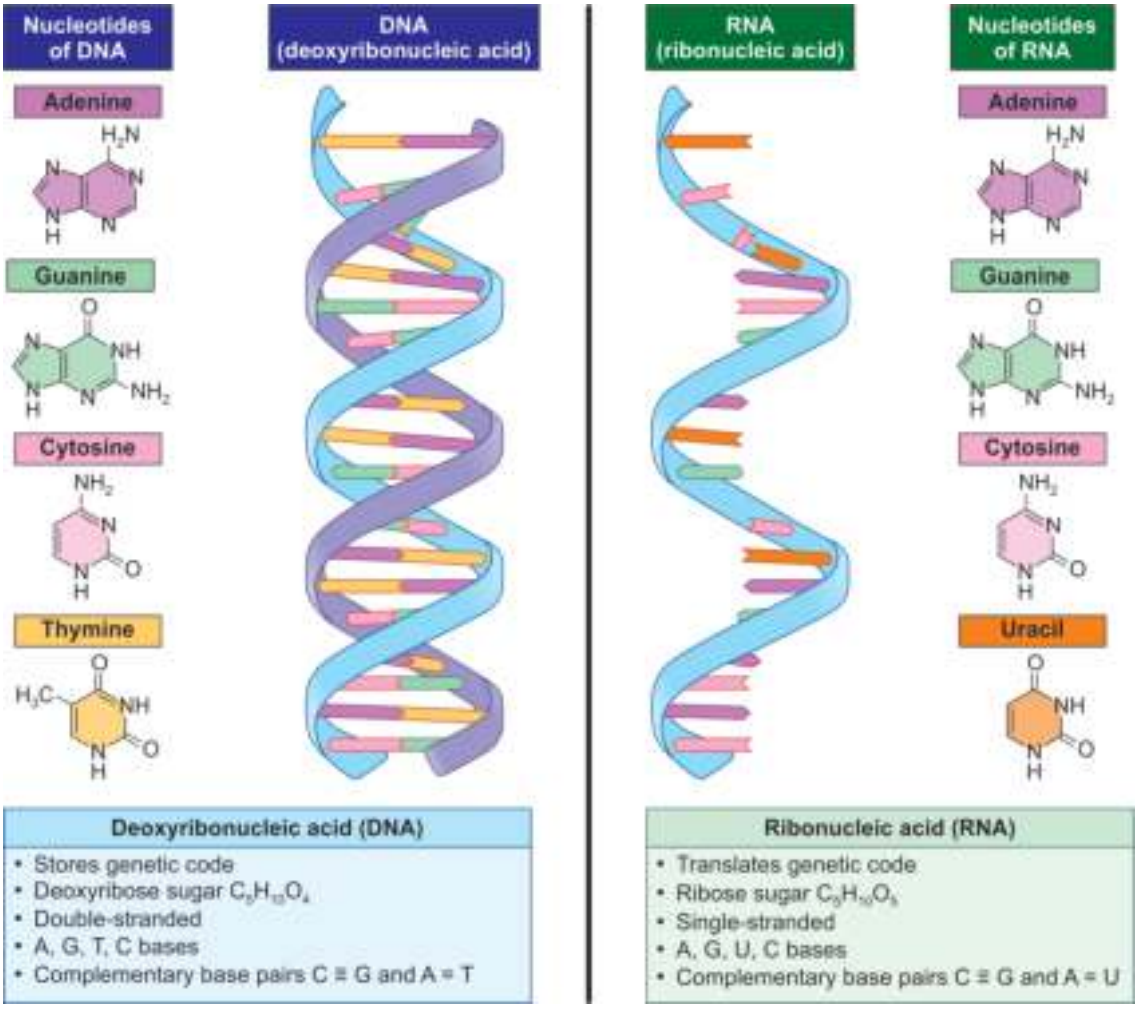

Fig. 5.4: Structure of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). DNA is double-stranded, and stores genetic code and has adenine, guanine, thymine and cytosine base pairs. Ribonucleic acid is single-stranded, and translates genetic code and has adenine, guanine, uracil and cytosine base pairs.

residue has an additional OH group present at 2′-position in the ribose. This is a reactive group and makes RNA labile and easily degradable.

- **Transfer RNA (tRNA)** delivers amino acids building blocks to proteins at the ribosome to extend the chains.

Table 5.4 Comparison of structure of DNA and RNA

Characteristics	DNA (Deoxyribonucleic Acid)	RNA (Ribonucleic Acid)
Pentose sugar	Deoxyribose	Ribose
Nitrogen bases	▪ Adenine (A)–Thymine (T) ▪ Guanine (G)–Cytosine (C)	▪ Adenine (A)–Uracil (U) ▪ Guanine (G)–Cytosine (C)
Adenine pairing	Adenine (A) pairs with thymine	Adenine (A) pairs with uracil (U)
Complementary nucleotide base pairs	C≡G, (A) = (T)	C≡G, A = U
Purine and pyrimidine ratio	Purine is equal to pyrimidine (Chargaff's rule)	Purine is not equal to pyrimidine
Structure	DNA (double-stranded) antiparallel helix	RNA (single-stranded), hairpin and loops
Stability provided to DNA	DNA is more stable and less reactive (thymine provides stability to genetic material)	RNA is less stable and more reactive (due to the presence of 2-OH group)
Genetic material	Present in all living in all organisms	Present in viruses
Length of the molecule	Quite large consisting millions of nucleotides	Short consisting of thousands of nucleotides
Location	DNA present in nucleus, nucleolus and extra-chromosomal mitochondria	Messenger RNA (mRNA) in nucleus, transfer RNA (tRNA) and ribosomal RNA (rRNA) in cytoplasm
Function(s)	DNA stores genetic information; present only in one form	▪ **Ribosomal RNA (rRNA)** makes up about 60% of ribosomal structure ▪ **Messenger RNA (mRNA)** records information from DNA and carries it to ribosomes ▪ **Transfer RNA (tRNA)** delivers amino acids building blocks to proteins at the ribosome to extend the chains
Process	Transcription	Translation
Protein synthesis	DNA dependent on RNA for synthesizing protein	RNA can directly code for the synthesis of proteins RNA is better for transmission of information
Other functions	DNA being double-stranded and having complementary strand further resists changes by evolving a process of repair	RNA is essential for life processes such as metabolism, translation and splicing, which evolve around RNA
Lifetime	Long	Short
Mutations occurrence	Slower rate	Faster rate (viruses have shorter life span)

GENETICS AND MOLECULAR BIOLOGY

Nucleus is a spherical shape organelle in human cells, that contains the genetic material. The structure of the nucleus includes nuclear bilipid membrane, 3×10^9 nucleotide base pairs of the DNA distributed over 23 pair of chromosomes, gel-like nucleoplasm and nucleolus. The nuclear pore is a protein-lined channel in the nuclear envelope that regulates the transportation of molecules between the nucleus and the cytoplasm. This is collectively known as human genome, that contains around 30,000 genes, each of which codes for one specific protein.

DNA: CHEMICAL BASIS OF HEREDITARY

Genetics is a branch of biology concerned with the study of genes. Chemical basis of hereditary is the cellular DNA. The DNA is a biological print, that carries information for the cell to live, grow and replicate; it provides consistency and variability. It is important for inheritance; coding proteins and genetic instruction guide for life and processes.

- The DNA molecule is inherited from each parent. Gene is a specific sequence of nucleotides in DNA in RNA usually located on a chromosome. Gene is the 'functional unit of inheritance' controlling the transmission and expression one or more traits by encoding specific protein.
- Humans typically have 23 pairs of chromosomes, each of which contains DNA. One of each chromosome is received from each parent. During meiosis, when gametes are formed, the pair of chromosomes are split up often recombining in the process. During reproduction, the DNA in the gametes of each parent is combined. It is the crossing over and recombination of chromosomes, which are responsible for variation.

HUMAN DNA: GENETIC UNITS

Genetic units of human DNA include: (a) nuclear DNA with around 30,000 genes, (b) mitochondrial DNA (non-nuclear) with 37 genes, (c) nitrogen base pairs in DNA/RNA, and (d) DNA double helix.

- Nucleus stores the genetic information in the form of DNA, that holds the instructions, how the cell should work. The molecules of DNA are organized into special structures called chromosomes.
- Mitochondrial DNA is transmitted almost exclusively from the mother to offspring through the ovum. Mitochondrial DNA test talks about maternal ancestors of offspring.
- Nitrogen base pair is a molecule that contains nitrogen and has the chemical properties of a base. The nitrogen base pairs in DNA are adenine (A), guanine (G), thymine (T) and cytosine (C). RNA has same nitrogen bases except uracil (U) replaces thymine (T). Hence, nitrogen bases in RNA are adenine (A), guanine (G), uracil (U) and cytosine (C).
- A DNA molecule consists of two strands that wind around each other like a twisted ladder. Both strands of double-stranded DNA stabilized by hydrogen bonds between nucleotides, store the same biological information, which is replicated when the two strands of DNA separate. A large part of DNA (more than 98% for human beings) is noncoding, meaning that these sections do not serve as patterns for protein sequences. Genetic units of human DNA (deoxyribonucleic acid) are given in Table 5.5.

Table 5.5 Genetic units of human DNA (deoxyribonucleic acid)

Nuclear DNA

- Diploid genome (two sets of chromosomes)
- DNA packed in 23 pairs of chromosomes
- Homologous chromosomal pairs 22 (autosomes)
- Sex chromosomes (XX or XY)
- Nucleotide base pairs 3.2 billion
- Approximately 30,000 genes

Mitochondrial DNA (Non-nuclear DNA)

- Nucleotide base pairs (16,569)
- Approximately 37 gene
- Higher gene mutation rate
- Naturally occurring polymorphisms (128)
- Maternal inheritance

Nitrogen Bases of DNA and RNA

- Purines
  - Adenine (A) present in both DNA and RNA
  - Guanine (G) present in both DNA and RNA
- Pyrimidines
  - Cytosine (C) present in both DNA and RNA
  - Thymine (T) in DNA
  - Uracil (U) in RNA (thymine replaced by uracil)
- Hydrogen bonds can form between a purine and pyrimidine
- Watson-Crick pairing: A = T, G = C

DNA Double Helix Molecule

- Nucleotide base pairs
  - Adenine 'A' always binds to thymine 'T' in DNA
  - Adenine 'A' binds to uracil 'U' in RNA
  - Cytosine 'C' always binds to guanine 'G' in DNA and RNA
- DNA double helix molecules are oriented in opposite directions
- 5' End is beginning of DNA strand
- 3' End is the end of DNA strand

HUMAN CHROMOSOMES

Deoxyribose nucleic acid (DNA) molecule is tightly coiled around histones, packaged into thread-like structures called chromosomes in the cell nucleus.

- Human genome is made up of 23 chromosome pairs for a total of 46 chromosomes with a total about three billion DNA base pairs.
- Twenty-two of these chromosomal pairs are called **autosomes**, which look similar in both males and females. The 23rd chromosomal pair, the sex chromosomes X or Y, differ between males and females.
- Males have 22 chromosomal pairs of autosomes and one pair of sex chromosome (XY). Females have 22 chromosomal pairs of autosomes and one pair of sex chromosome (XX). Chromosomes are numbered roughly in order of decreasing in size.
- Each pair consists of two chromosomes that are alike in size and structure and carry information for the same characteristics. Sister chromatids are copies of a chromosome held together at the centromere. Each chromosome has a centromere and telomeres.
- Telomeres are the specific DNA sequences and associated proteins located at the tips (ends) of whole linear chromosomes. The centromere is a constricted region of the chromosome where the kinetochores form and the spindle microtubules attach.
- Haploid term refers to half the number of chromosomes in germ cells (23).
- Diploid term refers to two sets of chromosomes organized in homologous pairs found in non-germ cells (46). Structure of human chromosome is shown in Fig. 5.5. Terminology used for number of chromosomes in the cell is given in Table 5.6.

AUTOSOMES

Chromosomes other than the sex chromosomes are referred to autosomes. Human genome contains total of

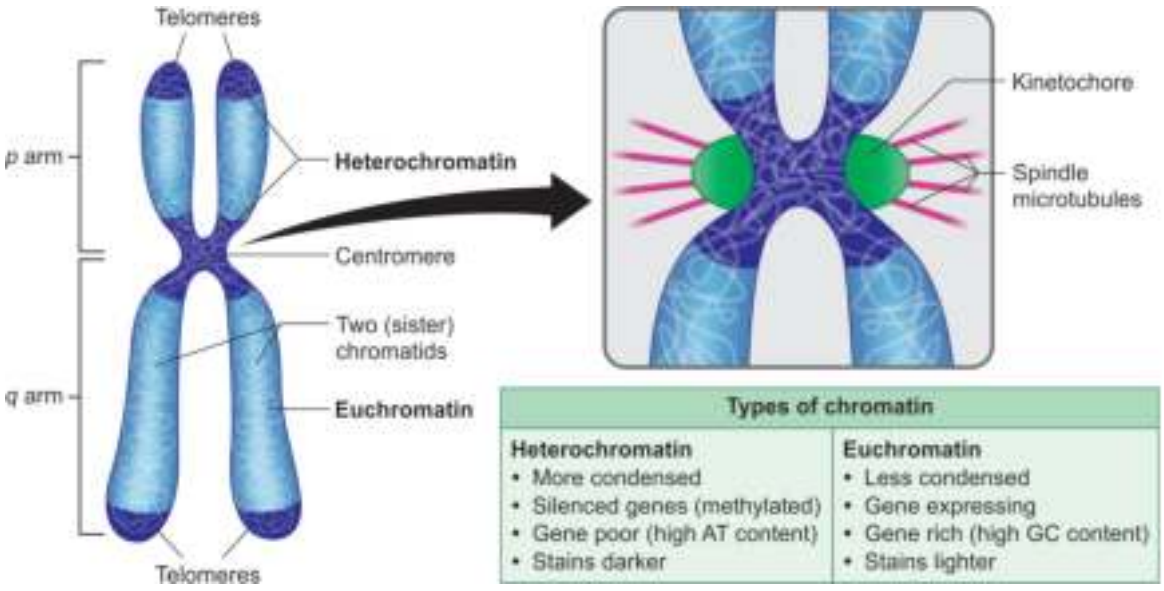

Fig. 5.5: Structure of human chromosome. Each cell normally contains 23 chromosomal pairs (total 46), i.e. 22 chromosomal pairs of autosomes and one chromosomal pair called sex chromosomes (XX, XY).

Table 5.6 Terminology used for number of chromosomes in the cell

Term	Characteristics
Haploid cell	Half the number of chromosomes in germ cells (23)
Diploid cell	Two sets of chromosomes organized in as homologous pairs found in non-germ cells (46)
Triploid cell	Number of chromosomes three times the haploid number (69)
Tetraploid cell	Number of chromosomes four times the haploid number (92)
Trisomy	Three copies of the same chromosome

46 chromosomes. Normal diploid cells have two copies of each autosome and two sex chromosomes either XX for females or XY for males. **Autosomes** are **homologous chromosomes**, which contain the same genes (regions of DNA) in the same order along chromosomal arms. Comparison of autosomes and sex chromosomes is given in Table 5.7.

Chromosome Morphology

The morphology of chromosomes can be best studied at the metaphase or anaphase of mitosis, when these are present as definite organelles, being most condensed or coiled.

- Chromosomes range, on an average from 0.5 to 30 μm in length and 0.2 to 3 μm in diameter. Variation in size of the chromosomes can be induced by a number of environmental factors. Cells dividing at low-temperature have shorter and more compact chromosomes than those dividing at higher temperature.

Table 5.7 Comparison of autosomes and sex chromosomes

Characteristics	Autosomes	Sex Chromosomes
Determines	Somatic traits	Gender
Copy of chromosomes	Males and females contain the same copy of autosomes	Males and females contain different copy of sex chromosomes, their size and behavior
Labelled with numbers from	1 to 22	XY, ZW, XO and ZO
Number of chromosomes in human genome	Majority of chromosomes	Few chromosomes
Chromosomes	22 pairs of autosomes are homologous in human beings	Female sex chromosomes (XX) are homologous; male sex chromosomes (XY) are nonhomologous
Position of the centromere	Identical	Not identical
Mendelian inheritance exhibits	Present	Absent
Number of genes	200 to 2000	X chromosome contains more than 300 genes; Y chromosome contains only a few chromosomes

- Colchicine, an alkaloid interferes with spindle formation and cell division resulting in shortening of the chromosomes. Rapid and repeated cell division results in smaller chromosomes, which appear because rate of cell division proceeds more rapidly than the formation of chromatic material as usual.
- Shape of the chromosome changes from phase to phase during cell division. In the resting phase of the cell, the chromosomes occur in the form of thin, coiled, elastic and contractile, thread-like structures, the chromatin threads.
- The position of centromere varies from chromosome to chromosome and it provides different shapes to the chromosomes. Eukaryotic chromosome can be divided into four major types based on the position of the centromere: metacentric, submetacentric, acrocentric, and telocentric.
  - Metacentric chromosomes are V-shaped and have centromeres in the center and forming two equal arms (1, 3, 16, 19, 20, X).
  - Submetacentric chromosomes are L-shaped and have centromere in the center and forming two equal arms (2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 17, 18).
  - Acrocentric chromosomes are J-like in shape, and have the centromere at one end thus giving a very short arm and exceptionally long arm (13, 14, 15, 21, 22, Y).
  - Telocentric chromosomes are rod-like in shape and have the centromere on the proximal end. Grouping and characteristics of chromosomes are given in Table 5.8.

Chromosome Structure

Functional chromosome contains the chromatids, centromere, secondary constrictions, nucleolar organizers, telomeres and satellites. The kinetophore is the multiprotein point of attachment for the spindle microtubules.

Chromatids

Chromosomes contain the genetic material of the cell. During metaphase after DNA replication, each chromosome is composed of two identical sister chromatids, which are held together by protein-mediated linkages. The chromatids are held together at a point along their length in the region of constriction of the chromosomes. The behavior of chromatids differs between mitotic and meiotic cells.

Centromere

Each chromosome contains one centromere, primary constriction, which is the specialized DNA sequence of a chromosomal locus that ensures delivery of one copy of each chromosome to each daughter cell during cell division. If there is no centromere, the cell cycle would not proceed.

- During mitosis or meiosis, spindle fibers attach to centromere via the kinetophore, the protein complex assembled at each centromere, which serves as the major point of contact between spindle microtubules and chromosomes.
- Kinetophores contain 50 different proteins, which take part in regulating and controlling their own interaction with spindle microtubules, verification of

Table 5.8 Grouping and characteristics of chromosomes

Group	Chromosomes	Characteristics	Location of Centromeres
Group A	1, 2, 3	Large metacentric chromosomes	Exactly in the middle of chromosome
Group B	4, 5	Large submetacentric chromosomes	Subterminal region dividing chromosome into short arm (p) and long arm (q)
Group C	6, 7, 8, 9, 10, 11,12 and X	Medium-sized submetacentric chromosomes	Subterminal region dividing chromosome into short arm (p) and long arm (q)
Group D	13,14,15	Large acrocentric chromosomes	Eccentrically located dividing chromosome in very short arm (p) and large long arm (q) capped by a telomere
Group E	16,17,18	Medium-sized acrocentric chromosomes	Eccentrically located dividing chromosome in very short arm (p) and large long arm (q) capped by a telomere
Group F	19, 20	Short metacentric chromosomes	Exactly in the middle of chromosome
Group G	21, 22 and Y	Short acrocentric chromosomes	Eccentrically located dividing chromosome in very short arm (p) and large long arm (q) capped by a telomere

1. French word petit meaning short is used to denote short arm of chromosome as 'p'.
2. Distal end of the chromosome is called telomere.
3. The centromere is a constriction at which the chromatids are joined.
4. Metacentric chromosomes (1, 3, 16, 19, 20, X), submetacentric chromosomes (2, 4, 5, 6, 7, 8, 9, 10, 11, 12, 17, 18) and acrocentric chromosomes (13, 14, 15, 21, 22, Y).

anchoring, activation of the spindle checkpoint and generation of force to propel chromosome movement during cell division.

- Unattached kinetophores act as signal generator for mitotic checkpoint, which arrest mitosis until all kinetophores have correctly attached to spindle microtubules, thereby representing the cell cycle control mechanism protecting against loss of a chromosome (aneuploidy).
- In addition to the primary constriction or centromere, the arms of the chromosome may show one or more secondary constriction on the long arms of chromosomes 1, 10, 13, 16 and Y nucleolar organizers.

Telomeres

Telomeres are the stabilizing ends of a chromosome. Telomeres are tandem repeat DNA nucleotide sequences (TTAGGG) present at the tips of human chromosomes, that prevent their degradation or fusion with neighboring chromosomes, thus stabilize the genome and structural integrity during cell division.

- Telomeres progressively shorten throughout life. The greatest period of telomere shortening occurs during the first four years of life.
- Telomeres are crucial for the survival of cancer cells. Telomerase are maintained by an enzyme called telomerase in the vast majority of malignancies.

Euchromatin and Heterochromatin

Euchromatin and heterochromatin are two major categories of chromatin and heterochromatin.

- Euchromatin constitutes over 90% of human genome and has loose chromatin structure and active for transcription.
- Heterochromatin constitutes for 10% of human genome and has condensed chromatin structure and is inactive for transcription. There are main types of heterochromatin, which include constitutive and facultative heterochromatin.
  - Constitutive heterochromatin refers to the regions of DNA in the chromosome present throughout the cell cycle and does not code for proteins.
  - Facultative heterochromatin is the region of the DNA, in which the genes are silenced by modifications. Therefore, the genes are only activated under certain conditions and not present throughout the cell.
- Comparison of mitosis and meiosis is given in Table 5.9. Comparison of euchromatin and heterochromatin is given in Table 5.10.
- Comparison of constructive and facultative heterochromatin is given in Table 5.11.

Chromosome Banding Techniques

New banding techniques have been introduced for staining of chromosomes by which distinct patterns of stained bands and highly stained inter-bands become evident. These staining methods are important to identify the overall morphology of the chromosomes.

- **G-banding:** G-banding or Giemsa banding is a diagnostic technique used in cytogenetics to produce a visible karyotype by staining condensed chromosome. G-bands appear in the regions which are rich in sulfur-rich proteins. Giemsa-banding technique is employed in detection of genetic disorders through photographic representation of the entire chromosome complement. Giemsa-stained preparations are more permanent, and require ordinary microscopy optics and illumination.
- **Q-banding:** Introduction of quinacrine mustard has brought revolution in cytogenetics. Fluorochrome band technique using quinacrine produces a yellow fluorescence of different intensity (Q-bands) on exposure to the ultraviolet light.
  - The regions of chromosome rich in adenine and thymine get stained intensely.
  - The guanine-cytosine regions of chromosome remain unstained. These regions are called Q-bands.
  - Q-banding technique allows price identification of the different chromosome pairs and also the

Table 5.9 Comparison of mitosis and meiosis

Characteristics	Mitosis	Meiosis
Type of reproduction	Asexual reproduction (regeneration of the skin's epithelial cells)	Sexual reproduction (fertilization)
Number of cell divisions	Single cell division	Two-cell division
Chromosome pairing	Chromosome pairing absent	Chromosome pairing present
Resulting number of chromosomes	Diploid cells with the same number of chromosomes as the parent cell has	Haploid cells with half of the chromosomes that the parent cell has
Crossing over	No crossing over; homologous chromosomes remain	Crossing over occurs to provide genetic variation
Genetic information	Identical genetic information as the parent cells	Genetic differences when compared to the parent cells

Table 5.10 Comparison of euchromatin and heterochromatin

Characteristics	Euchromatin	Heterochromatin
Constitutes in human genome	Over 90% of human genome	10% of human genome
Location	Present near center of the nucleus	Present near periphery of nucleus
Packaging of DNA in the chromosomes	Loosely packed hence less condensed	Tightly packed hence more condensed
Staining pattern	Stains lighter due to the loose packaging (visible during cell division)	Stains darker due to the densely packed chromatin regions
DNA density	DNA density low	DNA density high
Genes	▪ Gene expression present ▪ Gene rich (higher in GC content)	▪ Gene expression absent (silenced genes-methylated) ▪ Gene poor (higher AT content)
Heteropycnosis (variable staining of chromosomes)	Variable staining of chromosomes absent	Variable staining of chromosomes present
Genetically	Active	Inactive
Tasks	Protecting of the integrity of gene to the handling or processes like regulation of gene	Transcription of the DNA of the DNA to the mRNA products
Transcription state (protein synthesis)	Transcriptionally inactive protein	Transcriptionally active protein

Table 5.11 Comparison of constructive and facultative heterochromatin

Characteristics	Constitutive Heterochromatin	Facultative Heterochromatin
Stability	Stable	Reversible
Constituents	Satellite DNA	Lines sequences
Polymorphism	Present	Absent
C bonds	Present	Absent

identification of structural chromosome rearrangements such as deletions, duplications, inversions (pericentric or paracentric), and aneuploidy (monosomy or trisomy).

- **C-banding:** C-banding is a diagnostic technique used in cytogenetics in which chromosomes are treated with strong alkaline sodium hydroxide followed by warm saline and then stained with Giemsa stain. C-bands are evident around the centromere and in other chromosomes that stain highly repetitive constitutive heterochromatin.
- **R-banding:** R-banding is a cytogenetic technique that produces the reverse of the G-band stain on chromosomes. Chromosomes on slides are incubated in phosphate buffer at high-temperature and stained with Giemsa stain. R-bands correspond to the regions on chromosomes having proteins lacking sulfur.

SEX CHROMOSOMES

A sex chromosome X or Y determines sex of person. Human beings have two sex chromosomes: X and Y chromosomes.

- Females have two XX chromosomes in their cells inherited from parents, while males have both X and Y chromosomes in their cells.
- Males inherit X chromosome from their mothers and Y chromosome from their fathers. The pseudoautosomal regions (**PAR1** and **PAR2**) of human X and Y chromosomes pair and recombine during meiosis. Therefore, genes in this region are not inherited in a strict sex-linked fashion.
- PAR1 region is located at the terminal region of short arms, and PAR2 region at the tips of the long arms of these chromosomes. Comparison of X and Y chromosomes in XX and YY genotypes is shown in Fig. 5.6 and Table 5.12.

X Chromosome

The X chromosome is five times bigger than Y chromosome, and contains 155 million nucleotide base pairs, 1000 genes, large amount of euchromatin and small amount of heterochromatin. SRY gene is absent in X chromosome.

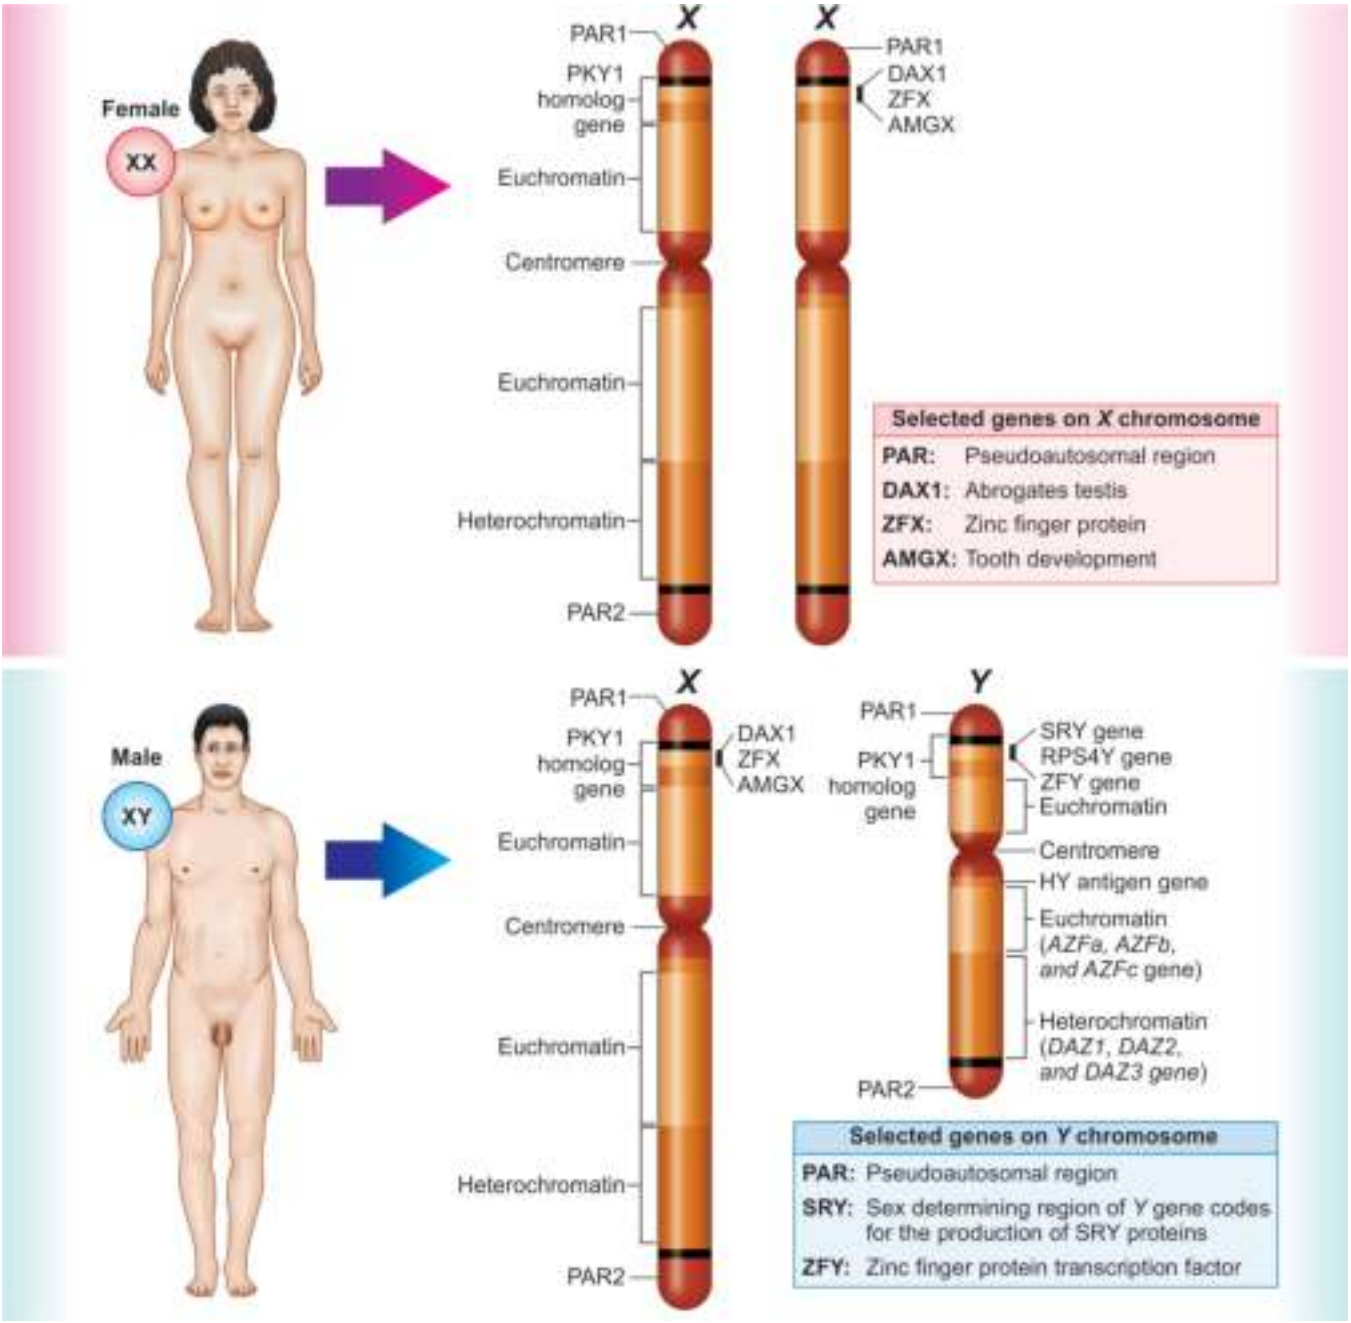

Fig. 5.6: Comparison of X and Y chromosomes in XX and YY genotypes.

- Genes on X chromosome give instructions to make protein. X chromosome represents 5% of the entire human genome. Each person normally has one pair of sex chromosomes in each cell.
- Early during embryonic development in females, one of the two X chromosomes is randomly and permanently inactivated in cells other than ovum. This phenomenon is called X-inactivation or lyonization.
- X chromosome ensures that females, like males, have one functional copy of the X chromosome in each cell. Some genes located at the ends of X chromosome escape inactivation, and such region on X chromosome is called pseudoautosomal region. Many genes located in pseudoautosomal region of X chromosome are essential for normal development.

Y Chromosome

Human Y chromosome has about 59 million nucleotide base pairs, i.e. the building blocks of DNA, which constitutes 2% of total DNA in male cell. Y chromosome contains 70 genes, which code for only

Table 5.12 Comparison of X and Y chromosomes in XX and YY genotypes

XX Genotype	XY Genotype
Female sex determination (XX genotype)	Male sex determination (XY genotype)
XX inherited from both parents	X inherited from mother
Large size chromosome	Small size chromosome
Genes (100) with 155 million nucleotide base pairs	Genes (70) with 59 million nucleotide base pairs
Constitutes 5% of human genome in females	Constitutes 1% of human genome in males
Pseudoautosomal regions (PAR1, PAR2) present	Pseudoautosomal regions (PAR1, PAR2) present
Sex determining region on Y (SRY) gene absent	Sex determining region on Y (SRY) gene present
ZFY (zinc finger protein-transcription factor) present	ZFY (zinc finger protein-transcription factor) present
PKX1 (protein kinase X-linked) gene present	PKX1 (protein kinase X-linked) gene present
Euchromatin large and heterochromatin small	Euchromatin small and heterochromatin large

1. X and Y chromosomes show several regions of homology in addition to pseudoautosomal regions (PAR1, PAR2). A crossover in PAR1 is essential in make meiosis to get proper segregation of chromosomes.
2.Relative few genes are functional on the Y chromosome, reflecting the limited somatic role of the Y chromosome, except for male-specific functions including spermatogenesis.
3. AZFa, AZFb and AZFc regions are deleted in azoospermia. The AZFc is located at the distal part of deletion interval 6 (subintervals 6C–6E) on the Y chromosome. While the AZFa and AZFb regions are essential in initiating spermatogenesis, the AZFc region is essential to complete the process of spermatogenesis.

Table 5.13 Genes on Y chromosomes involved in spermatogenesis

AMEY gene (codes for tooth enamel protein)
ANT3 gene (codes for adenine nucleotide translocase 3)
AZF1 gene (codes for azoospermia factor 1)
BRY2 (basic protein on the Y chromosome)
CSF2RA gene (codes for colony stimulating factor 2 receptor/ hematopoiesis)
DAZ1 gene (deleted in azoospermia resulting in male infertility)
DAZ2 gene (deleted in azoospermia resulting in male infertility)
IL-3RA gene (codes for interleukin 3 receptor)
MHC2 gene
PBDY gene spanning the pseudoautosomal boundary)
PRKY gene (codes for protein kinase, Y-linked)

Contd...

RBMY1A1 gene
SMCY putative gene for H-Y antigen
RPS4Y gene (codes for ribosomal protein subunit of low trans-criptional activity)
SRY gene (sex determining region)
STS gene (codes for steroid sulphatase)
TSPY gene (codes for testis-specific protein Y)
USP9Y gene
UTY (ubiquitously transcribed TPR gene on Y chromosome)
ZFY gene (codes for zinc finger protein-transcription factor)

Relative few genes are functional on the Y chromosome, reflecting the limited somatic role of the Y chromosome, except for male-specific functions including spermatogenesis.

23 proteins. Y chromosome is acrocentric and smaller than X chromosome.

- Y chromosome is unable to recombine with X chromosome, except for small pieces of pseudo-autosomal regions at the telomeres; which comprise about 5% of the chromosomes.
- The bulk of Y chromosome, which does not recombine is called 'NRY' or nonrecombining region of the Y chromosome. Y chromosome provides important roles in human males involving sex determination and spermatogenesis.
- Study of specific genes on Y chromosome important for spermatogenesis may allow the opportunity for new treatments for infertile men.
- Y chromosome provides important roles in human males involving sex determination and spermato-genesis. Study of specific genes on Y chromosome important for spermatogenesis may allow the opportunity for new treatments for infertile men. Genes on Y chromosomes involved in spermato-genesis are given in Table 5.13. Disorders of X and Y chromosomes are given in Table 5.14.

Table 5.14 Disorders of X and Y chromosomes

Disorders of X Chromosome
Paroxysmal nocturnal hemoglobinuria (PIG-A)
Menker's syndrome (MTP)
Alport's syndrome
Immunodeficiency with hyper-IgM
Adrenoleukodystrophy
Ocular albinism
Duchenne muscular dystrophy (DMD)
Retinitis pigmentosa
X-linked cleft palate
Fabry disease
Lesch-Nyhan syndrome
Hemophilia B
Hemophilia A (HEMA)
X-linked manic depressed illness
Color blindness
X-linked severe combined immunodeficiency (SCID)
Fragile X syndrome
Rett syndrome (MECP2)
Disorders of Y Chromosome
Azoospermia (AZFa, AZFb, AZFc gene deletion)
Microdeletion of Y-chromosome
Inborn errors of metabolism
Congenital adrenal hyperplasia
Alagille syndrome
α_1-Antitrypsin deficiency
Hereditary angioedema
Ataxia-telangiectasia

Contd...

THE NUCLEUS AND DNA REPLICATION

The nucleus is the small, round, largest and most prominent organelle in a cell, which consists of nuclear membrane, nucleoplasm, nucleolus and network of chromatin fibers packed in the form of chromosomes within DNA.

- Nucleus controls the cell, as it stores genetic instructors for manufacturing proteins. Muscle cells contain more than one nucleus.
- Mature red blood cells lack nuclei for making space for the large numbers of hemoglobin molecules. Without nuclei, the life span of red blood cells is short, and so the bone marrow must produce new ones constantly.
- Inside the nucleus lies the blueprint stored within DNA, that dictates cells to manufacture protein products. Every cell in the body except germ cells, contain the complete set of DNAs.
- When a cell undergoes division, the DNA must be duplicated so that each new cell receives a full complement of DNA.

ORGANIZATION OF THE NUCLEUS AND ITS DNA

Like most other cellular organelles, the nucleus is surrounded by a membrane called the nuclear membranous envelope made up of bilipid layer a thin fluid space in-between them. Spanning the nuclear membranes are nuclear pores.

- Nuclear pores allow small molecules (RNA, ribosomal proteins) and ions to freely pass, or diffuse, into or out of the nucleus; and also permit necessary proteins to enter the nucleus from the cytoplasm. If the proteins have special sequences that indicate that the proteins belong to the nucleoplasm. Inside the nuclear envelope, gel-like nucleoplasm is present, that contains solutes and building blocks of nucleic acids. A dark staining region in the center of nucleus is nucleolus most often visible under light microscope called a nucleolus.
- The nucleolus manufactures the components of ribosomes, which exit the cell's nucleus through the nuclear pores to the rest of the cell, where components of ribosome combine to form complete ribosome. Strands of DNA are wrapped around supporting histones. These proteins are increasingly bundled and condensed into chromatin, which is packed tightly into chromosomes when the cell is ready to divide. It is estimated that human beings have almost 22,000 genes distributed on 46 chromosomes. Structure of the nucleus is shown in Fig. 5.7.

DNA REPLICATION

When the cell divides, the two new daughter cells must contain the same genetic information (DNA), as the parent cell. The process of **duplication of DNA** is

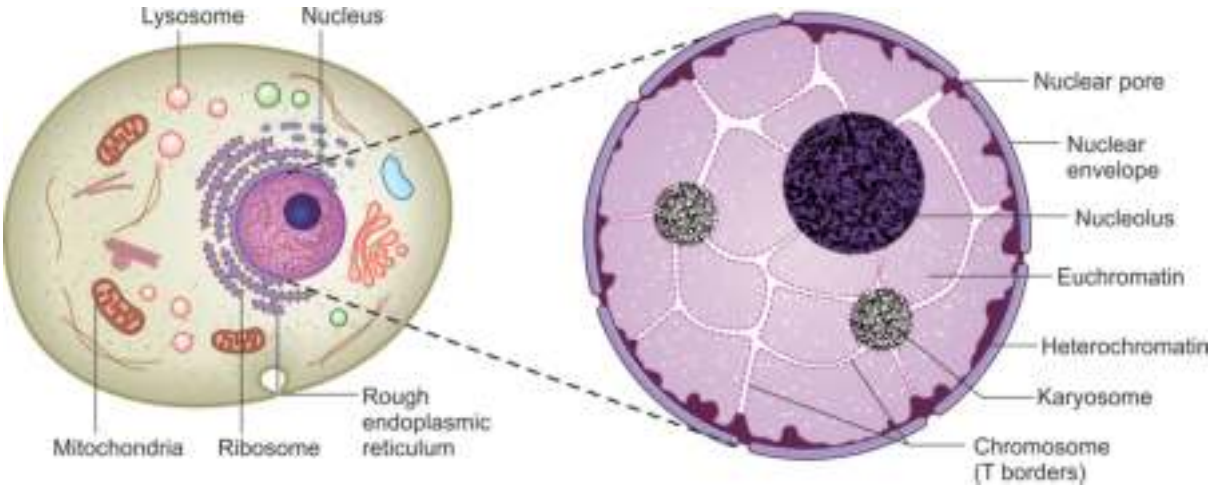

Fig. 5.7: Nuclear structure and organization. The nucleus is the control center of the cell. The nucleus of living cells contains the genetic material that determines the entire structure and function of that cell. The nuclear envelope surrounds the nucleus. Euchromatin is located near the center and heterochromatin is located near the periphery. Nuclear pores are specific portals of entry and exit to and from the nucleus. Transcription factors are regions where transcriptional complexes assemble with DNA and where transcription occurs. The nuclear matrix is a network of several proteins that add structure and support to the nucleus.

known as DNA replication, in which a double-stranded DNA molecule splits into its two single-strands during cell division. It is essential for cell division during growth, development and repair of damaged tissues.

- DNA replication is controlled by the Watson-Crick pairing of the nucleotide base pairs in the template strand with incoming deoxynucleoside triphosphates, and is directed by DNA polymerase enzymes. It is a complex process, particularly in eukaryotes, involving an array of enzymes such as helicase, gyrase, primase, DNA polymerase III, DNA polymerase I and ligase.
- Billions of new cells are produced in an adult human every day except permanent cells such as nerve cells, skeletal muscle and cardiac muscle. Cell division time of different cells varies. Three categories of cells are labile, stable and permanent cells.
  - Labile cells multiply continuously in various tissues such as epidermis, the mucosal layer of the internal hollow organs, bone marrow or seminiferous tubules of the testes.
  - Stable cells multiply only when needed. They spend most of the time in the quiescent G0 phase of the cell cycle and can be stimulated to enter the cell when required. Examples of stable cells include the liver, the proximal tubules of the kidney and endocrine cells.
  - Permanent cells are incapable of regeneration. Stable cells are considered to be terminally differentiated and hence do not proliferate in postnatal life such as neurons, cardiac muscle fibers, skeletal muscle fibers.
- Double-stranded DNA molecule take the shape of a long-twisted ladder. Each molecule of DNA is a double helix formed from two complementary strands of four types of nucleotide subunits help together by hydrogen bonds between adenine–thymine (A–T) and guanine–cytosine (G–C) base pairs with a 'sugar-phosphate backbone'. Adenine always binds with thymine, and cytosine always binds with guanine. The particular sequence of the nucleotide base pairs along DNA molecule

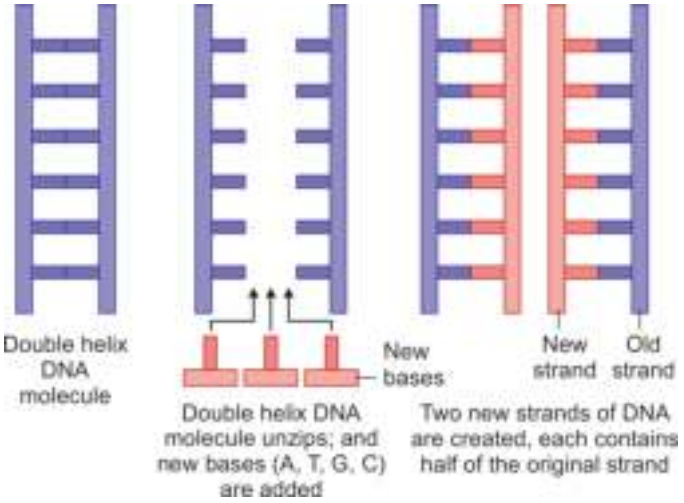

Fig. 5.8: DNA replication process creating of two new strands. DNA replication is semiconservative process, in which each strand in the DNA double helix acts as a template for the synthesis of a new, complementary DNA strand. In this process, newly formed double helix contains one new and one old strand. The sequence of the bases encodes genetic information. The three steps in this process of DNA replication are initiation, elongation and termination.

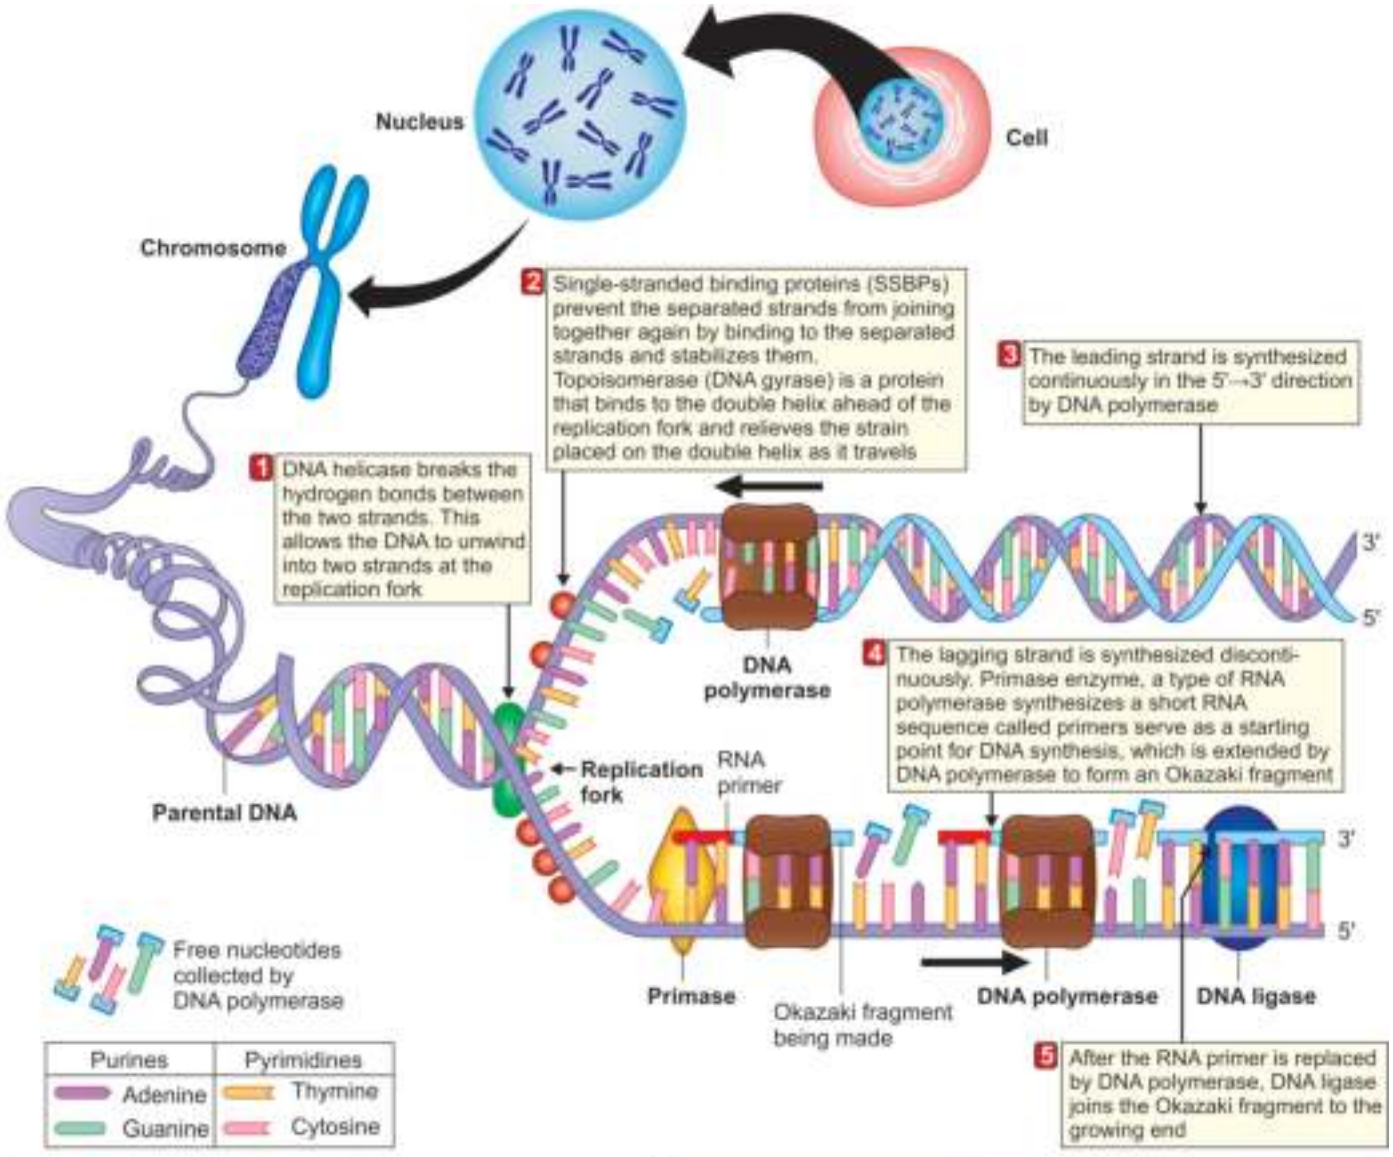


DNA replication

- Each of the nitrogenous bases can only pair with its partner (A—T and G—C). A purine (adenine and guanine) must base pair with a pyrimidine (cytosine and thymine).
- Each new strand contains one original and one new strand; therefore, DNA replication is said to be semiconservative and depends on complementary base pairing.
- Two new strands formed will be identical.

Free nucleotides

- Free nucleotides (deoxynucleotide triphosphates) are formed in the ribosomes of a cell, that make up the DNA and RNA.
- Four different types of DNA nucleotides include: adenine (A), thymine (T), guanine (G) and cytosine (C).
- Free nucleotides are collected by DNA polymerase and attached to the new strand by complementary base pairing.
- The extra phosphate groups carry energy, which is used for the formation of covalent bonds.

DNA polymerase

1. DNA polymerase 3 is essential for DNA replication of the leading and the lagging strands. DNA polymerase 1 is essential for removing of the RNA primers from the fragments and replacing it with the required nucleotides. These enzymes cannot replace each other as both have different functions to be performed.
2. DNA polymerase moves in 5'→3' direction.
3. DNA polymerase moves in opposite directions on each strand.
4. DNA polymerase links nucleotides together to form a new strand, using the pre-existing strand as a template.
5. DNA polymerase catalyzes the covalent phosphodiester bonds between sugars and phosphate groups.
6. DNA polymerase proof reads the complementary base pairing.
7. DNA polymerase uses 3'→5' exonuclease activity to remove the incorrectly inserted nucleotides from the 3' end of the new strand during polymerization.

Fig. 5.9: DNA replication process creating of two new strands. DNA replication duplicates the entire genome of the cell by number of DNA enzymes.

determines the DNA's instructions or genetic code. Duplication of the genetic information occurs by the use of one DNA strand as a template for the formation of a complementary strand. If one strand of DNA molecule has a region with the sequence AGTGCCT, then the sequence of the complementary strand would be TCACGGA.

- DNA is packed into tightly coiled structure called chromatin, which loosens prior to DNA replication, allowing the cell replication machinery to access the DNA strands.
- DNA replication process creating of two new strands is shown in Figs 5.8 and 5.9. Enzymes involved in DNA replication are given in Table 5.15.

Table 5.15 Enzymes involved in DNA replication

Enzyme in DNA Replication	Function
DNA helicases	▪ DNA helicase proteins bind to the double-stranded DNA and unwinds its strands by breaking hydrogen bonds down the center of strands ▪ DNA single-stranded binding proteins bind to the DNA as a tetramer and stabilize the single-stranded structure that is generated by the action of the helicases ▪ DNA replication is 100 times faster when these proteins are attached to the single-stranded DNA
DNA gyrase (also called topoisomerase)	▪ DNA gyrase relieves the buildup of torque (tension due to supercoiling of DNA) during unwinding and prevents DNA breakage ▪ DNA gyrase enzyme catalyzes the formation of negative supercoils and is thought to aid with the unwinding process ▪ There are two types of DNA strands: leading and lagging strands. • Leading strand or template strand (sense strand or also called coding strand): the strand which supports the continuous DNA synthesis is called as leading strand • Lagging strand or noncoding strand (antisense strand) is replicated in a discontinuous manner in short stretches (also known as 'Okazaki fragments')
RNA primase	▪ A free 3'-OH group is required for DNA replication ▪ RNA primase helps in synthesis of a free 3'-hydroxyl group at the initiation sites by laying down RNA primers
DNA polymerase III	DNA polymerase III is main enzymes involved in DNA synthesis with 3'→5' exonuclease activity (proofreading activity), that participates in proofreading and allows the incorrect base pair to be excised
DNA polymerase I	DNA polymerase I replaces RNA primers with DNA and repairs and damage with DNA; and also serves to connect Okazaki fragments by deleting RNA primers and replacing the strand with DNA
DNA ligase	▪ DNA ligase facilitates the sealing (joining) of DNA strands together by catalyzing the formation of a covalent phosphodiester linkage between 3'-hydroxyl and 5'-phosphate groups. and fills in the gap ▪ RNA editing may also take place before translation begins ▪ Genetic message is carried by mRNA moves out of nucleus into cytoplasm for translation and converts into polypeptide sequence of amino acids
Telomerase	Lengthens telomeric DNA by adding repetitive nucleotide sequences to the ends of chromosomes. This allows germ cells and stem cells to avoid Hayflick limit on cell division

1. Single-stranded binding protein (SSBP) stabilizes the separated DNA strands and prevent their re-association, so that each strand can serve as a template for new DNA synthesis.

2. Purified DNA ligase is used in gene cloning to join DNA molecules together to form recombinant DNA.

3. The Hayflick limit concept states that a normal human cell can only replicate and divide 40–60 times before it cannot divide anymore and will break down by apoptosis.

Pathology Pearls: DNA Replication Process

- DNA replication is the process by which DNA makes a copy of itself during cell division. During DNA replication, double helix structure of the DNA is unzipped by helicase enzyme, which breaks the hydrogen bonds holding the complementary bases of DNA together (adenine with thymine, cytosine with guanine). The separation of the two strands of DNA creates a 'Y' shape called a DNA replication fork.
- One of the strands of DNA molecule is oriented in the 3'→ 5' direction (towards the replication fork) called 'leading strand'. The other strand is oriented in the 5'→ 3' direction (away from the replication fork) called 'lagging strand'. As a result of their different orientations, the two strands (i.e. leading and lagging strands) are replicated differently.
- DNA polymerase binds to leading strand and then walks along it, adding new complementary nucleotide bases (adenine, cytosine, guanine and thymine) to the strand of DNA in 5'→ 3' direction. This sort of DNA replication is known as continuous.
- Primase enzyme also synthesize numerous RNA primers at various points along the lagging strand. The primer acts as the starting point for DNA synthesis. Chunks of DNA, called Okazaki fragments, are then added to the lagging strand also in 5'→ 3' direction. Once all of the nucleotide base pairs are matched (A with T, C with G), exonuclease enzyme strips away the primer(s). These gaps created by stripping away of primer(s) are then filled by more complementary nucleotides. Proofreading of new strand ensures no mistake in the new DNA sequence.
- Finally, DNA ligase enzyme seals up the sequence of DNA into tow continuous double-strands. The result of DNA replication is two DNA molecules consisting of one new and one old chain of nucleotides.
- That is the reason that DNA is described as semiconservative, half of the chain is part of this original DNA molecule and half is a brand new. Following DNA replication, the new DNA automatically winds up into double helix.

DNA REPLICATION: PHASES

In order to fit within a cell's nucleus. DNA is packed into tightly coiled structures called chromatin, which loosens prior to DNA replication machinery to access the DNA strands.

- DNA replication faithfully duplicates the entire genome of the cell. During DNA replication, a number of **different enzymes** work together to pull apart the two DNA strands, so each DNA strand can be used as a template to synthesize new complementary strands.
- The two new daughter DNA strands are formed, each contains one pre-existing strand and one newly synthesized strand. Thus, DNA replication is said to be "**semiconservative**". Three main steps in DNA replication include initiation, elongation and termination.

DNA Replication: Initiation Phase

The two complementary strands of DNA molecule are separated, much like unzipping a zipper.

- DNA helicase uses ATP to break hydrogen bonds between complementary nucleotide base pairs resulting in separation of two polynucleotide strands of DNA. The separation of the two single-strands of DNA creates a 'Y' shape called a replication fork.
- Single-stranded binding protein (**SSBP**) stabilizes the separated DNA strands and prevent their re-association, so that each DNA strand can serve as a template for new DNA synthesis. SSBP also fasten DNA replication 100 times.
- The stress produced by supercoiling of double helix DNA is released by DNA gyrase (also called topoisomerases) resulting in prevention of DNA breakage. During DNA replication, the leading strand is synthesized continuously in the 5′→ 3′ direction by DNA polymerase.
- DNA polymerase catalyzes the covalent phosphodiester bonds between sugars and phosphate groups. DNA polymerase links free nucleotides (i.e. deoxynucleoside triphosphates) and proofreading of complementary base pairing to new DNA strand, consequently mistakes are very infrequent occurring approximately once in every billion pairs. The lagging DNA strand is synthesized discontinuously by forming short segments known as Okazaki fragments.

DNA Replication: Elongation Phase

During elongation of DNA replication, the leading DNA strand is made continuously in the 5′→ 3′ direction, while the lagging DNA strand is made in pieces called Okazaki fragments.

- Okazaki fragments prevent elongation in the 3′→5′ direction. Each DNA strand becomes a template along which a new complementary strand is built. DNA polymerase catalyzes the elongation of DNA strand in the 5′→ 3′ and brings in the correct nucleotide base pairs to complement the template DNA strand, synthesizing a new strand base by base.
- DNA polymerase is an enzyme that adds free nucleotides to the end of a chain of DNA, making a new double-strand. This growing DNA strand continues to be built until it has fully complemented the template strand.

DNA Replication: Termination Phase

Termination of DNA replication occurs when replication forks converge on the same stretch of DNA, after DNA polymerase completes transcription of sequences

in DNA and gaps of backbone of double-stranded DNA are filled in and ligated and catenanes (**interlocked compounds**) are removed.

- DNA ligase repairs irregularities or breaks in the double-stranded DNA molecules, seals recombination fragments and connects Okazaki fragments (small DNA fragments formed during replication of double-stranded DNA).
- DNA replication is stopped with the creation of two new identical DNA molecules. Each new DNA molecule contains one strand from the original molecule and one newly synthesized strand. Thus, **DNA replication** is said to be 'semiconservative', because half of the original DNA molecule is conserved in each new DNA molecule. DNA replication takes place precisely, so that new cells in the body contain exact same material as their parent cells.
- Errors made during DNA replication, such as accidental addition of inappropriate nucleotide base pairs and formation of mismatch nucleotide base pairs resulting in formation of dysfunctional gene and genetic disease.

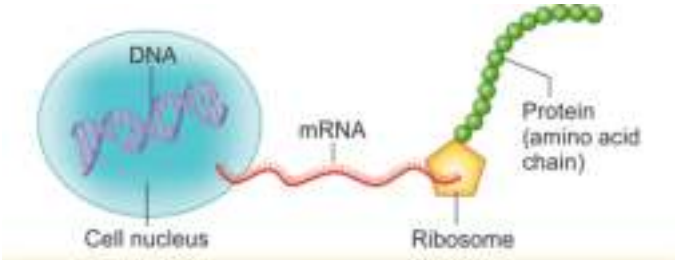
GENE EXPRESSION, TRANSCRIPTION, TRANSLATION AND PROTEIN FOLDING

DNA contains the information to synthesize proteins essential for the cell structure and function. Protein is the basic component of living cells, that is made up of carbon, hydrogen, oxygen, nitrogen and one or more chains of amino acids.

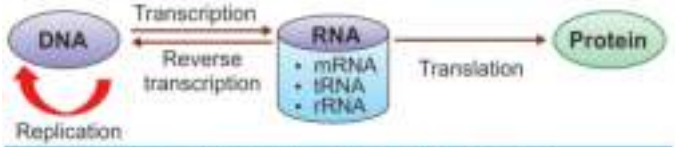
- DNA replication is the process by which a double-stranded DNA molecule is copied to produce two identical DNA molecules during cell division. Two new daughter cells must contain the same genetic information (DNA) as the parent cell. A gene is expressed through the processes if transcription and translation.
- During transcription, the enzyme RNA polymerase uses DNA as a template to produce a pre-messenger RNA (pre-mRNA). The pre-messenger RNA is processed to form a mature messenger RNA (mRNA) molecule, which leaves the nucleus and attaches to ribosome and translates to produce polypeptide chains of amino acids and then protein molecule by the original gene.
  - Transcription is the process of making an RNA copy of a gene sequence called primary RNA transcript that gets a cap added to the 5′ end and undergoes polyadenylation and splicing to produce messenger RNA (mRNA).
  - The mature messenger RNA leaves the cell nucleus and enters the cytoplasm, where it directs the synthesis of the protein molecules, which it encodes.
  - Transcription involves ribosomal RNA (rRNA), transfer RNA (tRNA), messenger RNA (mRNA), and various enzymes.
  - Ribosomal RNA (rRNA) constitutes 60% of ribosome, that is used to manufacture ribosomes.
  - Messenger RNA (**mRNA**) carries DNA sequence information to ribosomes in the cytoplasm. Transfer RNA (**tRNA**), the smallest structure decodes information and carries amino acids to the ribosomes; and hence provides linkage between mRNA and amino acids' transfer amino acids to ribosomes.
- Proteins provide structure and support to the cells and transport hormones. One of the most important classes of proteins is enzymes, which accelerate necessary biochemical reaction that take place inside the cell. Most genes contain the information required to construct functional molecules are called proteins. A few genes make other molecules that help the cell to assemble proteins. The journey from gene to protein synthesis is tightly controlled within each cell.
- Together, transcription and translation are known as gene expression. Protein synthesis takes place in cellular structures is called ribosome, found outside the nucleus. DNA alone cannot account for the expression of genes. RNA is needed to help out the instructions in DNA. The process by which genetic information is transferred from the nucleus to the ribosomes is called transcription.
  - DNA alone cannot account for expression of genes. RNA is needed to help in carrying out of the instructions in DNA. Like DNA, RNA is made up of nucleotide consisting of a 5′-carbon ribose, a phosphate group and a nitrogen base. Three main differences between DNA and RNA include: (a) RNA is generally single-stranded instead of double-stranded, (b) RNA uses the sugar ribose instead of deoxyribose, and (c) RNA contains uracil in place of thymine.

- The sequence of four nucleotide base pairs in a gene (purines: adenine–guanine and pyrimidines: cytosine–thymine) covalently linked to a phosphodiester backbone, translates to an amino acid sequence.
- There are 1200 nucleotide base pairs present in the double-stranded DNA. Three nucleotides are called a triplet or codon that codes for one particular amino acid in the protein. The nucleotide sequence in the DNA transcribed into a molecule of messenger RNA (ribonucleic acid). The mechanism by which cells turn the DNA to code for a protein product, which is a two-step process, with an RNA molecule and the intermediate product.

- Protein synthesis in human involving DNA replication, transcription and translation is shown in Fig. 5.10. Transcription and translation are shown in Figs 5.11 and 5.12. Reverse transcription of DNA from RNA is shown in Fig. 5.13. Comparison of DNA replication and gene transcription is given in Table 5.16. Comparison of transcription and translation in human cell is given in Table 5.17.



Gene expression: DNA replication, transcription and translation



Gene expression (DNA→RNA→Protein)	
• DNA replication	DNA→DNA copy occurs in nucleus.
• Transcription	DNA→mRNA occurs in nucleus, then mRNA moves on to ribosomes into the cytoplasm for translation.
• Translation	Protein synthesis occurs in cytoplasm (mRNA transcript is decoded into protein with the help of a ribosome and tRNA).
Human genome contains around 30,000 genes, each gene codes for one protein.	

Fig. 5.10: Protein synthesis in human involving DNA replication, transcription and translation. Human genome contains around 30,000 genes, each gene codes for one protein. The process by which DNA is copied to RNA is called transcription and that by which RNA is used to produce proteins is called translation.

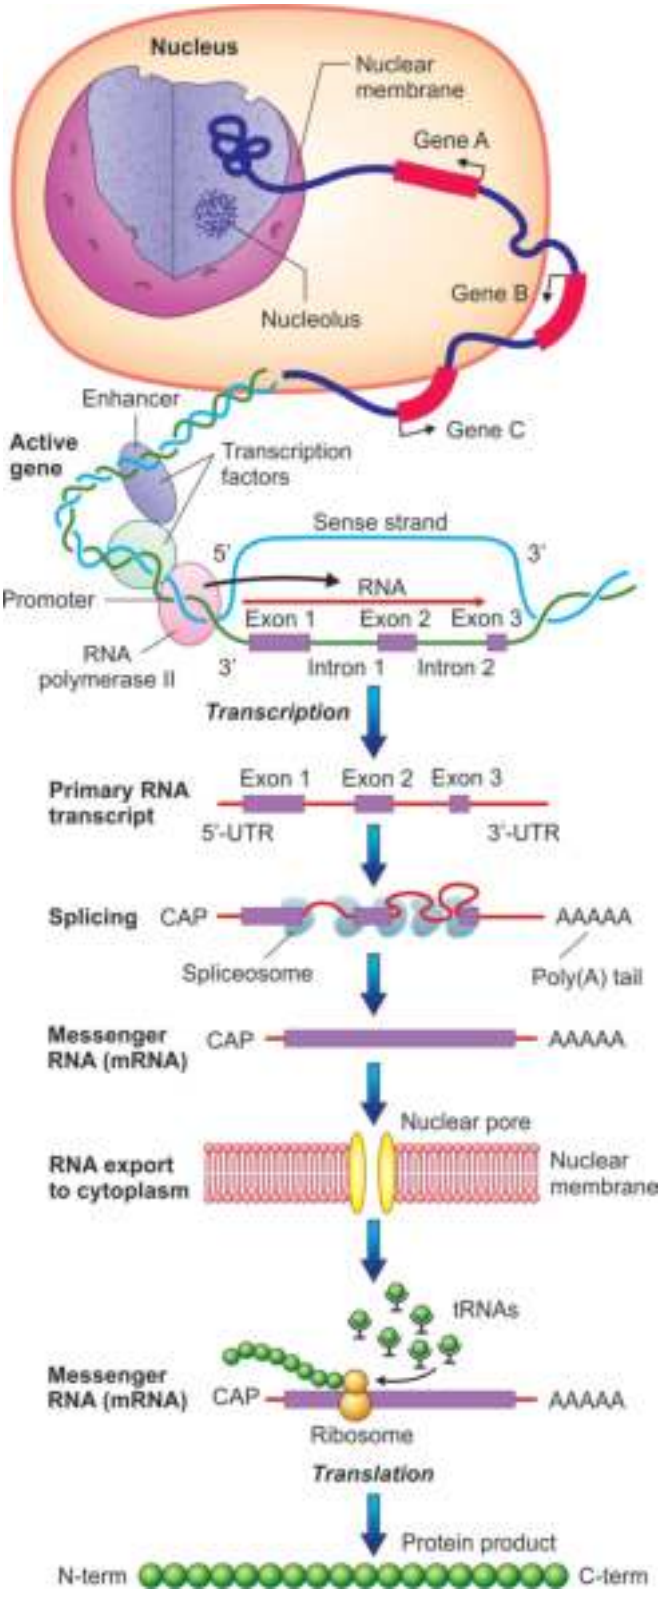


Fig. 5.11: Transcription and translation (RNA synthesis and its translation into protein in the cytosol). Transcription process yields a primary RNA transcript that gets a cap added to the 5' end and undergoes polyadenylation and splicing to produce messenger RNA (mRNA). Following transport of mRNA to the cytoplasm, mRNA is translated in the cytosol to protein molecules.

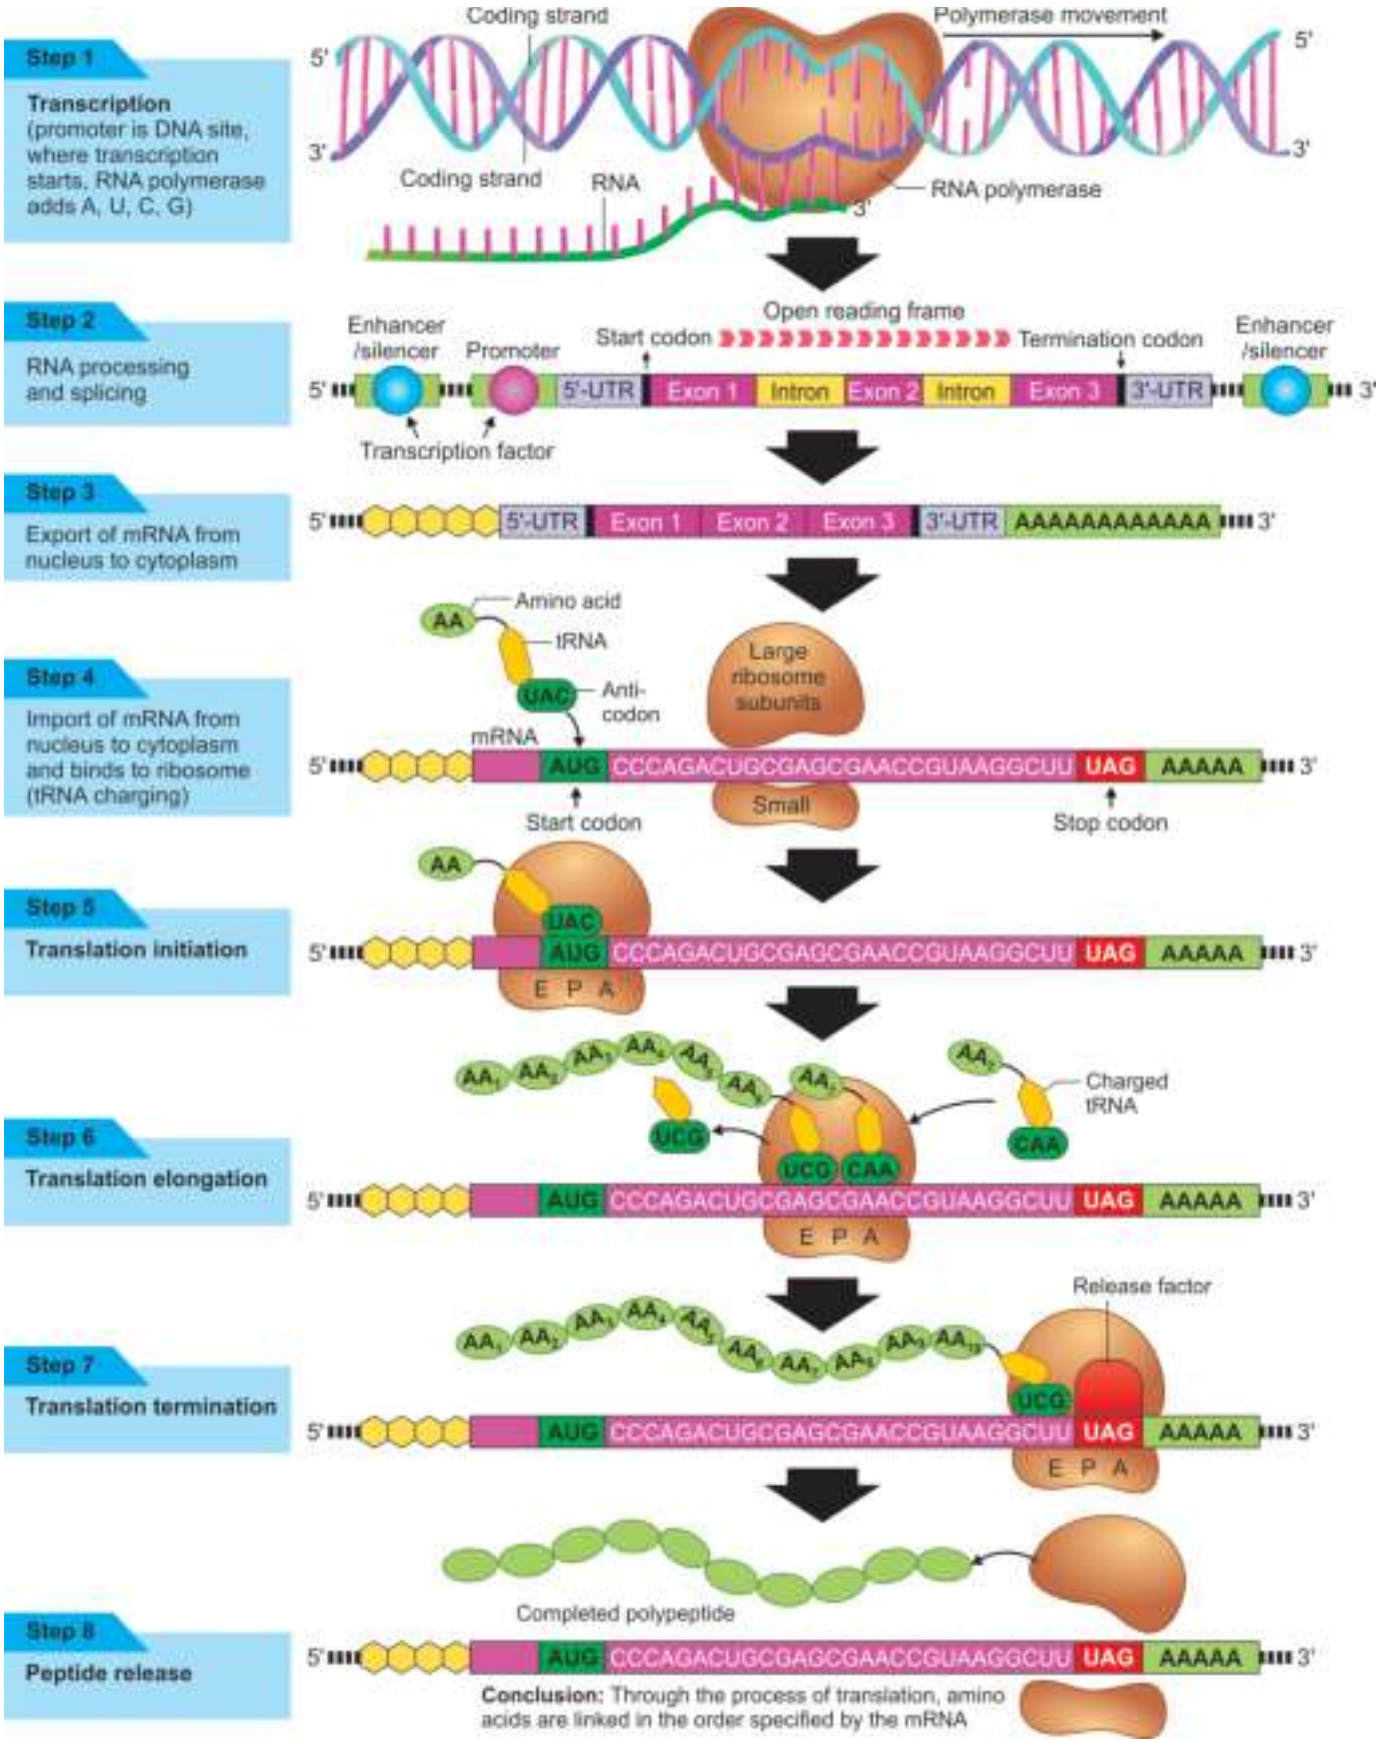

Fig. 5.12: Transcription and translation. Schematic representation demonstrates the process by which DNA is copied to RNA is called transcription, and that by which RNA is used to produce proteins is called translation.

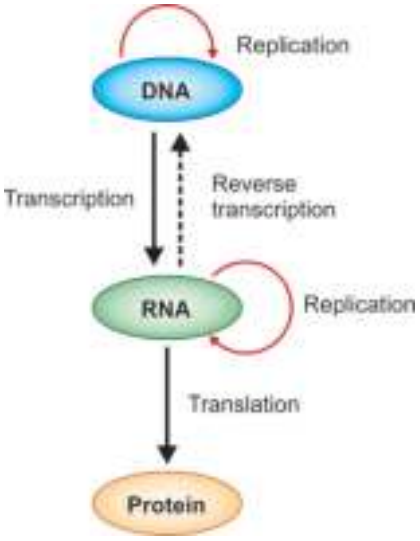

Fig. 5.13: Reverse transcription of DNA from RNA. A reverse transcriptase is an enzyme present in RNA virus, used to generate complementary DNA (cDNA) from an RNA template, a process is known as reverse transcription. DNA transcript of the RNA is incorporated into the genome of the cell, possibly altering permanently its behavior and potentially leading to tumor formation. Retroviral reverse transcriptase has three sequential biochemical activities: RNA-dependent DNA polymerase activity, ribonuclease H (RNase-H), and DNA-dependent RNA polymerase activity.

Pathology Pearls: Reverse Transcription Polymerase Chain Reaction (RT-PCR)

- Reverse transcription polymerase chain reaction (RT-PCR) is a technique to generate a complementary strand of DNA (cDNA) from single-stranded ribonucleic acid (RNA) template by transcriptase enzyme. Process involves three steps: denaturation, annealing and elongation.
- Denaturation is done by heating the DNA sample to separate it into two strands.
- The process permits exponential amplification of a desired sequence by using DNA primers that anneal to the sequence of interest. A heat-tolerant DNA polymerase (Taq) copies the strands results in elongation. Real-time or quantity, polymerase chain reaction detects the PCR amplification during their synthesis, and is more sensitive and quantitative than conventional PCR.
- The combination of reverse transcription polymerase chain reaction (RT-PCR) allows the detection of low abundance RNAs in a sample blood, semen, tissue, hair on crime scene and production of the corresponding complementary DNA (cDNA), thereby facilitating the cloning of low copy genes. One cycle of PCR yields two identical copies of the DNA sequence. A standard reaction of 30 cycles would yield 1,073,741,826 copies of DNA.

Table 5.16 Comparison of DNA replication and gene transcription

Characteristics	DNA Replication	Transcription
Function	▪ Making of DNA copy for a 'daughter cell' ▪ Synthesis of an identical DNA copy	▪ Making of RNA copy of a gene, copy of gene is called messenger RNA (mRNA) ▪ Synthesis of RNA using DNA as a template
Enzymes	DNA helicase, DNA polymerase, DNA ligase	DNA helicase, DNA polymerase
Nucleotides	dUMP, dCMP, dAMP, dGMP	UMP, CMP, AMP, GMP
Occurrence (happens in cell cycle phase)	▪ S phase of cell cycle ▪ Along both leading and lagging DNA strands ▪ Preparation for cell division	▪ G1 and G2 phase of cell cycle ▪ Along one template DNA strand ▪ Preparation for gene expression
Bonding	Copied DNA bonded to template	Copied RNA dissociates from DNA template
Requiring primer or not	RNA primer required	RNA primer not required
Products	▪ Deoxyribonucleic acid (DNA) molecules ▪ Double-strands bonded to original strands ▪ Stays within nucleus ▪ Product not degraded	▪ Ribonucleic acid (RNA) molecules ▪ mRNA exported to the cytoplasm ▪ mRNA exported to the cytoplasm ▪ Product degraded after performing work
Copying	Entire genome (all chromosomes)	Individual gene only
Unwinds or unzips	Entire DNA molecule	Only DNA with gene to be transcribed
Post-copy processing	DNA ligase joins Okazaki fragments	RNA 'editing/processing' splicing of noncoding 'introns' and joining of coding sequence 'exons'

Table 5.17 Comparison of transcription and translation in human cell

Characteristics	Transcription Process	Translation Process
Step of gene expression process	First step of gene expression process involving synthesis of RNA from DNA	Second step of gene expression process involving synthesis of proteins from RNA, which are copied from genes
Components	DNA, RNA polymerase core enzyme	mRNA, small and large ribosomal subunits, initiation factors, elongation factors, tRNA
Template	DNA (genes in human gene)	mRNA (messenger RNA)
Enzymes	RNA polymerase	Ribosome enzyme that contains ribosomal RNA (rRNA) and proteins
End product	RNA (production of several functional forms of RNA)	Protein
Location	Template is the genes in the nucleus	Template is the messenger RNA on rough endoplasmic reticulum in cytoplasm
Controlling factor	RNA polymerase	Ribosomes and ribosome complex
Production	Several functional forms of RNAs	Production of proteins
Main events in each stage of transcription and translation	▪ **Initiation:** Initially, RNA polymerase binds to the promoter region of DNA, DNA is denatured. Complementary ribonucleosides are inserted, joined by phosphodiester bonds ▪ **Elongation:** The RNA strand begins to separate from the DNA template strand ▪ **Termination:** A termination sequence signals the RNA to form a hairpin secondary structure, before dissociating from the DNA	▪ **Initiation:** Small and large ribosomal subunits and tRNA attach to mRNA ▪ **Elongation:** Two additional charged tRNA molecules attach to the mRNA; their amino acids bind and the next tRNA attaches ▪ **Termination:** GTP-dependent release factors lease the last amino acids in the polypeptide chain from the tRNA, before the tRNA is released

Salient Features: Transcription, Translation and Protein Folding

Transcription Process

- DNA in nucleus serves as a template for transcription. Gene transcription involves binding of RNA polymerase II to the promoter of genes being transcribed with other proteins (transcriptional factors) that regulate the transcriptional rate. Messenger RNA (mRNA) is processed before leaving the nucleus.
- The pre-messenger RNA (primary RNA transcript) is a copy of the whole gene and includes introns and exons. In the nucleus, a structure is called a spliceosome cuts out introns (noncoding regions) with in pre-mRNA transcript and reconnects the exons to form the mature messenger RNA (mRNA).
- Prior to its exit from the nucleus, a methylated guanosome nucleotide is added to the 5' end of the RNA (cap) and a string of adenine nucleotides are added to the 3' (poly(A) tail). This process protects the mRNA from degradation and facilitates transport into the cytoplasm.

Translation Process

- During translation, the mRNA transcript is "read" by a functional complex consisting of the ribosome and tRNA molecules. tRNAs bring the appropriate amino acids in sequence to the growing polypeptide chain by matching their anti-codons with codons on the mRNA strand.
- Messenger RNA (**mRNA**) moves into cytoplasm and becomes associated with ribosomes and the ribosome moves down the mRNA reading the sequence of nitrogen bases.
- Messenger RNA (mRNA) carries message from DNA to ribosomes in cytoplasm. Triplets (3) of nucleotides on the mRNA constitute a **codon sequence** that codes for a protein.
- Transfer RNA (**tRNA**) is involved in the next stage of protein synthesis, i.e. translation.
- AUG codon on messenger RNA (mRNA) is the **initiator codon**. AUG binds to the **P site** of the ribosome. AUG helps align the tRNA, the mRNA, and the ribosome and then signals the beginning of the gene to be expressed.
- Transfer RNA (**tRNA**) carry amino acids to mRNA. Each tRNA has an **anticodon** that binds to a complementary **codon** on the mRNA. Anticodons codon-codon complementary base pairing occurs.
- The 2nd transfer RNA (**tRNA**) molecule binds to the 2nd codon of the mRNA and a di-peptide is formed. The 1st transfer RNA (**tRNA**) is released from the E site of the ribosome.
- Translation process continues until a nonsense 'stop codon' (UAA, UGA, UAG) tells the ribosome that protein synthesis is complete.
- The **codons** from mRNA have now been translated into polypeptide, i.e. one amino acid at a time.
- The mRNA, polypeptide, tRNA, and ribosome disassemble. Polypeptide enters its lumen, where the polypeptide folds and is modified further.

Protein Folding in Endoplasmic Reticulum

- After translation, next step is folding of polypeptide in the endoplasmic reticulum.
- Signal recognition particle binds to signal peptide on the endoplasmic reticulum.
- Signal recognition particle (SRP) attaches to receptor; translocation channel opens; polypeptide enters into lumen of endoplasmic reticulum.
- A signal peptidase removes the signal peptide. Ribosome units and mRNA break away. Protein folds into final shape.

CENTRAL DOGMA OF BIOLOGY

A gene that encodes a polypeptide is expressed in two steps. In this process, information flows from DNA → RNA → protein, a directional relationship is known as the **central dogma of molecular biology**.

Concept: Central Dogma of Molecular Biology

- Central dogma describes the flow of genetic information from DNA → RNA → proteins
- One gene: one polypeptide
- Transcription: DNA → RNA
- Translation: RNA → protein

GENETIC CODE

Genetic code is the term used to the four nucleotide bases of DNA—adenine (A), cytosine (C), guanine (G), and uracil (U) are strung together in the cell and the ribosome can read them and turn them to potein. In the genetic code, three nucleotides present in a row are called triplets or codons that encodes single amino acid. Schematic representation of genetic code is shown in Fig. 5.14.

- The first step in decoding genetic information is transcription, during which a nucleotide sequence is copied from DNA to RNA. Second step is to join amino acids together to form a protein. The order in which amino acids are joined determine the properties, shape and function of a protein.
- Most of the amino acids are encoded by more than one codon. The code is based on sets of DNA bases and universal from bacteria to human. There are 64 possible base triplets and only 20 amino acids.
- Out of 64 codons, 61 codons code for amino acids, while 3 codons do not code for any amino acids;

Genetic Code

First base of codon	Second base of codon: U	C	A	G	Third base of codon
U	UUU, UUC: Phenylalanine	UCU, UCC, UCA, UCG: Serine	UAU, UAC: Tyrosine	UGU, UGC: Cysteine	U, C, A, G
	UUA, UUG: Leucine		UAA, UAG: Stop codon	UGA: Stop codon; UGG: Tryptophan	
C	CUU, CUC, CUA, CUG: Leucine	CCU, CCC, CCA, CCG: Proline	CAU, CAC: Histidine; CAA, CAG: Glutamine	CGU, CGC, CGA, CGG: Arginine	U, C, A, G
A	AUU, AUC, AUA: Isoleucine	ACU, ACC, ACA, ACG: Threonine	AAU, AAC: Asparagine; AAA, AAG: Lysine	AGU, AGC: Serine; AGA, AGG: Arginine	U, C, A, G
	AUG: Methionine; start codon				
G	GUU, GUC, GUA, GUG: Valine	GCU, GCC, GCA, GCG: Alanine	GAU, GAC: Aspartic acid; GAA, GAG: Glutamic acid	GGU, GGC, GGA, GGG: Glycine	U, C, A, G

Amino acids

- *Alanine*
- *Arginine*
- *Asparagine*
- *Aspartate*
- *Cysteine*
- *Glutamine*
- *Glutamate*
- *Glycine*
- *Histidine*
- *Isoleucine*
- *Leucine*
- *Lysine*
- *Methionine*
- *Phenylalanine*
- *Proline*
- *Serine*
- *Threonine*
- *Tryptophan*
- *Tyrosine*
- *Valine*

Genetic code feature

- Genetic code codes for 20 amino acids found in proteins.
- Amino acids are organic compounds composed of nitrogen, carbon, hydrogen and oxygen, along with other elements in side chain.
- Essential amino acids cannot be made by the body. As a result, they must be derived from food. The 9 essential amino acids are: *histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine.*
- Codon has 3 nucleotide bases; and 43 combinations of 64 codons.
- Codon properties: Codon contains signals, **start codon** (AUG) and **stop codon** (UAA, UGA, UAG).

Fig. 5.14: Schematic representation of genetic code. DNA holds all of the genetic information necessary to build a cell's proteins. The nucleotide sequence of a gene is ultimately translated into an amino acid sequence of the gene's corresponding protein.

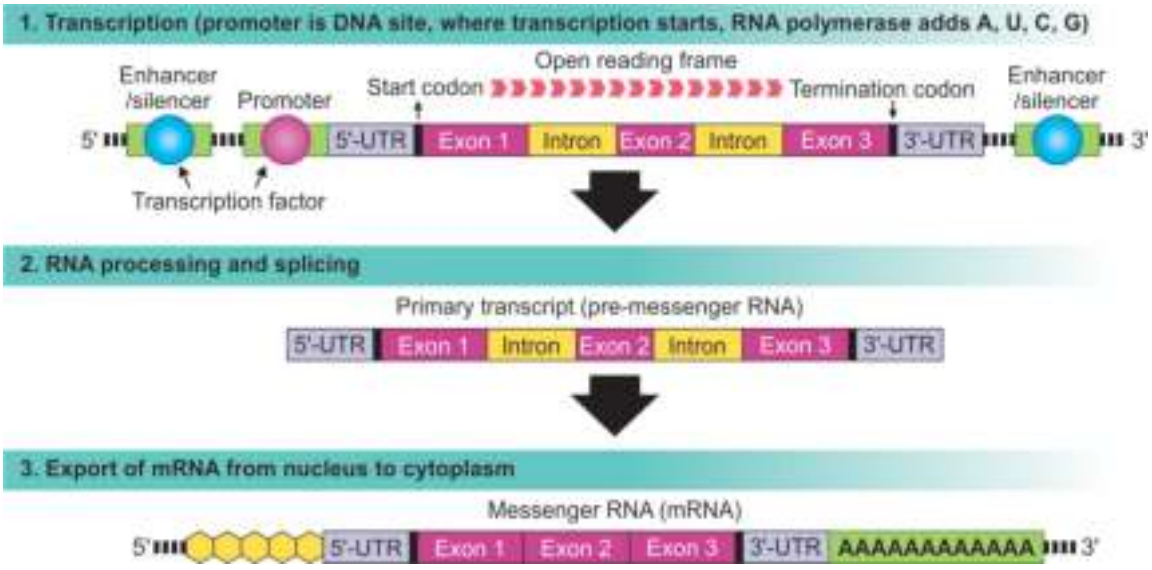

Fig. 5.15: Schematic representation of transcription. Transcription is the process by which the information in DNA strand is copied into a new molecule called messenger RNA, that leaves the cell nucleus and enters the cytoplasm and then serve as blueprints for protein synthesis during the process of translation (*see* Fig. 15.17).

and they function as '**stop codons**' and designate the termination of translation. Each codon codes for one of the 20 amino acids used in the synthesis of proteins, hence, it is specific.

TRANSCRIPTION

Transcription is the first step in gene expression. During this process, the DNA sequence of a gene is copied (transcribed) to make an RNA molecule in the nucleus. RNA polymerase is the main transcription enzyme. Schematic representation of transcription is shown in Fig. 5.15.

- DNA transcription unit is composed from its 3′→5′ end, of an RNA-coding region flanked by a promoter region and a terminator region. Regions to the left, or moving towards the 5′ end, of the transcription start site are considered. In RNA, adenine forms base pair with uracil instead of thymine.
- DNA transcription takes place in broad two steps. First, precursor messenger RNA (pre-mRNA or primary RNA) is synthesized, with the help of RNA polymerase enzymes in the nucleus.
- Then primary RNA transcript (**pre-mRNA**) gets a cap added to the 5′ end and undergoes polyadenylation and splicing to produce messenger RNA (mRNA). Following transport of mRNA to the cytoplasm, mRNA is translated in the cytosol to protein molecules. Transcription occurs in three steps: initiation, elongation (addition of nucleotides to the mRNA strand) and termination.

PROCESSING OF MESSENGER RNA (PRE-MESSENGER RNA→MATURE MESSENGER RNA)

Genetic information is stored in the genes in human genome, arranged in the strands of the DNA double helix in the nucleus. The genetic information is transcribed from DNA into a messenger RNA template by a process of transcription. Before the messenger RNA (mRNA) can be translated into the proteins, noncoding regions (**introns**) must be removed and protein-coding regions (**exons**) joined by RNA splicing to produce mature messenger RNA (mature mRNA). Schematic representation of process of primary RNA transcript to messenger RNA is shown in Fig. 5.16.

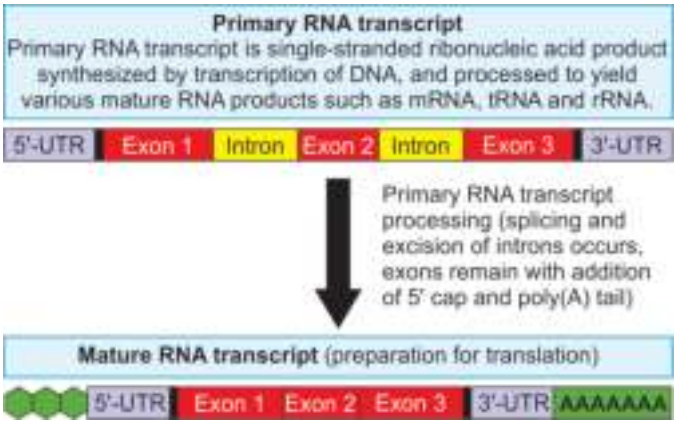

Fig. 5.16: Schematic representation of process of primary RNA transcript to messenger RNA. The genetic information is transcribed from DNA into primary RNA transcript (pre-messenger RNA) that becomes a messenger RNA (mRNA) after processing, that can be translated into the proteins, noncoding regions (introns) must be removed and protein-coding regions (exons) joined by RNA splicing to produce mature messenger RNA (mature mRNA).

Pre-messenger RNA (Pre-mRNA)/Precursor mRNA/Primary RNA Transcript

Precursor mRNA (pre-mRNA)/primary RNA transcript is synthesized from a DNA template in the cell nucleus by transcription. It is the primary transcript that becomes a messenger RNA (mRNA) after processing.

- Pre-mRNA comprises the bulk of heterogenous nuclear RNA (hnRNA). Pre-mRNA contains both coding sequences (**exons**) and noncoding sequences (**introns**).
- During RNA processing, intervening noncoding sequences (**introns**) are cut away by **spliceosome** and rejoining of exons to produce the final mature mRNA molecule containing only exons. Without RNA splicing of introns, primary transcript cannot leave the nucleus.
- Prior to exit of primary transcript from the nucleus, 7-methylguanosine cap is added to the 5′ end of the pre-mRNA of the growing transcript by a phosphate linkage, while elongation is still in progress.
- The 5′ cap protects the nascent mRNA from degradation and assists in ribosome binding during translation into the cytoplasm. In addition, factors involved in protein synthesis recognizes the 5′ cap to initiate translation by ribosomes.
- A poly(A) tail is added to the 3′ end of the pre-mRNA once elongation is complete. The resulting mature mRNA then exits the nucleus, and binds on the ribosomes in the cytoplasm.

Mature Messenger RNA (mRNA)

A fully processed mRNA includes a 5′ cap, 5′-UTR coding region, 3′-UTR, and poly(A) tail. This is known as a poly-A and is used for stability and guidance so that the mRNA can exit the nucleus find the ribosome in the cytoplasm.

- Mature mRNA binds to ribosomes and forms a template for protein production.
- Ribosomal RNA (**rRNA**) constitutes 60% of ribosome and consists of large and small ribosomal subunits.
- Mature messenger RNA (**mRNA**) carries the genetic information copied from DNA in the form of a series of three-base codes, each of which specifies a particular amino acid. Transfer RNA (**tRNA**) decodes information and provides linkage between mRNA and amino acids transfers amino acids to ribosomes in the cytoplasm.

TRANSCRIPTION PHASES

Transcription involves three steps: initiation, elongation and termination. In the initiation phase, the DNA molecule unwinds and separates to form a small open complex. During elongation phase, RNA polymerase moves along the template DNA strand that synthesizes a messenger RNA (mRNA), RNA polymerase will keep transcribing until it gets signals to halt. The process of ending transcription is called **termination**, and it happens once RNA polymerase transcribes a sequence of DNA is known as terminator. Transcription process involving initiation, elongation and termination phases is given in Table 5.18. Schematic representation of transcription phases is shown in Fig. 5.17.

Transcription Initiation Phase

Initiation of transcription occurs when the RNA polymerase enzyme binds to a region of a gene is called promoter region—a particular sequence of nucleotides. This signals the DNA to unwind so the enzyme RNA polymerase can 'read' in one of the DNA strands.

- RNA polymerase enzyme uses one of the DNA strands (template strand) as a template to make a new complementary RNA molecule.
- RNA polymerase enzyme then aligns the correct nucleic acid (A, C, G, or U) with its complementary base on the coding strand of DNA.

Transcription Elongation Phase

Once the RNA polymerase is in position at the promoter region, transcription elongation occurs by the addition of new nucleotides to the growing mRNA strand. This process builds a strand of mRNA.

- During transcription elongation phase, RNA polymerase moves along template strand of DNA in the 3′→5′ direction. For each nucleotide in the template, RNA polymerase adds a matching (complementary) RNA nucleotide to the 3′ end of the RNA strand.
- The RNA transcript is nearly identical to the non-template, or coding strand of DNA. However, RNA manuscript has the nucleotide base uracil (U) in place of thymine (T), as well as slightly different sugar in the nucleotide base.

Table 5.18 Transcription involving initiation, elongation and termination phases

Phases	Characteristics
Initiation phase	Initiation occurs when the enzyme RNA polymerase binds to a region of a gene called the promoter
Elongation phase	Process of addition of nucleotides to the mRNA strand
Termination phase	Transcription ends, when RNA polymerase receives polyadenylation signal in the RNA transcript to stop. Cutting results in release of RNA transcript from RNA polymerase enzyme

Transcription within the cell nucleus produces an mRNA molecule, which is modified and sent into cytoplasm for translation. The transcript is decoded into a protein with the help of a ribosome and tRNA molecules.

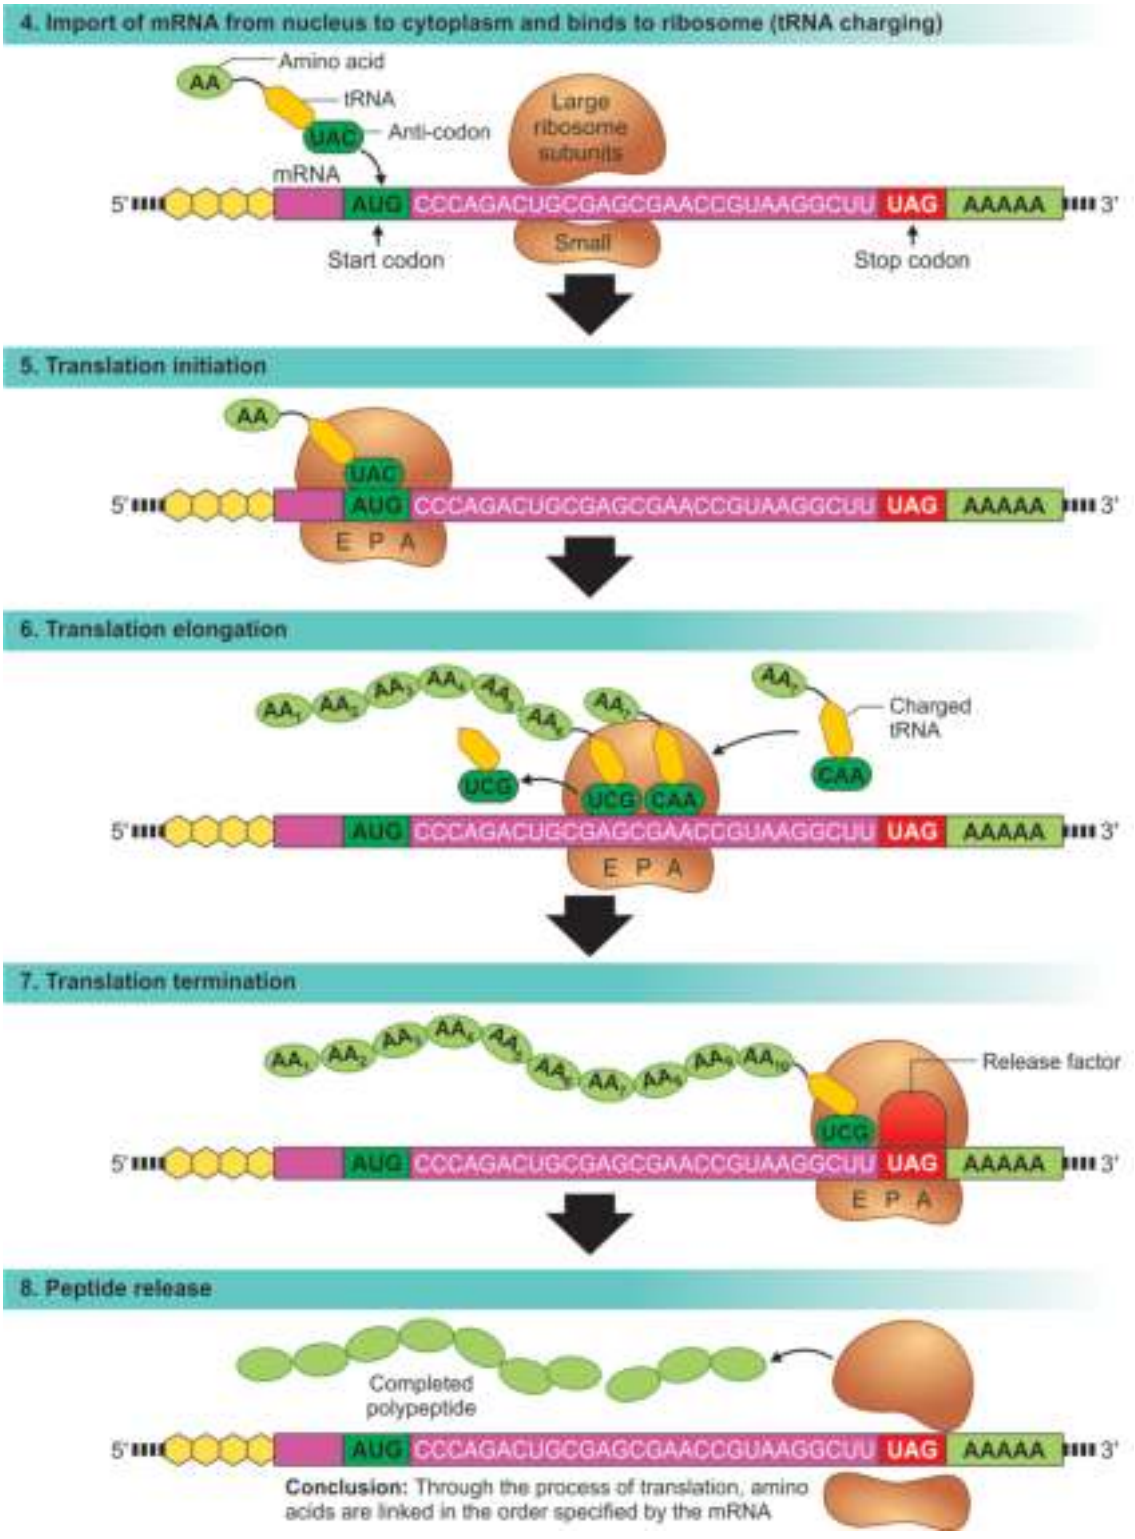

Fig. 5.17: Schematic representation of transcription phases. Transcription involves three steps: initiation, elongation and termination (*see* **Fig. 15.15**).

Transcription Termination Phase

RNA polymerase keeps on transcribing until it receives **polyadenylation signal** in the RNA transcript to stop. The process of ending transcription is called termination. The **polyadenylation signal** is recognized by an enzyme, that cuts the RNA transcript nearby releasing it from RNA polymerase enzyme.

TRANSLATION

Translation is the process of translating the sequence of a messenger RNA (mRNA) molecule to a sequence of amino acids is called polypeptide chains during protein synthesis in human cell. The substrate on which translation takes place is the ribosome found in cytoplasm.

- Translation is the process in which ribosomes in the cytoplasm or endoplasmic reticulum (ER) synthesize proteins after the process of transcription of DNA to RNA. Based on the size of sedimentation and genetic information, three major types of cellular RNAs include messenger RNA (mRNA), transfer RNA (tRNA) and ribosomal RNA (rRNA). Features of major classes of cellular RNAs involved in translation are given in Table 5.19.
- Messenger RNA carries the genetic information out of the nucleus for protein synthesis.
- Transfer RNA is the smallest and decodes the information.
- Ribosomal RNA is the largest and constitutes 50% of a ribosome, which is a molecular assembly involved in protein synthesis.
- Catalytic RNAs are involved in many reactions in cytoplasm of the cell.

TRANSLATION PHASES

In translation, messenger RNA (mRNA) is decoded in the ribosome decoding center to produce a specific amino acid chain, or polypeptide. Translation proceeds in three phases: initiation, elongation and termination. Translation phases are given in Table 5.20.

Translation Initiation Phases

Initiation of translation occurs when mRNA, **tRNA** and an amino acid meet up inside the ribosome.

- Ribosome binds to mRNA at start codon (AUG), that initiates translation of mRNA into amino acids. Each **tRNA** contains a set of **three nucleotides** is known as **anticodon**. The anticodon of a given tRNA binds to specific mRNA codon.
- The **tRNA** molecule also carries the appropriate amino acid encoded by codon to the ribosome to be added to the growing polypeptide chain. One amino acid synthesis occurs at a time.

Translation Elongation Phase

Elongation of nascent polypeptide (i.e. beginning but not completed) chains by covalent addition of successive adding of amino acid residues, which are carried to the ribosome and correctly positioned by its tRNA. Elongation of nascent polypeptide chain requires elongation factors, which are cytosolic proteins.

Translation Termination Phases

Ribosomes are attached to the membrane of the endoplasmic reticulum. When a stop codon is encountered, polypeptide chain formation stops.

- The transfer RNA (**tRNA**) stops carrying the amino acids to the ribosome. It leads to dissociation of polypeptide chain from the ribosome by a releasing factor.
- **Protein folding** occurs in a cellular compartment called endoplasmic reticulum (ER). This is a vital

Table 5.19 Features of major classes of cellular RNAs involved in translation

Classes of RNAs	Comments
Messenger RNA (mRNA)	mRNA migrates from nucleus to cytoplasm and binds to ribosomes and carries DNA sequence information to ribosomes
Transfer RNA (tRNA), smallest	Decodes information and provides linkage between mRNA and amino acids' transfers amino acids to ribosomes in the cytoplasm
Ribosomal RNA (rRNA), constitutes 60% of ribosome	Structural component of ribosomes involved in reading the order of amino acids and linking amino acids together

Catalytic RNAs are involved in many reactions in cytoplasm of the cell.

Table 5.20 Translation phases (translation, elongation and termination)

Process	Characteristics
Translation initiation	Ribosome binds mRNA at start codon (AUG), that initiates translation of mRNA into amino acids
Translation elongation	Polypeptide chains extends (elongates) by successive adding of amino acids transferred from transfer RNA (tRNA)
Translation termination	When a stop codon is encountered, polypeptide formation stops resulting in dissociation of ribosome from the polypeptide and then its (polypeptide) release

cellular process because proteins must be correctly folded into specific three-dimensional shapes in order to function correctly.

- Two types of proteins are synthesized: (a) structural proteins such as collagen and keratin, and (b) regulatory proteins such as enzymes, antibodies and hormones.

Pathology Pearls: General Features of RNA (Ribonucleic Acid)

- RNA is composed of nucleotides. Each nucleotide within the RNA structure has a nitrogen base, a ribose sugar and a phosphate. RNA is involved in many biological processes.
- RNA has a single-stranded nucleotide chain structure. RNA comprises ribose sugar in its nucleotides instead of deoxyribose sugar present in the DNA.
- RNA nucleotide base pairs comprise adenine, guanine, cytosine and uracil instead of thymine in DNA.
- RNA can catalyze important biological reactions similar to proteins but DNA cannot do so. RNA molecules functioning such as protein enzymes are called ribozyme.

Pathology Pearls: Classification of RNA (Ribonucleic Acid)

RNAs are divided into two groups: (a) **messenger RNAs (mRNAs)** are protein-coding RNAs, which mediate translation of genetic information in DNA into protein, and (b) **functional RNAs** are noncoding RNAs, which generate functional molecules instead of encoding proteins. Functional RNAs are described as below:

- **Transfer RNA (tRNA):** It brings amino acid toward the mRNA in the process of translation. All kinds of tRNAs are connected to a single kind of amino acid and carry it to the ribosome.
- **Ribosomal RNAs (rRNAs):** These are essential components of ribosomes, which guide assembly of amino acid chain. Ribosomal RNA which is composed of mRNA and tRNA with pretending to be large macromolecular machinery.
- **Small nuclear RNAs (snRNAs):** These are part of RNA transcription system in cells. Some small nuclear RNAs provide guidance to ribosomal RNAs (rRNAs) modifications. Others are combined with various protein subunits to form ribonucleoprotein processing complex.
- **Small nucleolar RNAs (snoRNAs):** More than 20, small nucleolar RNAs (snoRNAs) have been described, which are responsible for making various modifications after transcription for rRNA, tRNA, or small nuclear RNAs.
- **Micro-RNA (miRNA):** Micro-RNAs are conserved in a high level consisting of 18–26 nucleotides, encoded from the DNA regions, which are translated to protein. Micro-RNAs direct post-transcriptional regulation of gene expression. Micro-RNAs regulate a wide range of biological processes including development, cell proliferation, cell metabolism and apoptosis.

PROTEIN FOLDING

After translation, next step is folding of polypeptide in the endoplasmic reticulum. Protein folding is the process by which a protein structure assumes its functional conformation or shape. All protein molecules are heterogenous unbranched chains of amino acids. Proteins have no biological activity in an unfolded state.

- All proteins are made up of amino acids linked together by peptide bonds.
- Proteins have four levels of organization: primary, secondary, tertiary and quaternary.

Primary Structure of Protein

The primary structure of protein consists of linear structure of amino acids that are linked by peptide bonds and form linear chains of polypeptides.

- Primary structure of protein determines how the protein folds and interacts at the level of interactions. Dipeptide consists of two amino acids, oligopeptide 3–9 amino acids and polypeptide 8 or more amino acids linked together.
- Protein consists of several polypeptides. Hemoglobin contains four polypeptides. Human DNA polymerase contains at least 10 polypeptides.
- All amino acids have a carbon atom that form four bonds: amino group, carboxyl group, a hydrogen bond and one of 20 side chains.

Secondary Structure of Protein

Secondary structure of protein is two-dimensional structure and has secondary structures: α-helix polypeptide chain (rod-shaped and coiled) and β-pleated sheets.

- The α-helix of secondary structure of protein, a polypeptide chain is held by hydrogen bonds between the amino hydrogen and carboxyl oxygen atoms in the peptide backbone, that extend in one direction.
- β-Pleated sheets are made of β-strands (chains) connected laterally by two or more hydrogen bonds forming a backbone.
- In a β-pleated sheet, the β-chains are folded so that they lie alongside each other.
- Each β-chain is made of 3–10 amino acid residues. Hydrogen bonding of the peptide backbone causes the amino acids to fold into repeating pattern.

Tertiary Structure of Protein

Tertiary structure of protein is a three-dimensional arrangement of polypeptide chain. It is stabilized by four interactions of: (a) ionic bonding, (b) hydrogen bonding, (c) disulfide linkages, and (d) dispersion forces.

- Three-dimensional folding pattern of a protein occurs due to interactions between the side chains—the 'R' groups, which include ionic, hydrogen bonds, hydrophobic interactions, and disulfide bonds.
- Hydrophilic amino acids with polar side chains are present on outside to make the protein soluble.
- Hydrophobic amino acids tend to cluster together in the center of the protein. Hydrophobic amino acid side chains do not interact with water or other hydrophilic molecules.
- Sulfhydryl groups tend to form disulfide bonds with other sulfhydryl group. **Cysteine** is commonly involved in sulfhydryl bonds, which limits structure of the protein.
- Three-dimensional shape of a polypeptide chain is the result between all these tendencies as discussed.
- Fibrous proteins are structural proteins (e.g. cytoskeleton proteins, elastin, collagen). These have α-helices and β-pleated sheets, which tend to make the polypeptide as rigid structure. Globular chains are compact and flexible, which contain α-helices and β-pleated sheets interspersed with randomly coiled structure. The globular proteins usually have enzymatic activity.

Quaternary Structure of Protein

Quaternary structure of protein involves the association of two or more amino acid polypeptide chains into functional proteins held together by hydrophobic interactions of the amino acids and disulfide bridges.

DENATURING OF PROTEIN

Each protein has its own unique shape. If a protein loses its shape, it ceases to perform its specific function. The process of losing shape of the protein is called denaturation.

- Denaturation occurs in secondary, tertiary and/or quaternary structures; with intact primary structure and is usually caused by external stress on protein, such as chemical solvents, inorganic salts, exposure to acids or bases and high temperature. Disulfide bonds can be broken with reducing agents, which destroy hydrogen bonds, ionic bonds, or hydrophobic interactions of the protein resulting in denaturation.
- Denatured protein is usually nonfunctional. Since primary structure of the protein remains intact, denaturation of some proteins can be reversed. One example of irreversible denaturation of protein is fried egg. Many proteins do not fold by themselves, but instead get assistance from 'chaperone proteins' (chaperonins) found in endoplasmic reticulum and mitochondria.

Pathology Pearls: Chaperone Proteins

- **Chaperone proteins (chaperonins)** have ability to prevent non-specific aggregation by binding to non-native proteins. Examples of chaperon proteins are the '**heat shock proteins**'.
- Chaperonins may assist in protein folding when the nascent polypeptide is being synthesized by the ribosome.
- Chaperonins operate by binding to stabilize an otherwise unstable structure of a protein in its folding pathway, which have the ability to prevent nonspecific aggregation by binding to non-native proteins.

PROTEIN MISFOLDING AND AGGREGATION

Protein misfolding is a common cellular event, that can occur throughout the life span of a cell. In young and healthy cells, the misfolded protein load is disposed of by protein quality control (PQC) systems.

- In cells in aged persons and certain persons with genetic disease, misfolded proteins are not disposed of by protein quality control system.
- Genetic disorders can be caused by genetic mutations, translational errors, abnormal modification of protein, thermal or oxidative stress and incomplete formation of complex. Depending on the properties of the protein and the efficiency of the protein quality systems, the accumulated protein may be assembled or degraded into aggregates and toxic oligomers.
- Different protein misfolding disorders include phenylketonuria, α_1-antitrypsin deficiency, Parkinson's disease, familial neurophyseal diabetes insipidus, and certain acetyl-CoA dehydrogenase deficiency.

DNA DAMAGE AND REPAIR SYSTEMS

Deoxyribonucleic acid (DNA) in the living cell is subjected to many chemical alterations. The genetic information encoded in the DNA has to be uncorrupted. Any chemical alterations in DNA must be corrected. DNA damage is structural abnormality in the DNA, that can be recognized by DNA repair enzymes and correctly repaired. Major types of DNA damage are given in Table 5.21.

Table 5.21 Major types of DNA damage

Type of DNA Damage	Characteristics
Single-base alterations in DNA sequence (not affecting DNA replication, transcription and translation)	▪ Deamination: cytosine→uracil; adenine→hypoxanthine ▪ Depurination (caused by UV radiation, ionizing radiation, alkylating agents, reactive oxygen species) ▪ Insertion of adenine in place of cytosine ▪ Alkylation of base ▪ Insertion or deletion of base ▪ Base analog incorporation
Double nucleotide base pair alteration	▪ Ultraviolet light induced thymine-thymine (pyrimidine dimer) ▪ Bifunctional alkylating agent cross-linkage
Helical chain breaks	▪ Ionizing radiation ▪ Radioactive disintegration of backbone element ▪ Oxygen-derived free radical formation
Cross-linkage	▪ Between nucleotide base pairs in same DNA strand or opposite DNA strand ▪ Between DNA and protein molecules (histones)

DNA DAMAGE MECHANISMS

DNA damage refers to alterations in the chemical structure of DNA such as a break in a DNA strand, a nucleotide base missing from the sugar–phosphate backbone of DNA, and a chemical alteration in the base.

- Damage to DNA that occurs naturally can result from metabolic or hydrolytic processes. DNA damage can be caused by errors during DNA replication, alkylating agents, reactive oxygen species (ROS) during normal cellular respiration and other biochemical pathways, ultraviolet rays, X-rays and γ-radiation. DNA damage leads to genome instability, increased cancer risk, accelerated aging process and neurodegenerative disorders.
- DNA damage mechanisms include: (a) hydrolysis (deamination and depurination), (b) alkylation, (c) oxidation, (d) radiation reactions, (e) nucleotide base analogue and intercalating agents.
- The comet assay, or single cell gel electrophoresis assay (**SCGE**) is a common technique performed to analyze all types of DNA damage. It is a convenient diagnostic tool for measuring universal DNA damage in individual's cells.
- Mechanisms of DNA damage, DNA repair systems and outcome of DNA repair systems failure are shown in Fig. 5.18. Human DNA repair genes are given in Table 5.22.

HYDROLYSIS (DEAMINATION AND DEPURINATION)

Hydrolytic DNA damage may result from the biochemical reactions, various metabolites as well as overabundance of reactive oxygen species. A single nucleotide base pair transformation within a DNA molecule may be sufficient to cause a mutation or inactivate the DNA. Hydrolytic DNA damage involves deamination or total removal of individual nucleotide base pairs.

Deamination

Deamination is a reaction, where cytosine (C) is lost from DNA to produce uracil (U) resulting in mutagenic U:G mispairs. Deamination is the removal of an amino group from a molecule. The enzymes that catalyze this reaction are called deaminases.

- The deamination of cytosine to uracil takes place at significant rate in liver and kidney. Spontaneous deamination of cytosine forms uracil, which is recognized and removed by DNA repair enzymes.
- Deamination converts adenine (A) to hypoxanthine, that selectively affects nucleotide base pairs with cytosine (C) instead of thymine (T). This results in a post-replicative transition mutation, where the original adenine (A) to thymine (T) nucleotide base pair transforms to guanine (G) to cytosine (C) nucleotide base pair.
- Deamination of 5-methylcytosine forms thymine. This conversion of a DNA nucleotide base pair from cytosine (C) to thymine (T) can result in transition mutation.

Depurination

Depurination of DNA occurs by spontaneous hydrolysis of the β-N-glycosyl-linkage between deoxyribose and purine nucleotide base; leading to subsequent loss of purine bases, adenine (A) or guanine (G) from the DNA; leaving the DNA's sugar–phosphate chain intact, producing an abasic site (i.e. deoxyribose lacking a nucleotide base) in the DNA. Loss of DNA nucleotide base pairs can be mutagenic and if left unrepaired, they

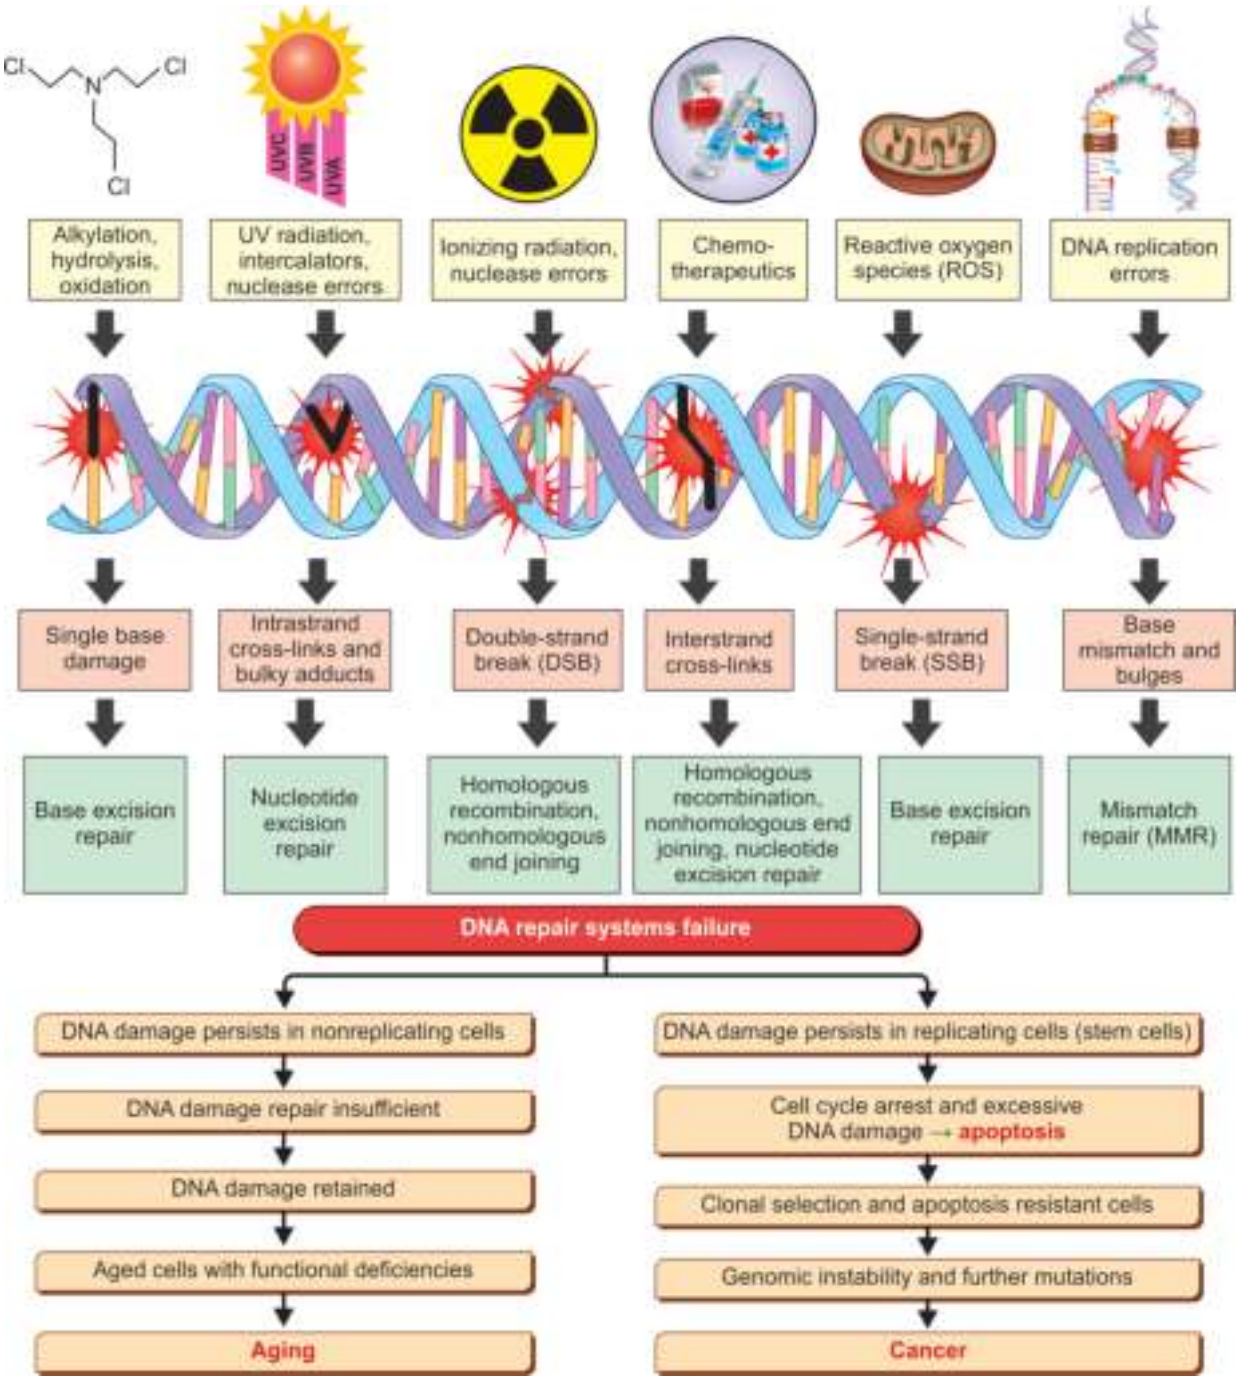

Fig. 5.18: Mechanism of DNA damage, DNA repair systems and outcome of DNA repair systems failure.

can inhibit transcription. Pyrimidine dimers can disrupt polymerases and prevent proper DNA replication.

ALKYLATION AND DNA DAMAGE

Methyl and ethyl group added to DNA nucleotide base pairs alters the structure of DNA. DNA alkylation refers to the addition (transfer) of alkyl (methyl or ethyl) groups to the reactive sites of specific nucleotide bases and to the phosphates in DNA backbone, resulting in alkylation products such as O^2-alkylamine, O^4-alkylamine, O^6-alkylamine, and O^8-alkylamine, which cause DNA mutations.

- Alkylation does not immediately result in mispairing. However, alkylation makes the bond between sugar and nucleotide base pair more labile, that may break and result in an apurinic site, a sugar without its purine.
- Hence, DNA molecule cannot be replicated properly, unless it is first repaired. If such cells sometimes attempt to replicate apurinic DNA, these frequently

Table 5.22 Genes involved in human DNA repair

DNA Repair Mechanism	Genes Proteins
Base-excision repair (BER)	UNG gene (12q24.11), SMUG1 gene (12q13.13), MBD4 gene (3p21.3), TDG gene (12q23.3)
Direct reversal of DNA damage	MGMT gene (10q26.3), ALKBH2 (ABH2) gene (12q24.11), ALKBH3 (DEPC1) gene (11p11.2), APEX1 gene (14.q11.2), APEX2 gene (Xp11.21), LIG3 gene (17q12), PARP1 gene (1q42.12), PARP2 gene (14q11.2)
Repair of DNA-protein cross-links	TDP1 gene (14q32.11), TDP2 (TTRAP) gene (6p22.3), SPRTN (Spartan) gene (1q42.12-q43)
Nucleotide-excision repair (NER)	XPA gene (9p22.33), XPB gene (13q233.1), XPC gene (3p25.1), XPD gene (19q13.32), XPE gene (11p11.2), XPF gene (16p13.12), XPG gene (2q13.3), XPV gene (6p21.1), RAD23B gene (9q31.2), ERCC1 gene (19q13.32)
Mismatch excision repair (MMR)	MLH1 gene (3p21), MSH2 gene (2p15), MSH3 gene (5q11.12), MSH4 gene (1p31.1), MSH5 gene (6p21.33), MSH6 gene (2p16), MLH3 gene (14q24.3), PMS1 gene (2p32.2), PMS2 gene (7p22.1), HFM1 gene (1p22.2)
Double DNA break repair	BRCA1 (17q21), BRCA2 (13q12), ATM gene (11q22.3)
Homologous recombination	RAD51 gene (15q15.1), RAD51B gene (14q24.1), RAD51D gene (17q12), HELQ gene (4q21.23), SW15 gene (9q34.11), SRCC2 gene (7q36.1), SRCC3 gene (14q32.33)
Nonhomologous end joining	XRCC6 gene (22q13.2), XRCC5 gene (2q35), PRKDC gene (8q11.21), LIG4 gene (13q33.3), XRCC4 gene (5q14.2), DCLRE1C gene (10p13), NHEJ1 gene (2q35)
Fanconi anemia gene encoding protein	FANCA gene (16q24.3), FANCB gene (Xp22.31), FANCC gene (9q22.32), FANCE gene (6p21.31), FANCF gene (11p14.3), FANCG gene (9p 13.3)
DNA replication fork repair	MLM gene (9p21), WRN gene (8p), RecQ4 gene (8q24.3)
Telomere maintenance	TERT gene (5p15.33)

ATM gene (11q22.3) is important checkpoint. TP53 gene (17p1.2) enhances transcription of PTEN. PTEN gene (10q23.3) protects p53 from MDM2-mediated degradation.

insert the wrong nucleotide base pairs across from an apurinic site, and this results in mutation.

- Alkylation changes nucleotide base-pairing properties resulting in mutation. Moreover, all the nitrogen and oxygen atoms involved in nucleotide base-pairing are also subject to allylation, which can directly disrupt nucleotide base-pairing leading to mutation. Many environmental carcinogens are electrophilic molecules that can attack DNA and alkylate it.
- Alkylating agents such as nitrogen mustard, cyclophosphamide, chlorambucil, melphalan and busulfan are administered to treat cancer patients by causing mutated DNA in clinical practice. These alkylating agents are nonspecific for cell cycle phase, but remain active during most parts of the cell cycle.
- Alkylating agent is a volatile organic solvent ethyl methanesulfonate (EMS, CH_8O_3S), which transfers ethyl (CH_3–CH_2) groups to DNA. The product of this methylation, O^6-methylguanine produces random point mutations in DNA by nucleotide substitution, particularly by guanine alkylation. The product also produces single-stranded break in DNA and chromosomal aberrations.

OXIDATIVE DNA DAMAGE

Oxidative DNA damage occurs from reactive oxygen species (ROS) derived from normal cellular metabolic processes and generated by ionizing radiation and chemical agents.

- However, cells also produce antioxidants that neutralize oxygen-derived free radicals. DNA damage occurs at guanine residues due to high oxidation potential of the nucleotide base pair relative to cytosine (C), thymine, and adenine.
- An important oxidation product is 8-hydroxyguanine, which mispairs with adenine, resulting in guanine (G): cytosine (C) to thymine (T): adenine (A) transversions.

RADIATION REACTIONS AND DNA DAMAGE

Both **ultraviolet rays** and **ionizing radiation** cause damage to DNA. Ionizing radiation is a high-energy radiation that releases electrons from atoms and molecules generating ions inducing DNA breaks, particularly, double-stranded DNA breaks.

- Secondary effects of radiation are the generation of reactive oxygen species (ROS) that oxidize proteins and lipids and also induce severe damage to DNA,

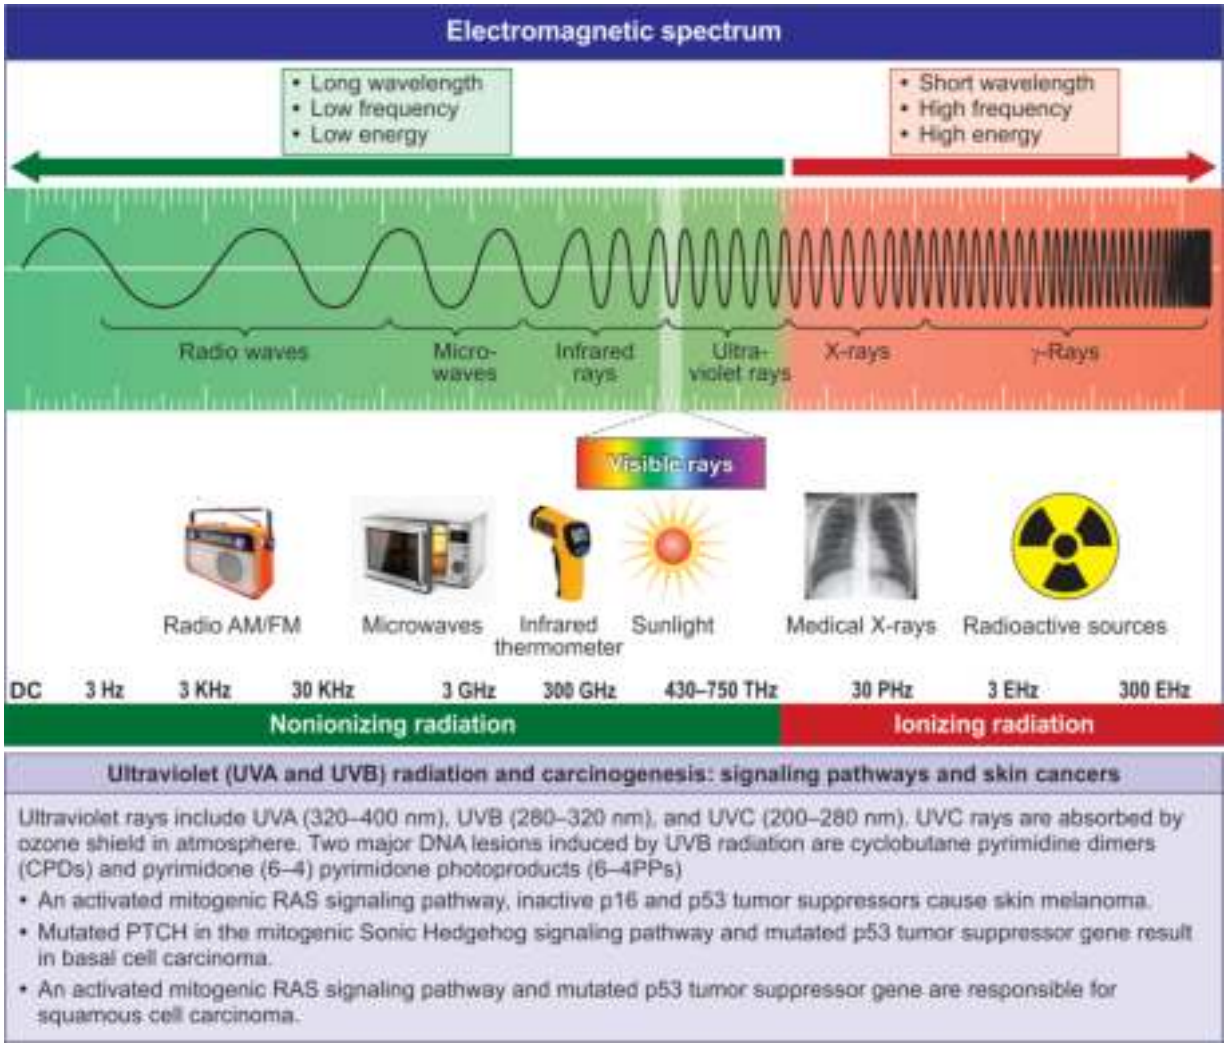

Fig. 5.19: Ultraviolet radiation-induced DNA damage and associated cancers.

like generation of abasic sites and single-strand DNA breaks.

- Collectively, all these cellular changes induce cell death and mitotic failure. Ultraviolet radiation-induced DNA damage and associated cancers are shown in Fig. 5.19.

Ultraviolet Radiation-induced DNA Damage

Ultraviolet radiation (UVB radiation: 290–320 nm) cross-links adjacent pyrimidines (thymine and cytosine) on the same DNA strand forming pyrimidine dimers, usually thymine dimers.

- Pyrimidine dimers disrupt DNA polymerases and prevent proper replication of DNA, because DNA replication machinery fails to convey which nucleotide base pairs to insert opposite the dimer. If DNA replication proceeds, wrong nucleotide base pairs are inserted at random resulting in mutation.
- Ultraviolet (UV) radiation from the sun is most important carcinogen in human beings. Exposure of the skin to UV radiation has multiple cellular and clinical effects including development of skin cancers (cutaneous squamous cell carcinoma, basal cell carcinoma and malignant melanoma). UVB radiation-induced DNA damage adversely affects signaling pathways resulting in impairment of cell cycle arrest, DNA repair and apoptosis.
- UV radiation-induced mutations in signature genes (UVA, UVB, ROS), tumor suppressor genes (TP53, PTCH, p16) and TNF-α gene lead to production of thymine dimers, dipyrimidine dimers, 'reactive oxygen species' and TNF-α, which cause damage to cellular biomolecules and DNA.

Ionizing radiation-induced DNA Damage

Ionizing radiation (gamma rays and X-rays) directly affects structure by inducing DNA breaks, particularly double-stranded breaks.

- The radiation causes formation of reactive oxygen species (ROS) which are indirectly involved in DNA damage. Reactive oxygen species, especially those

containing oxygen, are most reactive, which attack neighboring molecules.

- When oxygen-derived free radical attacks a DNA molecule, then it can change a nucleotide base pair, and frequently causes a single-strand or double-strand DNA break(s). Single-stranded DNA breaks are usually repaired by using template strand just by rejoining the ends of the damaged single-strand. But double-stranded DNA breaks are difficult to repair resulting in mutation.
- Ionizing radiation can also cause break in chromosomes. Exposure to ionizing radiation is known to increase the risk for development of cancers especially leukemia.
- Radiotherapy is high energy ionizing radiation commonly employed treatment in the management of more than 50% of human malignancies. Ionizing radiation destroys the cancer cells in the treated region by damaging DNA of cancer stem cells as well as normal cells in the surrounding region. The side effects of radiotherapy usually improve within a few weeks after radiotherapy.

BASE ANALOGUE AND INTERCALATING AGENTS: DNA DAMAGE

Mutations can be caused by compounds that substitute for normal nucleotide base pairs (base analogs) or slip between the nucleotide base pairs (intercalating agents) to cause error in replication.

Base Analogues

Base analogues are molecules which have similar structure to one of four nitrogen nucleotide base pairs present in DNA (adenine, guanine, cytosine and thymine).

- The base analogs form a structure identical to one of the DNA nucleotide base pairs and then can be used to form the new strand in semiconservative replication of DNA. Usually, substitution of a nucleotide base analogue results in altered nucleotide base pairings and structural changes that can affect DNA replication and transcription of genes. Since 5-bromouracil can pair with either adenine (A) or guanine (G).
- Base analogue 5-bromouracil causes frequent mistakes in forming correct base pair during DNA replication, which results in mutation. Nucleic acid analogues are structurally similar to natural occurring DNA and RNA, which are used in medicine and molecular biology research.

Intercalating Agents

Intercalating agents are **hydrophobic molecules** containing several polycyclic rings that resemble the ring structure of purine or pyrimidine base pair of the DNA. Intercalating compounds such as ethidium bromide, acridine orange, actinomycin D and proflavine bind to the major or minor grooves of DNA double helix and cause addition or deletion of bases during replication.

- Intercalating compounds may result in a frameshift mutation, which can alter the codon reading frame and result in interference in DNA replication and transcription.
- Proflavine, an intercalating compound, is used as an antimicrobial agent as a topical agent, that denatures bacterial DNA resulting in lysis of bacteria. Due to its intercalating property, it adversely affects host DNA, which has potential chances to induce skin cancer and other cancers.

POLYCYCLIC AROMATIC HYDROCARBONS

Polycyclic aromatic hydrocarbons (PAHs) are organic compounds containing carbon and hydrogen, and composed of multiple aromatic rings. PAHs occur naturally in coal, crude oil, and gasoline.

- Incomplete combustion of organic matter such as coal, wood, tobacco or garbage results in emission of PAHs. Examples of PAHs include benzene, toluene, naphthalene and anthracite.
- Polycyclic aromatic hydrocarbons (PAHs) induce carcinogenesis by causing DNA damage through the formation of adducts. A common marker for DNA damage due to PAHs is benzo(a) pyrene diol epoxide (BPDE). BPDE compound is found to be very reactive, and known to bind covalently to proteins, lipids, and guanine residues of DNA to produce BPDE adducts. If left unrepaired, BPDE-DNA adducts may lead to permanent mutations resulting in cell transformation and ultimately tumor development.

DNA REPAIR MECHANISMS

DNA damage is minimized by DNA repair systems. DNA repair systems recognize the correct damage of DNA molecules and repair the defects in DNA.

- DNA damage is repaired by various mechanisms include: (a) direct repair (reversal), (b) excision repair (free base-excision repair, nucleotide-excision repair), (c) mismatch repair, and (d) recombination repair of double-strand DNA break.
- Most of the DNA repair mechanisms depend on the presence of two strands of DNA because nucleotides in the damaged region are removed and replaced. Nucleotide base pairs are also replaced in mismatch repair, free base-excision repair and nucleotide-excision repair mechanisms.

Table 5.23 Type of DNA damage and repair mechanism

Type of DNA Damage	DNA Repair Mechanism
Methylated (O6 or N7) guanine	Direct repair (pyrimidine dimers; other specific types of alterations)
Hydrolytic DNA damage (deamination/depurination)	Base-excision repair (BER)
Bulky DNA lesions, DNA-protein adducts (DNA damage due to abnormal bases, modified bases, and pyrimidine dimers)	Nucleotide-excision repair (NER)
Mismatched nucleotide base pairs (replication errors, including mispaired bases and strand slippage)	Base-excision repair (BER)
Single-stranded DNA breaks (reactive oxygen species, ionizing radiation, spontaneous loss of sugar-phosphate)	Base-excision repair (BER), nucleotide-excision repair (NER)
Double-stranded DNA breaks	Homologous recombination (HR), nonhomologous end joining (NHEJ)

DNA damage is an alteration in the chemical structure of DNA, such as a break in a strand of DNA, a base missing from the backbone of DNA.

- Poly-ADP-ribosyl-polymerase (PARP) plays a central role in nucleotide-excision repair (NER) and base-excision repair (BER) and enables repair of damaged DNA caused by alkylating agents and chemotherapeutic agents. PARP is also involved in many other cellular processes including transcription and modulation of chromatin structure.
- However, nucleotide base pairs are not replaced by direct-repair mechanism. DNA repair mechanisms occur by using a common four-step pathway are given below. Type of DNA damage and repair mechanism are given in Table 5.23.

Pathology Pearls: Steps of DNA Repair Mechanisms

1. **Detection:** Damaged region of the DNA is recognized.
2. **Excision:** Endonuclease gives a small cut to the sugar-phosphate backbone on one or both sides of the DNA damage to remove one or more nucleotides.
3. **Polymerization:** DNA polymerase enzyme adds nucleotides to the newly exposed 3'-OH group by using the other strand of DNA as a template and replacing damaged nucleotides as well as some undamaged nucleotides in all three base-excision, mismatch and nucleotide repair mechanisms.
4. **Ligation:** DNA ligase seals and fills in the small gaps produced by the excision and removal of the damaged nucleotides in the sugar-phosphate backbone in all three: base-excision, mismatch and nucleotide repair mechanisms.

DIRECT DNA DAMAGE REVERSAL MECHANISM

Direct DNA damage reversal system acts directly on damaged single nucleotide chain, that restores the DNA genome to its normal original state in a single-reaction step. But only a few damaged nucleotides can be repaired directly. Pyrimidine dimers are repaired by a light-dependent direct system called photoreactivation.

EXCISION REPAIR MECHANISM

Excision repair mechanism involves excision of a segment of the polynucleotide containing a DNA damage site followed by synthesis of the correct nucleotide sequence by DNA polymerase enzyme and then ligation. Excision repair occurs by two mechanisms: base-excision repair and nucleotide-excision repair.

Base-excision Repair Mechanism

Base-excision repair mechanism refers to repair of damage to a single base caused by oxidation, alkylation, hydrolysis or deamination. The damaged nucleotide base pair is removed by DNA glycosylase enzyme, synthesis by DNA polymerase enzymes, and sealing by DNA ligase enzyme.

Nucleotide-excision Repair Mechanism

Damage to the DNA distorts the configuration of the molecule. An enzyme complex recognizes the distortion in DNA. DNA strand becomes separate. Single-stranded DNA-binding proteins stabilize the single-stranded regions of DNA. DNA glycosylase enzyme cleaves the damaged strand on both sides of the damage. Part of the damaged DNA strand is removed, and the gap is filled in by **DNA polymerase** and sealed by **gyrase**.

MISMATCH REPAIR MECHANISM

DNA replication is extremely accurate. Each new copy of DNA has less than one error per billion nucleotide base pairs. However, in the process of DNA replication, mismatched nucleotide base pairs are incorporated into the new DNA. Most of the errors that initially arise during DNA replication are corrected in MMR machinery human at genes and never becomes permanent mutations. Some of these errors in nucleotide base pairs are corrected during proofreading by polymerases.

- During proofreading, incorrect nucleotide base pairs are inserted to the newly synthesized strand of DNA. Mismatched nucleotide base pairs and other DNA errors are corrected by mismatch repair.
- **Exonucleases** remove nucleotide base pairs on the newly synthesized strand of DNA between the GATC sequence and the mismatch. DNA polymerase then replaces the nucleotide base pairs, correcting the mismatch, and DNA ligase seals the nick in the sugar-phosphate backbone.
- Human beings, who possess mutations in mismatch-repair genes often exhibit elevated **somatic mutation rates** and are frequently susceptible to **colon cancer**.

RECOMBINATION REPAIR OF SINGLE-STRAND AND DOUBLE-STRAND BREAK MECHANISM

Ionization, certain chemical agents and reactive oxygen species (ROS) can produce both single-strand breaks (SSBs) and double-strand breaks (DSBs) in the DNA backbone.

- Breaks in single-strand of DNA molecule are repaired using the same enzyme systems that are used in base-excision repair. The damaged nucleotide base pair is removed by DNA glycosylase enzyme, synthesis by DNA polymerase enzymes, and sealing by DNA ligase enzyme.
- Double-strand break in DNA inhibits DNA replication that may lead to chromosomal rearrangements such as deletions, inversions, duplication, and translocations.
- Two major pathways for repairing double-strand breaks in DNA include homologous recombination and nonhomologous end joining.

Homologous Recombination Repair Mechanism

Homologous recombination repair mechanism is a broken DNA molecule by using the identical or nearly identical genetic information contained in another DNA molecule, usually a sister chromatid or homologous chromosome.

- The process of homologous recombination is responsible for crossing over of chromosomes that results in creation of new combinations of DNA sequences in each chromosome.
- The breast cancer suppressor BRCA1 and BRCA2 genes are essential for the maintenance of genome integrity in human cells through their role in DNA repair by homologous recombination. Inherited mutations of BRCA1 and BRCA2 genes predispose women to breast and ovarian cancers.

Table 5.24 Disorders associated with defects in DNA repair systems

Disorder	Genetic Defect	Symptoms
Xeroderma pigmentosum	Defects in nucleotide-excision repair	Freckle-like spots on skin, sensitivity to sunlight, predisposition to skin cancer
Cockayne's syndrome	Defects in nucleotide-excision repair	Dwarfism, sensitivity to sunlight, premature aging, deafness, intellectual disability
Trichothiodystrophy	Defects in nucleotide-excision repair	Brittle hair, skin abnormalities, short stature, immature sexual development, characteristic facial features
Hereditary nonpolyposis colon cancer (HNPCC) also known as Lynch syndrome	Defects in mismatch repair	Predisposition to colon carcinoma
Fanconi anemia	Possibly defects in the repair of inter-strand predisposition to leukemia	Increased skin pigmentation, abnormalities of skeleton, heart, and kidneys, predisposition to leukemia
Li-Fraumeni syndrome	Defects in DNA damage response	Predisposition to cancer in many different tissues
Werner syndrome	Defect in homologous recombination	Premature aging, predisposition to cancer
Ataxia-telangiectasia	Defective repair of broken DNA	Impairment of certain areas of brain and cerebellum causing difficulty with movement and coordination, impaired immune system and predisposition to lymphoid malignancies
Bloom syndrome	Genome instability	Autosomal recessive disorder characterized by short stature and predisposition to cancer
Progeria (Hutchinson-Gilford progeria syndrome)	Genome instability due to lamin A (LMNA) gene mutation	Genetic disorder causing premature aging (two years child looking older)
Rothmund-Thompson syndrome	Mutation in DNA helicase RECOL4 gene causing defect in DNA replication	Presents with sparse hair, eyebrows and eyelashes, slow growth, small stature, chronic diarrhea, vomiting and abnormalities in teeth and nails; and predisposition to osteosarcoma, squamous cell carcinoma of skin and basal cell carcinoma of skin

Nonhomologous End Joining Repair Mechanism

Nonhomologous end joining repair mechanism occurs in double-strand breaks without using a homologous template. This pathway is most often used when the cell is in G1 phase of cell cycle and a sister chromatid is not available for repair through homologous recombination.

- Nonhomologous end joining repair mechanism uses proteins that recognize the broken ends of DNA molecule, bind to the ends and then join them together.
- Nonhomologous end joining repair mechanism is more prone to errors such as deletions, insertions and translocations than homologous recombination.
- Errors in nonhomologous end joining repair mechanism may be associated in translocation in various cancers such as Burkitt lymphoma, Philadelphia chromosome in chronic myelogenous leukemia, and B cell lymphoma.

GENETIC DISORDERS AND FAULTY DNA REPAIR SYSTEMS

Several human diseases are associated with defective DNA repair system and increased rate of mutation. Defects in DNA repair are the underlying cause of several genetic diseases. Many of these diseases are characterized by a predisposition to cancer. Disorders associated with defective DNA repair system include xeroderma pigmentosum, Cockayne's syndrome, trichothiodystrophy, hereditary nonpolyposis colon cancer, Fanconi anemia, Li-Fraumeni syndrome, Werner syndrome, ataxia-telangiectasia, Bloom syndrome, progeria (Hutchinson-Gilford progeria syndrome) and Rothmund-Thompson syndrome. Genetic disorders associated with defects in DNA-repair systems are given in Table 5.24.

CHROMOSOMAL DISORDERS

Normal cells are diploid, containing 46 chromosomes (23 pairs). Out of these, there are 22 pairs of autosomes and 1 pair of sex chromosomes (XX in females or XY in males). Chromosomes are rod-shaped filamentous bodies present in the nucleus, which become visible during cell division in the mitotic metaphase.

- Chromosomes are composed of thin chromatin threads called chromatin fibers, which undergo folding, coiling and supercoiling during prophase so that the chromosomes become progressively thicker and smaller in length. Therefore, chromosomes become readily observable under light microscope.
- Study of human chromosomal abnormalities is called cytogenetics.
- Chromosomal disorders may result in congenital malformations, mental retardation, miscarriage, stillbirths, fertility problems and/or malignancy. Chromosomal disorders can occur due to numerical abnormality (aneuploidy or polyploidy) or structural abnormality (structural rearrangement).
- Duplication of chromosomes in somatic cell lines involves mitosis.
- Mitosis is a type of cell division that results in two identical daughter cells, each having the same number and kind of chromosomes as the parent nucleus. The major purpose of mitosis is for the growth and replacement of worn-out cells. Mitosis consists of four phases: prophase, metaphase, anaphase, and telophase. Meiosis is limited to replicating germ cells (ova or sperms).
- Meiosis is a process where a single germ cell (sperm in male or ovum in female) divides to produce four cells containing half the original amount of genetic information.
  - In meiosis, the chromosome/chromosomes duplicate during interphase, and the homologous chromosomes exchange genetic information (chromosomal crossover) during the first division, called meiosis I (formation of two daughter cells).
  - The daughter cells undergo meiotic division again in meiosis II (formation of four daughter cells), splitting up sister chromatids to form haploid gametes. Two gametes (sperm and ovum) fuse during fertilization, creating a diploid cell with a complete set of paired chromosomes.
- Sex determination of an individual is shown in Fig. 5.20. Terminology used for chromosomal appearances and abnormalities are given in Table 5.25.

CHANGES IN AUTOSOME CHROMOSOME NUMBER AND STRUCTURE

Normally, all the individuals have same number of chromosomes. Presence of a whole set of chromosomes is called **euploidy**. Gametes normally contain only one set of chromosomes; this number is called **haploid (1n)**.

- Somatic cells usually contain two sets of chromosomes, i.e. diploid (2n), three sets of chromosomes, i.e. triploid (3n), and four sets of chromosomes, i.e. tetraploid (4n). The condition, in which the set of chromosomes in multiples of 'n' is called polyploidy.

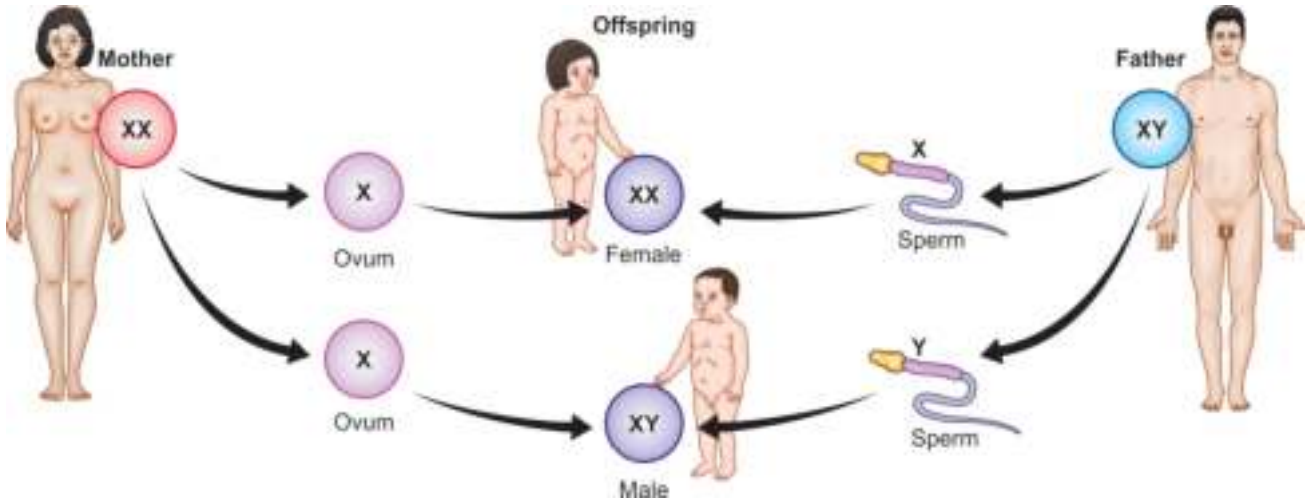

Fig. 5.20: Sex determination of an individual. In this system, the sex of an individual is determined by a pair of sex chromosomes. Normally, cells from female contain two X chromosomes (XX), and cells from male contain X and Y chromosomes (XY).

Table 5.25 Terminology used for chromosomal appearances and abnormalities

Term	Description
Centromere	The region that connects the two arms of the chromosome
Chromosomal marker	▪ A small extra piece of chromosomal material that travels with the other chromosomes ▪ Example of chromosomal marker is 46, XY, +mar
Deletion	▪ Loss of all or part of one chromosomal arm, usually a part toward the end of an arm ▪ An acentric chromosome (without a centromere) is typically lost completely after a few cell divisions. ▪ Example of deletion is 46, XX, 4p– or 46, XX, del (13) (q12q14)
Duplication	▪ A segment of chromatin that is repeated on the same or another chromosome. Many are incompatible with life ▪ Example of duplication is 46, XY, dup (1) (q11q22)
Fragile site	▪ There is a site on one arm that has a demonstrable fixed break point ▪ Example of fragile site is 46, fra(X) (q27.3), Y
Insertion	▪ There must be two break points in one chromosome that allow a segment to insert between a break point in another chromosome ▪ Example of insertion is 46, XX, ins (11) (p14q23q24)
Isochromosome	▪ The arms of a chromosome are mirror images of each other. Monocentric isochromosomes have two long arms or two short arms ▪ Dicentric isochromosomes have mirrored material between centromeres ▪ Example of isochromosome is 46, X, i(Xq)
Inversion	▪ Two break points in a chromosome allow a 180° turn of a segment with fusion ▪ The inversion is "paracentric" if it only involves one arm, while "pericentric" inversions involve the centromere and parts of p and q arms ▪ Example of inversion is 46, XX, inv (8) (p23q22)
Monosomy	▪ Only one of a chromosome pair is present in monosomy ▪ Autosomal monosomies yield nonviable embryos ▪ Only monosomy X is rarely liveborn ▪ Example of monosomy is 45, X or 45, XY, –14
Mosaic pattern	▪ Cells with an abnormal karyotype are present along with normal cells ▪ Example of mosaic pattern is 45, X/46, XX
p arm	The short arm of the chromosome
q arm	The long arm of the chromosome
Ring chromosome	Breakage of a chromosome at two points is followed by repair with fusion to a circular chromosome. Example of ring chromosome is 46, XX, r(1) (p36q44)

Table 5.25 Terminology used for chromosomal appearances and abnormalities (*Contd...*)

Term	Description
Translocation	▪ There is an exchange of material between arms on different chromosomes. The translocation is "reciprocal" if there is an exchange of two chromosome segments on different (nonhomologous) chromosomes ▪ Chromosomal translocation is 'balanced' if no genetic material is lost ▪ Unbalanced chromosomal translocation involves more breakpoints that lead to loss of genetic material in the exchange ▪ Example of translocation is 46, XY, t(9;22)
Triploidy	Three haploid sets of chromosomes are present in a cell (e.g. 69, XXY)
Trisomy	▪ An extrachromosome is present, making three copies ▪ Extragenetic material reduces viability ▪ Example of trisomy is 47, XX, +18 e

- When a change in the chromosome number does not involve entire sets of chromosomes, but only a few of the chromosome, it is called aneuploidy.
- Examples of changes in autosome chromosome number and structure are monosomy (2n–1), trisomies (2n+1), nullisomy (2n–2) and tetrasomy (2n+2).
- Mosaicism is defined as the mitotic error in the early development, that give rise to two population of cells with different chromosomal complement in some individuals, e.g. 45X/47XXX mosaicism.

CHANGES IN AUTOSOME CHROMOSOME NUMBER

Normal human somatic cell is diploid (46 chromosomes). Germ cell is haploid (23 chromosomes).

- Polyploidy refers to increase in number (a whole set) of chromosomes more than as in diploid, which occurs due to failure of cytokinesis after telophase stage of cell division. It can also bring about visible effects on the phenotype. Polyploidy is rarely compatible with life and usually results in spontaneous abortion.
- Triploidy (3X) is three times the haploid number; tetraploidy (4X) is four times the haploid number and so on. Chromosomal disorders caused by aneuploidy (numerical abnormalities) are given in Table 5.26.

Aneuploidy

In normal persons, somatic cells divide through mitosis to produce two identical diploid (2n) daughter cells. Meiosis occurs in germ cells, which produce four haploid (n) gametes (sperms or ova), that are generally unique from each other and the original parent (germ) cell.

Table 5.26 Chromosomal disorders caused by aneuploidy (numerical abnormalities)

Chromosomal Disorder	Trisomy or Monosomy	Incidence	Clinical Manifestations
Autosomal disorders			
Down syndrome	Trisomy 21	1 in 1000 live births	▪ Mental retardation ▪ Facial features (epicanthic folds, macroglossia, flat occiput) ▪ Simian crease ▪ Cardiac defects ▪ Increased risk of leukemia
Edward syndrome	Trisomy 18	1 in 5000 live births	▪ Multiple malformations (small head, small jaw, clenched fists with overlapping fingers and severe intellectual disability, cardiac defects) ▪ Most patients die during infancy
Patau syndrome	Trisomy 13	1 in 5000 live births	▪ Multiple malformations (severe mental disability, holoprosencephaly, polydactyly overlapping of fingers, i.e. clinodactyly, flexion of fingers, cleft lip and palate, neural tube defects, cardiac defects such as VSD, ASD, PDA) ▪ Most patients die during infancy
Sex chromosomal disorders			
Klinefelter syndrome	Trisomy XXY (47, XXY)	1 in 500–600 live male births	▪ Testicular hypoplasia ▪ Irreversible infertility (azoospermia) ▪ Eunuchoid body habitus ▪ Long extremities ▪ High FSH levels ▪ Low testosterone level ▪ Absence of secondary sexual characters
